On excitation of PS-I by light, the midpoint redox potential of the reaction centre chlorophyll changes to a value which exceeds ca. –1.0 volt; electrons ejected from the reaction centre of PS-I can therefore flow downhill to the ferredoxin-NADP<sup>+</sup> reductase complex and can be used for the reduction of NADP<sup>+</sup> to NADPH. A revised eukaryotic Z scheme includes the reduction of NADP by PSII [TIBS (1996) 21 121–122].

[Excited-state redox potentials in the Z scheme: TIBS (1985) 10 382–383.]

In addition to non-cyclic electron flow, a pmf-generating cyclic flow of electrons can occur via PS-I and cytochromes *b<sub>6</sub>* and *f*. There is also evidence for a cyclic flow of electrons around PS-II, possibly via cyt *b<sub>559</sub>*. [Photosynthetic electron transfer: Book ref. 85, pp. 95–148.]

In algae and cyanobacteria the dark reaction characteristically involves the CALVIN CYCLE.

Inhibitors of the photosynthetic electron transport chain include e.g. dibromomethyl-isopropyl *p*-benzoquinone (DBMIB) and DCMU, both of which inhibit electron flow between PS-II and PS-I, and hydroxylamine, which blocks electron flow from water to the reaction centre of PS-II.

Experimental electron donors to PS-II include e.g. benzidine and catechol, while electron acceptors for PS-II include e.g. ferricyanide; electron donors for PS-I include e.g. reduced phenylenediamines, while electron acceptors for PS-I include e.g. ferricyanide and METHYL VIOLOGEN.

[Molecular biology of the photosynthetic apparatus: Book ref. 163.]

See also CAROTENOID BAND SHIFT; ENHANCEMENT EFFECT; HILL REACTION; PHOTORESPIRATION; RED DROP; WARBURG EFFECT.)

**photosynthetic bacteria** A term which usually refers to bacteria of the RHODOSPIRILLALES (cf. CYANOBACTERIA).

**photosystems I and II** See PHOTOSYNTHESIS.

**phototaxis** A TAXIS in which an organism moves, directly or indirectly, from a region of low light intensity to one of higher light intensity (positive phototaxis) or vice versa (negative phototaxis). (A phototactic organism may be positively phototactic at low light intensities but negatively phototactic at high light intensities.)

In phototactic bacteria, changes in light intensity may affect the frequency of tumbling (in peritrichously flagellated organisms) and/or speed of swimming (cf. KINESIS sense 1). In purple photosynthetic bacteria, at least, phototaxis appears to be mediated by changes in proton motive force (cf. AEROTAXIS and CHEMOTAXIS) resulting from changes in the rate of energy conversion in the photosynthetic reaction centre. [Role of pmf in sensory transduction: ARM (1983) 37 551–573.] *Halobacterium salinarum* responds differently to light of different wavelengths. The cells of this species are bipolarly flagellated; they swim in the direction of the long axis of the cell, with spontaneous reversals in direction at intervals of ca. 10–50 sec. A sudden decrease in yellow-green light or a sudden increase in blue/UV light elicits an extra reversal in direction, while an increase in yellow-green light or a decrease in blue/UV light leads to a suppression of the spontaneous reversals. (See also SLOW-CYCLING RHODOPSIN.) Thus cells tend to accumulate in regions illuminated by yellow-green or white light (areas optimum for photophosphorylation by the purple membrane) but avoid areas exposed to (possibly damaging) UV radiation [SEBS (1983) 36 207–222].

See also STENTOR.

**phototopotaxis** A light-induced TOPOTAXIS.

**phototroph** An organism which can use light (and, in some species, infrared radiation) as a primary source of energy for metabolism and growth. (See also PHOTOSYNTHESIS and PURPLE MEMBRANE.) Some phototrophs are facultative CHEMOTROPHS. (See also LITHOTROPH and ORGANOTROPH.)

**phototropism** See TROPISM (sense 1).

**phoU gene** See PHO REGULON.

**phr gene** See PHOTOREACTIVATION.

**Phragmidium** See UREDINIOMYCETES.

**Phragmobasidiomycetidae** A subclass of fungi (class HYMENOMYCETES) characterized by the formation of *phragmobasidia* (see BASIDIUM). Orders [Book ref. 64, p. 189]: AURICULARIALES, SEPTOBASIDIALES, TREMELLALES.

**phragmobasidium** See BASIDIUM.

**phragmoplast** In e.g. some green algae (e.g. *Chara*): a plate which develops in the cleavage plane between two newly forming cells during the telophase stage of MITOSIS; it consists of microtubules of the persistent mid-region of the mitotic spindle together with vesicles (derived from dictyosomes) which collect between the microtubules. (cf. PHYCOPLAST.)

**phragmosporae** See SACCARDOAN SYSTEM.

**phthalimide antifungal agents** A group of agricultural non-systemic ANTIFUNGAL AGENTS which includes CAPTAFOL, CAPTAN, FOLPET etc.

**phthalylsulphathiazole** See SULPHONAMIDES.

**phthiocerols** Complex waxes found in mycobacteria [JGM (1983) 129 859–863].

**phthisis** *Syn.* TUBERCULOSIS.

**phycobilin** See PHYCOBILIPROTEINS.

**phycobiliproteins** (biliproteins) Water-soluble pigments which occur in CYANOBACTERIA, in algae of the RHODOPHYTA, and in CRYPTOPHYTES. In cryptophytes the pigments occur between the thylakoids and are antigenically unrelated to the cyanobacterial and rhodophytan pigments (which occur bound to thylakoids – see PHYCOBILISOMES). A phycobiliprotein consists of a protein ‘monomer’ comprising two distinct polypeptide chains ( $\alpha$  and  $\beta$ ), each of which is linked covalently (via a thioether bond) to an open-chain tetrapyrrole chromophore (*phycobilin* or *bilin*). The monomers tend to form trimers or hexamers which are the structural units of phycobilisomes. Phycobiliproteins function as light-harvesting pigments for photosystem II (see PHOTOSYNTHESIS); there are three main classes: *allophycocyanins* ( $\lambda_{\max}$  650–671 nm), *phycocyanins* ( $\lambda_{\max}$  617–620 nm), and *phycoerythrins* (including *phycoerythrocyanin*:  $\lambda_{\max}$  545–568 nm). Allophycocyanins and phycocyanins apparently occur in all cyanobacteria and red algae; phycoerythrins occur in most red algae and in many cyanobacteria, phycoerythrocyanin occurs in some cyanobacteria (e.g. *Anabaena variabilis*, ‘*Mastigocladus laminosus*’). Cryptophytes contain either phycocyanin or phycoerythrin, according to species. In cyanobacteria, the content of phycobiliproteins can be affected by many environmental factors, including temperature, CO<sub>2</sub> concentration, nitrogen starvation, wavelength and intensity of light [Book ref. 76, pp. 182–188]; in addition to its function as a photopigment, phycocyanin serves as a nitrogen reserve in cyanobacteria, being degraded by a specific protease induced during nitrogen starvation both in vegetative cells and in differentiating HETEROCYSTES. [Structure and function of cyanobacterial phycobiliproteins: Book ref. 75, pp. 23–42; the phycocyanin operon and light regulation of its expression in *Anabaena*: EMBO (1987) 6 871–884.]

**phycobilisomes** Structures, each ca. 20–70 nm across, which are attached in regular arrays to the surface of thylakoid membranes in CYANOBACTERIA (cf. GLOEOBACTER) and red algae (RHODOPHYTA). Phycobilisomes are composed mainly of PHYCOBILIPROTEINS together with ‘linker’ polypeptides; they vary in composition and morphology (being typically hemidisoid or hemispherical) according e.g. to species. The (mainly non-pigmented) linker polypeptides seem to have many functions – e.g. to stabilize the specific structure of phycobilisomes, to modify the phycobiliproteins so as to promote unidirectional

## phycobiont

energy flow within the phycobilisomes and to the reaction centres, and to link phycobilisomes to the photosynthetic membranes.

In general, each phycobilisome comprises two major structural domains: (i) a 'core' (consisting of two or three cylindrical elements), and (ii) five or six 'rods' (composed of stacked discs) that radiate from the core to form the hemidisoid or hemispherical structure. The core is composed of allophycocyanin (APC) and is anchored to the thylakoid membrane by a linker polypeptide. Where the rods are adjacent to the core, they consist of discs of phycocyanin (PC), but discs of phycoerythrin (PE) and/or phycoerythrocyanin (PEC), when present, occur at the periphery.

Absorbed light energy is transferred from the periphery to the core, and thence to chlorophyll *a* – thus: PE/PEC → PC → APC → Chl *a*; this transfer is almost 100% efficient.

[Structure of a 'simple' phycobilisome (in *Synechococcus*): Ann. Mic. (1983) 134 B 159–180. Phycobilisome structure: JB (1993) 175 575–576.]

**phycobiont** An algal symbiont. In lichenology, 'phycobiont' commonly refers to the main algal or cyanobacterial partner in a lichen, although in the latter case the term 'cyanobiont' is more appropriate. The term *photobiont* is a useful non-specific term for the principal photosynthetic partner in a LICHEN. (See also PHYCOZOAN.)

**phycocyanins** See PHYCOBILIPROTEINS.

**phycoerythrins** See PHYCOBILIPROTEINS.

**phycoerythrocyanin** See PHYCOBILIPROTEINS.

**phycology** The study of ALGAE.

**Phycomyces** See MUCORALES.

**phycomycetes** See LOWER FUNGI.

**phycomycosis** See ZYGOMYCOSIS and EQUINE PHYCOMYCOSIS.

**Phycopeltis** A genus of algae closely related to TRENTEPOHLIA.

The thallus is typically a circular monostromatic disc (ca. 1–3 mm diam.) of compacted, branched filaments. Species occur mainly as epiphytes, growing on – not beneath – the leaf cuticle (cf. CEPHALEUROS), and also as photobionts in certain (mainly tropical) lichens.

**phycoplast** In many green algae: a plate which develops in the cleavage plane between two newly forming cells in species in which the mitotic spindle is non-persistent; it contains microtubules orientated perpendicular to the axis of the former spindle. (cf. PHRAGMOPLAST.)

**phycosymbiodeme** See CEPHALODIUM.

**phycotoxin** Any TOXIN produced by an alga (see e.g. BREVETOXINS, CIGUATERA, GONYAUTOXINS, PRYMNESINUM, SAXITOXIN, ULVA) or – traditionally – by a cyanobacterium ('blue-green alga': see e.g. ANABAENA, APHANIZOMENON, LYNGBYA, MICROCYSTIS, NODULARIA).

**phycovirus** A VIRUS which infects one or more ALGAE. (cf. CYANOPHAGE.) Several polyhedral dsDNA viruses have been observed in green algae: e.g. a tailed polyhedral virus, resembling (at least superficially) a tailed bacteriophage, has been found in *Uronema gigas* [Virol. (1980) 100 156–165, 166–174], and various polyhedral dsDNA viruses have been observed in *Chlorella*-like algae, including the zoochlorellae of *Paramecium bursaria* and *Hydra viridis* [PNAS (1982) 79 3867–3871].

**phycozoan** A term proposed to refer to a 'compound organism' in which cells (or chloroplasts) of an alga (the phycobiont) live within the tissues or cells of an animal (the zoobiont: an invertebrate) [Book ref. 129, pp. 5–17].

(See e.g. ZOOCHLORELLAE and ZOOXANTHELLAE; cf. LICHEN.)

**phyletic classification** *Syn.* PHYLOGENETIC CLASSIFICATION.

**Phyllactinia** See ERYSIPIHALES.

**Phyllobacterium** A genus of Gram-negative bacteria of the RHIZOBIACEAE. Cells (in vitro) are straight rods which, in liquid media, form characteristic star-shaped clusters. Acid is formed from a wide range of carbohydrates. GC%: 59.6–61.3. Type species: *P. myrsinacearum*.

*P. myrsinacearum* and *P. rubiacearum* occur as pleomorphic cells (rod-shaped, ellipsoidal or branched) within leaf nodules which they induce in certain tropical plants of the Rubiaceae (e.g. madder), Myrsinaceae, Myrtaceae and Dioscoreaceae (e.g. yam). They have not been shown to be capable of nitrogen fixation.

[Book ref. 22, pp. 254–256.]

**phyllocladia** See STEREOCAULON.

**phyllody** (*plant pathol.*) A malformation in which normal floral components are replaced by leaf-like structures; it is a symptom of certain plant diseases: e.g. *green ear disease* of millet (*Pennisetum typhoides*) and other grasses caused by *Sclerospora graminicola*.

**Phyllopertha horticola** EPV See ENTOMOPOXVIRINAE.

**phyllplane** The surface(s) of a leaf. (cf. PHYLLOSHERE.) [Book ref. 158.]

**Phylloporus** See BOLETALES.

**phyloquinone** See QUINONES.

**phyllosphere** (1) *Syn.* PHYLLOPLANE. (2) The region immediately surrounding, and influenced by, a leaf. [Quantification of bacterial sugar consumption in the phyllosphere: PNAS (2001) 98 3446–3453.] (See also RHIZOSPHERE.)

**Phyllosticta** See SPHAEROPSIDALES.

**phylogenetic classification** (phyletic classification) Any form of classification in which the aim is to group organisms according to their ancestral lineage (i.e. evolutionary relationships). (cf. PHENETIC CLASSIFICATION.)

**phylogeny** The range of developmental stages in the evolution of an organism. (cf. ONTOGENY.)

**phylotype** A taxon which is defined solely by nucleic acid sequence data (no representative species of the taxon having been cultured). [Example of use: JCM (1999) 37 1469–1473.]

**phylum** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**Physarales** See MYXOMYCETES.

**Physarum** A large genus of slime moulds (class MYXOMYCETES) which usually form sporangia (some species form plasmodiocarps). *P. polycephalum* is widely used in laboratory studies. It generally forms a robust, conspicuous yellow phaneroplasmidium in which a network of major and subsidiary 'veins' leads to the advancing front edge. The sporangia are stalked, greyish, and typically multilobed.

**Physcia** A genus of small foliose LICHENS (order LECANORALES); photobiont: a green alga. The thallus generally consists of grey or greyish-brown, often pruinose, narrow branching lobes which are often radially orientated to form a rosette. Several species have cilia; some have soredia. Apothecia: lecanorine, with grey or blue-black, often pruinose discs. Ascospores: brown, one-septate. Species are generally nitrophilous, occurring e.g. on bark and/or on rocks.

**physiological heterothallism** See HETEROTHALLISM.

**physiological race** (*mycol.*) Organisms which are morphologically similar to, but which differ in physiological (and/or other) characteristics from, other members of the same FORMA SPECIALIS. A given race may be designated by a number, letter etc (see e.g. NOMENCLATURE).

**physoide** See PHAEOPHYTA.

**phytoalexins** Low-MWT antimicrobial compounds which are synthesized by, and accumulate in, higher plants exposed to

certain (pathogenic and non-pathogenic) microorganisms – or to heavy metals (e.g. copper, mercury), detergents or certain other chemicals, ultraviolet radiation or physical (e.g. freeze–thaw) damage. Phytoalexins are formed by many angiosperms (particularly by members of the Leguminosae and Solanaceae) and by some gymnosperms; they have not been detected in lower plants.

Under pre-stimulus conditions, phytoalexins may be either absent from plant tissues or present in extremely low concentrations.

The production of phytoalexins appears to be a local effect in the plant – their translocation has yet to be conclusively demonstrated; if phytoalexins are involved in a plant's natural resistance to disease, their localized accumulation may be an important factor in such resistance. In some cases the ability to produce phytoalexin(s) appears to enable a plant to resist the development of disease following infection by a pathogen; thus, e.g. resistance of the French bean to *Colletotrichum lindemuthianum* seems to correlate with the accumulation of a phytoalexin, phaseollin. In other cases the accumulation of phytoalexins appears not to be the sole factor which determines the plant's resistance to disease. Pathogens which are able successfully to invade a plant may (i) fail to induce the production of phytoalexins; (ii) be relatively insensitive to the phytoalexin(s) produced; or (iii) be able to convert a phytoalexin to an inactive form (see e.g. KIEVITONE and PISATIN). (See also HYPERSENSITIVITY sense 2.)

Elicitors of phytoalexins, i.e. specific chemical entities which promote the synthesis of phytoalexins, include the polypeptide *monilicolin A* (which elicits PHASEOLLIN) and various polysaccharides (such as  $\beta$ -1,3- and  $\beta$ -1,6-glucans and CHITOSAN) present e.g. in fungal cell walls or culture filtrates. Physical damage to plant tissues may cause release of the plant's own elicitors (*constitutive* or *endogenous* elicitors). [Phytoalexins and their elicitors: ARPphys. (1984) 35 243–275.]

Phytoalexins are structurally/chemically diverse compounds; they include e.g. CAMALEXIN; CAPSIDIOL; DEOXYHEMIGOSSYPOL; FALCARINDIOL; GLYCEOLLIN; HIRCINOL; IPOMEAMARONE; KIEVITONE; LUBIMIN; MOMILACTONES (see also WL 28325); ORCHINOL; PHASEOLLIN; PISATIN; PTEROSTILBENE; RISHITIN; VIGNAFURAN; VINIFERINS; and WYERONE.

(cf. AVENACIN; CAFFEIC ACID; CHLOROGENIC ACID; PATHOGENESIS-RELATED PROTEINS.)

[Phytoalexins (structure, role etc.): ARPpath. (1999) 37 285–306.]

**phytobiont** A plant symbiont – e.g. the plant partner in a MYCORRHIZA.

**phytoflagellates** See PHYTOMASTIGOPHOREA.

**phytoflavin** See FLAVODOXINS.

**phytoglycogen** A type of GLYCOGEN-like polysaccharide found e.g. in certain algae. (cf. CYANOPHYCEAN STARCH.)

**phytohaemagglutinin** (PHA) (1) A mitogenic LECTIN from the red kidney bean, *Phaseolus vulgaris*; it can agglutinate erythrocytes, and it binds to both B and T cells but is mitogenic mainly in T cells. PHA activity requires  $Ca^{2+}$  and  $Mg^{2+}$  and is inhibited e.g. by *N*-acetyl-D-galactosamine. (2) Any plant lectin which can agglutinate erythrocytes.

**phytohormones** (plant hormones) Compounds which are produced by plants and which regulate the plants' own metabolism, cell division, seed germination etc; they include ABSICISIC ACID, AUXINS, CYTOKININS, ETHYLENE and GIBBERELLINS.

**phytokinins** See CYTOKININS.

**Phytomastigophorea** (the phytoflagellates) A class of flagellated protozoa (subphylum MASTIGOPHORA) which either have chloroplasts or bear an obvious relationship to other members which have chloroplasts. Most phytoflagellates can also be regarded as algae and are alternatively classified in algal taxonomic schemes. Orders: Chloromonadida (the CHLOROMONADS); Chrysomonadida (the CHRYSOPHYTES); Cryptomonadida (the CRYPTOPHYTES); Dinoflagellida (the DINOFAGELLATES); Euglenida (the EUGLENOID FLAGELLATES); Heterochlorida (unicellular, flagellate and/or amoeboid members of the XANTHOPHYCEAE); Prasinomonadida (cf. PRASINOPHYCEAE); Prymnesiida (= PRYMNESIOPHYCEAE); Silicoflagellida (the SILICOFAGELLATES); Volvocida (including genera such as CHLAMYDOMONAS and VOLVOX).

**Phytomonas** (1) A genus of protozoa (family TRYPANOSOMATIDAE) parasitic in certain plants – particularly lactiferous plants (e.g. Euphorbiaceae) but also e.g. coffee plants (see e.g. PHLOEM NECROSIS) and palms; they are transmitted by sap-sucking bugs. The organisms occur in the promastigote form and are usually ca. 20  $\mu$ m in length; some species have been grown in vitro. [Plant diseases caused by *Phytomonas*: ARPpath. (1984) 22 115–132; cultivation of *P. françai*, a species associated with a root rot disease of cassava (*Manihot esculenta*): JP (1986) 33 511–513.]

(2) Obsolete name for *Xanthomonas*.

**phytoncide** (*plant pathol.*) A broad term for any substance which is produced (constitutively or inducibly) by a plant and which confers on that plant resistance to disease or infestation by killing or inhibiting the growth of a potential pathogen or parasite.

**phytone** A proteolytic digest (by PAPAINE) of plant material (e.g. soybean meal), used in certain media (see e.g. TRYPTICASE–SOY AGAR).

**phytopathology** Plant pathology.

**Phytophthora** A genus of fungi (order PERONOSPORALES) which include some important phytopathogenic species.

In many geographical regions, *P. infestans* (causal agent of LATE BLIGHT of potato) appears to overwinter as mycelium in infected tubers. In the spring, when the tubers produce shoots, the fungus grows into the developing shoots and subsequently gives rise to distinctive sporangiophores – bearing lemon-shaped sporangia – which emerge from the stomata of the leaves; the sporangia are dispersed e.g. by wind. A sporangium germinates to form either zoospores or a germ tube, depending on conditions. A zoospore subsequently encysts and later germinates, forming a germ tube; a germ tube may enter a host plant by means of an APPRESSORIUM or, directly, via a stoma. Within the new host a branching mycelium develops intercellularly, and elongated haustoria are formed; later, sporangiophores emerge from the stomata. Sexual reproduction occurs between strains of appropriate MATING TYPE. During gametangial development the oogonial initial penetrates and grows through the antheridium such that, when fully developed, the expanded, globose oogonium carries the antheridium as an encircling collar around its base; a fertilization tube develops between the two gametangia. The sexually-derived thick-walled oospore typically germinates to form a germ tube that terminates in a zoosporangium. Oospore formation is very rare in most geographical regions – though not in Mexico.

Other pathogenic species include e.g. *P. cactorum* (see CROWN ROT); *P. cinnamomi*, a worldwide pathogen of various trees and other plants (see e.g. JARRAH DIEBACK); *P. citricola* (see BLEEDING CANKER); *P. fragariae* (see RED CORE); *P. megasperma* var. *sojae* (causal agent of root and stem rot of soybean) [review: Book ref. 58, pp. 19–30]; *P. palmivora* (see BLACK POD DISEASE); and *P. parasitica* (see GUMMOSIS). *P. syringae* causes e.g. storage rot of apples and pears.

## phytoplankton

**phytoplankton** See PLANKTON.

**phytoplasma** See MLOS.

**Phytoreovirus** (plant reovirus subgroup 1) A genus of PLANT VIRUSES of the REOVIRIDAE. Genome: 12 linear dsRNA molecules. Replication occurs in cytoplasmic viroplasm; mRNA transcripts are capped. Transmission occurs propagatively via cicadellid leafhoppers; transovarial transmission occurs in the insect vector. The genus includes WOUND TUMOUR VIRUS (type species), RICE DWARF VIRUS, and RICE GALL DWARF VIRUS. [Review: Book ref. 83, pp. 505–563.]

**phytoxin** (1) A TOXIN produced by a microorganism and active against a plant or against plant cells/tissues. (2) A toxin produced by a plant.

**phytotron** An apparatus consisting of a chamber within which plants etc can be grown under a variety of accurately controlled conditions of temperature, light intensity, humidity, etc.

**pI** See ISOELECTRIC POINT.

**Pi** Inorganic orthophosphate (PO<sub>4</sub><sup>3-</sup>)

**pi particle** See PSEUDOCYTOBACTER.

**π protein** (Pi protein) See R6K PLASMID.

**pian** *Syn.* YAWS.

**pian bois** (forest yaws) A form of LEISHMANIASIS in which the pathogen spreads, typically via the lymphatic route, producing a chain of ulcers in the peripheral lymphatic system; pian bois occurs in South America.

**Pichia** A large, apparently polyphyletic genus of yeasts (family SACCHAROMYCETACEAE). Cells are spheroidal, ellipsoidal or elongate; vegetative reproduction occurs by multilateral budding. Pseudomycelium and, to a limited extent, true mycelium may be formed. Arthrospores may be formed by some species. Species are homothallic or heterothallic. Asci are usually dehiscent. Ascospores: bowler-hat-shaped, Saturn-shaped, hemispheroidal, or spheroidal, smooth-surfaced, usually 1–4 per ascus. Sugars may or may not be fermented; NO<sub>3</sub><sup>-</sup> is not assimilated. More than 56 species are recognized; type species: *P. membranaefaciens*. Several species have anamorphs in the form-genus *Candida*: e.g. the anamorph of *P. burtonii* is *C. variabilis* (and *Trichosporon variabile*), that of *P. guilliermondii* is *C. guilliermondii*, that of *P. membranaefaciens* is *C. valida*, etc. *Pichia* species are found in a wide range of habitats: e.g. tunnels and frass of wood-boring beetles, tree exudates, pickling brines, tanning liquors, grain and flour (e.g. *P. farinosa*), wine (e.g. *P. carsonii* [formerly *P. vini*], *P. membranaefaciens*), naturally fermented apple juice (e.g. *P. delftensis*), cacti (e.g. *P. cactophila*, *P. opuntiae*), human skin, faeces, etc. [Book ref. 100, pp. 295–378.]

(See also ALCOHOL OXIDASE, ALCOHOLIC FERMENTATION, BEER SPOILAGE, CIDER, METHYLOTROPHY, WINE SPOILAGE.)

**Pichinde virus** See ARENAVIRIDAE.

**pickling** A traditional method of FOOD PRESERVATION in which the pH is lowered either by direct addition of acid (e.g. VINEGAR, LACTIC ACID) or by a LACTIC ACID FERMENTATION of the food; cabbage (see SAUERKRAUT), cucumbers and olives are often preserved by fermentation [Book ref. 5, pp. 227–258]. Fresh vegetable material has a large and varied microflora, of which lactic acid bacteria form only a very small component; fermentation conditions must therefore specifically encourage the growth of the lactic acid bacteria. The vegetables are graded and washed (Spanish-style olives may be treated with NaOH to remove the bitter phenolic glucoside oleuropein), and salt is added; the salt extracts the sugar-containing juices, encouraging the growth of the lactic acid bacteria (mainly *Lactobacillus brevis*, *L. plantarum* and *Pediococcus pentosaceus* in the case of

olives and cucumbers – cf. SAUERKRAUT). [Lactic acid bacteria in vegetable fermentations: Food Mic. (1984) 1 303–313.] Fermentative yeasts may also be present; these may ferment any sugars remaining after the lactic acid bacteria have been inhibited by acidity. The combination of salt, anaerobiosis and low pH serves to discourage the growth of undesirable organisms.

Microbial spoilage of pickled vegetables may be due e.g. to oxidative pectinolytic moulds and yeasts which cause softening of the vegetable tissue; these organisms form a surface film unless precautions are taken to exclude air. Oxidative yeasts may also metabolize lactic acid and hence reduce acidity, allowing the subsequent growth of other spoilage organisms. Spoilage bacteria (e.g. coliforms, clostridia) tend to grow when the pH is too high and/or the salt concentration too low; they can cause softening, off-flavours and odours, and/or the formation of gas pockets within the vegetable (called ‘bloat damage’ in cucumbers, ‘fisheye spoilage’ in olives).

**picodnaviruses** Rejected name for the PARVOVIRIDAE.

**α-picolinic acid** Pyridine 2-carboxylic acid, a toxin produced by *Pyricularia oryzae*. (See also BLAST DISEASE and PRICULARIN.)

**Picornaviridae** A family of small, ssRNA-containing VIRUSES in which the icosahedral virion (ca. 22–30 nm diam.) is naked and ether-resistant. Most picornaviruses have a narrow host range, and some are important pathogens of man and animals; transmission generally occurs mechanically. The family includes four genera: APHTHOVIRUS, CARDIOVIRUS, ENTEROVIRUS and RHINOVIRUS; within the genera, species are distinguished by their susceptibility to specific neutralizing antibodies. Some picornaviruses are currently not classified into genera; these include equine rhinovirus types 1 and 2, and insect picornaviruses such as cricket paralysis virus, *Drosophila C* virus and *Gonometa* virus. Possible picornaviruses include ‘unclassified small RNA viruses of invertebrates’: e.g., bee acute paralysis virus, bee slow paralysis virus, bee virus X, black queen cell virus, *Drosophila P* and *A* viruses, FLACHERIE virus and SACBROOD virus. [Review of small RNA viruses of insects: JGV (1985) 66 647–659.]

*Virion structure.* The capsid comprises 60 subunits, a subunit consisting of one molecule each of the 4 major capsid polypeptides (VP1–VP4); portions of VP1, VP2 and VP3 are exposed at the virion surface, while VP4 is probably internal and may be associated with the RNA. [Virion structure in polioviruses: Science (1985) 229 1358–1365, and in rhinoviruses: Nature (1985) 317 145–153.] The RNA genome is a single molecule of linear positive-sense ssRNA (MWt ca. 2.5 × 10<sup>6</sup>) which is polyadenylated at its 3′ end and covalently linked at its 5′ end to a virus-encoded protein, VPg. In cardiaviruses and aphthoviruses (but not in enteroviruses or rhinoviruses) the RNA contains a poly(C) tract near the 5′ end, the length of which varies with strain. [Poly(C) secondary structure in aphthoviruses: JGV (1985) 66 1919–1929.]

*Replication cycle.* Virus replication occurs in the host cell cytoplasm. Infection begins when a virion attaches to receptors in the host cell plasma membrane; in e.g. poliovirus type 1 and mouse Elberfeld virus, entry into the host cell apparently occurs by endocytosis, and uncoating apparently occurs in endosomes and/or lysosomes [JGV (1985) 66 483–492]. In polioviruses, translation of the viral RNA is initiated at one site near the 5′ end of the RNA, resulting in the formation of a polyprotein; the polyprotein is initially cleaved, during translation, into three precursor proteins (P1, P2 and P3), each of which undergoes further cleavage. P1 gives rise to 1A, 1B, 1C and 1D (capsid polypeptides); P2 gives rise to 2A, 2B (a host-range determinant), and 2C (involved in RNA synthesis); P3 undergoes

intramolecular self-cleavage to form 3A, 3B (VPg), 3C (a protease which carries out most of the proteolytic cleavages), and 3D (an RNA polymerase which can elongate nascent RNA chains on an RNA template). [Nomenclature of picornavirus proteins: JV (1984) 50 957–959.] In contrast to polioviruses, aphthoviruses have two distinct translation initiation sites [JGV (1985) 66 2615–2626].

Replication of the RNA genome is associated with the smooth endoplasmic reticulum; (–)-strand synthesis may involve a primer formed by hairpin folding of the (+)-strand template, resulting in a product up to twice the length of the genome (at least in vitro) [JV (1986) 58 790–796].

Virus assembly is preceded by cleavage of P1 to form an immature 5S protomer containing VP0, VP1 and VP3. The immature protomers become associated with an RNA genome to form a provirion. During maturation most or all of the VP0 molecules are cleaved to form VP2 and VP4. The mature virions are eventually released by host cells lysis. (Some picornaviruses – e.g. hepatitis A virus – can cause non-lytic infections.)

Most picornaviruses can be propagated in cell cultures. Infected cells undergo drastic changes in their macromolecular metabolism: the rate of RNA synthesis declines shortly after infection, and cellular protein synthesis is inhibited soon after. [Review of inhibition of protein synthesis: Book ref. 150, pp. 177–221.] Characteristic CPEs generally develop in the infected cells: e.g., accumulation of chromatin on the inside of the nuclear envelope; appearance of membranous vesicles in the cytoplasm; formation of crystalline arrays of virions in the cytoplasm; alterations in membrane permeability leading to shrivelling of the cell; etc.

**picornaviruses** Viruses of the PICORNAVIRIDAE.

**picric acid** (2,4,6-trinitrophenol) An antimicrobial agent (see PHENOLS), a fixative (see e.g. BOUIN'S FLUID), and a DYE.

**pedra** See BLACK PIEDRA and WHITE PIEDRA.

**Piedraia** A genus of fungi of the DOTHIDEALES (anamorph: *Trichosporon*). (See BLACK PIEDRA.)

**piERICIDIN** An antibiotic, produced by *Streptovercillium mobarbaense*, which acts as a RESPIRATORY INHIBITOR in mitochondrial and bacterial ELECTRON TRANSPORT CHAINS (although *intact* cells may be impermeable and hence insensitive to piericidin); the (non-covalent) binding site(s) and mechanism of action of piericidin are apparently similar to those of ROTENONE.

**pif** A locus in the F PLASMID associated with the inability of certain phages (e.g. T7) to replicate in cells containing the F plasmid. (*pif* = phage-inhibitory function.) (See also FEMALE-SPECIFIC PHAGE.)

**pig bel** *Syn.* ENTERITIS NECROTICANS.

**pig diseases** (a) *Bacterial diseases*: see e.g. EPERYTHROZOONOSIS, FOOT-ROT, GLASSER'S DISEASE, GREASY PIG DISEASE, OEDEMA DISEASE, PARATYPHOID FEVER (sense 2), SWINE DYSENTERY, SWINE ERYSIPELAS, TULARAEMIA. (b) *Viral diseases*: see e.g. AFRICAN SWINE FEVER, AUJESZKY'S DISEASE, FOOT AND MOUTH DISEASE, INCLUSION BODY RHINITIS, PARVOVIRUS, SWINE FEVER, SWINE INFLUENZA, SWINE POX, SWINE VESICULAR DISEASE, TALFAN DISEASE, TESCHEN DISEASE, TRANSMISSIBLE GASTROENTERITIS, VESICULAR EXANTHEMA, VESICULAR STOMATITIS, VOMITING AND WASTING DISEASE.

**pigeonpox virus** See AVIPOXVIRUS.

**pil genes** The designation of genes which encode type IV FIMBRIAE in various Gram-negative bacteria – e.g. *Neisseria gonorrhoeae* and *Pseudomonas aeruginosa*; for example, in *N. gonorrhoeae*, *pilC* encodes the terminal adhesin, *pilE* encodes

the major subunit (see also ANTIGENIC VARIATION), and *pilQ* is a SECRETIN which is stabilized by an outer membrane lipoprotein encoded by *pilP*.

**Pilaira** A genus of fungi (order MUCORALES) which occur on the dung of herbivores. The long, positively phototropic sporangiophore bears a single non-projectile sporangium which, on maturity, becomes adhesive. (cf. PILOBOLUS.)

**pileate** (*mycol.*) Having a PILEUS.

**pileus** The structure on which the spore-bearing tissue is carried in the sexually-derived fruiting bodies of certain basidiomycetes and ascomycetes. Examples include the entire lamella-bearing structure ('cap') carried by the stipe in mushroom-shaped basidiocarps; the corky or leathery, non-stipitate fruiting bodies formed by certain wood-rotting fungi; and the ridged and pitted stipe-borne cylindrical structures of the morels (*Morchella* spp.).

**pili** (*singular*: pilus) (1) (conjugative pili; sex pili) Elongated or filamentous, proteinaceous, plasmid-encoded structures which extend from the surface of those (Gram-negative) bacteria which contain an (expressed) CONJUGATIVE PLASMID. Some types of pili have been shown to play an essential role in CONJUGATION (sense 1b), and it is generally believed (though not proven) that all pili have essential roles in conjugation. (cf. FIMBRIAE; SPINA; FLAGELLUM.)

Commonly, only a few pili (sometimes only one) occur on a given donor cell (cf. FIMBRIAE). At least some types of pili appear to be retractable, but the mechanism of retraction is unknown.

In general, thin, flexible pili mediate so-called 'universal' conjugation systems, i.e. systems in which conjugation can occur equally well within a body of liquid (e.g. broth) or on a moist (but not submerged) solid surface (e.g. an agar plate or membrane filter). Rigid pili often mediate 'surface-obligatory' mating, i.e. conjugation which occurs at a negligible frequency in liquid media but which may occur at high frequency on a moist, non-submerged solid surface. Thick, flexible pili may mediate in either 'surface-preferred' mating (in which conjugal transfer occurs more readily on solid surfaces than within liquids) or universal mating. [Surface mating systems in *Escherichia coli*: JB (1980) 143 1466–1470; surface mating systems in *Pseudomonas* spp: JGM (1983) 129 2545–2556.]

*F pili* (encoded by the F PLASMID) are thin, flexible filaments that are one to several micrometres in length, ca. 8 nm in diameter; each F-pilus has an axial channel, ca. 2 nm diameter, with a hydrophilic lumen. It has been assumed that the base of a pilus is associated with an ADHESION SITE or similar structure.

F pili are composed mainly or solely of a single type of subunit, *pilin*; the 70-amino acid pilin molecule is a single polypeptide containing one residue of D-glucose and two phosphate residues. The way in which the pilin subunits are assembled to form the pilus is not known. In one model, rings of five pilin subunits are stacked along the axis of the pilus, each ring being rotated 29° relative to the previous ring. In a second model, the pilin molecules are arranged helically. [Structure of F-pilin and a model for the organization of pilin subunits in the F pilus: Mol. Microbiol. (1997) 23 423–429.]

Bacteriophages which can bind to F pili include f1, fd and M13 (see INOVIRUS), and MS2 and Qβ (see LEVIVIRIDAE). (See also ANDROPHAGE.)

(Note that the term *pilin* is also used to refer to the subunits of other types of pili – and also to the subunits of fimbriae.)

*F-like pili* are serologically similar or identical to F pili, and they bind similar types of phage. They are encoded e.g. by the colicin plasmids ColV and ColI-K94.

## **Pilimelia**

*I-like pili* resemble F pili morphologically but they differ serologically and they bind different phages – e.g. If1 and If2 (see INOVIRUS). They are encoded e.g. by the Collb-P9 plasmid.

Short, rigid, nail- or thorn-like pili are encoded e.g. by IncN enterobacterial plasmids and *Pseudomonas* IncP-7 plasmids.

The precise role of the pilus is as yet unknown – see CONJUGATION. The currently favoured model (at least for the F pilus and related pili) is one in which the pilus makes initial contact with the recipient and then retracts to draw donor and recipient into wall-to-wall contact. Evidence supportive of this model includes the demonstration that a mutant donor with a temperature-dependent block in DNA transfer can achieve wall-to-wall contact with a recipient independently of DNA transfer; DNA transfer can occur subsequently at the permissive temperature, thus excluding the need for an extended pilus as a conducting tube for DNA [JB (1985) 162 584–590].

The role of the short, rigid pili encoded e.g. by IncN plasmids remains unknown.

(2) Collectively, pili (sense 1, above) and FIMBRIAE. Use of the term in this way should be discouraged owing to the confusion it causes (see FIMBRIAE for rationale).

**Pilimelia** A genus of keratinophilic bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in soil. The organisms resemble *Actinoplanes* spp but differ e.g. in that they form parallel chains of rod-shaped zoospores in spherical or cylindrical sporangia. Type species: *P. terevasa*. [Book ref. 73, pp. 65–66.]

**pilin** See FIMBRIAE and PILI.

**Pillotina** See SPIROCHAETALES.

**Pilobolaceae** See MUCORALES.

**Pilobolus** A genus of fungi (order MUCORALES) which occur on the dung of herbivores. In *Pilobolus* spp a single sporangium is carried on a subsporangial vesicle at the distal end of each long, positively phototropic sporangiophore; the (non-dehiscent) sporangium is propelled from the sporangiophore by a jet of liquid which escapes, explosively, from the subsporangial vesicle. (cf. PILAIRA.)

**Pilophorus** A genus of LICHENS (order LECANORALES); photobiont: a green alga. Erect pseudopodetia (see PSEUDOPODETUM) – which may bear terminal, convex, black apothecia – arise from a granular primary thallus which may be evanescent; cephalodia are generally present. Species grow e.g. on rocks, particularly in mountainous regions.

**pilot protein** A protein which is believed to aid the transfer of DNA from a donor cell to a recipient during bacterial CONJUGATION (sense 1b) or from a bacteriophage virion to a host cell during certain types of phage infection.

**pilus** See PILI.

**pimaricin** (natamycin; tennecetin) A MYCOSAMINE-containing tetraene POLYENE ANTIBIOTIC produced by *Streptomyces natalensis*. It is used e.g. in the treatment of mycotic keratitis and as an antifungal food preservative e.g. in sausages, fruit juices, cheese etc; it can be inactivated by enzymes produced by certain moulds (e.g. *Aspergillus flavus*).

**pin gene** See RECOMBINATIONAL REGULATION.

**pine diseases** Diseases of pine trees (*Pinus* spp) include BLISTER RUST and PITCH CANKER. *Pine wilt* may be caused by a species of the fungus *Ceratocystis* (vector: bark beetles) or by the nematode *Bursaphelenchus xylophilus* (vector: the pine sawyer). (See also TREE DISEASES.)

**pine disinfectants** (pine fluids) DISINFECTANTS which include certain volatile oils obtained synthetically or by steam-distillation of pine wood. The early pine fluids were made by solubilizing pine oil with soap; they were active mainly against Gram-negative

bacteria, but were poorly active against Gram-positive species. Modern pine fluids (with RW coefficients of ca. 3–5) typically contain phenolics (e.g., 2-phenylphenol, 4-chloro-3,5-xyleneol) together with e.g. terpineol (an antimicrobial constituent of pine oil) and a solubilizing agent, e.g., potassium ricinoleate; these fluids are active against both Gram-negative and Gram-positive bacteria. The activity of at least one pine fluid against *Pseudomonas aeruginosa* is greatly increased at temperatures above 30°C [Book ref. 13, pp. 85–90]. The recommended maximum dilution of a pine fluid is 20 times its RW coefficient.

**pink-eye** (pinkeye) (1) *Syn.* CONJUNCTIVITIS. (2) An acute contagious conjunctivitis caused by *Haemophilus aegyptius*. (3) *Syn.* INFECTIOUS KERATITIS (of cattle).

**Pinnularia** See DIATOMS.

**pinocytosis** The ingestion, by various types of eukaryotic cell (e.g. amoebae, macrophages), of minute droplets of fluid; in pinocytosis (as in PHAGOCYTOSIS) a small region of the CYTOPLASMIC MEMBRANE invaginates and is subsequently pinched off to form a closed, intracellular membranous sac (*pinocytotic vesicle*, *pinosome*) containing the ingested fluid. In one form of pinocytosis (*fluid-phase pinocytosis*) pinocytotic vesicles are formed continually at non-specific sites in the cytoplasmic membrane – samples of extracellular fluid being taken randomly; such vesicles often fuse with LYOSOMES.

*Receptor-mediated pinocytosis* (= *absorptive pinocytosis*) is a selective process in which specific types of macromolecule (or e.g. virus particle) are taken up. The macromolecules bind to specific receptors located at the outward-facing surface of the cytoplasmic membrane, groups of such receptors occurring in discrete regions of the cytoplasmic membrane known as *coated pits*; a coated pit bears on its inner (i.e., cytoplasmic) surface a characteristic array of molecules of the fibrous protein *clathrin* (MWt ca. 215000). Clathrin occurs in propeller-shaped ('three-legged') trimeric units (*triskelions*) which assemble into pentagons and hexagons, forming a polygonal network which comprises the cytoplasmic face of the coated pit. (Often, bundles of ACTIN microfilaments – *stress fibres* – occur in the cytoplasm beneath a coated pit.) Following receptor-mediated binding of macromolecules to a coated pit, the coated pit region invaginates and eventually pinches off to form a pinocytotic vesicle – the outer (cytoplasm-facing) surface of the vesicle being covered by a lattice-like network of clathrin; the vesicle, enclosed within its clathrin 'cage', is called a *coated vesicle*. Before fusing with e.g. a lysosome, a coated vesicle must have its clathrin removed in an ATP-dependent process. [Enzymatic recycling of clathrin from coated vesicles: Cell (1986) 46 5–9.]

**pinosome** See PINOCYTOSIS.

**pinoxylin** 3,5-Dihydroxy-*trans*-stilbene: an antifungal compound formed by many species of pine (*Pinus*); it appears to be at least partly responsible for the relative resistance of pine heartwood to fungal attack. (See also TIMBER PRESERVATION.)

**pinta** (mal del pinto; *syn.* spotted sickness) A chronic infectious human disease caused by *Treponema carateum*; it occurs in Central and South America. Symptoms: spots or patches of abnormally pigmented or depigmented skin; other tissues are rarely affected. *Chemotherapy*: e.g. penicillins.

**pInv plasmid** See EIEC.

**piannotes** In *Fusarium* spp: a flat spore mass which has a fat-like or greasy appearance.

**pipemidic acid** See QUINOLONE ANTIBIOTICS.

**Piptocephalis** A genus of fungi (order ZOOPAGALES) which are parasitic on other fungi, often other zygomycetes. The vegetative hyphae develop extracellularly on the host – from which

nutrients are abstracted by means of haustoria. Asexually derived spores are formed in merosporangia carried on (typically) deciduous 'head cells' at the distal ends of dichotomously branched sporangiophores; each merosporangium contains one or a few spores. Most species are apparently homothallic.

**Piptoporus** A genus of lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form typically annual, non-stipitate basidiocarps having a whitish or pale brown, corky, dimitic, non-xanthochroic context; the bracket-type basidiocarp has a porous hymenophore on the underside. *P. betulinus* ('razor-strop fungus') is saprotrophic and parasitic on birch (*Betula*); the upper surface of the basidiocarp has a thin, pale brown, separable outer layer, and the lower porous surface is whitish. Basidiospores: colourless, cylindrical, ca.  $5 \times 2 \mu\text{m}$ . (See also BROWN ROT and TIMBER SPOILAGE; cf. POLYPORUS.)

**pir gene** See R6K PLASMID.

**Pirella** See PASTEURIA.

**piricularin** (pyricularin) A toxin produced by *Pyricularia oryzae* (see BLAST DISEASE). Piricularin is toxic to the fungus itself, but *P. oryzae* produces a copper-containing 'piricularin-binding protein' which complexes the toxin and renders it non-toxic for the fungus without affecting its toxicity for the rice plant. CHLOROGENIC ACID can complex piricularin and inactivate it.

**Piromonas** A genus of fungi found in the RUMEN.

**piroplasm** (1) A member of the PIROPLASMASINA. (2) The intracytostic stage of *Theileria* spp.

**Piropalmasina** A subclass of protozoa (class SPOROZOASIDA) in which the APICAL COMPLEX is less well developed than in other members of the Sporozoasida, and in which the conoid is absent; reproduction occurs asexually (by binary fission or schizogony) and sexual reproduction occurs in at least some species. Motility involves e.g. cell flexion. Species are parasitic in the erythrocytes (and other cells) of vertebrates but do not form pigment from host cell haemoglobin (cf. HAEMOSPORORINA). Piroplasmas are heteroxenous and are transmitted by ticks. Genera: BABESIA, *Dactylosoma*, THEILERIA.

**Piroplasmea** A class of parasitic protozoa classified within the subphylum Sarcomastigophora [JP (1964) 11 7–20] and subsequently, as the subclass PIROPLASMASINA, in the class SPOROZOASIDA.

**Piroplasma** A subclass of protozoa [JP (1980) 27 37–58] equivalent to the PIROPLASMASINA.

**Piry virus** A virus (genus VESICULOVIRUS) antigenically related to VSV.

**pisatin** An isoflavonoid PHYTOALEXIN (3-hydroxy-7-methoxy-4',5'-methyleneoxychromanocoumaran) produced by the pea plant (*Pisum sativum*). Some isolates of *Nectria haematococca* which are pathogenic for *P. sativum* can tolerate pisatin and can 'detoxify' the phytoalexin by demethylating it.

**Pisolithus** A genus of saprotrophic or mycorrhizal fungi (order SCLERODERMATALES). *P. arhizus* (= *P. tinctorius*) forms large, club-shaped, partly hypogean, ochre to brownish basidiocarps (up to ca. 25 cm high) which contain closed pockets or chambers (*peridioles*) that eventually desiccate and crumble to release their content of basidiospores; this organism forms mycorrhizal associations with various trees and can apparently enhance the growth of e.g. pine trees under conditions which are normally suboptimal for their growth.

**pit connection** In many multicellular red algae: a structure located between two adjacent cells. A *primary* pit connection forms between two daughter cells during cell division: a central hole in the intercellular septum becomes blocked by a plug of electron-dense material, and a plug cap (formed from a flattened

vesicle) appears on each side of the plug; the cytoplasmic membrane thus remains continuous from one cell to another. (cf. PLASMODESMA.) A *secondary* pit connection may develop between two cells which have become juxtaposed. (See also CHOREOCOLAX.)

**pitch canker** A disease of pine trees (*Pinus* spp) caused by *Fusarium moniliforme* var. *subglutinans*; symptoms include dieback of terminal and lateral branches, and the formation of CANKERS characterized by a copious flow of resin.

**Pitelka convention** A system for numbering the microtubular triplets in a kinetosome. Looking at a cross-section of a ciliary kinetosome from the direction of the *interior* of the cell, the triplet associated with the ribbon of POST-CILIARY MICROTUBULES is designated number 5; the numbering sequence is clockwise – as in the GRAIN CONVENTION.

**Pithomyces** See HYPHOMYCETES; see also SPORIDESMINS.

**pitted keratolysis** A human skin disease characterized by focal erosion of the stratum corneum, usually on the soles and heels of the feet; it appears to be caused by an organism resembling *Dermatophilus congolensis*.

**Pittsburg pneumonia agent** *Legionella micdadei*.

**pityriasis nigra** (tinea nigra) A benign superficial human dermatomycosis in which brownish or black macules are formed (usually on the palms of the hands). Causal agents: *Exophiala werneckii* (= *Cladosporium werneckii*) or *Stenella aragata* (= *Cladosporium castellanii*).

**pityriasis versicolor** (tinea versicolor) A mild, chronic, superficial human dermatomycosis caused by *Malassezia furfur* ('*Pityrosporum orbiculare*'); flat or slightly raised, scaly, brownish or fawn spots (which gradually enlarge and coalesce) develop mainly on the chest, back, arms and neck. Lesions may fluoresce greyish-yellow under Wood's lamp.

**Pityrosporum** Syn. MALASSEZIA.

**pivampicillin** See PENICILLINS.

**Pixuna virus** See ALPHAVIRUS.

**P-K test** See PRAUSNITZ-KÜSTNER TEST.

**PKA** See CYCLIC AMP.

**PKC kinase** See CHEMOKINES.

**PKD** PROLIFERATIVE KIDNEY DISEASE.

**PKDL** POST-KALA-AZAR DERMAL LEISHMANIASIS.

**pKM101** See SOS SYSTEM and AMES TEST.

**PKR kinase** See INTERFERONS.

**Placidiopsis** See VERRUCARIALES.

**placoderm desmid** See DESMIDS.

**placodioid** (placoid) (*lichenol.*) Refers to a crustose thallus which is generally circular in outline with radial lobes at the periphery.

**placoid** Syn. PLACODIOID.

**Plagiacantha** See RADIOLARIA.

**Plagonium** See RADIOLARIA.

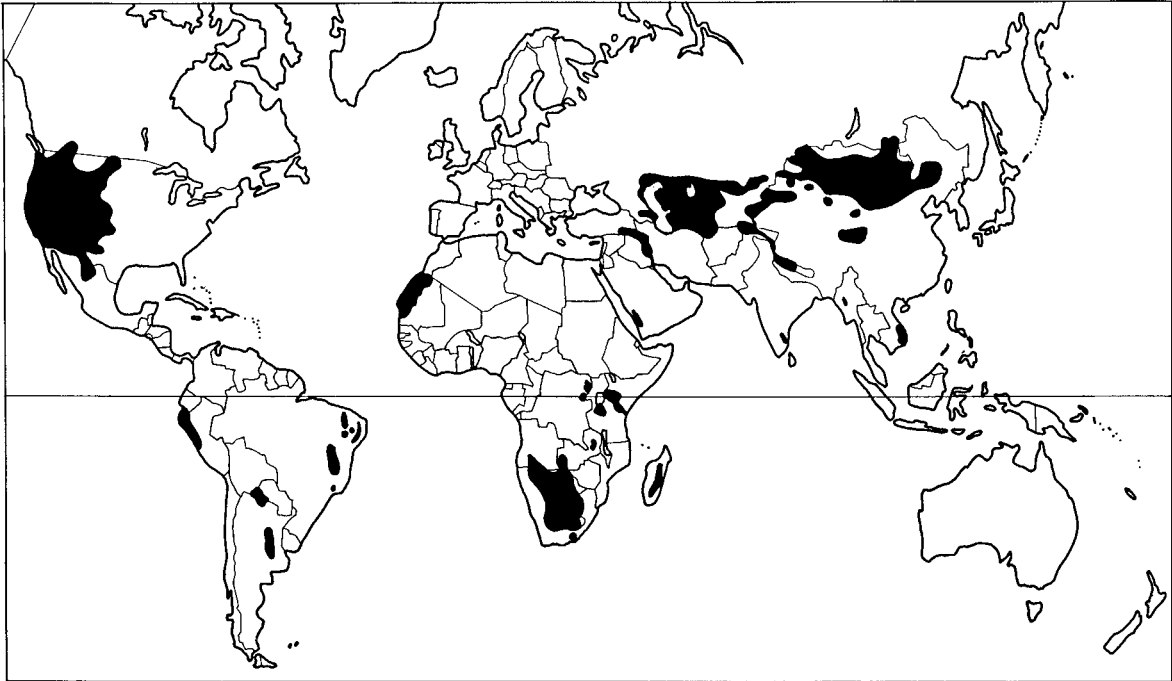

**plague** An acute infectious disease which primarily affects rodents but which can be transmitted to man; the causal agent is *Yersinia pestis* (see also VIRULON).

Before the availability of antibiotic therapy, epidemics and pandemics of plague caused enormous loss of life; for example, an outbreak in Europe during the 14th century (the 'Black Death') involved ca. 25 million deaths. The World Health Organization has recently recognized plague as a 're-emerging disease'.

An epidemic of human plague is commonly preceded by an epizootic among urban rats; *Rattus rattus* populations are rapidly decimated in such epizootics, but wild rodents in rural or wooded areas are less susceptible and provide a reservoir of infection.

## plague

PLAGUE: areas where endemic plague is known to have persisted near the end of the 20th century. Areas in black are regions in which there are populations of wild rodents that carry the plague bacillus.

Reproduced from *Medical Microbiology* 14th edition, Figure 36.1, page 406, David Greenwood, Richard Slack & John Peutherer (eds) (1992) copyright Churchill Livingstone (Harcourt Publishers Ltd, Edinburgh) (ISBN 0-443-04256-X) by courtesy of the author, Dr J. D. Coghlan, and with permission from the publisher.

Transmission from rat to rat, and from rat to man, occurs via the bite of the rat flea (especially *Xenopsylla cheopis*); the gut of an infected flea becomes blocked by plague bacilli which are regurgitated into the next bite. Person-to-person transmission may occur via the human flea, *Pulex irritans* (a less effective vector), or, in pneumonic plague, by droplet infection.

Plague bacilli have been reported to occur in the throats of symptomless human carriers.

In man, plague occurs in three clinical forms. In *bubonic plague*, the commonest form, the incubation period is 2–6 days; onset is sudden, with fever, prostration, haemorrhages and the development of *buboes*: swollen, inflamed, necrotic lymph nodes. Septicaemia may result in e.g. meningitis or secondary pneumonia. (cf. PESTIS MINOR.)

In *primary septicaemic plague* (incubation period: 2–6 days) there is a sudden onset with high fever, haemorrhages, vomiting and bloody diarrhoea, but no buboes.

*Primary pneumonic plague* results from infection by inhalation (incubation period: 2–3 days). There is high fever, prostration, severe pneumonia and frequently delirium and coma; the sputum contains large numbers of plague bacilli.

Mortality rates in untreated cases: e.g. bubonic plague 25–50%; pneumonic and septicaemic plague ~100%; early antibiotic therapy is associated with significantly lower mortality.

*Lab. diagnosis.* Demonstration of the pathogen in fluid from buboes, blood, CSF or sputum (by microscopy and/or culture) and/or serology for antibodies against the F1 ('fraction 1')

antigen (see YERSINIA). PCR-based diagnosis (amplification of a sequence of the *Y. pestis cafI* gene) under field conditions in Madagascar was found to be less sensitive than culture or serology and was not recommended [JCM (2000) 38 260–263].

[Rapid mAb/F1-based test for bubonic/pneumonic plague: Lancet (2003) 361 211–216.]

*Chemotherapy:* e.g. tetracyclines, streptomycin or chloramphenicol.

Vaccines containing either inactivated virulent cells or live avirulent cells may offer short-term protection.

[Molecular and cell biology aspects of plague: PNAS (2000) 97 8778–8783.]

Endemic plague persists in various regions of the world (see figure) and, significantly, transferable (plasmid-mediated) multidrug resistance has been reported in *Yersinia pestis* [NEJM (1997) 337 677–680]. [Dynamics of plague in the rat population, and transmission of the disease to humans: Nature (2000) 407 903–906. Bubonic plague (a metapopulation model of a zoonosis): Proc. RSLB (2000) 267 2219–2230.]

**planachromat** See ACHROMAT.

**planapochromat** See APOCHROMAT.

**Planctomyces** A genus of planktonic freshwater bacteria. Cells: cocci, or coccoid to pear-shaped forms, ca. 0.3–2.0 µm, which develop non-prosthecae, bristle-like appendages when mature; the cell wall contains no peptidoglycan. Reproduction occurs by budding. Types species: *P. bekefii*. Other species include e.g. *P. guttaeformis* and *P. stranskae* [IJSB (1984) 34 470–477];

'*P. gracilis*' has been excluded from the genus [JSB (1984) 34 465–469].

**plankter** See PLANKTON.

**plankton** Collectively, the microorganisms (chiefly microalgae and protozoa), small invertebrates (e.g. copepods and other small crustacea) and fish larvae etc which drift more or less passively in water currents within the pelagic zone of lakes, seas and other bodies of water; although many planktonic organisms are actively motile, even these organisms depend on water currents for significant amounts of displacement. The plant and plant-like components of plankton (including e.g. the photosynthetic flagellates) are referred to as *phytoplankton*, while the animal or animal-like components (including e.g. protozoa) are called *zooplankton*. An individual planktonic organism is called a *plankter*.

Plankton, particularly phytoplankton, is important as the basis of the aquatic food chain; it is consumed by a range of invertebrates and by certain fish and whales.

Microbial *marine* plankton includes e.g. DIATOMS, DINOFLAGELLATES, RADIOLARIA, members of the PRYMNESIOPHYCEAE and TINTINNINA, and certain foraminifera (e.g. GLOBIGERINA, GLOBIGERINOIDES). Microbial *freshwater* plankton includes e.g. CYANOBACTERIA, DESMIDS, DIATOMS, and members of the HELIOZOA.

Various schemes have been proposed for the classification of planktonic organisms according to size; thus, e.g. *nannoplankton* (= *nano plankton*) may include (depending on author) organisms which are less than 20 µm, less than 50 µm, 5–50 µm, 5–60 µm, or greater than 75 µm. Similarly, *mesoplankton* may include organisms of 0.5–1.0 mm, 0.2–2.0 mm, greater than 1.0 mm or 1–5 mm.

(cf. NEKTON, NEUSTON; see also BLOOM.)

**Planktothrix** A genus of gas-vacuolate CYANOBACTERIA. [Variation in gas vesicle genes: Microbiology (2000) 146 2009–2018.]

**Planobispora** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur in soil. The organisms form branching substrate and aerial mycelium,

the latter bearing elongated sporangia, singly or in groups, each sporangium containing a serially-arranged pair of spores; liberated spores become motile (flagellated). Type species: *P. longispora*. [Book ref. 73, pp. 111–112.]

**Planococcus** A genus of Gram-positive, asporogenous, catalase-positive, chemoorganotrophic, aerobic bacteria which occur as marine saprotrophs. Cells: cocci (each having 1–3 flagella) which occur in pairs and tetrads; the cell wall contains no teichoic acids. A yellow-brown pigment is formed. Carbohydrates are not utilized. Growth occurs e.g. on nutrient agar containing 12% NaCl. GC%: ca. 39–51. Species: *P. citreus* (type species) and *P. halophilus*.

**planofluorite** See FLUORITE OBJECTIVE.

**planogamete** A motile GAMETE.

**Planomonospora** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur in soil. The organisms form branching substrate and aerial mycelium, the latter bearing rows of parallel, elongated sporangia, each sporangium being attached at one end to the hypha; each sporangium contains one spore which becomes motile (flagellated) after release. Type species: *P. parontospora*. [Book ref. 73, 112–113.]

**planospore** A motile SPORE.

**plant viruses** VIRUSES which can infect and replicate in plants. (cf. VIROID; VIRUSOID.) Commonly, plant viruses show a low degree of host specificity, and some can also replicate in insects. Infection of a plant by a given virus may be systemic – spreading rapidly via the phloem (or occasionally xylem) or slowly from cell to cell via plasmodesmata – or may remain localized at the site of infection. (Spread is apparently a virus-specific function involving virus-encoded or virus-induced proteins [review: AVR (1984) 29 313–364].) Infection may be symptomless (silent, 'latent'), or may involve the development of symptoms ranging from mild to severe or lethal; symptoms, when present, often depend on the species and variety of the host plant, on the particular virus strain, and on environmental conditions, and may be affected by the presence of another virus or of a

PLANT VIRUSES: basic characteristics

Genome	Envelope	Nucleocapsid morphology	Virus group (or unclassified virus) <sup>a</sup>
dsDNA	–	isometric	caulimoviruses
ssDNA	–	paired isometric particles	geminiviruses
dsRNA	–	isometric	plant reoviruses (Reoviridae), rice ragged stunt virus, some cryptic viruses
ssRNA	+	± rod-shaped	plant rhabdoviruses (Rhabdoviridae), tomato spotted wilt virus
ssRNA			
monopartite	–	isometric	luteoviruses, maize chlorotic dwarf virus, sobemoviruses, tobacco necrosis virus, tobramoviruses, tymoviruses
monopartite	–	rod-shaped or filamentous	carlaviruses, closteroviruses, potexviruses, potyviruses, tobamoviruses
bipartite	–	isometric	comoviruses, dianthoviruses, nepoviruses, pea enation mosaic virus, velvet tobacco mottle virus
bipartite	–	rod-shaped or filamentous	furoviruses?, hordeiviruses (some strains), tobamoviruses
tripartite	–	± isometric	bromoviruses, cucumoviruses, ilarviruses
tripartite	–	± rod-shaped	alfalfa mosaic virus, hordeiviruses (some strains)
multipartite	–	filamentous	rice stripe virus group

<sup>a</sup> See separate entries for details.

## ***Plantago mottle virus***

SATELLITE VIRUS or SATELLITE RNA. Virus-infected plants may exhibit one or more of the following symptoms: CHLOROSIS, COLOUR-BREAKING, curling or distortion of leaves, ENATIONS, GALL-formation, MOSAIC, MOTTLE, NECROSIS, RINGSPOT, ROSETTE-formation, STREAK, stunting of growth, TOP NECROSIS, VEIN BANDING, VEIN CLEARING, VIRESCENCE, yellowing (see YELLOW), etc. (Plant structures which are fully matured at the time of infection may fail to develop symptoms.)

**Transmission** of many plant viruses can occur mechanically – e.g. by contact between plants or by contamination of a plant with sap from an infected plant (present e.g. on pruning implements, hands etc); in the laboratory mechanical transmission can often be achieved by rubbing the leaves of a plant with a virus preparation – often mixed with a mild abrasive. Some viruses can be transmitted via soil, via seeds or tubers, or by grafting (e.g. from an infected stock to an uninfected scion). Many plant viruses can be transmitted only by specific VECTORS such as sap-sucking or biting insects, mites, nematodes, fungi, or parasitic plants such as the dodder (*Cuscuta* spp.). (See CIRCULATIVE TRANSMISSION and NON-CIRCULATIVE TRANSMISSION.)

**Identification** of a plant virus is seldom possible from symptoms exhibited by infected plants in the field, but may be achieved e.g. by light or electron microscopy of infected tissues (many viruses induce characteristic inclusion bodies in infected cells), by inoculation of the virus into a range of suitable DIFFERENTIAL HOSTS, and/or by serological tests; plant viruses are generally effective immunogens, and specific antibodies against a known virus can be raised in animals and used for the identification of an unknown virus (e.g. by ELISA, IMMUNOELECTRON MICROSCOPY, IMMUNOSORBENT ELECTRON MICROSCOPY, precipitin tests, etc). A plant virus may be assayed e.g. using a LOCAL LESION host.

**Cultivation in vitro** of many plant viruses can be achieved in plant protoplasts derived e.g. from cell suspension cultures or mesophyll tissue of leaves [AVR (1984) 29 215–262] or from shoot cultures [e.g. of potatoes: JGV (1985) 66 1341–1346].

**Control of virus diseases of plants** may involve any of various preventive measures: e.g. use of virus-free seed (obtained e.g. by meristem culture), control of vector populations, ROUING, removal of volunteer plants or weeds in which the virus may overwinter, selection of resistant or tolerant plant cultivars, etc. Once a plant is infected with a virus there is no effective chemical treatment; however, certain viruses can be inactivated by subjecting the infected plant (or seeds in the case of seed-borne viruses) to air temperatures of 30–35°C (for days or weeks), to water immersion at ca. 40 or 50°C for shorter periods, etc ('thermotherapy'). [Heat treatment of lettuce seeds carrying lettuce mosaic virus: Ann. Appl. Biol. (1985) 107 137–145.]

**Nomenclature and classification.** Individual plant viruses are generally given names based on the common, first-recognized, or most important host plant, and on the main symptom(s) produced by the virus in that plant under natural conditions. (Examples: apple chlorotic leafspot virus; barley yellow dwarf virus.) In the majority of plant viruses the virus genome consists of RNA which is often segmented and sometimes distributed between two or more separate virus components (see MULTICOMPONENT VIRUSES). On the basis of the nature of the genome, shape of the virus particle(s), presence or absence of an envelope, etc, plant viruses are classified into 'groups' (see table); the name of a group is commonly a sigla derived e.g. from the name of the type virus (e.g. *caulimoviruses* from *cauli*flower mosaic virus). A few plant viruses are related to certain animal viruses and are included in animal virus classification schemes: see

e.g. REOVIRIDAE and RHABDOVIRIDAE. (cf. TOMATO SPOTTED WILT VIRUS.)

***Plantago mottle virus*** See TYMOVIRUSES.

***Plantago severe mottle virus*** See POTEXVIRUSES.

***Plantago virus*** See CAULIMOVIRUSES.

***Plantago virus X*** See POTEXVIRUSES.

**plantar wart** See PAPILLOMA.

**plantaricin S** See BACTERIOCINS.

**plaque** (1) A discrete, macroscopic or microscopic, usually circular region in a cell monolayer (see TISSUE CULTURE) or in a film or layer of bacterial growth (see LAWN PLATE) in which some or all of the cells have been lysed, or their growth has been strongly inhibited, as a result of the activity of a virus or other agent (e.g. BDELLOVIBRIO). In virology, it is generally assumed that each plaque develops following the replication of a single virion; thus, e.g., when the first-infected cell lyses, the progeny virions diffuse outwards, progressively infecting and lysing other cells until a visibly depopulated area (the plaque) is produced. Plaque characteristics – e.g. size, shape, nature of the margin – can be useful e.g. in identifying the infecting virus, or in determining whether or not a cell population is homogeneous in its susceptibility to the virus; thus, e.g., clear plaques (total cell lysis) on a lawn of susceptible bacteria are typically produced by virulent bacteriophages, while turbid plaques are characteristic of temperate phages – which lyse only some of the cells in the plaque area – and of non-lytic phages (see e.g. INOVIRIDAE).

(2) (*verb*) To inoculate a lawn plate or cell monolayer with a virus suspension in order to obtain plaques (sense 1).

(3) See DENTAL PLAQUE.

(4) (*med., vet.*) A patch or flat lesion e.g. on skin or mucous membranes (see e.g. DOURINE).

**plaque assay** A procedure for determining the PLAQUE TITRE of a given viral suspension.

**Bacteriophages.** Log dilutions of the phage suspension are initially prepared, and a measured volume of a given dilution is added to a known volume of molten (ca. 45–46°C) semi-solid agar containing an excess of sensitive bacteria; the whole is well mixed and poured onto a plate of solid nutrient agar, forming an upper layer 1–2 mm thick. An identical procedure is carried with each dilution; the plates are incubated at the growth temperature of the bacterium and subsequently examined for PLAQUES. Since each plaque is assumed to have been caused by a single phage, the plaque titre of the original phage suspension can be calculated from the volumes and dilutions used.

**Other viruses.** Plaque assay can be carried out for other viruses if suitably sensitive monolayer cultures (see TISSUE CULTURE) are available. In one method, each of a number of monolayer cultures is drained of growth medium and inoculated with a known volume of one of a range of log dilutions of the viral suspension; the cultures are rocked to enable viruses to adsorb throughout the cell sheet. The monolayers are then overlaid with buffered growth medium in semi-solid purified agar, incubated, and subsequently examined for plaques. (The agar overlay inhibits the spread of viruses from the plaque areas.)

**plaque-forming unit** (pfu) An entity – usually a virion, but also e.g. an 'infectious centre' (see ONE-STEP GROWTH EXPERIMENT) – which can give rise to a single PLAQUE under appropriate conditions. (See also EOP and PLAQUE TITRE.)

**plaque mutant** *Syn.* PLAQUE-TYPE MUTANT.

**plaque-reduction assay** See INTERFERONS.

**plaque titre** The number of PLAQUE-FORMING UNITS per unit volume.

**plaque-type mutant** (plaque mutant; plaque morphology mutant) A mutant virus which forms PLAQUES (sense 1) that differ from

those formed by the wild-type virus in a population of sensitive cells.

**plasma** (1) (in vivo) The fluid (non-particulate) part of blood. (2) (in vitro) Fluid obtained (e.g. by centrifugation) from blood which has been pre-treated with an ANTICOAGULANT. (cf. SERUM.)

**plasma cell** (*immunol.*) An antibody-secreting cell that develops from a B LYMPHOCYTE on appropriate antigenic stimulation (see ANTIBODY FORMATION); plasma cells occur e.g. in the spleen and (particularly) in lymph nodes which are draining an infected site. In the earliest stage of the immune response the secreted antibodies are of the IgM class; however (for TD antigens), antibodies of other classes are secreted subsequently following *class switching* (see ANTIBODY FORMATION).

Typical plasma cells are ovoid, ca.  $10 \times 15 \mu\text{m}$ , with an off-centre nucleus which, when stained, may have a 'clock-face' or 'cartwheel' appearance due to the arrangement of chromatin. The (non-granular) cytoplasm contains a well-developed, ribosome-rich endoplasmic reticulum (see also METHYL GREEN-PYRONIN STAIN).

**plasma clotting** See FIBRIN; COAGULASE; ANTICOAGULANT.

**plasma membrane** *Syn.* CYTOPLASMIC MEMBRANE.

**plasma volume extenders** (for blood transfusion) See DEXTRANS.

**plasmagel** See e.g. SARCODINA.

**plasmalemma** *Syn.* CYTOPLASMIC MEMBRANE.

**plasmalogen** A glycerophospholipid in which the glycerol bears a 1-alkenyl ether group. Plasmalogens occur e.g. in the cytoplasmic membrane in anaerobic bacteria.

**plasmasol** See e.g. SARCODINA.

**Plasmaviridae** (mycoplasma virus type 2 phages; L2 acholeplasma-virus group) A family of enveloped, pleomorphic MYCOPLASMAVIRUSES containing dsDNA. One genus: *Plasmavirus*; type species: BACTERIOPHAGE MV-L2. Other members: bacteriophage 1307 and possibly v1, v2, v4, v5 and v7.

**Plasmavirus** See PLASMAVIRIDAE.

**plasmid** In many types of prokaryotic and eukaryotic cell: a linear or covalently closed circular (ccc) molecule of DNA (q.v.) – distinct from chromosomal DNA, mtDNA, ctDNA or kDNA – which can replicate autonomously (i.e., independently of other replicons) and which is commonly dispensable to the cell; the term 'plasmid' is sometimes used to refer also to the dsRNA elements which occur in certain yeasts: see KILLER FACTOR. (cf. EPISOME.) (The stable, extrachromosomal (i.e., non-integrated) prophages of certain bacteriophages (e.g. BACTERIOPHAGE P1) conform to the definition of plasmid and are commonly referred to as plasmids.) Some plasmids appear to have arisen from chromosomal or mitochondrial DNA: see e.g. THREE-MICRON DNA PLASMID.

The following refers primarily to *prokaryotic* plasmids.

Plasmids occur in both Gram-positive and Gram-negative bacteria; in size they range from ca. 1.5 kb (MWt ca.  $10^6$ ) to ca. 300 kb (MWt ca.  $2 \times 10^8$ ). Most bacterial plasmids are ccc dsDNA molecules, and these are normally *supercoiled* (see DNA). However, some plasmids can occur as ccc ssDNA molecules [PNAS (1986) 83 2541–2545], while linear plasmids occur e.g. in *Streptomyces* and in *Borrelia* [Mol. Microbiol. (1993) 10 917–922]. Many bacterial plasmids carry one or more TRANSPOSABLE ELEMENTS. (cf. KILLER PLASMIDS; TWO-MICRON DNA PLASMIDS.)

Certain obligate pathogens in the alpha subclass of Proteobacteria normally *lack* plasmids, although plasmids occur in other members of the same subclass. It has been suggested that species of *Anaplasma*, *Bartonella*, *Brucella* and *Rickettsia* evolved without plasmids because their relatively constant (intracellular)

environment does not select for the genetic diversity needed by species in more challenging environments [FEMS Reviews (1998) 22 255–275]; however, some intracellular bacteria (e.g. *Chlamydia* spp) are known to contain plasmids [see e.g. Microbiology (1997) 143 1847–1854].

Many plasmids encode product(s) and/or function(s) which modify the phenotype of the host cell. Almost any feature may be encoded by plasmids, including e.g. resistance to particular ANTIBIOTIC(s) and/or HEAVY METAL(s) (see R PLASMID), and the synthesis of AGROCIINS, BACTERIOCINS, GAS VACUOLES (e.g. in certain strains of *Halobacterium*), restriction endonucleases (see also PHAGE TYPING), SIDEROPHORES, TOXINS (see e.g. ANTHRAX TOXIN, ETEC) or virulence factors (see e.g. CROWN GALL and VW ANTIGENS). Some plasmid-encoded products alter the antigenic characteristics of a cell (see e.g. ANTIGEN GAIN), and some confer the ability to utilize particular substrate(s) (see e.g. LACTOSE PLASMID, OCT PLASMID, TOL PLASMID). One plasmid may counteract the effects of another; for example, the pSa plasmid can abolish the specific adherence properties of *Agrobacterium* strains which are due to the presence of the Ti plasmid [JGM (1983) 129 3657–3660]. (See also CRYPTIC PLASMID.)

The presence of a plasmid within a cell may often be inferred from the cell's phenotype: certain characteristics are commonly plasmid-specified. Whether or not a plasmid is present may be determined e.g. by gel ELECTROPHORESIS of a CLEARED LYSATE, or by treating the cells with certain agents that eliminate plasmids (see CURING sense 2) and observing for the loss of particular phenotypic properties. [Plasmid technology: Book ref. 177.]

Some plasmids can promote their own intercellular transfer by CONJUGATION (sense 1b): see CONJUGATIVE PLASMID; some conjugative plasmids contain a TRANSFER OPERON which is DEREPRESSED for conjugal transfer. (See also EPIDEMIC SPREAD.) In addition to their own intercellular transfer, some conjugative plasmids can *mobilize* the host cell's chromosome (or certain types of non-conjugative plasmid) for intercellular transfer (see CONJUGATION sense 1b).

More than one type of plasmid can occur in a given cell; plasmids which have different modes of replication (see below) and of PARTITION are said to exhibit *compatibility*, i.e., they can co-exist stably in the same cell. Plasmids which have similar or identical replication/partition systems are incompatible, i.e., they cannot co-exist stably in the same cell; the phenomenon of incompatibility enables plasmids to be classified into a number of 'incompatibility groups' (Inc groups): see INCOMPATIBILITY.

**Plasmid replication.** A plasmid controls its own replication, using the cell's biosynthetic machinery to make any plasmid-encoded proteins etc. that are needed; plasmid DNA REPLICATION requires various host proteins – commonly e.g. the product of the DNAB GENE, the DNAC GENE, the *dnaE* gene (= *polC* gene: see DNA POLYMERASE) and the *dnaG* gene (see PRIMASE) in *Escherichia coli*. (See also DNAA GENE.)

Replication is not coupled to any specific stage or event in the CELL CYCLE, and in some plasmids it occurs throughout the cell cycle.

Replication and PARTITION appear to be independent processes, although both can determine INCOMPATIBILITY.

The rate-limiting step in replication is *initiation*, and the rate of initiation is controlled in ways that differ according to plasmid.

In some plasmids the control of initiation involves constitutive synthesis of small, *trans*-acting ANTISENSE RNA molecules. Thus, e.g. in plasmid ColE1 control involves the synthesis of two, free (i.e. non-duplexed) strands of plasmid-encoded RNA, one

## plasmid *pInv*

of which, RNA II, can bind at the plasmid's origin and act as a primer, thus permitting replication. The other strand, RNA I, can interfere by base-pairing with RNA II – such that the outcome of RNA I–RNA II interaction determines the occurrence, or otherwise, of replication (for further details see COLE1 PLASMID). (It appears that RNA I is normally polyadenylated, such polyadenylation facilitating its degradation; in *Escherichia coli*, mutations in the *pcnB* gene, which encodes a poly(A) polymerase, result in RNA I molecules that are stabilized through lack of polyadenylation – the effect of which is to inhibit replication of CoIE1, i.e. to reduce its copy number.) Once initiated, replication in CoIE1 proceeds as in the *E. coli* chromosome, although in this plasmid replication occurs *unidirectionally* from the origin.

In the R1 PLASMID (q.v.), antisense RNA molecules bind to, and inhibit translation of, the mRNA of the RepA protein – which, in turn, is involved in regulating the frequency of plasmid replication.

Many of the small circular plasmids in Gram-positive bacteria (and some in Gram-negative bacteria) replicate by a ROLLING CIRCLE MECHANISM. Replication is initiated by a plasmid-encoded *Rep* protein which, by nicking a specific strand at the origin, generates a 3' end for synthesis. One round of replication produces a complete dsDNA plasmid and a circular ssDNA copy, the latter then being replicated to the dsDNA state from an RNA primer. In some of these plasmids initiation is controlled by regulation of the synthesis/activity of the Rep protein (as the quantity of Rep protein affects the frequency of replication); in some cases small, plasmid-encoded RNA molecules bind to the *rep* mRNA and bring about either premature termination of transcription or inhibition of translation. Alternatively, the Rep protein may be inactivated *after only one use* by binding to a small plasmid-encoded oligonucleotide. [Replication control in rolling circle plasmids: TIM (1997) 5 440–446.]

In many plasmids of Gram-negative bacteria, the Rep initiator protein binds to 'direct repeats' of nucleotides (*iterons*) in the region of the plasmid's origin of replication, thus contributing to a nucleoprotein complex that initiates replication. For example, in the F PLASMID, RepE (the E protein) carries out this function; replication proceeds by a *bidirectional* Cairns-type mechanism (as in the *E. coli* chromosome). (See also R6K PLASMID.) For each plasmid, the iterons have a characteristic number, spacing and composition. In some plasmids, Rep can also repress transcription of its *own* gene by binding to inverted repeat sequences overlapping the promoter; in some cases (including the F plasmid) it has been shown that, while *monomers* of Rep bind to iterons (promoting replication), *dimers* bind to the promoters of their own genes (inhibiting replication). RepA monomers (as opposed to dimers) of the *Pseudomonas* plasmid pPS10 may be structurally suitable for RepA–iteron binding [EMBO (1998) 17 4511–4526].

In general, plasmid replication and PARTITIONING seem likely to depend on some kind of association between the plasmid and the cytoplasmic membrane [Mol. Microbiol. (1997) 23 1–10].

Under normal growth conditions, replication is initiated at a frequency which, for a given plasmid in a given type of cell under given conditions, leads to the establishment of a characteristic COPY NUMBER. During steady-state conditions each plasmid replicates, on average, once per cell division – although the inter-replication period may vary widely from one plasmid to another.

If protein synthesis is inhibited (e.g. by CHLORAMPHENICOL), some plasmids can continue to replicate, and can achieve copy numbers much higher than those achieved under normal

growth conditions. Such plasmids (e.g. CoIE1) are said to be under 'relaxed control'; a typical 'relaxed' plasmid is a small, non-conjugative MULTICOPY PLASMID whose copy number under *normal* conditions is ca. 10–30. (A 'relaxed' plasmid can exceed its normal copy number only under abnormal conditions. See also CLONING.) Plasmids which fail to replicate on inhibition of protein synthesis are said to be under 'stringent control'; a typical 'stringent' plasmid is a large, low-copy-number CONJUGATIVE PLASMID.

Whether a plasmid is 'relaxed' or 'stringent' depends on its system of replication control. Thus, e.g. in the 'relaxed' COLE1 PLASMID (q.v.), not only is ongoing protein synthesis not required for replication, but the inhibition of protein synthesis eliminates a protein (Rom/Rop) which is inhibitory to plasmid replication. Conversely, in 'stringent' plasmids replication involves e.g. the synthesis of proteins that are essential for the initiation of replication.

[Control of plasmid replication: Book ref. 161, pp. 189–214.]

Some plasmids have mechanisms for ensuring their persistence within a bacterial strain: see e.g. *ccd* mechanism in entry F PLASMID.

**Nomenclature.** Plasmids are designated in various ways. COLICIN PLASMIDS are designated according to the colicins they encode (e.g. CoIE1-K30 encodes colicin E1, CoIV-I-K94 encodes colicins V and Ia). Many antibiotic-resistance plasmids are designated by the letter 'R' followed by a number, e.g. R1, R46 etc; others include e.g. R6K, RK2, RP1 etc. Recombinant plasmids are often indicated by the prefix 'p', e.g. pML31. A number of plasmids are given trivial names (e.g.,  $\Delta$ ), while the names of some indicate particular functions (see e.g. Ti plasmid under CROWN GALL, and TOL PLASMID).

(See also entries for individual plasmids; e.g. COLE1 PLASMID; DELTA; F PLASMID; PBR322; PMB1; PML31; PSC101; R1 PLASMID; R46 PLASMID; R100 PLASMID; R6K PLASMID; RP1 PLASMID.)

**plasmid *pInv*** See EIEC.

**plasmid pYV** See FOOD POISONING (*Yersinia*).

**plasmin** See FIBRINOLYSIS.

**plasminogen** (profibrinolysin) An inactive precursor of FIBRINOLYSIS normally present in blood; it is a large (~90 kDa) glycoprotein.

Plasminogen has been found to bind disease-associated PRIONS, but not the normal protein (PrP<sup>C</sup>); this property may be useful in diagnostic tests for TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES [Nature (2000) 408 479–483].

**plasmodesma** (*pl.* plasmodesmata) A fine channel in a plant cell wall or a fungal SEPTUM through which cytoplasm can pass; plasmodesmata allow continuity between the cytoplasm of adjacent cells. (See also DESMOTUBULE, PIT CONNECTION and PLANT VIRUSES.)

**plasmodiocrarp** See MYXOMYCETES.

**Plasmodiophora** See PLASMODIOPHOROMYCETES and CLUBROOT.

**Plasmodiophorea** See RHIZOPODA.

**Plasmodiophorina** See GYMNOMYXA.

**Plasmodiophoromycetes** ('endoparasitic slime moulds') A class of eukaryotic organisms (division MYXOMYCOTA) which are obligate intracellular parasites in plants, algae and fungi. The vegetative stage of the organisms is a plasmodium (a naked, multinucleate protoplast); hyphae and fruiting bodies are apparently never formed. Although traditionally regarded as fungi, the true taxonomic position of these organisms remains uncertain; they are apparently unrelated to other members of the Myxomycota. rRNA data studies support the idea that they may be at the base of an evolutionary line leading to the

Chytridiomycetes, Ascomycotina and Basidiomycotina, but do not exclude the possibility of a protozoal ancestry [TBMS (1983) 80 107–112]. (cf. RHIZOPODA and GYMNOXYXA.) Genera include *Ligniera*, *Octomyxa*, *Plasmodiophora*, *Polymyxa*, *Sorodiscus*, *Sorosphaera*, *Spongospora*, *Tetramyxa*, *Woronina*. (cf. ENDEMOSARCA; PHAGOMYXA.) Species are parasitic in e.g. higher plants (e.g. *Plasmodiophora brassicae* in crucifers – see CLUBROOT; *Spongospora subterranea* in potatoes – see POWDERY SCAB; *Ligniera betae* in beet; *L. junci* in various monocots and dicots); in algae (e.g. *Woronina* in *Vaucheria*, *Sorodiscus* in *Chara*); and in certain aquatic fungi (e.g. *Woronina* in *Achlya*, *Pythium* or *Saprolegnia*). Infected tissues often exhibit hypertrophy and sometimes hyperplasia.

In e.g. *Plasmodiophora brassicae* and *Polymyxa betae*, infection of a new host is initiated when a ('primary') zoospore attaches to the wall of a root hair, withdraws its flagella, and encysts. Within the encysted cell there develops a tubular structure, the *Rohr*, containing an osmiophilic spine-like structure, the *Stachel*. The *Rohr* evaginates rapidly, and the *Stachel* punctures the host cell wall; the protoplast of the encysted zoospore then enters the host cell and develops into a vegetative primary (= sporangigenous) plasmodium. When mature, this plasmodium gives rise to uninucleate 'secondary' zoospores, each with two smooth flagella of different lengths. [Secondary zoospore development in *P. brassicae*: TBMS (1984) 82 339–342.] The zoospores are released either by disintegration of the host cell or via an 'exit tube' arising from the zoosporangium. The role of these zoospores in the life cycle is unclear; fusion between two zoospores has been reported, but karyogamy – when it occurs – is apparently delayed. A zoospore (or fused pair of zoospores?) infects another host cell, in which it develops to form a (diploid?) secondary (= cystogenous) plasmodium. When mature, this plasmodium eventually cleaves to form a number of uninucleate, thick-walled, resistant cysts (resting spores); meiosis has been observed at this stage in several species. [Ultrastructure of meiosis in *Woronina pythii*: Mycol. (1984) 76 1075–1088.] In some species the cysts are arranged in characteristic clusters (cystosori). [Fine structure of the cystosorus in *Spongospora subterranea*: CJB (1985) 63 2278–2282.] On disintegration of the host cell the cysts are liberated into the soil where they may remain viable for long periods (e.g. years). On germination, each cyst gives rise to a biflagellate (heterokont) zoospore which can infect another host, thus initiating a new cycle.

Some members of the Plasmodiophoromycetes are important as vectors of certain plant viruses: see e.g. BEET NECROTIC YELLOW VEIN VIRUS, SOIL-BORNE WHEAT MOSAIC VIRUS, POTYVIRUSES, TOBAMOVIRUSES.

**plasmodium** A multinucleated, usually motile mass of protoplasm which is usually naked (i.e., bounded only by a plasma membrane) and which is generally variable in size and form; plasmodia are the main vegetative forms in e.g. members of the ACARPOMYXEA, MYXOMYCETES (q.v. for types), MYXOSPORA and PLASMODIOPHOROMYCETES. (cf. PSEUDOPLASMODIUM.)

**Plasmodium** A genus of protozoa of the suborder HAEMOSPORINA. The genus includes the common causal agents of MALARIA in man: *P. falciparum* [genome: Nature (2002) 419 498–511], *P. malariae* (formerly *P. rodhaini*), *P. ovale* and *P. vivax*. *P. cynomolgi* and *P. knowlesi* are parasitic in non-human primates; they occasionally cause malaria in man, and have been widely used as models in research on human malaria. *P. berghei* and *P. yoelii* (also spelt *P. yoelli*) cause rodent malaria; they have been used for testing antimalarial drugs.

The life cycle is basically similar in all species. In *Plasmodium* spp. sexual reproduction occurs in a mosquito and leads to the formation of large numbers of fusiform or needle-shaped uninucleate cells (*sporozoites*), ca. 6–18  $\mu\text{m}$  in length, that are infective for the vertebrate host. (Below ca. 15°C *P. falciparum* will not develop within the mosquito, and below ca. 18°C its development is retarded; *P. vivax* can develop in mosquitoes at somewhat lower temperatures – which probably accounts for its presence in temperate as well as tropical and subtropical regions.) Transmission of the parasite occurs when the (female) mosquito takes a blood meal by inserting her proboscis into the tissues of a vertebrate host: sporozoites, present in the insect's saliva, quickly reach the bloodstream and initiate the cycles of asexual reproduction.

In man, the sporozoites rapidly enter parenchymatous cells in the liver; there, they typically grow and eventually undergo SCHIZOGONY, rupturing the liver cells and releasing into the bloodstream large numbers of minute cells (*merozoites*), each ca. 1  $\mu\text{m}$  in diameter. This stage is called *pre-erythrocytic* schizogony or *exoerythrocytic schizogony*; its duration ranges from ca. 5½ days (in *P. falciparum*) to ca. 15 days (in *P. malariae*), and is ca. 8 and 9 days respectively, in *P. vivax* and *P. ovale*. Instead of growth and schizogony, some or all of the sporozoites of some species – e.g. *P. cynomolgi*, *P. ovale*, *P. vivax* – form specialized cells (*hypnozoites*) which can remain dormant within the liver for e.g. 8–10 months; on resuming development, the hypnozoites follow the normal course of growth and schizogony and give rise to the (periodic) relapses which are characteristic of malaria caused by these species.

Merozoites bind to, and enter, erythrocytes – except e.g. in *P. berghei* and *P. yoelii*, in which the merozoites parasitize reticulocytes (erythrocyte precursor cells). Within an erythrocyte a merozoite forms a central vacuole and develops into the characteristic 'ring' or 'signet-ring' stage; in stained preparations this commonly appears as a ring of cytoplasm containing a bulging nucleus. The growing cell (now called a *trophozoite*) obtains nutrients from e.g. the protein part of the host cell's haemoglobin; *P. falciparum* apparently obtains its iron from outside the parasitized erythrocyte (see TRANSFERRIN; cf. HAEMOZOIN). At this stage the erythrocyte and/or parasite may exhibit certain inclusions: see HAEMOZOIN, MAURER'S CLEFTS, SCHÜFFNER'S DOTS and ZIEMANN'S DOTS. A protein designated exp-1 was detected in a cytoplasmic compartment in *P. falciparum*-infected erythrocytes; it was suggested that parasite-encoded proteins pass through this compartment on their way to the erythrocyte's plasmalemma [EMBO (1987) 6 485–491].

The fully grown parasite (now called a *schizont*), which no longer appears ring-shaped, subsequently undergoes schizogony to form a number of merozoites (each ca. 1  $\mu\text{m}$  diam.) which are released from the ruptured erythrocyte; these merozoites can infect fresh erythrocytes. Typically, merozoites are released more or less synchronously from large numbers of parasitized erythrocytes, thus accounting for the periodic symptoms of malaria; the duration of the erythrocytic cycle (i.e., from infection to rupture) typically ranges from ca. 2 days (*P. falciparum*) to ca. 3 days (*P. malariae*), but is only 1 day in *P. knowlesi*.

After one or more erythrocytic cycles, some of the intraerythrocytic merozoites develop into gametocytes (rather than schizonts); within the bloodstream, gametocytes may remain viable for one month or more, but they do not develop further unless ingested by an anopheline mosquito. On ingestion by a mosquito

## plasmogamy

the gametocytes develop into male and female gametes. In this process the (male) microgametocyte undergoes *exflagellation*: several nuclear divisions occur, up to eight thread-like appendages are formed, and the microgametocyte eventually breaks up to form uninucleate, uniflagellate male gametes (microgametes). A microgamete fuses with a (female) macrogamete to form a zygote which subsequently becomes motile (and is then called an *ookinete* or *vermicule*). The ookinete passes through the mosquito's gut wall, rounds off, and forms an oocyst in the outer layer of the gut wall (adjacent to the haemocoel). Sporozoites develop within the oocyst; they are subsequently released into the haemocoel, and many find their way to the insect's salivary glands, thus completing the cycle.

*Plasmodial antigens and antimalarial vaccines.* Certain plasmodial antigens have been used in the preparation of antimalarial vaccines. One such antigen is the *circumsporozoite protein* (CS protein), a protein (MWt ca. 60000) which forms a thick surface coat of the (mature) sporozoite. [CS proteins: Cell (1985) 42 401–403.] Monoclonal antibodies to CS proteins inhibit infectivity of sporozoites both in vitro and in vivo. (cf. CSP REACTION.) The CS proteins from different species of *Plasmodium* all contain a block of tandemly repeated peptides (though these vary in nature according to species); in e.g. *P. falciparum* there are multiple copies of the tetrapeptide asparagine–alanine–asparagine–proline (designated NANP), and these sequences are involved in the binding of anti-CS protein monoclonal antibodies. One experimental antimalarial vaccine consisted of a suspension of polypeptides each containing multiple repeats of NANP (and of another tetrapeptide, asparagine–valine–aspartic acid–proline (NVDP), also found in *P. falciparum*). Another experimental vaccine was prepared from an NANP trimer conjugated to tetanus toxoid.

The *ring-infected erythrocyte surface antigen* (RESA) is a parasite-encoded protein found in the plasmalemma in erythrocytes infected with the ring stage of *P. falciparum*; it is a protein of MWt ca. 155000, and is sometimes referred to as Pf155. Antibodies to a repeated amino acid sequence in RESA inhibit the invasion of erythrocytes by merozoites in vitro.

The possibility of a *transmission-blocking vaccine* arose from the observation that anti-gamete antibodies raised in an animal host can neutralize the gametes (of *Plasmodium*) in a mosquito which has taken a blood meal from that host; transmission of the parasite to a new host is therefore inhibited.

The problems of developing a satisfactory antimalarial vaccine are exacerbated by ANTIGENIC VARIATION in *Plasmodium*.

For more recent data on anti-malaria vaccines see the entry MALARIA.

*Subgenera of Plasmodium.* Subgenera are defined on the basis of (a) the vertebrate host(s), and (b) the morphology of the erythrocytic schizont and the gametocyte. Subgenera include:

*Haemamoeba.* Hosts: birds. Vector: the mosquito *Mansonia crassipes* (experimental vectors include *Aedes aegypti*, *Anopheles* spp, *Culex* spp). Schizonts are large, gametocytes spherical.

*Laverania.* Hosts: primates. Vector: anopheline mosquitoes. Schizonts are large, gametocytes elongated and crescentic. Species include *Plasmodium* (*Laverania*) *falciparum*.

*Plasmodium.* Hosts: primates. Vector: anopheline mosquitoes. Schizonts are large, gametocytes spherical. Species include *Plasmodium* (*Plasmodium*) *cynomolgi*, *P. (P.) knowlesi*, *P. (P.) malariae*, *P. (P.) ovale*, and *P. (P.) vivax*.

*Vinckeria.* Hosts: non-primate mammals. Vector: anopheline mosquitoes. Schizonts are small, gametocytes spherical.

Other (avian) subgenera: *Giovannolaia*, *Novyella*, *Huffia*.

**plasmogamy** Coalescence of the cytoplasm of two or more cells; in fertilization, plasmogamy is followed by KARYOGAMY.

**Plasmopara** A genus of fungi of the PERONOSPORALES; species include *P. viticola* and *P. halstedii*, the causal agents of DOWNY MILDEWS on grape and sunflower, respectively.

**plasmotomy** In certain multinucleate protozoa (e.g. *Actinosphaera*, *Pelomyxa*): an asexual reproductive process in which fission results in the formation of two or more multinucleate daughter cells, the nuclei of the parent cell being more or less evenly distributed between them; nuclear and cytoplasmic divisions appear to occur independently.

**plastids** (from bacteria) See BIOPOL.

**plastid** Any of various types of membrane-limited, typically DNA-containing organelle which occur within the cells of plants and algae but not in those of animals or prokaryotes. Examples: AMYLOPLAST, CHLOROPLAST, CHROMOPLAST, ELAIOPLAST, ETIOPLAST and LEUKOPLAST. (See also PLASTOME.)

**plastocyanin** A copper-containing BLUE PROTEIN which acts as an electron donor to photosystem I (see PHOTOSYNTHESIS). In certain algae (e.g. *Scenedesmus*) plastocyanin can apparently be replaced by a *c*-type cytochrome in the absence of copper. [Structure and function of plastocyanin: Book ref. 146, pp. 19–31.]

**plastoglobuli** Osmiophilic lipid globules in the stroma of a CHLOROPLAST.

**plastome** The genetic complement of a PLASTID.

**plastoquinone** See QUINONES and PHOTOSYNTHESIS.

**plate** (1) A solid MEDIUM in a PETRI DISH prepared (using an ASEPTIC TECHNIQUE) by pouring a sterile molten (AGAR- or GELATIN-based) medium into a Petri dish to a depth of 3–5 mm and allowing it to set. Freshly-poured plates to be used e.g. for STREAKING should be left for 10–20 min in a 37°C hot-air incubator with the lid partly off so that the surface moisture can evaporate; such 'drying' before inoculation prevents unwanted spreading of the inoculum in the surface film of moisture. (See also SPREAD PLATE.) (2) A *plate* CULTURE. (3) (*verb*) To inoculate a plate: see PLATING.

**plate dilution test** See DILUTION TEST.

**platelet factor 4** (PF4) See CHEMOKINES.

**platelets** (thrombocytes) Flat, disc-like, membrane-bounded bodies (ca. 2.5 µm diam.) which occur in mammalian blood (ca. 250000/mm<sup>3</sup> in human blood); they are formed by fragmentation of megakaryocytes in red bone marrow. Platelets adhere to rough or damaged surfaces and assist in blood clotting (though clotting can occur in their absence). Platelets contain e.g. HISTAMINE and SEROTONIN.

**plating** (1) The act of distributing an INOCULUM on the surface of a PLATE – see e.g. SPREAD PLATE and STREAKING. (2) (*serol.*) The use of specifically coated plastic (or other) surfaces for the separation of specific cells (or other entities) from heterogeneous populations. The procedure is based on antigen–antibody specificity; thus, e.g., antibody, immobilized (by its Fc portion) on an inert support, will bind, and thus remove from a mixture, those cells which bear homologous cell-surface antigens.

**Platyamoeba** See AMOEBIDA.

**Platymonas** See TETRASELMIS.

**plcB gene** See LISTERIOSIS.

**plectenchyma** (*mycol.*) A tissue composed of hyphae or cells; such tissues occur e.g. in LICHEN thalli, in fungal fruiting bodies, etc. There are two principal types of plectenchyma: *prosenchyma* (prosoplectenchyma), in which the hyphae remain distinguishable, are rather loosely woven, and are more or less parallel to each other; and *pseudoparenchyma* (paraplectenchyma), in

which hyphae are usually not distinguishable as such, the tissue consisting of closely packed, isodiametric or oval cells (resembling the parenchyma of higher plants). 'Palisade plectenchyma' occurs in the cortex of many lichen thalli, and consists of short hyphae orientated more or less perpendicular to the thallus surface.

**Plectonema** A genus of cyanobacteria of the LPP GROUP. Although non-heterocystous, *P. boryanum* can carry out NITROGEN FIXATION under microaerobic (but not under aerobic) conditions.

**Plectrovirus** (mycoplasma virus type 1 phages; L1 acholeplasma-virus group) A genus of BACTERIOPHAGES of the INOVIIRIDAE. Host: *Acholeplasma laidlawii*; plaques turbid (sometimes with a clear centre), 0.5–6.0 mm across. Other strains of *Acholeplasma* and *Mycoplasma* may be infected. The virions are short, naked, bullet-shaped rods (70–90 × 14–16 nm) comprising ss cccDNA (MWt 1.5 × 10<sup>6</sup>) and four proteins. Proposed type member: MV-L51 (= L1 strain L51). Other member: MV-L1 (= L1 strain L1). Possible member: SV-C1 (see SPIROPLASMAVIRUSES). See also MYCOPLASMAVIRUSES.

**pleiotropic** Refers to e.g. a gene or a mutation which has multiple effects: e.g., expression of a pleiotropic gene affects more than one phenotypic characteristic.

**Pleistophora** See MICROSPOREA.

**pleomorphic** Refers to e.g. an organism which exhibits PLEOMORPHISM.

**pleomorphism** (1) In general: an inherent variability in size and shape e.g. among the cells in a pure culture of a given organism. Cells of a pleomorphic organism (e.g. *Corynebacterium* spp, *Propionibacterium* spp) may occur in a wide range of indeterminate forms which are often variations of a single basic shape: e.g. the cells may be basically rod-shaped but may be swollen at one or both ends, curved or straight, branched or unbranched, etc. (cf. POLYMORPHISM sense 1.)

(2) *Syn.* POLYMORPHISM sense 1. (3) (*mycol.*) Degenerative changes – e.g. loss of the ability to form conidia and/or to synthesize pigment – which occur in some fungi (e.g. certain dermatophytes) when propagated in laboratory cultures.

**Pleospora** See DOTHIDEALES.

**Plesiomonas** ('C27 organisms') A genus of Gram-negative bacteria of the VIBRIONACEAE. Cells: straight, round-ended rods, 0.8–1.0 × 1–3 μm. Usually motile with 2–5 lophotrichous unsheathed flagella; lateral flagella may be formed in young cultures on solid media. Optimum growth temperature: ca. 35–38°C. Growth does not require NaCl and cannot occur with 7.5% NaCl. Growth media: e.g. SS, XLD or Hektoen agars [media, identification etc: Book ref. 46, pp. 1285–1288]. Oxidase +ve; acid but not gas is formed from glucose and e.g. inositol; extracellular DNase, gelatinase and lipase are not formed; most strains are sensitive to O/129. Strains may possess the enterobacterial common antigen, and a few share an O antigen with *Shigella sonnei*. GC%: 51. Type species: *P. shigelloides* – found in association with fish and other aquatic animals and in mammals; strains can cause e.g. gastroenteritis in man. [Book ref. 22, pp. 548–550.]

According to 5S rRNA sequence analysis, *P. shigelloides* is more closely related to *Proteus mirabilis* than is *Proteus vulgaris* and should therefore be included in the genus PROTEUS as *Proteus shigelloides* [SAAM (1985) 6 171–182]. (See also ENTEROBACTERIAL COMMON ANTIGEN.)

**Pleurasiga** See CHOANOFLAGELLIDA.

**Pleurastrrophyceae** See TETRASELMIS and TREBOUXIA.

**Pleurastrum** A genus of filamentous green algae related to TREBOUXIA; the filaments are branched and lack holdfasts. *P. terrestre* may also grow as unicells under certain conditions.

**Pleuroascus** See EUROTIALES.

**Pleurocapsa** See PLEUROCAPSA GROUP.

**Pleurocapsa group** A large and diverse group of unicellular CYANOBACTERIA (section II) in which growth and binary fission lead to the formation of irregular, sometimes pseudofilamentous cell aggregates; baecocytes initially lack a fibrous outer cell wall layer and are motile (by gliding). In some members (subgroup I) growth of the baecocyte is symmetrical, resulting in a spherical vegetative cell, while in others (subgroup II) growth is asymmetrical and vegetative cells are elongated prior to the onset of binary fission. The group includes organisms previously included in many phycological genera (e.g. *Hyella*, *Pleurocapsa*) which were based on characters such as endolithic habit, arrangement of vegetative cells in aggregates, etc. GC%: 39–47.

**pleurocapsalean** (1) Refers to BAEOCYTE-forming CYANOBACTERIA (section II). (2) Refers to any member of the phycological order Pleurocapsales.

**Pleurocapsales** See CYANOBACTERIA.

**Pleurococcus** A genus of unicellular green algae (division CHLOROPHYTA) which are extremely common on wood, bark etc; the cells generally occur in characteristic packets. The organisms have been referred to by various names (*Pleurococcus viridis*, *P. vulgaris*, *Protococcus viridis*, etc), but apparently should be called *Desmococcus olivaceus* [Taxon (1985) 34 671–672].

**pleurodynia** See BORNHOLM DISEASE.

**Pleuronema** See SCUTICOCILIATIDA.

**Pleurosigma** See DIATOMS.

**Pleurotus** A genus of fungi of the APHYLLOPHORALES (family Polyporaceae) in which the basidiocarp is commonly pileate and stipitate (stipe often eccentric or lateral); the hymenium is borne on decurrent lamellae (see LAMELLA). *P. ostreatus* is an edible species (see OYSTER FUNGUS) which grows on wood and which can be pathogenic for certain trees, particularly beech (*Fagus*).

**pligate** Folded.

**Plodia interpunctella** GV See GRANULOSIS VIRUSES.

**ploidy** The number of (complete) sets of chromosomes (or AUTOSOMES) in a cell. (See also DIPLOID, HAPLOID, POLYPLOID, ANEUPLOID.)

**plugging** (of pipettes) The insertion of a small plug of COTTON WOOL into the wide end of a pipette or PASTEUR PIPETTE before sterilization; liquids being pipetted are thus protected from contamination from the rubber bulb, pi-pump etc.

**plum pox** (sharka disease) A disease affecting many species of *Prunus* (e.g. plum, apricot, peach, blackthorn); it is caused by a virus of the POTYVIRUSES and is transmitted by aphids and by infected rootstocks. Symptoms commonly include diffuse mottling or ring-spots on the leaves, premature fruit-drop, and (depending on fruit type) dark bands or rings, or grooving and pitting, on the fruits.

**plumbagin** 5-Hydroxy-2-methyl-1,4-naphthoquinone.

**plunging jet** See JET LOOP FERMENTER.

**pluracidomycins** CARBAPENEM antibiotics.

**plurivorous** Able to use a range of hosts or substrates.

**Pluronic polyol F127** A copolymer of ethylene oxide and polypropylene oxide used e.g. as a solidifying agent for culture media. (See also MEDIUM.) A polyol-solidified medium can be liquefied by cooling, the gel–liquid transition temperature depending on the concentration of polyol used. The clear, paste-like medium is apparently unsuitable for streaking, but is

## plus-progamone

reported to be suitable for use e.g. in the pour plate technique for heat-sensitive organisms, and in gradient gel systems. [JGM (1984) 130 731–733.]

**plus-progamone** See PHEROMONE.

**plus strand** (of a gene) (*mol. biol.*) See CODING STRAND.

**plus strand** (*virol.*) See VIRUS.

**Pluteaceae** See AGARICALES.

**PM2 phage group** *Syn.* CORTICOVIRIDAE.

**pMB1** A small, multicopy PLASMID which carries genes for colicin E1, the colicin E1 immunity protein, and the *EcoRI* restriction and modification enzymes. pMB1 belongs to the same incompatibility group as the COLE1 PLASMID, and its *ori* region shares extensive homology with that of the Cole1 plasmid.

**pmf** Proton motive force: see CHEMIOSMOSIS.

**pMG25** See INCOMPATIBILITY.

**PML** PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY.

**pML31** An autonomous 9-kb plasmid obtained by digestion of the F PLASMID with *EcoRI* restriction endonuclease and the ligation of a part of the plasmid (containing an origin of replication) with an antibiotic-resistance determinant. (See also MINI-F PLASMID.)

**PMN** Polymorphonuclear leucocyte ('polymorph'; granulocyte): a type of LEUCOCYTE which has a lobed nucleus and granular cytoplasm (hence 'granulocyte'); diam. ca. 10–15  $\mu\text{m}$ . PMNs include NEUTROPHILS, BASOPHILS and EOSINOPHILS – so named because of the affinity of their cytoplasmic granules for particular dyes; they are short-lived cells which do not replicate and which are continually replaced by cells derived from bone marrow. 'Polymorph' may refer to PMNs in general, but is sometimes used to refer solely to neutrophils.

**PNA** (peptide nucleic acid) An analogue of DNA, the backbone chains of which are modified polypeptides (rather than sugar–phosphate units). Two strands of PNA can hybridize to form a DNA-like helical duplex [Nature (1994) 368 561–563]; the existence of such a molecule has prompted the suggestion that pre-biotic nucleic acids may not necessarily have had a sugar–phosphate backbone.

A strand of PNA can hybridize with a strand of DNA; this may be of use in DNA CHIP technology.

PNA probes have been used for identifying and enumerating specific microorganisms by an *in situ* hybridization technique [JAM (2001) 90 180–189].

**pncA gene** See PYRAZINAMIDE.

**pneumatocyst** (air bladder/vesicle; bladder; gas bladder) A gas-filled structure normally present in the thallus of certain algae (e.g. species of *Fucus*, *Pelagophycus* and *Sargassum*); a given thallus may contain many pneumatocysts. Pneumatocysts, which are generally observable as distinct swellings, contribute buoyancy to the thallus. (cf. GAS VESICLE.)

**pneumococcal pneumonia** See PNEUMONIA (a).

**pneumococcus** *Streptococcus pneumoniae*.

**pneumococcus capsule swelling reaction** *Syn.* QUELLUNG PHENOMENON.

***Pneumocystis*** A genus of fungi (formerly regarded as protozoa) now classified as members of the subdivision Ascomycotina. *P. carinii* is an important causal agent of pneumonia in HIV-infected patients; however, it can also give rise to infection in e.g. children and elderly individuals in the absence of HIV infection [BCID (1995) 2 461–470]. *P. carinii* is also a causal agent of disease in animals (e.g. pigs).

The cells of *P. carinii* are  $\sim 1\text{--}5\ \mu\text{m}$ ; asci (10–12  $\mu\text{m}$ ) each contain up to eight ascospores. No satisfactory culture technique has been developed.

Diagnosis of *Pneumocystis* pneumonia typically involves microscopy of induced sputum or of fluid from broncho-alveolar lavage. Asci can be seen by staining with either TOLUIDINE BLUE or Gomori's silver stain. Individual cells are detected with Giemsa or Wright's stain [AJCP (1984) 81 511–514]. Immunofluorescence stains are also available for *P. carinii*.

[*Pneumocystis carinii* (epidemiology, pneumonia, laboratory diagnosis, therapy etc.): BCID (1995) 2 409–576. Immune response to *P. carinii* infection: TIM (1998) 6 71–75. *P. carinii* pneumonia in pigs (immunohistochemical study): VR (2000) 147 544–549.]

**pneumolysin** See THIOL-ACTIVATED CYTOLYSINS.

**pneumonia** Inflammation of the lungs. It may involve the alveoli (cf. ALVEOLITIS) and/or the interstitial tissues (*interstitial pneumonia*); inflammation may affect most of the parenchyma in one or more lobes (*lobar pneumonia*) or may be diffuse. Pneumonia is commonly due to bacterial infection, often secondary to e.g. viral URTI (such as INFLUENZA) or other infection (e.g. MEASLES); other causal agents include e.g. viruses (see also PNEUMOCYSTIS). The pathogen may gain access to the lungs by inhalation or via the blood or lymph systems (see e.g. *bubonic PLAGUE*). Conditions which predispose to pneumonia include chronic lung disease, debilitating illness, immunosuppression, etc. Symptoms of pneumonia generally include fever, chills, rigors, malaise, dyspnoea and chest pain; cough may be initially dry, later productive of purulent, sometimes bloody sputum. *Lab. diagnosis*: examination of sputum, pleural fluid etc by microscopy, culture, and/or serological techniques (e.g. CIE). Sputum may be obtained by percutaneous aspiration from the trachea, rather than by expectoration, to reduce contamination by members of the normal respiratory tract flora.

(a) *Pneumococcal pneumonia* ('classical lobar pneumonia'), caused by certain strains of *Streptococcus pneumoniae* (the 'pneumococcus'), is the commonest form of bacterial pneumonia. Infection may be primary or secondary. The pathogen, present e.g. in the upper respiratory tract of carriers, gains access to the lungs by inhalation. Incubation period: 1–3 days. Affected lobes typically become consolidated, i.e., solidified with inflammatory material (leucocytes, fibrin, pneumococci etc). Sputum is initially purulent, becoming 'rusty' or blood-stained as the consolidation breaks down. Complications include e.g. pericarditis, meningitis etc. *Chemotherapy*: e.g. penicillins, erythromycin. Polyvalent vaccines containing polysaccharide antigens of various common pneumococcal serotypes are available for certain high-risk patients [NEJM (1984) 310 651–653; AIM (1986) 104 106–109, 110–112, 118–120].

(b) *Haemophilus influenzae* (usually type b) may cause primary pneumonia (mainly in children) or secondary pneumonia in patients with e.g. viral respiratory tract infection. The pneumonia may be diffuse or lobar, and abscesses may develop. *Chemotherapy*: e.g. ampicillin; tetracycline; chloramphenicol.

(c) *Staphylococcus aureus* can cause lobar or diffuse interstitial pneumonia, usually following e.g. influenza or staphylococcal septicaemia. Abscesses may develop in lungs and/or pleura. Sputum is yellow, purulent, and sometimes bloody. Proteases from some strains of *S. aureus* may activate influenza virus virions (by cleaving their haemagglutinins: see INFLUENZAVIRUS), thus promoting combined viral–bacterial pneumonia [Nature (1987) 325 536–537]. *Chemotherapy*: e.g.  $\beta$ -lactamase-resistant  $\beta$ -lactam antibiotics.

(d) *Friedländer's pneumonia* (caused by *Klebsiella pneumoniae*) is a severe form which usually occurs as a complication of e.g. chronic lung disease. Typically, one or more lobes become

densely infiltrated, and thin-walled abscesses occur. Sputum is often viscid, gelatinous and blood-stained. *Chemotherapy*: e.g. gentamicin; amikacin; cephalosporins.

(e) *Streptococcus pyogenes* may cause primary or secondary pneumonia which is usually diffuse and often leads to empyema. *Chemotherapy*: e.g. penicillins.

(f) Various other Gram-negative bacteria may cause primary or secondary pneumonia – particularly in the very young or elderly, debilitated, or immunosuppressed, often following antibiotic therapy. Nosocomial pneumonia may be due e.g. to species of *Enterobacter*, *Klebsiella*, *Proteus*, *Serratia*, *Escherichia coli* or *Pseudomonas aeruginosa*. Anaerobes (e.g. *Bacteroides* spp) may infect the lungs, often with abscess formation; infection originates from the mouth or – via the lymph or blood systems – from e.g. intra-abdominal abscesses. (See also LEGIONELLOSIS.)

(g) Certain viruses (e.g. adenoviruses, coxsackieviruses, parainfluenza viruses, respiratory syncytial virus) can cause pneumonia, particularly in small children. (See also (c), above.)

Cf. PNEUMONITIS and PRIMARY ATYPICAL PNEUMONIA. See also e.g. ASPERGILLOSIS; COCCIDIOIDOMYCOSIS; HISTOPLASMOSIS; PLAGUE; PNEUMOCYSTIS.

For pneumonia in *animals* see e.g. ATYPICAL INTERSTITIAL PNEUMONIA; BOVINE RESPIRATORY DISEASE; CALF PNEUMONIA; CONTAGIOUS BOVINE PLEUROPNEUMONIA; JAAGSIEKTE; MAEDI.

**pneumonia of mice virus** See PNEUMOVIRUS.

**pneumonic pasteurellosis** See BOVINE RESPIRATORY DISEASE.

**pneumonitis** (1) *Syn.* PNEUMONIA. (2) Inflammation of the lungs as part of a more generalized syndrome, or resulting from chemical or physical injury or allergy (as opposed to infection). (cf. ALVEOLITIS.)

**pneumotropic** Having an affinity for the lungs.

**Pneumovirus** A genus of viruses of the PARAMYXOVIRIDAE in which the virions have neither haemagglutinin nor neuraminidase activity. Type species: (human) respiratory syncytial virus (RSV), an important cause of respiratory disease in humans (particularly infants and young children) – see e.g. BRONCHIOLITIS, COMMON COLD, CROUP, PNEUMONIA (g). [Review of RSV: Arch. Virol. (1985) 84 1–52. Experimental models for RSV infections: RMM (1996) 7 115–122.]

Other members of the genus: bovine respiratory syncytial virus (see BOVINE RESPIRATORY DISEASE) and pneumonia of mice virus (common in laboratory mice, in which infection is latent or mild).

**PNPase** POLYNUCLEOTIDE PHOSPHORYLASE.

**P/O ratio** (P:O ratio) A measure of the efficiency of OXIDATIVE PHOSPHORYLATION: the number of molecules of ATP formed per atom of oxygen used. (cf.  $H^+/O$  RATIO.)

**POC** Particulate organic carbon. (cf. DOC.)

**Pocheina** See ACRASIMYCETES.

**pock** (1) (*med.*) A cutaneous pustule, as formed e.g. in SMALLPOX.

(2) (*virol.*) A lesion produced on the CAM (see EMBRYONATED EGG) by certain viruses; the nature and number of pocks formed can be useful in the identification and assay of the virus (see e.g. COWPOX VIRUS, VACCINIA VIRUS and VARIOLA VIRUS).

**pocket rot** (of timber) A form of WHITE ROT in which decay is limited to small, discrete regions ('pockets') and LIGNIN is attacked preferentially. Pocket rot fungi include *Phellinus pini* (in conifers) and *Inonotus* sp (in oaks). [Mycol. (1983) 75 552–556.]

**pod rot** (frosty pod; Quevedo disease) A CACAO DISEASE caused by *Monilophthora roreri* and characterized by a whitish ('frosted') powdery covering of spores on the pods; the spores

subsequently darken. [Phytopathol. Paper number 24 (March, 1981).]

**Podaxiales** See GASTEROMYCETES.

**podetium** (*lichenol.*) A vertical, stem-like, lichenized structure of generative tissue (sometimes called a 'secondary thallus') which develops from a crustose, squamulose or foliose basal ('primary') thallus and which supports one or more hymenial discs ('apothecia'); the entire podetium – together with its hymenial disc(s) – should be regarded as a fruticose APOTHECIUM [Lichenol. (1982) 14 105 – 113]. (cf. PSEUDOPODETIUM.) Podetia are formed e.g. by most species of CLADONIA; they are usually hollow and may be branched or unbranched or – in some *Cladonia* spp – may terminate in a cup- or funnel-shaped structure (the 'scyphus'). (According to the above definition, structures resembling podetia but lacking algae are not true podetia; such structures are formed e.g. by *Baeomyces* spp and *Cladonia caespiticia*.)

**Podophrya** See SUCTORIA.

**podophyllotoxin** A substance of plant origin (obtained from *Podophyllum peltatum*) which has antitumour activity. Podophyllotoxin, which contains a trimethoxy-substituted aromatic ring, binds to TUBULIN at a site close to (or identical with) that at which COLCHICINE binds – inhibiting the assembly of MICROTUBULES. Some *epipodophyllotoxins* (which have been used as antitumour agents) appear to affect DNA synthesis (rather than microtubule assembly) – apparently by inhibiting topoisomerase activity.

**Podoscypha** See APHYLLOPHORALES (Stereaceae).

**Podospheara** See ERYSPHALES.

**Podospora** A genus of fungi (order SORDARIALES) which occur e.g. on soil and dung; the organisms form dark ascospores, each bearing gelatinous appendages, in persistent asci formed in perithecia. In *P. anserina* the four binucleate ascospores per ascus each contain nuclei of compatible mating types (cf. secondary HOMOTHALLISM). (See also AMEXIS.)

**Podoviridae** A family of DNA-containing BACTERIOPHAGES which have isometric or elongated heads and short (ca. 20 nm) non-contractile tails. Members include BACTERIOPHAGE N4, P22,  $\phi$ 29, T3, T7 (type species), and TBILISI PHAGE (see separate entries). (See also MV-L3 PHAGE GROUP and SPIROPLASMAVIRUSES (SV-C3).)

**Pogosta disease** See SINDBIS VIRUS.

**Poikilovirus** See ALPHAHERPESVIRINAE.

**point mutation** (1) A type of MUTATION in which a single nucleotide is replaced by another: see TRANSITION MUTATION and TRANSVERSION MUTATION. A point mutation in a structural gene may result in a MIS-SENSE MUTATION, a NONSENSE MUTATION, or a SAME-SENSE MUTATION. Mutagens which can induce point mutations include e.g. 5-BROMOURACIL, HYDROXYLAMINE and NITROUS ACID.

(2) Any mutation involving a single nucleotide, including the gain or loss of a nucleotide (resulting in a FRAMESHIFT MUTATION) as well as transition and transversion mutations.

(cf. MULTISITE MUTATION.)

**poising system** See REDOX POTENTIAL.

**Poirrasia** See MUCORALES.

**pokeweed mitogen** (PWM) Any of five mitogenic LECTINS (designated Pa-1 to Pa-5) obtained from the roots, leaves and berries of the pokeweed, *Phytolacca americana*. All can stimulate T cells; Pa-1, in the presence of T cells and macrophages, can stimulate Ig secretion by B cells. PWM binds to oligomers of  $\beta$ -D-acetylglucosamine.

**poky mutant** A mutant strain of *Neurospora* which has a subnormal rate of growth owing to a deficiency in its respiratory

## **pol genes**

chain. The mutant gene (= *mi-1* or maternal inheritance-1 gene) appears to occur in the mitochondrial DNA, and is transmitted to sexually-derived progeny only from a female (ascogonial) parent; such MATERNAL INHERITANCE is presumed to be due to the absence of mitochondria in the (male) microconidium. (cf. PETITE MUTANT.)

**pol genes** (1) See DNA POLYMERASE. (2) See RETROVIRIDAE.

**polA gene** See DNA POLYMERASE.

**polar body** An intracellular granule at one or each pole of a cell – e.g. the deposits of PHB in *Beijerinckia*.

**polar cap** See MICROSPORA.

**polar capsule** See MYXOZOA.

**polar fibre** See MITOSIS.

**polar filament** See MICROSPORA and MYXOZOA.

**polar membrane** A multilaminar intracellular membrane, attached to the inside of the cytoplasmic membrane by bar-like links, present at the poles (sites of flagellar attachment) of the cells in species of helical and vibrioid bacteria (e.g. *Aquaspirillum*, *Campylobacter*, *Ectothiorhodospira*, *Oceanospirillum*, *Rhodospirillum*, *Spirillum*).

**polar microtubule** See MITOSIS.

**polar mutation** A mutation which, in addition to affecting the gene in which it occurs, reduces the expression of any gene(s) in the same (polycistronic) operon on the promoter-distal side of the mutation – a phenomenon known as *polarity*; genes between the promoter and the mutation are not affected. Thus, e.g., in the LAC OPERON a nonsense mutation in the  $\gamma$  gene may eliminate permease synthesis, does not affect  $\beta$ -galactosidase synthesis, and reduces the amount of transacetylase synthesis. The mutation is said to be strongly polar when the expression of promoter-distal genes is strongly inhibited; weakly polar mutations cause only slight inhibition. The strength of polarity depends on the distance between the mutation and the end of the gene in which it occurs (i.e., between the mutation and the next translation initiation site), being greatest when this distance is greatest.

According to one model for polarity, cessation of translation (due e.g. to the presence of a nonsense mutation) may expose in the mRNA a  $\rho$ -dependent TRANSCRIPTION termination site which is normally protected from the  $\rho$  factor by the presence of ribosomes; interaction of  $\rho$  with this site results in premature termination of transcription and hence loss of expression of promoter-distal genes. Polar mutations can be suppressed by mutations in the *rho* gene, the mutant  $\rho$  factor apparently failing to interact with the premature termination signal; polarity suppressors thus restore expression of genes downstream of the mutant gene but not of the mutant gene itself. (cf. SUPPRESSOR MUTATION.) The polar effects of certain TRANSPOSABLE ELEMENTS (e.g. IS2) have been attributed to the presence of a  $\rho$ -dependent terminator within the TE sequence.

In some cases a polar mutation does not appear to affect transcription; in such cases ribosomes, having dissociated from the mRNA at a nonsense mutation, may be unable to re-initiate translation at the next initiation site – possibly because of the formation of a secondary structure in the untranslated mRNA.

**polar plaque** *Syn.* SPINDLE POLE BODY.

**polar ring** An osmiophilic annular structure, one or more of which occur at the anterior end in members of the APICOMPLEXA. Polar ring(s) may act as support(s) for the opening in the inner layer of the pellicle, and they may be involved in the function of the conoid.

**polarilocular** Refers to a lichen spore consisting of two cells which are separated by a thick septum that has a central canal. (See also TELOSCHISTALES.)

**polaroplast** See MICROSPORA.

**polB gene** See DNA POLYMERASE.

**polC gene** See DNA POLYMERASE.

**poliomyelitis** (polio; infantile paralysis) An acute infectious disease of humans, particularly children, caused by any of three serotypes of human poliovirus (see ENTEROVIRUS). (A few non-human primates, e.g. chimpanzees, are also susceptible.) Transmission occurs by the faecal–oral route (e.g. by person-to-person contact or via sewage-contaminated water). Incubation period: 3–35 (usually 7–14) days. Infection may be asymptomatic; clinical forms are usually mild and self-limiting, with fever, headache, nausea and vomiting, and pharyngitis (*abortive poliomyelitis*). In a minority of cases the virus may invade the CNS, causing inflammation and destruction of the lower motor neurones in the brain stem and spinal cord. In *non-paralytic poliomyelitis* symptoms include those of MENINGITIS (e.g. stiffness of the neck and back). In *paralytic poliomyelitis* there is weakness and eventually flaccid paralysis of muscles (commonly of the legs); the paralysis may or may not be permanent. Polio is not usually fatal, but may be if respiratory muscles become involved. *Lab. diagnosis*: serological tests; culture of the virus from pharyngeal secretions and faeces. (See also SALK VACCINE and SABIN VACCINE.)

**polioviruses** See ENTEROVIRUS.

**Polish infectious dropsy** (of carp) See CARP ERYTHRODERMATITIS.

**pollen mould** *Betisia alvei* (q.v.).

**pollution** (environmental) See ENVIRONMENTAL POLLUTION.

**poly(A) tail** See MRNA.

**polyacetylenes** (polyynes) Linear compounds, containing both double and triple bonds, which are produced by certain higher fungi (particularly basidiomycetes) and which, in some cases, exhibit antifungal and antibacterial activity; the polyacetylene molecule usually has an oxygen-containing terminal group (e.g. a carboxyl or hydroxyl group). For example, mycorrhizal *Leucopaxillus cerealis* produces diatretyne nitrile ( $\text{HOOC}-\text{CH}=\text{CH}-\text{C}\equiv\text{C}-\text{C}\equiv\text{N}$ ) which is active e.g. against *Phytophthora cinnamomi*.

**polyacrylamide gel electrophoresis** ELECTROPHORESIS using a polyacrylamide gel – see e.g. SDS-PAGE.

**polyadenylated mRNA** See MRNA.

**polyamines** Polycationic compounds containing two or more amino groups; they appear to occur in all animal, plant and microbial cells and in certain viruses.

Putrescine [ $\text{NH}_2(\text{CH}_2)_4\text{NH}_2$ ], spermidine [ $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}_2$ ] and spermine [ $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}(\text{CH}_2)_3\text{NH}_2$ ] appear to be almost universally present in prokaryotic and eukaryotic microorganisms. However, their cellular location(s) and biological function(s) are still not known, although numerous effects on e.g. nucleic acid structure and enzyme activity have been observed *in vitro*; polyamines may have a role e.g. in protein synthesis in bacteria, and are necessary for the replication of at least some bacteriophages, including the T-even phages (which contain putrescine and spermidine) and bacteriophage  $\lambda$ . (See also BACTERIOPHAGE  $\phi$ W-14.)

Polyamines are synthesized primarily from amino acids – e.g. putrescine may be formed by the decarboxylation of ornithine or by the combined action of arginine decarboxylase and agmatine ureohydrolase. (See also DECARBOXYLASE TESTS.) In bacteria the polyamine content is significantly affected by the growth conditions. A number of novel polyamines have been described from extreme thermophiles: e.g. '*Thermus thermophilus*' contains polyamines such as thermine

[= *sym*-norspermine:  $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}_2$ ], *sym*-homosperrmidine [ $\text{NH}_2(\text{CH}_2)_4\text{NH}(\text{CH}_2)_4\text{NH}_2$ ], thermosperrmidine [ $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_4\text{NH}_2$ ] and also caldopentamine [ $\text{NH}_2(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}_2$ ]. These substances have been implicated in the maintenance of thermostability in cell components, enzymes, etc; however, *sym*-homosperrmidine has also been found in mesophilic bacteria [FEMS (1983) 20 159–161].

[Reviews: MR (1985) 49 81–99; ARB (1984) 53 749–790.]

**Polyangium** See MYXOBACTERALES.

**poly(A)polymerase** See MRNA.

**polybetahydroxybutyrate** See POLY- $\beta$ -HYDROXYBUTYRATE.

**polycentric** Refers to a thallus in which a number of regions, in different parts of the thallus, each have a reproductive function. (cf. MONOCENTRIC.)

**polychlorinated biphenyls (PCBs)** See BIOREMEDIATION.

**polychrome methylene blue** See METHYLENE BLUE.

**polycistronic mRNA** See MRNA.

**polyclonal activator (immunol.)** Any *non-specific* activator of lymphocytes, i.e. any agent which can bring about differentiation/proliferation in each of a number of different clones.

Polyclonal activators for B LYMPHOCYTES include lipopolysaccharides and various mitogens; such agents are THYMUS-INDEPENDENT ANTIGENS.

SUPERANTIGENS are polyclonal activators for T LYMPHOCYTES.

**polyclonal antiserum** Any antiserum prepared by injecting an animal with a given antigen; it contains a heterogeneous population of antibodies – each antibody being specific to one of the (usually many) determinants present on the antigen. (cf. MONOCLONAL ANTIBODIES.)

**polycycline** See TETRACYCLINES.

**Polycystinea** See RADIOLARIA.

**Polydnnaviridae** A family of viruses [Intervirol. (1986) 25 141–143], previously classified as subgenus *D* of the BACULOVIRIDAE, characterized by their polydisperse ccc dsDNA genomes. Virus replication occurs in host cell nuclei; virions are not occluded. The viruses infect certain species of parasitic hymenopteran insects. Two distinct groups (genera) are recognized. In one group (genus unnamed) the virion has a cylindrical nucleocapsid of variable length, and virions are surrounded – either individually or in groups – by a unit membrane envelope; these viruses infect braconid wasps. In the other group (genus *Polydnnavirus*) the virions have fusiform nucleocapsids surrounded by two envelopes; these viruses infect ichneumonid wasps (e.g. *Hyposoter* spp). Viruses of both groups can apparently be transmitted vertically [Virol. (1986) 155 120–131]. Type species: polydnnavirus type 1 (*Hyposoter exiguae* virus).

**polyene antibiotics** ANTIBIOTICS which contain region(s) of conjugated double bonds. There are two structurally and functionally distinct types.

(a) A group of MACROLIDE ANTIBIOTICS (produced by streptomycetes) characterized by a large lactone ring containing a rigid, lipophilic region of (generally) unsubstituted, all-*trans* conjugated double bonds and a flexible, hydrophilic, hydroxylated region; the lactone may be substituted with aminosugar, carboxyl, aliphatic or aromatic groups. These polyenes are classified according to the number of conjugated double bonds they contain (e.g. tetraenes, heptaenes). They are poorly soluble in water but are soluble in organic solvents; they are unstable in solution in the presence of light owing to photo-oxidation of the double bonds.

The macrolide polyenes interact with sterols in the cytoplasmic membrane of sensitive organisms, causing leakage of ions

and small molecules; the polyene molecule may form a pore in the membrane through which such leakage may occur. These antibiotics are microbistatic at low concentrations, microbicidal at higher concentrations.

Macrolide polyenes are effective against yeasts and other fungi and also against protozoa, but not against most bacteria (whose membranes lack sterols – cf. MYCOPLASMA).

The selective toxicity of the clinically useful macrolide polyenes is apparently due, at least in part, to their greater affinity for ergosterol (a principal sterol in fungal cytoplasmic membranes) compared with cholesterol (the main sterol in mammalian cell membranes) (cf. FILIPIN).

Macrolide polyenes include e.g. AMPHOTERICIN B; AUREOFUNGIN; CANDICIDIN B; ETRUSCOMYCIN; FILIPIN; HAMYCIN; NYSTATIN; PERIMYCIN; PIMARICIN; and TRICHOMYCIN.

(b) A group of structurally novel polyenes (produced by actinomycetes [FEMS (1984) 25 121–124]) which are active against prokaryotes, inhibiting PROTEIN SYNTHESIS. In bacteria, *aurodox*, *azdimycin*, *dihydromocimycin*, *efrotomycin*, *factumycin*, *kirromycin* (= mocimycin) and *kirrothricin* all act by binding to EF-Tu and preventing its dissociation from the ribosome; the structurally related antibiotic *pulvomycin* binds EF-Tu-GTP and prevents the formation of the aa-tRNA-GTP-EF-Tu complex, thus preventing the binding of aa-tRNA to the ribosomal A site. In archaeans, elongation factors are generally insensitive to kirromycin, and the elongation factors of only some archaeans are sensitive to pulvomycin [JB (1986) 167 265–271].

**polyether antibiotics** See MACROTETRALIDES.

**polyethylene glycol (PEG; Carbowax)** A polymer,  $\text{H}(\text{OCH}_2\text{CH}_2)_n\text{OH}$ , available in a range of grades of mean MWt between ca. 200 and ca. 20000; above MWt ca. 1000 it is a solid, below it is a liquid. PEG is used e.g. in cell fusion (see e.g. HYBRIDOMA), in PROTOPLAST FUSION, in artificial TRANSFORMATION systems, and as a precipitating agent in clinical chemistry. PEG is also used for concentrating, by osmosis, serum and other aqueous solutions and suspensions; serum etc is placed in a U-shaped tube of semipermeable material (e.g. Visking tubing) and the tubing partly submerged in a concentrated aqueous solution of PEG.

**poly(ethylene oxide)** A high-MWt polymer ( $-\text{CH}_2\text{CH}_2\text{O}-$ )<sub>n</sub> used e.g. to increase the viscosity of a medium in order to slow down rapidly motile organisms – see COUNTING METHODS. (cf. FICOLL.)

**polygenic mRNA** See MRNA.

**polyhedra (viro.)** Large inclusion bodies formed in the cells of insects infected with certain viruses (see CYTOPLASMIC POLYHEDROSIS VIRUS GROUP and BACULOVIRIDAE); a polyhedron is composed of a matrix of crystalline, virus-specific protein (*polyhedrin*) in which mature virions are embedded ('occluded'). Polyhedra are stable structures which appear to give some protection to the virions they contain; they serve as vehicles for virus transmission: ingestion of polyhedra by a new host is followed by degradation of polyhedrin in the gut and the release of infectious virions. Polyhedra can be isolated from infected cells e.g. by differential centrifugation.

**polyhedral bodies** See CARBOXYSOMES.

**polyhedrin** See POLYHEDRA and BACULOVIRIDAE.

**polyhedrosis** An INSECT DISEASE caused by a NUCLEAR POLYHEDROSIS VIRUS or by a virus of the CYTOPLASMIC POLYHEDROSIS VIRUS GROUP.

**poly- $\beta$ -hydroxyalkanoate** See POLY- $\beta$ -HYDROXYBUTYRATE.

**poly- $\beta$ -hydroxybutyrate (PHB)** A linear polymer of  $\beta$ -hydroxybutyrate (D(-)-3-hydroxybutyrate):  $\text{H}[\text{O}.\text{CH}(\text{CH}_3).\text{CH}_2.\text{CO}]_n\text{OH}$ . It occurs as refractile granules in the cells of various

## Polyhymenophorea

PROKARYOTES, including cyanobacteria and members of the Chromatiaceae and Rhodospirillaceae. PHB synthase (and possibly also de-polymerizing enzymes) occur at the surface of the granules. Each mature granule is bounded by a layer apparently <4 nm in thickness – believed to be a monolayer consisting mainly of amphiphilic proteins (*phasins*) and phospholipids, all the molecules orientated with their hydrophilic regions facing the cytoplasm [JBM (1997) 37 45–52]. PHB granules can be stained *in situ* (i.e. in the cell) by dyes such as NILE BLUE A.

In many bacteria PHB accumulates when nutrients other than carbon sources become limiting, being degraded when these conditions are reversed; PHB thus acts as a reservoir of carbon and/or energy. *Azotobacter beijerinckii* accumulates very large quantities (up to 80% of the cell mass) of PHB under conditions of oxygen limitation, PHB serving as a 'sink' for excess reducing power under these conditions.

Typically, PHB is synthesized via the pathway: acetyl-CoA → acetoacetyl-CoA →  $\beta$ -hydroxybutyryl-CoA → PHB (enzymes:  $\beta$ -ketothiolase,  $\beta$ -hydroxybutyryl-CoA dehydrogenase, PHB synthase). PHB degradation: PHB →  $\beta$ -hydroxybutyrate → acetoacetate → acetoacetyl-CoA → acetyl-CoA; the first enzyme in this pathway, PHB depolymerase, is reported to be granule-bound in some bacteria, soluble in others. Some bacteria, e.g. certain pseudomonads, can degrade exogenous PHB.

Other poly- $\beta$ -hydroxyalkanoates (PHAs): e.g. *Bacillus megaterium* may contain small amounts of  $\beta$ -hydroxyheptanoate together with PHB, and *Pseudomonas oleovorans* forms poly- $\beta$ -hydroxyoctanoate from *n*-octane.

[PHAs, including PHB and Biopol: FEMS Reviews (1992) 103 91–376.]

(See also BIOPOL.)

**Polyhymenophorea** A class of protozoa (phylum CILIOPHORA) in which the oral ciliature is typically well developed and conspicuous (often extending out of the buccal cavity); the PARORAL MEMBRANE is of the stichomonad, diplostichomonad or polystichomonad type; the somatic ciliature is often reduced or replaced by cirri; kinetodesmata are rare; STOMATOGENESIS is apokinetal or parakinetal; and neither toxicysts nor trichocysts are formed. Some species are sedentary, and some are loricate. Most species are free-living. All members are placed in the single subclass Spirotrichia which is divided into four orders: HETEROTRICHIDA, HYPOTRICHIDA, ODONTOSTOMATIDA, OLIGOTRICHIDA.

**poly(I:C)** See INTERFERONS.

**polykaryocyte** A multinucleate cell (e.g. a GIANT CELL).

**polyketide** A compound (often a secondary metabolite) which is, or may be regarded as, a condensation product of subunits such as acetate, propionate and/or malonate; polyketides, which may be classified according to the number of C<sub>2</sub> units they contain (e.g. a tetraketide is a C<sub>8</sub> compound), may undergo cyclization, glycosylation, oxidation etc.

Metabolites derived from polyketides include some antibiotics (e.g. erythromycin, tetracyclines) and mycotoxins (e.g. PATULIN – a tetraketide, AFLATOXINS, CYTOCHALASINS). Such compounds are synthesized from precursors such as acetyl-CoA and malonyl-CoA; for example, in aflatoxin biosynthesis, malonyl-CoA subunits condense with an acetyl-CoA 'starter', with concomitant decarboxylation, in a process analogous to fatty acid biosynthesis but minus dehydration and reduction [AAM (1983) 29 53–92].

The molecule of erythromycin, a MACROLIDE ANTIBIOTIC obtained from actinomycetes (e.g. *Streptomyces erythraeus* and *Saccharopolyspora erythraea*), has a cyclic polyketide nucleus

which is synthesized by a multifunctional enzyme, polyketide synthase. The possibility of developing new drugs by genetic engineering of the polyketide synthetic pathway has been hindered by the difficulty of carrying out such work with actinomycetes; to address this problem, synthetic potential (including polyketide synthase activity) has been incorporated into a strain of *Escherichia coli* – which can now synthesize the nucleus of the erythromycin molecule [Science (2001) 291 1790–1792; commentary: Science (2001) 291 1683].

**polylinker** A region of DNA containing close/overlapping sites for *different* RESTRICTION ENDONUCLEASES. Synonym: multiple cloning site (MCS).

**polymerase chain reaction** See PCR.

**polymetaphosphate** See POLYPHOSPHATE.

**polymorph** (polymorphonuclear leucocyte) (1) *Syn.* PMN. (2) *Syn.* NEUTROPHIL.

**polymorphic** Refers to e.g. an organism which exhibits POLYMORPHISM.

**polymorphism** (1) The ability of an organism to occur in two or more morphologically distinct forms (MORPHOTYPES), according e.g. to conditions (as in PHAEOODACTYLUM) or to the stage in the life cycle (e.g. TRYPANOSOMATIDAE). (cf. PLEOMORPHISM sense 1).

(2) *Syn.* PLEOMORPHISM (sense 1).

(3) (in nucleic acids) A variant region of nucleotides in a *related* nucleic acid molecule – e.g. a variant sequence found in a given allele in one or more strains of an organism but not in all strains of that organism. Some authors use the term even when the variation in sequence consists of only a point mutation.

**Polymyxa** See PLASMIDIOPHOROMYCETES.

**polymyxins** A group of peptide ANTIBIOTICS produced by various species of *Bacillus* (e.g. *B. polymyxa*); they include e.g. antibiotics formerly classified as circulins and colistins. Polymyxins are active against many Gram-negative bacteria – exceptions including e.g. many strains of *Neisseria* and *Proteus*, and the *eltor* biotype of *Vibrio cholerae* (the *cholerae* biotype is susceptible); most Gram-positive bacteria and most fungi are resistant, but some strains of e.g. *Candida* are susceptible. Against bacteria, polymyxins are bactericidal to both growing and non-growing cells.

Polymyxins have MWts of ca. 1000–1200, and they contain a high proportion of  $\alpha,\gamma$ -diaminobutyric acid (DAB). The polymyxin molecule is a cyclic heptapeptide with a peptide side-chain that terminates in a fatty acid residue; the fatty acid is 6-methyloctanoic acid in e.g. polymyxins A, B1, D1 and E1 (= colistin A), and is 6-methylheptanoic acid in e.g. polymyxins B2, D2 and E2. Variations also occur in the constituents of the cyclic and linear peptides. [Structure of polymyxins: Book ref. 14, pp. 189–194.]

In Gram-negative bacteria, polymyxins act by increasing the permeability of the CYTOPLASMIC MEMBRANE to small molecules and by damaging the OUTER MEMBRANE. Polymyxin B nonapeptide, a derivative of polymyxin B which lacks the fatty acid residue, lacks the bactericidal activity of polymyxin B but is able to damage the outer membrane [CJM (1986) 32 66–69].

(See also OCTAPEPTINS.)

**polynucleotide kinase** An enzyme used e.g. for the 5'-end labelling of a PROBE (q.v.).

**polynucleotide phosphorylase** (PNPase) An enzyme, present e.g. in *Escherichia coli* and other prokaryotes, which *in vitro* can catalyse e.g. the phosphorylation of poly- or oligoribonucleotides in the presence of phosphate, and the polymerization of ribonucleoside diphosphates.

**polyol** (polyhydric alcohol) Strictly: any compound containing more than one alcohol group. As commonly used, the term refers

to a sugar alcohol, i.e., the compound obtained when the aldo or keto group of a sugar is reduced to a hydroxy group. For example, reduction of galactose gives galactitol (dulcitol), ribose gives ribitol, etc. (cf. PLURONIC POLYOL F127.) [Polyol metabolism in fungi: AMP (1984) 25 149–193.] (See also e.g. PENTITOLS.)

**polyoma virus** (polyomavirus) (1) Mouse (murine) polyoma virus: see POLYOMAVIRUS. (2) Any virus of the genus *Polyomavirus* (q.v.).

**Polyomavirus** A genus of viruses of the PAPOVAVIRIDAE. Type species: mouse (murine) polyoma virus ('polyoma virus'); other members include e.g. BK virus and JC virus (human viruses), K virus (a mouse virus), SIMIAN VIRUS 40 (SV40), and stump-tailed macaque virus (STMV). (See also BUDGERIGAR FLEDGLING DISEASE VIRUS.) Polyoma viruses can be propagated readily in suitable cell cultures (see e.g. SIMIAN VIRUS 40; cf. PAPILLOMAVIRUS). The viruses generally appear to be common in their natural hosts, in which infection is usually asymptomatic (although JC virus – which seems to be common in humans – can cause PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY in certain circumstances); however, many polyoma viruses can be oncogenic in other hosts: e.g. SV40, JC and BK can induce tumours in newborn rodents and can transform several types of cell in culture. JC virus can also induce brain tumours in adult monkeys. Cells transformed by SV40 or murine polyoma virus contain viral DNA integrated into the host chromosomal DNA; integration occurs at non-specific sites and may involve the entire viral genome or only a portion of it. However, integration appears not to be essential for transformation by BK virus, and its significance in SV40 and polyoma virus transformation is unknown. Expression of early viral genes appears to be necessary for transformation in all cases.

[Polyomaviruses and disease of the central nervous system: RMM (1998) 9 79–85.]

In murine polyoma virus, at least three distinct genes appear to act in a coordinated manner to induce transformation in primary rat embryo fibroblasts; the product of each gene induces particular alterations in cell structure and growth control [Book ref. 113, pp. 109–116]. The three products are 'large T protein' or 'large T antigen' (MWt ca. 105000), 'middle T protein' or 'middle T antigen' (MWt ca. 56000), and 'small T (or t) protein' or 'small T antigen' (MWt ca. 22000). The large T protein is a DNA-binding protein which localizes in the host cell nucleus in association with the chromatin. The middle T protein localizes in the host cell plasma membrane; it is tightly associated with a tyrosine-specific protein kinase – identified as the *c-src* product pp60<sup>c-src</sup> (see SRC [EMBO (1984) 3 585–591]). The small T protein is found in the soluble cytoplasmic fraction of the cell; its activities are unknown, but it may disrupt actin cables in the cell.

Viruses SV40, BK and JC appear to encode proteins corresponding to large T and small T proteins but do not encode a middle T protein. In SV40, the large T antigen ('T antigen') is a multifunctional phosphoprotein MWt ca. 92000 which can alone induce neoplastic transformation in cells from a variety of species; it also acts as a key regulatory protein in the lytic cycle of SV40 in permissive monkey cells. The protein binds to SV40 DNA at multiple sites near the replication origin, has ATPase activity, and binds to a host protein of MWt 53000. The SV40 small T protein may also have a role in transformation; it has been detected in the host cell cytoplasm and in the nucleus [Book ref. 113, pp. 369–375].

**polyoxins** A group of antifungal nucleoside–oligopeptide antibiotics produced by *Streptomyces cacaoi*. Polyoxins are competitive inhibitors of chitin synthase, being structural analogues of

UDP-*N*-acetylglucosamine; other enzymes using this substrate seem not to be affected. Susceptible fungi take up polyoxins via peptide transport systems; resistant strains, which emerge readily, appear to have altered peptide permeases. Polyoxins have been used for the control of certain plant pathogens: e.g. *Alternaria kikuchiana* (black spot of pear); they have no clinical application. (See also GROWTH (fungal).)

**polypectate** *Syn.* pectate (see PECTINS).

**Polyphagus** See CHYTRIDIALES and MYCOPARASITE.

**polyphasic taxonomy** See TAXONOMY.

**polyphenoloxidases** See e.g. TANNINS.

**polyphosphate** (volutin) A linear phosphate polymer (poly-metaphosphate:  $[\text{PO}_3^{2-}]_n - \text{O} - [\text{PO}_3^-]_m - [\text{PO}_3^{2-}]_n$ ) which occurs in bacteria, fungi, algae, protozoa, and certain higher eukaryotes. In eukaryotic microorganisms (e.g. yeasts) polyphosphate appears to occur chiefly in the periplasmic region and/or in the cell vacuole; in most bacteria (including cyanobacteria) polyphosphate occurs mainly in the cytoplasm. (See METACHROMATIC GRANULES.) Polyphosphate is believed to function as a reserve of phosphate and, in at least some organisms, of energy; it may also play a role in the storage or sequestration of cations.

Polyphosphate is synthesized in some bacteria by the transfer of  $\gamma$ -phosphate from ATP to nascent polyphosphate, catalysed by an  $\text{Mg}^{2+}$ -dependent polyphosphate kinase (ATP-polyphosphate phosphotransferase). Other bacteria, and e.g. *Neurospora crassa*, synthesize polyphosphate by the transfer of phosphate from the 1-position of 1,3-bisphosphoglycerate. Some organisms (e.g. *Escherichia coli*) possess both enzyme systems. Degradation of polyphosphate can be achieved by several enzymes, including e.g. polyphosphate kinase, and an  $\text{Mg}^{2+}$ -dependent polyphosphate glucokinase – present in certain bacteria – which can catalyse the transfer of phosphate from polyphosphate to glucose to form glucose 6-phosphate. [Polyphosphate metabolism: AMP (1983) 24 83–171.]

(See also PYROPHOSPHATE.)

**polyphyletic** Refers to taxa which have not arisen from a common evolutionary line but which are classified together because they share certain feature(s) – due e.g. to convergent evolution. (cf. MONOPHYLETIC.)

**polyplanetism** The phenomenon in which *secondary* zoospores (see DIPLANETISM) undergo repeated cycles of encystment and excystment, successive populations of secondary zoospores being formed.

**polyploid** Having a PLOIDY greater than two.

**polypodial amoebae** Amoebae which usually have several pseudopodia at a given time. (cf. MONOPODIAL AMOEBAE.)

**Polyporaceae** See APHYLLOPHORALES.

**Polyporales** *Syn.* APHYLLOPHORALES.

**polypore** Any species of the APHYLLOPHORALES (particularly bracket fungi of the Polyporaceae) in which the basidiocarp has a porous hymenophore.

**Polyporus** (1) A genus of typically lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form bracket-type to stipitate (mushroom-shaped) fruiting bodies in which the stipe may be central, eccentric, lateral, or virtually non-existent; the hymenophore is porous. *P. squamosus* is the causal agent of heart rot in a range of deciduous trees, particularly elm (*Ulmus*); the fruiting body (context: dimitic) has a light brown, scaly upper surface and a pale underside, and the basidiospores are colourless, cylindrical, ca.  $12 \times 5 \mu\text{m}$ . For *P. dryadeus* see INONOTUS. (See also BLACKFELLOWS' BREAD.)

(2) *Polyporus* is sometimes used as a form genus to include those polypores which form annual, fleshy to leathery fruiting

## polyprotein

bodies; thus, e.g. *Piptoporus betulinus* is equivalent to the form species *Polyporus betulinus*. (cf. FOMES sense 2.)

**polyprotein** (*virol.*) A protein which is produced by the uninterrupted translation of two or more adjacent genes on a polycistronic mRNA; the products of individual genes are separated by post- or co-translational cleavage of the polyprotein. (See e.g. COWPEA MOSAIC VIRUS, PICORNAVIRIDAE and RETROVIRIDAE.) (Certain polypeptides of eukaryotes are also synthesized as polyproteins.)

**polyribosome** See PROTEIN SYNTHESIS.

**polysaccharide** (glycan) Any macromolecule that consists of monosaccharide (glycose) residues joined by glycosidic linkages. Polysaccharides containing only one kind of monosaccharide are called *homopolysaccharides* (= *homoglycans*), those containing two or more different kinds are called *heteropolysaccharides* (= *heteroglycans*). [Nomenclature: JBC (1982) 257 3352–3354.]

Several polysaccharides obtained from microorganisms have important commercial uses: see e.g. AGAR, ALGINATE, CARRAGEENAN, CURDLAN, DEXTRAN, FUNORAN, FURCELLARAN, GELLAN GUM and XANTHAN GUM.

**polysaprobic zone** See SAPROBITY SYSTEM.

**Polysiphonia** A large genus of filamentous marine algae (division RHODOPHYTA). (See also CHOREOCOLAX.)

**polysome** See PROTEIN SYNTHESIS.

**Polysphondylium** A genus of cellular slime moulds (class DICTYOSTELIOMYCETES) in which the sorocarp stalk tube resembles that of DICTYOSTELIUM in containing empty cells, but differs in bearing whorls of branches along its length; globose sori are borne on the tips of the stalks and at the ends of the branches. The spores are purple in *P. violaceum*, white to hyaline in other species (e.g. *P. pallidum*). In *P. violaceum* the ACRASIN is not cAMP but an unusual dipeptide, 'glorin' (*N*-propionyl- $\gamma$ -L-glutamyl-L-ornithine- $\delta$ -lactam ethyl ester [PNAS (1982) 79 7376–7379]). In this species a single cell, the *founder* cell, serves as the focus for aggregation. Six species are recognized [descriptions and key: Book ref. 144, pp. 368–392].

**Polyspira** See HYPOSTOMATIA.

**polystichomonad membrane** See PARORAL MEMBRANE.

**Polystigma** See POLYSTIGMATALES.

**Polystigmatiales** An order of primarily plant-pathogenic fungi of the subdivision ASCOMYCOTINA. Ascocarp: perithecioid, immersed. Asci: unitunicate, typically clavate. Ascospores: aseptate to multiseptate. Genera: e.g. *Magnaporthe* (see also PYRICULARIA), *Polystigma*, *Sphaerodothis*.

**polystromatic** Refers to a structure which is more than two cells thick. (cf. MONOSTROMATIC; DISTROMATIC.)

**polysulphide** See SULPHUR.

**polytenization** The repeated replication of a chromosome without separation of the daughter chromosomes; a polytene chromosome is thus a ribbon-like arrangement of multiple chromosomes lying parallel to one another.

**polythetic classification** Any form of classification based on a large number of criteria. (cf. MONOTHETIC CLASSIFICATION.)

**Polythrix** See RIVULARIACEAE.

**polytropic** *Syn.* DUALTROPIC.

**polyurethanase** Any enzyme which can degrade polyurethane. Such enzymes are produced by certain types of microorganism. Bacterial polyurethanase activity may be detected by a simple plate assay in which organisms are tested for their ability to degrade a colloidal form of polyurethane in the presence of rhodamine B, hydrolysis of the substrate being indicated by the development of orange fluorescence in the medium [LAM (2001) 32 211–214].

**polyvalent antiserum** Any antiserum which contains antibodies to a number of different antigens.

**polyvalent vaccine** A single VACCINE containing the PROTECTIVE ANTIGENS and/or toxoids from each of several different strains of one species of pathogen. (cf. MIXED VACCINE.)

**polyvinyl alcohol fixative** A FIXATIVE: SCHAUDINN'S FLUID with five times the usual concentration of glacial acetic acid, supplemented with polyvinyl alcohol (5% w/v) and glycerol (1.5 ml per 100 ml fluid). Specimens can remain in PVA fixative, without damage, for long periods of time.

**polyvinyl pyrrolidone-iodine** See IODINE (a).

**polyynes** *Syn.* POLYACETYLENES.

**pomona fever** LEPTOSPIROSIS caused by *L. interrogans* serotype *pomona*.

**Pontiac fever** See LEGIONELLOSIS.

**porcine circovirus** (PCV) A small isometric virus (diam. 17 nm) containing ccc ssDNA (MWt  $0.58 \times 10^6$ ). PCV was isolated from a porcine cell line, and is presumed to infect pigs since specific antibodies to the virus were present in randomly collected pig sera but not in the sera of other animals. PCV apparently represents a new family of ANIMAL VIRUSES. [Nature (1982) 295 64–66.]

**porcine haemagglutinating encephalitis virus** See CORONAVIRUS and VOMITING AND WASTING DISEASE.

**porcine icteronaemia** See EPERYTHROZOONOSIS.

**porcine parvovirus** See PARVOVIRUS.

**porcine reproductive and respiratory syndrome** See BLUE-EARED PIG DISEASE.

**porcine transmissible gastroenteritis virus** See CORONAVIRIDAE and TRANSMISSIBLE GASTROENTERITIS.

**pored epicortex** (*lichenol.*) A polysaccharide layer (ca. 0.6  $\mu$ m thick) which overlies the upper cortex in certain foliose lichen thalli and which is perforated by numerous more or less regular perforations ca. 15–25  $\mu$ m or more in diameter. The underlying cortex is continuous but is generally thin (e.g. 2–3 cell layers thick), the cells being relatively loosely packed; these cortical features, together with the pored epicortex, apparently allow sufficient gas exchange to obviate the need for pseudocyphellae or cyphellae [Lichenol. (1981) 13 1–10].

**porfiromycin** The *N*-methyl derivative of MITOMYCIN C.

**Poria** (1) A genus of lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form resupinate fruiting bodies (ranging from millimetres to centimetres in thickness) in which the hymenophore is porous; the whitish context is monomitic and lacks clamp connections. In perennial fruiting bodies the tubules are stratified (cf. HETEROBASIDIUM). (See also BROWN ROT, COAL BIODEGRADATION, DRY ROT, PACHYMAN and PAPER SPOILAGE.)

(2) *Poria* is sometimes used as a form genus to include those polypores which form annual or perennial resupinate fruiting bodies.

**porin** (formerly: matrix protein) In the OUTER MEMBRANE of Gram-negative bacteria: a type of protein molecule which – usually in trimeric form (but sometimes dimeric or monomeric) – forms a water-filled transmembrane channel ('pore') that permits the passage of certain ions and small molecules; porins are also found e.g. in the mitochondrial outer membrane. (See also LAMB PROTEIN and TSX PROTEIN.) Note that the term 'porin' is also used to refer to the *complete* pore structure – whether it be composed of one, two or three porin proteins.

*Bacterial porins.* Porins have been demonstrated in many types of Gram-negative bacteria, but most studies have been carried out on *E. coli* and *Salmonella typhimurium*. Although porins are typically trimeric, dimeric porins have been found

e.g. in *Paracoccus denitrificans* [JB (1985) 162 430–433]; monomeric porins occur in the cyanobacteria [JB (2000) 182 1191–1199].

The number of types of porin in a cell may vary according to conditions. For example, in *E. coli* the PhoE porin is induced when phosphate levels are low (see PHO REGULON). Moreover, extra porins may be acquired through LYSOGENY: the protein 2 (Lc protein) porin of *E. coli* K12 is present only when the cells are lysogenized by coliphage PA2.

The porins of *E. coli* typically include the products of genes *ompC*, *ompF* and (if phosphate is limiting) *phoE*; these products are designated OmpC (= Ib), OmpF (Ia) and PhoE, respectively. (See also OMP.) The OmpC and OmpF porins play a part in OSMOREGULATION (q.v.).

In addition to their role as channel components, porins may serve e.g. as receptor sites for phages; for example, in *Escherichia coli* the OmpF porin acts as a receptor for phages T2 and Tula, while OmpC is a receptor for T4 and Tulb. During infection by Gram-negative bacteria, porins are reported to induce the release of CYTOKINES from monocytes and lymphocytes.

In *E. coli*, each transmembrane pore is formed by a group of three porin proteins. Structurally, the OmpC and OmpF pores are similar: a single channel from the inner (periplasmic) side of the pore branches into three channels which exit from the outer (exterior) face of the pore; the OmpF channel is somewhat wider than the OmpC channel. When extracted with SDS, these porins can be isolated as undenatured trimers.

The PhoE pore differs in that it contains three channels which remain separate across the width of the pore; a similar structure is found e.g. in the protein F porin of *Pseudomonas aeruginosa*.

Cyanobacterial porin proteins are larger than those of other Gram-negative bacteria (50–70 kDa versus 30–40 kDa), and they occur as monomers [JB (2000) 182 1191–1199 (1193)].

*Salmonella typhimurium* typically contains the OmpC, OmpD and OmpF porins (previously referred to as 36K, 34K and 35K proteins, respectively).

In *Pseudomonas aeruginosa*, the porin channels have been reported to be larger [MR (1985) 49 1–32] and relatively smaller [FEMS (1984) 21 119–123] than those of *E. coli*.

The rate of diffusion of molecules through a porin channel depends strongly on the size, hydrophobicity and charge of the molecules. *E. coli* porin channels permit the passage of hydrophilic molecules of MWt up to ca. 650–850 (i.e. the 'exclusion limit' is ca. 650–850), but they are poorly permeable or impermeable to hydrophobic molecules (including many  $\beta$ -lactam antibiotics). By contrast, the pores in *Haemophilus influenzae* type b appear to be larger, and they offer little hindrance to the influx of a range of penicillins and cephalosporins [JB (1985) 162 918–924].

In *E. coli* the main porin channels are not equally permeable: glucose (for example) diffuses through the OmpC channel at about half the rate at which it diffuses through the OmpF channel, and the differential is even greater with larger, hydrophobic or charged molecules. Mutants which lack OmpF channels exhibit increased resistance to e.g. chloramphenicol, tetracyclines and  $\beta$ -lactam antibiotics. [In *Enterobacter aerogenes*, resistance to e.g. cefepime and other cephalosporin antibiotics has been associated with altered porins: Microbiology (1998) 144 3003–3009.]

The main porin channels in *E. coli* are preferentially permeable to cations (as opposed to anions), and they permit the entry of glucose at rates much higher than those of negatively charged

glucose derivatives; a similar preference is shown by porin channels in *Pseudomonas aeruginosa*, but those in e.g. *Neisseria gonorrhoeae* (and those in the mitochondrial outer membrane) are preferentially permeable to anions. Negative charge may make little difference (or enhance) the passage of a molecule through the PhoE channel in *E. coli*. [Role of porins in outer membrane permeability (review): JB (1987) 169 929–933.]

Porin channels in LIPOSOMES can be opened and closed by adjusting the value of the transmembrane potential; in this way they resemble the voltage-controlled mitochondrial porin channels (referred to as 'voltage-dependent anion channels' – VDACs). However, while the outer membrane can exhibit a transmembrane potential under certain conditions, the opening and closing of porin channels in intact cells has not been shown to be regulated in this way. (See also LIPOSOME SWELLING ASSAY.)

**poroconidia** See CONIDIUM.

**porogenous development** See CONIDIUM.

**porospore** See CONIDIUM.

**porphin** A cyclic TETRAPYRROLE in which the four pyrrole groups are linked by their  $\alpha$ -carbon atoms via methene ( $-\text{CH}=\text{}$ ) bridges; porphin is the parent compound of the PORPHYRINS.

**porphobilinogen** A substituted monopyrrole: an intermediate in the biosynthesis of PORPHYRINS.

**Porphyra** A genus of marine algae (division RHODOPHYTA). The nature of the thallus varies according to the stage in the life cycle; the thallus can be sheet-like (one or two cells thick) or filamentous – the filamentous form being called the '*Conchocelis* stage' since it was previously thought to be a different organism (designated *Conchocelis*). The organisms, which range from reddish-purple to olive green, attach to rocks etc by means of a holdfast. (See also LAVER and PORPHYRAN.)

**porphyran** A group of complex, mucilaginous, sulphated and methylated galactans (containing D- and L-galactose and 3,6-anhydro-L-galactose) produced by *Porphyra* spp.

**Porphyridium** A genus of unicellular, spherical algae (division RHODOPHYTA) which occur e.g. in freshwater habitats and on soil. Each cell contains a stellate chloroplast with a central pyrenoid; there is no cell wall, each cell being surrounded by a gelatinous polysaccharide capsule. When viewed in masses, the cells may be blood-red (e.g. *P. purpureum* – formerly *P. cruentum*) to blue-green (e.g. *P. aeruginum*), depending on the relative proportions of phycoerythrin and phycocyanin which they contain.

**porphyrin test** A test for determining the X FACTOR requirement of a *Haemophilus* strain by determining the ability of the strain to convert  $\delta$ -aminolaevulinic acid (ALA) to porphyrins or porphobilinogen. A medium (0.5-ml aliquot) containing ALA (2 mM) and  $\text{MgSO}_4$  (0.8 mM) in phosphate buffer (0.1 M, pH 6.9) is inoculated with a loopful of bacteria from an agar plate culture and incubated for ca. 4 hours at 37°C. A red fluorescence from the culture (or culture fluid) under WOOD'S LAMP (360 nm) indicates the formation of porphyrins (a positive test, i.e., the strain *does not* require the X factor); alternatively, 0.5 ml Kovács' indole reagent may be added, shaken vigorously, and the phases allowed to separate – a red coloration in the lower (aqueous) phase indicating the formation of porphobilinogen (a positive test). [Book ref. 22, pp. 561–562.]

**porphyrins** PORPHIN derivatives in which the pyrrole  $\beta$ -carbons are variously substituted: e.g., *aetioporphyrins* (= etioporphyrins) have 4 methyl and 4 ethyl substituents, *mesoporphyrins* have 4 methyl, 2 ethyl and 2 propionic acid substituents, and *protoporphyrins* have 4 methyl, 2 vinyl and

## port

2 propionic acid substituents. Isomers of a given porphyrin are usually denoted by Roman numerals: e.g. aetioporphyrin I is 1,3,5,7-tetramethyl-2,4,6,8-tetraethylporphyrin, and aetioporphyrin III is 1,3,5,8-tetramethyl-2,4,6,7-tetraethylporphyrin. *Protoporphyrin IX* (= protoporphyrin III) is 1,3,5,8-tetramethyl-2,4-divinylporphyrin-6,7-dipropionic acid. (The numbering system used in the Dictionary – illustrated in the figure for CHLOROPHYLLS – is the widely used Fischer system; alternative systems have been proposed in which, e.g., all carbon atoms in the tetrapyrrole ring are numbered sequentially, 1–20, starting with the  $\alpha$ -carbon of ring I next to the  $\delta$ -methene position [PAC (1979) 51 2251–2304].)

Porphyrins can readily chelate various metals, the metalloporphyrins being components of several important biological pigments: see e.g. CHLOROPHYLLS, CYTOCHROMES, HAEM. (See also CHLORIN; cf. PHYCOBILIPROTEINS.)

**port** See WINE-MAKING.

**Port Salut cheese** See CHEESE-MAKING.

**porter** See PERMEASE.

**positive control** (of an operon) See OPERON.

**positive interference** See INTERFERENCE (2).

**positive-sense genome** See VIRUS.

**positive staining** See ELECTRON MICROSCOPY (a).

**positive-strand virus** A VIRUS (q.v.) with a positive-sense genome.

**post-antibiotic effect (PAE)** The suppression of bacterial growth (typically for hours) which follows a short exposure to some types of antimicrobial agent – e.g. aminoglycosides, 4-quinolones,  $\beta$ -lactams, streptogramins and macrolides. PAE is a factor when considering the dose/dosage frequency of these antibiotics; it can be advantageous when coincident with low concentrations of an intermittently administered drug. PAE may involve different mechanisms in different organism–antibiotic combinations [AAC (1995) 39 1314–1319].

The post-antibiotic sub-MIC effect may be more relevant, clinically, than the PAE [JAC (1999) 43 71–77].

**post-ciliary microtubules** (*ciliate protozool.*) A ribbon of MICROTUBULES which arises from the right-hand posterior side of a kinetosome (close to triplet 9, GRAIN CONVENTION), extends upwards (towards the pellicle) and to the right, and then (sometimes) runs posteriorly between the kineties, the wider face of the ribbon being perpendicular to the body surface. (See also PITELKA CONVENTION.)

**posterior station** (*parasitol.*) The hindgut and/or rectum of an arthropod vector; infective forms of parasites in the posterior station can be transmitted to the vertebrate host via the faeces of the vector (see e.g. CHAGAS' DISEASE). (cf. CONTAMINATIVE INFECTION.)

**post-fixation** See FIXATION.

**post-herpetic neuralgia** See HERPES ZOSTER.

**post-kala-azar dermal leishmaniasis** A cutaneous leishmaniasis which may occur in a patient up to two years after that patient has been cured of VISCERAL LEISHMANIASIS. [PCR-based diagnosis of post-kala-azar dermal leishmaniasis: JCM (1998) 36 1621–1624.]

**post-meiotic segregation** The segregation of alleles during the first nuclear division after MEIOSIS; it results from the separation of strands of uncorrected heteroduplex DNA (in a chromatid) formed previously during recombinational events in meiosis (see RECOMBINATION).

**postoral suture** See SYSTÈME SÉCANT.

**post-replication repair** (1) A DNA REPAIR process which operates after DNA replication: e.g. daughter-strand gap repair (see

RECOMBINATION REPAIR) and some cases of MISMATCH REPAIR. (2) *Syn.* daughter-strand gap repair.

**post-streptococcal glomerulonephritis (PSGN)** GLOMERULONEPHRITIS which occurs as a late complication of *Streptococcus pyogenes* infection (usually IMPETIGO – cf. RHEUMATIC FEVER); PSGN is caused only by certain ('nephritogenic') strains of streptococci, and occurs mainly in young children. There may be a latent period of ca. 10–21 days between the original infection and the onset of PSGN.

**post-transfusion hepatitis** HEPATITIS transmitted by blood transfusion.

**post-zygotic exclusion** See PRE-ZYGOTIC EXCLUSION.

**potassium cyanide broth** See KCN BROTH.

**potassium permanganate** (as an antimicrobial agent) Potassium permanganate (KMnO<sub>4</sub>) is an OXIDIZING AGENT which is active against a wide range of microorganisms at concentrations ranging from 0.001% to 1% w/v; it has been used for the treatment of certain superficial mycoses, but it can act as an irritant at high concentrations. As an algicide, potassium permanganate has been reported to be superior to copper sulphate. At concentrations >ca. 0.002% w/v, potassium permanganate imparts a pink coloration to water; this, together with the toxicity of its manganese component, makes potassium permanganate unsuitable for the disinfection of potable water.

**potassium pump** See ION TRANSPORT.

**potassium transport** See ION TRANSPORT.

**potato aucuba mosaic virus** See POTEXVIRUSES.

**potato black ringspot virus** See NEPOVIRUSES.

**potato blight** See EARLY BLIGHT and LATE BLIGHT.

**potato diseases** See e.g. BLACKLEG (2); EARLY BLIGHT; GANGRENE (2); LATE BLIGHT; POTATO SCAB; POTATO VIRUS Y; POWDERY SCAB; SILVER SCURF; SPRAING; WART DISEASE.

**potato leaf roll virus** See LUTEOVIRUSES.

**potato mop top virus** See SOIL-BORNE WHEAT MOSAIC VIRUS, SPRAING and TOBAMOVIRUSES.

**potato paracrinkle virus** See CARLAVIRUSES.

**potato scab** (common scab) A POTATO DISEASE caused by *Streptomyces scabies*. The disease occurs particularly in light, sandy, alkaline soils; corky scabs of various sizes typically develop on the surface of tubers, deeper lesions sometimes occurring. In heavy, wet soils POWDERY SCAB may develop.

**potato slope** A wedge-shaped piece of potato autoclaved (in a test-tube or bottle) and used as a MEDIUM.

**potato spindle tuber viroid** See VIROID.

**potato virus A** See POTYVIRUSES.

**potato virus M** See CARLAVIRUSES.

**potato virus S** See CARLAVIRUSES.

**potato virus T** A filamentous (about 640 × 12 nm), ssRNA-containing virus (possible member of the CLOSTEROVIRUSES) which has a rather limited host range; in potato plants, infection may be symptomless (latent) or may result in a mild leaf mottle. Transmission occurs via seeds in some solanaceous plants.

**potato virus X** See POTEXVIRUSES.

**potato virus Y (PVY)** The type member of the POTYVIRUSES. Virion: ca. 730 × 11 nm. PVY infects mainly plants of the Solanaceae, causing important diseases in several commercial crop plants (e.g. potato, capsicum, tobacco, tomato). In the potato, symptoms depend on virus strain, host cultivar, and environmental conditions. PVY Y<sup>N</sup> strains may cause necrotic rings or spots, with mild mottling appearing later in the growing season; symptoms appearing in the second and subsequent years may include mild to severe mottling. PVY Y<sup>O</sup> strains may cause necrosis, mottling or yellowing of leaflets, leaf-drop, and

premature death (see also RUGOSE MOSAIC DISEASE). PVY Y<sup>C</sup> strains may cause necrosis, mottling, crinkling, and necrotic streaks on leaves, petioles and stem; necrosis may occur in the tubers. Symptoms of PVY infection in capsicum, tobacco and tomato typically include mild mottling, but Y<sup>N</sup> strains can cause a severe disease in tobacco ('tobacco vein necrosis disease') which may result in total loss of the crop.

**potato yellow dwarf virus** See RHABDOVIRIDAE.

**Poteroochromonas** See OCHROMONAS.

**potexviruses** (potato virus X group) A group of PLANT VIRUSES in which the virions are flexuous filaments (ca. 470–580 × 13 nm) comprising one type of coat protein (MWt ca. 18000–23000) and one molecule of linear positive-sense ssRNA (MWt ca. 2.1 × 10<sup>6</sup>). The RNA is capped at the 5' end (sequence: m<sup>7</sup>G<sup>5'</sup>pppGpA...) but is not polyadenylated at the 3' end; the adenine content of the RNA is ca. 30%. The host range for the group is wide, including monocots and dicots, but individual members infect only a narrow host range. Plants infected with potexviruses typically develop mosaic and ringspot symptoms. Virus particles form fibrous, sometimes banded, often large aggregates in the cytoplasm of infected cells; some members also induce nuclear inclusions. Transmission occurs mechanically.

Type member: potato virus X (PVX). Other members include e.g. cactus virus X, cassava common mosaic virus, clover yellow mosaic virus, *Cymbidium* mosaic virus, *Papaya* mosaic virus, *Plantago* severe mottle virus, *Plantago* virus X, white clover mosaic virus. Possible members include e.g. artichoke curly dwarf virus, bamboo mosaic virus, barley B-1 virus, *Boletus* virus, negro coffee mosaic virus, potato aucuba mosaic virus.

**Potomac horse fever** (equine monocytic ehrlichiosis) A HORSE DISEASE caused by *Ehrlichia risticii*, a species antigenically related to *E. canis* and *E. sensu lato* (and which can be transmitted, experimentally, to cattle [VR (2001) 148 86–87]). Symptoms are variable, and may include e.g. fever, depression, anorexia, colic, mild to severe diarrhoea, oedema, etc; mortality rates may exceed 30%.

**Potter–Elvehjem homogenizer** A type of blender used e.g. for preparing subcellular fractions of eukaryotic cells.

**Pott's disease** Tuberculosis of the spine – see OSTEOMYELITIS.

**potyviruses** (potato virus Y group) A large group of PLANT VIRUSES in which the virions are flexuous filaments (ca. 680–900 × 11 nm) comprising one type of coat protein (MWt ca. 32000–36000) and one molecule of linear positive-sense ssRNA (MWt ca. 3.0–3.5 × 10<sup>6</sup>). As a group, the viruses infect a wide range of host plants, including monocots and dicots, but individual members typically have a narrow host range; some members can cause important economic losses in crop plants. Symptoms depend on plant cultivar, virus strain, and environmental conditions, but typically include mosaic or mottle in the leaves, colour-breaking in flowers, mottling and/or distortion in the fruits; characteristic proteinaceous inclusion bodies (serologically unrelated to virus coat protein) are formed in the cytoplasm of infected plant cells, appearing as 'pinwheels' in transverse section or as 'bundles' in longitudinal section. A few members also form crystalline nuclear inclusions. Potyviruses are transmitted (non-persistently) by aphids (see NON-CIRCULATIVE TRANSMISSION sense 1) and can be transmitted mechanically; some viruses tentatively included in the group are transmitted by whitefly, mites or fungi.

Type member: POTATO VIRUS Y. Other members include e.g. bean common mosaic virus, bean yellow mosaic virus (of which pea mosaic virus is a strain), beet mosaic virus, blackeye cowpea

mosaic virus, carnation vein mottle virus, carrot thin leaf virus, celery mosaic virus, cocksfoot streak virus, cowpea aphid-borne mosaic virus (of which Azuki bean mosaic virus is a strain), leek yellow stripe virus, lettuce mosaic virus, onion yellow dwarf virus, *Papaya* ringspot virus, parsnip mosaic virus, peanut mottle virus, PLUM POX virus, potato virus A, soybean mosaic virus, sugarcane mosaic virus (of which maize dwarf mosaic virus is a strain), tobacco etch virus, tulip breaking virus, turnip mosaic virus.

Many other viruses have been tentatively included as 'possible members' of the potyviruses. These include (a) certain aphid-borne viruses: e.g. carrot mosaic virus, celery yellow mosaic virus, groundnut eyespot virus, tobacco vein mottling virus, tomato (Peru) mosaic virus, wheat spindle streak virus, wheat streak virus; (b) a group of viruses which are transmitted by eriophyid mites: e.g., *Agropyron* mosaic virus, oat necrotic mottle virus, ryegrass mosaic virus, *Spartina* mottle virus, wheat streak mosaic virus; (c) the whitefly-transmitted virus sweet potato mild mottle virus; and (d) a group of viruses transmitted by *Polymyxa graminis*: barley yellow mosaic virus, oat mosaic virus, rice necrosis mosaic virus, wheat spindle streak mosaic virus, wheat yellow mosaic virus. Some or all of these 'possible members' may actually belong to or constitute separate groups.

**pouch** (food processing) See RETORT POUCH.

**poultry diseases** Poultry (chickens, ducks, turkeys, etc) can be affected by a wide range of diseases – some specific for one species of bird, others affecting a range of birds. (a) *Bacterial diseases*: see e.g. AIR SACкулITIS; ARIZONOSIS; BUMBLEFOOT; COLISEPTICAEMIA; DIPHTHEROID STOMATITIS; Erysipelas (see SWINE ERYSIPELAS); FOWL CHOLERA; FOWL TYPHOID; HJÄRRE'S DISEASE; PSITTACOSIS; PULLORUM DISEASE. (b) *Fungal diseases*: see e.g. ASPERGILLOSIS; CANDIDIASIS; FAVUS. (c) *Protozoal diseases*: see e.g. BLACKHEAD; COCCIDIOSIS; HEXAMITIASIS. (d) *Viral diseases*: see e.g. AVIAN ACUTE LEUKAEMIA VIRUSES; AVIAN ENCEPHALOMYELITIS; AVIAN INFECTIOUS BRONCHITIS; AVIAN INFECTIOUS LARYNGOTRACHEITIS; AVIAN RETICULOENDOTHELIOSIS VIRUSES; AVIAN SARCOMA VIRUSES. DUCK VIRUS ENTERITIS; DUCK VIRUS HEPATITIS; FOWL PLAGUE; FOWL POX; HAEMORRHAGIC ENTERITIS OF TURKEYS; INCLUSION BODY HEPATITIS; INFECTIOUS BURSAL DISEASE VIRUS; LYMPHOID LEUKOSIS; MAREK'S DISEASE; NEWCASTLE DISEASE; OSTEOPETROSIS. (See also EGG-DROP SYNDROME, PARVOVIRUS and STUNTING SYNDROME.) (e) Diseases due to ingestion of *microbial toxins* include e.g. LIMBERNECK; TURKEY X DISEASE; WESTERN DUCK DISEASE.

**poultry spoilage** See MEAT SPOILAGE.

**pour plate** (1) A procedure (used e.g. as a COUNTING METHOD) in which a measured volume of liquid INOCULUM is placed in a PETRI DISH, a molten medium (e.g. an agar medium at 45–48°C) is added, and the whole swirled to disperse the inoculum throughout the medium; when set, the plate is incubated. (The inoculum may instead be mixed with the medium before the latter is poured into the Petri dish.) The medium may incorporate a reducing agent (e.g. sodium thioglycollate) so that even under aerobic incubation some anaerobes can grow *within* the medium. (2) A CULTURE prepared as in (1).

**pourriture noble** (French) *syn.* NOBLE ROT.

**povidone–iodine** See IODINE (a).

**POW virus** See POWASSAN ENCEPHALITIS.

**Powassan encephalitis** An acute, occasionally fatal, human ENCEPHALITIS caused by a flavivirus (see FLAVIVIRIDAE); it occurs e.g. in forested areas of Canada and Northern USA. The Powassan virus (POW virus) occurs in small mammals and is transmitted by ticks (usually *Ixodes* spp). [ARE (1981) 26 84–85.]

## powdery mildews

**powdery mildews** Plant diseases caused by members of the ERYSIPTALES and characterized by the formation of at least partially superficial hyphal growth carrying a dense layer of conidia in which individual conidium-bearing structures are difficult to distinguish under low magnification (cf. DOWNY MILDEWS); dark-coloured cleistothecia may develop among the hyphae during the summer – being the overwintering stage in some species.

Powdery mildews of cereals (including barley and wheat) are caused by *Erysiphe graminis*. White to grey (later brownish) mycelium develops on small chlorotic spots on leaves, and may also occur on the glumes (particularly in wheat); lodging may occur. Control: antifungals such as CARBENDAZIM and PROCHLORAZ.

**powdery scab** A POTATO DISEASE caused by *Spongospora subterranea* (PLASMODIOPHYCOMYCETES). Small wart-like swellings develop on the stolons, roots and tubers of infected plants; a dry brownish powder (consisting of masses of cystosori) forms within the tuber lesions. The cysts can persist in the soil for many years. The disease is favoured by wet soil conditions. The pathogen can also infect tomato roots.

**powdery yeasts** See FLOCCULATION (sense 2).

**pOX1 plasmid** See ANTHRAX TOXIN.

**pOX2 plasmid** See ANTHRAX TOXIN.

**Poxviridae** (the poxvirus group) A family of dsDNA-containing VIRUSES which infect mammals (including man), birds or insects; some members are important pathogens (e.g. the causal agents of SMALLPOX, MONKEYPOX, CONTAGIOUS PUSTULAR DERMATITIS (sense 1), etc). The family includes two subfamilies, CHORDOPOXVIRINAE (vertebrate poxviruses) and ENTOMOPOXVIRINAE (insect poxviruses), together with several unclassified viruses (e.g. MOLLUSCUM CONTAGIOSUM VIRUS, TANAPOX VIRUS, YABA MONKEY TUMOUR POXVIRUS) [Book ref. 23, pp. 42–46].

The poxvirus virion is the largest and structurally the most complex of all animal viruses. Depending on virus, it may be ovoid or brick-shaped, ca. 200–450 × 170–260 nm. It contains a central *core* (incorporating the genome) which is commonly bilaterally concave; on either side of the core – coincident with each concavity – is an ellipsoidal structure called the *lateral body*. (cf. ENTOMOPOXVIRINAE.) The core and its two associated lateral bodies are enclosed within a lipoprotein *outer membrane* which bears a characteristic pattern of ridges or tubules on its surface. (In some poxviruses the extracellular virions have an extra lipoprotein layer, the *envelope*, acquired from the host cell; these are believed to be the infective forms of the virus.) The virion contains a variety of enzymes, including enzymes involved in e.g. DNA replication, transcription, and RNA processing. In general, poxvirus virions are stable at room temperature and are resistant to desiccation; most are ether-resistant but may be inactivated e.g. by chloroform and by heating (e.g. 60°C/20 min).

The genome is a single molecule of dsDNA (MWt in the range 85–250 × 10<sup>6</sup>) in which – in at least some poxviruses – the two strands are covalently joined at each end of the molecule (i.e., the molecule is actually a single uninterrupted circular polynucleotide chain). The genome contains highly conserved sequences in the central region, and terminal hypervariable regions. [Genomes: orf virus, bovine papular stomatitis virus [JV (2004) 78 168–177]; goatpox, sheeppox [JV (2002) 76 6054–6061]; deerpox [JV (2005) 79 966–977].]

**Replication cycle.** Poxvirus replication occurs in the cytoplasm of the host cell; studies on replication processes have been carried out mainly with orthopoxviruses (particularly VACCINIA

VIRUS). Infection begins when the virion adsorbs to a host cell; vaccinia virus appears to bind to the host cell-surface epidermal growth factor (EGF) receptor [Nature (1985) 318 663–665]. The virus apparently enters the cell by fusion between viral and cell membranes and/or by viropexis. An early consequence of infection is the inhibition of host cell DNA, RNA and protein synthesis [review: Book ref. 150, pp. 391–429]. The viral core is uncoated in the cytoplasm, and enzymes of the core begin transcription of the viral DNA; early mRNA is synthesized by an  $\alpha$ -amanitin-resistant viral RNA polymerase, and viral enzymes then process the RNA to form the functional polyadenylated, capped and methylated mRNA. (Early mRNAs, at least, are apparently not spliced.) DNA replication then begins; this may involve nicking of the DNA to provide free 3'-ends which can act as primers. The onset of DNA replication allows initiation of the synthesis of late mRNA which codes for most of the structural proteins of the virion. Proteolytic processing of the structural proteins appears to be coupled to virus assembly. In the case of vaccinia virus, the mature virions each become enclosed in a double membrane derived from the Golgi apparatus and are transported to the cell periphery; it was suggested that the outer viral membrane may fuse with the cell membrane, resulting in the release of virions enclosed by a single layer of Golgi membrane [JGV (1985) 66 643–646].

The discrete cytoplasmic sites of virus replication are termed 'virus factories', 'factory areas', or 'viroplasm'; they are visible in suitably stained preparations as *B-type inclusion bodies* (= GUARNIERI BODIES). Some poxviruses (e.g. COWPOX VIRUS) form a second type of inclusion body, the *A-type inclusion body*: acidophilic structures which may or may not contain virions.

**poxvirus group** See POXVIRIDAE.

**pp** Prefix denoting (1) phosphoprotein (see e.g. RETROVIRIDAE), or (2) diphospho- or pyrophospho- (as in ppGpp).

**PPAR** Peroxisome proliferator-activated receptor: see PROSTAGLANDINS.

**PPD** See TUBERCULIN.

**PPFM** Pink-pigmented facultatively methylotrophic bacterium.

**ppGpp** See (i) CELL CYCLE; (ii) STRINGENT CONTROL (sense 1); and (iii) SPOT GENE.

ppGpp has been classified as an ALARMONE.

**PPi** Inorganic PYROPHOSPHATE (P<sub>2</sub>O<sub>7</sub><sup>4-</sup>).

**PPLOs** Pleuropneumonia-like organisms: an early name for *Mycoplasma* spp.

**PQQ** See QUINOPROTEIN.

**Pr** Prefix denoting a polyprotein product of transcription (see e.g. RETROVIRIDAE).

**PR proteins** PATHOGENESIS-RELATED PROTEINS.

**Pr65 gag precursor protein** (of FeLV) See FELINE LEUKAEMIA VIRUS.

**PRAS media** Pre-reduced anaerobically-sterilized media.

**Prasinocladus** See TETRAELMIS.

**Prasinomonadida** See PHYTOMASTIGOPHOREA.

**Prasinophyceae** A class of unicellular, flagellated green algae which have scaly flagella arising from an anterior flagellar pit. The class, which is no longer recognized [Book ref. 123, pp. 65–66], included e.g. TETRAELMIS and many of the genera in the MICROMONADOPHYCEAE.

**Prasiola** A genus of marine and freshwater green algae (division CHLOROPHYTA). The thallus is foliose or filamentous. Asexual reproduction occurs by the formation of diploid aplanospores. In at least some species sexual reproduction is preceded by meiosis in the cells of the upper portion of the blade followed by several mitotic divisions; this results in the formation of

polystromatic micro- and macrogametangial regions which give rise to biflagellate microgametes and non-motile macrogametes, respectively.

**Prausnitz–Küstner antibodies** *Syn.* REAGINIC ANTIBODIES.

**Prausnitz–Küstner test** (P–K test) A test used for demonstrating the presence of IgE antibodies homologous to a given allergen. Serum from a hypersensitive subject is injected intradermally into a normal subject; subsequent injection of the normal subject with the given allergen causes a WHEAL-AND-FLARE response to develop within minutes (a positive test). The P–K reaction can be inhibited by the prior injection of a fragment of  $\epsilon$ -chain [Nature (1985) 315 577–578].

**PRD** See CATABOLITE REPRESSION.

**PRD1 phage group** *Syn.* TECTIVIRIDAE.

**preaxostyle** See OXYMONADIDA.

**pre-B cell** See B LYMPHOCYTE.

**prebiotic** (1) A non-digestible part of a food (often an oligosaccharide) which, by selectively stimulating certain type(s) of colon bacteria, benefits the host.

(2) (*adj.*) The time before life appeared on Earth.

**prebuccal area** In some ciliates (e.g. *Paramecium*): a depression in the body surface leading to the BUCCAL CAVITY; its ciliature is essentially somatic (cf. VESTIBULUM).

**precipitation** (*serol.*) The formation of a precipitate when antibodies and *soluble* antigens react in suitable proportions (see e.g. OPTIMAL PROPORTIONS; cf. ANTIGEN EXCESS and AGGLUTINATION). (See also GEL DIFFUSION.)

**precipitin** An ANTIBODY which forms a precipitate with its homologous soluble antigen. (cf. AGGLUTININ.)

**precipitin test** Any serological test in which the interaction of antibodies with *soluble* antigens is detected by the formation of a precipitate.

**precipitinogen** (1) An antigen which elicits a PRECIPITIN. (2) Any agent (e.g. PROTEIN A) which can combine with antibody to form a precipitate.

**precyst** See CYST (a).

**prednisone** See IMMUNOSUPPRESSION.

**pre-erythrocytic schizogony** (in *Plasmodium*) See PLASMODIUM.

**pre-filtration** See FILTRATION.

**pre-fixation** See FIXATION.

**pre-genome** See HEPADNAVIRIDAE.

**pregnancy test** An IMMUNOASSAY in which urine is examined for human chorionic gonadotrophin (hCG), a hormone that appears during pregnancy. Urine is added to serum containing anti-hCG antibodies, which combine with hCG. Then, the absence of *uncombined* antibodies (a *positive* test) is shown by non-agglutination when latex-bound hCG is added.

**pre-initiation complex** See PROMOTER.

**Preisz–Nocard bacillus** See CORYNEBACTERIUM.

**pre-lesion terminus** In damaged DNA: the nucleotide immediately 5' of the lesion site.

**premunition** (concomitant immunity; non-sterilizing immunity) (*immunol.*) Protective immunity, in respect of a given pathogen, due to the persistence of small numbers of that pathogen in the host; the host can resist superinfection (i.e., infection by the same or closely related pathogens) but cannot achieve STERILIZING IMMUNITY. In an apparently analogous phenomenon, cells of a given tumour type fail to develop when injected into an animal suffering from the same type of tumour.

**preoral suture** See SYSTÈME SÉCANT.

**prepatent period** In a parasitic infection: the time interval between the initial infection and the appearance of parasites, or their cysts, in blood, tissues or faeces.

**prephenate** See AROMATIC AMINO ACID BIOSYNTHESIS.

**preprimosome** See PRIMOSOME.

**pre-protein** See SIGNAL HYPOTHESIS.

**pre-reduced medium** See ANAEROBE.

**preservation** (1) (of materials, products) The use of physical and/or chemical means to kill or prevent the growth of those microorganisms which, by their growth and/or activities, may cause BIODETERIORATION of a given material or product. Physical methods (e.g. heat STERILIZATION, freezing – see e.g. FOOD PRESERVATION) either kill contaminating organisms or render the materials or products unsuitable for the (rapid) growth of likely contaminants. Chemical agents (PRESERVATIVES) may be microbistatic or microbicidal.

(2) (of microorganisms) Viable populations of microorganisms may be preserved (i.e. maintained for reference purposes etc) by e.g. FREEZING, FREEZE-DRYING or DESICCATION. Some bacterial cultures can be preserved by sealing with a layer of sterile mineral oil and storing at ca. 4°C. A culture may be preserved by periodic SUBCULTURE (see also STABILATE).

**preservative** Any chemical used for the PRESERVATION of materials or products; in some industries such chemicals are referred to as BIOCIDES. For examples of preservatives and their usage see e.g. FOOD PRESERVATION, PAINT SPOILAGE, PAPER SPOILAGE, SAUSAGE, TEXTILE SPOILAGE, TIMBER PRESERVATION; see also ALCOHOLS, BISPHENOLS, CHLORBUTANOL, EGME, FORMALDEHYDE, GERMALL 115, PHENOLS, QUATERNARY AMMONIUM COMPOUNDS, SALICYLANILIDES, THIOMERSAL. A preservative may be inactivated e.g. by colloids (such as magnesium trisilicate or bentonite – cf. BENZOIC ACID; CHLORBUTANOL) or by certain container materials (polyethylene can inactivate e.g. dichlorophenol and other phenolics, while polypropylene can inactivate e.g. dichlorophenol and sorbic acid).

**prespore** See ENDOSPORE (sense 1(a)).

**pressure-cycle fermenter** See AIRLIFT FERMENTER.

**presumptive coliform count** See COLIFORM TEST.

**pretibial fever** *Syn.* FORT BRAGG FEVER.

**pretrichocyst** See TRICHO CYST.

**pretyrosine** See AROMATIC AMINO ACID BIOSYNTHESIS.

**Prevotella** A genus of Gram-negative, asporogenous, anaerobic, rod-shaped bacteria found e.g. in the human oral cavity; some species form black or brown pigments when grown on blood-containing media. Most species ferment sucrose and lactose.

Using quantitative culture on a non-selective blood-agar medium, studies on the anaerobic oral microflora in the first year of life found that organisms in the *Prevotella melaninogenica* group were among the early colonizers (18% at 2 months, rising to 57% at 6 months and 77% at 12 months); members of the *P. intermedia* group were apparently late colonizers, whereas isolation of non-pigmented species of *Prevotella* increased from 'occasional' at 2 months to 75% at 12 months [RMM (1997) 8 (supplement 1) S19–S20].

Species of *Prevotella* have been associated with e.g. abscesses and PERIODONTITIS. [Simultaneous detection of *Prevotella intermedia* and *Bacteroides forsythus* by multiplex PCR in clinical samples: JCM (1999) 37 1621–1624.]

**pre-zygotic exclusion** During processes such as CONJUGATION (sense 1b) and TRANSDUCTION: the absence of expression of a given donor gene in the recipient as a result of the failure of that gene to enter the recipient. If the gene entered the recipient but failed to recombine with the recipient's genome, the absence of expression of that gene is referred to as *post-zygotic exclusion*.

**prgI gene** (*Salmonella typhimurium*) See NEEDLE COMPLEX.

**Pribnow box** See PROMOTER.

## Pril

**Pril** A quaternary ammonium detergent used e.g. in certain media to prevent swarming by *Proteus* spp.

**prill** A solid in granular form.

**primaquine** See MALARIA (chemotherapy).

**primary amoebic meningoencephalitis** See MENINGOENCEPHALITIS.

**primary atypical pneumonia** (1) Any of a group of pneumonias characterized by symptoms distinct from those of 'classical' lobar PNEUMONIA and by a causal agent which cannot readily be isolated by routine laboratory methods; the group includes LEGIONELLOSIS; *Mycoplasma pneumoniae* pneumonia (see (2) below); PSITTACOSIS; Q FEVER.

(2) PNEUMONIA caused by *Mycoplasma pneumoniae*; it affects mainly children. Infection occurs by droplet inhalation. Incubation period: 2–3 weeks. Onset is insidious, with fever and malaise followed by symptoms of an upper respiratory tract infection; a persistent, non-productive cough typically develops, and ear infection is common. The disease is usually mild and self-limiting, with few chest signs; in only a minority of cases does frank pneumonia develop. *Chemotherapy*: e.g. erythromycin.

**primary constriction** *Syn.* CENTROMERE.

**primary culture** (1) A CULTURE prepared by inoculating a medium directly from a natural source of microorganisms (cf. SUBCULTURE). For example, a bacteriological medium may be inoculated directly from a faecal specimen. In TISSUE CULTURE a primary culture is one prepared from cells or tissues taken directly from an animal or plant. (2) The process of preparing a culture as in (1).

**primary fixation** *Syn.* pre-FIXATION.

**primary fluorescence** See FLUORESCENCE.

**primary host** (of rust fungi) See UREDINIOMYCETES.

**primary hyphae** See HYPHA.

**primary metabolism** Metabolism which is essential for and geared towards growth – i.e., energy metabolism, synthesis of cell components, etc. (cf. SECONDARY METABOLISM.)

**primary mycelium** (in actinomycetes) *Syn.* SUBSTRATE MYCELIUM.

**primary production** The production of new biomass by photosynthetic organisms as a result of their use of light (solar) energy. The phrase 'chemosynthetic primary production' has been used to refer to the production of biomass by those non-photosynthetic organisms which are believed to derive energy from the oxidation of e.g. sulphide and/or methane in the vicinity of HYDROTHERMAL VENTS in the ocean floor; these organisms (which include species of *Thiobacillus* and *Thiomicrospira*) appear to be at the start of a food chain which is unique in that it is not based on photosynthetic organisms.

**primary septum** See SEPTUM (b).

**primary zoospore** See e.g. DIPLANETISM and PLASMIDIOPHOMYCETES.

**primase** (DNA primase) An enzyme which, in vitro, can polymerize molecules of ribonucleoside triphosphate (rNTPs) and/or dNTPs in the 5'-to-3' direction to form short oligonucleotides on an ssDNA template. In vivo, *Escherichia coli* primase (*dnaG* gene product) synthesizes short RNA primers for the formation of Okazaki fragments in DNA REPLICATION, and also synthesizes primers for the initiation of DNA replication of isometric ssDNA phages.

Primase either recognizes a specific region of DNA directly (as in BACTERIOPHAGE G4) or, more commonly, it requires the co-operation of additional proteins (see PRIMOSOME).

Certain phages (e.g. T4, T7) encode their own primases.

Primase action is resistant to rifampicin (cf. RNA POLYMERASE).

**primate T-cell leukaemia virus** See SIMIAN T-CELL LEUKAEMIA VIRUS.

**prime plasmid** A PLASMID which has undergone aberrant excision from a bacterial chromosome. In some types of prime plasmid ('type I'), part of the plasmid has been left behind in the chromosome, and the plasmid carries a sequence of bacterial DNA; a 'type II' prime plasmid consists of the entire plasmid carrying a sequence of bacterial DNA. The particular sequence of bacterial DNA carried by a prime plasmid depends on the site within the chromosome occupied by the plasmid before excision; thus, e.g. it is possible to isolate various F' plasmids (derived from the F PLASMID) because this plasmid can integrate at various sites in the bacterial chromosome.

(See also specialized TRANSDUCTION.)

**primed** (*immunol.*) (1) (of persons, animals) Refers to those individuals who have had an initial immunological contact with a given antigen; such individuals may respond e.g. with ANTIBODY FORMATION. Subsequent exposure of a primed individual to the given antigen may bring about a heightened response (see ANAMNESTIC RESPONSE and HYPERSENSITIVITY (sense 1)). (See also IMMUNE RESPONSE.) (2) (of cells) Refers to those cells whose responsiveness to a given antigen has been heightened as a consequence of their previous contact with that antigen (or of previous contact between their precursor cells and that antigen). (cf. PRIMING.)

**primer** See (i) DNA REPLICATION; (ii) PCR; (iii) NASBA; (iv) SDA; and (v) FORWARD PRIMER.

**primer-dimer** In a PCR reaction mixture: an artefact resulting from the use of a pair of primers whose 3' terminal sequences are mutually complementary; during extension, each primer uses the other as a template – forming products that consist essentially of two double-stranded primers in tandem.

**priming** (1) (*mol. biol.*) The initiation of synthesis of a DNA strand e.g. by the synthesis of an RNA primer (see DNA REPLICATION). (For 'specific' and 'general' priming see DNAB GENE.)

(2) (*immunol.*) The process in which an individual becomes PRIMED.

**primate** The anterior organism of a pair of gregarines in SYZYG. (cf. SATELLITE.)

**primociliatid gymnostomes** Presumptively primitive ciliates (subclass GYMNOSTOMATIA, order Primociliatida) which are homokaryotic; species of STEPHANOPOGON are the only known examples.

**primordium** (*microbiol.*) *Syn.* INITIAL(s).

**primosome** A multiprotein complex involved in certain cases of primer synthesis (see DNA REPLICATION): e.g. in BACTERIOPHAGE  $\phi$ X174 DNA synthesis, and in Okazaki fragment synthesis during *Escherichia coli* chromosome replication and e.g. COLE1 PLASMID replication. Primosome formation on ssDNA coated with SINGLE-STRAND BINDING PROTEIN is initiated by protein n' (= factor Y) which recognizes and binds to specific short base sequences in the DNA. In the presence of ATP, a complex of DnaB (see DNAB GENE) and DnaC proteins is formed which, together with proteins i (= factor X), n, and n'' combine with n' to form a prepriming intermediate (preprimosome) at or near the n' recognition site. The preprimosome is recognized and bound by the DnaG protein (PRIMASE) to complete the primosome. The primosome migrates along the ssDNA template in a 5'-to-3' (anti-elongation) direction (i.e., in the direction of replication fork movement in dsDNA replication), driven by ssDNA-dependent ATP hydrolysis by n', and primase synthesizes short RNA primers at many different sites on the template DNA. The

direction of primase action is opposite to that of primosome migration; primer synthesis is assumed to occur within the domain of the primosome. [JBC (1981) 256 5273–5286.]

**primulin** A polycyclic fluorescent dye. (See also SCAR.)

**prion** (1) In man/animals: an aberrant form of a normal, chromosome-encoded glycoprotein; prions are now believed to be the aetiological agents of TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES. [Mapping the parameters of prion-induced neuropathology: PNAS (2000) 97 10573–10577.]

The normal protein, which is designated PrP<sup>c</sup>, is encoded (in humans) by the *PRNP* gene (on chromosome 20). PrP<sup>c</sup> is a component of the cytoplasmic membrane in certain types of cell – e.g. neurones, astrocytes, dendrocytes, lymphocytes and macrophages.

Synthesis of PrP<sup>c</sup> involves intranuclear transcription of *PRNP* and translation on the endoplasmic reticulum; post-translational modification includes glycosylation (although some molecules remain unglycosylated) and attachment to a glycolipid phosphatidylinositol (GPI) ‘anchor’. The PrP<sup>c</sup> molecule is apparently anchored at the cell surface for a short period of time and then internalized and degraded in a lysosome. The function of PrP<sup>c</sup> has not been established.

When a prion infects a cell, it appears that normal breakdown of (at least some) PrP<sup>c</sup> does not occur, and that the secondary structure of these PrP<sup>c</sup> molecules is changed to that of the prion. This is thought to occur either by interaction between individual PrP<sup>c</sup> and prion molecules (heterodimer model), or by interaction between individual PrP<sup>c</sup> molecules and organized aggregates of prion molecules (the ‘seed’ or ‘nucleus’ model). Accumulation of prions in the form of crystalloid structures eventually leads to the death of the cell. (Interestingly, specific parts of PrP<sup>c</sup> (particularly the central region: residues 90–120) undergo *spontaneous* re-arrangement to a conformation resembling that of the infectious form when immobilized on a surface with recombinant antibodies [EMBO (2001) 20 1547–1554].)

In the prion model of pathogenesis, prions may be present through *infection* – either via ingestion (as in KURU) or through their introduction by medical or surgical procedures. The *inherited* prion diseases, in which the *PRNP* gene is almost invariably heterozygous (wild-type and mutant alleles), are believed to result from the effect of mutant (prion) proteins on wild-type proteins. In the so-called ‘sporadic’ prion diseases, conversion of normal protein to prion protein is considered to result e.g. from random, spontaneous events.

The presence of normal (PrP<sup>c</sup>) protein appears to be necessary for the development of prion diseases: knockout mice which are unable to form PrP<sup>c</sup> do not develop disease on challenge with prion-containing tissue; this suggests that a prion cannot direct the production of further prions without a supply of the normal protein.

Prions do not differ, biochemically, from the normal protein, i.e. the amino acid sequence is identical. However, the conformation is different: about ~40% of normal protein is in the soluble, protease-sensitive  $\alpha$ -helical state – with little or no  $\beta$ -sheet formation; in contrast, the prion form (isoform) is insoluble and protease-resistant, and is composed of ~50%  $\beta$ -sheet and ~20%  $\alpha$ -helix forms. (See also PLASMINOGEN.)

Prions are resistant to e.g. heat, ionizing and ultraviolet radiation, formalin,  $\beta$ -propiolactone and bleach (as well as to proteases).

The prion form of PrP<sup>c</sup> is often designated PrP<sup>Res</sup> (indicating resistance). Some authors use PrP<sup>Sc</sup> (which, strictly, indicates the SCRAPIE prion) as a generalized designation for any prion;

others use superscripts which indicate the specific disease (e.g. ‘GSS’ for Gerstmann–Sträussler–Scheinker syndrome).

[Protein misfolding in prion disease: Cell (1997) 89 499–510; human prion diseases: Book ref. 215, pp. 39–77.]

(2) Strains of the yeast *Saccharomyces cerevisiae* contain a protein *release factor* (see PROTEIN SYNTHESIS) designated eRF3 (= Sup35, product of gene *SUP35*) which, through variation in its effective concentration in the cytoplasm, can influence the fidelity with which translation is terminated on the ribosome; thus, a lowered concentration of the release factor promotes readthrough at certain stop codons. A non-genetic mechanism which can control the concentration of eRF3 may therefore permit heritable variation in the organism without changes in the genome [see e.g. Nature (2000) 407 477–483].

Sup35 can exist in an aggregated, prion form (the [PSI<sup>+</sup>] state) or in a soluble form (the [psi<sup>-</sup>] state). In [PSI<sup>+</sup>] cells, aggregation of Sup35 protein reduces the amount available for terminating translation on the ribosomes, and this allows readthrough at certain stop codons.

Propagation of [PSI<sup>+</sup>] involves protein–protein interaction following the mixing of cytoplasm from different cells (e.g. during mating); in this process the soluble form of Sup35 is converted to the aggregated (prion) form. (Interestingly, if a [PSI<sup>+</sup>] strain of *S. cerevisiae* is grown in the presence of 2 M glycerol (or certain other agents) the aggregates of Sup35 break down to the soluble form of Sup35, i.e. a [psi<sup>-</sup>] strain of the yeast is formed.) [Elimination of [PSI<sup>+</sup>] by guanidine hydrochloride: Mol. Microbiol. (2001) 40 1357–1369.]

[eRF3 concentration in the termination of translation: Microbiology (2001) 147 255–269 (262–263).]

In vitro studies involving fusion between the prion domain of Sup35 proteins from *S. cerevisiae* and *Candida albicans* may help to explain factor(s) which determine the ability of a prion to cross a species barrier [Nature (2001) 410 223–227].

**pristane** An isoprenoid alkane: 2,6,10,14-tetramethylpentadecane.

**pristinamycins** See STREPTOGRAMINS.

**pRNA** See BACTERIOPHAGE  $\phi$ 29.

**PRNP gene** See PRION.

**probasidium** (1) A developing BASIDIUM at the stage at which karyogamy occurs; in many basidiomycetes the terms probasidium and METABASIDIUM refer to the same structure at different developmental stages.

(2) That *part* of a developing basidium in which karyogamy occurs – e.g. the teliospore (or its contents) of the rust and smut fungi, or, in *Septobasidium*, the typically thick-walled structure from which arises, by outgrowth, the septate, basidiospore-bearing metabasidium.

**probe** A short strand of DNA or RNA (often 10–25 nucleotides in length) which is *complementary* to a given target sequence of nucleotides; because a probe can hybridize specifically with its target sequence, it can be used e.g. to detect, identify or locate the target. To make the probe detectable it is ‘labelled’ either before or after it hybridizes to the target sequence (see below). (In addition to DNA or RNA, probes may also be prepared from PNA [JAM (2001) 90 180–189].)

Probe–target hybridization is affected e.g. by temperature, pH and concentration of electrolyte. Conditions can be chosen such that the probe will hybridize only to the *exact* target sequence, i.e. conditions under which mis-matches are not tolerated; such *high-stringency* conditions are used to promote specificity in probe–target binding. Under *low-stringency* conditions the effect of mis-matched base(s) can be minimized so

## probenecid

that hybridization may occur even when the probe–target duplex contains mis-matched base(s).

The detection of RNA targets may be achieved with greater rapidity and specificity by means of 2'-*O*-methyl oligoribonucleotide probes (compared with 2'-deoxy oligoribonucleotide probes) [NAR (1998) 26 2224–2229].

**Labelling of probes.** Probes may be labelled directly and covalently with radioactive isotopes (e.g.  $^{32}\text{P}$ ); such isotopic labels can be detected by autoradiography. Both DNA and RNA probes can be labelled at the 5' end with e.g. [ $\gamma$ - $^{32}\text{P}$ ]ATP (i.e. ATP with  $^{32}\text{P}$  in the  $\gamma$  position); this reaction is mediated by polynucleotide kinase. Radioactive labels are robust, and are associated with good sensitivity (but limited resolution).

Non-radioactive (non-isotopic) labelling with e.g. enzymes or fluorescent molecules is common. Labelling may be either direct or indirect. Thus, for example, *existing* probes may be labelled with a reactive fluorophore which binds covalently to the probe; such labelling systems are available commercially (e.g. Fluoreporter<sup>®</sup>, marketed by Molecular Probes Inc., Eugene, OR, USA). In the second form of direct fluorescent labelling, probes are *synthesized* in a reaction mixture containing fluorophore-conjugated nucleotides (which are thus incorporated into the probe). Such fluorescent nucleotides are available commercially (e.g. ChromaTide<sup>®</sup>; Molecular Probes Inc.). Fluorescent labels are detected by examining the preparation under ultraviolet light.

CHEMILUMINESCENCE is used in probe detection in certain commercial diagnostic tests (see e.g. *hybridization protection assay* in the entry TMA).

Note that, in direct labelling, the probe is already labelled prior to hybridization.

For *indirect* labelling (e.g. with an enzyme or fluorophore), a small molecule (e.g. a biotin or DIGOXIGENIN 'tag') is incorporated into the probe before use. *After* hybridization, the probe is detected by using a *conjugate* to link the tag with a fluorophore or enzyme – see e.g. DOT-BLOT. (It has been reported that short (~10-nucleotide) 5'-biotinylated probes give satisfactory results when labelled with a STREPTAVIDIN–alkaline phosphatase conjugate *prior to* the hybridization step [NAR (1999) 27 703–705].)

**Uses of probes.** Probes can be used e.g. to detect, identify or locate particular pathogens in clinical specimens (by demonstrating the presence of pathogen-specific sequences); specimens are commonly subjected to pre-test procedures in which any target nucleic acids that may be present are exposed (in single-stranded form) to specific probes. One example is the PACE 2C test (Gen-Probe, San Diego, USA) which, in a single assay, can detect *Chlamydia trachomatis* and/or *Neisseria gonorrhoea* in urogenital specimens [see e.g. JCM (1995) 33 2587–2591].

In situ hybridization (ISH) involves the use of strain- or species-specific probes e.g. for detecting pathogens in situ – i.e. at the actual site of infection within tissues or cells; bacterial, viral, fungal and protozoal pathogens may be detected. ISH is particularly useful for demonstrating nucleic acids which are focally distributed – e.g. virus-infected tissue. For example, ISH was found to be as sensitive as PCR for the detection of human papillomavirus in cervical scrapings [HJ (1995) 27 54–59]. Much of the early work in ISH was conducted with radioactive probes; currently, fluorescent probes are common (fluorescence in situ hybridization: FISH). FISH is both rapid and flexible. For example, the target area can be interrogated simultaneously with several different types of probe (each labelled with a different fluorophore); thus, when different probes bind to closely adjacent targets they can be distinguished by their emission characteristics.

Probes are also used in a *line probe assay* for detecting certain point mutations which confer resistance to antibiotics in *Mycobacterium tuberculosis*. Essentially, PCR is used to amplify a sequence in the chromosome associated with common resistance-conferring mutations, and the amplicons are denatured to the single-stranded state; these products are then tested for hybridization against a range of probes which include non-mutant and mutant copies of the given chromosomal sequence. The presence/absence of hybridization between the amplicons and each of the probes provides an indication of the probable resistance or susceptibility of the test strain to given antibiotic(s). [Evaluation of a line probe assay: JCM (1997) 35 1281–1283.]

In nucleic acid amplification processes, specialized probes can provide a real-time indication of progress in the reaction, and can also be used to assess the concentration of target molecules present in the sample prior to amplification (see TAQMAN PROBES). (See also MOLECULAR BEACON PROBES.)

[Probe-based methods in clinical microbiology: Book ref. 221, pp 44–55.]

**probenecid** A drug which e.g. delays the excretion of – and (thus) helps to maintain blood levels of – certain penicillins and cephalosporins.

Probenecid, which inhibits glucuronidation, may affect the metabolism of the antiretroviral drug AZT.

**probiotic** Any potentially beneficial preparation consisting typically of a culture of bacteria (or bacterial spores) of a type normally found in the healthy gut microflora. Oral administration of probiotics has been reported to restore normal gut microecology and e.g. to enhance intestinal IgA responses; perinatal and postnatal administration of the probiotic *Lactobacillus rhamnosus* (= *Lactobacillus* GG; ATCC 53103) has been associated with a significant reduction in the incidence of atopic disease (eczema) in at-risk infants [Lancet (2001) 357 1076–1079; see also commentary: Lancet (2001) 357 1057–1059].

The Shirota strain of *Lactobacillus casei* is reported to be useful therapeutically against an *Escherichia coli* urinary tract infection when administered intraurethally [AAC (2001) 45 1751–1760].

Probiotic activity has been reported for various strains of *Bacillus*. For example, the product Enterogermina (an aqueous suspension of spores) is used in Italy with the object of preventing or treating bacterial diarrhoea. [Molecular characterization of bacteria (*Bacillus clausii*) from samples of Enterogermina: AEM (2001) 67 834–839.]

(See also YAKULT and VSL#3; cf PREBIOTIC.)

**procapsid** A capsid precursor formed during the assembly of a virus.

**Procaryotae** An obsolete kingdom which comprised the PROKARYOTES; proposed divisions of the Procaryotae: FIRMICUTES; GRACILICUTES; MENDOSICUTES; TENERICUTES.

**procaryote** *Syn.* PROKARYOTE.

**processive enzyme** An enzyme which binds to a (macromolecular) substrate and then moves along it, functioning as it goes. (See e.g. HELICASES; DNA POLYMERASES.)

**Prochlorales** See PROCHLOROPHYTES.

**prochloraz** (trade name: e.g. Sportak) An agricultural systemic ANTIFUNGAL AGENT which inhibits sterol biosynthesis, thereby disrupting the cytoplasmic membrane in susceptible fungi. It is used e.g. against rhynchosporium, net blotch and powdery mildew of cereals, and – mixed with e.g. mancozeb – for the control of yellow rust (*Puccinia striiformis*) on wheat. Mixed with CARBENDAZIM ('Sportak Alpha') it is useful e.g. against eyespot, sharp eyespot, septoria and other CEREAL DISEASES.

**Prochlorococcus marinus** See PROCHLOROPHYTES.

**Prochloron** See PROCHLOROPHYTES.

**Prochlorophyta** See PROCHLOROPHYTES.

**prochlorophytes** A category of unicellular prokaryotes (order Prochlorales, division Prochlorophyta) which contain eukaryotic-type chlorophylls *a* and *b* (but lack phycobiliproteins) and carry out oxygenic photosynthesis.

The first member identified was *Prochloron didemni* (formerly *Synechocystis didemni*). The cells are more or less spherical, 6–25 µm in diameter, and the photosynthetic pigments are attached to THYLAKOIDS. The organisms occur as ectosymbionts on marine didemnid ascidians (sea-squirts) in tropical and subtropical coastal waters.

Species identified later include *Prochlorothrix hollandica* and *Prochlorococcus marinus*.

Taxonomically (in terms of genomic sequence data), the prochlorophytes have been grouped with the cyanobacteria and chloroplasts.

[Photosynthetic machinery in prochlorophytes: FEMS Reviews (1994) 13 393–414.]

**Prochlorothrix hollandica** See PROCHLOROPHYTES.

**prodigiosin** A red, water-insoluble, ethanol-soluble tripyrrole derivative. Prodigiosin and similar pigments are produced by some species and biotypes of SERRATIA and by other bacteria (e.g. *Streptomyces* spp.).

**prodromal** Refers to e.g. symptom(s) which precede the main symptoms of an infectious disease (e.g. Koplik's spots in MEASLES).

**prodrug** The precursor form of a drug – see e.g. FAMCICLOVIR.

**proenzyme** *Syn.* ZYMOGEN.

**professional phagocytes** PHAGOCYTES (including NEUTROPHILS and MACROPHAGES) which can kill and digest microorganisms which they have ingested.

**profibrinolysin** See FIBRINOLYSIN.

**profilin** See ACTIN.

**proflavine** (proflavin) See ACRIDINES.

**progametangium** In zygomycetes: an enlarged ZYGOPHORE which differentiates into a distal gametangium and a proximal SUSPENSOR. (See also ZYGOSPORE.)

**progamone** See PHEROMONE.

**progenote** A (hypothetical) primitive organism; progenotes are presumed to be the phylogenetic progenitors of both prokaryotes and eukaryotes.

**progressive multifocal leukoencephalopathy (PML)** A human demyelinating disease that occurs primarily in those with an underlying immunological dysfunction (e.g. Hodgkin's disease, chronic lymphatic leukaemia, AIDS); multiple small areas of demyelination develop in the white matter of the brain, resulting in progressive paralysis, mental deterioration etc. – death usually occurring within 6–12 months of the first symptoms. Characteristic of PML are enlarged nuclei in the oligodendrocytes (glial cells associated with myelin formation).

It is widely believed that the causal agent of PML is a POLYOMAVIRUS: the JC virus (JC = the initials of a patient who died from PML); it is also believed that some form of immunosuppression is a prerequisite for the development of the disease. Other factor(s) may be involved; for example, one *in vitro* study found that the Tat protein, encoded by the AIDS virus (HIV-1), could activate the late promoter of JC virus in glial cells [PNAS (1990) 87 3479–3483].

[Murine model for PML: Cell (1986) 46 13–18. Polyomaviruses and disease of the central nervous system: RMM (1998) 9 79–85.]

**progressive pneumonia virus** See LENTIVIRINAE.

**proguanil** See CHLORGUANIDE.

**prohead** A DNA-free phage head precursor formed during bacteriophage assembly. (See e.g. BACTERIOPHAGE T4; see also SCAFFOLDING PROTEIN.)

**prohormone** See PHEROMONE.

**prokaryote** (procaryote) A type of CELLULAR (sense 2 or 3) MICROORGANISM in which the CHROMOSOME(S) are not separated from the cytoplasm by a specialized membrane; the CYTOPLASMIC MEMBRANE is typically devoid of sterols; chloroplasts and mitochondria are absent (cf. INTRACYTOPLASMIC MEMBRANES); RIBOSOMES have a sedimentation coefficient of ca. 70S; a CELL WALL is typically present and may contain structural components such as PEPTIDOGLYCAN or PSEUDOMUREIN, or may consist e.g. of an S LAYER; storage compounds may include e.g. POLY-β-HYDROXYBUTYRATE; flagella (when present) are structurally relatively simple (see FLAGELLUM (a) and (c)).

CHEMOLITHOAUTOTROPHS, and the ability to carry out NITROGEN FIXATION, occur only among the prokaryotes.

The prokaryotes comprise two DOMAINS: the domain ARCHAEA (formerly referred to as the kingdom Archaeobacteria) and the domain BACTERIA [JB (1994) 176 1–6]. Members of the two domains differ in their 16S rRNA and e.g. in the composition, structure and/or mode of assembly of the cytoplasmic membrane, cell wall and flagella; differences also occur e.g. in the composition of the ribosomal proteins.

According to one hypothesis, EUKARYOTES arose from an energy-based symbiotic relationship between cells from the two prokaryotic domains [Nature (1998) 392 37–41].

**prolamellar body** In an ETIOPLAST: a paracrystalline array of tubules bearing a small lamellar structure (*prothylakoid*) which contains certain thylakoid components (e.g. the CF<sub>1</sub> unit of PROTON ATPASE); on illumination, prolamellar bodies disperse, and prothylakoids eventually develop into THYLAKOIDS.

**prolate** Of a phage head: having a shape in which the distance from one pole to the other is greater than the diameter at the mid-point of the head; an example of a prolate head occurs in BACTERIOPHAGE φ29.

**proliferative kidney disease (PKD)** A FISH DISEASE which can be economically important in young salmonid fish. Symptoms include exophthalmia, anaemia, abdominal swelling and kidney hypertrophy; mortality rate: 10–95%. PKD is caused by an unclassified protozoan which apparently has affinities with members of the MYXOZOA [JP (1985) 32 254–260].

**Proliferobasidium** See BRACHYBASIDIALES.

**L-proline biosynthesis** See Appendix IV(a).

**proloculus** See FORAMINIFERIDA.

**promastigote** A form assumed by the cells of many species of the TRYPANOSOMATIDAE (q.v.) during at least certain stages of their life cycles.

**prometaphase** See MITOSIS.

**Promicromonospora** A genus of asporogenous bacteria (order ACTINOMYCETALES, wall type VI) which occur e.g. in soil. The organisms form a yellow fragmenting mycelium. GC%: ca. 73. Type species: *P. citrea*. [Book ref. 73, pp. 53–54.]

**promiscuous plasmids** Those CONJUGATIVE PLASMIDS (sense 1) – e.g. IncP1 plasmids – which are capable of self-transmission between bacteria of a wide range of different species and genera.

**promitochondrion** See MITOCHONDRION.

**promoter** In a DNA strand: a nucleotide sequence which is recognized (directly or indirectly) and bound by a DNA-dependent RNA POLYMERASE (RPase) during the initiation of TRANSCRIPTION. Transcription is initiated at a position (the *start*

## promoter control

*point* or *start site*) which is commonly within the promoter sequence. The first nucleotide to be transcribed is designated +1; nucleotides *downstream* of this position (i.e. those in the direction of RNA elongation: 5'-to-3' with respect to the RNA) are numbered +2, +3, +4 etc., and nucleotides in the opposite (*upstream*) direction are numbered -1, -2, -3 etc.

Bacteria have several RPase holoenzymes (differing in their SIGMA FACTORS), each one recognizing a distinct class of promoter. In *Escherichia coli* most transcription is carried out by  $E\sigma^{70}$ ; the enzyme binds to a region of DNA extending from ca. 50 bp upstream to ca. 20 bp downstream of the start point. Comparison of the sequences of many promoters recognized by  $E\sigma^{70}$  has revealed that certain short sequences are more or less conserved. Thus, a CONSENSUS SEQUENCE, TATAAT (the *Pribnow box* or *-10 sequence*), is centred ca. 10 bp upstream from the start point, and another consensus sequence, TTGACA (the *-35 sequence*) is centred ca. 35 bp upstream of the start point. The start point itself is usually a purine, often an adenine residue in the sequence CAT.

Promoters recognized by  $E\sigma^{70}$  in *E. coli* differ to varying extents from the theoretical 'consensus promoter', and may also differ from one another in functional efficiency (efficient promoters being described as 'strong', inefficient ones as 'weak'). Efficiency may be affected e.g. by changes in the consensus sequences or in the transcribed region downstream of the start point. Changes at one site may be compensated for by changes at another: thus, promoters with the same efficiencies may have different base sequences; furthermore, a (synthetic) promoter containing the theoretical consensus sequences has been found to be relatively inefficient.

Bacterial promoters of other classes (recognized by different RPase holoenzymes) also typically have two short, distinctive conserved sequences upstream from the start point; however, the actual sequences vary from one class of promoter to another. For example, in *Bacillus subtilis* the main holoenzyme,  $E\sigma^{43}$ , recognizes the same type of promoter as does the  $E\sigma^{70}$  of *E. coli*, but  $E\sigma^{37}$  (see SIGMA FACTOR) recognizes a consensus sequence AGGATTNNA (N = any nucleotide) in the -35 region and GGAATTNTTT in the -10 region; the corresponding sequences for  $E\sigma^{29}$  are TTNAAA and CATATT. (The phage T4  $E\sigma^{gp55}$  recognizes a promoter which apparently lacks a -35 sequence; in promoters recognized by the  $E\sigma^{gp100}$  of e.g. *Klebsiella* a -35 sequence is apparently absent, but there is a consensus sequence in the -20 region.)

In eukaryotes, promoters are not recognized directly by the RNA polymerases; transcription initiation factors (TIFs) first bind to a promoter to form a *pre-initiation complex*, and only then does an RPase bind to form an *initiation complex*. Promoters for RPase II generally contain a short consensus sequence, TATA(A/T)A(A/T) (the *TATA box*, *Goldberg-Hogness box*, or *Hogness box*), ca. 25-30 bp upstream from the transcription start point; this appears to be the only well-conserved sequence in RPase II promoters [NAR (1986) 14 10009-10026], although other sequences upstream of the TATA box may be important sites for the action of promoter-specific TIFs [review: Nature (1985) 316 774-778]. (See also ENHANCER.)

The TATA box, found in many RPase II promoters, also occurs in a minority of type III promoters. The 'classical' RPase III promoters occur *within* the associated gene, i.e. intragenically, *downstream* of the start point; binding of the RPase at the promoter leads to initiation of transcription at a particular distance upstream of the binding site.

One factor, the TATA box-binding protein (TBP), is necessary for the formation of an initiation complex by each of the three

types of RPase (I, II and III) - regardless of whether or not their promoters include a TATA box; TBP was first identified as a DNA-binding element in complexes assembled on type II, TATA-containing promoters, but in TATA-lacking promoters TBP appears to bind not to DNA but (directly or indirectly) to a DNA-binding protein (as well as to the polymerase) in the initiation complex. [TBP (minireview): Cell (1993) 72 7-10.]

**promoter control** See OPERON.

**promycelium** See METABASIDIUM.

**Pronase** (proprietary name) A mixture of endopeptidases and exopeptidases (including carboxypeptidase(s) and aminopeptidases) which has non-specific protease activity. It is obtained from *Streptomyces griseus*.

**Prontosil** An early sulphphonamide, first used clinically in the 1930s; its activity was due to its breakdown in vivo to sulphaniilamide. It has been superseded by the more effective, less toxic modern SULPHONAMIDES.

**protonucleus** (1) The haploid nucleus of a gamete. (2) (*protozool.*) See AUTOGAMY and CONJUGATION.

**proof-reading** (*mol. biol.*) A system in which the accuracy of a process is increased by the removal of 'errors' immediately after they have occurred: see e.g. DNA REPLICATION and PROTEIN SYNTHESIS.

**propagative viruses** See CIRCULATIVE TRANSMISSION.

**propagule** Any disseminative unit of an organism, e.g. a spore, a mycelial fragment.

**propamidine** An aromatic DIAMIDINE used as an antiseptic; it is active mainly against asporogenous Gram-positive bacteria and certain fungi.

**propeller loop fermenter** A LOOP FERMENTER in which a motor-driven propeller promotes circulation in the column by impelling the culture vertically up (or down) the DRAFT TUBE.

**proper margin** (*excipulum proprium*) (*lichenol.*) *Non*-lichenized (i.e., wholly fungal) tissue forming the excipular margin (rim) of a lichen APOTHECIUM. A proper margin is often the same colour as the hymenial disc. (cf. THALLINE MARGIN; see also LECIDEINE APOTHECIUM.)

**properdin** A  $\gamma$ -globulin (MWt ca. 220000) which occurs in normal serum (ca. 25  $\mu$ g/ml). Properdin promotes the *alternative pathway* of COMPLEMENT FIXATION by stabilizing the C3 convertase (C3bBb) in the presence of specific activators of this pathway.

**prophage** See LYSOGENY.

**prophage immunity** See SUPERINFECTION IMMUNITY.

**prophase** See MITOSIS and MEIOSIS.

**prophylaxis** Measure(s) taken to prevent the occurrence of disease - e.g. DISINFECTION, IMMUNIZATION. (See also PROTECTANT.)

**propiconazole** (1-[2-(2,4-dichlorophenyl)-4-propyl-1,3-dioxolan-2,2-yl-methyl]-1H-1,2,4-triazole; trade names: e.g. Radar, Tilt) An agricultural AZOLE ANTIFUNGAL AGENT which has both contact and systemic action against a wide range of plant pathogenic fungi; it has both eradicant and protectant properties against e.g. cereal diseases such as eyespot, net blotch, powdery mildew, rhynchosporium, septoria, yellow and brown rusts, etc. It may be mixed with e.g. CARBENDAZIM to give a preparation with an even broader antifungal spectrum.

**propidium** A phenanthridine trypanocidal agent and INTERCALATING AGENT (apparent unwinding angle: 26°).

**$\beta$ -propiolactone (BPL)** A water-miscible and non-inflammable cyclic ether (b.p. 155°C) used e.g. (in vapour form) as a surface STERILANT; it has low powers of penetration, needs a high relative humidity (ca. 70%) for maximum activity, and may be poorly effective against e.g. dried spores (cf. ETHYLENE

OXIDE). BPL acts as an ALKYLATING AGENT, substituting proteins etc with propionic acid residues. Above 25°C it is readily hydrolysed to  $\beta$ -hydroxypropionic acid (hydracrylic acid); under acid conditions it forms an open-chain ester-linked polymer. BPL is an irritant and may be carcinogenic.

**Propionibacterium** A genus of Gram-positive, asporogenous, chemoorganotrophic, anaerobic bacteria which occur e.g. in dairy products (see e.g. CHEESE-MAKING) and on the human skin, and which form propionic acid as a main product in the PROPIONIC ACID FERMENTATION of hexoses or lactate. Cells: non-motile, pleomorphic, branched or unbranched rods or coccoid forms which may exhibit a 'Chinese letter' arrangement in stained preparations; some form pigments. The organisms can be cultured e.g. on yeast extract-lactate-peptone media. GC%: ca. 57–67. Type species: *P. freudenreichii*.

*P. acnes* (formerly *Corynebacterium parvum*). The organisms ferment glucose (but not maltose or sucrose), do not hydrolyse aesculin, and are indole-positive; they digest casein and liquefy gelatin. [Extracellular proteolysis: JAB (1983) 54 263–271.] Colonies older than ca. 4 days may become reddish. (See also ACNE and SKIN MICROFLORA.) [Pathogenicity: RMM (1994) 5 163–173.] [Possible association between *P. acnes* and sciatica: Lancet (2001) 357 2024–2025.]

Other species: *P. acidi-propionici*; *P. freudenreichii* (which incorporates *P. shermanii*) (see also PYROPHOSPHATE); *P. jensenii* (which incorporates *P. peterssonii* and *P. raffinosaceum*); *P. thoenii*. [Book ref. 46, pp. 1894–1902.]

**propionic acid fermentation** A FERMENTATION (sense 1), carried out e.g. by *Propionibacterium* spp, *Clostridium propionicum* and *Megasphaera elsdenii*, in which e.g. glucose and/or lactate yield propionic acid and acetic acid as the main end products. *Propionibacterium* spp ferment glucose or lactate via succinate [Appendix III(h)]; when lactate is the substrate the reduction of (endogenous) fumarate generates proton motive force (pmf), permitting ATP synthesis by electron transport phosphorylation. (cf. FUMARATE RESPIRATION.) *C. propionicum* and *M. elsdenii* ferment lactate via a different pathway (the *acrylate pathway*): lactate  $\rightarrow$  lactyl-CoA  $\rightarrow$  acrylyl-CoA  $\rightarrow$  propionyl-CoA  $\rightarrow$  propionic acid.

**Propionigenium** A genus of anaerobic, asporogenous bacteria. *P. modestum* converts succinate to propionate by reactions which include the decarboxylation of methylmalonyl-CoA; this decarboxylation is coupled to the outward pumping of Na<sup>+</sup> – generating a SODIUM MOTIVE FORCE which can be used for ATP synthesis by a membrane-bound ATPase [EMBO (1984) 3 1665–1670].

**Propionispira** A genus of Gram-negative, obligately anaerobic, asporogenous, nitrogen-fixing bacteria which occur in trees affected with WETWOOD. The cells are curved rods or long spiral filaments; peritrichously flagellate. Various compounds are fermented: e.g. galacturonate, lactate, mannitol, and a number of sugars (e.g. glucose, lactose, sucrose); propionate, CO<sub>2</sub> and acetate are major metabolic products. GC%: ca. 37. Type species: *P. arboris*. [JGM (1982) 128 2771–2779.]

**proplastid** See e.g. CHLOROPLAST.

**propylene glycol** See ALCOHOLS.

**propylene oxide** A water-miscible cyclic ether (b.p. 34°C) used (in vapour form) e.g. as a disinfectant for treating certain foods; on hydrolysis it yields propylene glycol. It is also used in the preparation of specimens for ELECTRON MICROSCOPY.

**Procoentrum** A genus of 'primitive' DINOFAGELLATES in which the cell is flattened, lacks a girdle and sulcus, and is divided longitudinally into two halves, each half containing a relatively thick, convex thecal plate. The two flagella are inserted apically.

**Prorodon** A genus of freshwater and marine carnivorous ciliates (subclass GYMNOSTOMATA). Cells: ovoid, up to ca. 200  $\mu$ m in length, with uniform somatic ciliature, an apical cytostome, and a cytopharynx with associated nematodesmata. Encystment is promoted e.g. by desiccation.

**prosenchyma** See PLECTENCHYMA.

**prosome** A stable ribonucleoprotein particle (ca. 19S) present in the nucleus and cytoplasm of various types of eukaryotic cell. Prosome are believed to be involved in the post-transcriptional regulation of gene expression. [Prosome – ubiquity and interspecies variation: JMB (1986) 187 479–493.]

**prosoplectenchyma** See PLECTENCHYMA.

**prostacyclin (PGI<sub>2</sub>)** A potent vasodilator, derived from PROSTAGLANDIN PGH<sub>2</sub>, which degrades spontaneously (in minutes) to 6-oxo-PGF<sub>1 $\alpha$</sub> ; PGI<sub>2</sub> promotes vascular permeability and induces pain. 6-Oxo-PGF<sub>1 $\alpha$</sub>  levels are raised in exudates from chronic granulomas.

**prostaglandins (PGs)** Compounds formed from ARACHIDONIC ACID via the activity of *cyclo-oxygenase*; this enzyme, which exists in two isoforms (COX-1 and COX-2), catalyses a two-step reaction in which the central region of the linear arachidonic acid molecule undergoes oxidative cyclization to form PGH<sub>2</sub>, a precursor of PGF<sub>2 $\alpha$</sub> , PGD<sub>2</sub>, PGE<sub>2</sub>, PGI<sub>2</sub> and thromboxane.

Prostaglandins are included within the category *eicosanoids*.

Cyclo-oxygenases are inhibited e.g. by compounds designated non-steroidal anti-inflammatory drugs (NSAIDs). Many of these drugs can block the activity of *both* COX-1 and COX-2 by binding to the enzyme in the region of an arginine residue at position 120. (The common drug aspirin (acetylsalicylic acid) – made synthetically, but also found naturally in the willow (*Salix* spp) – inhibits cyclo-oxygenase by acetylating a serine residue in the enzyme: Ser-530 in the COX-1 isoform, Ser-516 in COX-2.) Some NSAIDs (e.g. the tri-cyclic *coxibs* celecoxib and rofecoxib) *specifically* inhibit COX-2, such inhibition apparently involving the region near a valine residue at position 523 (isoleucine occupies 523 in COX-1); such specific inhibitors of COX-2 may be useful e.g. against certain types of cancer.

Cyclo-oxygenase is apparently activated in vitro by NITRIC OXIDE [PNAS (1993) 90 7240–7244].

COX-2 is inducible (e.g. by ENDOTOXIN, immune complexes, certain CYTOKINES – e.g. INTERLEUKIN-1 and TNF- $\alpha$  (although expression is inhibited by IL-4 and IL-10) – and phorbol esters). COX-1 is typically produced constitutively and seems to have a 'housekeeping' function. (It is generally thought that NSAIDs work by inhibiting COX-2 at sites of inflammation, and that their adverse gastrointestinal effects result from inhibition of COX-1.)

Particular PGs tend to be synthesized by particular types of cell. PGD<sub>2</sub> is formed e.g. by mast cells, PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub>  by macrophages and monocytes, and PGI<sub>2</sub> by endothelial cells.

Following synthesis, prostaglandins may exit the cell and then act on cell-surface receptors in an autocrine or paracrine fashion; for example, PGE<sub>2</sub> may promote an increase in the concentration of cAMP (cyclic AMP) by binding to the EP1 or EP4 receptor. Receptors for prostaglandins also occur in the cell nucleus – the so-called peroxisome proliferator-activated receptor (PPAR).

Prostaglandins have many physiological roles/effects – including vasodilation (e.g. PGE<sub>2</sub>), vasoconstriction (e.g. PGF<sub>2 $\alpha$</sub> ) and the febrile response. Prostaglandins, which occur e.g. in inflammatory exudates (see also INFLAMMATION), are associated with both inflammatory and anti-inflammatory activities. Prostaglandins have other roles e.g. in kidney function and certain aspects of reproduction.

## prostheca

(See also PROSTACYCLIN.)

**prostheca** In certain bacteria (PROSTHECATE BACTERIA): a narrow extension of the cell, bounded by the cell wall and cytoplasmic membrane; a cell may have one or more prosthecae – which may be long and narrow (e.g. in *Ancalomicrobium*) or short and conical (in *Prosthecomicrobium*), unbranched or branched. (A long, narrow prostheca is sometimes called a *hypha*.) In some genera prosthecae are involved in reproduction (see e.g. RHODOMICROBIUM); in *Caulobacter* the prostheca functions in ADHESION. (cf. STALK.)

**prosthecate bacteria** Those bacteria which form one or more prosthecae during at least some stage of their life cycle. Genera in which the prostheca appears to have an essential reproductive role include HYPHOMICROBIUM, RHODOMICROBIUM, and some species of RHODOPSEUDOMONAS. See also ANCALOMICROBIUM, ASTICCACAULIS, CAULOBACTER, HYPHOMONAS, PEDOMICROBIUM, PROSTHECOMICROBIUM and STELLA.

**Prosthechloris** See CHLOROBIAEAE and CHLOROBINEAE.

**Prosthecomicrobium** A genus of chemoorganotrophic, strictly aerobic PROSTHECATE BACTERIA found in natural waters. The cells are coccoid, ca. 1 µm, each bearing ca. 10–30 conically-shaped prosthecae. *P. pneumaticum* (type species) is non-motile and contains GAS VACUOLES; *P. enhydrium* is monotrichously flagellated and lacks gas vacuoles. *P. hirschii* is motile (monotrichously flagellated), lacks gas vacuoles, and forms short and/or long (*Ancalomicrobium*-like) prosthecae [JJSB (1984) 34 304–308]. Cell division apparently occurs by budding [ibid.].

**prosthetic group** In an enzyme: any low-MWt, non-protein component which is firmly bound to the APOENZYME and which is necessary for the activity of the enzyme. (cf. COENZYME sense 1.)

**protamines** Low-MWt, strongly basic proteins found e.g. in association with DNA in the sperm of fish and birds. (See also PARACOAGULATION.)

**Protargin** See SILVER.

**Protargol** A silver proteinate (see SILVER) used e.g. as an antiseptic and as a reagent for staining protozoan flagella.

**protease IV** See SIGNAL HYPOTHESIS.

**protease inhibitors (med.)** A category of ANTIRETROVIRAL AGENTS that includes the drugs amprenavir, indinavir, nelfinavir, ritonavir and saquinavir. Protease inhibitors bind to, and inhibit, the viral protease. The target enzyme, encoded by the *pol* region of HIV, is necessary for production of mature virions as it functions in post-translational processing of precursor proteins. Protease inhibitors have been associated with side-effects such as lipodystrophy.

**proteases (peptidases)** ENZYMES which hydrolyse peptide bonds in proteins and peptides. *Endopeptidases* cleave bonds within the peptide chain with varying degrees of specificity for particular amino acyl residues (e.g. the pancreatic enzyme trypsin hydrolyses arginyl and lysyl residues). *Endopeptidases* include e.g. *serine proteases* (characterized by a catalytically active serine residue in the active centre) and *thiol proteases* (in which free –SH groups occur). Serine proteases include e.g. trypsin, chymotrypsin and SUBTILISINS; they are inactivated by organic phosphate esters (e.g. diisopropylfluorophosphate, DFP) which acylate the active serine residue. Thiol proteases include e.g. BROMELAIN and PAPAINE; they are inhibited by SH-reagents such as heavy metals. *Exopeptidases* remove amino acids sequentially from one end of a peptide chain and include N-terminal exopeptidases (*aminopeptidases*) and C-terminal exopeptidases (*carboxypeptidases*). Proteases are termed acid, alkaline or neutral if they are active at low, high or neutral pH, respectively.

Microbial proteases have a number of commercial applications [Book ref. 31, pp. 49–114]. A major commercial use is

the addition of microbial proteases to domestic detergents for the digestion of proteinaceous stains in fabrics. Since most commercial detergents contain tripolyphosphate as a sequestering agent, Ca<sup>2+</sup>-requiring proteases (e.g. THERMOLYSIN) are not suitable for this purpose, and alkaline serine proteases (see SUBTILISINS) from *Bacillus* spp are usually used. Enzymes from *Rhizomucor pusillus*, *R. miehei* and *Endothia parasitica* have some use as rennin (rennet) substitutes in CHEESE-MAKING (see also CASEIN); the proteolytic-to-coagulating activity ratio of these enzymes is higher than that of rennin, and their use requires some modification of the cheese-making process in order to avoid the excessive formation of bitter peptides. Microbial proteases have some application in the manufacture of leather, although chemical methods are still cheaper; alkaline proteases from alkalophilic *Bacillus* spp may be used with lime for de-hairing hides, and proteases from e.g. *Aspergillus oryzae* or *Bacillus* spp may be used for bating hides (a process which makes the leather softer and more elastic). Other uses include e.g. treatment of flour to adjust its gluten composition (and hence baking qualities); as a digestive aid; and in the débridement of wounds (experimental) and dissolution of blood clots (see e.g. BRINASE). (See also PRONASE.)

Proteases produced by certain pathogenic microorganisms may act as virulence factors (see e.g. ELASTASE).

**proteasome** A hollow, intracellular proteolytic structure formed by the self-assembly (*autocompartmentalization*) of proteases and ATPases; proteolytic sites occur in the *interior* of the proteasome so that protein degradation can be carried out intracellularly without risk to the cell's integrity. A narrow entrance to the proteasome's interior restricts access to unfolded proteins.

In eukaryotes, proteasomes are used for the ATP-dependent degradation of various UBIQUITIN-bound proteins. For example, the ubiquitin–proteasome pathway is reported to be essential during changes in morphology (e.g. trypanomastigote → amastigote) in *Trypanosoma cruzi* [Biochem. (2001) 40 1053–1062].

Proteasomes also occur in prokaryotes – e.g. the archaeans *Methanosarcina thermophila* and *Thermoplasma acidophilum*, and the bacteria *Mycobacterium tuberculosis* and *Rhodococcus erythropolis*.

[Proteasomes in prokaryotes: TIM (1999) 7 88–92.]

(See also DEGRADOSOME.)

**proteactin** (prophylactic) (*plant pathol.*) Any chemical agent which prevents the occurrence of particular disease(s) among plants treated with that agent. (cf. ERADICANT.)

**protective antigens** Those antigens of a pathogen which can elicit an immune response that gives protective immunity against the pathogen.

**protective immunity** *Syn.* IMMUNITY (3).

**Proteeae** A tribe of bacteria (family ENTEROBACTERIACEAE) divided (e.g. on the basis of DNA relatedness) into three genera: MORGANELLA, PROTEUS and PROVIDENCIA. All members can oxidatively deaminate a range of amino acids. Most strains are motile (but may be non-motile at temperatures >30°C), urease +ve (cf. PROVIDENCIA), lactose –ve (although some strains may contain a Lac plasmid), indole +ve (cf. PROTEUS), VP –ve, MR +ve. Acid (± gas) is produced from glucose, and a reddish-brown pigment is produced on nutrient agar containing 5% tryptophan. Species are generally resistant to bacitracin, polymyxins and erythromycin. [Book ref. 46, pp. 1204–1224.]

**protein 2** A PORIN of *Escherichia coli*.

**protein A** (SpA) A cell wall protein (MWt ca. 42000) found in most strains of *Staphylococcus aureus*; it is covalently bound

to the wall peptidoglycan and can be released (intact) e.g. by LYSOSTAPHIN. SpA binds to the FC PORTION of IgG<sub>1</sub>, IgG<sub>2</sub> and IgG<sub>4</sub>; one SpA molecule can bind two IgG molecules. (cf. PROTEIN G.) SpA can also bind, apparently via the Fab region, to IgE, IgA, IgM, and some IgG<sub>3</sub>. SpA can elicit Arthus- and anaphylaxis-type reactions, histamine release from granulocytes, and complement fixation by the classical pathway.

**Applications.** (a) SpA immobilized on e.g. sepharose can be used in affinity CHROMATOGRAPHY for IgG purification; IgGs are eluted at pH ca. 4. (IgM and IgA elute at a lower pH.) (b) SpA-containing staphylococci can bind to specific (IgG) antibodies (via their Fc portions) and will then agglutinate on exposure to the homologous antigen (CO-AGGLUTINATION); such antibody-coated staphylococci can be used e.g. in slide co-agglutination tests for detecting and/or identifying bacteria, toxins, etc. (c) SpA may be bound to red blood cells (e.g. with glutaraldehyde) and used e.g. to detect IgG on the surface of lymphocytes (by rosette formation). (d) SpA conjugated with an enzyme (e.g.  $\beta$ -lactamase, horseradish peroxidase) can be used e.g. for the assay of IgG in serum. Antigen is immobilized, incubated with the serum, and any homologous antibody binding to the antigen is detected with the SpA-enzyme conjugate; the amount of SpA bound, and hence the amount of homologous IgG in the serum, is determined by an assay of the enzymic activity (e.g. PADAC hydrolysis for  $\beta$ -lactamase conjugates) [PTRSLB (1983) 300 399–410].

[Properties and applications of protein A: Book ref. 44, pp. 429–480.] (See also SORTASE.)

**protein G** A cell wall protein from group G streptococci; it resembles staphylococcal PROTEIN A in binding specifically to the Fc region of an IgG molecule, but it binds a broader range of IgG subclasses. [Structure of the IgG-binding regions of protein G: EMBO (1986) 5 1567–1575.]

**protein i** See PRIMOSOME.

**protein kinase** An enzyme which phosphorylates particular amino acid residues in a protein. The functions of certain proteins are regulated by phosphorylation/dephosphorylation both in eukaryotic cells (see e.g. ONCOGENE) and in *Escherichia coli* (see e.g. TCA CYCLE (isocitrate dehydrogenase)). (See also CYCLIC AMP.)

**protein kinase A** See CYCLIC AMP.

**protein n** (also n', n'') See PRIMOSOME.

**protein phosphatase** An enzyme which removes covalently bound phosphate from a protein; protein phosphatases have important roles e.g. in the regulation of the eukaryotic CELL CYCLE – in which they complement the activity of PROTEIN KINASES. Some protein phosphatases can cleave phosphate from more than one type of amino acid residue. (See also CYCLIN.)

**protein priming** See DNA REPLICATION (linear genomes).

**protein secretion (and export)** (in Gram-negative bacteria) At least five major modes of protein secretion occur in Gram-negative bacteria; they have been designated types I–V (but see note on types IV and V at the end of this entry).

**Type I systems.** Secretion by type I systems is energized by ATP hydrolysis and involves one-step translocation from cytoplasm to exterior without a free (periplasmic) intermediate; it is exemplified by secretion of  $\alpha$ -haemolysin by the ABC EXPORTER of *Escherichia coli*.

**Type II systems.** Secretion by type II systems (the *general secretory pathway*, GSP) requires energy from both ATP and pmf – and, in some cases, from GTP. The first stage, translocation across the cytoplasmic membrane (CM), depends on the products of genes analogous to the *sec* genes of *E. coli* (hence,

the alternative name for type II systems: the '*sec*-dependent pathway'); the products of certain *sec* genes form a secretory channel through the CM.

Proteins secreted by the GSP are synthesized with an N-terminal *signal sequence* (see SIGNAL HYPOTHESIS).

In one form of type II secretion, the initial phase (transport across the CM: *general export pathway*, GEP) begins in the cytoplasm when the secretory protein (i.e. the one being transported) binds to a *chaperone* protein, SecB; binding may occur during or after translation, but before folding (folding of *sec*-exported proteins occurs in the periplasm). SecB is targeted to a CM-linked ATPase, SecA. SecA is associated with a SecYEG protein complex (the *translocon*) [JB (1997) 179 5699–5704; Nature (2002) 418 662–665] which forms a secretory channel through the CM. SecB is released (to chaperone another protein), and translocation of the protein through the CM is associated with ATP hydrolysis at SecA. During, or directly after, translocation, the signal sequence is cleaved by a specific enzyme (a *signal peptidase*). *E. coli* has two distinct signal peptidases; *leader peptidase* (= *leader peptidase I*) is functional on a wide range of proteins, while *lipoprotein signal peptidase* (= *signal peptidase II*) acts only on certain modified proteins (e.g. BRAUN LIPOPROTEIN). (Signal peptidases may constitute a class of serine proteases mechanistically related to  $\beta$ -lactamases [TIBS (1992) 17 474–478].) Excised signal peptides are degraded by a *signal peptide peptidase*; in *E. coli* at least one enzyme ('protease IV') carries out this function.

In a variant type II pathway, transport to the CM necessarily begins at an early stage in translation. One scheme for this pathway (in *E. coli*) is as follows. Initially, the nascent polypeptide (with its ribosome) binds, via the N-terminal sequence, to a *signal recognition particle* (SRP) that consists of (i) a 4.5S RNA molecule, and (ii) a 48 kDa multifunctional protein (with GTPase activity) designated P48 (or Ffh). It is not known whether protein-SRP binding inhibits further translation on the ribosome (as occurs in eukaryotic systems); it has been suggested that, in prokaryotes, translation arrest may not be necessary, and that the SRP pathway may simply accelerate association of nascent polypeptide chains with the translocon. A free cytosolic FtsY protein binds to the complex, and the FtsY-SRP-ribosome-polypeptide entity binds transiently, via FtsY, to the CM; hydrolysis of GTP energizes dissociation of the components, and the nascent polypeptide (with its ribosome) binds at a SecYEG (or similar) translocon. [Model for the SRP pathway in *E. coli*: EMBO (1998) 17 2504–2512.] (Interestingly, in *Escherichia coli*, reduced levels of SRP lead to the induction of a heat-shock response (see HEAT-SHOCK PROTEINS); this may help to maintain viability by increasing the cell's capacity to degrade mislocalized CM proteins [JB (2001) 183 2187–2197].)

For any given nascent polypeptide, the choice of pathway – i.e. SecB-SecA or SRP – is believed to depend on the hydrophobicity of the N-terminal sequence. Among *secreted* proteins, the SRP pathway may be used preferentially by those (e.g.  $\beta$ -lactamases) which have relatively hydrophobic N-terminal sequences. However, the SRP pathway may be used mainly for targeting and elaboration of CM proteins – whose N-terminal sequences are characteristically very hydrophobic; for these proteins, this pathway may be advantageous in that completion of translation at a membrane-associated site could avoid the risk of aggregation of hydrophobic domains which may occur in the cytoplasm. In vitro studies involving replacement or modification of the signal peptide sequence indicate that

## protein synthesis

the targeting pathway of *Escherichia coli* pre-secretory and integral membrane proteins is specified by the hydrophobicity of the targeting signal [PNAS (2001) 98 3471–3476].

The second stage of the GSP, translocation across the OUTER MEMBRANE, depends on a number of specific secretion factors. Although the GEP occurs in *E. coli*, this organism apparently does not *secrete* proteins via the GSP, i.e. it does not carry out the second stage of the GSP. However, other species of the Enterobacteriaceae do secrete proteins via this pathway. For example, *Klebsiella oxytoca* secretes a lipoprotein enzyme, pullulanase (see DEBRANCHING ENZYME), whose translocation across the outer membrane requires the products of 14 *pul* genes. (Interestingly, if all the *pul* genes from *K. oxytoca* are expressed in *E. coli*, this organism can secrete pullulanase.) Again, the GSP is used by *Erwinia chrysanthemi* for secreting the enzymes pectinase and cellulase, secretion needing expression of the *out* genes. (*E. coli* encoding a gene for pectinase can secrete this enzyme if supplied with *out* genes.) The secretory systems in *K. oxytoca* and *E. chrysanthemi* are similar though not identical: *K. oxytoca* can synthesize – but not secrete – a pectinase encoded by a gene from *E. chrysanthemi*. (See also SECRETION.)

*Pseudomonas aeruginosa* secretes an exotoxin, and the enzymes elastase and alkaline phosphatase, via a secretory system involving the *xcp* genes. Interestingly, XcpA is identical to the PilD protein (involved in the formation of fimbriae) and is also homologous to PulO, a protein involved in the secretion of pullulanase, and it has been suggested that, in at least some cases, the second phase of the GSP may involve a protein complex similar to the fimbrial assembly apparatus [TIG (1992) 8 317–322; see also EMBO (2000) 19 2221–2228].

Folded proteins may cross the CM via the pmf-dependent Tat system [see Microbiology (2003) 149 547–556].

**Type III systems.** Secretion by type III systems occurs as a one-step process via a channel/pore which crosses the cell envelope from cytoplasm to cell surface; unlike type I systems, the type III pathway may involve 20 or more distinct proteins. (See also NEEDLE COMPLEX.) Type III systems occur in certain pathogens (including pathogens of plants [JB (1997) 179 5655–5662]). (See also VIRULON.) [Type III secretory systems and pathogenicity islands (review): JMM (2001) 50 116–126.]

Components of type III systems in various species exhibit homology. Moreover, some type III components exhibit homology with components of other secretory systems – e.g. components of the basal body of the (bacterial) FLAGELLUM.

Proteins secreted via type III systems include an N-terminal sequence which may be targeted to the pore or channel – but which it is not cleaved.

The energy requirements of these systems are unknown, but a pore-associated protein (YscN) in a type III system of *Yersinia* includes binding sites typical of ATPases.

In some type III systems, protein secretion seems to be activated by contact with a eukaryotic cell; at least some proteins are believed to be secreted *directly* into the eukaryotic cytoplasm because e.g. (i) proteins of the kind secreted by type III systems typically have little or no effect on eukaryotic cells in the absence of the secreting bacterium; (ii) some secreted proteins have been detected within eukaryotic cells; and (iii) some proteins (Yops) secreted by *Yersinia* have been associated with specific effects within eukaryotic cells (see VIRULON). In EHEC and EPEC strains of *Escherichia coli*, type III systems are reported to be regulated by QUORUM SENSING (q.v.).

Proteins secreted by type III systems include e.g. the IpaB protein of *Shigella* (which promotes APOPTOSIS in macrophages);

the EspB and EspE proteins of enteropathogenic *E. coli* (EPEC); and the various Yops of *Yersinia* [the *Yersinia* Yop virulon: Mol. Microbiol. (1997) 23 861–867].

[Type III secretion systems (review): TIM (1997) 5 148–156.]

**Type IV systems** are mechanistically distinct and not fully understood; the following is an outline of a current model. In these systems the secreted protein is synthesized as part of a larger protein that consists of (i) an N-terminal signal peptide, (ii) an  $\alpha$  domain, and (iii) a C-terminal  $\beta$  domain. Initially, the whole protein is translocated across the CM in a *sec*-dependent manner, with cleavage of the N-terminal signal peptide. To pass through the outer membrane, the  $\beta$  domain is believed to form a ‘ $\beta$ -barrel’ pore in the membrane through which the  $\alpha$  (‘passenger’) domain is translocated.

At the bacterial surface, the  $\alpha$  domain may (i) remain attached (exposed to the environment); (ii) undergo cleavage, but remain (non-covalently) attached; (iii) undergo cleavage and release to the environment. Cleavage may be autocatalytic, or it may involve another outer membrane protein such as the SopA protease of *Shigella* or the OmpT protease of *Escherichia coli*.

In a type IV system, the translated protein (i.e. N-terminal +  $\alpha$  domain +  $\beta$  domain) has been termed an *autotransporter*. (This term has also been used by some authors to refer specifically to the  $\beta$  domain; other authors have used the term to refer specifically to the  $\alpha$  domain.)

Proteins transported by type IV systems include the (cell-surface-retained) IcsA protein, associated with *Shigella* invasiveness in dysentery; the IGA1 PROTEASES of *Haemophilus influenzae*, *Neisseria gonorrhoeae* and *N. meningitidis*; and the AIDA-I system of *Escherichia coli*. The latter system has been used for AUTODISPLAY.

**Type V systems.** These include the mechanism by which T-DNA is transferred from *Agrobacterium tumefaciens* to the host cell in CROWN GALL, and the secretion of pertussis toxin by *Bordetella pertussis*.

**Note on the designation of type IV and type V systems.** The name ‘type IV’ secretion system has been widely used for autotransporters by a number of authors [see e.g. TIM (1998) 6 370–378; Book ref. 218 (1999), p 42; Book ref. 223 (1999), p 94]. Some authors [see Inf. Immun. (2001) 69 1231–1243] have suggested that (i) autotransporters be called type V systems, and that (ii) secretory mechanisms referred to above as type V systems be called type IV systems. In this dictionary the designation ‘type IV’ has been retained for autotransporters.

**protein synthesis** A protein consists essentially of one or more *polypeptides* – a polypeptide being a chain of amino acids linked by peptide bonds (–CO.NH–). Polypeptides are folded into a three-dimensional structure that is stabilized mainly by hydrogen and/or disulphide bonds formed between amino acids in different parts of the chain; the specific three-dimensional structure of a given protein is associated with its biological role.

The biosynthesis of a protein is a complex process in which the composition of the protein (i.e. the number, nature and sequence of its amino acids) is decoded from information contained in specific sequence(s) of nucleotides. In the majority of organisms (including all *cells*), proteins are encoded by DNA; in certain viruses, proteins are encoded by RNA. The information in nucleic acids is expressed via a GENETIC CODE (q.v.).

Unlike the polymerization of nucleotides (see e.g. DNA SYNTHESIS), polypeptide chains are not synthesized by the polymerization of amino acids on a template. In fact, protein synthesis occurs in several stages.

In all cases (in both prokaryotic and eukaryotic cells) the first stage is the synthesis of an RNA copy of the particular DNA

sequence that encodes the given protein (see TRANSCRIPTION); as this RNA transcript carries the genetic 'message' from DNA it is called *messenger RNA* (or, more usually, mRNA) – see MRNA.

In some cases (commonly in eukaryotes, less commonly in prokaryotes) the initial transcript must be processed to remove non-coding part(s) (called *introns*) from the nucleotide sequence – see SPLIT GENE; the resulting (mature) mRNA is then used to guide assembly of the polypeptide chain – the stage of protein synthesis called *translation*. mRNAs which lack introns can be used directly for translation. (See also RNA EDITING.)

Along the length of the mRNA molecule, groups of three consecutive bases each encode a particular amino acid. Each of these three-base groups is called a *codon*; thus, e.g. the codon UCA (uracil-cytosine-adenine) encodes the amino acid serine (see table in GENETIC CODE). Hence, the sequence of codons in mRNA encodes the sequence of amino acids in a polypeptide.

For the synthesis of a polypeptide, each amino acid must first bind to a small 'adaptor' molecule of RNA which is specific for that amino acid and which also has a binding site (a three-base *anticodon*) for the appropriate codon. These RNA adaptor molecules are called *transfer RNA* (tRNA) – see TRNA. The binding of a given amino acid to its tRNA (i.e. the 'charging' of a tRNA molecule) occurs in a two-step reaction. First, the amino acid reacts with ATP in the presence of a specific aminoacyl-tRNA synthetase (forming an enzyme-bound aminoacyl-AMP complex); the aminoacyl group is then transferred to the 2' or 3' position of the terminal adenosine residue in the tRNA (with release of AMP and synthetase). (See also MUPIROCIN.)

The synthesis of a polypeptide on mRNA (i.e. the translation process) takes place on a RIBOSOME. In prokaryotes, correct positioning of mRNA on the ribosome is facilitated by a particular sequence of nucleotides in the mRNA (the *Shine-Dalgarno sequence*) located 'upstream' of the coding region; this sequence base-pairs with part of a 16S rRNA molecule in the 30S subunit of the ribosome.

Essentially, following mRNA-ribosome binding, the ribosome moves along the mRNA molecule in such a way that each codon, in turn, binds the relevant tRNA, and each successive amino acid is linked, covalently, to the previous one.

The following outlines a generally accepted scenario for protein synthesis in *Escherichia coli*; some details of the process are still unknown. The process appears to be essentially similar in most or all other bacteria.

Translation is initiated when mRNA binds to the ribosome. Each ribosome has two (adjacent) binding sites for charged tRNA molecules: the *A site* (= acceptor or entry site) and the *P site* (= peptidyl or donor site). At the start of translation, the first codon of mRNA (the *initiator codon*) coincides with the P site. The initiator codon is usually AUG, but is sometimes e.g. GUG, UUG or AUU.

The initiator codon is recognized by a distinct *initiator tRNA* (tRNA<sub>i</sub>) which is charged with methionine (Met). In *E. coli* there are two tRNAs specific for methionine: tRNA<sub>m</sub> and tRNA<sub>f</sub>; only tRNA<sub>f</sub> can function as tRNA<sub>i</sub> (tRNA<sub>m</sub> being used for incorporation of Met in subsequent location(s) in the polypeptide chain). In the charged tRNA<sub>f</sub> the  $\alpha$ -amino group of the methionyl residue is formylated (via N<sup>10</sup>-formyltetrahydrofolate), giving fMet-tRNA<sub>f</sub>; hence, the first (N-terminal) amino acid to be incorporated in the polypeptide chain is N-formylmethionine. (The incorporation of N-formylmethionine as N-terminal amino acid is typical of prokaryotes – and of mitochondria and chloroplasts; in the eukaryotic cytoplasm, and in at least some archaeans, the methionine residue is not formylated, so that the N-terminal amino acid in these cases is methionine.)

Before discussing subsequent stages in protein synthesis, further consideration can be given to the initial binding of mRNA to the ribosome. In *E. coli* this preliminary step requires three protein *initiation factors*: IF-1, IF-2 and IF-3. The timing and mode of action of these factors is not yet fully understood, and there are several models for this phase of protein synthesis. According to one model: (i) mRNA binds to the (separate) 30S subunit of the ribosome; (ii) fMet-tRNA<sub>f</sub> binds to AUG at the P site on the 30S subunit before addition of the 50S subunit; (iii) IF-2 and GTP are needed for the binding of fMet-tRNA<sub>f</sub> to AUG; (iv) all three initiation factors will have been released by the time the 50S subunit has been added. During assembly of the complete 70S ribosome, the association of 30S and 50S subunits is linked to the hydrolysis of GTP; IF-2 acts as a GTPase. [Bacterial initiation factors in protein synthesis (review): Mol. Microbiol. (1998) 29 409–417.]

Initiation can apparently also occur with a 70S monosome. This may happen e.g. when initiation occurs at an internal initiator codon in a polycistronic mRNA, the ribosome terminating synthesis of one polypeptide and initiating synthesis of the next without dissociating from the mRNA.

Once tRNA<sub>i</sub> is bound to AUG at the P site on a 70S ribosome, the *elongation* process proceeds by sequential addition of amino acids according to the codons that follow AUG. Elongation begins when an aminoacyl-tRNA binds to the vacant A site – which is adjacent to the P site and coincident with the *second* codon; this *decoding* step requires GTP and the *elongation factor T* (EF-T; 'transfer factor'). EF-T comprises two components: EF-Tu (= EF-1A; see also TUFA, TUFB GENES) and EF-Ts (= EF-1B). A complex consisting of these two components interacts with GTP, EF-Ts being displaced and the EF-Tu-GTP complex being involved in binding of the incoming tRNA to the A site; during this process GTP is hydrolysed, EF-Tu-GDP and phosphate being released. EF-Ts displaces GDP, re-forming the original complex – which can then react with GTP to repeat the cycle.

The binding of an incoming tRNA to the A site is followed by *transpeptidation*, i.e. the formation of a peptide bond between the carboxyl group of fMet-tRNA<sub>f</sub> and the  $\alpha$ -amino group of the second amino acid (at the A site); transpeptidation is catalysed by the enzyme *peptidyltransferase*. (Peptidyltransferase is part of the 50S ribosomal subunit.) At this stage a dipeptidyl-tRNA occupies the A site.

In the next stage, *translocation*, the ribosome moves along the mRNA by a distance equal to one codon (in the 5'-to-3' direction), the tRNA at the P site being displaced in the process; the result of this movement is that the dipeptidyl-tRNA entity now occupies the P site – i.e. the A site is left vacant (and therefore ready to receive the third aminoacyl-tRNA). Translocation, which involves elongation factor EF-G, is accompanied by GTP hydrolysis (catalysed by EF-G); GTP hydrolysis may be necessary to effect detachment of EF-G from the ribosome [JMB (1986) 189 653–662]. (Release of EF-G from the ribosome is essential for continuation of elongation as EF-G and EF-Tu apparently bind to similar or identical sites.)

The third aminoacyl-tRNA now enters the A site (coincident with the third codon of mRNA); transpeptidation follows, the carboxyl of the dipeptide being covalently joined to the  $\alpha$ -amino group of the third amino acid.

The cycle of events outlined above – decoding, transpeptidation, translocation – is repeated for each incoming aminoacyl-tRNA during elongation.

The scheme described above is the *two-site model* for translocation. In the *three-site model* [MGG (1986) 204 221–228, q.v.

## protein synthesis

for references], described for *E. coli* and e.g. '*Halobacterium halobium*', tRNAs remain bound to the ribosome both before and after translocation, i.e. deacylated tRNA is not released from the P site during translocation; instead, it is transferred to a third ribosomal site (the *E site*) concomitantly with translocation. Release of deacylated tRNA from the E site is triggered by the entry into the A site of the next (incoming) aminoacyl-tRNA.

Base-pairing between mRNA codons and tRNA anticodons is not sufficiently stable, in itself, to guarantee the degree of accuracy and efficiency needed in translation. It has been suggested that *proof-reading* may occur e.g. at the level of amino acid selection by aminoacyl-tRNA synthetases; when synthetase specificity is not high enough to prevent binding of the 'wrong' amino acid, the latter may be recognized and removed either at the aminoacyl-AMP stage (*pre-transfer proof-reading*) or at the aminoacyl-tRNA stage (*post-transfer proof-reading*) [see e.g. NAR (1986) 14 7529–7539]. Proof-reading may also occur during elongation; aminoglycosides such as STREPTOMYCIN may exert their effect on translational accuracy by interfering with this proof-reading system. The ribosome itself may provide help, and this appears to be given by the rRNA [see e.g. Nature (1994) 370 597–598].

*Termination* of translation (i.e. cessation of polypeptide synthesis) occurs when a specific termination codon (UAA, UAG or UGA in *E. coli* – see GENETIC CODE) appears at the A site. These codons are recognized by protein *release factors* (RFs); RF-1 recognizes UAA and UAG, while RF-2 recognizes UAA and UGA. The recognition of a termination codon by an RF is followed by hydrolysis of the ester bond between the tRNA (at the P site) and the polypeptide chain it carries – thus releasing the completed polypeptide; hydrolysis is catalysed by peptidyl-transferase. A third factor, RF-3 (= 'S protein'), may stimulate the activities of RF-1 and RF-2.

Although the 'stop' signal is traditionally regarded as a *triplet* of bases (e.g. UAA), there is evidence that the base *following* a stop codon influences the efficiency of termination, and it may be that the actual stop signal is a four-base (or even longer) sequence [Mol. Microbiol. (1996) 21 213–219]. In *E. coli* the efficiency of termination at a stop codon is also influenced by the 5' (upstream) nucleotide context of the codon, the mechanism involving the C-terminal amino acid residues in the nascent polypeptide. [Translation termination and stop codon recognition (review): Microbiology (2001) 147 255–269.]

As one ribosome translocates along the mRNA another can fill the vacated initiation site and start translation of another molecule of the polypeptide; thus, a given mRNA molecule may carry a number of ribosomes along its length – forming a *polyribosome* or *polysome*. (A single ribosome is sometimes called a *monosome*.)

At some time after the start of elongation, the formyl group of formylmethionine (see earlier) – or formylmethionine itself – is excised from the polypeptide. In *E. coli*, formylmethionine is cleaved from about 50% of proteins; whether or not cleavage occurs in a given protein appears to depend on the identity of the *penultimate* N-terminal amino acid residue – the longer the side-chain on this residue the smaller the probability of cleavage of formylmethionine. When such cleavage does occur it is effected by METHIONINE AMINOPEPTIDASE (q.v.). When the formyl group (only) is cleaved, the reaction is catalysed by methionine deformylase (= peptide deformylase, PDF). (PDF is inhibited by certain derivatives of hydroxamic acid, but these compounds are unlikely to be useful as broad-spectrum antibacterial agents because (i) they were bacteriostatic in the organisms tested, and (ii) resistance develops readily [AAC (2001) 45 1058–1064].)

*Signal sequences*. Commonly, a protein which will form part of the cytoplasmic membrane, or pass through it, is synthesized with a special N-terminal sequence of amino acids (called a *signal sequence*) which facilitates passage into, or through, the membrane (see SIGNAL HYPOTHESIS).

*Protein folding*. As mentioned earlier, polypeptide chains must be folded correctly in order to form functional, biologically active proteins. Folding of periplasmic, membrane and secreted proteins, frequently involves the formation of disulphide bonds between specific amino acid residues in the polypeptide chain. (In *E. coli* the *cytoplasmic* proteins generally do not contain disulphide bonds as structural features; in the cytoplasm, disulphide bonds are usually reduced by enzymes such as the NADPH-dependent thioredoxin system [but see EMBO (1998) 17 5543–5550].)

In *E. coli*, disulphide bonds are catalysed in the periplasmic region by the Dsb proteins (encoded by genes *dsbA* and *dsbB*). Mutations which affect *dsb* genes are *pleiotropic* – i.e. they have multiple effects; the reason for this is that disulphide bonds stabilize a range of different proteins (with widely differing functions) – for example, flagellar proteins, membrane proteins and various secreted proteins. In pathogens, mutations in the *dsb* genes may affect secreted protein virulence factors (and thus possibly reduce the virulence of the organism).

Proteins containing *proline* residues may need peptidyl–prolyl isomerases for normal folding; several such isomerases (e.g. FkpA [function: Mol. Microbiol. (2001) 39 199–210], PpiA) are found in the periplasmic region in *E. coli*.

At least some protein-folding enzymes appear to be synthesized under the regulation of a TWO-COMPONENT REGULATORY SYSTEM [see e.g. GD (1997) 11 1169–1182]. Transcription of the genes encoding certain protein-folding enzymes appears to involve sigma factor  $\sigma^E$  [GD (1997) 11 1183–1193].

Protein folding is facilitated by so-called *molecular chaperones* (= 'chaperones'): molecules which bind to, and stabilize, nascent proteins – promoting correct folding/inhibiting incorrect folding; one or more chaperones may be involved in a given stage of folding or translocation. Chaperones may bind to proteins co-translationally [JBC (1997) 272 32715–32718] or post-translationally. (See also HEAT-SHOCK PROTEINS.) Although chaperones are typically *proteins*, the membrane lipid phosphatidylethanolamine acts as a chaperone for the *E. coli* protein LacY [EMBO (1998) 17 5255–5264].

[Disulphide bond formation (review): Mol. Microbiol. (1994) 14 199–205. Protein folding and misfolding (some concepts and themes): EMBO (1998) 17 5251–5254.]

Some proteins are folded in the cytoplasm and may be exported via the Tat system [Microbiology (2003) 149 547–556].

[Protein folding (review): TIBS (2000) 25 611–618.]

*Peptide synthesis without ribosomes*. Some very short polypeptides are synthesized by a multi-enzyme complex (rather than by ribosomes and RNA molecules). Such a process is used e.g. for the synthesis of certain antibiotics (including GRAMICIDINS and TYROCIDINS). [Non-ribosomal biosynthesis of peptide antibiotics (review): Eur. J. Bioch. (1990) 192 1–15.]

*Protein synthesis in eukaryotes*. Some differences between prokaryotic and eukaryotic protein synthesis are listed below.

Aminoacyl-tRNA synthetases occur in high-MWt multi-enzyme complexes [review: Bioch. J. (1986) 239 249–255].

There is apparently no equivalent to the Shine–Dalgarno sequence of prokaryotes.

In the cytoplasmic proteins of eukaryotes (and at least some archaeans) the N-terminal methionine is not formylated.

Initiation of synthesis of these proteins usually occurs at the AUG codon nearest the 5' end of the mRNA, and generally requires a capped mRNA (see MRNA) for maximum efficiency. At least nine initiation factors appear to be required.

The eukaryotic eEF-1, equivalent to EF-G in *E. coli*, differs from the bacterial factor in being susceptible to ADP-ribosylation by DIPHTHERIA TOXIN. (In at least some members of the Archaea the corresponding factor is susceptible to diphtheria toxin [Book ref. 157, pp 379–410].)

The sole eukaryotic release factor, designated eRF, requires GTP for activity and can recognize any termination codon.

**Antibiotics affecting protein synthesis:** AMINOGLYCOSIDE ANTIBIOTICS, ANISOMYCIN, AURINTRICARBOXYLIC ACID, CHLORAMPHENICOL, CYCLOHEXIMIDE, FUSIDIC ACID, LINCOSAMIDES, MACROLIDE ANTIBIOTICS, OXAZOLIDINONES, PACTAMYCIN, POLYENE ANTIBIOTICS (b), PUROMYCIN, SPARSOMYCIN, STREPTOGRAMINS (including e.g. QUINUPRISTIN/DALFOPRISTIN), TETRACYCLINES, TIAMULIN, THIOSTREPTON, VIOMYCIN.

**proteinase** (1) *Syn.* protease (see PROTEASES). (2) *Syn.* endopeptidase (see PROTEASES).

**proteinase K** A non-specific PROTEASE obtained from *Tritirachium album*. (cf. PRONASE.)

**Proteobacteria** A taxonomic category (= PURPLE BACTERIA, sense 2) within the domain BACTERIA defined on the basis of 16S rRNA sequences. Some constituent genera are listed below.

Alpha subdivision. *Anaplasma*, *Agrobacterium*, *Azospirillum*, *Bartonella*, *Beijerinckia*, *Bruceella*, *Ehrlichia*, *Hyphomicrobium*, *Methylobacterium*, *Rickettsia*, *Rochalimaea*, *Rhodospseudomonas*, *Rhodospirillum*, *Wolbachia*.

Beta subdivision. *Alcaligenes*, *Bordetella*, *Chromobacterium*, *Neisseria*, *Nitrosomonas*, *Rhodocyclus*, *Spirillum*.

Gamma subdivision. *Acinetobacter*, *Coxiella*, *Erwinia*, *Escherichia*, *Haemophilus*, *Legionella*, *Methylobacter*, *Methylocaldium*, *Methylococcus*, *Methylomicrobium*, *Methylomonas*, *Nitrosococcus*, *Pseudomonas*, *Proteus*, *Vibrio*.

Delta and epsilon subdivisions. *Bdellovibrio*, *Campylobacter*, *Desulfuromonas*, *Helicobacter*, *Myxococcus*, *Wolinella*.

**proteomics** (1) The study of a cell's *proteome* (collectively, all the proteins that can be expressed) as an integrated whole. (2) As in (1) with genetic and other aspects. [Microbiology and Molecular Biology Reviews (2002) 66 39–63.]

**protease** A soluble product of protein hydrolysis; proteases are not coagulated by heat but are precipitated in saturated (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>.

**proter** (*ciliate protozool.*) The anterior of the two cells formed during HOMOTHETOGENIC binary fission. (cf. OPISTHE.)

**Proteromonadida** An order of parasitic protozoa (class ZOOMASTIGOPHOREA). The cells have one or two pairs of flagella, without paraxial rods, and a single mitochondrion which lacks a kinetoplast; cysts are formed. Genera: e.g. *Karatomorpha*, *Proteromonas*.

**Proteromonas** See PROTEROMONADIDA.

**Proteus** A genus of Gram-negative bacteria of the tribe PROTEAE. Cells: ca. 0.4–0.8 × 1–3 μm. Most strains swarm at 37°C, typically forming characteristic concentric zones of growth on the moist surface of an agar or gelatin medium (see SWARMING and DIENES PHENOMENON). (Some strains may form a spreading, *uniform* film of growth.) Typical reactions: H<sub>2</sub>S (in TSI) +ve (delayed in *P. myxofaciens*); gelatin is liquefied at 22°C; lipase +ve; urease +ve; mannose and sugar alcohols are not attacked. Nicotinic acid (but not pantothenic acid) is required for growth. GC%: 38–41. Type species: *P. vulgaris*.

*P. inconstans*. See PROVIDENCIA.

*P. mirabilis*. Indole –ve; maltose –ve, ODC +ve.

*P. morganii*. See MORGANELLA.

*P. myxofaciens*. Indole –ve; maltose +ve; ornithine decarboxylase –ve; abundant slime produced e.g. in trypticase–soy broth.

*P. rettgeri*. See PROVIDENCIA.

*P. shigelloides*. See PLESIOMONAS.

*P. vulgaris*. Indole +ve; maltose +ve; ornithine decarboxylase –ve.

*P. mirabilis* and *P. vulgaris* occur e.g. in soil, polluted water, intestines of (healthy) man and animals, etc. *P. mirabilis*, in particular, is an important opportunist pathogen, causing nosocomial URINARY TRACT INFECTION, pneumonia, septicaemia, etc. *P. myxofaciens* was isolated from gypsy moth larvae (*Porthetria dispar*).

[Book ref. 22, pp. 491–494.]

**prothallus** (*lichenol.*) (1) *Syn.* HYPOTHALLUS (sense 1). (2) A lichen thallus in the initial stages of development.

**prothylakoid** See PROLAMELLAR BODY.

**proticins** BACTERIOCINS from *Proteus* spp.

**protist** A member of the PROTISTA.

**Protista** (1) A taxon (kingdom) which includes the ALGAE, FUNGI and PROTOZOA (collectively, the eukaryotic protists), and the PROKARYOTES. (2) A KINGDOM comprising the *eukaryotic* protists – see (1) above. (cf. MONERA.)

**protoacidium** See UREDINIOMYCETES stage I.

**protoaecium** See UREDINIOMYCETES stage I.

**Protococcidiorida** An order of protozoa of the subclass COCCIDIASINA.

**Protococcus** See PLEUROCOCCUS.

**protocooperation** In a mixed population of microorganisms: an interaction between two (or more) different microorganisms in which each organism benefits from the activities of the other (e.g. each organism may produce a substance which stimulates the growth of the other), but in which the interaction is not obligatory for either organism. (See e.g. YOGHURT; cf. MUTUALISM.)

**protofilament** See MICROTUBULES.

**Protogonyaulax tamarensis** *Syn.* *Gonyaulax tamarensis*.

**protohaem** See HAEM.

**protokaryote** Archaic term for PROKARYOTE.

**protokerogen** See KEROGEN.

**protomerite** In a cephaline gregarine: the anterior of the two main regions of the (septate) cell (cf. DEUTOMERITE). In the late trophozoite stage the anterior part of the protomerite may bear an EPIMERITE.

**protometer** In a cell: a hypothetical sensor which can respond to changes in proton motive force.

**protomite** See TOMITE.

**Protomonas** A genus of methylotrophic bacteria; the organisms have been re-classified in the genus *Methylobacterium* [IJSB (1985) 35 209].

**proton ATPase** (proton-translocating ATPase; H<sup>+</sup>-ATPase) Any ATPase which can couple ATP hydrolysis to the energy-dependent translocation of protons across an ENERGY-TRANSDUCING MEMBRANE (see CHEMIOSMOSIS) and/or which can catalyse the pmf-dependent phosphorylation of ADP to ATP. (cf. PROTON PPASE.)

The most-studied H<sup>+</sup>-ATPases are the (F<sub>0</sub>F<sub>1</sub>)-type H<sup>+</sup>-ATPases (also referred to as (F<sub>1</sub>F<sub>0</sub>)-type H<sup>+</sup>-ATPases) which occur e.g. in the bacterial cytoplasmic membrane, in the mitochondrial (inner) membrane, and in the thylakoid membranes of chloroplasts; these enzymes have a MWt of ca. 500000. Bacterial (F<sub>0</sub>F<sub>1</sub>)-type H<sup>+</sup>-ATPases consist of two distinct parts: (a) the

## proton circuit

F<sub>0</sub> moiety, a hydrophobic protein (typically containing three kinds of subunit – designated a, b and c in *Escherichia coli*) embedded in the membrane bilayer, and (b) the F<sub>1</sub> moiety, a hydrophilic protein (typically consisting of five kinds of subunit) which has ATPase activity, and which projects – like a knob on a short ‘stalk’ – from the cytoplasmic face of the membrane. (Some authors regard the *projecting* stalked knob as an artefact [JUR (1985) 93 138–143].) The ‘knob’ of F<sub>1</sub> consists of two types of subunit (designated  $\alpha$  and  $\beta$ ), and the ‘stalk’ consists of three types of subunit ( $\gamma$ ,  $\delta$  and  $\epsilon$ ). Mitochondrial (F<sub>0</sub>F<sub>1</sub>)-type H<sup>+</sup>-ATPases are essentially similar in structure but are somewhat more complex; the stalk region of the enzyme complex includes an OLIGOMYCIN-sensitivity-conferring protein (OSCP), which does not occur in bacterial or chloroplast ATPases, and a protein (called ‘inhibitor protein’, ‘I’, or ‘IF<sub>1</sub>’) which inhibits the hydrolysis of newly-made ATP. The mitochondrial, bacterial and chloroplast ATPases all contain, in the F<sub>0</sub> moiety, a DCCD-binding protein which confers sensitivity to DCCD.

**Nomenclature of H<sup>+</sup>-ATPases.** H<sup>+</sup>-ATPases from different sources are designated as follows: CF<sub>0</sub>F<sub>1</sub> (from chloroplasts); EF<sub>0</sub>F<sub>1</sub> (from *Escherichia coli*); MF<sub>0</sub>F<sub>1</sub> (from mitochondria); TF<sub>0</sub>F<sub>1</sub> (from certain thermophilic bacteria, e.g. ‘PS3’). Individual components may be designated e.g. CF<sub>0</sub>, EF<sub>1</sub>, MF<sub>0</sub> etc. The three types of subunit in TF<sub>0</sub> may be referred to as bands 4, 6 and 8 (from the SDS–gel electrophoresis pattern). Other types of H<sup>+</sup>-ATPase include the (E<sub>1</sub>E<sub>2</sub>)-type enzymes which occur e.g. in the cytoplasmic membrane in certain fungi; these enzymes differ from (F<sub>0</sub>F<sub>1</sub>)-type ATPases e.g. in that their activity involves the formation of a phosphorylated intermediate. (See also ATPASE for a general note on the nomenclature of ATPases.)

**ATP synthesis and hydrolysis.** H<sup>+</sup>-ATPase-catalysed ATP synthesis requires a minimum pmf of ca. 100–200 mV. During ATP synthesis protons flow through the enzyme system, passing down the proton concentration gradient; the actual route of proton flow appears to include the side-chains of particular amino acids – e.g. aspartic acid, glutamine, lysine and tyrosine. (Interestingly, it has been proposed that the proton-conducting pathway through another energy-transducing system, the purple membrane (see BACTERIORHODOPSIN), involves a similar range of amino acids.) Much or most of the energy derived from proton translocation may be used to effect the release of ATP from the tightly cohesive ATP–H<sup>+</sup>-ATPase complex – rather than to carry out the phosphorylation step itself. In one model it is proposed that protons passing through the F<sub>1</sub> moiety cause conformational changes in the enzyme which decrease the affinity of ATP for the catalytic site. This type of model is believed to be compatible with variable H<sup>+</sup>/P ratios – the number of protons needed to cause a given conformational change (with concomitant release of ATP) being postulated to vary with the prevailing pmf.

Under some conditions H<sup>+</sup>-ATPases may catalyse either the synthesis or hydrolysis of ATP in order that G<sub>ATP</sub> and pmf be more or less balanced (see CHEMIOSMOSIS). However, when pmf is below a certain level, H<sup>+</sup>-ATPases are rapidly (and reversibly) inactivated; such inactivation prevents depletion of ATP e.g. under those conditions in which, for any reason, the membrane is temporarily de-energized. In chloroplasts and bacteria inactivation of H<sup>+</sup>-ATPases occurs as a result of the tight binding between ADP and the catalytic site, while in mitochondria the enzyme is inactivated by the inhibitor protein. [Regulation of H<sup>+</sup>-ATPase activity: TIBS (1986) 11 32–35.]

Inhibitors of (F<sub>0</sub>F<sub>1</sub>)-type H<sup>+</sup>-ATPases include e.g. AUROVERTINS, CITREOVRIDIN, DCCD, EFRAPEPTIN, OLIGOMYCIN, QUERCETIN

and tributyltin chloride; TF<sub>1</sub> (in contrast to the F<sub>1</sub> moieties of mesophilic bacteria) is resistant to e.g. aurovertins, efrapeptin and quercetin.

[H<sup>+</sup>-ATPases, structure and function: ARB (1983) 52 801–824; H<sup>+</sup>-ATPase as an energy-converting enzyme: Book ref. 127, pp. 149–176.]

**proton circuit** See CHEMIOSMOSIS.

**proton motive force** See CHEMIOSMOSIS.

**proton PPase (H<sup>+</sup>-PPase)** Proton pyrophosphatase: a membrane-bound enzyme or enzyme complex which couples the hydrolysis or synthesis of PYROPHOSPHATE to the energy-linked transmembrane translocation of protons; H<sup>+</sup>-PPases occur widely e.g. in mammalian and yeast mitochondria, in chloroplasts, and in certain photosynthetic bacteria.

H<sup>+</sup>-PPases function in a way analogous to that of PROTON ATPASES. Thus, e.g. PPI hydrolysis by an H<sup>+</sup>-PPase can generate or augment a proton motive force (see CHEMIOSMOSIS) which can be used for energy-requiring processes such as ION TRANSPORT, reverse electron transport, and ATP synthesis (via an H<sup>+</sup>-ATPase). Conversely, an H<sup>+</sup>-PPase can use pmf, directly, for the synthesis of PPI (see also OXIDATIVE PHOSPHORYLATION); such synthesis has been reported to occur e.g. in mitochondria, in the chloroplasts of the alga *Acetabularia mediterranea* and of the pea plant, and in the bacterium *Rhodospirillum rubrum*.

(See also ELECTRON TRANSPORT CHAIN (figure).)

**proton pump** Any biochemical process which promotes the energy-requiring translocation of protons across an ENERGY-TRANSDUCING MEMBRANE: see e.g. ELECTRON TRANSPORT CHAIN and PROTON ATPASE.

**proton reducers** See ANAEROBIC DIGESTION.

**proton-reducing acetogen** See ACETOGEN.

**proton translocators (protonophores)** IONOPHORES which effectively increase the permeability, to protons, of the lipid bilayer in biological and/or artificial membranes; such agents act as mobile carriers of (specifically) protons, and can dissipate proton motive force (see CHEMIOSMOSIS) by effectively ‘short circuiting’ the membrane. (See also UNCOUPLING AGENTS.)

Proton translocators include a number of lipophilic weak organic acids which retain lipophilicity even in the deprotonated (dissociated) state (owing to delocalization of charge within the molecule); in the protonated state proton translocators deliver protons to one side of the membrane, while in the deprotonated state they accept protons from the other side. Examples include e.g. CCCP (carbonylcyanide-*m*-chlorophenylhydrazone), 2,4-dinitrophenol, and FCCP (carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone).

**protonmotive force** Proton motive force (see CHEMIOSMOSIS).

**protonmotive Q-cycle** See Q-CYCLE.

**protonophore** *Syn.* PROTON TRANSLocator.

**proto-*onc*** See ONCOGENE.

**protoplasmic cylinder** See SPIROCHAETALES.

**protoplast** See MYXOMYCETES.

**protoplast** (1) The spherical or near-spherical, osmotically sensitive structure formed by the *complete* removal of the cell wall (e.g. by enzymic action) from a cell suspended in an isotonic (or hypertonic) medium; a protoplast thus consists of the cytoplasmic membrane and cell contents. Protoplasts can continue to metabolize – and may be able to revert to normal cells – under appropriate cultural conditions; however, protoplasts cannot divide. Bacterial protoplasts are prepared more easily from Gram-positive cells (e.g. by using LYSOZYME) than from Gram-negative cells; they are resistant to phage infection,

but those from previously infected cells can support phage replication. (See also SPHAEROPLAST; AUTOPLAST; L-FORM; PROTOPLAST FUSION.)

(2) In an *intact* cell: the cytoplasmic membrane and all structures internal to it.

**protoplast fusion** A technique for *in vitro* genetic transfer in which a hybrid PROTOPLAST (and ultimately a hybrid cell) is formed by fusing protoplasts derived from different strains, species or genera. Protoplasts are initially prepared e.g. by treating cells with wall-degrading enzymes (e.g. LYSOZYME for some Gram-positive bacteria); populations of two types of protoplast are then mixed. Treatment of the mixture with e.g. POLYETHYLENE GLYCOL (PEG) increases the (low) spontaneous rate of fusion. (cf. ELECTROFUSION.) The protoplasts are then transferred to an appropriate (hypertonic) solid medium for cell wall regeneration. The resulting cells can be screened for those with genetic markers from both parents; e.g., if both parents were auxotrophic (with different growth requirements) the cells can be screened for prototrophs.

Hybrid bacterial protoplasts, containing a genome from each parent, are called *biparentals*. The two genomes may undergo recombination, or the diploids may be unstable, the two genomes segregating when the cell divides. In e.g. *Bacillus subtilis*, many of the progeny cells are unstable *complementary diploids* (i.e., genes on both genomes are expressed and can exhibit COMPLEMENTATION); however, some progeny cells are unstable *non-complementing diploids* (Ncd cells) in which one of the two parental genomes is expressed while the other is inactive until segregated on cell division. (cf. CONJUGATION sense 1b (ii).)

(See also TRANSFORMATION.)

**protoplast membrane** *Syn.* CYTOPLASMIC MEMBRANE.

**protoporphyrins** See PORPHYRINS.

**Protosporangium** See PROTOSTELIOMYCETES.

**Protostelia** See EUMYCETAZOEA.

**protostelids** See PROTOSTELIOMYCETES.

**Protosteliia** See EUMYCETAZOEA.

**Protosteliomycetes** (protostelids) A class of primitive slime moulds (division MYXOMYCOTA – cf. EUMYCETAZOEA) in which the vegetative phase consists of a small reticulate plasmodium or of simple amoebae which form filose – and sometimes also lobose – pseudopodia; in some species the amoebae bear one or more smooth flagella. ‘Shuttle streaming’ (i.e., rhythmic reversible flow of protoplasm) does not occur. An individual amoeba, or a segment of a plasmodium, gives rise to a fruiting body consisting of one to several spores borne on a slender tubular stalk, the whole being bounded by a sheath. Ballistospores are formed e.g. by *Protostelium nocturnum* [Mycol. (1984) 76 443–447], *P. expulsum* [TBMS (1981) 76 303–309], and *Schizoplasmodium cavostelioides* [sporocarp ultrastructure and development: Mycol. (1985) 77 848–860]. [Ultrastructural study of trophozoite and cyst stages of *P. pyriformis*: JP (1986) 33 405–411.] Protostelids are found in various habitats, including bark, rotting wood, etc. Other genera include e.g. *Cavostelium*, *Ceratiomyxella*, *Endostelium* [Mycol. (1984) 76 884–891], *Nematostelium* and *Protosporangium*. (cf. CERATIOMYXA.)

**Protostelium** See PROTOSTELIOMYCETES.

**Prototheca** A genus of unicellular eukaryotic microorganisms which are generally regarded as achlorophyllous strains of CHLORELLA. The cells are hyaline and roughly spherical or ovoid (ca. 1.3–13.4 × 1.3–16.0 μm, depending on species, growth conditions etc); when mature, a cell divides to form 2–20 or more ‘endospores’ which are released by rupture of the mother

cell. Species occur e.g. in soil and water, and some can behave as opportunist pathogens (see PROTOTHECOSIS).

**protothecosis** A disease, which affects man and animals, caused by a species of *Prototheca* (commonly *P. zopfii*); typically, it involves the formation of localized skin lesions – which may be nodular, ulcerating and papular, or (rarely) granulomatous. (See also MASTITIS.) A severe, often fatal, systemic form of the disease also occurs, particularly in animals.

**prototroph** A strain of microorganism whose nutritional requirements do not exceed those of the corresponding wild-type strain. (cf. AUXOTROPH.)

**prototunicate ascus** An ASCUS whose wall consists of a thin, delicate membrane; the ascospores are released when the ascus wall ruptures or deliquesces. Such asci are formed e.g. by ascogenous yeasts.

**protoxin** A precursor form of a TOXIN; see e.g. DELTA-ENDOTOXIN.

**protozoa** A diverse group of eukaryotic, typically unicellular microorganisms; they are classified as a subkingdom (Protozoa) within the kingdom Animalia or the kingdom PROTISTA. (Some of these organisms – e.g. the SLIME MOULDS and members of the PHYTOMASTIGOPHOREA – are also classified in botanical taxonomic schemes.) The earliest known protozoa lived in the late Precambrian (see e.g. FORAMINIFERIDA).

The protozoa exhibit a great variety of forms, structures and life styles, and are divided into seven phyla: APICOMPLEXA, ASCETOSPORAZOEA, CILIOPHORA, LABYRINTHOMORPHA, MICROSPORA, MYXOZOA and SARCOMASTIGOPHORA [JP (1980) 27 37–58]. Many protozoa are free-living organisms which occur in freshwater, brackish or marine habitats. Some protozoa occur e.g. in soil, some are common in SEWAGE TREATMENT plants, and some inhabit the gut in vertebrates or invertebrates (see e.g. RUMEN and TERMITE-MICROBE ASSOCIATIONS). Parasitic species include e.g. members of the Apicomplexa, Ascetospora, Microspora and Myxozoa; some protozoa are pathogenic in vertebrates (including man) or invertebrates (see e.g. BABESIA, BALANTIDIUM, EIMERIORINA, ENTAMOEBIA, GIARDIA, HISTOMONAS, NAEGLERIA, NOSEMA, PLASMODIUM, TOXOPLASMA, TRYPANOSOMA). PHYTOMONAS is parasitic in certain plants.

Protozoa range in size from ca. 1 μm to several millimetres; some have internal or external ‘skeletons’ of e.g. calcareous, siliceous and/or organic material. Many exhibit MOTILITY but some (see e.g. PERITRICHIA) are sedentary. Probably most protozoa are aerobic organisms, but some can grow microaerobically or anaerobically (see e.g. RUMEN and SAPROBITY SYSTEM). Feeding may occur saprotrophically and/or by pinocytosis – and/or it may occur holozoically (e.g. in many amoebae and ciliates), these organisms being classified as CARNIVOROUS, HERBIVOROUS or OMNIVOROUS. Some protozoa (see PHYTOMASTIGOPHOREA) can carry out PHOTOSYNTHESIS.

Asexual reproduction may involve binary fission, multiple fission and/or budding. Sexual processes occur in some species (see e.g. AUTOGAMY and CONJUGATION). According to species, protozoa may be haploid, diploid or polyploid; some (the foraminifera) exhibit an ALTERNATION OF GENERATIONS.

Populations of viable protozoa may be preserved by FREEZING (suitable e.g. for *Plasmodium*, *Tetrahymena*, *Trypanosoma*) or by repeated subculturing. CYST-forming species (e.g. *Didinium*, certain amoebae) may be encouraged to encyst (and thus survive for protracted periods) e.g. by slow desiccation or by starvation.

**prottrichocyst** *Syn.* EJECTOSOME.

**Providencia** A genus of Gram-negative bacteria of the tribe PROTEAEAE. Cells: ca. 0.6–0.8 × 1.5–2.5 μm. Swarming does not occur. Species do not produce H<sub>2</sub>S or lipase, do not

## provirus

liquefy gelatin at 22°C, and can metabolize mannose and one or more sugar alcohols; colonies on DCA typically develop yellow-orange centres due to the precipitation of Fe(OH)<sub>3</sub> by alkaline metabolic products. Nicotinic and pantothenic acids are not required for growth. GC%: 39–42. Type species: *P. alcalifaciens*.

*P. alcalifaciens* (formerly included in *Proteus inconstans*). Urease –ve (weak or delayed +ve in a few strains); trehalose –ve; inositol. –ve; adonitol +ve.

*P. rettgeri* (including most of the strains formerly regarded as *Proteus rettgeri*). Urease +ve; trehalose –ve; inositol +ve; adonitol +ve.

*P. stuartii* (incorporating strains formerly included in *Proteus inconstans* and *Proteus rettgeri*). Urease –ve (weak or delayed +ve in a few strains); trehalose +ve; inositol +ve; adonitol –ve.

*Providencia* spp are rare in the normal human intestine, and their natural habitat is unknown. Some strains can be opportunistic pathogens – *P. rettgeri* and *P. stuartii* causing e.g. nosocomial UTIs, *P. alcalifaciens* being more often associated with diarrhoeal illnesses.

[Book ref. 22, pp. 494–496.]

**provirus** Viral DNA which has become integrated into the chromosomal DNA of the host cell; in viruses of the RETROVIRIDAE the DNA is a transcript of the RNA genome, while in some DNA viruses the genome itself, or a portion of the genome, may integrate (see e.g. DEPENDOVIRUS, HEPATITIS B VIRUS and MASTADENOVIRUS).

**prozone (serol.)** (1) In a titration involving antibodies and *particulate* antigens: absence of visible AGGLUTINATION in tubes containing the higher concentration(s) of antibody. A prozone may be due e.g. to (i) relatively low titres of BLOCKING ANTIBODIES (sense 1) which are diluted out in tubes containing agglutinating titres of normal homologous antibodies; (ii) gross ANTIBODY EXCESS; or (iii) the presence in the antiserum of substances which inhibit agglutination non-specifically.

(2) In a titration involving antibodies and *soluble* antigens: the absence of visible precipitate in those tubes in which there is an ANTIGEN EXCESS.

**prozygosporangium** See ZYGOSPORE.

**PrP 27–30 (PrP)** See SCRAPIE.

**PrP<sup>c</sup>, PrP<sup>sc</sup>** See PRION.

**PRRS** Porcine reproductive and respiratory syndrome: see BLUE-EARED PIG DISEASE.

**pruinose** (of surfaces) Powdery in appearance.

**Prunus necrotic ringspot virus** See ILARVIRUSES.

**pruritis** Itching.

**Pruteen** See SINGLE-CELL PROTEIN.

**Prymnesiida** See PHYTOMASTIGOPHOREA.

**Prymnesiophyceae** (Haptophyceae) A class of unicellular, uniciliate, commonly biflagellated algae (sometimes regarded as protozoa – see PHYTOMASTIGOPHOREA). Typically, the motile cell has two smooth flagella of more or less equal length, together with a HAPTONEMA; the golden-brown chloroplasts (usually two per cell) contain chlorophylls *a*, *c*<sub>1</sub> and *c*<sub>2</sub>, and fucoxanthin. Storage compounds include CHRYSOLAMINARIN. Many members can ingest food phagocytically. Most prymnesiophytes bear a covering of delicate, typically oval scales embedded in a mucilaginous matrix external to the plasmalemma; these scales are produced in the Golgi apparatus (or in vesicles probably derived therefrom) before being passed to the cell exterior (cf. CHRYSOPHYTES). The scales may be entirely organic (e.g. in *Chrysochromulina* and *Prymnesium*) or may be calcified (in certain stages of the COCCOLITHOPHORIDS). Some of the

scales may bear long or short spines, and – according to species – different types of scales may be present on the same cell and/or on different cells in different stages of the life cycle. The nature of the scales (determined by electron microscopy) is an important taxonomic characteristic.

Prymnesiophytes are mostly marine organisms, forming an important component of the nanoplankton. Some species (e.g. PRYMNESIUM) occur in brackish waters, others in fresh water.

**Prymnesium** A genus of unicellular algae (class PRYMNESIOPHYCEAE) in which the HAPTONEMA is short and immobile. Species occur in brackish water. *P. parvum* produces a potent, cation-activated, pH-dependent, haemolytic PHYCOTOXIN (comprising at least 6 components) which can cause mass mortalities in fish and other gill-bearing vertebrates (as well as in invertebrates) in e.g. brackish-water culture ponds.

**PS3** A strain of thermophilic bacteria of uncertain taxonomic affiliation.

**PS-5** A CARBAPENEM antibiotic.

**PSA fimbriae** ('PSA pili') See FIMBRIAE.

**Psalliota** See AGARICUS.

**Psammetta** See XENOPHYOPHOREA.

**Psammina** See XENOPHYOPHOREA.

**Psammomitra** See HYPOTRICHIDA.

**psammophilic** Preferring a sandy habitat.

**Psathyrella** See AGARICALES (Coprinaeae).

**pSC101** A 9.4-kb, low-copy-number PLASMID which encodes tetracycline resistance and which has a single *EcoRI* cleavage site in a non-essential region, making it a useful CLONING vector. Replication of pSC101 occurs unidirectionally, does not require DNA polymerase I (cf. e.g. COLEI PLASMID) or the host cell's DnaA protein (see DNAA GENE) but requires a pSC101-encoded initiator protein. [Nucleotide sequence of pSC101: NAR (1984) 12 9427–9440.]

**PSE-type β-lactamases** See β-LACTAMASES.

**Pseudallescheria** (syn. *Petriellidium*) A genus of fungi of the order MICROASCALES. *P. boydii* ('*Allescheria boydii*') (anamorph: *Scedosporium apiospermum*) occurs e.g. in soil and in faecally contaminated cattle feed. It can cause mycotic abortion e.g. in cattle; in man it is a causal agent of MADUROMYCOSIS and may be implicated in infections of the respiratory tract, sinuses etc, particularly in immunosuppressed patients. [Clinical significance of *P. boydii*: Mayo Clin. Proc. (1985) 60 531–537.]

**Pseudanabaena** A genus of filamentous CYANOBACTERIA (section III) in which the trichomes are composed of cylindrical cells, with constrictions between adjacent cells; trichomes are motile and non-sheathed, and the cells contain polar GAS VACUOLES. GC%: 44–52. The genus probably includes at least some strains of '*Oscillatoria redekei*'.

**pseudoaethalium** See MYXOMYCETES.

**pseudoappendicitis** See e.g. FOOD POISONING (j); see also PSEUDOTUBERCULOSIS.

**Pseudocaeidibacter** A genus of Gram-negative bacteria which occur as endosymbionts in strains of *Paramecium*. Cells: non-motile rods, ca. 0.25–0.7 × 0.5–4.0 μm, which do not contain R bodies (cf. CAEIDIBACTER) and which may or may not (according to species) confer a killer characteristic on their host paramecia. GC%: ca. 35–39. Type species: *P. conjugatus*.

*P. conjugatus* (see also MU PARTICLE) confers the MATE KILLER characteristic; in vitro cultivation has been reported.

*P. falsus* (nu and pi particles) does not confer a killer characteristic.

*P. minutus* (gamma particles) confers the killer characteristic. [Book ref. 22, pp. 807–808.]

**pseudocapillitium** In the aethalia or pseudoaethalia of certain MYXOMYCETES: a system of threads (generally irregular in width) and/or of membranous or perforated plate-like structures present among the spores; it has been suggested that these structures may be remnants of sporangial walls.

**pseudocatalase** A non-haemoprotein substance which catalyses the breakdown of H<sub>2</sub>O<sub>2</sub> into water and O<sub>2</sub>; pseudocatalases occur e.g. in various lactic acid bacteria, including strains of *Lactobacillus*, *Enterococcus faecalis*, and in some species of *Veillonella*. Unlike CATALASE, pseudocatalases are not inhibited by low concentrations of azide or cyanide. A manganese-containing protein pseudocatalase (a 'manganicatalase') has been isolated from a strain of *Lactobacillus plantarum* [JBC (1983) 258 6015–6019].

**Pseudocercospora** See HYPHOMYCETES; see also EYESPOT (sense 2).

**pseudocilia** See TETRASPORA.

**pseudocoagulase** In certain strains of *Staphylococcus*: any protease that mimics the effects of STAPHYLOCOAGULASE by proteolytic activation of prothrombin, thus causing a false-positive reaction in a COAGULASE TEST. 'Pseudocoagulase' is believed to be a metalloprotease(s) and can be inhibited by adding EDTA to the plasma. [Book ref. 44, p. 530.]

**pseudocolumella** In the fruiting bodies of certain MYXOMYCETES: a COLUMELLA-like, spherical or rod-shaped, calcareous structure which occurs in the centre of the sporangium; it is not attached to the peridium, but may be attached to capillitial threads.

**pseudocowpox** A mild, usually benign CATTLE DISEASE characterized by the formation of papular, scab-forming lesions on the teats which may predispose to MASTITIS; the causal agent is a PARAPOXVIRUS. (See also MILKERS' NODULE; cf. COWPOX.)

**pseudocyphella** (*lichenol.*) A small pore (ca. 0.1–2.0 mm diam.) in the (upper and/or lower) cortex of the thallus in various lichens (e.g. species of *Cetraria*, *Parmelia*, *Pseudocyphellaria*). Pseudocyphellae have no definite margin (cf. CYPHELLA); they appear to be formed by the disintegration of the pseudoparenchymatous cortex, and are believed to facilitate gas exchange [Lichenol. (1981) 13 1–10]. (cf. PORED EPICORTEX.)

**Pseudocyphellaria** A genus of foliose LICHENS (order PELTIGERALES) which closely resemble STICTA spp but differ in that the tomentose underside is perforated with PSEUDOCYPHELLAE. The upper surface may bear soredia which are yellow in *P. crocata*, bluish-grey in *P. intricata*. Species occur on soil, trees, rocks, etc.

**pseudocyst** (*protozool.*) See e.g. CHAGAS' DISEASE and TOXOPLASMO-SIS.

**pseudoepthecium** In some types of APOTHECIUM: a layer, at the surface of the hymenium, which consists of the tips of paraphyses immersed in an amorphous matrix. (cf. EPITHECIUM.)

**pseud-Fiji disease** See FIJI DISEASE.

**pseudogene** In a eukaryotic chromosome: a DNA segment which resembles a known functional gene but differs in carrying deleterious mutations and in having no apparent function. Many pseudogenes resemble cDNA copies of cellular mRNAs: they have a short A–T tract at the 3' end (corresponding to the 3'-poly(A) of mRNA), lack introns, and are often flanked by direct repeats; such pseudogenes are believed to have arisen by reverse transcription of cellular mRNAs.

Pseudogenes have also been found in prokaryotes. For example, in *Mycobacterium leprae* about 27% of the genome is reported to consist of pseudogenes [Nature (2001) 409 1007–1011].

**pseudoglanders** *Syn.* EPIZOOTIC LYMPHANGITIS.

**pseudohaemoptysis** (pseudohaemoptysis) The apparent expectoration of blood due to the coloration of sputum by red-pigmented bacteria (e.g. *Serratia* sp).

**Pseudohydnum** See TREMELLALES.

**pseudohyphae** *Syn.* SPROUT MYCELIUM.

**Pseudoklossia** See EIMERIORINA.

**pseudolumpy skin disease** See LUMPY SKIN DISEASE.

**pseudolysogeny** A phenomenon in which an association between a BACTERIOPHAGE and its host mimics LYSOGENY in that host cell lysis is delayed or does not occur, but true lysogeny is not established. A bacterial population exhibiting pseudolysogeny can be freed of phage by prolonged incubation with neutralizing anti-phage antiserum or by serial subculture from isolated colonies. Different types of pseudolysogeny occur in different phage–bacterium systems. For example, when a population of susceptible bacteria (e.g. *Shigella dysenteriae*) is exposed to a virulent bacteriophage (e.g. T7) at a low multiplicity of infection, a few cells become infected. On lysis, these cells may release an enzyme which destroys the phage receptors on other cells in the population; phage virions therefore fail to adsorb to these cells – which, as a result, become (temporarily) resistant to infection (phenotypic resistance). These cells regain their susceptibility to infection after subculture in the absence of phage.

In other cases the phage genome may be carried, but not expressed or replicated, within a cell in a susceptible population of bacteria, and the genome is passed to only one of the daughter cells at each cell division; a culture containing a proportion of such 'carrier cells' is known as a CARRIER CULTURE. After several successive transits from cell to daughter cell, the phage genome enters the lytic cycle and progeny phages are released by cell lysis. These may infect other cells which may in turn become carrier cells. This type of pseudolysogeny may occur e.g. when most of the host cells are repressed for one or more functions needed for phage replication.

In *Azotobacter* strain O certain phages can apparently establish a pseudolysogenic state accompanied by the phenotypic conversion of the host cells (see BACTERIOPHAGE CONVERSION); the cells lose their polysaccharide capsule, become flagellated and motile, and acquire a yellow pigmented appearance [Virology (1980) 102 267–277].

**pseudomembranous colitis** A severe, acute form of COLITIS. There is a profuse, watery diarrhoea, cramps, fever, and the formation of pseudomembranous patches of inflammatory exudate on the colonic mucosa (sometimes also in the small intestine). It may follow chemotherapy (e.g. with some β-LACTAM ANTIBIOTICS, clindamycin) and is linked to *CLOSTRIDIUM difficile*; toxins A and B kill gut epithelial cells e.g. by disrupting tight junction proteins. Inadequate IgG response may promote disease/relapse. [Review: BCG (2003) 17 475–493.]

**pseudomethylotroph** An organism which oxidizes C<sub>1</sub> compounds to CO<sub>2</sub> and which assimilates C<sub>1</sub> carbon only via the Calvin cycle.

**Pseudomicrothorax** See HYPOSTOMATIA.

**Pseudomonadaceae** A family of Gram-negative, aerobic, chemoorganotrophic or facultatively chemolithotrophic, typically motile (usually polarly flagellate), rod-shaped bacteria. GC%: 58–71. Genera: FRATEURIA, PSEUDOMONAS, XANTHOMONAS, ZOOGLOEA. [Book ref. 22, pp. 140–219.]

**Pseudomonadales** A poorly defined, obsolete order of bacteria.

**Pseudomonas** A genus of Gram-negative, aerobic, chemoorganotrophic or facultatively chemolithoautotrophic bacteria of the family PSEUDOMONADACEAE; species occur as free-living organisms in soil and aquatic habitats, and as pathogens in man,

## *Pseudomonas*

other animals, and plants – see e.g. BLUE PUS, BROWN BLOTCH, GINGER BLOTCH, OLIVE KNOT and TABTOXIN. [Mechanisms of plant pathogenesis: CJM (1985) 31 403–410.] (See also BUTTER and MEAT SPOILAGE.) The cells are straight or slightly curved rods,  $0.5\text{--}1.0 \times 1.5\text{--}5.0 \mu\text{m}$ . In most species the majority of strains are motile with one or several unsheathed polar flagella per cell; however, sheathed flagella are formed e.g. by *P. andropogonis*, and some species produce both polar and lateral flagella – particularly when grown on solid media. [Biochemical and serological properties of flagella of some *Pseudomonas* spp: JGM (1985) 131 873–883.] Polarly fimbriate strains may exhibit TWITCHING MOTILITY. Cell walls and cytoplasmic membranes resemble those of other Gram-negative bacteria. (See also PORIN, OUTER MEMBRANE and S LAYER.) Catalase +ve; many strains are oxidase +ve. GC%: 58–70. Type species: *P. aeruginosa*.

**Nutrition, metabolism, growth.** Typically, the organisms are nutritionally and metabolically highly versatile: most species will grow on inorganic salts with an organic carbon source, while some can grow chemolithoautotrophically; however, certain species (e.g. *P. diminuta*, *P. vesicularis*) require factors such as biotin, cyanocobalamin and pantothenate. Metabolism is respiratory (oxidative); many species can carry out NITRATE RESPIRATION. The TCA CYCLE operates in all species investigated. In e.g. *P. aeruginosa*, *P. fluorescens* and *P. putida*, glucose can be oxidized by EXTRACYTOSOLIC OXIDATION to gluconate which may then be metabolized via the ENTNER–DOUDOROFF PATHWAY. Carbohydrates are metabolized anaerogenically. [Alternative pathways of carbohydrate metabolism in *Pseudomonas*: ARM (1984) 38 359–387.] HYDROCARBONS can be metabolized by some strains. Some metabolic activities are plasmid-dependent: e.g., the ability to degrade camphor, salicylate, toluate and xylene is associated with plasmids CAM, SAL, TOL and XYL, respectively. Under nitrogen-limiting conditions some species accumulate POLY- $\beta$ -HYDROXYBUTYRATE. Under iron-deficient conditions, siderophores (some fluorescent) may be secreted (see NOCARDAMINE, PYOVERDIN). (See also PYOCYANIN.) Some species produce bacteriocins (see e.g. PYOCIN). In many species growth occurs optimally at ca. 28–30°C and is generally inhibited at or below ca. pH 4.5.

**Sensitivity to antimicrobial agents.** In general, pseudomonads are resistant to a range of common antimicrobial agents; resistance may or may not be plasmid-mediated. *P. aeruginosa* may be sensitive to e.g. certain AMINOGLYCOSIDE ANTIBIOTICS (e.g. amikacin, gentamicin); it is resistant to many common DISINFECTANTS (cf. DETTOL CHELATE) but is usually lysed rapidly by EDTA.

**Susceptibility to phages.** *Pseudomonas* spp are susceptible to a variety of phages: see e.g. BACTERIOPHAGE  $\phi 6$ ; BACTERIOPHAGE  $\phi W$ -14; INOVIRUS; TECTIVIRIDAE. The transducing phages F116 and G101 were used for mapping the chromosome of *P. aeruginosa*. Lysogeny is very common in *P. aeruginosa*, but is uncommon in other species.

**Genetic aspects.** Genetic studies have often been carried out with *P. aeruginosa* strain PAO. [Chromosomal maps of *P. aeruginosa* PAO and *P. putida* PPN compared: JGM (1985) 131 885–896.] Gene transfer can occur by transduction and conjugation; most conjugative plasmids transfer better on solid media than in liquids [JGM (1983) 129 2545–2556]. Transformation in *P. aeruginosa* has been achieved with  $\text{CaCl}_2$ -treated cells.

**Taxonomy.** A number of pseudomonads were classified by rRNA oligonucleotide cataloguing (q.v.) into rRNA

groups I–V. Group I included fluorescent species (e.g. *P. aeruginosa*, *P. aureofaciens*, *P. chlororaphis*, *P. putida*, *P. syringae*) and non-fluorescent species (e.g. *P. alcaligenes*, *P. pseudoalcaligenes*, *P. stutzeri*), all of which (apart from some strains of *P. pseudoalcaligenes*) do not accumulate poly- $\beta$ -hydroxybutyrate (PHB). Species of groups II and III do accumulate PHB; group II included pathogens (e.g. *P. cepacia*, *P. mallei*, *P. solanacearum*), while group III consisted of non-pathogens (e.g. *P. acidovorans*, *P. testosteroni*) and included some autotrophs which can grow chemolithotrophically (e.g. *P. facilis*, *P. flava*, *P. paleronii* and *P. saccharophila*). Group IV consisted of *P. diminuta* and *P. vesicularis*, while group V contained only *P. maltophilia*; these three species require growth factors, and the last two are unable to assimilate nitrate. For group II see BURKHOLDERIA. For group V see *P. maltophilia*, below.

Many species have not been assigned to rRNA groups, and their relationship to rRNA-grouped species is uncertain; such species include e.g. *P. agarici*, *P. amygdali*, *P. andropogonis*, *P. aurantiaca*, *P. avenae*, *P. cattleyae*, *P. fragi*, *P. fulva*, *P. lemoignei*, *P. marina* (see DELEYA), *P. nautica*, *P. spinosa* and *P. woodii*.

*P. aeruginosa* (formerly *P. pyocyanea*). Occurs in soil, river water etc, and is an important opportunistic pathogen in man and other animals – being isolated from infected burns, urinary tract infections, etc. (See also BLUE PUS; EXOENZYME S; EXOTOXIN A.) It can occasionally be pathogenic in (stressed) plants. Motile strains usually have one polar flagellum per cell; rarely non-motile. Polarly fimbriate. Colonies on nutrient agar are often roundish, flat, dull and butyrous (R-type), but can be e.g. smooth and umbonate (S-type). Mucoid (M-type) colonies are formed by ALGINATE-producing strains isolated e.g. from CYSTIC FIBROSIS patients; only some mucoid strains can produce alginate on minimal agar. Most strains produce PYOCYANIN, and may also produce e.g. PYOVERDIN, while a few strains can form a brown pigment (*pyomelanin*) or a red pigment (*pyorubin*). (Pyomelanin production is enhanced in mineral salts media containing 1% L-tyrosine; 1% DL-glutamate enhances pyorubin production.) All strains are catalase +ve and oxidase +ve; many are urease +ve. Optimum growth temperature: 37°C; all strains can grow at 42°C. GC%: ca. 67.

The production of virulence factors by *P. aeruginosa* may be inhibited through inhibition of the organism's QUORUM SENSING mechanisms by the macrolide antibiotic azithromycin [AAC (2001) 45 1930–1933].

*P. alcaligenes*. A non-fluorescent species which cannot utilize e.g. glucose, fructose, maltose or gluconate, but which can use e.g. L-arginine, malate, and propionate. Monotrichously flagellate. Growth can occur at 41°C; optimum temperature ca. 35°C. GC%: 64–68.

*P. andropogonis* (= *P. stizobii*). A non-fluorescent, typically oxidase –ve species pathogenic e.g. for sorghum. The organisms form sheathed flagella at ca. 28°C but are non-flagellate when grown at 34°C.

*P. carboxydohydrogena*. See CARBOXYDOBACTERIA.

*P. carboxydovorans*. See CARBOXYDOBACTERIA.

*P. cepacia*. A former species (see BURKHOLDERIA) found e.g. in soil, water. Oxidase +ve. Lophotrichously flagellate. Non-fluorescent pigments often formed. Opt. growth: 30–35°C. Pathogenic in man (see CYSTIC FIBROSIS) and a causal agent of soft rot in onions.

*P. cichorii*. A fluorescent, PYOVERDIN-forming species pathogenic for chicory: Lophotrichously flagellate. Weakly oxidase +ve. Optimum growth temperature: ca. 30°C. GC%: 59.

'*P. cocovenans*' (*incertae sedis*). See BONGKREKIC ACID.

*P. facilis* (formerly *Hydrogenomonas facilis*). A non-fluorescent, non-pigmented species which occurs e.g. in soil. Monotrichously flagellate. Oxidase +ve. Glucose, fructose and malonate can be utilized; extracellular PHB is hydrolysed. The organisms can grow chemolithoautotrophically using hydrogen and oxygen (see KNALLGAS REACTION). Optimum growth temperature: ca. 28°C. GC%: 62–64.

*P. fluorescens*. A fluorescent, PYOVERDIN-forming species which occurs e.g. in soil and water. Lophotrichously flagellate. Oxidase +ve. Gelatinase +ve. Growth can occur at 4°C but not at 41°C; optimum growth temperature: 25–30°C. GC%: ca. 59–61. (See also MUPIROCIN.)

*P. fragi*. A psychrophilic, peritrichously fimbriate species which can cause spoilage of refrigerated foods (e.g. BUTTER).

*P. mallei*. A non-motile, non-pigmented species which causes GLANDERS. Oxidase +ve, gelatinase +ve. D-xylose is utilized, D-ribose is not. (See BURKHOLDERIA.)

*P. maltophila*. A former species found in e.g. soil, water and milk. Lophotrichously flagellate. Most strains need cystine or methionine; PHB is not accumulated. Strongly lipophilic. No growth at 4°C or 41°C. Re-classified initially as *Xanthomonas maltophila* [IJSB (1983) 33 409–413] and then as *Stenotrophomonas maltophila* (see CYSTIC FIBROSIS).

*P. marina*. See DELEYA.

*P. nigrificiens*. See ALTEROMONAS.

*P. phaseolicola*. See *P. syringae*.

*P. pseudoalcaligenes*. A non-fluorescent species, some strains of which are pathogenic for watermelon. Monotrichously flagellate. Fructose can be utilized (cf. *P. alcaligenes*). GC%: 62–64.

*P. pseudomallei*. Occurs e.g. in soil and is the causal agent of MELIOIDOSIS. Motile, lophotrichously flagellate. Oxidase +ve. Gelatinase +ve. D-Ribose can be utilized, D-xylose cannot. Yellow or orange pigments may be formed. (See BURKHOLDERIA.)

*P. putida*. A fluorescent species which occurs e.g. in soil and water. Lophotrichously flagellate. Oxidase +ve. Optimum growth temperature: 25–30°C. Two biovars: A and B; strains of biovar B can utilize L-tryptophan and testosterone.

*P. putrefaciens*. See ALTEROMONAS.

*P. pyocyanea*. See *P. aeruginosa*.

*P. saccharophila*. The sole strain of *P. saccharophila* was isolated from mud. Monotrichously flagellate. Growth can occur chemolithoautotrophically with hydrogen as electron donor. PHB is accumulated. Oxidase +ve. Optimum growth temperature: ca. 30°C. GC%: ca. 69.

*P. solanacearum*. A plant-pathogenic species which causes wilts in e.g. members of the Solanaceae. Lophotrichously flagellate. Oxidase +ve. Some strains form brown pigments. GC%: ca. 66–68. (See BURKHOLDERIA.)

*P. stizobii*. See *P. andropogonis*.

*P. stutzeri*. Occurs e.g. in soil and water. Non-fluorescent. PHB is not accumulated. Monotrichously flagellate, but lateral flagella are formed under certain conditions. Oxidase +ve. Starch is hydrolysed. GC%: 60–66. (See also BIOMIMETIC TECHNOLOGY.)

*P. syringae*. A fluorescent, plant-pathogenic species. [Genetic determinants of pathogenicity in pathovar *syringae*: PNAS (1985) 82 406–410.] Lophotrichously flagellate. Oxidase –ve. Optimum growth temperature: ca. 25–30°C. GC%: 59–61. The species is divided into a large number of pathovars; these include (with their hosts) e.g. *P. syringae* pv. *coronafaciens* (e.g. oats); *P. syringae* pv. *glycinea* (soybean); *P. syringae* pv. *morsprunorum* (*Prunus* spp – see CANKER); *P. syringae* pv. *phaseolicola* (formerly *P. phaseolicola*) (e.g. beans); *P. syringae* pv.

*pisi* (peas); *P. syringae* pv. *savastanoi* (olive trees – see OLIVE KNOT); *P. syringae* pv. *syringae* (lilac) (see also SYRINGOMYCIN); *P. syringae* pv. *tabaci* (tobacco – see TABTOXIN).

*P. thermocarboxydovorans*. See CARBOXYDOBACTERIA.

*P. tolaasii*. The causal agent of BROWN BLOTCH in mushrooms. [Book ref. 22, pp. 140–199; ecology, isolation, culture: Book ref. 45, pp. 655–741; the biology of *Pseudomonas*: Book ref. 198.]

**pseudomonic acid A** *Syn.* MUPIROCIN.

**pseudomurein** A CELL WALL polymer present in some members of the ARCHAEA (METHANOBACTERIALES); it consists of (1 → 3)-β-linked backbone chains – containing *N*-acetyl-D-glucosamine (and/or *N*-acetyl-D-galactosamine, according to species) and *N*-acetyl-L-talosaminuronic acid – cross-linked by peptides which contain only L-amino acids (lys, glu, ala or thr). (cf. PEPTIDOGLYCAN.) Pseudomurein is resistant to LYSOZYME and to antibiotics such as penicillins and vancomycin. [Book ref. 157, pp. 416–423.]

**pseudomycelium** *Syn.* SPROUT MYCELIUM.

**pseudonavicella** See MONOCYSTIS.

**pseudonigeran** A water-insoluble, alkali-soluble (1 → 3)-α-D-glucan present in the CELL WALL in certain fungi; e.g. *Aspergillus nidulans*, *Paracoccidioides brasiliensis* (yeast form), *Schizophyllum commune*. Pseudonigeran can act as a reserve carbohydrate for cleistothecium formation in the teleomorph of *A. nidulans* (*Emericia nidulans*). (cf. NIGERAN.)

**Pseudonocardia** A genus of bacteria (order ACTINOMYCETALES, wall type IV) which occur e.g. in manure and soil. The organisms form non-fragmenting substrate mycelium, and unbranched aerial hyphae which give rise to chains of cylindrical spores. Mycolic acids are not formed. GC%: ca. 79. Type species: *P. thermophila*. [Book ref. 73, pp. 125–126; ecology, isolation, cultivation: Book ref. 46, pp. 2103–2117.]

**pseudoparaphysis** A type of sterile, typically branched and anastomosing, usually septate filament (of unknown function) which originates in the upper wall of a pseudothecial locule and grows downwards between the asci, subsequently fusing with the lower wall. (cf. PARAPHYSIS; see also HAMATHECIUM.)

**pseudoparenchyma** See PLECTENCHYMA.

**pseudoperithecium** See ASCOSTROMA.

**Pseudoperonospora** See PERONOSPORALES.

**pseudopilins** Certain components of the SECRETON which exhibit a region of homology with the pilins of type IV fimbriae; homology is limited to the 30 (hydrophobic) amino acids found at the N-terminal of the protein, i.e. those residues which, in the pilins, interact during fimbrial assembly.

Studies on those bacteria which encode both the secreton and type IV fimbriae suggested that a functional relationship may exist between the operation of the secreton and the mechanism of fimbriation. Subsequently, when genes encoding the pullulanase secreton of *Klebsiella oxytoca* were expressed in *Escherichia coli* K-12, one of the pseudopilins, PulG, was found to assemble into a pilus-like structure [EMBO (2000) 19 2221–2228].

**pseudoplasmodium** (1) A multicellular, commonly motile structure formed by the aggregation of amoeboid cells (prior to fruiting) in CELLULAR SLIME MOULDS. (2) The ectoplasmic net of members of the LABYRINTHULOMYCETES. (3) In the MYXOBACTERIALES: a number of individual cells embedded in a slime matrix.

**pseudopodetium** (*lichenol.*) A vertical, fruticose, branched or unbranched, usually solid secondary thallus which develops by growth from the primary thallus and is thus a purely thalline (vegetative, somatic) structure (cf. PODETIUM); ascocarp initials

## pseudopodium

develop on the pseudopodietia. Pseudopodietia occur e.g. in species of PILOPHORUS and STEREOCAULON.

**pseudopodium** An extension of an amoeboid cell formed by extrusion of the cytoplasm (bounded by the plasmalemma). Pseudopodia are characteristically formed by protozoa of the SARCODINA; according to species, pseudopodia may function in locomotion and/or in feeding, and one or more may be formed at a time by a given cell. Various types of pseudopodia are formed by sarcodines. A *lobopodium* (lobose pseudopodium) is blunt-ended and generally broad, and often has a clear ectoplasmic area (the *hyaline cap*); lobopodia may be formed eruptively, i.e., by a burst of cytoplasmic movement, or more slowly by a steady cytoplasmic flow. A *filopodium* (filose or filiform pseudopodium) is slender, filamentous, sometimes tapered and sometimes branched, but lacks rigid axial elements (cf. AXOPODIUM) – although it may contain microtubules. Fine, filamentous pseudopodia which branch and anastomose to form a network are called *reticulopodia* or *rhizopodia*. In some sarcodines more or less fine ‘subpseudopodia’ may arise from a broader pseudopodial lobe (see e.g. ACANTHAMOEBA).

In e.g. *Amoeba proteus* (see AMOEBA) the lobose pseudopodia function in both feeding and locomotion. When a prey organism comes into the vicinity of a pseudopodium, the pseudopodium flows around it, initially forming a ‘cup’ (*food cup*) containing the prey; the plasmalemma eventually closes around the prey to form a FOOD VACUOLE. (cf. AXOPODIUM.) Locomotion in *A. proteus* involves the extension of pseudopodia which apparently adhere to the substratum; cytoplasm then continues to flow into one of the pseudopodia, which expands to accommodate it, and further pseudopodia are extended, etc. This type of locomotion is often regarded as typical ‘amoeboid movement’, although other forms of motility occur in other sarcodines. For example, in *Pelomyxa* the cell moves along by steady cytoplasmic flow without the formation of obvious pseudopodia. (See also HELIOZOEAE and TAXOPODIDA.) Apart from functioning in active motility, pseudopodia in some amoebae (e.g. *Vannella* spp) can apparently function as flotation devices; such amoebae can, under certain conditions, produce distinct ‘flotation forms’ characterized by fine, usually hyaline pseudopodia which radiate from the central cell mass.

The mechanism of pseudopodial movement is not understood. It appears to involve microfilaments of ACTIN which lie just beneath – and which interact with – the plasmalemma.

**pseudorabies** *Syn.* AUJESZKY'S DISEASE.

**pseudoraphe** See DIATOMS.

**pseudorinderpest** *Syn.* PESTE DES PETITS RUMINANTS.

**pseudorubella** *Syn.* EXANTHEM SUBITUM.

**pseudoseptum** See SEPTUM (b).

**pseudospores** See USTILAGINALES.

**pseudostem** See PHALLALES.

**pseudotemperate bacteriophage** A BACTERIOPHAGE which can establish PSEUDOLYSOGENY.

**pseudothecium** See ASCOSTROMA.

**Pseudotrebouxia** A genus of sarcinoid unicellular green algae (division CHLOROPHYTA) which occur as photobionts in many LICHENS. The cells are more or less spherical (up to ca. 30 µm in diam.). *Pseudotrebouxia* spp closely resemble TREBOUXIA spp except in that asexual reproduction occurs not only by the formation of zoospores and aplanospores but also by ‘vegetative cell division’, i.e., basically, the division of one cell into two non-motile vegetative cells, etc – the resulting cells remaining in contact (at least initially) to form sarciniform groupings. [*Pseudotrebouxia* species in lichens, and discussion of vegetative cell division: Lichenol. (1981) 13 65–86.]

**pseudotuberculosis** A self-limiting or fatal (septicaemic) disease of animals (especially rodents) due to *Yersinia pseudotuberculosis*; symptoms e.g.: mesenteric adenitis, chronic diarrhoea, internal caseous lesions. (Infected humans may have mesenteric adenitis or, if debilitated, septicaemia.) Wild animals form a reservoir of the pathogen.

**pseudotype** (*virol.*) A virus particle which, as a result of PHENOTYPIC MIXING, contains the genome of one virus and polypeptide(s) encoded by another virus; e.g., the genome of a replication-defective virus may be encapsidated by proteins encoded by a replication-competent helper virus.

**pseudotyping** (*genetic engineering*) A technique in which e.g. the envelope proteins of a retrovirus are replaced by the G glycoprotein of vesicular stomatitis virus; the pseudotyping of retroviruses enables them to infect a wider range of types of cell. [Example of use (in gene therapy): PNAS (1999) 96 10379–10384.]

Some viruses used for gene delivery (in GENE THERAPY) have the disadvantage that they infect *too many* types of cell. Thus, if a gene is to be delivered to a specific type of cell, then viruses with a wide spectrum of target cells may have to be administered in high doses in order to allow for losses during interaction with other types of cell; such high doses of virus may expose the patient to the risk of adverse reactions. One such virus with a wide tropism is adenovirus type 5; in vitro, plasmid-mediated modification of the virion's attachment site (pseudotyping) has been able to de-target the virus from its (widely expressed) host receptor, allowing the development of an engineered virion which is more specifically targeted [JV (2001) 75 2972–2981].

**pseudovirion** A ‘virion’ which contains only host-cell nucleic acid. (See e.g. TRANSDUCTION.)

**pseudovitellus** The mycetome of an aphid.

**pseudo-wild phenotype** See e.g. SUPPRESSOR MUTATION.

ψ Pseudouridine (see TRNA).

[PSI<sup>+</sup>] See PRION (sense 2).

**psicofuranine** (9-β-D-psicofuranosyladenine) An antitumour, antimicrobial NUCLEOSIDE ANTIBIOTIC from *Streptomyces hygroscopicus*. It (and its close relative *decoyinine*) inhibits GMP synthesis by mimicking the allosteric inhibition by adenosine of XMP aminase [see Appendix V(a)].

**psilocin** See HALLUCINOGENIC MUSHROOMS.

**Psilocybe** See AGARICALES (Strophariaceae) and HALLUCINOGENIC MUSHROOMS.

**psilocybin** See HALLUCINOGENIC MUSHROOMS.

**Psilolechia** See LECIDEA.

**psittacine beak and feather disease** A disease of psittacines due to an ssDNA circovirus; feather, beak and immune cells are killed and the birds may die of other infections.

**psittacosis** (parrot fever; ornithosis\*) An acute infectious disease which primarily affects birds – both psittacine (parrots, parakeets etc) and non-psittacine (e.g. pigeons, sparrows, canaries, domestic fowl) – but which is also transmissible to man; it is caused by *Chlamydia psittaci*. In birds, *C. psittaci* usually causes a mild or asymptomatic infection but can cause a fatal disease. The spleen and liver may be enlarged, with areas of focal necrosis; symptoms may include e.g. ocular and nasal discharge, weakness and diarrhoea. *C. psittaci* is present in the faeces, nasal secretions, feathers etc of infected birds. Man usually becomes infected by inhalation of dust from contaminated birds; person-to-person transmission is also known. Incubation period: 4–15 days. The disease may be mild and self-limiting, resembling influenza, but it can be fatal; symptoms may include e.g. fever, cough, headache, photophobia, myalgia, and lobular pneumonitis

with an alveolar and interstitial exudate (cf. PRIMARY ATYPICAL PNEUMONIA). *Lab. diagnosis*: serological tests. *Chemotherapy*: e.g. tetracyclines. [Review: BMB (1983) 39 163–167.]

\*Although the terms 'psittacosis' and 'ornithosis' are used by some authors as synonyms for the disease caused by *C. psittaci* in both psittacine and non-psittacine birds and in man, others reserve the term 'ornithosis' for the disease in (i) psittacine and non-psittacine birds (i.e., excluding man); (ii) non-psittacine birds and humans infected from non-psittacine birds; or (iii) non-psittacine birds only.

**Psora** See LECIDEA.

**psoralens** (furocoumarins) Three-ringed heterocyclic compounds found e.g. in certain fungi and tropical fruits. A psoralen binds intercalatively (see INTERCALATING AGENT) and non-covalently to DNA or RNA in the dark. On irradiation of this complex with light (365 nm) the psoralen becomes covalently linked to a pyrimidine residue in one strand; it may then react photochemically with a second pyrimidine to form a cross-link. Owing to the small size of a psoralen molecule, two pyrimidines can be cross-linked only when they are very close (e.g. on complementary strands in a double helix or a hairpin loop). Psoralens are useful in studies on the secondary structures of DNA and RNA molecules [ARBB (1981) 10 69–86].

**psoroptic mange** A disease of animals caused by mite bites (see e.g. SHEEP SCAB).

**pst operon** See PHO REGULON.

**PstI** A RESTRICTION ENDONUCLEASE from *Providencia stuartii*; CTGCA/G.

**PSTV** Potato spindle tuber VIROID.

**Psychrobacter** A genus of Gram type-negative bacteria formerly proposed as a member of the family Neisseriaceae [IJSB (1986) 36 388–391] but later classified within the family Moraxellaceae [IJSB (1991) 41 310–319].

Strains of *P. immobilis* are oxidase +ve and catalase +ve coccobacilli found e.g. in fish and processed meat products; most are psychrotrophic (optimum growth temperature: 20–25°C). GC% 44–46.

**psychrophile** An organism which grows optimally at or below 15°C, which has an upper limit for growth of ca. 20°C, and which has a lower limit for growth of 0°C or below [Bact. Rev. (1975) 39 144–167]. (This is currently the most widely accepted definition; however, some authors still use the term, very loosely, to include PSYCHROTROPHS.) Psychrophilic organisms include certain algae and fungi, a number of Gram-negative bacteria (e.g. some species of *Pseudomonas* and *Vibrio*), and a few Gram-positive bacteria (e.g. some *Clostridium* spp). [Ecology and physiology of psychrophilic bacteria: Book ref. 191, pp. 1–23.] (cf. MESOPHILE and THERMOPHILE.)

**psychrotroph** An organism which can grow at low temperatures (e.g. 0–5°C) but which has an optimum growth temperature >15°C and an upper limit for growth >20°C. (cf. PSYCHROPHILE.) Psychrotrophs include e.g. certain algae and fungi, and various Gram-negative and Gram-positive bacteria.

**pT181 plasmids** See INCOMPATIBILITY.

**Pterosperma** See MICROMONADOPHYCEAE.

**pterostilbene** A stilbene PHYTOALEXIN produced by the grapevine (*Vitis vinifera*).

**pteroylglutamic acid** *Syn.* FOLIC ACID.

**PTFE** Polytetrafluoroethylene (Teflon).

**PTLV** Primate T-cell leukaemia virus: see SIMIAN T-CELL LEUKAEMIA VIRUS.

**PTS** (phosphoenolpyruvate-dependent phosphotransferase system)

A TRANSPORT SYSTEM, found in both Gram-negative and Gram-positive bacteria, in which the substrate (e.g. a hexose, disaccharide or hexitol) is phosphorylated in a reaction which is an essential part of the transport process. The source of energy (and of phosphate) is normally phosphoenolpyruvate (PEP); the formula of PEP is given in Appendix I(a). (Certain enzymes can generate PEP from ATP or GTP.)

In members of the Enterobacteriaceae, sugars whose uptake is PTS-dependent ('PTS sugars') include glucose, fructose, mannose, mannitol, sorbitol, glucosamine, *N*-acetylglucosamine and *N*-acetylmannosamine. (cf. LACTOSE.) (Lactose is a PTS sugar e.g. in *Staphylococcus aureus*.)

Because sugars are often metabolized via their phosphate derivatives – e.g. glucose 6-phosphate in Appendix I(a) – phosphorylation during uptake is a positive aspect of PTS transport. (Note, however, that a *non-metabolizable* substrate may be phosphorylated and transported by a PTS – e.g. the sugar analogue methyl  $\alpha$ -glucoside can be transported by the glucose-PTS of *Escherichia coli* and of *Clostridium pasteurianum*.) (See also STREPTOZOTOCIN.)

A PTS consists of both cytoplasmic (soluble) and membrane-bound protein components; the early nomenclature for PTS components (enzymes I, II and III) has been somewhat modified. In the simplest case (mannitol uptake in *E. coli*: see diagram), PEP feeds energy and phosphate into the PTS by sequential phosphorylation of two soluble energy-coupling proteins: enzyme I (here designated I) and a histidine-containing protein, HPr (here designated H). (Genes encoding I and H occur in the same (*pts*) operon.) The phosphate and energy are transferred from H to a sugar-specific permease (the so-called II complex) in the cytoplasmic membrane; the permease includes a transmembrane component (IIC), involved in the binding and translocation of substrate, and two phosphorylation sites (IIA, IIB) – phosphorylation and *concomitant* transport (uptake) of mannitol apparently occurring only at the IIB site.

Uptake of glucose by PTS (see diagram) differs in that the IIA component is soluble – adding a further cytoplasmic step to the chain of phosphorylation.

Phosphorylated forms of components I and H have high free energies of hydrolysis (approximately that of PEP). The I and H components are not substrate-specific, i.e. they are required for the phosphorylation and transport of all PTS substrates; thus, mutation causing loss of one or both of these components will be pleiotropic, i.e. the mutant will be unable to transport any PTS-dependent substrate. In contrast, inactivation of a given II complex will affect the transport of only the relevant permease-specific substrate(s).

[PTS (review): Mol. Microbiol. (1994) 13 755–764.]

In enterobacteria, some complex II components apparently contain oxidizable sulphhydryl groups, and it seems that only reduced forms are active [Biochem. (1985) 24 47–51]; this may indicate an energy-dependent regulation of the PTS, and may account for the observed pmf-related regulation of PTS activity.

In some II complexes the components are grouped in other ways. For example, the fructose permease of enteric bacteria consists of a membrane-bound protein, containing IIC and IIB, and a separate protein containing the functions of both IIA and HPr. In *Rhodobacter capsulatus*, the fructose permease includes a single protein which carries out the functions of IIA, HPr and enzyme I.

## PTS regulation domain

PTS (phosphoenolpyruvate-dependent phosphotransferase system). Transport of mannitol and glucose across the cytoplasmic membrane (CM) by the PTS in *Escherichia coli* (simplified, diagrammatic); transport is from the periplasm (above) to the cytoplasm (below). Note that mannitol and glucose are taken up by different membrane-associated systems (permeases).

The source of energy for transport is phosphoenolpyruvate (PEP). Energy is fed into the system by the sequential transfer of phosphate (P) from PEP to enzyme I (shown here as I) and then to the HPr protein (shown here as H). In mannitol transport, phosphate is transferred from H direct to a membrane-bound permease (enzyme II complex, here designated II). The permease for mannitol consists of three domains: IIA, IIB and IIC. IIC is a hydrophobic, transmembrane domain which binds the specific substrate and appears to contain, or contribute to, a channel through which the substrate is translocated. The IIA and IIB domains each contain a phosphorylation site, but phosphorylation of the substrate seems directly to involve only the IIB domain.

In the glucose permease, IIA is a separate (cytoplasmic, soluble) protein; however, the sequence of phosphorylation is the same as that in the mannitol permease, i.e. IIA → IIB → substrate.

In all cases, phosphorylation of the substrate is an integral part of the transport mechanism.

Reproduced from *Bacteria*, 5th edition, Figure 5.12, page 91, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

In the proposed nomenclature of PTS permeases [JB (1992) 174 1433–1438], the mannitol permease of *E. coli* is designated IICBA<sup>Mtl,Eco</sup>, and the glucose permease is IICB<sup>Glc,Eco</sup> + IIA<sup>Glc,Eco</sup> (see diagram).

In some cases a cell responds chemotactically to substrates taken up by a PTS (see CHEMOTAXIS). Moreover, a PTS can control some aspects of carbon *utilization*; thus, PTS phosphate carriers (see diagram) can regulate the activity of certain operons involved in the catabolism of carbon sources – sometimes via regulator sites designated ‘PTS regulation domains’ (PRD) [Mol. Microbiol. (1998) 28 865–874] (see CATABOLITE REPRESSION).

**PTS regulation domain (PRD)** See CATABOLITE REPRESSION.

**pts operon** See PTS.

***Ptychodiscus*** See RED TIDE and BREVETOXINS.

**Pu** Purine (nucleotide).

**PU** Palindromic unit: see REP SEQUENCE.

**pubescent** Downy.

***Puccinia*** A genus of typically macrocyclic and heteroxenous rust fungi (class UREDINIOMYCETES) which characteristically form cupulate aecia, non-peridiate uredia, and pedicellate, two-celled teliospores. *Puccinia* species are parasitic on a wide range of plant hosts, including monocotyledonous and dicotyledonous species. See UREDINIOMYCETES for the life cycle of *P. graminis tritici*. (See also BLACK STEM RUST, BROWN RUST, CHRYSANTHEMUM WHITE RUST, CROWN RUST and YELLOW RUST.)

***Pucciniastrum*** See UREDINIOMYCETES and PERIDERMIOID.

**puerperal fever** (childbed fever; puerperal sepsis) An acute, febrile condition, following childbirth, due to infection of the uterus and/or adjacent regions – usually by streptococci but sometimes

by e.g. *Clostridium* spp; complications (e.g. septicaemia) may occur, and mortality rates are high in untreated cases.

**puerperal mastitis** See MASTITIS.

**puerperal sepsis** *Syn.* PUERPERAL FEVER.

**puffball** See LYCOPERDALES and GASTEROMYCETES (Tulostomatales).

**puffing (mycol.)** See ASCOSPORE.

**pul genes** See PROTEIN SECRETION (type II systems).

**pullorum disease** (bacillary white diarrhoea, BWD) An acute infectious POULTRY DISEASE caused by *Salmonella pullorum*; it affects mainly chicks, but also occurs e.g. in turkey poults and pheasants. Symptoms: e.g. lethargy, anorexia, white diarrhoea, weakness and neurological symptoms; lungs or joints may be affected. Mortality rates may be high. Survivors become chronic carriers: the pathogen localizes in the ovaries and infects a proportion of the eggs; chicks hatching from these eggs develop the disease, and infection can then spread to other chicks – either by ingestion of food contaminated with faeces from infected (or carrier) birds, or by inhalation of fluff from infected chicks. *Lab. diagnosis*: identification of *S. pullorum* from e.g. liver, spleen or ovaries. Carriers are detected by an agglutination test (cf. FOWL TYPHOID). *Treatment*: e.g. furazolidone, furaltadone.

**pullulan** An extracellular, water-soluble, linear D-glucan synthesized by *Aureobasidium (Pullularia) pullulans*; it consists predominantly of MALTOTRIOSE units linked by (1 → 6)- $\alpha$ -glucosidic bonds.

**pullulanase** See DEBRANCHING ENZYMES.

***Pullularia*** *Syn.* AUREOBASIDIUM.

**pullulation** Asexual reproduction by BUDDING.

**pulmonary adenomatosis (vet.)** *Syn.* JAAGSIEKTE.

**pulpwood spoilage** See PAPER SPOILAGE.

**pulpy kidney** An acute toxæmic disease of ruminants (especially lambs) caused by growth and toxigenesis by *Clostridium perfringens* type D in the intestines. Symptoms: diarrhoea, convulsions, paralysis, sudden death.

**pulque** A white, viscous, acidic, alcoholic Mexican beverage made by fermenting the juices of *Agave* spp. The alcohol is produced by *Saccharomyces cerevisiae* ('*S. carbajali*') and *Zymomonas mobilis*. Acidity and viscosity are contributed, respectively, primarily by *Lactobacillus plantarum* and dextran-producing strains of *Leuconostoc*. Pulque is rich in B vitamins. *Tequila* is made by the distillation of pulque. (See also WINE-MAKING; SPIRITS.)

**pulse-chase technique** A technique in which e.g. living cells are exposed to a pulse of labelled substrate for a fixed period of time – followed immediately by a high concentration of the unlabelled substrate (the 'chase' phase); the chase effectively stops further uptake/use of the labelled substrate, thus defining the duration of the pulse. The technique has been used e.g. to follow the intracellular movement of a secreted protein from the time of its synthesis to the time of secretion; for this experiment, the period of the pulse is increased in a stepwise manner.

**pulsed electric field (PEF)** A technique involving electric fields of typically >20 kV/cm applied in pulses of up to several  $\mu$ s (microseconds) for the inactivation of susceptible microorganisms in a liquid medium; exposure to PEF treatment appears to bring about irreversible structural damage to the cells. In one experiment, the use of 2500 pulses of a 30 kV/cm field at 50°C reduced the level of viable cells of *Mycobacterium paratuberculosis* in milk by ca. 5.9 log<sub>10</sub> cfu/ml [AEM (2001) 67 2833–2836].

This technique may have applications e.g. in the food industry.

**pulsed-field gel electrophoresis** See PFGE.

**pulverulent** Powdery.

**pulvinate** Cushion-like; forming a swelling.

**pulvomycin** See POLYENE ANTIBIOTICS (b).

**punctate** Having surface dot(s), pore(s) etc.

**punctiform** Dot-like.

**Punta Toro virus** See PHLEBOVIRUS.

**PUO** Pyrexia (fever) of unknown origin.

**pure culture** See CULTURE.

**purified protein derivative** See TUBERCULIN.

**purine nucleotide biosynthesis** See NUCLEOTIDE and Appendix V(a).

**purity plate** A plate inoculated from a given culture and subsequently incubated to determine whether the culture was pure or contaminated – the presence of two or more types of colony on the purity plate indicating a contaminated culture.

**puromycin** (6-dimethyl-3'-deoxy-3'-*p*-methoxyphenylalanylaminoadenosine) A NUCLEOSIDE ANTIBIOTIC obtained from *Streptomyces alboniger* or synthesized chemically; it is active against prokaryotes and eukaryotes. It acts primarily as an inhibitor of PROTEIN SYNTHESIS, acting as an analogue of the aminoacyl-adenyl portion of an aminoacyl-tRNA. When a peptidyl-tRNA occupies a ribosomal P site, puromycin can enter the A site and a peptide bond can be formed between the amino group of puromycin and the C-terminus of the peptide. However, puromycin does not have a hydrolysable ester bond like that linking the aminoacyl group to a tRNA, and puromycin binds only weakly to the ribosome; thus, nascent polypeptide chains (in which the C-terminus is blocked by puromycin) are released.

**purple bacteria** (1) Bacteria of the RHODOSPIRILLINEAE. (2) A category (= PROTEOBACTERIA – q.v.) within the domain BACTERIA originally distinguished on the basis of 16S rRNA sequence

analysis [SAAM (1985) 6 143–151]. Organisms in this category are believed to have evolved from photosynthetic bacteria similar to members of the Rhodospirillineae; they are divided into the alpha, beta, gamma, delta and epsilon subdivisions.

**purple liver** See LAVER.

**purple membrane** In some strains of *Halobacterium salinarum*: functionally and structurally differentiated, purple-pigmented regions of the cytoplasmic membrane which develop under microaerobic or anaerobic conditions in the light; purple membrane may occupy up to 50% of the total membrane area – the remaining cytoplasmic membrane (which contains red carotenoid pigments) often being called the 'red membrane'. The purple membrane utilizes light energy to effect transmembrane translocation of protons, thus generating or augmenting a *proton motive force* (pmf) (see CHEMIOSMOSIS); cells can therefore grow as phototrophs under anaerobic conditions (see HALOBACTERIUM).

The protein component of the purple membrane consists almost entirely of BACTERIORHODOPSIN (q.v.) but includes another retinal-containing purple pigment, HALORHODOPSIN, and (in at least some cases) SLOW-CYCLING RHODOPSIN. (Strains of *H. salinarum* which cannot synthesize retinal may form an apoprotein-containing 'white membrane'.)

The lipids of the purple membrane are similar to those in the remainder of the cytoplasmic membrane, but they include a glycosulpholipid which is apparently unique to the purple membrane.

While photocycling in bacteriorhodopsin causes an outward efflux of protons, photocycling in halorhodopsin appears to cause an inward pumping of chloride ions (rather than an outward pumping of sodium ions as was previously thought).

The combined activities of light-energized bacteriorhodopsin and halorhodopsin may account for the various ion fluxes across the membrane and for the complex pattern of changes in transmembrane pH differential.

When whole cells are illuminated, the steady-state or 'resting' membrane potential (typically ca. 100–110 mV) is increased by ca. 10–40 mV, and the 'resting' transmembrane pH differential (ca. 2 units at pH 5, ca. 0 units at pH 8) changes by 0–1 unit; the increased membrane potential serves to energize e.g. photophosphorylation (phosphorylation of ADP), uptake of potassium ions and efflux of sodium ions.

**purple non-sulphur bacteria** See RHODOSPIRILLACEAE.

**purple sulphur bacteria** See CHROMATIACEAE.

**purpura** (*med.*) A condition characterized by reddish or purple patches due to haemorrhage into skin or mucous membrane and underlying tissues. A pin-point-sized haemorrhage is called a *petechia*, a larger one is known as an *ecchymosis*.

**purse** (*mycol.*) See CYATHUS.

**purulent** Containing, consisting of, or forming PUS.

**pus** A thick, usually yellowish, fluid product of inflammation formed at the site of an infection. Pus contains proteins, leucocytes, cell fragments, and e.g. living and/or dead bacteria. (cf. BLUE PUS.)

**pustulan** A (1 → 6)- $\beta$ -D-glucan produced by *Lasallia* (*Umbilicaria*) *pustulata*.

**pustule** A small, raised, pus-filled skin lesion. (cf. VESICLE.)

**pusule** In many DINOFAGELLATES: an intracellular vesicular structure which opens to the exterior via a canal and a pore; it is believed to function in osmoregulation but is apparently non-contractile (cf. CONTRACTILE VACUOLE).

**putidaredoxin** See FERREDOXINS.

**putrefaction** The microbial degradation of proteinaceous materials with the formation of evil-smelling products such as amines

## putrescine

(e.g. cadaverine and putrescine formed by the decarboxylation of lysine and ornithine, respectively) and HYDROGEN SULPHIDE (from sulphur-containing amino acids). Putrefaction is typically an anaerobic process and may be carried out e.g. by proteolytic clostridia; however, certain pseudomonads can bring about the aerobic putrefaction of e.g. meat.

**putrescine** See POLYAMINES, DECARBOXYLASE TESTS and PUTREFACTION.

**Puumala virus** See HANTAVIRUS.

**pv.** Pathovar; see VARIETY.

**PVA** See POLYVINYL ALCOHOL FIXATIVE.

***pvdS* gene** See PYOVERDIN.

**PVP-iodine** See IODINE (a).

***PvuI*** See RESTRICTION ENDONUCLEASE (table).

**PWM** POKEWEED MITOGEN.

**Py** Pyrimidine (nucleotide).

**pyaemia** (pyemia) A particular form of SEPTICAEMIA in which *pyogenic* bacteria are disseminated via the bloodstream.

**pycnidiospore** A CONIDIUM formed in a PYCNIDIUM.

**pycnidium** A hollow, typically spherical, flattened, or flask-shaped fungal fruiting body (generally ca. 100–500 µm in size) within which conidia (= pycnidiospores) are produced, and which, at maturity, is – or becomes – open to the environment e.g. via one or more pores. Pycnidia, which may superficially resemble perithecia or cleistothecia, are formed by many members of the SPHAEROPSIDALES. According to species, a pycnidium may be thick-walled or thin-walled, unilocular or multilocular, black, brown or brightly coloured (e.g. orange or yellow), glabrous or setose; it may develop superficially or may be immersed – or partly immersed – within the substratum or within a fungal stroma. [Symphogenous development of pycnidia in *Chaetomella acutisetata*: CJB (1980) 58 1129–1137.]

**pycniospore** A mononucleate, haploid SPERMATIIUM formed in a pycnium (see UREDINIOMYCETES).

**pycnium** See UREDINIOMYCETES stage 0.

***Pyromonas*** A subgenus of TRYPANOSOMA within the SALIVARIA. *T. (P.) suis* occurs in wild and domestic pigs in parts of Africa (e.g. Zaire) and is transmitted by *Glossina* spp. The organisms are stout trypomastigotes, ca. 10–20 µm, in which there is a subterminal kinetoplast and a free flagellum.

**pycnosis** *Syn.* PYKNOSIS.

**pycnospore** An obsolete term for a pycnidiospore or a pycnospore.

**Pycnothyriales** An order of fungi (class COELOMYCETES) in which the vegetative mycelium and conidiomata may be superficial or immersed in the substratum; conidiomata may be e.g. multiloculate, and in some species each is elevated on a central columnar structure.

**pyelitis** See PYELONEPHRITIS.

**pyelonephritis** Inflammation of the kidney (nephritis) and the renal pelvis (pyelitis). (The renal pelvis is the region at the kidney–ureter junction.) Pyelitis and/or nephritis may be caused by infection with e.g. enterobacteria (particularly strains of *Escherichia coli*), staphylococci or streptococci; infection may occur either via the bloodstream or via the urethra, bladder and ureter. Symptoms usually include fever and pain in the loins, and there may be bacteraemia.

(See also CYSTITIS, GLOMERULONEPHRITIS, UPEC and URINARY TRACT INFECTION.)

**pyemia** See PYAEMIA.

**PYG medium** Peptone–yeast extract–glucose medium, used e.g. for culture of anaerobes. It contains peptone, yeast extract,

cysteine-HCl, NaCl, resazurin, and glucose (added after autoclaving), and may be used as a broth (PYGB) or as an agar medium (PYGA). [Recipe: Book ref. 53, p. 1428.]

**Py-GLC** PYROLYSIS GAS–LIQUID CHROMATOGRAPHY.

**pyknosis** (pynosis) (*histopathol.*) The shrinkage of a cell's nucleus, resulting in the formation of a smaller, densely staining body. (cf. KARYOLYSIS; KARYORRHEXIS.)

**pyo-** Prefix meaning *pus*.

**pyocin** (pyocine; aeruginocin) Any BACTERIOCIN produced by *Pseudomonas aeruginosa*; pyocins are bactericidal – log-phase target cells apparently being the most sensitive. R-type pyocins (MWt ca. 10<sup>7</sup>) resemble phage tails and are relatively insensitive to proteases; S-type pyocins (MWt ca. 10<sup>5</sup>) are amorphous and are sensitive to proteases.

*Pyocin typing*: see BACTERIOCIN TYPING.

**pyocyanin** (pyocyanine) A blue-green, water-soluble and non-fluorescent phenazine pigment synthesized by *Pseudomonas aeruginosa* from chorismate (an intermediate in the biosynthesis of aromatic amino acids; see Appendix IV(f)); it becomes red-purple when acidified. Pyocyanin has oxygen-dependent antimicrobial activity which appears to involve the (enzyme-independent) oxidation of NADH with production of SUPEROXIDE and H<sub>2</sub>O<sub>2</sub> [JB (1980) 141 156–163]; it also inhibits the beating of human respiratory cilia in vitro [JCI (1987) 79 221–229].

(cf. CYANOMYCIN; see also IRON.)

**pyoderma** Any purulent skin disease – e.g. IMPETIGO.

**pyofluorescein** *Syn.* PYOVERDIN.

**pyogenic** Able to cause formation of pus.

**pyomelanin** See PSEUDOMONAS (*P. aeruginosa*).

**pyorubin** See PSEUDOMONAS (*P. aeruginosa*).

**pyoverdin** (pyoverdine; pyofluorescein; 'fluorescein') Any of a range of yellowish, fluorescent, water-soluble pigments produced by certain species of *Pseudomonas* under iron-deficient conditions; the pyoverdins act as SIDEROPHORES.

A model for the iron-regulated induction of pyoverdin in *P. aeruginosa* proposes that, under iron-deficient conditions, the (regulatory) Fur protein dissociates from a transcriptional control site upstream of the *pvdS* gene, allowing synthesis of PvdS; PvdS is a sigma factor which promotes transcription of genes involved in the synthesis of pyoverdin [JB (1996) 178 2299–2313].

The pyoverdin of *P. fluorescens* contains a quinoline chromophore linked to a cyclic peptide; this compound represses synthesis of another siderophore, quinolobactin [AEM (2000) 66 487–492].

[Functional analysis of PvdS: JB (2000) 182 1481–1491.]

**PYR** A substrate (*N,N*-dimethylaminocinnamaldehyde) which is apparently hydrolysed by all strains of *Streptococcus pyogenes* but by no other streptococci. In an identification test for *S. pyogenes*, the organisms are grown aerobically on agar plates overnight at 35°C; when PYR is added to the surface growth, colonies of *S. pyogenes* become red, while those of other streptococci become yellow or do not change colour.

PYR is also hydrolysed by strains of ENTEROCOCCUS.

**Pyr(6–4)Pyo** See ULTRAVIOLET RADIATION.

**pyracarbolid** (2H-3,4-dihydro-6-methylpyran-5-carboxanilide)

An agricultural systemic ANTIFUNGAL AGENT which is active e.g. against various rusts, smuts, and *Rhizoctonia* spp.

**Pyramimonas** See MICROMONADOPHYCEAE.

**pyrazinamide** 1,4-Diazine carboxamide: a drug active against *Mycobacterium tuberculosis* in vivo (including cells within phagosomes) and (at e.g. pH 5.6) in vitro. *M. bovis* is not susceptible.

Pyrazinamide is a prodrug which is converted, *in vivo*, to the active compound pyrazinoic acid; conversion involves the enzyme pyrazinamidase, which is encoded by gene *pncA* in *Mycobacterium tuberculosis*. Most pyrazinamide-resistant clinical isolates of *M. tuberculosis* have been found to have mutations in the *pncA* gene.

Expression of *M. smegmatis* pyrazinamidase in mutant (pyrazinamide-resistant) *M. tuberculosis* confers hypersensitivity to pyrazinamide and related amides [JB (2000) 5479–5485].

**pyrazinoic acid** See PYRAZINAMIDE.

**pyrazophos** An antifungal ORGANOPHOSPHORUS COMPOUND which is active against various powdery mildews. It is readily absorbed by leaves and shoots, and is translocated within the plant; it is poorly absorbed by roots.

**pyrBI, pyrE genes** See OPERON.

**pyrenoid** A dense proteinaceous body which occurs within a CHLOROPLAST; in some cases a pyrenoid may be 'stalked' – protruding from the chloroplast but always contained by the chloroplast envelope. The pyrenoid appears to be the site of synthesis of storage polysaccharide; the enzyme RuBisCO has been isolated as the main protein component of the pyrenoids in some species.

**Pyrenomycetes** A class of ascomycetes characterized by the formation of unitunicate asci in a perithecium or a cleistothecium. The class is not recognized in most modern taxonomic schemes.

**Pyrenophora** See DOTHIDEALES.

**Pyrenula** See PYRENULALES.

**Pyrenulales** An order of saprotrophic and lichenized fungi of the ASCOMYCOTINA. Ascocarp: ascolocular and perithecioid (see ASCOCARP). Asci: bitunicate. Ascospores: multiseptate. Genera: e.g. *Acrocordia*, *Pyrenula*.

**Pyricularia** A genus of fungi of the HYPHOMYCETES; teleomorph: *Magnaporthe*. *P. oryzae*, the causal agent of rice BLAST DISEASE, forms a septate mycelium and gives rise to typically pyriform, commonly biseptate conidia.

**pyricularin** *Syn.* PIRICULARIN.

**pyridine haemochrome** See CYTOCHROMES.

**pyridine nucleotide coenzymes** NAD (q.v.) and NADP.

**pyridine nucleotide salvage cycle** See NAD.

**pyridoxal phosphate** See PYRIDOXINE.

**pyridoxamine** See PYRIDOXINE.

**pyridoxine** (pyridoxin; vitamin B<sub>6</sub>; pyridoxol) A water-soluble and photolabile VITAMIN: 2-methyl-3-hydroxy-4,5-di-(hydroxymethyl)pyrimidine; related compounds such as pyridoxal and pyridoxamine (bearing, respectively, –CHO and –CH<sub>2</sub>NH<sub>2</sub> at the 4-position) may also be referred to as 'vitamin B<sub>6</sub>'. The coenzyme form of the vitamin is *pyridoxal 5-phosphate* ('codecarboxylase'); *pyridoxamine 5-phosphate* is involved in some reactions. The coenzyme is important in amino acid metabolism – e.g., in reactions involving transamination, decarboxylation, racemization (interconversion of D- and L-amino acids), serine–glycine interconversion, etc.

Certain microorganisms (e.g. *Clostridium* spp, *Lactobacillus* spp, some yeasts, *Crithidia fasciculata*, *Tetrahymena* spp) require an exogenous supply of pyridoxine; the various derivatives are not necessarily equally effective in this respect.

**pyridoxol** *Syn.* PYRIDOXINE.

**pyriform** Pear-shaped.

**pyrimethamine** (2,4-diamino-5-(*p*-chlorophenyl)-6-ethylpyrimidine) A FOLIC ACID ANTAGONIST used – usually in combination with e.g. a sulphonamide – in the treatment of MALARIA and of toxoplasmosis and other coccidiosis; it is active against the trophozoite, but resistance tends to develop readily.

**pyrimidine dimer** See ULTRAVIOLET RADIATION.

**pyrimidine nucleotide biosynthesis** See NUCLEOTIDE and Appendix V(b).

**pyrimine** See SERRATA.

**Pyrocystis** See BIOLUMINESCENCE.

**Pyrodictium** A genus of chemolithoautotrophic prokaryotes (order THERMOPROTEALES) isolated from a submarine volcanic region. Growth occurs as a network of filaments associated with 'discs', each ca. 0.3–2.5 μm in diameter. Optimum growth temperature: 105°C. Growth occurs in up to 12% NaCl.

**Pyrodinium** See BIOLUMINESCENCE.

**pyrogen** (1) A fever-inducing agent. (2) LIPOPOLYSACCHARIDE.

**pyrogenic exotoxin C** See TOXIC SHOCK SYNDROME.

**pyrogram** See PYROLYSIS GAS–LIQUID CHROMATOGRAPHY.

**pyrolysate** See PYROLYSIS.

**pyrolysis** A technique, used e.g. in microbial taxonomy, in which a small sample of a microbial culture is thermally degraded, in a vacuum or in an inert atmosphere (e.g. nitrogen), to form a range of volatile low-MWt compounds characteristic of the organism(s); the products (*pyrolysate*) may be analysed by e.g. Py-GLC or Py-MS (see following entries). In *filament pyrolysers* the sample may be coated onto a platinum filament which is then heated by the transmission of an electric current. (See also CURIE POINT PYROLYSIS.) Laser pyrolysers have also been used.

**pyrolysis gas–liquid chromatography** (Py-GLC) An analytical technique, intended e.g. for the rapid characterization of microorganisms, in which microbial cells are subjected to PYROLYSIS and the pyrolysate components are separated by gas–liquid CHROMATOGRAPHY and recorded as a complex trace (*pyrogram*).

**pyrolysis–mass spectrometry** (Py-MS) An analytical technique, intended e.g. for the rapid characterization of microorganisms, in which microbial cells are subjected to PYROLYSIS and the pyrolysate is analysed by mass spectrometry.

**Pyronema** A genus of fungi (order PEZIZALES) which occur e.g. on burnt soils. The apothecium (commonly 1–2 mm diam.), which develops on a subiculum, may be white, pale orange or pinkish. Ascospores: uninucleate, colourless, eguttulate.

**pyronin** A red basic xanthene DYE.

**pyrophosphate** (inorganic pyrophosphate; PPI) Pyrophosphate (P<sub>2</sub>O<sub>7</sub><sup>4-</sup>) is involved in various metabolic reactions in both prokaryotic and eukaryotic organisms. In many organisms PPI is released from nucleoside triphosphates e.g. during the biosynthesis of nucleic acids and proteins; in some organisms it is synthesized by photophosphorylation (e.g. in *Rhodospirillum rubrum*) or OXIDATIVE PHOSPHORYLATION (e.g. in animal and plant mitochondria) involving a PROTON PPASE.

In e.g. *Propionibacterium freudenreichii* (formerly *P. shermanii*) and *Entamoeba histolytica*, PPI is used for the (reversible) phosphorylation of fructose 6-phosphate catalysed by PPI:phosphofructose dikinase – a reaction which appears to be important in the glycolytic pathway in these organisms. In DESULFOTOMACULUM (q.v.) PPI is used for the SUBSTRATE-LEVEL PHOSPHORYLATION of ADP; sulphate-reducing bacteria which lack the enzyme acetate:PPI phosphotransferase (e.g. *Desulfovibrio*) cannot use PPI in this way.

**pyrophosphotransferase** See STRINGENT CONTROL (1).

**Pyrosequencing**<sup>™</sup> A rapid method for sequencing short DNA templates based on detection of the pyrophosphate released when a series of (known) nucleotides sequentially extend a primer [principle, details: Science (1998) 281 363–365].

**Pyrrhophyta** *Syn.* PYRRHOPHYTA.

## pyrrolo-(1,4)-benzodiazepine antibiotics

**pyrrolo-(1,4)-benzodiazepine antibiotics** See ANTHRAMYCIN.

**pyrrolo-quinoline quinone** See QUINOPROTEIN.

**Pyrrhophyta** (Pyrrhophyta) A division of the algae which includes the DINOFLLAGELLATES and sometimes also the CRYPTOPHYTES.

**Pyrrsonympha** See OXYMONADIDA.

**pyruvate** An intermediate in a wide range of (aerobic and anaerobic) metabolic pathways; for examples of formation and fates of pyruvate see Appendices I, II, III and IV(b, e).

**pyruvate carboxylase** A BIOTIN ENZYME which is an important anaplerotic enzyme (see Appendix II (b)). [Structure: FEMS Reviews (1993) 104 330–332.]

**pyruvate dehydrogenase complex** See e.g. Appendix II(a).

**pyruvate synthase** See TCA CYCLE and REDUCTIVE TRICARBOXYLIC ACID CYCLE.

**pyruvic phosphoroclastm** See PHOSPHOROCLASTIC SPLIT.

**Pythium** A genus of aquatic and terrestrial fungi (order PERONOSPORALES) which include saprotrophs, parasites, and pathogens of higher plants (see e.g. DAMPING OFF), certain algae (see ALGAL DISEASES), and mammals (see EQUINE PHYCOMYCOSIS). (See also MYCOPARASITE.) The thallus is a well-developed, branching mycelium, and sporangia are borne on sporangiophores which typically resemble somatic hyphae.

The generalized life cycle of a representative species, *P. debaryanum*, is as follows. A reniform zoospore (flagella arising from the concave surface) encysts and later forms a germ

tube which penetrates the host plant – giving rise to both intercellular and intracellular mycelium; haustoria are not formed. Later, spherical or ovoid, non-deciduous sporangia develop, in terminal or intercalary positions, on undifferentiated sporangiophores. A sporangium germinates by extruding a thin tube which terminates in a thin-walled, bubble-like vesicle; the multinucleate contents of the sporangium flow into the vesicle where they differentiate into zoospores.

In sexual reproduction, a spherical oogonium and a smaller, club-shaped or elongated antheridium develop on the hyphae in a terminal or intercalary position. (Most species of *Pythium* appear to be homothallic, but at least one species, *P. sylvaticum*, is heterothallic.) Meiosis is generally thought to occur in the gametangia. A fertilization tube develops between antheridium and oogonium, and a male nucleus passes into the oogonium where fertilization occurs. The resulting thick-walled oospore germinates to form a germ tube which may terminate in a zoosporangium.

**Pythium red rot** See ALGAL DISEASES.

**Pythonella** See EIMERIORINA.

**pyuria** The presence of pus in the urine. ‘Sterile pyuria’ (= ‘abacterial pyuria’) is a condition in which pus is repeatedly found in samples of urine from which no bacteria can be cultured by routine methods; common causes are probably chlamydiae or mycoplasmas.

**pYV plasmid** See VIRULON.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see ‘Notes for the User’ at the front of the Dictionary.

# Q

**Q** (1) See TEMPERATURE COEFFICIENT. (2) QUEUOSINE. (3) Glutamine (see AMINO ACIDS).

**Q-band** (in ESR) See ELECTRON SPIN RESONANCE.

**Q bases** Bases formed by the modification of guanine in tRNA; they contain a pentenyl ring attached (via NH) to the methyl group of *N*-methylguanine. An example is queuine, the Q base of QUEUOSINE. (See also Y BASES.)

**Q-cycle** (protonmotive Q-cycle) A hypothetical pathway originally proposed (as part of the classical respiratory LOOP MODEL) to account e.g. for proton extrusion at Complex III of the mitochondrial ELECTRON TRANSPORT CHAIN; this pathway requires the presence of oxidized forms of ubiquinone (UQ and UQH<sub>2</sub>, respectively) and the free radical, semiquinone (UQH). In one form of the Q-cycle, an electron which enters the matrix side of Complex III is taken up, together with one proton from the matrix side, by UQH – forming UQH<sub>2</sub>. On passing to the cytoplasmic side, UQH<sub>2</sub> undergoes oxidation to UQH – one proton being extruded, and one electron passing back to the matrix side via *b*-type cytochromes; this electron, together with a proton from the matrix side, reduces UQ, thus regenerating UQH at the matrix side. At the cytoplasmic side, the UQH formed from UQH<sub>2</sub> undergoes oxidation to regenerate UQ, one proton being extruded, and one electron passing to cyt *c*<sub>1</sub>.

[Thermodynamic and kinetic considerations of Q-cycle mechanisms: JBB (1985) 17 51–64.]

**Q enzyme** A BRANCHING ENZYME which can convert amylose into an amylopectin-type polysaccharide; it cannot introduce branches into amylopectin. It occurs in certain algae and in higher plants.

**Q fever** In man, an acute disease caused by *Coxiella burnetii* (see COXIELLA). Infection may occur e.g. by the inhalation of contaminated dust or the ingestion of contaminated milk. After an incubation period of 2–3 weeks there is a sudden onset with headache, malaise, fever, muscular pain, and (often) respiratory symptoms (pneumonitis); there is no rash. Complications (e.g. endocarditis) may occur but the disease is rarely fatal. Diagnosis may include e.g. serological tests and/or attempts to culture *C. burnetii* from blood or sputum samples. Tetracyclines and chloramphenicol have been used therapeutically. Reservoirs of infection occur e.g. in sheep and cattle and in argosid and ixodid ticks. [Minireview: JMM (1996) 44 77–78.]

[Goat-associated Q fever in Newfoundland: EID (2001) 7 413–419.]

**QAC** See QUATERNARY AMMONIUM COMPOUNDS.

**Qalyub group** See NAIROVIRUS.

**Qiagen® plasmid kit** Any of several commercial kits (marketed by Qiagen GmbH, Hilden, Germany) used for isolating plasmids from bacteria (e.g. *Escherichia coli*); up to 20 µg of plasmid DNA can be isolated with the ‘mini’ kit, and up to 10 mg can be isolated with larger kits.

For *E. coli* (and other Gram-negative bacteria) the outer membrane is initially disrupted by a Tris–EDTA buffer. Then, controlled lysis of the cytoplasmic membrane with SDS (sodium dodecyl sulphate) permits release of plasmids and soluble proteins etc. (but not chromosomal DNA); contaminating RNA is digested with RNase A. SDS and proteins (but not plasmids) are precipitated in buffer, and a cleared lysate (containing the plasmids) is obtained by centrifugation. The spun lysate is passed through Qiagen anion-exchange resin; the resin is washed

to remove contaminants (and to remove any DNA-binding proteins), and the plasmids are eluted with buffer of appropriate pH and ionic strength. Plasmid DNA is precipitated with isopropanol; after centrifugation, the supernatant is discarded and the DNA is washed with 70% ethanol, air-dried, and suspended in buffer.

**qinghaosu** (artemisinin, artemisinin, or arteannuin) An orally administered ANTIMALARIAL AGENT obtained from qinghao (*Artemisia annua*): a Chinese medicinal herb which has been used in China for at least 2000 years for the treatment of malaria [Chinese Medical Journal (1979) 92 811–816, cited in BMB (1982) 38 197]. Qinghaosu, a sesquiterpene lactone endoperoxide, is structurally distinct from all other known antimalarials. [Structure and chemical synthesis: PAC (1986) 58 817–824.]

Qinghaosu is a rapidly acting blood schizonticide. It appears to be taken up selectively by infected erythrocytes [TRSTMH (1984) 78 265–270], and is apparently effective against *Plasmodium falciparum* (including strains resistant to chloroquine) and *P. vivax*. In culture, the drug rapidly inhibits protein synthesis and, subsequently, nucleic acid synthesis in *P. falciparum*. It seems that iron, within the parasite, activates the drug and gives rise to potent free radicals [TRSTMH (1994) 88 (supplement 1) 31–32].

Parenteral derivatives of qinghaosu, *artemether* and *artesunate*, have been used successfully for treating severe malaria e.g. in Indochina [BCID (1995) 2 309–330].

**QPCR** Quantitative PCR.

**qscR gene** See QUORUM SENSING.

**quadrulus** A four-rowed ribbon of cilia which runs, in a spiral, down the buccal cavity in *Paramecium*.

**quail disease** Ulcerative enteritis in chickens, quail and pheasants; the causal agent is *Clostridium colinum* [IJSB (1985) 35 155–159].

**quail pea mosaic virus** See COMOVIRUSES.

**quailpox virus** See AVIPOXVIRUS.

**Quantiplex™** See BDNA ASSAY.

**quarantine** (1) The isolation of an individual (usually an animal), e.g. prior to entering a country, in order to determine whether or not that individual is suffering from a particular infectious disease; the period of isolation should be equal to or longer than the longest incubation period of the suspected disease. (From Italian *quarantina* = 40 days.) (2) The isolation of an individual suffering from an infectious disease in order to prevent the transmission of the disease to others.

**quarg** (quark) A soft, unripened German cheese made from e.g. skim milk in much the same way as is cottage cheese (see CHEESE-MAKING (e)); a B-type LACTIC ACID STARTER and rennin are used to coagulate the milk protein. [AVL (1983) 49 83–84.]

**quartan malaria** See MALARIA.

**quasi-equivalence** See ICOSAHEDRAL SYMMETRY.

**quasispecies** Of a given RNA virus: a population or sample which, as a consequence of the *normal* rate of replication error, is genetically heterogeneous; the range of genomes present will depend e.g. on the effects of selection. [See JINF (1997) 34 201–203.]

**quaternary ammonium compounds** (QACs; quats; *syn.* onium compounds) A group of cationic surfactants used as ANTISEPTICS, DISINFECTANTS and PRESERVATIVES; they appear to act by

## quats

disrupting the cytoplasmic membrane and (at high concentrations) by denaturing proteins. A QAC may be regarded as an ammonium halide with four substituents: a long-chain alkyl group (C<sub>8</sub> to C<sub>18</sub> for high antimicrobial activity) and short-chain alkyl and/or benzyl or heterocyclic groups. QACs are bacteriostatic at low concentrations, bactericidal at high concentrations. They are typically more active against Gram-positive than Gram-negative bacteria, are reported to be fungistatic, trypanocidal, and active against certain viruses, but have little or no activity against *Mycobacterium tuberculosis*, *Pseudomonas aeruginosa* and bacterial endospores. They have a DILUTION COEFFICIENT of 1, and are inhibited e.g. by low pH, organic matter (serum, faeces etc), anionic detergents, soaps, phospholipids, and certain cations (e.g. Ca<sup>2+</sup>, Mg<sup>2+</sup>) which may compete for sites on the (negatively charged) cell surface. Various substances, (e.g. agar, glass) strongly adsorb QACs.

QACs are used e.g. for pre-operative skin cleansing and surgical dressings, and for the disinfection of equipment used in the food and dairy industries. They include e.g. *benzalkonium chloride* (= *Zephiran*, a mixture of alkyldimethylbenzylammonium chlorides) – used e.g. as a preservative in ophthalmic solutions; *benzethonium chloride* (a substituted benzalkonium chloride); *Cetrimide* (= *Cetavlon*, a mixture of hexadecyl-, cetyl-, tetradecyl- and dodecyl-trimethylammonium bromides); *cetylpyridinium chloride* (1-hexadecylpyridinium chloride); *CTAB* (cetyltrimethylammonium bromide); *Domiphen bromide* (dodecyldimethyl-2-phenoxyethylammonium bromide).

**quats** QUATERNARY AMMONIUM COMPOUNDS.

**Quayle cycle** *Syn.* RMP PATHWAY.

**Queensland tick typhus** In man, a tick-borne disease caused by *Rickettsia australis*.

**Quellkörper** Within the closed ascocarps of certain fungi: a gelatinous mass of cells believed to be involved in the rupture of the (mature) ascocarp wall.

**quellung phenomenon** A phenomenon – originally described by Neufeld for *Streptococcus pneumoniae* – in which the bacterial CAPSULE becomes more easily observable (appears darker) in the presence of antiserum specific for the capsular material. Antibodies mark the outer limit of the capsule by combining with its outermost layer. Since in the absence of antibodies the capsule may be invisible by microscopy, antibodies were originally thought to cause the capsule to swell (*Quellung* = swelling); in fact, little actual swelling appears to occur.

**quench-freezing** The process of rapidly FREEZING a specimen by plunging it into a suitable CRYOGEN.

**Querbalken** Lysozyme-sensitive crossbands in the prosthecae of species of *Asticcacaulis* and *Caulobacter*.

**quercetin** A mutagenic flavonol glycoside pigment widely distributed in plants; it binds non-covalently to and inhibits (F<sub>0</sub>F<sub>1</sub>)-type PROTON ATPASES.

**queuine** See QUEUOSINE.

**queuosine (Q)** A hypermodified guanosine derivative (7-[4,5-*cis*-dihydroxy-1-cyclopentene-3-aminomethyl]-7-deazaguanosine) present in the wobble position (see WOBBLE HYPOTHESIS) of tRNAs for aspartic acid, asparagine, histidine and tyrosine in most prokaryotic and eukaryotic organisms investigated (but not in *Saccharomyces cerevisiae*). The Q BASE queuine pairs with either C or U. Modification of G to Q in the wobble position of a tRNA anticodon can influence codon selection by the tRNA in vivo [EMBO (1985) 4 823–827]. In eukaryotes, the tRNA Q content is variable and correlates with certain developmental changes [e.g. in *Dictyostelium discoideum*: JGM (1984) 130 135–144].

**Quevedo disease** See POD ROT.

**quinacrine** A weakly basic, yellow fluorescent ACRIDINE dye (chromophore: 2-methoxy-6-chloro-9-aminoacridine) which has been used in the chemotherapy of e.g. malaria and giardiasis, and which is used as a chromosome stain.

**quinapyramine** An anti-trypanosomal agent used e.g. for the treatment of dourine.

**quinghaosu** See QINGHAOSU.

**quinic acid** See CHLOROGENIC ACID.

**quinidine** See QUININE.

**quinine** An alkaloid obtained from the bark of the *Cinchona* tree; the sulphate and hydrochloride are ANTIMALARIAL AGENTS effective against the intraerythrocytic stage (blood schizont) of the parasite (*Plasmodium*).

The diastereoisomer of quinine, *quinidine*, is used in place of quinine e.g. in the USA; compared to quinine it is less protein-bound but more cardiotoxic.

Quinine appears to interfere with the parasite's detoxification of ferriprotoporphyrin IX (FP). FP, formed when the parasite digests haemoglobin, is able to lyse the parasite unless it is detoxified by polymerization to insoluble granules of pigment (see HAEMOZOIN); such polymerization seems to involve a 'haem polymerase' [Nature (1992) 355 108–109], and the quinoline-type drugs (including e.g. quinine) possibly inhibit this enzymic activity. In a photoaffinity labelling experiment, quinine competitively inhibited the binding of a chloroquine analogue to specific proteins (perhaps 'haem polymerase'?) within parasitized erythrocytes – suggesting the presence of targets common to the quinoline-type antimalarial agents [JBC (1994) 269 6955–6961].

**8-quinolinol** *Syn.* 8-HYDROXYQUINOLINE.

**quinolobactin** A SIDEROPHORE, from *Pseudomonas fluorescens*, whose synthesis is repressible by pyoverdinin [AEM (2000) 66 487–492].

**quinolone antibiotics** A group of synthetic ANTIBIOTICS whose targets are GYRASE [gyrase-targeted antibiotics: TIM (1997) 5 102–109] and topoisomerase IV; each antibiotic contains a substituted 4-quinolone ring.

The original antibiotics in this group – cinoxacin, NALIDIXIC ACID, OXOLINIC ACID and piperidic acid – are active mainly against Gram-negative bacteria (but not against *Pseudomonas aeruginosa*); being rapidly excreted in urine, they have been used for treating UTIs caused by members of the Enterobacteriaceae. However, these drugs are not well absorbed when given orally and/or are readily inactivated in the body; they have a limited antibacterial spectrum, and resistance develops readily.

Antibiotics subsequently added to the group were fluorinated, piperazinyl-substituted derivatives (so-called *fluoroquinolones*); they include ciprofloxacin, enoxacin, norfloxacin, ofloxacin and pefloxacin. Compared to the earlier quinolones, these drugs have a wider spectrum of activity (being active against e.g. *Pseudomonas aeruginosa* and certain Gram-positive cocci, including MRSA), are effective at much lower in vivo concentrations and are more stable in the body; moreover, resistance to these drugs develops less readily. [Comparison of activities of various quinolones: JAC (1985) 16 475–484, 485–490. Laboratory and clinical evaluation of pefloxacin: JAC (1986) 17 (supplement B) 1–118.]

The fluoroquinolone *danofloxacin* has been used e.g. against *Mycoplasma bovis* in the treatment of CALF PNEUMONIA; little resistance to danofloxacin has developed in *M. bovis*, although significant levels of resistance have developed against other anti-*M. bovis* antibiotics, including oxytetracycline, spectinomycin and the macrolide tilimicosin [VR (2000) 146 745–747].

QUININE and some other antimalarial drugs (see MALARIA for further details of these and other antimalarials).

Reproduced from *Antimicrobial Drug Action*, Figure 7.3, page 123, R.A.D. Williams, P.A. Lambert & P. Singleton (1996) copyright Bios Scientific Publishers, UK (ISBN 1-872748-81-3) with permission from the publisher.

Some strains of *Acinetobacter baumannii* resistant to quinolone antibiotics (ciprofloxacin, nalidixic acid) have mutations in the *gyrA* (gyrase) and/or *parC* (topoisomerase IV) genes [RMM (1998) 9 87–97]; a similar mechanism of resistance has also been found in other species. Mutations in *gyrA* and topoisomerase IV are commonly found in the so-called *quinolone resistance-determining regions*: a particular sequence in the *gyrA* gene and a homologous sequence in *parC*. However, in *Streptococcus pneumoniae*, mutations in *gyrA* and *parE* (the gene encoding the other subunit in topoisomerase IV) have been found in a strain showing increased resistance to certain of the newer fluoroquinolones (*moxifloxacin*, *sparfloxacin*, *grepafloxacin*) but with only slight (or no) increased resistance to older fluoroquinolones (ciprofloxacin, pefloxacin) – and with greater sensitivity to novobiocin [AAC (2001) 45 952–955].

Other modes of resistance to quinoline antibiotics include reduced permeability of the cell envelope and efflux mechanisms. [Efflux-mediated resistance to fluoroquinolones in Gram-negative bacteria: AAC (2000) 44 2233–2241.]

The activities of some of the newer fluoroquinolones (including gatifloxacin, grepafloxacin, levofloxacin, moxifloxacin and trovafloxacin) have been ascertained against ciprofloxacin-resistant *Streptococcus pneumoniae*; these newer drugs were found to have improved activities compared with that of ciprofloxacin [AAC (2001) 45 1654–1659].

Various drugs (including gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin and moxifloxacin) are discussed in the Report of the 7th International Symposium on New Quinolones (Edinburgh, June 10–12th, 2001) [JAC (2001) 47 (supplement S1)].

(See also CcdB in F PLASMID.)

**quinomycins** See QUINOXALINE ANTIBIOTICS.

**quinone antifungal agents** A group of agricultural ANTIFUNGAL AGENTS which includes e.g. BENQUINOX, CHLORANIL, DICHLONE and DITHIANON.

**quinones** Aromatic dioxo (diketo) compounds which are typically coloured (usually yellow, orange or red) and are e.g. constituents of many natural pigments. Quinones are classified as benzoquinones, naphthoquinones etc according to the nature of the aromatic ring system. Microorganisms contain a range of

## quinoprotein

quinones, the nature of which can be a useful taxonomic feature [in bacteria: MR (1981) 45 316–354].

QUINONES. (a) A ubiquinone. (b) The reduced form of a ubiquinone: a hydroquinone. (c) A menaquinone (a vitamin K<sub>2</sub>). R =  $-\text{[CH}_2\text{.CH=C(CH}_3\text{).CH}_2\text{]}_n\text{H}$ .

Benzoquinones include plastoquinones (2,3-dimethylbenzoquinones) and ubiquinones (coenzymes Q); the latter are 2,3-dimethoxy-5-methyl-1,4-benzoquinones with a variable-length isoprenoid side-chain at the 6-position. (Ubiquinones are given various designations based either on the number of isoprenoid units or on the number of carbon atoms in the side-chain: e.g., a ubiquinone with a side-chain containing 8 isoprenoid units may be designated ubiquinone-8, UQ-8, UQ<sub>8</sub>, coenzyme Q<sub>8</sub>, or ubiquinone-40, UQ-40, etc.) [Book ref. 89.]

Naphthoquinones include e.g. various pigments and toxins (see e.g. NAPHTHAZARINS and XANTHOMEGNIN), as well as the K vitamins: derivatives of 2-methyl-1,4-naphthoquinone (vitamin K<sub>3</sub>, menadiene) in which the 3-position may be substituted with a mono-unsaturated phytyl chain (in vitamin K<sub>1</sub>, = phyloquinone) or with a variable-length polyisoprene chain (in vitamins K<sub>2</sub>, = menaquinones). (Menaquinone terminology resembles that for ubiquinones: hence, e.g., menaquinone-6, MK-6, MK-30, vitamin K<sub>2(30)}</sub> etc.) Some bacteria (e.g. members of the PASTEURACEAE) contain menaquinones which lack the 2-methyl group (2-demethyl-vitamins K<sub>2</sub>). In mammals, vitamins K are important components of the blood coagulation system; mammals cannot synthesize these vitamins, depending on diet (particularly green plants) and on the bacterial flora of the gut (particularly *Escherichia coli* and *Bacteroides* spp) for an adequate supply.

Quinones can be reversibly reduced to hydroquinones; they function e.g. in aerobic and anaerobic ELECTRON TRANSPORT CHAINS, in PHOTOSYNTHESIS, etc. For example, *E. coli* synthesizes both ubiquinone-8 and menaquinone-8 in proportions which depend on growth conditions; the quinones function as carriers of reducing equivalents between dehydrogenases and terminal enzyme complexes (cytochrome oxidases, nitrate reductase, or fumarate reductase) – ubiquinone reduction involving the gain of two electrons followed by the addition of two protons. The menaquinone is specifically required for FUMARATE RESPIRATION, and is also required for the anaerobic synthesis of e.g. pyrimidines (linking dihydro-orotate dehydrogenase with fumarate reductase in the anaerobic synthesis of uracil). (See also QUINOPROTEIN.)

**quinoprotein** A class of ENZYME in which the prosthetic group is pyrrolo-quinoline quinone (PQQ; 2,7,9-tricarboxy-1H-pyrrolo(2,3f)-quinoline-4,5-dione. Quinoproteins include e.g. methanol dehydrogenase (in which PQQ is called *methoxatin*), and glucose dehydrogenase (EC 1.1.99.17). [PQQ and quinoproteins in microbial oxidations: FEMS Reviews (1986) 32 165–178.] (See also EXTRACYTOPLASMIC OXIDATION and METHYLLOTROPHY.)

**quinovosamine** 2-Amino-2,6-dideoxyglucose: a TRIFOLIIN A-binding component of LPS in strains of *Rhizobium leguminosarum* biotype *trifolii*.

**quinoxaline antibiotics** Bifunctional INTERCALATING AGENTS ( $\phi$  ca. 48°), each having two quinoxaline 2-carboxylic acid chromophores linked by a cyclic octapeptide dilactone containing D- and L-amino acids; the peptide has a central cross-bridge (thioacetal in the *quinomycins*, disulphide in the *trioistins*). The two parallel chromophores project from the (relatively rigid) peptide ring and intercalate at sites two base pairs apart; the peptide ring seems to fit into the minor groove of the DNA. The quinoxalines *echinomycin* (= quinomycin A) and *trioistin A* differ only in the nature of the cross-bridge; both show some preference for GC-rich natural DNAs. TANDEM (des-*N*-tetramethyltrioistin A: a synthetic analogue of trioistin A) shows a marked preference for AT-rich sequences. Quinoxalines are antimicrobial and antitumour agents; they inhibit the chain elongation stage of DNA-directed RNA synthesis.

**Quinqueloculina** See FORAMINIFERIDA.

**quinsy** Peritonsillar ABSCESS (usually due to *Streptococcus pyogenes*) – a complication of TONSILLITIS.

**quintozene** (PCNB) Pentachloronitrobenzene, an agricultural antifungal agent used mainly for the treatment of soil; it is effective against a number of soil- and seed-borne diseases, e.g. DAMPING OFF, various rots of bulbs. Quintozone is insoluble in water and is used as a dust; it is very stable and has low volatility – hence it is very persistent in the soil. (cf. TECNAZENE, DICLORAN.)

**quinupristin/dalfopristin** (RP 59500; Synercid®) A bactericidal antibiotic (within the STREPTOGRAMIN group) which is active against e.g. most streptococci (including *S. pneumoniae*), MRSA, and *Enterococcus faecium* (*E. faecalis* is resistant); it has a long POST-ANTIBIOTIC EFFECT [Drugs (1996) 51 (supplement 1) 31–37]. [In vitro activity against *Staphylococcus aureus*: JAC (1997) 39 53–58.]

Quinupristin/dalfopristin (administered intravenously) has been conditionally licenced in Europe and the USA; it has been useful e.g. for treating vancomycin-resistant infections. Side-effects include arthralgia and myalgia.

[Quinupristin/dalfopristin (when to use?): JAC (2000) 46 347–350.]

**quindai-cai** See UNDARIA.

**quorum sensing** The phenomenon in which cells express particular characteristic(s) only when present as a population whose density is above a certain minimum (*quorum*). (Here, the 'density' of a population refers to the number of cells per unit volume.) Thus, in some cases, cells in a high-density population exhibit characteristics which are absent when the *same* cells are in a low-density population.

One example of quorum sensing is that of *Photobacterium fischeri* (sometimes referred to as *Vibrio fischeri*). *P. fischeri* can occur either as a free-living organism (in low-density populations), or as a symbiont in high-density populations within the light-emitting organs of certain fish; as a symbiont, *P. fischeri* produces a blue-green BIOLUMINESCENCE – whereas in the free-living state (low-density population) it produces little or no light.

(Bacterial bioluminescence is used by the fish to signal to one another.)

The mechanism of quorum sensing involves certain secreted molecules which, only in high-density populations of the secreting cell, reach a threshold concentration which is sufficient to trigger specific gene(s) within the cells. The secreted signalling molecule is referred to as an *autoinducer* because the cells themselves produce it.

Autoinducers are low-molecular-weight molecules. Different bacteria may produce different types of autoinducer that regulate different characteristics; however, in some cases different species may produce the same type of autoinducer for regulating different genes. A given species may produce a range of autoinducers to control the expression of various characteristics.

In many Gram-negative bacteria, the autoinducer is an *N*-acyl-L-homoserine lactone (AHL). [AHL-based quorum sensing; TIBS (1996) 21 214–219.] In general, AHLs appear to act by diffusing into the cell and binding to an appropriate cytoplasmic protein involved in regulating the transcription of relevant gene(s). In the case of *P. fischeri*, an AHL triggers the *lux* operon (see BIOLUMINESCENCE). [Evolution of LuxI and LuxR as regulatory molecules in quorum sensing; Microbiology (2001) 147 2379–2387.]

Strain CV026 of *Chromobacterium violaceum* is an inducer-negative mutant which produces VIOLACEIN when exposed to exogenous inducers, including all tested molecules of AHL and AHT (*N*-acylhomocysteine thiolactone) with *N*-acyl side-chains between C<sub>4</sub> and C<sub>8</sub>; this mutant strain can therefore be used as a biosensor for detecting a range of inducer molecules [Microbiology (1997) 143 3703–3711].

In *Pseudomonas aeruginosa* the genes encoding certain virulence factors are regulated by at least two quorum sensing systems – the *las* and *rhl* systems that involve different AHL autoinducers; these systems appear to act hierarchically, i.e. one system is always activated before the other [TIM (1997) 5 132–134]. The product of gene *qscR* appears to be a negative regulator of quorum-sensing-controlled genes; it probably acts by repressing gene *lasI* (which encodes *N*-3-(oxododecanoyl) homoserine lactone) [PNAS (2001) 98 2752–2757].

Quorum sensing has been reported to regulate expression of the type III PROTEIN SECRETION system in both EHEC and EPEC strains of *Escherichia coli* – this involving induction of genes in the LEE PATHOGENICITY ISLAND; regulation of the LEE operons involves an autoinducer encoded by gene *luxS*. To account for the unusually low infectious dose (low-density population) of *E. coli* O157:H7, it has been suggested that inducer may

be derived from non-pathogenic strains of *E. coli* in the gut [PNAS (1999) 96 15196–15201]. The existence of quorum sensing mechanisms in pathogens may permit therapy based on inhibition of autoinducers. Interestingly, the macrolide antibiotic AZITHROMYCIN has been reported to inhibit quorum sensing in *Pseudomonas aeruginosa* strain PAO1, the result (possibly advantageous e.g. in CYSTIC FIBROSIS patients [Lancet (1998) 351 420]) being an inhibition of the pathogen's production of virulence factors [AAC (2001) 45 1930–1933].

In *Burkholderia cepacia* there is evidence that swarming, and the maturation of biofilms, are aspects of the organism's physiology that are regulated by a quorum-sensing mechanism [Microbiology (2001) 147 2517–2528].

In *Escherichia coli* O157:H7 quorum sensing has been reported to be a global regulatory mechanism involved in basic physiological functions as well as in the formation of virulence factors [JB (2001) 183 5187–5197].

Interestingly, studies on *Pseudomonas aeruginosa* indicate that the stringent response (see STRINGENT CONTROL sense 1) can activate quorum sensing independently of cell density, a feature which may be important in nutrient-limited conditions during infection [JB (2001) 183 5376–5384].

In Gram-positive bacteria, the signalling molecules used in quorum sensing are generally *peptides* (= *pheromones*). Thus, for example, when cells of *Bacillus subtilis* grow to high density, at least two types of pheromone accumulate in the extracellular environment: ComX and CSF. ComX promotes competence in TRANSFORMATION by activating a TWO-COMPONENT REGULATORY SYSTEM; it causes autophosphorylation of a membrane-bound histidine kinase (ComP) which, in turn, phosphorylates (activates) the transcription factor ComA – a regulator of the *comS* gene that is required for competence.

The pheromone CSF appears to be one of a number of factors involved in the initiation of sporulation. It is taken up by cells via an ATP-dependent oligopeptide permease transport system in the cytoplasmic membrane; within the cytoplasm CSF apparently inhibits the activity of certain phosphorylases that would otherwise de-phosphorylate Spo0F~P, thereby promoting the phosphorelay and sporulation.

In *Enterococcus faecalis*, conjugation involves secretion of pheromones by potential recipients.

[Peptide signalling (review): TIM (1998) 6 288–294.]

In the (dimorphic) fungus *Candida albicans*, farnesol (a sesquiterpene alcohol) acts as a quorum-sensing molecule whose effect is reported to be inhibition of yeast-to-mycelium conversion [AEM (2001) 67 2982–2992].

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# R

**R** (1) RÖNTGEN (q.v.). (2) (in cell cycle) See CELL CYCLE.  
(3) Arginine (see AMINO ACIDS).

**R antigen** (streptococcal) *Syn.* R PROTEIN.

**R body** A refractile, intracellular structure which occurs e.g. in certain bacterial endosymbionts of protozoa (see CAEDIBACTER) and which appears to confer killer characteristics on the protozoan host cell. An R body consists of a proteinaceous ribbon, ca. 0.2–0.5 µm wide and ca. 10–15 µm in length, which is rolled up to form a cylinder; under negative phase-contrast MICROSCOPY it appears as a bright ring or (when viewed in section from the side) as a pair of parallel rods. Its presence within a bacterial cell is apparently associated with the presence of plasmid(s) and/or phage(s). R bodies appear to unroll in the food vacuoles of sensitive paramecia; unrolling appears to occur from the inside or outside of the coil according to the species of the bacterium of origin.

R bodies have also been found in free-living strains of *Pseudomonas* which are toxic for sensitive paramecia [Arch. Micro. (1979) 121 9–15] and in a free-living *Pseudomonas*-like bacterium [JGM (1986) 132 2801–2805].

**r-chromatin** Chromatin containing rRNA genes.

**R factor** (1) See R PLASMID. (2) Release factor: see PROTEIN SYNTHESIS.

**R-glucan** Alkali-resistant (i.e. alkali-insoluble) glucans of fungal CELL WALLS.

**R loop** (*mol. biol.*) A single-stranded loop of DNA formed when a short ssRNA molecule pairs with a complementary region of one strand of a dsDNA molecule, displacing the corresponding region of the homologous strand (the R loop). An R loop can be observed by electron microscopy using the KLEINSCHMIDT MONOLAYER TECHNIQUE. If the ssRNA used is a mature mRNA derived from a SPLIT GENE, an intron in the DNA – having no homologous region in the mRNA – will appear as a loop of dsDNA extruded between two R loops (each R loop corresponding to one of the two adjacent exons); thus, R-looping can be used e.g. to detect introns in genes. (cf. D LOOP.)

**r plasmid** See R PLASMID.

**R plasmid** (formerly R factor, drug resistance factor etc) Any PLASMID which encodes resistance to one or more ANTIBIOTICS and/or to other antimicrobial agents (including e.g. heavy metal ions). A bacterium containing an R plasmid may express resistance e.g. by synthesizing a (plasmid-encoded) enzyme which destroys/modifies an antibiotic (see e.g. CHLORAMPHENICOL, β-LACTAMASES) or which modifies the target site (see e.g. MLS ANTIBIOTICS), or by synthesizing a drug-resistant form of a target enzyme (see e.g. SULPHONAMIDES).

A conjugative (= transmissible) R plasmid also contains genes which specify the intercellular transfer of the plasmid by CONJUGATION (sense 1b) (see also RTF); a non-conjugative (= non-transmissible) R plasmid does not specify its own conjugal transfer but it may be 'mobilized' by a conjugative plasmid. (Some authors refer to a non-conjugative R plasmid as an 'r plasmid'.) R plasmids belong to various Inc groups (see INCOMPATIBILITY).

**R point** (in cell cycle) See CELL CYCLE.

**r-protein** Ribosomal protein: see RIBOSOME.

**R protein** (R antigen) (in streptococci) A cell-surface protein found in streptococci of groups A, B, C and G. R protein is

only moderately immunogenic and is apparently not associated with virulence. It occurs in two antigenically distinct forms: R28 (trypsin-resistant) and R3 (trypsin-sensitive). (See also M PROTEIN and T PROTEIN.)

**R strain** See SMOOTH–ROUGH VARIATION.

**r-strand** (in adenoviruses) See ADENOVIRIDAE.

**R-TEM β-lactamase** *Syn.* TEM-1 β-LACTAMASE.

**R1 plasmid** A low-COPY NUMBER, IncFII CONJUGATIVE PLASMID (MWt ca. 60000) which occurs in enterobacteria; it encodes resistance to e.g. ampicillin, chloramphenicol, sulphonamides and streptomycin. Replication is promoted, at the origin, by the (plasmid-encoded) RepA protein, and the frequency of plasmid replication is controlled by the regulation of RepA synthesis. The main negative control exerted on RepA synthesis is carried out by the *copA* product, an unstable, constitutively produced micRNA (see ANTISENSE RNA), of half-life ca. 1–2 minutes, which binds to the complementary sequence (*copT*) on the *repA* mRNA, thus inhibiting translation of the RepA protein; the inhibitory influence of the *copA/copT* system decreases with decrease in copy number – thereby providing a mechanism for stabilizing copy number. (CopA also has a role in INCOMPATIBILITY in IncFII plasmids.) It has been proposed that the level of *repA* expression is also affected by a region (designated 7k) within the *repA* leader sequence; translation of (i.e., the presence of ribosomes in) this region, which overlaps the *copT* sequence, is believed to counteract the negative control of the *copA/copT* system [EMBO (1987) 6 515–522].

**R6 plasmid** An enterobacterial IncFII CONJUGATIVE PLASMID (COPY NUMBER: 1–2); it encodes resistance to e.g. chloramphenicol, streptomycin, sulphonamides and mercury.

**R6K plasmid** A multicopy enterobacterial CONJUGATIVE PLASMID (ca. 38 kb) which carries genes specifying resistance to ampicillin and streptomycin. R6K apparently undergoes *sequential bidirectional replication* from any of three origins (designated α, β and γ), all of which are located within a 4-kb region of the plasmid. Replication initiated at an origin apparently proceeds first in one direction, stopping at a specific termination site (*ter*); re-initiation then occurs at the same origin and proceeds in the opposite direction to *ter*, thus completing replication of the plasmid.

Initiation of replication at any of the three origins requires a *trans*-acting R6K-encoded DNA-binding protein (the π or Pi protein) and a region within the γ-origin containing seven tandemly-arranged 22-bp direct repeats (ITERONS). Plasmids from which the γ-origin has been deleted cannot be replicated even when π is supplied in *trans*; the α- and β-origins each appear to have a minimum functional size of ca. 2 kb which includes the seven iterons in the region of the γ-origin. (Deletion of three or more of the iterons results in loss of plasmid replicability.) The π protein binds preferentially to the iterons and positively regulates initiation of replication from one of the origins (α, β or γ). At high concentrations, π can also play a role in the negative regulation of R6K replication, apparently by specifically repressing replication from the γ origin. (Experiments involving variation in the levels of π over a wide range suggest that the level of π in the cell is *not* responsible for controlling the copy number of R6K.)

The π protein can also bind to the promoter–operator region of its own gene (*pir*, located near the γ origin); this region

contains an 8th iteron together with a pair of imperfect inverted repeats. The  $\pi$ -binding site overlaps the RNA polymerase-binding site at the *pir* promoter, and at high concentrations  $\pi$  can act as a repressor of its own synthesis.

[Review: Book ref. 161, pp. 125–140; binding of  $\pi$  to R6K DNA: JMB (1986) 187 225–239.]

**R10 medium** RAPPAPORT-VASSILLADIS BROTH.

**R18 plasmid** See RPI PLASMID.

**R46 plasmid** An IncN PLASMID (ca. 52 kb) which encodes resistance to ampicillin, streptomycin, sulphonamides and tetracycline. (See also PARTITION and SOS SYSTEM.)

**R68 plasmid** See RPI PLASMID.

**R100 plasmid** (*syn.* NR1 plasmid; R222 plasmid) An Inc-FII enterobacterial CONJUGATIVE PLASMID (COPY NUMBER: 1–2) that encodes resistance to e.g. chloramphenicol, streptomycin, sulphonamides and mercury. (The tetracycline-resistance gene is carried on a TRANSPOSON – see entry for Tn10.) The R100.1 derivative is a DRD PLASMID.

**R222 plasmid** See R100 PLASMID.

**R1822 plasmid** See RPI PLASMID.

**Ra strain** See SMOOTH – ROUGH VARIATION.

**rabbit fibroma virus** See LEPORIPOXVIRUS.

**rabbit herpesvirus** See GAMMAHERPESVIRINAE.

**rabbitpox virus** See ORTHOPOXVIRUS.

**rabies** (hydrophobia; lyssa) An acute, almost invariably fatal disease of man and animals – particularly carnivores, though most mammals can be infected. The rabies virus (see LYSSAVIRUS) is transmitted (in saliva) mainly by the bite of a rabid animal. The virus remains at the site of infection for a time before entering peripheral nerves and travelling along the nerves to the CNS.

*Rabies in man.* Incubation period: usually 2–13 weeks, but may be 6 days to a year or more, depending e.g. on the distance between the site of infection and the CNS. Early symptoms are non-specific: fever, headache, malaise etc. These are followed by neurological symptoms, including excitability and pharyngeal spasms (triggered e.g. by attempts to drink or even by the sight of water – hence ‘hydrophobia’); periods of hyperactivity may alternate with periods of relative normality. Convulsions and paralysis precede death. (Occasionally, paralytic symptoms predominate, with little hyperactivity.) *Lab. diagnosis:* detection of the virus in saliva, CSF etc – e.g., by electron microscopy or by fluorescent antibody staining; when possible, confirmation of rabies in the animal which inflicted the bite – e.g., by postmortem detection of (pathognomonic) NEGRI BODIES and rabies virus. Rabies virus can be detected in brain samples by an rTPCR-based approach; an rTPCR–ELISA test has been evaluated on 60 isolates of rabies and rabies-related viruses [JVM (1997) 69 63–72]. *Treatment:* none is effective once the disease is established. Post-exposure prophylaxis includes thorough washing of the wound followed by treatment with both rabies antiserum (part of which is instilled directly into the wound) and rabies vaccine; pre-exposure vaccination may be given to individuals at special risk (e.g. veterinarians, animal handlers). Inactivated vaccines are used for human treatment; these include *duck embryo vaccine* (DEV) (prepared from virus grown in embryonated duck eggs), and *human diploid cell vaccine* (HDCV) (prepared from virus grown in cultures of human diploid embryo lung fibroblasts). These vaccines are safer than those prepared from animal nerve tissue (e.g. SEMPLE VACCINE).

*Rabies in animals.* Dogs and other carnivores (wolves, foxes etc) may initially show excitement, violence etc (‘furious rabies’), followed by depression and paralysis (‘dumb rabies’).

In cattle and horses, symptoms are variable. In vampire bats (important reservoirs of infection in Central and South America) only the dumb form occurs. Vaccines for use in animals may be live attenuated (see e.g. FLURY VIRUS) or inactivated. (cf. AUJESZKY'S DISEASE.)

**rac prophage** See RECF PATHWAY.

**race** (1) (*mycol.*) PHYSIOLOGICAL RACE. (2) A non-specific designation which may refer e.g. to a STRAIN or a VARIETY.

**racket mycelium** *Syn.* RACQUET MYCELIUM.

**racquet mycelium** (racket mycelium) In DERMATOPHYTES: mycelium composed of hyphal cells which have terminal swellings and which thus resemble long-handled tennis racquets.

**rad** Radiation absorbed dose: a unit of absorbed radiation equal to 100 ergs of energy absorbed by 1 g of material (0.01 joules absorbed by 1 kg). (See also GRAY and IONIZING RADIATION; cf. RÖNTGEN.)

**RadA protein** In members of the Archaea: a protein apparently analogous to the bacterial RecA protein [GD (1998) 12 1248–1253].

**radappertization** Irradiation of food with levels of IONIZING RADIATION sufficient to inactivate the spores of *Clostridium botulinum*. (cf. RADICIDATION; RADURIZATION.)

**Radar** See PROPICONAZOLE.

**radiation** (in disinfection and sterilization) See IONIZING RADIATION; MICROWAVE RADIATION; ULTRAVIOLET RADIATION.

**radicidation** Irradiation of food with levels of IONIZING RADIATION sufficient to inactivate certain non-spore-forming pathogens (e.g. *Salmonella* spp). (cf. RADURIZATION; RADAPPERTIZATION.)

**radioallergosorbent test** See RAST.

**radioautography** *Syn.* AUTORADIOGRAPHY.

**radioimmunoassay** (RIA) A highly sensitive IMMUNOASSAY by which antigens or antibodies are quantified using radioactive labelling.

*Antibody assay.* Essentially, the antiserum under test is allowed to react with excess homologous antigen (radiolabelled e.g. with <sup>125</sup>I), and the immune complex is separated from any uncombined antigen – e.g. by precipitation (as in the FARR TECHNIQUE); the amount of antigen in the immune complex is then determined from the level of radioactivity in the complex, and the amount of antibody can hence be calculated.

*Antigen assay.* This is based on the fact that the proportion of a fixed amount of radiolabelled antigen which combines with a fixed amount of homologous antibody depends on the amount of unlabelled antigen present: the more unlabelled antigen present, the smaller the proportion of labelled antigen – and the lower the level of radioactivity – in the immune complex. Thus it is possible to construct a standard curve for the amount of unlabelled antigen corresponding to given levels of radioactivity in the immune complex. In antigen assays, the antigen to be quantified is the unlabelled antigen, the amount of which can be derived from the standard curve. (cf. IMMUNORADIOMETRIC ASSAY.)

**radioimmunosorbent test** See RIST.

**radiolaria** A group of free-living, marine, mostly planktonic protozoa (superclass ACTINOPODA) in which the cells are typically more or less spherical (<100  $\mu$ m to several millimetres in diameter) or thimble-shaped, and are generally solitary, although some species form aggregates or colonies up to 10 cm or more across. Most radiolaria have a siliceous ‘skeleton’ consisting of a delicate internal latticed shell and/or an array of radiating spines. The cell characteristically contains a *central capsule*: a spherical membranous structure, concentric with the cell, which separates the ectoplasm (extracapsular zone) from the endoplasm

## radiolarian ooze

(intracapsular zone); the capsule is perforated by few to many pores. The endoplasm contains the nucleus or nuclei (according to species), mitochondria, food reserves, etc. The ectoplasm may comprise three more or less distinct regions. The *sarcomatrix*, next to the capsule, is rich in food vacuoles and appears to be the site of digestion. Next to the *sarcomatrix* is the *calymma*: a highly vacuolated region; the vacuoles increase the buoyancy of the cell, and the cell can apparently control its vertical position in the water by collapsing and regenerating these vacuoles. The *peripheral zone* of the ectoplasm gives rise to radially arranged axopodia and/or to an elaborate *rhizopodial network* consisting of branching and anastomosing protoplasmic filaments.

Radiolaria are classified (e.g. on the basis of skeletal structure and nature of the central capsule) into two classes: Phaeodarea and Polycystinea [JP (1980) 27 37–58]. In the Phaeodarea the skeleton, when present, is composed of a silicified organic material and usually consists of hollow spines and/or latticed shells. The capsular membrane is very thick and has three pores, the largest of which is called the *astropyle*, the other two (the *parapyles*) occurring more or less opposite the astropyle. A brownish mass of waste material (*phaeodium*) collects in the ectoplasm near the astropyle. Six orders are recognized; genera include e.g. *Astracantha* and *Aulacantha*. In the Polycystinea most species have a skeleton composed of solid siliceous elements which either form one or more latticed shells, with or without radiating spines, or occur as isolated spicules. The capsular membrane usually consists of polygonal plates and is perforated by many pores; in the order Nassellarida (e.g. *Eucoronis*, *Plagiacantha*, *Plagonium*) these pores are clustered in one region, whereas in the order Spumellarida (e.g. *Coccodiscus*, *Collosphaera*, *Thalassicolla*) they are uniformly distributed. [Radiolarian fine structure and silica deposition: Book ref. 137, pp. 347–379.]

Radiolaria typically feed on protozoa, small crustacea etc which are trapped by the axopodia/rhizopodial network. Many radiolaria contain endosymbiotic algae – commonly dinoflagellates, but sometimes ‘prasinophytes’ – which occur within vacuoles in the ectoplasm. Under certain conditions (e.g. prolonged darkness) some of these endosymbiotic cells may be digested. [Radiolarian symbioses: Book ref. 129, pp. 69–89.]

Reproduction occurs by binary or multiple fission. Small flagellated cells (‘flagellospores’) may be produced by some species, but the nature of these is uncertain; they may be gametes, or they may be escaped cells of endosymbiotic dinoflagellates.

Fossil radiolarian tests have been found e.g. in ocean deposits (e.g. *radiolarian ooze*, a deep-sea ooze containing 30% or more of radiolarian tests) and in certain sedimentary rocks. Fossil radiolaria date from the Precambrian onwards; they are useful in the biostratigraphy of Mesozoic and Cenozoic deep-sea sediments. [Stratigraphy of planktonic radiolaria: Book ref. 136, pp. 573–712.]

**radiolarian ooze** See RADIOLARIA.

**radiomimetic** Refers to a compound whose physiological effects (particularly mutagenic effects) mimic those of IONIZING RADIATIONS.

**Radiomycetaceae** See MUCORALES.

**Radiophrya** See ASTOMATIDA.

**radurization** Irradiation of food with levels of IONIZING RADIATION sufficient to inactivate the more sensitive spoilage organisms. (cf. RADICIDATION; RADAPPERTIZATION.)

**raffinose** A non-reducing trisaccharide:  $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  6)- $\alpha$ -D-glucopyranosyl-(1  $\leftrightarrow$  2)- $\beta$ -D-fructofuranoside.

Raffinose is second to sucrose as the most abundant free sugar in plants. It can be metabolized by many yeasts and fungi and by certain bacteria; the ability to ferment raffinose is used to distinguish between top- and bottom-fermenting strains of BREWERS' YEAST.

**ragi** A type of STARTER culture made in Asian countries by growing mould(s) on cakes of rice or wheat flour. A ragi is used as an inoculum in the preparation of various foods, and may contain e.g. species of *Mucor*, *Rhizopus*, *Neurospora*, various yeasts etc. (cf. ONCOM; KOJI.)

**Rahnella** A genus of bacteria of the ENTEROBACTERIACEAE, found in fresh water and occasionally in human clinical specimens. Cells are motile when grown at 25°C, non-motile at 36°C. VP +ve; MR usually +ve. [Book ref. 22, p. 513.]

**Ralfsia** See PHAEOPHYTA.

**Ramalina** A genus of fruticose LICHENS (order LECANORALES). Thallus: strap-like (but not dorsiventral) and erect or pendulous, attached to the substratum by a discoid holdfast. Apothecia: terminal and/or marginal. Species occur in unpolluted regions e.g. on coastal rocks (*R. polymorpha*, *R. siliquosa*) or on tree-bark (*R. farinacea*, *R. fastigiata*, *R. fraxinea*).

**Rambacterium ramosum** See CLOSTRIDIUM (*C. ramosum*).

**Ramon titration** A serological titration in which a constant volume of a given antigen solution is added to each of a number of serial dilutions of homologous antiserum; precipitation occurs most rapidly in that dilution in which antibody and antigen are present in OPTIMAL PROPORTIONS.

**Ramsay Hunt syndrome** HERPES ZOSTER affecting the facial nerve, causing pain in the ear and face.

**Ramularia** See HYPHOMYCETES.

**ramus** A branch. (See also PENICILLIUM.)

**Ranavirus** A genus of viruses (family IRIDOVIRIDAE) which infect amphibians. Type species: FROG VIRUS 3.

**rancidity** In certain lipid-containing foods: a form of spoilage characterized by the presence of organoleptically detectable amounts of the products of lipid autoxidation (see OXIDATIVE RANCIDITY) and/or of the products of the microbial hydrolysis of lipids (see e.g. BUTTER, CHEESE SPOILAGE).

**random amplified polymorphic DNA** See RAPD.

**random coil** See HELIX-COIL TRANSITION.

**random walk** A pattern of motility, exhibited e.g. by (peritrichously flagellated) enterobacteria, in which periods of smooth swimming are interrupted by episodes of tumbling (see FLAGELLAR MOTILITY for mechanism); tumbling causes a cell to adopt a new direction entirely at random, so that – in a uniform environment – cells move (‘walk’) randomly in three dimensions. Although tumbling results in a random change of direction, a cell can nevertheless bias the net direction of its motility in response to certain directional stimuli (see TAXIS) by increasing or decreasing the frequency of tumbling when travelling in (respectively) an unfavourable or favourable direction. During CHEMOTAXIS, for example, cells of e.g. *Escherichia coli* which encounter an unfavourable gradient of nutrients increase their frequency of tumbling – thus reducing the time they swim in an unfavourable direction; conversely, the tumbling response is repressed if a more favourable location is encountered, and a longer period of smooth swimming supervenes. Thus, there is a net movement towards a favourable stimulus and away from an unfavourable one – a type of tactic response known as a *biased random walk*.

**Ranikhet disease** *Syn.* NEWCASTLE DISEASE.

**RANTES** (chemokine). See CHEMOKINES.

**RapA phosphatase** See ENDOSPORE (sense 1).

**RapB phosphatase** See ENDOSPORE (sense 1).

**RAPD** Random amplified polymorphic DNA: a form of ARBITRARILY PRIMED PCR (q.v. for mechanism) which is used e.g. for TYPING. When typing strains by RAPD it is common to repeat the assay with each of a range of different primers because different primers produce different fragments (as they bind to different 'best-fit' sequences); this increases the chance of detecting differences between the strains.

RAPD has been used e.g. for typing strains of *Listeria monocytogenes* [AEM (1993) 59 304–308], *Staphylococcus haemolyticus* [LAM (1994) 18 86–89], *Campylobacter* spp [LAM (1996) 23 167–170], *Vibrio vulnificus* [AEM (1999) 65 1141–1144] and *Serratia marcescens* [LAM (2000) 30 419–421].

**raphe** A slit or fissure, e.g., that which develops in the pycnidium of *Chaetomella acutisetata* (allowing release of conidia) [CJB (1980) 58 1129–1137], or that present in the frustule in certain DIATOMS.

**Raphidiophrys** A genus of small uninucleate heliozoa (order CENTROHELIDA). The cell (ca. 20–60 µm diam.) has an outer gelatinous layer in which numerous siliceous spicules are embedded – particularly at the bases of the axopodia. *R. pallida* occurs among vegetation in fresh water.

**Raphidophyceae** See CHLOROMONADS.

**rapid lysis mutant** A mutant of BACTERIOPHAGE T4 (designated *r*) which does not show LYSIS INHIBITION in at least some host strains; such mutants form plaques which are larger and have sharper edges than those of wild-type (*r*<sup>+</sup>) strains. The *r* phenotype may result from a mutation in genes *r*I, *r*II (actually two genes, *r*IIA and *r*IIB) or *r*III. [*r*II genes: Book ref. 99, pp. 327–333.]

**rapid sand filter** See WATER SUPPLIES.

**Rappaport–Vassiliadis broth** (R10 medium; RV medium) A medium (containing tryptone, MgCl<sub>2</sub> and malachite green) used for the ENRICHMENT of salmonellae; the medium is inhibitory to lactose- and sucrose-negative organisms which can form colonies similar to those of salmonellae. [Review: JAB (1983) 54 69–76; evaluation of commercial RV media: J. Hyg. (1986) 96 425–429.]

**ras** Designation for a family of ONCOGENES first discovered in HARVEY MURINE SARCOMA VIRUS (*H-ras* or *Ha-ras*) and KIRSTEN MURINE SARCOMA VIRUS (*K-ras* or *Ki-ras*); cellular *ras* genes have been highly conserved during evolution and occur e.g. in humans, rodents and *Saccharomyces cerevisiae* [Book ref. 113, pp. 419–423]. The *ras* genes code for highly related proteins (generic designation: p21) containing 189 amino acid residues; p21 proteins have GTP-binding, GTP-hydrolysing, and autophosphorylating activities. A *ras* oncogene can be activated e.g. by chemical carcinogens; transforming *ras* genes can differ from normal cellular *ras* genes by a single point mutation which results in a single amino acid substitution involving the 12th or 61st amino acids in p21. [Human *ras* genes and transformation: Book ref. 110, pp. 291–313.]

**Ras superfamily** See G PROTEINS.

**raspberry cane blight** See CANE BLIGHT.

**raspberry diseases** See e.g. CANE BLIGHT, ELSINOE and GREY MOULD.

**raspberry leaf curl virus** See LUTEOVIRUSES.

**raspberry ringspot virus** See NEPOVIRUSES.

**raspberry vein chlorosis virus** See RHABDOVIRIDAE.

**RAST** (radioallergosorbent test) An IMMUNOASSAY used for detecting specific IgE antibodies. The allergen, bound to the surface of a paper disc, is exposed to the test serum and washed;

bound IgE is detected by the addition of radiolabelled anti-IgE antibodies.

**rat-bite fever** Either of two human diseases contracted from the bite of a rat or, less commonly, a cat, dog etc. One form (*Haverhill fever*) is caused by *Streptobacillus moniliformis*; symptoms include e.g. the development of a fluid-filled sore at the site of the bite, a skin rash, recurrent fever, lymphadenopathy, and more or less generalized arthritis. The second form (*sodoku*) occurs more commonly in Japan and other Eastern countries and is caused by '*Spirillum minus*' (see SPIRILLUM); symptoms resemble those of Haverhill fever, but there is usually no arthritis.

**rat leukaemia viruses** Ecotropic type C retroviruses (subfamily ONCOVIRINAE) which are apparently ubiquitous in rats; none is known to be leukaemogenic or to have any oncogenic potential. [Book ref. 114, pp. 101–104.]

**rat virus** See PARVOVIRUS.

**rate-zonal centrifugation** See CENTRIFUGATION.

**Ratkowsky plot** The square root of growth rate plotted against absolute temperature; in various bacteria, this plot shows a linear relationship over the full biokinetic range [JB (1983) 154 1222–1226].

**Rauscher virus (RV)** A virus complex consisting of at least two components: a replication-competent MURINE LEUKAEMIA VIRUS (Ra-MuLV) and a replication-defective SFFV (cf. FRIEND VIRUS); within ca. 14 days of infection of newborn or adult mice, RV induces splenomegaly and anaemia (erythroblastosis), followed after several weeks by the onset of lymphocytic leukaemia.

**raw water** See WATER SUPPLIES.

**ray body** (*Strahlenkörper*) A microgamete or an isogamete of *Babesia* or *Theileria*.

**ray fungus** Archaic term for an ACTINOMYCETE.

**razor-strop fungus** *Piptoporus betulinus*.

**RB** Reticulate body (see CHLAMYDIA).

**RBC** Red blood cell (erythrocyte).

**Rc strain** See SMOOTH-ROUGH VARIATION.

**RCF** (relative centrifugal field) See CENTRIFUGATION.

**RCM** REINFORCED CLOSTRIDIAL MEDIUM.

**Rd<sub>1</sub> strain** See SMOOTH-ROUGH VARIATION.

**Rd<sub>2</sub> strain** See SMOOTH-ROUGH VARIATION.

**RD-114 viruses** See FELINE LEUKAEMIA VIRUS.

**RDE** RECEPTOR-DESTROYING ENZYME.

**rDNA** DNA coding for rRNA.

**RE** RESTRICTION ENDONUCLEASE.

**Re strain** See SMOOTH-ROUGH VARIATION

**REA** See DNA FINGERPRINTING.

**reaction centre** In photosynthetic membranes: a type of pigment-containing complex, distinct from LIGHT-HARVESTING COMPLEXES, to which radiant energy is channelled and at which charge separation occurs (see PHOTOSYNTHESIS).

In algae and cyanobacteria, the photosynthetic membranes contain two types of reaction centre (RC). The RC in photosystem I includes a specialized form of CHLOROPHYLL *a* designated P<sub>700</sub> (indicating its absorption maximum of 700 nm); the RC chlorophyll represents only ca. 1/300th of the chlorophyll content of the membrane. The RC of photosystem II also appears to contain a chlorophyll *a* moiety (designated P<sub>680</sub> – again, to indicate its absorption maximum) together with e.g. phaeophytin *a*.

The RCs of several anoxygenic photosynthetic bacteria have been characterized. Thus, e.g. that in *Rhodospseudomonas sphaeroides* includes bacteriochlorophyll *a* (P<sub>870</sub>), bacterio-phaeophytin *a*, ubiquinone and ferrous iron; the RC in *R. viridis* includes bacteriochlorophyll *b*, bacteriophageophytin *b*, and

## reactivation

(apparently) a *c*-type cytochrome, while that in *Rhodospirillum rubrum* includes bacteriochlorophyll *a* (P<sub>870</sub>), bacteriopheophytin, ubiquinone, ferrous iron and spirilloxanthin.

**reactivation** (*virol.*) (1) (genetic reactivation) A phenomenon in which a DEFECTIVE VIRUS can produce infectious progeny virions in the presence of another (defective or non-defective) virus as a result of recombination between or reassortment of the two genomes. If only one of the two 'parent viruses' is defective, reactivation is called *cross-reactivation* or *marker rescue*; if both parents are defective it is called *multiplicity reactivation*. Obviously, multiplicity reactivation can occur only if the genetic lesions are present at different sites on the two genomes. [Book ref. 148, pp. 115–116.] (cf. NON-GENETIC REACTIVATION.)

(2) The re-establishment of replication by a virus previously in a latent (non-replicating) form – see e.g. HERPES ZOSTER.

**reactive arthritis** ARTHRITIS which commonly develops in certain genetically predisposed (HLA B27<sup>+</sup>) people after an acute infection with *Salmonella*, particularly *S. typhimurium* or *S. enteritidis*; in these people, certain microbial antigens – especially outer membrane components – seem to persist in the body and to provoke an inflammatory response in the joints. [Review: Lancet (1992) 339 1096–1098.]

**reactive lysis** (*immunol.*) The lysis of a cell as a consequence of the attachment to its surface of complex C5b67 (see COMPLEMENT FIXATION) which was formed at another site; lysis follows the development of the membrane attack complex.

Reactive lysis is also called *bystander lysis*.

**reactor** (1) (*biotechnol.*) *Syn.* BIOREACTOR. (2) (*med., vet.*) One who gives a reaction to a given test procedure, e.g. a SKIN TEST.

**reading frame** (*mol. biol.*) See GENETIC CODE. (See also OPEN READING FRAME.)

**Reading unit** (RU) A unit used in respect of the antibiotic NISIN; 40 RU correspond to ca. 1 µg of pure nisin.

**readthrough** (1) A phenomenon in which, during PROTEIN SYNTHESIS, polypeptide chain elongation is continued past a stop codon, an amino acid being inserted at the stop codon. Readthrough may occur as a result of an intergenic nonsense SUPPRESSOR MUTATION, but can also occur in the presence of certain normal tRNAs; thus, e.g., the A1 protein of bacteriophage Qβ (see LEVIVIRIDAE) is produced by occasional readthrough of a UGA stop codon at the end of the coat protein gene, translation continuing until a UAG codon 195 codons further on is reached.

(2) The continuation of TRANSCRIPTION through a transcription terminator. (See also ANTITERMINATION.)

**reagin** (1) *Syn.* REAGINIC ANTIBODY. (2) See STANDARD TESTS FOR SYPHILIS.

**reaginic antibodies** CYTOPHILIC ANTIBODIES which are elicited by an ALLERGEN and which can bind to the surface of MAST CELLS (see TYPE I REACTION). The most effective reaginic antibodies are of the IgE type, although IgG antibodies can also function in this way. (cf. REAGIN and HOMOCYTOTROPIC ANTIBODIES.)

**real-time PCR** See PCR, TAQMAN PROBES, Book ref. 221.

**reassortant virus** In a virus with a SEGMENTED GENOME: a hybrid virion which contains genome segments from different parents; such a virion is produced in a cell coinfecting with different (e.g. mutant) strains of a given virus. (See e.g. INFLUENZAVIRUS.)

**REBASE**<sup>®</sup> A source of information on RESTRICTION ENDONUCLEASES etc.: <http://rebase.neb.com/rebase/rebase.html>.

**recA gene** See RECA PROTEIN.

**RecA protein** A multifunctional protein (MWt ca. 37800) encoded by the *recA* gene in *Escherichia coli* and other enterobacteria. (*RecA*-like genes or gene products have also been detected e.g. in *Agrobacterium tumefaciens* [MGG (1986) 204

161–165], *Bacillus subtilis* [JBC (1985) 260 3305–3313], *Methylophilus methylotrophus* [Gene (1986) 44 47–53], *Vibrio cholerae* [MGG (1986) 203 58–63], and *Ustilago maydis* (the *rec1* gene product) [Cell (1982) 29 367–374].) In members of the Archaea, the RadA protein is homologous to RecA [GD (1998) 12 1248–1253].

The RecA protein plays an essential role in general RECOMBINATION, and can promote various interactions between DNA molecules (including synapsis, strand exchange and branch migration) provided that at least one of the DNA molecules is at least partly single-stranded. For example, in vitro, RecA can promote base-pairing between a ccc ssDNA molecule and its complementary strand in a (linear) dsDNA molecule; the ssDNA 'invades' the dsDNA molecule and displaces the homologous strand (a phenomenon known e.g. as 'single-strand assimilation'). This reaction is initiated when RecA binds stoichiometrically and cooperatively to ssDNA in the presence of ATP to form a helical nucleoprotein filament [structure: JMB (1986) 191 677–697] (*presynaptic stage*); polymerization is accelerated in the presence of SINGLE-STRAND BINDING PROTEIN (SSB protein) and is inhibited by ADP. The RecA–ssDNA complex then interacts with dsDNA to form a ternary dsDNA–ssDNA–RecA complex in which the dsDNA becomes extensively unwound. The ternary complex can be formed in the absence of homology; it is generally believed that a 'search' for homology between the ssDNA and dsDNA must then occur. Juxtaposition of complementary regions (*synapsis*) results in the formation of a nascent heteroduplex joint. Recent studies suggest that (contrary to an earlier view) the 'search' for homology is unlikely to involve a triplex DNA intermediate – but may involve unwinding of the target duplex coupled with local strand exchange; it also appears that the polarity of RecA–ssDNA does not affect its ability to interact with a circular target duplex [NAR (2001) 29 1389–1398].

RecA-promoted strand exchange can continue through regions of mismatched bases, past thymine dimers, and past deletions or insertions in one of the strands.

The single-strand assimilation reaction *per se* is probably of limited significance in vivo (cf. TRANSFORMATION). However, in vitro, the RecA protein can also promote pairing between two dsDNA molecules provided that there is a gap in one of them, a reaction which may resemble more closely a homologous recombination event in vivo; the necessary regions of ssDNA may be provided e.g. by the RECBC PATHWAY.

[Role of RecA in recombination: CSHSQB (1984) 49 507–580; mechanistic aspects of DNA strand exchange activity of RecA: TIBS (1987) 12 141–145.]

The RecA protein is normally synthesized at a low level in the cell, being repressed to this level by the product of the *lexA* gene. However, under certain conditions – e.g. in the presence of damaged DNA – the RecA protein becomes 'activated', acquiring the ability to trigger proteolytic cleavage of the LexA protein (thus inducing the SOS SYSTEM *q.v.*) and of the repressor proteins of BACTERIOPHAGE LAMBDA and other LAMBDROID PHAGES (thus initiating prophage induction).

**RecA\*** See SOS SYSTEM.

**recapitulation theory** See ONTOGENY.

**recB gene** See RECBC PATHWAY.

**RecBC pathway** A pathway for general RECOMBINATION in *Escherichia coli* and related bacteria; it appears to be the major pathway for recombination following CONJUGATION. The pathway requires the products of the *recA* gene (see RECA PROTEIN) and of the *recB* and *recC* genes, the latter two being components of a

multifunctional enzyme formerly known as the RecBC enzyme or exonuclease V. More recently, this enzyme (~330 kDa) has been re-designated the RecBCD enzyme.

The RecBCD enzyme carries out functions in one of two major pathways ('recombination machines') for homologous recombination in *Escherichia coli*. In this pathway the enzyme is responsible e.g. for repairing double-stranded breaks in DNA; repairs can be carried out only on *linear* substrates – including circular molecules with a double-stranded break.

The RecBCD enzyme has helicase and nuclease activities, and it also has a *synaptogenic* function (see later). One of the differences between the RecBCD pathway and the RecF pathway is that the former involves a single, multi-subunit enzyme while the latter involves the activities of a number of separate enzymes.

As in the RecF pathway, recombination can be *initiated* in the RecBCD pathway; in RecF, initiation is triggered e.g. by a single-stranded gap in the chromosome, while in the RecBCD pathway initiation is prompted e.g. by DNA damage involving a double-stranded break. Given a double-stranded break, the (ATP-dependent) RecBCD nuclease may degrade a 5' terminal, leaving a free (single-stranded) 3' terminal – to which molecules of the RecA protein bind, forming the *nucleoprotein filament*. (RecBCD mediates the *exclusion* of single-strand binding proteins from the 3' terminal; this is necessary in order to permit binding of RecA monomers.)

A nucleoprotein filament is apparently the initial structure formed in all cases of homologous recombination (including recombination mediated by RecBCD and RecF systems).

The nucleoprotein filament is believed to 'search' another (target) duplex for a sequence of nucleotides homologous to the sequence in the nucleoprotein itself. This may involve local unwinding of the target duplex. The juxtaposition of homologous sequences (*synapsis*) leads to the formation of a hybrid duplex (*heteroduplex*). Events may then proceed as described for the Holliday model: see RECOMBINATION.

Recombination via the RecBCD pathway is stimulated by the presence of certain sequences of nucleotides within the chromosomal DNA. For example, the *E. coli* chromosome has about 1000 copies of the sequence:

i.e. about one copy per 5 kb of DNA; these sequences, which are called chi ( $\chi$ ) sites, enhance homologous recombination in their vicinity.

The RecBCD enzyme has an affinity for chi sites and, as a result of interaction between RecBCD and a chi site, a chi site tends to be found at or near the 3' terminus of DNA in the nucleoprotein filament.

Chi-dependent activity has been reported in other enterobacteria, and e.g. in some species of the family Vibrionaceae, but appears to be absent in various other bacteria; it may be that different sequences of nucleotides play a similar role in other types of bacteria.

More recently it has been found that certain functions of the RecBCD and RecF pathways are interchangeable; if, for example, a null mutation occurs in the *recD* (nuclease) subunit of RecBCD then this function can be compensated for by the RecJ nuclease of the RecF pathway. [Interchangeable parts of the *Escherichia coli* recombination machinery: Cell (2003) 112 741–744.]

**recC gene** See RECBC PATHWAY.

**recE gene** See RECF PATHWAY.

**RecE pathway** See RECF PATHWAY.

**receptacle** (*mycol.*) See e.g. PHALLALES.

**receptive hyphae** *Syn.* FLEXUOUS HYPHAE.

**receptor-destroying enzyme** (RDE) An enzymic component of a virion which destroys the (virion-specific) surface receptors of the host cell. (See e.g. NEURAMINIDASE; cf. e.g. INFLUENZA VIRUS C.)

**receptor-mediated pinocytosis** See PINOCYTOSIS.

**recessive allele** See DOMINANCE.

**recF gene** See RECF PATHWAY.

**RecF pathway** A *recA*-dependent, *recBC*-independent pathway for general RECOMBINATION in *Escherichia coli*.

Components of the RecF pathway are used in *recBC* mutants of *E. coli* which have reverted to recombination proficiency as a result of a mutation in the *sbcb* gene (= *xonA* gene, encoding exonuclease I – an enzyme that degrades ssDNA from the 3' end). This pathway apparently involves (as well as *recA*) at least genes *recF*, *recJ*, *recN*, *recQ* and *ruv*, the first four of these genes are apparently from the RecF pathway.

Another pathway (= RecE pathway) involving components of the RecF pathway occurs in *recBC* mutants which have reverted to recombination proficiency by a mutation in *sbca* (a gene in a prophage designated *rac*); this pathway involves *recE* – encoding exonuclease VIII, an enzyme that degrades one strand of dsDNA (5'→3') – and *recA*, *recF* and *recJ*. The *sbca* mutation appears to induce RecE.

Apart from the instances mentioned above, the RecF pathway is itself a major 'recombination machine' in *E. coli* which e.g. repairs single-stranded gaps in the chromosome. Unlike the recBC pathway, its activity involves a number of separate proteins – some of which can compensate for functional deficiencies in the recBC enzyme [interchangeable parts of the *E. coli* recombination machinery: Cell (2003) 112 741–744].

At least some genes in the RecF pathway are inducible and are regulated by *lexA* (see SOS SYSTEM).

**recipient** Any cell or organism which receives genetic information e.g. by CONJUGATION, TRANSDUCTION or TRANSFORMATION.

**reciprocal recombination** A process of RECOMBINATION involving the mutual exchange of sequences by CROSSING OVER between the two participating nucleic acid molecules (or between two regions in the same molecule).

**recJ gene** See RECF PATHWAY.

**reckless DNA degradation** The rapid and extensive degradation of DNA, carried out by the RecBC nuclease, which occurs in cells of *recA* mutants of *Escherichia coli* on exposure to UV radiation or other DNA-damaging treatment.

**recN gene** See RECF PATHWAY.

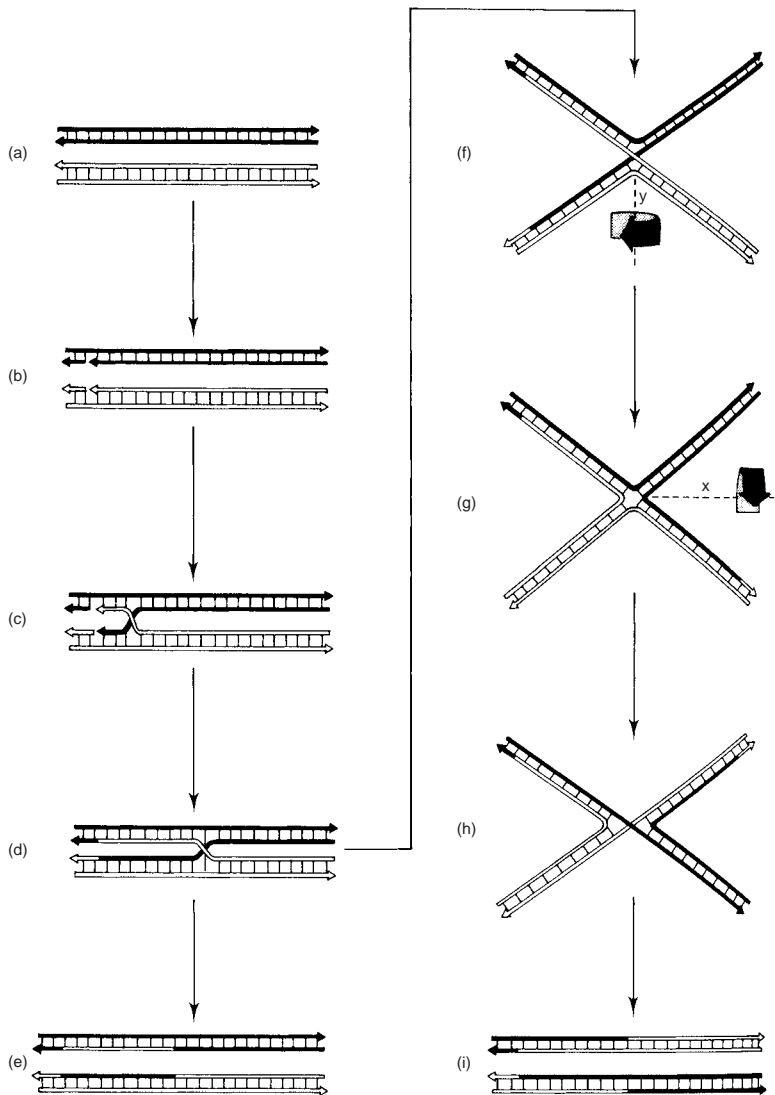

**recombinant** (1) (*noun*) An organism whose genome is a product of RECOMBINATION. (2) (*adj.*) Refers to an organism as in (1) above, or to a nucleic acid which has resulted from recombination; the term *recombinant DNA* is commonly used specifically for DNA molecules which have been constructed in vitro using various GENETIC ENGINEERING techniques.

**recombinant immunoblot assay** (RIBA) See HEPATITIS C.

**recombinase** See SITE-SPECIFIC RECOMBINATION.

**recombination** (genetic recombination) A process in which one or more nucleic acid molecules are re-arranged to generate new combinations or sequences of genes, alleles, or other nucleotide sequences; it may involve e.g. the physical exchange of material between two molecules, the integration of two molecules to form a single molecule, the inversion of a segment within a molecule, etc. There are several categories of recombination, including *general recombination* (see below), *SITE-SPECIFIC RECOMBINATION*, and *transpositional recombination* (see TRANSPOSABLE ELEMENT). (cf. ILLEGITIMATE RECOMBINATION.)

RECOMBINATION: Figure 1. *Holliday model* [Genet. Res. (1964) 5 282–304]. (a) Two homologous DNA duplexes; the 3' ends are identified by arrowheads. (b) A nick occurs at corresponding sites in one strand of each duplex. (c) One strand from each duplex begins to pair with the complementary strand of the other duplex to form a *heteroduplex joint*. (d) Ligation results in a branched 'half-chiasma' (a *Holliday structure* or *Holliday junction*); the position of the branch may move (*branch migration*) in either direction and may increase the length of the heteroduplex region (as shown). Resolution of the Holliday structure by nicking, exchange and re-ligation of the crossed strands results in the molecule shown at (e); in this case markers flanking the heteroduplex region are not exchanged (i.e., there is no *CROSSING OVER*). (f) Unstacking of the bases at the site of the joint allows the formation of a symmetrical 'chi structure' which can undergo the *isomerizations* shown at (g) and (h): rotation through 180° of the two lower arms about axis y gives the structure at (g), and a subsequent 180° rotation of the two right-hand arms about axis x gives the structure at (h). This results in the crossing of the previously un-nicked (outer) strands; resolution of the Holliday structure by nicking, exchange and ligation of these strands results in reciprocal exchange of flanking markers (*crossing over*) to give the recombinant duplexes shown at (i).

RECOMBINATION: Figure 2. *A. Meselson–Radding model (Aviemoire model)* [PNAS (1975) 72 358–361]. (a) Recombination is initiated by a nick in one strand of one of the two homologous duplexes (the ‘donor’ duplex). (All 3’ ends are identified by arrowheads.) (b) The 3’ end generated by the nick serves as a primer for DNA synthesis and is extended (shaded portion), displacing the 5’ end which then ‘invades’ a homologous region of the other (‘recipient’) duplex to generate a D LOOP. (c) The donor strand is ligated in place, and the D loop is degraded. (d) The heteroduplex region can be extended by further nuclease action on the recipient duplex and DNA polymerase action on the donor duplex. Ligation completes the Holliday structure. (e) Branch migration may occur (e.g. as shown). Resolution of the Holliday structure may occur by exchange between the inner strands, with no crossing over (f), or – following isomerization (see Fig. 1) – between the outer strands, resulting in crossing over (g).

*B. Double-strand break – repair model* [Cell (1983) 33 25–35]. (a) Recombination is initiated by nicks in both strands of one of the two homologous duplexes (the ‘recipient’ duplex). (b) The nicks are enlarged to gaps by exonuclease action, and (c) a free 3’ end thus generated ‘invades’ a homologous region of the donor duplex, giving rise to a D loop. (d) Extension of the 3’ end of the invading strand by repair synthesis enlarges the D loop until a sequence homologous to the second recipient fragment is exposed. (e) Further repair synthesis and ligation complete two Holliday junctions; branch migration may occur (not shown). Cutting and ligation at x and X, as in (f), or at y and Y (not shown) resolve the Holliday structures without crossing over; cutting and ligation at X and y, as in (g), or at x and Y (not shown), result in crossing over.

## recombination frequency

*General recombination (homologous recombination)* occurs only between two sequences which have fairly extensive regions of homology; the sequences may be in different molecules or in different regions of the same molecule. Early models for the mechanism of general recombination were basically of two types. *Copy-choice models* supposed that recombination occurs during nucleic acid synthesis and involves switching of the polymerase from one template strand to another (homologous) template strand to form a new recombinant daughter strand. *Breakage-and-reunion models* supposed that recombination involves strand breakage, exchange of the broken strands, and rejoining of the exchanged strands to complete the recombinant molecule(s); when strand exchange is symmetrical the process is called *reciprocal recombination* (see CROSSING OVER). The copy-choice model may be applicable to recombination in (RNA) viruses of the RETROVIRIDAE, but recombination between DNA molecules appears generally to occur by a breakage-and-reunion-type mechanism – often in conjunction with limited DNA synthesis; some models are depicted in Figures 1 and 2 (on pages 646 and 647).

In addition to homology, another requirement for homologous recombination is the availability of single-stranded DNA in at least one of the molecules. Moreover, the RECA PROTEIN has an essential role in the process, being able to promote various interactions between DNA molecules. In the Holliday model (Figure 1), a free end of ssDNA (derived from a nicked duplex) is juxtaposed to homologous ssDNA in the un-nicked strand of another nicked duplex, both strands then forming a hybrid duplex (*heteroduplex*) that may contain one or more mismatched bases; similarly, the free end displaced from the second duplex may base-pair with ssDNA in the first duplex – again, forming a heteroduplex (Figure 1(c)). The structure at (c) is called a *heteroduplex joint*. If each free end is now ligated, the result is a branched structure (a ‘half chiasma’) called a *Holliday structure*, *Holliday junction* or *chi structure* (from its  $\chi$ -like shape in electronmicrographs); this is a region where two duplexes are held together by two single strands crossing between the duplexes (Figure 1(d)). Each strand may continue to separate from its parent duplex and base-pair with ssDNA of the other duplex – so that the position of the branch migrates between the duplexes in the corresponding direction (*branch migration*): compare the position of the branch in Figure 1(c) and Figure 1(d). The extent of branch migration determines the final length of the heteroduplex. In *Escherichia coli* branch migration is driven by two ring-shaped helicases (one on either side of the Holliday junction) through which DNA passes; each helicase is a hexamer of the RuvB protein. Resolution of a Holliday junction (i.e. separation of duplexes) involves an endonuclease, RuvC, which cuts each strand, thus allowing ligation to occur in each duplex. In *E. coli*, RuvB and RuvC appear to interact co-operatively [EMBO (1998) 17 1838–1845].

The precise role of RecA in homologous recombination is not understood. Apparently, this protein initially binds to a free ssDNA strand to form a helical nucleoprotein ‘filament’ containing six monomers of RecA per helical turn. The filament must then ‘search’ the target DNA duplex for a region homologous to the ssDNA; the searching process appears to involve unwinding of the target duplex, and local strand exchange, leading to juxtaposition of homologous strands (*synapsis*) and the formation of a heteroduplex [NAR (2001) 29 1389–1398].

The region of heteroduplex DNA in a heteroduplex joint may be extensive. If the two strands in the joint carry different

alleles (e.g. one wild-type, one mutant) the heteroduplex will have a region of mispaired bases at the mutation site. Such mismatched regions may be recognized by a MISMATCH REPAIR system in which nucleotides are removed from one of the strands and replaced, by repair synthesis, using the other strand as template; thus, the nucleotide sequence of one strand is converted to a sequence complementary to that of the template, a phenomenon known as *gene conversion* (an example of *non-reciprocal recombination*). (In a bacterial merozygote, the term ‘gene conversion’ may be restricted to cases in which a sequence in the recipient’s DNA is converted to a sequence of the donor fragment.) Extensive mismatch repair within a long region of heteroduplex DNA can lead to the conversion of two or more adjacent alleles (*co-conversion*). (cf. INTERFERENCE (sense 2) and POST-MEIOTIC SEGREGATION.)

Although it was originally thought that general recombination could occur with equal probability between any regions of homology of a given length, it has been found that certain nucleotide sequences (‘recombinators’ or ‘recombinogenic sequences’) can specifically enhance general recombination in their vicinity: see e.g. *chi site* under RECBC PATHWAY.

In prokaryotes, general recombination may occur e.g. between donor and recipient DNA in a MEROZYGOTE, between homologous regions of different plasmids or of a plasmid and the chromosome, etc; in *Escherichia coli*, at least, several possible pathways of general recombination are known, all of which apparently require the product of the *recA* gene (see RECA PROTEIN and e.g. RECBC PATHWAY).

In species of the domain ARCHAEA the RadA protein appears to be equivalent, in function, to the RecA protein.

In viruses, general recombination may occur e.g. between genomes of viruses that are co-infecting the same cell (cf. REASSORTANT VIRUS). In certain bacteriophages recombination is apparently an essential step in the viral replication cycle (see e.g. BACTERIOPHAGE T4).

In eukaryotes, general recombination may occur in meiosis – and occasionally in mitosis: see PARASEXUAL PROCESSES.

**recombination frequency** Following general RECOMBINATION (e.g. after meiosis): the number of recombinant progeny, in respect of the alleles of two different genes, as a proportion of the total progeny (expressed as a percentage). Recombination frequency (RF) gives an indication of the relative positions of markers (genes or mutations) in the genome. An RF of 50% indicates that the markers segregate independently between progeny, e.g., they occur on different chromosomes; lower frequencies indicate that the markers occur on the same chromosome – the lower the frequency, the smaller the distance between them. (See also INTERFERENCE (sense 2) and RECOMBINATOR.)

**recombination nodule** See SYNAPTONEMAL COMPLEX.

**recombination repair** In e.g. *Escherichia coli*: a *recA*-dependent DNA REPAIR process which can repair e.g. thymine dimers or double-strand breaks. During replication of a dsDNA molecule containing e.g. a thymine dimer, the DNA polymerase stops at the site of the dimer; DNA synthesis may be re-initiated by primer synthesis at a site beyond the lesion, leaving a gap in the daughter strand opposite the dimer in the damaged parent strand. This gap can be filled by RECOMBINATION between the gapped daughter strand and an undamaged homologous region of the strand complementary to the damaged parent strand (*daughter-strand gap repair*). The resulting gap in the homologous parent strand can then be filled by repair synthesis, its daughter strand acting as template. The dimer is thus not removed, but is effectively ‘diluted out’. Genes apparently involved in daughter-strand gap repair include *recA*, *ruv*, *lexA* and *recF*; levels

of the products of these genes, and hence the potential for recombination repair, are increased by induction of the SOS SYSTEM.

*E. coli* also has an inducible *double-strand break repair* system which requires the presence of at least one other dsDNA molecule homologous to the damaged molecule. This system requires e.g. *recA* and *recN* (SOS genes) and possibly involves a mechanism similar to that shown in RECOMBINATION (Fig. 2).

**recombinational regulation** A type of genetic regulation in which intramolecular recombination acts as a mechanism for switching gene expression on and off. In several cases a segment of DNA is inverted by SITE-SPECIFIC RECOMBINATION catalysed by a specific recombinase: see e.g. PHASE VARIATION (in *Salmonella*), BACTERIOPHAGE MU (G segment) and BACTERIOPHAGE P1 (C segment). A similar system – involving an invertible *P* segment (formerly known as the e14 element) and a recombinase encoded by *pin* – occurs in the chromosome of *Escherichia coli* K12 strains. The amino acid sequences of the Hin, Gin, Cin and Pin recombinases show high degrees of homology, and the enzymes are functionally interchangeable.

Other types of recombinational regulation are known: see e.g. FIMBRIAE; MATING TYPE; NIF GENES; VSG. (See also SHUFFLON.)

**recombinator** (recombinogenic element) A 'recombinational hot-spot', i.e., a nucleotide sequence in a DNA molecule which enhances general RECOMBINATION in its vicinity. An example is the chi site in *Escherichia coli*: see RECBC PATHWAY.

**recombinogenic element** *Syn.* RECOMBINATOR.

**recQ gene** See RECF PATHWAY.

**rectus–flexibilis** See SPIRA.

**recurrent fever** *Syn.* RELAPSING FEVER.

**red algae** Algae of the RHODOPHYTA.

**red bread mould** See BREAD SPOILAGE.

**red clover mottle virus** See COMOVIRUSES.

**red clover necrotic mosaic virus** See DIANTHOVIRUSES.

**red clover vein mosaic virus** See CARLAVIRUSES.

**red core** (of strawberry) A soil-borne STRAWBERRY DISEASE that is caused by *Phytophthora fragariae*. Plants become obviously stunted, and within the darkened, rotting roots the stele becomes red or purplish-brown. *P. fragariae* forms resistant oospores which can remain viable in soil for many years; in wet conditions the oospores can germinate to form zoospores, aiding the spread of disease.

**red diaper syndrome** The (apparently non-pathological) presence of red-pigmented *Serratia* spp in the faeces of neonates and infants.

**red disease of pike virus** See RHABDOVIRIDAE.

**red drop** In algae and green plants: an abrupt decrease in PHOTOSYNTHESIS which occurs when the wavelength of incident monochromatic light increases beyond ca. 680 nm; photosynthetic activity is virtually abolished at ca. 700 nm. (cf. ENHANCEMENT EFFECT.)

**red leg** A (usually fatal) disease of frogs and other freshwater aquatic animals, caused by *Aeromonas hydrophila*. Symptoms include haemorrhagic skin lesions and septicaemia.

**red membrane** See PURPLE MEMBRANE.

**red mouth** A FISH DISEASE common in trout farms when fish are stressed e.g. by overcrowding. The causal agent varies but is often *Aeromonas hydrophila*. Symptoms: reddening of the mouth, throat, and gill opercula. (cf. ENTERIC REDMOUTH.)

**red nose** *Syn.* INFECTIOUS BOVINE RHINOTRACHEITIS.

**red pest** Either of two diseases of eels involving haemorrhagic ulceration of the skin. Pathogens: *Listonella anguillarum* in marine and brackish waters, *Aeromonas hydrophila* in fresh water. (See also FISH DISEASES.)

**red rice** *Syn.* ANG-KAK.

**red rot** (1) A SUGARCANE DISEASE caused by *Colletotrichum falcatum*; fungal attack is generally concentrated within the stem and midribs of the leaves, with reddening of internal tissues and withering of the tips and margins of the leaves.

(2) See ALGAL DISEASES.

**red rust** (algal rust) A disease of tea (*Camellia sinensis*) and various other commercially important plants (e.g. avocado, cacao, citrus, coffee, mango) caused by a species of CEPHALEUROS. The alga grows beneath the cuticle of the leaves and stems, resulting in the formation of elevated, velvety, reddish or orange-brown lesions. Infected leaves may exhibit a 'wound response', with necrosis of tissue around the lesions, which may help to prevent the spread of the alga. Infections of leaves and fruit generally cause little harm to the plant, apart from the unsightly lesions and – in heavily infected plants – premature leaf-drop. However, infections of young stems may be more serious, and plants may even be killed if the stems are completely girdled. [Review: Book ref. 129, pp. 173–204.] The disease has been controlled with copper sprays. (See also BLISTER BLIGHT.)

**red snow** In mountainous areas of western North America: snow which appears reddish owing to the abundant growth of *Chlamydomonas nivalis*, *C. nivalis* grows – in spring and summer – mainly near the surface of the melting snow; it forms the basis of a fairly extensive food-chain involving protozoa, rotifers, nematodes and crustaceans.

**red tide** (red water) A phenomenon in which regions of the sea or of an estuary become discoloured (often red or reddish) owing to extensive BLOOMS of certain algae – particularly DINOFLAGELLATES. (Blossoms of the cyanobacterium TRICHODESMIUM are sometimes called red tides.) For example, *Gonyaulax catenella* and *G. tamarensis* (= e.g. *G. excavata*, *Protogonyaulax tamarensis*, *Alexandrium tamarense*) are common causes of red tides on the coasts of North America, while *Ptychodiscus brevis* (= *Gymnodinium breve*) forms red tides in the Gulf of Mexico and along the Florida coast. Blossoms of *G. tamarensis* are seasonal; evidence has been obtained for the existence of an endogenous annual 'clock' (circannual rhythm) in *G. tamarensis* from deep coastal waters [Nature (1987) 325 616–617].

A red tide can cause massive mortalities in fish and other aquatic animals – due to oxygen depletion and/or to the production of various toxins (e.g. BREVETOXINS, GONYAUTOXINS, SAXITOXIN). These toxins can also cause poisoning in man, particularly when shellfish from affected waters are eaten (see *paralytic* SHELLFISH POISONING).

**red vent disease** *Syn.* ENTERIC REDMOUTH.

**red wasting disease** See ALGAL DISEASES.

**red water** (1) (of calves) An acute, febrile, often fatal disease of young calves, characterized by jaundice and haemoglobinuria; it is caused by *Leptospira interrogans* serotype *pomona* (cf. LEPTOSPIROSIS).

(2) Any of various diseases characterized by haemoglobinuria. (See also REDWATER FEVER.)

(3) *Syn.* RED TIDE.

**red water fever** See REDWATER FEVER.

**redox couple** See REDOX POTENTIAL.

**redox dye** See REDOX POTENTIAL.

**redox potential** (oxidation–reduction potential;  $E_h$ ;  $E$ ) A measure of the tendency of a given system to donate electrons (i.e., to act as a reducing agent) or to accept electrons (i.e., to act as an oxidizing agent); the  $E_h$  of a given system may be determined e.g. by measuring the electrical potential difference between that system and a standard hydrogen electrode whose potential is,

## reduction division

by convention, arbitrarily taken to be zero volts. ( $E_h$  may be recorded in volts (V) or in millivolts (mV).) The redox state of certain microbial components can determine their activity: see e.g. TRANSPORT SYSTEMS.

A *redox couple* is a pair of mutually interconvertible substances (ions and/or atoms or molecules) which are present, in a given system, in proportions which can be altered by the addition or removal of electrons (and, in some cases, protons). An example is the  $Fe^{2+}/Fe^{3+}$  couple ('iron electrode'). A solution containing only ferric ions is fully oxidized; such a solution has no reducing power – but it has maximum oxidizing capacity and, by convention, it is said to have the highest (most positive)  $E_h$  for the  $Fe^{2+}/Fe^{3+}$  system; conversely, a solution containing only ferrous ions has maximum reducing power and the lowest possible (most negative)  $E_h$  for the system. Solutions containing both ferric and ferrous ions have intermediate values of  $E_h$ ; the actual  $E_h$  in a given system depends e.g. on the ratio of *activities* (i.e., effective concentrations) of the two species of ion. If electrons are added to the  $Fe^{2+}/Fe^{3+}$  system, some or all of the  $Fe^{3+}$  ions are reduced, and the  $E_h$  falls to a lower value; similarly, removal of electrons raises the  $E_h$ .

Other redox couples include e.g. oxidized cytochrome/reduced cytochrome,  $NAD(P)^+/NAD(P)H$ , and  $H^+/1/2 H_2$ .

*Standard redox potential* (half-reduction potential; mid-point potential;  $E_0$ ;  $E^0$ ;  $E_m$ ). In any redox couple: when the ratio of the activities of the reduced and oxidized species is 1:1, the  $E_h$  (relative to the standard hydrogen electrode) is referred to as the standard redox potential,  $E_0$ , of that couple. The value of  $E_0$  varies with pH; the  $E_0$  at pH 7 is usually written  $E_0'$  or  $E_m.7$ . (For the hydrogen electrode,  $E_0$  at pH 0 is 0 V, while  $E_0'$  is  $-420$  mV.)

$E_0$  can be used to calculate the  $E_h$  of a given redox couple when the ratio oxidized:reduced species is not unity:

$$E_h = E_0 - \frac{RT}{nF} \log_e \frac{\text{activity of reduced species}}{\text{activity of oxidized species}}$$

where R is the gas constant (8.31 J/mol/degree abs.); T is the absolute temperature; F is the Faraday (96,490 C/mol); and n is the number of electrons transferred to/from each atom/ion/molecule – e.g. 1 in the  $Fe^{2+}/Fe^{3+}$  system.

$E_0$  can also be used to predict possible interactions between redox couples; thus, e.g. a given redox couple may oxidize a second of lower (less positive, or more negative)  $E_0$ . A redox system which can maintain a given  $E_h$ , within certain limits, in the presence of other redox couple(s) is referred to as a *poising system*; in a redox couple dominated by a poising system, the ratio oxidized:reduced species adjusts to conform to the imposed  $E_h$ .

*Measurement of  $E_h$* . The most accurate determination of  $E_h$  involves the use of a hydrogen electrode (or other standard electrode). The hydrogen electrode consists of a suitably prepared platinum plate immersed in 1.228 N HCl (activity of  $H^+ = 1$  gram ion/litre); when a stream of hydrogen gas (under standard conditions) impinges on the plate the following equilibrium is set up:

and the potential difference between plate and acid is taken to be zero volts. The potential difference between the hydrogen electrode and a given redox couple (i.e. the  $E_h$  of the given couple) can be measured by a potentiometric (zero-current) method – i.e. a method which does not disturb the equilibrium in either redox couple.

Certain dyes (*redox dyes*, or *indicators*) can indicate  $E_h$  by changing from a coloured to a colourless state (and vice versa) within a given  $E_h$  range; thus, e.g. a dye may become completely colourless (at pH 7) when the  $E_h$  is  $\leq$  ca.  $-40$  mV (e.g. METHYLENE BLUE), ca.  $-70$  mV (e.g. toluidine blue), ca.  $-110$  mV (e.g. resazurin), and ca.  $-310$  mV (e.g. phenosafranin). (See also TETRAZOLIUM.)

*$E_h$  of microbiological media*. In general, an obligate ANAEROBE can grow only on or in media which are at or below a certain value of  $E_h$ . For this reason media are often *poised* at a certain  $E_h$ ; poisoning is analogous to buffering in the context of pH – i.e., while the  $E_h$  produced depends on the ratio oxidized:reduced poising agent, the stability of  $E_h$  is influenced by the absolute amount of poising agent in the medium. Poising agents used in media include e.g. ASCORBIC ACID, cysteine hydrochloride and thioglycollate.

**reduction division** *Syn.* MEIOSIS.

**reductive carboxylic acid cycle** *Syn.* REDUCTIVE TRICARBOXYLIC ACID CYCLE.

**reductive pentose phosphate cycle** *Syn.* CALVIN CYCLE.

**reductive tricarboxylic acid cycle** A pathway for  $CO_2$  fixation in certain prokaryotic AUTOTROPHS (mainly members of the Chlorobiaceae – cf. SULFOLOBUS). The pathway is effectively the reverse of the TCA CYCLE [see Appendix II], one molecule of acetyl-CoA being formed for every two of  $CO_2$  fixed; the irreversible steps of the TCA cycle are bypassed by other enzymes: the 2-oxoglutarate dehydrogenase complex is replaced by 2-oxoglutarate:ferredoxin oxidoreductase (= 2-oxoglutarate synthase), and citrate synthase by ATP-citrate lyase (citrate + coenzyme A + ATP  $\rightarrow$  oxaloacetate + acetyl-CoA + ADP + Pi). Succinate dehydrogenase is replaced by a (probably NADH-dependent) fumarate reductase. Acetyl-CoA can be converted to pyruvate (by ferredoxin-dependent pyruvate synthase) and thence e.g. to phosphoenolpyruvate – which may in turn be carboxylated to oxaloacetate or used for GLUCONEOGENESIS etc, depending on the requirements of the cell.

**redundant** (of genes etc) Present in more than one copy per chromosome or per genome. (cf. TERMINAL REDUNDANCY.)

**redwater fever** (murrain; cattle tick fever; Texas fever) An acute, sometimes fatal disease of cattle and other animals caused by species of BABESIA; it is transmitted by blood-sucking ixodid ticks (e.g. species of *Boophilus*, *Dermacentor*, *Rhipicephalus*). The incubation period is ca. 4–14 days. *Babesia* grows within and destroys the host's erythrocytes, causing e.g. fever and haemoglobinuria (hence 'redwater fever').

**Reed–Muench method** See END-POINT DILUTION ASSAY.

**reference strain** In bacteriology: any strain which is not a type strain or a neotype but whose name (or other designation) is used to define or identify products, antigens etc produced by that strain.

**refractile** Refers to structures which appear bright when viewed by bright-field MICROSCOPY.

**refrigeration** (of foods) See FOOD PRESERVATION (b).

**regulator gene** A GENE whose product is a regulator protein which regulates the transcription of one or more STRUCTURAL GENES (see e.g. OPERON).

**regulon** A system in which two or more (usually non-contiguous) structural genes and/or OPERONS, each with its own promoter, are subject to coordinated regulation by a common regulator molecule (e.g., a repressor or activator); the genes/operons share common or related regulatory sequences (e.g. operators or initiators) which can each be recognized by the regulator molecule.

(cf. OPERON.) Examples of regulons in *Escherichia coli* include the *araBAD/araFG/araE* system (see ARA OPERON); the *arg* regulon (see ARGININE BIOSYNTHESIS); CATABOLITE REPRESSION; HEAT-SHOCK PROTEINS; NTR GENES; PHO REGULON; SOS SYSTEM.

**Reichstein process** See ASCORBIC ACID.

**reindeer moss** See CLADONIA.

**re-infection** A second or subsequent infection of a given individual by a given type of exogenous pathogen. (cf. AUTOINFECTION.)

**reinforced clostridial medium (RCM)** A medium used (e.g. with a supplement of blood, egg yolk or milk) for the culture of *Clostridium* spp. RCM contains yeast extract, meat extract, peptone, starch, glucose, cysteine hydrochloride, sodium chloride and sodium acetate; it may be used in liquid form or gelled with 1.5% (w/v) agar.

**Reiter antigens** Group treponemal antigens, i.e., antigens found in a range of pathogenic and non-pathogenic treponemes, including e.g. the Reiter treponeme and *Treponema pallidum*. (See also FTA-ABS TEST.)

**Reiter protein CFT** See TREPONEMAL TESTS.

**Reiter treponeme** The reference strain of *Treponema phagedenis*; it contains significant amounts of antigen(s) common to a number of species of *Treponema*, including *T. pallidum*.

**Reiter's syndrome** A post-infection, often recurrent syndrome characterized by the triad of symptoms: acute polyarthritis, conjunctivitis, and urethritis; it commonly affects young males after infection of the genitourinary tract (particularly chlamydial urethritis) or intestinal tract. The majority of patients with this syndrome have tissue antigen HLA-B27. [*Yersinia enterocolitica* and Reiter's syndrome: Imm. Rev. (1985) 86 27–45.]

**relA gene** See STRINGENT CONTROL (sense 1).

**relapsing fever** (recurrent fever; borreliosis) Any one of several human infectious diseases caused by *Borrelia* spp and transmitted by ticks (*Ornithodoros* spp) or, contaminatively, by lice (*Pediculus* spp). Incubation period: ca. 3–10 days. Symptoms: fever, usually with severe headache, myalgia and arthralgia, and sometimes jaundice and rash. The fever lasts ca. 2–4 days and then subsides, but is then followed 3–10 days later by another bout of symptoms. This cycle may be repeated several times; the fever typically becomes progressively less severe, but fatalities occasionally occur. The relapses are due to ANTIGENIC VARIATION in the surface antigens of the pathogen; bacteria isolated from the bloodstream during each relapse carry different major surface antigens. In *B. hermsii*, the genes encoding the surface antigens are carried on a multicopy *linear* PLASMID; antigenic variation apparently involves a mechanism in which different structural genes are periodically juxtaposed (by a single site-specific recombination event between different plasmid molecules) with a single 'expression site' [Nature (1985) 318 257–263].

*Lab. diagnosis:* detection of the pathogen in blood or urine samples taken during febrile periods. *Chemotherapy:* e.g. penicillins; tetracyclines.

**relative centrifugal field** See CENTRIFUGATION.

**relative light units (RLUs)** See TMA.

**relative molecular mass** ( $M_r$ ) The ratio of the mass of a given molecule to one-twelfth of the mass of a neutral  $^{12}\text{C}$  atom;  $M_r$  is unitless. The  $M_r$  of a molecule is commonly referred to as its 'molecular weight'. (See also ATOMIC MASS UNIT.)

**relaxase** See CONJUGATION (1b)(i).

**relaxation complex** See CONJUGATION (1b)(i).

**relaxed control** See PLASMID (replication).

**relaxed DNA** DNA which is not supercoiled (see DNA).

**relaxed mutant** See STRINGENT CONTROL (sense 1).

**relaxing enzyme** (1) A type I TOPOISOMERASE.

(2) Any enzyme capable of relaxing supercoiled DNA.

**relaxosome** See CONJUGATION (1b)(i).

**release factors** (in protein synthesis) See PROTEIN SYNTHESIS (termination).

**Relenza<sup>TM</sup>** See ZANAMIVIR.

**relomycin** See MACROLIDE ANTIBIOTICS.

**Renibacterium** A genus of aerobic, asporogenous, catalase-positive, oxidase-negative bacteria (order ACTINOMYCETALES, wall type VI); the type species, *R. salmoninarum* (formerly '*Corynebacterium salmoninus*') is the causal agent of KIDNEY DISEASE in salmonid fish. The organisms are rods or coccobacilli,  $0.3\text{--}1.0 \times 1.0\text{--}1.5 \mu\text{m}$ , which frequently occur in pairs. Growth occurs optimally at ca.  $15\text{--}18^\circ\text{C}$  on e.g. cysteine-serum agar (cysteine being required for growth). [Selective isolation of *Renibacterium*: FEMS (1983) 17 111–114.] GC%: ca. 53–54.

**reniform** Kidney-shaped.

**rennet substitutes** See PROTEASES.

**rennin** See CASEIN.

**rennin substitutes** See PROTEASES.

**Reoviridae** A family of viruses in which the (non-enveloped) virion is typically icosahedral or amorphous ( $\sim 60\text{--}80 \text{ nm}$  in diam.) and contains a segmented genome of 10–12 different linear dsRNA molecules. The virion may contain up to 10–13 species of protein; it consists of a *core* (characteristically a double-layered structure incorporating the genome) commonly or always enclosed by an 'outer capsid layer', the latter being lost during viral penetration of the host cell. (The outer capsid layer is generally thought to be important for initial attachment to the target cell; however, cores of the bluetongue virus – from which the outer capsid layer has been removed – are still infective for the insect vector, even though poorly infective for mammalian cells [Virology (1996) 217 582–593].) The viral core, released into the cytoplasm of the target cell, may include e.g. transcriptase, nucleotide phosphohydrolase, guanylyltransferase and transmethylase – enzymes responsible for synthesis and modification of the viral transcripts. In several reoviruses, the core's diameter has been reported to be  $\sim 700 \text{ \AA}$  [bluetongue virus: Nature (1998) 395 470–478; reovirus: Nature (2000) 404 960–967]. Reoviruses replicate in viroplasm in the cytoplasm, sometimes forming crystalline arrays.

The family has been divided into genera on the basis of capsid structure, number of genome segments and nature of host. Hosts include vertebrates (ORBIVIRUS, REOVIRUS, ROTAVIRUS), insects (CYTOPLASMIC POLYHEDROSIS VIRUS GROUP – cf. HOUSEFLY VIRUS) and plants (FIJIVIRUS, PHYTOREOVIRUS).

**Reovirus** ('respiratory enteric orphan virus'; *Orthoreovirus*) A genus of viruses of the family REOVIRIDAE. The viruses can infect various animals, including primates (e.g. man), birds, cattle and bats – and can be cultured in cells obtained from many types of vertebrate.

The reovirus virion comprises an inner *core* enclosed by a heat- and protease-labile 'outer shell' or 'outer capsid layer'. The outer capsid layer of the virion is lost during viral penetration of the host cell.

The core consists of a double-layered structure associated with (i) the genome: 10 (apparently tightly coiled) dsRNA segments, and (ii) enzymes responsible for synthesis and modification of viral transcripts; each segment of genomic RNA may be associated with a transcriptase complex. Of the eight species of protein comprising the complete virion, five occur in the core. The core is about  $700 \text{ \AA}$  in diameter. [Structure of the reovirus core at  $3.6 \text{ \AA}$  resolution: Nature (2000) 404 960–967.]

## reoviruses

The cell-surface receptor for reoviruses is reported to be the *junction adhesion molecule* (JAM) – an integral tight-junction (zona occludens) protein which binds the viral attachment protein,  $\sigma 1$ , and which may also be involved in intracellular signalling [Cell (2001) 104 441–451].

Following viral penetration, the core of the virion remains intact and becomes transcriptionally active [see also Book ref. 83]. Each transcript is capped but not polyadenylated; mature transcripts are exported to the cytoplasm. Initially, only four of the genome segments are expressed, the other six being derepressed by the product(s) of early genes. Early in the cycle, viral mRNA is translated by the host cap-dependent translational machinery; later, uncapped mRNA is produced, and translation becomes cap-independent. Mature virions accumulate in the cell, which eventually undergoes lysis.

**reoviruses** (1) Members of the REOVIRIDAE. (2) Members of the genus REOVIRUS.

**rep-PCR** Repetitive sequence-based PCR: a PCR-based method for TYPING those bacteria whose chromosome contains multiple copies of a 'repetitive sequence' of nucleotides – such as the REP SEQUENCE, ERIC SEQUENCE or SERE.

rep-PCR (principle, diagrammatic; see entry). In the diagram, three REP (R) sequences are shown in one strand of chromosomal DNA. A primer (P) has bound to each REP sequence, and elongation has proceeded from left to right; an arrowhead marks the end of a newly formed fragment. Note that elongation from a given primer cannot continue beyond the next primer. (The fragments do not join together because the reaction mixture does not contain the type of enzyme (ligase) which could make such a join.) After a number of cycles of PCR the different-sized molecules are separated by electrophoresis, yielding a fingerprint characteristic of the given strain. Differences between the fingerprints of different strains reflect differences in REP → REP distances in their respective chromosomes.

Reproduced from *Bacteria* 5th edition, Figure 16.4(d), Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

When typing is based on the REP sequence (= REP-PCR; cf. rep-PCR), primers are designed to bind to a CONSENSUS SEQUENCE at the 5' end of the REP region in a range of strains. Extension of primers on a given chromosomal template gives rise to a number of fragments which reflect a range of REP → REP distances (see figure); these inter-REP distances can vary between strains, so that amplicons from a given strain, on electrophoresis, will give rise to a fingerprint characteristic of that strain.

The analogous method based on ERIC sequences is referred to as ERIC-PCR, while that based on SERE is called SERE-PCR. rep-PCR has been used e.g. for typing strains of *Haemophilus somnus* (ERIC-PCR) [JCM (1997) 35 288–291], *Vibrio parahaemolyticus* (ERIC-PCR) [JCM (1999) 37 2473–2478], viridans streptococci (REP-PCR, ERIC-PCR SERE-PCR) [JCM (1999) 37 2772–2776] and *Listeria monocytogenes* (REP-PCR, ERIC-PCR) [JCM (1999) 37 103–109].

**Rep protein** (1) See HELICASES. (2) A plasmid-encoded protein which functions as an activator of replication of that plasmid. (See e.g. INCOMPATIBILITY (pT181); R1 PLASMID; R6K PLASMID ( $\pi$  protein).)

**REP sequence** (repetitive extragenic palindromic sequence; palindromic unit) A highly conserved PALINDROMIC SEQUENCE with hypenated dyad symmetry, ca. 500–1000 copies of which are distributed in the chromosome in e.g. *Escherichia coli*, *Salmonella typhimurium* and other enterobacteria; REP sequences have also been found in e.g. *Listeria monocytogenes*. REP sequences occur between genes, or in the untranslated promoter-distal region (beyond the genes) in many operons, but they have not been detected within coding sequences. (See also ERIC SEQUENCE.)

REP sequences can potentially form cruciform structures in DNA, or stem-and-loop structures in the corresponding mRNA; thermodynamically, the latter is more likely.

REP sequences may play a role in nucleoid structure (earlier, evidence was obtained that REP sequences have protein-binding sites [FEBS (1986) 206 323–328], and they are now known to be associated with HU PROTEIN).

REP sequences have been used in the typing of bacteria (by REP-PCR) [e.g. JCM (1999) 37 103–109; JCM (1999) 37 2772–2776].

Repetitive sequences – either clustered or dispersed through the genome – have long been recognized in higher eukaryotes: see e.g. ALU SEQUENCES.

**REP1, REP2 genes** See TWO-MICRON DNA PLASMID.

**repair** (of DNA) See DNA REPAIR.

**repeating spore** (*mycol.*) A spore from which arises mycelium of the same type as that from which the spore was formed.

**repetitive extragenic palindromic sequence** See REP SEQUENCE.

**repetitive sequence-based PCR** See REP-PCR.

**replacement vector** A CLONING VECTOR which has a pair of cleavage sites flanking a dispensable sequence (the 'stuffer'); the stuffer sequence is removed and replaced by a sequence of exogenous DNA. (cf. INSERTION VECTOR.)

**replica** (in microscopy) See ELECTRON MICROSCOPY (a) and (b).

**replica plating** A technique for isolating mutants from a population of microorganisms grown under *non-selective* conditions. For the isolation of e.g. auxotrophic mutants from a population of prototrophic bacteria, a *master plate* is prepared by inoculating a plate of complete medium with an inoculum from the prototrophic population. Following incubation, a disc of sterile velvet (attached to one end of a cylindrical wooden block) is pressed lightly onto the surface of the master plate; the disc, to which has adhered growth from the master plate, is then used to inoculate one or more plates of minimal medium (the *replica plates*) – a careful record being made of the orientation of the disc relative to the master plate and to the replica plates during inoculation. The replica plates are then incubated; only prototrophic cells form colonies. The positions of colonies on the master and replica plates are compared, and presumptive auxotrophs can be identified by their absence from the replica plates.

**replicase** See RNA-DEPENDENT RNA POLYMERASE.

**replication fork** See DNA REPLICATION.

**replicative form** See RF.

**replicative intermediate** See RI.

**replicative recombination** See TRANSPOSABLE ELEMENT.

**replicombinase** A TRANSPOSASE which catalyses replicative recombination (see TRANSPOSABLE ELEMENT).

**replicon** Any DNA sequence or molecule which possesses a replication origin and which is therefore potentially capable of being replicated in a suitable cell (see DNA REPLICATION).

**replication** The process in which a circular dsDNA molecule, capable of replication, is formed within a cell from DNA that has been taken up e.g. by CONJUGATION (sense 1b).

**replisome** See DNA REPLICATION.

**reporter gene** See IVET (legend) and FUSION PROTEIN.

**repressor protein** See e.g. OPERON.

**repressor titration** A selective procedure used for detecting those cells which contain certain plasmid vectors. Use is made of (i) a specially constructed strain of *Escherichia coli* whose chromosome contains a kanamycin-resistance gene under the regulatory control of the *lac* operator–promoter system, and (ii) a *multicopy* plasmid vector that incorporates the *lac* operator sequence (see LAC OPERON). Cells which lack the plasmid vector will fail to grow on a kanamycin-containing medium because (in the absence of lactose or IPTG) transcription from the *lac* promoter is blocked by the LacI repressor protein. A cell which contains the multicopy plasmid will have many extra copies of the (plasmid-borne) *lac* operator sequence, and these extra copies will compete with the chromosomal *lac* operator for LacI; under these conditions, LacI fails to repress the kanamycin-resistance gene so that the cell will grow on kanamycin-containing media.

Because the vector does not carry an antibiotic-resistance gene (as is common in other selective methods) it can be smaller – and therefore transformable with greater efficiency. [Repressor titration: NAR (1998) 26 2120–2124.]

**reptation** During gel ELECTROPHORESIS: the movement of a (linear) nucleic acid molecule in an end-on orientation, i.e. aligned parallel to the current.

**RER** Rough ENDOPLASMIC RETICULUM.

**res** In insertion sequence  $\gamma\delta$ : the region corresponding to the IRS of Tn3 (see Tn3).

**RESA** See PLASMODIUM.

**resazurin test** (for milk) A test which resembles the METHYLENE BLUE TEST (q.v.) in principle and method but which employs *resazurin* instead of methylene blue as the redox indicator. Resazurin (a member of the quinone–imine group of dyes) is blue when fully oxidized; when the REDOX POTENTIAL is lowered sufficiently the compound becomes irreversibly reduced to the pink *resorufin*. On further reduction the colourless *hydroresorufin* is formed.

**reservoir** (1) (*epidemiol.*) Human and/or animal population(s) in which a given pathogen is maintained in a viable, infective state and which can serve as a source of infection for susceptibles (see EPIDEMIOLOGY); the pathogen may or may not cause overt symptoms of disease within the reservoir.

(2) (flagellar pocket) See TRYPANOSOMA.

(3) (in euglenids) See EUGLENOID FLAGELLATES.

**residual body** See LYSOSOME.

**residual chlorine** See WATER SUPPLIES.

**resistance–nodulation–division superfamily** See RND.

**resistance transfer factor** See RTF.

**resolvase** (in transposable elements) See Tn3.

**resolvase-type recombinase** See SITE-SPECIFIC RECOMBINATION.

**resolving power** (limit of resolution) In MICROSCOPY: the ability of a microscope to reveal fine detail in a specimen (cf. MAGNIFICATION). In light microscopy resolving power depends mainly on the characteristics of the objective lens, but correct illumination of the specimen is also necessary to exploit the resolving power of a given lens. The resolving power ( $d_{\min}$ ) of an objective is the minimum distance between two details that can be distinguished with the lens; with a lens of inferior resolving power the two details would appear as one. For a given objective:

$$d_{\min} \propto \frac{\lambda}{\mu \sin \theta}$$

in which  $\lambda$  is the wavelength of light forming the image,  $\mu$  is the refractive index of the medium between objective and specimen, and  $\theta$  is *half* the apical angle of the widest cone of light which can enter the objective from the specimen plane. The quantity  $\mu \sin \theta$  is the *numerical aperture* (NA) of the objective; the higher the NA the better the resolving power. (The NA of a CONDENSER is also given by  $\mu \sin \theta$ ; here,  $\theta$  is half the apical angle of the widest cone of light which can be focused in the specimen plane.) When the medium between objective and specimen is air ( $\mu = 1.0$ ) the NA is less than 1.0. A greater NA is obtainable with an *immersion lens*: a lens designed to work with a liquid bridge between it and the specimen; an *oil-immersion objective* uses IMMERSION OIL ( $\mu$  ca. 1.5), and a *water-immersion objective* uses distilled water ( $\mu$  ca. 1.3). The use of oil or water enables the objective to receive a wider cone of light from the specimen plane; this increases resolving power by increasing the amount of diffracted light received from the specimen (see MICROSCOPY (a)). When using immersion oil, one drop is placed on the objective lens and another on the cover-glass; the objective is racked down until the drops coalesce, and the specimen is then brought into focus. This method avoids the risk of trapping air bubbles between lens and cover-glass – a risk greater with objectives that have a concave front lens; air bubbles cause flare and distortion. Usually, an *oil-immersion substage condenser* is used when using an oil-immersion objective lens; in this case the top lens of the condenser should be oiled to the underside of the slide in order to obtain maximum resolving power from the objective lens.

The resolving power of a good light microscope is about 200 nm; with an ultraviolet microscope it is about 130 nm, and with an electron microscope it can be less than 1 nm.

**resorcinol** 1,3-Dihydroxybenzene.

**resorufin** See RESAZURIN TEST.

**respiration** Energy-yielding metabolism in which the oxidation of an energy substrate involves an *exogenous* electron acceptor (i.e., an externally derived oxidizing agent); the participation of an exogenous electron acceptor results in the *net* oxidation of the energy substrate, and makes possible an energy yield significantly greater than that obtainable by the fermentation of the given substrate (cf. FERMENTATION sense 1). Respiration can occur aerobically or anaerobically (see ANAEROBIC RESPIRATION), and may involve an inorganic electron acceptor (e.g. oxygen or nitrate – see also NITRATE RESPIRATION) or an organic electron acceptor (see e.g. FUMARATE RESPIRATION).

In the respiratory (= ‘oxidative’) metabolism of an energy substrate, the exogenous electron acceptor commonly, but not always, undergoes reduction at the (most positive) end of an ELECTRON TRANSPORT CHAIN (ETC); electron flow from the substrate, via an ETC, to the electron acceptor typically generates proton motive force (see CHEMIOSMOSIS) which can be used for e.g. ATP synthesis (see OXIDATIVE PHOSPHORYLATION). Respiratory metabolism can occur without the involvement of an electron transport chain, ATP being synthesized entirely by substrate-level phosphorylation: see e.g. ‘nitrite respiration’ in *Escherichia coli* in entry NITRATE RESPIRATION.

Respiratory substrates include organic compounds (see ORGANOTROPH) and inorganic compounds or ions (see LITHOTROPH); according to species and conditions, the electron acceptor may be e.g. oxygen, nitrate, CO<sub>2</sub>, sulphate or fumarate. In that the exogenous electron acceptor is involved in the final oxidative step in a respiratory pathway it is commonly called the *terminal electron acceptor*.

**respiratory burst** See NEUTROPHIL.

## respiratory chain

**respiratory chain** See ELECTRON TRANSPORT CHAIN.

**respiratory control** Control of the electron flow in a respiratory chain by proton motive force (see CHEMOSMOSIS). According to its value, pmf may inhibit or promote the further extrusion of protons across the membrane – usually with a concomitant decrease or increase, respectively, in electron flow. In the so-called *State 3* (active state) the rate of respiration is high owing to decreased pmf; in the presence of UNCOUPLING AGENTS (which can abolish pmf entirely) respiration is maximal (*State 3<sub>unc</sub>* or *3u*). In *State 4* (the controlled or resting state) respiration is minimal owing to the maximal thermodynamic back-pressure of the pmf; however, a low level of respiration may occur in order e.g. to balance the effects of proton leakage across the membrane.

In *Escherichia coli* the adsorption of certain bacteriophages has been shown to cause a transient release from respiratory control, phage adsorption apparently inducing an inflow of protons similar to that induced by protonophores [JB (1985) 161 179–182].

**respiratory inhibitors** Substances which inhibit the flow of electrons along a respiratory chain: see e.g. AMYTAL, ANTIMYCIN A, AZIDE, BAL, CARBON MONOXIDE (b) CYANIDE, DCMU, HYDROXYQUINOLINE-N-OXIDES, PIERICIDIN and ROTENONE. (cf. UNCOUPLING AGENTS; OLIGOMYCIN.)

**respiratory syncytial virus** See PNEUMOVIRUS.

**respiratory tract microflora** The human nasal passages commonly harbour species of *Corynebacterium* and *Staphylococcus* (usually *S. epidermidis*, sometimes *S. aureus* also) and occasionally species of e.g. *Moraxella* and *Streptococcus*. In the nasopharynx the predominating organisms are often streptococci; various opportunist pathogens (e.g. *Haemophilus influenzae*, *Streptococcus pneumoniae*, strains of *Moraxella*) may also be present. (See also MOUTH MICROFLORA.)

The trachea, bronchi, bronchioli and lungs may be sterile or may have small numbers of contaminating organisms. The ability of extraneous air-borne particles (see AIR) to reach the trachea, or to penetrate further into the respiratory tract, is governed largely by the size and shape of such particles. For example, spores > ca. 10 µm (e.g. those of *Alternaria* and *Fusarium*) tend to be trapped in the nose, but may reach the bronchi during mouth-breathing; such spores may induce e.g. a TYPE I REACTION. Spores 5–10 µm (formed e.g. by many species of *Cladosporium* and *Mucor*) may be deposited in the bronchi or bronchioles where they may incite attacks of asthma in susceptible individuals; spores of this size may even penetrate into the alveoli if an individual is exposed to very large numbers of spores. Spores < 5 µm (e.g. those formed by species of *Aspergillus* and *Penicillium*, and by many actinomycetes) may reach the alveoli; the spores of actinomycetes are commonly implicated in certain types of EXTRINSIC ALLERGIC ALVEOLITIS.

(See also BODY MICROFLORA and e.g. BRONCHITIS; COMMON COLD; CYSTIC FIBROSIS; PNEUMONIA.)

**response regulator** See TWO-COMPONENT REGULATORY SYSTEM.

**resting spore** (winter spore) (*mycol.*) A thick-walled spore, particularly one formed by a sexual process, which germinates only after an extended period of dormancy – e.g. an overwintering teliospore. (cf. SUMMER SPORE.)

**restricted transduction** See TRANSDUCTION.

**restriction endonuclease** (REase, RE; restriction enzyme) An ENDONUCLEASE which binds to dsDNA, usually at a specific *recognition sequence* (= *recognition site*), and typically makes a single cut in each strand – *provided that* specific bases at that site are *unmethylated* (for some REs) or methylated (for others); the cleaved duplex may exhibit STICKY ENDS or BLUNT-ENDED

DNA, according to RE. Some REs have no unique recognition site, some have several. DNA may be cleaved within the site or outside it; some REs (e.g. *BaeI*) cut on both sides, excising a segment that includes the recognition site. (See also STAR ACTIVITY.)

REs with various specificities have been isolated from a wide range of prokaryotes. (In some cases, REs from different species recognize the same nucleotide sequence: see ISOSCHIZOMERS.)

An RE has a three-letter designation (based on the name of the host species) followed by a strain designation and/or a Roman numeral that indicates a particular RE from a given strain or species: see table for examples; there is currently a trend to avoid italics [RE nomenclature: NAR (2003) 31 1805–1812]. Recognition sequences are written 5'-to-3' (sequence for one strand only); an arrow (or stroke) shows a cleavage site (if within the recognition site).

What purpose do REs serve in their host cells? The main role seems to be protection against 'foreign' DNA – particularly phage DNA [MR (1993) 57 434–450]. However, this protective mechanism is not always effective; for example, some phages encode specific inhibitors of REs. Moreover, antirestriction enzymes are encoded by certain plasmids [JB (1992) 174 5079–5085], and resistance to restriction enzymes is a typical feature of conjugative transposons [e.g. ARM (1995) 49 367–397].

Several distinct types of RE are recognized.

*Type I* REs can methylate and cut DNA. ATP-dependent cleavage occurs outside the recognition sequence at a non-specific site; the enzyme may bind to its recognition site while DNA is passed through another part of the enzyme until a cleavage site is reached. Example: *EcoK1*. [New type I REs from *Escherichia coli*: NAR (2005) 33 (13) e114.]

*Type II* REs generally recognize a specific sequence and cleave both strands, independently of ATP, at a particular location in or near the recognition site; each strand is left with a 5'-phosphate terminus and a 3'-hydroxyl terminus. These REs are useful in recombinant DNA technology owing to their ability to cut DNA precisely; >3500 are now known. Subtypes of type II REs include:

IIA. REs that recognize asymmetric sites.

IIB. REs that cut on both sides of the recognition site – e.g. *BaeI*, whose recognition (underlined)/cutting sites are:

in which 4N = any four nucleotides, Y = C or T; this strand is cut 10 nucleotides upstream, its complementary strand 15 nucleotides upstream – 12/7 indicating downstream cutting sites for both strands.

IIC. REs with cutting and methylation functions combined in a single polypeptide.

IIIE. REs which cut at the recognition site but need interaction with another copy of that site in order to function.

IIIF. REs that bind to, and cut, both copies of the recognition site.

IIIM. REs which cut at (fixed) sites where there is a specific pattern of methylation – e.g. *DpnI*. (cf. *Type IV*, below.)

IIIP. REs with a fixed cutting site within, or very close to, the symmetrical (palindromic) recognition site – e.g. *EcoRI*.

*Type III*. REs that interact with two inversely orientated, non-palindromic sites; cleavage, at a distance from one of the sites, requires ATP-dependent translocation. Examples: *EcoP11*, *EcoP15I*.

*Type IV*. REs with methylated recognition sites but which (unlike the IIIM REs) apparently cut without specificity.

RESTRICTION ENDONUCLEASES (REs): some examples<sup>d</sup>

RE	Source (organism)	Recognition sequence <sup>a</sup>
<i>Aar</i> II	<i>Acetobacter aceti</i>	GACGT/C
<i>Alu</i> I	<i>Arthrobacter luteus</i>	AG/CT
<i>Apa</i> I	<i>Acetobacter pasteurianus</i>	GGGCC/C

<i>Xho</i> I	<i>Xanthomonas campestris</i> var <i>holcicola</i>	C/TCGAG
<i>Bae</i> I	<i>Bacillus sphaericus</i>	/(10/15) <u>AC(4N)GTAYC</u> (12/7)/

<sup>a</sup> Recognition sequence in one strand (in the 5'-to-3' direction); the cutting site is shown as '/'.  
A = adenine; C = cytosine; G = guanine; T = thymine.

<sup>b</sup> Produces 'blunt-ended' cuts.

<sup>c</sup> The eight-nucleotide sequence of a 'rare-cutting' enzyme.

<sup>d</sup> The proposed new nomenclature uses a non-italic format [NAR (2003) 31 1805–1812]. Currently, the literature refers to REs in both italic and non-italic formats. Modified from Table 2.1, page 18, in *DNA Methods in Clinical Microbiology*, Paul Singleton (2000) copyright Kluwer Academic Publishers, Dordrecht, The Netherlands (ISBN 0-7923-6307-8) with kind permission from the publisher.

Some *nicking enzymes* (which cut *one* strand of dsDNA) resemble REs [e.g. *Bst*NBI: NAR (2001) 29 2492–2501]. In some cases the recognition site of an RE can be chemically modified such that the enzyme cuts one specific strand of dsDNA; this approach is used e.g. in SDA.

**restriction endonuclease analysis** See DNA FINGERPRINTING.

**restriction fragment length polymorphism** See RFLP.

**restriction–modification system** (R–M system) The system, present in many bacteria, in which DNA is modified by

specific enzyme(s) in a manner characteristic of the particular bacterial strain, the modification serving to protect the DNA against enzymic degradation ('restriction') by the cell's own endonucleases. Modification generally involves a specific pattern of *methylation* of nucleotide residues in the DNA (see DNA METHYLATION); using *S*-adenosylmethionine as methyl donor, the methylation enzymes ('methylases') act on dsDNA in which one or both strands are unmodified. The sites at which modification occurs are also recognized by corresponding

## restriction point

RESTRICTION ENDONUCLEASES (REs); the REs cannot cleave DNA in which these sites have been modified in one or both strands. Modification does not interfere with normal base-pairing, so that semiconservative replication of fully modified dsDNA will result in two duplexes, each containing one (modified) parent strand and one unmodified daughter strand. The modified parent strand protects the duplex from restriction, and the daughter strand is modified before further DNA replication; thus, DNA susceptible to restriction does not normally occur in the cell. However, if 'foreign' DNA lacking the modification pattern of the strain enters the cell (e.g. by conjugation, transformation, phage infection etc) it will generally be degraded. (See also HOST-CONTROLLED MODIFICATION.)

Certain bacteriophages encode their own R–M systems: see e.g. T-EVEN PHAGES and BACTERIOPHAGE MU.

**restriction point** (in cell cycle) See CELL CYCLE.

**restrictive conditions** See CONDITIONAL LETHAL MUTANT.

**resupinate** (*mycol.*) Refers to a fruiting body which forms a crust on the surface of the substratum, the spore-bearing surface being outermost.

**reticle** See MICROMETER.

**reticulate body** See CHLAMYDIA.

**reticule** See MICROMETER.

**reticuloendotheliosis viruses** See AVIAN RETICULOENDOTHELIOSIS VIRUSES.

**reticulopodium** See PSEUDOPODIUM.

**reticulum** See RUMEN.

**retinaculum apertum** See SPIRA.

**retinal** The purple component of various photosensitive proteins, e.g. BACTERIORHODOPSIN, HALORHODOPSIN, SLOW-CYCLING RHODOPSIN. The free retinal molecule is R–[CH=CH–C(CH<sub>3</sub>)=CH]<sub>2</sub>–CHO where R = 2,6,6-trimethyl-1-cyclohexenyl. (The corresponding alcohol, retinol, is vitamin A.) Linkage of the aldehyde group of retinal to a lysine residue in a halobacterial opsin creates a Schiff base. The synthesis of retinal in *Halobacterium salinarium* is inhibited e.g. when the organism is grown in the presence of nicotine.

**retort** (in canning) See BATCH RETORT.

**retort pouch** A flexible container used in the food processing industry as an alternative to the can. Typically, the pouch is made of a laminate consisting of aluminium foil sandwiched between an outer layer of polyester and an inner layer of e.g. polypropylene and nylon – the layers being bonded together by e.g. a polyester–isocyanate adhesive. (See also CANNING.)

**Retortamonadida** An order of parasitic protozoa (class ZOOMASTIGOPHOREA). The cells, which are not bilaterally symmetrical, have two to four flagella, one of which is directed posteriorly along the ventral surface; cells lack mitochondria, Golgi apparatus, an axostyle and an undulating membrane. Genera: e.g. CHILOMASTIX, *Retortamonas*.

**Retortamonas** See RETORTAMONADIDA.

**retrogressive development** See CONIDIUM.

**retrohoming** See INTRON HOMING.

**retroid viruses** Viruses which resemble members of the RETROVIRIDAE in that they appear to employ a replication mechanism which involves reverse transcription of an RNA intermediate; retroid viruses include CAULIFLOWER MOSAIC VIRUS [review: TIBS (1985) 10 205–209] and members of the HEPADNAVIRIDAE. [Possible common evolutionary origin of hepatitis B virus and retroviruses: PNAS (1986) 83 2531–2535.]

**retrotron** In some strains of *Escherichia coli* (and certain other Gram-negative bacteria); a chromosomal genetic element encoding a REVERSE TRANSCRIPTASE structurally similar to that encoded by retroviruses. Retrotron-containing strains can synthesize a unique, branched, hybrid RNA–DNA molecule called *multicopy single-stranded DNA* (msDNA); in this molecule, the 5' end of single-stranded DNA is linked (via a phosphodiester bond) to the 2' position of an *internal* (i.e. non-terminal) guanosine residue in the RNA. Synthesis of msDNA involves the reverse transcriptase. A cell may contain many copies (up to 500) of msDNA, but the function of this molecule is unknown.

Retrons seem to be 'foreign' or imported elements in *E. coli*.

Retrons are referred to by a system of nomenclature in which the initials of the host species are followed by the number of bases in the DNA part of the corresponding msDNA; for example, Mx162 is a retrotron in *Myxococcus xanthus* in which the DNA of the msDNA contains 162 bases.

Retrons also occur e.g. in *Klebsiella*, *Proteus*, *Rhizobium* and *Salmonella* [JB (1993) 175 4250–4254].

**retroposon** *Syn.* RETROTRANSPONSON.

**retroregulation** (*mol. biol.*) A mode of post-transcriptional regulation in which expression of a gene is influenced by a *cis*-acting sequence *downstream* of the gene; if transcription proceeds into the *cis*-acting sequence, the resulting RNA is degraded and the gene is thus not expressed, whereas if transcription stops before the *cis*-acting sequence the RNA is not degraded and the gene is expressed. (See BACTERIOPHAGE λ (*int* gene expression).)

**retrotranscription** See REVERSE TRANSCRIPTASE.

**retrotransfer** The flow of genetic material from recipient to donor during bacterial CONJUGATION. In *Escherichia coli*, retrotransfer was reported to be inhibited by streptomycin, and it occurred to a lesser extent during conjugation mediated by plasmids encoding strong SURFACE EXCLUSION; it has been suggested that retrotransfer is newly initiated conjugation between transconjugants and donors [JB (1993) 175 583–588] – an hypothesis supported by subsequent studies [JB (1996) 178 1457–1464].

**retrotransposon** (retroposon) A TRANSPOSABLE ELEMENT in which transposition involves a retrovirus-like process of reverse transcription with the formation of an RNA intermediate (see e.g. TY ELEMENTS). It has been argued that such TEs may be degenerate retroviruses [Cell (1985) 40 481–482, and 42 507–517]. (See also A-TYPE PARTICLES.)

**Retroviridae** A family of enveloped ssRNA-containing animal viruses in which the genome is replicated via a dsDNA intermediate. Retroviruses have been isolated from a wide range of vertebrates – including mammals, birds and reptiles – and retrovirus-like particles have been observed e.g. in tapeworms and insects. Retrovirus infection in a given host may be asymptomatic or may result in any of various diseases, including e.g. pneumonia, anaemia, and malignant tumours and/or leukaemias. (See also AIDS.) Interestingly, retroviral RNA has been detected in the brain and CSF of individuals suffering from schizophrenia, suggesting a possible link [PNAS (2001) 98 4634–4639]. Transmission may occur horizontally and/or vertically (see below).

The retrovirus virion is more or less spherical, ca. 80–120 nm diam., consisting of a nucleoprotein core (sometimes called the 'nucleoid') surrounded by an envelope derived largely from the host plasma membrane (or intracytoplasmic membranes). The core contains the viral REVERSE TRANSCRIPTASE and other viral proteins, the viral genome complexed with protein (also called the 'nucleoid') and low-MWt RNAs of host origin; the envelope contains a virus-encoded glycoprotein which determines the host

RETROVIRIDAE: Figure 1. The retrovirus genome, showing generalized features (*not to scale*). The genomes of some retroviruses have additional coding sequences not shown here.

R	=	Terminal redundancy.
U5	=	Sequence unique to the 5' end (present at each end in proviral DNA).
(-) PBS	=	Primer binding site for the (-) DNA strand primer (a host tRNA).
L	=	Leader sequence.
<i>gag</i>	=	Group-specific antigen genes (coding region for nucleocapsid proteins).
<i>pol</i>	=	Coding region for e.g. reverse transcriptase.
<i>env</i>	=	Coding region for envelope glycoprotein.
P	=	Polypurine tract and probable primer binding site for (+) DNA strand synthesis.
U3	=	Sequence unique to the 3' end (present at each end in proviral DNA).
Cap	=	5' Cap nucleotide (m <sup>7</sup> G <sup>5'</sup> ppp <sup>5'</sup> ...), added after transcription and not copied during DNA synthesis.
A <sub>n</sub>	=	3' Polyadenylate tract (e.g. ca. 100–200 nucleotides long), added after transcription and not copied during DNA synthesis.

range of the virus and is the target for neutralizing antibodies. All of the genetic information of the virus is encoded by a single piece of positive-sense ssRNA (ca. 3.5–9.8 kb) which has the structural features characteristic of eukaryotic mRNA (see Figure 1); however, in the virion the genome occurs in a 60S–70S dimer in which two identical (or similar) 30S–35S viral RNA molecules ('monomers') are held together at their 5' ends by hydrogen bonds (i.e., the virion is 'diploid'). The virions are sensitive to heat, lipid solvents and detergents, but are relatively resistant to UV- and X-irradiation.

Retroviruses are classified according to their virion structure, host range, pathological effects (both on the host and in cell cultures) etc. Three subfamilies are recognized: LENTIVIRINAE, ONCOVIRINAE and SPUMAVIRINAE.

**Replication cycle.** The mode of replication appears to be generally similar in the various types of retrovirus. Infection is initiated by interaction between the virus envelope glycoprotein and specific host cell surface receptors. In the host cytoplasm, a linear viral DNA is synthesized by the viral REVERSE TRANSCRIPTASE acting within the (presumably modified) infecting virus particle. Synthesis of the first (-) DNA strand is initiated at the (-) PBS at the 3' boundary of the U5 region (see Figures 1 and 2), a host tRNA acting as a primer for initiation; most retroviruses use host tRNA<sup>pro</sup> as primer, but mouse mammary tumour virus, visna virus, and the AIDS virus use tRNA<sup>lys</sup>. The viral RNA is degraded by viral RNase H (see RNASE H), and a second strand of DNA is synthesized using the (-) DNA strand as template. The resulting linear dsDNA molecule is slightly longer than the RNA template due to the duplication of regions U3 and U5 and the consequent generation of the long terminal repeats (LTRs: see Figure 2); the LTRs contain sequences necessary for the next stage in the cycle – integration of the viral DNA into the host cell DNA to form a *provirus* – and for the control of virus gene expression.

In e.g. HIV (q.v.) the dsDNA is circularized, and one or more copies are inserted into the host cell DNA. Integration appears to be an essential step for replication of the retroviral genome, and, in general, integration may occur at random sites in the host DNA. For at least some retroviruses, two or more base pairs are lost from each LTR, prior to or during integration, and a short sequence of cellular DNA is duplicated such that the provirus is flanked by short direct repeats. (cf. TRANSPOSABLE ELEMENT.)

Once established in the host chromosome, a provirus may be quiescent or – depending e.g. on its location, on the strength of its promoters, on the physiological state of the cell, and on the presence or absence of specific regulators – may be transcribed to form progeny RNA genomes and mRNAs. The LTRs contain most of the signals for the regulation of transcription, including a promoter, an enhancer (in some retroviruses), and signals for termination of transcription and for polyadenylation of the transcript. Transcription appears to be carried out by host RNA polymerase II and is highly sensitive to  $\alpha$ -amanitin. Primary transcripts are approximately the length of a viral RNA monomer; they are polyadenylated, and then processed further (e.g. by splicing).

By convention, retroviral gene products are designated by their MWts  $\times 10^{-3}$  prefixed by p, pp or gp for protein, phosphoprotein or glycoprotein, respectively: e.g. pp12<sup>gag</sup> = a phosphorylated product of *gag*, MWt ca.  $12 \times 10^3$ ; polyprotein precursors are prefixed by Pr.

The 'genes' *gag*, *pol* and *env* (all necessary for virus replication) encode polyproteins. The *gag*-encoded polyprotein is cleaved to form the 4 or 5 components of the virus core. The *pol* sequence is apparently expressed with *gag* such that a *gag-pol* polyprotein precursor is formed (Pr180<sup>gag-pol</sup> in e.g. avian leukosis and murine leukaemia viruses); this precursor undergoes a series of cleavages, and the mature protein complex has reverse transcriptase, RNase H and DNA endonuclease activities. The *env*-encoded product is synthesized via a subgenomic spliced mRNA; the product is cleaved to remove a signal peptide, and is then glycosylated and cleaved to form the major protein component of the viral envelope. Envelope glycoproteins may continue to be synthesized until they saturate the plasma membrane receptors and thus prevent superinfection by any virus competing for those receptors.

Nucleoprotein cores assembled in the cytoplasm subsequently bud through the plasma or internal membranes of the host cell; the released virions apparently undergo further maturation, involving e.g. condensation of the nucleoid, cleavage of *gag* and *gag-pol* proteins, etc.

**Transmission.** Retroviruses may be transmitted by three distinct routes, not all of which can occur in all retroviruses. Horizontal transmission may occur e.g. by direct contact, via saliva, via insect vectors, etc, depending on virus. Vertical transmission may occur e.g. in avian retroviruses by infection of progeny via

RETROVIRIDAE: Figure 2. Model for retroviral dsDNA synthesis from the ssRNA genome. (Thin lines = RNA; thick lines = DNA.) (Continued on page 659.)

the egg albumen, or in mammalian retroviruses by infection of the fetus via the placenta. Some authors regard this as a form of horizontal transmission, as distinct from the third route of transmission: vertical transmission by inheritance of the provirus through the germ line – i.e., the provirus is inherited as is any other chromosomal sequence. (cf. ENDOGENOUS RETROVIRUS and EXOGENOUS RETROVIRUS.)

**Genetic interactions.** Retroviruses appear to be genetically unstable and give rise to defective and recombinant variants at high frequencies. For example, recombination may occur between the genomes of closely related retroviruses infecting the same cell. An intermediate in such recombination may be a heterozygous virus particle in which the two RNA 'monomers' are contributed by different viruses; recombination may result from a 'copy-choice' mechanism involving the transfer of nascent DNA strands from one template to another during reverse transcription. Recombination can also occur e.g. between the nucleic acid of an infecting exogenous retrovirus and that of an endogenous virus, or between retroviral and host nucleic acids. The mechanism for such recombination is unknown; it could occur by a copy-choice mechanism involving RNA transcripts of the relevant sequences, or by a breakage-and-reunion mechanism involving e.g. proviral DNA and chromosomal DNA. Recombination between retroviral and chromosomal sequences may lead to the incorporation of host genes into the viral genome. Such a recombinant viral genome is usually replication-defective since the cellular sequences are usually acquired at the expense of viral coding sequences. These viruses can thus replicate only in the presence of a replication-competent helper virus (i.e., one with intact *gag*, *pol* and *env* genes) which can provide the missing replication functions; the defective genome may then be packaged into particles (PSEUDOTYPES) which can infect other cells, thereby resulting in the *transduction* of cellular DNA to other host cells.

**Oncogenesis.** The transducing ability of retroviruses was discovered when certain replication-competent viruses – which are normally capable of inducing neoplastic disease in their hosts only at very low frequencies and after long latent periods – were found to give rise to acutely oncogenic, usually replication-defective variants; many of these variants were found to contain sequences derived from cellular ONCOGENES, and appear to have arisen by recombination between sequences of the infecting retrovirus and host *c-onc* sequences. The viral oncogenes (*v-onc*) differ from their cellular counterparts e.g. in that they lack introns; they are subject to viral, rather than cellular, control signals, and appear to confer on the virus the ability to induce neoplastic disease efficiently and after a short latent period. (Not

all *v-onc*<sup>+</sup> viruses are replication-defective: certain strains of ROUS SARCOMA VIRUS contain the oncogene *v-src* in addition to a full complement of viral genes.) All known *v-onc*<sup>+</sup> viruses can transform at least some type(s) of cell in culture; by contrast, very few *v-onc*<sup>-</sup> viruses can transform cells in culture (cf. HTLV), although a few can cause CPE (e.g. vacuolization, syncytium formation, cell death) – usually only in certain types of cell. (See also e.g. AVIAN LEUKOSIS VIRUSES, FELINE LEUKAEMIA VIRUS, MURINE LEUKAEMIA VIRUSES; cf. FRIEND VIRUS and MCF VIRUSES.)

**retroviruses** Viruses of the RETROVIRIDAE.

**retting** The process by which cellulose fibres are released from the stems of flax (*Linum usitatissimum*), hemp (*Cannabis sativa*), or jute (*Corchorus* spp, Tiliaceae) by the action of pectinolytic fungi and bacteria; these organisms soften the stems, and the fibres are then separated by beating ('scutching'). The fibres are used in the textile industry e.g. for the manufacture of linen (from flax), hessian (from hemp or jute), twine (from hemp) etc. In aerobic retting processes ('dew retting') the organisms involved include e.g. *Cladosporium herbarum*, *Aureobasidium pullulans*, and species of *Cryptococcus*, *Rhizopus*, *Rhodotorula*, *Bacillus* and *Pseudomonas*. In anaerobic processes the stems are submerged in water-tanks, and the main retting agents are *Clostridium* spp, especially *C. felsineum*.

**REV** (REV-T, REV-A) See AVIAN RETICULOENDOTHELIOSIS VIRUSES.

**reversal reaction** See LEPROSY.

**reverse CAMP test** See CAMP TEST.

**reverse electron transport** Energy-dependent ('uphill') electron flow along an ELECTRON TRANSPORT CHAIN (or part of an ETC); the energy for reverse electron transport is derived from proton motive force (see CHEMIOSMOSIS), and, in e.g. animal mitochondria, the electrons may derive from the oxidation of succinate. Reverse electron transport is an essential process in e.g. photosynthetic bacteria of the Rhodospirillaceae; in these organisms, pmf derived from PHOTOSYNTHESIS is used not only for the synthesis of ATP but also for the generation of reducing equivalents by uphill electron flow to NAD<sup>+</sup>. In *Thiobacillus ferrooxidans*, reduction of pyridine nucleotides is reported to involve uphill electron flow through the *bc<sub>1</sub>/NADH-Q* oxidoreductase complex acting in reverse [JB (2000) 182 3602–3606].

**reverse gyrase** A TOPOISOMERASE which can introduce *positive* supercoiling into ccdDNA, using the energy of ATP hydrolysis; the enzyme has been found e.g. in the archaean *Sulfolobus acidocaldarius* [Nature (1984) 309 669–681] and in bacteria of the order Thermotogales [JB (1991) 173 3921–3923] – all being *thermophilic* organisms. The function of reverse gyrase is unknown, but one suggestion is that it may have an important

RETROVIRIDAE: Figure 2 (continued)

1. The ssRNA retroviral genome.
2. (–)-Strand DNA synthesis by reverse transcriptase is initiated on the tRNA primer at the (–) PBS, and (–)-strand DNA is synthesized to the 5' end of the template.
3. The 5' R region of the RNA template is removed by RNase H. The DNA R region can then pair with the RNA 3'-R region, thus providing the template for continued DNA elongation.
4. As the (–) DNA strand elongates, the RNA template is degraded by RNase H; a short sequence of RNA at P [(+)PBS?], apparently being resistant to RNase H action, remains to function as a primer for the initiation of (+)-strand DNA synthesis [JB (1984) 52 314–319].
5. (–)-Strand DNA synthesis reaches the end of the RNA template, thus providing a template for continued (+)-strand DNA synthesis.
6. (–)-Strand synthesis continues beyond the RNA genome length to duplicate the U3–R–U5 region.
7. Continued (+)-strand synthesis into the U3–R–U5 region results in the completed dsDNA molecule with a U3–R–U5 sequence (long terminal repeat, LTR) at each end.

## reverse mutation

role in life at high temperatures. Possibly, the enzyme pre-dates the evolutionary split between archaeans and bacteria.

**reverse mutation** *Syn.* BACK MUTATION.

**reverse passive latex agglutination test** See LATEX PARTICLE TEST.

**reverse primer** See FORWARD PRIMER.

**reverse transcriptase** RNA-dependent (i.e. RNA-directed) DNA polymerase: an enzyme which synthesizes DNA on an RNA template. Reverse transcriptases are encoded by viruses of the RETROVIRIDAE, by RETROID VIRUSES, and by certain retrovirus-like elements (e.g. A-TYPE PARTICLES and TY ELEMENTS); a reverse transcriptase has been isolated from the protozoan *Paramecium tetraurelia* [Eur. J. Biochem. (1987) 163 569–575], and genes encoding a reverse transcriptase have been demonstrated in certain myxobacteria and in *Escherichia coli* [Nature (1989) 339 254] (see also RETRON). (The DNA polymerase I of *Escherichia coli* has reverse transcriptase ability but, in this capacity, it has rather poor processivity [EMBO (1993) 12 387–396].)

Like DNA-dependent DNA POLYMERASES, a reverse transcriptase requires a short RNA primer for the initiation of DNA synthesis, and catalyses polymerization in the 5'-to-3' direction; divalent cations ( $Mg^{2+}$  or  $Mn^{2+}$ ) are necessary for activity. The initial result of DNA synthesis on an RNA template (a process which is called reverse transcription or *retrotranscription*) is a DNA–RNA hybrid (see CDNA); at least some reverse transcriptases have RNase H activity (see RNASE H) and are able to degrade the RNA strand of the hybrid, allowing a complementary strand of DNA to be synthesized on the newly formed strand (giving rise to ds cDNA).

Reverse transcriptases lack 3'-to-5' exonuclease activity, i.e. they have no proof-reading capacity (cf. DNA POLYMERASE), so that their synthesis of DNA is error-prone. These enzymes seem able to switch from one template to another during polymerization, possibly allowing recombination by a 'copy-choice' mechanism (see RETROVIRIDAE).

Reverse transcriptase can be inhibited e.g. by AZT, PHOSPHONOFORMATE and SURAMIN but is insensitive to many other inhibitors of DNA and RNA.

Reverse transcriptases are employed in several techniques (e.g. REVERSE TRANSCRIPTASE PCR (rtPCR), NASBA) which are used for the in vitro amplification of nucleic acids. Commonly used enzymes include avian myeloblastosis virus reverse transcriptase (AMV reverse transcriptase) and Moloney murine leukaemia virus reverse transcriptase (MMLV reverse transcriptase).

MMLV reverse transcriptase is a cloned enzyme of MWt ~71000 which has RNase H activity.

The AMV reverse transcriptase comprises two types of subunit:  $\alpha$  (MWt 68000) and  $\beta$  (MWt 92000). The  $\alpha\beta$  form has both DNA-dependent DNA polymerase and bidirectional RNase H activity (these two functions residing in the  $\alpha$  subunit). [Example of use of AMV reverse transcriptase: JCM (1999) 37 524–530].

**reverse transcriptase PCR** (rtPCR, rt-PCR, RT-PCR; formerly: RNA PCR) A procedure in which (i) a strand of DNA is synthesized on an RNA target molecule by a REVERSE TRANSCRIPTASE – forming a hybrid RNA/DNA duplex; (ii) the strand of RNA is degraded, either by RNase H or by the RNase H activity of reverse transcriptase; (iii) a complementary strand of DNA is synthesized on the first strand, forming double-stranded cDNA; (iv) the dsDNA copy of the original RNA amplicon is amplified by standard PCR methodology. The initial phase (reverse transcription) may be carried out as a separate stage in a 'two-tube' approach [e.g. JVM (1997) 69 63–72]; alternatively,

both phases (reverse transcription and PCR proper) may be carried out in a single tube [e.g. JCM (1999) 37 524–530].

Reverse transcription, which requires a primer, is carried out isothermally at e.g. 50°C. Such relatively low temperatures can be problematic if the target RNA contains secondary structures that are destabilized only at a higher temperature: the presence of secondary structures can block the synthesis of cDNA by physically impeding the polymerase. The problem of secondary structures may be overcome by carrying out reverse transcription at a higher temperature. This approach requires a thermostable polymerase such as the *rTth* DNA polymerase (Perkin-Elmer) – a recombinant form of the *Thermus thermophilus* enzyme which can operate as a reverse transcriptase at 60–70°C in the presence of  $Mn^{2+}$  and can also amplify DNA in the cycling phase of PCR in the presence of  $Mg^{2+}$ .

rtPCR can be used e.g. to detect specific types of mRNA molecule. It is particularly useful for studying RNA viruses; examples include: dengue virus [JCM (1999) 37 2543–2547]; hepatitis G virus [JCM (1997) 35 767–768]; hepatitis C virus and HIV-1 [Lancet (1999) 353 359–363].

**reverse transcription** See REVERSE TRANSCRIPTASE.

**reversion** Restoration of the original phenotype of a mutant organism by means of a BACK MUTATION or a SUPPRESSOR MUTATION; the resulting organism is called a *revertant*.

**revertant** See REVERSION.

**Reyes syndrome** An acute disease of children and adolescents; it involves e.g. non-inflammatory encephalopathy with fatty infiltration and dysfunction of the liver, and is characterized clinically by persistent and profuse vomiting and neurological dysfunction – sometimes progressing to delirium, coma and death. The aetiology is unknown. The syndrome characteristically follows infection with certain viruses, particularly influenza A or B or varicella-zoster viruses. An association has also been recognized between the occurrence of Reyes syndrome and the administration of aspirin during the prodromal phase of the viral infection; in the USA, decreasing use of salicylates in children has apparently correlated with a decrease in the incidence of Reyes syndrome [Pediatrics (1986) 77 598–602].

**RF** Replicative form, an intermediate formed during the replication of certain ssDNA or ssRNA viral genomes; an RF is a double-stranded structure consisting of the viral strand base-paired with its (newly synthesized) complementary strand. (cf. RI.) In e.g. SSDNA PHAGES the RF is a circular dsDNA molecule; the supercoiled ccc form is designated RFI (cf. DNA I), while the relaxed form – nicked in one strand – is designated RFII (cf. DNA II).

**RF-1, RF-2, RF-3** See PROTEIN SYNTHESIS (termination).

***rfb* gene** See EHEC.

**RFLP** Restriction fragment length polymorphism: a phrase which refers to differences in fragment length which may be obtained when related sequences of DNA are exposed to the same RESTRICTION ENDONUCLEASE(S); such differences may arise e.g. if sequence(s) have lost or gained one or more (relevant) restriction sites as a result of mutation, or if particular fragment(s) are longer or shorter, respectively, as a result of insertion or deletion of nucleotides. The concept of RFLP is illustrated in the figure.

RFLP analysis is used e.g. for TYPING. For typing short sequences (e.g. a plasmid, viral DNA, or a short sequence in a bacterial chromosome), the fragments formed by restriction are examined by electrophoresis and staining (thus providing a *fingerprint*). This approach has been used e.g. for detecting variation in the genome of herpes simplex virus type 1 [RMM (1998) 9 217–224].

RFLP (principle, diagrammatic). Horizontal lines represent related DNA duplexes. The top duplex has two sites for a given restriction endonuclease; enzymic cleavage (arrow) at each of these two sites produces three restriction fragments. In the centre duplex, the second cleavage site has been lost through mutation; enzymic cleavage produces only two fragments, fragment 1 being the same as before. The lower duplex contains an extra short sequence of nucleotides (dashed line); enzymic cleavage of this duplex produces three fragments, but fragment 2 is longer than that in the top duplex. Electrophoresis of the fragments from each duplex will produce different fingerprints.

RFLP-based typing proceeds differently when large sequences (e.g. a whole bacterial chromosome) are involved. Initially, chromosomes of the test strain are cleaved by restriction enzyme(s) and the fragments separated by electrophoresis in polyacrylamide gel. Bands of fragments in the gel are 'blotted' onto a membrane, and the membrane is then exposed to labelled probes complementary to a specific target sequence in the chromosome; thus, probes will hybridize only to those bands of fragments which include the target sequence, and only these bands will be made visible by the probe's label. Suppose, for example, that the probe's target is a sequence in a single-copy gene. In this case probes will hybridize to only one band of fragments on the membrane; however, this may be sufficient to reveal differences between test strains as the target-containing fragment may vary in length among the different strains (giving rise to bands in different relative positions in the gel). In some cases the probe is complementary to a *multicopy* target sequence; any target which occurs in multiple copies in the genome has the advantage that it will probably give rise to a fingerprint consisting of more than one band and (for this reason) is likely to have superior discriminatory power as a typing procedure. One example of this is IS6110-based typing of *Mycobacterium tuberculosis*; most strains have multiple copies of IS6110 (strain H37Rv has 16 copies [Nature (1998) 393 537–544]), and, because IS6110 is a mobile genetic element, it can insert at different sites in the chromosome and (thus) give rise to new strains (with new fingerprints).

Note that RIBOTYPING (q.v.) is a particular form of RFLP-based typing.

A possible problem in RFLP-based typing arises because chromosomal DNA isolated from a test strain will have undergone modification (i.e. methylation of bases in certain sequences); such modification will inhibit certain restriction endonucleases so that a careful choice of enzymes is necessary. This problem can be avoided by amplifying a chromosomal target sequence *in vitro* by PCR; the amplicons (which lack methylation owing to synthesis *in vitro*) can then be used for RFLP analysis. PCR-RFLP analysis has been used e.g. for typing isolates of *Staphylococcus aureus* from cows and sheep with mastitis [JCM (1999) 37 570–574].

**RGD motif** See INTEGRINS.

**rhl gene (rhl gene)** See PHASE VARIATION.

**rhabdocyst** A rod-like EXTRUSOME which occurs in some gymnostome ciliates.

**Rhabdomonas** See EUGLENOID FLAGELLATES.

**rhabdomyosarcoma** See SARCOMA.

**rhabdos** A type of (non-curved) CYTOPHARYNGEAL APPARATUS whose walls are strengthened externally by nematodesmata and are frequently lined by longitudinally arranged TRANSVERSE MICROTUBULES arising from peri-oral kinetosomes. Toxicysts are sometimes present. The rhabdos is believed to be more primitive than the CYRTOS.

**rhabdosarcoma** See SARCOMA.

**Rhabdostyla** See PERITRICHIA.

**Rhabdoviridae** A family of enveloped, ssRNA-containing VIRUSES which can infect vertebrates, invertebrates or plants; the family includes some important pathogens, e.g. the causal agents of RABIES and VESICULAR STOMATITIS. The rhabdovirus virion contains 4–5 proteins designated L (large), G (glycoprotein), N (nucleocapsid), NS (non-structural) and M (matrix); 15–25% lipid (composition depending on host cell); and ca 3% carbohydrate. Genome: one molecule of linear negative-sense ssRNA (MWt ca.  $3.5\text{--}4.6 \times 10^6$ ). Maturation involves budding through host membranes. Rhabdoviruses are stable at pH 5–10 (unstable at pH 3), but are rapidly inactivated by heating to 56°C, by UV and X-irradiation, and by lipid solvents.

*Animal rhabdoviruses* are typically 'bullet-shaped' (i.e. cylindrical with one end flat, the other rounded), measuring e.g. ca.  $170 \times 70$  nm (VSV). The virion consists of a helical nucleocapsid composed of an RNA-N protein complex, associated with proteins L and NS, and surrounded by protein M – the whole being enclosed within the lipoprotein (ether-sensitive) envelope. The G protein forms surface projections ca. 5–10 nm long; antibodies to the G protein neutralize the virus. Various enzymic activities are associated with the virion, including e.g. transcriptase, protein kinase, 5' capping enzymes, etc. Virus replication occurs in the cytoplasm. Two genera: LYSSAVIRUS and VESICULOVIRUS. Other 'probable members' include e.g. BOVINE EPHEMERAL FEVER virus, EGTVED DISEASE virus, INFECTIOUS HAEMATOPOIETIC NECROSIS virus, red disease of pike virus, rhabdovirus of blue crab, rhabdovirus of *Entamoeba*, rhabdovirus of grass carp, SIGMA VIRUS of *Drosophila*, SPRING VIRAEMIA OF CARP virus.

*Plant rhabdoviruses* are usually bacilliform, sometimes bullet-shaped, typically ca.  $200\text{--}350 \times 70\text{--}95$  nm; all contain proteins N and G, some have proteins L, M and NS, others have proteins 'M1' and 'M2'. Each member generally infects only one or a few plant species, and is transmitted (circulatively) by one or more particular vectors (aphids, leaf-hoppers, plant-hoppers, bugs or mites); some members (not those infecting gramineous hosts) can be transmitted mechanically under experimental conditions. Two subgroups of plant rhabdoviruses (A and B) have been distinguished on the basis of the site of virus assembly, virion protein composition, and transcriptase activity *in vitro*. Members of subgroup A – e.g. lettuce necrotic yellows virus (type member), broccoli necrotic yellows virus, wheat striate mosaic virus – share some properties with *Vesiculovirus*: virions mature and accumulate in the host cell cytoplasm, contain protein M, and have readily detectable transcriptase activity *in vitro*. Members of subgroup B – e.g. potato yellow dwarf virus (type member), eggplant mottled dwarf virus – bud at the inner membrane of the nuclear envelope and accumulate in the perinuclear space, contain proteins M1 and M2, and have low transcriptase activity *in vitro*. Other probable (but ungrouped)

## rhabdovirus

members of the plant rhabdoviruses include e.g. carrot latent virus, lucerne enation virus, raspberry vein chlorosis virus, and strawberry crinkle virus (all aphid-borne); barley yellow striate mosaic virus (= cereal striate virus), cereal chlorotic mottle virus, finger millet mosaic virus, maize mosaic virus, oat striate virus, rice transitory yellowing virus, Russian winter wheat mosaic virus, and wheat chlorotic streak virus (all hopper-borne); beet leaf curl virus (lace bug-borne); coffee ringspot virus (mite-borne). Listed by the ICTV [Book ref. 23, pp. 112–114] as 'possible members' are some non-enveloped viruses (e.g. *Citrus leprosis virus* and orchid fleck virus) and many virus-like particles; these appear to resemble rhabdovirus nucleocapsids (ca. 100–120 × 35 nm) and form characteristic 'spoked-wheel' structures in the plant cell nucleus.

**rhabdovirus** A virus of the RHABDOVIRIDAE.

**rhamnogalacturonan** See PECTINS.

**rhamnolipid** (2-*O*- $\alpha$ -L-rhamnopyranosyl- $\alpha$ -L-rhamnopyranosyl- $\beta$ -hydroxydecanoyl- $\beta$ -hydroxydecanoate) An extracellular glycolipid BIOSURFACTANT produced by certain strains of *Pseudomonas aeruginosa* during growth on HYDROCARBONS.

**L-rhamnose** 6-Deoxy-L-mannose; it occurs e.g. in many plant glycosides and PECTINS, many streptococcal C SUBSTANCES, and some LIPOPOLYSACCHARIDES (e.g. the O-specific chains of certain *Salmonella* serotypes).

**Rhaphidophyceae** See CHLOROMONADS.

**rhabidosomes** Rod-shaped or tubular structures, 20–30 nm in diameter, which occur in many species of bacteria (e.g. *Flexibacter*, *Pseudomonas* spp) and cyanobacteria (e.g. *Spirulina*). Rhabidosomes (in different organisms) have been variously regarded as bacteriocins, defective phage tails, particles of mesosomal membrane, and cell components involved in motility.

**Rheinberg illumination** (coloured field illumination; optical staining) Illumination analogous to that used in low-power *dark-field* MICROSCOPY (q.v.). Instead of an opaque stop, the condenser is fitted with a *Rheinberg disc*: a transparent disc with a central circular area of one colour and a surrounding annulus of one or more lighter colours; the central colour forms the background light while the specimen is lit by the peripheral rays of the lighter colour(s).

**rheotaxis** A TAXIS in which the stimulus is a current; a positively rheotactic organism swims against a prevailing current (i.e., it swims 'upstream').

**rheotropism** See TROPISM (sense 1).

**rheumatic fever** A condition which occurs as a late complication of SCARLET FEVER or a group A streptococcal infection of the throat ('strep throat', tonsillitis) or middle ear (OTITIS MEDIA); it may follow an asymptomatic streptococcal infection, but rarely or never occurs after streptococcal skin infection (e.g. IMPETIGO, ERYSIPELAS) – cf. POST-STREPTOCOCCAL GLOMERULONEPHRITIS. Rheumatic fever occurs most commonly in children aged between 5 and 15. An asymptomatic latent period of 1–3 weeks may occur between the original infection and the onset of rheumatic fever. Onset is usually rather insidious, with malaise, fever, and inflammation of joints; other symptoms may include e.g. subcutaneous nodules, rash, and/or involuntary twitching movements (Sydenham's chorea, 'St Vitus's dance'). Endocarditis may develop and may lead to chronic rheumatic valvular heart disease. An individual who has suffered an attack of rheumatic fever has greatly increased susceptibility to subsequent streptococcal infection. Rheumatic fever is apparently unrelated to the presence of living streptococci and is believed to be caused by an immunopathological mechanism; it may be due to an autoimmune reaction between anti-group A streptococcal antibody and a host tissue component.

**rheumatoid arthritis** A chronic, systemic disease involving inflammatory changes in the body's connective tissues, resulting in a progressive, deforming ARTHRITIS. Pathogenesis appears to involve an autoimmune reaction (in genetically predisposed individuals) which is triggered by an unknown environmental factor (possibly a virus); IgM autoantibodies ('rheumatoid factor') to IgG are formed, and IgG–IgM immune complexes are deposited in the synovium and blood vessels, causing inflammation. Whether or not viruses have a role in the pathogenesis of rheumatoid arthritis is controversial, but parvovirus-like particles have been detected in synovial tissue from the joints of a rheumatoid arthritis patient [Science (1984) 223 1425–1428]. (See also ROSE-WAALER TEST.)

**rheumatoid factor** See RHEUMATOID ARTHRITIS and ROSE-WAALER TEST.

**rhexolysis** See CONIDIUM.

**rhinitis** Inflammation of the nasal mucous membranes. It occurs e.g. in the COMMON COLD and in allergic reactions such as hay fever.

**Rhinocladia** See HYPHOMYCETES; see also CHROMOBLASTOMYCOSIS.

**rhinophycomycosis** Nasofacial or rhinocerebral ZYGOMYCOSIS.

**rhinosporidiosis** A chronic disease of man and animals, caused by *Rhinosporidium seeberi*, characterized by the formation of polyp-like growths chiefly on the mucosae of the nose and upper respiratory tract; breathing may be obstructed. Dissemination is rare.

**Rhinosporidium** A genus of fungi of uncertain taxonomic position; *R. seeberi*, causal agent of RHINOSPORIDIOSIS, apparently resembles 'Hyphochytridiomycetes' rather than Chytridiomycetes [JMM (1985) 20 x (abstr.)]. In infected tissues, *R. seeberi* forms spherical sporangia (up to ca. 300  $\mu$ m, depending e.g. on stage of development) which, when mature, develop thick refractile walls and undergo nuclear and cytoplasmic division to form numerous uninucleate endospores (6–7  $\mu$ m); endospores are released on rupture of the cell wall.

**rhinotracheitis** Inflammation of the mucous membranes of the nose and trachea. See e.g. FELINE RHINOTRACHEITIS and INFECTIOUS BOVINE RHINOTRACHEITIS.

**Rhinovirus** A genus of viruses (family PICORNAVIRIDAE) which are acid-labile (being rapidly inactivated at pH < 6) and which infect the mammalian upper respiratory tract (cf. ENTEROVIRUS). Human rhinoviruses are the major causal agents of the COMMON COLD; many serotypes are known. They can be propagated in various human cell cultures (e.g. WI-38) and have an optimum growth temperature of 33°C. Most strains are stable at or below room temperatures and can withstand freezing; some strains are stable at 50°C for 1 hour. Most heat-labile serotypes (but not type 30) can be stabilized to heat by the presence of MgCl<sub>2</sub>. Rhinoviruses can be inactivated by e.g. citric acid (see COMMON COLD), tincture of iodine or phenol/alcohol mixtures, but generally not by e.g. alcohols, bile salts, hexachlorophene, organic solvents, or quaternary ammonium compounds. [Clinical and epidemiological aspects: Book ref. 148, pp. 795–816. Nucleotide sequences of the genomes of human rhinovirus types 2 and 14: NAR (1985) 13 2111–2126 and PNAS (1985) 82 732–736, respectively.]

Other members of the genus include the bovine rhinoviruses; 'equine rhinoviruses' may represent a separate genus.

**Rhipicephalus** A genus of ixodid ticks which are vectors of certain diseases: e.g. REDWATER FEVER.

**Rhipidium** See LEPTOMITALES.

**Rhizoclema** A genus of siphonaceous, calcified green seaweeds (division CHLOROPHYTA).

**Rhizamoeba** See ACARPOMYXEA.

**Rhizidiomyces** A genus of unicellular fungi (class HYPHOCHYTRIOMYCETES) which occur in soil and as parasites of certain water moulds (members of the Saprolegniaceae) and algae (e.g. *Vaucheria*).

**Rhizidiomycetaceae** See HYPHOCHYTRIOMYCETES.

**rhizine** (rhizina) (*lichenol.*) A root-like structure consisting of a compact bundle of hyphae. Rhizines (rhizinae) arise mainly from the lower surface of the (usually foliose) thallus and serve to anchor the thallus to the substratum; in some species they may also facilitate the uptake of water and nutrients by the thallus [Bryol. (1981) 84 1–15]. Rhizines may be unbranched or may be sparsely or extensively branched – branching being e.g. ‘squarrose’ (short branchlets emerging at ca. 90°) or dichotomous.

**Rhizobiacea** A family of Gram-negative, asporogenous, rod-shaped, motile, aerobic, chemoorganotrophic bacteria; all (except *Agrobacterium radiobacter*) can induce tumour-like growths in plants. Genera: AGROBACTERIUM, BRADYRHIZOBIUM, PHYLOBACTERIUM, RHIZOBIUM.

**Rhizobium** A genus of Gram-negative bacteria of the RHIZOBIACEAE. Cells: rods, 0.5–0.9 × 1.2–3.0 µm; pleomorphic under adverse conditions. Motile: one (usually subpolar) flagellum (in *R. loti*) or several lateral or sometimes polar flagella (in *R. leguminosarum* and *R. meliloti*); in some strains ‘complex flagella’ occur: see FLAGELLUM. Refractile PHB granules are common, especially in older cells. Colonies: mucilaginous, usually 2–4 mm diameter in 3–5 days on yeast extract–manitol–mineral salts agar (cf. BRADYRHIZOBIUM). Acid (no gas) is formed from a range of carbohydrates (e.g. mannitol). Abundant extracellular slime (including a neutral (1 → 2)-β-glucan) is produced in carbohydrate-containing media. [Media and methods: Book ref. 45, pp. 824–834.] GC%: 59–64. Type species: *R. leguminosarum*.

*Rhizobium* spp are common in soil [ecology: Book ref. 45, pp. 818–822] and can incite ROOT NODULE formation in certain leguminous plants (mainly in temperate regions – cf. STEM NODULES); the free-living organisms appear to be incapable of nitrogen fixation. Strains which are both *infective* (able to induce nodule formation) and *effective* (able to fix nitrogen) tend to become ineffective (but may remain infective) e.g. after continual laboratory cultivation.

*R. phaseoli*, *R. trifolii* and *R. viceae* are currently regarded as biotypes of *R. leguminosarum*. *R. lupini* is currently not a recognized species; it may be a species or biotype of *Bradyrhizobium*. *R. japonicum*: see BRADYRHIZOBIUM.

[Book ref. 22, pp. 235–242.]

**Rhizocarpon** A genus of LICHENS (order LECANIDIALES); photobiont: a green alga. The thallus is crustose, typically forming a mosaic of yellow or grey areolae between which the black hypothallus is visible. Saxicolous. Apothecia: black, lecidine; ascospores: septate to muriform. [Ascus structure: *Lichenol.* (1980) 12 157–172.]

**Rhizoclonium** A genus of filamentous, siphonocladous green algae (division CHLOROPHYTA) in which the filaments are unbranched or bear laterally inserted rhizoidal branches.

**Rhizoctonia** A genus of fungi (order AGONOMYCETALES) which include some important plant pathogens. *R. leguminicola*, the causal agent of blackpatch disease of clover (see SLAFRAMINE), can form sclerotia under appropriate conditions. *R. solani* can cause DAMPING OFF and EYESPOT (sense 2). (See also FOOT-ROT sense 2.) [Systematics and phylogeny of the *Rhizoctonia* complex: *Bot. Gaz.* (1978) 139 454–466; genetics and pathology of *R. solani*: *ARPPath.* (1982) 20 329–347.]

**rhizogenic** Capable of inducing root formation.

**rhizoid** A root-like structure which forms part of the thallus in certain algae and fungi; it may anchor the organism to the substratum and/or act as an absorptive organ or organelle. (cf. RHIZOMYCELIUM.)

**rhizomania** See BEET NECROTIC YELLOW VEIN VIRUS.

**rhizomorph** (*mycol.*) A macroscopic, typically dark-coloured thread of hard, compacted tissue formed by certain higher fungi, e.g. *Armillaria mellea*; the tissue generally appears to consist of individual cells rather than hyphae. Rhizomorphs are enduring structures which can remain dormant under adverse conditions and which can enable a fungus to spread into the surrounding environment – e.g. those of *A. mellea* permit the fungus to spread from an infected tree to an uninfected tree via the soil. (See also DRY ROT.)

**Rhizomucor** A genus of fungi of the MUCORALES. *R. pusillus* (formerly *Mucor pusillus*) can cause ZYGOMYCOSIS. (See also COMPOSTING.) *R. miehei* (formerly *Mucor miehei*) and *R. pusillus* form PROTEASES which are used as rennin substitutes.

**rhizomycelium** (*mycol.*) Branching, nucleate or sparsely nucleate, rhizoidal filaments of variable width which form part of the thallus e.g. of *Nowakowskiella* and of some species of the Laboulbeniales.

**Rhizophidium** See RHIZOPHYDIUM.

**Rhizophydium** (*Rhizophidium*) A genus of eucarpic fungi (order CHYTRIDIALES) which occur as saprotrophs or as parasites of aquatic or terrestrial plants; *R. graminis* parasitizes the root cells of mono- and dicotyledonous plants (apparently without causing them harm), while *R. couchii* has been reported to parasitize *Spirogyra*. In the asexual cycle of *R. couchii*, a zoospore encysts on the surface of a host and gives rise to a thallus whose rhizoids penetrate the host; the extracellular part of the thallus subsequently becomes converted into a zoosporangium. In the sexual cycle, zoospores develop into extracellular, rhizoid-bearing gametangia; after plasmogamy (and karyogamy?) the zygote becomes a thick-walled resting zoosporangium.

**rhizoplane** The root surface – cf. RHIZOSPHERE.

**rhizoplasmodium** See LABYRINTHULAS.

**rhizopod** An organism of the RHIZOPODA.

**Rhizopoda** A superclass of protozoa (subphylum SARCODINA) which are motile by means of lobopodia, filopodia or reticulopodia (see PSEUDOPODIUM) or by flow of protoplasm without the formation of discrete pseudopodia. Classes: ACARPOMYXEA; ACRASEA (see ACRAZIOMYCETES); EUMYCETAZOEA; FILOSEA; GRANULORETICULOSEA; LOBOSEA; Plasmodiophorea (= PLASMODIOPHOROMYCETES); XENOPHYOPHOREA.

**rhizopodium** See PSEUDOPODIUM.

**Rhizopogon** See GASTEROMYCETES (Hymenogastres).

**Rhizopus** A genus of fungi (order MUCORALES) which occur on soil, fruit etc. The organisms form a branched, aseptate mycelium. *R. nigricans* (= *R. stolonifer*) can attach to the substratum by means of branching rhizoids; a *stolon* (a surface hypha analogous to the stolons in higher plants) grows for some distance and then gives rise to more rhizoids and to one or more vertical sporangiophores. The organisms form ZYGOSPORES (see also COMPATIBILITY sense 2). *Rhizopus* spp are used commercially e.g. in the preparation of ONCOM, RAGI and TEMPEH and in certain STEROID BIOCONVERSIONS. (See also BREAD SPOILAGE and ZYGOMYCOSIS.)

**Rhizosolenia** A genus of freshwater and marine centric DIATOMS. Some (marine) species contain a nitrogen-fixing cyanobacterial symbiont, *Richelia intracellularis*, which occurs as short, *Calothrix*-like filaments – each with a heterocyst at one end or,

## rhizosphere

in the dividing diatom, at both ends. The association is not obligatory, and *Richelia* may also be found free-living or as an epiphyte on diatoms of the genera *Chaetoceros*, *Hemiaulus* and *Rhizosolenia*. (cf. RHOPALODIA.)

**rhizosphere** An environment regarded, variously, as e.g. (a) that region of the soil which is modified as a result of the uptake and deposition of substances by a growing root [AEE (1985) 12 99–116]; (b) the root itself, together with that volume of soil which it influences [Book ref. 112, p. 237]; or (c) the root surface (*rhizoplane*) together with that region of the surrounding soil in which the microbial population is affected, qualitatively and/or quantitatively, by the presence of a root. The rhizosphere may extend a few millimetres, or centimetres, from the rhizoplane.

From a growing root, a number of substances pass out into the soil. These substances include various carbohydrates (see also MUCIGEL), vitamins, amino acids and sugars – many of which serve as nutrients and/or as sources of energy for microorganisms. Presumably as a result of this, the microflora of the rhizosphere differs appreciably from that of the surrounding soil. In the rhizosphere, bacterial numbers are often 10- to 50-fold higher than they are in the surrounding soil; the bacteria are mainly Gram-negative rods (e.g. pseudomonads), Gram-positive bacteria typically being less numerous than they are outside the rhizosphere. It has been reported that the presence of a vesicular-arbuscular MYCORRHIZA (involving *Glomus fasciculatum*) reduces the proportion of fluorescent pseudomonads and increases the proportion of facultatively anaerobic bacteria in the rhizosphere – but does not affect the absolute number of Gram-negative bacteria [SBB (1986) 18 191–196].

Numerically, fungi may be present in similar or slightly greater abundance in the rhizosphere as compared with the surrounding soil. However, there may be qualitative (species) differences between rhizosphere and non-rhizosphere fungi, and in at least some cases there is evidence that the rhizospheres of certain plants encourage, or select, particular fungi.

The extent to which the plant benefits from the rhizosphere microflora remains unclear. It seems possible that the microflora may play some part in protecting the plant from the incursions of soil-borne pathogens; additionally, the plant may benefit from the mineralizing activities of these organisms, and it is generally believed that the presence of the rhizosphere microflora promotes the uptake of minerals (e.g. phosphate) by the root.

**rhizothamnium** A *Myrica*-type ACTINORRHIZA.

**rhl genes** See QUORUM SENSING.

**rho factor** ( $\rho$  factor) See TRANSCRIPTION.

**rho-form** See MYCOPLASMA (*M. mycoides*).

**rho gene** In e.g. *Escherichia coli*: the gene encoding the  $\rho$  factor (see TRANSCRIPTION).

**rho<sup>-</sup> petite** See PETITE MUTANT.

**rho<sup>0</sup> petite** See PETITE MUTANT.

**rhodamine** A generic term for a group of substituted xanthene FLUOROCHROME dyes; examples: rhodamine B (fluorescence red – see also AURAMINE–RHODAMINE STAIN and LISSAMINE RHODAMINE), rhodamine S (fluorescence yellow), rhodamine O (red), rhodamine 3G (orange). The rhodamines include cationic, anionic and neutral dyes. Uptake of *cationic* rhodamines (e.g. rhodamine 123) appears to depend on membrane potential in viable, functioning mitochondria [JCB (1981) 88 526–535] and bacteria [FEMS (1984) 21 153–157]. (See also VITAL STAINING.)

**rhodanese** (thiosulphate sulphurtransferase; EC 2.8.1.1) An enzyme that catalyses e.g. the formation of thiocyanate (SCN<sup>-</sup>) and sulphite (SO<sub>3</sub><sup>2-</sup>) from THIOSULPHATE and cyanide; it

occurs e.g. in certain bacteria (including *Bacillus subtilis*, *Desulfotomaculum nigrificans*, *Thiobacillus* spp), in plants, and in most mammalian tissues. It has been suggested that one of the roles of rhodanese is to donate sulphur to a thiophilic anion (e.g. dihydroliopate) which can complex iron and promote the formation of IRON–SULPHUR PROTEINS [TIBS (1986) 11 369–372; discussion: TIBS (1987) 12 56–57].

**Rhodobacter** A proposed genus of bacteria [IJSB (1984) 34 340–343] which includes species transferred from RHODOPSEUDOMONAS (q.v.) and re-designated *Rhodobacter adriaticus*, *R. capsulatus* (type species), *R. sphaeroides* and *R. sulfidophilus*. The genus includes motile and non-motile organisms; the cells divide by binary fission.

**Rhodochaete** See RHODOPHYTA.

**rhodocladonic acid** A bright-red naphthoquinone pigment found in the hymenial discs of certain CLADONIA spp.

**Rhodococcus** A genus of aerobic, chemoorganotrophic, non-motile bacteria (order ACTINOMYCETALES, wall type IV) which occur e.g. in soil, in aquatic habitats, and as pathogens of man and other animals. In culture, the cells of all species are cocci, or coccobacilli, which – depending on species – give rise e.g. to pleomorphic rods or to a branching mycelium; the rods or mycelium subsequently fragment to form the next generation of coccoid forms. Acid-fastness appears to be variable. The cell wall contains MYCOLIC ACIDS. The organisms grow well on nutrient media at 30°C; some strains need thiamine. Colonies are often pigmented (e.g. yellow, orange, red). Glucose is metabolized oxidatively. GC%: ca. 63–73. Type species: *R. rhodochrous*.

The genus includes *R. bronchialis*; *R. coprophilus* (a mycelial species); *R. equi* (formerly *Corynebacterium equi*: a non-mycelial species which is the causal agent of e.g. suppurative bronchopneumonia in the horse); *R. erythropolis*; *R. fascians* (formerly *Corynebacterium fascians* [SAAM (1984) 5 225–229]); *R. globerulus*; *R. luteus*; *R. maris*; *R. rhodnii*; *R. rhodochrous* (a species which forms branching rods, but not mycelium); *R. ruber* (a mycelial species); *R. rubropertinctus*; and *R. terrae*. [Book ref. 73, p. 93.] [A marine species, *R. marinonascens*: IJSB (1984) 34 127–138.] (See also CORYNECINI.)

**Rhodocyclus** A proposed genus of non-motile, spiral-shaped photosynthetic bacteria (family RHODOSPIRILLACEAE) consisting of a single species, *R. purpureus* [IJSB (1978) 28 283–288]. It was later proposed that certain species be transferred from the genera RHODOPSEUDOMONAS (q.v.) and RHODOSPIRILLUM (q.v.) and re-designated *Rhodocyclus gelatinosus* and *R. tenuis*, respectively [IJSB (1984) 34 340–343].

**Rhodomicrobium** A genus of photosynthetic bacteria (class RHODOSPIRILLACEAE); the sole species, *R. vannielii*, occurs e.g. in freshwater muds and in estuarine and marine habitats. *R. vannielii* contains Bchl *a* and carotenoids (mainly  $\beta$ -carotene and spirilloxanthin) in lamellar intracytoplasmic membrane systems; cell suspensions are typically pink-brown. Growth occurs photoorganotrophically under anaerobic conditions, or chemoorganotrophically under microaerobic to aerobic conditions in the dark.

*R. vannielii* undergoes one of two types of vegetative cell cycle, depending on growth conditions. In one type, a non-motile, ovoid cell (ca. 1–3  $\mu$ m) becomes prostheca, and a daughter cell is formed by budding at the tip of the PROSTHECA. The daughter cell remains attached, forms a prostheca at the opposite pole, and buds in turn. This leads eventually to an array of cells which are joined together by branched and unbranched filaments (ca. 0.3  $\mu$ m wide) derived from the

prosthecae. (Branches arise from the filaments.) Each cell is separated from its neighbour by a plug formed within the filament joining them. Such arrays – apparently the commonest form under natural conditions – may be produced under conditions of high light intensity and low concentrations of CO<sub>2</sub>. If the light dims and CO<sub>2</sub> levels rise (e.g. as the array becomes large), motile (peritrichous) *swarmer* cells form at the ends of filaments and are released by binary fission; under suitable conditions swarmer cells shed their flagella and become non-motile prosthecae cells, thus completing the cycle. If conditions of low light and high CO<sub>2</sub> persist, a second ('simplified') cell cycle occurs: arrays are not formed – budding cells giving rise only to swarmers; array formation can subsequently occur if CO<sub>2</sub> concentration decreases and light intensity increases. Under starvation conditions, cell arrays give rise to *exospores*: angular structures, resistant to heat and drying, which form at the tips of filaments and are released by binary fission; the exospores can germinate under aerobic conditions in the dark or anaerobically in the light, forming up to four vegetative cells. (Exospores are not formed in the 'simplified' cycle; late exponential phase cultures contain 'tiny' cells which are not resistant to stress [JGM (1980) 117 47–55].)

[Reviews: ARM (1981) 35 567–594; Book ref. 28, pp. 188–210.]

(See also HYPHOMICROBIUM.)

**rhodomycin** See ANTHRACYCLINE ANTIBIOTICS.

**Rhodophyceae** See RHODOPHYTA.

**Rhodophyta** (red algae) A division of ALGAE. Over 95% of the ca. 5000 species of red algae are marine organisms; those which occur in freshwater and/or soil habitats include species of *Audouinella*, *Bangia*, *Batrachospermum*, *Chroodactylon*, *Hildenbrandia*, *Lemanea* and *Porphyridium*. (Some genera, e.g. *Bangia*, *Bostrychia* and *Hildenbrandia*, contain both marine species and freshwater species.) A few red algae are parasitic on other algae (see e.g. CHOREOCOLAX and HOLMSELLA).

In most red algae the thallus is a branched filament or ribbon. However, some species are sheet-like (e.g. *Porphyra*) or crust-like (e.g. *Lithophyllum*), while a few (e.g. PORPHYRIDIUM) are unicellular. Some red algae are calcified – e.g. *Corallina* spp (thalli: erect, articulated) and *Lithophyllum*. Multicellular thalli (which are commonly 5–50 cm in length) are typically attached to rocks etc by a holdfast. The CELL WALL may contain cellulose or xylans. Plasmodesmata appear to be absent, but many multicellular red algae contain PIT CONNECTIONS. There are no flagellated species, and flagellated gametes are not produced. Marine species are usually some shade of red, while freshwater species are typically blue-green, yellow-green, brown or grey.

Red algae contain CHLOROPHYLL *a*, and some also contain chlorophyll *d*; the THYLAKOIDS occur singly (i.e., unassociated) and bear PHYCOBILISOMES containing phycoerythrins and/or phycocyanins. Various CAROTENOIDS (e.g. xanthophylls and  $\beta$ -carotene) are usually present. Storage products include FLORIDEAN STARCH and FLORIDOSIDE (see also ISOFLORIDOSIDE).

Sexual reproduction occurs in most species (but apparently not in *Porphyridium*) and oogamy is common; life cycles are often complex.

Certain red algae are used as sources of AGAR and CARRAGEENAN, while some are used as food (see e.g. LAVER, NUNGHAM, PALMARIA).

All species are placed in one class: Rhodophyceae. Orders [Book ref. 130]: Bangiales (e.g. *Bangia*, PORPHYRA);

Ceramiales (e.g. *Bostrychia*; *Ceramium*, *Griffithsia*, *Polysiphonia*); Compsopogonales (e.g. *Compsopogon*); Cryptonemiales (e.g. CHOREOCOLAX, *Corallina*, *Gloiopeltis*, *Hildenbrandia*, HOLMSELLA, *Lithophyllum*); Gigartinales (e.g. *Chondrococcus*, *Chondrus*, *Euclima*, *Furcellaria*, *Gardneriella*, GIGARTINA, *Gracilaria*, *Iridaea*); Nematiales (e.g. *Audouinella*, *Batrachospermum*, *Gelidium*, *Lemanea*); Palmariales (e.g. *Palmaria*); Porphyridiales (e.g. *Chroodactylon*, *Cyanidium*, PORPHYRIDIUM); Rhodochaetales (e.g. *Rhodochaete*); Rhodymeniales (e.g. *Coeloseira*, *Rhodymenia*).

[Biology of freshwater red algae: Book ref. 167, pp. 89–157.]

**Rhodopila** A proposed genus of bacteria [JJSB (1984) 34 340–343] which includes a species transferred from RHODOPSEUDOMONAS (q.v.) and re-designated *Rhodopila globiformis*; the coccoid, flagellated cells of *R. globiformis* grow only at low pH.

**Rhodopseudomonas** A genus of photosynthetic bacteria (family RHODOSPIRILLACEAE). Cells: flagellated (or non-motile) rods or cocci, typically 1–5  $\mu$ m; most species contain Bchl *a*, *R. sulfoviridis* and *R. viridis* contain Bchl *b*. *R. acidophila*, *R. palustris* (the type species), *R. sulfoviridis* and *R. viridis* divide by budding; other species divide by binary fission. *R. palustris* and *R. viridis* form prosthecae. The oval to rod-shaped species *R. adriatica*, *R. capsulata*, *R. sphaeroides* and *R. sulfidophila* all have vesicular-type photosynthetic membranes, and it has been proposed that they be transferred to a new genus: RHODOBACTER; it has also been proposed that the coccoid species *R. globiformis* (which has a vesicular photosynthetic membrane) and the curved, rod-shaped species *R. gelatinosa* be transferred to the genera RHODOPILA and RHODOCYCLUS, respectively [JJSB (1984) 34 340–343].

[Gene transfer mechanisms: Ann. Mic. (1983) 134B 195–204.] (See also CAPSUDUCTION.)

**Rhodospirillaceae** (purple non-sulphur bacteria, or non-sulphur purple bacteria; Athiorhodaceae) A heterogeneous family (see RHODOSPIRILLALES) of photosynthetic bacteria (suborder RHODOSPIRILLINEAE); they occur typically in those anaerobic habitats in which a range of simple organic substrates has been made available by the metabolic activities of chemoorganotrophic bacteria – e.g. in the mud of ponds and rivers, and in sewage lagoons. The organisms occur in freshwater, brackish and marine habitats and in moist soils. Most species contain only Bchl *a* (two species of *Rhodopseudomonas* have only Bchl *b*) – see CHLOROPHYLLS; these pigments, and various carotenoids, occur in lamellar, tubular or vesicular intracytoplasmic membrane systems, according to species. The organisms include cocci, rods and spiral forms; most species divide by binary fission, but several divide by budding (see e.g. RHODOPSEUDOMONAS). Heat-resistant forms are produced by *Rhodomicrobium vannielii*. Most species (not e.g. *Rhodocyclus purpureus*) exhibit flagellar motility. Gas vacuoles are absent. The organisms are primarily photoorganotrophic heterotrophs under anaerobic conditions, but a few species, e.g. *Rhodopseudomonas sulfidophila*, can grow as photolithotrophic autotrophs (using sulphide as electron donor), and some other members of the family can use sulphide as electron donor only when it is present in low concentrations. It has been shown that at least some species can oxidize elemental sulphur [JGM (1985) 131 791–798]; sulphide (or thiosulphate) can be oxidized to sulphate (without sulphur formation) by e.g. *Rhodopseudomonas sulfidophila*. Many species can oxidize sulphide with the production of extracellular deposits of sulphur. A number of species can use hydrogen as an electron donor for

## Rhodospirillales

photolithotrophic growth. Typically, growth requires one or more factors such as biotin, *p*-aminobenzoic acid and thiamine; many species can carry out nitrogen fixation, but a good rate of growth generally requires a source of organic nitrogen. Under aerobic or microaerobic conditions most species are chemoorganotrophic.

Genera: RHODOMICROBIUM, RHODOPSEUDOMONAS, RHODOSPIRILLUM (the type genus); see also RHODOBACTER, RHODOCYCLUS, RHODOPILA.

**Rhodospirillales** An order of Gram-negative anoxygenic photosynthetic bacteria (cf. CYANOBACTERIA). All species can carry out anoxygenic PHOTOSYNTHESIS under anaerobic conditions, but some (e.g. *Chloroflexus aurantiacus*, *Thiocapsa roseopersicina*, most members of the Rhodospirillaceae) can also grow chemoorganotrophically under aerobic or microaerobic conditions. All species contain one or more bacterioCHLOROPHYLLS and CAROTENOIDS; maximum concentrations of the pigments occur only under anaerobic conditions in low levels of light. (cf. ERYTHROBACTER.) The order includes cocci, rods, filaments and spiral forms; motile species may have flagella or may exhibit GLIDING MOTILITY. Endospores are not formed. In most species cell division occurs by binary fission; *Pelodyctyon clathratiforme* can divide by ternary fission, and BUDDING occurs in some species of *Rhodopsseudomonas* and in *Rhodomicrobium vannielii*. Many species can carry out NITROGEN FIXATION. Suborders: CHLOROBIINEAE and RHODOSPIRILLINEAE.

The order appears to be taxonomically unsound; thus, e.g. not only is there a wide divergence between the two suborders, but some members of the family Rhodospirillaceae seem to be more closely related to certain non-photosynthetic bacteria than to other members of the family. (See also CHLOROBIINEAE.)

(See also HELIOBACTERIUM.)

**Rhodospirillineae** (purple bacteria) A suborder of photosynthetic bacteria (order RHODOSPIRILLALES); species contain bacteriochlorophyll *a* (usually) or *b* (in a few cases) in intracellular membrane systems that are continuous with the cytoplasmic membrane (cf. CHLOROBIINEAE). Most species are motile (flagellate). The suborder includes metabolically diverse species; CO<sub>2</sub> fixation occurs mainly via the CALVIN CYCLE. Families: CHROMATIACEAE and RHODOSPIRILLACEAE.

**Rhodospirillum** A genus of photosynthetic bacteria (family RHODOSPIRILLACEAE). Cells: spiral-shaped, polarly flagellated, 3–10 µm long and 0.5–1.5 µm wide; they contain vesicular, lamellar or stacked photosynthetic membranes. The cells divide by binary fission. Species: *R. fulvum*, *R. molischianum*, *R. photometricum*, *R. rubrum* (type species), and *R. salexigens*; it has been proposed that *R. tenue* be transferred to the genus RHODOCYCLUS [IJSB (1984) 34 340–343].

**Rhodospirillum haem protein** See RHP.

**Rhodospiridium** See SPORIDIALES and RHODOTORULA.

**Rhodotorula** A genus of imperfect yeasts (class HYPHOMYCETES). The cells are spheroidal, ovoid or elongate; vegetative reproduction occurs by multilateral budding. Pseudomycelium and true mycelium may be formed by some strains of some species. Ballistospores are not produced. Visible carotenoid pigments are synthesized by cultures on e.g. malt agar; the colonies are typically red, pink, orange or yellow, and may be mucoid (capsulated strains), pasty, or dry and wrinkled. Metabolism is strictly respiratory; inositol is not assimilated. NO<sub>3</sub><sup>-</sup> is assimilated by all species except *R. minuta* and *R. rubra*. Other species include e.g. *R. aurantiaca*, *R. glutinis* (a complex of anamorphs of at least three teleomorphic species: *Rhodospiridium diobovatum*, *Rhodospiridium sphaerocarpum* and *Rhodospiridium toruloides*) and *R. graminis*. Strains have been isolated from e.g. plants and

plant debris, beverages, pickling brines (see also SAUERKRAUT), seawater, fresh water, etc. [Book ref. 100, pp. 893–905.]

**Rhodymenia** See RHODOPHYTA (cf. PALMARIA).

**Rhopalodia** A genus of pennate DIATOMS. The freshwater species *R. gibba* and *R. gibberula* contain, in addition to the typical diatom chloroplast, intracellular inclusion bodies which closely resemble thin-walled unicellular cyanobacteria and which carry out light-dependent nitrogen fixation. (cf. RHIZOSOLENIA.)

**Rhopalomyces** See ZOOPAGALES.

**rhoptries** (*sing.* rhoptry) In members of the APICOMPLEXA: elongate (e.g. club-shaped) osmiophilic organelles found at the anterior end of the cell; two such organelles per cell occur e.g. in the merozoites of *Isospora* spp and many *Eimeria* spp, while more than two per cell occur e.g. in some *Eimeria* merozoites and in *Sarcocystis* and *Toxoplasma*. Rhoptries appear to secrete enzymes which assist in host cell penetration [JUR (1983) 83 85–98].

**RHP** (*Rhodospirillum* haem protein; cytochromoid *c*) Original name for CYTOCHROMES *c'* and *cc'* which occur in at least some purple phototrophic bacteria and in *Pseudomonas denitrificans*.

**Rhynchodida** See HYPOSTOMATIA.

**Rhynchoidomonas** A genus of monoxenous protozoa (family TRYPANOSOMATIDAE) parasitic in the gut (particularly the Malpighian tubules) of flies. The organisms, 10–50 µm long, occur in the trypanostigote form but lack a free flagellum.

**Rhynchomonas** See BODONINA.

**rhynchosporium** A plant disease caused by *Rhynchosporium* sp: see e.g. LEAF BLOTCH.

**Rhynchosporium** See HYPHOMYCETES; see also LEAF BLOTCH.

**Rhytidhysterion** See ASCOSTROMA.

**Rhytisma** A genus of fungi of the RHYTISMATALES. *R. acerinum* causes *tar spot* disease in *Acer* spp (e.g. maple): conspicuous, flat, roundish, black stromata (ca. 1–2 cm diam.) develop on the upper surfaces of leaves from mid-summer onwards, the stromata bearing conidiophores of the imperfect (*Melasmia*) stage during the autumn; ascocarps (the over-wintering stage) develop within the stromata, each stroma splitting radially in the spring to expose the apothecial hymenia of asci containing filiform ascospores.

**Rhytismatales** An order of fungi (subdivision ASCOMYCOTINA) which include saprotrophic and plant-parasitic species. Ascocarp: APOTHECIOID, immersed in a stroma or in host tissue; hamathecium: filiform paraphyses. Asci: unitunicate; sometimes stipitate. Ascospores: septate or aseptate. Genera: e.g. *Coccomyces*, *Hypoderma*, RHYTISMA.

**RI** Replicative intermediate, an intermediate formed during the replication of certain ssRNA viral genomes; an RI is a partially double-stranded structure with many (growing) single-stranded 'tails' formed as a result of the concomitant synthesis of many new RNA strands on the same RNA template strand. (cf. RF.)

**RI plasmid** See HAIRY ROOT.

**RIA** RADIOIMMUNOASSAY.

**RIBA** See HEPATITIS C.

**ribavirin** (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide; Virazole) An ANTIVIRAL AGENT which is active against a wide range of viruses and which has been used therapeutically against infections caused e.g. by the hepatitis C, Lassa fever and SARS (coronavirus) viruses.

Ribavirin is phosphorylated in cells; the monophosphate inhibits IMP dehydrogenase (and hence GMP and GTP synthesis: see Appendix V(a)), while the triphosphate directly inhibits e.g. influenzavirus RNA-dependent RNA polymerase. A suggestion that ribavirin may act as a cap analogue (see MRNA (b)) was not confirmed [RNA (2005) 11 1238–1244].

Analogues and derivatives of ribavirin include e.g. ribavirin 2', 3', 5'-triacetate (RTA) and selenazofurin (= selenazole, 2-β-D-ribofuranosylselenazole-4-carboxamide), both of which are apparently more effective than ribavirin itself.

**Ribi cell fractionator** An apparatus similar in principle to the FRENCH PRESS but capable of higher pressures.

**ribitol** (adonitol) An optically inactive PENTITOL formed e.g. by the reduction of RIBOSE; it is a component of e.g. RIBOFLAVIN and some TEICHOIC ACIDS, and is a major product of photosynthesis in certain green algae (e.g. *Coccomyxa*, *Myrmecia*, *Trentepohlia*). (See also HONEYDEW and Appendix III(d).)

**riboflavin** (riboflavine; vitamin B<sub>2</sub>; lactoflavin) A water-soluble, photolabile, heat-stable VITAMIN: 6,7-dimethyl-9-(1'-D-ribyl)-isoalloxazine. The important coenzyme forms are riboflavin 5'-phosphate (= *flavin mononucleotide*, FMN) and *flavin adenine dinucleotide* (FAD) – see figure; these are the prosthetic groups of *flavoproteins*: proteins which act as hydrogen-carriers in a wide range of redox reactions. The hydrogen atoms are carried at the N<sup>1</sup> and N<sup>10</sup> positions of the isoalloxazine ring. Some reduced flavoproteins may be re-oxidized directly by molecular oxygen, HYDROGEN PEROXIDE being a product; others may be re-oxidized via an ELECTRON TRANSPORT CHAIN. Riboflavin may act as a photoreceptor in the phototropic responses of certain fungi; FMN is involved in bacterial BIOLUMINESCENCE.

Most microorganisms can apparently synthesize riboflavin, but it is required as a growth factor e.g. by *Lactobacillus* spp, *Crithidia fasciculata* and *Tetrahymena* spp. Under certain cultural conditions some organisms (e.g. *Ashbya gossypii*, *Eremothecium ashbyii*, certain yeasts, *Clostridium* spp) secrete large quantities of riboflavin into the medium; *A. gossypii* and *E. ashbyii* are important commercial sources of the vitamin.

**ribonuclease** See RNASE.

**ribonucleic acid** See RNA.

**ribonucleoside** See NUCLEOSIDE.

**ribonucleotide** See NUCLEOTIDE.

**ribonucleotide reductase** See NUCLEOTIDE. (See also IRON.)

**riboophage** A BACTERIOPHAGE with an RNA genome.

**ribophorins** Glycoproteins which, in eukaryotes, appear to play a role in binding RIBOSOMES to the rough ENDOPLASMIC RETICULUM.

**RiboPrinter™** An automated system (manufactured by Qualicon, Wilmington, DE, USA) designed for rapidly characterizing a bacterium to strain level on the basis of its ribotype. The apparatus is intended primarily for use in the food industry, and its database contains ribotype patterns of hundreds of strains of food-borne pathogens (with which the ribotypes of new isolates can be compared). [Comparison of the RiboPrinter™ with traditional ribotyping: LAM (1999) 28 327–333.]

[Use of automated riboprinter and PFGE for epidemiological studies of *Haemophilus influenzae* in Taiwan: JMM (2001) 50 277–283.]

**ribose** An aldopentose (see PENTOSEs) which plays many important roles in cell structure and metabolism. Phosphorylated derivatives of ribose and 2-deoxyribose are components of NUCLEOTIDES and NUCLEIC ACIDS [see also Appendix V(a) and (b)], and ribose phosphates are important intermediates in certain metabolic pathways: e.g. CALVIN CYCLE, HEXOSE MONOPHOSPHATE PATHWAY [Appendix I(b)], biosynthesis of phenylalanine, tyrosine and tryptophan [Appendix IV(f)] and of histidine [Appendix IV(g)], etc. [See also Appendix III(d).]

**ribose phosphate pathway** *Syn.* RMP PATHWAY.

**ribosome** A ribonucleoprotein intracellular organelle (about 25–30 nm in diameter) which mediates PROTEIN SYNTHESIS (q.v. for function). Some ribosomes occur in the cytoplasm; others (see e.g. ENDOPLASMIC RETICULUM) are membrane-bound. Ribosomes are usually present in large numbers in the cell.

Each ribosome consists of two subunits – one larger than the other; both subunits contain RNA and protein.

Different types of ribosome are characterized by different sedimentation coefficients (S) on ultracentrifugation (see also SVEDBERG UNIT). Bacterial ribosomes have a sedimentation coefficient of ca. 70S; each consists of one 30S subunit and one 50S subunit. Ribosomes of the eukaryotic cell cytoplasm have a sedimentation coefficient of ca. 80S; each consists of one 40S subunit and one 60S subunit. Other ribosomes reported: those in mammalian mitochondria (ca. 60S), in chloroplasts of plants and algae (ca. 70S), in mitochondria of plants (ca. 78S), and those in the mitochondria of yeasts and other lower eukaryotes (ca. 73S).

RIBOFLAVIN and its corresponding coenzymes.

## ribosome

*Ribosomal RNA* (rRNA) comprises ca. 65% (by mass) of the bacterial ribosome, and ca. 50–60% of the eukaryotic 80S ribosome.

The bacterial ribosome contains one molecule of 16S rRNA (in the 30S subunit), and one molecule each of 5S rRNA and 23S rRNA in the 50S subunit; the 16S and 23S rRNA molecules contain modified nucleotides. All three species of bacterial rRNA – together with tRNAs – are transcribed as a single molecule of RNA that is cut at specific sites; in this cutting process the ribozyme RNASE P is required for trimming the 5' ends of tRNA molecules.

Crystallographic analysis of the 30S subunit from the bacterium *Thermus thermophilus* has shown that (as predicted) most of the interfacial region of the subunit, i.e. that part in contact with the 50S subunit, consists of RNA [Nature (1999) 400 833–840]. (Results from the study also suggest that some of the proteins may be more directly involved in ribosomal function than has hitherto been assumed.)

The eukaryotic 80S ribosome contains one molecule of 18S rRNA (in the 40S subunit), and one molecule each of 28S, 5.8S and 5S rRNA in the 60S subunit; the 28S and 18S rRNAs contain modified nucleotides (the level of modification being greater than that in bacterial 23S and 16S rRNAs). Genes which encode the 5.8S, 18S and 28S rRNAs occur in the NUCLEOLUS, the gene encoding 5S rRNA being found outside the nucleolus. (For details of rRNA synthesis see entry RRNA.)

*Ribosomal proteins* (r-proteins). The r-proteins are closely associated with rRNA.

In *Escherichia coli* the small (30S) ribosomal subunit contains 21 distinct r-proteins which are designated S1–S21 ('S' for 'small') – according to their electrophoretic mobilities (S1 having the highest MWt). (These proteins were also designated ES1–ES21 – 'ES' for 'eubacterial small'.) Only one molecule of each type of protein is present in the subunit, and all except S1, S2 and S6 are basic proteins. (S1 is reported to be only loosely associated with the 30S subunit; there is apparently no S1 protein in the ribosomes of *Bacillus* spp.)

The large (50S) subunit of *E. coli* was originally reported to contain 34 r-proteins – which were designated L1–L34 (or EL1–EL34). Subsequently, the protein initially designated 'L8' was found to be a complex of L7, L10 and L12; 'L6' was identified as S20; and L7 and L12 were found to be almost identical – differing only in that L7 is acetylated at the amino terminus. The other L proteins retained their original L numbers. All the L proteins are present in single copy except L7/L12, which is present in four copies; this is the only acidic protein in the 50S subunit.

Eukaryotic 80S ribosomes are more complex; they contain >70 r-proteins.

Archaeal ribosomes resemble (at least superficially) those of bacteria; for example, they contain only three types of rRNA and have a sedimentation coefficient of ca. 70S. However, those of certain archaeans (e.g. *Halobacterium cutirubrum* and some methanogens) contain many acidic r-proteins which show little or no homology with those of bacteria; moreover, some of the r-proteins from *H. cutirubrum* appear to share some homology with eukaryotic r-proteins. Furthermore, archaeal ribosomes are insensitive to certain antibiotics (e.g. CHLORAMPHENICOL) which interfere with bacterial ribosome function, while some are sensitive to the 80S (eukaryotic) ribosome inhibitor ANISOMYCIN. [Archaeal ('archaeobacterial') ribosomes: Book ref. 157, pp 345–377.]

*Ribosome structure.* The rRNA molecules can adopt complex secondary structures – extensive intramolecular base-pairing

resulting in the formation of HAIRPINS and STEM-AND-LOOP STRUCTURES etc. [rRNA structure: ARB (1984) 53 119–162.]

The integrity of a ribosome appears to involve hydrogen-bonding and both ionic and hydrophobic interactions, magnesium ions generally playing an important role in maintaining the structure.

The basic architecture of a ribosome has been strongly conserved during evolution, although ribosomes from e.g. bacteria, the eukaryotic cytoplasm and archaeans appear to show certain distinctive morphological features (cf. PHOTOCYTA.) [Evolving ribosome structure: ARB (1985) 54 507–530. Three-dimensional model of the *E. coli* ribosome: Prog. Biophys. Mol. Biol. (1986) 48 67–101.]

*Taxonomic role of rRNA.* Certain regions of rRNA have been very highly conserved during evolution, and sequence homology studies in rRNAs are widely used to indicate evolutionary relationships among organisms. [Evolutionary changes in 5S rRNA higher order structure: NAR (1987) 15 161–179.] (See also RIBOTYPING.)

*Biogenesis of ribosomes.* Biogenesis appears to involve an assembly process in which, initially, some of the r-proteins bind to particular regions of rRNA; other r-proteins then bind cooperatively to this 'core' structure. [Protein–rRNA recognition and ribosome assembly: Book ref. 84, pp 331–352.]

In rapidly growing cells of *E. coli* the number of ribosomes per cell is essentially proportional to the growth rate; this necessitates control mechanisms for co-ordinated expression of the genes encoding r-proteins and rRNAs.

Genes encoding the r-proteins are grouped into a number of distinct OPERONS. For example, the *str* operon contains genes for (in order of transcription) S22, S7 and translation elongation factors EF-G and EF-Tu (see PROTEINS SYNTHESIS); the  $\alpha$  operon contains genes for S13, S11, S4, RNA polymerase subunit  $\alpha$  and L17; the  $\beta$  operon contains genes for L10, L7/L12 and RNA polymerase subunits  $\beta$  and  $\beta'$ . Co-ordination of the synthesis of r-proteins involves post-transcriptional AUTOGENOUS REGULATION (*translational feedback regulation*). One model for the control of these operons postulates that one of the r-proteins encoded by a given operon acts as a regulatory molecule (translational repressor) for that operon by binding to its own (polycistronic) mRNA and blocking translation of some or all of the encoded proteins; thus, for example, in the  $\beta$  operon L10 represses the translation of L10 and L7/L12, but not of the co-transcribed RNA polymerase  $\beta$  and  $\beta'$  subunits. (See also RPO GENES.) The *E. coli* IF3–L35–L20 operon contains the genes *infC*–*rpmI*–*rplT* which encode (respectively) initiation factor IF3 (see PROTEIN SYNTHESIS) and the r-proteins L35 (*sic*) and L20; IF3 acts as a repressor of its own gene, and L20 apparently acts as a translational repressor (in a concentration-dependent way) by binding to a site (a *translational operator*) upstream of the *rpmI* sequence in the mRNA, thus blocking translation of both r-proteins. The mechanism of repression by L20 is unknown, but translational control of the operon apparently involves a pseudoknot which affects the control region of *rpmI* [EMBO (1996) 15 4402–4413].

Some of the operon-regulatory proteins also have binding sites on either 16S or 23S rRNA. It is thought that, if the growth rate decreases, the decreased amount of 16S and 23S rRNA available in nascent ribosomes will leave these proteins free to inhibit translation of their respective transcripts. Note that, in this model, synthesis of ribosomal proteins is linked to the availability of rRNA, regulation of the rRNA genes being the key step in regulating the biogenesis of ribosomes; a *ribosome*

*feedback regulation* model has been proposed in which rRNA synthesis is repressed (directly or indirectly) by the presence of 'free' (i.e. non-translating) ribosomes. [Review of regulation of ribosome biogenesis: Book ref. 188, pp 199–220.]

Synthesis of rRNA is linked to the cell's translational needs and is thus susceptible to up-regulation or down-regulation according to prevailing conditions. In *E. coli* the 16S, 23S and 5S rRNAs are co-transcribed (in that order) as a single transcript from the *rrn* operon; the *E. coli* chromosome contains seven copies of the *rrn* operon (designated A–E, G, H), each operon containing one copy each of the three kinds of rRNA – except the D operon, which contains two copies of the 5S gene. If (e.g. through mutation) any reduction occurs in the levels of 16S or 23S rRNA, a compensatory mechanism up-regulates the *rrn* operons. Interestingly, however, deletion of two or more copies of the 5S rRNA gene in *E. coli* brings about a sharp drop in growth rate (i.e. there is no compensatory effect) – such a reduction in growth rate being almost reversible by insertion of a plasmid-borne 5S rRNA gene [NAR (1999) 27 637–642].

**ribostamycin** An AMINOGLYCOSIDE ANTIBIOTIC.

**riboswitch** In an mRNA molecule: a regulatory region consisting of an *aptamer*, which can bind a specific ligand, and an *expression platform*, which, when the ligand is bound, adopts a conformation that affects (typically inhibits) the mRNA's function. Riboswitches occur in prokaryotes [e.g. JB (2005) 187 791–794; JB (2005) 187 8127–8136] and at least in some eukaryotes. [RibEx (for locating riboswitches): NAR (2005) 33 (Web server issue) W690–W692.]

**ribotype** See RIBOTYPING.

**ribotyping** A method of TYPING in which: (i) chromosomes of the test strain are fragmented by a RESTRICTION ENDONUCLEASE; (ii) the fragments are subjected to gel electrophoresis; and (iii) the gel is examined with a labelled PROBE complementary to a region in the *rrn* (rRNA-encoding) operon. Only those bands of fragments which bind the probe are made visible in the gel by the probe's label (cf. DNA FINGERPRINTING).

Most bacteria contain multiple copies of the *rrn* operon (which includes the 16S, 23S and 5S rRNA genes); moreover, the space between any two of these three genes (the *intergenic spacer region*) can vary in length in different copies of the operon. Consequently, hybridization of probes to fragments containing the *rrn* target commonly yields a fingerprint consisting of a number of bands (often 3–6). (Species which do not contain multiple copies of *rrn* include *Mycobacterium tuberculosis* and *Tropheryma whipplei*.)

A strain defined by ribotyping is a *ribotype*; the ribotypes of a species reflect variation in *rrn* operons among strains. In *Vibrio cholerae*, ribotype variation may have arisen by recombination between *rrn* operons in the same chromosome [Microbiology (1998) 144 1213–1221]; over time, such events may be reversed, affecting long-term monitoring by ribotyping. Even so, ribotyping can be useful for monitoring under short-term or outbreak conditions – e.g. distinguishing strains of *Legionella pneumophila* serogroup 1 (identical by routine serotyping) [FEMS Imm. (1994) 9 23–28], *Vibrio parahaemolyticus* [JCM (1999) 37 2473–2478] and *Pseudomonas syringae* [AEM (2000) 66 850–854].

(See also PCR-RIBOTYPING and RIBOPRINTER.)

**ribovirus** A VIRUS with an RNA genome.

**ribozyme** Any RNA molecule which can function as a catalyst (cf. ENZYME). Ribozymes occur in both eukaryotic and prokaryotic cells and e.g. in some viruses (including phages) and viroids; in nature, they are involved in processing RNA precursor molecules

(see e.g. RNASE P and self-splicing introns in SPLIT GENE). (A shortened form of the self-splicing pre-rRNA intron of *Tetrahymena thermophila* can, in vitro, act as an RNA polymerase and (under different conditions) as an RNase [Science (1986) 231 470–475].)

The roles of ribozymes have been adapted, in the laboratory, for the cleavage or modification of specific RNA or DNA target molecules.

[Characteristics and properties of ribozymes: FEMS Reviews (1999) 23 257–275.]

**ribulose** A ketopentose (a pentulose). Phosphorylated ribulose derivatives are important intermediates in various metabolic pathways: e.g. CALVIN CYCLE, HETEROLACTIC FERMENTATION [Appendix III(b)], HEXOSE MONOPHOSPHATE PATHWAY [Appendix I(b)], PENTOSE metabolism [see e.g. Appendix III(d)], RMP PATHWAY.

**D-ribulose 1,5-bisphosphate carboxylase–oxygenase** (RuBisCO, Rubisco, or RUBISCO; D-ribulose 1,5-bisphosphate carboxylase, RuBPCase; D-ribulose 1,5-diphosphate carboxylase; carboxydismutase) A bifunctional enzyme (EC 4.1.1.39) which catalyses the carboxylation of ribulose 1,5-bisphosphate (RuBP) in the CALVIN CYCLE and, in the presence of high levels of O<sub>2</sub> and low levels of CO<sub>2</sub>, the oxygenation and cleavage of RuBP to form phosphoglycolate and 3-phosphoglycerate (see PHOTORESPIRATION). RuBisCO from most sources consists of two types of subunit: 'large' (L) and 'small' (S). The L subunits appear to bear the active site; the function of the S subunits is unknown. RuBisCO containing 8 L and 8 S subunits (8L8S) has been isolated from a wide range of autotrophs, including algae, higher plants, cyanobacteria, '*Alcaligenes eutrophus*', *Paracoccus denitrificans*, *Pseudomonas facilis*, *Thiobacillus* spp, etc. (In plants, the S subunits are specified by nuclear genes, the L subunits by chloroplast genes.) *Rhodospseudomonas sphaeroides* and *R. capsulata* each contain two distinct forms of RuBisCO: an 8L8S form and a 6L form (containing six L subunits only). *Chlorobium thiosulfatophilum* contains a 6L enzyme, *Methylococcus capsulatus* contains a 6L6S enzyme, while RuBisCO from *Rhodospirillum rubrum* contains only two L subunits. [Book ref. 115, pp. 129–173.]

(See also CARBOXYSOME.)

**ribulose monophosphate pathway** Syn. RMP PATHWAY.

**ribulose 5-phosphate kinase** See CALVIN CYCLE.

**rice black-streaked dwarf virus** See FIJIVIRUS.

**rice blast disease** See BLAST DISEASE.

**rice diseases** See CEREAL DISEASES.

**rice dwarf virus** (RDV) A virus of the genus PHYTOREOVIRUS which infects rice (*Oryza sativa*) and certain other grasses. On rice, RDV causes e.g. yellowish spots or streaks on young leaves, stunting, and the formation of many small tillers which give the plant a rosette-like appearance. Vector: mainly *Nephotettix cincticeps*.

**rice gall dwarf virus** (RGDV) A virus of the genus PHYTOREOVIRUS [Intervirology (1985) 23 167–171]; RGDV is an important cause of disease in rice e.g. in Malaysia and Thailand. Infected plants are dark green, stunted, and develop small tumours on the lower surfaces of the leaves. Vector: *Nephotettix* spp. [RGDV structural proteins: JGV (1985) 66 811–815.]

**rice grassy stunt virus** See RICE STRIPE VIRUS GROUP.

**rice hoja-blanca virus** See RICE STRIPE VIRUS GROUP.

**rice necrosis mosaic virus** See POTYVIRUSES.

**rice ragged stunt virus** (RRSV) An unclassified virus which may have affinities with the genus FIJIVIRUS but which appears to lack an outer capsid layer; genome: 10 dsRNA segments.

## rice-straw mushroom

[Component proteins and structure of RRSV: JGV (1986) 67 1711–1715.] RRSV is an important pathogen of rice in many parts of Asia, causing stunting, leaf distortion, excessive tillering, and enations. Transmission occurs propagatively via the brown rice planthopper *Nilaparvata lugens*. Viroplasms occur in the cells of infected plants and vectors.

**rice-straw mushroom** *Syn.* PADI-STRAW MUSHROOM.

**rice stripe virus group** A group of planthopper-transmitted PLANT VIRUSES which have characteristic filamentous virions (ca. 8 nm wide) which may adopt circular, spiral, pleomorphic, or branched configurations; the virions contain four or more pieces of ssRNA, and those of rice stripe virus (RSV) apparently contain an RNA-dependent RNA polymerase [JGV (1986) 67 1247–1255]. RSV causes serious damage to Japonica-type rice varieties. Other members of the group include maize stripe virus, rice grassy stunt virus, and rice hoja-blanca virus. [Review of RSV: MS (1986) 3 347–351.]

**rice transitory yellowing virus** See RHABDOVIRIDAE.

**rice tungro virus** A virus which resembles MAIZE CHLOROTIC DWARF VIRUS e.g. in morphology,  $S_w^{20}$ , and vector relationships, but which is serologically unrelated to MCDV.

**rice vinegar** See VINEGAR.

**rice-water stools** See CHOLERA.

**rice yellow mottle virus** See SOBEMOVIRUSES.

**Richelia** See RHIZOLENIA.

**ricin** See SHIGA TOXIN.

**ricinoleic acid** (12-hydroxy-9-octadecenoic acid) A fatty acid present (in glycerides) in castor oil and certain other vegetable oils, and in immature sclerotia and mycelium of *Claviceps purpurea*.

**Rickettsia** A genus of Gram-negative bacteria of the tribe RICKETTSIAE; species are obligate intracellular parasites or pathogens in vertebrates (including man) and arthropods (ticks, mites, fleas etc). The cells are non-flagellated, non-fimbriate bacilli,  $0.8\text{--}2 \times 0.3\text{--}0.6 \mu\text{m}$ , which generally stain well with the GIMÉNEZ STAIN; the outer membrane is similar to that of other Gram-negative bacteria. Growth occurs only in living systems, e.g. in chick embryo cells, in the yolk sacs of hens' eggs, or in certain tissue cultures (such as HeLa, HEp-2); rickettsiae grow mainly in the cytoplasm, sometimes in the nucleus. Optimum growth temperature is  $32\text{--}35^\circ\text{C}$ . Metabolism appears to be oxidative (respiratory) with glutamate as the main energy-yielding substrate; glucose is not metabolized. Division occurs by transverse binary fission. The organisms are sensitive to disinfectants such as phenol and hypochlorite, and are killed within 30 min at temperatures above  $56^\circ\text{C}$ ; tetracyclines and chloramphenicol have been used to treat diseases of rickettsial aetiology. GC% range for species examined: 29–33. Type species: *R. prowazekii*. Species (which can be distinguished by serological and other means) include e.g. *R. akari* (see RICKETTSIALPOX), *R. conorii* (see BOUTONNEUSE), *R. prowazekii* (see TYPHUS FEVERS and BREINL STRAIN), *R. rickettsii* (see ROCKY MOUNTAIN SPOTTED FEVER), *R. tsutsugamushi* (see SCRUB TYPHUS), *R. typhi* (= *R. mooseri*) (causal agent of murine typhus – see TYPHUS FEVERS). Other species: *R. australis*, *R. canada*, *R. montana*, *R. parkeri*, *R. rhipicephali*, *R. sibirica*. (For *R. quintana* see ROCHALIMAEAE; for *R. sennetsu* see EHRlichIA.) [Book ref. 22, pp. 688–698.]

**Rickettsiaceae** A family of bacteria (RICKETTSIALES) with tribes RICKETTSIAE, EHRlichIAE, WOLBACHIAE [Book ref. 22]. For recent taxonomic changes see ANAPLASMATACEAE; in this edition of the dictionary all lower taxa in this family reflect earlier classifications.

**rickettsiae** (1) Organisms of the RICKETTSIAEAE. (2) Organisms of the genus RICKETTSIA.

**Rickettsiales** An order of Gram-negative bacteria which includes the families ANAPLAMATACEAE and RICKETTSIAEAE.

**rickettsialpox** An acute, usually mild disease of man caused by *Rickettsia akari*. House mice seem to be the main reservoir of infection; the mite *Allodermanyssus sanguineus* transmits the pathogen to man. Incubation period: 10 days to 3 weeks. There may be a lesion at the site of the mite bite, and this is followed by sudden onset of fever with headache, chills, anorexia and photophobia; there may be a sparse maculopapular rash. The disease is usually self-limiting; no deaths have been reported.

**Rickettsiae** A tribe of bacteria of the RICKETTSIAEAE comprising the genera COXIELLA and RICKETTSIA. The genus *Rochalimaea* (including *R. quintana*, formerly *Rickettsia quintana*) has been unified with the genus BARTONELLA (q.v.).

**Rickettsiella** A genus of Gram-negative bacteria of the tribe WOLBACHIAE; species grow intracellularly in, and are pathogenic in, arthropod hosts (including arachnids, crustaceans and insects). Growth does not occur in cell-free media. Cells: rod- or disc-shaped, maximum dimension typically  $<0.8 \mu\text{m}$ . The species: *R. chironomi* (parasitic e.g. in midges and spiders); *R. grylli* (e.g. in crickets – *Gryllus* spp – and the desert locust *Schistocerca gregaria*); *R. popilliae* (in various beetles – including the Japanese beetle, *Popillia japonica* – and the crane fly).

**rickettsiosis** Any disease caused by a species of RICKETTSIA.

**Rickia** See LABOULBENIALES.

**Rideal–Walker test** A SUSPENSION TEST used to determine the PHENOL COEFFICIENT of a (phenolic) disinfectant; the test determines that dilution of the test disinfectant which gives the same rate of kill of a test organism as does a standard dilution of phenol. Serial dilutions (in water) of the test disinfectant are equilibrated at  $17\text{--}18^\circ\text{C}$ . Each dilution (5 ml) is inoculated with a 24-hour broth culture (0.2 ml) of the test organism (e.g. *Salmonella typhi* NCTC 786) and incubated at  $17\text{--}18^\circ\text{C}$ . After 2.5, 5, 7.5 and 10 minutes, a standard loopful of the test suspension (from each dilution) is transferred to a separate volume of sterile broth which is incubated at  $37^\circ\text{C}$  for 2–3 days to detect surviving cells. A similar procedure is carried out with phenol. For one particular dilution of the test disinfectant, growth will occur in broths inoculated at 2.5 and 5 minutes but not in those inoculated at 7.5 and 10 minutes; a similar result will be obtained for one particular dilution of phenol (within the range 1/95 to 1/115 w/v). The phenol coefficient (*Rideal–Walker coefficient*) is given by the ratio of the dilution factors of these two particular dilutions:

$$\frac{\text{dilution factor of test disinfectant}}{\text{dilution factor of phenol}}$$

[Book ref. 13, pp. 1–15.] (cf. CHICK–MARTIN TEST.)

**Ridomil** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**Rieske protein** Any of a range of  $[2\text{Fe–}2\text{S}]$  IRON–SULPHUR PROTEINS which occur e.g. in mitochondria and in various bacteria, and which characteristically have an  $E_m$  value within the range ca. +150 to +330 mV.

**rifamide** See RIFAMYCINS.

**rifampicin** See RIFAMYCINS.

**rifampin** Rifampin: see RIFAMYCINS.

**rifamycins** A family of highly substituted macrocyclic ANTIBIOTICS (ANSAMYCINS) produced by '*Nocardia mediterranei*'. Mixtures of rifamycins A–E are generally produced in cultures of '*N. mediterranei*', but the proportion of rifampin B can be increased by the addition of sodium diethylbarbiturate to the

medium. In aqueous oxygenated solutions rifamycin B spontaneously gives rise to e.g. rifamycins O and S which show much higher antibacterial activity than rifamycin B itself. Rifamycin S is an important starting point for the production of semisynthetic rifamycins – which include e.g. rifamycin SV (= ‘rifamycin’, obtained by mild reduction of rifamycin S), rifamide, and rifampicin (= rifampin).

Rifamycins are generally highly active against Gram-positive bacteria (including mycobacteria, staphylococci and streptococci) and against some Gram-negative bacteria (e.g. *Brucella*, *Chlamydia*, *Haemophilus*, *Legionella* and *Neisseria* spp); other Gram-negative bacteria (e.g. enterobacteria) are less sensitive, spirochaetes and mycoplasmas are insensitive. Rifamycins specifically inhibit bacterial DNA-dependent RNA POLYMERASE, binding to the  $\beta$  subunit and inhibiting initiation of transcription. Resistance to rifamycins may result from e.g. a mutation which modifies the RNA polymerase  $\beta$  subunit such that it no longer binds to the drug. Rifamycins do not inhibit mammalian RNA polymerase or bacterial PRIMASE.

In some countries (including the USA), strains of *Mycobacterium tuberculosis* that are resistant to rifampicin are usually also resistant to at least certain other anti-tuberculosis drugs, so that resistance to rifampicin is a useful marker for multidrug-resistant strains of the pathogen [see e.g. JAMA (1994) 271 665–671].

Resistance-conferring mutations occur at a number of sites in the *rpoB* gene (which encodes the  $\beta$  subunit of RNA polymerase), and specific mutations may occur with different frequencies in different geographical areas [e.g. Italy: JCM (1999) 37 1197–1199].

Using DNA chip technology, high-density arrays have been used to identify *M. tuberculosis* and, simultaneously, to test for resistance to rifampicin [JCM (1999) 37 49–55].

**Rift Valley fever** An acute, febrile disease of man and e.g. cattle, sheep, camels, rats, mice etc; it occurs in Africa. The causal agent, a virus of the genus PHLEBOVIRUS, is transmitted mainly by insects (chiefly mosquitoes); rodents may provide a reservoir of the virus. In lambs and calves, the incubation period is ca. 12 hours; onset is sudden, with high fever, hepatitis, incoordination, collapse and (usually) death within 36 hours. In adult sheep and cattle the main symptom is abortion, but there may be high fever and a mortality rate of ca. 20–30% in sheep, 10% in cattle. In man, the disease resembles influenza; onset is abrupt, with chills, fever, headache, myalgia and arthralgia. The disease is rarely fatal in man, but retinal haemorrhages may lead to (temporary or permanent) visual impairment.

**Riftia** See TROPHOSOME.

**right-handed DNA** See DNA.

**right splice site** See SPLIT GENE.

**Rigidoporus** See APHYLLOPHORALES (Polyporaceae).

**Riley virus** *Syn.* LACTATE DEHYDROGENASE VIRUS.

**rimantadine** See AMANTADINE.

**rinderpest** (bovine typhus; cattle plague) An acute, often fatal CATTLE DISEASE which occurs e.g. in parts of Africa and Asia; other animals, e.g. pigs, are also susceptible. The causal agent is a *Morbillivirus*, and infection apparently occurs by inhalation of aerosols. Incubation period (in cattle): ca. 1 week. Symptoms: fever and anorexia, followed by lesions in the mouth and a purulent nasal discharge; necrotic lesions appear on the lips and gums, and severe diarrhoea follows the development of intestinal lesions. Mortality rates may be very high. (cf. PESTE DES PETITS RUMINANTS.)

**ring-infected erythrocyte surface antigen** See PLASMODIUM.

**ring slide** A slide used e.g. in some serological tests; it is larger and thicker than a normal microscope SLIDE, and on one face it has a number of fixed, raised rings (1 to 3 cm in diameter) made of ceramic or other material.

**ring spot** See RINGSPOT.

**ring stage** (of *Plasmodium*) See PLASMODIUM.

**ring test** (*serol.*) A qualitative PRECIPITIN TEST, carried out in a narrow tube, in which a solution containing antigen is layered over one containing antibody. A positive reaction is indicated by a band of white precipitate which forms at the interface of the two solutions.

**ring vaccination** (*vet.*) Vaccination of animals in the annular region surrounding an isolated outbreak of disease; the object is to contain (i.e. prevent the spread of) the disease.

**Ringer's solution** A solution used e.g. as a general diluent; composition (g/100 ml distilled water): NaCl (0.9), KCl (0.042), CaCl<sub>2</sub> (0.048), NaHCO<sub>3</sub> (0.02).

**ringspot** (*plant pathol.*) A type of LOCAL LESION consisting of single or concentric rings of discoloration or necrosis, the regions between the concentric rings being green; the centre of the lesion may be chlorotic or necrotic.

**ringworm** (dermatophytosis; tinea) Any MYCOSIS of man and animals in which keratinized tissues (skin, hair, nails etc) are infected by a DERMATOPHYTE (q.v.). Infection occurs by direct contact with an infected individual or with fomites. Ringworm infections in man may be categorized according to the area of the body involved: tinea barbae = beard ringworm; tinea capitis (tinea tonsurans) = scalp ringworm, caused e.g. by *Microsporum audouinii*, *M. canis* or *Trichophyton schoenleinii* (cf. FAVUS); tinea corporis (tinea circinata) = body ringworm, caused e.g. by *Microsporum* or *Trichophyton* spp; tinea cruris = groin ringworm, caused e.g. by *Epidermophyton cruris*; tinea manus = hand ringworm; tinea pedis (ATHLETE'S FOOT) = foot ringworm; tinea unguium = nail ringworm, caused e.g. by *T. mentagrophytes* or *T. rubrum*. Lesions on skin are typically circular or ring-shaped (sometimes coalescing to become confluent), dry and scaling (but cf. KERION), and may or may not be painful or pruritic. Usually only the superficial layers of skin are affected. Adults are generally less susceptible to skin infection than are children owing to the fungistatic properties of fatty acids in the sebum. Infected nails become opaque and discoloured, distorted, and hard or flaky. Infected hairs usually break. *Lab. diagnosis:* e.g. microscopic and cultural examination of epidermal scales and hairs. Under WOOD'S LAMP, hairs infected with certain dermatophytes show characteristic fluorescence: e.g. hairs infected with *M. audouinii* or *M. canis* fluoresce bright green; those infected with *Trichophyton* spp may appear a (non-diagnostic) bluish-white colour. *Chemotherapy:* e.g. oral GRISEOFULVIN or POLYENE ANTIBIOTICS; topical ointments containing e.g. tolnaftate or salicylic, benzoic or propionic acids.

**Rio Bravo virus** See FLAVIVIRIDAE.

**Rio Grande virus** See PHLEBOVIRUS.

**RISE-resistant tuberculosis** TUBERCULOSIS which is resistant to treatment with a number of antibiotics, including – at least – rifampin, isoniazid, streptomycin and ethambutol. [RISE-resistant tuberculous meningitis in an AIDS patient: Lancet (1993) 341 177–178.]

**riser** In a LOOP FERMENTER: the ascending column of liquid or that part of the fermenter which contains it. (cf. DOWNCOMER.)

**rishitin** A sesquiterpenoid PHYTOALEXIN produced by potato tubers.

**RIST** (radioimmunosorbent test) An IMMUNOASSAY used e.g. for quantifying IgE in serum. Essentially, immobilized anti-IgE

## ristocetin

antibodies are exposed to (i) a standard amount of radio-labelled IgE and (ii) the serum under test; any IgE in the serum competes with the radio-labelled IgE, and the quantity of serum IgE can be estimated from the amount of bound radio-labelled IgE.

**ristocetin** A glycopeptide antibiotic related to VANCOMYCIN (q.v.); it is not used as a clinical antimicrobial agent owing to its ability to cause aggregation of platelets.

**RITARD model** Reversible ileal tie adult rabbit diarrhoeal disease model: an in vivo model for studying the effects of enteric bacteria. With a ligated caecum, bacteria are injected into the ileum at a location proximal to a temporary ligature; after a few hours the ligature is removed and the animals observed for a few days for the development of diarrhoea.

**ritonavir** See ANTIRETROVIRAL AGENTS.

**Ritter's disease** See SCALDED SKIN SYNDROME.

**river blindness** See WOLBACHIA.

**Rivulariaceae** A phycological family of 'blue-green algae' (CYANOBACTERIA) in which genera (e.g. *Dichothrix*, *Fremyella*, *GLOEOTRICHIA*, *Polythrix*, *Rivularia*) are distinguished on the basis of field characteristics: e.g., colony form, false branching, etc. However, in culture these characteristics are often lost or variable; thus, all cyanobacteria with tapered trichomes and terminal heterocysts were placed in a single genus: CALOTHRIX [JGM (1979) *III* 1–61 (p. 36)].

**RK2 plasmid** See RP1 PLASMID.

**RLUs** See TMA.

**RM organism** *Yersinia ruckeri*.

**R-M system** RESTRICTION-MODIFICATION SYSTEM.

**RMP pathway** (allulose phosphate pathway; hexulose phosphate pathway; Quayle cycle; ribose phosphate pathway; ribulose monophosphate pathway; RuMP pathway) A cyclic metabolic pathway used by some types of methylotrophic bacteria for the assimilation of formaldehyde (see METHYLOTROPHY). The pathway may be considered in three phases (1–3 or a–c).

In phase 1 (formaldehyde fixation) the regenerated intermediate ribulose 5-phosphate (Ru5P) condenses with formaldehyde (enzyme: hexulose phosphate synthase, EC 4.1.2.-) to form a hexulose 6-phosphate (allulose 6-phosphate) which is converted, by an isomerase, to fructose 6-phosphate (F6P).

In phase 2 some of the F6P is cleaved into two 3-carbon compounds via one of two routes. In the 'glycolytic' or 'Embsden–Meyerhof variant' route F6P is phosphorylated, and fructose 1,6-bisphosphate is cleaved (by fructose bisphosphate aldolase) to glyceraldehyde 3-phosphate (G3P) and dihydroxyacetone phosphate (DHAP) – the latter being assimilated into cell biomass. In the 'Entner–Doudoroff variant' route F6P is converted, via glucose 6-phosphate and 6-phosphogluconate, to 2-oxo-3-deoxy-6-phosphogluconate which is cleaved (by 2-oxo-3-deoxy-6-phosphogluconate aldolase) to G3P and pyruvate – the latter being assimilated into cell biomass.

Phase 3 ('rearrangement reactions') involves regeneration of the formaldehyde acceptor, Ru5P. As in phase 2, there are two possible routes. One route is similar to part of the HEXOSE MONOPHOSPHATE PATHWAY, a key enzyme being transaldolase. In this route G3P with F6P (enzyme: transketolase, EC 2.2.1.1) forms erythrose 4-phosphate (E4P) and xylulose 5-phosphate (Xu5P). E4P with F6P (transaldolase, EC 2.2.1.2) forms G3P and sedoheptulose 7-phosphate (S7P). S7P with G3P (transketolase) forms Xu5P and ribose 5-phosphate – each of which is then converted (by an epimerase and an isomerase, respectively) to Ru5P.

The alternative route in phase 3 resembles part of the CALVIN CYCLE. In this route F6P is phosphorylated, and fructose 1,6-bisphosphate is cleaved to G3P and DHAP. G3P with F6P

forms E4P and Xu5P; Xu5P is converted (by an epimerase) to Ru5P, and E4P condenses with DHAP to form sedoheptulose 1,7-bisphosphate – which is then converted (by sedoheptulose bisphosphatase) to S7P. S7P with G3P forms ribose 5-phosphate and Xu5P, each of which is converted (by an isomerase and an epimerase, respectively) to Ru5P.

In some methylotrophic bacteria the RMP pathway can be used to generate energy from certain substrates. This involves a modified 'Entner–Doudoroff' route in phase 2: a dehydrogenase (EC 1.1.1.44) converts 6-phosphogluconate to Ru5P with concomitant elimination of CO<sub>2</sub> and reduction of NAD(P).

In the assimilatory mode, the consumption of energy by the RMP pathway varies according to the particular routes taken in phases 2 and 3. Thus, e.g. a combination of the 'Entner–Doudoroff' route in phase 2 and the sedoheptulose bisphosphate route in phase 3 consumes the largest amount of energy; no organism has been reported to use this combination. The (energetically) most economical routes of the RMP pathway consume less energy than does either the SERINE PATHWAY or the XMP PATHWAY.

**Rms148, Rms149 plasmids** See INCOMPATIBILITY.

**RNA** Ribonucleic acid: a NUCLEIC ACID consisting of ribonucleotides, each of which contains one of the bases adenine, guanine, cytosine or uracil, or, in some RNAs, a modified form of one of these bases. (cf. DNA.) The 2'-OH group in the RNA backbone makes the molecule more reactive and less flexible than DNA. RNA molecules are usually single-stranded, but an RNA strand can form a duplex (resembling A-DNA in conformation) with a complementary strand of RNA or DNA; ssRNA molecules commonly adopt secondary structures (e.g. HAIRPINS, STEM-AND-LOOP STRUCTURES) by base-pairing between complementary regions of the same molecule.

RNA (double- or single-stranded) constitutes the genome in various ANIMAL VIRUSES, BACTERIOPHAGES and PLANT VIRUSES. In prokaryotic and eukaryotic cells the major RNAs are involved in all stages of PROTEIN SYNTHESIS (see MRNA, RRNA, TRNA), and many other types of RNA play regulatory, catalytic or other roles: see e.g. ANTISENSE RNA, RIBOZYME, SCRNA, SIGNAL RECOGNITION PARTICLE, SNRNA.

**RNA I** See COLE1 PLASMID.

**RNA II** See COLE1 PLASMID.

**RNA III** See AGR LOCUS.

**RNA blotting** See BLOTTING.

**RNA degradosome** See DEGRADOSOME.

**RNA-dependent DNA polymerase** *Syn.* REVERSE TRANSCRIPTASE.

**RNA editing** In animals, plants and certain microorganisms: an in vivo mechanism which can generate new functional transcripts from existing ones. One (mammalian) example is the editing of the mRNA for apolipoprotein B (apoB) by cytidine deaminase (an enzyme which converts C to U); the unedited mRNA yields a product of 4536 amino acids, while the edited mRNA (which contains an internal stop codon formed by cytidine deaminase) yields a product of 2152 amino acids.

Studies have suggested that RNA editing may be involved in the differentiation/maturation of antigen-stimulated B cells in germinal centres – a period of development that includes *affinity maturation* and *class switching* (see ANTIBODY FORMATION). Thus, a deficiency in *activation-induced cytidine deaminase* (AID) – an enzyme found specifically in germinal centre B cells – has been found to inhibit both affinity maturation and class switching [Cell (2000) *102* 553–563].

Deficiency in the AID enzyme has also been reported to be responsible for the autosomal recessive form of *hyper-IgM*

*syndrome* (HIGM2), a rare human immunodeficiency with normal/raised IgM, no IgG (or other isotypes), lymph node hyperplasia and high vulnerability to bacterial infection [Cell (2000) 102 565–575]. X-linked HIGM1, due e.g. to a mutated CD40L gene (see CD40), involves lack of B cell development.

In the KINETOPLAST, minicircles encode *guide RNAs* (gRNAs: ~ 55–70 bases) which direct the editing of RNAs. [Editing in *Trypanosoma brucei*: NAR (2001) 29 703–709.]

**RNA interference** (RNAi) In plant and animal cells: an antiviral response triggered by dsRNA; dsRNA is cleaved by an endonuclease ('Dicer') to *small interfering RNA* (siRNA). siRNA complexes with proteins, forming the *RNA-induced silencing complex* which can degrade *homologous* mRNA – silencing the corresponding gene(s). [Possible therapeutic use: BMJ (2004) 328 1245–1248; see GENE THERAPY.]

**RNA PCR** See REVERSE TRANSCRIPTASE PCR.

**RNA-dependent RNA polymerase** A type of RNA POLYMERASE, encoded by (probably all) RNA viruses (see VIRUS), which synthesizes RNA on an RNA template. Viral RNA-dependent RNA polymerases are responsible for replicating the genome and for synthesizing mRNA on a (–)-strand RNA template; the terms *replicase* and *transcriptase* are sometimes used specifically for enzymes with the former and latter functions, respectively, but may also be used as synonyms for any RNA-dependent RNA polymerase, regardless of function. (A clone of cDNA specific for an RNA-dependent RNA polymerase has been isolated from the tomato plant [Plant Cell (1998) 10 2087–2101].)

**RNA phages** See LEVIVIRIDAE and BACTERIOPHAGE  $\phi$ 6.

**RNA polymerase** Any enzyme which can polymerize ribonucleoside 5'-triphosphates (with elimination of P<sub>i</sub>) to form an RNA strand on a (DNA or RNA) template; however, when used without qualification, the term 'RNA polymerase' (RPase) usually refers specifically to a *DNA-dependent RNA polymerase* responsible for the TRANSCRIPTION of complete RNA molecules from a DNA template. (cf. RNA-DEPENDENT RNA POLYMERASE and PRIMASE.)

*Escherichia coli* contains one major type of (DNA-dependent) RPase which is responsible not only for RNA synthesis in the cell but also for some cases of priming of DNA REPLICATION. The RPase consists of a *core enzyme* comprising two  $\alpha$  subunits, a  $\beta$  subunit and a  $\beta'$  subunit; the core enzyme can elongate an RNA strand, but for *initiation* of TRANSCRIPTION it must combine with another protein, a SIGMA FACTOR, to form the RPase *holoenzyme*. (See also RPO GENES.) RPases from other bacteria also have the  $\alpha_2\beta\beta'\sigma$  holoenzyme structure; however, additional proteins may be more or less tightly associated with the enzyme in some species: e.g. a  $\delta$  factor is associated with the RPase of *Bacillus subtilis* (vegetative and sporulating cells) and plays a role in suppressing non-specific binding to DNA and/or transcription initiation by the polymerase. Bacterial RPases are generally inhibited by e.g. RIFAMYCINS and STREPTOLYDIGIN.

*Eukaryotes* have three distinct nuclear RPases, each comprising many polypeptide subunits. RPase I (or A) occurs in the NUCLEOLUS and is responsible for synthesizing most rRNA species; RPases II (or B) and III (or C) both occur in the nucleoplasm, the former synthesizing mRNA and U1–U5 snRNAs, the latter tRNA, 5S rRNA, and U6 snRNA.

Eukaryotic RPases require certain protein factors (*transcription initiation factors*) in order to form an operational complex at the PROMOTERS. One such factor, needed by all the eukaryotic nuclear RPases (types I, II and III), is the TATA box-binding protein (TBP) – which acts in association with other initiation factors (see PROMOTER).

Eukaryotic nuclear RPases are not inhibited by rifamycins or streptolydigin (cf.  $\alpha$ -AMANITIN).

RPases from mitochondria and chloroplasts are distinct from the nuclear enzymes, being e.g. much smaller.

The RPases of members of the ARCHAEA (formerly Archaeobacteria) appear to be much more closely related to those of the eukaryotic nucleus than to the bacterial enzyme; they contain many components, and are relatively insensitive to rifamycins, streptolydigin and  $\alpha$ -amanitin. [Archaeobacterial (archaeal) RPases: Book ref. 157, pp. 499–524.]

Some bacteriophages encode their own RPases; those of e.g. T3 and T7 each consist of a single polypeptide chain. (See also BACTERIOPHAGE N4 and BACTERIOPHAGE SP6.) In some cases a phage modifies (and alters the specificity of) its host's RNA polymerase: see e.g. BACTERIOPHAGE T4 and BACTERIOPHAGE SPO1.

**RNA splicing** See SPLIT GENE.

**RNA thermometer** See HEAT-SHOCK PROTEINS.

**RNA tumour viruses** Viruses of the ONCOVIRINAE.

**RNAase** See RNASE.

**RNAi** See RNA INTERFERENCE.

**RNAP** RNA POLYMERASE.

**RNase** (RNAase; ribonuclease) An enzyme which cleaves RNA. An RNase may be an ENDONUCLEASE (= endoribonuclease) or an EXONUCLEASE (= exoribonuclease); enzymes in the latter category may act randomly (dissociating from the substrate after each catalytic event) or processively (see PROCESSIVE ENZYME).

A given RNase generates 3'-hydroxyl and 5'-phosphate or 3'-phosphate and 5'-hydroxyl termini. Most RNases rely on the conformation of the RNA substrate (rather than nucleotide sequence per se) for their specificity (cf. RNASE E).

RNases have important roles in RNA processing (see e.g. MRNA, RRNA, TRNA), in certain types of regulatory process (e.g. RETROREGULATION), and in degrading RNA molecules which have fulfilled their function.

For examples of RNases see following entries.

RNases can be inactivated by DIETHYLPYROCARBONATE.

**RNase\*** See MRNA (a).

**RNase I** In *Escherichia coli*: an endoribonuclease (see RNASE) which can degrade most RNA molecules to oligonucleotides with 3'-phosphate and 5'-hydroxyl termini.

**RNase II** In *Escherichia coli*: an exoribonuclease (see RNASE) which removes nucleoside 5'-phosphate residues from the 3' end of an RNA molecule which has little or no secondary structure.

**RNase III** In *Escherichia coli*: an endoribonuclease (see RNASE) which cleaves double-stranded regions in RNA molecules. RNase III is involved in rRNA precursor processing (see RRNA), in the RETROREGULATION of *int* gene expression in BACTERIOPHAGE LAMBDA, and in the release of monocistronic mRNAs from the polycistronic early-gene transcript in BACTERIOPHAGE T7; the target sites for RNase III action typically occur in stem-and-loop or hairpin structures in the RNA.

**RNase BN** See TRNA.

**RNase D** See TRNA.

**RNase E** In *Escherichia coli*: an endoribonuclease (see RNASE) which is involved e.g. in the formation of 5S rRNA from pre-rRNA (see RRNA). RNase E also cleaves RNA I (involved in the replication of the COLE1 PLASMID and related plasmids), cleavage occurring between the 5th and 6th nucleotides from the 5' end of the molecule. The cleavage site occurs in a sequence of 10 nt which is almost identical in the two RNA substrates [JMB (1985) 185 713–720].

(See also DEGRADOSOME.)

**RNase F** See INTERFERONS.

## RNase H

**RNase H** An RNASE which specifically cleaves an RNA strand base-paired to a complementary DNA strand, generating 3'-OH and 5'-phosphate termini. Such enzymes have been isolated from a wide range of prokaryotic and eukaryotic organisms and are encoded by certain viruses. For example, RNase H from *Escherichia coli* is an endoribonuclease which is apparently involved e.g. in certain types of plasmid replication (see COLE1 PLASMID). RNase H exoribonuclease activity is associated with the reverse transcriptase of viruses of the RETROVIRIDAE (q.v.); this enzyme cleaves oligonucleotides (ca. 6–12 nt long) from either end of the RNA strand.

**RNase L** See INTERFERONS.

**RNase P** An endoribonuclease (see RNASE) which, in most organisms, generates the 5' termini of tRNAs from precursor tRNA molecules (see TRNA). The catalytic activity of RNase P is mediated by an RNA component (M1 RNA) 375 nt long in e.g. *Escherichia coli*. Under certain conditions in vitro the purified M1 RNA of the *E. coli* enzyme can itself catalyse the cleavage of precursor tRNA [reaction mechanism: Biochem. (1986) 25 1509–1515]; however, both protein and RNA components are apparently necessary in vivo since a mutation in either of the genes *mnpA* and *mnpB* (genes for the protein and RNA components, respectively) leads to loss of RNase P function. In *Schizosaccharomyces pombe* RNase P apparently contains two RNA components, K1 and K2 (285 and 270 nt long, respectively) [EMBO (1986) 5 1697–1703].

[Synthetic inhibitors of the processing of pre-tRNA by RNase P: Biochem. (2001) 40 603–608.]

**RNase T** An exoribonuclease (see RNASE) of *Escherichia coli*; it specifically catalyses 'end turnover' of tRNA: RNase T removes the terminal AMP residue from the 3' CCA end of an uncharged (non-aminoacylated) tRNA molecule – the residue being replaced by tRNA nucleotidyltransferase [PNAS (1985) 82 6427–6430].

**RNase T1** (RNase T<sub>1</sub>) An endoribonuclease obtained commercially from *Aspergillus oryzae*. It cleaves RNA specifically at guanosine residues (Gp ↓ N), and is used e.g. in the analysis of RNA (see e.g. OLIGONUCLEOTIDE FINGERPRINTING and RRNA OLIGONUCLEOTIDE CATALOGUING).

**RND** Resistance–nodulation–division superfamily: a category of TRANSPORT systems which mediate e.g. efflux-dependent resistance to antibiotic(s) in certain Gram-negative bacteria; these systems typically include a MEMBRANE FUSION PROTEIN and apparently involve (pmf-dependent) drug–proton antiport.

**rnh gene** In e.g. *Escherichia coli*: a gene encoding RNASE H.

**rnpA, rnpB genes** See RNASE P.

**rNTP** Ribonucleoside-5'-triphosphate.

**Robbins device** An apparatus used in corrosion studies: a metal pipe whose wall contains a series of removable panels; after a sample has been cycled through the pipe, removal of the panel(s) permits examination of e.g. adherent microorganisms.

**Robertson's cooked meat medium** See COOKED MEAT MEDIUM.

**Roccella** A genus of fruticose LICHENS (order OPEGRAPHALES). Photobiont: *Trentepohlia*. The thallus consists of blue- or grey-green to violet, terete or flattened, strap-like branches which form erect or pendulous tufts; bluish-white soralia may be present. Species occur mainly on rocks by the sea; they have been used commercially as sources of LITMUS, ORCHIL and ORCINOL.

**Rochalimaea** A (former) genus of Gram-negative bacteria which included *R. quintana* (formerly *Rickettsia quintana*) and *R. vinsonii*; on the basis of nucleic acid studies, members of this genus were transferred to the genus BARTONELLA (q.v.).

**Rocio virus** See FLAVIVIRIDAE.

**rock tripe** *Umbilicaria* spp. or the edible species *U. esculenta* eaten (as 'iwatake') in Japan.

**rocket immunoelectrophoresis** (electroimmunoassay) IMMUNOELECTROPHORESIS in which (typically) antibody, at or near its isoelectric point, is uniformly distributed in a gel layer, and homologous antigen (in a well in the layer) is subjected to an electric field. Antigen moves towards one of the poles, and forms (with the antibody) a 'rocket-shaped' line of precipitate – an extended paraboloid with the wide end towards the well; the length of the 'rocket' is proportional to the initial concentration of antigen in the well.

**Rocky Mountain spotted fever** A rickettsial disease of man which occurs in parts of North America, particularly in late spring and summer; the causal agent, *Rickettsia rickettsii*, is transmitted by ticks – chiefly species of *Dermacentor*. Infection, by the bite of an infected tick, is followed by an incubation period of 2–14 days; symptoms include headache, joint and muscular pains, and a sustained fever. A rash develops on the limbs and trunk (in that order); the lesions may become haemorrhagic and necrotic. Mortality in untreated cases may be 5–90%. Reservoirs of infection occur e.g. in the dog (which can develop clinical signs) and in wild rodents. *Lab. diagnosis*: e.g. a CFT and/or the WEIL–FELIX TEST.

**rod** (*bacteriol.*) *Syn.* BACILLUS sense 2.

**rod organ** (pharyngeal rod organ) See PERANEMA.

**roentgen** See RÖNTGEN.

**roestelioid** (cornute) Refers to an elongated acium which projects through the epidermis of the host; at maturity the exposed portion of the peridium typically ruptures by a number of longitudinal slits, the torn strips of peridium often curling back in a rosette-like pattern. Such acia are formed e.g. by species of *Gymnosporangium*.

**rofecoxib** See PROSTAGLANDINS.

**roguing** (*plant pathol.*) The removal of diseased plants from a crop in order to (e.g.) prevent the spread of the disease.

**Rohament P** A commercial PECTIC ENZYME preparation consisting mainly of endopolygalacturonase.

**Rohr** See PLASMIDIOPHOROMYCETES.

**roll-tube technique** (Hungate technique; *syn.* Virginia Polytechnic Institute (VPI) technique) A technique used for the isolation, culture and enumeration of strict, O<sub>2</sub>-sensitive ANAEROBES. Pre-reduced, agar-based media are sterilized in tubes, under anaerobic conditions, and the processes of inoculation, incubation and subculture are also carried out anaerobically; anaerobic conditions are maintained within the tube during e.g. inoculation by inserting a sterile cannula into the tube and passing in a gentle stream of O<sub>2</sub>-free gas (e.g. CO<sub>2</sub>) during any period when the tube is unstoppered. For inoculation, the medium is melted, cooled to ca. 45°C, and mixed with the inoculum; the tube is then held horizontally and rotated about its long axis so that the agar solidifies in a thin layer around the inner surface of the tube. The tube is then incubated until individual colonies develop on and within the medium. (If a heat-labile reducing agent is used in the medium it is incorporated immediately prior to inoculation.)

**roller culture** In TISSUE CULTURE, a method of incubating bottles and other vessels of circular cross-section: the culture vessels are placed on a horizontal array of parallel, closely spaced rotating rollers such that each vessel rotates about its long axis; during incubation a monolayer develops as a continuous band on the vessel's inner surface. Culture vessels may be rotated at ca. 0.1–3.0 r.p.m. on commercially available apparatus. Benefits of roller culture include a more efficient use of culture vessels, and the various advantages of a continually mixed medium.

**rolling** (of leukocytes) See INFLAMMATION.

**rolling circle mechanism** A mechanism for the replication of a cccDNA molecule (or a cccRNA molecule – see VIROID). In e.g. a dsDNA molecule, one strand of the parent molecule is nicked, and DNA synthesis proceeds by elongation of the 3'-OH end (with progressive displacement of the 5' end), the unbroken circular strand acting as template (see DNA REPLICATION). The partly replicated intermediate is thus a double-stranded circular DNA with a single-stranded displaced tail ( $\sigma$  structure – cf. CAIRNS' MECHANISM). The displaced strand may itself serve as a template for Okazaki fragment synthesis. When one round of replication has been completed, elongation may continue past the original initiation site (yielding a CONCATEMER), or the daughter strand may be cleaved by endonuclease at this site (yielding a parent-length strand). (See e.g. BACTERIOPHAGE  $\phi$ X174.)

**rolling hairpin model** (DNA replication) See PARVOVIRUS.

**rom gene** See COLEI PLASMID.

**Romaña's sign** Conjunctivitis, with parotid lymphadenopathy, after contamination of eyes by *Trypanosoma cruzi*. (See also CHAGAS' DISEASE.)

**Romanowsky stains** A range of composite stains (e.g. Giemsa's stain, Leishman's stain, Wright's stain) each of which includes METHYLENE BLUE, azure A and/or azure B, EOSIN, and (sometimes) methylene violet; they are used e.g. to detect/identify blood parasites (e.g. *Plasmodium* spp, trypanosomes) in blood smears. The stains are commonly used in solution in methanol, or in methanol and glycerol, and are often diluted in buffer before use. Typical staining reactions: erythrocytes and SCHÜFFNER'S DOTS pink; protozoan nuclei and KINETOPLASTS red; protozoan cytoplasm bluish-purple.

**Romney Marsh disease** *Syn.* STRUCK.

**rondomycin** See TETRACYCLINES.

**röntgen** (R; roentgen) A unit of radiation exposure (i.e., dose): the dose which causes ionization that liberates  $2.58 \times 10^{-4}$  coulombs of charge, of each sign, per kilogram of air. (cf. RAD.)

**Röntgen rays** *Syn.* X-rays. (See also IONIZING RADIATION.)

**root nodules** GALL-like (hypertrophic, hyperplastic) structures, containing endosymbiotic nitrogen-fixing bacteria, formed on the roots of certain plants – particularly members of the Leguminosae (cf. ACTINORRHIZAE and NOSTOC). Legumes (e.g. peas, beans, clovers, alfalfa) form root nodules in association with strains of RHIZOBIUM and BRADYRHIZOBIUM, often with a degree of plant–bacterium specificity. The endosymbionts occur within the nodules as modified, membrane-enclosed, often pleomorphic cells (*bacteroids*). The plant provides the bacteroids with nutrients (including fixed nitrogen), while the bacteroids reduce atmospheric nitrogen to ammonia (see NITROGEN FIXATION) which is assimilated by the plant, enabling it to thrive in nitrogen-deficient soils. (The bacteroids themselves are apparently incapable of utilizing  $\text{NH}_3$ .) [Nitrogen assimilation in legumes: Book ref. 55, pp. 129–178.] Increased levels of exogenous fixed nitrogen inhibit root nodule formation (cf. STEM NODULES), and soil conditions may influence the effectiveness of nitrogen fixation by the nodules [Book ref. 45, pp. 820–822].

In legumes, there are two principal types of root nodule, indeterminate and determinate, although other types and infection strategies are also known. [Book ref. 55, pp. 95–128.]

*Indeterminate* (= *meristematic*) nodules – formed e.g. in clovers, peas, alfalfa (lucerne), and some beans – are elongate-cylindrical in shape. Nodulation begins when capsulated rhizobia become polarly attached to a root hair. Attachment may involve interaction between root surface LECTINS (e.g. TRIFOLIIN A) and bacterial surface polymers (e.g. polysaccharide, LPS)

[Book ref. 55, pp. 3–31, cf. pp. 116–119]. Attachment may be followed by a tight curling of the root hair tip (due to differential cell wall synthesis in the root hair), resulting in the formation of a pocket which encloses the bacteria. The bacteria then penetrate the root hair via a tubular *infection thread* which, originating at the site of infection, grows to the base of the root hair and penetrates the underlying cortex. [Infection process: ARM (1983) 37 399–424.] The wall of the infection thread seems to be of plant origin, resembling the primary plant cell wall in composition; mucopolysaccharide (apparently of bacterial origin) in the lumen may serve to protect the invading bacteria from the host's defence mechanisms [Book ref. 55, pp. 58–93]. The infection thread ramifies extensively within the cortex, and cortical cells ahead of it proliferate – apparently in response to a diffusible substance(s) (?phytohormones). (Rhizobia can produce IAA and cytokinins *in vitro*, but the significance of this in nodule formation is unclear.) The invading bacteria are released from the tips of the ramifying infection thread into the proliferating cortical cells, within which they undergo morphological and other changes to become pleomorphic bacteroids enveloped in a membrane of plant origin (the *peribacteroid membrane*). Once infected, host cells cease to divide and begin to swell; they remain vacuolated. Cells beyond the infection zone continue to divide until they too are invaded; thus, throughout the development of the nodule there is an advancing zone of meristematic cells. The bacteroid-containing cells contain LEGHAEMOGLOBIN and form a pink zone between the white zones of the meristem and of the ramifying infection thread. In indeterminate nodules the fixed nitrogen is exported from the nodule to the rest of the plant mainly as *asparagine*.

*Determinate* nodules occur in certain tropical legumes, soybeans, cowpeas etc. Infection threads enter the root cortex from an infected root hair but do not ramify extensively after entering the cortex; bacteria are spread mainly by division of infected cortical cells. The nodules are spherical, with a cortical cell layer surrounding a central, pink-pigmented zone containing both infected and non-infected cells; the meristematic stage is transient, restricted to the initial stage of nodule development. Infected cells are not vacuolated, and the bacteroids are (non-pleomorphic) rods and swollen rods which divide to form up to ca. 16 bacteroids within the peribacteroid membrane. Fixed nitrogen is exported from the nodule as *ureides* (mainly allantoin and allantoic acid).

An alternative infection strategy occurs in e.g. the peanut (*Arachis hypogea*): bacteria enter the root at the junction between the root hair and epidermal cells ('crack entry'), and an infection thread is not formed. Interestingly, crack entry has been exploited in the experimental infection of wheat with the nitrogen-fixing bacterium *Azorhizobium caulinodans*; *A. caulinodans* became established within the xylem and root meristem such that experimental plants showed significantly increased dry weight and nitrogen content in comparison to uninoculated control plants [Proc. RSLB (1997) 264 341–346].

Nodulation involves coordinated expression of plant and bacterial genes, with derepression of certain plant genes (see e.g. NODULINS) and bacteroid genes (e.g. NIF GENES). (See also LEGHAEMOGLOBIN.) In *Rhizobium* spp many of the genes involved in the initiation of root hair infection, nodule formation, and nitrogen fixation are located on a large plasmid (*Sym plasmid*), although chromosomal genes are also involved (at least in nitrogen fixation). *Sym* plasmids may code for additional functions such as bacteriocin production, plasmid transfer, pigment production, etc. *Sym* plasmids appear not to occur

## rootlet

in *Bradyrhizobium* spp. [Nodulation genes in *Rhizobium*: TIBS (1986) 11 296–299.]

Nodulating strains of *Rhizobium* and *Bradyrhizobium* have been used commercially to inoculate legume seeds, prior to planting, in order to establish suitable strains in soils which lack them; this may be necessary e.g. when introducing plants (e.g. soybeans) into new geographical regions [Book ref. 45, pp. 822–824].

**rootlet** See BASAL BODY (b).

**rop gene** See COLEI PLASMID.

**ropiness** A form of FOOD SPOilage in which long, stringy threads of (usually) polysaccharide – e.g. DEXTRANS, LEVANS – are formed by spoilage bacteria: e.g. species of *Acetobacter* (in beer), *Bacillus* (e.g. *B. subtilis* in bread), *Leuconostoc* (see WINE SPOilage) and *Lactococcus* (but cf. TALETTE).

**Roquefort cheese** See CHEESE-MAKING.

**roridins** See TRICHOHECENES and STACHYBOTRYOTOXICOSIS.

**Rosalina** See FORAMINIFERIDA.

**rosanilin** A bluish-red TRIPHENYLMETHANE DYE.

**Rosculus** See AMOEBIDA.

**rose bengal** A deep-pink fluorescent dye – sodium tetraiodo-tetrachlorofluorescein; it is sometimes used in media for the isolation of certain soil fungi owing to its antibacterial properties and its ability to inhibit some rapidly-growing fungi. (See also PHOTODYNAMIC EFFECT.)

**rose black spot** See BLACK SPOT (3).

**Rose–Waal test** A serological test used to detect and quantify the rheumatoid factor (see RHEUMATOID ARTHRITIS). Essentially, the test determines the ability of the patient's serum to agglutinate sheep erythrocytes which have been sensitized (SENSITIZATION sense 3) with a subagglutinating amount of homologous IgG antibody; rheumatoid factor agglutinates such sensitized erythrocytes by combining with the Fc portions of the sensitizing IgG antibodies. Non-sensitized erythrocytes are used as a control.

**roseola infantum** *Syn.* EXANTHEM SUBITUM.

**Roseolovirus** A genus of viruses in which the type species is human (beta) herpesvirus 6 (see BETAHERPESVIRINAE) [ratification of genus name: Arch. Virol. (1993) 133 491–498].

**rosette** (1) (*bacteriol.*) A radially arranged cluster of cells or filaments (see e.g. CAULOBACTER).

(2) (*protozool.*) An intracellular structure present near the cytosome in some members of the HYPOSTOMATA.

(3) (*plant pathol.*) In a plant: an abnormal condition in which the leaves form a radial cluster on the stem due e.g. to stunting (involving a shortening of internodes) – a symptom of infection with certain PLANT VIRUSES.

(4) (*serol.*) See IMMUNOCYTE ADHERENCE TECHNIQUE.

(5) (*med.*) See MALARIA.

**rosette technique** IMMUNOCYTE ADHERENCE TECHNIQUE.

**rosetting** See MALARIA.

**Ross River virus** An ALPHAVIRUS which causes epidemics of polyarthritis (often with maculopapular rash) in humans; it occurs e.g. in Australasia and in the western Pacific region. Various other vertebrates – including domestic animals – can be infected, and wild rodents may be reservoirs of infection. The virus has been isolated from e.g. *Aedes vigilax* and *Culex annulirostris* mosquitoes.

**Rotaliina** See FORAMINIFERIDA.

**Rotavirus** (*Duovirus*, *Stellavirus*) A genus of viruses of the family REOVIRIDAE. Hosts include mammals and birds. Rotaviruses are important causes of acute, often severe, diarrhoeal disease, particularly in infants, young children and young animals – including calves (e.g. Nebraska calf diarrhoea), foals,

lambs, mice and piglets. (See also FOOD POISONING (i) and SUDDEN INFANT DEATH SYNDROME.) Rotaviruses replicate in the intestinal epithelial cells; the faeces of infected individuals may contain up to e.g.  $10^9$ – $10^{10}$  virions per gram.

A serological classification system for rotaviruses was proposed in 1985 [Ann. Vir. (1985) 136E 5–12]. Vaccination has been used against rotavirus infection [see e.g. JID (1986) 153 815–822, 823–831 and 832–839]; however, the tetravalent vaccine was withdrawn in 1999 (owing to side-effects), so that there is currently no vaccination available against rotavirus infections.

The capsid of the rotavirus virion is icosahedral in shape and is triple-layered, the outermost layer being lost during entry of the virion into a host cell. The capsid comprises various types of polypeptide – the innermost layer consisting of 120 copies of the VP2 protein, while the adjacent (middle) layer consists of 260 trimers of VP6.

The rotavirus genome consists of 11 dsRNA molecules.

Inside infected cells the double-layered viral particles become transcriptionally active, mRNAs passing out through pores in the capsid. VP6 is necessary for transcription, but its exact role is unknown. The crystal structure of VP6 from a group A rotavirus has been determined to 2 Å resolution; the results suggest that, during assembly of the capsid, the addition of the VP6 layer begins with the binding of VP6 trimers to the inner layer at the 20 icosahedral three-fold axes [EMBO (2001) 20 1485–1497]. (See also PARAROTAVIRUSES.)

**rotenone** A mitochondrial RESPIRATORY INHIBITOR which inhibits electron flow between the Fe–S centres of Complex I and ubiquinone (see ELECTRON TRANSPORT CHAIN); it binds, non-covalently, to a site which is apparently close to that at which ubiquinone is reduced. Many bacterial systems are insensitive to rotenone.

**Rothia** A genus of aerobic, facultatively anaerobic, catalase-positive, asporogenous bacteria (order ACTINOMYCETALES, wall type VI) which occur e.g. in the human mouth. The organisms form a rudimentary mycelium which fragments into non-motile rods and coccoid forms, the latter being ca. 1–5 µm in diameter. Growth occurs on rich media, e.g. trypticase–soy agar, at 37°C; no growth occurs on Sabouraud's dextrose agar. Various sugars can be fermented; glucose metabolism yields mainly lactic acid. GC%: ca. 65–70. Type species: *R. dentocariosa*. [Strain differentiation in *R. dentocariosa*: IJSB (1984) 34 102–106.]

**Rotorod** An instrument used e.g. for sampling the airborne microflora. (See also AIR.) Essentially, two vertically-orientated adhesive- or grease-coated rods, at opposite ends of a horizontal bar, are whirled at ca. 2500 rpm; the rods may be detached and examined e.g. by microscopy.

**rotund body** See THERMUS.

**rough endoplasmic reticulum** See ENDOPLASMIC RETICULUM.

**rough strain** See SMOOTH–ROUGH VARIATION.

**Rous-associated viruses** See AVIAN LEUKOSIS VIRUSES.

**Rous sarcoma virus** (RSV) An AVIAN SARCOMA VIRUS originally isolated from a naturally occurring sarcoma of a chicken; when inoculated into chickens or other fowl, RSV can cause sarcomas and a fatal acute erythroblastic leukaemia within 2–3 weeks. There are several strains of RSV which differ e.g. in oncogenicity, host range, etc. Most strains are replication-defective; all carry the ONCOGENE *v-src* (see SRC). Some strains can induce tumorigenesis on inoculation into mammals (e.g. mice, rabbits, monkeys). RSV can be cultivated in chick embryo cells or in embryonated eggs – defective strains requiring the presence of an appropriate helper virus (Rous-associated virus: see AVIAN LEUKOSIS VIRUSES).

**routine test dilution (RTD)** The highest dilution of a virus suspension (i.e. the lowest concentration of viruses) which can bring about confluent lysis in a monolayer of sensitive cells or (in the case of bacteriophage) in a lawn plate prepared with a sensitive strain of bacteria.

**Roux flask** (Roux bottle) A flat-sided, rectangular, glass or plastic vessel which opens at one end via a short wide tube; it is used, on its side, for TISSUE CULTURE.

**roxithromycin** A MACROLIDE ANTIBIOTIC.

**Royce indicator sachet** See ETHYLENE OXIDE.

**Rozella** See CHYTRIDIALES and MYCOPARASITE.

**RP 59500** See QUINUPRISTIN/DALFOPRISTIN.

**RP1  $\beta$ -lactamase** *Syn.* TEM-2  $\beta$ -LACTAMASE.

**RP1 plasmid** (*syn.* R1822 plasmid) A CONJUGATIVE PLASMID (COPY NUMBER: 1–2) which occurs in both enterobacteria and *Pseudomonas* spp (IncP/IncP-1); it encodes resistance to carbenicillin, kanamycin and tetracycline. Plasmids R18, R68, RK2 and RP4 are very similar or identical to RP1.

**RP4 plasmid** See RP1 PLASMID.

**RPase** RNA POLYMERASE.

**RPCF test** See TREPONEMAL TESTS.

**RPG effect** The phenomenon (discovered by R. P. Gunsalus) in which METHANOGENESIS from CO<sub>2</sub> and H<sub>2</sub> (in crude extracts of certain methanogens) is stimulated by methyl-coenzyme M.

**rpl genes** Genes encoding r-proteins of the large ribosomal subunit: see RIBOSOME.

**rpo genes** Genes which encode DNA-dependent RNA POLYMERASE subunits; in e.g. *Escherichia coli*, *rpoA*, *rpoB*, *rpoC* and *rpoD* encode subunits  $\alpha$ ,  $\beta$ ,  $\beta'$ , and the major SIGMA FACTOR, respectively. [Autogenous control of *rpo* genes: Genet. Res. (1986) 48 61–64.] (See also RIBOSOME (biogenesis).)

**rpoB gene** In *Mycobacterium tuberculosis*: a gene encoding the  $\beta$  subunit of RNA polymerase. Mutations in *rpoB* are associated with resistance to the drug rifampicin; such mutations are detected by various genotypic methods which are used for testing isolates of *M. tuberculosis* for resistance to rifampicin – for further details see SSCP, PROBE and TUBERCULOSIS.

**rpoH gene** (*htpR* gene) See HEAT-SHOCK PROTEINS.

**rpoN gene** See NTR GENES.

**rpoS gene** See SIGMA FACTOR.

**RPR test** Rapid plasma reagin test: a qualitative or quantitative STANDARD TEST FOR SYPHILIS in which the cardiolipin–lecithin–cholesterol antigen is modified by the incorporation of choline chloride; this modification permits serum to be tested without prior heating (cf. VDRL TEST). In the RPR (circle) card test the antigen suspension contains particles of charcoal; this permits flocculation to be assessed macroscopically. (cf. RST.)

**rps genes** Genes encoding r-proteins of the small ribosomal subunit: see RIBOSOME.

**rrn operons** See RRNA and RIBOTYPING.

**rRNA** Ribosomal RNA: the major component of a RIBOSOME (q.v. for structure etc). In e.g. *Escherichia coli* rRNA is encoded by 7 separate operons (designated *rrnA* to *rrnG*), each of which is transcribed (see TRANSCRIPTION) to give a single RNA precursor molecule (pre-rRNA, ca. 30S) which contains all three rRNA species. An *rrn* operon has two promoters (P1 and P2) separated by 109–119 bp, and has the overall structure: P1–P2–leader–16S rRNA gene–spacer–23S rRNA gene–5S rRNA gene–terminator; one or two tRNA genes lie in the ‘transcribed spacer’ between the 16S and 23S rRNA genes, and in some cases one or two tRNA genes also occur at the 3′ (distal) end of the operon.

The 30S pre-rRNA contains internal inverted repeats which can base-pair to form secondary structures. The 16S and 23S

rRNA sequences each form the loop in a separate stem-and-loop structure, and are released from the pre-rRNA by the endoribonuclease RNASE III; RNase III makes a staggered break in each of the double-stranded stem regions to liberate individual 16S and 23S rRNA precursors (designated p16S and p23S) which are slightly longer than the mature molecules. The RNase III cleavage sites show no homology; the enzyme presumably recognizes secondary and/or tertiary structure in the RNA. Subsequent processing of the individual precursors to form the mature rRNA molecules is not well understood; that of the 5S rRNA involves the endonuclease RNASE E. (For processing of the tRNA(s) see TRNA.)

Because rRNA genes are transcribed but not translated, they might be expected to show a high incidence of premature transcription termination owing to the absence of the protective effect of ribosomes (see POLAR MUTATION). Apparently, specific ANTITERMINATION mechanisms operate in the *rrn* operons of *E. coli*: modification of the RNA polymerase as it transcribes certain sequences in the *rrn* leader region may occur, allowing the polymerase to continue transcription until it reaches a strong *rrn* terminator [minireview: JB (1986) 168 1–5].

Eukaryotes synthesize an rRNA precursor (ca. 45S) which contains a leader sequence and sequences for the 28S, 18S, and 5.8S rRNAs separated by transcribed spacers; 45S transcripts are transcribed from many tandemly repeated sets of genes separated by non-transcribed spacer sequences. The 45S precursor is synthesized by RNA polymerase I in the NUCLEOLUS [minireview: Cell (1986) 47 839–840]; the 5S rRNA genes are organized separately and are transcribed by RNA polymerase III. (In certain lower eukaryotes – e.g. in *Dictyostelium discoideum*, and in the macronucleus of *Tetrahymena* – rRNA genes occur on extrachromosomal DNA molecules present in many copies per nucleus.) (See also SPLIT GENE (b).)

**rRNA oligonucleotide cataloguing** A procedure once used in bacterial TAXONOMY. Essentially, rRNA (usually 16S rRNA) is cleaved by a sequence-specific endonuclease (e.g. RNase T1); the fragments are end-labelled, separated by electrophoresis, and then sequenced – giving a ‘catalogue’ of sequences characteristic of the species. The catalogues of various species can then be compared and used as a basis for classification. [16S rRNA oligonucleotide cataloguing: Book ref. 138, pp 75–107.]

rRNA oligonucleotide cataloguing was one of the earlier methods used in molecular taxonomy. Subsequently, more informative methods (e.g. sequencing of the entire rRNA molecule) were developed.

**rRNA superfamily VI** See HELICOBACTER.

**RS layer** *Syn.* S LAYER.

**Rsd protein** See ANTI-SIGMA FACTOR.

**RSF1010 plasmid** See INCOMPATIBILITY.

**RSF1030 plasmid** See COLE1 PLASMID.

**RSSE** RUSSIAN SPRING–SUMMER ENCEPHALITIS.

**RST** Reagin screen test: a qualitative or quantitative STANDARD TEST FOR SYPHILIS in which the antigen has been dyed blue in order to permit macroscopic assessment of flocculation (cf. RPR TEST).

**RSV** (1) Respiratory syncytial virus. (2) Rous sarcoma virus.

**Rta** See ZEBRA.

**RTD** ROUTINE TEST DILUTION.

**RTEM  $\beta$ -lactamase** *Syn.* TEM-1  $\beta$ -LACTAMASE.

**RTF** (1) Resistance transfer factor: that part of a *conjugative* R PLASMID which contains the genes specifying CONJUGATION; thus, a conjugative R plasmid consists of the RTF together with the gene(s) encoding resistance (resistance determinants). The RTF is usually self-repressed. (See also SEX FACTOR.)

## rtPCR

(2) *Syn.* R plasmid, or conjugative R plasmid.

**rtPCR** See REVERSE TRANSCRIPTASE PCR.

**rTth DNA polymerase** See REVERSE TRANSCRIPTASE PCR.

**RTX toxins** A category of TOXINS, secreted by certain Gram-negative bacteria, which have in common various structural and functional characteristics; the name 'RTX' derives from the series of calcium-binding, glycine-rich nonapeptide repeat units (repeats in toxin) which occur near the C-terminal end in each toxin. At least two of the toxins – the HlyA (haemolysin) of *Escherichia coli* and the CYCLOLYSIN of *Bordetella pertussis* – are secreted by an ABC EXPORTER.

A feature shared by all RTX toxins is the ability to form pores in eukaryotic cell membranes – in some cases leading to osmotic lysis. Although high concentrations of toxin can kill effector cells of the immune system (leading e.g. to local inflammation and tissue damage), other modes of activity have been recorded. For example, quite low levels of HlyA can bring about a loss of killing power in PMNs, while cyclolysin can inhibit the oxidative burst in phagocytes; in the latter case, the pathogen may use this advantage to establish an intracellular carrier state. At lower, sub-lytic concentrations, RTX toxins may behave as MODULINS. Cyclolysin differs from the other RTX toxins in that it has ADENYLATE CYCLASE activity; in phagocytes, increased levels of intracellular cAMP can result in a reduction or loss of phagocytic activity. In general, the RTX toxins apparently behave primarily as virulence factors directed against the host's immune response.

Other RTX toxins include the LktA (leukotoxin) of *Pasteurella haemolytica*, the causal agent of an acute pneumonia in ruminants (cattle, sheep); this toxin is a particularly potent lytic agent for the white blood cells and platelets of ruminants. The cytolytic activity of this toxin is reported to be enhanced by lipopolysaccharide [MP (2001) 30 347–357].

The pathogen *Actinobacillus pleuropneumoniae*, associated with pleuropneumonia in pigs, forms two haemolysins, designated ApxIA and ApxIIA, while a leukotoxin, AktA, is secreted by *Actinobacillus actinomycetemcomitans*, a pathogen linked to oral disease and abscesses in man.

[RTX toxins (review): RMM (1996) 7 53–62.]

**RU** READING UNIT.

**rubber spoilage** Natural rubber is essentially a long-chain polymer of isoprene units; *vulcanized* rubber contains a high proportion of sulphur. Rubber may also contain fillers (e.g. clay, carbon black), antioxidants, antimicrobial preservatives etc. Both natural and vulcanized rubbers are susceptible to microbial spoilage – e.g. staining or discoloration due to surface colonization (e.g. by species of *Bacillus*, *Serratia*, *Aspergillus*, *Cladosporium*, *Penicillium*) or degradation of the polymer itself. In general, organisms cannot attack the long isoprene chains enzymically, and initial deterioration is usually chemical (e.g. oxidation); short-chain fragments can then be metabolized e.g. by species of *Nocardia*, *Streptomyces*, *Aspergillus*, *Fusarium* and *Penicillium*. Vulcanized rubber can be degraded e.g. by *Nocardia* sp [AEM (1985) 50 965–970]; *Thiobacillus thiooxidans* can produce sulphuric acid from the sulphur, the acid causing extensive degradation of the polyisoprene. Rubber is particularly susceptible to spoilage when damp, in contact with soil, etc; microbial deterioration can cause problems e.g. with rubber insulation on buried cables, rubber joints in water and sewer pipes etc. Various antimicrobial preservatives (e.g. pentachlorophenol, cresylic acid, organoarsenicals) may be added to delay spoilage. Synthetic rubbers such as butyl, silicone and polychloroprene (neoprene) rubbers are more resistant than natural rubber to both chemical and microbial degradation. (See also LATEX.)

**rubella** (German measles) (1) An acute infectious human disease, which affects mainly children and young adults, caused by a virus (see RUBIVIRUS).

*Acquired rubella.* Infection occurs by droplet inhalation. Incubation period: 2–3 weeks. Early symptoms may include mild upper respiratory tract symptoms, mild fever, and enlargement of the lymph nodes of the head and neck. Following a stage of viraemia, a maculopapular rash appears first on the face, then on the rest of the body. Patients are infectious for ca. 1 week before and ca. 1 week after the onset of symptoms. The disease is usually mild and self-limiting; occasional complications include e.g. arthritis and encephalitis.

*Congenital rubella.* Maternal rubella acquired during pregnancy can lead to a persistent infection of the fetus and neonate, resulting in teratogenic effects which may range from mild (e.g. low birth weight) to fetal death; intermediate manifestations include permanent defects in the CNS (e.g. mental retardation), ears (nerve deafness), eyes (e.g. cataracts, retinal damage), heart etc (cf. TORCH DISEASES). Damage is most severe if infection is acquired during the first 3 months of pregnancy. A progressive rubella panencephalitis resembling SUBACUTE SCLEROSING PANENCEPHALITIS has been reported as a late manifestation of congenital rubella [NEJM (1975) 292 990–993, 994–998].

*Lab. diagnosis:* detection of rubella-specific antibodies e.g. by a haemagglutination-inhibition test, radial haemolysis, ELISA etc. Rubella virus can be isolated from e.g. nasopharyngeal swabs. *Prophylaxis:* vaccination with a live, attenuated vaccine (see also MR and MMR).

(2) *Syn.* INFECTIOUS DROPSY (of carp).

**rubelliform** Refers to a RUBELLA-like disease or rash.

**rubeola** (1) (English, German) *Syn.* MEASLES. (2) (French, Spanish) *Syn.* RUBELLA.

**rubidomycin** See ANTHRACYCLINE ANTIBIOTICS.

**RuBisCO** RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE–OXYGENASE.

**Rubivirus** A genus of viruses (family TOGAVIRIDAE) which currently includes only the RUBELLA virus. Man is apparently the only natural host; some laboratory animals can be infected, but none develops a disease analogous to that in man. (There is no invertebrate host.) The rubivirus virion is relatively unstable at room temperatures, loses infectivity within ca. 30 min at 56°C, but is stable for ca. 1 week in protein-containing solutions at 4°C; it can be stored at or below –60°C, and can withstand freeze-drying. It can be inactivated by pH <6.8 or >8.1, by organic solvents, UV radiation, deoxycholate, ethylene oxide, etc. The virions promote Ca<sup>2+</sup>-dependent haemagglutination of RBCs from various species (those from newly hatched chick, adult goose or pigeon, or human O-type RBCs being commonly used in HI tests). Rubella virus can grow in various types of cell culture; primary African green monkey kidney cells have been widely used for primary isolation. The virus is non-cytopathogenic in most vertebrate cells, and can be detected e.g. by immunofluorescence techniques and by its ability to prevent the replication of a superinfecting 'challenge virus' such as echovirus type 11 (see INTERFERENCE). [Clinical aspects: Book ref. 148, pp. 1005–1020.]

**RuBP** Ribulose 1,5-bisphosphate.

**RuBPCase** See RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE–OXYGENASE.

**rubratoxins** MYCOTOXINS produced e.g. by strains of *Penicillium rubrum*; toxin production is associated with active fungal growth. Consumption of rubratoxins by animals causes congestion of tissues (often with haemorrhage) – especially in the stomach and intestine; liver damage and brain lesions can also occur. Rubratoxins and AFLATOXINS act synergistically.

**rubredoxins** See IRON-SULPHUR PROTEINS.

**Rudimicrosporea** A class of protozoa (phylum MICROSPORA) which are hyperparasites of gregarines in annelid worms. The spores have a simple (rudimentary) extrusion apparatus consisting of a polar cap and thick polar tube terminating in a funnel (the infundibulum). There is no polaroplast. Genera: e.g. *Amphicantha*, *Metchnikovella*.

**rugose** Wrinkled.

**rugose mosaic disease** (1) The disease of potatoes caused by POTATO VIRUS Y (Y<sup>o</sup> strains) in the second and subsequent years of infection. (2) A severe disease of potatoes caused by mixed infection with potato virus X and POTATO VIRUS Y (Y<sup>o</sup> strains).

**rule of desmodexy** (*ciliate protozool.*) The rule, based on observation, that each kinetodesma lies on the right-hand side of its corresponding kinetosome: see KINETODESMA.

**rum** See SPIRITS.

**rumen** One of four compartments which form the stomach in *ruminants* (cattle, deer, giraffes, goats, sheep etc); the other compartments are the *reticulum* (an outpocketing of the rumen usually included with the rumen proper when reference is made to the 'rumen'), the *omasum*, and the *abomasum* or 'true stomach'.

In the adult or weaned ruminant, food passes from the oesophagus to the rumen. The rumen (capacity ca. 5–10 litres in sheep, 100–150 litres in cattle) is essentially an anaerobic muscular sac which contains a large population of microorganisms (on average ca. 10<sup>10</sup> cells/ml) – primarily bacteria and protozoa, but sometimes including a significant proportion of fungi; these microorganisms play an essential role in ruminant nutrition by breaking down the ruminant's diet of plant material (see ANAEROBIC DIGESTION) and providing the animal with assimilable nutrients and sources of energy. (The microflora of the rumen is indispensable to the ruminant since many of the components of plant material are not attacked by the enzymes of animal digestive systems. The rumen itself does not secrete enzymes.) To allow adequate time for microbial action, large particles of food may remain in the rumen for several days. Periodically a bolus of partly digested material (a *cud*) is regurgitated to the mouth, chewed, and swallowed; cuds return to the rumen where they undergo further digestion. The net effect of digestion in the rumen is the conversion of dietary materials to a mixture of fatty acids (mainly acetic, butyric and propionic acids), gases (primarily CO<sub>2</sub> and CH<sub>4</sub> – which are voided by eructation), and microbial biomass. Fatty acids are absorbed by the rumen and are used by the ruminant as primary sources of carbon and energy. Microbial biomass passes from the rumen to the omasum – where residual fatty acids, water and salts are absorbed – and then to the abomasum where the biomass undergoes true ('gastric') digestion; digested material passes into the small intestine where it is absorbed by the ruminant – amino acids derived from the digestion of *microbial* protein constituting the principal source of nitrogen for the ruminant. Certain vitamins synthesized by the rumen bacteria (e.g. VITAMIN B<sub>12</sub>) are also absorbed as the rumen contents pass through the abomasum and intestines.

Ruminants produce large amounts of saliva; the saliva contains bicarbonate and phosphate which buffer the rumen contents – maintaining a pH of ca. 6.0–6.5 despite the ongoing formation of acidic products by microbial fermentations. The temperature of the rumen (in the cow) is ca. 39–40°C, slightly higher than the body temperature (ca. 38°C) due partly to the exothermic microbial metabolism. The E<sub>h</sub>' of the rumen has been reported to be in the range –145 mV to –260 mV. [Influence

of E<sub>h</sub> on in vitro culture of rumen bacteria: JGM (1984) 130 223–229.]

The types and numbers of microorganisms in the rumen of an adult or weaned ruminant depend primarily on species, on the animal's diet, and on the period of time since the last intake of food; thus, for example, the proportion of non-bacterial microorganisms in the rumen is much higher in Red deer and reindeer – which feed on e.g. heather and lichens – than it is in sheep consuming more easily digestible materials. Protozoa – e.g. common in the rumen include species of *Dasytricha*, *Diplodinium*, *Entodinium*, *Epidinium* and *Isotricha*. Ciliates usually adhere to the ends of broken fibres, or to the rumen wall; some are cellulolytic and/or amylolytic, while others depend on soluble sugars. At least some protozoa ingest bacteria in the rumen. [Rumen ciliates: AP (1980) 18 121–173; rumen holotrich ciliates: MR (1986) 50 25–49.] Some rumen microorganisms which were once thought to be protozoa are now known to be fungi – e.g. the species *Neocallimastix frontalis* (see NEOCALLIMASTIX), *Piromonas communis* and *Sphaeromonas communis*. Various bacteria (mainly Gram-negative anaerobes) occur in the rumen (see later). [New developments in rumen microflora: TIM (1997) 5 483–488.]

In a given ruminant, some species of microorganism are commonly present in large numbers and appear to play more or less well-defined roles in digestive processes within the rumen; although protozoa are normally present, experiments with defaunated animals indicate that they are not always essential. Disturbances of the overall balance of microorganisms in the rumen can occur e.g. in certain dietary regimes – leading to disorders such as ACIDOSIS and BLOAT.

*Carbohydrate utilization in the rumen.* The main dietary carbohydrates of a ruminant typically include plant polysaccharides such as CELLULOSE, HEMICELLULOSES and PECTINS which occur in leaves and stems; the free sugar and starch content of leaves and stems is relatively small. Cellulose is degraded by a range of bacteria, including species of BACTEROIDES (e.g. *B. succinogenes*) and RUMINOCOCCUS, and '*Micromonospora ruminantium*'; by protozoa (e.g. *Epidinium*); and by fungi (e.g. *Piromonas communis*). (See also CELLULOSES.) CELLOBIOSE is attacked by *Bacteroides ruminicola* and species of BUTYRIVIBRIO (e.g. *B. fibrisolvens*) and SELENOMONAS (e.g. *S. ruminantium*). Pectins are degraded by some organisms (e.g. *Ruminococcus flavefaciens*) which do not use the breakdown products; other organisms (e.g. *Bacteroides ruminicola*, *Lachnospira multiparus*) degrade pectins and utilize the products. Other pectinolytic organisms include *Treponema saccharophilum* [AEM (1985) 50 212–219]. XYLANS are attacked e.g. by *Bacteroides ruminicola* and *Butyrivibrio fibrisolvens* [rumen xylanolytic systems: FEMS Reviews (1993) 104 68–70].

Animals which are fed on cereal concentrates have a higher-than-normal intake of STARCH, and this may be reflected in the nature of the rumen microflora. Organisms which can degrade starch include *Bacteroides amylophilus* and *B. ruminicola*, *Succinomonas amyolytica*, and *Succinivibrio dextrinosolvens*; *S. dextrinosolvens* seems to be a major fermenter of dextrins in high-starch diets. Starch can also be digested by some ciliates.

The presence in the diet of material with high levels of tannins can affect the composition of the rumen microflora – tannins depressing the growth rate of some organisms more than that of others (see TANNINS).

Products of the initial breakdown of polysaccharides include a range of mono- or disaccharides which are fermented to volatile fatty acids (VFA) – particularly acetic, butyric and propionic

## rumenitis

acids – and to other products such as lactic and succinic acids; these primary fermentations are carried out by many of the bacteria involved in the initial cleavage of polysaccharides – and e.g. by *Streptococcus bovis* and certain LACTIC ACID BACTERIA. VFA are absorbed by the rumen (and used by the ruminant) while e.g. lactic acid may be used as a substrate for a secondary fermentation (e.g. by *Veillonella parvula* and species of *Selenomonas* and MEGASPHERA) with the formation of acetic and propionic acids. Other rumen bacteria (e.g. species of DESULFOBULBUS and DESULFOTOMACULUM) can oxidize lactic and propionic acids to acetic acid. (See also ANAEROBIC DIGESTION.)

Some of the CO<sub>2</sub> and H<sub>2</sub> derived from fermentations is used, by rumen METHANOGENS, for the production of methane (see METHANOGENESIS). In general, methane is produced in molar proportions greater than those of either propionate or butyrate. Theoretically, suppression of methanogenesis should increase yields of the other products – thus increasing feed conversion efficiency; this has been found to be the case in practice, and various agents (e.g. MONENSIN) have been used specifically for this purpose.

**Lipid utilization in the rumen.** Dietary lipids consist mainly of mono- and digalactoglycerides (in e.g. grasses) and triglycerides (in cereal concentrates); these lipids contain a high proportion of polyunsaturated long-chain fatty acids. In the rumen some of these lipids undergo lipolysis and hydrogenation to form free, more or less saturated, C<sub>16</sub>–C<sub>18</sub> fatty acids, while others are used for the synthesis of microbial lipids. (Owing to the hydrogenation of dietary lipids by certain rumen bacteria, the storage fats of ruminants are less affected by the nature of the dietary lipids than is the case in non-ruminants.) Lipolytic rumen bacteria include *Anaerovibrio lipolytica* and some strains of *Butyrivibrio*.

**Nitrogen metabolism in the rumen.** In the rumen, most dietary protein is initially degraded to peptides and amino acids. Many species of microorganism can carry out proteolysis in the rumen, some of the most actively proteolytic bacteria being closely associated with the rumen epithelium. In sheep, *Bacteroides rumicola* has been found to be the major proteolytic bacterium in the rumen fluid [JGM (1985) 131 821–832]. Although some of the amino acids are taken up by the rumen microorganisms, most are rapidly deaminated – the resulting ammonia constituting the principal source of nitrogen for the rumen microorganisms. (cf. FOG FEVER.) The metabolism of protein in this way is a relatively inefficient use of feedstuffs (by the ruminant) since, e.g., some of the ammonia is absorbed by the rumen, and some of this is excreted (as urea) in the urine (but see next paragraph). Attempts have been made to inhibit proteolysis in the rumen by modifying dietary protein (by heating or by treatment with e.g. formaldehyde); the modified protein is resistant to degradation in the rumen (near-neutral pH) but is readily digested in the (acidic) abomasum. (Some unmodified proteins, e.g. albumins and  $\gamma$ -globulins, are resistant to degradation in the rumen.) An alternative strategy is to inhibit the deamination of amino acids in the rumen; inhibition of *in vitro* deamination has been achieved with sodium arsenite (suggesting the involvement of the STICKLAND REACTION), and inhibition both *in vitro* and *in vivo* can be achieved e.g. by the use of diaryliodonium compounds. However, deamination of amino acids yields certain fatty acids (e.g. isobutyric acid from valine) which are needed by some of the rumen bacteria (e.g. *Ruminococcus* spp).

Other nitrogenous compounds (e.g. urea) are also used as sources of nitrogen by rumen microorganisms. Urea formed by the ruminant itself can be excreted (in urine) but much passes

to the rumen (via the rumen wall, or in the saliva); here, the urea is cleaved by microbial ureases and the resulting ammonia is incorporated into microbial biomass. Thus, dietary nitrogen is conserved, and ruminants can survive on low-nitrogen diets. Feedstuffs low in nitrogen can be supplemented with e.g. urea.

In the *suckling* ruminant the rumen is poorly developed; milk passes from the oesophagus, via the oesophageal groove, directly to the omasum and abomasum (i.e., by-passing the rumen) and is digested by processes similar to those in other young mammals; the intestinal flora includes species of *Lactobacillus* and *Streptococcus*.

[Review of microbial ecology and activities in the rumen: CRM (1982) 9 165–225 (part I) and 253–320 (part II).]

**rumenitis** Inflammation of the RUMEN. Primary rumenitis, involving erosion of the rumen wall, can occur as a result of ACIDOSIS; the weakened rumen wall may subsequently be invaded by pathogenic microorganisms which may give rise e.g. to necrotic foci in the rumen and/or in other tissues (such as the liver).

**rumensin** *Syn.* MONENSIN.

**ruminal** Of or pertaining to the RUMEN.

**ruminal tympany** *Syn.* BLOAT.

**ruminate** (1) (*verb*) To chew the cud. (See also RUMEN.) (2) (*adj.*) Much folded – as though having been chewed.

**Ruminococcus** A genus of GRAM TYPE-positive, asporogenous, anaerobic, typically cellulolytic bacteria which occur e.g. in the RUMEN; GC%: ca. 40–45. Cells: cocci (ca. 1  $\mu$ m diam.) which occur in pairs or chains. Metabolism is typically heterofermentative; the main products of carbohydrate metabolism include acetic and formic acids (lactic acid may be formed in small amounts). CELLOBIOSE and (commonly) CELLULOSE are fermented; glucose and other simple sugars may or may not be fermented, according to strain (many strains lack a glucose transport system). Ammonia is essential as a source of nitrogen for most or all strains. Other growth requirements may include e.g. B vitamins. Type species: *R. flavefaciens*. Other species: *R. albus*.

**RuMP pathway** *Syn.* RMP PATHWAY.

**rumposome** In zoospores of certain members of the CHYTRIDIOMYCETES (e.g. *Monoblepharella*): a body of unknown function (though thought to be light-sensitive) which occurs beneath the cytoplasmic membrane at the posterior end of the cell.

**Runella** A genus of pink-pigmented bacteria (family SPIROSOMACEAE). The cells, 0.5–0.9  $\times$  2.0–4.5  $\mu$ m, are typically moderately or strongly curved – the ends of curved cells sometimes overlapping to form ‘ring-shaped’ structures. Acid is formed from few carbohydrates. GC%: 49–50. Type species: *R. slithyformis*.

**Runyon groups** In the genus *Mycobacterium*: groups of species distinguished on the basis of growth rate and pigmentation; slow-growing species are placed in groups I (photochromogens), II (scotochromogens), and III (others), while fast-growing species are placed in group IV.

**Russian autumn encephalitis** *Syn.* JAPANESE B ENCEPHALITIS.

**Russian flu** See INFLUENZAVIRUS.

**Russian spring–summer encephalitis (RSSE)** An acute human ENCEPHALITIS caused by a flavivirus (see FLAVIVIRIDAE); it occurs in epidemics, chiefly in and around the forests of Siberia. It is transmitted by ticks (e.g. *Ixodes* sp); human infection can also occur by ingestion of meat or milk from infected animals. The disease varies from mild to fatal; encephalitis may be followed by chronic progressive neuromuscular disorders or paralysis months or years after the original infection, apparently due to the persistence of the RSSE virus in the CNS. [ARE (1981) 26 80–82.]

**Russian winter wheat mosaic virus** See RHABDOVIRIDAE.

**Russula** A genus of fungi (family RUSSULACEAE) which form mushroom-shaped, lamellate fruiting bodies that do not form 'latex' (cf. LACTARIUS). *R. emetica* is a poisonous species ('the sickener') which forms a fruiting body having a bright red, shiny cap; it is commonly found under or near pine trees. *R. mairei* ('the beechwood sickener') is another red-capped, poisonous species found near beech trees.

**Russulaceae** A family of fungi (order RUSSULALES) which form ballistospores on stipitate, agaricoid to gasteroid fruiting bodies. Genera include LACTARIUS and RUSSULA.

**Russulales** An order of fungi (subclass HOLOBASIDIOMYCETIDAE) in which a characteristic feature is the presence of SPHAEROCYSTS in the tissues of the fruiting body. The two families are Elasmomycetaceae (members form statismospores in gasteroid fruiting bodies) and RUSSULACEAE. (See also GASTEROMYCETES (Hymenogastres) and SECOTIOID FUNGI.)

**rust** See RUSTS.

**rusticyanin** A BLUE PROTEIN (MWt ca. 16500) which occurs in

*Thiobacillus ferrooxidans* (see also EXTRACYTOPLASMIC OXIDATION);  $E_m$ : ca. 680 mV.

**rusts** (1) Fungi of the class UREDINIOMYCETES. (2) Any of various plant diseases caused e.g. by members of the Urediniomycetes or by species of ALBUGO. (See also WHITE RUST and RED RUST.) Diseases caused by urediniomycetes are called 'rusts' because many of the causal agents form rust-coloured spores on affected plants; these diseases include e.g. BLISTER RUST, COFFEE RUST, various CEREAL DISEASES, CROWN RUST and FLAX RUST.

**rutamycin** An agent which binds non-covalently to and inhibits mitochondrial ( $F_0F_1$ )-type PROTON ATPASES.

**ruthenium red** A dye used for staining mucopolysaccharides and e.g. as a specific inhibitor of certain ATPases [JGM (1980) 120 183–198].

**ruv gene** See RECF PATHWAY.

**RV medium** RAPPAPORT-VASSILIADIS BROTH.

**RW coefficient** See RIDEAL-WALKER TEST.

**rye diseases** See CEREAL DISEASES.

**ryegrass mosaic virus** See POTYVIRUSES.

**ryegrass staggers** See PENITREMS.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# S

**s** Sedimentation coefficient: see SVEDBERG UNIT.

**S** (1) SVEDBERG UNIT. (2) Serine (see AMINO ACIDS).

**S fimbriae** FIMBRIAE which occur on many of the strains of *Escherichia coli* which cause meningitis in human neonates; they bind to sialyl galactoside receptors on human erythrocytes.

**S-glucan** Alkali-soluble glucans of fungal CELL WALLS. (cf. R-GLUCAN.)

**s. lat.** SENSU LATO (q.v.).

**S layer** In a prokaryotic cell: a continuous layer – often the outermost layer of the cell – consisting of a repeating pattern of protein or glycoprotein subunits ('S proteins') arranged in squares, hexagons etc. S layers occur in bacteria (including strains of e.g. *Aeromonas*, *Campylobacter*, *Clostridium*, DEINOCOCCUS, *Lactobacillus*, *Nitrosomonas*, *Pseudomonas*, *Treponema*, some cyanobacteria) and archaeans (including strains of e.g. *Desulfurococcus*, *Halobacterium*, *Methanococcus*, *Sulfolobus*).

In bacteria, the S layer usually overlays the cell wall proper – e.g. in Gram-negative species it is external to the outer membrane. A *Bacillus* sp with an S layer on both sides of the cell wall has been reported [FEMS (1987) 40 75–79]. Double S layers, containing the same or different subunits, occur e.g. in strains of *Aquaspirillum*, *Bacillus* and *Corynebacterium*. (See also GLYCOALYX.)

In a strain of *Bacillus stearothermophilus* it has been found that variation in the S layer involves a chromosome–plasmid re-arrangement of DNA [JB (2001) 183 1672–1679].

In some archaeans the S layer is the only cell wall component, being immediately external to the cytoplasmic membrane.

S proteins are typically rich in acidic residues. In Gram-negative bacteria the S proteins interact with LPS – in at least some cases by non-covalent links; changes in composition of LPS have been associated with the loss of an S layer. The mRNAs of S protein genes are typically long-lived (~10–20 minutes).

S proteins typically have an N-terminal signal peptide, indicating secretion by a type II (*sec*-dependent) system (see PROTEIN SECRETION). However, the way in which these proteins aggregate to form an S layer, and their mode of binding to LPS in Gram-negative bacteria, is not understood.

[Review: ARM (1983) 37 311–339. Principles of S layer organization: JMB (1986) 187 251–253. Secretion of S layers in Gram-negative bacteria: FEMS Reviews (2000) 24 21–44 (35–38).]

**S matrix** In NUMERICAL TAXONOMY, *similarity matrix*: the percentage similarity between each OTU and each of every other OTU (in a given study) expressed in tabular form – the ordinate and abscissa of the matrix each comprising a complete list of designations of the OTUs under study.

**S organism** See METHANOBACILLUS OMELIANSKII.

**S phase** (of cell cycle) See CELL CYCLE.

**S protein** (*immunol.*) A protein (MWt ca. 80000) found in normal plasma. S protein binds to the fluid-phase (i.e. non-membrane-bound) complex C5b67 formed during COMPLEMENT FIXATION, destroying its membrane-binding and haemolytic potential. (See also REACTIVE LYSIS.)

**S→R variation** See SMOOTH–ROUGH VARIATION.

**S ring** See FLAGELLUM (a).

**s. str.** SENSU STRICTO (q.v.).

**S strain** See SMOOTH–ROUGH VARIATION.

**s zonal centrifugation** See CENTRIFUGATION.

**S1 (S<sub>1</sub>) endonuclease** *Syn.* ENDONUCLEASE S<sub>1</sub>.

**S1–S21 proteins** See RIBOSOME.

**Sabin–Feldman dye test** TOXOPLASMA DYE TEST.

**Sabin vaccine** An oral anti-poliomyelitis vaccine containing attenuated strains of three types of poliovirus (see ATTENUATION (1)); each strain may be administered separately to avoid mutual interference. The vaccine encourages an active viral infection of the gut and stimulates local secretory IgA formation. (cf. SALK VACCINE.)

**sabkha** A hypersaline pool.

**Sabouraud's medium** A medium used for the culture of various fungi pathogenic in man or animals. It contains e.g. 1–1.5% peptone (or phytone), 2–4% D-glucose ('Sabouraud's dextrose medium') or maltose ('Sabouraud's maltose medium'), and – for solid media – ca. 2% agar. The pH is adjusted to 5.4–5.6 (which inhibits the growth of many bacteria), and various antibiotics may be added to further suppress bacteria and unwanted fungi.

**SacII** See RESTRICTION ENDONUCLEASE (table).

**sacbrood** A BEE DISEASE which affects *Apis mellifera* and *A. cerana*; it is caused by an unclassified RNA virus (cf. PICORNAVIRIDAE). Infected larvae fail to pupate, apparently because they cannot shed their last larval skin; they become yellow and surrounded by fluid, and death occurs within a few days. The virus rapidly loses infectivity in the dried remains of the larvae; adult bees appear to act as carriers.

**Saccammina** See FORAMINIFERIDA.

**Saccamoeba** See AMOEBIDA.

**Saccardoan system** A system of classification, introduced by Saccardo, in which the form genera of the DEUTEROMYCOTINA are grouped into sections on the basis of the characteristics of their spores (conidia). The sections are as follows. Amerosporae: spores rounded or slightly elongate, aseptate; didymosporae: spores ovoid or slightly elongate, uniseptate; phragmosporae: spores elongate with two or more transverse septa; dictyosporae: spores ovoid or elongate, having both transverse and longitudinal septa; scolecosporae: spores filamentous, septate or aseptate; helicosporeae: spores helical, septate or aseptate; staurosporae: spores stellate.

Subsections may be formed e.g. on the basis of colour; thus, e.g. spores ovoid, uniseptate, colourless: hyalodidymae; spores rounded, aseptate, pigmented or dark: phaeosporae.

**saccharase** *Syn.* INVERTASE.

**saccharification** The degradation of polysaccharides (such as STARCH, CELLULOSE) to simple sugars (e.g. glucose).

**Saccharomonospora** A genus of bacteria (order ACTINOMYCETALES, wall type IV) which occur e.g. in composts and soil. The organisms form aerial mycelium and a non-fragmenting substrate mycelium; spores are borne singly on unbranched sporophores which arise at short intervals on the aerial hyphae. Strains grown at 40–50°C usually form a white aerial mycelium which becomes grey-green as sporulation occurs; sporulation is typically accompanied by the formation of a soluble green pigment. Mycolic acids are not formed. GC%: ca. 74–75. Type species: *S. viridis*. [Book ref. 73, pp. 126–127.]

**Saccharomyces** A genus of yeasts (family SACCHAROMYCETACEAE). Cells are spheroidal, ellipsoidal or cylindrical; vegetative reproduction occurs by multilateral budding. Pseudomycelium may be formed by some species, but true hyphae are absent.

The vegetative cells are normally predominantly diploid (or polyploid) – predominantly haploid species having been placed in the genera ZYGOSACCHAROMYCES and TORULASPORA. Asci, which are persistent, develop directly from the diploid vegetative cells. Ascospores are spheroidal, usually smooth, 1–4 per ascus. Conjugation occurs on, or shortly after, germination of the ascospores, i.e., it occurs between ascospores or between haploid somatic cells derived therefrom. Species can ferment one or more sugars, and can also carry out respiratory metabolism of a range of substrates.  $\text{NO}_3^-$  is not assimilated. Seven species have been recognized [Book ref. 100, pp. 379–395]; type species: *S. cerevisiae*.

*S. cerevisiae* (including many varieties and physiological races formerly accorded species status – e.g. *S. acetii*, *S. carlsbergensis*, *S. diastaticus*, *S. ellipsoideus*, *S. globosus*, *S. intermedius*, *S. inusitatus*, *S. sake*, *S. uvarum* etc). Cells (e.g. after 3 days at 25°C in malt extract) are ca. 3–10 × 4–20(–30) µm, occurring singly or in pairs, short chains or clusters. (See also CELL WALL.) Pseudohyphae may be formed e.g. on cornmeal agar. Many strains are heterothallic (see MATING TYPE). Sporulation is encouraged by media which are low in nitrogen and which contain acetate as the main or sole carbon source. All strains can ferment glucose, some can ferment galactose, sucrose and maltose, none can ferment lactose. (See also ALCOHOLIC FERMENTATION.) In the presence of O<sub>2</sub>, strains can metabolize (oxidatively) substrates such as glycerol, ethanol and lactate. All strains are sensitive to cycloheximide (100 ppm). Strains have been isolated from e.g. alcoholic beverages, fruits and fruit juices, soil, human skin and sputum, etc.

Selected strains of *S. cerevisiae* are widely used in the manufacture of alcoholic beverages and fermented foods: see e.g. BREAD-MAKING (and BAKERS' YEAST), BREWING (and BREWERS' YEAST), CIDER, KEFIR, PULQUE, SAKE, WINE-MAKING, YEAST EXTRACT. (See also CHEESE-MAKING (c), IMMOBILIZATION (sense 1), STEROID BIOCONVERSIONS, WINE SPOILAGE.) *S. cerevisiae* is also widely used in genetic studies and for the propagation of genetically engineered genes. (See also e.g. KILLER FACTOR, KILLER PLASMIDS, TWO-MICRON DNA PLASMID, THREE-MICRON DNA PLASMID.) [Genetic map of *S. cerevisiae*: MR (1985) 49 181–212.]

*S. dairenensis* (= *S. castellii*). Cells (in malt extract): ca. 3.0–5.5 × 3.5–7.0 µm, occurring singly or in pairs. Glucose and galactose are fermented; sucrose, maltose and lactose are not. Most strains can grow in the presence of cycloheximide at 100 ppm but not at 1000 ppm. Strains have been isolated from buttermilk, soil and fermenting cucumber brines.

*S. exiguus* (anamorph: *Candida holmii*). Cells (in malt extract): ca. 2.5–5.0 × 3.5–6.5 µm, occurring singly or in pairs. Glucose, galactose and sucrose are fermented; maltose and lactose are not. Most strains can grow in the presence of cycloheximide at 100 ppm but not at 1000 ppm. Strains have been isolated from soil, fruit, fermenting cucumber brines etc. (See also BREAD-MAKING.)

*S. kluyveri*. Cells (in malt extract): ca. 3.5–7.0 × 4.0–11.0 µm, occurring singly or in pairs or clusters; pseudohyphae are usually formed e.g. on cornmeal agar. Glucose, galactose and sucrose are fermented, maltose and lactose generally are not, although some strains can ferment maltose weakly. All strains are sensitive to cycloheximide (100 ppm). The organisms closely resemble *S. cerevisiae* but can be distinguished by their ability to grow on ethylamine, cadaverine or L-lysine as sole nitrogen source. Strains have been isolated from *Drosophila* spp, tree exudates, soil, and fruit juice.

*S. lactis*. Now *Kluyveromyces marxianus* var. *lactis*: see KLUYVEROMYCES.

*S. rouxii*. Now *Zygosaccharomyces rouxii* (q.v.).

*S. servazzii*. Cells (in malt extract): ca. 3.0–4.5 × 4.0–5.5 µm, occurring singly or in pairs. Glucose and galactose are fermented; sucrose, maltose and lactose are not. Growth can occur in the presence of cycloheximide (100 ppm or 1000 ppm). Strains have been isolated from soil.

*S. telluris* (anamorph: *Candida pintolopesii*). Cells (in malt extract): 3.5–6.5 × 4.5–8.5(–17.0) µm, occurring singly or in pairs, short chains or small clusters. Asci contain one, occasionally two, ascospores which are slightly rough to distinctly spiny. Glucose is fermented; galactose, sucrose, maltose and lactose are not. All strains are sensitive to cycloheximide (100 ppm). Strains have been isolated from poultry, pigeons, rodents and rodent faeces, soil, etc.

*S. transvaalensis*. Now *Pachytichospora transvaalensis*.

*S. unisporus* (= *S. mongolicus*). Cells (in malt extract): ca. 2.5–4.5 × 3.0–6.0 µm, occurring singly or in pairs. Asci contain one, occasionally two, smooth ascospores. Glucose and galactose are fermented; sucrose, maltose and lactose are not. Growth occurs in the presence of cycloheximide (100 ppm and 1000 ppm). Strains have been isolated from e.g. cheese and KEFIR.

*S. uvarum*. See *S. cerevisiae*.

**Saccharomycetaceae** A family of fungi (order ENDOMYCETALES) which are predominantly unicellular, the cells being spherical, ovoid, cylindrical etc. (See YEASTS; see also CELL WALL.) The cells may occur singly, in pairs, or in short chains, and reproduce asexually by BUDDING, by BUD FISSION, or by FISSION. Many members can form pseudomycelium, at least under certain conditions, and some can form a true mycelium which may give rise to arthrospores or blastospores. The vegetative cells may be predominantly haploid or predominantly diploid. According to species, sexual reproduction may involve conjugation between two somatic cells, between two ascospores, between a bud and its mother cell, etc; species may be homothallic or heterothallic (see also MATING TYPE). An ascus develops meiotically either directly from the zygote or from a vegetative cell derived mitotically from the zygote. Asci typically contain 1–4 (occasionally 8) ascospores (those of *Kluyveromyces polysporus* each contain hundreds of spores); ascospores are e.g. spherical, ovoid, hemispherical, Saturn-shaped, bowler-hat-shaped, etc, but are rarely fusiform and never acicular (cf. METSCHNIKOWIACEAE). Asci may be persistent (i.e. spores are not liberated but germinate within the ascus) or evanescent (ascospores are liberated by partial or complete dissolution of the ascus wall). Most members of the family can carry out fermentative as well as respiratory metabolism of glucose and certain other sugars; a few members are non-fermentative. Genera are distinguished on the basis of mode of sexual reproduction, nature of the ascospores, ability to assimilate nitrate, ability to ferment particular sugars, ability to assimilate various carbon compounds, coenzyme Q content, etc. They include: AMBROSIOZYMA, ARTHROASCUS, CITEROMYCES, CLAVISPORIA, CYNICLOMYCES, DEBARYOMYCES, DEKKERA, GUILLIERMONDELLA, HANSENIASPORA, HANSENULA, ISSATCHENKIA, KLUYVEROMYCES, LIPOMYCES, LODDEROMYCES, NADSONIA, PACHYSOLEN, *Pachytichospora*, PICHIA, SACCHAROMYCES, SACCHAROMYCODES, SACCHAROMYCOPTIS, SCHIZOSACCHAROMYCES, SCHWANNIOMYCES, SPOROPACHYDERMIA, STEPHANOASCUS, TORULASPORA, WICKERHAMIA, WICKERHAMIELLA, WINGEA, *Yarrowia*, ZYGOSACCHAROMYCES.

Members of the Saccharomycetaceae occur in a wide range of habitats, e.g. on fruits, in tree exudates, in the tunnels of wood-boring beetles, in soil, in faeces, etc. Apparently, no species is

## Saccharomycodes

significantly pathogenic in either plants or animals, but some are important spoilage organisms (see e.g. BEER SPOILAGE and WINE SPOILAGE). Some species have important commercial uses – e.g. for fermenting foods and beverages (see e.g. BREAD-MAKING, BREWING, SOY SAUCE, WINE-MAKING), as foods (see e.g. SINGLE-CELL PROTEIN and YEAST EXTRACT), for the production of certain enzymes (see e.g. INVERTASE), for carrying out biochemical conversions (see e.g. STEROID BIOCONVERSIONS), etc.

**Saccharomycodes** A genus of yeasts (family SACCHAROMYCETACEAE). Cells are usually lemon-shaped or elongated (ca.  $4\text{--}7 \times 8\text{--}23 \mu\text{m}$ ) and reproduce by bipolar budding on a broad base (bud-fission); pseudomycelium is absent or poorly developed. An ascus develops from a (diploid) somatic cell which has undergone meiosis. Asci contain 4 smooth, spherical spores occurring in pairs; on germination, the members of each pair may conjugate, each fused pair giving rise to a 'sprout mycelium' from which vegetative cells arise by budding. (In some strains germination may occur without conjugation.) Glucose, sucrose and raffinose are fermented; galactose, lactose and maltose are not.  $\text{NO}_3^-$  is not assimilated. One species: *S. ludwigii*, isolated e.g. from grape juice, wine, slime flux of trees. [Book ref. 100, pp. 396–398.]

**Saccharomycopsis** A genus of fungi (family SACCHAROMYCETACEAE) which form yeast cells, pseudomycelium, and abundant true mycelium with blastospores; arthrospores may be formed. Hyphal septa have plasmodesmata. According to species, ascus formation is preceded by conjugation between yeast cells, between hyphal cells, and/or between blastospores; ascospores: spherical, bowler-hat-shaped, or Saturn-shaped, smooth or warty, 1–4 per ascus. Some species can ferment e.g. glucose, others are non-fermentative;  $\text{NO}_3^-$  is not assimilated. Species include *S. capsularis* (type species; formerly e.g. *Endomycopsis capsularis*), *S. crataegensis*, *S. fibuligera* (formerly e.g. *Endomycopsis fibuligera*), *S. malanga*, *S. synnaedendra* and *S. vini* (formerly *Endomycopsis vini*). Species occur e.g. on fruit, foods, soil, and in tunnels of wood-boring beetles. [Book ref. 100, pp. 399–413.]

'*S. lipolytica*' (formerly e.g. *Endomycopsis lipolytica*, anamorph: *Candida lipolytica*) lacks plasmodesmata in its septa and was classified in a new genus: *Yarrowia* [AvL (1980) 46 517–521].

(See also SINGLE-CELL PROTEIN.)

**saccharopine** See Appendix IV(e).

**Saccharopolyspora** A genus of bacteria (order ACTINOMYCETALES, wall type IV) isolated e.g. from sugar-cane bagasse. The organisms form a substrate mycelium which fragments into rod-shaped forms, and sparse white aerial hyphae which give rise to chains of rounded spores. Mycolic acids are not formed. GC%: ca. 77. Type species: *S. hirsuta*. [Book ref. 73, p. 128.]

**saccharose** *Syn.* SUCROSE.

**saccoderm desmid** See DESMIDS.

**sacculus** Any small, sac-like structure – e.g. the 'murein sacculus' in bacteria (see PEPTIDOGLYCAN).

**sacrificial cell** *Syn.* NECRIDIUM.

**sad mutants** Mutants defective in ribosomal subunit assembly.

**saddle-back fungus** *Polyporus squamosus* (q.v.).

**saddle fungi** See HELVELLA.

**SAF** SCRAPIE-associated fibril.

**safety cabinet** ('sterile cabinet') A cabinet within which microbiological work is carried out so as to prevent contamination (by airborne microorganisms) of (a) cultures etc. and/or (b) personnel and the environment. (See also AEROSOL.) *Class I cabinet.* Air is sucked into the cabinet and passes out via a filter. Work

is conducted through an open front panel or by means of arm-length rubber gloves fitted into holes in the panel. The operator and environment are given some protection, but cultures etc are not. *Class II cabinet.* Sterile (filtered) air enters the cabinet and passes downward onto the work surface; air (some of which may be re-circulated) passes to the exterior via an exit port (situated below the work surface) and is filtered before discharge to the environment. Work is conducted via an open front panel; the downward, laminar air-flow inside the cabinet, and the entry of air via the front panel, together form a moving 'curtain' of air which helps to protect the user, the cultures etc. and the environment. *Class III cabinet.* Sterile, filtered air enters the *gas-tight* cabinet, and air is filtered before discharge; a negative pressure is maintained inside during use. Work is conducted via arm-length rubber gloves fitted into the front panel. Access to the interior of the cabinet is via a separate two-door sterilizing/disinfecting chamber. [Book ref. 2, pp. 495–499.]

**safranin O** A red basic composite azine DYE.

**SAG** Sammlung von Algenkulturen (algal culture collection), Pflanzenphysiologisches, Universität Göttingen, Göttingen, Germany.

**Sag** SUPERANTIGEN.

**sagenogen** See LABYRINTHULAS and THRAUSTOCHYTRIDS.

**sagenogenetosome** See LABYRINTHULAS and THRAUSTOCHYTRIDS.

**Sagiyama virus** See ALPHAVIRUS.

**saguaro cactus virus** See TOMBUSVIRUSES.

**SAIDS** SIMIAN AIDS.

**saimiriine herpesvirus** See e.g. GAMMAHERPESVIRINAE ('*Herpesvirus saimiri*').

**Saint Anthony's fire** (1) *Syn.* ERGOTISM. (2) *Syn.* ERYSIPELAS.

**Saint Louis encephalitis** See ST LOUIS ENCEPHALITIS.

**Saint Vitus's dance** See RHEUMATIC FEVER.

**sakacin A** A 41-amino-acid, pore-forming class IIa BACTERIOCIN produced by *Lactobacillus sake*; synthesis is reported to be temperature-dependent and regulated by a three-component system [Microbiology (2000) 146 2155–2160].

**saké** Japanese rice wine. Rice starch is degraded to fermentable sugars by *Aspergillus oryzae* in a steamed rice KOJI; this is inoculated with '*Saccharomyces sake*', a strain of *S. cerevisiae* with a high alcohol tolerance. A succession of organisms follows *A. oryzae*: nitrate-reducing bacteria, followed by lactic acid bacteria, followed by yeasts – '*S. sake*' finally becoming dominant [Book ref. 6, pp. 417–419]. The alcohol content reaches 20% v/v or higher.

**Saksenaea** See MUCORALES.

**Saksenaaceae** See MUCORALES.

**SAL plasmid** An IncP-9 *Pseudomonas* PLASMID (ca. 85 kb) which encodes the capacity to metabolize salicylate. (cf. TOL PLASMID.)

**SaII** A RESTRICTION ENDONUCLEASE from *Streptomyces albus*; G/TCGAC.

**salami** Salami and salami-type sausages are manufactured by the fermentation of comminuted meat (usually salted and spiced) by (mainly) LACTIC ACID BACTERIA; traditional methods rely on the microflora of the meat, equipment, environment etc, but commercial starter cultures may be used. The product is extremely resistant to microbial spoilage owing to its low pH (usually ca. 4.8–5.2) and low  $a_w$  (usually ca. 0.7–0.8); however, it may be susceptible to spoilage by moulds and xerophilic yeasts. The lactic acid bacteria contribute to the preservation of salami by lowering the pH (by LACTIC ACID FERMENTATION of carbohydrates) and e.g. by the production of antibiotics (see FOOD PRESERVATION (e)); they also contribute to the flavour and

texture of the product. Some salami-type sausages are mould-ripened, usually with *Penicillium* spp.

**salicin** 2-Hydroxymethylphenyl- $\beta$ -D-glucopyranoside. It can be hydrolysed by  $\beta$ -glucosidase to D-glucose and saligenin (2-hydroxymethylphenol).

**salicylanilides** (as antimicrobial agents) Salicylanilide (2-hydroxy-N-phenylbenzamide) and its halogenated derivatives have antifungal and antibacterial activity and are used e.g. as antiseptics and industrial PRESERVATIVES. Salicylanilide itself (*Shirlan*) is used e.g. as an antifungal agent in textiles and wood pulps and for the antifungal treatment of walls and ceilings; it has also been used for the treatment of cutaneous mycoses.

**salicylic acid** (2-hydroxybenzoic acid) An antimicrobial, mildly keratinolytic ORGANIC ACID used for the topical treatment of e.g. ACNE and (with other agents) superficial mycoses. (cf. SALICYLANILIDES.)

**saligenin** See SALICIN.

**saline agglutination** *Syn.* AUTO-AGGLUTINATION.

**salinomycin** An ionophore antibiotic, produced by *Streptomyces albus*, which is used as an anti-coccidial agent in poultry and as a FEED ADDITIVE for e.g. ruminants and pigs.

**Salivaria** One of two groups of subgenera of mammalian trypanosomes; salivarian trypanosomes infective for the vertebrate host develop in the ANTERIOR STATION. The group comprises DUTTONELLA, NANNOMONAS, PYCNOMONAS and TRYPAZOON. (cf. STERCORARIA.)

**Salk vaccine** An anti-poliomyelitis vaccine containing formalin-inactivated strains of three types of poliovirus; it is administered intramuscularly. (cf. SABIN VACCINE.)

**salmon disease** See ULCERATIVE DERMAL NECROSIS.

**salmon poisoning** (in dogs) See NEORICKETTSIA.

**Salmonella** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v. for general features). Cells: straight rods, ca. 0.5–1.0  $\times$  1–5  $\mu$ m; most strains are motile. Reactions for most salmonellae: indole –ve; MR +ve; VP –ve; citrate +ve; acid and gas from glucose at 37°C; lactose usually –ve; H<sub>2</sub>S +ve (in TSI); urease –ve; lysine decarboxylase +ve; ornithine decarboxylase +ve (cf. serotypes listed below). Reactions may be altered e.g. by the presence of metabolic plasmids (e.g. a plasmid carrying genes for lactose utilization [FEMS (1983) 17 127–130]). Salmonellae can grow e.g. on NUTRIENT AGAR, MACCONKEY'S AGAR, and DCA, but usually not in KCN media. Enrichment media: e.g. MÜLLER-KAUFFMANN BROTH, RAPPAPORT-VASSILIADIS BROTH, SELENITE BROTH, TETRATHIONATE BROTH. Selective media: e.g. BRILLIANT GREEN AGAR, HEKTOEN MEDIUM, SS AGAR. GC%: 50–52. Type species: *S. choleraesuis*.

*Note on the pronunciation of 'Salmonella'.* This genus was named after the American bacteriologist D. E. Salmon; the correct pronunciation of the genus name is therefore 'Salmonella', i.e. with the first 'l' silent. Vocalization of the first 'l' in *Salmonella* (as is frequently done e.g. by television newscasters) is equivalent to vocalization of the 'p' in 'cupboard'.

Salmonellae occur mainly in the intestines of man and animals, where they can be important pathogens (see SALMONELLOSIS and FOOD POISONING (e)); at least some strains are toxigenic. In a number of salmonellae, virulence factors are encoded by genes on PATHOGENICITY ISLANDS, including e.g. type III secretion systems (see PROTEIN SECRETION) specified by the *inv-spa* genes; some pathogenicity islands may contain genes that specifically encode enteropathogenicity [e.g. Mol. Microbiol. (1998) 29 883–891].

Some salmonellae are apparently host-specific ('host-adapted') (e.g. *S. typhi* in man, *S. abortusovis* in sheep), but most have a wider host range.

Salmonellae from faeces or sewage can survive for weeks in water and for months in soil under favourable conditions. Salmonellae are normally killed by routine chlorination of WATER SUPPLIES, by PASTEURIZATION, and by many common DISINFECTANTS.

Nomenclature of the salmonellae does not follow the rules of the international Code of Nomenclature of Bacteria in that binomials usually refer to *serotypes* rather than to species. Salmonellae were originally named according to the disease (or host) with which they were associated – e.g. *S. typhi* for typhoid, *S. abortusovis* for strains causing abortion in sheep. Subsequently, serotypes have been named according to the place where they were first isolated (e.g. *S. london*, *S. dublin*). Each serotype is also given an ANTIGENIC FORMULA and classified by the KAUFFMANN-WHITE CLASSIFICATION scheme. (See also SMOOTH-ROUGH VARIATION.)

The genus *Salmonella* is sometimes divided into five subgenera (I–V) on the basis of biochemical tests. Subgenus I (sometimes regarded as a species, '*S. kauffmannii*') contains most of the named serotypes isolated from man and warm-blooded animals; members of subgenera II ('*S. salamae*'), III ('*S. arizonae*'), IV ('*S. houtenae*') and V ('*S. bongori*') are typically found in the intestines of poikilotherms (e.g. reptiles). In an alternative scheme, members of subgenus III – which (typically) can carry out a delayed fermentation of lactose – are regarded as a separate genus, *Arizona*, with one species, *A. hinshawii*; *S. typhi*, *S. choleraesuis* and *S. enteritidis* are given species status, and all remaining named serotypes are regarded as serotypes of *S. enteritidis*. In yet another scheme, the genus comprises a single species, *S. choleraesuis*, with six subspecies corresponding to the earlier subgenera I, II, III (monophasic), III (diphasic), IV, and V – named, respectively, subspecies *choleraesuis*, *salamae*, *arizonae*, *diarizonae*, *houtenae* and *bongori*. Serotypes may be further subdivided by biochemical, antibiotic, bacteriocin and bacteriophage TYPING.

More recently, it has been suggested that all the serotypes of *Salmonella* be considered as members of a single species, *S. enterica*. (The name of the type species, *S. choleraesuis* was not chosen as this was considered likely to cause confusion.) Subspecies of *S. enterica* are listed in the table [see also JMM (1992) 37 361–363].

In this scheme, individual serotypes within subspecies I are referred to by *name*; for example: *S. enterica* subsp *enterica* serotype Typhimurium; *S. enterica* subsp *enterica* serotype Agona; *S. enterica* subsp *enterica* serotype Dublin etc. Less cumbersome forms of designation, suitable for routine use,

*Salmonella enterica*: designation of subspecies<sup>a,b</sup>

Subspecies name	Subspecies number
<i>enterica</i>	I
<i>salamae</i>	II
<i>arizonae</i>	III(a)
<i>diarizonae</i>	III(b)
<i>houtenae</i>	IV
<i>bongori</i>	V
<i>indica</i>	VI

<sup>a</sup> See text.

<sup>b</sup> Subspecies I (*enterica*) contains the majority of salmonellae pathogenic in man and warm-blooded animals.

## Salmonella/microsome assay

would be e.g. *Salmonella* serotype Typhimurium, *Salmonella* Typhimurium, or simply Typhimurium etc. [see JMM (1992) 37 361–363].

For serotypes of subspecies II–VI it has been suggested that individual serotypes be designated by a combination of (i) subspecies number and (ii) antigenic formula.

Over 2000 named serotypes have been listed in the Kauffmann–White classification scheme; the following (antigenic formulae in brackets) are some of medical and veterinary importance.

*S. abortusovis* (4,12:c:1,6). Host: sheep; causes abortion.

*S. agona* (1,4,12:f,g,s:-). Associated e.g. with fishmeal from South America. (See also FOOD POISONING.)

*S. choleraesuis* (6,7:c:1,5). Gas from glucose; H<sub>2</sub>S –ve (var. *kunzendorf* is H<sub>2</sub>S +ve); citrate (delayed) +ve. Isolated from pigs (see PARATYPHOID FEVER sense 2) but can be pathogenic e.g. in man.

*S. dublin* (1,9,12,[Vi]:g,p:-). Aerogenic, but anaerogenic variants are common. Isolated mainly from cattle (see PARATYPHOID FEVER (2)).

*S. gallinarum* (probably = *S. pullorum* 1,9,12:-:-). Non-motile. No gas from glucose; H<sub>2</sub>S –ve; citrate –ve. Host: fowl (see FOWL TYPHOID).

*S. hadar* (6,8:z<sub>10</sub>:e,n,x). Associated with turkeys. (See also FOOD POISONING.)

*S. paratyphi*. Gas from glucose. Host: man (see PARATYPHOID FEVER (1)). *S. paratyphi-A* (1,1,12:a: [1,5]): H<sub>2</sub>S (usually) –ve; citrate –ve. *S. paratyphi-B* (= *S. schottmuelleri*) (1,4, [5], 12:b:1,2): H<sub>2</sub>S +ve; citrate +ve; produces a slime layer on media containing 0.5% glucose and 0.2 M sodium phosphate (pH 7). *S. paratyphi-C* (= *S. hirschfeldii*) (6,7, [Vi]: c:1,5): H<sub>2</sub>S +ve; citrate +ve.

*S. pullorum* (probably = *S. gallinarum*) (1,9,12:-:-). Non-motile. Gas from glucose. Host: fowl (see PULLORUM DISEASE and FOWL TYPHOID).

*S. typhi* (formerly *S. typhosa*) (9,12, [Vi]:d:-). Wild strains may have H antigen z<sub>66</sub> instead of d. No gas from glucose; H<sub>2</sub>S weakly +ve; citrate –ve; ornithine decarboxylase –ve. Host: man (see TYPHOID FEVER).

*S. typhimurium* (1,4,[5],12:i:1,2). Gas from glucose. Host range includes man and other animals (see also FOOD POISONING (e) and ENTERIC FEVER).

**Salmonella/microsome assay** *Syn.* AMES TEST.

**salmonella–shigella agar** *See* SS AGAR.

**salmonellosis** Any of certain diseases, in man or animals, in which the causal agent is a serotype of *Salmonella*. In man, salmonellosis generally refers to *Salmonella* FOOD POISONING (cf. PARATYPHOID FEVER (1) and TYPHOID FEVER). For salmonellosis in animals see e.g. PARATYPHOID FEVER (2). (See also FOWL TYPHOID and PULLORUM DISEASE.)

**Salpingella** *See* TINTINNINA.

**salpingitis** Inflammation of a tube – usually the Fallopian tube of the uterus. [Chlamydial salpingitis: BMB (1983) 39 145–150.]

**salt flotation** *See* FLOTATION.

**saltant** An organism which exhibits SALTATION.

**saltation** (dissociation) (*mycol.*) A phenotypic change in a thallus or colony (or part thereof) due e.g. to a mutation or to the segregation of nuclei in a heterokaryon.

**saltatorial cilia** In certain ciliates (e.g. *Halteria*): long cilia which are sparsely distributed on the cell and which are used to produce a characteristic darting motility.

**saltng** (of food) *See* FOOD PRESERVATION (c).

**salvage cycle** (salvage pathway) *See* e.g. NUCLEOTIDE and NAD.

**salvage pathway** (complement fixation) *See* COMPLEMENT FIXATION (d).

**salvarsan** *See* ARSENIC.

**same-sense mutation** A POINT MUTATION in a structural gene which results in a mutant codon specifying the same amino acid as did the original codon (owing to the degeneracy of the GENETIC CODE). (cf. SILENT MUTATION.)

**San Joaquin Valley fever** *Syn.* COCCIDIOIDOMYCOSIS.

**San Miguel sea lion virus** (SMSV) A virus (family CALICIVIRIDAE) isolated from sea lions (in which it may cause abortion) and apparently widespread among marine mammals, fish etc in the Pacific. SMSV is very closely related to vesicular exanthema of swine virus, and can cause a disease similar to vesicular exanthema in pigs; it is only distantly related to FELINE CALICIVIRUS. SMSV can be propagated e.g. in Vero cells.

**sand filter** *See* WATER SUPPLIES.

**sandfly fever group** *See* PHLEBOVIRUS.

**sandwich technique** A type of indirect IMMUNOFLUORESCENCE technique used e.g. to demonstrate the presence of specific antibodies at the surface of antibody-forming cells. Essentially, a suitably prepared section or smear is incubated with antigen homologous to the given antibody, and subsequently washed free of uncombined antigen; the preparation is then exposed to a fluorescent antibody of the same specificity as that being sought in the specimen, washed, and examined by fluorescence MICROSCOPY. The antigen is thus sandwiched between homologous antibody in the specimen and homologous, fluorescent antibody.

**Sanger's chain-termination method** *See* DNA SEQUENCING.

**sanitizer** Any preparation with both cleansing and antimicrobial properties (e.g. TEGO COMPOUNDS).

**sap-stain** Discoloration of freshly felled (moist) timber due to growth of fungi primarily or solely in the sapwood; wood may become e.g. green, purple or blackish, but more often appears bluish-grey (see BLUE-STAIN). Sap-staining fungi include e.g. *Aureobasidium pullulans*, *Cladosporium herbarum*, and species of *Diplodia* and *Graphium*. (See also TIMBER PRESERVATION.)

**sap transmission** Transmission of a plant virus by a mechanical VECTOR.

**saponins** A diverse group of powerful glycoside surfactants produced by a wide range of plants. Saponins have antifungal properties which depend on their ability to affect membrane permeability by complexing with sterols in the CYTOPLASMIC MEMBRANE (see e.g. TOMATINE); certain bacteria (e.g. MYCOPLASMA spp) can be lysed by saponins. (See also AVENACIN, BIOSURFACTANTS and DIGITONIN.)

**saprobe** *Syn.* SAPROTROPH.

**saprobity system** The system by which an organically polluted river or stream undergoing SELF PURIFICATION may be divided into a number of distinct zones, each zone being characterized e.g. by its level of pollution, content of dissolved oxygen, and types of microorganism (indicator-organisms) present. The *polysaprobic zone* is the zone most heavily polluted with organic matter (sewage etc), i.e., the zone nearest the source of pollution. In this zone oxygen consumption is high (dissolved O<sub>2</sub> is minimal) and there is a vigorous production of ammonia and H<sub>2</sub>S. The organisms found in this zone may include e.g. the flagellates *Bodo* and *Euglena*, the ciliate *Glaucoma scintillans*, and various bacteria such as *Beggiatoa*, *Thiothrix* and *Oscillatoria*. In the *α-mesosaprobic zone* MINERALIZATION and oxygen consumption continue vigorously, but the content of dissolved O<sub>2</sub> is higher than that in the polysaprobic zone; there is some in situ utilization of ammonia, and there is no free H<sub>2</sub>S. Organisms in this zone may include e.g. *Oscillatoria*, and the ciliates

*Carchesium*, *Stentor* and *Vorticella*. In the  $\beta$ -mesosaprobic zone oxygen consumption is low since mineralization is almost complete; the dissolved O<sub>2</sub> levels are considerably higher than those in the  $\alpha$ -mesosaprobic zone, and levels of free ammonia are low. Organisms in this zone may include e.g. the cyanobacterium '*Phormidium*' and the ciliates *Halteria grandinella* and *Vorticella striata*. In the oligosaprobic zone (= xenosaprobic zone) mineralization is complete and dissolved O<sub>2</sub> is abundant. Aerobic, photosynthetic organisms may predominate in this zone.

In rivers, flow rates and dilution factors are important factors which determine the existence or extent of the various zones.

**Saprodinium** A genus of protozoa (order ODONTOSTOMATIDA) in which the cells have posteriorly directed terminal spines and isolated tufts of somatic cilia; species occur e.g. in organically polluted and stagnant waters.

**Saprolegnia** A genus of fungi (order SAPROLEGNIALES) which occur in aquatic environments and soil; the organisms are typically saprotrophic, but some species are parasitic on fish (see SAPROLEGNIASIS). *Saprolegnia* spp appear to be commonly hermaphroditic and homothallic. (See also DIPLANETISM and GEMMA.) [*Saprolegnia diclina-parasitica* complex: CJB (1983) 61 603–625.]

**Saprolegniales** An order of fungi (class OOMYCETES) which occur typically as saprotrophs in water and soil – though some species are parasitic in e.g. fish, fish eggs, invertebrates, algae, and higher plants. According to species, the thallus ranges from a single cell to a well-developed mycelium; hyphae, when formed, lack constrictions (cf. LEPTOMITALES). Asexual reproduction commonly involves the formation of long, cylindrical zoosporangia at the ends of hyphae. In e.g. *Saprolegnia*, once a zoosporangium has released its zoospores another zoosporangium may develop inside it; such zoosporangia remain attached to the hyphae which bear them. In e.g. *Dictyuchus*, zoosporangia are typically deciduous at maturity. In addition to zoosporangia, some species form *gemmae* (see GEMMA). Genera include ACHLYA, APHANOMYCES, ATKINSIELLA, *Calyptralegnia*, *Dictyuchus*, *Ectrogella*, *Leptolegnia* (*L. baltica* and *L. chapmanii* have been associated with mortality in copepods and mosquito larvae, respectively), and SAPROLEGNIA. (See also BRANCHIOMYCES.)

**saprolegniasis** A freshwater FISH DISEASE caused by *Saprolegnia* spp; any of a wide range of fish, both wild and cultivated, may be affected. In salmonids the pathogen is usually *S. diclina* Type 1 (formerly *S. parasiitica*). Conspicuous fluffy white patches or rings develop on the skin, increasing skin permeability and leading to osmoregulatory imbalance which is usually rapidly fatal. Predisposing factors: other infections, wounding. The fish's main defence seems to be the removal of fungal spores and cysts by epidermal mucus secretion. [Book ref. 1, pp. 271–297.]

**sapropel** The anaerobic, putrefying matter – rich in H<sub>2</sub>S – which forms the bottom mud of some aquatic habitats. (See also ANAEROBIC DIGESTION.)

**saprophyte** (1) A 'plant-like' SAPROTROPH: e.g., a saprotrophic bacterium or fungus. (2) *Syn.* SAPROTROPH. (Hence *adj.* saprophytic – cf. SAPROTROPHIC.)

**Saprosipira** A genus of non-sheathed, helical, filamentous, pigmented, chemoorganotrophic GLIDING BACTERIA (see CYTOPHAGALES) which occur in aquatic habitats.

**saprotroph** (saprobe; saprovore) An organism which obtains its nutrients from non-living organic matter (commonly dead and decaying plant or animal matter) by absorbing soluble organic compounds; a saprotroph may produce extracellular enzymes (e.g., CELLULASES, XYLANASES) which release soluble components from insoluble materials. Saprotrophs are important agents

of decay and MINERALIZATION, and are thus essential links in the cycles of matter (see e.g. CARBON CYCLE). Some saprotrophs are facultative PARASITES. (cf. SAPROPHYTE; SAPROZOITE.)

**saprotrophic** (saprobic) Refers to a SAPROTROPH or to the mode of nutrition of a saprotroph.

**saprovore** *Syn.* SAPROTROPH.

**saprozoite** An 'animal-like' SAPROTROPH: e.g., a saprotrophic protozoan. (Hence *adj.* saprozoic – cf. SAPROTROPHIC.)

**saquinavir** See ANTIRETROVIRAL AGENTS.

**saramyctin** A polypeptide antifungal antibiotic produced by *Streptomyces saraceticus*; it has been used e.g. against aspergillosis, blastomycosis and histoplasmosis.

**Sarcina** A genus of Gram-positive, asporogenous, anaerobic bacteria which occur e.g. in the gut in man and other animals. Cells: non-motile cocci (ca. 2–3  $\mu$ m diam.) which typically occur in cubical packets. The type species, *S. ventriculi*, commonly has a CELLULOSE microcapsule. Metabolism is fermentative; the main products of glucose fermentation are acetic acid and ethanol (in *S. ventriculi*) or butyric and acetic acids (in *S. maxima*). GC%: ca. 29–31.

**sarcina sickness** See BEER SPOILAGE.

**sarciniform** (sarcinaeform) Arranged in PACKETS.

**sarcinoid** Refers to an alga in which the cells are more or less SARCINIFORM. (See e.g. FRIEDMANNIA and PSEUDOTREBOUXIA.)

**Sarcinosporon** A genus of imperfect, non-fermentative fungi in which both budding yeast cells and septate hyphae are formed; blastospores develop from the mycelium, and septation in different planes in the blastospores and hyphal cells results in the formation of sarciniform clusters of cells. Asexual endospores are formed. One species: *S. inkin*, isolated from a human skin lesion. [Book ref. 100, pp. 906–908.]

**sarcocyst** See SARCOCYSTIS.

**Sarcocystis** A genus of coccidian protozoa (suborder EIMERIORINA) which are obligately heteroxenous parasites in a range of animals, including man (see SARCOSPORIDIOSIS). The vegetative cells resemble those of TOXOPLASMA. In the intermediate host, ingestion of oocysts or sporocysts is followed by schizogony in internal organs, and merozoites later localize in muscle tissues; a merozoite becomes rounded to form a *metrocyte* which, by repeated division, gives rise to an immature *sarcocyst*: a collection of slowly-dividing metrocytes bounded by a cyst wall. Over a period of ca. 2 months the contents of the sarcocyst change from metrocytes only to a mixture of metrocytes and merozoites, and finally (in the mature sarcocyst) to merozoites only. Ingestion of sarcocyst-containing flesh by the final host is followed by sexual reproduction (only) in intestinal tissues: gametogony is followed by ENDOSPORULATION, resulting in disporic, tetrazoic oocysts, or free sporocysts, which are shed in faeces; the oocysts lack a MICROPYLE, and the sporocysts lack a STIEDA BODY. (cf. FRENKELIA.) [Taxonomy of *Sarcocystis*: J. Parasitol. (1986) 72 372–382.]

**sarcocystosis** *Syn.* SARCOSPORIDIOSIS.

**Sarcodina** A subphylum of protozoa (phylum SARCOMASTIGOPHORA) in which the vegetative cells form one or more pseudopodia (see PSEUDOPODIUM) or are motile by cytoplasmic flow without the formation of discrete pseudopodia. Flagella are formed only in temporary stages of certain species. In many sarcodines the cytoplasm is more or less clearly differentiated into an inner, typically granular, *endoplasm* (= *granuloplasm* or *plasmalol*) and a surrounding, typically hyaline layer (*ectoplasm*, *hyaloplasm*, *plasmagel*) immediately beneath the plasmalemma. Sarcodine morphology ranges from the simple, naked, amoeboid cell of e.g. *Amoeba* spp to relatively complex forms

## sarcoidosis

with external tests (e.g. foraminifera) or internal skeletal structures (e.g. heliozoa, radiolaria). CYSTS are commonly formed. Asexual reproduction occurs by fission; sexual processes occur in some species. Sarcodines are commonly solitary, free-living organisms in aquatic habitats, soil, etc; some are parasitic. There are two superclasses: ACTINOPODA and RHIZOPODA.

**sarcoidosis** A chronic, granulomatous human disease which resembles disseminated tuberculosis, with lesions (rarely necrotic) in e.g. liver, lungs and spleen; other sites, including skin, salivary glands and eyes may also be affected. The disease is apparently self-limiting in the majority of cases.

Cause: unknown; *Propionibacterium* may be a better candidate than *Mycobacterium* [JCM (2002) 40 198–204].

**sarcoma** A malignant tumour derived from connective tissue – e.g. bone (osteosarcoma), cartilage (chondrosarcoma), muscle (rhabdomyosarcoma, = rhabdosarcoma), fat cells (liposarcoma), lymphoid tissue (lymphosarcoma), etc. (cf. FIBROSARCOMA and FIBROMA.) Sarcomas may be induced by infection with certain viruses: see e.g. KAPOSZ'S SARCOMA, MURINE SARCOMA VIRUSES, ROUS SARCOMA VIRUS, SIMIAN SARCOMA VIRUS.

**Sarcostigophora** A phylum of PROTOZOA [JP (1980) 27 37–58] which have flagella or pseudopodia or both; cells typically have a single type of nucleus. Subphyla: MASTIGOPHORA, OPALINATA and SARCODINA.

**sarcomatrix** See RADIOLARIA.

**sarcomeme** A MICRONEME in *Sarcocystis*.

**Sarcoscypha** See PEZIZALES.

**sarcosine** See SARKOSYL.

**sarcosporidiosis** Any disease of man and other animals – e.g. cattle, pigs, sheep – caused by species of SARCOCYSTIS. In cattle and sheep the experimentally-induced disease can involve lesions in a wide range of tissues and can lead to abortion (cf. DALMENY DISEASE). In man the disease typically involves parasitization of the muscles, but experimentally-induced disease, involving ingestion of meat infected with *S. hominis*, leads to abdominal pain, diarrhoea, and the excretion of sporocysts. [AP (1982) 20 352–396.]

**sarcotoxins** Antibacterial proteins produced in the haemolymph of larvae of the flesh fly (*Sarcophaga peregrina*) either on exposure to bacteria or following mechanical injury; sarcotoxin I appears to affect cytoplasmic membrane functions in *Escherichia coli*. [Sarcotoxin II: Biochem. (1987) 26 226–230.] (cf. CECROPINS.)

**Sargassum** See PHAEOPHYTA.

**Sarkosyl** An anionic detergent: *N*-lauroylsarcosine. (Sarcosine = *N*-methylaminoacetic acid.)

**SARS** Severe acute respiratory syndrome: a sometimes-fatal coronavirus infection [Lancet (2003) 362 263–270; EID (2004) 10 (whole issue) 167–387].

**Sartorya** A genus of fungi (order EUROTIALES) which include the teleomorph of *Aspergillus fumigatus*.

**satellite** The posterior gregarine in SYZYGY. (cf. PRIMITIVE.)

**satellite colonies** See SATELLITE PHENOMENON.

**satellite lesions** Lesions remote from the original site of infection.

**satellite phenomenon** (satellitism) The phenomenon in which certain growth-factor-requiring organisms can grow on a medium which lacks the required growth factor but which is supporting the growth of another ('feeder') organism which can supply the required growth factor – a manifestation of SYNTROPHISM. For example, to determine the V factor requirement of a *Haemophilus* strain, blood agar (in which V FACTOR is unavailable) is inoculated with the *Haemophilus* strain, and the

inoculated area is crossed with a single streak of *Staphylococcus aureus*; V factor from the growing staphylococci diffuses into the medium and allows the growth of *satellite colonies* of a V-factor-requiring *Haemophilus* strain in the immediate vicinity of the line of staphylococcal growth.

**satellite RNA** A small, linear ssRNA molecule which may be encapsidated within a specific plant virus and which is totally dependent on that ('helper') virus for its replication; unlike a VIRUSOID, a satellite RNA is not necessary for the replication of the helper virus. (cf. VIROID and SATELLITE VIRUS.) The presence of a satellite RNA may significantly affect both plant (altering symptoms) and virus (reducing yield) – see CUCUMOVIRUSES.

**satellite virus** A virus which is inherently entirely dependent on the presence of a particular 'helper virus' for its replication in a host cell. (cf. SATELLITE RNA.) Satellite viruses may be associated with certain plant viruses (see e.g. TOBACCO NECROSIS VIRUS), certain animal viruses (see e.g. DELTA VIRUS and DEPENDOVIRUS), or certain bacteriophages (see e.g. BACTERIOPHAGE P4). [Satellites of plant viruses: ARPpath. (1982) 20 49–70.]

**satellitism** *Syn.* SATELLITE PHENOMENON.

**satratoxins** See STACHYBOTRYOTOXICOSIS.

**satsuma dwarf virus** See NEPOVIRUSES.

**Sau3AI** See RESTRICTION ENDONUCLEASE (table).

**sauerkraut** Cabbage pickled by a natural lactic acid fermentation (see PICKLING). The cabbage is wilted, washed, shredded, salted (to ca. 2.25% w/w NaCl), and packed into tanks which are then covered; the temperature should be ca. 18–21°C. Early in the fermentation, *Leuconostoc mesenteroides* grows and produces lactic and acetic acids (which rapidly lower the pH and discourage the growth of spoilage organisms) and CO<sub>2</sub> (which helps to generate anaerobic conditions). Fermentation is then continued by *Lactobacillus brevis* and *L. plantarum*, the latter being responsible for the final high levels of acidity. The product may be marketed raw or canned. (cf. KIMCHI.)

Spoilage by pectinolytic bacteria may occur if salt levels are low. Salt levels above ca. 3% may allow the growth of yeasts – e.g. *Rhodotorula* spp may cause a pink discoloration.

**Saug–Kappe process** A method of TIMBER PRESERVATION, similar to the BOUCHERIE PROCESS, in which preservative is sucked into the sapwood of newly felled timber by application of a vacuum to one end of each log. (cf. BETHELL PROCESS.)

**sausage** (microbiological aspects) Raw, non-fermented sausage is susceptible to spoilage by typical MEAT SPOILAGE organisms; preservatives used include e.g. sodium metabisulphite. For fermented sausage see SALAMI.

**Savillea** See CHOANOFAGELLIDA.

**Savlon** See CHLORHEXIDINE.

**saxicolous** Growing on and/or in rock or stone etc (cf. ENDOLITHIC and EPILITHIC).

**saxitoxin** A potent heterocyclic (nitrogen-containing) neurotoxin produced e.g. by the dinoflagellates *Gonyaulax catenella* and *Gonyaulax tamarensis* (RED TIDE organisms) and apparently also by the cyanobacterium *Aphanizomenon flos-aquae*. In warm-blooded animals, saxitoxin blocks the transmission of nerve impulses, causing paralysis and eventually death by asphyxiation; poikilotherms are generally less sensitive to saxitoxin, while many filter-feeding bivalve molluscs are apparently insensitive, accumulating the toxin in their tissues (see *paralytic SHELLFISH POISONING*). (Saxitoxin was originally isolated from the Alaskan butter clam, *Saxidomus giganteus*, a frequent cause of PSP.) Several toxins structurally related to saxitoxin have been isolated from *Gonyaulax* and other dinoflagellates: e.g. *neosaxitoxin* (a hydroxylated derivative of saxitoxin) and the

GYNAUTOXINS. [Biosynthesis of saxitoxin and related toxins: PAC (1986) 58 257–262.] (See also PHYCOTOXIN.)

**sbcA gene** See RECF PATHWAY.

**sbcB gene** See RECF PATHWAY.

**SBE** Subacute bacterial ENDOCARDITIS.

**ScaI** See RESTRICTION ENDONUCLEASE (table).

**scab** (1) (*plant pathol.*) Any of a wide range of unrelated plant diseases: see e.g. APPLE SCAB, POTATO SCAB, WHEAT SCAB. (2) (*vet.*) See e.g. SHEEP SCAB.

**scabby mouth** *Syn.* CONTAGIOUS PUSTULAR DERMATITIS *sense* 1.

**scabrous** (scabrid) With a rough surface.

**scaffolding protein** (1) A protein – or complex of proteins – that forms a 'scaffolding' (i.e., a temporary structural framework) for the assembly of e.g. a bacteriophage head, but which is absent from the mature head. The head precursor (prohead or procapsid) is assembled on the scaffolding protein; the latter is then eliminated and either re-cycled (e.g. in phages P22 and  $\phi$ 29) or degraded (e.g. in phages  $\lambda$  and T4). (2) (scaffold) See CHROMOSOME (b).

**scalariform** Ladder-shaped. *Scalariform conjugation*: see SPIROGYRA.

**scald** (1) (benign foot-rot) (of sheep) A mild form of FOOT-ROT caused by a weakly virulent strain of *Bacteroides nodosus*; the lesion is odourless, and severe lameness does not occur.

(2) General term for any of various plant diseases (see e.g. LEAF BLOTCH).

**scalded skin syndrome** (Lyell's syndrome) A rare exfoliative disease which occurs mainly in children but which can affect adults; in neonates it may be called *Ritter's disease* or *pemphigus neonatorum*. The disease is caused by strains of *Staphylococcus aureus* (primarily of phage group II) which produce an exfoliative toxin (see EPIDERMOLYTIC TOXIN). The characteristic feature is a generalized exfoliative dermatitis, but there are manifestations of the disease which occur in only some patients – e.g. an erythematous rash similar to that seen in scarlet fever. Outer layers of epidermis separate at the stratum granulosum from the underlying tissue, and sterile bullae form quickly. Healing generally occurs within a few weeks. In this disease, the toxin may be acting as a serine protease in the epidermis and/or as a SUPERANTIGEN – the exfoliative toxin ETA (see EPIDERMOLYTIC TOXIN) having known ability to stimulate particular subsets of T cells. Treatment can include  $\beta$ -lactam antibiotics or (if resistant) vancomycin. (See also TOXIC EPIDERMAL NECROLYSIS.)

[Scalded skin syndrome (review): RMM (1998) 9 9–15.]

**scales** (of an agaric) See UNIVERSAL VEIL.

**scanning electron microscopy** See ELECTRON MICROSCOPY (b).

**scar** (*mycol.*) In certain fungi: a differentiated region of the cell wall marking the location at which cell separation occurred during BUDDING or FISSION. In e.g. *Saccharomyces cerevisiae* two types of scar can be distinguished: the *bud scar* on the parent cell, and the *birth scar* on the daughter cell. If cells of *S. cerevisiae* are stained with primulin and examined by fluorescence microscopy, the bud scar appears as a ring of bright fluorescence on the non-fluorescent (or weakly fluorescent) cell wall; the ability of the bud scar to take up primulin may reflect a local change in the microfibrillar structure of the cell wall. In the multipolar budding yeasts, one, several or many bud scars may occur on the wall of a given cell, and in *S. cerevisiae* the scar rings appear never to overlap. In *S. cerevisiae* the region of the bud scar seems to contain CHITIN in concentrations greater than those found elsewhere in the cell wall.

**scarlatina** *Syn.* SCARLET FEVER.

**scarlet caterpillar fungus** See CORDYCEPS.

**scarlet fever** (scarlatina) An acute infectious human disease which affects mainly children; it is caused by erythrogenic toxin-producing strains of *Streptococcus pyogenes*. Transmission may occur by direct contact, by droplet infection, or via contaminated milk etc; infection usually occurs via nose or mouth, occasionally via wounds or via the birth canal ('puerperal scarlet fever'). Incubation period: 2–5 days. Symptoms: e.g. sore throat, fever, swelling of the cervical lymph nodes, and a characteristic bright-red punctate rash on the body followed by desquamation. The tongue often develops a greyish coating through which the swollen red papillae can be seen ('strawberry tongue'). The disease ranges from mild to severe or occasionally fatal. Complications: e.g. RHEUMATIC FEVER. *Chemotherapy*: e.g. penicillins, erythromycin. (See also DICK TEST; SCHULZ-CHARLTON TEST.)

*Non-streptococcal* scarlatiniform rash (in which e.g. 'strawberry tongue' does not occur) is caused e.g. by staphylococci.

**SCAT** SHEEP CELL AGGLUTINATION TEST.

**Scatchard plot** A graph which can be used to analyse molecular interactions in a mixed population of molecules in which molecules of different types bind reversibly to one another. In serology, for example, a Scatchard plot can indicate (i) the association constant (= AFFINITY) of antigen–antibody binding (given by the slope of the curve); (ii) the nature of the antibody population: MONOCLONAL ANTIBODIES give a straight-line plot, while POLYCLONAL ANTISERUM gives a curved plot; and (iii) the number of binding sites per molecule.

**Scodosporium** See PSEUDALLESCHERIA and HYPHOMYCETES.

**Scenedesmus** A genus of non-motile, coenobial green algae (division CHLOROPHYTA) which occur – often abundantly – in a wide range of freshwater habitats. The coenobia each consist of 2, 4, 8, or occasionally 16 elongate or fusiform cells in a palisade arrangement (i.e., side-by-side). In some species the two outermost cells bear a spine or tuft of bristles at each corner of the free side of the cell; however, morphology may vary considerably according to environmental conditions. Each cell contains one nucleus and one chloroplast which usually has a single conspicuous pyrenoid. Asexual reproduction occurs by the formation of a complete daughter coenobium within each cell of a parent coenobium; the daughter coenobia are released – often explosively – by rupture of the parent cell wall. Biflagellate zoospores may also be formed, at least in some species. Sexual reproduction involves the formation of biflagellate isogametes.

**Schaeffer–Fulton stain** See ENDOSPORE STAINS.

**Schardinger dextrins** (cycloamyloses or cyclodextrins) Cyclic DEXTRINS formed from starch or glycogen by an extracellular enzyme, cyclodextrin glucosyltransferase, from *Bacillus macerans* (a similar enzyme is produced e.g. by *B. megaterium*);  $\alpha$ -,  $\beta$ - and  $\gamma$ -cyclodextrins contain 6, 7 and 8 (1  $\rightarrow$  4)- $\alpha$ -linked D-glucose residues, respectively.

**Schaudinn's fluid** A FIXATIVE: mercuric chloride (100 ml saturated, aqueous) and 95% ethanol (50 ml) supplemented immediately before use with glacial acetic acid (1.5 ml).

**scheduled diseases** NOTIFIABLE DISEASES of animals.

**Schellackia** See EIMERIORINA.

**Schick test** A test which determines a person's susceptibility to DIPHTHERIA. Diphtheria toxin is injected intradermally into one arm; as a control, inactivated toxin is injected into the other arm. A *positive* test (person *susceptible*) is indicated, after several days, by an inflammatory response at the site of injection of the potent toxin. No reaction (*negative* test) indicates the presence of antitoxin and hence resistance to the disease.

**Schiff's reagent** Basic FUCHSIN decolorized with sulphurous acid; it reacts with aldehydes to give a red-purple colour. (See FEULGEN REACTION and PAS REACTION.)

## Schizoblastosporion

**Schizoblastosporion** A genus of non-fermentative yeasts (class HYPHOMYCETES). The cells are ellipsoidal to cylindrical; they reproduce by bipolar budding on a broad base. Pseudomycelium may be formed. One species: *S. starkeyi-henricii*, isolated from soil. [Book ref. 100, pp. 909–910.]

**Schizochytrium** See THRAUSTOCHYTRIDS.

**schizogenous** (schizogenic; schizogenetic) Formed by splitting, cracking, or fission.

**schizogony** (merogony) Asexual reproduction in which the nucleus of a cell undergoes division several or many times, resulting in a multinucleate *schizont* which subsequently gives rise to a number of uninucleate cells (*merozoites*).

**schizogregarines** See GREGARINASINA.

**schizolysis** See CONIDIUM.

**Schizomycetes** Obsolete class for the BACTERIA.

**schizont** See SCHIZOGONY.

**schizonticide** Any agent which can kill a schizont. For example, most ANTIMALARIAL AGENTS can kill the intraerythrocytic (blood schizont) stage of *Plasmodium*, while a few (primaquine, proguanil) can kill tissue schizonts.

**schizophrenia** See RETROVIRIDAE.

**Schizophyceae** Obsolete class for the CYANOBACTERIA.

**Schizophyllaceae** See APHYLLOPHORALES.

**Schizophyllum** A genus of fungi of the APHYLLOPHORALES (family Schizophyllaceae) which form non-stipitate, fan-shaped or lobed, bracket-type fruiting bodies. In *S. commune* the upper surface of the fruiting body is grey-brown and finely hairy, and the underside bears a number of pale, lamella-like, longitudinally grooved ridges ('split gills') which radiate out from the point of attachment of the fruiting body; the hymenium lines the outer surfaces of each split gill. Basidiospores: elongated, colourless, ca.  $6 \times 3 \mu\text{m}$ . *S. commune* grows on various types of wood; it has also been isolated as a human pathogen: e.g. in a case of maxillary sinus infection [JCM (1986) 23 1001–1005]. (See also CHOLESTEROL OXIDASE and COMPATIBILITY sense 2.)

**Schizophyta** Obsolete division for the PROKARYOTES.

**Schizoplasmodium** See PROTOSTELIOMYCETES.

**Schizopyrenida** An order of naked, roughly cylindrical, typically uninucleate amoebae (class LOBOSEA) which are motile by the more or less eruptive formation of (usually) a single hemispherical 'bulge'. Many members can form flagellate stages. Genera include NAEGLERIA, TETRAMITUS and VAHLKAMPFIA.

**Schizosaccharomyces** A genus of fungi (family SACCHAROMYCETACEAE) which form single globose to cylindrical cells that reproduce by FISSION, or true hyphae that tend to fragment into arthrospores. (See also CELL WALL.) The organisms are homothallic. Sexual reproduction typically involves the fusion of (haploid) somatic cells and the development of a 4-, 6- or 8-spored ascus direct from the zygote; asci are evanescent. All species ferment glucose but not galactose or lactose. Nitrate is not assimilated. Species (*S. japonicus*, *S. malidevorans*, *S. octosporus*, *S. pombe*) are distinguished on the basis of e.g. number of spores per ascus, ability to ferment particular sugars, etc [Book ref. 100, pp. 414–422]; they occur e.g. in fruit-juices, molasses, fermented beverages, etc. (See also WINE-MAKING.)

**Schizothrix** See LPP GROUP.

**Schizotrypanum** A subgenus of TRYPANOSOMA, within the STERCORARIA, which includes the causal agent of CHAGAS' DISEASE, *T. (S.) cruzi*; two biochemically distinct subspecies are recognized: *T. (S.) cruzi cruzi* (in man) and *T. (S.) cruzi marinkellei* (in bats). These organisms occur in the Americas in the approximate belt  $40^\circ\text{N}$ – $40^\circ\text{S}$ .

In man, *T. (S.) c. cruzi* occurs in the blood as non-dividing trypanomastigotes, typically ca.  $20 \mu\text{m}$  in length (range 12– $30 \mu\text{m}$ ),

in which there is a large kinetoplast situated close to the pointed posterior end of the cell, and a free flagellum; intracellular amastigote and epimastigote forms occur in pseudocysts. In the vector, epimastigotes, sphaeromastigotes and metacyclic forms occur in the gut and rectum. [Cell biology of *T. cruzi*: Int. Rev. Cytol. (1984) 86 197–283.] *T. (S.) c. cruzi* can be cultured in e.g. NNN MEDIUM. [A minimal medium for the cultivation of infective *T. cruzi* epimastigotes: JGM (1983) 129 285–291; improved method for purification of metacyclics from the insect vector *Triatoma infestans*: JP (1986) 33 132–134.]

**schlepper** (*immunol.*) Any substance which, by combining with a second substance, promotes the immunogenicity of the latter.

**schlieren system** An optical system for measuring a refractive index *gradient*.

**Schmutzdecke** The film or layer of microorganisms which develops e.g. in a slow sand filter (see WATER SUPPLIES); it usually contains algae, bacteria and protozoa.

**Schüffner's dots** In erythrocytes infected with *Plasmodium vivax* or *P. ovale*: numerous fine dots observed on staining with Romanowsky stains. (cf. ZIEMANN'S DOTS.)

**Schulz–Charlton test** A test sometimes used in the diagnosis of SCARLET FEVER. Antibody to the streptococcal erythrogenic toxin is injected into the skin of a suspected case; in a positive test (scarlet fever present) there is a localized blanching of the rash after 6–12 hours.

**Schwagerina** See FORAMINIFERIDA.

**Schwanniomyces** A genus of yeasts (family SACCHAROMYCETACEAE) in which the (haploid) vegetative cells are spheroidal or ovoid (occasionally elongate to cylindrical) and reproduce by multilateral budding; pseudomycelium is absent or rudimentary. Ascospores: globose, with a warty surface, an equatorial ridge, and a conspicuous lipid globule. Glucose and e.g. sucrose are fermented;  $\text{NO}_3^-$  is not assimilated. One species: *S. occidentalis*; two varieties: var. *occidentalis* (which can assimilate xylose and *n*-alkanes) and var. *persoonii* (which cannot assimilate xylose or *n*-alkanes). Strains have been isolated from soil. [Book ref. 100, pp. 423–426.]

**Schwartzman reaction** (Schwartzmann reaction) Common misspellings for SHWARTZMAN REACTION.

**sciaphilic** *Syn.* SKIAPHILIC.

**SCID** See SEVERE COMBINED IMMUNODEFICIENCY.

**SCIDX1** See SEVERE COMBINED IMMUNODEFICIENCY.

**scintillon** See BIOLUMINESCENCE.

**scirpene** See TRICHOETECENES.

**Sclerocystis** See ENDOGONALES.

**Scleroderma** See SCLERODERMATALES.

**Sclerodermatales** An order of saprotrophic (humicolous or lignicolous) or mycorrhizal fungi (class GASTEROMYCETES) which typically form globose or reniform, non-stipitate basidiocarps ('earth balls'), ca. several centimetres across, in which the basidia are scattered throughout the gleba (i.e., there is no distinct hymenium) and in which, in most species, the gleba forms a dark, powdery mass at maturity; the release of basidiospores usually depends on the rupture of the characteristically tough peridium. Genera include *Astraeus*, PISOLITHUS, *Scleroderma* and SPHAEROBOLUS.

**Sclerophthora** See PERONOSPORALES.

**Sclerospora** A genus of fungi (order PERONOSPORALES) which include organisms parasitic on members of the Gramineae (see e.g. PHYLLODY). The lemon-shaped zoosporangia are borne on sporangiophores which have multibranching ends.

**sclerotan** A  $(1 \rightarrow 3)$ - $\beta$ -D-glucan found in *Sclerotinia* spp.

**sclerotic bodies** See CHROMOBLASTOMYCOSIS.

**Sclerotinia** A genus of fungi (order HELOTIALES) which include various plant-parasitic species – e.g. *S. fructigena* (see BROWN ROT sense 2), *S. homeocarpa* (see DOLLAR SPOT), and *S. trifoliorum* (see CLOVER ROT). *Sclerotinia* can sometimes cause serious loss in oilseed rape (*Brassica napus*); symptoms: whiteheading, white stem lesions, and black sclerotia within the stem cavity.

*Sclerotinia* spp form stipitate apothecia directly from sclerotia; the ascospores are typically ellipsoidal.

**sclerotinia crown and stem rot** See CLOVER ROT.

**sclerotium** (1) Of certain phaneroplasmoidal MYXOMYCETES: a dormant, resistant structure formed by the conversion of the plasmodium into a hardened, irregularly shaped mass. In e.g. *Physarum polycephalum* the sclerotium is a thick-walled, yellowish mass which is divided internally into a number of (usually) multinucleate sections called *spherules*; the walls of the spherules apparently contain a rare polysaccharide, a polymer of galactosamine (found also in the spore walls in this species). Sclerotia may be formed in response to adverse environmental conditions (e.g. desiccation, starvation, low temperatures), and in some species the sclerotium is the overwintering form of the organism; under favourable conditions the sclerotium germinates to give rise to a vegetative plasmodium.

(2) (*mycol.*) A resting form produced by certain fungi; sclerotia are hard, resistant, plectenchymatous bodies which, under favourable conditions, may give rise to mycelium or to sexual or asexual fruiting bodies. The sclerotium of e.g. *Claviceps purpurea* (see ERGOT) is a black, elongated body ca. 1 cm in length. (See also BLACKFELLOW'S BREAD.)

**Sclerotium** A genus of fungi (order AGONOMYCETALES) which include some important plant pathogens (see e.g. ONION ROT and FOOT-ROT sense 2). *S. rolfsii* causes disease in various host plants, particularly in the tropics and subtropics. [Biology, ecology and control of *S. rolfsii*: ARPPATH. (1985) 23 97–127.] Some species have a teleomorph in the Ascomycotina or the Basidiomycotina.

**scolecosporae** See SACCARDOAN SYSTEM.

**Scolytidae** A family of wood- or bark-boring beetles, many of which are associated (specifically or non-specifically) with fungi: see e.g. AMBROSIA FUNGI and DUTCH ELM DISEASE.

**scombroid poisoning** See FISH SPOILAGE.

**scopoletin** 6-Methoxy-7-hydroxycoumarin. Scopoletin occurs in a number of higher plants, often as *scopolin* (scopoletin 7-glucoside). It accumulates in the tissues of certain microbially infected plants – e.g. in potato tubers affected with LATE BLIGHT, and in tobacco plants affected by GRANVILLE WILT. Scopoletin, which inhibits 'IAA-oxidase' (see AUXINS), may be a factor in the pathogenesis of certain diseases.

**scopolin** See SCOPOLETIN.

**scopula** In certain (particularly sessile) peritrichs: an aboral, frequently cup-shaped organelle consisting of a large number of kinetosomes, each typically carrying a short, immobile cilium; presumed functions include the formation of a stalk.

**Scopulariopsis** See HYPHOMYCETES.

**Scorias** See SOOTY MOULDS.

**Scotobacteria** A proposed class of the GRACILICUTES comprising the non-photosynthetic Gram-negative bacteria.

**scotochromogen** Any strain of *Mycobacterium* which forms carotenoid pigment when growth occurs either in the light or in the dark (cf. PHOTOCROMOGEN). Scotochromogens include some slow-growing species (e.g. *M. scrofulaceum*) and some fast-growing species (e.g. *M. phlei*).

**Scourfieldia** See MICROMONADOPHYCEAE.

**scours** (*vet.*) DIARRHOEA – a common symptom in many types of infectious disease (see e.g. COLIBACILLOSIS, JOHN'S DISEASE,

PARATYPHOID FEVER (2)), but also a symptom e.g. of certain mycotoxicoses and of secondary copper deficiency syndromes (e.g. peat scours, scouring disease, teart) in ruminants. (See also CALF SCOURS; TRANSMISSIBLE GASTROENTERITIS; WINTER DYSENTERY.)

**SCP** SINGLE-CELL PROTEIN.

**scrapie** A TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHY (q.v.) which, in nature, affects sheep and goats. After an incubation period of months or years the infected animal exhibits neurological symptoms – e.g. evidence of intense itching, incoordination and trembling – followed by emaciation and (after weeks or months) death. Histopathology in the central nervous system: e.g. vacuolation, gliosis and astrocytosis. No inflammatory response is elicited at any stage, interferons are not induced, and there is no specific immune response. Different breeds of sheep differ markedly in their susceptibility to scrapie.

The causal agent is a PRION designated PrP<sup>Sc</sup>. It can be transmitted experimentally e.g. to mice and hamsters – in which animals the disease follows a much shorter course and may involve different symptoms (for example, scrapie-infected mice do not scratch). PrP<sup>Sc</sup> is initially demonstrable in the spleen and lymphoid tissues; eventually it reaches maximum titres in the brain. Abnormal, amyloid-like fibrillar structures can be seen in synaptosomal and spleen preparations of infected mice; these *scrapie-associated fibrils* (SAFs) contain a protein subunit formerly designated 'PrP 27–30' (because its MWt was apparently 27000–30000). SAFs appear to be closely associated with infectivity.

**screening test** (1) Any test used to detect the presence of a given agent (e.g. a specific antibody or microorganism) in each of a large number of specimens; such tests are typically simple and inexpensive but are usually not completely specific for the antibody or microorganism. A certain proportion of false-positive results may be tolerated as a positive screening test may be followed up by other tests which are more specific. (2) Any test which enables a given (unknown) organism to be assigned to one of a possible range of taxa.

**scRNA** Small cytoplasmic RNA. scRNAs occur in the cytoplasm of eukaryotic cells in the form of ribonucleoprotein particles (scRNPs or *scryps*), including PROSOMES. (cf. SNRNA.)

**scrofula** Cervical lymphadenitis caused by *Mycobacterium scrofulaceum* or by other members of the MAC.

**scrub typhus** (tsutsugamushi disease) An acute, systemic human disease caused by *Rickettsia tsutsugamushi* (= *R. orientalis*) and transmitted by the bite of the larval stage of a trombiculid mite; rodents are a reservoir of infection. The disease occurs in Asia, Australia, and the Pacific area. Incubation period: 1–3 weeks. A primary lesion (an ESCHAR) often develops at the location of the bite; subsequent symptoms resemble those of epidemic typhus (see TYPHUS FEVERS). *Lab. diagnosis*: e.g. the WEIL–FELIX TEST. *Chemotherapy*: tetracyclines, chloramphenicol.

**SCSR** See CLOVER ROT.

**Scutellinia** A genus of fungi (order PEZIZALES) which form apothecia bearing dark, pointed setae. *S. scutellata* (common on rotting wood) forms brick-red apothecia typically several millimetres across.

**scutica** In members of the SCUTICOCILIATIDA: a transient, hook-like structure, consisting of a number of (generally non-ciliated) kinetosomes, formed during STOMATOGENESIS.

**Scuticociliatida** An order of protozoa (subclass HYMENOSTOMATIA) in which somatic ciliature is uniform to sparse (sometimes involving distinctive caudal ciliature), and in which the buccal ciliature often includes a large, protruding and conspicuous PARORAL MEMBRANE; STOMATOGENESIS is buccokinetal and involves

## scutulum

the appearance of a SCUTICA. Cyst formation is common. Genera include e.g. *Ancistrum*, *Boveria*, CYCLIDIUM, *Loxocephalus*, *Parauronema*, *Philaster*, *Pleuronema*, and *Uronema*.

**scutulum** See FAVUS.

**SeV** *Saccharomyces cerevisiae* virus (see MYCOVIRUS).

**scyllitol** See INOSITOL.

**Scyphidia** See PERITRICHIA.

**scyphus** (*lichenol.*) See PODETIUM.

**scyrps** See SCRNA.

**Scytonema** A genus of filamentous CYANOBACTERIA (section IV) in which the mature trichomes are uniform in width (cf. CALOTHRIX) and are composed of disc-shaped, isodiametric or cylindrical vegetative cells; young trichomes from hormogonia each have a heterocyst at only one end. GC%: ca. 44.

In nature, trichomes are heavily ensheathed and exhibit frequent FALSE BRANCHING. A distinction is often made between *Tolypothrix* (false branches occur singly) and *Scytonema* (false branches occur in pairs); however, since false branching is variable in culture, these two genera are generally considered as one, *Scytonema* [Book ref. 45, p. 254]. (See also STROMATOLITE.)

**Scytosiphon** See PHAEOPHYTA.

**SD sequence** (SD region) Shine–Dalgarno sequence: see PROTEIN SYNTHESIS.

**SDA** Strand displacement amplification: a method for copying ('amplifying') a given sequence of nucleotides in DNA. Like NASBA (but unlike LCR or PCR), SDA is carried out isothermally; originally the operating temperature was ~40°C but, owing to suboptimal specificity, it was later raised to ≥50°C (= thermophilic SDA; tSDA).

SDA is considerably more complex than other nucleic-acid-amplification procedures. It has two distinctive features: (i) the use of a DNA polymerase which can displace an existing strand of DNA by using the complementary strand as a template, and (ii) the use of a RESTRICTION ENDONUCLEASE for repeatedly nicking a modified cutting site in a mechanism for regenerating templates.

Only certain types of DNA polymerase are able to carry out strand displacement – one of which is the exonuclease-deficient form of the KLENOV FRAGMENT. As illustrated in the figure, the strand-displacing activity of a polymerase can be manifested in two ways. In one mode, a so-called *bumper primer* binds upstream of the strand to be displaced; extension of the 3' end of the bumper primer by a (strand-displacing) DNA polymerase displaces the strand downstream. (In SDA, displacement of the 5' end of the strand begins while the 3' end is still being synthesized.) The second mode of strand displacement occurs at a NICK site; here, the polymerase extends the 3' end of the nick and, in so doing, displaces the downstream region of the same strand. (In effect, the 3' end at the nick site functions as a primer.)

The restriction endonuclease used in SDA is *HincII*; it has the (generalized) recognition site:

(Py = a pyrimidine, Pu = a purine). The oblique (/) indicates the cleavage site in each strand; thus, *HincII* normally makes a 'blunt-ended' cut across both strands.

The specific *HincII* recognition site used in SDA is:

and the sequence 5'-GTTGAC-3' is used as a terminal tag in both primers (S1 and S2).

During amplification of the target in SDA, all strand synthesis is carried out in a reaction mixture that contains a chemically modified form of deoxyadenosine triphosphate:  $\alpha$ -thiophosphoryl dATP (dATP $\alpha$ S). Hence, when a complementary strand is synthesized on the *HincII* site of a primer, the sequence (3'...CAACTG...5') contains two of the modified nucleotides (AA) adjacent to the cleavage site; this strand is resistant to cleavage by *HincII* – i.e. the double-stranded *HincII* site contains one cleavable sequence (in the primer) and one non-cleavable sequence (in the newly synthesized, complementary strand). Such a 'hemi-modified' or 'hemiphosphorothioate' *HincII* site can be nicked between 'T' and 'G' in the primer strand. When such a nick is made, the polymerase can extend the 3' end and displace the strand downstream of the nick site. Importantly, note that the strand formed by extension from the nick site (5'-GTT →→→) will incorporate a modified nucleotide at the 'A' position of GAC; despite this, the *HincII* site in the newly synthesized strand 5'-GTTGAC.....3' is 'nickable' – i.e. incorporation of a single modified nucleotide in GAC does not affect nickability (unlike the incorporation of two modified nucleotides in the sequence 3'...CAACTG...5' in the complementary strand).

In practical terms the method is uncomplicated. Essentially, sample dsDNA is heat-denatured in a reaction mixture containing all components except the polymerase and restriction endonuclease; the mixture is cooled to an appropriate temperature, the enzymes are added, and incubation is continued for the required period.

SDA-based diagnostic procedures are being developed by the Becton Dickinson organization. The BDProbe Tec system has been tested for its ability to detect *Mycobacterium tuberculosis* in respiratory specimens [JCM (1999) 37 137–140], and a more recent system, BDProbe Tec™ ET, has been evaluated for the detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* [CC (1999) 45 777–784].

[SDA, NASBA, TMA in clinical microbiology: Book ref. 221, pp 126–151.]

**SDS** Sodium dodecyl (= lauryl) sulphate.

**SDS-PAGE** ('Laemmli electrophoresis' [Nature (1970) 227 680–685]) Sodium dodecyl sulphate polyacrylamide gel electrophoresis: a specialized form of ELECTROPHORESIS used e.g. for determining the molecular weight of a protein, or for separating mixtures of proteins.

*Molecular weight determination by SDS-PAGE.* At concentrations > ca. 10<sup>-4</sup> to 10<sup>-3</sup> M, sodium dodecyl sulphate (SDS; CH<sub>3</sub>(CH<sub>2</sub>)<sub>11</sub>OSO<sub>3</sub>Na) binds cooperatively to proteins and denatures them, forming long rod-like SDS-polypeptide complexes; virtually all proteins bind a similar amount of SDS per unit weight of protein. Each SDS molecule binds via its hydrophobic end, and the coating of SDS molecules effectively masks the charges on the polypeptide. Since the length of an SDS-polypeptide complex is roughly proportional to the molecular weight of the polypeptide, the electrophoretic mobility of such a complex will give an approximate indication of the molecular weight of the polypeptide. Thus, if the SDS complex of an unknown protein is subjected to PAGE together with the SDS complexes of reference proteins (of known molecular weights), the molecular weight of the unknown protein can be calculated by comparing the electrophoretic mobilities.

Some proteins (e.g. pepsin, many viral capsid proteins) form SDS complexes only if they are *heated* in the presence

SDA (strand displacement amplification) – I: the target-generation phase (diagrammatic). The target DNA is denatured by heat to the single-stranded form prior to SDA.

(a) The antisense (3'-to-5') strand of the target duplex showing the amplicon delimited by two short, vertical bars. (For clarity, and economy of space, only one strand of the amplicon is considered; corresponding events occur on the complementary strand.) A primer (S1) has bound at the 3' end of the amplicon; the 5' end of this primer is tagged with (one strand of) the *HincII* recognition sequence: (5'-GTTGAC-3') (□□). A bumper primer (B1, see entry) has bound upstream of primer S1. Extension of S1 will produce a 'sense' strand on the antisense template, and this strand will be displaced when B1 is extended; the displaced sense strand is shown at (b).

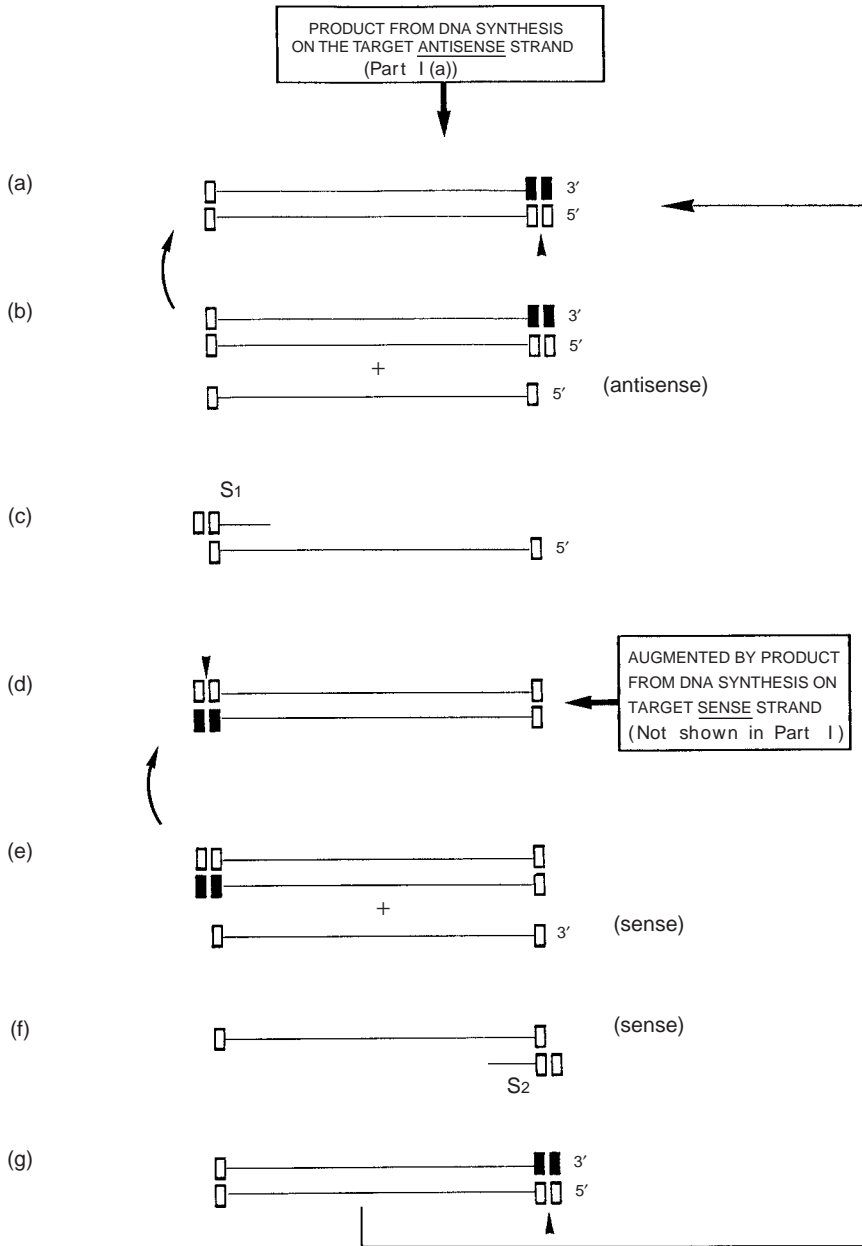

(c) Primer S2 has bound at the 3' end of the amplicon on the sense strand; like S1, its 5' end is tagged with the recognition sequence of *HincII*. The bumper primer B2 has bound upstream of S2. Extension of S2 produces an antisense amplicon which is tagged at both ends by a *HincII* recognition sequence; this strand, which is displaced by the extension of B2, is shown at (d). Notice that the 3' *HincII* sequence in this strand, having been synthesized with dATP $\alpha$ S, is modified – as indicated by (■ ■); this sequence is not susceptible to *HincII*.

(d) Primer S1 (not shown) binds at the 3' end of this strand, the *HincII* sequence in S1 hybridizing with the modified sequence in the strand. Extension of S1 forms the double-stranded amplicon at (e). Each end of this amplicon consists of a hemi-modified recognition site for *HincII*; a hemi-modified site can be nicked in the *non*-modified strand (arrowhead). Nicking of the upper strand at (e) is followed by extension of the 3' end of the nick – this displacing the strand downstream of the nick site; this displaced strand is shown at (f).

(g) Primer S2 binds to the displaced strand. Extension of S2 forms the product at (h).

(h) This double-stranded product feeds into the amplification phase (see part II of figure).

SDA (strand displacement amplification) – II: the amplification phase (diagrammatic).

(a) A double-stranded product from the target-generation phase; notice that this product derives from S<sub>1</sub>-primed DNA synthesis on the *antisense* strand of the target sequence (see part I(a)). The antisense strand in this product contains a nickable *HincII* restriction site (arrowhead) derived from the tag in primer S<sub>2</sub> (see part I (g)). When this restriction site is nicked, DNA synthesis proceeds from the 3' end at the nick site. During synthesis, the polymerase displaces the downstream section of the strand, producing an antisense copy of the target sequence which is flanked, on each side, by half a restriction site; moreover, the newly synthesized strand regenerates the original duplex – and the restriction site in this duplex is still nickable because a modified nucleotide occurs only in the 5'-GAC-3' sequence (see text). Both of these products (the displaced strand and the regenerated duplex) are shown at (b).

Thus, the product shown at (a) can undergo repeated nicking, strand extension and regeneration in a cyclical fashion, displacing many copies of the antisense strand. (Continued on page 695.)

of SDS – or e.g. treated with 2-mercaptoethanol (or similar reagent) to cleave intraprotein disulphide bonds.

[Effect of SDS on proteins: BBA (1975) 415 29–79 (47–50).]

**sea ivory** *Ramalina siliquosa*.

**sea lettuce** *Ulva lactuca*: see ULVA.

**sea lion virus** See SAN MIGUEL SEA LION VIRUS.

**sea sawdust** See TRICHODESMIUM.

**seasoning** (of timber) See TIMBER PRESERVATION.

**seaweed** Any macroscopic marine alga of the CHLOROPHYTA ('green seaweeds'), PHAEOPHYTA ('brown seaweeds') or RHODOPHYTA ('red seaweeds').

**seaweed diseases** See ALGAL DISEASES.

**sec-dependent pathway** See PROTEIN SECRETION.

**sec genes** See PROTEIN SECRETION.

**SecA, SecB** See PROTEIN SECRETION.

**secalonic acids** *Syn.* ERGOCHROMES.

**secnidazole** See NITROIMIDAZOLES.

**second-site reversion** See SUPPRESSOR MUTATION.

**secondary fixation** *Syn.* post-FIXATION.

**secondary fluorescence** See FLUORESCENCE.

**secondary homothallism** See HOMOTHALLISM.

**secondary hyphae** See HYPHA.

**secondary metabolism** Metabolism which is not essential for, and plays no part in, growth; it commonly occurs maximally under conditions of restricted growth or absence of growth (e.g. at the end of log-phase or trophophase growth in BATCH CULTURES). Secondary metabolites ('idiolites') include substances such as ANTIBIOTICS and MYCOTOXINS and are produced from substrates provided by PRIMARY METABOLISM – particularly shikimic acid (precursor of many aromatic compounds), amino acids (precursors of many alkaloids and antibiotics), and acetate (precursor of isoprenoids and many toxins – see also POLYKETIDE).

[Review: AMP (1984) 25 1–60; secondary metabolism in fungi: Book ref. 117, pp. 336–367. Secondary metabolites: Book ref. 205.]

**secondary response** (*immunol.*) See ANTIBODY FORMATION.

**secondary zoospore** See e.g. DIPLANETISM and PLASMIDIOPHORMYCETES.

**secotioid fungi** Fungi whose sexually-derived fruiting bodies typically resemble AGARICOID fruiting bodies but differ from them in that the margin of the pileus may not separate from

the stipe, the lamellae are characteristically convoluted, and the spores are not forcibly discharged; the secotioid fruiting body may be epigeal or hypogean, the latter type closely resembling the fruiting body of a typical gasteromycete. Secotioid fungi are found in various taxa; they include e.g. certain members of the Russulales. *Secotium*, formerly classified in the Agaricales, is now included in the Gasteromycetes (Podaxales). [The secotioid syndrome: Mycol. (1984) 76 1–8.]

**Secotium** See SECOTIOID FUNGI.

**secretin** Any one type of a family of proteins which oligomerize to form pores in the OUTER MEMBRANE; in at least some cases the multimeric pores are stabilized by a specific outer membrane lipoprotein.

One example of a secretin is the PilQ protein of *Neisseria gonorrhoeae*; this protein, which is involved in the formation of type IV FIMBRIAE, forms an outer membrane pore that is stabilized by the PilP protein. Another example is the *usher* protein, PapC, involved in the formation of P fimbriae (type I fimbriae); the corresponding structure is stabilized by the PapH protein. The YscC protein of the *Yersinia* VIRULON is a further example.

**secretion** (of a protein) The transmembrane translocation of a protein, towards the cell's exterior, with eventual release of the protein to the external environment. (cf. EXPORT.)

**secretion of proteins** (by Gram-negative bacteria) See PROTEIN SECRETION.

**secretion sequence** See ABC EXPORTER.

**secretion** In type II PROTEIN SECRETION systems: the complex of proteins which, together, enable proteins to cross the OUTER MEMBRANE, i.e. the 'terminal branch' of the type II system; thus, a protein may be translocated across the cytoplasmic membrane in a *sec*-dependent manner and then secreted to the cell's exterior via the secretion.

The secretion is functionally analogous to the protein transport system involved in the formation of certain fimbriae [EMBO (2000) 19 2221–2228].

**secretory ampulla** *Syn.* AMPULLA sense 1 or 2.

**secretory component** (secretory piece) A glycoprotein (MWt ca. 60000) produced (as a membrane protein) in hepatocytes and in epithelial cells of various mucosal surfaces in the body; it is a component of sIgA (see IgA). Secretory component binds to

SDA (strand displacement amplification) – II (*continued*) (c) Each antisense strand from (b) can bind primer S<sub>1</sub>. Extension of S<sub>1</sub>, and of the (recessed) 3' end of the antisense strand, forms the product at (d). Extension of the 3' end of the antisense strand has formed a modified, non-nickable *HincII* restriction sequence (■■■) because the three terminal nucleotides in this strand (3'-CAA-5') include two modified nucleotides (dATP $\alpha$ S).

(d) This product has a nickable restriction site (arrowhead) derived from primer S<sub>1</sub>. Like the product at (a), it can undergo a cyclical process of nicking, strand extension and regeneration, concurrently displacing copies of a single-stranded product; however, this single-stranded product is a *sense* strand of the target sequence. The regenerated product and sense strand are shown at (e).

Recall that part I illustrates the events arising from DNA synthesis on the *antisense* strand of the target duplex. If events are followed on the sense strand, the resulting product is identical to that shown here at (d).

(e) The single-stranded (*sense*) product shown here is able to bind primer S<sub>2</sub>.

(f) The single-stranded product from (e) has bound primer S<sub>2</sub>. DNA synthesis (i.e. extension from S<sub>2</sub>, and also from the recessed end of the sense strand) then gives rise to the product seen at (g). (DNA synthesis at the 3' end of the sense strand forms a non-nickable restriction site for the reason given under (c), above.)

(g) This product is equivalent to the one shown at (a).

Summarizing, two types of double-stranded product from the target-generation phase, derived from different strands of the target, undergo cyclical nicking, strand synthesis and regeneration, concurrently displacing numerous copies of antisense and sense strands of the target sequence. Antisense strands bind primer S<sub>1</sub> and form the (double-stranded) product which yields sense strands; sense strands bind primer S<sub>2</sub> and form the (double-stranded) product which yields antisense strands. Nickable *HincII* restriction sites are provided by the 5'-tags on S<sub>1</sub> and S<sub>2</sub> primers (which are present in excess in the reaction mixture).

Parts I and II reproduced from Figures 5.3 and 5.4, pages 134–137, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission from Kluwer Academic Publishers, Dordrecht, The Netherlands.

## secretory IgA

the dimeric IgA–J chain complex at the basal surface of (e.g.) a mucosal epithelial cell; the (IgA)<sub>2</sub>–J chain–secretory component complex is then taken into the cell by endocytosis and passes through the cell cytoplasm (in an endocytotic vacuole), sIgA being released at the mucosal surface by proteolytic cleavage of the (transmembrane) secretory component.

**secretory IgA** See entry IgA.

**section** (*histol.*) See MICROTOME.

**sectoring** (in a colony) The development of a sector or wedge-shaped region of growth which differs, in e.g. appearance, from the rest of the colony.

**SecYEG** See PROTEIN SECRETION.

**sedentary** *Syn.* SESSILE (sense 1).

**sedimentation basin** See WATER SUPPLIES.

**sedimentation coefficient** See SVEDBERG UNIT.

**sedoheptulose** A 7-carbon ketosugar originally isolated from *Sedum* sp (stonecrop; Crassulaceae) in which it occurs as the free monosaccharide. Phosphorylated derivatives of sedoheptulose are intermediates in the CALVIN CYCLE, the HEXOSE MONOPHOSPHATE PATHWAY [Appendix I(b)], and the RMP PATHWAY.

**seed** (*verb*) To inoculate.

**seeligerolysin** See THIOL-ACTIVATED CYTOLYSINS.

**segmented genome** In a virus: a genome which occurs as two or more pieces of nucleic acid. (See e.g. ARENAVIRIDAE, BACTERIOPHAGE  $\phi$ 6, BUNYAVIRIDAE, ORTHOMYXOVIRIDAE, REOVIRIDAE.)

**segregation** (*genetics*) The separation of homologous chromosomes or chromatids, or homologous or non-homologous (incompatible) plasmids, or of particular named genes or alleles, etc, into different daughter cells during cell division.

**segregation lag** A delay in the phenotypic expression of a newly acquired genotype owing to the time required for the segregation of the new allele(s) to a cell which has no corresponding wild-type allele(s). Thus, e.g., if a mutation occurs in one chromosome in a bacterial cell which contains two or more chromosomes, the mutant phenotype will be expressed only when the mutant chromosome is segregated (by cell division) into a cell which lacks a wild-type chromosome.

**segregational petite** See PETITE MUTANT.

**Seitz filter** See FILTRATION.

**selC gene** See PATHOGENICITY ISLAND.

**selectins** A family of calcium-dependent CELL ADHESION MOLECULES with the properties of LECTINS. E-selectin (see CD62E) is expressed on endothelial cells during INFLAMMATION. L-selectin (LECAM-1; = CD62L) occurs on leukocytes, and is involved in lymphocyte homing and in the interaction between leukocytes and endothelium during inflammation. P-selectin (PADGEM; = CD62P) is found e.g. on (activated) platelets and endothelial cells during inflammation; in the unstimulated state, P-selectin occurs in  $\alpha$  granules in platelets and within endothelial cells. P-selectin is the largest of the selectin molecules (140 kDa); the lymphocyte-associated form of L-selectin is the smallest (~75 kDa).

**selection synchrony** See SYNCHRONOUS CULTURE.

**selective medium** See MEDIUM.

**selenate respiration** ANAEROBIC RESPIRATION, found in certain (Gram-positive and Gram-negative) bacteria (e.g. *Thauera selenatis* [IJSB (1993) 43 135–142]), in which the terminal electron acceptor is selenate. Some species of bacteria can use arsenate as terminal electron acceptor. [Arsenic- and selenium-respiring bacteria: FEMS Reviews (1999) 23 615–627.]

**selenazofurin** See RIBAVIRIN.

**selenazole** See RIBAVIRIN.

**Selenidium** A genus of the GREGARINASINA.

**selenite broth** (selenite F broth) A MEDIUM used e.g. for the ENRICHMENT of strains of *Salmonella* in samples of faeces; selenite inhibits many of the common enteric bacteria. The medium consists of an aqueous solution of peptone (0.5%), lactose or mannitol (0.4%), NaHSeO<sub>3</sub> (0.4%), and either Na<sub>2</sub>HPO<sub>4</sub> (1.0%) or a combination of Na<sub>2</sub>HPO<sub>4</sub> and NaH<sub>2</sub>PO<sub>4</sub> to give a final pH of ca. 7.0. The medium should not be autoclaved, but may be steamed for 30 min. Incubation of the inoculated medium should not exceed ca. 12–18 hours.

**Selenococcidium** See EIMERIORINA.

**Selenomonas** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN and in the human gingival crevice. Cells: curved (crescent- or kidney-shaped) rods, 0.9–1.1  $\times$  3.0–6.0  $\mu$ m, with a tuft of flagella arising from the concave side of the cell. Substrates include sugars and, sometimes, amino acids and lactate; glucose fermentation yields propionic and acetic acids as major products together with e.g. CO<sub>2</sub> and/or lactate. GC%: ca. 54–61. Type species: *S. sputigena* (which does not ferment cellobiose, dulcitol or salicin, and which occurs in the human mouth); other species: *S. ruminantium* (which ferments cellobiose, dulcitol and salicin, and which occurs in the rumen).

**Selenophoma** A genus of fungi of the COELOMYCETES.

**self-cloning experiment** A CLONING experiment in which the DNA to be cloned is derived from the same strain or species as that in which the recombinant DNA is to be replicated; a recombination-deficient strain may be used to prevent recombination between the cloned DNA and the organism's genome.

**self fertilization** (*protozool.*) *Syn.* AUTOGAMY.

**self purification** The natural process in which organic material (faeces etc) in rivers, streams etc undergoes MINERALIZATION, and the resulting simple substances (e.g. nitrates) are made available to photosynthetic and other organisms. Self purification can occur only if the polluting load is not excessive. (See also SAPROBITY SYSTEM.)

**self-splicing introns** See SPLIT GENE (b) and (c).

**self tolerance** (natural immunological tolerance) Unresponsiveness of the immune system to an individual's own (autologous) antigens.

**self-transmissible plasmid** See CONJUGATIVE PLASMID.

**selfing** (*ciliate protozool.*) *Syn.* CYTOGAMY.

**Seliberia** A genus of Gram-negative, iron-accumulating, BUDDING BACTERIA which occur e.g. in soil; the organisms typically occur as radial clusters of rod-shaped cells. [Book ref. 45, pp. 516–519.]

**Selysina** See EIMERIORINA.

**SEM** See ELECTRON MICROSCOPY (b).

**semiapochromatic objective** *Syn.* FLUORITE OBJECTIVE.

**semiconservative replication** Replication of a double-stranded nucleic acid such that each daughter duplex contains one parental strand and one new strand. (See DNA REPLICATION.)

**semipermissive cells** (*virol.*) A cell population in which only some of the cells are permissive for lytic infection by a given virus. (cf. PERMISSIVE CELLS; see also CARRIER CULTURE.)

**semipersistent transmission** See NON-CIRCULATIVE TRANSMISSION.

**semi-rough mutant** See SMOOTH–ROUGH VARIATION.

**semi-solid agar** See AGAR AND MEDIUM.

**Semliki Forest virus** (SFV) An ALPHAVIRUS which was first isolated from mosquitoes in Uganda. Its natural hosts and vectors are unknown, but antibodies to the virus have been detected in humans and wild primates in various parts of Africa, Malaya and North Borneo. The virus is apparently non-pathogenic in

man. When injected into mice, SFV can cause an acute, lethal encephalitis; virulent strains appear to damage neurones (or particular neurone subsets) directly, while other strains infect oligodendrocytes and cause demyelination – apparently by triggering an autoimmune response [JGV (1985) 66 2365–2373; review: JGV (1985) 66 395–408]. SFV can be transmitted transplacentally in mice, causing e.g. abortion or malformation of infected fetuses. (See TOGAVIRIDAE for replication cycle etc.)

**Simple vaccine** An anti-RABIES vaccine consisting of a phenol-inactivated preparation of rabbit-fixed rabies virus (i.e. rabies virus passaged in rabbit brain).

**sen gene** See EIEC.

**Sendai virus** See PARAMYXOVIRUS.

**senior synonym** See SYNONYM.

**sennetsu rickettsiosis** See EHRLICHIA.

**sens. lat.** SENSU LATO (q.v.).

**sense codon** A codon which specifies an amino acid: see GENETIC CODE.

**sense strand** (of DNA) See CODING STRAND.

**sensitin** Any preparation (e.g. an extract of a given microorganism, as in brucellin, coccidioidin etc) which can act as an ALLERGEN; sensitins are used in SKIN TESTS.

**sensitivity agar** Any of various standardized, solid, agar-based media used for carrying out ANTIBIOTIC-sensitivity tests.

**sensitization** (*immunol.*) (1) (of a person or animal) The initial exposure of an individual to an allergen such that a manifestation of HYPERSENSITIVITY occurs on subsequent exposure(s) of the individual to that allergen. (2) (of persons, animals or cells) The process of *priming* (see PRIMED). (3) The combination of cell-surface antigens with their homologous antibodies (see e.g. HAEMOLYTIC SYSTEM). (4) The coating of erythrocytes with soluble antigens (see BOYDEN PROCEDURE). (5) Any procedure of the type in which certain strains of staphylococci are coated ('sensitized') with unrelated antibodies (see PROTEIN A) for use in a PASSIVE AGGLUTINATION TEST for the homologous antigen. (6) The combination of cells with cytophilic antibodies (see e.g. REAGINIC ANTIBODIES).

**sensu lato** (s.l.; sens. lat.) Of a term or name: (1) used in a broad or more inclusive sense, or (2) used with a meaning other than the original meaning.

**sensu stricto** (s.s.; s. str.) Of a term or name: (1) used with a precise or narrow meaning, or (2) used with the original meaning.

**Seoul virus** See HANTAVIRUS.

**sepB gene** See PATHOGENICITY ISLAND.

**Sephadex** See DEXTRANS and GEL FILTRATION.

**Sepek virus** See FLAVIVIRIDAE.

**sepsis** (*med., vet.*) (1) The state in which pathogen(s) are present in particular tissue(s). (cf. ASEPSIS; SEPTICAEMIA.) (2) The symptoms associated with microbial infection of tissues. (See also SIRS.)

**septa** Plural of SEPTUM.

**septal pore cap** See DOLIPORE SEPTUM.

**septate** Having one or more septa.

**septic** (1) (*med., vet.*) Refers to SEPSIS (generally sense 2). (2) Refers to the presence or activities of microorganisms involved in putrefaction or decay (see e.g. SEPTIC TANK).

**septic diphtheria** See DIPHTHERIA.

**septic shock** *Syn.* ENDOTOXIC SHOCK.

**septic tank** A ventilated tank into which domestic sewage flows and within which the sewage undergoes primary purification (settlement of suspended solids) and some degree of ANAEROBIC DIGESTION; solids (sludge and scum) are periodically removed for disposal. The highly polluting supernatant overflows and

must be treated, e.g. by aerobic biological oxidation or (when permissible, and when underground water supplies would not be contaminated) allowed to disperse in the soil below the surface ('subsurface irrigation'). A septic tank can serve e.g. 1–50 houses. (cf. CESSPOOL; see also SEWAGE TREATMENT.)

**septicaemia** (septicemia; blood poisoning) A particular form of BACTERAEMIA in which there are clinical symptoms (e.g. fever). The term may also refer to the presence of *Candida albicans* or other fungi in the bloodstream. (cf. VIRAEMIA.)

(See also SEPSIS and SIRS.)

**septicemia** *Syn.* SEPTICAEMIA.

**septicolysin** See THIOL-ACTIVATED CYTOLYSINS.

**Septobasidiales** An order of fungi (subclass PHRAGMOBASIDIOMYCETIDAE) which form non-gelatinous fruiting bodies; they include parasites of scale insects (insects of the superfamily Coccoidea). Genera: *Septobasidium* and *Uredinella*.

**Septobasidium** See SEPTOBASIDIALES.

**septoria** A plant disease caused by a species of *Septoria*: see e.g. GLUME BLOTCH and HALO SPOT.

**Septoria** A genus of fungi (order SPHAEROPSIDALES) which include many plant pathogens – e.g. *S. apiicola*, the causal agent of late blight (leaf spot) of celery. (See also e.g. GLUME BLOTCH and HALO SPOT.) Conidia are filiform and typically multiseptate and colourless; they are formed in dark, ostiolate pycnidia immersed in the substratum.

**septum** (cross-wall) (a) (*bacteriol.*) A partition which (i) divides a parent cell into daughter cells during BINARY FISSION, (ii) occurs between adjacent cells in a filament (see e.g. ACTINOMYCETALES), and (iii) separates a developing ENDOSPORE from the rest of the mother cell.

Septum formation is an essential phase in the CELL CYCLE (q.v. for details of septum formation in bacteria).

During sporulation in *Bacillus subtilis*, one of the early stages is the formation of an *asymmetric* septum, i.e. one which (unlike that formed during cell division) develops near one pole of the cell. Initially, an FtsZ ring (see CELL CYCLE) forms at the mid-cell position but then become helical and finally forms an FtsZ ring at both polar sites; septation occurs at only one site [Science (2002) 298 1942–1946].

(b) (*mycol.*) A partition, one or more of which divides certain fungal structures (hyphae, spores etc.) into cells; septa are also formed in fission yeasts (e.g. *Schizosaccharomyces*) during cell division.

A *primary* septum is one formed in association with nuclear division, i.e. one serving to separate daughter cells. An *adventitious* septum develops independently of nuclear division.

Septate hyphae are characteristic of the higher fungi, but septa are also formed in certain lower fungi – although often only in ageing hyphae and/or in order to delimit reproductive structures (such as sporangia).

Septate (multicellular) spores are formed by various fungi (e.g. macroconidia in *Fusarium*).

In general, 'true' septa (*eusepta*) have essentially the same composition as the hyphal CELL WALL, but certain fungal structures (e.g. the mycelium of some of the more complex chytridiomycetes, and the conidia in certain hyphomycetes) have septum-like *pseudo-septa* (= *distosepta*) whose composition is distinct from that of the cell wall.

Hyphal septa appear always to be formed by centripetal growth from annular rims which develop on the inner surface of the hyphal wall. In some cases growth of the septum continues inwards until a complete plate is formed. In other cases, growth stops before the septum is complete, so that a small pore (ca.

## sequence capture PCR

0.4–1.0 µm diam.) remains in the centre of the septum; such pores (characteristic of ascomycetes) may permit passage of cytoplasm and nuclei from one hyphal cell to the next, but in many fungi the pores may be plugged or occluded (see e.g. WORONIN BODIES).

*Plasmodesmata* (fine, cytoplasm-filled channels) occur in the septa of certain fungi.

(See also DOLIPORE SEPTUM.)

**sequence capture PCR** See PCR and DYNABEADS.

**sequencing** (of DNA and RNA) See DNA SEQUENCING.

**Sequestrene** *Syn.* VERSENE.

**SER** Smooth ENDOPLASMIC RETICULUM.

**sera** Plural of SERUM.

**SERE** *Salmonella enteritidis* repetitive element: a widely dispersed bacterial repetitive DNA element [JMM (1998) 47 489–497]. (See also REP-PCR.)

**SERE-PCR** See REP-PCR.

**Serény test** A test used with the intention of determining the invasiveness of a bacterial pathogen. The conjunctival sac of a guinea pig is inoculated with the pathogen; invasiveness is indicated by ulceration of the cornea. An HEP-2 tissue culture test may be used as a more humane alternative [JCM (1981) 13 596–597.]

**serial dilutions** A set of dilutions (of a given sample) prepared by initially diluting an aliquot of the sample, then diluting an aliquot of this dilution, and so on. In *doubling dilutions* the dilution factor progressively doubles: 1/2, 1/4, 1/8 etc. In *log dilutions* the dilution factors are related thus: 1/10, 1/100, 1/1000 etc.

**serial passage** (1) (*syn.* passage) Any procedure in which a pathogen (usually a virus) is transferred from one to another of a succession of animals, eggs or tissue cultures etc – growth (or replication) of the pathogen taking place before each transfer. Serial passage is sometimes used e.g. for the ATTENUATION (sense 1) of a pathogen. For example, the rabies virus may be attenuated by adapting it to chick embryo tissues – the virus being serially passaged through a series of hens' eggs. (See also AVIANIZED VACCINE and FLURY VIRUS.) For use in a vaccine, a successfully passaged pathogen should (a) be non-pathogenic for particular host(s), and (b) retain its specific immunogenicity in order to stimulate the formation of protective antibodies.

(2) In TISSUE CULTURE, 'passage' refers to the transfer of an inoculum of cells from an existing cell culture to fresh growth medium in another vessel (i.e. subculture); 'serial passage' refers to repeated subculture. (This contrasts with the serial passage of a virus in tissue cultures: when a virus is passaged the *supernatant* is transferred.)

**series** A taxonomic rank (sometimes used in mycology) between subclass and order.

**L-serine biosynthesis** See Appendix IV(c).

**serine pathway** A cyclic metabolic pathway used by some types of methylotrophic bacteria for the assimilation of 1-C substrates (see METHYLOTROPHY). (A strain of *Streptomyces* has been reported to use both the serine pathway and the RMP PATHWAY, while at least some moulds (as opposed to yeasts) apparently use the serine pathway [Book ref. 3, p. 180].) In those methylotrophic bacteria which use the serine pathway, 1-C substrates are assimilated partly as formaldehyde (HCHO) and partly as CO<sub>2</sub>.

HCHO condenses with tetrahydrofolate (THF), thus forming 5,10-methylene-THF (MTHF); MTHF with glycine (enzyme: serine hydroxymethyltransferase, EC 2.1.2.1) yields serine and regenerates THF. Serine is deaminated (serine glyoxylate aminotransferase, EC 2.6.1.45) to hydroxypyruvate – this reaction

being linked to the conversion of glyoxylate to glycine. The reaction sequence continues thus: hydroxypyruvate → glycerate → 2-phosphoglycerate, the latter either being converted to 3-phosphoglycerate (phosphoglycerate mutase, EC 2.7.5.3) and assimilated into biomass, or converted to phosphoenolpyruvate (PEP). CO<sub>2</sub> enters the cycle at this point: with PEP (PEP carboxylase, EC 4.1.1.31) it forms oxaloacetate. The cycle continues oxaloacetate → malate → malyl-CoA, the latter being split (by a lyase, EC 4.1.3.24) to glyoxylate (used to regenerate glycine – see above) and acetyl-CoA. Acetyl-CoA with oxaloacetate (citrate synthase) initiates a subsidiary cycle, first forming citrate and then isocitrate – which is split (isocitrate lyase, EC 4.1.3.1) to glyoxylate and succinate, the latter being converted, in several steps, to oxaloacetate which re-enters the subsidiary cycle [see Appendix II(b)]; as before, glyoxylate is used to regenerate glycine.

The pathway described above is referred to as the icl<sup>+</sup> or icl<sup>+</sup> (isocitrate lyase) serine pathway. Some organisms which use the serine pathway (e.g. '*Pseudomonas* AM1') contain neither malate thiokinase (and hence cannot form malyl-CoA) nor isocitrate lyase (and hence cannot regenerate glyoxylate in the subsidiary cycle); the pathway in these organisms is called the icl<sup>-</sup> serine pathway. The way in which acetyl-CoA is used to regenerate glyoxylate (and glycine) in the icl<sup>-</sup> serine pathway is not yet understood; in the proposed 'homo-isocitrate pathway' acetyl-CoA condenses with 2-oxoglutarate to form homocitrate and then homoisocitrate which is cleaved to glyoxylate and glutarate – the latter being used to regenerate 2-oxoglutarate.

**serine proteases** See PROTEASES and type II systems in PROTEIN SECRETION.

**seroconversion** The development of antibodies in response to exposure to antigen.

**seroconversion illness** See AIDS.

**serodiagnosis** Diagnosis based on serological tests.

**serofactor 1** See YERSINIA (*Y. pestis*).

**serofast** Refers to a patient whose serum (sampled at intervals of time) consistently gives positive results in a given serological test.

**serological tests for syphilis** *Syn.* STANDARD TESTS FOR SYPHILIS.

**serological typing** See TYPING.

**serology** The study of in vitro reactions involving one or more of the constituents of SERUM (e.g. a particular type of ANTIBODY, or a component of COMPLEMENT) or of PLASMA (see e.g. clumping factor in COAGULASE); serology is used e.g. in medical diagnostic procedures to detect and/or quantify particular antigens or antibodies. See e.g. HAEMAGGLUTINATION-INHIBITION TEST, IMMUNOASSAY, WIDAL TEST.

**serotonin** 5-Hydroxytryptamine: a base (derived from tryptophan) with physiological activity similar to that of HISTAMINE; it occurs e.g. in the platelets of many species, and is also found e.g. in the MAST CELLS and basophils of some species.

(See also ENTEROCHROMAFFIN CELLS.)

**serotype** (serological type; serovar) A serologically (antigenically) distinct VARIETY (usually) within a bacterial species.

**serotyping** A method of TYPING in which strains are distinguished on the basis of differences in their surface ANTIGENS (e.g. cell wall, flagellar and/or capsular antigens). Essentially, each strain to be typed is tested with a variety of antibodies (different antibodies being specific for antigens on different strains of the organism). If the cells of an unknown (i.e. untyped) strain bind a particular antibody (indicated in vitro by agglutination or precipitation of the cells), the unknown strain is placed in the same category (type) as the strain homologous to that antibody.

Serotyping may be carried out in small test tubes (see also DREYER'S TUBE) or on slides (see SLIDE AGGLUTINATION TEST). (See also LATEX PARTICLE TEST.)

Strains distinguished mainly on the basis of their antigens are called *serotypes*.

**serovar** *Syn.* SEROTYPE.

**Serpens** A genus (*incertae sedis*) of catalase-positive, oxidase-positive, microaerophilic, chemoorganotrophic, Gram-negative bacteria which occur e.g. in sediments in freshwater ponds. Cells: flexible rods or filaments, 0.3–0.4 × 8.0–12.0 μm, which have bipolar tufts of flagella (4–10 flagella in each tuft) and some lateral flagella; the cells can exhibit motility in liquids of low and high viscosity, and a 'serpentine-like' motility within agar gels. Metabolism is respiratory (oxidative), with oxygen as terminal electron acceptor. The principal source of carbon and energy is lactate; carbohydrates are not used. NH<sub>4</sub>Cl or e.g. peptone (but not nitrite or nitrate) can serve as a source of nitrogen. Optimum temperature: 28–30°C. GC%: ca. 66. Type species: *S. flexibilis*. [Book ref. 22, pp. 373–375.]

**Serpula** A genus of fungi of the APHYLLOPHORALES (family Coniophoraceae). *S. lacrymans* (formerly *Merulius lacrymans*) causes DRY ROT; it typically forms a thick, resupinate, leathery, initially pale grey fruiting body which, when the basidiospores develop, becomes rusty red with a pale mycelial margin. The hymenium may be wrinkled or shallowly pitted, or it may occur on a layer of irregularly shaped, pendulous, tooth-like processes (the so-called 'stalactite' fruiting body); basidiospores: ellipsoidal, ca. 5 × 10 μm.

**serrated wrack** *Fucus serratus*.

**Serratia** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: 0.5–0.8 × 0.9–2.0 μm, usually motile. Some species and strains produce the non-diffusible pigment PRODIGIOSIN, forming colonies that are red or have red centres, margins or sectors; prodigiosin production is optimum on peptone–glycerol agar at 20–35°C, and occurs only under aerobic conditions. In the presence of Fe<sup>2+</sup>, some strains of *S. marcescens* produce a water-soluble pink pigment *pyrimine*, L-2-(2-pyridyl)-Δ'-pyrroline-5-carboxylic acid, which diffuses into the agar surrounding the colonies. Typical reactions: citrate +ve; MR –ve; VP +ve at 30°C, but may be –ve at 37°C (O'Meara's method may be –ve); extracellular enzymes include gelatinase, lipase and DNase. Glucose is fermented by the ENTER-DOUDOROFF PATHWAY. Lactose +ve or –ve, according to species. GC%: 52–60. Type species: *S. marcescens*.

*S. ficaria*. Prodigiosin –ve. Cultures have a musty, potato-like odour. Occurs mainly in association with figs and fig-wasps [Curr. Micro. (1979) 2 277–282].

*S. fonticola*. Atypical (species *incertae sedis*).

*S. liquefaciens* (formerly *Enterobacter liquefaciens*). Prodigiosin –ve. A heterogeneous species which may be split into three: *S. liquefaciens sensu stricto*, *S. proteamaculans* and *S. grimesii*.

*S. marcescens*. Biogroups A1 and A2 produce prodigiosin. Some strains produce pyrimine. *S. marcescens* is reported to exhibit a flagellum-independent *spreading* motility in which surface tension may be involved [JB (1995) 177 987–991].

*S. odorifera*. Prodigiosin –ve. Cultures have a musty, potato-like odour.

*S. plymuthica*. Most strains produce prodigiosin.

*S. rubidaea* (= *S. marinorubra*). Most strains produce prodigiosin.

*Serratia* spp occur in water and soil, on plants, in insects, and in man and animals (see also DFD MEAT). *S. marcescens*

and *S. liquefaciens* may cause lethal septicaemia in insects [JGM (1983) 129 453–464]. Species have also been associated with disease in reptiles, spoilage of hens' eggs, bovine mastitis etc. In man, *S. marcescens* (especially non-pigmented strains) are increasingly frequent causes of nosocomial infections (e.g. pneumonia, UTI). (See also PSEUDOHAEMOPTYSIS; RED DIAPER SYNDROME.)

[Book refs. 22, pp. 477–484, and 46, pp. 1187–1203.]

**serum** The fluid fraction of coagulated (clotted) blood; it differs from PLASMA e.g. in that it does not contain FIBRINOGEN (a factor in the clotting mechanism). Normal serum contains e.g. various nutrients, electrolytes, albumins, immunoglobulins, waste products.

**serum amyloid A** See ACUTE-PHASE PROTEINS.

**serum hepatitis** *Syn.* HEPATITIS B.

**serum killing** The killing of some strains of Gram-negative bacteria, by either immune or non-immune serum, due mainly or solely to activation of the alternative pathway of COMPLEMENT FIXATION; such *serum sensitivity* may be greater in rough mutants and less or non-existent in capsulated strains [JGM (1983) 129 2181–2191]. (See also SURFACE EXCLUSION.)

**serum sensitivity** See SERUM KILLING.

**serum sickness** A systemic condition, involving a TYPE III REACTION, which may occur ca. 8 days after the initial administration of a large amount of antigen (given e.g. during passive immunization); in such cases antigen is still circulating when antibody first appears in the plasma, and soluble antigen–antibody complexes are formed due to ANTIGEN EXCESS. A generalized inflammatory reaction occurs, with fever, enlargement of lymph nodes, swelling of joints, a generalized urticarial rash, and sometimes renal dysfunction. (cf. GLOMERULONEPHRITIS.)

**serum sugars** See PEPTONE-WATER SUGARS.

**serum water sugars** See under PEPTONE-WATER SUGARS.

**sessile** (1) Of an organism (e.g. a protozoon): attached to the substratum (with or without a stalk), i.e., not free-swimming. (2) Of a fruiting body, spore etc: attached directly, i.e., *without* a stalk, to the substratum, sporophore etc; e.g., the sessile basidiospores of the smut fungi lack sterigmata, arising directly from the basidia.

**Sessilina** See PERITRICHIA.

**sessilinid** A member of the Sessilina.

**seston** All the fine particulate matter which drifts passively in lakes, seas and other bodies of water; it includes PLANKTON and TRIPTON.

**set2 gene** See EIEC.

**seta** (*pl.* setae) A bristle-like structure. Setae occur e.g. in some types of fungal fruiting body; in some species of *Colletotrichum*, some of the setae which occur in acervuli have truncated, near-colourless apices which give rise to conidia, while the darker, usually pointed setae are sterile [Mycol. (1984) 76 359–362].

**setose** Bearing setae – see SETA.

**severe combined immunodeficiency (SCID)** A heterogeneous group of immune deficiency diseases in which the common feature is a block in the development of T lymphocytes; in some of these diseases there is also a deficiency in B lymphocytes and/or NK cells. A consequence of such immunodeficiency is a marked susceptibility to opportunist pathogens coupled with a poor prognosis. (cf. DIGEORGE SYNDROME.)

One of the SCID diseases is ADENOSINE DEAMINASE DEFICIENCY (q.v.), resulting from mutation in the *ADA* gene.

Another of these diseases is caused by mutation in the gene encoding the γc subunit that is common to the cell-surface receptors of various CYTOKINES – including the interleukins IL-2, IL-4, IL-7, IL-9 and IL-15 [see e.g. Cell (1993) 73 147–157];

## severin

deficiency in the receptor for IL-7 inhibits development of T cells, while deficiency in the receptor for IL-15 inhibits development of NK cells. The gene encoding the  $\gamma$ c subunit occurs on the X chromosome, and this (X-linked) disease is designated XSCID or SCIDX1.

SCIDX1 can be treated successfully by GENE THERAPY: CD34<sup>+</sup> cells were infected, *ex vivo*, with a retrovirus-derived vector carrying the gene for  $\gamma$ c [Science (2000) 288 669–672]. In one patient, however, this therapy apparently caused a leukaemia-like illness [Nature (2002) 420 116–118].

During normal stimulation of cell-surface receptors containing the (wild-type)  $\gamma$ c subunit, a kinase, designated JAK-3, binds to the intracellular domain of  $\gamma$ c as part of the intracellular signalling process. A phenotype similar to that of SCIDX1 can therefore be caused by mutation in the *JAK-3* gene which inactivates the kinase; unlike the gene encoding  $\gamma$ c, *JAK-3* is an autosomal gene, and mutations in *JAK-3* give rise to an autosomal recessive form of the disease in which (like the X-linked form) both T cells and NK cells are affected.

[Primary immunodeficiency diseases (an experimental model for molecular medicine): Lancet (2001) 357 1863–1869 (SCID: 1864–1865).]

**severin** See ACTIN.

**sewage fungus** Slimy, macroscopic masses of mixed microbial growth which develop on rocks etc in many organically polluted (e.g. sewage-polluted) freshwater habitats. The organisms which contribute to sewage fungus are typically those which occur as part of the normal microflora of the habitat; they include bacteria (e.g. *Sphaerotilus natans*, *Zoogloea* spp), fungi (e.g. *Fusarium* spp, *Geotrichum candidum*), protozoa (e.g. *Carchesium polypinum*), and algae (e.g. *Stigeoclonium* spp). Usually, a particular sample of sewage fungus contains one, or a few, dominant species; the dominance of a given species may correlate e.g. with the availability of a particular carbon source.

**sewage treatment** Sewage includes domestic wastes (from drains, water closets etc.) – sometimes with varying amounts of agricultural and/or industrial effluent – and (often) the contents of rain-water drains; it contains substances in suspension, in solution and in colloidal form.

If discharged to environmental waters, sewage can be harmful in several ways. For example, it can act as a source of infection – encouraging the spread of water-borne diseases such as CHOLERA and TYPHOID FEVER. (See also SHELLFISH POISONING.) Another problem is its content of biodegradable organic matter. In metabolizing these nutrients, the large numbers of sewage organisms can rapidly deplete the oxygen at a locally polluted site, especially in slow-moving or static waters; the consequent development of a microaerobic or anaerobic environment means a loss of habitat for all oxygen-dependent organisms (e.g. fish) in the vicinity. Moreover, anaerobic conditions allow the growth of SULPHATE-REDUCING BACTERIA and other microorganisms whose metabolic products include sulphide and other malodorous substances.

Sewage treatment has two main objectives: (i) to eliminate (or reduce the numbers of) pathogens which cause water-borne diseases, and (ii) to diminish the oxygen-depleting capacity of sewage, i.e. to reduce its BOD.

Small quantities of sewage (e.g. from one or several houses in isolated rural areas) may be treated in a SEPTIC TANK.

Large-volume sewage (from urban areas) is treated by a two-stage process, described below.

*Primary treatment* may involve simply passing the raw (i.e. untreated) sewage through a screen of metal bars to separate, and

dispose of, the grosser debris; the screened sewage may then be passed through a *comminutor* (a rotary shredding device which breaks up the smaller solids). The screened, comminuted sewage effluent then passes slowly through a sedimentation (settling) tank in which some particulate matter settles out (and is removed as sludge). Sedimentation is sometimes assisted by the addition of alum as the effluent enters the sedimentation tank.

*Secondary treatment* is designed to reduce the BOD of the primary effluent to acceptable levels by microbial oxidation of the dissolved organic content. This is usually achieved by one of three types of (aerobic) process: the trickle filter, the activated sludge process and the (more recent) biological aerated filter (BAF); these processes are considered below.

The *trickle filter* (*biological filter*, *percolating filter*) consists of a bed of crushed rock, ca. 2 m deep, over which the primary sewage effluent is sprayed. The bed of rock may be enclosed within a circular wall, the sewage being sprayed through holes in the arms of a rotary sprinkler; with a rectangular bed of rock, sewage is sprayed from a distributor arm moving backwards and forwards. The rock surface bears a film of microorganisms – for example, the bacterium *Zoogloea ramigera* and species of ciliate protozoa (e.g. *Carchesium*, *Chilodonella*, *Opercularia* and *Vorticella*). (Also commonly present are e.g. rotifers, crustaceans, insects and arachnids.)

Percolating slowly through the crushed rock, the sewage makes close contact with surfaces that bear the biofilm. The sprayed sewage carries with it dissolved oxygen, so that some of the dissolved organic matter can be oxidized by organisms in the sewage and by those in the biofilm; moreover, some dissolved organic carbon is assimilated, as biomass, by these organisms. The system is not intended to act as a mechanical sieve – but rather to permit close contact between the biofilm and sewage under aerobic conditions; this reduces the level of dissolved organic matter. Moreover, large numbers of sewage bacteria are ingested by protozoans in the biofilm.

Effluent leaving the bed usually contains small particles of biofilm washed from the rock; these particles may be allowed to settle in a *humus tank* before the supernatant is discharged as the final effluent. The final effluent has a much lower BOD – so that, if discharged to a river etc., it will take less oxygen from the water.

The *activated sludge* process is another form of aerobic secondary treatment. Effluent from the primary treatment stage enters a vessel containing activated sludge – a mass of organisms consisting mainly of bacteria (e.g. species of *Acinetobacter* and *Alcaligenes*, *Sphaerotilus natans* and *Zoogloea ramigera*) and protozoa; the latter include ciliates (e.g. *Aspidisca*, *Carchesium*, *Opercularia*, *Trachelophyllum*, *Vorticella*), flagellates, and the testate amoebae *Cochliopodium* and *Euglypha* – amoebae often being found in large numbers and sometimes forming the major component of the biomass. Other organisms present include fungi, rotifers and nematodes. Effluent and sludge are vigorously agitated and aerated for e.g. 6–12 hours so that much of the soluble organic matter in the effluent is oxidized, or assimilated, by the biomass; the BOD is thus greatly reduced, and large numbers of sewage bacteria are ingested by protozoa. The treated effluent is then left in a sludge-settling tank. Good-quality final effluent depends on efficient *flocculation* (= aggregation) of the organisms, this facilitating clarification of the effluent by sedimentation. Flocculation is encouraged by cell-surface hydrophobicity which promotes (i) adherence of cells to flocs, and (ii) *penetration* of the flocs by cells via channels/pores within the

flocs [see Microbiology (1998) 144 519–528]. [Microbial communities in sewage treatment plants: FEMS Ecol. (1998) 25 205–215.]

In this process, the sludge increases in mass due to microbial growth; following sedimentation, most is removed for disposal, some being retained for treating the next batch of sewage.

The *biological aerated filter* (BAF) is a more efficient approach to aerobic secondary treatment. It consists of a *submerged* bed of fine granular material coated with biofilm; the sewage passes downwards through the bed while air is pumped in at the base of the bed. Because the granules are small, the system can function as a mechanical filter (for fine particulate matter) as well as allowing mineralization of dissolved organic matter. The biofilm in a BAF contains up to five times more biomass than that in a trickle filter of equivalent size – so that, for a given treatment capacity, a BAF can be much smaller.

Appropriate flow conditions in the BAF allow adequate aeration and the establishment of nitrifying bacteria in the biofilm. The importance of this is that NITRIFICATION facilitates the elimination of nitrogen from sewage; thus, if nitrification can be achieved it can be followed by DENITRIFICATION. To encourage denitrification the BAF can be operated anaerobically; much of the nitrogen in sewage can therefore be eliminated by operating aerobic and anaerobic BAF reactors in series. [Combined nitrification–denitrification: FEMS Reviews (1994) 15 109–117.]

*Anaerobic* treatment is useful for sewage containing a high proportion of solids (e.g. farm waste, sludge from the activated sludge process). In this process (ANAEROBIC DIGESTION), the stirred sludge is digested in a tank maintained at ca. 35°C. This reduces the bulk of sludge, giving a less offensive material which can be de-watered in sludge-drying beds; much of the carbon is eliminated as methane (which can supply most or all of the energy needs of the plant). (See also IMHOFF TANK.)

Anaerobic treatment can also be used e.g. for wastewater containing terephthalic acid (1,4-benzenedicarboxylic acid) and its isomers – compounds used in the manufacture of polyester products and plastic bottles; in one study, organisms associated with the anaerobic granular sludge system included a high proportion of unidentified bacteria of the  $\delta$ -Proteobacteria and a number of archaeans related to *Methanosaepta* and *Methanospirillum* [Microbiology (2001) 147 373–382].

*Tertiary treatment* is sometimes used to reduce still further the BOD of the effluent; this may be needed e.g. if discharge of final effluent to a river is associated with a low dilution factor. To reduce the amount of fine particulate matter, the effluent can be passed through a *microstrainer*: a hollow cylinder of fine-mesh stainless steel fabric, closed at one end, which rotates on a horizontal axis; effluent is pumped into the cylinder, and strained effluent passes out through the mesh – material retained on the inner surface of the cylinder being constantly removed by jets of water.

The *Immediat filter* is a sand filter in which the grain size increases progressively from top to bottom; effluent flows *upwards* through the filter. Other forms of filter, and grassland irrigation, are also used for tertiary treatment.

The main purpose of tertiary treatment is often regarded as the reduction of BOD by elimination of *carbon* from the effluent. However, removal of *nitrogen* (present mainly as ammonia and nitrate) and *phosphorus* is also desirable in order to discourage the development of algal BLOOMS in the receiving waters. (See also EUTROPHICATION.) The elimination of nitrogen was considered earlier (see BAF). Phosphorus has been removed

by using a cycle of alternating anaerobic and aerobic treatments. Anaerobically, some organisms increase in biomass but release phosphorus; aerobically, the (increased) biomass assimilates phosphorus – and is subsequently separated and disposed of. The bacterium *Acinetobacter calcoaceticus* is reported to accumulate phosphate (up to ~10% dry weight), >50% as POLYPHOSPHATE. [Biological phosphorus removal: MS (1984) 1 149–152. Identification of polyphosphate-accumulating bacteria for biological phosphorus removal in activated sludge plants: AEM (2000) 66 1175–1182.]

*Disinfection* of final effluent has been carried out with e.g. CHLORINE or OZONE. In at least one plant in the USA, de-watered sludge (50% solids) has been disinfected with IONIZING RADIATION (dose: 1 Mrad from a <sup>137</sup>caesium *gamma* source).

[Bacterial activities in sewage treatment plants: AvL (1984) 50 665–682. Environmental health engineering in the tropics: Book ref. 216. Low-cost sewerage for developing countries: Book ref. 217.]

**sewer gas** See ANAEROBIC DIGESTION.

**sewer swab** *Syn.* MOORE SWAB.

**sex factor** (1) A general term for a CONJUGATIVE PLASMID (sense 1). (2) Collectively, those genes in a conjugative plasmid which specify conjugation (see e.g. RTF). (3) *Syn.* F PLASMID.

**sex pheromone** See PHEROMONE.

**sex pili** See PILLI.

**sex-ratio organism** See SRO.

**sexduction** The transfer, by CONJUGATION (sense 1b), of *chromosomal* genes from one bacterium to another. Sexduction may involve an HFR DONOR or a donor strain carrying a PRIME PLASMID; if the chromosome of the Hfr donor is mobilized by the F PLASMID, or if conjugal transfer is promoted by an F' plasmid, the process is called *F-duction*.

**sexually transmitted disease** (STD) Any disease which can be transmitted by intimate contact with e.g. genitals, mouth or rectum. In addition to the 'classical' VENEREAL DISEASES, STDs include e.g. AIDS, HEPATITIS B, HERPES SIMPLEX, MOLLUSCUM CONTAGIOSUM, NON-GONOCOCCAL URETHRITIS, TRICHOMONIASIS, and genital warts (see PAPPILLOMA), as well as parasitic infestation by lice ('crab') or mites (scabies, 'the itch').

**Sézary syndrome** (SS) A cutaneous T-cell lymphoma which resembles – but is distinct from – ADULT T-CELL LEUKAEMIA; HTLV-I provirus has been detected only rarely in SS, and does not appear to be a primary causal agent. The neoplastic T cells in SS may resemble those of ATL, but the nucleus is more commonly cerebriform than multilobed; ATL and SS cells are antigenically distinct and are functionally distinct *in vitro* [Book ref. 106, pp. 275–284].

**SFFV** See FRIEND VIRUS and RAUSCHER VIRUS.

***sfiA*, *sfiB* genes** See SOS SYSTEM.

**SFV** SEMLIKI FOREST VIRUS.

**S<sub>G</sub>** Gower coefficient. In the comparison of two strains by NUMERICAL TAXONOMY: an expression of the degree of similarity in which the comparison involves both simple, discontinuous data (e.g. + and –, or 0 and 1) and continuous (quantitative) data. (cf. entry S<sub>SM</sub>.)

**SH-activated cytolytins** THIOL-ACTIVATED CYTOLYSINS.

**SH antigen** *Syn.* HBsAg: see HEPATITIS B VIRUS.

**shaded matrix** In NUMERICAL TAXONOMY: a graphic representation of the interrelationships between the OTUs in a given study. It is a triangular tabulation, the ordinate and abscissa each consisting of a complete list of designations of the OTUs under study; the degree of mutual similarity between the OTUs in any given cluster is indicated by the intensity of shading; the highest degree of similarity corresponds to the darkest shading.

## shadow-casting

**shadow-casting** See ELECTRON MICROSCOPY (a).

**shadow yeasts** *Syn.* MIRROR YEASTS.

**shadowing** See ELECTRON MICROSCOPY (a).

**shake culture** (1) A procedure used e.g. for the isolation of anaerobic bacteria. The inoculum is dispersed (by gentle shaking) in a molten agar medium (at ca. 48°C) in a long glass test-tube or a VEILLON TUBE; the agar is allowed to set, and the tube is incubated. An individual colony in the lower (anaerobic) part of the agar can be removed for subculture. (2) A culture in a *liquid* medium which is continually shaken to ensure aerobiosis in the medium.

**sharka disease** *Syn.* PLUM POX.

**sharp eyespot** See EYESPOT (sense 2).

**sheath** (1) In SHEATHED BACTERIA: a secreted, tubular structure formed around a chain of cells or around a bundle of filaments; cells may or may not subsequently separate from the sheath.

(2) In certain bacteria: a layer of outer membrane covering the flagellum (see FLAGELLUM (a)).

(3) See 'outer sheath' in SPIROCHAETALES.

**sheath blight** (of rice) CEREAL DISEASES.

**sheathed bacteria** Species of e.g. HALISCOMENOBACTER, LEP-TOTHRIX, SPHAEROTILUS, THIOPLOCA and THIOTHRIX which form sheathed trichomes or fascicles.

**sheathed flagellum** See FLAGELLUM (a).

**sheep cell agglutination test (SCAT)** (1) The PAUL-BUNNELL TEST or, in general, any test in which non-sensitized sheep erythrocytes are agglutinated. (2) The ROSE-WAALER TEST.

**sheep diseases** Sheep are susceptible to a wide range of diseases, some of which are specific to sheep. (a) *Bacterial diseases*: see e.g. ANTHRAX, BLACK DISEASE, BRAXY, BRUCELLOSIS, CAMPYLOBACTERIOSIS, ENZOOTIC ABORTION, FOOT ROT, JOHN'S DISEASE, JOINT-ILL, LAMB DYSENTERY, LISTERIOSIS, LUMPY WOOL, PULPY KIDNEY, SCALD, STRUCK, SWELLED HEAD, TULARAEMIA; cf. WIMMERA GRASS POISONING. (b) *Fungal diseases*: see e.g. ASPERGILLOSIS. (c) *Mycotoxicoses*: see e.g. LUPINOSIS, PASPALUM STAGGERS, PENITREMS, SPORIDESMINS. (d) *Viral diseases*: see e.g. BLUETONGUE, BORDER DISEASE, CONTAGIOUS PUSTULAR DERMATITIS (sense 1), FOOT AND MOUTH DISEASE, JAAGSIEKTE, LOUPING-ILL, MAEDI, NAIROBI SHEEP DISEASE, PESTE DES PETITS RUMINANTS, RIFT VALLEY FEVER, SHEEP POX, VISNA; cf. SCRAPIE. (See also SHEEP SCAB.)

**sheep pox** (variola ovina) An acute, infectious disease specific to sheep; the causal agent, a *Capripoxvirus*, appears to infect via abrasions or e.g. by droplet infection. Incubation period: 2 days to 2 weeks. Adult sheep typically develop vesicular, scab-forming lesions on the skin; there is no systemic involvement and mortality rates are generally low, but in ewes the disease may predispose towards mastitis if the udder is affected. In lambs (and sometimes in adult sheep) the disease involves e.g. fever, nasal discharge, and the development of lesions on the skin and buccal mucosa and in the alimentary, respiratory and urogenital tracts; mortality rates can be high, and lambs may die even before the skin lesions develop. (cf. GOAT POX.)

**sheep-pox subgroup** See CAPRIPPOXVIRUS.

**sheep scab** A (non-microbial) disease caused by bites of the mite *Psoroptes ovis*; symptoms: itching, skin lesions, and wool shedding.

**shelf fungi** *Syn.* BRACKET FUNGI.

**shell** (*virol.*) A term used by some authors to refer to a CAPSID.

**shell disease** (1) *Syn.* BURNED SPOT DISEASE. (2) See OSTRACOBLABE IMPLEXA.

**shell vial assay** A (qualitative or quantitative) method for detecting human cytomegalovirus (HCMV) in which the specimen

is centrifuged onto a culture of fibroblasts and the preparation subsequently stained with fluorescent monoclonal antibodies specific for the 72 kDa phosphoprotein product (p72) of an immediate-early gene.

**shellfish diseases** See e.g. CRUSTACEAN DISEASES and OYSTER DISEASES.

**shellfish poisoning** A form of FOOD POISONING which results from the consumption of shellfish (molluscs, crustacea) contaminated with toxins or pathogens. Aquatic *bivalve molluscs* (clams, cockles, mussels, oysters etc) obtain their food by filtering microscopic organisms from the ambient water. Any human pathogens present in the water can thus be concentrated in the bodies of the shellfish and can cause disease when these are eaten by humans. Pathogens transmitted in this way include e.g. HEPATITIS A virus, enteroviruses, 'parvovirus-like agents' (see FOOD POISONING (i)), and salmonellae (including *S. typhi*); such pathogens typically derive from sewage, whereas *Vibrio parahaemolyticus* (see FOOD POISONING (h)) is a natural inhabitant of brackish and marine waters. *Gastropod molluscs* (e.g. whelks, winkles) and *crustacea* (e.g. lobsters, prawns) are not filter-feeders but may nevertheless become contaminated with pathogens which may be derived from the natural habitat of the animal (as e.g. in the case of *V. parahaemolyticus*) or may be introduced during the handling and processing of the shellfish (as e.g. in the case of staphylococci). (See also FISH SPOILAGE.)

*Paralytic shellfish poisoning (PSP, 'mussel poisoning')* is a severe, often fatal condition resulting from the consumption of shellfish (commonly mussels or clams) which have themselves consumed neurotoxin-forming dinoflagellates (e.g. *Gonyaulax* spp) and accumulated the toxin(s) – e.g. SAXITOXIN – in their tissues. (See also RED TIDE.) Symptoms of PSP (caused by saxitoxin) typically include diarrhoea, fatigue, and a tingling sensation beginning around the face and spreading to the arms, fingers, and toes; later, numbness may develop, followed by weakness, paralysis, and death (usually within 12 hours) from respiratory paralysis. (cf. CIGUATERA.)

**sherry** See WINE-MAKING.

**ShET2 enterotoxin** See EIEC.

**Shewanella** A genus of bacteria proposed to include *Alteromonas hanedai* (*S. hanedai*), *A. putrefaciens* (*S. putrefaciens*), and strains of barophilic bacteria (see BAROPHILE) isolated from deep-sea waters (*S. benthica*) [SAAM (1985) 6 171–182; name validation: IJSB (1986) 36 354–356]. (cf. ALTEROMONAS.)

**shield cell** (*algol.*) See CHAROPHYTES.

**shift up, shift down** (Refers to) a change in (experimental) conditions which causes the growth rate of a microorganism to increase (shift up) or decrease (shift down).

**Shiga-Kruse bacillus** *Shigella dysenteriae* serotype 1.

**shiga-like toxins** See SHIGA TOXIN.

**shiga toxin** A protein toxin, produced by strains of *Shigella dysenteriae*, which apparently causes at least some of the symptoms of (bacillary) DYSENTERY; the toxin is cytotoxic *in vivo*, and is also toxic for some types of cultured cells (e.g. HeLa).

The shiga holotoxin consists of an A subunit associated with a pentameric ring of B subunits. The holotoxin binds, via B subunits, to glycolipid receptor sites on the target cell; these receptors – globotriosylceramide (Gb<sub>3</sub>) – are found e.g. in the membrane of endothelial cells (cells that line blood vessels). Shiga toxin is reported to be active against e.g. endothelial cells, colonic/ileal epithelial cells, and B lymphocytes expressing the CD77 ANTIGEN.

On uptake of toxin by a cell, the A subunit undergoes proteolytic cleavage, the (catalytic) part of the subunit remaining

attached temporarily by a disulphide bond – which is later reduced. The catalytic part of the A subunit has *N*-glycosidase activity: it cleaves a *specific* adenine residue from the 28S rRNA in eukaryotic ribosomes; this inhibits protein synthesis (by inhibiting the EF-1-mediated binding of tRNA), resulting in cell death. (This mechanism is identical to that of the plant toxin *ricin*.)

[Enteric bacterial toxins (mode of action and relevance to intestinal secretion): MR (1996) 60 167–215.]

*Shiga-like toxins* (verotoxins; verocytotoxins; Vero cell cytotoxins) are produced by so-called *enterohaemorrhagic* strains of *Escherichia coli* (see EHEC). These (phage-encoded) toxins are classified as shiga-like toxins I and II (SLT-I, SLT-II); SLT-I is virtually identical to the shiga toxin of *Shigella dysenteriae* type 1. Note that these toxins are also called ‘shiga toxins’ or ‘Shiga toxins’; thus, with this terminology, SLT-I has been abbreviated to Stx1, and SLT-II to Stx2. There are a number of variant forms of SLT-II, each designated by a lower-case letter. A new variant form of SLT-II (Stx2f) has been isolated from *E. coli* in the faeces of pigeons (*Columba livia*) [AEM (2000) 66 1205–1208].

All members of the shiga toxin family appear to share a common membrane receptor site and apparently have the same mode of action.

The precise role of these toxins in pathogenesis is uncertain. However, it has been suggested that they may act as *vasculotoxins* whose primary target is the vascular endothelium. In one model of EHEC pathogenesis, macrophages, adherent at toxin-mediated vascular lesions, are stimulated to secrete certain pro-inflammatory cytokines (TNF- $\alpha$ , IL-1) which upregulate local expression of Gb<sub>3</sub> sites – resulting in further toxin binding and exacerbation of vascular damage [TIM (1998) 6 228–233].

(See also STARFISH.)

**Shiga's bacillus** *Shigella dysenteriae* serotype 1.

**Shigella** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: straight rods, 0.5–1.0  $\times$  1–3  $\mu$ m, non-motile. Growth occurs e.g. on nutrient agar, MacConkey's agar and EMB agar, may or may not occur on more inhibitory media (e.g. DCA, SS agar), and does not occur on KCN media. Sugars are fermented to acid (usually without gas). MR +ve; VP –ve; citrate –ve; H<sub>2</sub>S –ve (in TSD); phenylalanine deaminase –ve; lysine decarboxylase –ve. GC%: 49–53. Type species: *S. dysenteriae*.

*Shigella* spp are intestinal pathogens of man and other primates (see bacillary DYSENTERY); other animals are normally resistant. In animal studies, *Shigella* is reported to be taken up by the M cells of Peyer's patches [e.g. TIM (1998) 6 359–365].

*S. boydii* (= subgroup C). 18 serotypes. Mannitol is fermented, lactose is not.

*S. dysenteriae* (= subgroup A). 12 serotypes. Serotype 1 is catalase –ve and produces SHIGA TOXIN. Mannitol and lactose are (usually) not fermented.

*S. flexneri* (= subgroup B). 6 serotypes. Most strains ferment mannitol but not sucrose or lactose; serotype 6 includes the Newcastle strain (mannitol not fermented, gas produced from glucose), the Manchester strain (acid and gas from glucose and mannitol), and the Boyd 88 strain (acid, no gas, from glucose and mannitol).

*S. sonnei* (= subgroup D). One serotype with two ‘phases’, I and II (resembling the SMOOTH-ROUGH VARIATION of other enterobacteria). Mannitol is fermented; fermentation of lactose and sucrose is detectable after 24 hours. Strains are identified by colicin TYPING.

[Book ref. 22, pp. 423–427; serology: Book ref. 68, pp. 113–142.]

[Recommendations on the classification of shigellae: IJSB (1984) 34 87–88.]

**shigellosis** See DYSENTERY (a). (cf. SLEEPY FOAL DISEASE.)

**shii-take** The edible mushroom *Lentinula edodes* (formerly *Lentinus edodes* or *Cortinellus edodes*) traditionally cultivated in Japan. Hardwood logs are inoculated via drill-holes; fruiting, which occurs in spring and autumn, begins after ca. 8 months and may continue for several years.

**shikimate pathway** See Appendix IV (f).

**Shine–Dalgarno sequence** See PROTEIN SYNTHESIS.

**shingles** *Syn.* HERPES ZOSTER.

**shipping fever** See BOVINE RESPIRATORY DISEASE.

**shipyard eye** *Syn.* EPIDEMIC KERATOCONJUNCTIVITIS.

**Shirlan** See SALICYLANLIDES.

**shmoo cell** A large, asymmetrical, often pear-shaped yeast cell formed e.g. by the action of a sex PHEROMONE.

**shock-sensitive transport system** *Syn.* BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**shoestrings** *Syn.* boot laces: see ARMILLARIA.

**Shope fibroma virus** See LEPORIPOXVIRUS.

**Shope papilloma virus** See PAPILOMAVIRUS.

**short-incubation hepatitis** *Syn.* HEPATITIS A.

**short patch repair** See EXCISION REPAIR.

**shotgun experiment** A CLONING experiment in which the entire genome of an organism is cut into random fragments and cloned (e.g. to generate a genomic LIBRARY).

**showdomycin** A NUCLEOSIDE ANTIBIOTIC which structurally resembles uridine; it inhibits e.g. UMP kinase and other enzymes.

**shoyu** *Syn.* SOY SAUCE.

**shufflon** A term proposed for a cluster of DNA segments (within e.g. a plasmid) which can invert independently or in groups, resulting in complex rearrangements of the DNA. Such a ‘clustered inversion region’ has been observed in the IncI $\alpha$  plasmid R64; it appears to function as a biological switch, regulating the selection of one of 7 possible open reading frames [NAR (1987) 15 1165–1172]. (cf. RECOMBINATIONAL REGULATION.)

**Shukla's method** See IMMUNOSORBENT ELECTRON MICROSCOPY.

**shut-down cell** *Syn.* GROWTH PRECURSOR CELL.

**shuttle vector** (bifunctional vector) A CLONING vector which can replicate in more than one type of organism; e.g., a shuttle vector which can replicate in both *Escherichia coli* and *Saccharomyces cerevisiae* can be constructed by linking sequences from an *E. coli* plasmid with sequences from the yeast 2 $\mu$  plasmid.

**SHV  $\beta$ -lactamase** See  $\beta$ -LACTAMASES.

**Shwartzman reaction** The *local* Shwartzman reaction involves localized skin necrosis which occurs when an intravenous injection of e.g. ENDOTOXIN (sense 1) is given some hours after an intradermal injection of endotoxin.

The *generalized* Shwartzman reaction (GSR) is a poorly understood, complex syndrome exhibited when a second intravenous injection of endotoxin is given 24 hours after the first; it is characterized by intravascular coagulation and shock. Various mechanisms have been proposed to account for the intravascular coagulation; in one, COMPLEMENT-FIXATION leads to injury of immature PMNs which release factors that promote clotting. In other models macrophages are considered to be the primary cellular effectors. (cf. ENDOTOXIC SHOCK.)

**sialic acids** See NEURAMINIC ACID.

**sialyl-Lewis x** See INFLAMMATION.

**sib sequence** See BACTERIOPHAGE  $\lambda$ .

**sibiromycin** See ANTHRACYCIN.

**Sicilian sandfly fever virus** See PHLEBOVIRUS.

## sickener

**sickener** See RUSSULA.

**SID test** (*vet.*) SINGLE INTRADERMAL TEST.

**SIDD** Supercoiling-induced duplex destabilization (= stress-induced duplex destabilization); destabilization (involving strand separation) of a particular region (a SIDD site) in a DNA duplex as a response to a given level of superhelicity. In a model for the activation of the *ihv*<sub>PG</sub> promoter in *Escherichia coli*, destabilization of an upstream SIDD site is counteracted by the binding of INTEGRATION HOST FACTOR close to the site; this causes translocation of superhelical energy to the (downstream) –10 sequence of the promoter – thus facilitating the formation of an open complex and initiating transcription from the promoter [see e.g. Mol. Microbiol. (2001) 39 1109–1115 (1112)].

**sideramines** (1) *Syn.* SIDEROPHORES. (2) *Syn.* hydroxamate SIDEROPHORES.

**Siderocapsa** A genus of IRON BACTERIA. Cells: cocci or coccoid forms which occur singly or in clusters within a common capsule. Type species: *S. treubii*.

**siderochromes** *Syn.* SIDEROPHORES.

**Siderococcus** A genus of bacteria found e.g. in soil [see e.g. Book ref. 45, pp. 1049–1059].

**sideromycins** Iron-chelating ANTIBIOTICS, formed by certain actinomycetes, which are structurally related to hydroxamate SIDEROPHORES; it appears that the iron-chelating part of the molecule permits transport into the target cell, and that the other part of the molecule, which is released by intracellular hydrolysis, is the (as yet uncharacterized) toxic moiety. Sideromycins include *albomycin* and the *ferrimycins* – analogues of ferrichrome and ferrioxamine, respectively.

**siderophilins** A family of ferric IRON-chelating glycoproteins which occur in vertebrates: see e.g. LACTOFERRIN and TRANSFERRIN. (cf. FERRITIN; see also SIDEROPHORES.) Certain pathogens (such as *Neisseria gonorrhoeae* and *N. meningitidis*) can obtain iron directly from siderophilins [acquisition of transferrin-bound iron by pathogens: Mol. Microbiol. (1994) 14 843–850]; some pathogens (including the species of *Neisseria* referred to) have cell-surface receptors for human transferrin, and such receptors have been considered as potential targets for VACCINE production.

**siderophores** (*syn.* ironophores; siderochromes) Low-molecular-weight ferric iron-chelating compounds synthesized and exported by most microorganisms for the sequestration and uptake of IRON (q.v.). The two main structural classes of siderophores are catecholamides and hydroxamates; a given organism may produce siderophores of one or both classes. (Typically, iron is bound more tightly by catecholamides than by hydroxamates.) Some siderophores are PLASMID-encoded (see e.g. COLV PLASMID).

*Catecholamides* ('phenolates') are derivatives of catechol (*o*-dihydroxybenzene). One example is *enterobactin* (= *enterochelin*): a cyclic trimer of 2,3-dihydroxy-*N*-benzoyl-L-serine produced e.g. by various enterobacteria; in *Escherichia coli* it is synthesized by condensation of 2,3-dihydroxybenzoic acid (formed via chorismic acid) with L-serine – the synthesis involving products of genes *entA–entG*. In *E. coli* the cell-surface receptor for enterobactin is the FEPA PROTEIN. *Parabactin* is a catecholamide formed by *Paracoccus denitrificans* from *N*<sup>1</sup>,*N*<sup>8</sup>-bis(2,3-dihydroxybenzoyl)spermidine ('compound II'). *Vibrio anguillarum* forms a novel catechol-type siderophore, *anguibactin* [characterization of anguibactin: JB (1986) 167 57–65].

*Hydroxamates*, derivatives of hydroxamic acid (R.CO.NHOH), include *aerobactin*, a siderophore formed e.g. by various enterobacteria; genes encoding the aerobactin system – the

siderophore itself (*iucA–iucD*) and its (outer membrane) receptor protein (*iutA*) – are carried by many COLV PLASMIDS, although the system may also be chromosomally encoded. [Plasmid-specified aerobactin system: Book ref. 161, pp. 741–757; characterization of the *iucA* and *iucC* genes: JB (1986) 167 350–355.] The products of the *fluB*, *fluC* and *fluD* genes, located in the cytoplasmic membrane and/or periplasm, may form a binding system for the uptake of iron by aerobactin and other hydroxamate siderophores [JGM (1992) 138 597–603].

In *Escherichia coli*, the outer membrane receptor for aerobactin, the IutA protein, can also bind CLOACIN DF13. In *E. coli*, the aerobactin and enterobactin systems can be induced independently [Inf. Immun. (1986) 51 942–947]; both systems apparently require the TONB PROTEIN for transport into the periplasm [JGM (1992) 138 597–603].

Other hydroxamate siderophores include e.g. *coprogen* (produced by many fungi); *ferrichrome* (formed e.g. by species of *Aspergillus*, *Neurospora* and *Ustilago*); a cyclic hexapeptide consisting of a glycine tripeptide and a tripeptide of  $\delta$ -*N*-acetyl-L- $\delta$ -*N*-hydroxyornithine; *ferrioxamines* and DESFERRIOXAMINE (formed e.g. by certain bacteria); NOCARDAMINE; and the *terregens factor* (a growth requirement of e.g. *Arthrobacter* spp).

For extracellular growth, the pathogen *Mycobacterium tuberculosis* uses a peptide siderophore, EXOCHELIN, and a cell-wall-associated lipophilic compound: MYCOBACTIN; exochelin appears to obtain iron from SIDEROPHILINS and to pass it to mycobactin for internalization.

Certain siderophores, e.g. parabactin, have been found to be active, in vitro, against a murine leukaemia cell line and against herpes simplex type 1 virus [TIBS (1986) 11 133–136].

(See also PYOVERDIN.)

**SIDS** SUDDEN INFANT DEATH SYNDROME.

**sIg** Any immunoglobulin at the surface of a B LYMPHOCYTE.

**sIgA** Secretory IgA (see entry IgA).

**sigatoka disease** *Syn.* BANANA LEAF SPOT.

**sigF gene** See SIGMA FACTOR.

**sigla** Plural of SIGLUM.

**siglum** A designation consisting of letters (particularly initial letters) and/or other characters. Some sigla are acronyms.

$\sigma$  (superhelix density) See DNA.

$\sigma$  factor (sigma factor) A protein which can bind to a DNA-dependent RNA POLYMERASE (RPase) core enzyme and confer on it the ability to initiate TRANSCRIPTION from a particular type of PROMOTER.

Cells typically or always encode more than one type of sigma factor, and different types of sigma factor generally confer on the RNA polymerase the ability to transcribe (in vivo) from different promoters; by synthesizing particular type(s) of sigma factor, at appropriate times, the cell can thus control expression of particular gene(s).

In *Escherichia coli* the main sigma factor is  $\sigma^{70}$  (MWt ~70000) encoded by gene *rpoD*; an RPase holoenzyme containing  $\sigma^{70}$  ( $E\sigma^{70}$ ) can initiate transcription from most promoters in the *E. coli* genome – sometimes in association with positive regulatory factors (as e.g. in CATABOLITE REPRESSION). Other sigma factors in *E. coli* include e.g.  $\sigma^{32}$  (RpoH, formerly HtpR; see HEAT-SHOCK PROTEINS) and  $\sigma^{60}$  (the NtrA protein; see NTR GENES).

There are many examples of the way in which the timing of gene expression is controlled by the activity of particular sigma factor(s). In *E. coli*, assembly of the FLAGELLUM from a number of different proteins is a highly organized process in which components are added in strict sequence – the corresponding genes being expressed in a way that reflects this sequence.

Thus, class III genes are expressed only after genes of classes I and II, and the expression of class III genes depends on synthesis of a sigma factor encoded by the *fliA* gene; however, even when FliA has been synthesized, this sigma factor is temporarily inactivated by an *anti-σ* factor (FlgM, product of gene *flgM*) until the basal body and hook of the flagellum have been completed – completion of the hook apparently acting as a signal that allows release of FlgM and consequent transcription of the class III genes. [Genetic control of flagellar assembly: Cell (1995) 80 525–527.]

The *E. coli* sigma factor  $\sigma^s$  (encoded by *rpoS*) was once associated solely with stationary-phase events but is now known to be involved in the regulation of various responses to stress under log-phase, as well as stationary-phase, conditions [Mol. Microbiol. (1996) 21 887–893]. Under in vitro conditions, either  $E\sigma^{70}$  or  $E\sigma^s$  can be used for transcription from some promoters, but, in vivo, many promoters exhibit specificity for one of the two holoenzymes –  $E\sigma^{70}$  or  $E\sigma^s$ ; studies on sigma factor specificity in the *osmY* gene have indicated that specificity for  $\sigma^s$  in this gene is influenced strongly (perhaps even determined) by three global regulators – the cAMP–CRP complex (see CATABOLITE REPRESSION), the integration host factor (IHF) and the leucine-responsive regulator protein (Lrp) – which preferentially inhibit  $E\sigma^{70}$ -dependent expression from the *osmY* promoter [EMBO (2000) 19 3028–3037].

Expression of the *rpoS* gene is reported to be regulated by the HU PROTEIN [Mol. Microbiol. (2001) 39 1069–1079] and also by a small, novel RNA molecule which interacts with *rpoS* mRNA and relieves the inhibitory activity of a stem- and-loop structure [Mol. Microbiol. (2001) 39 1382–1394].

In vegetative cells of *Bacillus subtilis* the major sigma factor is  $\sigma^{43}$  (formerly called  $\sigma^{55}$ ; encoded by gene *rpoD*); this sigma factor shows some homology with the *E. coli*  $\sigma^{70}$  and recognizes the same class of promoters. There are also a number of minor sigma factors. A sigma factor may be present at low levels during normal growth but up-regulated under appropriate conditions. For example,  $\sigma^H$  (encoded by gene *spoOH*) is up-regulated during the initiation of sporulation in *Bacillus subtilis* as a consequence of repression of *abrB* by Spo0A~P (see figure (a) in ENDOSPORE). Later in the initiation process, the sporulation-specific sigma factors  $\sigma^E$  (formerly  $\sigma^{29}$ ; encoded by *spoIIG*) and  $\sigma^F$  are synthesized to promote the next stage of sporulation.

The  $E\sigma^{28}$  of *B. subtilis* can initiate transcription at *E. coli* heat-shock promoters.

In *B. subtilis*, many of the genes and operons so far investigated have two or more overlapping or adjacent promoters which are usually specific for RPase holoenzymes containing different sigma factors; this presumably allows control of gene expression under various conditions and/or during different stages of development.

In *Mycobacterium tuberculosis*, the discovery of a gene (*sigF*) [PNAS (1996) 93 2790–2794] encoding a protein homologous to a sporulation-specific sigma factor in *Streptomyces coelicolor* has provided some evidence in support of the hypothesis that latency (persistence) in this pathogen is associated with the presence of a spore-like state. [Mechanisms of latency in *M. tuberculosis*: TIM (1998) 6 107–112.]

Certain bacteriophages encode sigma factors that are necessary for the expression of some of their genes: see e.g. BACTERIOPHAGE SPO1 and BACTERIOPHAGE T4 (gp55).

In some cases, the expression of a sigma factor results from up-regulated translation of its mRNA (rather than increased transcription of the gene). In *E. coli*, for example, the increase in

$\sigma^{32}$  following heat shock is due mainly to increased translation of mRNA; translation is up-regulated because the higher temperature destabilizes a secondary structure in the mRNA which, under normal conditions, represses translation [GD (1999) 13 633–636].

*Enhancer-dependent sigma factors* ( $\sigma^{54}$ ; =  $\sigma^N$ ). This unique type of sigma factor, once thought to occur only in higher organisms, is found in many species of bacteria (although not in all species [FEMS (2000) 186 1–9]). When bound to a promoter, the  $\sigma^{54}$ -RNA polymerase holoenzyme must be *activated* by an energy-dependent process before DNA melting (formation of an 'open complex', and initiation of transcription) can occur at the promoter. Such activation involves a specialized *activator* protein which binds to DNA at an *enhancer* region remote from the promoter – but which can be brought close to the holoenzyme through *looping* of the intervening DNA; with activator and holoenzyme juxtaposed, the activator's ATPase activity (triggered e.g. by phosphorylation) provides the energy for localized melting (open complex formation) in the promoter region. (In some cases, DNA looping involves the INTEGRATION HOST FACTOR.)

One early example of an enhancer-dependent sigma factor is the *rpoN* (= *ntrA*) gene product involved in regulating nitrogen metabolism (see NTR GENES). A more recent example is a  $\sigma^{54}$ -regulated operon concerned with the processing of RNA [JBC (1998) 273 25516–25526].

[ $\sigma^{54}$  (minireview): JB (2000) 182 4129–4136.]

(See also ANTI-SIGMA FACTOR.)

**sigma particles** See LYTCUM.

**$\sigma$  structure** See ROLLING CIRCLE MECHANISM.

**sigma virus** A probable member of the RHABDOVIRIDAE. Sigma virus infects fruit-flies (*Drosophila melanogaster*) and is transmitted by the female flies to their offspring. The virus is normally non-pathogenic; however, on brief exposure to CO<sub>2</sub> at certain concentrations, infected flies are paralysed and die within a few hours, whereas non-infected flies recover completely. [Sigma virus in cell culture: JGV (1984) 65 91–99.] (See also DROSOPHILA X VIRUS.)

$\sigma^E$  (AlgU) See ALGINATE.

**sigmamycin** A mixture of TETRACYCLINE and OLEANDOMYCIN.

**signal amplification** (bdNA) See BDNA ASSAY.

**signal hypothesis** The hypothesis that a protein which is destined to pass through (or into) a membrane is synthesized in a precursor form (*pre-protein*) with a specific N-terminal sequence of amino acid residues (= *signal sequence*, *signal peptide*, *leader peptide*) which is essential for the initiation of translocation and is typically excised (cleaved) during translocation. Translocation in this mode has been demonstrated for many (but not all) secreted and membrane proteins in prokaryotes and eukaryotes; in other cases, protein translocation involves distinct processes which lack the characteristics described above (see later).

A signal sequence often consists of several hydrophilic terminal amino acid residues followed by a sequence of >10 predominantly hydrophobic residues and a specific cleavage site; the hydrophobic residues have a tendency to form an  $\alpha$ -helix conformation. It is generally assumed that a signal sequence adopts a conformation which spans the membrane and facilitates translocation of the remainder of the polypeptide.

[Signal sequences: Mol. Microbiol. (1994) 13 765–773.]

In addition to a terminal signal sequence, the pre-protein may incorporate other sequence(s) which ensure that it reaches the correct final destination; for example, a membrane protein (as opposed to a secreted protein) may contain a *membrane anchor*

## signal peptidase

*sequence* (= 'anchor' or 'stop transfer' sequence) that holds the mature protein on or within the correct membrane. Moreover, a protein may undergo post-translational modification to ensure that it is targeted to the correct membrane site (see e.g. BRAUN LIPOPROTEIN).

In *eukaryotes*, secretory proteins (i.e. those to be secreted) – and proteins destined e.g. for the plasma membrane, or for LYOSOMES – are synthesized on ribosomes of the rough ENDOPLASMIC RETICULUM. Initially, synthesis begins on a free (cytosolic) ribosome, but the newly synthesized (N-terminal) signal sequence binds to a SIGNAL RECOGNITION PARTICLE (SRP) – and this stops polypeptide chain elongation. The ribosome–signal peptide–SRP complex then binds to a 'docking protein' at a site on the cytoplasmic surface of the rough endoplasmic reticulum; the SRP is released, and the signal sequence inserts into a transmembrane 'translocation complex' such that, on resumption of chain elongation, the nascent polypeptide is translocated through the ER co-translationally – apparently driven mechanically by chain elongation. The signal peptide is excised by an endopeptidase (*signal peptidase*) whose catalytic site occurs on the lumen-facing side of the ER. Secretion then follows the PALADE PATHWAY.

By contrast, most of the proteins destined to enter a MICROBODY (e.g. a PEROXISOME) are synthesized on free (cytosolic) ribosomes without a cleavable signal sequence [BBA (1986) 866 179–203]. [Protein import into organelles (hierarchical targeting signals): Cell (1986) 46 321–322.]

In *prokaryotes* the role of the signal sequence is essentially similar in that its function involves insertion into the transmembrane translocation system. (An earlier view – the 'membrane trigger' or 'trigger' hypothesis – supposed that the signal peptide confers on the pre-protein the ability to change conformation following contact with the membrane, thus initiating uptake by the membrane.)

In Gram-negative bacteria, signal sequence-dependent secretion is involved in type II and type IV forms of PROTEIN SECRETION (q.v.); in type II systems, the secretion of *some* proteins is mediated by a signal recognition particle (see PROTEIN SECRETION). During, or immediately after, translocation of the protein, the signal sequence is cleaved by an enzyme (*signal peptidase*); in *Escherichia coli*, one of the two signal peptidases (*leader peptidase*; = *leader peptidase I*) is active on a wide range of proteins, while the second enzyme (*lipoprotein signal peptidase*; = *signal peptidase II*) is active only on specific, modified proteins (such as the BRAUN LIPOPROTEIN). (In both of these signal peptidases the catalytic site is apparently on the periplasmic side of the cytoplasmic membrane.) Excised signal peptides are degraded by an enzyme (*signal peptide peptidase*) – e.g. *protease IV* in *E. coli*.

In some cases the signal sequence is not excised following transmembrane translocation of a protein. One such exception is the export of the TONB PROTEIN to the periplasm in *E. coli* [JBC (1988) 263 11000–11007].

Secretion that is independent of a cleavable N-terminal signal sequence occurs in type I and type III forms of protein secretion in Gram-negative bacteria.

**signal peptidase** See SIGNAL HYPOTHESIS and PROTEIN SECRETION.

**signal peptidase II** See PROTEIN SECRETION.

**signal peptide** See SIGNAL HYPOTHESIS.

**signal peptide peptidase** See SIGNAL HYPOTHESIS.

**signal recognition particle (SRP)** In *eukaryotes*: a particle that is involved in translocation of proteins across the endoplasmic

reticulum (see SIGNAL HYPOTHESIS); an SRP contains six polypeptides together with a 7S RNA which is essential for function [Nature (1982) 299 691–698].

In *prokaryotes*: a particle involved in the translocation of certain proteins across the cytoplasmic membrane (see type II systems in PROTEIN SECRETION).

**signal sequence** See SIGNAL HYPOTHESIS.

**signal transducers and activators of transcription (STATs)** See CYTOKINES.

**signal transduction pathway** See TWO-COMPONENT REGULATORY SYSTEM.

**signature-tagged mutagenesis** A form of TRANSPOSON MUTAGENESIS which can be used to detect those genes, in a pathogen, which are necessary for the pathogen's growth within the host organism. The principle of signature-tagged mutagenesis is outlined in the figure. (See also IVET.)

**signet-ring stage (of *Plasmodium*)** See PLASMODIUM.

**significant bacteriuria** BACTERIURIA in which a sample contains potentially pathogenic bacteria in numbers high enough to indicate a URINARY TRACT INFECTION; the numbers of such bacteria must be significantly higher than those which might be expected to occur from contamination of the sample.

In the absence of infection, an MSU (taken correctly) should contain no more than  $\sim 10^4$  (commonly  $< 10^3$ ) contaminating bacteria/ml, and these contaminants will typically consist of several species – giving rise to different types of colony on the culture plate.

By contrast, counts greater than  $\sim 10^5$ /ml – usually consisting of one species (but sometimes two species) – are likely to indicate an infection of the urinary tract; note that counts at this level may not be obtained after chemotherapy with an effective agent. (Note also that an inappropriately high count may be obtained if the specimen of urine has been stored, prior to culture, under conditions which allow multiplication of bacteria; ideally, the sample should be examined promptly.)

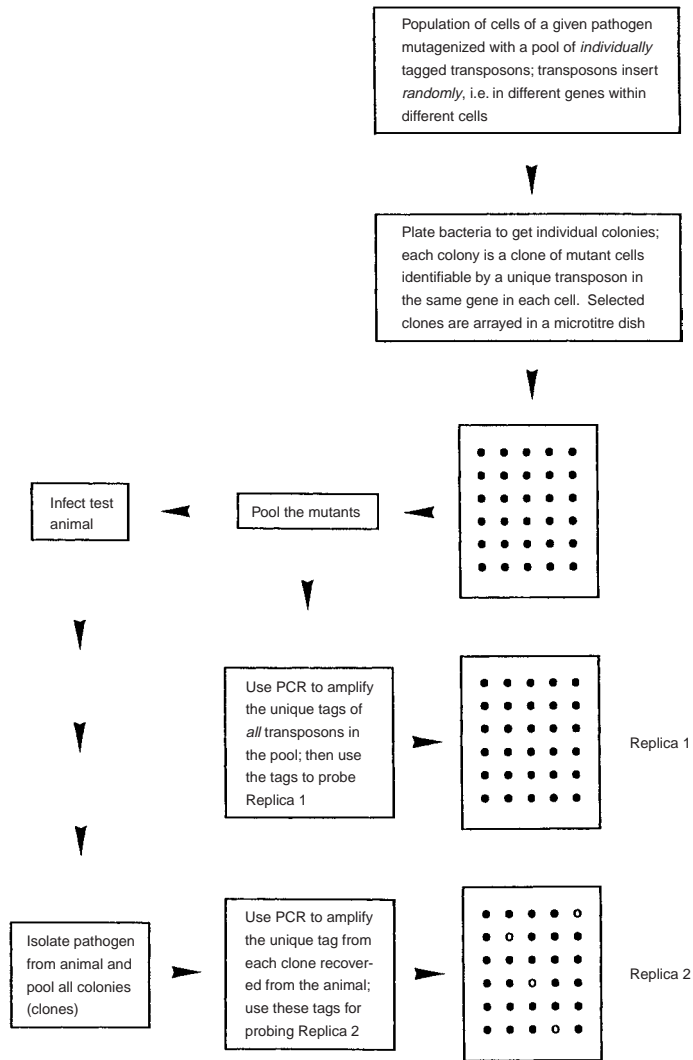

In some cases a significant bacteriuria can be demonstrated in an asymptomatic patient *prior to* development of pyelonephritis. Conversely, some samples from patients with a urinary tract infection may give low-level counts. Thus, interpretation of counts must reflect the overall clinical picture.

Some pathogens can persist *intracellularly* in the facet cells of bladder epithelium (see UPEC), so that counts of bacteria in urine samples may not necessarily reflect the level of pathogenic organisms within the urinary tract.

[Automated detection of significant bacteriuria by flow cytometry: JCM (2000) 38 2870–2872.]

**silage** A feed for animals (particularly ruminants) which is made by the anaerobic storage of large masses of finely chopped grasses, legumes or other green crops. Bacteria – mainly *Lactobacillus* spp – which are present on the vegetation and/or in the storage vessel (*silo*) metabolize the plant sugars (especially glucose, fructose and sucrose) primarily by a LACTIC ACID FERMENTATION, thereby causing a rapid fall in pH; the low pH (ca. 4.0) inhibits various putrefactive organisms (particularly *Clostridium* spp), thus helping to preserve the nutrient value of the crop, and inhibits the growth of *Listeria monocytogenes* (see also LISTERIOSIS). (cf. AIV PROCESS.) Ensilage may take ca. 1–4 months.

The crop to be ensiled is harvested when its nutrient value is high, and before ensilage it may or may not be 'wilted' (i.e., allowed to lose water); wilting to a dry-matter level (DM level) of ca. 300 g/kg is usually sufficient to inhibit the growth of putrefactive clostridia – which need a minimum WATER ACTIVITY

**SIGNATURE-TAGGED MUTAGENESIS: a method for identifying virulence-associated genes in a pathogen (general principle).**

A unique sequence ('tag') of about 40 base-pairs in length is inserted into each of a population of transposons, i.e. the tag in each transposon is different from that in all the other transposons. Each tag is flanked, on both sides, by a short primer-binding site – these sites being the same in all transposons. The transposons are used to mutagenize cells of the pathogen, and they insert, randomly, into different genes in different cells.

The mutagenized cells are plated to form individual colonies; a given colony consists of a clone of mutant cells, each containing the same uniquely tagged transposon in the same gene. A number of colonies are chosen, and an inoculum from each colony is arrayed, separately, in a microtitre dish. (The dish shown in the diagram has 30 wells, but larger dishes are normally used.) Two replica 'blots' of the array are made on membranes (for subsequent DNA hybridization studies); in these blots the cells are lysed and their chromosomal DNA is exposed and fixed to the membrane in single-stranded form.

Cells are taken from each of the wells and pooled. The pool is used in two ways. First, it provides an inoculum for infection of the test animal. Second, cells from this ('input') pool are lysed, and PCR is used – with labelled primers – to amplify the unique tags of all transposons in the pool. The amplified, labelled tags are then used as probes on one of the replica blots; in this blot (Replica 1), each (unique) tag should hybridize with the DNA from cells containing the corresponding transposon. This 'pre-screening' process (on Replica 1) checks for efficient amplification of each unique tag in the pool. (The need to pre-screen may be avoidable if a set of 'dedicated' tags is used [TIM (1998) 6 51].)

The pathogen is recovered from the test animal by plating an appropriate specimen. The resulting colonies are pooled (forming the 'recovered' pool), and PCR is used (with labelled primers) to amplify the tag from each clone in this pool. The amplified, labelled tags are then used to probe the second replica blot (Replica 2). (Continued on page 708.)

## silent mutation

higher than that required by lactic acid bacteria. The vegetation is chopped into pieces ca. 2.5 cm in length and may be treated with additives such as (a) a bacterial culture (usually certain *Lactobacillus* spp) to augment the natural microflora, (b) a carbohydrate (e.g. molasses) to augment the plant sugars, and/or (c) formic acid, which e.g. can quickly establish a low pH suitable for the growth of lactic acid bacteria. (At ca. pH 5, formic acid is much more inhibitory to clostridia and enterobacteria than it is to lactic acid bacteria; it thus tends to promote the correct, i.e., lactic acid, fermentation.) The chopped/treated vegetation is packed into the silo. When the silo is sealed, microbial metabolism quickly results in anaerobiosis.

Organisms dominant in fermenting silage include homo- and heterofermentative species of LACTOBACILLUS, particularly *L. brevis*, *L. buchneri*, *L. curvatus* and *L. plantarum*; other organisms may include e.g. *Enterococcus faecium*, *Lactococcus lactis*, and species of *Pediococcus* and *Leuconostoc*. (Enterobacteria and *Bacillus* spp can be dominant during the first day or so in vegetation of relatively low DM and high pH.) The heterofermentative organism *L. brevis* ferments glucose or fructose to lactic and acetic acids, but does not form ethanol since it apparently lacks aldehyde dehydrogenase [see Appendix III(b)]; in this species the excess reducing power can be used to reduce exogenous fructose to mannitol (cf. RESPIRATION). Interestingly, the mannitol and acetic acid formed by *L. brevis* can be used as substrate and electron acceptor, respectively, by the homofermentative species *L. plantarum* [Food Mic. (1986) 3 73–81].

When the silage is eventually removed from the silo it can undergo aerobic deterioration if left uneaten; particularly prone to such deterioration is silage made from overwilted vegetation or made in a non-airtight silo – i.e., circumstances which tend to increase the aerobic silage microflora. Organisms particularly associated with aerobic deterioration include yeasts (e.g. *Hansenula*, *Pichia*, *Saccharomyces*), other fungi (e.g. *Aspergillus*, *Byssoschlamys*, *Fusarium*, *Geotrichum* and *Mucor*), and *Bacillus* spp. The addition of certain compounds (e.g. propionic acid) to the vegetation at the beginning of ensilage can reduce subsequent aerobic deterioration in the finished silage. Sorbic acid can have a similar effect.

Various additives are used e.g. to increase the efficiency of the process and/or to enhance the performance of animals fed on the silage. One common additive includes strains of lactic acid bacteria that carry out a homolactic fermentation. Ideas for improved additives include (i) strains of lactic acid bacteria particularly suited to specific target crops; (ii) lactic acid bacteria that carry out a heterolactic fermentation – the volatile fatty acids inhibiting growth of fungi when the silage is exposed to air at feeding time; (iii) genetically engineered lactic acid bacteria which can utilize polysaccharides in those silage crops with low levels of soluble carbohydrates [new trends in silage additives: FEMS Reviews (1996) 19 53–68].

*Choice of crops for ensilage.* An ideal silage crop should have a DM level > ca. 200 g/kg and a good content of soluble, fermentable carbohydrates. (Among common grasses, rye-grasses (*Lolium* spp) tend to have the highest content of carbohydrate, and cocksfoot (*Dactylis glomerata*) the lowest.) A silage crop should also have a low buffering capacity (measured e.g. in mE of alkali needed to bring the pH from 4 to 6 in 1 kg DM); a low buffering capacity permits the in-silo pH to drop rapidly, while a high buffering capacity may allow the occurrence of a non-lactic acid fermentation and/or of clostridial spoilage. In e.g. maize (*Zea mays*) the buffering capacity can be as low as ca. 150–200 mE/kg, while in some grasses, and lucerne (*Medicago sativa*), it can be up to ca. 500–600 mE/kg; other factors which make maize a good silage crop include its high DM and its content of water-soluble sugars (which can reach e.g. ca. 300 g/kg DM). (A disadvantage of maize is its low content of crude protein; this can be overcome by adding urea – as a source of nitrogen – to the crop at the beginning of ensilage.)

*Effluents.* Effluent from a silo has a high BOD and can cause serious pollution if discharged into streams etc. Factors which affect effluent formation include the DM levels of the ensiled vegetation.

[Book ref. 195.]

(See also RUMEN.)

**silent mutation** A MUTATION which has no apparent effect on the phenotype of the organism in which it occurs (see also SAME-SENSE MUTATION and MIS-SENSE MUTATION). Note that a same-sense mutation may not be 'silent' if it introduces a detectable CODON BIAS: in *Escherichia coli*, a synonymous but infrequent (mutant) codon in the leader region of the *ompA* gene strongly affected *in vivo* translation, giving rise to a significant reduction in the synthesis of OmpA protein [NAR (1998) 26 4778–4782].

Silent mutations may also affect the results of e.g. DNA-based identification tests [Book ref. 221, pp 16, 172 and 218].

**silica deposition vesicle** A vesicle, bounded by a unit-type membrane (the *silicalemma*), present in most – if not all – algae and protozoa which (endogenously) form siliceous structures: e.g. the scales of certain CHRYSOPHYTES, the frustules of DIATOMS, skeletal elements of RADIOLARIA. [Siliceous structures in biological systems: Book ref. 137.]

**silica gel** Hydrated silicon dioxide; silica gel can be prepared in an aqueous, jelly-like form for use e.g. as the basis of a solid MEDIUM. A silica-gel-based medium can be used for the culture of autotrophs (in the complete absence of organic material) and e.g. for testing the ability of heterotrophs to use particular substrates as the sole source of carbon. Powdered silica gel (10 g) is dissolved by heating in 100 ml 7% (wt/vol) aqueous KOH; the solution is dispensed in 20-ml aliquots and autoclaved. To each 20-ml aliquot is added 20 ml of a sterile double-strength liquid nutrient medium, followed by a (pre-determined) volume (ca. 4 ml) of a 20% solution of *o*-phosphoric acid sufficient to give a

**SIGNATURE-TAGGED MUTAGENESIS** (*continued*) Considering the original, mutagenized cells in the 'input' pool, the cells of interest are those which, through a (transposon-mediated) mutation, are *unable* to grow within the test animal, i.e. cells whose virulence has been lowered; such cells will be absent, or few in number, in the 'recovered' pool (compared with those cells which were able to grow normally in the test animal). Hence, the signature tags of these 'virulence-attenuated' cells will be present in the input pool but absent (or rare) in the recovered pool; consequently, such cells can be identified by hybridization on Replica 1 but an *absence* of (or weak) hybridization on Replica 2 (see figure). (If 'dedicated' tags had been used, virulence-attenuated cells would be identified by the absence of hybridization on a single blot.)

In a given 'virulence-attenuated' clone, the relevant gene (identifiable from the inserted transposon) can be isolated, cloned and sequenced for further study.

Reproduced from *Bacteria*, 5th edition, Figure 8.22, pages 218–219, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

pH of 7.0. After mixing, the solution is immediately dispensed to Petri dishes. Solidification starts in ca. 1 min and is complete in ca. 15 min. The water of syneresis can be evaporated in an incubator. Incubation of inoculated plates should be carried out in a moist chamber to prevent excessive drying of the medium.

**silicalemma** See SILICA DEPOSITION VESICLE.

**silicoflagellates** A group of unicellular planktonic marine algae of uncertain taxonomic position (formerly included in the Chrysophyceae). (cf. PHYTOMASTIGOPHOREA.) The organisms possess a characteristic net-like, siliceous endoskeleton composed of tubular elements which are often arranged in a polygonal 'ring' with supporting struts and projecting spines. The cells each have a single emergent flagellum and many brownish chloroplasts. Present-day genera include *Dictyocha*. Fossil silicoflagellate skeletons are known from the Late Cretaceous onwards [Book ref. 136, pp. 811–846].

**Silicoflagellida** See PHYTOMASTIGOPHOREA.

**silkworm diseases** For diseases of the silkworm (*Bombyx mori*) see e.g. CYTOPLASMIC POLYHEDROSIS VIRUS GROUP, FLACHERIE, and NOSEMA (pébrine). (See also BEAUVERIA.)

**silver** (as an antimicrobial agent) Silver is a HEAVY METAL which, in elemental or compound form, is typically microbistatic in low concentrations; the functional antimicrobial moiety is the silver *ion* – which appears to act by binding to e.g. thiol, amine, phosphate and other groups in proteins, nucleic acids and/or other targets. In at least some cases binding is reversible. Antimicrobial agents consisting of metallic or other forms of silver appear to differ primarily in the rate at which they yield silver ions. Gram-positive bacteria are typically much less susceptible than Gram-negative species, and antimicrobial activity can be diminished by non-living organic matter. In bacteria, resistance to silver may be plasmid-borne.

*Silver nitrate* (lunar caustic,  $\text{AgNO}_3$ ) has astringent properties and may be microbistatic or microbicidal according to concentration; aqueous solutions are used e.g. on dressings for burns (0.5% w/v) and for the treatment of ulcers on mucous membranes (10%). (See also Credé procedure in GONORRHOEA.) The *silver nitrate pencil* is a fused mass containing ca. 98%  $\text{AgNO}_3$  – together with  $\text{AgCl}$  and  $\text{KNO}_3$  – cast in a pencil-shaped mould; the moistened tip of the pencil is used e.g. for the cauterization of wounds and the destruction of warts. *Ammoniacal silver nitrate* has been used in dentistry for the disinfection of tooth cavities. *Colloidal silver* has been used in medicine (e.g. *Colsargen*: an isotonic suspension of colloidal silver (0.5%) used for treating mucous surfaces). (See also KATADYN SILVER.) *Silver proteinates* (e.g. *Argyn*, *Argyrol*, *Protargin*, *Protargol*) may be made by precipitating a soluble silver salt, or silver oxide, with protein and then solubilizing with excess protein; they have been used e.g. in various gynaecological preparations. (The antimicrobial activity of a silver proteinate depends on the amount of silver ions it liberates rather than on the proportion of silver in the preparation.) *Silver sulphadiazine* (1% in an ointment) is used e.g. for the treatment of burns; this compound (which can be bactericidal) releases silver ions, and – unlike  $\text{AgNO}_3$  – causes blebs in the cell envelope of *Pseudomonas aeruginosa*.

**silver dag** A suspension of colloidal silver in a quick-drying organic solvent. (See also ELECTRON MICROSCOPY (b).)

**silver leaf** A disease of trees of the Rosaceae (particularly plum trees) caused by *Chondrostereum purpureum*. Infection occurs via wounds; the fungus grows in the wood, causing discoloration but little or no decay. Infected trees show a characteristic 'silvering' of the leaves; this is apparently due to the production of fungal toxin(s) which cause leaf tissues to separate, the

resulting air spaces giving the silvery effect. The fungus itself does not occur in the leaves.

**silver line system** (argyrome) (*ciliate protozool.*) A regular pattern of lines observed in the superficial layer(s) of silver-stained ciliates; these lines of deposited silver were first described by Klein in the 1920s. While some of the lines appear to coincide with cell-surface detail, others appear to correspond to the locations of certain subpellicular structures. Thus, e.g. the main (most densely staining) lines in *Tetrahymena* correspond to the rows of kinetosomes which mark the locations of the kineties; these (longitudinal) lines have been termed *primary meridia*. Other, more weakly staining, lines observed between the primaries, have been termed *secondary meridia*. Cross-striations have also been observed; some workers believe that lines of deposited silver are formed at the junctions of the pellicular alveoli. (See also KINETY and PELLICLE.)

**silver–methenamine stain** See METHENAMINE–SILVER STAIN.

**silver scurf** A POTATO DISEASE caused by *Helminthosporium solani*; the skin of the tuber exhibits brown or silver patches which extend on storage.

**silver stains** See e.g. DIETERLE SILVER STAIN; FONTANA'S STAIN; METHENAMINE–SILVER STAIN. (See also SILVER LINE SYSTEM.)

**silver top** (*syn.* white top) A disease of turf grasses caused by *Fusarium poae*; the seedheads of infected plants wither before maturing, appearing at first silvery, later white. (cf. WHITEHEAD.)

**Simbu group** See BUNYAVIRUS.

**simian AIDS** (SAIDS) A disease which occurs in macaque monkeys; SAIDS closely resembles human AIDS e.g. in its clinical manifestations, including immune deficiency, progressive depletion of CD4 T cells. The causal agent is a lentivirus, the *simian immunodeficiency virus* (SIV); SIV differs from the human immunodeficiency virus e.g. in structure and antigenicity of envelope proteins. (Severe immunodeficiency is also caused by a betaretrovirus, the MASON-PFIZER MONKEY VIRUS, but the pathology differs.) Rapid pathogenesis in SAIDS may be accompanied by selection of gp120 variants with decreased ability to bind to CD4 T cells [JV (2002) 76 7903–7909]. [Assay of SIV: JV (2004) 78 5324–5337.]

**simian foamy virus** See SPUMAVIRINAE.

**simian haemorrhagic fever virus** (SHFV) A virus which can cause a fatal haemorrhagic disease in e.g. rhesus monkeys (*Macaca mulatta*); the natural reservoir of the virus is believed to be the African patas monkey (*Erythrocebus patas*).

SHFV is an enveloped ssRNA virus formerly linked with the family FLAVIVIRIDAE: it resembles flaviviruses e.g. in the 5' cap structure on the viral RNA [Virology (1986) 151 146–150], but differs in that at least some of the RNA molecules are polyadenylated [Virology (1985) 145 350–355]. SHFV has been placed in the arterivirus group (see ARTERIVIRUS).

**simian immunodeficiency virus** See SAIDS.

**simian malaria** See MALARIA.

**simian parvovirus** See ERYTHROVIRUS.

**simian sarcoma virus** (SSV; woolly monkey sarcoma virus) A mammalian type C retrovirus (subfamily ONCOVIRINAE) isolated from a fibrosarcoma in a woolly monkey. It is a replication-defective, *v-onc*<sup>+</sup> virus which carries the *sis* oncogene (see SIS). SSV occurs in association with a replication-competent virus – simian sarcoma-associated virus, SSAV – which is serologically related to the GIBBON APE LEUKAEMIA VIRUS; the SSV/SSAV complex can cause fibrosarcomas or fibromas in various monkeys.

**simian T-cell leukaemia virus** (STLV; simian T-lymphotropic virus; primate T-cell leukaemia virus, PTLV) A generic term

## simian virus 40

for exogenous retroviruses which infect the T cells of monkeys and other subhuman primates. STLV-I (formerly 'STLV') is closely related to HTLV-I (see HTLV); it infects Old World monkeys and apes, and can cause lymphomas in e.g. macaques. STLV-III has been isolated from rhesus monkeys (*Macaca mulatta*) and African green monkeys (*Cercopithecus aethiops*) and appears to be closely related to the human AIDS virus; a virus similar to STLV-III can apparently infect humans, and it has been suggested that the AIDS virus and STLV-III may have had a common origin [Science (1986) 232 238–243]. (cf. SIMIAN AIDS.)

**simian virus 40 (SV40; vacuolating agent)** A virus of the genus POLYOMAVIRUS. SV40 was originally isolated from kidney cells of the rhesus monkey (*Macaca mulatta*) and is common (in latent form) in such cells; early polio and adenovirus vaccines prepared in rhesus monkey kidney cells were frequently contaminated with SV40. (See also MASTADENOVIRUS.) In kidney cells from the African green monkey (*Cercopithecus aethiops*) SV40 causes CPE, including characteristic vacuolation of the cytoplasm. SV40 is usually non-pathogenic in its natural host, but can induce fibrosarcomas and gliomas in newborn rodents (though not in immunocompetent adult animals): see POLYOMAVIRUS for details.

**similarity matrix** See S MATRIX.

**Simkania negevensis** See SPLIT GENE (bacterial).

**Simmons' citrate agar** KOSER'S CITRATE MEDIUM incorporating BROMOTHYMOLO BLUE (0.008%) and agar (1.5–2.0%).

**Simonsiella** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur in the oral cavity in man and other vertebrates. The organisms are flat filaments (ca. 2–4 µm in length), each composed of elongated cells arranged side-by-side; the outer face of each terminal cell is rounded. Gliding occurs in a direction parallel to the long axis of the filament. Metabolism: chemoorganotrophic.

**Simonsiellaceae** See CYTOPHAGALES.

**simple matching coefficient** See entry S<sub>SM</sub>.

**Simplexvirus** See ALPHAHERPESVIRINAE.

**Sin Nombre virus** See HANTAVIRUS.

**SIN virus** SINDBIS VIRUS.

**Sindbis virus (SIN virus)** An ALPHAVIRUS which occurs in Africa, Asia, Australia and Europe; it is apparently maintained primarily in birds and is transmitted by mosquitoes which feed on birds (e.g. *Culex univattatus* in Africa). Other vertebrates can be infected, and the virus is occasionally associated with human illness characterized by arthralgia and a maculopapular rash ('Sindbis fever'); human diseases caused by Sindbis or related viruses are known as Karelian fever in the former USSR, Ockelbo disease in Sweden, and Pogosta disease in Finland. (See TOGAVIRIDAE for replication cycle etc.)

**sinefungin** An ANTIBIOTIC (obtained from *Streptomyces griseolus*) which has antifungal, antiprotozoal and antiviral activity; it acts as an analogue of ornithine, inhibiting ornithine decarboxylase and hence putrescine formation.

**single burst experiment** A procedure for studying the lysis of a single cell by a virus (e.g. to determine the BURST SIZE). Essentially, a suspension of cells is infected with viruses and then diluted such that each of a large number of aliquots has a low probability of containing more than one virus-infected cell. Following incubation and lysis, the pfu counts in the aliquots can be statistically analysed e.g. to assess individual burst sizes. The single burst experiment can also be used e.g. to investigate recombination in bacteriophages, genetic analysis being made of the phage progeny from a single bacterial cell coinfecting with two genetically distinct phages.

**single-cell protein (SCP)** SCP refers to the cells of microscopic organisms (bacteria, yeasts, moulds or microalgae) grown in large-scale cultures for use primarily as a source of protein in human or animal diets. Although not yet fully exploited commercially, SCP has many advantages over the more conventional sources of protein such as soybean meal and fishmeal. (i) It is rich in protein – ca. 40–85% crude protein, depending e.g. on source; typically, SCP is superior to soybean meal both in protein content and amino acid profile. (Protein content is usually given either as 'crude protein', i.e. Kjeldahl nitrogen × 6.25, which includes e.g. nitrogen in nucleic acids, or as 'true protein' determined e.g. by the Biuret reaction or by estimation of total amino acids.) (ii) The yield coefficient of SCP, Y<sub>s</sub> (g cell mass produced/g carbon utilized), is much higher than that of either plants or animals. (iii) SCP can be produced rapidly (owing to the high growth rates of microorganisms) and, unlike agricultural crops, production can be continuous throughout the year – even in countries with little or no agricultural potential or expertise. (iv) A wide range of raw materials, including wastes from other industries, can be used as substrates. In some cases this has the additional advantage of reducing the BOD of certain trade effluents. However, SCP also has disadvantages as a food source. (i) Microbial proteins tend to be deficient in sulphur-containing amino acids, particularly L-methionine (an essential amino acid for man); this can be overcome by supplementing SCP products with L-methionine or its hydroxy analogue (see HMA). (ii) Some microbial components, e.g. cell walls, cannot be digested by non-ruminant animals or man. (iii) SCP is rich in nucleic acids (ca. 5–15%), mainly RNA. Digestion of purine nucleotides yields uric acid which can be broken down by most mammals; however, man has no uricase, and an intake of more than 2 g nucleic acid per day causes deposition of urates in joints and kidneys, leading to gout and kidney stones. Nucleic acids may be removed e.g. by enzymatic treatment. (iv) Some SCP can affect man adversely in ways not always indicated by animal feeding experiments. Such effects may be due e.g. to residues of toxic substances from the growth medium, or to cell products or components – e.g. fatty acids with odd numbers of carbon atoms (in yeasts grown on hydrocarbons), D-amino acids – usually absent in traditional diets. (v) Cost. Weight for weight, SCP is significantly more expensive than either soybean meal or fishmeal (at least on early cost analyses).

A wide range of microorganisms has been evaluated for SCP production, but few are currently used on a commercial scale. *Bacteria* have advantages such as rapid growth rates and the ability to use a wide range of substrates. They are rich in protein which has a better range of essential amino acids than that found in soybean protein; their content of methionine and cysteine is higher than that of yeasts, although still limiting. However, for human consumption, bacterial SCP needs extensive treatment to remove nucleic acids, LPS etc, and public acceptance is low owing to a tendency to associate bacteria with disease; additionally, the (small) cells are not easy to harvest. *Cyanobacteria* lack some of these problems (see e.g. SPIRULINA). *Yeasts*, being larger, are easier to harvest, and they can grow at low pH (reducing the risk of microbial contamination); they have a high content of lysine (an essential amino acid) and have good public acceptability. However, compared with bacteria, yeasts tend to have a lower content of protein and are poorer in methionine. (Yeasts grown primarily for food, rather than for the production of other foods – cf. BAKERS' YEAST – are called 'food yeasts': see e.g. TORULA YEAST.) *Mycelial fungi* are easy to harvest but they have

relatively low growth rates and protein content. Protein from *microalgae* is inferior, nutritionally, to that of most other microbial sources, and algal SCP has poor acceptability in taste, colour, odour etc. The problem of indigestible algal cell walls may be overcome by cultivating protoplasts or wall-less algae (e.g. *Dunaliella* [AEM (1976) 31 602–604] and *Cosmarium* [AEM (1976) 32 436–437]).

**Production of SCP.** Bacteria, yeasts and moulds are generally cultured in well-aerated liquid media in a FERMENTER; typically, the process is continuous (see CONTINUOUS CULTURE) with limiting carbon (C:N less than ca. 10:1) to minimize production of storage compounds such as poly- $\beta$ -hydroxybutyrate. Algae are grown in batch or semi-continuous culture in ponds with large surface areas. Yeasts and bacteria are harvested by centrifugation; in one process (Pruteen, see later) the bacteria are initially agglutinated so that a more concentrated slurry can be fed to the centrifuge – thus increasing the efficiency of centrifugation. Algae and moulds are harvested by filtration. The concentrated biomass is washed, dried, and used either directly (e.g. in animal feeds) or (for human consumption) its protein content may be extracted and used as a nutrient supplement or as a ‘functional’ ingredient (e.g. to alter the texture of traditional foods).

**Substrates.** The choice of substrate involves considerations such as cost, efficiency of utilization, continuity of supply, and risk of toxic residues. There is, with some exceptions, a good correlation between cell yield and substrate energy content for substrates with heats of combustion up to ca. 11 kcal/g of substrate carbon (approximately that of glycerol); above this value cell yields do not increase [Book ref. 11, pp. 33–34].

(a) **High-energy substrates.** Hydrocarbons, e.g. natural gas (80–95% methane) and *n*-alkanes (particularly C<sub>10</sub>–C<sub>23</sub>), can be utilized very efficiently by certain bacteria and yeasts, and the risk of microbial contamination is low owing to the inability of most potential contaminants to grow on these substrates. However, hydrocarbons are poorly soluble in (aqueous) growth media, and they may contaminate the final product – although methane, being gaseous, is easily eliminated; the *n*-alkanes can be used in low concentrations in media containing ammonium salts, phosphate, etc. A further (operational) problem is that hydrocarbon substrates require high rates of oxygenation and heat removal. Organisms which have been grown on hydrocarbons on an industrial scale include yeasts – e.g. *Yarrowia lipolytica* (= *Saccharomycopsis* (*Candida*) *lipolytica*) – and bacteria (e.g. *Pseudomonas* spp which utilize waxy residues of crude petroleum); they have been used as animal feeds. (See also HYDROCARBONS and METHANOTROPHY.) [Hydrocarbons as substrates in industrial fermentations: Book ref. 155, pp. 643–683.]

Methanol and ethanol are more soluble than hydrocarbons, are readily available in pure form, and are easily removed from the SCP – but they are more expensive. Of organisms grown on methanol, higher yields are given by those which use the RMP PATHWAY rather than the SERINE PATHWAY. One commercial product manufactured in the 1980s, was prepared by growing the obligate methylotroph *Methylophilus methylotrophus* on methanol in an AIRLIFT FERMENTER. The product (‘Pruteen’) (Imperial Chemical Industries, UK) was marketed (ca. 70000 metric tons annually) as an animal feed, with purified carbon dioxide as a by-product; the process was subsequently discontinued owing to a fall in the price of protein.

Owing to the high cost of ethanol, ethanol-derived SCP is likely to be prepared only for human consumption; it includes TORULA YEAST – which has been produced at the rate of over 7000 tons annually by one American company.

(b) **Waste products.** (i) *Molasses* (from sugar-refining) is used mainly for growing yeasts (see e.g. BAKERS’ YEAST) but is also used in Taiwan and Japan for growing *Chlorella* heterotrophically. (ii) *Sulphite waste liquor* (from paper mills) can be used as a substrate (e.g. for torula yeast) after the hemicellulose has been hydrolysed, by sulphurous acid, to hexoses, pentoses, and acetic, galacturonic and formic acids; sulphite levels are reduced with lime, residual sulphur compounds are removed by steam stripping, and ammonia and various salts are added. In the Pekilo process (Finnish Pulp and Paper Institute), the mould *Paecilomyces varioti* has been grown in continuous culture and used as animal feed. (iii) *Whey* (from CHEESE-MAKING) contains ca. 4% lactose which can be utilized efficiently by only a few SCP organisms; the yeast *Kluyveromyces marxianus* (*K. fragilis*: ‘fragilis yeast’) is one such organism, ca. 5000 tons of which have been produced annually by one American company. Pilot-scale production of the mould *Penicillium verrucosum* (*P. cyclopium*) has been carried out in France. (iv) *Starch-rich wastes* (e.g. from potato and rice processing) are converted to SCP in the Symba process (Swedish Sugar Corporation) in which one yeast, *Saccharomycopsis fibuligera* (*Endomycopsis fibuligera*), produces  $\alpha$ - and  $\beta$ -amylases which hydrolyse the starch to glucose and maltose, while a second yeast, *Candida utilis*, utilizes these sugars to form the bulk of the SCP. This process reduces the BOD of the waste by ca. 90% and thus reduces difficulties in disposal. Cassava starch has been used as a substrate for ‘*Cephalosporium eichhorniae*’ [AEM (1982) 43 403–411]. (v) *Sewage effluents* are used for the culture of e.g. *Chlorella*, *Scenedesmus* and photosynthetic bacteria (e.g. *Rhodospseudomonas capsulata*).

(c) **Renewable sources** (e.g. wood and other plant materials). Lignocellulosic materials need pre-treatment to separate the LIGNIN, HEMICELLULOSE and CELLULOSE components. Once free, cellulose can be hydrolysed to fermentable sugars by acid treatment or by CELLULASES (e.g. those from *Trichoderma* spp). Yeast SCP (*Candida* sp) has been grown on wood hydrolysates in the former USSR.

The future potential of SCP may depend e.g. on advances in technology (such as improved methods for harvesting and protein isolation), on the availability of cheap(er) substrates, and on strain improvement; thus, e.g., the ICI Pruteen strain had improved AMMONIA ASSIMILATION (with consequent improvement in yield) owing to the introduction of the *gdh* (glutamate dehydrogenase) gene from *Escherichia coli* [Nature (1980) 287 396–401]. However, other (economic) factors, e.g. the price of ‘conventional’ protein, may be pivotal – although the link between SCP and pollution control may alter the balance of economic viability.

**single diffusion (serol.)** GEL DIFFUSION in which only one component of the system (e.g. antigen) diffuses through the gel – the other component being uniformly pre-distributed throughout the gel. (cf. DOUBLE DIFFUSION.) In the *Oudin test* (single diffusion, single DIMENSION), antibody is pre-distributed throughout a column of agar (or similar) gel, and a suspension of antigen is layered on top; a band of precipitate forms where the antigen, diffusing downward, meets homologous antibody in OPTIMAL PROPORTIONS. As more antigen reaches the precipitate an ANTIGEN EXCESS occurs at this location and the precipitate dissolves – the zone of equivalence (and the band of precipitate) thus moving down the gel column; the distance moved by the band of precipitate is proportional to the square root of the time taken for the movement. If several different antigen–antibody systems are present, several bands of precipitate will form (and move) independently.

## single dimension

In the *Mancini test* (= single radial diffusion test, or single radial immunodiffusion test) – a single diffusion, double dimension method – antibody is pre-distributed uniformly throughout a flat sheet of gel, and the antigen preparation is put into a small, cylindrical hole ('well') cut into the gel sheet; antigen diffuses radially outwards and forms, with the antibody, a halo of precipitate; the area of the circle formed by the halo is proportional to the initial concentration of antigen.

**single dimension** (*serol.*) See DIMENSION.

**single intradermal comparative tuberculin test** *Syn.* COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST.

**single intradermal test** (*vet.*) A TUBERCULIN TEST involving an injection of human or bovine tuberculin into an anal fold or into the neck. The test cannot distinguish between infections due to different species of *Mycobacterium* (cf. COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST and STORMONT TEST).

**single linkage** In NUMERICAL TAXONOMY: a method in which two groups ('clusters') of OTUs unite (coalesce) at a similarity level determined by the pair of OTUs – one from each cluster – which exhibit the maximum mutual degree of similarity.

**single radial diffusion test** See SINGLE DIFFUSION.

**single radial immunodiffusion test** See SINGLE DIFFUSION.

**single-site mutation** *Syn.* POINT MUTATION.

**single-step growth experiment** *Syn.* ONE-STEP GROWTH EXPERIMENT.

**single-strand binding protein** (SSB protein; helix destabilizing protein; 'unwinding protein') A class of proteins which bind specifically and cooperatively to ssDNA; they protect the DNA from the action of many nucleases and e.g. can prevent transcription. They have no known enzymic activity, and do not unwind dsDNA. Their roles in the cell are believed to include the stabilization and protection of ssDNA formed e.g. during processes such as DNA replication and DNA repair – although they are now believed to be excluded e.g. during homologous recombination mediated by the RecBCD enzyme. SSB proteins include *Escherichia coli* binding protein I, phage T4 gp32, phage fd gp5 (see INOVIRUS), and proteins encoded by the F plasmid and other conjugative plasmids.

**single strand conformation polymorphism** See SSCP.

**single-stranded DNA phage** *Syn.* SSDNA PHAGE.

**single-vent Petri dish** See VENT.

**singlet oxygen** ( $^1\text{O}_2$  or  $\text{O}_2^1$ ) An energized and reactive, but uncharged, form of oxygen which can be toxic to cells. Singlet oxygen may be produced e.g. (i) during ULTRASONICATION; (ii) during the transfer of energy from photoexcited fluorescent dyes to oxygen (see also PHOTODYNAMIC EFFECT); (iii) during the formation of HYDROXYL RADICAL by the reaction between SUPEROXIDE and HYDROGEN PEROXIDE; (iv) during the reaction between hypohalite and  $\text{H}_2\text{O}_2$  (see also MYELOPEROXIDASE). (Some of the oxygen produced during the spontaneous, i.e. non-enzymatic, dismutation of superoxide has been reported to be singlet oxygen.) Singlet oxygen is quenched e.g. by CAROTENOIDS.

**sinI gene** See ENDOSPORE (figure (a) legend).

**Sinorhizobium meliloti** See OSMOREGULATION.

**sintered glass filter** See FILTRATION.

**sinuate** (1) Wavy; undulating. (2) (*syn.* emarginate) In an agaric: refers to a LAMELLA in which the lower edge is notched at its junction with the stipe.

**Sinuolinea** See MYXOSPOREA.

**sinus** Any groove, constriction or cavity in an organism or cell: see e.g. *placoderm* DESMIDS.

**sinusitis** Inflammation of one or more of the paranasal sinuses – often a complication of e.g. a COMMON COLD or a tooth infection. Symptoms include pain at the affected site, purulent nasal discharge, and fever. Common causes of acute sinusitis are *Haemophilus influenzae* or *Streptococcus pneumoniae* (or both); less commonly, *S. pyogenes*, *Staphylococcus aureus*, *Branhamella catarrhalis*, or anaerobes (e.g. *Bacteroides* spp) may be involved.

**siomycin** See THIOSTREPTON.

**siphonaceous** (siphonous) Refers to a tubular or vesicular, coenocytic, basically aseptate algal thallus in which the cytoplasm (containing the chloroplasts, nuclei etc) forms a peripheral layer around a large central vacuole. (Septa may separate reproductive structures from the rest of the thallus, and may be formed in response to wounding.) According to species, a siphonaceous thallus may be a simple or branched tube or vesicle (see e.g. BOTRYDIUM and VAUCHERIA); in some algae (e.g. CODIUM) the thallus is made up of a complex combination of such tubes and/or vesicles. (cf. SIPHONOCLADOUS.)

**siphonein** See CAROTENOIDS.

**siphonocladous** Refers to a filamentous algal thallus which is composed of multinucleate cells (as in e.g. CHAETOMORPHA, CLADOPHORA, RHIZOCLONIUM, SIPHONOCLADUS, VALONIA). (cf. SIPHONACEOUS.)

**Siphonocladus** A genus of marine, mainly tropical, siphonocladous green algae (division CHLOROPHYTA) in which the mature thallus is erect with lateral branches.

**siphonous** *Syn.* SIPHONACEOUS.

**siphonoxanthin** See CAROTENOIDS.

**sirenin** See PHEROMONE.

**siRNA** See RNA INTERFERENCE.

**sirodesmins** See EPIPOLYTHIAPIPERAZINEDIONES.

**sirohaem** A HAEM (sense 1) which is the prosthetic group in e.g. DESULFOVIRIDIN, in the sulphite and nitrite reductases of e.g. *Escherichia coli*, and in certain IRON-SULPHUR PROTEINS in green plants.

**Sirolopidium** See LAGENIDIALES.

**SIRS** Systemic inflammatory response syndrome: specific symptoms (e.g. temperature  $>38^\circ\text{C}$  or  $<36^\circ\text{C}$ ; white blood cell count  $>12000/\text{mm}^3$ ,  $<4000/\text{mm}^3$  or  $>10\%$  immature forms) used to define SEPSIS (sense 2) precisely. [Sepsis/SIRS: JAC (1998) 41 (suppl A) 1–112.]

**SIRS virus** See BLUE-EARED PIG DISEASE.

**sis** An ONCOGENE originally identified as the transforming determinant of SIMIAN SARCOMA VIRUS; the v-*sis* product has an amino acid sequence almost identical to that of human platelet-derived growth factor (PDGF), and may cause transformation by mimicking PDGF [EMBO (1986) 5 1535–1541].

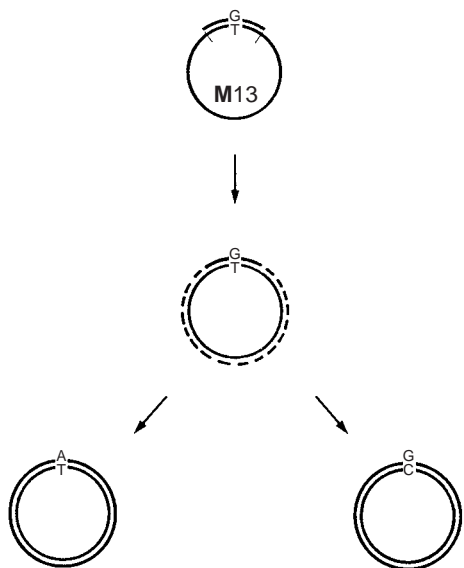

**sisomycin** 4',5'-DehydroGENTAMICIN C<sub>1a</sub>.

**sister chromatid** See CHROMATID.

**site-directed mutagenesis** *Syn.* SITE-SPECIFIC MUTAGENESIS.

**site-specific mutagenesis** The (in vitro) induction of MUTAGENESIS at a specific site in a given (target) DNA molecule.

In one method (D-loop mutagenesis), small fragments of ssDNA, each corresponding to the site to be mutated, are mixed (in vitro) with the full-sized supercoiled dsDNA target molecules in the presence of RecA protein (q.v.) and ATP; under these conditions the fragment invades the dsDNA, generating a single-stranded D-loop which is susceptible to the ssDNA-specific mutagen BISULPHITE. The bisulphite-treated DNA is then introduced into *ung*<sup>-</sup> cells (see URACIL-DNA GLYCOSYLASE) by TRANSFORMATION; during a subsequent round of DNA synthesis, the uracil residues (generated from cytosine by the bisulphite) pair with adenine, leading to G-C → A-T transitions.

SITE-SPECIFIC MUTAGENESIS (oligonucleotide-directed mutagenesis) (diagrammatic).

Here, a phage M13 cloning vector is being used to create a point mutation at a known site in a given gene. The purpose of phage M13 is to make single-stranded copies of the relevant gene. Initially, the (double-stranded) gene is inserted into a circular, double-stranded form of the M13 genome – the so-called *replicative form* (an intermediate stage in phage replication); during the final stage of replication (in a bacterium), M13 produces ccc ssDNA genomes, each genome incorporating one single-stranded copy of the target gene.

The diagram (*top*) shows one single-stranded phage M13 genome. Within the M13 genome, a 20-nucleotide sequence of the target gene (its size exaggerated for clarity) is shown between two bars. Within this sequence of the target gene we wish to replace deoxythymidine (T) with deoxycytidine (C).

The first step is to synthesize an oligonucleotide that is *complementary* to the 20-nucleotide sequence of the target gene – except for one mismatch at the required site: deoxyguanosine (G) opposite deoxythymidine (T). Each of the synthesized oligonucleotides is then bound to a copy of the target gene (*top*) and used to prime *in vitro* DNA synthesis (*dashed line, centre*); subsequent ligation results in dsDNA molecules, each containing the single mismatch in the target gene. These dsDNA molecules are inserted into bacteria by transformation; within the bacteria, replication of the molecules will segregate mutant molecules (*bottom, right*) and non-mutant molecules (*bottom, left*).

Reproduced from *Bacteria* 5th edition, Figure 8.20, page 215, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

Another method involves the use of a chemically synthesized oligonucleotide containing the desired mutant base sequence; this method (*oligonucleotide-directed mutagenesis*) is outlined in the figure.

**site-specific recombination (SSR)** RECOMBINATION involving CROSSING OVER between short, *specific* dsDNA sequences, in the

same or different molecules, with no synthesis or degradation of DNA – and without hydrolysis of phosphodiester bonds (i.e. the reaction is independent of ATP and other energy sources). The initial juxtaposition (*synapse*) of the sequences involves DNA-binding proteins; the two sequences are often identical, but in some cases (e.g. the *attB* and *attP* sites in phage  $\lambda$  integration) they are dissimilar. Cuts are made at staggered sites in the two strands of a given duplex, either concurrently or sequentially, and similar cuts are made in the juxtaposed duplex; strand exchange, between the duplexes, is followed by ligation.

Each particular type of SSR involves a protein (a *recombinase*) which recognizes specific sequences and appears to mediate cutting, strand exchange and ligation; as well as a recombinase, accessory proteins (e.g. the HU PROTEIN) may be needed.

Recombinases are of two main types. One type is exemplified by Tn3 resolvase (see TN3), the other by phage  $\lambda$  integrase [TIG (1992) 8 432–439, and erratum in TIG (1993) 9 45].

A resolvase-type recombinase (encoded e.g. by Tn3, Tn21 and Tn552) forms an intermediate in which all four strands are cut concurrently, with 5' phosphate bound to recombinase. (Phosphate–protein binding conserves energy for subsequent ligation.) The integrase-type recombinase (e.g.  $\lambda$  Int, and the *lox/Cre* system of BACTERIOPHAGE P1) cuts/joins strands pairwise; this enzyme forms an intermediate equivalent to a *Holliday junction* (see RECOMBINATION) in which only one pair of strands has been exchanged.

Examples of SSR include: integration/excision of BACTERIOPHAGE  $\lambda$  (q.v.); RECOMBINATIONAL REGULATION systems of *Salmonella* and phage Mu; *lox/Cre* in BACTERIOPHAGE P1; the resolvase of Tn3 (q.v.) and other transposable elements; gene splicing; monomerization of plasmid dimers; some cases of plasmid–chromosome interaction [JB (1992) 174 7495–7499]; and insertion of the gene cassette into an integron [JAC (1999) 43 1–4].

Some authors regard transposition as a form of (non-conservative) site-specific recombination.

**sitophilous** Living or growing on food (especially cooked or prepared food).

**Sivatoshella** See EIMERIORINA.

**sixth disease** *Syn.* EXANTHEM SUBITUM.

**S<sub>J</sub>** Jaccard coefficient (sometimes spelt Jacquard coefficient). In NUMERICAL TAXONOMY: a coefficient which is similar to S<sub>SM</sub> (q.v.) but which is calculated on the basis of matching *positive* characteristics; if a given characteristic is negative in both OTUs it is discounted.

**skeletal hyphae** See HYPHA.

**Skeletonema** See DIATOMS.

**skiaphilic** (skiaphilous) Shade-loving.

**skin microflora** Human skin is a relatively hostile environment for most microorganisms due e.g. to its low  $a_w$  and the presence of antimicrobial fatty acids released from sebum by the resident flora. Resident bacteria normally include staphylococci (e.g. *S. epidermidis*) and *Propionibacterium acnes*; these organisms generally occur in scattered colonies on the skin and in the pilosebaceous follicles [JGM (1984) 130 797–801; 803–807]. (See also ACNE.) Other organisms commonly present on skin include yeasts (e.g. *Malassezia* spp), aerobic coryneforms, and micrococci. Transient organisms depend e.g. on standards of personal hygiene, and may include coliforms, streptococci, pseudomonads etc.

A reduction in the numbers of microorganisms on the skin may be desirable for various reasons (e.g. to prevent wound

## skin substantivity

infection, body odour etc) and may be achieved by washing or by treatment with ANTISEPTICS. Washing with SOAPS may remove large numbers of organisms, particularly Gram-negative bacteria, but may simply redistribute the resident microflora; organisms in pilosebaceous follicles are almost impossible to eliminate entirely. 'Body odour' is due to the metabolism of apocrine sweat gland secretions by the skin microflora with the formation of malodorous substances (e.g. amines); this can be countered by washing and by the use of deodorants containing aluminium salts (to inhibit sweating) and antiseptics to inhibit microbial action.

**skin substantivity** The extent to which a residue of an antiseptic remains on the skin after washing with a soap containing that antiseptic.

**skin test** Any test in which an antigenic preparation (derived e.g. from a pathogen) is injected into the skin, or applied to the surface of the skin (a *patch test*), and in which the ensuing reaction (if any) may be used e.g. to assist in a medical diagnosis, to indicate susceptibility to a given disease, or to detect an allergy. (See e.g. BRUCCELLIN TEST; DICK TEST; FREI TEST; HISTOPLASMIN TEST; LEPROMIN TEST; SCHICK TEST; TUBERCULIN TEST; VOLLMER PATCH TEST.)

**skin tuberculosis** A chronic disease of cattle in which hard lesions develop in the skin, often on the legs. Acid-fast organisms are often found in the lesions, but the aetiology is uncertain. Affected animals may react to tuberculin (see COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST).

**Skrjabinella** See EIMERIORINA.

**Skulachev ions** See CHEMIOSMOSIS.

**s.l.** SENSU LATO (q.v.).

**slaframine** A parasympathomimetic alkaloid MYCOTOXIN produced by *Rhizoctonia leguminicola*, a fungus which causes 'blackpatch disease' of red clover; consumption of the infected red clover by livestock results in a MYCOTOXICOSIS characterized by excessive salivation ('slobber syndrome') and feed refusal. Slaframine itself has no biological activity but it is converted in the liver to an active form which, chemically and physiologically, closely resembles acetylcholine. (The active form can also be generated photochemically in the presence of FMN.)

**slant** *Syn.* SLOPE.

**slapped cheek syndrome** *Syn.* ERYTHEMA INFECTIOSUM.

**sleeping sickness** (African trypanosomiasis) A human TRYPANOSOMIASIS which occurs in Africa and which is transmitted by species of GLOSSINA. The causal agent is *Trypanosoma (Trypanozoon) brucei gambiense* (in West and West Central Africa, and sometimes also in e.g. Sudan and Uganda), or *T. (T.) brucei rhodesiense* (mainly in East Africa, from Ethiopia to Botswana); the disease caused by *T. (T.) b. rhodesiense* tends to be more acute. [See book ref. 72, pp 97–128.]

Weeks or months after the initial infected bite there is an irregular, recurrent fever, enlargement of lymph nodes (see also WINTERBOTTOM'S SIGN), malaise, joint pains and loss of weight; later symptoms may include e.g. insomnia or drowsiness, epileptic attacks and coma. The disease is usually fatal if untreated.

*Lab. diagnosis:* e.g. microscopy of thick blood smears, lymph node aspirate or cerebrospinal fluid (CSF); MAECT; serological methods – e.g. an indirect fluorescent antibody test.

*Chemotherapy.* SURAMIN has been used in the early stages of the disease when there is no CNS involvement; in later stages (when the CNS is involved) agents such as *melarsoprol* (see ARSENIC) and *eflornithine* are used because they can pass the blood–brain barrier.

*Eflornithine* (DL- $\alpha$ -difluoromethylornithine; DFMO) is used against *Trypanosoma (T.) brucei gambiense* but is not effective against *T. (T.) brucei rhodesiense*; this agent inhibits the enzyme ornithine decarboxylase (ODC), thus inhibiting the synthesis of *trypanothione* (see ARSENIC). The ability of eflornithine to act therapeutically may depend on a slow turnover of trypanosomal ODC (relative to that of mammalian ODC); this appears to be the case with a cattle-infecting trypanosome [JBC (1990) 265 11823–11826]. Eflornithine is useful in late-stage trypanosomiasis as it readily enters the CSF.

**sleepy foal disease** ('shigellosis') An acute, usually fatal, septicæmic disease of newborn foals, caused by *Actinobacillus equuli*. Infection may occur in utero or postnatally.

**slide** (microscope slide) A piece of flat, transparent, colourless glass, about 75 × 25 × 1 mm, on which a specimen is placed (or a SMEAR made) for microscopical examination; the specimen may be overlaid with a COVER-GLASS. (The slide *plus its specimen* is also referred to as a 'slide'.) A suitably prepared specimen (e.g. a fixed, dehydrated, cleared section of tissue) may be made permanent by mounting it (e.g. in CANADA BALSAM) and overlaying it with a cover-glass; when dry, the balsam cements cover-glass to slide. (cf. CAVITY SLIDE, RING SLIDE.)

**slide agglutination test** Any agglutination test in which antigen and antibody preparations are mixed and allowed to interact on the surface of a slide; one or more dilutions of the antigen and/or antibody preparations may be used in the test – a given dilution reacting with a standard amount of the other reactant. Such tests are generally used only when detectable agglutination occurs within minutes. (Agglutination may be detected e.g. by low-power microscopical examination.)

**slim disease** In Africa: the name for a condition characterized by a profound loss of weight and constant diarrhoea; the condition is commonly (or always) AIDS.

**slime bacteria** Bacteria of the MYXOBACTERALES.

**slime layer** See CAPSULE.

**slime moulds** A category of eukaryotic organisms which typically have some fungus-like attributes (e.g., the production of spores in or on fruiting bodies) and some animal-like attributes (e.g., a phagocytic, amoeboid vegetative phase); as commonly used, the term 'slime moulds' refers specifically to the so-called 'true' or acellular slime moulds (see MYXOMYCETES) and the CELLULAR SLIME MOULDS. Taxonomically, these organisms are variously classified – together with certain other groups of organisms – as fungi (division MYXOMYCOTA), as protozoa (mostly in classes of the RHIZOPODA – the labyrinthulas and thraustochytrids being placed in a separate phylum, Labyrinthomorpha), or as a distinct phylum (GYMNOMYXA) of the kingdom PROTISTA (sense 2).

**slimicide** An antimicrobial agent used to inhibit slime-forming organisms.

**slipper animalcule** The ciliate *Paramecium*.

**slit sampler** Any instrument, used for sampling the airborne microflora, in which AIR is drawn in through a narrow slit onto an adhesive collecting surface – see e.g. HIRST SPORE TRAP.

**slobber syndrome** (*vet.*) See SLAFRAMINE.

**slope** (*slant*) (1) A solid medium which has been allowed to set (in the case of e.g. agar or gelatin media) or which has been inspissated (in the case of e.g. DORSET'S EGG) in a diagonally oriented test-tube or bottle. (See also BUTT and POTATO SLOPE.)

(2) A CULTURE prepared by the inoculation and incubation of a slope (sense 1).

**sloppy agar** (semi-solid agar) See AGAR and MEDIUM.

**slow-cycling rhodopsin** (SCR) A RETINAL-containing protein, small amounts of which have been detected in some of the strains

of *Halobacterium salinarium* which contain a PURPLE MEMBRANE. On illumination with yellow light, a 375-nm-absorbing form of SCR accumulates, while illumination with blue (or near-UV) light causes an accumulation of a 590-nm-absorbing form. It has been suggested that SCR may act as the photosensitive pigment during PHOTOTAXIS in halobacteria.

**slow disease** (slow virus infection) An infectious human or animal disease which is characterized by a long, usually asymptomatic, incubation period (months or years) and a prolonged, progressive course, usually or always ending in death. See e.g. PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY, SUBACUTE SCLEROSING PANENCEPHALITIS and VISNA. [Pathogenesis of slow virus diseases: JID (1986) 153 441–447.] (See also LATENT INFECTION and PERSISTENCE.)

‘Unconventional slow virus infections’ was the former name for the PRION-mediated TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**slow-opsin** See OPSIN.

**slow sand filter** See WATER SUPPLIES.

**slow virus** (1) A virus of the LENTIVIRINAE. (2) Any virus (or subviral agent) responsible for a SLOW DISEASE in man or animals.

**SLT-I** See SHIGA TOXIN.

**SLT-II** See SHIGA TOXIN.

**sludge gas** See ANAEROBIC DIGESTION.

**slug** (of slime moulds) See DICTYOSTELIUM.

**SM medium** A medium widely used for the culture of cellular slime moulds (e.g. DICTYOSTELIUM). SM medium generally contains (w/v) peptone (1%); D-glucose or lactose (1%); Na<sub>2</sub>HPO<sub>4</sub>·12H<sub>2</sub>O (0.1%); KH<sub>2</sub>PO<sub>4</sub> (0.15%); agar (2%). The pH is adjusted to 6.5. Other ingredients – e.g. yeast extract (0.1%) and MgSO<sub>4</sub> (0.05%) – may be added. The medium is inoculated with suitable prey (e.g. *Escherichia coli*) and with spores or myxamoebae of the slime mould; incubation is commonly carried out at ca. 20–25°C. [Cultivation of dictyostelids: Book ref. 144, pp. 48–86.]

**SmaI** A RESTRICTION ENDONUCLEASE from *Serratia marcescens*; CCC/GGG.

**SMAC medium** See EHEC.

**small cytoplasmic RNA** See SCRNA.

**small iridescent insect viruses** See IRIDOVIRUS.

**small nuclear RNA** See SNRNA.

**small round structured viruses** (SRSVs) A heterogeneous group of small (~20–40 nm) viruses that include common causal agents of food-borne and water-borne diarrhoeal disease/gastroenteritis; the name SRSVs reflects their appearance under the electron microscope. Viruses with this description have been referred to as e.g. ASTROVIRUSES, human caliciviruses (HCVs) and parvo-like viruses; many have been named after the location of particular outbreaks of disease – e.g. NORWALK VIRUS.

Because the SRSVs have not been cultured, most of the information about them has come from epidemiological studies, studies with volunteers, and laboratory investigations – the latter relying heavily on electron microscopy. Specialized applications of electron microscopy that have been useful include immunoelectron microscopy (IEM) (in which viruses and antibodies react in the fluid phase), and solid-phase immunoelectron microscopy (SPIEM) (in which viruses are captured by grid-bound antibodies).

SRSVs have a genome of positive-sense ssRNA (~7.5 kb in several which have been sequenced). They have been classified in the CALICIVIRIDAE; however, comparison of the sequence and genome organization of Manchester virus (a calicivirus) with those of SRSVs suggests that SRSVs are taxonomically distinct

from caliciviruses. Sequencing data also show that SRSVs are genetically diverse. Phylogenetic analysis indicates at least two genogroups, each consisting of a number of genotypes; for example, Norwalk virus, Southampton virus and Desert Shield virus comprise genogroup 1, while three clusters (one consisting of Hawaii virus and Melksham virus) form genogroup 2.

[SRSVs (review): RMM (1997) 8 149–155.]

**small T antigen** See POLYOMAVIRUS.

**smallpox** (variola major) An acute infectious human disease caused by the variola major virus (see VARIOLA VIRUS). Infection occurs by droplet inhalation and by direct contact with infected persons or fomites. (Contaminated clothing, scabs etc can remain infective for years.) Incubation period: 7–17 days. Typically, symptoms begin abruptly, with fever, headache, nausea, and muscle and joint pains; 2–4 days later the characteristic skin lesions appear. The lesions are most numerous on exposed parts of the body (face, hands etc); they begin as macules, becoming vesicular, then pustular, finally drying to form thick crusts which eventually drop off, leaving scars (pockmarks). The disease may be fatal; recovery is followed by long-term immunity. Other forms of the disease occur. *Haemorrhagic smallpox* is the most severe, with generalized haemorrhages and mortality rates of ca. 100%. *Variola sine eruptione* is a mild, feverish illness (without skin lesions) resembling the prodromal stage of classical smallpox; it occurs mainly in vaccinated individuals. *Alastrim* (variola minor, Kaffir pox, amaas) is a mild form resembling classical smallpox; it is caused by the variola minor virus. *Complications* of smallpox include e.g. secondary bacterial infection of skin lesions followed by septicaemia; lesions in the eyes may lead to blindness. *Lab. diagnosis*: identification and/or culture of the virus from vesicle fluid, smears from skin lesions etc (see also GUARNIERI BODIES); serological tests (e.g. precipitin test, CFT). *Vaccines* against smallpox contain live VACCINIA VIRUS which is injected into the skin to establish a localized viral infection in which a smallpox-like lesion forms at the vaccination site. *Complications* of vaccination include e.g. eczema vaccinatum (see ECZEMA), post-vaccinal ENCEPHALITIS, and generalized vaccinia. Immunity induced by vaccination wanes after several years, although an allergic sensitivity to viral proteins may persist.

In the past, smallpox occurred in epidemics and pandemics throughout the world, with enormous suffering and loss of life. A world-wide eradication programme (based on vaccination, isolation of cases etc), launched by the WHO in 1967, has led to the complete extinction of the disease in nature – the first disease to have been conquered on a global scale. The last recorded naturally acquired cases occurred in October 1975 (variola major) and October 1977 (variola minor). Eradication was possible since there is no asymptomatic human carrier state and apparently no animal reservoir (cf. MONKEYPOX).

**Smc protein** See CELL CYCLE (b).

**smear** (film) Any material (e.g. bacterial culture, wound exudate) prepared for microscopical examination as a thin film on a SLIDE; a smear is often dried, fixed (see e.g. FLAMING), and stained prior to microscopical examination.

**SMEDI viruses** See ENTEROVIRUS.

**smf** SODIUM MOTIVE FORCE.

**smoking** (of meats, fish) A method of FOOD PRESERVATION in which the foodstuff is exposed to smoke for hours or days; smoking has a drying effect, lowering the WATER ACTIVITY and raising the salt concentration of the food. *Wood* smoke contains various phenolic, cresylic and aldehyde components which have antibacterial and antifungal properties.

## smooth endoplasmic reticulum

**smooth endoplasmic reticulum** See ENDOPLASMIC RETICULUM.

**smooth-rough variation** (S→R variation) In many types of (Gram-positive and Gram-negative) bacteria: a change in cell-surface composition which occurs spontaneously during *in vitro* or *in vivo* growth. Some types of S→R variation are reversible; in some cases reversion from the rough to the smooth condition occurs if the rough strain is grown in a living animal. In a number of cases S→R variation appears to involve selection of mutants.

S→R variation was first recorded in the enterobacteria. In these organisms, *smooth* (glossy) colonies may be formed on primary isolation, and *rough* (dull) colonies may develop on subculture; however, because cell-surface components differ widely in different bacteria, the colonies of strains designated 'smooth' or 'rough' do not always conform to this description.

In pathogenic bacteria an S→R transition is, by definition, associated with a lowering of virulence; thus, e.g. smooth (capsulated) strains of *Streptococcus pneumoniae* are virulent, whereas rough (non-capsulated) strains are found to be avirulent in experimental animals.

In general, an S→R transition involves some or all of the following changes:

- (a) the formation of colonies of altered appearance;
- (b) loss of specific smooth-strain antigens and (hence) loss of agglutinability in specific antiserum;
- (c) an increase in cell-surface hydrophobicity;
- (d) an increased susceptibility to hydrophobic antibacterial agents;
- (e) an increased susceptibility to phagocytosis;
- (f) an increased autoagglutinability in saline;
- (g) altered susceptibility to certain phage(s) and bacteriocin(s);
- (h) loss of, or reduction in, virulence.

Enterobacterial *smooth* (S) strains are those in which the cell wall LIPOPOLYSACCHARIDES are entire, i.e. they include the (complete) O-specific chains. In *semi-rough* (SR) mutants only one oligosaccharide subunit is present – such strains apparently lacking the ability to polymerize the (normally repeating) subunits of the O-specific chains. In *rough* (R) mutants the O-specific chains are lacking altogether; such strains are deficient in antigenic specificity (see O ANTIGEN) because their cell-surface constituents (core oligosaccharide + lipid A) may be similar or identical to those in organisms of related species or genera. In some mutants, not only is the O-specific chain missing, but part of the core oligosaccharide is also missing; such mutants are referred to as *deep roughs*.

In *Salmonella typhimurium*, rough mutants designated Ra, Rc, Rd<sub>1</sub>, Rd<sub>2</sub> and Re strains lack, respectively, the O-specific chain, terminal glucose and galactose residues, the proximal glucose residue, the distal heptose residue, and the proximal heptose residue of the core oligosaccharide (see figure in entry LIPOPOLYSACCHARIDE). Because rough strains fail to agglutinate with anti-O antisera, smooth strains of enterobacteria are used in agglutination tests.

**Smooth strain** See SMOOTH-ROUGH VARIATION.

**SMP** Submitochondrial particle: see ETP.

**smudge** A disease of e.g. onions (mainly white varieties) and leeks caused by *Colletotrichum circinans*. Fungal stromata form dark patches on the bulb; in wet conditions the stromata may form a mass of conidiophores. (See also ONION ROT.)

**smut fungi** See USTILAGINALES.

**smut spores** See USTILAGINALES.

**smuts** (1) Fungi of the order USTILAGINALES, particularly those of the family Ustilaginaceae.

(2) Plant diseases caused by the smut fungi (Ustilaginales); those caused by members of the Tilletiaceae on cereals are called 'stinking smuts' or bunts (see e.g. COMMON BUNT and KARNAL BUNT). In *covered smuts* of cereals, the smut sori remain intact within the glumes, so that the spores are not normally released until the grain is threshed; in *loose smuts*, disruption of the host's tissues by the sori permit the spores to be easily dispersed by wind etc. Some smut fungi incite GALLS in the host plant.

Covered smuts on barley and oats are caused by *Ustilago hordei* (formerly *U. kolleri* on oats) and are characterized by blackened ears and (often) the absence of awns; control: antifungal seed treatment. Loose smuts of barley and wheat are caused by (different strains of) *U. nuda* and are characterized by the development of powdery masses of black spores in place of the grains – diseased ears emerging slightly early, and the stems which bear them often being taller than normal stems; the dispersed spores can infect healthy grain which, if used as seed grain, perpetuates the disease. Loose smut was once controlled by immersing seed grain in warm water (e.g. 49°C for 1.5 hours); it is now controlled by the use of certified (pathogen-free) seed grain or by the use of a systemic antifungal agent (e.g. CARBOXIN). Common smut of maize is caused by *U. maydis* and is characterized by the development of whitish, glistening galls on various parts of the plant (including the ears); the galls rupture to release a mass of black spores.

**SnaBI** See RESTRICTION ENDONUCLEASE (table).

**SNAP-25** See TETANOSPASMIN.

**snap-freezing** *Syn.* QUENCH-FREEZING.

**snow algae** See e.g. RED SNOW.

**snow blight** A disease of Scots pine and other conifers caused by *Phacidium infestans*. It occurs in regions of prolonged deep snow cover, the fungus apparently spreading among the needles of young trees under snow; in spring the affected needles turn brown and fall.

**snow mould** Any of several fungi which cause disease in various winter-sown crop plants, developing preferentially under a cover of snow. Common examples: *Fusarium nivale*, which can cause a severe disease in winter-sown cereals such as wheat and rye (sometimes causing complete crop loss), and *Typhula* spp which can cause disease ('snow rot', 'typhula blight') in snow-covered turf-grasses and cereals. (The term 'snow mould' is sometimes used specifically for *F. nivale*.)

**Snow Mountain agent** (SMA) A Norwalk-like virus (see NORWALK VIRUS) which can cause acute gastroenteritis in humans. [RIA for the detection of SMA: JMV (1986) 19 11–18.]

**snow rot** See SNOW MOULD.

**snowshoe hare virus** See BUNYAVIRUS.

**SNP** Single-nucleotide polymorphism.

**SNPV** See NUCLEAR POLYHEDROSIS VIRUSES.

**snRNA** Small nuclear RNA. The eukaryotic nucleus contains numerous small RNA molecules which are typically <300 nt long. In e.g. metazoa 6 snRNAs are particularly abundant (e.g. 2–10 × 10<sup>5</sup> of each type per nucleus), and these are designated U1–U6 (owing to their high content of uridylic acid). These U-RNAs have been strongly conserved during evolution. U1–U5 RNAs are synthesized by RNA POLYMERASE II, and each has a 2,2,7-trimethylguanosine cap at the 5' end (cf. MRNA (b)). U6 RNA is synthesized by RNA polymerase III [JBC (1987) 262 75–81]; it is capped and has a poly(U) sequence at its 3' end. In *Saccharomyces cerevisiae* there are apparently at least 24 distinct snRNAs which vary in size and abundance (at least four are >300 nt long), but are generally much less numerous than the metazoan U-RNAs.

snRNAs function in the nucleus in the form of 'small nuclear ribonucleoprotein particles' (snRNPs or *snurps*). Some proteins are common to several snurps, and some snurps contain more than one snRNA (e.g. U4 and U6 both occur – apparently base-paired together – in the same snurp). Snurps are believed to play important roles in mediating and regulating post-transcriptional RNA processing events: e.g. the splicing of introns from nuclear pre-mRNA (see SPLIT GENE (a)). [Nature (1985) 316 105–106; functions for snRNAs in yeast: TIBS (1986) 11 430–434; conservation of U-snRNPs in fungi, plants and vertebrates: EMBO (1987) 6 469–476.] (cf. SCRNA.)

**snRNP** See SNRNA.

**snurp** See SNRNA.

**Snyder–Theilen feline sarcoma virus** See FES.

**soaps** (as antimicrobial agents) In general, soaps (sodium or potassium salts of long-chain fatty acids) have little or no intrinsic antimicrobial activity, but their surfactant properties can help to reduce the number of microorganisms on the skin. Some soaps are given positive antimicrobial properties by the incorporation of certain antiseptics (see e.g. BISPHENOLS); carbolic soap contains phenol, and some antiseptic soaps contain TCC (see CARBANILIDES). Critical concentrations of soap are needed for the activity of some disinfectants (e.g. Lysol – see PHENOLS). Some antimicrobial agents (e.g. QUATERNARY AMMONIUM COMPOUNDS) may be inactivated by soaps.

**SOB system** See SOS SYSTEM.

**sobemoviruses** (southern bean mosaic virus group) A group of ssRNA-containing PLANT VIRUSES, each of which has a relatively narrow host range; transmission occurs via beetles, via seeds (in some hosts), and mechanically. Type member: southern bean mosaic virus (SBMV); other member: turnip rosette virus. Possible members include e.g. blueberry shoestring virus, cocksfoot mottle virus, and rice yellow mottle virus.

Virion: icosahedral (ca. 30 nm diam.) stabilized by divalent cations. The structure of SBMV is similar to that of TOMBUSVIRUSES, but the coat protein (MWt ca. 30000) lacks a P domain. Genome: one molecule of linear positive-sense ssRNA (MWt ca.  $1.4 \times 10^6$ ); the 3' end is neither polyadenylated nor tRNA-like, and the 5' end is associated (in SBMV and TRV) with a small protein which is necessary for infectivity. Virions occur in both nucleus and cytoplasm in infected plant cells, sometimes forming crystalline arrays in the cytoplasm.

**SOD** SUPEROXIDE DISMUTASE.

**Sodalis** A genus of Gram-negative bacteria of the family Enterobacteriaceae which occur as intra- and intercellular symbionts in various tissues of the tsetse fly (GLOSSINA) (but which can also be grown in vitro). Studies on the genome of *S. glossinidius* have indicated that, compared with the genome of *Escherichia coli*, many of the genes concerned with energy metabolism and with the assimilation of carbon compounds appear to be missing; it was suggested that this may indicate an adaptatin to the use of those energy sources which are available in blood [genome size and coding capacity of *S. glossinidius*: JB (2001) 183 4517–4525].

(See also WIGGLESWORTHIA and WOLBACHIA.)

**sodium azide** See AZIDE.

**sodium dodecyl sulphate** See SDS-PAGE.

**sodium motive force (smf)** The energy associated with a transmembrane electrochemical gradient of sodium ions; smf is analogous to proton motive force (pmf) (see CHEMIOSMOSIS).

In some organisms smf is generated by  $\text{Na}^+/\text{H}^+$  antiport and is used as a driving force for certain TRANSPORT SYSTEMS; for example, the  $\text{Na}^+$ /melibiose symport system is used by

*Escherichia coli* for uptake of the sugar melibiose – melibiose being transported together with sodium ions (i.e. transport at the expense of smf); in such cases smf is secondary to (i.e. dependent on) pmf. (See also ION TRANSPORT.)

The marine bacterium *Vibrio alginolyticus* can generate smf by a primary sodium pump: in this organism respiration can be directly coupled to the outward pumping of sodium ions at the NADH–quinone oxidoreductase segment of the respiratory chain; smf thus generated is insensitive to PROTON TRANSLOCATORS such as CCCP. In *V. alginolyticus* the primary sodium pump (which is inhibited by HOQNO) operates when the extracellular medium is alkaline, but under acidic conditions smf is generated by CCCP-sensitive (pmf-dependent)  $\text{Na}^+/\text{H}^+$  antiport;  $\Delta\psi(\text{Na}^+)$  is maximum at ca. pH 8.5, minimum at ca. pH 6.0. In this organism smf can be used e.g. for the uptake of a range of amino acids and for rotation of the FLAGELLUM. [ $\text{Na}^+$ -motive respiratory chain in marine bacteria: MS (1985) 2 65–71, and in *Vibrio parahaemolyticus*: JB (1985) 162 794–798.] Smf is also used to energize rotation of the polar flagellum in *Vibrio cholerae* [JB (1999) 181 1927–1930]; moreover, the exogenous and endogenous levels of sodium ions appear to be regulatory factors in the expression of virulence factors in *V. cholerae* [PNAS (1999) 96 3183–3187].

*Propionigenium modestum* apparently lacks a respiratory chain, but it can generate smf (see PROPIONIGENIUM); it seems that this organism can live independently of pmf – ATP being generated by a membrane-bound  $\text{Na}^+$ -ATPase [EMBO (1984) 3 1665–1670].

In the higher range of growth temperatures, the cytoplasmic membrane tends to become more permeable to both protons and sodium ions; however, the increase in permeability is greater for protons than it is for sodium ions. At these higher temperatures, organisms whose energy metabolism is based on protons have to use more energy to generate a given level of pmf – simply in order to compensate for the higher rate of inward diffusion of protons. In some organisms, the composition of the cytoplasmic membrane is such that this problem is minimized. However, some thermophilic bacteria do not use protons in their energy metabolism; for example, *Clostridium fervidus* uses sodium ions as the sole energy-coupling ion (i.e. pmf is not used in this species). [Ion permeability at high temperatures: FEMS Reviews (1996) 18 139–148.]

[Enzymes that translocate sodium ions: BBA (1997) 1318 11–51.]

**sodium perborate** See HYDROGEN PEROXIDE (a).

**sodium o-phenylphenate** See PHENOLS.

**sodium polyanetholsulphonate** See SPS.

**sodium pump** See ION TRANSPORT.

**sudoku** See RAT-BITE FEVER.

**soft chancre** *Syn.* CHANCREOID.

**soft core ham** A canned ham (see CANNING) which has undergone spoilage (e.g. souring) due to the growth of e.g. *Enterococcus faecalis* var. *liquefaciens*. (See also FLAT SOUR.)

**soft rot** (1) (of timber) A softening – initially superficial, becoming progressively deeper – in wood which is very moist, or which is kept wet and aerobic (e.g. the wooden slats in cooling towers); it is due to the growth of various cellulolytic ascomycetes (e.g. *Chaetomium globosum*) and deuteromycetes (e.g. *Humicola*, *Monodictys*) within the cell walls ( $S_2$  layer) of the wood. Soft rot fungi can cause serious economic losses of timber, but they do not become established if there is competition from other wood-rotting fungi (e.g. basidiomycetes). [Book ref. 39, pp. 165–169; ultrastructure of soft rot fungi: Mycol.

## soft swell

(1985) 77 447–463, 594–605.] (See also TIMBER SPOILAGE; TIMBER PRESERVATION.)

(2) (of fruit and vegetables) A type of rot, caused by pectinolytic organisms, in which fruit or vegetables degenerate into a wet slimy mass. In acidic fruits (e.g. tomatoes, apples) soft rot is commonly caused by pectinolytic fungi (e.g. species of *Botrytis*, *Penicillium*, *Rhizopus*), while in non-acid fruits and vegetables (e.g. potatoes, carrots) it is more commonly caused by bacteria (e.g. species of *Clostridium*, *Erwinia*, *Pseudomonas*). (See also BROWN ROT (sense 2) and PECTIC ENZYMES; cf. DRY ROT (2).)

**soft swell** See SWELL.

**sog gene** See CONJUGATION (1b) (i).

**soil-borne wheat mosaic virus (SBWMV)** A rod-shaped ssRNA-containing virus which causes mosaic, stunting and yield reduction in winter wheat in parts of Europe, Japan and the USA. It is transmitted by the 'fungus' *Polymyxa graminis*. Isolates of SBWMV consist of at least two components, virion I (281–300 nm long) and virion II (138–160 or 92–110 nm long) – both of which are necessary for infectivity. SBWMV has been classified with the TOBAMOVIRUSES, but in view of its bipartite nature and mode of transmission it has been proposed as the type member of the *furuviruses* (fungus-borne rod-shaped viruses); other members of the group may include e.g. BEET NECROTIC YELLOW VEIN VIRUS, potato mop top virus, and peanut clump virus [JGV (1984) 65 119–127].

**Solanum nodiflorum mottle virus (SNMV)** See VELVET TOBACCO MOTTLE VIRUS and VIRUSOID.

**solfatar** A dormant or decadent volcanic vent which (gently) emits sulphurous gases.

**solid-phase immunoelectron microscopy** See SMALL ROUND STRUCTURED VIRUSES.

**Solorina** A genus of foliose LICHENS (order PELTIGERALES). Photobiont: *Coccomyxa*, usually also with *Nostoc*. In e.g. *S. spongiosa* the thallus consists of two distinct parts: rounded, bright-green, *Coccomyxa*-containing lobes, each with a large, central, pitcher-shaped apothecium, and blue-black, *Nostoc*-containing squamules. In *S. crocea*, *Nostoc* occurs within the thallus in a layer below the green algal layer. In *S. saccata*, *Nostoc* occurs in discrete internal cephalodia. *Solorina* spp occur mainly on calcareous soils, particularly at high altitudes.

**solvent fermentation** *Syn.* ACETONE–BUTANOL FERMENTATION.

**somatic** (1) Refers to an assimilatory, 'vegetative' (i.e., non-reproductive) structure or function.

(2) Refers to the 'body' or main part of a cell. Thus, e.g. a *somatic antigen* is a molecule which forms part of the body of a cell, usually at the cell surface, rather than one which occurs e.g. in a capsule or flagellum. (See e.g. O ANTIGENS.)

(3) Refers to 'common pili', i.e., FIMBRIAE, as opposed to PILI.

**somatic cell hybridization** See HYBRIDOMA.

**somatic hypermutation** See ANTIBODY FORMATION.

**somatogamy** The fusion of somatic (vegetative) cells or hyphae involving PLASMOGAMY but not KARYOGAMY.

**Sonacide** An acidic GLUTARALDEHYDE solution.

**Sonderia** See TRICHOSTOMATIDA.

**sonicate** (1) (*verb*) To carry out SONICATION. (2) (*noun*) The product of sonication.

**sonication** The use of audible sound waves, produced by a SONICATOR, e.g. for the disintegration of cells in a liquid medium (cf. ULTRASONICATION).

**sonicator** (sonifier) An instrument which provides sound energy for SONICATION or ULTRASONICATION. Sonicators commonly work on the principle of magnetostriction: the resonant deformation exhibited by certain types of metal in an alternating magnetic

field; the resonating metal is mechanically linked to a metal *probe* (a cylindrical metal rod) which dips into the liquid and acts as the transmitter of sound energy. The sound waves used are often between 10 kHz and 25 kHz with amplitudes of ca. 10–50  $\mu\text{m}$ . (1 kHz = 1 kc/s = 1000 cycles/second.)

**sonifier** *Syn.* SONICATOR.

**sooty bark** A disease of *Acer* spp (maple, sycamore) caused by *Cryptostroma corticale*; the bark of standing trees peels away to reveal dark-brown masses of conidia. (See also MAPLE BARK STRIPPERS' DISEASE.)

**sooty moulds** Fungi of the family Capnodiaceae and of certain other families of the order DOTHIDEALES. The organisms grow epiphytically, utilizing HONEYDEW, and form dark, spongy, hyphal mats on the surfaces of certain plants. Genera: e.g. *Capnodium*, *Scorias*. (cf. BLACK MILDEWS.)

**sop locus** See PARTITION.

**SopA protein** See PROTEIN SECRETION (type IV systems).

**SopB** See FOOD POISONING (*Salmonella*).

**sophorolipids** Extracellular glycolipid BIOSURFACTANTS produced by '*Torulopsis*' sp during growth on hydrocarbons; they consist of sophorose covalently linked to the hydroxy group of a hydroxy fatty acid.

**sophorose**  $\beta$ -D-Glucopyranosyl-(1  $\rightarrow$  2)-D-glucopyranose – an effective inducer or certain CELLULASES. It occurs e.g. in certain plant glycosides and as an impurity in commercial glucose.

**soralium** (*lichenol.*) A delimited mass of soredia (see SOREDIUM) present on the thallus in certain lichens. Soralia may occur in positions and forms which are characteristic for a given lichen species: they may be e.g. marginal (at the edges of the thallus), capitate (at the tips of lobes or branches), laminal (on the upper or lower surface of the thallus), etc.

**Sorangium** See MYXOBACTERALES.

**sorbates** See SORBIC ACID.

**sorbic acid** ( $\text{CH}_3(\text{CH}=\text{CH})_2\text{COOH}$ ) An antibacterial and antifungal ORGANIC ACID used (as the free acid or e.g. as the potassium salt) as a PRESERVATIVE (e.g., in soft drinks, wines, pickles, cheese, pharmaceuticals). It has been reported that both dissociated and undissociated forms of sorbic acid have antimicrobial activity, but that organisms differ greatly in their susceptibilities [JAB (1983) 54 383–389]. Potassium sorbate (1–2% w/v) has been shown to reduce the germination rate of *Clostridium botulinum* type E endospores under acidic conditions [AEM (1982) 44 1212–1221].

**sorbitol** (glucitol) The POLYOL corresponding to glucose; D-sorbitol may be obtained e.g. by reduction of D-glucose, D-fructose or L-sorbose (see also ASCORBIC ACID). Sorbitol occurs naturally e.g. in certain plants, including a few unicellular green algae and a single red alga (*Bostrychia scorpioides*) [Book ref. 37, pp. 165–167]. D-Sorbitol is used e.g. as a food sweetener for diabetics, and as a substrate in biochemical characterization tests for bacteria (it is attacked by many species).

**sorbitol–MacConkey agar** See EHEC.

**sorbose fermentation** A commercial FERMENTATION (sense 2) in which D-sorbitol (see SORBITOL) is oxidized to the 2-ketohexose L-sorbose by *Acetobacter* or *Gluconobacter* spp, especially *G. oxydans* ('*Acetobacter suboxydans*'). L-Sorbose is used mainly as an intermediate in the manufacture of ASCORBIC ACID.

**Sordaria** A genus of fungi (order SORDARIALES) which occur e.g. on dung and soil; the organisms form brown or black ascospores in persistent asci within dark perithecia – see ASCOSPORE for mode of spore discharge. Many species apparently do not form conidia. *S. fimicola* is homothallic.

**Sordariales** An order of fungi (subdivision ASCOMYCOTINA) which occur typically as saprotrophs on wood, soil or dung; the organisms typically form perithecia which are not immersed in a stroma and in which a hamathecium is absent. Asci: unitunicate, cylindrical to clavate, sometimes deliquescent. Ascospores: often dark, sometimes appendaged or bearing a gelatinous coat. Genera include e.g. *Cercophora*, *CHAETOMIUM*, *Melanospora*, *NEUROSPORA*, *Nitschkea*, *PODOSPORA*, *SORDARIA*, *Sphaerodes*, *Triangularia*.

**sordelliolysin** See THIOL-ACTIVATED CYTOLYSINS.

**sorediate** Bearing or consisting of soredia.

**soredium** (*lichenol.*) A vegetative propagule (25–100 µm diam.) consisting of a few algal cells enmeshed in a few fungal hyphae; there is no cortex. Soredia appear, macroscopically, as powdery or granular structures on the thallus surface – often occurring in clusters (see SORALIUM). They originate in the medulla and are pushed up through pores or cracks in the cortex.

**Soret band** See CYTOCHROMES.

**sori** See SORUS.

**sorocarp** A fruiting body, formed by certain SLIME MOULDS, consisting of a stalk bearing a mass of spores or chains of spores. (cf. SOROCYST.)

**sorocyst** A fruiting body, formed by certain SLIME MOULDS, which resembles a SOROCARP but lacks a stalk.

**Sorodiscus** See PLASMODIOPHOROMYCETES.

**sorogen** In cellular slime moulds (e.g. DICTYOSTELIUM): the total cell mass which is undergoing differentiation to form a sorocarp.

**Sorsphaera** See PLASMODIOPHOROMYCETES.

**sortase** In *Staphylococcus aureus*: an enzyme, associated with the cytoplasmic membrane, which catalyses a reaction in which certain proteins, secreted through the membrane, undergo site-specific cleavage and covalent linkage to the cell envelope peptidoglycan. Such proteins, which are thus tethered to the cell wall (cf. AUTODISPLAY in *Escherichia coli*), are characterized by a C-terminal *cell wall sorting signal* that includes the conserved sequence LPXTG (see AMINO ACIDS); sortase cleaves between threonine and glycine and links the threonine residue to peptidoglycan. PROTEIN A is an example of a cell-wall-anchored protein.

[Sortase-catalysed anchoring of surface proteins to the cell wall of *S. aureus*: Mol. Microbiol. (2001) 40 1049–1057.]

**sorus** (*pl. sori*) A type of fruiting structure composed essentially of a mass of spores (e.g. in fungi of the Uredinales and Ustilaginales, and in certain SLIME MOULDS) or sporangia (e.g. in SYNCHYTRIUM).

**SOS box** See SOS SYSTEM.

**SOS chromotest** A colorimetric assay for GENOTOXINS using a genetically engineered strain of *Escherichia coli*. In this strain the SOS gene *sulA* (= *sfiA*) is fused with *lacZ* such that *lacZ* (structural gene for β-galactosidase) behaves as an SOS gene, being induced in response to DNA damage (see SOS SYSTEM). The strain also has mutations in *uvrA* (preventing excision repair) and in *rfa* (rendering it LPS-deficient and more permeable to certain chemicals); it also synthesizes alkaline phosphatase constitutively. Basically, the test involves incubating cultures of the 'tester' strain with various concentrations of a suspected genotoxin, and assaying for β-galactosidase activity using (e.g.) ONPG as substrate. The possibility that the chemical under test may inhibit protein synthesis can be excluded by assaying for alkaline phosphatase activity. [Mut. Res. (1985) 147 65–78, 79–95.] (cf. AMES TEST.)

**SOS mutagenesis** See SOS SYSTEM.

**SOS response** In *Escherichia coli*: expression of genes of the SOS SYSTEM in response to conditions which induce that system.

**SOS system** A system in which the expression of certain genes ('SOS genes') is induced (turned on, or enhanced) in response to damaged DNA or to inhibition of DNA replication – caused e.g. by the effects of ULTRAVIOLET RADIATION or the action of an ALKYLATING AGENT or quinolone antibiotic (such as NALIDIXIC ACID). (The SOS system can also be induced e.g. by the CcdB toxin: an agent, encoded by the F plasmid, which affects gyrase at sites other than those targeted by the quinolone antibiotics [TIM (1998) 6 269–275].)

The SOS response results in e.g. inhibition of cell division, an increased capacity for DNA repair, alleviation of restriction, an altered pattern of energy metabolism, and (in those strains which contain a COLICIN PLASMID) production of colicin; it also gives rise to an increased rate of mutation.

The SOS system has been studied mainly in *Escherichia coli*, and the following account refers primarily to the operation of the SOS system in that organism.

*Control of the SOS response.* The SOS system consists of about 30 unlinked genes which are normally repressed by the LexA protein (*lexA* gene product). LexA (perhaps as a dimer) inhibits transcription by binding to an operator sequence (an *SOS box*) in the promoter region of each gene or operon; the binding site for LexA is apparently the consensus sequence 5'-CTGTN<sub>8</sub>ACAG-3' (in which N<sub>8</sub> is an 8-nucleotide sequence). Different SOS boxes have different levels of affinity for LexA, and many of the SOS genes are expressed at low levels even in the repressed state. (At least one SOS gene, *uvrB*, has a second promoter which is not subject to control by LexA.) The LexA protein also represses its own synthesis; however, the SOS box of the *lexA* gene has a low affinity for LexA, so that there is always enough LexA to repress the other SOS genes.

Damaged DNA 'activates' the RECA PROTEIN in an unknown way, i.e. the precise nature of the SOS-inducing signal is not known – although it is generally believed to involve a region of ssDNA and/or product(s) of DNA degradation.

Activated RecA (designated RecA\*) behaves as a CO-PROTEASE which triggers the autocatalytic cleavage of LexA – permitting expression of the SOS genes. In vitro studies on the cleavage of LexA have suggested that cleavage occurs more rapidly when a chi (χ) site (5'-GCTGGTGG-3') occurs near a double-stranded break in DNA; it may be that the presence of χ promotes activation of RecA [Cell (1998) 95 975–979].

Weak SOS-inducing signals (due e.g. to low-level damage to DNA) may lower the intracellular concentration of LexA to only a limited extent – so that only those SOS genes with low-affinity SOS boxes will be induced.

*Inhibition of cell division.* One aspect of the SOS response is a temporary inhibition of septum formation (and, hence, cell division); mutants in which the SOS system is constitutively de-repressed form aseptate filaments.

During induction of the SOS system, septum formation is prevented as a result of inhibition of polymerization of the FtsZ protein (product of the *ftsZ* gene: see 'Z ring' in CELL CYCLE (b)). Polymerization of FtsZ is blocked by SulA, product of the SOS gene *sulA* (= *sfiA*) [JB (1998) 180 3946–3953]; cells may continue to grow as septum-less filaments. (Previously, some mutant alleles of *ftsZ* were referred to as *sulB* and *sfiB*.)

SulA is normally very unstable, so that when repression of *sulA* is re-imposed normal septation is rapidly restored. At least part of the instability of SulA is due to its proteolytic inactivation by the product of the *lon* gene; in *lon* mutants SulA is much more stable, and induction of the SOS response – even by mild ultraviolet radiation – may lead to lethal filamentation.

## souma

(Lon is a HEAT-SHOCK PROTEIN; note that the heat-shock response can be triggered by certain factors – such as ultraviolet radiation – which induce the SOS system.)

A temporary inhibition of cell division may be advantageous to the cell in that the cell is given time to carry out repairs to damaged DNA.

**DNA repair.** The UvrABC-dependent nucleotide excision repair system (including genes *uvrA* and *uvrB*) and the RECOMBINATION REPAIR system are enhanced in the SOS response; these repair systems have a high degree of accuracy ('error-free' repair).

Another repair system, which is apparently expressed only when the SOS system is induced, involves genes *umuC* and *umuD*; the operation of this so-called 'error-prone' repair system (also called *mutagenic repair*) results in an increased rate of mutation (which is referred to as *SOS mutagenesis*). In this process, RecA\*, acting as a co-protease, mediates autocatalytic cleavage of UmuD to an active fragment, UmuD' (see DNA POLYMERASE V). SOS mutagenesis is believed to involve DNA (repair) synthesis on a template strand that contains a 'lesion' – e.g. a pyrimidine dimer (two adjacent, covalently linked pyrimidines on the same strand); such *translesion* synthesis is likely to involve specific DNA polymerase(s) induced as part of the SOS response – including DNA POLYMERASE V, DNA POLYMERASE IV and DNA polymerase II (*polB* gene product) [TIBS (2000) 25 74–79]. Because of a local loss of base-pairing specificity at the lesion, repair synthesis is likely to introduce incorrect bases and give rise to a mutant genome. (See also WEIGLE REACTIVATION.)

Once the damaged DNA has been repaired, RecA becomes inactive as a co-protease; as the *lexA* gene is induced during the SOS response, the high level of LexA being synthesized means that, when activated RecA disappears, repression of the SOS genes (and restoration of normal cell function) can occur rapidly.

Systems resembling the SOS system in *E. coli* have been observed in some other Gram-negative bacteria – e.g. species of *Bacteroides*, *Rhizobium* and *Salmonella* – as well as in *Bacillus subtilis* ('SOB system').

Many bacteria appear to be inherently resistant to mutagenesis induced by ultraviolet radiation, and seem not to possess a *umuDC* function; such bacteria include *Deinococcus radiodurans*, *Haemophilus influenzae*, *Proteus mirabilis*, *Streptococcus pneumoniae* and *Salmonella typhimurium*.

Functional homologues of *umuC* and *umuD* are carried by certain conjugative plasmids (e.g. ColI, R46 and its derivative pKM101, R205); the genes *mucA* and *mucB* in pKM101 are able to suppress the non-mutability of *E. coli umuC* and *umuD* mutants, and when introduced into cells which normally lack a *umuCD* system, pKM101 can decrease the susceptibility of those cells to killing while increasing their susceptibility to mutagenesis on exposure to *umuCD*-dependent mutagens. (See also AMES TEST.) [Plasmid genes affecting DNA repair and mutation: JCS (1987) 6 (supplement) 303–321.]

The SOS system may be viewed as an adaptive genetic response to specific types of unfavourable environment. Under these conditions it is advantageous for bacteria to be able to make essential repairs and to adapt rapidly by making use of any (fortuitous) new combinations of nucleotides that may enhance their survival. This is reflected in increased repair activity and also in SOS mutagenesis – the latter offering the possibility of beneficial as well as lethal mutations. Suppression of restriction may favour exploitation of imported DNA, while inhibition of cell division may help e.g. to conserve energy and avoid the formation of non-viable daughter cells.

*Error-prone repair in in vitro mutagenesis.* A variety of mutagenic agents depend on the *umuDC* system for their mutagenic effects; thus, *umuDC* mutants of *E. coli* are resistant to the mutagenic effects of e.g. ultraviolet radiation and methylmethane sulphonate (see ALKYLATING AGENTS) – but can still be mutated by agents such as MNNG and ethylmethane sulphonate (see ALKYLATING AGENTS) which cause lesions leading directly to base mispairing.

**souma** NAGANA caused (usually or exclusively) by *Trypanosoma vivax*.

**sour cream** Cultured sour cream is made by the fermentation of pasteurized and homogenized cream (18–20% milk fat) using the same organisms as for BUTTERMILK.

**sourdough bread** See BREAD-MAKING.

**South American blastomycosis** *Syn.* PARACOCIDIOIDOMYCOSIS.

**Southampton virus** See SMALL ROUND STRUCTURED VIRUSES.

**Southern bacterial wilt** *Syn.* GRANVILLE WILT.

**southern bean mosaic virus** See SOBEMOVIRUSES.

**Southern blot** (Southern blotting) (1) A BLOTTING technique in which DNA is transferred from a gel to a nitrocellulose matrix (see figure).

(2) Erroneously, a synonym of SOUTHERN HYBRIDIZATION.

**Southern hybridization** A procedure used e.g. to detect a specific sequence of nucleotides among fragments of DNA which have been separated by gel electrophoresis. Initially, using the SOUTHERN BLOT technique (q.v.), single-stranded forms of the fragments are bound to a matrix. In the next step (Southern hybridization) the matrix is exposed to a labelled PROBE complementary to the sequence of interest; HYBRIDIZATION (sense 1) between the probe and a specific region of the blotted DNA (detected by the probe's label) indicates the required sequence.

**Southwestern blotting** A technique for detecting DNA-binding proteins in a cell lysate etc. The sample is initially subjected to gel electrophoresis, and the *proteins* thus separated are electroblotted (see BLOTTING) onto a nitrocellulose filter. The affinity of any blotted protein for a specific DNA sequence is then determined by using labelled DNA sequences as probes and detecting the label of any probe which has bound to a given protein.

**soy paste** *Syn.* MISO.

**soy sauce** (shoyu) A condiment traditionally prepared by fermenting soybeans and (usually) wheat (cf. TAMARI SAUCE). A KOJI (made from whole or defatted soybeans and crushed roasted wheat) is transferred to a deep vessel and is suspended in brine (to 17–19% NaCl) to form 'moromi'; the moromi is allowed to ferment, usually with occasional agitation and aeration, for e.g. 6–8 months or more. During this stage, enzymes from the koji mould hydrolyse proteins and starch in the raw materials to provide low-MWT substrates which are initially fermented primarily by lactic acid bacteria (e.g. *Lactobacillus delbrueckii*, *Pediococcus halophilus*); the pH falls rapidly to ca. 5.0 or lower, after which fermentation is continued primarily by yeasts (e.g. *Zygosaccharomyces rouxii*). '*Torulopsis*' spp (*Candida etchellsii*, *C. versatilis*) may grow at later stages in the fermentation; these yeasts produce substances which contribute to the flavour and aroma of the final product. The soy sauce fermentation may be carried out by microorganisms naturally present in the raw materials, or pure cultures of selected strains may be used. After the fermentation, the raw soy sauce is decanted or pressed from the solid residue and is pasteurized, filtered and bottled. [Book ref. 5, pp. 39–86; microbes used in soy sauce manufacture: Food Mic. (1984) 1 339–347.]

**SOUTHERN BLOT** (Southern blotting): the transfer of DNA fragments from a gel strip to a sheet of nitrocellulose by capillary action.

Within the gel, the fragments are distributed in discrete zones, according to size, having been previously separated by gel electrophoresis. The fragments are first denatured (made single-stranded) by exposing the gel to alkali; the gel is then exposed to neutral buffer and arranged as shown in the diagram. Driven by capillary action, the neutral, saline solution in the dish rises, via the wick, into and through the gel, through the (permeable) nitrocellulose, and into the stack of paper towels; this upward stream of liquid carries the DNA fragments from the gel to the sheet of nitrocellulose. Importantly, the relative positions of fragments on the sheet are the same as they were in the gel. The sheet is removed and baked at 70°C under vacuum to bind the DNA. The fragments can then be examined e.g. by exposing the sheet to a specific labelled probe; probe–target binding (= *Southern hybridization*), detected by the probe's label, identifies the required sequence.

One alternative to nitrocellulose is *APT PAPER* (q.v.). This not only avoids the need for baking, it also permits removal of probes – so that different probes can be subsequently used on the same sheet.

*Northern blotting* refers to the transfer of RNA from gel to matrix.

*Western blotting* refers to the transfer of protein from gel to matrix.

*Electroblotting* is a faster method which uses an electric field for effecting transfer.

Figure reproduced from *Bacteria* 5th edition, Figure 8.13, page 195, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

**soybean casein digest agar** *Syn.* TRYPTICASE–SOY AGAR.

**soybean dwarf virus** See LUTEOVIRUSES.

**soybean mosaic virus** See POTYVIRUSES.

**S<sub>p</sub>** Pattern coefficient. In the comparison of two strains by NUMERICAL TAXONOMY: a coefficient which indicates the degree of similarity corrected for any difference(s) due solely to inter-strain differences in metabolic vigour. (cf. entry D<sub>p</sub>.)

**sp** An unspecified SPECIES: e.g. *Bacillus* sp (a species of *Bacillus*); spp indicates two or more unspecified species or *may* indicate all the species of the given genus.

**sp. n.** See SPECIES NOVA.

**sp. nov.** See SPECIES NOVA.

**SpA** PROTEIN A.

**Sparassidaceae** See APHYLLOPHORALES.

**Sparassis** A genus of fungi (family Sparassidaceae). *S. crispa* (the 'brain fungus' or 'cauliflower fungus') is an edible species which typically grows at the base of conifer trees; the thallus (branching, flattened lobes) is pale buff, up to ca. 50 cm across, and the basidiospores are whitish or cream-coloured, ca. 6 × 4 μm.

**sparfloxacin** See QUINOLONE ANTIBIOTICS.

**sparrowpox virus** See AVIPOXVIRUS.

**sparsomycin** An ANTIBIOTIC which inhibits PROTEIN SYNTHESIS in both prokaryotic and eukaryotic cells; it binds to the larger ribosomal subunit and inhibits the peptidyl transferase reaction.

**Spartina mottle virus** See POTYVIRUSES.

**spasmoneme** The MYONEME within the stalk of a contractile peritrich (such as VORTICELLA).

**Spathularia** See HELOTIALES.

**Spathulospora** See SPATHULOSPORALES.

**Spathulosporales** An order of fungi (subdivision ASCOMYCOTINA) which are parasitic on red algae. The thallus is a crustose

or intracellular stroma. Ascocarp: perithecioid. Asci: unitunicate, deliquescent. Ascospores: appendaged, some spoon-shaped (spathulate). The sole genus, *Spathulospora*, is classified in the LABOULBENIALES by some authors.

**spawn** (*mycol.*) Mycelium – usually of *Agaricus brunescens* (*A. bisporus*) – growing e.g. in a block ('brick') of horse manure, used as an inoculum in MUSHROOM CULTIVATION. It may be derived from a previous culture or may be grown by inoculating sterile compost with spores of a selected strain.

**spc operon** In e.g. *Escherichia coli*: an OPERON containing genes for r-proteins L14, L24, L5, S14, S8, L6, L18, S5, L30, and L15, and gene *prlA* (= *secY*: involved in protein secretion), listed in order of transcription. (See RIBOSOME.)

**SpeI** See RESTRICTION ENDONUCLEASE (table).

**speB gene** (*Streptococcus*) See NECROTIZING FASCIIITIS.

**special form** *Syn.* FORMA SPECIALIS.

**specialized transduction** See TRANSDUCTION.

**speciation** (1) The evolutionary process which leads to the formation of new species. (2) The taxonomic process by which species are delimited.

**species** (*microbiol.*) (singular and plural: species) One of the less-inclusive categories in TAXONOMY – the individuals of a given species displaying a high degree of mutual similarity; a universally applicable and acceptable definition of 'species' is currently not available.

Among microorganisms, SPECIATION (sense 2) was particularly unsatisfactory for prokaryotes prior to the mid-1960s. Since then, molecular methods have progressively provided a basis for what is thought to be a PHYLOGENETIC CLASSIFICATION of these organisms. Such methods include DNA HOMOLOGY studies and the comparison of organisms on the basis of nucleotide sequences in their 16S rRNA.

## species nova

DNA homology studies suggest e.g. that bacterial strains whose DNA exhibits >70% relatedness are likely to belong to the same species. Moreover, 16S rRNA sequences in different species of a given genus have generally been found to differ by at least 1.5%. These two measurements therefore help to determine which strains belong to a given species and which strains belong to different species. However, certain species of *Bacillus* – which are clearly differentiated at the species level by DNA homology studies – were shown to have virtually identical sequences in their 16S rRNA molecules [IJSB (1992) 42 166–170]; a possible explanation is that the genomes of these species have diverged recently (on an evolutionary scale) and that their 16S rRNA sequences have had insufficient time to reflect the change.

Strains within a given species may exhibit variation in character due e.g. to the effects of MUTATION (see also ECOTYPE; cf. ECAD) or to the acquisition (or loss) of a PLASMID. Strains can be differentiated by various TYPING techniques.

The term 'species' is also used, for convenience, to refer to the *organisms* belonging to one or more given species – as, for example, in: 'Gram-negative species were isolated from the sample'.

(See also BINOMIAL, TYPE SPECIES; TYPE STRAIN.)

**species nova** (n. sp.; sp. n.; sp. nov.) A designation used to indicate a newly proposed species at the time of its initial publication.

**specific epithet** See BINOMIAL.

**specific growth rate** ( $\mu$ ) Of a given organism: the number of grams of biomass formed per gram of biomass per hour; the unit of  $\mu$  is hour<sup>-1</sup>. In any given case,  $\mu$  depends on factors which include the strain of organism, the temperature, and the concentration of nutrients. Under steady-state conditions in CONTINUOUS CULTURE  $\mu$  can often be calculated from the Monod equation:

$$\mu = \mu_{\max} \frac{s}{k_s + s}$$

in which  $s$  is the concentration of a potentially limiting nutrient,  $\mu_{\max}$  is the value of  $\mu$  when the given nutrient is not limiting, and  $k_s$  is numerically equal to the concentration of the given nutrient when  $\mu = 0.5 \mu_{\max}$ . (See also DILUTION RATE.)

**specific immunity** Any form of IMMUNITY specific to a given antigen – including e.g. antibody-mediated protective immunity, hypersensitivity, immunological tolerance. (cf. NON-SPECIFIC IMMUNITY.)

**specific pathogen free (SPF)** Refers to the condition of an animal which was born (or removed from the uterus) and reared under conditions in which specific pathogen(s) have been rigorously excluded. (cf. GNOTOBIOTIC.)

**specific-phase antigen** See PHASE VARIATION.

**spectinomycin** An aminocyclitol usually classified as an AMINOGLYCOSIDE ANTIBIOTIC (even though it does not contain an aminosugar). Spectinomycin is produced by *Streptomyces spectabilis* and is (reversibly) bacteriostatic. Spectinomycin-dependent strains of *Escherichia coli* have been found to be double mutants – one mutation conferring resistance to the drug by modifying ribosomal protein S5, the other conferring drug dependence [MGG (1977) 151 261–267]; spectinomycin does not support the growth of STREPTOMYCIN-dependent bacteria.

**spermagonium** (*syn.* spermogonium, spermatogonium) In certain fungi: a structure within which male reproductive cells (spermatia) are formed. In rust fungi, a spermagonium is called a *pycnium*.

**spermatiphore** A modified or undifferentiated hypha which bears a SPERMATIUM.

**spermatium** A non-motile male reproductive cell which can function in SPERMATIZATION. (cf. MICROCONIDIUM (sense 1) and PYCNOSPORE.)

**spermatization** In certain higher fungi: the union of a SPERMATIUM with a female reproductive structure (e.g. a TRICHOGYNE or a FLEXUOUS HYPHA).

**spermatogonium** *Syn.* SPERMAGONIUM.

**spermidine** See POLYAMINES.

**spermine** See POLYAMINES.

**spermogonium** *Syn.* SPERMAGONIUM.

**Spermophthora** See METSCHNIKOWIACEAE.

**Spermophthoraceae** *Syn.* METSCHNIKOWIACEAE.

**SPF** SPECIFIC PATHOGEN FREE.

**SPF66 vaccine** See MALARIA.

**Sphacelia** See PHAEOPHYTA.

**Sphacelia** A genus of fungi of the HYPHOMYCETES; teleomorphs occur e.g. in the genus CLAVICEPS.

**Sphaceloma** A genus of fungi of the COELOMYCETES. Teleomorph: *Elsinoë*.

**Sphaelotheca** See USTILAGINALES.

**Sphaeractinomyxon** See ACTINOSPOREA.

**Sphaeriales** An order of fungi (subdivision ASCOMYCOTINA) which typically form carbonaceous perithecia (often containing filiform paraphyses) immersed in a stroma. Asci: unitunicate, cylindrical or ellipsoidal. Ascospores: aseptate or septate, colourless or dark. Genera: e.g. *Ascotricha*, *Camarops*, DALDINIA, *Hypoxylon*, XYLARIA.

**Sphaerobolus** A genus of lignicolous and coprophilous fungi (order SCLERODERMATALES) formerly classified in the Nidulariales. *S. stellatus* forms globose basidiocarps (ca. 1.5–2.5 mm diam.) in which the peridium is composed of six layers. At maturity, the glebal mass is violently discharged following rupture of the peridium and the sudden eversion of certain inner layers; eversion occurs apparently as a result of increased osmotic pressure in one of the inner layers (due to the breakdown of glycogen to soluble sugars) and the consequent stress upon this (and an adjacent) layer on absorption of water. [Culturing for fruiting bodies: Mycol. (1984) 76 944–946.]

**sphaerocyst** A spherical or ovoid cell, numbers of which occur in the TRAMA, and in other parts of the CONTEXT, e.g. in fungi of the genera *Lactarius* and *Russula*.

**sphaerocyte** An (abnormal) spherical or subspherical form of an erythrocyte formed, e.g., as a result of the activity of *Escherichia coli*  $\alpha$ -haemolysin.

**Sphaerocytophaga** A genus of bacteria; the organisms are similar or identical to species of CAPNOCYTOPHAGA [Book ref. 45, pp. 356–379 (365)].

**Sphaerodes** See SORDARIALES.

**Sphaerodothis** See POLYSTIGMATALES.

**sphaeromastigote** A form assumed by the cells of species of *Trypanosoma* during certain stages of their life cycles: see TRYPANOSOMATIDAE.

**Sphaeromonas** A genus of fungi found in the RUMEN.

**Sphaeromyxa** See MYXOSPOREA.

**Sphaerophoraceae** See CALICIALES.

**Sphaerophorus** (1) (*mycol.*) See CALICIALES. (2) (*bacteriol.*) Obsolete genus of bacteria which are currently included in the genera BACTEROIDES and FUSOBACTERIUM.

**Sphaerophrya** See SUCTORIA.

**sphaeroplast** (spheroplast) A spherical or near-spherical, osmotically sensitive structure which resembles a PROTOPLAST but is

formed by the disruption or *partial* removal of the cell wall of a cell suspended in an isotonic (or hypertonic) medium – i.e., cell wall fragments remain adhering to the cytoplasmic membrane. *Bacterial* sphaeroplasts are typically formed from Gram-negative cells, since it is generally difficult to effect the complete removal of the cell wall from such cells. Sphaeroplasts from Gram-negative bacteria may be prepared by suspending the cells in a solution containing EDTA, TRIS, LYSOZYME, and (hypertonic) sucrose, or by exposing the cells (in a hypertonic medium) to antibiotics (e.g. PENICILLINS) which inhibit cell wall synthesis. Sphaeroplasts may be formed from Gram-positive cells by limited action of wall-lysing enzymes. (cf. AUTOPLAST.) *Yeast* sphaeroplasts may be prepared by treating yeast cells with e.g. ZYMOLYASE.

**Sphaeropsidales** An order of fungi (class COELOMYCETES) in which the vegetative mycelium and the conidiomata may develop on the surface or within the substrate or host, and the conidiogenous cells line discrete pycnidia (see PYCNIDIUM) or locules in a stroma. Genera include e.g. ASCHERSONIA, ASCOCHYTA, *Chaetomella*, *Coniothyrium*, *Dendrophoma*, *Diplodia* (see also BLUE-STAIN and SAP-STAIN), PHOMA, *Phomopsis* (see also LUPINOSIS), *Phyllosticta*, SEPTORIA, *Sphaeropsis*, ZYTHIA.

**Sphaeropsis** See SPHAEROPSIDALES.

**Sphaerospora** See MYXOSPOREA.

**Sphaerotheca** See ERYSPHIALES.

**Sphaerotilus** A genus of Gram-negative, rod-shaped, obligately aerobic, asporogenous bacteria which occur in flowing, organically polluted fresh water (see SEWAGE FUNGUS) and in activated sludge (see SEWAGE TREATMENT). Individual cells ('swarmers') of the type (sole) species, *S. natans*, are ca. 1–2 × 3–10 µm, each with a subpolar or polar tuft of flagella; the cells commonly occur as sheathed trichomes, the SHEATH (sense 1) consisting of a polysaccharide–protein–lipid complex. (Sheaths are not formed in nutritionally rich media, and trichomes in activated sludge have thin, colourless sheaths. In some cases a sheath bears a slime layer containing an accumulation of Fe(OH)<sub>3</sub>.) Sheathed trichomes are commonly attached (at one end) to the substratum. The organisms can utilize a wide range of carbon and nitrogen sources; VITAMIN B<sub>12</sub> (replaceable by methionine) is a growth requirement. PHB may be accumulated. GC%: ca. 70. [Book ref. 45, pp. 425–440 (428–431).]

**Sphaerulina** See DOTHIDEALES.

**spheroid** (*virol.*) See ENTOMOPOXVIRINAE.

**spheroidin** See ENTOMOPOXVIRINAE.

**spheroidosis** (*pl.* spheroidoses) See ENTOMOPOXVIRINAE.

**spheroplast** *Syn.* SPHAEROPLAST.

**spherule** (1) See COCCIDIOIDES. (2) See SCLEROTIUM (sense 1). (3) See ENTOMOPOXVIRINAE.

**spherulin** An antigen, prepared from the spherule stage of *Coccidioides immitis*, said to be more sensitive than COCCIDIOIDIN in skin tests for COCCIDIOIDOMYCOSIS.

**Sphingobacterium** A genus proposed for sphingolipid-containing strains of *Flavobacterium* [see e.g. FEMS (1983) 20 375–378].

**sphingolipid** A lipid derived from the aminoalcohol *sphingosine*. (Sphingosine is CH<sub>3</sub>.(CH<sub>2</sub>)<sub>12</sub>.CH=CH.CH(OH).CH(NH<sub>2</sub>).CH<sub>2</sub>OH.) Sphingolipids include the phospholipid SPHINGOMYELIN and the non-phospholipids *cerebroside* (in which the C-1 hydroxyl of sphingosine is linked to a sugar residue) and GM gangliosides (in which the hydroxyl group is linked e.g. to several sugar residues and a residue of *N*-acetylneuraminic acid).

**Sphingomonas chlorophenolica** See BIOREMEDIATION.

**sphingomyelin** A SPHINGOLIPID (q.v.) which occurs e.g. in the plasma membrane in erythrocytes; in sphingomyelin, the amino

group at C-2 of sphingosine forms an amide bond with a long-chain fatty acid (forming *ceramide*), and the terminal (C-1) hydroxyl is esterified with phosphorylcholine.

**sphingomyelinase** A PHOSPHOLIPASE (q.v.) which cleaves SPHINGOMYELIN. An example is the staphylococcal β-HAEMOLYSIN, a C-type phospholipase which cleaves sphingomyelin to phosphorylcholine and ceramide. (See also HOT-COLD LYSIS.) *Corynebacterium pseudotuberculosis* (formerly *C. ovis*) forms a sphingomyelinase (a D-type phospholipase) which cleaves choline from sphingomyelin.

**sphingosine** See SPHINGOLIPID.

**SPI** *Salmonella* PATHOGENICITY ISLAND.

**spiculum** A narrow, apical extension of a STERIGMA on which a spore is borne.

**spin killing** A type of killing of sensitive strains of *Paramecium* by certain types of killer paramecia (e.g. strains containing *Caedibacter varicaedens*); affected cells swim with rapidly reversing rotational movements.

**spin label** See ELECTRON SPIN RESONANCE.

**spina** (*pl.* spinae) In certain prokaryotes (e.g. some pseudomonads): a hollow, rigid, apparently non-prosthecate appendage, one or more of which project from the cell surface; it is a thin-walled structure formed from a cross-linked helical filament. [Conical spinae: CJM (1984) 30 716–718. Possible function: JGM (1991) 137 1081–1086.]

**spinach latent virus** See ILARVIRUSES.

**spindle** (1) See MITOSIS and MEIOSIS. (2) (*virol.*) See ENTOMOPOXVIRINAE.

**spindle pole body** (*syn.* centriolar plaque; polar plaque) In some types of eukaryotic cell (including e.g. *Saccharomyces cerevisiae*): a body which is embedded in the nuclear membrane and which can act e.g. as a MICROTUBULE-ORGANIZING CENTRE during MITOSIS.

**spinning disease** A FISH DISEASE which affects the Atlantic menhaden (*Brevoortia tyrannus*); the disease tends to occur in large-scale annual epizootics with massive mortalities. Terminal symptoms include loss of coordination and erratic swimming behaviour. The causal agent is a virus which closely resembles (and may be identical to) IPN VIRUS.

**spinoculation** Centrifugally-assisted enhancement of transduction efficiency (a procedure in which the virus vector and cells are centrifuged together).

**spira** Refers to helical aerial hyphae – one of three categories used in a system for the morphological classification of streptomycetes; the other two categories are *rectus*–*flexibilis* (straight to flexuous hyphae) and *retinaculum apertum* (hook-shaped, looped, or spiral hyphae with one or two turns). [Disadvantages of the system: Book ref. 46, p. 2067.]

**spiral plate count method** A method used for counting bacteria in samples of milk. Essentially, the inoculum is delivered from a syringe onto a rotating plate so that it is deposited along a spiral path; the volume of inoculum delivered to a particular region of the plate can be read off from the apparatus. A colony count is made after incubation of the plate.

**spiramycins** See MACROLIDE ANTIBIOTICS.

**Spirillaceae** A family of bacteria which formerly included the genera *Campylobacter* and *Spirillum* but which has been abandoned pending further taxonomic studies [Book ref. 22, p. 71].

**Spirillospora** A genus of bacteria (order ACTINOMYCETALES, wall type II; group: maduromycetes) which occur e.g. in soil and leaf litter. The organisms form thin (<1 µm diam.) branching substrate and aerial mycelium, the latter giving rise to spherical sporangia (up to ca. 24 µm diam.); in water, mature sporangia

## spirilloxanthins

release motile (flagellated) rod-shaped spores. Type species: *S. albidus*. [Book ref. 73, p. 113.]

**spirilloxanthins** See CAROTENOIDS.

**spirillum** (1) Any spiral-shaped, relatively rigid bacterial cell. (2) Any species or strain of *Spirillum*.

**Spirillum** A genus of Gram-negative, asporogenous bacteria. Cells: rigid, helical, ca.  $1.4\text{--}1.7 \times 14\text{--}60 \mu\text{m}$ . POLAR MEMBRANES and PHB granules are formed, COCCOID BODIES are not. Motile: bipolar tufts of flagella of long wavelength. Microaerophilic. Metabolism is respiratory; nitrate respiration does not occur. Oxidase +ve; catalase -ve; phosphatase +ve; indole -ve; arylsulphatase -ve. Growth is inhibited by NaCl levels  $>0.02\%$ , and by phosphate  $>0.01$  M. Carbohydrates are not utilized; carbon sources: salts of organic acids (e.g. succinate). GC%: 38. Type species: *S. volutans*, found in stagnant freshwater habitats. (cf. AQUASPIRILLUM; AZOSPIRILLUM; OCEANOSPIRILLUM; SPOROSPIRILLUM.)

Species *incertae sedis*: '*S. minus*' (= '*S. minor*'), causal agent of one form of RAT-BITE FEVER; cells: ca.  $0.2 \times 3\text{--}5 \mu\text{m}$ , usually spiral, actively motile by one or more flagella at each pole. '*S. pulli*', apparent causal agent of DIPHTHEROID STOMATITIS in chickens; cells: rigid spirals, ca.  $1.0 \times 5\text{--}12 \mu\text{m}$ , motile with one flagellum at each pole.

[Book ref. 22, pp. 90–93. Culture, media etc: Book ref. 45, pp. 597–599.]

**spirits** Alcoholic beverages prepared by the distillation of fermented liquors or mashes. The characteristic flavours and qualities of the various spirits are determined by the nature of the fermented raw materials, conditions of distillation, effects of ageing, etc. The fermentation stage generally resembles that in BREWING or WINE-MAKING. Use is made of yeast (*Saccharomyces*) strains which effect maximum attenuation (i.e. they convert the maximum amount of carbohydrate to alcohol); these strains are characterized by high alcohol-tolerance. Distillers' yeasts produce a range of higher alcohols (FUSEL OIL) which contribute to the aroma and flavour of the product. Spirits are not subject to microbial spoilage owing to their high alcohol content.

*Bourbon* is an American whisky (whiskey) made by distilling a fermented mash containing maize and rye. *Brandy (cognac)* is prepared by distilling grape wine. *Gin* is made by distilling fermented rye or maize worts and redistilling the product in a still containing herbs and juniper berries ('botanicals'). *Rum* is a distillate of fermented molasses or sugarcane products. *Tequila*: see PULQUE. *Whisky* is distilled either from a wort derived from malted barley (*malt whisky*) or from a mash of unmalted grain (often barley or maize) mixed with a proportion of malted barley (*grain whisky*).

**Spirochaeta** A genus of Gram-negative bacteria of the family SPIROCHAETACEAE; the organisms, which include both obligate and facultatively anaerobic species, occur as free-living inhabitants of freshwater and marine environments, including muds, and are common in  $\text{H}_2\text{S}$ -containing habitats. The cells are  $0.2\text{--}0.75 \times 5\text{--}250 \mu\text{m}$ ; the type species, *S. plicatilis*, contains many periplasmic flagella per cell, but the other species contain only two per cell. The organisms are motile in liquids and can also creep over solid surfaces and migrate through agar ( $\leq 1\%$ ) – the latter feature being useful in isolation procedures. In most species the anaerobic metabolism of carbohydrates yields ethanol, acetate,  $\text{CO}_2$  and  $\text{H}_2$ ; *S. zuelzeriae* forms lactate and succinate. GC%: ca. 51–65.

Species differentiation is based on e.g. cell diameter, ability to grow aerobically, NaCl requirement and pigmentation. Six species are recognized [Book ref. 22, pp. 39–46]: *S. aurantia*

and *S. halophila* (both facultative anaerobes; *S. halophila* is halophilic and forms a red pigment); *S. litoralis* and *S. stenostrepta* (both obligate anaerobes; *S. litoralis* is halophilic); *S. plicatilis* (cell diameter ca.  $0.75 \mu\text{m}$ ); and *S. zuelzeriae* (obligate anaerobe, forms succinate). (All species except *S. plicatilis* have been grown in pure culture.)

**Spirochaetaceae** A family of anaerobic, facultatively anaerobic or microaerophilic bacteria of the order SPIROCHAETALES; the cells typically do not have hooked ends, their cell wall PEPTIDOGLYCAN contains the diamino acid L-ornithine, and their carbon and energy sources are carbohydrates and/or amino acids (cf. LEPTOSPIRACEAE). Genera: BORRELIA, CRISTISPIRA, SPIROCHAETA, TREPONEMA.

**Spirochaetales** An order of helical, flexible, asporogenous, Gram type-negative bacteria which include free-living, parasitic and pathogenic species. The cells are  $0.1\text{--}3.0 \mu\text{m}$  in width and  $5\text{--}250 \mu\text{m}$  in length, according to species, and they divide by transverse binary fission; motility in liquid media involves periplasmic flagella (see below and FLAGELLAR MOTILITY), and the organisms can also creep over solid surfaces. Depending on size, spirochaetes may be seen by bright-field MICROSCOPY (e.g. after staining with dyes or silver-deposition techniques), by dark-field microscopy, or by fluorescence microscopy following treatment with fluorochrome-labelled antibodies. Species include anaerobes (obligate and facultative) and microaerophiles (family SPIROCHAETACEAE) and aerobes (family LEPTOSPIRACEAE). The organisms are chemoorganotrophs which have fermentative and/or respiratory (oxidative) type(s) of metabolism.

*Ultrastructure.* The spirochaetal cell consists of a helical *protoplastic cylinder* (= PROTOPLAST (sense 2) covered by a 'cell wall' of PEPTIDOGLYCAN), the whole being enclosed within an *outer sheath* (= outer envelope) similar to the OUTER MEMBRANE of other Gram type-negative bacteria; one or more *periplasmic flagella* (= axial fibrils, axial filaments, endoflagella, periplasmic fibrils) arise at *each* end of the protoplasmic cylinder and wind around the protoplasmic cylinder – i.e. they are located between the protoplasmic cylinder and the outer sheath. The periplasmic flagellum is similar in ultrastructure to the prokaryotic FLAGELLUM; the number of periplasmic flagella per cell is a stable characteristic of the various species and genera of spirochaetes.

[Structure/motility of spirochaetes: JB (1996) 178 6539–6545.]

*Habitats.* Spirochaetes occur in host tissues (BORRELIA, CRISTISPIRA, LEPTOSPIRA, TREPONEMA) and in soil and aquatic habitats (LEPTOSPIRA, SPIROCHAETA). Spirochaetes occur also in the hindgut of termites (see TERMITE-MICROBE ASSOCIATIONS); these have not been isolated in pure culture, and the names proposed for these organisms (e.g. *Diplocalyx*, *Hollandina*, *Pillotina*) have not been validly published [Book ref. 22, pp. 67–70].

**spirochaete** (spirochete) A member of the SPIROCHAETALES.

**Spirochona** See HYPOSTOMATIA.

**Spirocystis** A genus of protozoa (suborder EIMERIORINA) parasitic in oligochaetes.

**Spirogyra** A genus of unbranched filamentous green algae (division CHLOROPHYTA) in which sexual reproduction occurs by a process of conjugation; flagellated cells are never formed. Species are common in standing fresh water; the filaments are usually free-floating, but are sometimes attached to stones etc.

Each filament is composed of a chain of cylindrical cells (arranged end-to-end); the filaments are coated with mucilage and may be capable of GLIDING MOTILITY. Each cell has a thin peripheral layer of cytoplasm surrounding a large central vacuole; a single nucleus is suspended in the centre of the

vacuole by fine cytoplasmic threads. The cytoplasm contains one or more (according to species) ribbon-like, spirally arranged chloroplasts (containing many pyrenoids) extending throughout the length of the cell.

Asexual reproduction occurs by fragmentation of the filaments; zoospores are not formed.

Sexual reproduction occurs by conjugation: typically, two filaments lie side-by-side (held together by mucilage), and a conjugation tube is formed between two juxtaposed cells (one cell in each filament: *scalariform* conjugation). (Conjugation can also occur between adjacent cells in a single filament: *lateral* conjugation.) One protoplast (designated male) passes from one cell to the other via the conjugation tube, and syngamy occurs. (In some species a zygote is formed within the conjugation tube.) The zygote develops a thick, resistant wall and undergoes a period of dormancy. Meiosis occurs before germination, and 3 of the 4 resulting nuclei disintegrate; on germination, a single haploid filament develops.

Genera related to *Spirogyra* include e.g. MOUGEOTIA, ZYGNEMA and ZYGOGONIUM; see also DESMIDS.

**Spiromyces** See KICKXELLALES.

**Spiroplasma** A genus of facultatively anaerobic bacteria (family SPIROPLASMATACEAE) which occur as epiphytes or as intracellular or extracellular parasites or pathogens in a range of invertebrates and plants (see e.g. YELLOWS). (See also MLO and SRO.) Cells: pleomorphic, ranging from helical filaments (commonly 0.1–0.2  $\mu\text{m} \times 3.0$ –5.0  $\mu\text{m}$ ) which typically occur in the logarithmic phase of growth (and which may persist into the stationary phase), to branched non-helical filaments and to coccid and coccoid forms (ca. 0.3  $\mu\text{m}$  diam.); in some infected tissues the cells of some strains may be indistinguishable from MLOs. Helical filaments contain a system of fibrils [JGM (1985) 131 983–992] which may be involved in the characteristic flexing and other movements of which these forms are capable; the cells lack flagella. NADH oxidase occurs in the cytoplasm (cf. ACHOLEPLASMA). The organisms are chemoorganotrophs which require sterols for growth; with the exception of SROs, they can be cultured e.g. on serum-containing media. GC%: ca. 25–31. Type species: *S. citri*.

*S. apis*. The causal agent of a May-disease-like disorder of the honey bee (*Apis mellifera*) in France; isolated also e.g. from flowers.

*S. citri*. Isolated e.g. from citrus plants suffering from STUBBORN DISEASE, from other naturally-infected plants (e.g. broad beans; see also CORN STUNT DISEASE), and from leafhoppers; some strains are pathogenic for honey-bees.

*S. floricola*. Isolated e.g. from magnolia flowers; can cause disease in beetles of the genus *Melolontha*.

*S. kunkelii*. See CORN STUNT DISEASE.

*S. mirum*. Isolated e.g. from rabbit ticks; can cause disease in e.g. rodents and chick embryos under experimental conditions.

*Spiroplasma* spp are divided into serogroups I (e.g. *S. citri*, *S. melliferum*), II (SROS), III (*S. floricola*), IV (*S. apis*) and V (*S. mirum*).

(See also SPIROPLASMAVIRUSES.)

*Mycoplasma*-like organisms have been referred to by the trivial name 'phytoplasma' [see ARM (2000) 54 221–255].

**Spiroplasmataceae** A family of (typically) helical and filamentous, cell-wall-free bacteria (order MYCOPLASMATALES) which are associated with various invertebrates and plants. Sole genus: SPIROPLASMA. [Book ref. 22, pp. 781–787.]

**spiroplasmaviruses** BACTERIOPHAGES which infect *Spiroplasma* spp. SV-C1 phages are filamentous (230–280  $\times$  10–15 nm) and

contain DNA; they may belong in the INOVIRIDAE. In SV-C2 phages there is an icosahedral-type head (52–58  $\times$  48–51 nm) with a tail (75–83  $\times$  6–8 nm) attached at one vertex. SV-C3 phages (= C3 strain C3 phages) probably belong to the PODOVIRIDAE; the icosahedral-type head (ca. 40  $\times$  35–37 nm) contains linear dsDNA (MWt 1.4  $\times 10^7$ ) and has a short tail (13–18  $\times$  6–8 nm) attached at one vertex. SV-C3 progeny virions seem to be released in host-derived membrane vesicles. (See also MYCOPLASMAVIRUSES.)

**Spirosoma** A genus of yellow-pigmented bacteria (family SPIROSOMACEAE). The cells, 0.5–1.0  $\times$  1.5–6.0  $\mu\text{m}$ , are commonly helical or curved rods – 'ring-shaped' forms sometimes being seen as a result of overlap of the ends of highly curved cells. Acid is formed from many carbohydrates. GC%: 51–53. Type species: *S. linguale*.

**Spirosomaceae** A family of Gram-negative, obligately aerobic, chemoorganotrophic, pink- or yellow-pigmented bacteria which occur in soil and aquatic habitats; the organisms are rigid, straight, curved or spiral, non-motile rods. Growth (optimum temperature range: 20–30°C) occurs e.g. on peptone–yeast extract–glucose agar. Genera: FLECTOBACILLUS, RUNELLA, SPIROSOMA. [Book ref. 22, pp. 125–132.]

**Spirostomum** A genus of ciliate protozoa (order HETEROTRICHIDA) which occur e.g. in microaerobic freshwater and estuarine habitats. Cells: elongate, cylindrical, up to ca. 4 mm in length – but able to contract to a fraction of their normal length; somatic ciliature is uniform, and the cytostome is lateral. A large posterior contractile vacuole discharges via a long canal which opens to the exterior near the anterior end. In some species (e.g. *S. ambiguum*) the macronucleus is moniliform, in others (e.g. *S. teres*) it is ovoid.

**spirotrich** A member of the Spirotrichia.

**Spirotrichia** See POLYHYMENOPHOREA.

**Spirotrichonympha** See HYPERMASTIGIDA.

**Spirulina** A genus of filamentous CYANOBACTERIA (section III) in which the trichomes are helical with little or no constriction between adjacent cells. GC%: 44–53. The trichomes show GLIDING MOTILITY, and the tips are capable of a twitching or jerking motion which may be brought about by a contractile (actin-like?) protein [Book ref. 76, pp. 420–421]. *Spirulina* typically occurs in warm, saline, alkaline lakes, where it forms dense tangled masses. For centuries it has been used as food by people in the Lake Chad region of Africa, and was also eaten by the Aztecs of ancient Mexico; in Africa, the masses of growth are collected, sun-dried, and made into thin cakes which may be eaten directly or after cooking.

**Spitzenkörper** (apical granule) A small, densely staining body which occurs, close to the cytoplasmic membrane, in the tip of an actively growing fungal hypha; in at least some fungi it consists of a cluster of vesicles associated with microfilaments. (See also GROWTH (fungal).)

**spleen focus-forming virus** (SFFV) See FRIEND VIRUS and RAUSCHER VIRUS.

**splenic fever** See ANTHRAX.

**splice sites** See SPLIT GENE.

**spliceosome** See SPLIT GENE (a).

**splicing** (1) (of RNA) See SPLIT GENE. (2) (of DNA) See e.g. CLONING.

**split gene** (interrupted gene) A structural gene (encoding e.g. a protein, rRNA or tRNA) that contains one, several or many specific sequences of nucleotides (*intervening sequences*; *introns*) which, although represented in the primary RNA transcript of the gene, are absent from the mature RNA molecule (mRNA,

## split gene

tRNA etc.) and, hence, do not encode any part of the gene product. Thus, *maturation* of the primary RNA transcript of a split gene must involve a process of *splicing* in which sequence(s) corresponding to intron(s) are deleted ('spliced out') and the remaining sequences (termed *exons*) are joined together; for example, in the case of mRNA (q.v.), the amalgamated exons form the complete coding sequence of the gene together with any non-coding leader and/or trailer sequences.

In some cases a given gene can be spliced in different ways to yield different versions of the encoded product, i.e. splicing can give rise to different combinations of exons – producing correspondingly different coding sequences. Such *alternative splicing* can be advantageous to a cell e.g. in that synthesis of multiple products from a single gene permits economy in the size of the genome.

Introns are often non-coding sequences that are degraded following excision – but see (b) and (c), below, and INTRON HOMING.

Split genes occur in eukaryotes and in certain prokaryotes (including bacteria and archaeans) and viruses. Many (or most) eukaryotic genes contain at least one intron – sometimes many; the gene encoding type I collagen appears to contain about 50 introns. By contrast, the (human) insulin gene contains only one intron, while the gene encoding interferon- $\beta$  is intron-less.

In higher eukaryotes, many (perhaps most) of the nuclear structural genes are split genes, but in typical eukaryotic microorganisms (e.g. *Dictyostelium*, *Saccharomyces*) fewer of these genes are reported to contain introns, and the introns tend to be smaller than those in higher eukaryotes; by contrast, no intron-less protein-encoding genomic sequences were seen in the database of *Physarum polycephalum* – each gene containing, on average, 3.7 introns [NAR (2000) 28 3411–3416].

*Splicing* of the RNA transcript of a split gene involves cleavage of a precise phosphodiester bond at both ends of each intron (at the exon–intron junctions) – the 5' and 3' *splice sites*; this is followed by the formation of a phosphodiester bond between the exon at the 5' end of the intron (the 5' *exon*) and the exon at the 3' end (the 3' *exon*). Details of the splicing mechanism differ in different types of split gene.

Split genes in eukaryotes are considered in (a) to (d), below; split genes in prokaryotes and viruses are considered in (e).

(a) *Nuclear mRNA introns*. In nuclear protein-encoding genes of e.g. *Saccharomyces cerevisiae*, the introns have been found to contain three CONSENSUS SEQUENCES that are necessary for splicing:

GTATGT

at the 5' end of the intron,

PyAG

at the 3' end, and

TACTAAC

(the 'TACTAAC box') near the 3' end. These sequences are those in the DNA strand which has the same sequence as the RNA transcript; they may also be written in terms of the RNA itself, e.g. TACTAAC = UACUAAC.

The consensus sequences mentioned above may differ somewhat in other eukaryotes, but nearly all introns of this type have the 5' terminal GT (the 5', *left* or *donor* splice site) and the 3'-terminal AG (the 3', *right* or *acceptor* splice site); this is the so-called *GT...AG* (or *GU...AG*) rule.

Excision of an intron from a pre-mRNA molecule (transcribed by RNA polymerase II) depends on *trans*-acting factors and

initially involves cleavage at the 5' splice site, thus releasing the 3' end of the 5' exon, and formation of an intron–3'-exon intermediate in the form of a *lariat* (a tailed, circular molecule); the lariat results from the formation of a 2'–5' phosphodiester bond between the (free) 5' end of the intron and a site within the intron near its 3' end (the *branch point*). In yeast, this branch occurs at the last adenine residue in the TACTAAC box.

Subsequently, the 3' splice site is cleaved, and the 5' and 3' exons are ligated. The intron, released as a lariat, is 'debranched', enzymically, to release a free linear intron (which is degraded *in vivo*). Debranching enzymes from *S. cerevisiae* and *Schizosaccharomyces pombe* exhibit some homology with the human RNA lariat debranching enzyme [NAR (2000) 28 3666–3673].

Secondary or tertiary structure in the intron appears not to be important for the juxtaposition of splicing sites in nuclear introns (cf. other mechanisms below).

The splicing reaction depends on certain small molecules of RNA – snRNAs (see SNRNA) – which apparently act as *external guide sequences* (EGSs) to locate the relevant sites in the pre-mRNA. In higher eukaryotes, U1 snRNP binds to the 5' splice site (the 5' end of U1 snRNA probably base-pairing with the conserved sequence GUNAGU), U2 snRNP binds to the branch point, and U5 snRNP probably binds to the 3' splice site.

Interactions between the snRNPs, and between snRNPs and the RNA substrate, presumably bring about juxtaposition of the 3' and 5' splice sites. Splicing of the pre-mRNAs in yeasts and in higher eukaryotes involves a large (40S–60S) ribonucleoprotein particle (the *spliceosome*) which, in e.g. human cells, contains U snRNPs; in yeasts, the spliceosome contains at least three snRNAs, and its assembly is dependent on the presence of a 5' splice site and a TACTAAC box within the RNA [Cell (1986) 45 869–877].

(b) *Group I introns* (= *class I introns*). Introns of this type occur in nuclear pre-rRNA of *Tetrahymena thermophila* and *Physarum polycephalum*, in several fungal mitochondrial pre-rRNAs and pre-mRNAs, and in certain chloroplast tRNA genes. They are characterized by a common splicing mechanism and by a number of conserved sequences; interaction between these sequences apparently folds the intron into a 'core structure' in which the 5' and 3' splice sites are brought into close proximity. Excision of this type of intron is an intrinsic property of the RNA itself, i.e. group I introns are *self-splicing* or *autocatalytic*; in some cases splicing can occur *in vitro* when the RNA is incubated with divalent cations and guanosine or a guanosine nucleotide (GMP, GDP or GTP – or a G at the 3' end of an oligo- or polynucleotide) in the absence of protein. (cf. RIBOZYME.)

Splicing involves two distinct and independent cleavage–ligation steps – and transesterification reactions in which the total number of phosphodiester bonds remains constant (so that splicing does not require an additional source of energy).

Cleavage occurs first at the 5' splice site concomitantly with the formation of a phosphodiester bond between the 3'-OH of a guanine nucleoside or nucleotide and the 5' end of the intron. Subsequently, cleavage of the 3' splice site is coupled with ligation of the 5' and 3' exons. In many cases the excised linear intron circularizes by a transesterification reaction in which the 3'-terminal residue (usually or always a guanosine residue) forms a covalent bond at a site near the 5' end, the terminal oligonucleotide being released.

It has been proposed that, during the splicing process, a nucleotide sequence within the 5' exon (adjacent to the 5' splice site) base-pairs with a complementary sequence within the intron

(the *internal guide sequence*, IGS) to form a secondary structure that defines the 5' splice site and holds the 5' exon in place for the second (exon-ligation) step [Nature (1986) 322 86–89, (discussion 16–17)]; the actual nucleotide sequence of the IGS is different in different introns (i.e. it is not a conserved sequence).

Some group I introns are not capable of autocatalytic splicing *in vitro* in the absence of protein – protein(s) apparently being necessary for the correct folding of the molecule. Certain introns in fungal mitochondrial genes encode a small protein (a *maturase*) which is apparently synthesized by readthrough from the preceding exon; in at least some cases the maturase is necessary for the splicing of the intron encoding it – possibly being involved in folding the intron to align the splice sites correctly.

(c) *Group II introns (class II introns)*. Introns of group II are distinct from those of group I in their conserved sequences and secondary structure (e.g. they have a conserved stem-and-loop or hairpin structure near the 3' end). Group II introns occur e.g. in fungal mitochondrial protein-encoding genes and in *Euglena* chloroplast genes.

Certain yeast mitochondrial group II introns are self-splicing *in vitro* in the presence of magnesium ions and spermidine; however, the reaction does not require guanosine or any other nucleotide, and the excised intron initially occurs in the form of a *lariat* similar to that formed by nuclear pre-mRNA splicing [Cell (1986) 44 213–223, 225–234; 46 557–565].

Group II introns also differ from those in group I in having at their splice sites conserved sequences which are similar to those in nuclear pre-mRNA introns. Nevertheless, splicing of group II introns resembles that of group I introns e.g. in being autocatalytic and in not requiring *trans*-acting RNA molecules (an IGS may be involved); furthermore, certain group II introns apparently encode 'maturases'. Thus, group II introns appear to be intermediate in character between group I and nuclear pre-mRNA introns. [Splicing of nuclear pre-mRNA and groups I and II introns (minireview): Cell (1986) 44 207–210.]

Interestingly, certain group II introns encode potential products which appear to exhibit homology (over part of their length) with several reverse transcriptases encoded by viruses and transposable elements [Nature (1985) 316 641–643 (discussion 574–575)].

(d) *Nuclear tRNA introns*. In yeast, at least some nuclear tRNAs contain a single intron in the anticodon arm of the pre-tRNA (see tRNA); the intron contains a sequence that is complementary to the anticodon of the tRNA, and this may allow the anticodon arm to adopt a secondary structure which can be recognized by the splicing enzymes. Splicing requires at least two distinct enzymes. The first catalyses endonucleolytic cleavage with the generation of 5'-OH ends and 3' ends bearing a 2',3'-cyclic phosphate group; the second (an *RNA ligase*) catalyses exon ligation in an ATP-dependent reaction.

(e) *Introns in viruses and prokaryotes*. Introns have been found in the genomes of certain viruses – including bacteriophages. For example, in phage T4 there are three group I introns: a 598-bp intron in gene *nrdB* (encoding ribonucleotide reductase), a 1033-bp intron in *nrDD* (= *sunY*) (encoding anaerobic ribonucleotide reductase), and a 1016-bp intron in gene *td* (encoding thymidylate synthase); efficient splicing of *td* is reported to require a ribosomal function [GD (1998) 12 1327–1337]. All three introns in the T4 genes can self-splice *in vitro*. [Phage T4 introns: ARG (1990) 24 363–385.] Similar introns also occur in other T-even phages.

In adenovirus-infected cells, different patterns of RNA splicing can generate different proteins from the same RNA

transcript. Thus, the very long polycistronic viral RNA transcripts produced in these cells can be spliced in different ways – generating functional mRNAs in which the same 5' cap and leader sequence is spliced onto different coding sequences. (See also SUBGENOMIC MRNA.) Certain small adenovirus-encoded RNAs (the VA RNAs) which associate with cellular proteins – forming RNP particles – may be involved in splicing viral RNA; VA1 RNA is apparently complementary to splicing junctions in some adenovirus genes.

Among archaeans, some tRNA genes contain an intron which, when transcribed, gives rise to a corresponding sequence within the anticodon arm of the pre-tRNA molecule; the position of the intron is generally similar to that in yeast tRNA genes (i.e. on the 3' side of the anticodon), but in the extreme thermophile *Thermoproteus tenax* a tRNA<sup>Leu</sup> contains an intron within the anticodon sequence itself, while tRNA<sup>Ala</sup> has an intron in a unique position on the 5' side of the anticodon in the stem of the anticodon arm [EMBO (1987) 6 523–528].

Bacterial introns appear to be mainly or solely of the autocatalytic type (group I or group II). The bacterial group I introns seem to occur primarily within tRNA genes; they have been found e.g. in the purple bacterium *Azoarcus* and the cyanobacterium *Synechococcus* [structure–function relationships of the intron ribozymes of *Azoarcus* and *Synechococcus*: NAR (2000) 28 3269–3277], in *Anabaena* and other cyanobacteria, in *Agrobacterium tumefaciens* and in *Simkania negevensis* (a member of the Chlamydiales in which the intron interrupts a 23S rRNA gene).

Bacterial group II introns (like group I introns) are mobile genetic elements but are not primarily associated with tRNA genes. Group II introns have been found e.g. in *Lactococcus* spp and in *Escherichia coli*, *Pseudomonas alcaligenes* and *Streptococcus pneumoniae*. [Bacterial group II introns (review): Mol. Microbiol. (2000) 38 917–926.]

In some cases, splicing in bacteria may occur while the transcript is still bound to a ribosome [splicing and translation in bacteria (perspective): GD (1998) 12 1243–1247]. Splicing *in vivo* has been demonstrated for a group II intron in the conjugative transposon Tn5397 [JB (2001) 183 1296–1299].

Bacterial introns (of both groups I and II) can propagate by INTRON HOMING. [Barriers to intron promiscuity in bacteria: JB (2000) 182 5281–5289.]

**split-product vaccine** (split-virus vaccine) A VACCINE which contains *some* of the components of a virus (as opposed to whole virions).

**split-virus vaccine** See SPLIT-PRODUCT VACCINE.

**splitter** See TAXONOMY.

**spoilage** See BIODETERIORATION.

**spoligotyping** A rapid, PCR-based method for simultaneously detecting and typing strains of the *Mycobacterium tuberculosis* complex [original description: JCM (1997) 35 907–914]. Essentially, PCR is used to amplify spacer sequences in the direct repeat (DR) locus of the chromosome (which apparently

## Spondweni virus

SPOLIGOTYPING (simplified protocol; principle, diagrammatic) (see entry).

The direct repeat (DR) locus is a distinct region in the chromosome of members of the *Mycobacterium tuberculosis* complex. It consists of a variable (strain-dependent) number of highly conserved 36-bp direct repeats (DRs) between which are spacer sequences of 34–41 base-pairs in length; the presence/absence and length of spacer sequences varies from strain to strain. (Such variation in the DR locus may result from homologous recombination between different sections of the locus and/or from integration of the insertion sequence IS6110.) In the reference strain *M. tuberculosis* H37Rv, the chromosome contains 48 DRs; each intervening spacer is identified by a number.

*Top.* Part of a strand of chromosomal DNA in the direct repeat (DR) locus of *Mycobacterium tuberculosis*. The (non-repetitive) sequences ('spacers') which separate the DRs vary in length from 34 to 41 nucleotides and are numbered consecutively.

For spoligotyping, all the spacers of a given strain are amplified by PCR. Here, a primer (small arrow) is shown binding to a (conserved) sequence in a DR; primers bind to the same sequence in all other DRs. During cycling, primers are extended across the subsequent spacers. The amplicons from a given test strain are then examined for their ability to hybridize to one row of immobilized oligonucleotides which represent selected spacer sequences of *M. tuberculosis* strain H37Rv. (In the actual method used by Kamerbeek et al (1997) there were 43 25-mer oligonucleotides in each horizontal row; these oligonucleotides represented spacers 1–19, 22–32 and 37–43 of *M. tuberculosis* strain H37Rv, and spacers 20–21 and 33–36 of *M. bovis* BCG.)

*Below.* Simplified protocol showing a membrane to which has been covalently bound 11 identical horizontal rows of oligonucleotides; in each row the oligonucleotides represent sequences from selected spacers of *M. tuberculosis* strain H37Rv. Each horizontal row was exposed to amplicons from one of the test strains; hybridization (dark spot) has occurred when a DR spacer in the test strain matched the sequence of a spacer in strain H37Rv. Note clustering of strains 6, 7 and 8 (the kind of result which might be obtained with a group of strains isolated from a single outbreak of disease).

Reproduced from Figure 7.7, page 195, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission of Kluwer Academic Publishers, Dordrecht, The Netherlands.

occurs only in members of the *M. tuberculosis* complex); spacer amplicons from the test strain are then hybridized to a set of oligonucleotides which represent spacer sequences from a standard reference strain (*M. tuberculosis* strain H37Rv). (The name 'spoligotyping' is thus a contraction of 'spacer oligotyping'.) For a given strain, the pattern of matching and mis-matching of spacers (compared with those of the reference strain) is the *spoligotype*.

A simplified form of the method is outlined in the figure.

In addition to typing strains of the *M. tuberculosis* complex, spoligotyping is also useful for distinguishing between *M. tuberculosis* and *M. bovis* – a task which can be difficult by traditional methods; such differentiation is based on the absence, in *M. bovis*, of the five 3' outermost spacers (which are present in *M. tuberculosis* strain H37Rv – and in a large number of other strains of this species which have been examined). This feature of spoligotyping is particularly useful as *M. bovis* commonly contains only a single copy of the insertion sequence

IS6110 – making it difficult to distinguish between strains of *M. bovis* by IS6110 fingerprinting. Spoligotyping may help to promote investigations on the animal reservoirs of *M. bovis* which are potential sources of infection for both animals and humans.

Spoligotyping has also been used for checking the validity of IS6110-based typing of *M. tuberculosis* [JCM (1999) 37 788–791] and for investigating laboratory cross-contamination [JCM (1999) 37 916–919].

[Spoligotype database of *Mycobacterium tuberculosis* (biogeographic distribution of shared types, and epidemiological and phylogenetic perspectives); EID (2001) 7 390–396.]

**Spondweni virus** See FLAVIVIRIDAE.

**spongiform encephalopathies** See SUBACUTE SPONGIFORM ENCEPHALOPATHIES.

**Spongilla** See ZOOCHLORELLAE.

**spongiome** See CONTRACTILE VACUOLE.

**spongioplasm** See CONTRACTILE VACUOLE.

**Spongospora** See PLASMIDIOPHOMYCETES and POWDERY SCAB.  
**spontaneous generation** *Syn.* ABIOGENESIS.

**spontaneous mutation** (background mutation) Any MUTATION which occurs 'naturally', i.e., in the absence of any obvious external MUTAGEN; such mutations normally occur at low frequencies (cf. MUTATOR GENE). Mutations which are apparently spontaneous may arise e.g. as a result of the effects of environmental mutagens (e.g. natural gamma radiation, ULTRAVIOLET RADIATION, heat) or of endogenous mutagens produced during metabolism (e.g. peroxides, and possibly the endogenous alkylating agent *S*-adenosylmethionine). However, mutations are usually regarded as truly spontaneous only when they result from errors in DNA replication or repair, or from chemical reactions which tend to occur spontaneously in the DNA itself. For example, deamination of bases and depurination (or, less commonly, depyrimidination) of nucleotides are spontaneous reactions of DNA; thus, e.g., deamination of cytosine to uracil leads to mutagenesis since, during subsequent DNA synthesis, uracil pairs with adenine (resulting in a G-C-to-A-T transition). (cf. URACIL-DNA GLYCOSYLASE.) Certain regions of a given DNA molecule may be particularly prone to spontaneous mutagenesis: e.g., in *Escherichia coli* such 'hotspots' occur e.g. at sites occupied by the modified base 5-methylcytosine (see DNA METHYLATION); spontaneous deamination of this base generates thymine, resulting in a G-C-to-A-T transition. (The thymine residue, being a normal component of DNA, cannot be recognized by any DNA REPAIR system.) Other hot-spots may contain e.g. DIRECT REPEATS or INVERTED REPEATS, and these are apparently associated with insertions or deletions (and hence e.g. FRAMESHIFT MUTATIONS). In *E. coli*, error-prone DNA repair (see SOS SYSTEM) is apparently responsible for a low level of random (non-targeted) mutagenesis. Deletions, insertions, inversions etc may also be attributable to the activities of TRANSPOSABLE ELEMENTS.

[Analysis of spontaneous mutations in the *lacI* gene of *E. coli*: JMB (1986) 189 273–284.]

**spoonleaf** A disease of redcurrants caused by the raspberry ring-spot virus (a NEPOVIRUS).

**spora** That fraction of the particulate matter in AIR (q.v.) consisting of, or including, SPORES.

**sporobola** (*mycol.*) The trajectory of a forcibly-discharged basidiospore.

**sporadin** The gametocyte form of a gregarine.

**sporangiote** *Syn.* SPORANGIOLUM.

**sporangiolum** (sporangiote) (*mycol.*) A SPORANGIUM-like structure containing a single spore or a small number of spores; it characteristically lacks a columella. Some fungi form both sporangiola and sporangia (see e.g. Choanephoraceae in MUCORALES). The sporangiolum may be an evolutionary intermediate between the sporangium and the CONIDIUM.

**sporangiomycin** See THIOSTREPTON.

**sporangiophore** A modified or undifferentiated, simple or branched hypha which bears at least one SPORANGIUM or SPORANGIOLUM. In some fungi (e.g. *Pilaira*, *Pilobolus*) the sporangiophores are positively phototropic.

**sporangiospore** (*mycol.*) A thin-walled, motile or non-motile spore formed in a SPORANGIUM or in a SPORANGIOLUM; such spores are characteristic of the lower fungi. (cf. CONIDIUM.)

**sporangium** (1) (*mycol.*) In some lower fungi: a sac-like structure whose contents are converted into motile or non-motile spores (sporangiospores). (cf. MEROSPORANGIUM; SPORANGIOLUM; ZOOSPORANGIUM.) Sporangia are often globose or elongated, and may occur e.g. singly and terminally on a sporangiophore, in clusters on branched sporangiophores, or (e.g. in *Albugo*) in

basipetally formed chains; in many fungi (e.g. *Mucor*) the sporangium contains a COLUMELLA. A sporangium may be deciduous at maturity (e.g. in *Dictyuchus*) or it may remain attached to the sporangiophore (e.g. in *Saprolegnia*); the spores may be released via a pore or by dissolution of the sporangial wall. In e.g. *Pilobolus* the entire sporangium is forcibly discharged. (See also *meiosporangium* and *mitosporangium* under ALLOMYCES, and *zygosporangium* under ZYGOSPORE.)

(2) (*bacteriol.*) The cell in which an ENDOSPORE is formed.

(3) (*bacteriol.*) That part of a cell which subsequently develops into an endospore.

(4) (*bacteriol.*) In e.g. *Actinoplanes* and members of the MYXOBACTERIALES: a specialized structure containing one or more spores.

**spore** A differentiated form of an organism which may be (a) specialized for dissemination; (b) produced in response to, and characteristically resistant to, adverse environmental conditions; and/or (c) produced during or as a result of an asexual or sexual reproductive process. (Not all microorganisms can produce spores.) A spore may be unicellular (i.e., it may contain only one protoplast), bicellular, or multicellular; it may be thick-walled or thin-walled, pigmented or non-pigmented, motile or non-motile. Under suitable conditions, disseminative and resistant forms of spore typically give rise to a vegetative organism(s); a spore formed in a reproductive process may e.g. give rise to a vegetative organism or act as a gamete.

**Bacterial spores.** Bacterial ENDOSPORES (q.v.) are resistant (and may be disseminative) forms rather than reproductive forms, while the EXOSPORES formed e.g. by species of the ACTINOMYCETALES (q.v.) are characteristically reproductive and disseminative forms. (See also *myxospores* in MYXOBACTERIALES.)

**Fungal spores.** See e.g. ASCOSPORE; AZYGOSPORE; BALLISTOSPORE; BASIDIOSPORE; CHLAMYDOSPORE; CONIDIUM (and SACCARDOAN SYSTEM); GEMMA; OIDIUM; SPORANGIOSPORE; STATISMOSPORE; THALLOSPORE; ZYGOSPORE. (See also UREDINIOMYCETES and USTILAGINALES.)

Some fungal spores exhibit DORMANCY. *Exogenous* dormancy is that due to the effects of environmental conditions; germination occurs only under conditions favourable for vegetative growth. *Endogenous* (= *constitutive*) dormancy is due to internal factors; these may include (a) the presence of a permeability barrier to nutrients, (b) the existence of a (reversible) metabolic block, and/or (c) the presence of an endogenous chemical inhibitor of germination. The self-inhibitor in e.g. uredospores of *Puccinia graminis* is methyl-*cis*-ferulate (which inhibits removal of the germination plug in the spore wall), while in the uredospores of some other rusts the inhibitor is methyl-*cis*-3,4-dimethoxycinnamate (which blocks initiation of the germ tube). In general, self-inhibitors may account for the low rate of germination of spores in masses; the leaching of inhibitor may account for the enhancement in germination when such spores are washed with water.

Dormancy can be broken by *activation* e.g. by certain chemical agents (*activators*) that include detergents and organic solvents; by heating the spores to ca. 50–60°C for 10–20 min (e.g. *Neurospora* spp); or by subjecting the spores to cold (e.g. teliospores of *Puccinia graminis*). Some spores can be induced to germinate by damaging the spore wall.

[Physiology and biochemistry of fungal sporulation: ARPPath. (1982) 20 281–301.]

**Protozoal spores.** See e.g. ASCETOSPORA; MICROSPORA; MYXOZOA.

**spore ball** See USTILAGINALES.

## spore coat

**spore coat** See ENDOSPORE (sense 1 (a)).

**spore print** (*mycol.*) A deposit of spores formed when the cap of a mature agaric is left, gills-down, on a piece of plain white paper; it is useful e.g. for determining spore colour.

**spore stains** See e.g. ENDOSPORE STAINS.

**spore strip** A strip of filter paper, foil etc on which a suspension of endospores (e.g. those of *Bacillus stearothermophilus*) has been allowed to dry; it is used e.g. for monitoring the performance of an AUTOCLAVE. [Commercial spore strip performance: AEM (1982) 44 12–18.]

**sporic meiosis** MEIOSIS in a life cycle characterized by an ALTERNATION OF GENERATIONS.

**Sporichthya** A genus of bacteria (order ACTINOMYCETALES, wall type I) which occur e.g. in soil. The organisms form an aerial mycelium consisting of sparingly-branched hyphae (0.5–1.2 µm in diameter, up to ca. 25 µm in length) which are anchored to the medium by holdfasts; no substrate mycelium is formed. Aerial hyphae divide into coccoid and rod-shaped forms which, in the presence of water, give rise to motile (flagellated) propagules. Growth occurs at room temperatures and at 37°C. Type species: *S. polymorpha*. [Book ref. 73, pp. 101–102.]

**sporicide** Any chemical agent which inactivates spores (particularly bacterial ENDOSPORES) irreversibly.

**sporidesmins** Cyclic depsipeptide MYCOTOXINS produced by *Pithomyces chartarum*. Sporidesmins can cause a mycotoxicosis, 'facial eczema', in sheep or cattle grazing pastures contaminated with *P. chartarum*; facial eczema occurs in parts of Australasia, Africa and the USA. Symptoms, which are strongly dose-dependent, include e.g. anorexia, diarrhoea, dehydration, photosensitivity, jaundice, and inflamed oedematous swellings on the lips, face and vulva; death may occur. Thiabendazole has been used to control the fungus in pastures. Sporidesmin and sporidesmin E inhibit the growth of certain bacteria (e.g. *Bacillus subtilis*) and are extremely toxic (at <1 ng/ml) to a range of mammalian cell cultures (an early effect apparently being the disruption of microfilaments in the cells [JCS (1986) 85 33–46]). [Book ref. 16, pp. 29–68.]

**Sporidiales** An order of fungi (class USTILAGINOMYCETES) which are typically saprotrophic, although the anamorph of at least one species, *Filobasidiella neoformans* (see FILOBASIDIELLA), is a human pathogen; the organisms characteristically occur in a yeast-like (unicellular) form, but most or all species can form a true mycelium or a pseudomycelium. Teliospores are formed by species of *Leucosporidium*, *Rhodosporeidium* and SPORIDIOBOLUS but not by members of the FILOBASIDIACEAE.

**Sporidiobolus** A genus of fungi (order SPORIDIALES) which form budding, yeast-phase cells, pseudomycelium and true mycelium, and which give rise to ballistoconidia and to intercalary or terminal teliospores. The teliospores germinate to form haploid basidiospores (in heterothallic species) or diploid basidiospores (in homothallic species) on basidia which may be phragmobasidia or holobasidia. (In both homothallic and heterothallic species, karyogamy occurs in the teliospore; in heterothallic species meiosis occurs during germination of the teliospore.) Carotenoid pigments (e.g. pink, red) are formed. *S. salmonicolor* and *S. pararoseus* (both heterothallic) are the teleomorphs of two species of SPOROBOLOMYCETES: *S. salmonicolor* and *S. shibatanius*, respectively. [Book ref. 100, pp. 532–540.]

**sporidium** (1) A BASIDIOSPORE formed by the rust or smut fungi. (2) In smut fungi: a spore formed by GERMINATION BY REPETITION.

**sporistasis** The state in which germination and outgrowth of a viable spore are prevented by chemical and/or other factors.

**sporoactinomycetes** A category within the order ACTINOMYCETALES which includes spore-forming organisms that are characterized by a morphology more complex than that of the NOCARDIOFORM ACTINOMYCETES.

**Sporobolomyces** A genus of fungi (see SPOROBOLOMYCETACEAE) which form spheroidal, ovoid or elongate budding yeast cells; some species can form pseudomycelium and true mycelium. The cell walls lack xylose, and growth on malt agar is pink, red or orange due to the presence of carotenoid pigments (cf. BULLERA). Ballistospores are formed on hyphal and yeast cells; they are typically bilaterally symmetrical (e.g. reniform or sickle-shaped) and develop obliquely at the tips of branched or unbranched sterigmata. Metabolism is strictly respiratory. NO<sub>3</sub><sup>-</sup> is assimilated by *S. holsaticus*, *S. puniceus* (formerly *Candida punicea*), *S. roseus* and *S. salmonicolor*, but not by *S. albo-rubescens*, *S. gracilis* or *S. shibatanius*. Species may be anamorphs of SPORIDIOBOLUS spp; they have been isolated e.g. from plant material, from beer (*S. roseus*), etc. [Book ref. 100, pp. 911–920.]

**Sporobolomycetaceae** A family of anamorphic fungi (see BLASTOMYCETES) which are characterized by the formation of BALLISTOSPORES. The organisms, which have basidiomycetous affinities, form budding yeast cells; some can form pseudomycelium and/or true mycelium. The family includes BULLERA and SPOROBOLOMYCES. (See also MIRROR YEASTS.)

**sporocarp** *Syn.* FRUITING BODY.

**Sporochneus** See PHAEOPHYTA.

**sporocladium** See KICKXELLALES.

**sporocyst** (1) In most coccidia: a sac, formed within an oocyst, containing one or more (often 2, 4 or 8) sporozoites; there may be one or more sporocysts per oocyst. Sporocysts may be ovoid, spherical or elongated, and those of some species have a STIEDA BODY. (See also EIMERIORINA and SPORULATION.) (2) See MONOCYSTIS.

**Sporocytophaga** A genus of GLIDING BACTERIA of the CYTOPHAGALES. The cells are pigmented rods, up to ca. 8 µm long, from which resting cells (*microcysts*) develop; the microcyst is a spherical, desiccation-resistant structure which has a thick capsule. The organisms are chemoorganotrophic; growth occurs aerobically on cellulose (see CELLULASES), cellobiose, or glucose (mannose is used by some strains). Growth is inhibited by high concentrations of organic nitrogen or of sugars.

**sporodochium** A pad- or cushion-like fungal STROMA which bears a surface layer of conidiophores. Sporodochia are formed e.g. by species of *Fusarium* and *Nectria*.

**sporogony** (1) The division of a zygote (= *sporont*) into a number of haploid cells (*sporozoites*). (2) The (mitotic) division of a cell (*sporont*) into a number of spores or sporozoites. (3) A process which involves the formation and fusion of gametes and the division of the zygote to form spores or sporozoites.

**Sporolactobacillus** A genus of Gram-positive, chemoorganotrophic, microaerophilic, catalase-negative, ENDOSPORE-forming bacteria which occur e.g. in soil. Cells: flagellated rods, ca. 1 × 3–5 µm. Lactic acid is formed, anaerogenically, from e.g. glucose and other sugars and from sugar alcohols. Type species: *S. inulinus*.

**Sporomusa** A genus of Gram-negative, anaerobic, ENDOSPORE-forming bacteria isolated e.g. from river-mud, soil, waste water etc. Cells: mainly banana-shaped, motile (with up to 15 lateral flagella). The organisms can use e.g. *N*-methyl compounds (e.g. betaine, sarcosine), primary alcohols, hydroxy fatty acids, and 2,3-butanediol as substrates, acetate being the characteristic product of metabolism; H<sub>2</sub> and CO<sub>2</sub> are converted to acetate.

$\text{NO}_3^-$  and  $\text{SO}_4^{2-}$  are not used as electron acceptors. Cells contain a cytochrome *b* and ubiquinone. GC%: ca. 41.3–47.4. Species: *S. ovata* and *S. sphaeroides*. [Arch. Micro. (1984) 139 388–396.]

**sporont** See SPOROGONY.

**Sporopachydermia** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are ovoid, ellipsoidal, or elongate; vegetative reproduction occurs by multilateral budding. Pseudomycelium and true mycelium are not formed. Asci contain 1–4 spheroidal or ellipsoidal ascospores which are smooth-surfaced and have very thick walls; the spores are embedded in a highly refractile material – both within the ascus and after their release. Non-fermentative;  $\text{NO}_3^-$  is not assimilated. Inositol can be used as sole carbon source. A characteristic offensive odour is produced by cultures on a range of media. The species are *S. cereana* (formerly *Cryptococcus cereanus*) and *S. lactativora* (type species; formerly *Cryptococcus lactativorus*); they have been isolated from (respectively) rotting cacti (*Cereus* spp) and e.g. Antarctic sea-water. [Book ref. 100, pp. 427–430.]

**sporophore** Any SPORE-bearing structure – e.g. a CONIDIOPHORE, a HYMENOPHORE, or a spore-bearing hyphal branch of *Actinoplanes*.

**sporophyte** See ALTERNATION OF GENERATIONS.

**sporoplasma** (1) (*protozoal*). In the ASCETOSPORIA, MICROSPORA and MYXOZOA: an amoeboid, initially intrasporal cell which, when released from the spore, functions as the infective/invasive form of the parasite. (2) (*mycol.*) The cytoplasm of a developing ascus or sporangium.

**sporopollenin** A polymer which is highly resistant to chemical, physical and enzymic degradation; it can be degraded by strong oxidizing agents such as chromic acid. Sporopollenin or sporopollenin-like polymers occur e.g. in the exines of pollen grains, in the zygosporangium walls of e.g. *Mucor mucedo*, and in the cell walls of certain algae (e.g. *Coccomyxa* and other lichen photobionts [CJB (1985) 63 2221–2230], *Chlorella* spp, *Scenedesmus* spp). Sporopollenin is believed to be formed by the oxidative polymerization of CAROTENOIDS.

**Sporosarcina** A genus of Gram-positive, chemoorganotrophic, obligately aerobic, ENDOSPORE-forming bacteria which occur e.g. in soil. The type species, *S. ureae*, can grow in media containing 5–10% urea; the cells are flagellated cocci (max. diam. ca. 2.5  $\mu\text{m}$ ) which occur e.g. in tetrads or packets. Each cell may give rise to a centrally located endospore. GC%: ca. 40–43. [*S. halophila*: SAAM (1983) 4 496–506; motility, behaviour and aggregation of *S. ureae*: FEMS (1983) 17 201–204.]

**Sporospirillum** A genus (*incertae sedis*) of motile, rigid, helical bacteria (1.8–4.8  $\times$  40–100  $\mu\text{m}$ ) which have been observed in the intestinal contents of tadpoles; the cells contain one or two ENDOSPORE-like structures. [Book ref. 22, pp. 89–90.]

**sporothallus** See ALTERNATION OF GENERATIONS.

**Sporothrix** A genus of dimorphic fungi of the HYPHOMYCETES. Species are saprotrophs (e.g. in soil, on timber, etc; *S. schenckii* is an opportunistic pathogen (see SPOROTRICHOSIS). In *S. schenckii*, branched, septate hyphae are formed at room temperature; single-celled, pyriform conidia (2–3  $\times$  3–6  $\mu\text{m}$ ) are borne (on sterigmata) along the hyphae, and on terminal conidiophores. The yeast form occurs in culture at 37°C and in host tissues; cells are round, oval or cigar-shaped (2–3  $\times$  3–10  $\mu\text{m}$ ) and reproduce by budding.

**sporotrichosis** A MYCOSIS, affecting man and animals (particularly horses), caused by *Sporothrix schenckii*. Infection occurs via wounds or by inhalation. Typically, chronic subcutaneous

nodules are formed – often in a line following a lymphatic vessel; the nodules eventually ulcerate, and lymphangitis may occur. Occasionally, internal organs may be infected. Potassium iodide has been used for treatment.

**Sporotrichum** A genus of fungi of the HYPHOMYCETES. *S. pulverulentum* is the anamorph of the WHITE ROT basidiomycete *Phanerochaete chrysosporium*.

**Sporozoa** A subphylum of parasitic protozoa comprising the classes Telosporia, Toxoplasmea and Haplosporea [JP (1964) 11 7–20]; organisms in this taxon (excluding those of the Haplosporea) have since been classified, with the piroplasms, in the APICOMPLEXA.

**Sporozoasida** A class of protozoa of the phylum APICOMPLEXA (q.v. for ref.) in which the APICAL COMPLEX is generally well developed, and the conoid, when present, forms a complete truncate cone; typically, cyst formation and both sexual and asexual reproduction occur. Motility involves e.g. cell flexion; the microgametes of some species are flagellated. Some species are parasitic in vertebrates, some in invertebrates. Subclasses: COCCIDIASINA, GREGARINASINA and PIROPLASMASINA.

**Sporozoea** A class of protozoa [JP (1980) 27 37–58] equivalent to the SPOROZOASIDA.

**sporozoite** See SPOROGONY.

**sporulation** (1) The process of development of a SPORE (see e.g. ENDOSPORE sense 1(a)).

(2) In coccidia: the formation, within the oocyst, of (haploid) sporozoites from the zygote (see EIMERIORINA); in most species the sporozoites are formed in SPOROCYSTS. In many species (e.g. most *Eimeria* spp) sporulation occurs *outside* the host, i.e. only unsporulated oocysts are found in fresh faeces; for identification purposes the oocysts in faeces can be concentrated (e.g. by FLOTATION) and sporulated in a 2–3% solution of potassium dichromate for 2–7 days at e.g. 20–30°C. (cf. ENDOSPORULATION.)

**spoT gene** In *Escherichia coli*: a gene encoding an enzyme which can synthesize and degrade ppGpp.

**spotted fevers** A group of human rickettsioses which includes e.g. ROCKY MOUNTAIN SPOTTED FEVER, BOUTONNEUSE, QUEENSLAND TICK TYPHUS and RICKETTSIALPOX. In spotted fevers the rash develops first on the extremities, later on the trunk. (In TYPHUS FEVERS and SCRUB TYPHUS the rash appears first on the trunk, later on the extremities.)

**spotted sickness** *Syn.* PINTA.

**spp** Plural form of 'sp' (q.v.).

**SPR** See BIACORE.

**spraing** A POTATO DISEASE caused either by the tobacco rattle virus (see TOBRAVIRUSES) or the potato mop top virus (see TOBAMOVIRUSES). TRV causes brown, crescent-shaped corky regions to develop in the tubers, and small yellow rings to form on the leaves. PMTV may cause e.g. yellowish or brown V-shaped lesions on leaves, and crescent-shaped lesions within tubers.

**spread plate** (1) A method of INOCULATION: a liquid INOCULUM (e.g. 0.05–0.1 ml) is spread over the surface of a 'dried' PLATE with a sterile SPREADER or SWAB; the inoculated plate is then dried before incubation. The spread plate procedure is used e.g. as a COUNTING METHOD. (2) A plate inoculated as in (1).

**spreader** A simple L-shaped tool used in preparing a SPREAD PLATE; it can easily be made by fusing the tip of a Pasteur pipette and bending the fine-bore tube to a convenient angle.

**spreading factor** *Syn.* HYALURONATE LYASE.

**spring viraemia of carp** (German INFECTIOUS DROPSY) A FISH DISEASE important among cultured carp (*Cyprinus carpio*) in

## springer

Europe. The causal agent is a virus (a probable member of the RHABDOVIRIDAE). Symptoms include abdominal distension, internal haemorrhage, and oedema.

**springer** A can (see CANNING) in which one end is distended (convex) but can be pressed back into the normal position – the opposite end concomitantly becoming distended. (cf. SWELL.)

**sprout mycelium** (pseudohyphae; pseudomycelium) A mycelium-like structure consisting of chains of cells formed by sequential sprouting (budding).

**SPS** Sodium polyanetholsulphonate (or sodium polyanetholesulphonate): a blood anticoagulant used e.g. (at ~0.025%) in BLOOD CULTURE; its toxicity for e.g. *Neisseria gonorrhoeae* or *Peptostreptococcus anaerobius* may be nullified by gelatin.

SPS is reported to inhibit PCR [JCM (1998) 36 2810–2816].

**Spumavirinae** (foamy viruses) A subfamily of viruses of the RETROVIRIDAE. Spumaviruses have been isolated from various mammalian species; viral infection is persistent but appears not to be associated with any disease. In tissue cultures the spumaviruses induce characteristic CPE, including syncytium formation and the development in infected cells of a highly vacuolated ('foamy') cytoplasm. Spumaviruses do not transform cells in vitro and are non-oncogenic in their animal hosts. The subfamily includes bovine syncytial virus, feline syncytial virus, human foamy viruses, and simian foamy virus [macaque → human transfer of SFV: Lancet (2002) 360 387–388].

**Spumellarida** See RADIOLARIA.

**spur** (*serol.*) See OUCHTERLONY TEST.

**Spurr's medium** An embedding medium containing, *inter alia*, the epoxy resin vinylcyclohexene dioxide. (See also ELECTRON MICROSCOPY.)

**sputter-coating** A method for coating a specimen with metal prior to examination in the SEM – see ELECTRON MICROSCOPY (b). The apparatus consists essentially of two electrodes in a chamber; the cathode is made of the metal (e.g. gold, platinum) to be used for coating the specimen. The specimen, on a stub, is placed on the anode. The chamber is evacuated and then filled with argon at a pressure of ca. 0.1 torr (ca. 0.1 mm Hg). A potential difference of ca. 1 kV is applied across the electrodes; the argon ionizes, and (positive) argon ions strike the cathode, dislodging atoms of metal which then permeate the chamber. Metal atoms impinge on the specimen from all angles – penetrating fine crevices and forming a continuous metal film.

**sputum** (*med.*) Secretions ejected from the lungs, bronchi and trachea by coughing and spitting (Latin *spuere*: spit). Sputum consists of mucus and may contain pus and/or microorganisms; specimens obtained via the mouth normally contain saliva. Sputum is examined microbiologically in the diagnosis of lung infections (see e.g. PNEUMONIA and TUBERCULOSIS).

**squalene synthase inhibitors** See ZARAGOZIC ACIDS.

**squamulose** Bearing or consisting of small scales. Of a LICHEN: having a thallus consisting of small scales or lobes (squamules), each of which is attached to the substratum by one edge; the squamules may be imbricated.

**square bacteria** Flat, often square bacteria (side: 2–5 µm) found e.g. in hypersaline pools; the cell wall consists of regularly arranged hexagonal and tetragonal subunits [JB (1982) 150 851–860]. (cf. BOX-LIKE BACTERIA.)

**squash mosaic virus** See COMOVIRUSES.

**squirrel fibroma virus** See LEPORIPPOXVIRUS.

**SR mutant** See SMOOTH–ROUGH VARIATION.

**SRBC** Sheep red blood cell (erythrocyte).

**src** An ONCOGENE originally identified as the transforming determinant of ROUS SARCOMA VIRUS. The *v-src* product (pp60<sup>v-src</sup>)

has tyrosine-specific protein kinase activity. The *c-src* product also has tyrosine kinase activity, but *c-src* is expressed at very low levels in most normal cells; cells transformed by RSV usually contain relatively high levels of pp60<sup>v-src</sup>. The *c-src* and *v-src* products are similar but not identical, differing in their C-terminal amino acid sequences; this difference in structure may be at least partly responsible for the transforming capacity of pp60<sup>v-src</sup> [Book ref. 113, pp. 19–25].

**SrfI** See RESTRICTION ENDONUCLEASE (table).

**SRID** Single radial immunodiffusion: see SINGLE DIFFUSION.

**sRNA** 'Soluble RNA', an early term for tRNA.

**SRO** Sex-ratio organism: any of several strains of *Spiroplasma* (serogroup II) which can infect *Drosophila* spp, inducing a trait in which infected female flies produce only female progeny. SROs can be transmitted transovarially; they have not been cultivated in vitro.

**SRP** SIGNAL RECOGNITION PARTICLE.

**srrAB genes** See AGR LOCUS.

**SRSVs** SMALL ROUND STRUCTURED VIRUSES.

**s.s.** SENSU STRICTO (q.v.).

**ss** (of DNA or RNA) Single-stranded.

**SS agar** (salmonella–shigella agar) An agar medium containing e.g. beef extract, lactose, thiosulphate, ferric citrate, bile salts, neutral red and brilliant green [recipe: Book ref. 2, p. 137]. SS agar is used as a differential and selective medium for salmonellae and shigellae. Colonies are pink for lactose +ve strains, colourless for lactose –ve strains; for H<sub>2</sub>S-producing strains, each colony has a black centre.

**SSA** See SUPERANTIGEN.

**SSB protein** SINGLE-STRAND BINDING PROTEIN.

**SSC** See STANDARD SALINE CITRATE.

**ss(c)DNA** Single-stranded circular DNA.

**SSCP** (single strand conformation polymorphism) SSCP analysis is a method (used e.g. for TYPING) in which *related* samples of single-stranded DNA (e.g. homologous sequences from related strains) are compared by comparing their electrophoretic speeds in polyacrylamide gel; strands in which even one base differs may be distinguishable if this change in sequence affects intra-strand base-pairing (conformation) in such a way that electrophoretic speed is altered. (A *non*-denaturing gel is used for SSCP analysis in order to promote/preserve intra-strand base-pairing.) Typically, strands of ~100–300 bp in length are examined by SSCP analysis.

Samples of single-stranded DNA can be produced by PCR; such a protocol (PCR-SSCP) has been used e.g. for typing *Neisseria meningitidis* [JCM (1997) 35 1809–1812].

PCR-SSCP has also been used e.g. for detecting point mutations that confer resistance to the antibiotic rifampicin in *Mycobacterium tuberculosis*. In this procedure, PCR amplifies a specific mutation-prone region in the *rpoB* gene (which encodes the β subunit of RNA polymerase – the target for rifampicin); amplicons from a given test strain are then compared, by SSCP analysis, with the corresponding sequences from wild-type (i.e. rifampicin-sensitive) and mutant strains. Resistance to other antibiotics can be assessed similarly by analysing relevant sequences of the genome; in one study, SSCP analysis was used for detecting resistance to rifampicin and isoniazid by examining four chromosomal loci [JCM (1997) 35 719–723].

One problem with SSCP analysis is that some silent mutations produce conformations that simulate those of resistant strains, giving rise to false-positive results [JCM (1997) 35 492–494].

(See also DGGE.)

**ssDNA phage** (single-stranded DNA phage) Any BACTERIOPHAGE which contains ss cccDNA: see INOVIRIDAE and MICROVIRIDAE.

ssDNA phages are widely studied as models for bacterial DNA REPLICATION. Replication of the phage genome involves three stages. *Stage I*: synthesis of a complementary (*c* or *minus*) strand on the viral (*v* or *plus*) ss cccDNA to form a ds cccDNA replicative form (RF). Stage I requires only host proteins and involves the synthesis of RNA primer(s) on SINGLE-STRAND BINDING PROTEIN-coated *v* DNA by one of three mechanisms (see INOVIRUS, BACTERIOPHAGE G4, BACTERIOPHAGE  $\phi$ X174); primers are elongated with DNA by host DNA POLYMERASE III holoenzyme, and the RNA is then excised and replaced with DNA by host DNA polymerase I. The ends of the *c* strand are then joined by DNA ligase. *Stage II*: semiconservative replication of RF to yield progeny RF. Usually the *v* strand is nicked at a specific site by a phage-coded enzyme (cf. BACTERIOPHAGE G4); elongation of the 3'-end thus formed is carried out by host DNA polymerase III holoenzyme (using *c* strand as template) in a ROLLING CIRCLE MECHANISM, the RF strands being unwound by host Rep protein (see HELICASES). The displaced *v* strand serves as template for *c* strand synthesis. *Stage III*: asymmetric synthesis in which only *v* ss cccDNA is produced from RF. This stage requires phage-coded proteins (see INOVIRUS and BACTERIOPHAGE  $\phi$ X174). [DNA replication in ssDNA phages: BBA (1985) 825 111–139.]

**SSF** Simultaneous saccharification and fermentation: a batch-type process in which dextrans are enzymically hydrolysed to glucose (saccharification), the glucose being immediately taken up and fermented by organisms in the dextrin solution.

**S<sub>SM</sub>** Simple matching coefficient. In the mutual comparison of two OTUs by NUMERICAL TAXONOMY: the number of characteristics which match – i.e. which are the same (both positive or both negative) – in the given pair of OTUs, expressed as a percentage of the total number of characteristics (criteria) used in the comparison. S<sub>SM</sub> can be used only when the characteristics can be expressed in simple, discontinuous form, e.g. + or –, 0 or 1 (cf. entry S<sub>G</sub>).

**ssp** Subspecies.

**SsrA–SsrB** See TWO-COMPONENT REGULATORY SYSTEM.

**SSSS** Staphylococcal SCALDED SKIN SYNDROME.

**SST** See STANDARD TESTS FOR SYPHILIS.

**ST** See ETEC.

**St Anthony's fire** (1) *Syn.* ERGOTISM. (2) *Syn.* ERYSIPELAS.

**St Louis encephalitis** (SLE) An acute, viral ENCEPHALITIS caused by a flavivirus (see FLAVIVIRIDAE); it occurs in epidemics in urban regions of central and southern USA. The virus is prevalent in wild birds and is transmitted by *Culex* spp (mosquitoes) which feed on birds and man. The disease may be benign with few sequelae, but can be fatal, particularly in the elderly.

**St Vitus's dance** See RHEUMATIC FEVER.

**ST-I** *Syn.* STa (see ETEC).

**ST-II** *Syn.* STb (see ETEC).

**STa** *Syn.* ST-I (see ETEC).

**sta locus** See PARTITION.

**STAA medium** A selective medium used e.g. for isolating *Brochothrix thermosphacta* from meat and meat products; it consists of a basal growth medium containing streptomycin, thallous acetate and Actidione (cycloheximide).

**stab culture** See CULTURE.

**stabilate** A population of viable microorganisms preserved by FREEZE-DRYING or by FREEZING so that their characteristics remain unchanged. (Populations preserved by repeated subculture are subject to genetic change by selection of mutants.)

**stabilized erythrocyte** See HAEMAGGLUTINATION.

**stable RNA** In prokaryotes: a term sometimes used to refer to rRNA and tRNA – as opposed to the (typically) short-lived mRNA.

**Stachel** See PLASMIDIOPHOROMYCETES.

**stachybotryotoxicosis** A MYCOTOXICOSIS (affecting e.g. horses, cattle, poultry, man) caused by the ingestion or inhalation of (or skin contact with) toxins of *Stachybotrys atra* (present e.g. in mouldy hay); the toxins involved are TRICHOHECENES, including e.g. roridin E and satratoxins F, G and H. Symptoms include e.g. irritation and ulceration of the mucous membranes of the mouth, throat and nose, widespread haemorrhages, leucopenia; death may occur.

**Stachybotrys** A genus of fungi (class HYPHOMYCETES) which form septate mycelium; dark, spherical or elongated conidia are produced in chains from conidiophores which each consist of a straight hypha bearing a terminal cluster of phialides. (See also CELLULASES, PAPER SPOILAGE and STACHYBOTRYOTOXICOSIS.)

**stachyose** A non-reducing tetrasaccharide:  $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  6)- $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  6)- $\alpha$ -D-glucopyranosyl-(1  $\leftrightarrow$  2)- $\beta$ -D-fructofuranoside (6<sup>G</sup>- $\alpha$ -galactobiosylsucrose); it occurs e.g. in soybeans, peanuts etc.

**stage 0, I, II etc** (1) (of sporulation) See ENDOSPORE sense 1(a). (2) (of rust fungi) See UREDINIOMYCETES.

**stage micrometer** See MICROMETER.

**stagers** (megrim) (*vet.*) A general term for certain conditions characterized by incoordination and a loss of balance in an animal. (See e.g. PASPALUM STAGGERS.)

**staghorn calculi** See STRUVITE.

**stag's horn fungus** Abnormal (branching, antler-like) fruiting bodies formed in the dark by *Lentinus lepideus* (see LENTINUS).

**stain** See DYE and STAINING.

**staining** In microbiology: any process which imparts colour, opacity (or electron density), contrast, or the ability to fluoresce to part(s) of a specimen – usually prior to examination by MICROSCOPY (or ELECTRON MICROSCOPY); staining is commonly used to facilitate detection or observation of specific organisms or intracellular features. Staining is generally carried out on dead, fixed cells or tissues (cf. VITAL STAINING). Extra contrast between different features in a given specimen may be achieved by COUNTERSTAINING; in *negative staining* the background is stained or made opaque (see e.g. CAPSULE STAIN; ELECTRON MICROSCOPY (a)).

In light microscopy most substances used for staining ('stains') are themselves coloured, and they impart their colour to the specimen in various ways (cf. DYE and LYSOCHROME). (See also METACHROMATIC DYE.) Some staining procedures depend on in situ chemical reaction to produce colour (see e.g. FEULGEN REACTION and PAS REACTION). Others involve the deposition of metallic silver (e.g. FONTANA'S STAIN) or of a dye-containing complex (e.g. LEIFSON'S FLAGELLA STAIN); such methods generally involve the use of a *mordant*, i.e. a substance which helps to bind a stain to the target surface.

The usefulness of a given stain may depend on its ability to stain some types of cell or cell component more effectively than others; thus e.g. certain stains are commonly used for staining protein (e.g. amido black 10B, COOMASSIE BRILLIANT BLUE), nucleic acids (e.g. ACRIDINES, CHROMOMYCIN, DAPI, METHYL GREEN-PYRONIN STAIN), lipid (e.g. NILE BLUE A, SUDAN BLACK B), and cellulose (e.g. CONGO RED). General purpose stains include e.g. EOSIN, FUCHSIN, METHYLENE BLUE; see also LACTOPHENOL COTTON BLUE. Whether or not a given dye can stain a particular cell or intracellular feature may depend not only on the nature and solubility of the dye but also on factors such as the permeability or integrity of the cell membrane (see e.g. TOXOPLASMA DYE TEST). Another important factor is pH; thus, e.g., a protein at pH below its ISOELECTRIC POINT can be

## staling

stained by an acidic dye, and at pH above its IEP by a basic dye. The differential staining effect of some composite stains (e.g. methyl green–pyronin stain) depends on pH and on the admixture of component dyes in their correct proportions. (See also ACID FAST STAIN; ALBERT'S STAIN; ENDOSPORE STAINS; GIMÉNEZ STAIN; GRAM STAIN; KOSTER'S STAIN; METHENAMINE–SILVER STAIN; ROMANOWSKY STAINS.)

**staling** Adverse, growth-inhibitory changes in the environment in the immediate vicinity of a colony, or in a batch culture, due, apparently, to the accumulation of waste metabolic products of the organism.

**stalk** (1) (*bacteriol.*) *Syn.* PROSTHECA. (2) (*bacteriol.*) A non-prosthecate appendage such as that formed by species of GALLIONELLA. (3) (*bacteriol.*) The supportive part of the fruiting body formed by certain members of the MYXOBACTERIALES. (4) (*mycol.*) *Syn.* STIPE. (5) (*protozool.*) Part of the vegetative cell in species of e.g. CARCHESIUM and VORTICELLA; some species form contractile stalks.

**standard redox potential** See REDOX POTENTIAL.

**standard saline citrate (SSC)** A saline solution (0.15 M NaCl) containing sodium citrate (0.015 M); pH 7.0.

**standard serological tests** *Syn.* STANDARD TESTS FOR SYPHILIS.

**standard tests for syphilis (STS; serological tests for syphilis; standard serological tests, SST; non-treponemal tests)** Tests in which a non-treponemal antigen is used to detect or quantify non-treponemal antibodies (*reagins*) which occur in the serum of patients suffering from SYPHILIS; the antigen used is a suspension of fine particles of CARDIOLIPIN–lecithin–cholesterol. STS include COMPLEMENT-FIXATION TESTS (e.g. Kolmer CFT, WASSERMANN REACTION) and flocculation tests (e.g. ART, RPR TEST, RST, USR TEST, VDRL TEST); flocculation tests are typically carried out on slides or on cards. Because reagins also occur in the serum of patients with certain other diseases (e.g. infectious mononucleosis, leprosy, malaria, measles), and during pregnancy and certain other conditions, STS may give BIOLOGICAL FALSE POSITIVE REACTIONS. (cf. TREPONEMAL TESTS.)

**Stannophyllum** See XENOPHYOPHOREA.

**staphyla** (*mycol.*) See FUNGUS GARDENS.

**staphylocoagulase** See COAGULASE.

**staphylococcal food poisoning** See FOOD POISONING (g).

**staphylococcal scalded skin syndrome** See SCALDED SKIN SYNDROME.

**staphylococcal toxic shock syndrome** See TOXIC SHOCK SYNDROME.

**staphylococcin** Any BACTERIOCIN produced by *Staphylococcus* sp; some staphylococcins are reported to be bacteriostatic. [Effect of staphylococcin 1580 on *Staphylococcus aureus*: AvL (1978) 44 35–48; a staphylococcin-like substance bacteriostatic for Gram-positive and Gram-negative bacteria: JGM (1984) 130 2291–2300.]

**Staphylococcus** A genus of Gram-positive, catalase-positive, chemoorganotrophic, characteristically halotolerant bacteria of the family MICROCOCCACEAE which are usually highly sensitive to LYSOSTAPHIN; most staphylococci are facultatively anaerobic (*S. saccharolyticus* is obligately anaerobic). The cell wall generally contains appreciable amounts of TEICHOIC ACIDS, and the ratio of glycine to lysine in PEPTIDOGLYCAN is characteristically >2 (cf. MICROCOCCUS).

Cells: spherical, ca. 1 µm diam., occurring in characteristic clusters (the name *Staphylococcus* derives from the Greek for 'bunch of grapes'). Non-motile. Orange/yellow CAROTENOID pigments occur in *S. aureus* and in strains of some other species. A CAPSULE may be present. (Capsulation can e.g. interfere

with phage typing, prevent the clumping factor reaction (in the COAGULASE TEST), and affect the morphology of the colony.) Most species appear to contain only *a*- and *b*-type CYTOCHROMES (*c*-type cytochromes occur in *S. sciuri*) [Book ref. 44, p 399].

Staphylococci occur as commensals/parasites and pathogens in man and other animals. Diseases caused by species of *Staphylococcus* in man and animals include e.g. ARTHRITIS, BLACK POX, BOIL, BRONCHITIS, BUMBLEFOOT, CARBUNCLE, CYSTITIS, ENDOCARDITIS, FOOD POISONING, IMPETIGO, JOINT-ILL, KERATOCONJUNCTIVITIS, MENINGITIS, OSTEOMYELITIS, PNEUMONIA, SCALDED SKIN SYNDROME and TOXIC SHOCK SYNDROME. (See also EAR MICROFLORA, GENITOURINARY TRACT FLORA, RESPIRATORY TRACT MICROFLORA, SKIN MICROFLORA, VAGINA MICROFLORA.)

GC%: ca. 30–39. Type species: *S. aureus*.

**Classification of the staphylococci.** Staphylococci are divided into COAGULASE-positive and coagulase-negative strains. Strains of *S. aureus* and *S. intermedius* are coagulase-positive, as are some strains of the animal pathogen *S. hyicus* subsp *hyicus*; most species of *Staphylococcus* are coagulase-negative. In terms of pathogenic potential, *S. aureus* is considered to be the most important species; however, other species, including a number of coagulase-negative staphylococci (CNS), are also associated with disease, often as opportunist pathogens.

Species include:

*S. albus*. See *S. epidermidis*.

*S. aureus*. A major pathogen of man and other animals. The cells, ca. 1 µm in diam., are often pigmented (see STAPHYLOXANTHIN), particularly in freshly isolated strains. The cell wall usually contains *ribitol* teichoic acids, and most strains form PROTEIN A; the PEPTIDOGLYCAN contains little or no L-serine. The cell wall lipoteichoic acid is a virulence factor: it acts as an adhesin which binds to fibronectin (a glycoprotein component of e.g. epithelial cells). Protein adhesins of *S. aureus* bind to mammalian targets such as collagen and fibronectin [TIM (1998) 6 484–488]. (See also SORTASE.)

The expression of virulence factors by *S. aureus* is controlled by various mechanisms which involve e.g. the AGR LOCUS. The expression of certain virulence factors, including exotoxin, appears to involve a TWO-COMPONENT REGULATORY SYSTEM that responds to levels of environmental oxygen [JB (2001) 183 1113–1123].

In general, the expression of virulence factors in *S. aureus* depends on the growth phase and/or on conditions of growth. Regulation of exotoxins and wall-associated proteins (e.g. PROTEIN A) is complex [FEMS Reviews (2004) 28 183–200].

The organism forms a thermostable DEOXYRIBONUCLEASE, and produces both free coagulase and clumping factor (see COAGULASE and COAGULASE TEST). [Evaluation of the STAPHYLOSLIDE and other agglutination tests: JCM (1985) 21 726–729.] All strains coagulate e.g. human and rabbit plasma.

Glucose is usually fermented to DL-lactic acid, and lactose metabolism involves the tagatose 6-phosphate pathway (see Appendix III(a)). Mannitol is utilized aerobically and anaerobically, and maltose is utilized aerobically. VP +ve. (See also HYALURONATE LYASE and PHOSPHATASE.)

*S. aureus* is characteristically sensitive to NOVOBIOCIN (MIC <1.6 µg/ml). Most strains are resistant to benzylpenicillin (owing to the action of staphylococcal β-LACTAMASES), and some strains are resistant to methicillin (see MRSA). MRSA has been detected by multiplex PCR, target sequences being in *mecA* (encoding PBP 2a) and the *coa* gene (encoding coagulase, and used as a marker for *S. aureus*) [JMM (1997) 46 773–778].

Antibiotics that have been used therapeutically against *S. aureus* include various  $\beta$ -lactams (e.g. flucloxacillin), clindamycin, erythromycin and vancomycin.

*S. aureus* is susceptible to effective concentrations of phenolic disinfectants, HYPOCHLORITES, CHLORHEXIDINE and povidone-iodine (see IODINE). The organism can withstand 60°C/30 min. The D VALUE of *S. aureus* at 70°C is often less than 1 minute (although much longer in some strains).

*S. aureus* has been divided into four biotypes: A–D (biotypes E and F are now classified as *S. intermedius*). The biotypes usually correlate with source: man (A), poultry and pigs (B), bovines and sheep (C), and hares (D). The biotypes of *S. aureus* are distinguishable e.g. by FIBRINOLYSIN production (A strains only); coagulation of bovine plasma (C strains only); formation of  $\alpha$ -haemolysin (see HAEMOLYSIN, sense 2e) (A strains, some B and C strains); formation of  $\beta$ -haemolysin (C and D strains, most B strains, few A strains); mannitol fermentation within 5 days (A and B strains, some C strains).

PHAGE TYPING of *S. aureus* is carried out with five groups of phages. A strain of *S. aureus* which can be lysed by phage(s) of lytic group I is referred to as *S. aureus* phage type I; a strain lysed by phage(s) of group II is referred to as *S. aureus* phage type II etc. A given strain may be lysed by the phages of more than one group; for example, many of the (phage-typable) strains of MRSA are lysed by phages of groups I and III (while other strains of MRSA may be lysed by group III phages only). The phages used for typing *S. aureus* have been standardized: they belong to the 'international set'; for example, group I phages include those designated 29, 52, 52A, 79 and 80. The phages of group IV are used for typing isolates of *S. aureus* derived from animals. (Some strains of *Staphylococcus* are not typable by this system; such strains presumably lack the receptors for relevant phages.)

*S. aureus* can also be typed by MLST [database: JCM (2000) 38 1008–1015]. A further method is PCR-RFLP with a species-specific target – e.g. a sequence in the gene *aroA* (which encodes the enzyme 5-enolpyruvylshikimate-3 phosphate, used in the synthesis of aromatic amino acids and folate) [JCM (1999) 37 570–574]. Other typing methods include PFGE. [A comparison of PFGE with five other molecular methods for typing *S. aureus* (MRSA): JMM (1998) 47 341–351.]

*S. capitis*. Coagulase-negative. The cell wall contains glycerol teichoic acids. Sensitive to novobiocin (MIC <1.6  $\mu$ g/ml). Acid is not formed, aerobically, from e.g. maltose, trehalose or melezitose. Occurs e.g. on the normal human scalp, but has been associated with several cases of infective endocarditis and with urinary tract infections.

*S. caprae*. [Original species proposal: IJSB (1983) 33 480–486.] Isolated from both animal and human specimens. Evidence for pathogenicity in man [see e.g. RMM (1995) 6 94–100 (97)].

*S. carnosus*. [Original species proposal: IJSB (1982) 32 153–156.]

*S. caseolyticus*. [Original species proposal: IJSB (1982) 32 15–20.]

*S. cohnii*. Coagulase-negative. The cell wall contains glycerol teichoic acids. Resistant to novobiocin (MIC  $\geq$ 1.6  $\mu$ g/ml). Acid is not formed, aerobically, from sucrose or melezitose. Occurs on human skin.

*S. epidermidis* (formerly *S. albus*). Coagulase-negative. The cell wall contains glycerol teichoic acids. Novobiocin-sensitive (MIC <1.6  $\mu$ g/ml). Acid is not formed, aerobically, from L-arabinose, D-mannitol, trehalose or D-xylose but is produced from sucrose. Anaerobic growth occurs in thioglycollate

medium. *S. epidermidis* is found on human skin; it can be pathogenic. The cell wall lipoteichoic acid acts as an adhesin which binds to host-cell fibronectin. [Epidemiological typing of *S. epidermidis*: MR (1985) 49 126–139.]

*S. gallinarum*. [Original species proposal: IJSB (1983) 33 480–486.] Referred to ENTEROCOCCUS.

*S. haemolyticus*. Coagulase-negative. The cell wall contains glycerol teichoic acids. Novobiocin-sensitive (MIC <1.6  $\mu$ g/ml). Bovine blood is commonly haemolysed. Occurs on the skin of humans and non-human primates.

*S. hominis*. Similar to *S. haemolyticus*, but haemolysis of bovine blood is weak or absent.

*S. hyicus*. *S. hyicus* subsp *chromogenes* contains only coagulase-negative strains; *S. hyicus* subsp *hyicus* contains coagulase-negative and coagulase-positive strains. The coagulase-positive strains contain glycerol teichoic acids, and their peptidoglycan contains little or no L-serine; like *S. aureus*, they form a thermostable deoxyribonuclease, but they form L-lactic acid from glucose, are VP –ve, and do not form clumping factor or utilize maltose or mannitol aerobically. Strains of *S. hyicus* subsp *hyicus* have been implicated in GREASY PIG DISEASE.

*S. intermedius*. Coagulase-positive with bovine or rabbit plasma (some strains also coagulate human plasma); clumping factor is formed by only some strains. The cell wall contains glycerol teichoic acids. A  $\beta$ -haemolysin and a thermostable deoxyribonuclease are formed. Mannitol is not utilized within 5 days. VP –ve. Strains occur on the skin and/or nares of e.g. dogs, foxes, horses and mink.

*S. lentus*. [Proposed species (re-classified from *S. sciuri* subsp *lentus*): SAAM (1983) 4 382–387.]

*S. lugdunensis*. [Original species proposal: IJSB (1988) 38 168–172.] Coagulase-negative. The organism resembles *S. aureus* in producing a thermostable deoxyribonuclease. Resistance to cadmium has been recorded in many isolates. Almost all strains isolated in Europe are reported to be sensitive to  $\beta$ -lactam antibiotics, but those isolated in the USA are often resistant (many produce  $\beta$ -lactamases). *S. lugdunensis* is one of the most pathogenic species of CNS, and has been identified as the cause of a number of cases of infective endocarditis and e.g. abscesses [see RMM (1995) 6 94–100 (95–96)].

*S. saccharolyticus*. A species re-classified from *Peptococcus saccharolyticus* [name validation: IJSB (1984) 34 91–92]. Anaerobic. Coagulase-negative. The organism has been reported to cause infective endocarditis [JCM (1990) 28 2818–2819].

*S. saprophyticus*. Coagulase-negative. The cell wall contains ribitol teichoic acids. Resistant to novobiocin (MIC  $\geq$ 1.6  $\mu$ g/ml). Acid is formed, aerobically, from maltose, sucrose and trehalose. Bovine blood is not haemolysed. Occurs e.g. on the skin of humans and pigs, and can cause e.g. urinary tract infections (see e.g. CYSTITIS).

*S. schleiferi*. [Original species proposal: IJSB (1988) 38 168–172.] Coagulase-negative. Two subspecies: *schleiferi* and *coagulans*. Some strains have been reported to clot plasma [JCM (1994) 32 388–392]. Isolated e.g. from bacteraemic patients and from an infected dog's ear.

*S. sciuri*. Coagulase-negative. Occurs e.g. on certain squirrels.

*S. simulans*. Coagulase-negative. Occurs e.g. on human skin.

*S. warneri*. Coagulase-negative. Occur e.g. on the skin of humans and non-human primates. The organism has been associated e.g. with endocarditis [JCM (1992) 30 261–264] and urinary tract infections.

*S. xylosus*. Coagulase-negative. Isolated e.g. from the skin of dogs, goats and sheep.

## staphylokinase

**staphylokinase** A protein, produced by many strains of coagulase-positive staphylococci, which activates profibrinolysin (from various species) to fibrinolysin, thus causing indirect FIBRINOLYSIS. Its mechanism of action appears to be similar to that of STREPTOKINASE. [Assay, properties etc: Book ref. 44, pp. 790–796.]

**staphylomycins** See STREPTOGRAMINS.

**Staphyloslide** A test used to detect clumping factor (see COAGULASE) in strains of *Staphylococcus aureus*; essentially, a given strain is examined (on a slide) for its ability to clump fibrinogen-coated sheep erythrocytes.

**Staphylothermus** A genus of heterotrophic, coccoid archaeans. The type species, *S. marinus*, grows optimally at ca. 92°C under anaerobic conditions; it was isolated from a HYDROTHERMAL VENT. [Book ref. 196, pp. 69–71.]

**staphylothrombin** See COAGULASE.

**staphyloxanthin** The main CAROTENOID pigment in *Staphylococcus aureus*. [Structure and synthesis: JB (1981) 147 900–919.]

**star activity** (of a restriction endonuclease) A change, or reduction, in the specificity of certain RESTRICTION ENDONUCLEASES (e.g. *Bam*HI, *Eco*RI, *Sal*I) which occurs under non-optimal conditions.

**starch** A composite D-glucan consisting of amylose (ca. 20–25%, depending on source) and amylopectin. *Amylose* is a water-soluble linear (1 → 4)- $\alpha$ -D-glucan which forms blue-black complexes with iodine. *Amylopectin* is a highly branched (1 → 4)- $\alpha$ -D-glucan with (1 → 6)- $\alpha$ -D-glucosidic branch points; it is water-insoluble and forms violet or red-brown complexes with iodine (cf. GLYCOGEN). Starch is abundant as the main storage carbohydrate in higher plants and in certain algae, e.g., members of the Chlorophyta ('chlorophycean starch'); an amylose-like glucan occurs in the cell walls of certain fungi, and yeasts of the genus *Cryptococcus* characteristically form an extracellular CAPSULE of an amylose-like polysaccharide. (See also CYANOPHYCEAN STARCH; FLORIDEAN STARCH; LICHENIN.) Starch may be stained e.g. with iodine or (non-specifically) by the PAS REACTION.

Starch is attacked by a wide range of microorganisms (see e.g. AMYLASES and DEBRANCHING ENZYMES). That from higher plants is an important raw material for a number of biotechnological processes – see e.g. INDUSTRIAL ALCOHOL and SINGLE-CELL PROTEIN.

**STARFISH** A water-soluble multivalent carbohydrate ligand (a starfish-shaped molecule) which can bind to, and neutralize, the shiga-like toxins (SLT-I and SLT-II) of *Escherichia coli* O157:H7 with subnanomolar activity; the structure of STARFISH is related to that of the (glycolipid) toxin-binding sites (Gb<sub>3</sub>) on mammalian vascular endothelium. (See also SYN-SORB P<sup>k</sup>.) [STARFISH: Nature (2000) 403 669–672.]

**starlingpox virus** See AVIPOXVIRUS.

**Starria** A genus of filamentous CYANOBACTERIA in which the trichomes are triradiate in cross-section; *S. zimbabweensis* has been recorded in only one geographical location. [J. Phycol. (1977) 13 288–296.]

**start** (in cell cycle) See CELL CYCLE.

**start point** (start site) See TRANSCRIPTION.

**starter** (starter culture) An INOCULUM, usually consisting of a pure or mixed culture of microorganisms, used to initiate a commercial FERMENTATION (sense 2) (see e.g. LACTIC ACID STARTERS). Starter cultures are often grown under aseptic conditions in a laboratory (but cf. e.g. KEFIR and *sourdough* BREAD-MAKING).

**State 3, State 3u, State 4** (*bioenergetics*) See RESPIRATORY CONTROL.

**stathmokinesis** Inhibition of cell division (e.g. by COLCHICINE).

**stationary phase** (of growth) See BATCH CULTURE.

**statismospore** (*mycol.*) A spore which is not forcibly discharged. (cf. BALLISTOSPORE.) In basidiomycetes, a BASIDIOSPORE which is a statismospore is either formed in a *symmetrical* orientation on its sterigma, or it is formed directly from the basidium, i.e., with no sterigma. (cf. GASTEROID BASIDIOSPORE.)

**statolith** See e.g. MÜLLER'S VESICLE.

**statospore** (algol.) (1) Any resting cell. (2) Any resting cell ('spore' or 'cyst') which is formed *within* a vegetative cell: see e.g. CHRYSOPHYTES and XANTHOPHYCEAE.

**STATS** See CYTOKINES.

**Staurastrum** A large, probably artificial genus of placoderm DESMIDS. The cells are morphologically highly variable, but each semicell appears triangular when viewed from one end; sometimes spines or projections extend from the corners.

**Stauroidesmus** A genus of placoderm DESMIDS.

**Stauroneis** See DIATOMS.

**staurospora** See SACCARDOAN SYSTEM.

**Staurothele** See VERRUCARIALES.

**stavudine** See NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS.

**STb** *Syn.* ST-II (see ETEC).

**STD** SEXUALLY TRANSMITTED DISEASE.

**steam** (for disinfection and sterilization) See e.g. AUTOCLAVE; LOW-TEMPERATURE STEAM DISINFECTION; LOW-TEMPERATURE STEAM-FORMALDEHYDE STERILIZATION; STEAMER. (See also CANNING.)

**steam trap** In an AUTOCLAVE: a valve which permits the passage of air and/or water ('condensate') but which blocks the passage of saturated steam. One form of steam trap incorporates a metal bellows which contains a small amount of water. When steam at the required shut-off temperature flows around the bellows to the outlet line the vapour pressure in the bellows causes the bellows to expand and thus close the valve.

**steamer** A vessel in which objects or materials may be subjected to steam at *atmospheric* pressure (cf. AUTOCLAVE); it is used e.g. for TYNDALLIZATION.

**STEC** See EHEC.

**Steers' replicator** A multipoint plate inoculator.

**Stefansky's bacillus** *Mycobacterium lepraemurium*.

**steganacin** See MICROTUBULES.

**Stella** A genus of Gram-negative, asporogenous, non-motile, flat, prosthecate (typically 'six-pronged star-shaped') bacteria found in fresh water, sewage and soil. The organisms are chemoorganotrophic, growing on amino acids and organic acids. *S. vacuolata* contains GAS VACUOLES, *S. humosa* does not. [JJSB (1985) 35 518–521.]

**stellacyanin** See BLUE PROTEINS.

**stellate** Star-shaped.

**Stellatospora** A class of protozoa (phylum ASCETOSPORA) in which the spore contains one or more sporoplasms and 'haplosporosomes' (membrane-bounded, osmiophilic, ovoid or spherical bodies – possibly polysaccharide reserves). Two orders are recognized: Occlusosporida (>1 sporoplasm per spore, spore wall entire (imperforate); genera: e.g. *Martellia*) and Balanosporida (1 sporoplasm per spore, spore wall with an orifice covered externally by an operculum or internally by a diaphragm; genera: e.g. HAPLOSPORIDIUM, MINCHINIA, *Urosporidium*).

**Stellavirus** *Syn.* ROTAVIRUS.

**STEM** See ELECTRON MICROSCOPY (c).

**stem-and-loop structure** (*mol. biol.*) A secondary structure in a nucleic acid molecule in which complementary sequences within a strand base-pair to form the 'stem', nucleotides between these sequences forming the single-stranded 'loop'; such structures can

occur in regions of hyphenated dyad symmetry (see PALINDROMIC SEQUENCE).

**stem blight** (stem spot) (of lupins) See LUPINOSIS.

**stem nodules** Nitrogen-fixing nodules formed, as a result of association with *Rhizobium* strains [JGM (1983) 129 3651–3655], on the stems of certain (mainly tropical or subtropical) leguminous plants (genera *Aeschynomene*, *Sesbania* and *Neptunia*); the plants may form nodules either on stems or on roots, or both. Nitrogen fixation in stem nodules is comparable in efficiency with that in soybean ROOT NODULES, and stem nodulation is not significantly inhibited by increased concentrations of applied nitrogen. [Book refs 55, pp. 255–268, and 112, pp. 161–169.] (See also *Gunnera* under NOSTOC.)

**Stemonitales** See MYXOMYCETES.

**Stemonitis** A genus of slime moulds (class MYXOMYCETES) which form aphanoplasmodia that give rise to clusters of long, narrow, often brownish sporangia borne on slender, glossy black stalks. Capillitial threads ramify through the spore mass, extending from a central black columella (continuous with the stalk) and anastomosing at the periphery of the spore mass to form a surface network. Species occur on rotting wood, humus, etc.

**Stenella** See HYPHOMYCETES; see also PITYRIASIS NIGRA.

**steno-** A prefix signifying 'narrow' or 'limited' – e.g. a *stenohaline* organism is one able to tolerate only a narrow range of salt concentrations. (cf. EURY-.)

**Stenocybe** See CALICIALES.

**Stenophora** See GREGARINASINA.

**Stenotrophomonas maltophilia** See CYSTIC FIBROSIS.

**stenoxenus** Having a narrow host range.

**Stentor** A genus of freshwater ciliate protozoa (order HETEROTRICHIDA). Cells: funnel- or trumpet-shaped, up to ca. 2 mm in length, and contractile; the cytostome is at the broader end, and the narrow end of the cell is often attached to the substratum. A mucilaginous lorica is formed by some species. The macronucleus may be moniliform (e.g. in *S. coeruleus*), ovoid (e.g. in *S. igneus*) or elongate and of uniform width (e.g. in *S. roeseli*). A contractile vacuole at the broader end of the cell communicates with a longitudinal canal. *S. coeruleus* contains a blue pigment; other species may be e.g. yellow, red or brown. (See also ZOOCHLORELLAE.)

*S. coeruleus* exhibits PHOTOTAXIS (see also STENTORIN). [The photoreceptor in *S. coeruleus*: SEBS (1983) 36 503–520.]

**stentorin** The presumed photoreceptor in *Stentor coeruleus* (see STENTOR); it consists of the chromophore *hypericin* bound to protein. Stentorin occurs in rows of subpellicular membranous vesicles or granules.

**Stephanosascus** A genus of fungi (family SACCHAROMYCETACEAE) which form budding yeast cells, pseudomycelium, and abundant branched, septate, true mycelium; blastospores are formed, arthrospores are not. Hyphal septa contain plasmodesmata. Ascospores: initially bowler-hat-shaped, becoming hemispherical with a thick convex wall. Non-fermentative; NO<sub>3</sub><sup>-</sup> is not assimilated. One species: *S. ciferrii* (anamorph: *Candida ciferrii*), isolated e.g. from soil and from clinical specimens from man and animals. [Book ref. 100, pp. 431–433.]

**Stephanodiscus** See DIATOMS.

**Stephanoecca** See CHOANOFLAGELLIDA.

**stephanokont** Refers to a cell which bears a ring of flagella (of equal length) encircling the cell near one end. (See e.g. DERBESIA; cf. ISOKONT; HETEROKONT.)

**Stephanopogon** A genus of marine benthic ciliates (subclass GYMNOSTOMATIA). *Stephanopogon* is considered to be a primitive ciliate owing e.g. to its possession of an apical cytostome and

(unlike any other known ciliate) the possession of only one type of nucleus.

**Stephanopyxis** See DIATOMS.

**sterc-** Indicates a connection with faeces, e.g., *stercorous*: resembling faeces.

**Stercoraria** One of two groups of subgenera of mammalian trypanosomes; stercorarian trypanosomes infective for the vertebrate host develop in the POSTERIOR STATION. The group comprises HERPETOSOMA, MEGATRYPANUM and SCHIZOTRYPANUM. (cf. SALIVARIA.)

**Stereaceae** See APHYLLOPHORALES.

**Stereocaulon** A genus of LICHENS (order LECANORALES); photobiont: a green alga. Erect pseudopodetia (see PSEUDOPODETIUM) – typically richly branched and fruticose, covered with scale-like, finger-like or coralloid outgrowths (*phyllocladia*) – arise from a granular, usually rapidly evanescent primary thallus. Dark-brown apothecia may occur terminally or laterally on the pseudopodetia, and dark-coloured cephalodia are commonly present. Species occur on soil and rocks, some being associated with habitats rich in heavy metals.

**stereocilium** *Syn.* CLAVATE CILIUM.

**Stereomyxa** See ACARPOMYXEA.

**Stereum** A genus of lignicolous fungi of the APHYLLOPHORALES (family Stereaceae) which form typically resupinate or effused-reflexed, leathery or woody fruiting bodies in which the context lacks clamp connections and is usually dimittic. (See also PAPER SPOILAGE, PARTRIDGE WOOD, WOODWASP FUNGI and XYLANASES.)

**Steriflamme process** A form of heat treatment used for canned foods (see CANNING). Cans are initially heated to a given temperature by steam at atmospheric pressure. The rapidly spinning cans are then exposed directly to gas flames so that their contents are quickly heated to ca. 120–130°C. The cans are held at the processing temperature for the required time and are then cooled by water sprays.

**sterigma** (*pl.* sterigmata) (*mycol.*) (1) In certain fungi: a small or substantial protrusion from which a spore or daughter cell is produced – see e.g. BASIDIUM and STERIGMATOMYCES. (See also SPICULUM.)

(2) See ASPERGILLUS.

**sterigmatocystin** A carcinogenic, hepatotoxic MYCOTOXIN which contains a bifuran moiety fused at the 4,5 positions to a substituted xanthone (cf. AFLATOXINS); it is produced e.g. by *Aspergillus nidulans* and *A. versicolor*.

**Sterigmatomyces** A genus of fungi (class HYPHOMYCETES) which form spherical to ovoid yeast cells and which may form a true mycelium. A vegetative cell produces one or more fine projections (sterigmata), at the end of each of which a daughter cell forms by budding. When mature, the daughter cell may in turn produce sterigmata, often resulting in the formation of short, branching chains of cells; cells may separate by the formation of a septum in the middle or at the distal end of the sterigma, according to species. Metabolism is strictly respiratory. Six species are recognized; type species: *S. halophilus*. [Book ref. 100, pp. 921–929; cell cycle in *S. halophilus*: JGM (1983) 129 2129–2162.]

**sterilant** Any chemical agent which, under carefully controlled conditions, can sterilize objects, materials etc (see STERILIZATION; cf. DISINFECTANT); examples include e.g. ETHYLENE OXIDE, GLUTARALDEHYDE, β-PROPIOLACTONE (cf. FORMALDEHYDE). If conditions are not carefully controlled, a sterilant may fail to sterilize [JAB (1983) 54 91–99]. (cf. BIOCIDES.)

**sterile** (1) Refers to the condition of an object, or an environment, which is free of all living cells, all viable spores (and

## sterile cabinet

other resistant and disseminative forms), and all viruses and sub-viral agents capable of replication. (An effective STERILIZATION process must therefore irreversibly inactivate all organisms.) For most practical purposes the main criterion of sterility is satisfied by the failure to detect viable cells, spores, viruses etc on or in a given object, material or environment; it should be appreciated that a viable organism can be detected only if it is provided with conditions suitable for its growth or replication or other form of expression.

(2) Refers to any structure or tissue which does not or cannot have a reproductive function.

**sterile cabinet** *Syn.* SAFETY CABINET.

**sterile immunity** *Syn.* STERILIZING IMMUNITY.

**sterile pyuria** See PYURIA.

**sterile technique** *Syn.* ASEPTIC TECHNIQUE.

**sterility** The state or condition of being STERILE. (cf. COMMERCIAL STERILITY.)

**sterilization** (1) Any process by which objects, materials, or environments may be rendered STERILE (sense 1). (Since sterility is an absolute condition, the expression 'partial sterilization' is meaningless – cf. DISINFECTION.) When contaminating organisms are known to consist entirely of vegetative or other vulnerable forms, sterility can usually be achieved by mild heat or chemical treatments; however, 'sterilization' commonly refers to those processes which guarantee sterility regardless of the nature of the contaminating microflora.

(a) *Methods of sterilization.*

(i) *Physical methods.* Heat is the most reliable (and generally the preferred) sterilizing agent; it can reach organisms that may be protected from the action of chemical sterilizing agents or from radiation. The lethal action of heat is due largely to the denaturation of microbial proteins and nucleic acids and to the lability of membranes; at sterilizing temperatures nucleic acids may be deaminated, depurinated or otherwise degraded.

*Dry heat.* Sterilization of clean glassware etc may be carried out in a HOT-AIR OVEN (q.v.); under such conditions proteins are denatured, cytoplasm desiccated, and various cell and virus components are oxidized. *Infrared radiation* ( $\lambda$  within the range  $7.5 \times 10^{-5}$  to  $4 \times 10^{-2}$  cm) has been used e.g. for the sterilization of small items of medical glassware. *Incineration* (combustion) is used e.g. for the disposal of used surgical dressings, and is the basis of FLAMING.

*Moist heat* (steam) is more rapidly lethal than dry heat at the same temperature. The relative ease with which moist heat denatures proteins may be due to facilitated rupture of the protein-stabilizing hydrogen bonds; these bonds are broken more easily when water molecules are available for hydrogen bonding. Moist heat also effects an efficient transfer of heat since steam which condenses on a cooler object (during the heating-up period) delivers up a large amount of latent heat. Moist heat sterilization is generally carried out in an AUTOCLAVE (q.v.).

*Radiation.* See IONIZING RADIATION; MICROWAVE RADIATION; ULTRAVIOLET RADIATION.

*Filtration.* See FILTRATION.

*Ultrasonication.* ULTRASONICATION may achieve sterility in some cases, but it is not a reliable method of sterilization.

(ii) *Chemical methods.* Among the few reliable STERILANTS are ETHYLENE OXIDE, GLUTARALDEHYDE and  $\beta$ -PROPIOLACTONE; such agents must be used in effective concentrations under carefully controlled conditions.

(iii) *Combined physical and chemical methods.* In the pharmaceutical industry, the vapour of e.g. chlorocresol (see PHENOLS) is used at 98–100°C in a procedure that has been called

'heating with a bactericide'. (See also e.g. LOW-TEMPERATURE STEAM-FORMALDEHYDE STERILIZATION.)

(b) *Kinetics of sterilization (some basic ideas).* In a single-species microbial population, the death rate produced by many types of lethal agent (including heat, radiation, various chemical disinfectants and sterilants) follows approximately first-order kinetics. However, close approximations to first-order kinetics are obtained only when sterilizing temperatures are relatively high, or when disinfectants or sterilants are used in relatively high concentrations. Under these conditions, the decrease in numbers of microbial contaminants may be summarized by the equation:

$$\log_e N_0 - \log_e N = kt$$

where  $N_0$  is the initial number of viable organisms,  $N$  is the number of survivors at time  $t$ , and  $k$  is the *death rate constant*. For a given organism, different values of  $k$  can be obtained for different sterilizing temperatures or different concentrations of a disinfectant or sterilant. In a mixed microbial population the cells will have different degrees of resistance to heat, chemicals etc, and a sterilization process will not follow first-order kinetics; in such cases the curve obtained by plotting  $\log_e N$  versus  $t$  (to find  $k$ ) will be a composite curve.

(See also APPERTIZATION; DISINFECTION; D VALUE;  $F_0$  VALUE; MPED; THERMAL DEATH POINT; THERMAL DEATH TIME; Z VALUE.)

(2) (*med., vet.*) Complete elimination of a parasite or pathogen from a host either by the immune response (see STERILIZING IMMUNITY) or by chemotherapy.

**sterilizer** (1) Any apparatus used for STERILIZATION, e.g., an AUTOCLAVE or a HOT-AIR OVEN. (2) A STEAMER. (3) Any of certain types of apparatus used in the CANNING industry for APPERTIZATION.

**sterilizing immunity** (sterile immunity) An immune response which results in the total elimination of a parasite or pathogen from the body. (cf. PREMUNITION.)

**Sterne strain** A toxin-producing strain of *Bacillus anthracis* which lacks the poly-D-glutamic acid capsule; it is used as a live vaccine against ANTHRAX. The lack of a capsule allows the elimination of the organism by phagocytosis.

**steroid bioconversions** Certain steroid hormones and related compounds are produced commercially by a process in which most of the steps are effected chemically, but some rely on the selective action of certain microorganisms; the microbial reactions have the advantages of being site-specific and stereo-specific. *Examples.* Production of corticosteroid hormones (e.g. cortisol) involves the chemical conversion of stigmasterol (from various plants) or diosgenin (e.g. from yams) to progesterone; the  $11\alpha$ -hydroxylation step is achieved e.g. by *Rhizopus nigricans* or *Aspergillus* spp. (The remainder of the synthesis is achieved chemically.) In the synthesis of testosterone, the reduction of 4-androstene-3,17-dione to the  $17\beta$ -hydroxy derivative can be achieved e.g. by strains of *Saccharomyces cerevisiae*. [Book ref. 31, pp. 369–465.] (See also CHOLESTEROL OXIDASE and BILE ACIDS.)

**Ster-zac** See BISPHENOLS.

**stibamine** See ANTIMONY.

**stibanilic acid** See ANTIMONY.

**stibophen** See ANTIMONY.

**stichobasidial** Refers to a *longitudinal* arrangement of nuclear spindles in a developing BASIDIUM. (cf. CHIASTOBASIDIAL.)

**Stichococcus** A genus of freshwater or terrestrial green algae (division CHLOROPHYTA) which are apparently closely related to KLEBSORMIDIUM. When undisturbed, the organisms grow as

filaments, but these readily fragment into bacilliform, uninucleate cells which each contain a single large chloroplast. Asexual reproduction occurs by cell division and fragmentation of filaments.

**stichodyad membrane** See PARORAL MEMBRANE.

**Sticholonche** See TAXOPODIDA.

**stichomonad membrane** See PARORAL MEMBRANE.

**stichonematic** Refers to a eukaryotic FLAGELLUM which bears a single row of fine hairs along its length.

**Stickland reaction** In many proteolytic species of *Clostridium*: an energy-yielding reaction in which, typically, the oxidation of one amino acid (the reductant) is coupled to the reduction of another (the oxidant). Essentially, the reductant undergoes oxidative deamination to an  $\alpha$ -ketoacid (=  $\alpha$ -oxoacid), NAD<sup>+</sup> being reduced. The ketoacid is oxidatively decarboxylated to a fatty acid in a reaction requiring coenzyme A and inorganic phosphate, NAD<sup>+</sup> being reduced and ATP synthesized. NAD<sup>+</sup> is regenerated from NADH by the reduction or reductive deamination of the oxidant.

Some amino acids (e.g. alanine, valine) act preferentially as reductants, while others (e.g. glycine) act preferentially as oxidants; according to organism, leucine and the aromatic amino acids phenylalanine and tryptophan may act either as oxidants or reductants. Some species (e.g. *C. sporogenes*) can use ornithine by converting it to proline (an oxidant). In some cases leucine can be used as both oxidant and reductant, and some species can use e.g. BETAINE or sarcosine (*N*-methylaminoacetic acid) as oxidant, betaine yielding acetate and trimethylamine.

**sticky ends** (cohesive ends) (*mol. biol.*) Complementary single-stranded ends of a double-stranded nucleic acid molecule – generated e.g. by staggered cleavage of a circular dsDNA molecule by certain RESTRICTION ENDONUCLEASES; base-pairing between sticky ends of the same molecule or of two identical molecules generates (after ligation) cccDNA or a CONCATEMER, respectively. (See e.g. BACTERIOPHAGE  $\lambda$ .)

**Sticta** A genus of foliose LICHENS (order PELTIGERALES). Photobiont: *Nostoc* (e.g. in *S. sylvatica*) or a green alga (e.g. in *S. canariensis*); the mycobiont of *S. canariensis* can alternatively associate with a cyanobacterium to form a distinct morphotype ('*S. dufourii*') – cf. CEPHALODIUM. Thallus: large, lobed, corticate on both surfaces; the upper surface may bear isidia (e.g. *S. sylvatica*) or soredia (e.g. *S. limbata*), the lower surface is tomentose and is perforated by characteristic cyphellae (see CYPHELLA). Species occur mainly on mossy trees and rocks.

**Stieda body** In some species of the APICOMPLEXA (e.g. some *Isopora* spp): a structure which may form part of, or is intimately associated with, the polar wall of the sporocyst; it is probably involved in excystation.

**stiff agar** See AGAR and MEDIUM.

**Stigeoclonium** A genus of polymorphic, filamentous (often heterotrichous) green algae related to CHAETOPHORA. The filaments are uniseriate, branched, and may terminate in multicellular hyaline hairs; both prostrate and erect filaments may form rhizoids. Each cell contains a single parietal chloroplast. Reproduction is predominantly asexual, quadriflagellate zoospores and aplanospores being produced. Sexual reproduction is isogamous. Species occur worldwide in standing or running fresh water, growing attached to rocks, plants, etc. (See also SEWAGE FUNGUS.)

**stigma** (*algol.*) *Syn.* EYESPOT (sense 1).

**Stigmatella** See MYXOBACTERIALES.

**stigmatomycosis** An insect-transmitted disease of cotton (*Gossypium*) and other plants, caused by members of the METSCHNIKOWIACEAE (e.g. *Ashbya gossypii*, *Nematospora gossypii*).

**Stigonematales** See CYANOBACTERIA.

**stilbaceous** Having synnemata.

**Stilbellales** See HYPHOMYCETES.

**Stilton cheese** See CHEESE-MAKING.

**stimulatory hypersensitivity** *Syn.* TYPE V REACTION.

**stinkhorns** See PHALLALES.

**stinking smut** *Syn.* bunt: see COMMON BUNT and KARNAL BUNT.

**stipe** A stalk or stem. In e.g. an agaric-type fungal fruiting body the stipe is composed of hyphae which are characteristically orientated parallel to the axis of the stipe (cf. *receptacle* in PHALLALES). In PENICILLIUM spp 'stipe' refers to the (single) hypha which supports the penicillus.

**stipitate** Having a STIPE.

**stirred tank reactor (STR)** A FERMENTER in which the culture is agitated by a mechanical device (e.g. a turbine) but in which there is no circulatory loop (cf. LOOP FERMENTER). The traditional STR is a squat, cylindrical vessel, but the *multistage STR* is a tall ('column') fermenter in which the mechanical agitators are arranged in a vertical series on a common drive shaft. The STR is generally more flexible than other fermenters, i.e., it is suitable for a wider range of operating conditions.

**STLV** SIMIAN T-CELL LEUKAEMIA VIRUS.

**stn gene** See FOOD POISONING (*Salmonella*).

**stock** Any uncharacterized population of trypanosomes derived from a natural host animal; a given stock may contain different strains of trypanosomes.

**Stoffel fragment** See DNA POLYMERASE.

**stolon** (*mycol.*) See e.g. RHIZOPUS.

**stomach** (human) See GASTROINTESTINAL TRACT FLORA.

**stomate** Having a 'mouth', stoma(ta), or CYTOSTOME.

**stomatitis** Inflammation of the tissues of the mouth. The causes of stomatitis include e.g. irritation of the tissues by ill-fitting dentures, vitamin deficiency, and infection by any of a range of microorganisms: see e.g. CANDIDIASIS, GINGIVITIS, HAND FOOT AND MOUTH DISEASE, HERPES SIMPLEX (oral herpes), PERIODONTITIS and VINCENT'S ANGINA. (See also LUDWIG'S ANGINA.)

**Stomatochroon** A genus of obligately endophytic algae related to TRENTEPOHLLIA. The organisms typically inhabit the stomata of leaves, their prostrate filaments growing between the cells of the leaf mesophyll.

**Stomatococcus** A genus of facultatively anaerobic, Gram-positive cocci of the family MICROCOCCACEAE. *S. mucilaginosus*, the sole species, occurs in the human mouth; it has been associated with endocarditis and (in immunosuppressed individuals) with bacteraemia. Catalase weakly +ve. Oxidase –ve. Carbohydrate metabolism: fermentative. Colonies are small, dark and mucoid. The cells are resistant to LYSOSTAPHIN. Unlike *Staphylococcus*, the organism is sensitive to bacitracin.

**stomatogenesis** The formation of the oral structures and infrastructures during the overall process of binary fission in a stomate ciliate; morphogenetic details – particularly the origin of kinetosomes of the new oral region – differ among the various groups of ciliates. There are four principal modes of stomatogenesis: apokinetal, buccokinetal, parakinetal and telokinetal (listed in the order which approximates an evolutionary sequence from most advanced to most primitive). *Apokinetal* ('de novo') *stomatogenesis* involves the appearance of a group of oral kinetosomes which do not appear to have arisen either from those of the parental oral apparatus or from those of the somatic ciliature. In *buccokinetal stomatogenesis* at least some of the kinetosomes appear to be derived from the division of kinetosomes in the parental buccal area; in *parakinetal stomatogenesis* they may be derived from kinetosomes of somatic cilia posterior to the buccal

## stone-brood

area. In *telokinetal stomatogenesis* (which occurs in 'primitive' ciliates of the KINETOPHAGMINOPHOREA) oral kinetosomes derive from those which occur at – or which (presumably) had an evolutionary origin in – the anterior end of the somatic kineties.

**stone-brood** A BEE DISEASE caused by *Aspergillus flavus* or *A. fumigatus*. Infected larvae appear white and fluffy at first, becoming pale brownish or greenish yellow; most die after being sealed in their cells prior to pupation.

**stoneworts** See CHAROPHYTES.

**stop** See MICROSCOPY (b).

**stop codon** See GENETIC CODE.

**stop transfer sequence** See SIGNAL HYPOTHESIS.

**stopping filter** See MICROSCOPY (e).

**Stormont test (vet.)** A TUBERCULIN TEST in which an injection of PPD is given in the animal's neck, and a second injection is given at the same site seven days later; the test is designed to detect weakly reactive animals. In a positive test, skin thickening is detectable one day after the second injection. The test is negative for *M. avium* infections, but positive e.g. in animals with SKIN TUBERCULOSIS.

**stormy clot** (stormy fermentation) A type of clot obtained when certain bacteria (e.g. *Clostridium perfringens*) are cultured in a milk-containing liquid medium (e.g. LITMUS MILK); the clot has a characteristic turbulent appearance owing to the formation of copious amounts of gas within the medium.

**STR** STIRRED TANK REACTOR.

**str operon** See RIBOSOME (biogenesis).

**Strahlenkörper** *Syn.* RAY BODY.

**straight wire** An instrument used in bacteriology e.g. to SUBCULTURE from an isolated colony, or to prepare a stab-CULTURE; the rod-shaped metal handle holds, at one end, a straight piece of platinum or nickel-steel wire commonly 5–8 cm long. Before and after each use the wire is sterilized by FLAMING and allowed to cool. In use, the tip of the sterile wire is brought into contact with e.g. the centre of a colony; the small quantity of bacterial growth which adheres to the wire can be used as an INOCULUM. (cf. LOOP; CITRATE TEST.)

**strain** An organism, or population of organisms, distinguishable from at least some of the other organisms or populations within a given named taxon, or within a given category of organisms; the members or cells of a given strain are generally regarded as being genetically similar or identical.

**strain T virus** See AVIAN RETICULOENDOTHELIOSIS VIRUSES.

**stramineous** Straw-coloured.

**strand** (of DNA and RNA) A single chain of nucleotide subunits. Double-stranded nucleic acids result from base-pairing between the complementary bases of two strands. For triple-stranded DNA see TRIPLEX DNA. (See also CODING STRAND.)

**strand displacement amplification** See SDA.

**strangles** (distemper) A HORSE DISEASE characterized by inflammation of the upper respiratory tract, abscess formation in adjacent lymph nodes, fever, anorexia, and a purulent nasal discharge; the causal agent, *Streptococcus equi*, enters the body on contaminated feedstuffs or by droplet infection. The disease occurs world-wide, and typically affects young horses (<5 years). *Treatment:* antibiotic therapy. *Control:* vaccination.

**stratigraphy** See BIOSTRATIGRAPHY.

**straw mushroom** *Syn.* PADI–STRAW MUSHROOM.

**strawberry crinkle virus** See RHABDOVIRIDAE.

**strawberry diseases** See e.g. CROWN ROT; GREY MOULD; RED CORE; XANTHOMONAS (*X. fragariae*).

**strawberry foot-rot** A proliferative dermatitis of sheep, affecting chiefly the lower parts of the limbs, caused by *Dermatophilus congolensis*. (See also DERMATOPHILOSIS.)

**strawberry latent ringspot virus** See NEPOVIRUSES.

**strawberry vein-banding virus** See CAULIMOVIRUSES.

**streak** (*plant pathol.*) Roughly parallel lines of discoloration or necrosis which develop on the stems or leaves of plants infected e.g. with certain PLANT VIRUSES.

**streaking** INOCULATION of the surface of a solid MEDIUM in such a way that, during INCUBATION, individual colonies form on at least part of the surface. One method is as follows. A LOOP carrying an INOCULUM is drawn back and forth (i.e. *streaked*) on the surface of a 'dried' PLATE as at A (see figure). The loop is then flamed (see FLAMING), allowed to cool, and streaked as at B. Streakings C, D, and E are similarly made, the loop being flamed and cooled between each streaking and after the last. In this way the inoculum is progressively thinned out as it is distributed along the streak lines. On incubation, each well-isolated viable cell capable of growth on the medium gives rise to a single COLONY.

STREAKING. The pattern of inoculation used in one method of streaking. (See text for explanation.)

**street virus** A wild-type, virulent strain of rabies virus, i.e., one present in an animal or person with naturally acquired rabies. (cf. FIXED VIRUS.)

**strep throat** A sore throat caused by *Streptococcus pyogenes* infection; other symptoms may include fever, rash etc. (See also RHEUMATIC FEVER.)

**streptavidin** A protein, obtained from *Streptomyces avidinii*, which resembles AVIDIN in binding with high affinity to BIOTIN; it can be used instead of avidin e.g. in the ABC IMMUNOPEROXIDASE METHOD.

**streptidine** Diguanyldinositol, a component of certain AMINOGLYCOSIDE ANTIBIOTICS.

**Streptoalloteichus** A genus of bacteria (order ACTINOMYCETALES, wall type III). The organisms form substrate mycelium which bears spheroidal sporangia (each containing 1–4 rod-shaped, motile spores), and an aerial mycelium which gives rise to chains of spores. Type species: *S. hindustanus*. [Book ref. 73, pp. 118–119.]

**Streptobacillus** A genus (*incertae sedis*) of anaerobic, facultatively aerobic, chemoorganotrophic, Gram-negative bacteria which occur e.g. in the throat and nasopharynx in rats and which cause one form of RAT-BITE FEVER. Cells: non-motile rods, ca. 0.1–0.7 × 1.0–5.0 μm (occurring singly or in chains), or filaments, which may be highly pleomorphic – cell shape depending e.g. on cultural conditions. L-FORMS may arise spontaneously. Metabolism is primarily fermentative. Growth requires

e.g. serum or blood. Acid (no gas) is formed from glucose and other carbohydrates. Nitrate is not reduced. Oxidase –ve. Catalase –ve. GC%: ca. 24–26. Type species: *S. moniliformis*. [Book ref. 22, pp. 598–600.]

**Streptobacterium** See LACTOBACILLUS.

**streptobiosamine** A disaccharide component of STREPTOMYCIN, consisting of L-streptose (5-deoxy-3-formyl-L-lyxose) and 2-deoxy-2-methylamino-L-glucose.

**Streptococcaceae** A family of Gram-positive (or Gram type positive), asporogenous, facultatively anaerobic, chemoorganotrophic, spherical or coccoid bacteria; genera: *Aerococcus*, *Gemella*, *Leuconostoc*, *Pediococcus* and *Streptococcus* [Book ref. 21, pp. 490–517].

**streptococcal superantigen A** See SUPERANTIGEN.

**Streptococcus** A genus of Gram-positive, asporogenous, chemoorganotrophic, facultatively anaerobic, catalase-negative and oxidase-negative cocci or coccoid bacteria, typically ca. 1 µm diam., which generally occur in pairs or chains; non-motile. CAPSULE-formation is common in some species. Growth usually occurs optimally in the range 30–37°C. Typically fermentative, with carbohydrates metabolized anaerogenically and homofermentatively – glucose usually yielding L-lactic acid as the main product; however, in the presence of oxygen, some streptococci (e.g. strains of *S. mutans*) can oxidize NADH by NADH oxidase and NADH peroxidase activities [AvL (1985) 51 577–578]. On blood agar some streptococci give rise to clear HAEMOLYSIS ('β-haemolysis'); the VIRIDANS STREPTOCOCCI characteristically give rise to zones of partial haemolysis with greenish to brownish discoloration (so-called 'α-haemolysis').

The organisms occur as commensals/parasites and as pathogens in man and other animals.

Streptococci are killed by PASTEURIZATION and by many common disinfectants.

GC%: 34–46. Type species: *S. pyogenes*.

*Classification of the streptococci.* *Streptococcus* is a large genus (~40 species) which is divided into three main groups of species on the basis of 16S rRNA studies: the pyogenic group, the oral group and 'other species'.

The pyogenic group includes species associated with pyogenic infections in man and other animals – e.g. *S. agalactiae*, *S. dysgalactiae*, *S. equi* and *S. pyogenes*.

The oral group contains species (commonly isolated from the oral cavity) which are associated with pyogenic and other infections in various sites – including mouth, heart (infective endocarditis), joints, skin, muscle and central nervous system (e.g. brain abscesses). The species in this group include *S. anginosus*, *S. mutans*, *S. oralis* and *S. salivarius*. (See also VIRIDANS STREPTOCOCCI.) [Oral streptococci (taxonomy, and relation to infections): RMM (1994) 5 151–162.]

The 'other' species include e.g. *S. acidominimus*, *S. bovis*, *S. equinus* and *S. suis*. Most of these species occur in domestic animals (although e.g. *S. bovis* is an infrequent cause of endocarditis in man).

A number of organisms, previously classified as streptococci, have been transferred to the genera ENTEROCOCCUS and LACTOCOCCUS. (See also ATOPOBIUM.)

In addition to the three main groups of species (mentioned above), many streptococci have been classified by LANCEFIELD'S STREPTOCOCCAL GROUPING TEST – which identifies certain group-specific cell-wall compounds; thus, e.g. species in the pyogenic group (see above) include those in Lancefield group A (*S. pyogenes*), B (*S. agalactiae*), C (strains of *S. dysgalactiae*) and G (*S. canis*). Note that the cell wall in some species does

not contain components which react in the Lancefield grouping test, so that these species cannot be assigned to a Lancefield group. (For group R see *S. suis*, below.)

Other components of the streptococcal cell wall (e.g. the M PROTEIN and T PROTEIN) are also involved in streptococcal typing. Species (and some former species) include:

*S. acidominimus*. Viridans streptococci, isolated e.g. from cattle, from raw milk and from the human mouth. No Lancefield group.

*S. adjacens*. See NUTRITIONALLY VARIANT STREPTOCOCCI.

*S. agalactiae*. Pyogenic group, isolated from man and cattle. Lancefield group B. α-, β- and non-haemolytic strains occur, some being pigmented. A causal agent of bovine MASTITIS (see also CAMP TEST) and e.g. pneumonia or meningitis in human neonates/infants. [Phage typing of *S. agalactiae*: Book ref. 143, pp 1–22.] β-Lactam antibiotics are often used as chemoprophylaxis against infection of the neonate, while e.g. erythromycin may be used as an alternative. However, while most strains of *S. agalactiae* are currently susceptible to β-lactams, a recent study found that >20% of 126 clinical isolates expressed resistance to macrolides. [Antibiotic susceptibility and mechanisms of erythromycin resistance in clinical isolates of *S. agalactiae* (a multicentre study): AAC (2001) 45 2400–2402.]

*S. anginosus*. See '*S. milleri*' (below).

*S. avium*. Lancefield group D. Typically α-haemolytic organisms which occur in the intestine in man and fowl. Referred to ENTEROCOCCUS.

*S. bovis*. Lancefield group D (most strains). Strains occur e.g. in the human gut (also found in domestic animals); infrequent cause of endocarditis in man. (See also BLOAT; THIOPEPTIN.) [Taxonomic study: SAAM (1984) 5 467–482.]

*S. canis*. [Species proposal: IJSB (1986) 36 422–425.] Pyogenic group, isolated from cows with mastitis and from dogs with genital, skin or wound infections. Lancefield group G. β-Haemolytic.

*S. constellatus*. See '*S. milleri*' (below).

*S. cremoris*. Lancefield group N organisms (see LACTOCOCCUS).

*S. cricetus*. A species isolated from hamsters (formerly referred to as serotype a of *S. mutans*).

*S. durans*. Lancefield group D. α-, β- and non-haemolytic strains. Referred to ENTEROCOCCUS.

*S. dysgalactiae*. Pyogenic group, isolated from cattle, pigs, man. Includes strains of Lancefield groups C, G and L.

*S. equi*. Pyogenic group. Lancefield group C. Two subspecies: *equi* and *zooepidemicus*. Causal agents of e.g. STRANGLES in equines and glomerulonephritis and pharyngitis in humans. (See also MASTITIS.)

*S. faecalis*. Lancefield group D. Referred to ENTEROCOCCUS.

*S. faecium*. Lancefield group D. Referred to ENTEROCOCCUS.

*S. ferus*. Oral group. Formerly referred to as strains of *S. mutans*. Isolated from rats.

*S. gallinarum*. Lancefield group D. β-Haemolytic on horse-blood agar. Occurs e.g. in the intestines of fowl. Referred to ENTEROCOCCUS.

*S. gordonii*. Oral group. Organisms previously referred to as strains of *S. sanguis*.

*S. hyointestinalis*. Pyogenic group, isolated from pigs. No Lancefield group.

*S. intermedius*. See '*S. milleri*' (below).

*S. lactis*. Lancefield group N. Referred to LACTOCOCCUS.

*Streptococcus* MG. See STREPTOCOCCUS MG.

'*S. milleri*'. Streptococci associated with various types of endogenous pyogenic infection in humans; they occur e.g. in

## *Streptococcus*

the oropharyngeal region and the gastrointestinal tract. The organisms include  $\alpha$ -,  $\beta$ - and non-haemolytic strains, and strains of Lancefield groups A, C, F and G (as well as some strains which are non-typable by the Lancefield method). Strains of group C can be distinguished from the others e.g. in that they agglutinate human platelets.

These organisms often form acid from lactose, salicin, sucrose and trehalose (but not sorbitol) and hydrolyse arginine and aesculin. All are VP +ve.

Bacteria within the '*S. milleri*' group have been classified in three species: *S. anginosus*, *S. constellatus* and *S. intermedius* [RMM (1997) 8 73–80]. [Iliac osteomyelitis and gluteal muscle abscess caused by *S. intermedius*: JMM (2001) 50 480–482.]

*S. mutans*. Oral group. Organisms which occur e.g. in the human mouth and which are associated with DENTAL PLAQUE (see also MUTAN). Some of the strains originally included in this species have been transferred to other species on the basis of e.g. differences in GC%, type of murein and metabolic characteristics (*S. cricetus*, *S. downei*, *S. ferus*, *S. macacae*, *S. rattus*, *S. sobrinus*) [see e.g. IJSB (1985) 35 482–488].

*S. oralis*. Oral group, viridans streptococci found e.g. in the human mouth. The species includes some strains previously designated e.g. *S. sanguis* II and *S. viridans* I, II and IV [IJSB (1985) 35 482–488].

*S. parauberis*. Pyogenic group, isolated e.g. from cattle, and a causal agent of bovine MASTITIS.

*S. plantarum*. Referred to LACTOCOCCUS.

*S. pluton*. See *Melissococcus pluton* in EUROPEAN FOULBROOD.

*S. pneumoniae* (the 'pneumococcus'). Oral group, related to *S. oralis*. Strains of *S. pneumoniae* occur as part of the human RESPIRATORY TRACT MICROFLORA. The organism is associated with various diseases: e.g. BRONCHITIS, MENINGITIS, OTITIS MEDIA, PNEUMONIA and SINUSITIS. [Diagnosis of *S. pneumoniae* infections: RMM (1994) 5 224–232.] Until quite recently most isolates were susceptible to penicillin but many strains are now resistant [Drugs (1996) 51 (supplement 1) 1–5]. Mutations in some strains are associated with enhanced resistance to certain of the newer fluoroquinolone antibiotics [AAC (2001) 45 952–955].

[Activities of newer fluoroquinolones against ciprofloxacin-resistant *Streptococcus pneumoniae*: AAC (2001) 45 1654–1659.]

Cells: ovoid, often in pairs (diplococci) with the longitudinal axes of the cells aligned (hence the common, but erroneous, designation '*Diplococcus pneumoniae*'). No Lancefield antigen. Characteristically there is a polysaccharide CAPSULE which may exist in any of a number of antigenically distinct forms (this variation being used as a basis for pneumococcal TYPING); the type III pneumococcal polysaccharide, for example, consists of repeating subunits of cellobiuronic acid linked by  $\beta$ -(1 → 3) glucosidic bonds. The existence of a large number of serotypes (~100) has tended to undermine the value of anti-*S. pneumoniae* CONJUGATE VACCINES – which are useful against only a small proportion of the serotypes. (Multivalent conjugate vaccines that cover more serotypes would be expensive.) As an alternative approach to anti-*S. pneumoniae* vaccines it has been suggested that certain cell-surface *proteins* of the pathogen (which show little antigenic variation) may offer better protection [TIM (1998) 6 85–87].

[Complete genome sequence of a virulent isolate of *Streptococcus pneumoniae*: Science (2001) 293 498–506.]

On blood-agar the typical colonial form is the DRAUGHTSMAN COLONY. *S. pneumoniae* is sensitive to OPTOCHIN. (See also BILE SOLUBILITY and QUELLUNG PHENOMENON.)

Some strains of *S. pneumoniae* form products such as HYALURONATE LYASE, NEURAMINIDASE and THIOL-ACTIVATED CYTOLYSIN.

*S. porcinus*. A species associated with e.g. abscesses in the cervical lymph nodes of pigs and with porcine pneumonia and septicaemia. The species includes strains of Lancefield groups E, P, U and V [SAAM (1984) 5 402–413].

*S. pyogenes* (formerly *S. haemolyticus*). Pyogenic group. Lancefield group A. Characteristically  $\beta$ -haemolytic. In broth cultures, cells commonly form long chains, sometimes with a HYALURONIC ACID capsule. (See also PYR.) Extracellular products may include e.g. HYALURONATE LYASE, STREPTODORNASE, STREPTOKINASE, STREPTOLYSIN O, STREPTOLYSIN S. [Complete genome sequence of an M1 strain of *S. pyogenes*: PNAS (2001) 98 4656–4663.]

*S. pyogenes* is associated with various diseases: see e.g. ERYSIPELAS, GLOMERULONEPHRITIS, IMPETIGO, NECROTIZING FASCITIS, OTITIS MEDIA, PHARYNGITIS, PNEUMONIA (e), QUINSY, SCARLET FEVER, SINUSITIS, STREP THROAT, TONSILLITIS and TOXIC SHOCK SYNDROME. (See also SUPERANTIGEN.)

Some group A streptococci have the ability to enter (and survive within) human respiratory-tract cells; invasion is promoted by a protein encoded by the pathogen's *prtF1* gene. An intracellular location would effectively protect the pathogen from those antibiotics (including e.g.  $\beta$ -lactams) which remain largely extracellular; it is therefore of importance that invasive group A streptococci have been associated with resistance to erythromycin (a drug which can enter eukaryotic cells) [Lancet (2001) 358 30–33].

*S. raffinolactis*. Lancefield group N. Referred to LACTOCOCCUS.

*S. rattus*. See *S. mutans* (above).

*S. saccharolyticus*. A non-haemolytic species isolated from e.g. cows and straw bedding [SAAM (1984) 5 467–482].

*S. salivarius*. Oral group, isolated from e.g. the human mouth; viridans streptococci related to *S. thermophilus*. Some strains form extracellular LEVANS. [Identification of *S. salivarius* by PCR and DNA probe: LAM (2001) 32 394–397.]

*S. sanguis*. Viridans streptococci which occur e.g. in the human mouth. Some strains form extracellular DEXTRANS. (See also CO-AGGREGATION.)

*S. sobrinus*. See *S. mutans* (above).

*S. suis*. Associated with disease in pigs (e.g. meningitis, endocarditis, bronchopneumonia, reproductive disorders); serotype 2 is the most common serotype found in infections. [Serotypes 3–28 associated with disease in pigs: VR (2001) 148 207–208.] Serotype 2 (also referred to as the group R streptococcus) can cause meningitis, respiratory infections and septicaemia in people exposed to infected pigs/pork.

*S. thermophilus*. Oral group, related to *S. salivarius*; the organisms are isolated from dairy products. No Lancefield group. Characteristically weakly  $\alpha$ -haemolytic. Growth occurs at 50°C, and the organisms can survive 65°C/30 min. (See also LACTIC ACID STARTERS, LEBEN, YOGHURT.)

*S. zooepidemicus*. Re-classified as a subspecies of *S. equi*.

**Streptococcus MG** The designation used for certain non- $\beta$ -haemolytic streptococci which have been included in a species referred to as '*Streptococcus milleri*' [JCM (1985) 22 772–777]. At least some strains are agglutinated by the sera of patients who are suffering from mycoplasma pneumoniae. [The '*Streptococcus miller*' group: RMM (1997) 8 73–80.]

**streptodornase** (streptococcal nuclease) An extracellular nuclease produced by *Streptococcus* spp. Such enzymes are frequently synthesized e.g. by strains of Lancefield groups A and

E – group A strains producing at least four serologically distinct nucleases designated A, B, C and D; all four types of nuclease cleave the backbone of DNA, while types B and D are also active against RNA. The activity of streptodornases is promoted by divalent cations, particularly  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ . In contrast to staphylococcal DEOXYRIBONUCLEASE (q.v.), the products of streptococcal nucleases are 5'-nucleotides.

**streptogramins** A group of closely related MLS ANTIBIOTICS that includes mikamycins, ostreogrycins, patricins, pristinamycins, staphylomycins, synergistins, vernamycins and VIRGINIAMYCINS (at least some of these names are synonyms). (cf. GRISEOVIRIDIN, VIRIDOGRISEIN.)

Each of these antibiotics is a complex of at least two different components. The 'A' (formerly 'M') component is a polyunsaturated macrolactone ring, while the 'B' (formerly 'S') component is a cyclic hexadepsipeptide which contains unusual amino acids (e.g. pipecolic acid).

Both the A and B molecules inhibit PROTEIN SYNTHESIS by binding to the 50S ribosomal subunit. In at least some cases, the A and B components are (jointly) bactericidal owing to synergistic action; individually, the components may be bacteriostatic. The A component inhibits transpeptidation, while the B component inhibits the binding of aminoacyl-tRNA complexes to the ribosome and/or binding of the growing peptide chain at the P site during translation of certain amino acids (e.g. proline), thus causing premature release of the polypeptide chain. In at least some cases, binding of the A component distorts the ribosome in a way that facilitates binding of the B component.

Resistance to A-type streptogramins may be due to O-acetylation of the antibiotic (in at least some cases by a plasmid-encoded enzyme).

Resistance to B-type streptogramins (and other MLS antibiotics) in e.g. staphylococci and streptococci can be due to  $N^6$ -methylation of adenines in 23S rRNA (preventing antibiotic-ribosome binding); this site may be methylated by inducible, plasmid-encoded enzymes or by constitutively expressed enzymes. (Strains designated  $\text{MLS}_{B/C}$  contain constitutively expressed methylases.) In at least some cases (e.g. quinupristin), resistance is reported to occur only if methylases are expressed constitutively.

QUINUPRISTIN/DALFOPRISTIN is a recently introduced member of the group which is useful e.g. against vancomycin-resistant strains of certain Gram-positive pathogens.

**streptokinase** A protein (produced e.g. by certain streptococci of Lancefield groups A and E) which activates profibrinolysin (plasminogen) and thus has *indirect* fibrinolytic activity (see FIBRINOLYSIS). Streptokinase interacts with profibrinolysin to form a complex which releases active fibrinolysin. [Mechanism: JBC (1978) 253 1090–1094.] Streptokinase is assumed to be an AGGRESSIN, assisting the invasiveness of pathogenic streptococci by lysing the fibrin barrier which may enclose streptococcal lesions [TIM (1997) 5 466–467].

Streptokinase is used clinically e.g. in the treatment of thrombosis.

**streptolydigin** An ANTIBIOTIC which binds reversibly to the  $\beta$ -subunit of bacterial RNA POLYMERASE, inhibiting elongation of nascent RNA chains; at low concentrations the antibiotic slows the rate of polymerization without significantly affecting the accuracy of transcription. (Tirandamycin appears to be structurally and functionally similar.) (cf. RIFAMYCINS.)

**streptolysin O** A THIOL-ACTIVATED CYTOLYSIN (q.v.) produced by strains of streptococci of groups A, C and G. In haemolytic activity, monomers of streptolysin O bind to cholesterol-containing

sites on red blood cells (RBCs) and then oligomerize into ring-shaped structures which form pores of  $\sim 30$  nm (larger than the pores formed e.g. by the MAC in COMPLEMENT FIXATION). Haemolysis is inhibited by free cholesterol.

Streptolysin O is immunogenic (cf. STREPTOLYSIN S), and it cross-reacts with the *theta* toxin of *Clostridium perfringens*. In certain diseases (e.g. RHEUMATIC FEVER) the titre of antistreptolysin O antibodies is typically elevated (see ANTISTREPTOLYSIN O TEST).

[Mechanism of assembly of the streptolysin O pore: EMBO (1998) 17 1598–1605.]

**streptolysin S** An oxygen-stable, non-immunogenic leucocidin and haemolysin produced e.g. by many group A streptococci (cf. STREPTOLYSIN O); it appears that some streptolysin S may remain cell-bound while the rest is released by the cell. The haemolytic activity of streptolysin S is inhibited by low levels of certain phosphatides, e.g. phosphatidylethanolamine.

**Streptomyces** A genus of Gram-positive, aerobic bacteria (order ACTINOMYCETALES, wall type I) which occur e.g. in soil and aquatic habitats – a few species being pathogenic in plants (e.g. potato, sugar beet) and man (see MADUROMYCOSIS). The organisms form both AERIAL MYCELIUM and a non-fragmenting, branched SUBSTRATE MYCELIUM, and in most species spores are formed only by the aerial mycelium which fragments to give rise to non-verticillate chains of spores [differentiation and spore formation: Book ref. 67, pp. 89–115]; the genus includes organisms which have been referred to as species of *Actinopycnidium*, *Actinosporangium* and *Chainia*, and the genus definition has been widened to include *Elytrosporangium* and *Microellobosporia* (organisms which form spores on both substrate and aerial mycelium) [Book ref. 73, pp. 94–105; JGM (1983) 129 1743–1813]. (cf. STREPTOMYCETE.) The organisms are chemoorganotrophic (metabolism: oxidative) and are not nutritionally fastidious; usable carbon sources include e.g. chitin, glucose, lactate, starch. Colonies are typically coloured, and many species form a diffusible pigment. ANTIBIOTIC production is common: see e.g. CARBAPENEMS, CHLORAMPHENICOL, CLAVULANIC ACID, MACROLIDE ANTIBIOTICS and STREPTOMYCIN. [Book ref. 201.] (See also COMPLESTATIN.) GC%: 69–78. Type species: *S. albus*.

Studies on the cell envelope of *S. griseus* have revealed the presence of a hydrophilic channel that runs through the cell wall, and have further identified a streptomycin-binding site within the channel [Mol. Microbiol. (2001) 41 665–673].

Many of the hundreds of named species of *Streptomyces* have been amalgamated to form a much smaller number of species [see e.g. JGM (1983) 129 1743–1813]. [Ecology, isolation and cultivation of streptomycetes: Book ref. 46, pp. 2028–2090.]

**streptomycete** Any organism of the (related) genera *Intrasporangium*, *Kineosporia*, *Nocardioidea*, *Sporichthya*, *Streptomyces* and *Streptoverticillium* [Book ref. 73, pp. 94–105].

**streptomycin** A broad-spectrum AMINOGLYCOSIDE ANTIBIOTIC produced by *Streptomyces griseus*; it consists of the base STREPTIDINE linked glycosidically to STREPTOBIOSAMINE. Streptomycin is active against e.g. *Mycobacterium tuberculosis*, some staphylococci, *Brucella* spp and many other Gram-negative bacteria (including some strains of *Pseudomonas aeruginosa*); bactericidal activity increases with concentration. The antibiotic is less active, or inactive, under anaerobic conditions. Streptomycin also inhibits vegetative growth and sporulation of certain fungi [JGM (1983) 129 3401–3410].

When used as a chemotherapeutic agent, streptomycin is associated with certain side-effects, including dose-dependent

## streptonigrin

damage to the 8th cranial nerve (resulting in impairment of hearing); hypersensitivity reactions may also occur.

Streptomycin affects many bacterial cell functions – e.g., it binds to protein S12 (also called P10) in the 30S subunit of bacterial 70S RIBOSOMES and inhibits PROTEIN SYNTHESIS by causing the formation of aberrant initiation complexes. Sublethal concentrations of streptomycin cause misreading of mRNA; misreading occurs mainly at the pyrimidine (rarely the purine) bases in codons, and may be due to conformational changes in the ribosome caused by streptomycin binding.

Resistance to streptomycin may be due to a mutation in the *strA* gene (= *rpsL* gene) resulting in a modified S12 protein which may fail to bind streptomycin or which may alter the effect of the bound antibiotic; such one-step high-level resistance to streptomycin occurs quite commonly. Resistance may also be due e.g. to a plasmid-specified enzyme *streptomycin phosphotransferase*. [Resistance to aminoglycoside antibiotics: TIM (1997) 5 234–240.]

In certain ('streptomycin-dependent') *str* mutants the mutation results in non-functional ribosomes – such mutants being able to grow only in the presence of streptomycin or certain other aminoglycoside antibiotics (e.g. kanamycin, neomycin, paromomycin), or e.g. ethanol; these substances apparently distort the ribosome in such a way that translation can occur. *Conditional* streptomycin dependence is exhibited by certain auxotrophs which can grow in the absence of their required growth factor only when supplied with (sublethal) concentrations of e.g. streptomycin – 'conditional' referring to the fact that streptomycin dependence is exhibited only when the growth factor is absent.

**streptonigrin** An antitumour antibiotic which, in the presence of O<sub>2</sub> and a reducing agent (e.g. Fe<sup>2+</sup>), causes DNA strand breakage; streptonigrin action is inhibited in the presence of free radical scavengers (including superoxide dismutase).

**L-streptose** 5-Deoxy-3-formyl-L-lyxose (cf. STREPTOSAMINE).

**Streptosporangium** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur e.g. in soil, leaf litter, and dung. The organisms form branching substrate and aerial mycelium, the latter bearing clusters of spherical sporangia (each 1–40 µm diam., according to species). GC%: ca. 69–71. Type species: *S. roseum*. [Book ref. 73, pp. 114–115.]

**streptotrichosis** *Syn.* DERMATOPHILOSIS.

**streptovaricins** See ANSAMYCINS.

**Streptovorticium** A genus of aerobic bacteria (order ACTINOMYCETALES, wall type I) which occur e.g. in soil. The organisms form a non-fragmenting substrate mycelium, and an aerial mycelium characterized by the formation of spore chains in verticils. GC%: ca. 69–73. Type species: *S. baldaccii*.

**streptovitacins** See CYCLOHEXIMIDE.

**streptozotocin** An antibiotic – 2-deoxy-2-(3-methyl-3-nitrosoureido)-D-glucopyranoside – which can cause diabetes in experimental animals (e.g. rats) [FEBS (1980) 120 1–3] and which is bactericidal in certain (growing) Gram-positive and Gram-negative bacteria. In bacteria, susceptibility to streptozotocin requires a functional PTS for *N*-acetylglucosamine which is responsible for the uptake of the streptozotocin; the antibiotic enters the cytoplasm as streptozotocin 6-phosphate, a substance which gives rise to the highly toxic and mutagenic compound diazomethane. Since non-growing cells are unaffected, and cells killed by streptozotocin do not lyse, this antibiotic can in some cases be a more useful agent than penicillin for the selection of e.g. rare AUXOTROPHS.

**stress fibre** See PINOCYTOSIS.

**stretch-activated channel** See MECHANOSENSITIVE CHANNEL.

**Striaria** See PHAEOPHYTA.

**Striatella** See DIATOMS.

**strict** (1) *Syn.* OBLIGATE. (2) A term used to emphasize the extent to which a given term is applicable. For example, a strict anaerobe is an organism which grows only in the complete absence of oxygen (and which may also require a pre-reduced medium), and strict anaerobiosis refers to the condition in which there is a complete absence of oxygen. Similarly, a strict autotroph can grow in the complete absence of organic carbon, i.e. its carbon requirements can be satisfied by CO<sub>2</sub> alone.

**Strigomonas** *Syn.* CRITHIDIA.

**Strigula** See CEPHALEUROS.

**string of pearls effect** See BACILLUS (*B. anthracis*).

**stringency** (in PCR) See PCR.

**stringent control** (1) (of rRNA and protein synthesis) In bacteria: a control mechanism in which cells lacking an essential amino acid respond with e.g. decreased synthesis of rRNA and proteins. The response is triggered by an uncharged tRNA at a ribosomal A site (see PROTEIN SYNTHESIS); this stimulates a ribosome-bound enzyme, pyrophosphotransferase (*RelA*; the *relA* gene product; stringent factor), to synthesize ppGpp (in which G is guanosine, p is phosphate) from GTP (or GDP) and ATP. ppGpp (= guanosine 5'-diphosphate 3'-diphosphate; 'guanosine tetraphosphate') is an example of an ALARMONE. (Cells with a null mutation in *relA* do not exhibit the stringent response and are said to be *relaxed*.)

ppGpp can apparently enhance transcription from certain operons that control the synthesis of particular amino acids (e.g. histidine). ppGpp may thus help to maintain a correct balance of amino acids in the cell; for example, given a level of histidine low enough to trigger the stringent response, increased synthesis of ppGpp may help to restore the balance by (i) slowing down protein synthesis, and (ii) stimulating the *his* operon.

A high-resolution study revealed that ppGpp can bind to RNA polymerase in different orientations. This suggested that base-pairing between ppGpp and cytosines in non-template DNA might be important in transcriptional control by ppGpp [Cell (2004) 117 299–310].

(2) (of plasmid replication) See PLASMID.

**stringent factor** See STRINGENT CONTROL (sense 1).

**stripe rust** *Syn.* YELLOW RUST.

**stroma** (1) (*mycol.*) A compact mass of prosenchymatous or pseudoparenchymatous fungal tissue (or of intermingled fungal and non-fungal tissue) on or within which spore-bearing or spore-containing structures often develop. Stromata are formed by many fungi – e.g. by species of *Nectria* and *Xylaria*. (See also ASCOSTROMA, SCLEROTIUM, SPORODOCHIUM.)

(2) See CHLOROPLAST.

**stromatolites** Rock-like accretions, often columnar or domed, generally believed to have been formed by the incorporation of sediment and/or precipitated calcareous/siliceous material in MICROBIAL MATS within marine and non-marine habitats; the oldest of such 'organosedimentary' structures, ca. 3.5 × 10<sup>9</sup> years old, occur in Western Australia.

Stromatolites commonly exhibit a laminar (i.e. stratified) pattern of construction; some authors use the term 'thrombolite' for analogous, non-laminar structures.

Calcified stromatolites apparently do not yield fossil microorganisms; however, cyanobacterium-like microfossils have been detected in silicified stromatolites – such organisms including filaments (e.g. *Gunflintia minuta*) and coccoid organisms (e.g. *Huroniospora microreticulata*). [Book ref. 154.]

Studies have been carried out on stromatolites which are currently forming around the Bahamas. [Role of microbes in accretion, lamination and early lithification of modern marine stromatolites: *Nature* (2000) 406 989–992.]

**Strombidium** See OLIGOTRICHIDA.

**Strombilidium** See OLIGOTRICHIDA.

**Strongylidium** See HYPOTRICHIDA.

**γ-strophanthin** Syn. OUABAIN.

**Stropharia** See AGARICALES (Strophariaceae).

**Strophariaceae** See AGARICALES.

**struck** (syn. Romney Marsh disease) A SHEEP DISEASE caused by *Clostridium perfringens* type C; it occurs in one- to two-year-old animals and involves intestinal congestion and enterotoxaemia.

**structural gene** A GENE whose product is e.g. an enzyme, structural protein, tRNA, rRNA etc – cf. REGULATOR GENE.

**structured granules** CYANOPHYCIN granules.

**struvite** Magnesium ammonium phosphate ( $MgNH_4PO_4 \cdot 6H_2O$ ), a major component of ‘infectious stones’ of the urinary tract, i.e. calculi typically associated with alkaline urine resulting from infection with urease-forming bacteria (such as *Proteus* spp). (See also UROLITHIASIS.) Struvite-based calculi may also include calcium phosphate, forming so-called ‘triple phosphate’. When calculi are branched (*staghorn* calculi), their development has involved deposition of minerals within the collecting system of the kidneys.

**STS** STANDARD TESTS FOR SYPHILIS.

**Stuart’s transport medium** A TRANSPORT MEDIUM used e.g. for a range of anaerobic bacteria, delicate organisms such as *Neisseria gonorrhoeae*, and *Trichomonas vaginalis*. Most formulations include e.g. sodium thioglycollate or thioglycollic acid (a reducing agent), methylene blue (a redox indicator), and agar (0.2–1.0% giving a liquid or semi-solid medium, respectively). (See also GELLAN GUM.) The medium is commonly prepared in bijou bottles which are filled nearly to the brim; the sterilized medium should be colourless.  
[Recipe: Book ref. 53, p. 1411.]

**stub** See ELECTRON MICROSCOPY (b).

**stubborn disease** A disease of citrus trees caused by strains of *Spiroplasma citri*. The disease affects mainly young trees and is transmitted by insects (particularly leaf-hoppers); it occurs e.g. in the USA (California) and in the Middle East.

**stuffer** (*mol. biol.*) See REPLACEMENT VECTOR.

**stump-tailed macaque virus** See POLYOMAVIRUS.

**stumpy form** A short, broad TRYPOMASTIGOTE which has an UNDULATING MEMBRANE but lacks a *free* flagellum.

**stunting syndrome** (infectious stunting syndrome) A POULTRY DISEASE which affects chickens ca. 3–6 days old. Infected birds develop diarrhoea and a hunched appearance. The causal agent is unknown, but virus particles have been observed in the enterocytes in jejunal villi of infected birds [VR (1986) 118 303–304].

**Stx1, Stx2** See SHIGA TOXIN.

**sty** Syn. STYE.

**sty** (sty; hordeolum) An inflamed, suppurative lesion on the eyelid due to infection (usually by staphylococci) of the sebaceous gland at the base of an eyelash.

**stylet-borne transmission** Syn. non-persistent transmission (see NON-CIRCULATING TRANSMISSION).

**Stylochona** See HYPOSTOMATIA.

**Stylonychia** See HYPOTRICHIDA.

**Stylopage** See ZOOPAGALES and NEMATOPHAGOUS FUNGI.

**Styloviridae** A proposed family of BACTERIOPHAGES in which the virion consists of a polyhedral (isometric or elongated) head

and a long, non-contractile tail. Type species: BACTERIOPHAGE λ (q.v.). Other members: e.g., ACTINOPHAGES φC, R1, R2 and VP5; *Bacillus* phages BPP1, φ105 (q.v.), SPβ and SPP1; *Caulobacter crescentus* phage φCbkK; enterobacterial phages χ (a FLAG-ELLOTROPIC PHAGE), PA2, φ80, φD328, and T5; *Pseudomonas* phage F116 (q.v.). Possible member: (virulent) coliphage T1. (cf. LAMBDOID PHAGES.)

**stylovirus** A member of the STYLOVIRIDAE.

**subacute bacterial endocarditis** See ENDOCARDITIS.

**subacute sclerosing panencephalitis** (SSPE) An uncommon disease of children and adolescents associated with persistent measles virus (MV) infection (see MORBILLIVIRUS). Symptoms begin insidiously, with intellectual deterioration and memory loss followed by convulsions, spasticity, coma and death. MV nucleocapsids can be detected as inclusion bodies in CNS tissues, but budding viruses and infectious virions usually cannot be detected. Persistence apparently involves defective MV gene expression which may lead e.g. to a defect in MV maturation. It is frequently associated with the absence or reduced amounts of the virion M protein and/or with loss of haemadsorption – possibly resulting from M protein instability and failure to process the H protein, respectively [Virol. (1985) 143 536–545]. [Altered transcription of a defective MV genome derived from a case of SSPE: EMBO (1987) 6 681–688.] SSPE viruses have been propagated by co-culture of infected brain cells with e.g. Vero cells or human embryonic lung cells. [Neurovirulence of cultured SSPE virus: JGV (1985) 66 373–377.]

**subacute spongiform encephalopathies** (SSEs) The former name for PRION-mediated diseases which are now referred to as TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**subclinical infection** (*med.*) INFECTION (sense 2) in which symptoms are not apparent – or the stage before symptoms become apparent.

**subculture** (1) A CULTURE prepared by inoculating a medium from an existing culture (cf. PRIMARY CULTURE). (2) The process of preparing a culture as in (1). (3) (*verb*) To prepare a culture as in (1).

**suberin** An aromatic polymer, somewhat similar to LIGNIN, to which are attached (by ester linkages) aliphatic components, e.g. ω-hydroxy acids, dicarboxylic acids, C<sub>20</sub>–C<sub>30</sub> alcohols. Suberin occurs, with waxes, in the cell walls of underground parts of higher plants, and is deposited e.g. at wound sites. (cf. CUTIN.) It provides protection against infection etc, but the cutinases of certain plant-pathogenic fungi may have some action on suberin. [Book ref. 58, pp. 79–100.]

**suberization** The deposition of SUBERIN by a plant e.g. at a site of injury caused by fungi, insects etc.

**suberosis** An EXTRINSIC ALLERGIC ALVEOLITIS associated with inhalation of cork dust contaminated with *Penicillium frequentans*.

**subgenomic mRNA** Of an RNA virus: an mRNA, produced in an infected (eukaryotic) cell, which is shorter than the genomic RNA. In eukaryotic cells, translation generally cannot be initiated from an internal site in an mRNA strand; the formation of a subgenomic mRNA allows an initiation site which is located internally in the viral genome to be located terminally, thus permitting independent translation of genes within the genome (cf. POLYPROTEIN). Subgenomic mRNAs may be monocistronic or polycistronic. (See e.g. CORONAVIRIDAE, RETROVIRIDAE, TOBACCO MOSAIC VIRUS, TOGAVIRIDAE; cf. e.g. FLAVIVIRIDAE.)

**subhyemenium** Generative tissue immediately underlying a HYMENIUM. (See also APOTHECIUM.)

## subiculum

**subiculum** (*mycol.*) A pad or felt of hyphae on which, or partly within which, fruiting bodies develop.

**submitochondrial particle** See ETP.

**subpellicular tubules** In various protozoa: a system of MICROTUBULES beneath the PELLICLE. In e.g. coccidia the subpellicular tubules extend posteriorly from a POLAR RING (see also APICAL COMPLEX).

**subpseudopodia** See PSEUDPODIUM.

**subset** (*immunol.*) A category or group within a population of cells (see e.g. T LYMPHOCYTE).

**subsp** Subspecies.

**subspecies** (subsp; ssp) (1) A taxonomic rank immediately below species. (2) Any given taxon with the rank of subspecies (sense 1); such a taxon is designated by the binomial of the species followed by the subspecific epithet: e.g. *Campylobacter sputorum* subsp *bubulus*. (3) Organisms belonging to one or more subspecies.

**substage condenser** See CONDENSER.

**substage diaphragm** See CONDENSER.

**substantivity** (of antiseptics) See SKIN SUBSTANTIVITY.

**substrate-accelerated death** The phenomenon in which a population of starving bacteria (suspended in a non-nutrient medium) exhibits a very high death rate when provided with more of the energy source (substrate) whose depletion had led to starvation. In at least some cases the phenomenon is associated with a sharp fall in the intracellular concentration of cyclic AMP, and is inhibited by magnesium ions.

**substrate-level phosphorylation** The phosphorylation of ADP to ATP, or the phosphorylation of other nucleoside diphosphates, by a process which occurs in the cytoplasm and in which the energy is derived, directly, from an energy-yielding chemical reaction; the latter reaction must be characterized by a yield of free energy greater than that required for phosphorylation. (cf. OXIDATIVE PHOSPHORYLATION.) Substrates involved in substrate-level phosphorylation include 'high-energy' phosphates (e.g. phosphoenolpyruvate) and acyl-coenzyme A thioesters (e.g. succinyl-CoA). Examples of substrate-level phosphorylation include the pyruvate kinase and phosphoglycerate kinase reactions of the EMBDEN-MEYERHOF-PARNAS PATHWAY, the succinyl-CoA synthetase reaction of the TCA CYCLE, and the acetokinase reaction in DESULFOTOMACULUM. (See also FERMENTATION sense 1.)

**substrate mycelium** (primary mycelium; vegetative mycelium) In many actinomycetes: mycelium which occurs on the surface of, and which may penetrate, the medium (cf. AERIAL MYCELIUM). Spores are formed on the substrate mycelium e.g. in species of *Micromonospora* (see also STREPTOMYCETES). [Book ref. 73, pp. 166–169.]

**subterranean clover mottle virus** See VELVET TOBACCO MOTTLE VIRUS.

**subterranean clover red leaf virus** See LUTEOVIRUSES.

**subterranean clover stunt virus** See LUTEOVIRUSES.

**subtilin** An antibiotic, structurally related to NISIN, produced by *Bacillus subtilis*.

**subtilisins** Extracellular, alkaline serine proteases (EC 3.4.21.4) produced by *Bacillus* spp. Subtilisin Carlsberg, from *B. licheniformis*, is the most widely used enzyme in 'biological' washing powders (see PROTEASES). It has a broad specificity, hydrolysing most types of peptide bond and some ester bonds. It does not require  $\text{Ca}^{2+}$  for stability and hence is not inactivated by chelating agents. It is stable over a broad pH range (e.g. 6–10). Subtilisin Novo (= subtilisin BPN), produced e.g. by *B. amyloliquefaciens*, differs in specificity from, but shows extensive homology with, subtilisin Carlsberg and is more

dependent on  $\text{Ca}^{2+}$  for stability. [Production and properties: Book ref. 31, pp. 57–69.]

**subtilysin** *Syn.* SURFACTIN.

**subviral agents** Acellular infectious agents which lack one or more of the essential features of a VIRUS; such agents include SATELLITE RNAS, VIROIDS, VIRUSOIDS, PRIONS and the (hypothetical) VIRINOS.

**subviral particle** A particle – formed by certain viruses as an intermediate in the replication cycle – which consists of the virion minus certain of its components (see e.g. REOVIRUS and BACTERIOPHAGE  $\phi$ 6).

**succinate thiokinase** See Appendix II(a).

**Succinimonas** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN. Cells: coccobacilli or short rods,  $1.0\text{--}1.5 \times 1.0\text{--}3.0 \mu\text{m}$ , which are monotrichously (polarly) flagellated. Glucose, maltose or e.g. dextrans or starch can be fermented; succinate and acetate are major products of glucose fermentation. Fermentation is anaerogenic, and butyrate is not formed. Type species: *S. amylolytica*.

**Succinivibrio** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN. Cells (when freshly isolated): curved or helical rods,  $0.4\text{--}0.6 \times 1.0\text{--}7.0 \mu\text{m}$ , with pointed ends; monotrichously (polarly) flagellated. The main products of glucose metabolism include succinate, acetate and formate; glucose fermentation occurs anaerogenically, and butyrate is not formed. The type species, *S. dextrinosolvans*, appears to be a major fermenter of dextrans in ruminants fed on high-starch diets.

**succinylsulphathiazole** See SULPHONAMIDES.

**sucrase** *Syn.* INVERTASE.

**sucrose** A non-reducing disaccharide:  $\alpha$ -D-glucopyranosyl- $\beta$ -D-fructofuranoside. It is produced by almost all photosynthetic eukaryotes (but not by e.g. some diatoms and some red and green algae). Sucrose can be metabolized by a range of microorganisms. Certain bacteria (e.g. *Leuconostoc* spp, *Streptococcus* spp) split sucrose into its constituent monosaccharides, one of which is metabolized while the other is polymerized to form DEXTRAN or levan (see FRUCTANS). (See also INVERTASE.) High concentrations of sucrose can inhibit microorganisms and are used e.g. in FOOD PRESERVATION.

**Suctorina** A subclass of freshwater and marine ciliates (class KINETOFRAGMINOPHOREA) in which the adult cells are characteristically sedentary (commonly on a non-contractile stalk), lack cilia (though they generally contain an infraciliature), and generally have few to many haptocyst-bearing tentacles. Prey organisms are ingested at the tips of the tentacles. Reproduction occurs by budding, typically with the formation of motile, ciliated larval forms which lack tentacles. (See also BROOD POUCH.) Some species are loricate. Genera include e.g. *Acineta*, *Dactylostoma*, *Dendrosoma*, *Podophrya*, *Sphaerophrya*, and *Tokophrya*. (See also PHALACROCLEPTES.)

**suctorian** A ciliate of the subclass SUCTORIA.

**Sudan black B** A blue-black diazo LYSOCHROME used (0.3% w/v in 70% ethanol) for staining intracellular lipid: see BURDON'S STAIN.

**sudanophilic** Having an affinity for lipid stains (e.g. SUDAN BLACK B).

**sudden infant death syndrome** (SIDS; *syn.* cot death, crib death) The sudden death of an infant (typically aged between ca. 3 weeks and 5 months) with no apparent cause. Various infections have been implicated as causes of SIDS, including e.g. rotavirus infection [JMV (1982) 10 291–296] and BOTULISM, but often there is no evidence of microbial involvement.

**Sudol** See PHENOLS.

**suffocation disease** A disease of the rice plant which is apparently due to toxic levels of hydrogen sulphide produced by microorganisms in the flooded soils used for rice cultivation. Plants may be protected from sulphide by the activities of sulphide-utilizing microorganisms (e.g. *Beggiatoa*). (See also CEREAL DISEASES and SULPHATE-REDUCING BACTERIA.)

**sufu** A Chinese fermented soybean food resembling soft cream cheese. Soybeans are ground, boiled or steamed, strained, and a coagulant (e.g. CaSO<sub>4</sub>, MgSO<sub>4</sub>, acetic acid) is added to the liquid fraction to precipitate proteins. The precipitate is pressed to form a cubical cake-like curd (*tofu*), surface-inoculated with a fungus (e.g. *Actinomucor elegans*, *Mucor* spp), and incubated at e.g. 20°C for 3–7 days. The cubes are salted, rinsed, and immersed in brine containing alcohol, flavouring etc, and aged for e.g. 1–3 months. [Book ref. 8, pp. 516–520.]

**sugar alcohol** See POLYOL.

**sugar beet yellows virus** (SBYV) The type member of the CLOSTEROVIRUSES. SBYV can infect a wide range of plants; in sugar beet, symptoms include yellowing and necrosis spreading inwards from the leaf tips and margins.

**sugarcane diseases** Diseases of sugarcane (*Saccharum officinarum*) include e.g. FIJI DISEASE and RED ROT. [Details of various sugarcane diseases classified according to causal agent: Phytopathol. Paper number 29, February 1986.]

**sugarcane Fiji disease virus** See FIJIVIRUS.

**sugarcane mosaic virus** See POTYVIRUSES.

**sugars** See PEPTONE-WATER SUGARS.

**suicide gene** Any gene whose expression in a cell is lethal for that cell.

**suicide substrate** Any substrate whose uptake or metabolism by a cell is lethal for that cell.

**suid (alpha) herpesvirus 1** See ALPHAHERPESVIRINAE.

**suid herpesvirus 1 group** See ALPHAHERPESVIRINAE.

**suid herpesvirus 2** See BETAHERPESVIRINAE.

**Suipoxvirus** (swinepox subgroup) A genus of viruses of the CHORDOPOXVIRINAE; the genus includes the swinepox virus (see SWINE POX).

**sulA gene** See SOS SYSTEM.

**sulB gene** See SOS SYSTEM.

**sulbactam** A β-LACTAMASE INHIBITOR. (See also SULTAMICILLIN.)

**sulconazole** See AZOLE ANTIFUNGAL AGENTS.

**sulcus** A groove: see e.g. DINOFLAGELLATES.

**sulfate-** See sulphate-.

**sulfazecin** See MONOBACTAMS.

**Sulfolobus** A genus of thermophilic, aerobic and facultatively anaerobic sulphur-dependent prokaryotes (domain ARCHAEA, formerly Archaeobacteria) which occur e.g. in certain hot springs (see also COAL BIODEGRADATION). Cells: cocci, coccoid or irregularly shaped forms; the CELL WALL is an S LAYER. Growth occurs between ca. 50 and 90°C, at pH ca. 1–5. Many strains are facultatively CHEMOLITHOAUTOTROPHIC (q.v.), but some are obligately heterotrophic. Energy is obtained by the oxidation of sulphur (or Fe<sup>2+</sup>) and/or by SULPHUR RESPIRATION. CO<sub>2</sub> is assimilated via a reductive tricarboxylic acid pathway. Species include *S. acidocaldarius*, *S. ambivalens* and *S. solfataricus*. (See also REVERSE GYRASE and SULPHUR CYCLE.)

**sulfur-** See sulphur-.

**sulpha drugs** (1) *Syn.* SULPHONAMIDES. (2) The sulphonamides and the SULPHONES.

**sulphacetamide** See SULPHONAMIDES.

**sulphadiazine** 4-Amino-*N*-2-pyrimidinylbenzenesulphonamide: one of the more effective and less toxic of the antibacterial

SULPHONAMIDES; it is rapidly absorbed from the gut, and is effective against e.g. streptococci, *Neisseria* spp, *Escherichia coli*, etc. Sodium sulphadiazine may be given intravenously e.g. in the treatment of meningococcal meningitis; silver sulphadiazine (see SILVER) is used topically in the treatment of burns.

**sulphadimethoxine** See SULPHONAMIDES.

**sulphadimidine** See SULPHONAMIDES.

**sulphadoxine** A SULPHONAMIDE which has been used (e.g. in combination with pyrimethamine) for the treatment of clinically uncomplicated, chloroquine-resistant MALARIA. Sulphadoxine and pyrimethamine act synergistically to block (i) the synthesis of dihydrofolate (DHF) and (ii) the reduction of DHF to tetrahydrofolate (THF). Resistance to sulphadoxine may arise through the effects of mutation on the target enzyme [Eur. J. Bioch. (1994) 224 397–405].

**sulphaguandine** See SULPHONAMIDES.

**sulphamethazine** See SULPHONAMIDES.

**sulphamethizole** See SULPHONAMIDES.

**sulphamethoxazole** See SULPHONAMIDES.

**sulphamylon** *Syn.* MARFANIL.

**sulphanilamide** See SULPHONAMIDES.

**sulphate assimilation** See ASSIMILATORY SULPHATE REDUCTION.

**sulphate-reducing bacteria** A phrase traditionally used to refer to a (non-taxonomic) category of strictly anaerobic bacteria which are characterized by their ability to carry out DISSIMILATORY SULPHATE REDUCTION. The organisms include cocci, rods and filaments, most stain Gram-negatively, and the cells of one genus (DESULFOTOMACULUM) form endospores. They occur e.g. in soil; in anaerobic muds and sediments in freshwater, brackish and marine habitats; in the RUMEN, and in the intestinal tract in man and other animals; and in sewage. Some species tolerate or need salt (NaCl); the spore-forming sulphate-reducing bacteria tolerate a maximum of ca. 2% NaCl. In vitro culture requires the use of pre-reduced media in which the REDOX POTENTIAL is more negative than ca. –100 mV.

Substrates used as electron donors include e.g. lactate, propionate, pyruvate and certain alcohols; according to species these may be oxidized to acetate and CO<sub>2</sub> or (completely) to CO<sub>2</sub>. [Use of amino acids as energy substrates by marine strains of *Desulfovibrio*: FEMS Ecol. (1985) 31 11–15.] Electron acceptors include sulphate, sulphite (see also DESULFOVIRIDIN), thio-sulphate and tetrathionate; such oxidized compounds of sulphur may be derived from biological activity (see e.g. SULPHURETUM) or from the autoxidation of sulphide [FEMS Ecol. (1985) 31 39–45]. At least some strains can use nitrate and/or fumarate as electron acceptors instead of oxidized sulphur compounds.

Some strains can grow mixotrophically by oxidizing H<sub>2</sub> (see e.g. DESULFOVIBRIO), some can gain energy from pyrophosphate (see DESULFOTOMACULUM), and many can derive energy from pyruvate via the PHOSPHOROCLASTIC SPLIT. In the absence of an oxidized sulphur compound some species exhibit fermentative metabolism, although carbohydrates are rarely used. (See also FERMENTATION sense 1.)

The activities of the sulphate-reducing bacteria are responsible for much of the H<sub>2</sub>S produced in organically polluted waters. In rice paddies H<sub>2</sub>S can be beneficial (e.g. by killing parasitic nematodes) but high concentrations of H<sub>2</sub>S are phytotoxic and can damage crops (see also SUFFOCATION DISEASE); nitrate (which inhibits sulphate reduction) has been used to control this problem. Sulphide from these bacteria is often at least partly responsible for the corrosion of underground ferrous pipes (see also CATHODIC DEPOLARIZATION THEORY and TUBERCLE (sense 2)) and for the degeneration of concrete and stonework; metals

## sulphate reduction

can be affected by the sulphide itself, but damage to concrete and stone derives primarily from the action of sulphuric acid produced from the sulphide by e.g. thiobacilli.

[Microbial sulphate reduction in the early Archaean era: Nature (2001) 410 77–81.]

(See also DESULFOBACTER, DESULFOBULBUS, DESULFOCOCCUS, DESULFOTOMACULUM, DESULFOMONAS, DESULFONEMA, DESULFOSARCINA, DESULFOVIBRIO.)

[Book ref. 102.]

**sulphate reduction** The microbial reduction of sulphate may involve ASSIMILATORY SULPHATE REDUCTION or DISSIMILATORY SULPHATE REDUCTION. (See also SULPHUR CYCLE.)

**sulphate respiration** *Syn.* DISSIMILATORY SULPHATE REDUCTION.

**sulphathiazole** See SULPHONAMIDES.

**sulphide** See HYDROGEN SULPHIDE.

**sulphite fermentation** See NEUBERG'S FERMENTATIONS.

**sulphonamides** A group of chemotherapeutic agents. The antimicrobial sulphonamides are mostly derivatives of *sulphanilamide* (*p*-aminobenzenesulphonamide:  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\cdot\text{NH}_2$ ) (cf. MARFANIL); they are microbistatic for a wide range of Gram-positive and Gram-negative bacteria, and for various protozoa (e.g. coccidia, *Plasmodium* spp). Sulphonamides are used – usually in combination with other chemotherapeutic agents (see e.g. FOLIC ACID ANTAGONISTS) – for treating certain urinary tract infections, MALARIA (q.v.), coccidiosis, etc.

Sulphonamides act as structural analogues of *p*-aminobenzoic acid (PABA), competitively inhibiting the incorporation of PABA during the formation of dihydropteroic acid in FOLIC ACID synthesis. Those organisms which synthesize their own folic acid and which cannot use an exogenous supply of the vitamin are sensitive to sulphonamides (provided that the cells are permeable to the drugs), while organisms which require exogenous folic acid for growth are insensitive. A lag period of several generations occurs between exposure of sensitive cells to sulphonamide and growth inhibition; during this time the cells exhaust their pre-formed supply of endogenous folic acid. This delayed effect allows sulphonamides to be used in combination with antibiotics (e.g. penicillins) which are active only against growing organisms.

The inhibitory effect of sulphonamides may be neutralized by supplying the cells with those metabolites which normally require folic acid for their synthesis (e.g. purines, certain amino acids); such substances may be present e.g. in pus, so that sulphonamides may be ineffective in the treatment of certain suppurative infections. Bacteria readily develop resistance to sulphonamides: e.g., in *Streptococcus pneumoniae* modification of dihydropteroic acid synthetase by a single-step mutation may reduce the affinity of the enzyme for sulphonamides without significantly reducing its affinity for PABA. Plasmid-borne resistance also occurs, and can involve e.g. a plasmid-encoded sulphonamide-resistant dihydropteroic acid synthetase. (See also entries Tn21 and Tn2410.)

The many sulphonamides differ e.g. in their clinical properties, toxicities, etc. Most are derivatives bearing substituents at the nitrogen of the sulphonamide group ( $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\cdot\text{NHR}$ ). Substitution at the *p*-amino group results in the loss of antibacterial activity; however, such derivatives may be hydrolysed in vivo to an active derivative. For example, *p*-*N*-succinylsulphathiazole and phthalylsulphathiazole are inactive and are poorly absorbed from the gut, but they are hydrolysed in the lower intestine to release the active component sulphathiazole; these drugs have been used e.g. pre- and post-operatively in abdominal surgery.

Sulphonamides include e.g. *sulphacetamide* (*N*-[(4-amino-phenyl)sulphonyl]-acetamide); SULPHADIAZINE; *sulphadimethoxine* (4-amino-*N*-(2,6-dimethoxy-4-pyrimidinyl)benzenesulphonamide); *sulphadimidine* (= *sulphamethazine*: 4-amino-*N*-(4,6-dimethyl-2-pyrimidinyl)benzenesulphonamide); *sulphaguanidine* (4-amino-*N*-(aminoiminomethyl)benzenesulphonamide); *sulphamethizole* (4-amino-*N*-(5-methyl-1,3,4-thiadiazol-2-yl)benzenesulphonamide); *sulphamethoxazole* (4-amino-*N*-(5-methyl-3-isoxazolyl)benzenesulphonamide); *sulphathiazole* (4-amino-*N*-2-thiazolylbenzenesulphonamide); etc.

(See also PAS; PRONTOSIL; SULPHONES.)

**sulphonation** See WATER SUPPLIES.

**sulphones** Antibacterial agents (general formula:  $\text{R}_2\text{SO}_2$ ) active against a range of species; owing to toxicity they are not widely used in medicine. An example is DAPSONE.

**sulphorhodamine 101 acid chloride** See TEXAS RED.

**sulphorhodamine B** See LISSAMINE RHODAMINE.

**sulphur** (as an ANTIFUNGAL AGENT) Elemental sulphur is generally effective against certain plant diseases of fungal aetiology, e.g., apple scab, powdery mildews, black spot of roses; it may be applied as a fine dust, as a WETTABLE POWDER, or in colloidal form. The degree of fungitoxicity is related to the size of the sulphur particles, the smallest particles generally being the most toxic.

Sulphur may be applied as *polysulphide*: a product (formed by the reaction of certain metal sulphides with sulphur under alkaline conditions) which, when acidified e.g. by atmospheric  $\text{CO}_2$ , liberates elemental sulphur. An early preparation, *liver of sulphur* (potassium polysulphide), was made by the fusion of potassium hydroxide and sulphur. *Lime sulphur* is prepared by boiling sulphur with lime – the resulting solution containing calcium thiosulphate and calcium polysulphide; it tends to be phytotoxic and is incompatible with many chemical pesticides owing to its alkalinity. *Green sulphur* contains finely divided sulphur and certain iron compounds; it is formed as a by-product of a coal-gas purification process in which hydrogen sulphide reacts with ferric oxide.

Elemental sulphur can cause premature defoliation and dropping of fruit in certain varieties of fruit tree – a phenomenon called *sulphur shyness*.

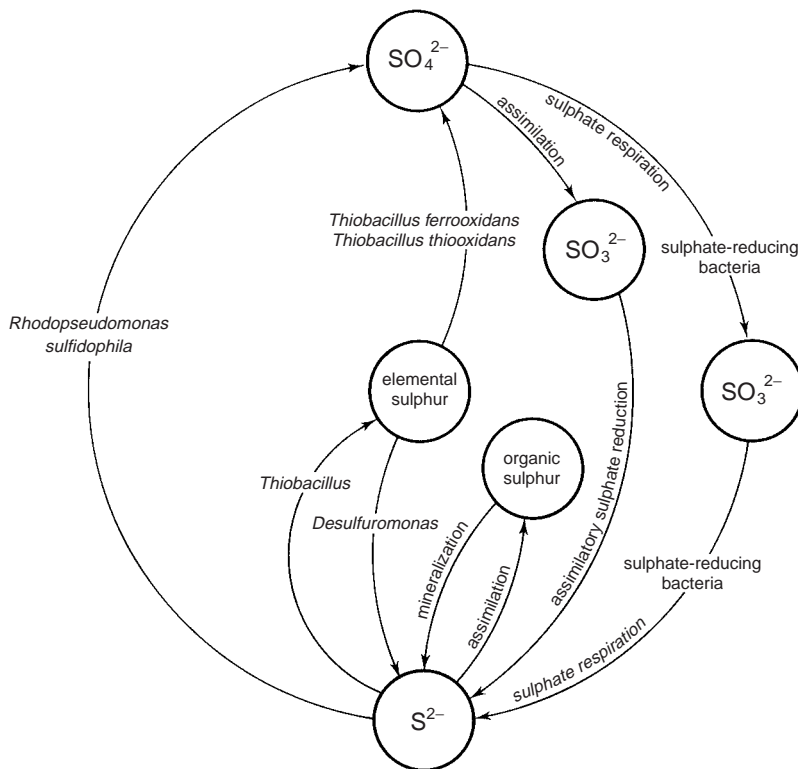

**sulphur bacteria** Those bacteria which contribute to stage(s) of the SULPHUR CYCLE other than assimilatory sulphate reduction and the decomposition of organic sulphur compounds to sulphide; they include the SULPHATE-REDUCING BACTERIA, certain photosynthetic bacteria, and species/strains of *Beggiatoa*, *Desulphuromonas*, *Oscillatoria* and *Thiobacillus*. (cf. COLOURLESS SULPHUR BACTERIA.) [Biochemistry and ecology of the sulphur bacteria: PTRSLB (1982) 298 429–602.]

(See also SULPHUR-DEPENDENT ARCHAEANS.)

**sulphur cycle** In nature: the cyclical interconversion of sulphur and its compounds. The figure shows some of the interconversions carried out by bacteria (see also SULPHUR-DEPENDENT ARCHAEANS).

In addition to biological interconversions, sulphide can be oxidized by *autoxidation* [see e.g. FEMS Ecol. (1985) 31 39–45] to e.g. elemental sulphur, thiosulphate and sulphate.

Sulphur is required e.g. for the synthesis of certain amino acids, ferredoxins and cofactors such as coenzyme A. Many bacteria assimilate sulphur in the form of sulphate – which is usually available in adequate quantities in the environment; the sulphate is initially reduced to sulphide (see ASSIMILATORY SULPHATE REDUCTION).

**SULPHUR CYCLE:** some interconversions carried out by bacteria. Many species can use sulphate as a source of sulphur (shown here as assimilatory sulphate reduction). The sulphate is reduced, intracellularly, to sulphide, and the sulphide is incorporated in different ways by different species; in e.g. *Escherichia coli*, sulphide is incorporated into *O*-acetylserine to form cysteine.

In a dissimilatory mode, sulphate respiration is carried out e.g. by the 'sulphate-reducing bacteria' – sulphate being used as terminal electron acceptor in anaerobic respiration. Elemental sulphur is used as terminal electron acceptor by *Desulfuromonas*. *Thiobacillus* spp carry out aerobic respiration in which e.g. sulphide or elemental sulphur is oxidized. *Rhodopseudomonas sulfidophila* is one of a number of species which use sulphide as an electron donor in anaerobic phototrophic metabolism.

Reproduced from *Bacteria* 5th edition, Figure 10.3, page 262, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

Elemental sulphur and sulphur compounds can also be used in a dissimilatory mode (see e.g. DISSIMILATORY SULPHATE REDUCTION and SULPHUR RESPIRATION).

A range of compounds, not shown in the figure, are associated with certain stages of the sulphur cycle. For example, thiosulphate and polythionates are thought to be important metabolites in the bacterial oxidation of pyrite (metal sulphides) [AEM (1996) 62 3424–3431]. [Metabolism of sulphonates and sulphate esters by Gram-negative bacteria: FEMS Reviews (2000) 24 135–175.]

[Antiquity of the biological sulphur cycle (evidence from sulphur and carbon isotopes in 2700-million-year-old rocks of the Belingwe Belt, Zimbabwe): Proc. RSLB (2001) 268 113–119.]

See: BEGGIATOIA; CHLOROBIACEAE; CHROMATIACEAE; HYDROGEN SULPHIDE; HYDROTHERMAL VENT; MINERALIZATION; OSCILLATORIA; RHODANESE; RHODOSPIRILLACEAE; SULFOLOBUS; SULPHATE-REDUCING BACTERIA; SULPHUR BACTERIA; SULPHUR-OXIDIZING

BACTERIA; SULPHUR-REDUCING BACTERIA; SULPHURETUM; THIOBACILLUS.

(See also CARBON CYCLE and NITROGEN CYCLE.)

**sulphur-dependent archaeans** Collectively, members of the order THERMOPROTEALES and of the genus SULFOLOBUS, many of which can obtain energy only by the metabolism of elemental sulphur (S<sup>0</sup>). (See also SULPHUR RESPIRATION.) [Review: Book ref. 157, pp. 85–170.]

**sulphur dioxide** (as antimicrobial agent) Sulphur dioxide (SO<sub>2</sub>) has antibacterial and antifungal properties which are believed to depend on its ability to reduce disulphide bonds in enzymes. It is used for FUMIGATION and as a food PRESERVATIVE in e.g. fruit juices and pulps, jams, beers and wines; it is also used as an antioxidant to prevent browning in e.g. fruit and vegetables. In WINE-MAKING, SO<sub>2</sub> inhibits the growth of contaminating yeasts and bacteria – the wine-making yeasts being relatively resistant; it also protects wine from excessive oxidation during storage, and combines with acetaldehyde (produced during fermentation) which has undesirable organoleptic properties.

## sulphur granules

Acid solutions of sulphites, bisulphites, and metabisulphites (e.g. sodium metabisulphite,  $\text{Na}_2\text{S}_2\text{O}_5$ ) – all of which release  $\text{SO}_2$  – are often used in place of gaseous  $\text{SO}_2$ . (See also FOOD PRESERVATION.)

**sulphur granules** See ACTINOMYCOSIS (1).

**sulphur mustards** Structural and functional analogues of the NITROGEN MUSTARDS – e.g. mustard gas:  $\text{Cl}(\text{CH}_2)_2\text{S}(\text{CH}_2)_2\text{Cl}$ .

**sulphur-oxidizing bacteria** Bacteria which can use elemental sulphur ( $\text{S}^0$ ) as an electron donor in lithotrophic metabolism – e.g. certain photosynthetic species and some species of THIOBACILLUS.

**sulphur polypore** *Laetiporus sulphureus*.

**sulphur-reducing bacteria** Bacteria which can use elemental sulphur ( $\text{S}^0$ ) as terminal electron acceptor in anaerobic respiratory metabolism – e.g. species of DESULFUROMONAS. (See also SULPHUR RESPIRATION.)

**sulphur respiration** Energy-yielding metabolism in which elemental sulphur ( $\text{S}^0$ ) is used anaerobically as terminal electron acceptor. Such metabolism is found in certain bacteria (see DESULFUROMONAS) and in some archaeans (e.g. many strains of SULFOLOBUS and species of the THERMOPROTEALES); in at least some species of *Thermoproteus*, cystine or malate can be used instead of sulphur.

**sulphur shyness** See SULPHUR.

**sulphur tuft** *Hypholoma fasciculare*.

**sulphuretum** A temporary, or more or less stable, region of e.g. a pond or a marine sediment containing a number of metabolically interrelated organisms which, collectively, metabolize sulphur and its compounds through cycles of oxidation and reduction. For example, a pond polluted by leaf litter would initially support a population of aerobic bacteria which, by their mineralizing activities (see MINERALIZATION), enrich the water with inorganic salts, and – by using oxygen – create an anaerobic environment in the lower layers of the pond. Sulphide, formed by SULPHATE-REDUCING BACTERIA, may then be oxidized in the upper (aerobic or microaerobic) water by e.g. species of *Beggiatoa* and *Thiobacillus*, and in the lower (anaerobic) water by e.g. photosynthetic bacteria such as *Chromatium*; sulphate (or other oxidized compounds of sulphur) released by these organisms may then be re-used by the sulphate-reducers. Eventually, through e.g. loss of  $\text{H}_2\text{S}$  to the atmosphere, sulphate supplies become exhausted and the cycling of sulphur ceases.

**sultamicillin** (VD-1827) An antibiotic formed by linking a molecule of penicillanic acid sulphone (sulbactam) to one of ampicillin by a hydrolysable ester bridge.

**Sulzberger–Chase phenomenon** General, systemic, immunological unresponsiveness to challenge by certain types of antigen as a consequence of the prior oral administration of those antigens; the phenomenon appears to be due, at least in part, to the enhancement of suppressor T cell activity. Despite systemic unresponsiveness, antigenic challenge may lead to enhanced antibody secretion at mucosal sites.

**summer mastitis** See MASTITIS.

**summer spore** (*mycol.*) A type of spore (e.g. a CONIDIUM), typically produced in large numbers in the season of rapid growth, which can germinate soon after its formation. (cf. RESTING SPORE.)

**summer truffles** See TRUFFLES.

**sun animalcules** See HELIOZOEAE.

**sunY gene** See SPLIT GENE (e).

**sup genes** See SUPPRESSOR MUTATION.

**superantigen** (SAg) A protein which can bind *simultaneously* to (i) the T cell receptor (TCR) of a T lymphocyte (T cell)

that expresses a particular  $V\beta$  chain (see T CELL RECEPTOR), and (ii) an MHC class II molecule on an antigen-presenting cell (e.g. a macrophage or B cell); such binding, in which the superantigen acts as a cross-link between the  $V\beta$  chain and the class II molecule, causes (i) T cell proliferation, and (ii) release of cytokines from the T cell and from the antigen-presenting cell. Because many different strains of T cell express a given  $V\beta$  chain, a superantigen causes *polyclonal* activation of T cells (as though the corresponding range of antigens had been present); this is accompanied by a massive release of cytokines. During the joint stimulation of a T cell and a macrophage, the cytokines released include IL-1, IL-2, IL-4, IL-6, IL-8, TNF- $\alpha$ , TNF- $\beta$  and IFN- $\gamma$ .

Superantigens are able to activate both  $\text{CD4}^+$  and  $\text{CD8}^+$  cells, binding to the  $V\beta$  chain at a site outside the normal antigen-binding region. Activation and proliferation of T cells naturally gives rise to an initial increase in the number of T cells of the given  $V\beta$  subset; however, there is evidence to suggest that many of the T cells which bind superantigen either become unresponsive (= *T cell anergy*) or undergo apoptosis. Thus, while the T cell population of a given subset may initially rise, there may be a net loss of functional cells of that subset in the longer term.

Superantigens include the five major ENTEROTOXINS of *Staphylococcus aureus* (SEA, SEB, SEC, SED and SEE), the toxic shock syndrome toxin 1 (TSST-1; formerly enterotoxin F) of *S. aureus*, and the exotoxin A of *Streptococcus pyogenes* (= streptococcal superantigen A; SSA). Different superantigens bind preferentially to different  $V\beta$  chains; for example, TSST-1 binds to  $V\beta$  type 2, SED binds to  $V\beta$  5 and 12, and SEA binds to  $V\beta$  types 1, 5, 6, 7 and 9.

Superantigens are apparently associated with some viruses, e.g. rabies virus.

The ability of a superantigen to induce massive release of cytokines is apparently involved in the pathogenesis of TOXIC SHOCK SYNDROME. It has been suggested that this mechanism may also be responsible for at least some of the symptoms of certain other diseases (such as KAWASAKI DISEASE).

'B cell superantigens' are analogous molecules; they bind to the  $V_H$  chain of the B cell receptor.

[Clinical significance of T cell superantigens: TIM (1998) 6 61–65.]

**superchlorination** See WATER SUPPLIES.

**supercoiled DNA** See DNA.

**supercoiling-induced duplex destabilization** See SIDD.

**superelongation disease** (of cassava) See GIBBERELLLINS.

**superhelical DNA** See DNA.

**superhelix density** ( $\sigma$ ) See DNA.

**superhelix winding number** ( $\tau$ ) See DNA.

**superinfection exclusion** See SUPERINFECTION IMMUNITY.

**superinfection immunity** A phenomenon in which a virus-infected cell can resist infection by a second virus of the same or a similar type. The second virus may be prevented from adsorbing to or penetrating the cell (*superinfection exclusion*), or it may enter the cell but be unable to replicate. For example, if a bacterial cell contains a  $\lambda$  prophage (see LYSOGENY), any incoming  $\lambda$  genome will immediately be subject to repression by the repressor encoded by the incumbent prophage. When phage P22 establishes a lysogenic infection in *Salmonella typhimurium*, it causes glycosylation of the LPS of the host cell, resulting in modification of the P22 receptor sites and preventing further infection by P22. These are examples of *lysogenic* (or *prophage*) immunity; superinfection immunity may also be exhibited by lytic phages such as T4. (See also e.g. RETROVIRIDAE.)

Phages which belong to the same 'immunity group' (i.e., one cannot infect a cell already infected by any of the others in the group) are said to be *homoimmune*; phages of different immunity groups are said to be *heteroimmune*. (See e.g. LAMBDROID PHAGES.)

(The term superinfection immunity has also been applied to some cases of INCOMPATIBILITY in plasmids.)

**superoxide** (superoxide radical) A term used to refer either to  $O_2^-$  (superoxide anion, also written  $\cdot O_2^-$  or  $O_2^-$  etc) or to the more highly oxidizing species  $HO_2\cdot$ ; these two species are interconvertible,  $O_2^-$  being the conjugate base of the weak acid  $HO_2\cdot$  ( $pK_a$  4.8). The conversion of  $O_2^-$  to  $HO_2\cdot$  is encouraged e.g. by low pH, and is influenced by the dielectric constant of the microenvironment.

$O_2^-$  is generated, under aerobic conditions, in both prokaryotic and eukaryotic cells e.g. during autoxidation of reduced cytochrome *c* (or ferredoxins) and during oxidations catalysed by e.g. aldehyde oxidase, dihydroorotate dehydrogenase, or xanthine oxidase (see also PYOCYANIN); it is also formed during the 'respiratory burst' in activated NEUTROPHILS. The generation of  $O_2^-$  can also occur extracellularly; thus, e.g., suspensions of *Escherichia coli* can take up and reduce paraquat, the reduced paraquat (which is released into the medium) undergoing autoxidation and giving rise to  $O_2^-$  [JBC (1979) 254 10846–10852].

$O_2^-$  does not act indiscriminately on cell constituents; however, it inactivates CATALASE and it reacts with the NADH–lactate dehydrogenase complex and e.g. with catechols and oxyhaemoglobin. The protonated form,  $HO_2\cdot$ , is significantly more reactive. In aerobic organisms, and in most aerotolerant anaerobes, the potentially harmful effects of endogenously formed  $O_2^-$  are prevented by the action of intracellular SUPEROXIDE DISMUTASE. [Superoxide as an endogenous toxicant: ARPT (1983) 23 239–257.] Superoxide and other reduced oxygen species, e.g. HYDROXYL RADICAL, are produced e.g. during PHAGOCYTOSIS and are generally believed to function as antimicrobial agents. (See also SINGLET OXYGEN.)

[Oxygen toxicity and oxygen radicals (review): Bioch. J. (1984) 219 1–14.]

**superoxide anion** See SUPEROXIDE.

**superoxide dismutase** (SOD; superoxide oxidoreductase; EC 1.15.1.1) Any of a range of metalloenzymes which catalyse the dismutation of SUPEROXIDE (e.g.  $HO_2\cdot + O_2^- + H^+ \rightarrow H_2O_2 + O_2$ ); SODs occur widely in both prokaryotic and eukaryotic cells and are believed to have as their main or sole function the protection of aerobic or aerotolerant organisms from the toxic effects of superoxide. (SODs occur in some anaerobic organisms, e.g., *Bacteroides melaninogenicus*.)

The SODs of prokaryotes characteristically contain iron or manganese (in e.g. *Propionibacterium shermanii* Fe and Mn appear to be interchangeable [JBC (1982) 257 13977–13980]) and are typically insensitive to cyanide, while those of eukaryotes characteristically contain copper and zinc and are typically sensitive to cyanide; however, a bacterial CuZnSOD (*bacteriocuprein*) occurs e.g. in *Caulobacter crescentus* [JBC (1982) 257 10283–10293], in both *Pseudomonas diminuta* and '*P. maltophilia*' [JB (1985) 162 1255–1260], and (possibly as a result of gene transfer from its eukaryotic host) in *Photobacterium leiognathi* [PNAS (1985) 82 149–152], while MnSODs occur e.g. in the cytosol of human liver cells and in the mitochondrial matrix.

SODs have been reported to be inducible (in both prokaryotes and eukaryotes) e.g. by increases in intracellular superoxide anion or by increases in the partial pressure of oxygen; however, in *Escherichia coli* – which synthesizes a constitutive,

periplasmic (*sodB*-encoded) FeSOD and an inducible, cytoplasmic (*sodA*-encoded) MnSOD – the intracellular concentration of superoxide anion appears not to regulate the oxygen-dependent synthesis of the MnSOD [PNAS (1984) 81 4970–4973].

In *Lactobacillus plantarum* (in which SODs are absent) the dismutation of  $O_2^-$  is carried out by manganese – a metal accumulated to an intracellular concentration of ca. 25 mM; the low efficiency of manganese as a 'dismutase' appears to be offset by its high intracellular concentration. (*L. plantarum* becomes oxygen-sensitive in manganese-deficient media.) Certain other organisms (e.g. *Mycoplasma pneumoniae* [BBRC (1980) 96 98–105]) lack SODs but their functional equivalent(s) (if any) are unknown.

[Varieties, distribution, physiological functions of SODs: ARPT (1983) 23 239–257 (pp. 244–249); SOD, an evolutionary puzzle: PNAS (1985) 82 824–828; SOD mutants of *Escherichia coli*: EMBO (1986) 5 623–630.]

**superoxide radical** *Syn.* SUPEROXIDE.

**superoxol test** A form of CATALASE TEST in which 20% or 30%  $H_2O_2$  is used in place of the more usual 3%. It may be used e.g. in the presumptive identification of *Neisseria gonorrhoeae* [BJVD (1984) 60 87–89].

**super-repressor** See e.g. LAC OPERON.

**supertwisted DNA** Supercoiled DNA.

**supervital staining** See VITAL STAINING.

**support film** See ELECTRON MICROSCOPY (a).

**suppressive petite** See PETITE MUTANT.

**suppressive soils** Soils which suppress the survival, growth, and/or pathogenic activity of particular plant-pathogenic fungi. In at least some cases suppression is due to the presence of an antagonistic microflora: e.g., mycophagous amoebae may be involved in the suppression of TAKE-ALL [SBB (1984) 16 197–199].

**suppressor mutation** (suppressor) A MUTATION which alleviates the effects of a previous (*primary*) mutation at a different locus ('second-site reversion'); commonly, the wild-type phenotype is only partially restored, resulting in a *pseudo-wild* phenotype. (cf. BACK MUTATION.)

In *intragenic suppression*, both primary and suppressor mutations occur in the same gene. For example: (a) A (*primary*) MIS-SENSE MUTATION – which results in an inactive gene product – can be countered by a second (suppressor) mutation elsewhere in the same gene which allows the gene product to adopt a conformation capable of at least some activity. (b) A primary FRAMESHIFT MUTATION may be suppressed by a second nucleotide deletion/insertion which restores the correct reading frame; the nucleotide sequence between the two mutations will still be read out of phase.

In *intergenic suppression* the suppressor mutation occurs in a gene (designated *sup*) other than that containing the primary mutation. A *direct* intergenic suppressor (*informational suppressor*) usually affects a tRNA molecule and results in e.g. the insertion of an amino acid at the site of a nonsense mutation (*nonsense suppressor*) or a different amino acid at the site of a mis-sense mutation (*mis-sense suppressor*). The activity of the resulting gene product will depend on the suitability of the amino acid inserted. Various types of direct intergenic suppressor are known. For example: (a) A mutation in a tRNA gene may alter the anticodon of the tRNA such that it recognizes a codon containing a nonsense mutation or a mis-sense mutation. Thus, e.g., an *ochre suppressor* in a gene for tRNA<sup>Gln</sup> may alter the anticodon from NUG to NUA (N = nucleotide), allowing the tRNA to recognize the

## suppressor-sensitive mutation

ochre codon UAA instead of a glutamine codon; thus glutamine is inserted at the site of an ochre mutation, and premature polypeptide chain termination is avoided. (Owing to 'wobble pairing' – see WOBBLE HYPOTHESIS – an ochre suppressor can also suppress an amber mutation, albeit more weakly; however, amber suppressors can suppress only amber mutations.) (b) A mutation in a tRNA gene may alter the nucleotide sequence of the tRNA at a site other than the anticodon; the resulting change in tRNA structure may either interfere with the accuracy of codon recognition (e.g., a nucleotide change in the D arm of tRNA<sup>Trp</sup> allows it to recognize UGA (opal) and UGU (Cys) as well as the correct codon UGG), or may cause the tRNA to be recognized by the wrong aminoacyl-tRNA synthetase and hence to be charged with the wrong amino acid. (c) Intergenic suppressors of *frameshift mutations* may involve e.g. the insertion of an extra nucleotide in the anticodon of a tRNA such that it reads a quadruplet instead of a triplet codon, restoring the correct reading frame in the case of a +1 frameshift. Alternatively, the structure of a tRNA may be altered so that it interferes with the reading of an adjacent codon by another tRNA when both tRNAs are occupying the A and P sites of the ribosome. In either case the sequence between the primary mutation and the site of action of the mutant tRNA will still be read out of phase.

In general, an intergenic suppressor can function only if it occurs in a gene present in more than one copy per cell, or in a gene encoding one of a family of tRNAs which recognize the same codon(s) (i.e. enough normal tRNA must be present for normal translation to occur). Intergenic suppressors operate with varying degrees of efficiency, depending not only on the nature of the suppressor (e.g. amber suppressors are generally much more efficient than ochre suppressors) but also e.g. on the context in which the primary mutation occurs. This may, in part, explain why e.g. a nonsense suppressor does not necessarily seriously impair normal polypeptide chain termination, since natural termination codons may occur in a distinct context which allows them to operate even in the presence of nonsense suppressors. (cf. READTHROUGH.) [Precision in protein synthesis: Book ref. 60, pp. 23–63.]

*Indirect suppression* involves the bypass of the effects of a primary mutation: e.g., the product of the gene containing the suppressor mutation may activate an alternative metabolic pathway which may bypass that blocked by the primary mutation.

(cf. PHENOTYPIC SUPPRESSION.)

**suppressor-sensitive mutation** As commonly used: an amber mutation, i.e., a mutation which can be suppressed by an intergenic amber SUPPRESSOR MUTATION.

**suppuration** The formation and/or discharge of PUS.

**Suprasyllaria** A category ('section') of LEISHMANIA species which multiply in the midgut of the arthropod vector and then migrate to the pharynx, cibarium and proboscis; it includes e.g. *L. aethiopica*, *L. donovani*, *L. major*, *L. mexicana* and *L. tropica*. (cf. HYPOPYLARIA, PERIPYLARIA.)

**supravital staining** See VITAL STAINING.

**suramin** A drug, 8-(3-benzamino-4-methyl-benzamino)naphthalene-1,3,5-trisulphonic acid, used e.g. for the treatment and prophylaxis of TRYPANOSOMIASIS; it cannot pass the blood-brain barrier and is thus not effective in the later stages of the disease.

In the alternative pathway of COMPLEMENT FIXATION, suramin blocks the inactivation of C3b by Factors H and I; it apparently acts on the C3b molecule, making it resistant to cleavage by Factors H and I.

Suramin inhibits the reverse transcriptase of a number of animal retroviruses, including the AIDS virus [review: Antiviral

Res. (1987) 7 1–10]; however, its potential in the treatment of AIDS is probably limited [see e.g. AIM (1986) 105 32–37].

**surface electrophoresis** See ELECTROPHORESIS.

**surface exclusion** (entry exclusion) The phenomenon in which the presence of a conjugative plasmid in a cell reduces the ability of that cell to receive an identical or related plasmid, by CONJUGATION (sense 1b), from another cell. (cf. SUPERINFECTION IMMUNITY.) In the *Escherichia coli*/F PLASMID conjugal system, surface exclusion involves the products of genes *traS* (a cytoplasmic membrane protein) and *traT* (an OUTER MEMBRANE protein); the *traT* product appears to inhibit stable contact between donor cells. The effect of surface exclusion may be lost if e.g. donor cells progress to the stationary phase of growth or are starved of amino acids; such cells, which can act as recipients, are called *F<sup>-</sup> phenocopies*. (Cells which express the *traT* gene are, incidentally, less susceptible to PHAGOCYTOSIS and to SERUM KILLING; resistance to serum killing apparently derives from the ability of the TraT protein to inhibit the assembly or action of the *membrane attack complex* (see COMPLEMENT FIXATION) [JGM (1985) 131 1511–1521].)

An analogous effect appears to occur in cells of *Enterococcus faecalis* carrying the conjugative plasmid pCF-10; when these donor cells are exposed to recipient PHEROMONES they form a cell-surface protein which inhibits their ability to act as recipients for a derivative of pCF-10 [PNAS (1985) 82 8582–8586].

**surface-obligatory conjugation system** See PILI.

**surface plasmon resonance** See BIACORE.

**surface-preferred conjugation system** See PILI.

**surfactin** ('subtilysin') A highly effective lipopeptide BIOSURFACTANT produced by *Bacillus subtilis*; it consists of a cyclic heptapeptide covalently linked to a hydroxy fatty acid. Surfactin is haemolytic and can also lyse the protoplasts of certain bacteria; it is not immunogenic.

**Surirella** See DIATOMS.

**surra** A disease of e.g. camels and horses which occurs in Africa (including Madagascar and Mauritius), Asia (e.g. India) and South America (cf. MAL DE CADERAS); it is caused by *Trypanosoma evansi* and is transmitted non-cyclically by biting flies (e.g. *Stomoxys*, *Tabanus*) or, in South America, by blood-sucking vampire bats (*Desmodus*). (Various animals, e.g. buffaloes, cattle, deer, sheep, may act as reservoirs of infection.) Symptoms include weakness, recurrent fever, and wasting; the disease is often fatal. *Lab. diagnosis*: e.g. indirect fluorescent antibody and haemagglutination tests. *Treatment*. In horses, the disease has been treated with e.g. arsenicals (e.g. tryparsamide), while prophylaxis has been achieved e.g. with quinapyramine-SURAMIN complexes.

**surrogate light chains** See B LYMPHOCYTE.

**sus mutant** A suppressor-sensitive (amber) mutant.

**suspension test** A test, used to determine the efficacy of a DISINFECTANT, in which the disinfectant is allowed to act for a specified time(s) on organisms suspended in a liquid medium and/or diluent. (cf. CARRIER TEST.) In a *qualitative* suspension test (e.g. the RIDEAL-WALKER TEST) the effect of the disinfectant is determined by subculturing the test suspension to a liquid growth medium to detect the presence of viable organisms; in *quantitative* suspension tests (e.g., the FIVE-FIVE-FIVE TEST) the effect of the disinfectant is determined by counting the viable organisms remaining in the test suspension.

**suspensor** (*mycol.*) A clavate or conical structure formed by a PROGAMETANGIUM. In some species (e.g. *Phycomyces blakesleeanus*) the suspensor gives rise to short filaments or spines.

**surface** (1) A line which marks the junction of two parts or structures. (2) (*ciliate protozool.*) See SYSTÈME SÉCANT.

**suzukacillin** See ALAMETHICIN.

**SV40** SIMIAN VIRUS 40.

**SVD** SWINE VESICULAR DISEASE.

**Svedberg unit (S)** The unit in which the *sedimentation coefficient* of a particle (e.g. a macromolecule) is commonly quoted. The sedimentation coefficient (= sedimentation constant), *s*, is given by:

$$s = \frac{dx}{dt} \cdot \frac{1}{\omega^2 r}$$

in which  $dx/dt$  is the measured sedimentation rate (in the ultracentrifuge),  $\omega$  is the angular velocity (radians  $\text{sec}^{-1}$ ), and  $r$  is the distance (cm) between a point within the sample and the axis of rotation; when values are substituted in the above expression,  $s$  is obtained in terms of reciprocal seconds. The unit is the Svedberg unit ( $10^{-13}$  sec).

**swab (microbiol.)** A device used for sampling the microflora at a given site. Swabs suitable for laboratory or clinical use typically consist of a compact piece of COTTON WOOL securely attached to one end of a thin wooden stick or a piece of wire; a *sterile* swab may be used for transferring material e.g. from the throat to a bacteriological culture medium. (See also SPREAD PLATE.) (Calcium ALGINATE wool may be used instead of cotton wool; it dissolves in e.g. aqueous sodium citrate, or in 1% sodium hexametaphosphate in quarter-strength Ringer's solution – thus releasing all organisms trapped in its fibres.) (See also MOORE SWAB.)

**swamp cancer** *Syn.* EQUINE PHYCOMYCOSIS.

**swamp fever** (equine infectious anaemia) An infectious HORSE DISEASE caused by a retrovirus (generally considered to be a member of the LENTIVIRINAE). Swamp fever occurs e.g. in Europe, Canada and the USA. It is transmitted by biting flies and mosquitoes. Incubation period: 2–4 weeks. The initial stage of the disease is typically acute, with e.g. anaemia, depression, incoordination, intermittent fever, myocarditis and splenomegaly. Animals may recover temporarily (only to relapse after 2–3 weeks with similar but usually less severe signs), or they may become progressively weaker and die after ca. 10–14 days. In survivors, relapses – which apparently result from ANTIGENIC VARIATION in virion surface glycoprotein – may continue to occur, and the animals probably remain carriers for life; viraemia occurs even during remissions. The virus replicates in and destroys host macrophages, and many of the symptoms may result from the deposition of immune complexes. *Lab. diagnosis:* e.g. an agar gel immunodiffusion test for serum precipitins. *Control:* e.g. slaughter of infected animals. [Book ref. 33, pp. 713–717.]

**swan animalcule** The ciliate *Lacrymaria olor*.

**swan-neck flask** Apparatus used by Pasteur to refute the doctrine of ABIOGENESIS. Each spherical glass flask had a long narrow neck which was bent downwards then upwards, thus inhibiting the access of airborne microorganisms to the sterilized contents of the flask.

**swarm** (1) (*verb*) To exhibit SWARMING (sense 1 or 2). (2) (*bacteriol.*) A motile colony formed e.g. by gliding bacteria. (3) A PSEUDOPLASMODIUM (sense 3).

**swarm cell** (1) *Syn.* SWARMER. (2) See e.g. SWARMING.

**swarm period** See e.g. DIPLANETISM.

**swarm spores** Motile spores.

**swarmer** (swarm cell) An actively motile cell which has developed from a non-motile precursor – see e.g. CAULOBACTER, RHODOMICROBIUM.

**swarming** (1) A phenomenon, involving morphological and functional differentiation, exhibited when certain species of

bacteria (for example, *Proteus mirabilis* and *P. vulgaris*) are cultured on suitable solid media (e.g. media containing a concentration of AGAR lower than that found in normal growth media). In the case of *Proteus* spp, the first-formed progeny cells at the point of inoculation are short, sparsely flagellated bacilli ca. 2–4  $\mu\text{m}$  in length, and these cells form a colony in the usual way. After several hours of growth, some of the cells at the edge of the colony grow to lengths of 20–80  $\mu\text{m}$  and develop numerous flagella; these cells are called *swarm cells*. Swarm cells migrate outwards to positions a short distance from the edge of the colony; migration then stops, and each swarm cell divides into several short bacilli of the type present in the original colony. The short bacilli grow and divide normally for several generations, forming a ring of growth which surrounds, and is concentric with, the original colony. Subsequently, another generation of swarm cells is produced and the cycle is repeated. (See also DIENES PHENOMENON.)

Swarming can be prevented e.g. by culturing on stiff AGAR, on certain inhibitory media (such as MacConkey's agar) or on CLED MEDIUM. (See also PRIL.)

Swarming also occurs in other (Gram-negative and Gram-positive) bacteria, including e.g. *Escherichia coli* and *Serratia marcescens*. Unlike *P. mirabilis*, which forms concentric rings of growth due to discrete periods of swarming, some bacteria swarm continuously, forming a thin layer of growth, while others give rise to individual microcolonies.

Interestingly, although swarming in *E. coli* involves components of the CHEMOTAXIS system, the substances/signals that provoke swarming differ from the known chemoeffectors that mediate chemotaxis [PNAS (1998) 95 2568–2573].

[Swarming (review): Mol. Microbiol. (1994) 13 389–394.]

(2) In general, the process in which motile organisms actively spread on the surface of a suitably moist solid medium.

**sweet clover necrotic mosaic virus** See DIANTHOVIRUSES.

**sweet curdling** See MILK SPOILAGE.

**sweet potato mild mottle virus** See POTYVIRUSES.

**swell** (blower; blown can) A can (see CANNING) whose ends are distended by internal pressure due to gas production by microbial or chemical activity within the can; in a *hard swell* the ends of the can cannot be moved by thumb pressure, while in a *soft swell* the ends are movable by thumb pressure but they cannot be pressed back into their normal positions. A can becomes a FLIPPER and then a SPRINGER before becoming a swell. Organisms which can cause swells include e.g. *Bacillus polymyxa*, *Clostridium thermosaccharolyticum*, and certain non-sporing species (e.g. *Staphylococcus* and *Streptococcus* spp). (cf. HYDROGEN SWELL; PANELLING.)

**swelled head** In sheep, MALIGNANT OEDEMA which is often confined to the head region and which may follow fighting among rams.

**swimmers' itch** See LYNGBYA.

**swine diseases** See PIG DISEASES.

**swine dysentery** Infectious mucohaemorrhagic colitis involving invasion of the colonic epithelium by *Treponema hyodysenteriae* (which may require the presence, in the gut, of other bacteria – e.g. *Fusobacterium necrophorum*, *Bacteroides vulgatus*); the disease occurs world-wide. Infection occurs orally. Onset is generally insidious, with reduction in appetite, followed e.g. by fever, (typically) grey to black diarrhoea, oedema and haemorrhage. Death may occur (within days) from dehydration and toxemia or from shock. A carrier state occurs. (See also DYSENTERY.)

**swine erysipelas** (diamond skin disease) An acute or chronic PIG DISEASE caused by *Erysipelothrix rhusiopathiae*. Infection

## swine fever

occurs via the mouth or wounds; it may lead to sudden death, or symptoms may include e.g. fever, prostration, abortion, and (pathognomonic) diamond-shaped skin lesions. Affected animals may die, may recover (but remain carriers), or may develop chronic disease with e.g. progressive unthriftiness, arthritis, and valvular lesions in the heart. *Treatment*: e.g. penicillins. *Prophylaxis*: e.g. vaccination.

*E. rhusiopathiae* can also cause 'erysipelas' in poultry (particularly turkeys); the disease is commonly fatal. Birds may be protected by vaccination.

**swine fever** (European swine fever; hog cholera) A highly infectious, mild or severe PIG DISEASE caused by a virus of the genus *Pestivirus* (see TOGAVIDAE). Infection occurs via the mouth or nose; the incubation period is usually ca. 5–10 days. In the acute disease there is fever, lethargy, conjunctivitis with discharge, and constipation followed by diarrhoea; reddish patches appear on the skin, and there are signs of CNS involvement (convulsions, circling, incoordination, ataxia). Haemorrhagic lesions of internal organs are found post mortem. Mortality rates may be high. In the chronic disease (low-virulence virus) there may be transient fever with few other clinical signs; 'button ulcers' (1–2 cm diam.) may be found (mainly) in the large intestine post mortem. The virus may cross the placenta and infect fetuses, causing abortion or congenital tremor. (cf. AFRICAN SWINE FEVER.)

**swine infertility and reproductive syndrome virus** See BLUE-EARED PIG DISEASE.

**swine influenza** A PIG DISEASE, affecting the respiratory tract, apparently caused jointly by an influenza A virus (see INFLUENZA-VIRUS) and *Haemophilus parasuis* [Book ref. 33, pp. 790–791]. Symptoms: coughing, dyspnoea and prostration. Recovery is usually rapid, but may be complicated by secondary infection with e.g. *Pasteurella multocida*. Virus commonly persists in carrier pigs and can be carried e.g. by the lungworm *Metastrongylus apri*.

**swine pox** A (usually benign) PIG DISEASE caused by a *Suipoxvirus*; typical vesicular pox lesions develop mainly on the abdomen. Mortality rates may be high in suckling piglets. The virus is commonly transmitted by the pig louse (*Hematopinus suis*).

**swine vesicular disease (SVD)** An infectious PIG DISEASE clinically indistinguishable from FOOT AND MOUTH DISEASE (although cattle and sheep are not affected); it occurs e.g. in Europe and Japan. SVD is caused by a porcine ENTEROVIRUS. Infection occurs mainly via the tonsils, but also via the gut, wounds, abrasions etc. Incubation period: 2–7 days; the mortality rate is usually low. Transmission is mainly by pig–pig contact; a carrier state is unknown. The virus can survive for months e.g. in moist pig faeces; it is stable between pH 2.5 and 12, but can be inactivated by moist heat (60°C/30 min).

**swineherds' disease** LEPTOSPIROSIS caused by *L. interrogans* serotype *pomona*.

**swinepox subgroup** See SUIPOXVIRUS.

**Swiss cheeses** See CHEESE-MAKING.

**swivelase** A type I TOPOISOMERASE.

**SXT** A combination of sulphamethoxazole and trimethoprim; SXT-impregnated discs are used in an identification test for streptococci –  $\beta$ -haemolytic streptococci of Lancefield groups A and B usually being resistant to SXT.

**SYBR® Green I** See PCR.

**Syc** Specific Yop chaperone: see VIRULON.

**Sydenham's chorea** See RHEUMATIC FEVER.

**Sym plasmid** See ROOT NODULES.

**Symba process** See SINGLE-CELL PROTEIN.

**Symbiodinium** See ZOOXANTHELLAE.

**symbiogenesis** The (presumed) evolutionary development of chloroplasts and mitochondria from endosymbiotic microorganisms.

**symbiont** One of the participants in a symbiotic relationship (SYMBIOSIS sense 1).

**symbiosis** (1) A term used originally for any stable condition in which two different organisms (*symbionts*) live in more or less close physical association – regardless of the nature of the relationship. Subsequently, the term came to be used, in a more restricted sense, to refer only to those instances in which both organisms derive benefit from the association; however, there is currently a strong tendency to revert to the original meaning – which is considered here as sense 1.

For a given symbiont, the symbiotic mode of life may be optional or obligatory. The nature of the relationship between symbionts ranges from mutually beneficial (MUTUALISM) to antagonistic (PARASITISM). (See also COMMENSALISM and NEUTRALISM.)

The continued association of symbionts, from generation to generation, may be achieved in various ways. Thus, e.g., in many alga–protozoan relationships the symbionts divide synchronously, or near-synchronously, and in many LICHENS dispersal involves the formation of propagules (e.g. soredia) containing both symbionts.

For examples of (primarily mutualistic) symbioses see FUNGUS GARDENS, MYCETOCYTE, MYCORRHIZA, ROOT NODULES, RUMEN, TERMITE–MICROBE ASSOCIATIONS, WOODWASP FUNGI, ZOOCHLORELLAE and ZOOXANTHELLAE. (See also CYTOBIOSIS, ECTOSYMBIONT, ENDONUCLEOBIOSIS and ENDOSYMBIONT.)

(2) A stable condition in which two different organisms form a close association to their mutual benefit, i.e., MUTUALISM. This meaning is tending to be superseded by that given in sense 1, above.

**sym-homospermidine** See POLYAMINES.

**symmetrogenic** Refers to the type of cell division typical of flagellates: longitudinal fission, the two daughter cells being mirror images of one another. (cf. HOMOTHETOGENIC.)

**sym-norspermine** See POLYAMINES.

**sympatric** Existing in the same environment or geographical region (cf. ALLOPATRIC).

**symphogenous development** (*mycol.*) The development of certain fungal structures (e.g. pycnidia) by the convergence, interweaving, growth and differentiation of hyphal branches from a number of different hyphae. (cf. MERISTOGENOUS DEVELOPMENT.)

**symp plasma** (*pl. symplasmata*) In certain bacteria (e.g. *Enterobacter agglomerans/Erwinia herbicola*): a rounded or elongated aggregate of cells which may be surrounded by a translucent sheath.

**symplectic metachrony** See METACHRONAL WAVES.

**sympodial** (*adj.*) (1) Refers to the form or mode of development of a branching structure whose long axis consists of a number of sections – each being a branch of the preceding section. (cf. MONOPODIAL.)

(2) Refers to entities which are formed or united on a common structure or base.

**Sympodiomyces** A genus of marine (possibly ascomycetous) yeasts in which an elongated conidiophore may develop from each vegetative yeast cell; one species: *S. parvus*. [Book ref. 100, pp. 930–932.]

**symport** (co-transport) The coupled (linked) transmembrane transport of two solutes (e.g. ions) in the same direction. Symport may be electrogenic (see e.g. END-PRODUCT EFFLUX) or

non-electrogenic – as e.g. when an anion is transported in symport with a cation. (cf. ANTIPORT, UNIORT; see also ION TRANSPORT.)

**synanamorph** (*mycol.*) One of two or more ANAMORPHS of a given TELEOMORPH.

**synapsis** The pairing of homologous chromosomes during MEIOSIS, or the juxtaposition of homologous regions of DNA prior to general RECOMBINATION e.g. in prokaryotes, or the juxtaposition of appropriate sequences prior to SITE-SPECIFIC RECOMBINATION.

**synaptobrevin** See TETANOSPASMIN.

**synaptonemal complex** A structure, visible by electron microscopy, which lies between homologous chromosomes in the early stages of MEIOSIS; it consists of three parallel electron-dense strands (a 'central element' sandwiched between two 'lateral elements') – the whole being aligned with the long axis of the homologous pair of chromosomes, and interposed between them. One or more rounded or elongated structures (*recombination nodules*) may be embedded within, or may bridge, the synaptonemal complex; these nodules may be involved e.g. in the initiation of recombination since their number and distribution appear to coincide with those of the chiasmata.

**syncaryon** *Syn.* SYNKARYON.

**Syncephalastraceae** See MUCORALES.

**Syncephalastrum** See MUCORALES.

**synchronous culture** A form of CULTURE (sense 2) in which all the cells pass through the same stage of the CELL CYCLE at the same time. Synchronous culture is used e.g. to study particular biochemical events at specific stage(s) of the cell cycle.

Synchrony may be achieved in various ways. For example, synchronous cultures of certain algae can be obtained by the use of controlled cycles of light and dark. Synchrony in bacterial cultures may be achieved by subjecting the cells, for a given period of time, to an inhibitor of protein synthesis (e.g. chloramphenicol). Yeast cultures have been made synchronous by the use of EDTA or the IONOPHORE A23187 [JGM (1979) 114 391–400]. Synchronous cultures of *Tetrahymena pyriformis* have been obtained by heat shock: the brief exposure of a non-synchronous culture to an elevated temperature (e.g. 40°C). All of these methods, however, tend to perturb normal metabolic activity so that they may be unsuitable for use in studies on cell-cycle-linked physiology. A method which avoids this problem can be used for endospore-forming bacteria; in this method a population of endospores is induced to germinate at a given time so that the resulting vegetative cells – at least initially – behave synchronously.

A more generally applicable method of obtaining synchronous cultures is termed *selection synchrony*; in this method, cells at a given stage of the cell cycle are separated out from a non-synchronous culture by purely physical means. In one selection method (used e.g. to obtain synchronous bacterial cultures) advantage is taken of the fact that the mass:volume ratio of the cell varies during the cell cycle; a non-synchronous, log-phase culture is subjected to density gradient CENTRIFUGATION so that the fraction of maximum density (consisting of cells about to divide, and new daughter cells) can be separated from the least-dense fraction – which consists of a population of cells at a particular stage of the cell cycle. [Selection synchrony method for bacterial cultures: Book ref. 2, pp. 166–168.] A selection method has also been used e.g. with cultures of *Dictyostelium discoideum* [JGM (1982) 128 2449–2452].

Synchronization of mammalian cells (e.g. in tissue cultures) may be achieved e.g. by the *double thymidine blockade*. A non-synchronous culture is exposed to a high concentration of

thymidine. Cells passing through the S phase of the CELL CYCLE remain blocked in that phase, while all other cells continue their development to the end of G<sub>1</sub>. (Development beyond G<sub>1</sub> does not occur during the blockade.) The cells are then exposed to a thymidine-free medium for a period of time equal to that of the S phase; during this time all the cells continue their development, and, at the end of the period, no cells are passing through phase S. The cells are then re-exposed to excess thymidine until all the cells have reached the end of G<sub>1</sub> – i.e., the culture has become synchronous.

In a simpler, 'selective' method for synchronization of mammalian cells, a tissue culture is gently agitated; cells undergoing mitosis are more easily detached from the glass, and can be decanted with the growth medium, giving a suspension of approximately synchronous M phase cells.

In the absence of a synchronizing influence, synchronous cultures normally return to the asynchronous condition.

**Synchytrium** A genus of unicellular, endobiotic, holocarpic fungi (order CHYTRIDIALES) which are parasitic on various plants (see e.g. WART DISEASE). The asexual cycle of *S. endobioticum* resembles that of OLPIDIUM species except that e.g. each zoospore may give rise to a group of sporangia (a *sorus*). Sexually-formed thick-walled resting sporangia are also produced.

**syncylium** A group or tuft of cilia which resembles other forms of COMPOUND CILIATURE but which differs in the infraciliary organization; syncylia occur in the ENTODINIOMORPHIDA.

**syncytium** (1) A multinucleate cell or structure formed by the cytoplasmic fusion, without nuclear fusion, of a number of individual mononucleate protoplasts or cells (see e.g. GIANT CELLS). (2) *Syn.* COENOCYTE.

**syndrome** (*med., vet.*) A group of symptoms and/or signs which, taken together, characterize or are indicative of a distinct disease or abnormality.

**Synechococcus** A genus of unicellular CYANOBACTERIA (section I) in which the cells are often more or less rod-shaped, occur singly, contain thylakoids, and lack a sheath; division occurs by equal binary fission in one plane. This genus [see JGM (1979) 111 1–61] includes organisms with a wide range of types of morphology, physiology, GC% (39–71), etc. and proposals have been made to subdivide the genus into four genera [Ann. Mic. (1983) 134B 21–36]: *Cyanobacterium* (GC%: 39–41, cells 1.7–2.3 µm wide); *Cyanobium* (GC%: 66–71, cells ca. 0.8–1.4 µm wide); *Cyanothece* (GC%: ca. 42, cells ca. 4–6 µm wide); *Synechococcus* (GC%: 47–56, cells 1–2(–3.5) µm wide). These organisms occur in a wide range of habitats: e.g., as plankton in the open ocean [Nature (1979) 277 293–294], in hypersaline environments such as salt evaporation ponds (e.g. *Cyanothece* (*Aphanothece*) *halophytica*), and in hot springs – e.g. *S. lividus* can grow at temperatures up to ca. 70°C.

Certain strains of *Synechococcus* (*sensu lato*) exhibit a swimming (not gliding) motility – even though the organisms lack flagella; swimming speeds are 5–25 µm/sec, and the type of swimming is influenced by cell morphology: coccoid cells carry out looping and spiral movements, while rods move in relatively straight paths [Science (1985) 230 74–76]. Flagellumless, calcium-dependent motility (of unknown mechanism) has been reported in strains of *Synechococcus* [JB (1997) 179 2524–2528].

Circadian regulation of the gene *psbAI* (which encodes a component of photosystem II) has been studied in *Synechococcus* [TIM (1998) 6 407–410].

**Synechocystis** A genus of unicellular CYANOBACTERIA (section I) in which the cells are coccoid and divide by equal binary

## Synercid®

fusion in two or three planes, giving rise to clusters of cells; a sheath is not formed. GC%: 35–48. This definition tentatively includes the phycological genera *Aphanocapsa*, *EUCAPSIS*, *MERIS-MOPEDIA* and *MICROCYSTIS* [JGM (1979) 111 1–61]. (See also PROCHLOROPHYTES.)

**Synercid®** See QUINUPRISTIN/DALFOPRISTIN.

**syneresis** The spontaneous expulsion of liquid from a gel.

**synergism** (in antibiotic action) The phenomenon in which a mixture of two antibiotics exerts an antimicrobial effect (on a given organism) which is (1) greater than that exerted by the more active antibiotic acting alone, or (2) greater than the additive effect of the two antibiotics acting independently. (cf. ANTAGONISM).

**synergistins** See STREPTOGRAMINS.

**syngamy** The fusion of gametes.

**syngen** (*ciliate protozool.*) A group of individuals, within a given species, in which two or more 'mating types' can usually be distinguished – CONJUGATION normally taking place only between members of different mating types within a given syngen. *Paramecium aurelia* has at least 12 syngens, and *P. bursaria* has at least 6; syngens occur also e.g. in *Euplotes* and *Tetrahymena*. Each syngen may be referred to by a number. It has been suggested that each syngen should be recognized as a distinct species.

**syngeneic** Derived from a genetically identical individual. (cf. ALLOGENEIC; XENOGENEIC.)

**Synhymeniida** See HYPOSTOMATIA.

**synkaryon** (syncaryon) (1) The diploid *nucleus* of a zygote. (2) A zygote.

**synnema** In some fungi: an erect tuft of spore-bearing hyphae in which there is characteristically an appreciable degree of hyphal fusion. (cf. COREMIUM and SPORODOCHIUM; see also CONIDIUM.) Analogous structures are formed by certain bacteria (e.g. ACTINOSYNNEMA).

**synnematin B** *Syn.* PENICILLIN N.

**synnematospores** Spores produced on a SYNNEMA.

**synonym** (taxonomy) (1) Objective synonym: any of two or more names which refer to the nomenclatural type of one particular taxon. (2) Subjective synonym: any of two or more names which do not refer to a common nomenclatural type but which, in the opinion of some taxonomist(s), refer to organisms which should be included in the same species.

A synonym is designated 'senior' or 'junior' according to whether it was published earlier or later, respectively, than a particular co-synonym.

**Synsorb P<sup>k</sup>** A synthetic carbohydrate whose molecules, which mimic the binding sites of shiga-like toxins, are linked to insoluble particles of silica. Synsorb P<sup>k</sup> is a potential therapeutic agent being evaluated for its ability to prevent toxin-mediated damage e.g. in HAEMOLYTIC URAEMIC SYNDROME; it is used with the object of binding (sequestering) toxin in the gut – thereby preventing uptake and (hence) denying the toxin access to its binding sites on vascular endothelium. (See also STARFISH.)

**syntaxin** See TETANOSPASMIN.

**synthase** A term applied to various enzymes *excluding* any belonging to EC class 6 (these being termed *synthetases* or LIGASES).

**synthetase** *Syn.* LIGASE. (cf. SYNTHASE.)

**syntrophism** The phenomenon in which the growth of one organism depends on (or is improved by) the provision of one or more growth factors or substrates by another organism growing in the vicinity. (See e.g. SATELLITE PHENOMENON; cf. CROSS-FEEDING.) *Syntrophism tests* can be used e.g. in the elucidation

of biosynthetic pathways. AUXOTROPHS which have blocks at different points in the same pathway may exhibit a syntrophic relationship: a substrate of a particular blocked reaction tends to accumulate and diffuse into the surrounding medium, supporting the growth of any auxotrophs blocked at *earlier* stages in the common pathway.

**Syntrophobacter** A genus of Gram-negative, anaerobic, non-motile bacteria which oxidize propionate to acetate, CO<sub>2</sub> and H<sub>2</sub>; growth occurs only in the presence of H<sub>2</sub>-scavenging systems – e.g. in co-culture with *Desulfovibrio* in the presence of sulphate. [Genus proposed in AEM (1980) 40 626–632.] (cf. SYNTROPHOMONAS.)

**Syntrophomonas** A genus of Gram-negative, anaerobic bacteria which can use only protons as electron acceptors in the oxidation of short-chain fatty acids (e.g. butyrate) to acetate (or to a mixture of acetate and propionate); the organisms can grow only in the presence of H<sub>2</sub>-scavenging systems – e.g. in co-culture with methanogens (see ANAEROBIC DIGESTION). Cells: round-ended, curved or helical rods with 2–8 flagella arising from the concave side of the cell. (cf. SYNTROPHOBACTER.)

**Syntrophus** A proposed genus of Gram-negative anaerobic bacteria. *S. buswellii*, the type species, was isolated from anaerobic digester sludge. Cells: round-ended rods with monotrichous polar flagella in the early stages of growth. Benzoate is metabolized with the formation of acetate, CO<sub>2</sub> and H<sub>2</sub> (or formate). Growth is inhibited by H<sub>2</sub> and requires the presence of appropriate hydrogenotrophic bacteria. [JJSB (1984) 34 216–217.]

**syntype** (cotype) Each of several specimens – none having been designated a HOLOTYPE – on which an author has based a published description of a new taxon.

**Synura** A genus of colonial CHRYSOPHYTES. Each elongate-pyriform cell has two flagella of similar length. The cells are compactly arranged – flagellate (anterior) ends outwards – in a globular, motile colony (100–400 µm diam.). Intricate siliceous spicules occur at the anterior end of each cell. Species occur in freshwater lakes and reservoirs with hard water, sometimes forming blooms; *S. petersenii* has been implicated as a cause of obnoxious 'fishy' taste and odour in lake waters [CJB (1985) 63 1482–1493].

**syphilis** A chronic human disease caused by *Treponema pallidum*. Infection generally occurs by direct contact with lesions of primary or secondary syphilis (see *T. pallidum* under TREPONEMA; see also VENEREAL DISEASE); *T. pallidum* can apparently penetrate undamaged mucous membranes, and is rapidly disseminated through the body via the blood and lymphatic systems. **Primary syphilis.** The first clinical manifestation is the *chancre*: a relatively painless, indurated lesion which develops at the infection site ca. 10–90 days after infection; in women the chancre may develop on the cervix and may thus be undetected. The chancre heals, without treatment, after ca. 10–40 days. **Secondary syphilis** begins one to several months after the disappearance of the chancre, and involves e.g. a rash of cutaneous lesions (which may be papular, macular, wart-like etc), thin white sores on the mucous membranes ('mucous patches'), loss of hair, lymphadenopathy, and mild general symptoms (slight fever, malaise etc). GLOMERULONEPHRITIS may occur. **Latent syphilis** occurs between the (spontaneous) disappearance of secondary symptoms and the development of late syphilis. The latent infection may persist for 1–40 years or more; there is no clinical evidence of infection (although symptoms of secondary syphilis may recur), but serological tests may be positive. **Late syphilis** (*tertiary syphilis*) may involve any tissue or organ – e.g., skin, bones, eyes (often leading to blindness), CNS (leading e.g. to

insanity and death), and cardiovascular system (which may result in heart failure, aortic rupture following aortitis, etc). The characteristic lesion is the *gumma*: a granuloma with caseating necrosis, formed as a result of a localized allergic reaction.

**Congenital syphilis.** Syphilis is rarely acquired by a fetus from an infected mother before the 4th month of gestation; fetal infection may actually occur before this, but disease does not develop – possibly because the early fetus is not immunologically capable of mounting the inflammatory response which leads to congenital syphilis. The likelihood of fetal infection decreases with increasing duration of the mother's disease, being greatest during primary or secondary syphilis in the mother. Consequences of fetal infection include miscarriage, stillbirth, or a severely affected infant. The neonate may show no symptoms at birth, but ca. 3 weeks later may develop skin lesions (mainly on the face, anogenital region, palms and soles), 'snuffles', hepatosplenomegaly etc; death may occur in the first year. Sequellae of congenital syphilis include notched incisors (Hutchinson's teeth), bossed ('mulberry') molars, saddle-shaped nose, mental deficiency, nerve deafness etc. Congenital syphilis can be prevented by treating the mother before the 4th month of pregnancy.

**Lab. diagnosis:** material from lesions etc may be examined by dark-field microscopy. For serological tests see STANDARD TESTS FOR SYPHILIS and TREPONEMAL TESTS. **Chemotherapy:** penicillins; tetracyclines or erythromycin. (See also JARISCH-HERXHEIMER REACTION.)

When diagnosis is uncertain (e.g. borderline serology), a fine-needle aspirate of inguinal lymph node may be examined for treponemal DNA by PCR; this method confirmed syphilis in three patients with suspected secondary or latent

disease. PCR amplified regions within *tpn47* (a gene encoding the major treponemal membrane lipoprotein), fragments being analysed by (i) gel ELECTROPHORESIS and (ii) Southern hybridization (see SOUTHERN BLOT) [Lancet (2002) 360 388–389].

**syringomycin** A peptide-containing phytotoxin, produced by *Pseudomonas syringae* pv. *syringae*, which causes a rapid, detergent-like lysis of plant and fungal cytoplasmic membranes. (cf. SYRINGOTOXIN.) [Regulation of syringomycin production: JAB (1985) 58 167–174.]

**syringotoxin** A phytotoxin produced by citrus-infecting strains of *Pseudomonas syringae* [PPP (1981) 18 41–50]. (cf. SYRINGOMYCIN.)

**systematics** (1) *Syn.* TAXONOMY. (2) The range of studies (theoretical and practical) involved in the classification of organisms.

**système sécant** (*ciliate protozool.*) A 'line', marked by the absence of kinetosomes, which delimits adjacent groups or fields of kineties. Examples include e.g. the *preoral suture* (which typically runs along the ventral surface between the oral region and the anterior pole) and the *postoral suture* (which typically runs, ventrally, between the oral region and the posterior pole).

**systemic** (1) (*med., vet.*) Involving the whole body. (2) (*plant pathol.*) Refers to a chemical agent (e.g. an ANTIFUNGAL AGENT) which penetrates and is translocated within the tissues of a plant.

**systole** See CONTRACTILE VACUOLE.

**syzygy** In certain protozoa; a stage of sexual reproduction in which gametocytes become physically joined without losing their identity as separate cells. A pair of cells 'in syzygy' usually encysts and gives rise to male and female gametes.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# T

**T** (1) Thymine (or the corresponding nucleoside or nucleotide) in a nucleic acid. (2) (*virol.*) See ICOSAHEDRAL SYMMETRY. (3) Threonine (see AMINO ACIDS).

**T antigen** (1) Tumour antigen: i.e., an antigen specific to a tumour cell. (See e.g. POLYOMAVIRUS.) (2) (in streptococci) *Syn.* T PROTEIN.

**T cell** (*immunol.*) *Syn.* T LYMPHOCYTE.

**T cell anergy** See SUPERANTIGEN.

**T cell receptor (TCR)** An antigen-specific receptor which occurs on every T LYMPHOCYTE; the same receptor occurs on all T cells of the same clone, while different receptors are found on T cells of different clones. The role of the TCR is to interact with its specific antigen. (See also IMMUNOGLOBULIN SUPERFAMILY.)

A TCR consists of two distinct, transmembrane peptide chains, linked by a disulphide bond, which project from the surface of the cell. In some TCRs the two chains are referred to as  $\alpha$  and  $\beta$ ; in other TCRs the two chains have sequences which differ from those of the  $\alpha$  and  $\beta$  chains, and in these TCRs the chains are called  $\gamma$  and  $\delta$ . Thus, a given TCR may consist of either  $\alpha\beta$  chains or  $\gamma\delta$  chains.

In a given TCR, the extracellular region of each chain includes a distal variable (V) region and a proximal constant (C) region; thus, for example, in an  $\alpha\beta$ -type TCR the  $\alpha$  chain includes  $V\alpha$  and  $C\alpha$  regions, and the  $\beta$  chain contains  $V\beta$  and  $C\beta$  regions. The two variable (V) regions constitute the antigen-binding part of the TCR.

In humans, the  $V\beta$  region of the TCR is encoded by a gene which is formed by random selection and assembly of small gene segments during maturation of the T cell; consequently, this gene occurs in about 25 different variant forms, each identified by a number (e.g.  $V\beta 1$ ,  $V\beta 2$  etc.). Note that those T cells which exhibit any given variable region (e.g.  $V\beta 1$ ) will include a very large number of different T cell clones. (See also SUPERANTIGEN.)

The TCR is part of a small group of transmembrane cell-surface structures called the *T cell receptor complex*. This complex comprises (i) the TCR, (ii) CD3 (q.v.) and (iii) a molecule consisting of two identical disulphide-linked  $\zeta$  (zeta) peptides or a heterodimer of one  $\zeta$  peptide and one  $\eta$  (eta) peptide (the  $\zeta\zeta$  homodimer occurs in most TCRs).

**T-dependent antigen** THYMUS-DEPENDENT ANTIGEN.

**T-DNA** See CROWN GALL.

**T-even phages** A category of virulent (lytic) enterobacterial dsDNA-containing BACTERIOPHAGES which includes T2, T4 and T6. (See also MYOVIRIDAE.) These phages resemble one another morphologically, they cross-react serologically, and their genomes can undergo recombination with each other when present in the same host cell. They differ e.g. in their host cell receptor sites: the T4 receptor on *Escherichia coli* B strains is the  $\alpha$ -glucosyl-(1  $\rightarrow$  3)-glucose terminus of the rough LPS core, while on K strains the LPS and OUTER MEMBRANE protein OmpC serve as separate, independent receptors; the T2 receptor is the OmpF protein, that of T6 is the Tsx protein.

The virions of T-even phages are structurally extremely complex, containing many components. Each consists of an elongated head attached to a long, complex, contractile tail. The head (ca. 110  $\times$  85 nm) apparently contains between 9 and 19 polypeptide species and has icosahedral symmetry elongated along a 5-fold axis by the insertion of an extra row of capsomers. It is attached – via a complex neck region which includes a

‘collar’ bearing six ‘whiskers’ – to a tail (ca. 100  $\times$  22 nm) consisting of two coaxial tubes (an inner ‘core’ and an outer contractile sheath). The distal end of the tail terminates in a hexagonal base-plate consisting of a central hub or ‘core’ surrounded by six wedges. In T4, the hub contains at least 8 proteins – including a thymidylate synthase (*gptd*), a glutamyl carboxypeptidase (*gp28*), an ATP-requiring folyl polyglutamyl synthetase (*gp29*), and a lysozyme (*gp5*) which is apparently able to induce LYSIS FROM WITHOUT as well as lysis from within [JV (1985) 54 460–466]; the hub also contains dihydropteroyl (dihydrofolyl) hexaglutamate. The wedges each contain at least six proteins, including a dihydrofolate reductase (*gpfid*). Each corner of the base-plate bears a long jointed tail fibre (ca. 150  $\times$  3–4 nm) and a short tail fibre (ca. 35  $\times$  3–4 nm) – the latter containing zinc.

The phage genome consists of a linear, circularly permuted, terminally redundant dsDNA molecule ca. 170 kb long (including the terminal redundancy of ca. 2.3%). The DNA contains hydroxymethylcytosine (HMC) instead of cytosine, and may also be modified by glucosylation of HMC residues and (in T2 and T4, but not in T6) N<sup>6</sup>-methylation of a small proportion of the adenine residues.

See BACTERIOPHAGE T4 for infection cycle.

**T helper cell** ( $T_H$ ;  $T_H$ ) See T LYMPHOCYTE.

**T-independent antigen** THYMUS-INDEPENDENT ANTIGEN.

**T lymphocyte (T cell)** A type of LYMPHOCYTE involved in e.g. ANTIBODY FORMATION, CELL-MEDIATED CYTOTOXICITY, INFLAMMATION and DELAYED HYPERSENSITIVITY. There are various types (subsets) of T cell, each subset being distinguishable by function and/or cell-surface antigens. Like B LYMPHOCYTES, T cells develop from haemopoietic stem cells (in the bone marrow) via the lymphoid pathway of development. The (morphologically distinguishable) large granular lymphocytes known as NK CELLS also develop from T cell precursors; NK cells are thus related to, but distinct from, T cells. (Other leukocytes, including macrophages and PMNs, develop from haemopoietic stem cells via the myeloid pathway.)

An antigen-specific T CELL RECEPTOR enables each T cell to respond to a unique antigen (T cells in the same *clone* responding to the same antigen). Unlike B cells (which bind soluble, i.e. free or isolated, antigen), T cells react to specific antigen only when it appears in suitable form on the surface of another cell; for example, during the process of ANTIBODY FORMATION, a T cell of a particular subset interacts with antigen presented in association with an MHC class II molecule on the surface of a B cell. *Cytotoxic* T cells (see later) interact with ligands on their target cells; cytotoxic cells have the important function of killing host cells that are infected with e.g. viruses or intracellular bacteria. In general, when a T cell interacts with its specific antigen the T cell is induced to proliferate (i.e. multiply), thus forming a clone (or a larger clone) of cells reactive to that specific antigen; such proliferation of a T cell of given antigenic specificity is called *clonal expansion*.

Although T cells respond to *antigens* only when the latter are cell-associated, they can respond to other isolated (soluble) molecules such as CYTOKINES.

Unlike B cells, most or all T cells undergo their process of maturation in the thymus gland. (The mouse is reported to have a

subset of mature, thymus-independent T cells.) Individuals with a non-functional thymus gland have a defective immune system.

Most *mature* (i.e. thymus-processed) lymphocytes of the  $\alpha\beta$  type (see T CELL RECEPTOR) express a cell-surface *co-receptor* (or *accessory molecule*) that is closely (but non-covalently) associated with the TCR. The co-receptor is either a CD4 molecule (q.v.) or a CD8 molecule. An *immature* cell has the potential to develop either as a CD4<sup>+</sup> or CD8<sup>+</sup> cell, i.e. to express either the CD4 or the CD8 molecule, respectively; whether a given cell develops as CD4<sup>+</sup> or CD8<sup>+</sup> is reported to depend on the duration of antigen receptor signalling during the maturation process [Nature (2000) 404 506–510]. CD4 and CD8 subsets of T cells are considered separately below.

CD4<sup>+</sup> T cells are also referred to as T helper cells, helper T cells, T<sub>H</sub> cells or T<sub>h</sub> cells.

When a CD4<sup>+</sup> T cell *initially* binds antigen it differentiates into one of two main types of helper cell – Th1 and Th2, the cells of each type being characterized by their secretion of a particular range of CYTOKINES (q.v.). (*Prior* to binding antigen the T cell is described as a *naïve* cell; such cells are often referred to as Th0.) (See also CD28.) [The expanding universe of T-cell subsets: IT (1996) 17 138–146.]

Th1 and Th2 cells also interact in characteristic ways with other cells of the immune system. For example, a Th1 cell may interact with a macrophage that has engulfed a bacterium. The macrophage acts as an ANTIGEN-PRESENTING CELL, presenting bacterial antigen, linked to an MHC class II molecule, to the (antigen-specific) T cell; the T cell binds antigen via its TCR, and binds the class II molecule with its co-receptor (CD4). Following such binding, the T cell releases IFN- $\gamma$  (see INTERFERONS) – which promotes activation of the macrophage; when activated, the macrophage behaves more aggressively towards the engulfed bacterium (e.g. by producing NITRIC OXIDE and toxic free radicals) and it also secretes e.g. INTERLEUKIN 12.

Th2 cells characteristically interact with B cells during ANTI-BODY FORMATION (q.v) and also give rise to specific cytokines (e.g. IL-4, IL-5, IL-10) that promote development of the Th2 subset of T cells and stimulate defences against parasitic infections.

CD8<sup>+</sup> T cells are generally referred to as *cytotoxic* (or *cytolytic*) T cells (sometimes written as T<sub>cyt</sub>). (See also CELL-MEDIATED CYTOTOXICITY.) These T cells kill host cells that are infected with viruses or certain other pathogens; in such cases it appears that the T cell makes direct physical contact with the target cell in an antigen-specific manner. Killing may involve interaction between the target cell's Fas receptor (see FAS) and the T cell's Fas L ligand (leading to APOPTOSIS). Alternatively, the T cell may release (i) proteins (*perforins*) that damage the membrane of the target cell, and (ii) serine proteases (*granzymes*) that inflict damage on the target cell and/or promote apoptosis.

Cells bearing the CD8 co-receptor are restricted by MHC class I antigens.

T cells with a  $\gamma\delta$  TCR (see T CELL RECEPTOR) include some which are CD4<sup>+</sup> and some which are CD8<sup>+</sup>; however, it appears that many or most have neither a CD4 nor a CD8 antigen. T cells of the  $\gamma\delta$  type are found among the so-called *intra-epithelial lymphocytes* (IELs) associated with mucosal epithelium.

The proportion of  $\gamma\delta$  T cells in the overall T cell population is much lower than that of the  $\alpha\beta$  T cells;  $\gamma\delta$ -type cells are reported to occur in all mammalian species examined so far.

At least some of the  $\gamma\delta$ -type T cells, and a small subset of  $\alpha\beta$ -type T cells which lack both CD4 and CD8 antigens (*double*

*negatives*), can recognize non-peptide antigens; for example mycobacterial cell components, including mycolic acids, can be recognized by the  $\alpha\beta$ -type cells.

**T-lysin** See FURUNCULOSIS (sense 1).

**T number** See ICOSAHEDRAL SYMMETRY.

**T odd phages** Bacteriophages T1 and T5 (STYLOVIRIDAE) and T3 and T7 (PODOVIRIDAE).

**T protein** (T antigen) (in streptococci) A cell-surface protein found in certain group A streptococci. T proteins are not associated with virulence, but are highly antigenic and may be used in typing of group A streptococci. Particular T-antigenic types are usually associated with particular M-antigenic types (see M PROTEIN sense 1). (cf. R PROTEIN.)

**T-strain mycoplasmas** Earlier name for members of the genus UREAPLASMA.

**T-strand** See CONJUGATION (1b)(i).

**T1 side-chains** See O ANTIGENS.

**T-2 toxin** A TRICHOHECENE mycotoxin.

**T2H test** (TCH test) A test used in the identification of strains of *Mycobacterium*. Essentially, the test determines the ability of a given strain to grow (*positive* result) on a medium (e.g. Löwenstein–Jensen medium) containing thiophene-2-carboxylic acid hydrazide (T2H, TCH) – often at 10  $\mu\text{g/ml}$ , a concentration inhibitory to *M. bovis* but not to most strains of *M. tuberculosis*; those strains of *M. tuberculosis* which are inhibited by 10  $\mu\text{g/ml}$  T2H may be able to grow on media containing 1–5  $\mu\text{g/ml}$  (concentrations still inhibitory to *M. bovis*) [Book ref. 53, p. 1710].

**T7 phage group** A genus of phages of the PODOVIRIDAE. Type species: BACTERIOPHAGE T7; other members: e.g., bacteriophages T3, W31,  $\phi$ I and  $\phi$ II.

**T90** The time required for 90% mortality to occur in a population of microorganisms exposed to a given hostile regime.

**TAB** An INACTIVATED VACCINE containing the cells of *Salmonella typhi* and *S. paratyphi* A and B.

**Tabellaria** See DIATOMS.

**TABT** TAB vaccine incorporating tetanus toxoid.

**tabtoxin** A  $\beta$ -lactam-containing dipeptide toxin produced by e.g. *Pseudomonas syringae* pv. *tabaci*. In the tobacco plant, tabtoxin is enzymically hydrolysed to tabtoxinine- $\beta$ -lactam which inhibits glutamine synthetase; the consequent accumulation of ammonia appears to be an important factor in the pathogenesis of WILDFIRE DISEASE. [APRpath. (1984) 22 218–221; susceptibility of bacterial glutamine synthetase to tabtoxinine- $\beta$ -lactam: JGM (1985) 131 1061–1067; contribution of tabtoxin to the pathogenicity of *Pseudomonas syringae* pv. *tabaci*: PPP (1984) 25 55–69.]

Tabtoxin-producing strains of *P. syringae* can be detected rapidly by PCR-based methodology [LAM (2001) 32 166–170].

**Tac antigen** A T lymphocyte surface antigen associated with the receptor for INTERLEUKIN-2.

**tac promoter** A hybrid PROMOTER constructed in vitro by fusion between elements of the *lac* and *trp* promoters of *Escherichia coli* (see LAC OPERON and TRP OPERON). The *tacl* promoter contains the Pribnow box from the *lac* promoter and the –35 sequence from the *trp* promoter; *taclI* contains the *trp* –35 sequence but its Pribnow box is a hybrid between those of the *trp* and *lac* promoters. The *tac* promoters are stronger than either 'parent' promoter; they can be repressed by the *lac* repressor and induced by IPTG.

**Tacaribe virus** See ARENAVIRIDAE.

**tâche noir** See BOUTONNEUSE.

**tachyzoite** *Syn.* ENDOZOITE.

**TACTAAC box** See SPLIT GENE (a).

**tactic response** *Syn.* TAXIS.

## tactophily

**tactophily** A tendency to adhere to, and to grow on, solid surfaces.

**taette** A Scandinavian food made by fermenting milk with yeasts and a rope-forming strain of *Lactococcus lactis*. (cf. ROPINESS.) (See also DAIRY PRODUCTS.)

**tag gene** See ADAPTIVE RESPONSE.

**tagatose 6-phosphate pathway** See LACTOSE and Appendix III(a).

**tailoring** (*mol. biol.*) The addition of nucleotides to the 3' end of a DNA strand using dNTPs and the enzyme *terminal deoxynucleotidyltransferase* (= terminal transferase); if only one type of dNTP is used (for example, dATP), the resulting tail is homogeneous (e.g. -A-A-A-) and the process is called *homopolymer tailing*.

**Taka-amylase** *Syn.* TAKADIASTASE.

**Takadiastase** (Taka-amylase) A commercial enzyme preparation, containing mainly  $\alpha$ -AMYLASES, obtained from *Aspergillus oryzae* grown on the surface of a solid substrate (usually moist wheat-bran or rice).

**Takatsi technique** A technique for preparing doubling dilutions (see SERIAL DILUTIONS) using an instrument consisting of a small spiral of wire attached to the end of a metal rod (handle). When immersed in a liquid and withdrawn, the wire carries a fixed volume of liquid. The wire is then immersed in diluent (equal in volume to that carried by the wire) and the handle is rotated between forefinger and thumb; this mixes the liquids, giving a 1-in-2 dilution. The wire is then withdrawn and immersed in a fresh volume of diluent, and so on. Another version of the instrument consists of a small slotted metal block at the end of a metal handle – liquid being carried in the slots of the block.

**take-all** A CEREAL DISEASE, caused by *Gaeumannomyces graminis* (formerly *Ophiobolus graminis*), which can affect wheat, barley, rye and oats; it can also affect turf grasses ('ophiobolus patch disease'). Symptoms on wheat include stunting of seedlings, the formation of fewer (or no) tillers, and a dry, black rot in the roots and in the lower stem (where perithecia may develop); the heads are characteristically bleached and lack grain ('whiteheads'). Infection apparently occurs by means of hyphae which grow out from the roots of previously infected plants. The disease is currently not susceptible to chemical control (cf. SUPPRESSIVE SOILS).

**talampicillin** See PENICILLINS.

**Talaromyces** A genus of fungi of the order EUROTIALES; anamorphs occur in the genus PENICILLIUM. (For some authors, *Talaromyces* includes only those species which form asci in chains – species forming asci singly, from croziers, being placed in the genus *Hamigera*.)

**Talfan disease** (benign enzootic paresis) A mild form of TESCHEN DISEASE affecting young pigs. It occurs in e.g. Australia, Denmark, North America and the UK. Symptoms include fever and impaired control of the hind legs. Affected pigs may recover, or muscular weakness may persist; fatalities are unusual.

**tamari sauce** (1) *Syn.* SOY SAUCE. (2) SOY SAUCE made entirely from soybeans.

**Tamiami virus** See ARENAVIRIDAE.

**Tamm–Horsfall protein** (THP; urinary mucoprotein; uromucoid) A mucoprotein component of the mucus on the surface of human uroepithelial cells; it binds e.g. *Escherichia coli* type 1 (mannose-sensitive) FIMBRIAE – such binding possibly being an important host defence mechanism [Lancet (1980) *i* 887]. (See also URINARY TRACT INFECTION.) [Possible relevance of THP in chronic pyelonephritis: YJBM (1985) 58 91–100.] THP is a leukocyte adhesion molecule [BBRC (1994) 200 275–282].

**Tanapox virus** A virus of the POXVIRIDAE which can infect humans, causing an acute, febrile illness with localized, pock-like skin lesions; the illness has occurred in epidemics among people in the region of the Tana River, Kenya. Tanapox virus can also infect monkeys. It does not grow in the CAM but can be cultivated in monkey kidney cell cultures. In serological tests the Tanapox virus shows partial cross-reactivity with YABA MONKEY TUMOUR POXVIRUS.

**TANDEM** See QUINOXALINE ANTIBIOTICS.

**tane koji** See KOJI.

**tanned cells** See BOYDEN PROCEDURE.

**tanned ox haemagglutination** See FIMBRIAE.

**tannic acid** (1) Penta-(*m*-digalloyl)-glucose, a hydrolysable tannin. (2) Any hydrolysable tannin (see TANNINS).

**tannins** A heterogeneous group of complex polyhydroxybenzoic acid derivatives which occur e.g. in plants and in brown algae (see PHAEOPHYTA). *Hydrolysable tannins* consist of a sugar (often glucose) partially or wholly esterified with e.g. gallic acid (3,4,5-trihydroxybenzoic acid), digallic acid (a DEPSIDE), or ellagic acid; hydrolysis yields the component sugar and acids. *Condensed (non-hydrolysable) tannins* are believed to be oligomers of flavanoid compounds; they tend to polymerize (e.g. under acid conditions) to form insoluble reddish compounds (*phlobaphenes*).

Tannins can precipitate and inactivate proteins by forming cross-links (a property exploited e.g. in leather tanning and in the BOYDEN PROCEDURE). In plants, tannins occur mainly in bark and woody tissues but also in certain leaves (e.g. tea-leaves); they may occur in vacuoles, in cell walls, or in specialized cells. They are also formed in damaged plant tissues as a result of the oxidation (in the presence of air) of phenolic compounds in the cell vacuoles by polyphenoloxidases normally sequestered in lysosomes. Tannins are believed to play a role in the resistance of plants to disease: e.g., by inhibiting enzymes (such as PECTIC ENZYMES) produced by invading pathogens, and by binding to and reducing the availability of proteins in the damaged plant tissue.

A comparison of two species of rumen bacteria, *Streptococcus bovis* and *S. gallolyticus* (= *S. caprinus*), found that the latter species can adapt to higher levels of tannins e.g. by upregulating the enzyme gallate decarboxylase and forming an extracellular polysaccharide matrix [Microbiology (2001) 147 1025–1033].

**tap gene** See CHEMOTAXIS (*Escherichia coli*).

**Taphrina** A genus of dimorphic fungi (order TAPHRINALES) which include species parasitic e.g. on various trees – including alder (*Alnus*); birch (*Betula*); cherry, peach and plum (*Prunus*); and oak (*Quercus*). *Taphrina* spp form an intercellular or subcuticular septate mycelium; some species form haustoria. Asci (see ASCUS) may develop as a subcuticular, erumpent layer, each ascus (containing ovoid or spheroidal ascospores) developing from a cell produced by hyphal fragmentation. In culture, *Taphrina* spp may grow only in a budding, yeast-like form.

*T. deformans* can cause e.g. WITCHES' BROOM and peach (and almond) *leaf curl*. In leaf curl, the young leaves become distorted and yellowish with reddish patches, and a white or silvery film develops on their upper surfaces; the leaves later become brown and drop prematurely. Young shoots, flowers and fruit may also become distorted.

**Taphrinales** An order of plant-parasitic fungi of the subdivision ASCOMYCOTINA. Ascocarps are not formed; the asci develop, directly or indirectly, from the hyphae, or from individual cells formed by the fragmentation of hyphae. Genera: e.g. TAPHRINA.

**Taq DNA polymerase** See DNA POLYMERASE.

**TaqI** See RESTRICTION ENDONUCLEASE (table).

**TaqMan<sup>®</sup> probes** Oligonucleotide probes (marketed by PE Applied Biosystems) which are used for (i) monitoring the progress of amplification in PCR, and (ii) estimating the initial (pre-amplification) concentration of target sequences in the sample. The structure and activity of these probes are shown diagrammatically in the figure.

TaqMan<sup>®</sup> probes: structure and activity (diagrammatic).

*Top.* One strand of an amplicon (3'-to-5'). A primer has bound to the 3' end, and a TaqMan probe has bound to an internal target site. The TaqMan probe consists of a target-specific oligonucleotide to which are covalently linked (i) a fluorophore ('reporter' dye) (O), and (ii) a quencher of fluorescence (●); the close proximity of the quencher to the reporter dye inhibits fluorescence.

*Centre.* Extension from the primer (dashed line) has reached the probe. The polymerase now exerts 5'-to-3' exonuclease activity: it displaces and degrades the probe – separating reporter and quencher so that the reporter can now produce a fluorescent signal; note that the release of one molecule of reporter is linked to the synthesis of one product strand. (Not all polymerases have 5'-to-3' exonuclease activity; the use of a polymerase with this function is thus essential when working with TaqMan probes.)

*Below.* Ongoing extension completes the strand.

Reproduced from Figure 4.4, page 64, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission from Kluwer Academic Publishers, Dordrecht, The Netherlands.

TaqMan<sup>®</sup> probes are added (in large numbers) to the reaction mixture prior to amplification. During cycling, ongoing synthesis of amplicons is paralleled by a rise in the number of fluorescent (unquenched) reporter molecules from degraded probes. Amplification can therefore be monitored at any given time by measuring the level of fluorescence in the reaction mixture.

*Quantification* (estimation of the initial number of target sequences in the sample). From the beginning of cycling, the level of fluorescence is monitored on a cycle-by-cycle basis. The first cycle in which reporter fluorescence exceeds background fluorescence is the *threshold cycle*. Identification of the threshold cycle in a given reaction allows calculation of the number of target sequences in the sample prior to amplification. Such calculation depends on the inverse linear relationship between (i) threshold cycle and (ii)  $\log_{10}$  of the initial number of target sequences – a relationship seen as a straight-line graph when threshold cycle (1, 2, 3...25, 26, 27...etc.) is plotted against  $\log_{10}$  of the initial number of target sequences. This graph, initially constructed from experimental data (with known

numbers of target molecules), permits estimates to be made from samples in which the initial target numbers are unknown.

Threshold cycles in PCR can also be determined with MOLECULAR BEACON PROBES (q.v.); fluorescence levels from these probes are recorded, cycle-by-cycle, at the primer annealing stage (when the amplicon-bound probes are fluorescent).

TaqMan<sup>®</sup> probes have been used e.g. for the quantitative estimation of *Borrelia burgdorferi* in specimens of tissue [JCM (1999) 37 1958–1963].

**tar gene** See CHEMOTAXIS (a).

**tar spot** See RHYTISMA.

**tartar emetic** See ANTIMONY.

**tartronic semialdehyde pathway** See TCA CYCLE [and Appendix II(b)] and PHOTORESPIRATION.

**Tat** See PROTEIN SECRETION (end of type II systems).

**TATA box** See PROMOTER.

**TATA box-binding protein** See PROMOTER.

**Tatlockia** See LEGIONELLACEAE.

**Tatumella** A genus of bacteria of the ENTEROBACTERIACEAE, isolated from human clinical (usually respiratory tract) specimens. Non-motile at 36°C; many strains are motile at 25°C [JCM (1981) 14 79–88].

$\tau$  (superhelix winding number) See DNA.

**tau protein** See MICROTUBULE-ASSOCIATED PROTEINS.

**Tauber trap** A simple instrument used for sampling airborne particles. (See also AIR.) It consists of a cylindrical vessel with an aerodynamically shaped lid containing a central hole.

**Taumelkrankheit** In fish: a loss of muscular coordination leading to a spiral swimming motion; it may be a (uncommon) symptom of ICHTHYOPHONOSIS or of thiamine deficiency.

**taurine** An aminosulphonic acid ( $\text{NH}_2\text{CH}_2\text{CH}_2\text{SO}_3\text{H}$ ) derived from cysteine; it occurs e.g. conjugated with BILE ACIDS.

**taurocholic acids** See BILE ACIDS.

**taurolin** A wide-spectrum FORMALDEHYDE-releasing antimicrobial agent which has been used e.g. for the treatment of peritonitis. [Review: JAB (1980) 48 89–96.]

**taxa** Plural of TAXON.

**taxis** A locomotive response to an external stimulus, exhibited by certain (motile) cells or organisms, in which the direction – or net change in direction – of locomotion is related to the direction or orientation of the stimulus. (cf. KINESIS; TROPISM.) In general, a tactic response is triggered only when the level of the stimulus is above a minimum (threshold) value; however, extreme levels of stimulation may promote tactic responses different from those produced by moderate stimulation (see e.g. PHOTOTAXIS). (See also ADAPTATION.)

In bacteria, some taxes depend on changes in the cell's proton motive force (see e.g. AEROTAXIS and PHOTOTAXIS; cf. CHEMOTAXIS). [Pmf-dependent taxis: ARM (1983) 37 551–573.]

See also e.g. ELASTICOTAXIS; GALVANOTAXIS; GEOTAXIS; MAGNETOTACTIC BACTERIA; RHEOTAXIS; THIGMOTAXIS.

**taxol** A complex substance of plant origin (obtained from *Taxus brevifolia*) which has antitumour activity, and which can e.g. inhibit the growth of HeLa cells at a concentration of 0.25  $\mu\text{M}$ . Taxol apparently enables the assembly of MICROTUBULES to occur with very low concentrations of tubulin (ca. 0.01 mg/ml in vitro) – i.e., it decreases the value of the critical concentration of tubulin – thereby promoting microtubule assembly; it also stabilizes MTs and (hence) prevents a cell from disassembling its MTs preparatory to the formation of a mitotic spindle. Taxol permits in vitro assembly of MTs in the absence of GTP.

**taxometrics** *Syn.* NUMERICAL TAXONOMY.

**taxon** (*pl.* taxa) In a given system of biological classification: any category, consisting of one or more kinds of organism,

## taxonomy

regarded as having an identity distinct from that of any other category in that system; a taxon may be a group of strains, species, genera, etc.

**taxonomy** The science of biological classification, i.e. the grouping of organisms according to their natural affinities. (cf. SYSTEMATICS.) A classified arrangement of organisms permits a logical and informative system of naming (see NOMENCLATURE) and can also be useful e.g. for identifying newly isolated organisms.

Ideally, biological classification should reflect the natural (evolutionary) relationships between organisms (i.e. PHYLOGENETIC CLASSIFICATION; cf. PHENETIC CLASSIFICATION). Such a phyletic approach has been used traditionally in taxonomic schemes for higher animals and plants (in which evolutionary relationships can be deduced from structural and other features). However, among microorganisms, the prokaryotes have (until recently) presented particular difficulties for taxonomists, and earlier forms of classification tended to suffer from artificiality and subjectivity; attempts to introduce a more rational basis for the taxonomy of these organisms lead to increased interest in e.g. NUMERICAL TAXONOMY. (An objective approach was also sought in areas such as enzymological analysis [e.g. CRM (1982) 9 227–252], protein structure (MICROCOMPLEMENT FIXATION), RIBOSOME structure, and the *sequence* of loci in the genome [JUSB (1985) 35 217–220].)

The modern approach to prokaryotic taxonomy began with molecular studies in which organisms are compared and classified according to the sequences of nucleotides in their nucleic acids (see e.g. RRNA OLIGONUCLEOTIDE CATALOGUING and DNA HOMOLOGY). Thus, the concept of a SPECIES (q.v.) may be considered in terms of the similarity (%) between chromosomal DNA from different strains; moreover, different species in a given genus commonly exhibit a certain minimum level of difference in their 16S rRNA sequences. However, reliance on 16S rRNA sequences as a guide to species identity has been questioned [JUSB (1992) 42 166–170]. (16S rRNA is widely used for the phyletic classification of prokaryotes for two main reasons. First, it occurs in all prokaryotes. Second, it contains highly conserved (i.e. stable) sequences as well as more variable sequences; the highly conserved sequences are considered to be appropriate for classification at the higher end of the taxonomic spectrum – e.g. kingdom, domain – while variable sequences are deemed to be useful for lower-rank taxa.) 16S rRNA oligonucleotide cataloguing initially revealed two kingdoms – Archaeobacteria and Eubacteria – each later elevated to domain status (Archaea and Bacteria, respectively).

There is also a 'consensus' form of taxonomy – *polyphasic taxonomy* – in which the aim is to base classification on the *maximum* amount of information available, including both phenotypic and molecular data [polyphasic taxonomy: MR (1996) 60 407–438].

A *taxonomic hierarchy* is a classificatory system in which a single, all-inclusive category (e.g. 'bacteria' or 'fungi') is progressively divided into smaller and less-inclusive categories, all the organisms in a given category conforming to the same criteria (i.e. all having, or lacking, certain feature(s)). A taxonomic hierarchy may have the following principal ranks (listed in descending order of inclusiveness): *division* (in botanical schemes) or *phylum* (in zoological schemes); *class*; *order*; *family*; *genus*; SPECIES; one or more species constitute a genus, one or more genera constitute a family, and so on. There are also intermediate ranks: see e.g. the table in the entry NOMENCLATURE. (See also FORM GENUS and SACCARDOAN SYSTEM.) A species can be subdivided into STRAINS which are distinguishable by TYPING procedures. (See also FORMA SPECIALIS; SEROTYPE; VARIETY.)

Taxonomists themselves are sometimes classified as *lumpers* or *splitters*. In any given system of classification, a 'lumper' would tend e.g. to 'lump together' a number of more or less similar species to form a single genus; a 'splitter' – emphasizing differences between the species – would tend to establish two or more genera from those same species. (The scope for lumping and splitting would seem to be less in the era of modern molecular taxonomy.)

(See also ALGAE; ARCHAEA; BACTERIA; CYANOBACTERIA; FUNGI; PROTOZOA; VIRUS.)

**Taxopodia** An order of protozoa (class HELIOZOEAE) which are bilaterally symmetrical; the axopodia are arranged in parallel longitudinal rows, and the organisms apparently swim by a 'rowing' action of the axopodia. Siliceous spines are present. Genera include *Sticholonche*.

**taxospecies** Any given group of strains which exhibit a high degree of mutual phenetic similarity.

**tazobactam** A substituted penicillanic acid sulphone which acts as a  $\beta$ -LACTAMASE INHIBITOR; it is used e.g. with piperacillin.

**TB** TUBERCULOSIS.

**Tb phage** TBILISI PHAGE.

**TBE virus** Tick-borne encephalitis virus: see FLAVIVIRIDAE.

**Tbilisi phage** (bacteriophage Tb; Tb phage) A group 1 *Bruceella* phage (family PODOVIRIDAE) which can replicate efficiently only in smooth (S), smooth-intermediate (SI) and intermediate (I) strains of *B. abortus*; some replication can occur in S, SI and I strains of *B. neotomae* but the EOP is low. High concentrations of Tb phage can lyse S, SI and I strains of *B. suis*.

**TBP** See PROMOTER.

**TbpA, TbpB** See VACCINE.

**TBSV** Tomato bushy stunt virus – see TOMBUSVIRUSES.

**TBTO** (tributyltin oxide; bis(tri-*n*-butyltin) oxide) A compound of TIN used e.g. for TIMBER PRESERVATION and as an anti-algal constituent in ships' anti-fouling paints. (The green alga *Ankistrodesmus falcatus* concentrates TBTO with an apparent bioconcentration factor of  $3 \times 10^4$ , converting it to the dibutyl derivative and to small amounts of the monobutyl derivative and inorganic tin [CJFAS (1984) 41 537–540].)

**TCA cycle** (tricarboxylic acid cycle; citric acid cycle; Krebs cycle) A cyclic sequence of reactions [see Appendix II(a)] which plays a central role in the metabolism of many microorganisms, both eukaryotic and prokaryotic, as well as of higher organisms. In eukaryotes the enzymes of the TCA cycle are located in the MITOCHONDRION; in both prokaryotes and eukaryotes most of the enzymes are soluble (in the cytoplasm or matrix, respectively), but the succinate dehydrogenase is membrane-bound in both cases. The TCA cycle can have both catabolic and anabolic functions, the relative importance of which often depends largely on the physiological state of the cell.

When the TCA cycle is functioning *catabolically*, acetyl-CoA – derived from carbohydrate metabolism (via pyruvate: see Appendix I) or e.g. from fatty acid degradation – enters the cycle by condensation with oxaloacetate (OAA) to form citrate; with one complete turn of the cycle, 2 molecules of CO<sub>2</sub> are eliminated, 3 molecules of NAD(P)<sup>+</sup> and one of FAD are reduced, one molecule of ATP (or GTP) is synthesized (by SUBSTRATE-LEVEL PHOSPHORYLATION), and one molecule of OAA is regenerated. Thus, the acetyl group is effectively completely oxidized. The NADH and FADH<sub>2</sub> may be reoxidized via a respiratory chain (see ELECTRON TRANSPORT CHAIN) to yield energy. The enzyme isocitrate dehydrogenase is specific for NADP in most bacteria and e.g. in yeasts, and this reaction – together with the HEXOSE MONOPHOSPHATE

PATHWAY – is probably an important source of NADPH for biosynthesis in many organisms [e.g. yeasts: JGM (1983) 129 953–964].

When functioning *anabolically*, the TCA cycle provides precursors for various biosynthetic pathways [see Appendix II(b)]. Since intermediates withdrawn from the cycle cannot be used to regenerate OAA, OAA must be generated in some other way if the cycle is to continue to operate; various reactions for achieving this occur in microorganisms: e.g., OAA may be formed directly by the carboxylation of pyruvate or of phosphoenolpyruvate (PEP) [see Appendix II(b)]. Such replenishing reactions are known as *anaplerotic sequences*. (See also GLUCONEOGENESIS.)

Many bacteria can use TCA cycle intermediates (di- and tricarboxylic acids) as sole sources of carbon and energy. (However, possession of the TCA cycle does not necessarily enable an organism to grow on such compounds; the presence of a TRANSPORT SYSTEM for the substrate is also necessary – see also CIT PLASMID.) Citrate, for example, can be converted to OAA via reactions of the TCA cycle; however, acetate must then be formed (from another molecule of citrate) if the cycle is to continue. This may be achieved by the decarboxylation of malate (by the ‘malic enzyme’) to pyruvate which, in turn, is converted to acetyl-CoA by the pyruvate dehydrogenase complex [Appendix II(b)]. (See also CITRIC ACID.)

If acetate (or an acetate-generating substrate such as a fatty acid) is used as the sole source of carbon and energy under aerobic conditions, acetate can be converted to acetyl-CoA by acetyl-CoA synthetase (with concomitant formation of AMP and PPi from ATP) and can thus be metabolized via the TCA cycle. However, if intermediates are withdrawn from the cycle for biosynthesis, OAA cannot be generated by carboxylation of pyruvate or PEP since in aerobic organisms pyruvate cannot be synthesized directly from acetate. Under these conditions dicarboxylic acids are synthesized by the *glyoxylate cycle* (*glyoxylate shunt*) involving two reactions, catalysed by isocitrate lyase (ICL) and malate synthase, which bypass the decarboxylation reactions of the TCA cycle [see Appendix II(b)]. Thus, in effect, one molecule of a 4-C dicarboxylic acid is generated from two of acetate for each turn of the glyoxylate cycle; pyruvate – required e.g. for GLUCONEOGENESIS – can be formed by the decarboxylation of OAA generated in this way. The key enzyme in controlling whether isocitrate is metabolized via the TCA cycle or via the glyoxylate cycle is *isocitrate dehydrogenase* (ICDH); ICDH has a much higher affinity for isocitrate than does ICL. In *Escherichia coli*, growth on acetate induces the synthesis of a bifunctional enzyme, *ICDH kinase-phosphatase*, which catalyses the phosphorylation and dephosphorylation of ICDH; phosphorylation inactivates ICDH, allowing isocitrate to reach concentrations sufficient to permit its flow into the glyoxylate cycle. The phosphatase function of ICDH kinase-phosphatase is stimulated, and the kinase function inhibited, by various metabolites – particularly pyruvate [JGM (1986) 132 797–806]. (See also PROTEIN KINASE and GLYOXYLATE CYCLE.)

Some bacteria can grow on glyoxylate (formed e.g. by purine degradation), or on glyoxylate precursors such as glycolate, by using the glyoxylate cycle. In this case acetyl-CoA is formed via 3-phosphoglycerate produced by the *tartronic semialdehyde pathway* (= *glycerate pathway*) [see Appendix II(b)]; acetyl-CoA may then condense with another molecule of glyoxylate to form malate and hence OAA.

TCA cycle enzymes are subject to various control mechanisms affecting their biosynthesis and/or activity. For example, in *E. coli* they are repressed by anaerobiosis. However, when

conditions are such that some of the enzymes are necessary for biosynthesis, the levels of those enzymes are increased despite anaerobiosis; under such conditions 2-oxoglutarate dehydrogenase (=  $\alpha$ -ketoglutarate dehydrogenase) remains repressed and the pathway ceases to be cyclic, functioning in biosynthesis as two linear pathways: an oxidative pathway from citrate to 2-oxoglutarate, and a reductive pathway from OAA to succinyl-CoA. 2-Oxoglutarate dehydrogenase is also repressed by anaerobiosis in many other facultatively anaerobic organisms. The TCA cycle is inherently incomplete in some bacteria: e.g. in cyanobacteria, in *Gluconobacter*, and in some members of the Methylococcaceae; in at least some cyanobacteria succinyl-CoA is formed via the glyoxylate cycle rather than via the reductive pathway from OAA. (See also GLUTAMIC ACID.) A complete cycle is apparently involved in the oxidation of acetate by sulphate in the obligately anaerobic sulphate-reducing bacterium *Desulfobacter postgatei* (see DESULFOBACTER), although some of the enzymes involved are unusual in certain respects: e.g., malate and possibly succinate dehydrogenases appear to use quinones instead of pyridine nucleotides as coenzymes, and 2-oxoglutarate dehydrogenase is specific for a ferredoxin instead of NAD<sup>+</sup> as electron acceptor. In *D. postgatei*, pyruvate (and hence OAA) can be synthesized from acetyl-CoA by direct reductive carboxylation catalysed by a ferredoxin-dependent pyruvate synthase.

[Bacterial TCA cycle enzymes (particularly citrate synthase and succinate thiokinase): AMP (1981) 22 185–244.]

(See also REDUCTIVE TRICARBOXYLIC ACID CYCLE.)

**TCBS agar** Thiosulphate–citrate–bile salts agar: a medium containing peptone, sucrose, thiosulphate, citrate, cholera, oxgall, ferric citrate, NaCl, thymol blue, and bromthymol blue [recipe: Book ref. 46, p. 1276]. It is used for the isolation of *Vibrio* spp, especially *V. cholerae*; sucrose-fermenting strains form yellow colonies. The medium is strongly inhibitory for most faecal enterobacteria, pseudomonads, and Gram-positive bacteria.

**TCC** See CARBANILIDES.

**TCCR** (cytokine receptor) See CYTOKINES.

**TCD<sub>50</sub>** An alternative expression for TCID<sub>50</sub> (q.v.).

**tdcA, tdcB, tdcE genes** See LYSIS PROTEIN (sense 3).

**TCGF** See INTERLEUKIN-2.

**TCH test** *Syn.* T<sub>2</sub>H TEST.

**TCID<sub>50</sub> (TCD<sub>50</sub>)** Tissue culture infective dose (50%): that dose of a viral suspension which, when used to inoculate each of a number of TISSUE CULTURES, causes observable effects in 50% of those cultures. (See also END-POINT DILUTION ASSAY.)

**TCNB** See TECNAZENE.

**TCP** Toxin co-regulated pili: see CHOLERA, BACTERIOPHAGE CTX $\Phi$  and PATHOGENICITY ISLAND.

**TCR** See T CELL RECEPTOR.

**t<sub>D</sub>** See THERMAL DEATH TIME.

**TD antigen** THYMUS-DEPENDENT ANTIGEN.

**td gene** (in bacteriophage T4) See SPLIT GENE.

**TDH** See FOOD POISONING (*Vibrio*).

**tDNA** DNA which encodes tRNA.

**T-DNA** See CROWN GALL.

**tea diseases** Diseases of the tea plant, *Camellia sinensis* (= *Thea sinensis*), include e.g. BLISTER BLIGHT and RED RUST.

**teat** See SCOURS.

**teat (microbiol.)** A rubber bulb used e.g. for operating a pipette.

**tecnazene (TCNB)** An agricultural antifungal agent (2,3,5,6-tetrachloronitrobenzene) used e.g. (as a dust) for the control of dry rot (*Fusarium coeruleum*) of stored potatoes; it also inhibits the sprouting of stored potatoes. TCNB is also used (as

## **Tectibacter**

a smoke) in glasshouses for the control of *Botrytis* infections. (cf. QUINTOZENE.)

**Tectibacter** A genus of Gram-negative bacteria which occur as endosymbionts in the cytoplasm of strains of *Paramecium aurelia*. Cells: peritrichously flagellated straight rods, ca. 0.4–0.7 × 1.0–2.0 μm. No strains appear to be toxic to protozoa. Type species: *T. vulgaris* (earlier name: delta particles).

[Book ref. 22, p. 811.]

**Tectiviridae** (PRD1 phage group) A family of lipid-containing, icosahedral BACTERIOPHAGES (diam. (53–)65(–80) nm) which contain linear dsDNA (MWt ca. 10<sup>7</sup>). One genus: *Tectivirus*; type species: phage PRD1. Host range for the family includes Gram-negative and Gram-positive bacteria. Phage progeny are released by cell lysis. Plaques: clear or turbid, minute to large. The virion contains a dense core, probably solely of DNA, surrounded by a lipid bilayer – the whole being enclosed by the icosahedral protein shell; single spikes (ca. 20 nm long) are sometimes seen on the vertices. Some virions have a ‘tail’ (length variable) which appears when DNA is ejected or virions are damaged and which may be part of a mechanism for DNA ejection. Virions are sensitive to organic solvents and detergents.

Phages PRD1, PR3, PR4, PR772 (probably = PR4), PR5 and L17 are closely related and are specific for Gram-negative bacteria (e.g. *Escherichia coli*, *Salmonella typhimurium*, *Pseudomonas aeruginosa*) which harbour IncN, IncP1 or IncW plasmids. The site of phage adsorption is controversial: phage may adsorb to pili (which may then retract) or directly to the cell surface.

Other tectiviruses attack *Bacillus* spp. Phages AP50 (host: some strains of *B. anthracis*) and Bam35 (hosts: *B. cereus*, *B. megaterium*, *B. thuringiensis*) are very similar and are both highly sensitive to heat. Phage φNS11 is acidophilic and thermophilic (as is its host, *B. acidocaldarius*). φNS11 is stable at pH 2–5 but is rapidly inactivated at pH above 6; it contains the unusual ω-cyclohexyl fatty acids characteristic of *B. acidocaldarius* cell membranes.

**Tectivirus** See TECTIVIRIDAE.

**tectum** (protozool.) See COCHLIPODIUM.

**teeth** (diseases of) See DENTAL CARIES and PERIODONTITIS.

**Teflon filter** See FILTRATION.

**Tego compounds** A range of antimicrobial ampholytic surfactants used e.g. as antiseptics and disinfectants; an example is Tego 103S (dodecyl-di(aminoethyl)-glycine hydrochloride). [Book ref. 65, pp. 335–345.]

**tegulicolous** Growing on tiles.

**tegument** See HERPESVIRIDAE.

**teichoic acids** (TAs) Polymers which typically consist mainly of glycerol phosphate or ribitol phosphate (or rarely mannitol phosphate) substituted more or less extensively with amino acids and/or sugars; they occur in the cell envelope in most Gram-positive bacteria. (TAs are very rare in Gram-negative bacteria, but have been found in strains of *Butyrivibrio* and of *Escherichia coli* – see below.)

*Glycerol teichoic acids* (GTAs) occur in the CYTOPLASMIC MEMBRANE, in the periplasmic region, and/or in the CELL WALL; they are commonly composed of glycerol residues linked 1 → 3 by phosphodiester bridges and substituted with e.g. D-alanine, N-acetylglucosamine (GlcNAc), glucose, KOJIBIOSE, etc. (See also C SUBSTANCE.) In some GTAs a sugar forms an integral part of the polymer backbone. (The K2 capsular antigen of *E. coli* contains alternating galactofuranosylglycerol phosphate and galactopyranosylglycerol phosphate residues [Biochem. (1982) 21 1279–1284].)

*Ribitol teichoic acids* (RTAs) occur mainly in the cell wall, and consist of ribitol residues linked 1 → 5 by phosphodiester bridges; sugar residues may occur within the chain. The ribitol residues are usually substituted with D-alanine and sometimes also with e.g. GlcNAc, glucose, etc.

In both types of TA the nature and extent of substitution, and e.g. the ratio of GTA to RTA, may vary greatly between strains and even in the same strain under different growth conditions. (See also TEICHURONIC ACIDS.) TAs may account for ca. 20–60% of the dry weight of the cell wall in Gram-positive bacteria. Wall TA tends to be concentrated towards the cell surface, and is linked covalently to PEPTIDOGLYCAN via a ‘linkage unit’ attached to the 6-position of a muramic acid residue; in the RTAs of e.g. *Staphylococcus aureus* strains the linkage unit consists of tri-(glycerol phosphate)-N-acetylglucosamine 1-phosphate, while in the GTAs of strains of *Bacillus subtilis* and *B. licheniformis* it is N-acetylmannosaminyl-(1 → 4)-N-acetylglucosamine [JB (1984) 158 990–996]. In the cytoplasmic membrane, TAs are linked covalently to glycolipid, forming *lipoteichoic acid* (LTA); membrane LTAs are found in most Gram-positive bacteria, and have been isolated from *Butyrivibrio fibrisolvens* [JGM (1976) 94 126–130] (cf. BUTYRIVIBRIO). In e.g. group A streptococci the LTA appears to be anchored to the cytoplasmic membrane by the glycolipid and to extend through the cell wall into the medium. (TAs may also be released into the medium.)

[Teichoic acids in the genus *Nocardopsis*: FEMS Reviews (2001) 25 269–283.]

TAs bind cations and may function as a cation-exchange system, regulating the flow of ions through the cell envelope and controlling the availability of ions (particularly Mg<sup>2+</sup>) necessary for the function of membrane-bound enzymes (e.g. autolysins). (cf. BILE SOLUBILITY.) Streptococcal LTA may function as an ADHESIN. TAs at the cell surface can also act as phage receptors.

Antibodies to staphylococcal RTAs can be found in serum from patients with staphylococcal infections, and the detection of such antibodies can be useful e.g. in the diagnosis of staphylococcal endocarditis. [Evaluation of commercial antibody assay ENDO-STAPH: Arch. Int. Med. (1984) 144 250–252, 261–264.]

*Biosynthesis* of wall TAs begins with the synthesis of the linkage unit. In the case of the wall RTAs of *S. aureus*, GlcNAc phosphate is transferred (in a TUNICAMYCIN-sensitive step) from its UDP derivative to a cytoplasmic membrane-bound polyisoprenol phosphate carrier (see] BACTOPRENOL); three glycerol phosphate residues are then added sequentially from three CDP-glycerol molecules (synthesized from glycerol 1-phosphate and CTP). Ribitol phosphate units are then transferred from CDP-ribitol molecules (synthesized from ribitol 5-phosphate and CTP) and polymerized on the linkage unit. After the addition of the various substituents, the entire molecule is transferred to peptidoglycan. The transmembrane translocation of wall polymers apparently requires a pmf [JB (1984) 159 925–933]. [Review of TA biosynthesis: Book ref. 125, pp. 279–307.]

**teichomycin A2** *Syn.* TEICOPLANIN.

**teichuronic acids** Cell wall polymers which contain glycuronic acid(s) and other sugars, but not phosphate; they are formed – either in place of or in addition to TEICHONIC ACIDS – by many Gram-positive bacteria growing in phosphate-deficient media. Teichuronic acids may contain e.g. D-glucuronic acid and N-acetylgalactosamine (in strains of *Bacillus licheniformis*); glucose, rhamnose and D-glucuronic acid (*B. megaterium*); or N-acetylmannosaminuronic acid and glucose (*Micrococcus luteus*). As with teichoic acids, teichuronic acids are covalently

linked by phosphodiester bridges to muramic acid residues in peptidoglycan – via a ‘linkage unit’ in *M. luteus* but apparently directly in *B. licheniformis*. [Biosynthesis: Book ref. 125, pp. 279–307.]

**teicoplanin** (teichomycin A2) A glycopeptide ANTIBIOTIC produced by *Actinoplanes teichomyceticus*. It resembles VANCOMYCIN both structurally and functionally, but is more active against e.g. enterococci [AAC (1986) 29 52–57].

**teleology** The doctrine which states that developments or phenomena tend to be determined by the purpose or function which they serve.

**telemorph** (*mycol.*) The sexual (= perfect) stage or state of a given fungus. (cf. ANAMORPH and HOLOMORPH.)

**teliosorus** See UREDINIOMYCETES stage III.

**teliospore** See UREDINIOMYCETES stage III and USTILAGINALES.

**Teliomycetes** (Hemibasidiomycetes) An obsolete class of fungi which included the rusts and smuts – organisms now included in the UREDINIOMYCETES and USTILAGINIOMYCETES respectively.

**teliospore** A type of thick-walled spore characteristic of fungi of the UREDINIOMYCETES and USTILAGINALES, and of some fungi of the SPORIDIALES; on germination, a teliospore usually gives rise to a basidium.

**telium** See UREDINIOMYCETES stage III.

**Tellina tenuis virus** See IPN VIRUS.

**tellurite media** Media which are inhibitory to many species of bacteria owing to their content of potassium tellurite ( $K_2TeO_3$ ); in sensitive cells of *Escherichia coli*, tellurite is apparently taken up by a phosphate transport system, and resistance to tellurite can result from mutation in the *phoB*–*phoA* region of the PHO REGULON [AAC (1986) 30 127–131]. (Tellurite resistance in e.g. *Citrobacter*, *Klebsiella* and *Pseudomonas* spp may be plasmid-mediated.) Cystine–tellurite–blood agar [recipe: Book ref. 2, pp. 132–133], which contains 0.0375% (w/v)  $K_2TeO_3$ , is used e.g. for the primary isolation of *Corynebacterium diphtheriae*, a species inherently resistant to tellurite. Certain bacteria can reduce  $K_2TeO_3$  to (black) metallic tellurium. In a test for strains of the *Mycobacterium avium* complex, 2 drops of sterile aqueous  $K_2TeO_3$  (0.2%) are added to a 7-day culture in Middlebrook 7H-9 broth (5 ml); a black precipitate within ca. 4 days is a positive reaction. (See also MONSUR MEDIUM.)

**telokinetal stomatogenesis** See STOMATOGENESIS.

**telomere** A terminal section of a eukaryotic chromosome – comprising perhaps a few hundred base pairs – which has a specialized structure [ARB (1984) 53 175–194] and which is involved in chromosomal replication and stability.

**telophase** See MITOSIS and MEIOSIS.

**Telioschistales** An order of fungi of the ASCOMYCOTINA; members include LICHENS and lichenicolous fungi. Ascocarp: APOTHECIOID, with paraphyses. Asci: bitunicate (lecanoralean). Ascospores: ellipsoidal, aseptate or POLARILOCULAR. Genera: e.g. CALOPLACA, TELOSCHISTES, XANTHORIA (these three genera being in the family Teloschistaceae).

**Teloschistes** A genus of fruticose LICHENS of the order TELOSCHISTALES. The thallus contains PARIETIN and is usually yellow or orange (but may be grey in some species); it is more or less branched, the branches being flattened (e.g. in *T. chrysophthalmus*) or terete (e.g. in *T. flavicans*). Species occur on rocks, trees etc.

**Teliosporea** A class of parasitic protozoa (comprising the subclasses Coccidia and Gregarinia) classified in the subphylum SPOROZOA; these organisms, together with those of the TOXOPLASMEA and the PIROPLASMEA, have been incorporated in the class SPOROZOASIDA.

**telotroch** The motile (ciliated) immature stage of a sedentary peritrich. (See also TROCHAL BAND.)

**TEM** See ELECTRON MICROSCOPY (a).

**TEM-1  $\beta$ -lactamases** See  $\beta$ -LACTAMASES.

**TEM-2  $\beta$ -lactamases** See  $\beta$ -LACTAMASES.

**tempeh** (tempe kedele) A food, originally from Indonesia, consisting of soybeans fermented and bound into a cake by mycelium of *Rhizopus* spp (e.g. *R. oligosporus*); a strain of *Klebsiella pneumoniae* is also present and contributes vitamin B<sub>12</sub> to the product [Book ref. 6, pp. 414–416]. Soybeans are soaked, dehulled, boiled, surface-dried, and mixed with an inoculum of *Rhizopus* sp; the beans are then packed tightly into a container and incubated until they are coated and bound by an abundant white mycelium (e.g. 32°C for ca. 20 hours). *Bongkrek* (*tempe bongkrek*) is a similar product made from coconut press-cake or grits remaining after the extraction of coconut oil; fermentation may be carried out by *R. oligosporus* or by *Neurospora intermedia*. (See also BONGKREKIC ACID; cf. ONCOM.)

[Tempe (recent data): Book ref. 228.]

**temperate bacteriophage** A BACTERIOPHAGE which can lysogenize its host cell (see LYSOGENY). (cf. VIRULENT BACTERIOPHAGE.)

**temperature coefficient** ( $\theta$ ; Q) Of a given DISINFECTANT acting on a single-species population of microorganisms: a coefficient which indicates the factor by which the death rate increases when the temperature rises by 1°C – or, more commonly, 10°C, in which case the temperature coefficient is designated  $\theta^{10}$  or Q<sub>10</sub>. The temperature coefficient for a given temperature range (e.g. 10–20°C) is not necessarily the same as that for other ranges (e.g. 0–10°C; 20–30°C).

**temperature-sensitive mutant** (*ts* mutant) A mutant (e.g. a CONDITIONAL LETHAL MUTANT) in which the mutated gene is functional at certain temperatures (*permissive* temperatures) but not at others (*non-permissive* or *restrictive* temperatures); *ts* mutations are commonly MIS-SENSE MUTATIONS which alter an essential protein such that it functions at the permissive temperature but not at the restrictive (usually higher) temperature.

**template strand** (of DNA) See CODING STRAND.

**temporal temperature gradient gel electrophoresis** (TTGE) See DGGE.

**TEN** TOXIC EPIDERMAL NECROLYSIS.

– **10 sequence** See PROMOTER.

**Tenericutes** A proposed division of the PROCARYOTAE comprising one class (MOLLICUTES).

**tennecetin** *Syn.* PIMARICIN.

**tentoxin** A cyclic tetrapeptide TOXIN produced by *Alternaria* spp; it binds non-covalently to, and inhibits, (F<sub>0</sub>F<sub>1</sub>)-type PROTON ATPASES, inducing chlorosis in various plants.

**tequila** See PULQUE.

**teratogen** Any agent which causes developmental abnormalities in an embryo or fetus. (See also TORCH DISEASES; SYPHILIS.)

**teratoma** A neoplasm composed of more than one type of tissue.

**terbinafine** A synthetic allylamine antifungal agent which is used clinically e.g. against dermatophyte infections.

The activity of terbinafine against *Aspergillus* spp has been compared, in vitro, with the activities of itraconazole and amphotericin B; compared with these two agents, terbinafine had greater activity against *A. flavus*, *A. terreus* and *A. niger* but it was less effective against *A. fumigatus* [AAC (2001) 45 1882–1885].

**terbutryne** An ALGICIDE and herbicide which is active against a range of algae (e.g. species of *Cladophora*, *Enteromorpha*, *Rhizoclonium*, *Spirogyra*) and against certain aquatic vascular plants. It is useful for the control of algae and water-weeds in static and slow-moving waters (lakes, canals, farm ponds, etc).

## terconazole

**terconazole** See AZOLE ANTIFUNGAL AGENTS.

**terete** Circular in transverse section.

**terminal deoxynucleotidyl transferase** See TAILING.

**terminal electron acceptor** See e.g. RESPIRATION.

**terminal protein (TP)** See BACTERIOPHAGE  $\phi$ 29.

**terminal redundancy** (*mol. biol.*) The presence of identical base sequences at the two ends of a linear nucleic acid molecule. In e.g. a terminally redundant dsDNA molecule, removal of nucleotides from e.g. the 3' end of each strand results in the formation of STICKY ENDS.

**terminal transferase** See TAILING.

**termination codon** See GENETIC CODE.

**terminator** See TRANSCRIPTION.

**Termitaria** A genus of fungi of the COELOMYCETES; *T. snyderi* is parasitic on termites.

**termite-microbe associations** Termites are social insects of the Isoptera, found mainly in tropical regions; there are ca. 2000 species, many of which can feed on wood and can cause severe economic damage in buildings etc. Many species depend on symbiotic associations with microorganisms for the digestion of cellulose and other components in their diet.

In 'lower' termites (Hodotermitidae, Kalotermitidae, Mastotermitidae, Rhinotermitidae, Serritermitidae) the hindgut is densely packed with microorganisms, including cellulolytic flagellate protozoa (e.g. TRICHONYMPHA) and various facultatively or strictly anaerobic bacteria (e.g. strains of *Bacillus*, *Bacteroides*, enterobacteria, spirochaetes (see SPIROCHAETALES), *Staphylococcus* and *Streptococcus*). The protozoa phagocytose particles of cellulosic material ingested by the termite and ferment the cellulose to acetate, CO<sub>2</sub> and H<sub>2</sub>. Acetate is absorbed by the termite and used as the major oxidizable energy source for termite metabolism. The H<sub>2</sub> and CO<sub>2</sub> are used by methanogens and bacteria (possibly including *Acetobacterium*-like acetogens; cf. ANAEROBIC DIGESTION). Other bacteria may generate acetate and other volatile fatty acids from mono-, di- and oligosaccharides present in material ingested by the termite or released from the protozoa. Thus, the protozoa are the main agents of cellulose degradation, while prokaryotes serve to remove H<sub>2</sub> (which would inhibit further cellulose degradation), maintain anaerobiosis, and possibly provide essential nutrients for the protozoa which feed on them. Some of the bacteria are also important in the nitrogen economy of the termite. The termites' diet is often low in nitrogen, and the gut bacteria may play an important role by NITROGEN FIXATION and/or by recycling the nitrogen of uric acid produced in the termite tissues; uric acid is passed into the hindgut where it is used as an energy source by e.g. *Bacteroides*, *Citrobacter*, and *Streptococcus* spp, being fermented to NH<sub>3</sub>, CO<sub>2</sub> and acetate. (cf. RUMEN.) The gut microflora is also apparently involved in the degradation of other plant components (e.g. hemicelluloses, lignin), but the mechanisms are less well understood. [Review: Book ref. 77, pp. 173–203.]

In 'higher' termites (Termitidae) the hindgut contains a large population of bacteria [AEM (1985) 49 1226–1236] but no cellulolytic protozoa. Members of the subfamily Macrotermitinae 'cultivate' a fungus (*Termitomyces* sp) in *fungus combs* analogous to the FUNGUS GARDENS of the parasol ants; the termites construct a comb from small fragments of plant tissue and termite faeces, and the surface of this comb becomes covered with a sparse fungal mycelium which develops numerous white, spherical nodules (*mycotêtes* or *gongylidia*) 0.5–2.0 mm in diameter. The termites feed on these nodules and on the comb itself; fungal cellobiohydrolases (exoglucanases – see CELLULASES) consumed with the nodules are used in the digestion of cellulose components in the diet [Book ref. 77, pp. 156–161]. When new termite

colonies are established, the inoculum of *Termitomyces* necessary for establishing a new fungus comb may be either carried (as conidia) in the guts of the winged insects (e.g. in *Macrotermes bellicosus*, *Microtermes* spp) or collected (as basidiospores) by foraging workers (e.g. in *Macrotermes subhyalinus*, *Ancistrotermes*, *Odontotermes*).

(See also INSECT-MICROBE ASSOCIATIONS.)

**Termitomyces** A genus of white-rot fungi (family Amanitaceae) found only in certain termite nests (see TERMITE-MICROBE ASSOCIATIONS).

**ternary combination** In NOMENCLATURE: a designation which consists of a binomial together with a subspecific epithet – see e.g. SUBSPECIES. (cf. TRINOMIAL.)

**ternary fission** An asexual reproductive process in which more than two cells are formed from one cell (cf. BINARY FISSION); ternary fission occurs e.g. in PELODICTYON.

**terramycin** See TETRACYCLINES.

**Terrazole** See ETRIDIAZOLE.

**terregens factor** See SIDEROPHORES.

**terricolous** Growing on soil, peat, sand etc.

**tertian malaria** See MALARIA.

**Teschen disease** A PIG DISEASE caused by a porcine ENTEROVIRUS; it occurs e.g. in Central Europe and is named after the Teschen (Cieszyn) district of (the former) Czechoslovakia. Symptoms include fever followed by signs of encephalomyelitis: incoordination, tremors, convulsions and paralysis; the virus can be isolated from the faeces of infected pigs. The mortality rate may be 70% or higher, death occurring in 3–4 days. The disease may be controlled by slaughter or by vaccination using a live, attenuated vaccine. (cf. Talfan Disease.)

**tesla (T)** A unit of magnetic flux density; 1 tesla = 10000 gauss.

**TESPA** See AAS.

**test** (*protozool.*) (1) A close-fitting protective 'shell' which surrounds the cell e.g. in certain (testate) amoebae; the test may be predominantly or entirely organic (as in e.g. ARCELLA) or may incorporate inorganic materials such as sand grains (e.g. DIFFLUGIA), silica (e.g. EUGLYPHA), etc. (See also FORAMINIFERIDA.) (2) *Syn.* LORICA.

**test medium** See MEDIUM.

**Testacealobosia** A subclass of testate amoebae (see ARCELLINIDA and TRICHOSIDA). (cf. GYMNAMOEBIA.)

**testate** Possessing a TEST.

**testosterone synthesis** See STEROID BIOCONVERSIONS.

**Tet protein** See TETRACYCLINES.

**tetA gene** See TETRACYCLINES.

**tetaine** *Syn.* BACILYSIN.

**tetanolysin** A THIOL-ACTIVATED CYTOLYSIN produced by *Clostridium tetani*; it is distinct from TETANOSPASMIN.

**tetanospasmin** (tetanus toxin) A plasmid-encoded neurotoxin, produced by *Clostridium tetani*, which causes the symptoms of TETANUS.

Tetanospasmin is a single polypeptide of ~150 kDa. Activation involves proteolytic cleavage to form a di-chain structure consisting of an H chain (~100 kDa) and an L chain (~50 kDa) held together by a disulphide bond.

The activated toxin binds, via the H chain, to specific sites on the cell membrane of a neurone at the nerve-muscle junction; receptor sites on the membrane may include (i) polysialogangliosides and (ii) a specific protein.

Surface-bound toxin is internalized by uptake within a vesicle. Toxin-containing vesicles are then translocated back along the axon to interneurons in the spinal cord. According to one model, release of the active component (the L chain) occurs after

acidification of the vesicle has brought about a conformational change in the H chain; the H chain may then insert into the vesicle's membrane and bring about the translocation of the L chain from the vesicle to the cytoplasm of the neurone. Reduction of the disulphide bond then releases the active toxin.

Normally, in the absence of toxin, contraction of a given muscle stimulates the interneurons to release an inhibitory neurotransmitter (?glycine) which prevents contraction of the corresponding antagonist muscle. Neurotransmitter, present in vesicles within the interneurone, is released into the (extracellular) synaptic cleft by a process in which the vesicles first 'dock' at specific sites on the (inner) surface of the cell's membrane and then fuse with the membrane (= *exocytosis* or *neuroexocytosis*); this process is triggered by appropriate electrical stimulation and the resulting intracellular rise in levels of  $Ca^{2+}$ .

During neuroexocytosis, docking and fusion of vesicles involves specific interaction between molecules in the vesicle membrane and others at the inner surface of the neurone's membrane. These molecules include VAMP/synaptobrevin (VAMP = vesicle-associated membrane protein), and (on the neurone's membrane) SNAP-25 and syntaxin.

Tetanus toxin acts as a zinc-endopeptidase which recognizes and cleaves a specific molecule required for vesicle-docking in neuroexocytosis, i.e. it prevents the docking of vesicles and (thus) inhibits the release of neurotransmitter to the synaptic cleft. Absence of the *inhibitory* neurotransmitter permits simultaneous contraction of both protagonist and antagonist muscles in a given pair, thus giving rise to spastic (rigid) paralysis. The target for tetanus toxin is apparently VAMP/synaptobrevin.

Tetanus toxin is also able to act peripherally, at the nerve-muscle junction, giving rise to a local, flaccid, paralysis.

[Mechanism of action of tetanus neurotoxin: Mol. Microbiol. (1994) 13 1-8.]

**tetanus** (lockjaw) An acute disease, affecting man and animals, caused by toxigenic strains of *Clostridium tetani*. The disease develops when *C. tetani* contaminates wounds or other lesions, especially those which have become anaerobic due e.g. to necrosis or to infection with other bacteria; common sources of *C. tetani* are faeces and soil. The incubation period may be days or weeks; short incubation periods correlate with high mortalities, and vice versa. Symptoms – caused by TETANOSPASMIN – may begin with stiffness or spasms of the jaw muscles, typically followed by a generalized tetanus: movements or external stimuli (e.g. noise) trigger violent, painful, convulsive spasms of the muscles in the trunk and limbs, and there is a characteristic contorted facial expression (*risus sardonicus*). Death may result from asphyxia or exhaustion. Less common forms of the disease include *local tetanus* (rigidity and increased muscle tone in the vicinity of the infected wound) and *cephalic tetanus* (in which certain cranial nerves become paralysed, usually following infection of a head lesion). *Treatment* may involve e.g. administration of (preferably human) antitoxin, anticonvulsant drugs, and/or neuromuscular blockade. Antitoxin may also be used for short-term prophylaxis; longer-term (but still temporary) protection is achieved by vaccination with tetanus TOXOID. (cf. DPT and TABT.)

**tetanus toxin** TETANOSPASMIN. (cf. TETANOLYSIN.)

**tethering** (of leukocytes) See INFLAMMATION.

**tetracyclines** A family of broad-spectrum ANTIBIOTICS whose structure is based on the naphthacene skeleton (see figure); they are produced by species of *Streptomyces* (e.g. *S. aureofaciens*, *S. rimosus*) and/or made semi-synthetically.

The tetracyclines are used primarily as antibacterial (bacteriostatic) agents in the treatment of human and animal diseases

TETRACYCLINES: tetracycline ( $R_1, R_2 = H$ ), chlortetracycline ( $R_1 = H, R_2 = Cl$ ), and oxytetracycline ( $R_1 = OH, R_2 = H$ ).

caused e.g. by species of *Brucella*, *Chlamydia*, *Mycoplasma*, *Rickettsia* and *Vibrio*. (Tetracyclines have also been used against certain plant diseases – e.g. COCONUT LETHAL YELLOWING and FIREBLIGHT.)

In most or all susceptible bacteria, tetracyclines are taken up in an energy-dependent manner. The drugs bind to ribosomes, inhibiting PROTEIN SYNTHESIS by inhibiting the binding of aminoacyl-tRNA complexes to the A site on the 30S ribosomal subunit. It appears that only one drug molecule per ribosome is sufficient for inhibition; in *Escherichia coli* tetracyclines bind preferentially to protein S7 near the A site.

*Bacterial resistance to tetracyclines.* Resistance to tetracyclines can arise in several distinct ways, and resistance to one of the drugs commonly means resistance to most or all of them.

Resistance may involve bacterial modification (i.e. detoxification) of the drugs, but this appears to occur only rarely.

In another mechanism, the Tet(M) protein appears to interact with the machinery of protein synthesis, reducing the influence of tetracyclines on aminoacyl-tRNA-ribosome binding [JB (1993) 175 7209-7215]. (The Tet(M) protein is encoded by gene *tet(M)*; *tet(M)* occurs in all conjugative transposons (see CONJUGATIVE TRANSPOSITION) from pathogenic species.)

Resistance can be due to an EFFLUX MECHANISM. For example, in some strains of *Escherichia coli* an inducible protein in the cytoplasmic membrane, Tet, appears to pump tetracycline outwards into the periplasm [JB (1995) 177 998-1007]; the gene encoding this pump (*tetA*) is found e.g. in transposon Tn10. (See also Tn1721.) Resistance determinants may also be carried on R PLASMIDS.

[Tetracycline resistance: FEMS Reviews (1996) 19 1-24.]

A tetracycline referred to as 'GAR-936' (the 9-*t*-butylglycylamido derivative of minocycline) has been designed with the object of evading bacterial defences, including efflux [in vitro and in vivo antibacterial activities of GAR-936: AAC (1999) 43 738-744].

*Clinically useful tetracyclines.* These include e.g. *chlortetracycline* (aureomycin); 7-chlorotetracycline; *demeclocycline* (declomycin, demethylchlortetracycline); 6-demethyl-7-chlorotetracycline; *doxycycline* (vibramycin); 5-hydroxy-6-deoxytetracycline; *methacycline* (rondomycin); 6-demethyl-6-deoxy-5-hydroxy-6-methylenetetracycline; *minocycline*: 6-demethyl-6-deoxy-7-dimethylaminotetracycline; *oxytetracycline* (terramycin); 5-hydroxytetracycline; and *tetracycline* (achromycin, polycycline, tetramycin): see figure. These tetracyclines differ mainly in lipophilicity, the more lipophilic members being more readily absorbed via the gastrointestinal tract.

**tetrad** A group of four – e.g. four cells (particularly a regular arrangement of four cocci), or the four chromatids of a bivalent in MEIOSIS.

**tetra-*O*-di(biphytanyl) diglycerol** See ARCHAEA.

## **Tetragoniomyces**

**Tetragoniomyces** A genus of fungi which have been placed in the order TREMELLALES [CJB (1981) 59 1034–1040]. *T. uliginosus* forms structures referred to as basidia, each of which gives rise, *internally*, to four cells that may be regarded as spores [BBMS (1983) 17 82–94 (92)] – although these cells are not described as basidiospores in the original genus description.

**tetrahydrofolic acid** See FOLIC ACID.

**tetrahydromethanopterin** See METHANOGENESIS.

**tetrahydrosarcinapterin** See METHANOGENESIS.

**Tetrahymena** A genus of ciliate protozoa (order HYMENOSTOMATIDA); species occur in various freshwater habitats, and some are endoparasitic in metazoa. Of the many species, *T. pyriformis* has been studied extensively; this organism can be grown in a sterile, defined medium (yielding an axenic culture) and its cell division can be readily synchronized (see SYNCHRONOUS CULTURE).

*T. pyriformis* is commonly pear-shaped, ca. 50 µm in length (range ca. 30–80 µm) with a uniform somatic ciliature of some 15 to 26 longitudinal kineties. One micronucleus and one macronucleus are commonly present, but amiconucleate strains are known. A contractile vacuole lies near the blunt posterior end, and the cytoproct is also posterior. Trichocysts are not formed. Fine structural details differ among the various SYNGENS. The cytostome is lateral, near the tapered anterior end; the buccal cavity contains one undulating membrane (= PARORAL MEMBRANE) on the right, and a group of three membranelles (AZM) on the left – an arrangement referred to, in other organisms, as ‘tetrahymenal’. *Microstome* strains have a small buccal cavity; *macrostomes* have a large buccal cavity. The growth requirements of *T. pyriformis* include FOLIC ACID, LIPOIC ACID, NICOTINIC ACID, PANTOTHENIC ACID, PYRIDOXINE, RIBOFLAVIN and THIAMINE. Cultures can be kept viable at –196°C by the use of a cryoprotectant (e.g. DMSO). (See also BIOASSAY.)

**tetramethyl-*p*-phenylenediamine** See TMPD.

**tetramethylsilane (TMS)** See NUCLEAR MAGNETIC RESONANCE.

**Tetramitus** A genus of amoeboflagellates of the SCHIZOPYRENIDA; the flagellate stage has four flagella and a cytostome-like opening.

**tetramycin** See TETRACYCLINES.

**Tetramyxa** See PLASMIDIOPHOROMYCETES.

**tetraphenylborate** See CHEMIOSMOSIS.

**tetrapolar heterothallism** See HETEROTHALLISM.

**tetrapyrrole** See e.g. PORPHIN, PHYCOBILIPROTEINS, VITAMIN B<sub>12</sub>, and METHANOGENESIS (factor 430).

**Tetraselmis** A genus of unicellular, quadriflagellate, marine and freshwater green algae (division CHLOROPHYTA); the genus currently includes the former genera *Platymonas* and *Prasinocladus*. The cell has a THECA (sense 1), and the flagella – which arise from a deep pit at the anterior end of the cell – bear minute scales. The interzonal mitotic spindle is not persistent. (cf. MICROMONADOPHYCEAE.) Sexual reproduction is unknown. (See also CONVOLUTA.) [Batch and continuous culture of the marine species *T. suecica*: Wat. Res. (1985) 19 185–190.]

*Tetraselmis* (formerly a member of the PRASINOPHYCEAE) is a genus in the order Tetraselmidales of the class Pleurostrophyceae [Book ref. 123, pp. 29–72]. (cf. TREBOUXIA.)

**Tetraspora** A genus of freshwater green algae (division CHLOROPHYTA) which are apparently closely related to CHLAMYDOMONAS spp. The vegetative stage is a colony of non-motile cells embedded in a gelatinous matrix (a ‘tetrasporal’ or ‘palmelloid’ colony: cf. PALMELLOID PHASE). In some species the cells bear characteristic long flagellum-like (but motionless) *pseudocilia*; these are similar in structure to the eukaryotic FLAGELLUM but lack one

or both of the central microtubules of the axoneme. Biflagellate isogametes are released from the colonies.

**tetrasporal colony** See TETRASPORA.

**tetraspore** A type of spore which develops in groups of four.

**tetrasporic** Of a coccidian oocyst: containing four sporocysts.

**tetra-tetra dimers** (in peptidoglycan) See PEPTIDOGLYCAN (figure legend).

**tetrathionate broth** A medium containing peptone, bile salts, sodium thiosulphate, and CaCO<sub>3</sub>; immediately before use, iodine (in KI solution) is added (to convert thiosulphate, S<sub>2</sub>O<sub>3</sub><sup>2-</sup>, to tetrathionate, S<sub>4</sub>O<sub>6</sub><sup>2-</sup>), after which the medium should not be heated. [Recipe: Book ref. 47, p. 666.] It is used e.g. for the enrichment of salmonellae, although *Proteus* spp also grow well in it.

**tetrazoic** Of a coccidian oocyst: containing four sporozoites per sporocyst.

**tetrazolium** Tetrazolium salts – e.g. nitroblue tetrazolium (NBT), 2,3,5-triphenyltetrazolium chloride (TTC, = tetrazolium red) – can be reduced to coloured formazan compounds, each salt being reduced at a specific REDOX POTENTIAL. Tetrazolium salts have a wide range of applications as redox indicator dyes. For example, they may be used to demonstrate reducing microenvironments generated as a result of microbial activity: e.g., regions of concentrated bacterial growth on the surfaces of meat or other foods may be demonstrated by the development of a colour in these regions following treatment with a tetrazolium salt solution. (Reduction of tetrazolium salts may be prevented by low pH and hence may not occur in the presence of fermentative organisms.) NBT reduction in the cytoplasm of NEUTROPHILS (resulting in the formation of bluish-black granules) is indicative of a normal ‘metabolic burst’ associated with PHAGOCYTOSIS, and is used in a test for normal neutrophil function [test: Book ref. 53, pp. 1255–1256]. TTC is used in commercial kits for the diagnosis of bacteriuria, TTC reduction being taken as indicative of the presence of significant numbers of actively metabolizing bacteria.

**tetronomycin** See MACROTETRALIDES.

**tetrose** A 4-carbon sugar (e.g. ERYTHROSE).

**Texas fever** *Syn.* REDWATER FEVER.

**Texas red** Sulphorhodamine 101 acid chloride: a FLUOROCHROME (excitation at ca. 568 nm) used e.g. in FLOW CYTOMETRY.

**Tex-KL bacterium** *Legionella dumoffii*.

**textile spoilage** Textiles made from vegetable (cellulosic) fibres – e.g. cotton, linen, hessian (cf. RETTING) – are susceptible to attack by a range of cellulolytic fungi (e.g. *Aspergillus* spp, *Chaetomium globosum*, *Cladosporium herbarum*), especially under damp conditions, resulting in loss of strength and flexibility of the fabric, odour production, discoloration, etc. *Zalerion* spp can cause rotting of twines and ropes exposed to seawater. Preservatives for textiles (usually for outdoor use) include e.g. copper (or zinc) naphthenate, copper-oxine, cuprammonium hydroxide, dichlorophane, SALICYLANILIDES. (See also WOOL SPOILAGE.)

**Textularia** See FORAMINIFERIDA.

**Textulariina** See FORAMINIFERIDA.

**TF<sub>0</sub>F<sub>1</sub>H<sup>+</sup>-ATPase** See PROTON ATPASE.

**TFT** TRIFLUOROTHYIMIDINE.

**TGE** TRANSMISSIBLE GASTROENTERITIS.

**T<sub>h</sub> (T<sub>H</sub>) (immunol.)** Helper T cell (see T LYMPHOCYTE).

**Th1 T cells** See T LYMPHOCYTE.

**Th2 T cells** See T LYMPHOCYTE.

**Thalassicolla** See RADIOLARIA.

**Thalassiophyllum** See PHAEOPHYTA.

**Thalassiosira** See DIATOMS.

**thalidomide** (as therapy for mycobacterial and HIV infections)

See INTERFERONS.

**thallic conidiogenesis** See CONIDIUM.

**thalline** (1) Of or pertaining to a THALLUS. (2) *Syn.* SOMATIC (sense 1).

**thalline margin** (excipulum thallinum) (*lichenol.*) In a LECANORINE APOTHECIUM: *lichenized* tissue (i.e., tissue containing both algal and fungal cells) external to (surrounding, and sometimes obscuring) the PROPER MARGIN; the thalline margin is generally the same colour as the thallus, but may differ in colour from the hymenial disc.

**thallium salts** (inhibitory action) Low concentrations of thallium salts (e.g. 0.01% thallos acetate) inhibit the growth of many species of bacteria. Some species of *Mycoplasma* are not inhibited, and thallos acetate is used in a selective medium for the primary isolation of these organisms. (Thallium salts inhibit the growth of *M. genitalium*, some strains of *M. hominis*, and the related organism, *Ureaplasma urealyticum*.)

**Thallobacteria** A proposed class of bacteria (division FIRMICUTES) comprising branching, thread-like organisms (ACTINOMYCETES and related organisms) [Book ref. 22, p. 33]. (cf. e.g. THERMOACTINOMYCES.)

**Thallophyta** A division of the plant kingdom containing those organisms whose vegetative form is a thallus, i.e., the fungi, algae etc.

**thallose** Consisting of or resembling a thallus.

**thallospore** (*mycol.*) Any SPORE formed by fragmentation of part or all of a fungal thallus – e.g. an ARTHROSPORE, CHLAMYDOSPORE or OIDIUM.

**thallus** A vegetative form of an organism which is not differentiated into stem and leaves, as in fungi, algae and lichens.

**THAM** See TRIS.

**Thamniaceae** See MUCORALES.

**Thamnidium** See MUCORALES.

**Thamnocephalis** See MUCORALES.

**Thamnozia** A genus of fruticose LICHENS; photobiont: a green alga. The thallus is hollow and may be erect or prostrate; fruiting structures are unknown.

**Thanatephorus** See TULASNELLALES.

**Thauera selenatis** See SELENATE RESPIRATION.

**Thayer–Martin agar** (VCN agar) An enriched growth medium containing vancomycin, colistin and nystatin; it is used for the selective culture of *Neisseria* spp from swabs taken e.g. from the genitourinary tract. For culture of rectal swabs, trimethoprim may be added to suppress swarming by *Proteus* spp. [Recipe: Book ref. 2, p. 138.]

**theca** (1) In certain algae of the Chlorophyta: a type of cell 'wall' which lacks the microfibrillar structure typical of a true algal CELL WALL, being composed of very small, more or less isodiametric units or scales; such thecae appear to have evolved as modifications of scaly coverings, and occur in certain flagellates (e.g. TETRASELMIS). [Book ref. 123, p. 31.]

(2) See DINOFLAGELLATES.

**Thecamoeba** See AMOEBIDA.

**thecate** Possessing a THECA.

**thecium** An ambiguous term which can refer e.g. to the HYMENIUM of an ascomycete or to the entire ascocarp.

**Theileria** A genus of protozoa (subclass PIROPLASMASINA) parasitic in animals and transmitted by ticks (see EAST COAST FEVER for life cycle); *Theileria* spp infect both red and white blood cells of the vertebrate host (cf. BABESIA). The cells resemble those of *Babesia* but are typically smaller. [Characterization of some East African *Theileria* species by isoenzyme analysis: IJP (1985) 15 271–276.]

**Theiler's murine encephalomyelitis virus** (TMEV; or murine poliovirus) A murine ENTEROVIRUS. TMEV strains are common in mice; infection is usually asymptomatic, but occasional individuals develop flaccid paralysis of the hind limbs ('mouse poliomyelitis'). Young mice injected intracerebrally with TMEV may develop a chronic inflammatory demyelinating disease; in nu/nu mice demyelination apparently results from lytic infection by TMEV of oligodendrocytes, and is independent of functional T cells [Lab. Inv. (1986) 54 515–522] (cf. MULTIPLE SCLEROSIS).

**Thelidium** See VERRUCARIALES.

**Thelohanelius** See MYXOSPOREA.

**Thelohania** A genus of protozoa (class MICROSPOREA) which are parasitic e.g. in mosquitoes (e.g. *T. legeri* in anophelines, *T. opacita* in culicines), in shrimps, etc.

**Thelotrema** See GRAPHIDALES.

**2-thenoyltrifluoroacetone** See TTFA.

**theophylline** 1,3-Dimethyl-2,6-dihydroxypurine – a specific phosphodiesterase inhibitor.

**therapeutic index** For a given drug, the ratio maximum tolerated dose/minimum effective dose; medically useful drugs should ideally have a high therapeutic index.

**thermal cycler** See THERMOCYCLER.

**thermal death point** The lowest temperature at which a single-species population of microorganisms, in neutral aqueous suspension, can be heat-killed in ten minutes; thermal death point depends e.g. on the size of the population.

**thermal death time** ( $t_D$ ) The time required, at a given temperature, for the heat-killing of a single-species population of microorganisms – or of a given proportion of that population – in aqueous suspension;  $t_D$  depends e.g. on the size of the population and on the pH of the suspension.

**thermal inactivation point** (TIP) (*virol.*) The temperature at which a virus preparation must be held for 10 min in order to inactivate all the viruses. For many plant viruses the TIP is 50–60°C; for e.g. tobacco mosaic virus it is >90°C.

**thermal melting profile** (of DNA) A plot of UV absorption against temperature for a given sample of dsDNA. The absorption of UV radiation (at 260 nm) by two single strands of DNA is about 40% greater than that by the same strands united in a double helix. dsDNA is progressively converted to ssDNA as the temperature increases (from a value which depends e.g. on the ionic strength and pH of the solution and on the solvent used); this conversion results in a corresponding increase in the level of UV absorption. The thermal melting profile is essentially linear between minimum absorption (all dsDNA) and maximum absorption (all ssDNA); the temperature corresponding to the midpoint between these two extremes is the  $T_m$  (=  $T_m$ ). The  $T_m$  (typically ca. 85–95°C) depends on the proportion of GC pairs in the DNA – GC pairs, having three hydrogen bonds, being more stable than AT pairs which have only two. (See also GC%.) In the presence of a reagent (e.g. formamide) which destabilizes hydrogen bonds, the  $T_m$  is greatly reduced, and this allows strand separation to occur at much lower temperatures (e.g. 40°C); under these conditions much of the damage to the DNA which may occur at high temperatures can be avoided.

**thermine** See POLYAMINES.

**Thermoactinomyces** A genus of (typically) thermophilic bacteria which occur e.g. in composts, soil and sediments. The organisms form substrate and aerial mycelium and, for this reason, were classified (on a morphological basis) in the order ACTINOMYCETALES; however, the organisms form endospores and have a relatively low GC% (ca. 53), and these features, together with e.g. rRNA oligonucleotide cataloguing data, indicate that

## **Thermoascus**

*Thermoactinomyces* spp have an affinity with genera such as *Bacillus*. Endospores are formed in both aerial and substrate mycelium; they occur singly, though a given hypha may contain many individual endospores. *T. vulgaris* (syn. *T. candidus*) has been associated with FARMERS' LUNG, while *T. sacchari* has been implicated in BAGASSOSIS. Type species: *T. vulgaris*.

**Thermoascus** A genus of fungi of the order EUROTIALES; anamorphs occur e.g. in the genus PAECILOMYCES. [Ascomorph morphology and development: TBMS (1981) 76 457–478.]

**Thermobacterium** See LACTOBACILLUS.

**Thermobacteroides** A genus of Gram-negative, obligately anaerobic, chemoorganotrophic, rod-shaped (non-motile or peritrichously flagellated) bacteria which have an optimum growth temperature within the range 55–70°C; growth does not occur below 35°C. [IJSB (1985) 35 425–428.]

**thermocline** Syn. METALIMNION.

**Thermococcus** A genus of anaerobic, marine and freshwater archaeans (order THERMOPROTEALES) which metabolize peptides and sugars, growth being stimulated by the reduction of sulphur; growth occurs optimally >75°C. Cells: cocci, ca. 1 µm diam. *T. celer* is polarly flagellate. GC%: ca. 40–60%.

[Strains of *Thermococcus* from sites in the Pacific Ocean: FEMS Ecol. (2001) 36 51–60.]

**thermocycler** (thermal cycler) An instrument used in certain nucleic-acid-amplification techniques (LCR and PCR) for automatically making the cyclical changes in temperature. Such instruments can simultaneously process a number of reaction mixtures and can usually be programmed for any of a range of time/temperature protocols.

The way in which reaction mixtures are heated and cooled is based on one of two methods. In the Peltier system, each reaction mixture is processed in a thin-walled tube which fits snugly in a hole in a metal block; temperature cycling involves heating and cooling the block according to the particular protocol. Cycling times are affected by the rate at which the block can be heated and cooled; in one commercial instrument, heating can occur at a rate of up to 3°C/second while the maximum rate of cooling is ~2°C/second. In these (open-tube) methods the problem of evaporation (loss of sample) is tackled in two ways. One approach involves the use of an oil overlay. Another solution is to use a *heated lid* cycler in which a temperature of up to 120°C is maintained over the sample tubes.

Alternatively, the sample may be sealed into a capillary glass tube which is heated and cooled by means of a forced air current; in the LightCycler™ (Roche), the air temperature around each tube can be changed at a rate of 20°C/second, permitting rapid cycling.

Some instruments (including the LightCycler) incorporate a system for detecting and/or quantifying the products of amplification.

**Thermodiscus** A genus of prokaryotes of the order THERMOPROTEALES. Cells: disc-shaped, ca. 0.3–3.0 µm diameter, ca. 0.2 µm thick.

**thermoduric** (thermotolerant) Refers to an organism which can survive temperature–time combinations that are normally lethal for many or most vegetative microorganisms. In dairy microbiology the term refers to those organisms which survive PASTEURIZATION (e.g., many strains of *Microbacterium* can survive 70–80°C/15 minutes). (See also THERMOPHILE.)

**Thermofilum** A genus of chemolithoheterotrophic prokaryotes (order THERMOPROTEALES) which occur in Icelandic solfataras; the organisms metabolize e.g. peptides. Cells: rods or filaments, ca. 0.2 × 5–100 µm. *T. pendens* is non-flagellated. GC% ca. 57.

**thermolysin** A heat-stable, neutral metallo-PROTEASE (EC 3.4.24.4) produced by a strain of *Bacillus stearothermophilus* ('*B. thermoproteolyticus*'). It is the most heat-stable protease available commercially, retaining 50% activity after 1 hour at 80°C. Thermolysin contains zinc and four Ca<sup>2+</sup> ions/molecule. It has a broad specificity.

**Thermomicrobium** A genus (*incertae sedis*) of aerobic, catalase-positive, chemoorganotrophic, thermophilic, Gram-negative bacteria which occur e.g. in hot springs. Cells: non-motile, pleomorphic, pink-pigmented rods, ca. 1.3–1.8 × 3.0–6.0 µm. Optimum growth temperature: 70–75°C; optimum pH: 8.2–8.5. GC%: 64. Type species: *T. roseum*. [Book ref. 22, pp. 338–339.]

**Thermomonospora** A genus of (typically) thermophilic bacteria (order ACTINOMYCETALES, wall type III) which occur e.g. in soil and composts. The organisms form branching substrate and aerial mycelium; of the five recognized species, *T. alba*, *T. curvata*, *T. fusca* and *T. mesophila* form white aerial mycelium, while *T. chromogena* forms yellowish-brown aerial mycelium. Spores are borne singly at the ends of short branched or unbranched sporophores on the aerial hyphae (or, in at least *T. fusca*, on both aerial and substrate mycelium). The organisms are metabolically versatile – e.g. *T. alba* and *T. curvata* can degrade agar, cellulose, and keratin, while *T. alba* can also degrade pectin. Type species: *T. curvata*. [Book ref. 73, pp. 119–121; taxonomy and identification: JGM (1984) 130 5–25.] (cf. ACTINOBIFIDA.)

**Thermomyces** See HYPHOMYCETES; see also COMPOSTING.

**thermonuclease** See DEOXYRIBONUCLEASE.

**thermophile** An organism whose optimum growth temperature is >45°C; this definition is widely used [see e.g. Book ref. 45, p. 236, and Book ref. 196, p. 40] and is compatible with the definition of MESOPHILE. (See also PSYCHROPHILE.) Many published ad hoc definitions of 'thermophile' are mutually incompatible, often because a given definition may be applicable in only a limited context; moreover, such definitions are frequently incompatible with the generally accepted upper limit of 'mesophile'.

Thermophiles occur e.g. in hot springs and other habitats (see e.g. COMPOSTING, LEACHING, HYDROTHERMAL VENT); they include e.g. species of METHANOCOCCUS, PYRODICTIUM, SULFOLOBUS, THERMOBACTEROIDES, THERMOFILUM, THERMOMICROBIUM, THERMOPLASMA, THERMOPROTEUS, THERMOTRIX and THERMUS.

A super-thermophile archaean, designated 'strain 121', has been cultured from samples taken from a HYDROTHERMAL VENT; it grows at 85–121°C [Science (2003) 301 934].

(See also CALDOACTIVE.)

**Thermoplasma** A genus of aerobic, heterotrophic prokaryotes (order THERMOPLASMALES, formerly class MOLLICUTES) which occur e.g. in hot springs and self-heating coal refuse piles. *T. acidophilum* grows on yeast extract at 50–64°C at a pH of 0.8–3.0. Cells: pleomorphic cocci, ca. 0.1–0.3 µm diameter, to filamentous. GC%: ca. 46. [Book ref. 157, pp. 88–91.]

**Thermoplasmales** An order of aerobic, thermophilic prokaryotes of the domain ARCHAEA (formerly Archaeobacteria) characterized by the absence of a cell wall. One genus: THERMOPLASMA.

**Thermoproteales** An order of thermophilic, anaerobic sulphur-dependent prokaryotes (domain ARCHAEA, formerly Archaeobacteria) which occur e.g. in hot springs; growth is typically chemolithoautotrophic and/or chemolithoheterotrophic. Cells: cocci, rods or irregularly shaped forms, the cell wall typically being a detergent-resistant S LAYER. Genera: DESULFUROCOCCUS, PYRODICTIUM, THERMOCOCCUS, THERMODISCUS, THERMOFILUM and THERMOPROTEUS.

**Thermoproteus** A genus of thermophilic prokaryotes (order THERMOPROTEALES) found e.g. in Icelandic solfataras. Cells: rods or filaments, ca.  $0.5 \times 1\text{--}80 \mu\text{m}$ . Chemolithoautotrophic and/or chemolithoheterotrophic, according to species; heterotrophs use e.g. ethanol, formate, glucose, methanol, sucrose. Energy is obtained by SULPHUR RESPIRATION. Species include *T. neutrophilus* (obligate autotroph) and *T. tenax* (facultative autotroph). GC%: ca. 55–56.

**thermospermine** See POLYAMINES.

**thermotaxis** A TAXIS in which the stimulus is a temperature gradient.

**thermotherapy** (*plant virol.*) See PLANT VIRUSES.

**Thermothrix** A genus of thermophilic bacteria. *T. thiopara* is a facultatively anaerobic, rod-shaped or filamentous organism which occurs in hot springs ( $45\text{--}75^\circ\text{C}$ ); it is facultatively chemolithoautotrophic, electron donors including e.g. sulphide and elemental sulphur. [Ecology and metabolism: AAM (1986) 31 233–270.]

**Thermotoga** See BACTERIA (taxonomy).

**Thermotogales** See BACTERIA (taxonomy).

**thermotolerant** *Syn.* THERMODURIC.

**Thermus** A genus (*incertae sedis*) of aerobic, chemoorganotrophic, thermophilic, Gram-negative bacteria which occur e.g. in hot springs. Cells: non-motile rods,  $0.5\text{--}0.8 \times 5.0\text{--}10.0 \mu\text{m}$ , or filaments, which typically contain yellow, orange or red carotenoid pigments and novel POLYAMINES. The cell ultrastructure resembles that of other Gram-negative bacteria, but the 'outer wall' (external to the peptidoglycan layer) seems to be more substantial than the typical outer membrane of Gram-negative cells; the peptidoglycan lacks DAP, contains ornithine, and has a high proportion of glycine and glucosamine. Most strains give rise to 'rotund bodies': membrane-enclosed spherical aggregates of cells (average: 14 cells per aggregate), ca.  $10\text{--}20 \mu\text{m}$  in diameter; the limiting membrane of a rotund body is formed by fusion of the outer walls of adjacent cells at the periphery of the body, the inward-facing surface of these cells lacking an outer wall. Metabolism is respiratory (oxidative), with  $\text{O}_2$  as terminal electron acceptor. Carbon sources include e.g. sugars and organic acids; nitrogen sources: e.g.  $\text{NH}_4^+$ , amino acids. Optimum growth temperature: ca.  $66\text{--}75^\circ\text{C}$ ; optimum pH: ca. 7.0. Oxidase +ve. Catalase +ve GC%: ca. 61–71. Type species: *T. aquaticus*. [Book ref. 22, pp. 333–337.] [Proposed species – *T. ruber* (revised name): IJSB (1984) 34 498–499.]

**theront** In the polymorphic life cycles of certain protozoa: a cell which 'searches for' or 'hunts' a new host organism or a source of food; see e.g. ICHTHYOPHITHIRIUS.

$\theta$  See TEMPERATURE COEFFICIENT.

$\theta$  (**theta**) replication *Syn.* CAIRNS' MECHANISM.

**THF** TetrahydroFOLIC ACID.

**thiabendazole** 2-(4'-Thiazolyl)-benzimidazole. Originally used as an anti-helminthic agent, thiabendazole is now regarded as an efficient fungicide and is used e.g. to protect against seed-borne smuts and bunts of cereals, and to prevent rots of stored fruit and vegetables. Thiabendazole has been widely used as the principal agent for the protection of stored citrus fruit against *Penicillium digitatum* and *P. italicum*; however, thiabendazole-resistant strains of these and other citrus rot fungi have emerged [Book ref. 121, pp. 149–162].

(See also BENZIMIDAZOLES; GANGRENE (sense 2); SPORIDESMINS.)

**thiacetazone** See THIOSEMICARBAZONES.

**thiamine** (thiamin; vitamin  $\text{B}_1$ ; aneurin) A water-soluble VITAMIN: 3-(2-methyl-4-amino-5-pyrimidinylmethyl)-5-( $\beta$ -hydroxyethyl)-4-methylthiazole (see figure); the molecule carries a net

positive charge and is usually supplied commercially as thiamine chloride hydrochloride ('thiamine hydrochloride'). The coenzyme form is *thiamine pyrophosphate* (TPP, cocarboxylase). TPP functions in decarboxylation reactions (e.g. pyruvate  $\rightarrow$  acetaldehyde); in oxidative decarboxylations – e.g. (in conjunction with LIPOIC ACID) of pyruvate and 2-oxoglutarate [see Appendix II(a)]; in  $\alpha$ -ketol formation – e.g. acetoin formation [Appendices III(c) and III(f)]; in transketolase and phosphoketolase reactions [Appendices I(b) and III(b), respectively]; etc.

THIAMINE

Microorganisms which require exogenous thiamine (or one or both of the pyrimidine and thiazole precursors) include e.g. *Euglena* spp, certain fungi (e.g. *Phycomyces blakesleeianus*, *Phytophthora* spp, *Trichophyton* spp, many yeasts), some bacteria (e.g. *Lactobacillus* spp, *Leuconostoc* spp, *Staphylococcus aureus*), and various protozoa (e.g. *Acanthamoeba castellanii*, *Crithidia fasciculata*, *Tetrahymena* spp).

**Thielaviopsis** See HYPHOMYCETES; see also FOOTROT (sense 2).

**thienamycin** An antibiotic produced by *Streptomyces cattleya* and by *S. penemifaciens*; it is a CARBAPENEM (see  $\beta$ -LACTAM ANTIBIOTICS for structure) in which  $\text{R}' = \text{CH}_3\cdot\text{CHOH}$  and  $\text{R}'' = \text{NH}_2\cdot(\text{CH}_2)_2\cdot\text{S}$ . Thienamycin binds to the PENICILLIN-BINDING PROTEINS of *Escherichia coli* (preferentially to PBP-2); it is highly active against Gram-positive and Gram-negative bacteria (including species of *Pseudomonas*) and is resistant to many  $\beta$ -LACTAMASES, but is chemically unstable. Many naturally occurring and semi-synthetic derivatives of thienamycin have been isolated; the *N*-formimidoyl derivative (*imipenem*; MK-0787) is less unstable than thienamycin, is resistant to many  $\beta$ -lactamases, has a similar level of activity against most bacteria, and is more active against *Pseudomonas* spp. [Imipenem (review): AIM (1985) 103 552–560.]

**Thiery staining** A procedure for detecting polysaccharides by electron microscopy.

**thigmotaxis** A TAXIS in which the stimulus is 'touch' (physical contact); an organism may move towards the contact (positive thigmotaxis) or away from it (negative thigmotaxis).

**thimerosal** *Syn.* THIOMERSAL.

**thin-layer chromatography** See CHROMATOGRAPHY.

**Thiobacillus** A genus of Gram-negative, obligately or facultatively chemolithoautotrophic (or mixotrophic) bacteria which occur e.g. in soil, marine muds, mine drainage and hot springs. The cells are typically polarly flagellated rods, ca.  $0.5 \times 1.0\text{--}3.0 \mu\text{m}$ . Most species obtain energy by oxidizing sulphur and/or reduced sulphur compounds (sulphide, sulphite and thiosulphate); in at least some cases *c-type* cytochromes are involved. GC%: ca. 50–68. Type species: *T. thioparus*.

*Thiobacillus* A2. See *T. versutus* (below).

*T. delicatus*. Non-motile. Facultative anaerobe. Capable of nitrate respiration. Electron donors: e.g. sulphide, thiosulphate. Optimum temperature:  $30\text{--}35^\circ\text{C}$ . Optimum pH: 5.5–6.0. [IJSB (1984) 34 139–144.]

## Thiocapsa

*T. denitrificans*. Electron donors: e.g. sulphide and thiosulphate. Under aerobic conditions oxygen is the electron acceptor; anaerobically, nitrate, nitrite or nitrous oxide can function as electron acceptor, and is reduced to nitrogen. Optimum pH: 6–8.

*T. ferrooxidans*. Aerobic; growth also occurs anaerobically with ferric ions as electron acceptor for the oxidation of reduced sulphur compounds. Electron donors include sulphur, thiosulphate, sulphide and ferrous ions. Capable of NITROGEN FIXATION. Optimum growth temperature: ca. 20°C. Growth occurs within the approximate pH range 1.4–6.0. (See also LEACHING.) [Molecular genetics of *T. ferrooxidans*: MR (1994) 58 39–55.]

*T. thiooxidans*. Electron donors include e.g. thiosulphate and (particularly) elemental sulphur. Optimum pH: ca. 2–4; growth occurs within the approximate range 0.5–6.0. Can cause RUBBER SPOILAGE. (See also LEACHING.)

*T. thioparus*. Motile rods. Electron donors include sulphide and thiosulphate; some strains can use thiocyanate (CNS<sup>-</sup>). A sulphur-containing pellicle may be formed on thiosulphate-containing liquid media. Nitrate is reduced to nitrite during anaerobic growth. Optimum growth temperature: ca. 28°C. Optimum pH: ca. 6–8; growth ceases below ca. pH 4.5.

*T. versutus* (formerly *Thiobacillus* A2). A species capable of chemolithoautotrophic or mixotrophic growth. Oxidation of organic substrates (but not inorganic sulphur compounds) can be coupled to the reduction of nitrate.

Other species include *T. intermedius* and *T. perometabolis* [IJSB (1984) 34 139–144], *T. acidophilus*, *T. neapolitanus*, *T. novellus* and *T. organoparus*.

[Media and culture: Book ref. 45, pp. 1023–1036.]

**Thiocapsa** A genus of photosynthetic bacteria (family CHROMATIACEAE). The cells are non-motile cocci; in addition to various carotenoids, *T. roseopersicina* (1.2–3.0 µm) contains Bchl *a*, and *T. pfennigii* (ca. 1.5 µm) contains Bchl *b* – cell suspensions typically being reddish and orange-brown, respectively. In *T. pfennigii* the pigments occur in tubular intracytoplasmic membrane systems. Gas vacuoles are absent. *T. roseopersicina* is moderately tolerant of organic pollution, and may give rise to reddish blooms in sewage lagoons; it is capable of chemoorganotrophic growth under microaerobic conditions in the dark.

**thioctic acid** *Syn.* LIPOIC ACID.

**Thiocystis** See CHROMATIACEAE.

**Thiodictyon** See CHROMATIACEAE.

**thioglycollate broth** See e.g. BREWER'S THIOGLYCOLLATE MEDIUM.

**thiol-activated cytolysins** (SH-activated cytolysins) A class of cytolysins, formed by certain bacteria, which are active only in the reduced state, and which can be (reversibly) activated by thiols; the cytolytic activity of these toxins is confined to those cells (including e.g. erythrocytes) whose cytoplasmic membrane contains cholesterol. Thiol-activated cytolysins are formed by species of the (Gram-positive) bacteria *Bacillus*, *Clostridium*, *Listeria* and *Streptococcus*. (A thiol-activated cytolysin was reported to be formed by the (Gram-negative) species *Klebsiella pneumoniae* [CJM (1985) 31 297–300].)

The thiol-activated cytolysins are proteins of ~47–60 kDa; they are optimally active at similar values of pH and temperature, they cross-react serologically, and their haemolytic activity is irreversibly lost in the presence of cholesterol or stereochemically related sterols.

The thiol-activated cytolysins are pore-forming agents. They bind reversibly, in a temperature-independent manner, to cholesterol-containing membranes, and oligomerize to form (typically) ring-shaped formations (pores in the membrane) of

up to ~40 nm in diameter. Oligomerization is temperature-dependent, activity being reduced at low temperatures.

Studies with animal models have indicated that at least some of the toxins (e.g. pneumolysin) can contribute to virulence.

The thiol-activated cytolysins include:

alveolysin (*Bacillus alvei*)

bifermentolysin (*Clostridium bifermentans*)

botulinolysin (*C. botulinum*)

cereolysin (*B. cereus*)

chouveolysin (δ-toxin of *C. chauvoei*)

histolyticolysin (ε-toxin of *C. histolyticum*)

ivanolysin (*Listeria ivanovii*)

laterosporolysin (*B. laterosporus*)

listeriolysin (*L. monocytogenes*)

oedematolysin (δ-toxin of *C. novyi*)

perfringolysin (θ-toxin of *C. perfringens*)

pneumolysin (*Streptococcus pneumoniae*)

seeligerolysin (*L. seeligeri*)

septicolysin (δ-toxin of *C. septicum*)

sordelliolysin (*C. sordelli*)

STREPTOLYSIN O (q.v.)

tetanolysin (*C. tetani*)

thuringiolysin (*B. thuringiensis*)

[Thiol-activated cytolysins: RMM (1996) 7 221–229.]

**thiol protease** See PROTEASES.

**thiomersal** (merthiolate; thimerosal) Sodium ethylmercurithiosalicylate, C<sub>2</sub>H<sub>5</sub>.Hg.S.C<sub>6</sub>H<sub>4</sub>.COONa. An antibacterial and antifungal agent used as a preservative e.g. in biological laboratory reagents; it is effective in low concentrations (e.g. 0.01–0.02%).

**Thiomicrospira** A genus of bacteria which occur e.g. in estuarine muds and in the vicinity of HYDROTHERMAL VENTS. Cells: curved or spiral rods; many strains are motile by means of a single polar flagellum. The organisms resemble THIOBACILLUS in general physiology. *T. denitrificans* and *T. pelophila* are both obligate chemolithotrophs. [Culture: Book ref. 45, pp. 1023–1036; *T. crunogena*, an obligately chemolithoautotrophic species from a hydrothermal vent: IJSB (1985) 35 422–424.]

**thionin** (Lauth's violet) A blue–purple dye structurally related to METHYLENE BLUE. (See also BRUCELLA.)

**Thiopeptida** See CHROMATIACEAE and COENOBIUM.

**thiopeptin** A peptide antibiotic related to THIOSTREPTON; it is active against e.g. *Streptococcus bovis*. Thiopeptin inhibits experimentally-induced lactic ACIDOSIS in ruminants.

**thiophanate-methyl** (1,2-bis(3-methoxycarbonyl-2-thioeido)benzene) An agricultural antifungal agent (see BENZIMIDAZOLES) which is effective e.g. against *Rhizoctonia solani* infections in seedlings, *Pyricularia oryzae* in rice, eyespot and *Rhynchosporium* infection in cereals, and black spot of roses; it also has some effect in controlling clubroot in crucifers.

**thiophene-2-carboxylic acid hydrazide test** *Syn.* T2H TEST.

**α-thiophosphoryl dATP** See SDA.

**Thioploca** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur e.g. in sulphide-containing muds (freshwater to marine). The organisms occur as sheathed fascicles, each fascicle (macroscopic in some species) consisting of a longitudinally arranged bundle of filaments; individual filaments (ca. 1–10 µm wide; wider in marine species) can glide in the sheath and emerge from it. In at least some species metabolism involves oxidation of sulphide. Sulphur is deposited intracellularly. Type species: *T. schmidlei*. Other species: e.g. *T. ingrica* from lake sediments [IJSB (1984) 34 344–345], *T. araucae*, *T. chilaeae* (marine benthic species) [IJSB (1984) 34 414–418].

Strains from a HYDROTHERMAL VENT have vacuoles that seem not to be involved in the accumulation of nitrate for use in anoxic conditions [AEM (2004) 70 7487–7496].

**thioredoxin** A heat-stable 109-amino-acid protein which occurs ubiquitously in cells; in *Escherichia coli* it is encoded by the *trxA* gene. Thioredoxin functions as a hydrogen donor e.g. for the reduction of ribonucleotides by ribonucleotide reductase (see nucleotide), in assimilatory sulphate reduction, in the reduction of thiol groups in proteins, etc; the active site of the oxidized form of thioredoxin contains a disulphide bridge between two cysteine residues, and this disulphide bridge can be reduced by the enzyme thioredoxin reductase, using NADPH as hydrogen donor. Thioredoxin also functions as an essential component of BACTERIOPHAGE T7-specific DNA polymerase, and is required for filamentous phage assembly (see INOVIRUS). Thioredoxin can be released from *E. coli* cells by osmotic shock, and may be located at the ADHESION SITES in the cell envelope.

**Thiorhodaceae** See CHROMATIACEAE.

**Thiosarcina** See CHROMATIACEAE.

**thiosemicarbazones** Derivatives of thiosemicarbazone ( $R_2C=N.NH.CS.NH_2$ ) – e.g. *thiacetazone*: 4-acetamidobenzaldehyde thiosemicarbazone – have been utilized as chemotherapeutic agents against tuberculosis. The earlier drugs have been largely superseded by less toxic drugs, but 2-acetylpyridine thiosemicarbazones were synthesized for potential use in antiparasite (e.g. antimalarial), antibacterial and antineoplastic therapy; they apparently function by inhibiting ribonucleoside diphosphate reductase. Some of these thiosemicarbazones also have antiviral activity, inactivating the ribonucleoside diphosphate reductase of e.g. herpes simplex virus type 1 in a time-dependent manner [JGV (1986) 67 1625–1632]. (See also ISATIN- $\beta$ -THIOSEMICARBAZONE.)

**Thiospira** A genus of Gram-negative, helical, polarly flagellated bacteria which occur in freshwater and marine H<sub>2</sub>S-containing habitats; the cells typically contain globules of sulphur.

**Thiospirillum** A genus of photosynthetic bacteria (family CHROMATIACEAE). The cells are spiral, ca. 10–100  $\mu$ m long by up to 4  $\mu$ m wide, and motile by lophotrichous flagella; in addition to various carotenoids, they contain Bchl *a* – cell suspensions being typically orange-brown. All strains are strict anaerobes and require sulphide and vitamin B<sub>12</sub>.

**thiostrepton** A sulphur-containing peptide antibiotic, produced by *Streptomyces azureus*, which is active against Gram-positive bacteria and certain members of the Archaea (methanogens); it binds strongly to the 50S ribosomal subunit and inhibits protein synthesis. Antibiotics which appear to be structurally and functionally related include siomycin, sporangiomycin and THIOPEPTIN.

**thiosulphate** A salt of thiosulphuric acid; the thiosulphate ion is S<sub>2</sub>O<sub>3</sub><sup>2-</sup>. Thiosulphate can be used as a substrate for lithotrophic metabolism e.g. by *Thiobacillus* spp. and as an electron acceptor e.g. by SULPHATE-REDUCING BACTERIA; it is used as a source of sulphur in e.g. KLIGLER'S IRON AGAR. (See also RHODANESE.)

**thiosulphate–citrate–bile salts agar** See TCBS AGAR.

**Thiothrix** A genus of GLIDING BACTERIA (see CYTOPHAGALES); species occur e.g. attached to surfaces in sulphide-containing freshwater and marine habitats, particularly in flowing water, where dissolved oxygen levels are ca. 10% of the saturation value. The organisms are sheathed, non-gliding filaments which form gliding gonidia from the unattached end of the filament; filaments adhere to the substratum or form rosettes. Metabolism appears to be mixotrophic: in those strains examined, small amounts of simple carbon compounds are required, and energy

seems to be derived from the oxidation of sulphide or thiosulphate; sulphur is deposited intracellularly. One strain of *Thiothrix* has been found to contain carboxysome-like structures, suggesting that it may be autotrophic. [Review: ARM (1983) 37 354–359.]

**thiourea derivatives** (as antimicrobial agents) Antimicrobial derivatives of thiourea, (NH<sub>2</sub>)<sub>2</sub>CS, include e.g. *diphenylthiourea*, (C<sub>6</sub>H<sub>5</sub>NH)<sub>2</sub>CS, which has been used as an antimycobacterial agent, and the THIOSEMICARBAZONES.

**Thiovulum** A genus of bacteria (Proteobacteria) found e.g. in marine habitats characterized by the simultaneous presence of sulphide and oxygen; the organisms obtain energy by oxidizing sulphide/sulphur, and typically form a whitish layer at the interface of sulphidogenic sediments and oxygenated water. Cells of the sole species, *T. majus*, are spherical, with a diameter reported to range from 5 to 25  $\mu$ m; the (flagellate) organisms can reach speeds of ~600  $\mu$ m/second [Microbiology (1994) 140 3109–3116].

**thiram** (TMTD) TetramethylTHIURAM DISULPHIDE: (CH<sub>3</sub>)<sub>2</sub>.N.CS.S.S.CS.N.(CH<sub>3</sub>)<sub>2</sub>; an ANTIFUNGAL AGENT which is also active against (mainly) Gram-positive bacteria. (cf. DMDC.) Thiram has been used as an antiseptic in the topical treatment of dermatophyte infections, and as an agricultural antifungal agent (e.g. as a seed dressing, and for the control of apple scab, *Botrytis* fruit rots, etc). Thiram (being insoluble in water) is used in aqueous suspensions.

–**35 sequence** See PROMOTER.

**thistle mottle virus** See CAULIMOVIRUSES.

**thiuram disulphides** These compounds (R<sub>2</sub>.N.CS.S.S.CS.N.R<sub>2</sub>) are formed by the mild oxidation of DITHIOCARBAMATES. See e.g. METIRAM and THIRAM.

**Thogoto virus** An unclassified virus (see ORTHOMYXOVIRIDAE) which has been isolated from ticks and mammals; it has been implicated in a severe human disease (optic neuritis, meningoencephalitis) in Africa.

**Thoma chamber** See COUNTING CHAMBER.

**thraustochytrids** A category of eukaryotic organisms which are generally classified together with the LABYRINTHULAS (q.v.). (The thraustochytrids were formerly included within the Oomycetes – either as a family, Thraustochytriaceae, of the Saprolegniales, or as a distinct order, Thraustochytriales.) The organisms are widely distributed in marine and estuarine waters, living – apparently mainly as saprotrophs – on algae, plants, organic detritus, etc. The vegetative stage consists of a rounded or oval, somewhat amoeboid cell from which arise ectoplasmic filaments which branch and anastomose to form a rhizoid-like ectoplasmic net. The net is produced from sagenogenetosomes (sagenogens, 'bothrosomes') which are essentially similar to those of labyrinthulas; it appears to function in adhesion and nutrition (which is osmotrophic) and to some extent in motility, but the cell does not move into the net (cf. LABYRINTHULAS). The cell body serves as a sporangium which, in most species, gives rise to laterally biflagellate zoospores resembling those of LABYRINTHULAS (although apparently lacking an eyespot). Genera include *Aplanochytrium* (which produces aplanospores instead of zoospores), *Japonochytrium*, *Labyrinthuloides*, *Schizochytrium* and *Thraustochytrium*.

**Thraustochytrium** See THRAUSTOCHYTRIDS.

**three-component regulatory system** See BACTERIOCINS.

**three-for-one model** (3-for-1 model) A model which describes the mode in which newly synthesized PEPTIDOGLYCAN (q.v.) is incorporated in the sacculus of a growing cell [Microbiology (1996) 142 1911–1918].

### three-micron DNA plasmid

**THREE-FOR-ONE MODEL:** incorporation of newly synthesized peptidoglycan in the sacculus of a growing cell of *Escherichia coli* (simplified outline, diagrammatic). In PEPTIDOGLYCAN (q.v.), the glycan backbone chains are *perpendicular* to the long axis of the cell; the diagram shows an *end-on* view of backbone chains (open circles) joined by peptide bridges (straight lines).

(a) A peptidoglycan monolayer; the monolayer is a stress-bearing structure and is under considerable tension. The chain in the centre (X) – a ‘docking’ chain – is to be replaced by three chains (hence 3-for-1).

(b) A triplet of three linked chains is located below (i.e. on the cytoplasmic side of) the peptidoglycan monolayer, with the flanking chains of the triplet covalently bound either side of the docking chain; in this particular plane, a stem peptide from each flanking chain has bound to the  $\epsilon$ -amino group of a dimeric peptide bridge to form a *trimeric* bridge (see legend to figure in entry PEPTIDOGLYCAN).

(c) The docking chain has been removed by enzymic action, and – because of the tension in the monolayer – the incoming triplet of chains has taken up its position in the sacculus; note that this contributes to cell *elongation*. The model assumes that the central chain in the incoming triplet will, when incorporated in the sacculus, function as a new docking chain; for this reason, the dimeric bridge to each flanking chain is assumed to have a free  $\epsilon$ -amino group located in the stem peptide of the flanking chain.

For cell length to *double* during the cell cycle, the model assumes that (i) docking and non-docking chains alternate in the sacculus, and (ii) only those docking chains which are present at the *start* of the new cell cycle will be replaced by an incoming triplet; that is, ‘new’ docking chains inserted *during* the current cell cycle will not be replaced until the next cell cycle. For this purpose, the growth mechanism must be able to distinguish ‘old’ from ‘new’ docking chains. This is possible because newly synthesized peptidoglycan is linked to the sacculus solely by tetra-tetra peptide bridges; it is therefore postulated that ‘new’ chains (identified by their tetra-tetra links) are not recognized as docking chains, but that, at the start of each new cell cycle, all tetra-tetra links will have been changed enzymically (by an LD-carboxypeptidase) to tetra-tri links, and that this allows recognition of the functional docking chains.

Reproduced from *Bacteria*, 5th edition, Figure 3.1, page 42, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471–98880–4) with permission from the publisher.

An outline of the model is shown in the diagram. It is postulated that co-ordination of the synthetic and lytic aspects of the process involves enzymes that include PENICILLIN-BINDING PROTEINS and ‘lytic transglycosylases’ (enzymes that degrade a glycan strand processively).

**three-micron DNA plasmid** (3 $\mu$  plasmid; also 3 $\mu$ m plasmid) A cccDNA plasmid, of unknown biological role, found e.g. in strains of *Saccharomyces cerevisiae* and other yeasts; 3 $\mu$  plasmids appear to be excised portions of chromosomal DNA – each corresponding to a unit of the host cell’s repetitive sequence of rRNA genes. [ARM (1983) 37 266.] (See also TWO-MICRON DNA PLASMID.)

**three-site model** (of translation) See PROTEIN SYNTHESIS.

**threitol** A 4-carbon POLYOL. D-Threitol occurs in certain fungi, e.g. *Armillaria mellea*.

**L-threonine biosynthesis** See Appendix IV(d).

**threshold cycle** (in quantitative PCR) See TAQMAN PROBES.

**-thrix** A suffix signifying a *hair* or *thread*.

**thrombin** See FIBRIN.

**thrombocytes** *Syn.* PLATELETS.

**Thrombocytozoons ranarum** An intracellular parasite of certain frogs (e.g. *Rana septentrionalis*, the mink frog) which occurs

exclusively in the thrombocytes of its host; *T. ranarum* is apparently a Gram-type-positive prokaryote. [J. Parasitol. (1984) 70 454–456.]

**thrombolite** See STROMATOLITES.

**thrush** See CANDIDIASIS.

**thujaplicins** Isopropyltropolones, fungitoxic compounds formed by the Western Red Cedar (*Thuja plicata*); they appear to be responsible for the high resistance to fungal attack of timber from *T. plicata*. (See also TIMBER PRESERVATION.)

**thuringiensin** ( $\beta$ -exotoxin) An exotoxin produced by *Bacillus thuringiensis*; it is apparently a specific inhibitor of DNA-dependent RNA polymerase, acting as an ATP analogue. Thuringiensin is toxic to a wide range of insects and to some vertebrates; strains of *B. thuringiensis* used commercially for biological control (see DELTA-ENDOTOXIN) are therefore usually not thuringiensin-producers.

**thuringiolysin 0** See THIOL-ACTIVATED CYTOLYSINS.

**thylakoids** Flattened, membranous vesicles which occur in the cytoplasm of nearly all CYANOBACTERIA (cf. GLOEOBACTER) and in the CHLOROPLASTS of ALGAE and higher plants; thylakoid

membranes contain the CHLOROPHYLLS and electron carriers etc involved in PHOTOSYNTHESIS.

In cyanobacteria, thylakoids typically occur near, and parallel to, the cell envelope, but seem to be structurally distinct from the cytoplasmic membrane; unlike the thylakoids in higher plants and some algae, those in cyanobacteria are not stacked (cf. PROCHLOROPHYTES). (See also PHYCOBILIPROTEINS.) In at least some cyanobacteria, thylakoid membranes are the sites of respiratory (as well as photosynthetic) electron transport; during photosynthetic or respiratory activity protons are pumped into the thylakoid vesicles – generating a proton motive force (see CHEMIOSMOSIS) across the thylakoid membrane [Book ref. 75, pp. 199–218].

Algal chloroplasts may contain individual (unassociated) thylakoids (in the Rhodophyta); longitudinally-adjacent pairs of thylakoids (in the cryptophytes); bands of three thylakoids (in the chrysophytes, diatoms, dinoflagellates, euglenoid flagellates, and members of the Phaeophyta, Prymnesiophyceae and Xanthophyceae); or bands of 2–6 thylakoids (Chlorophyta). A stack of ca. four or more thylakoids is termed a *granum*.

**thylaxoviruses** Viruses of the ONCOVIRINAE.

**thymic aplasia** (congenital) *Syn.* DIGEORGE SYNDROME.

**thymidine** See NUCLEOSIDE and Appendix V(b). (See also *double thymidine blockade* in SYNCHRONOUS CULTURE.)

**thymidine kinase** (TK; ATP:thymidine 5'-phosphotransferase; EC 2.7.1.21) An enzyme which catalyses the phosphorylation of thymidine to thymidine 5'-monophosphate; it is an important enzyme in the pyrimidine salvage pathway. TKs occur in various bacteria [JGM (1985) 131 3091–3098] and in eukaryotic cells (in the cytoplasm and mitochondria), and are encoded by many DNA viruses [review: MS (1985) 2 369–375]. (See also e.g. ACYCLOVIR and HYBRIDOMA.)

**thymine dimer** See ULTRAVIOLET RADIATION.

**thymocyte** An immature T cell undergoing development in the thymus gland.

**thymol** See PHENOLS.

**thymol blue** A PH INDICATOR. Acid range: pH 1.2–2.8 (red to yellow); pK<sub>a1</sub> 1.5. Alkaline range: pH 8.0–9.6 (yellow to blue); pK<sub>a2</sub> 8.9.

**thymolphthalein** A PH INDICATOR: pH 9.3–10.5 (colourless to blue); pK<sub>a</sub> 9.9.

**thymus-dependent antigen** (TD antigen; T-dependent antigen) Any antigen (e.g. most soluble proteins) which can trigger ANTIBODY FORMATION in antigen-specific B LYMPHOCYTES only with the help of T LYMPHOCYTES. (TD antigens do not elicit antibody in congenitally athymic individuals.)

**thymus-independent antigen** (TI antigen; T-independent antigen) Any antigen which can trigger ANTIBODY FORMATION in antigen-specific B LYMPHOCYTES without help from T LYMPHOCYTES. TI antigens include e.g. lipopolysaccharides, polymerized flagellin, dextrans and levans. (See also POLYCLONAL ACTIVATOR.)

**TI antigen** THYMUS-INDEPENDENT ANTIGEN.

**TI plasmid** See CROWN GALL.

**tiamulin** A semisynthetic antibiotic which inhibits PROTEIN SYNTHESIS in bacteria but which has little or no effect against archaeans. It apparently interacts with the 50S subunit of the ribosome, inhibiting the peptidyltransferase reaction.

**ticarcillin** See PENICILLINS.

**tick-borne encephalitis virus** See FLAVIVIRIDAE.

**Tilletia** A genus of plant-parasitic fungi (order USTILAGINALES) which typically attack the ovaries of the host plant, though the leaves may also be parasitized; *Tilletia* spp are the causal agents of e.g. COMMON BUNT and dwarf bunt.

In a typical life cycle, a teliospore germinates to give rise to an elongated, aseptate or uniseptate structure bearing an apical tuft of eight or more thread-like basidiospores (sometimes called 'primary sporidia' or 'primary conidia'); in e.g. *T. caries* (which exhibits HETEROTHALLISM) the basidiospores on a given structure are of two different mating types. While still attached, the basidiospores conjugate in pairs, giving rise to H-shaped forms within which plasmogamy occurs; subsequently, each (detached) H-shaped binucleate form, or mycelium derived from it, gives rise to binucleate ballistoconidia (sometimes called 'secondary sporidia' or 'secondary conidia'). The conidia germinate to form dikaryotic hyphae which initiate infection of a fresh host and subsequently give rise to teliospores.

**Tilletiaceae** See USTILAGINALES.

**tilmicosin** A MACROLIDE ANTIBIOTIC which has been used e.g. against *Mycoplasma bovis* in the treatment of CALF PNEUMONIA; in vitro tests on field isolates of *M. bovis* indicate that significant levels of resistance have developed against tilmicosin [VR (2000) 146 745–747].

**Tilopteris** See PHAEOPHYTA.

**tilorone** (2,7-bis-[2-(diethylamino)ethoxy]-9-fluorenone) An antiviral, antitumour agent which seems to (a) induce INTERFERON synthesis, and (b) interfere directly with virus expression by functioning as an INTERCALATING AGENT ( $\phi$  ca. 13°) with a preference for AT-rich regions of dsDNA.

**Tilsit cheese** See CHEESE-MAKING.

**Tilt** See PROPICONAZOLE.

**timber decay** See TIMBER SPOILAGE and TREE DISEASES.

**timber preservation** The *seasoning* (i.e. drying) of timber renders it less susceptible to fungal attack (see TIMBER SPOILAGE), and may facilitate penetration by chemical preservatives; once dried, timber can be preserved by e.g. preventing the access of air and moisture by the use of sealants or paint films (see also PAINT SPOILAGE). In some cases (e.g. elm wood) decay can be inhibited by waterlogging which limits the supply of oxygen to potential spoilage fungi.

Decay of timber may also be prevented or delayed by the use of PRESERVATIVES – e.g. CREOSOTE, sodium fluoride, pentachlorophenol, borates (alone or with QACs), copper naphthenate, and tributyl tin oxide (alone or with QACs). Most of these substances are inherently fungitoxic, but tributyl tin oxide (TBTO) inhibits fungal attack by binding strongly to cellulose, rendering it insusceptible to fungal CELLULASES; wood treated with TBTO may still be susceptible to lignin-utilizing WHITE ROT fungi unless TBTO is used in conjunction with e.g. a phenolic preservative to protect the lignin. The control of SOFT ROT can be achieved only by the use of preservatives which penetrate into the cell walls of the wood. Preservatives may be applied either as surface coatings or by the use of specialized procedures (see e.g. BETHELL PROCESS; BOUCHERIE PROCESS; SAUG-KAPPE PROCESS). Aqueous preservatives may be retained in treated timbers e.g. by the formation of insoluble precipitates; the insolubility of some preservatives prevents leaching under damp or wet conditions. (Certain types of wood contain natural fungitoxic substances – e.g. PINOSYLVIN in pine, TANNINS in oak, THUJAPLICINS in Western Red Cedar.) (See also HETEROBASIDIUM.)

Decay of chemically treated timber may occur e.g. through splitting – which permits fungal penetration through a treated zone. Rhizomorphs may enable a fungus to cross treated (or non-nutrient) zones (see e.g. DRY ROT), while some fungi can detoxify copper preservatives by converting them to copper oxalate.

**timber spoilage** Microbial spoilage of timber is caused primarily by fungi – particularly basidiomycetes – and involves decay

## timber staining

(see e.g. BROWN ROT, DRY ROT, POCKET ROT, SOFT ROT, WET ROT, and WHITE ROT) and/or staining (see TIMBER STAINING). Commonly, only wood having a moisture content greater than ca. 20% is susceptible to fungal attack (cf. DRY ROT); the moisture content is calculated as the weight of water in a sample of timber divided by the dry weight of that sample. In fallen or freshly felled timber the sapwood is particularly vulnerable to SAP-STAIN and early decay by any of a range of fungi; thus e.g. fallen birch branches rapidly succumb to a brown cubical rot (caused by e.g. *Piptoporus betulinus*) or to a soft white fibrous rot (caused e.g. by *Heterobasidion annosum* – see HETEROBASIDIUM). Timber may also support a surface growth of non-cellulolytic, non-lignolytic ascomycetes and deuteromycetes (cf. SOFT ROT (1)); such growth generally causes little or no damage to the timber. Fungi of importance in the decay of domestic and industrial timbers include e.g. *Serpula lacrymans* (see DRY ROT) and *Coniophora puteana* (see WET ROT); *Lentinus lepideus* is moderately resistant to creosote and can cause a brown rot in e.g. railway sleepers. (See also PAPER SPOILAGE; TIMBER PRESERVATION; TREE DISEASES.)

**timber staining** (by fungi) Various wood-infecting fungi cause discoloration in felled timber and in standing trees; some infections are superficial, but in others the fungus grows into the timber or is carried in by wood-boring beetles. Superficial staining can be caused by a range of fungi (e.g. species of *Alternaria*, *Fusarium*, *Penicillium*) and typically does not affect the strength or value of the timber; deep staining may weaken the timber (see e.g. BROWN OAK). Staining may be due to the production of a fungal pigment or to an optical effect (see BLUE-STAIN). (See also GREEN OAK; TIMBER PRESERVATION.)

**Timentin** A composite antibiotic consisting of ticarcillin (see PENICILLINS) and CLAVULANIC ACID. [Clinical evaluation: Am. J. Med. (1985) 79 Supplement 5B 1–196; laboratory and clinical perspective: JAC (1986) 17 Supplement C 1–244.] (cf. AUGMENTIN.)

**timothy-grass bacillus** *Mycobacterium phlei*.

**tin** (as an antimicrobial agent) Tin is a HEAVY METAL which, in elemental or compound form, can exert antimicrobial activity. The presence of metallic tin has been reported to inhibit growth and toxin production by *Clostridium botulinum* in food contained in tin-plate cans [cited in Book ref. 35, p. 282]. (If the inside of a can is significantly de-tinned – e.g. by CURING salts, or by certain acidic fruits – the underlying steel may rapidly corrode and give rise to a HYDROGEN SWELL.)

Organotins (i.e. tin-containing organic compounds) are typically more active than inorganic compounds of tin – trialkyltins (e.g. TBTO) being among the most effective. (See also FENTIN.) Trisubstituted organotins exhibit microbistatic activity at low concentrations – apparently by inhibiting ATP synthesis; at high concentrations they can be microbicidal, possibly by disrupting the cytoplasmic membrane.

**tinangaja disease** A disease of coconut palms which occurs on the island of Guam; it is apparently caused by the COCONUT CADANG-CADANG VIROID.

**tincture of iodine** See IODINE (a).

**tinder fungus** *Fomes fomentarius*.

**tinea** See RINGWORM. (See also e.g. FAVUS; PITIRIASIS NIGRA; PITIRIASIS VERSICOLOR.)

**tinidazole** See NITROIMIDAZOLES.

**Tinopal AN** A FLUORESCENT BRIGHTENER used e.g. as a selective antibacterial agent; in e.g. *Escherichia coli* it apparently inhibits RNA polymerase [JGM (1984) 130 1999–2005]. [Use for distinguishing phytopathogenic from saprotrophic *Pseudomonas* spp: JAB (1985) 58 283–292.]

**tinsel flagellum** See FLAGELLUM (b).

**tintinnid** See TINTINNINA.

**Tintinnidium** See TINTINNINA.

**Tintinnina** ('tintinnids') A suborder of ciliate protozoa (order OLIGOTRICHIDA); most species are marine pelagic organisms, but some occur in freshwater habitats. Cells: cylindrical, conical or vase-shaped, typically one hundred to several hundred micrometres in length; all are loricate and highly contractile. Somatic ciliation is reduced, but oral ciliation is conspicuous and includes a closed ring of cilia around the apical oral region. A perilemma is commonly or always present, and in some cases the lorica is covered by small inorganic particles. Genera include e.g. *Codonella*, *Salpingella*, *Tintinnidium*, *Tintinnopsis*, and *Tintinnus*. [Grazing, respiration, excretion and growth rates of tintinnids: Limn. Ocean. (1985) 30 1268–1282.]

**Tintinnopsis** See TINTINNINA.

**Tintinnus** See TINTINNINA.

**tioconazole** An AZOLE ANTIFUNGAL AGENT. [Review of antimicrobial activity and therapeutic use in superficial mycoses: Drugs (1986) 31 29–51.]

**TIP** (1) THERMAL INACTIVATION POINT. (2) Tumour-inducing principle: the Ti plasmid responsible for CROWN GALL formation.

**Tipula iridescent virus** See IRIDOVIRUS.

**tir gene** See PATHOGENICITY ISLAND.

**tirandamycin** An antibiotic which appears to be structurally and functionally similar to STREPTOLYDIGIN.

**Tissierella** A proposed genus of bacteria which includes organisms currently classified as *Bacteroides praeacutus* (proposed new name: *T. praeacuta*) [JJSB (1986) 36 461–463].

**tissue culture** (1) The in vitro culture (growth) or maintenance of isolated mammalian (or other) tissues or organs, or of populations of individual cells obtained by disruption of such tissues. Those procedures which involve populations of individual cells are also referred to as *cell culture*; the following account refers specifically to cell culture.

Cell cultures (TISSUE CULTURE sense 2) are widely used e.g. for the culture of viruses, and for studies in cancer research, immunology, toxicology etc; they are also used to culture certain bacteria (e.g. species of *Chlamydia* and *Rickettsia*).

Cell cultures are prepared and handled with an ASPETIC TECHNIQUE. Culture vessels include LEIGHTON TUBES, medical flats, roller bottles (see ROLLER CULTURE), Roux flasks, test-tubes etc; vessels may be made of (neutral-pH) glass (e.g. borosilicate or flint glass) or of certain plastics (e.g. polystyrene).

*Media.* A *growth medium* permits cellular growth and division; it consists essentially of a BALANCED SALT SOLUTION supplemented with e.g. glucose and/or peptone, various amino acids and vitamins, a pH indicator (e.g. PHENOL RED), a buffer system (often bicarbonate or HEPES), antibiotic(s), and (usually) 5–10% calf serum. (Serum-less media are also used.) Antibiotics are included to prevent the development of microbial contaminants which may be present; however, the continual suppression of contaminants during SERIAL PASSAGE is undesirable, and periodic subcultures should be made in antibiotic-free media in order to detect contaminants. Common bacterial contaminants include species of *Acholeplasma* and *Mycoplasma* (PCR-based detection e.g. with *Mycoplasma Plus*<sup>TM</sup> PCR Primer Set from Stratagene). Common growth media include various modifications of EAGLE'S MEDIUM – e.g. basal medium Eagle (BME), and minimal essential medium (MEM) – and medium 199. A *maintenance medium* is used to preserve the viability and properties of a population of cells while restricting to a minimum their growth and division; growth media containing lower levels of serum (e.g. 1%) are often used as maintenance media.

In *monolayer* culture a population of cells is incubated in a shallow layer of growth medium until the cells form a more or less confluent layer, one cell thick, on the inner surface of the culture vessel; macroscopically, the monolayer appears as a translucent film. The initial cell suspension may be derived from fresh tissue (see PRIMARY CULTURE) or from an ESTABLISHED CELL LINE.

**Preparation of a monolayer culture from fresh tissue.** Selected tissue is cut into small pieces and washed several times with pre-warmed (30–37°C) phosphate-buffered saline (PBS). The tissue is then subjected to trypsinization, i.e., digested in PBS containing trypsin (see PROTEASES) (0.05–0.1% w/v) – the whole being kept at 30–37°C and stirred mechanically for 20–30 min. (Trypsin weakens the intercellular bonds; excessive trypsinization can damage cells.) The turbid supernatant (containing damaged cells) is discarded, and the tissue fragments are again digested in fresh PBS–trypsin. The supernatant, containing single cells and small aggregates, is centrifuged (ca. 150–200 g/5 min) and the pellet of cells is resuspended in fresh growth medium. The concentration of viable cells is determined (see COUNTING CHAMBER and VITAL STAINING) and is adjusted (by diluting with growth medium) to ca.  $10^5$  cells/ml. A small volume of the suspension is then incubated (37°C for mammalian cells) for several days, or a week or more, until a monolayer develops on the inner surface of the culture vessel; for flat-surfaced culture vessels (e.g. medical flats, Roux flasks) ca. 15–20 ml of cell suspension is required for an area of 100 cm<sup>2</sup>. (Test-tubes or bottles of circular cross-section are used for ROLLER CULTURE.) When cultured, animal cells generally become either spindle-shaped ('fibroblast-like') or polygonal ('epithelioid'). For SERIAL PASSAGE, the cells are first *stripped*, i.e. detached from the surface on which they have been grown: the monolayer is subjected for 1–2 min to a stripping agent – e.g. PBS containing VERSENE (ca. 0.02–0.05%) and ca. 0.1% trypsin; the stripping agent is decanted, and the detached, disaggregated cells are washed and resuspended in fresh growth medium, and can be used to prepare fresh cultures. Cells, in ampoules, can be preserved for long periods e.g. by FREEZING.

**Transformation.** After a certain number of serial passages, cells may die out or may develop into an ESTABLISHED CELL LINE. In the latter case the cells undergo certain alterations (usually termed *transformation*) such that they exhibit some or all of the properties characteristic of tumour cells: an apparent capacity for unlimited in vitro growth and division; the ability to grow in soft agar; the development of new surface antigens; the ability to form tumours when injected into animals; an increase in the rate of nutrient uptake; a loss of *contact inhibition* (i.e. inhibition of movement and cell division due to contact with neighbouring cells). (Loss of contact inhibition in a monolayer culture permits the development of multilayer colonies from the clones of transformed cells.) These changes may also be brought about by certain viruses, e.g. SV40 and Rous sarcoma virus.

The characteristics of cultured cells may be monitored e.g. by serological means or by examining the KARYOTYPE of the (COLCHICINE-treated) cells.

(2) Any population of cells involved in tissue culture (sense 1).

(See also HYBRIDOMA and SYNCHRONOUS CULTURE.)

**tissue cyst** (of coccidia) See e.g. TOXOPLASMOSIS.

**tissue-destructive factor** See LEGIONELLOSIS.

**tissue factor** (TF) See DISSEMINATED INTRAVASCULAR COAGULATION.

**tissue factor pathway inhibitor** (TFPI) See DISSEMINATED INTRAVASCULAR COAGULATION.

**titer** See TITRE.

**titration** (*mol. biol.*) Concentration-dependent interaction between a regulatory molecule and other molecule(s) or specific nucleotide sequence(s) by means of which the level of activity of the regulatory molecule is controlled. (See e.g. F PLASMID (*replication*)).

**titre** (titer) (*serol., virol.*) A numerical expression for the 'concentration' of specific antibodies, antigens, virions etc in a given sample. If the titre of antibodies or antigens is determined by an END-POINT TITRATION, the titre is equal, numerically, to the dilution factor of the highest dilution of sample giving a positive serological reaction. For example, if the end-point reaction mixture consisted of a 1/200 dilution of serum (antibody) and an equal volume of antigen, the titre of antibody can be given as 200 ('initial serum dilution') or 400 ('final serum dilution'); these titres may, alternatively, be quoted as 1/200 and 1/400, respectively.

Virus titres may be determined e.g. by the PLAQUE ASSAY method (see also END-POINT DILUTION ASSAY).

**TK** THYMIDINE KINASE.

**TLC** Thin-layer CHROMATOGRAPHY.

**T<sub>m</sub>** (T<sub>m</sub>) See THERMAL MELTING PROFILE.

**TMA** Trimethylamine (see e.g. FISH SPOILAGE).

**TMA** (transcription-mediated amplification) A method used for the isothermal amplification of RNA target sequences; the principle of TMA is the same as that of NASBA (q.v.) – one practical difference being that, in the commercial applications of TMA, use is made of the RNase H activity of reverse transcriptase, so that only two enzymes are used.

Commercial TMA- and NASBA-based tests differ also in the way in which amplified target sequences are detected. In TMA-based tests, the targets are detected by a so-called *hybridization protection assay* (HPA). HPA involves the use of DNA probes labelled with acridinium ester. After allowing time for probe–target hybridization, an added reagent hydrolyses the acridinium ester label on all *unbound* probes – the label on bound probes being protected as a consequence of its location within the probe–target duplex; subsequent addition of other reagents elicits CHEMILUMINESCENCE from the *bound* probes – emitted light being measured by a luminometer in *relative light units* (RLUs).

Commercial applications of TMA include several diagnostic tests – one of which, the amplified *Mycobacterium tuberculosis* direct test (AMTDT; Gen-Probe, San Diego, USA), was approved by the U.S. Food & Drug Administration (FDA) for detection of *Mycobacterium tuberculosis* in (smear-positive) respiratory specimens (e.g. sputa). A new-format 'enhanced' AMTDT, which uses a larger volume of sample, was approved by the FDA in 1998.

A TMA-based test for *Chlamydia trachomatis* in urogenital specimens was approved by the FDA in 1996; the principle of this test (AMP CT) is identical to that of the AMTDT.

[Evaluation of AMP CT for the detection of *Chlamydia trachomatis* in a high-risk population of women: JCM (1997) 35 676–678. Evaluation of AMTDT for non-respiratory specimens: JCM (1997) 35 307–310. Comparison of original and 'enhanced' versions of AMTDT for respiratory and non-respiratory specimens: JCM (1998) 36 684–689. Evaluation of 'enhanced' AMTDT for rapid diagnosis of pulmonary tuberculosis in a high-risk prison population: JCM (1999) 37 1419–1425. False-positive results with AMTDT in patients with *Mycobacterium avium* and *M. kansasii* infections: JCM (1999) 37 175–178.]

## TMAO

[Isothermal nucleic-acid-amplification methods (TMA, NASBA, SDA): Book ref. 221, pp 126–151.]

**TMAO** Trimethylamine-*N*-oxide (see e.g. FISH SPOILAGE).

**TMEV** THEILER'S MURINE ENCEPHALOMYELITIS VIRUS.

**TMPD** Tetramethyl-*p*-phenylenediamine: a reagent which can e.g. reduce cytochrome oxidase (see ELECTRON TRANSPORT CHAIN); oxidized TMPD can be reduced by ascorbic acid. (See also KOVACS' OXIDASE REAGENT.)

**TMS** Tetramethylsilane (see NUCLEAR MAGNETIC RESONANCE).

**TMTD** See THIRAM.

**TMV** TOBACCO MOSAIC VIRUS.

**Tn1** See Tn3.

**Tn2** See Tn3.

**Tn3** A 4957-bp class II TRANSPOSON which has identical 38-bp terminal inverted repeats and carries a gene (*bla*) for a TEM-type  $\beta$ -LACTAMASE; Tn3 occurs e.g. in plasmid R1*drd-19*. Tn3 insertion tends to occur preferentially at target sites in AT-rich regions of DNA, and results in a 5-bp duplication of target DNA. Two Tn3 genes (*mpA* and *mpR*) are necessary for transposition, which occurs by a two-stage mechanism via a COINTEGRATE intermediate. The *mpA* gene specifies a transposase responsible (at least in part) for the formation of a cointegrate. The *mpR* gene specifies a resolvase which can catalyse resolution of the cointegrate by SITE-SPECIFIC RECOMBINATION involving a region – termed IRS (internal resolution site) – between the *mpA* and *mpR* genes in each Tn3 copy. Tn3 resolvase acts specifically on a replicon containing two IRS regions in the same orientation, and cannot act on IRS regions in different replicons; the resolution reaction is therefore irreversible. [Model for Tn3 resolvase action: Cell (1985) 40 147–158.] (Tn3 cointegrate intermediates can also be resolved by general recombination involving the host *recA* system.) The *mpR* resolvase also regulates the frequency of Tn3 transposition by acting as a repressor and preventing expression of both *mpA* and *mpR* genes.

Many bacterial TRANSPOSABLE ELEMENTS are closely related to Tn3: all have related short (35–40 bp) inverted repeats, all induce a 5-bp duplication in target DNA on insertion, all are transposed by a two-stage mechanism involving the formation and resolution of a cointegrate, and most show TRANSPOSITION IMMUNITY. Tn3-like elements include e.g. Tn1 and Tn2 (both ca. 5 kb, encoding TEM-like  $\beta$ -lactamase), Tn4 (encoding resistance to ampicillin, streptomycin and sulphonamides), Tn21 (q.v.), Tn501 (q.v.), Tn551 (5.3 kb, encoding resistance to erythromycin, derived from a *Staphylococcus aureus* plasmid), Tn1721 (q.v.), Tn2603 (22 kb, encoding an OXA-1  $\beta$ -lactamase and resistance to streptomycin, sulphonamides and mercury – cf. Tn2410), and  $\gamma\delta$  (= IS1000, a 5.8-kb INSERTION SEQUENCE which shares extensive DNA homology with Tn3). Tn3 and the Tn3-like elements are sometimes collectively termed TnA.

Two subgroups of "TnA" elements are recognized e.g. on the basis of whether the *mpA* and *mpR* genes are transcribed in opposite directions (as in Tn3 and  $\gamma\delta$ ) or in the same direction (as in Tn4, Tn21, Tn501, Tn1721, Tn2603).

[Review of Tn3 and related transposons: Book ref. 20, pp. 223–260.]

**Tn4** See Tn3.

**Tn5** A 5818-bp composite TRANSPOSON containing three antibiotic-resistance genes, one of which encodes aminoglycoside 3'-phosphotransferase (conferring resistance to kanamycin and other aminoglycoside antibiotics). The three, contiguous antibiotic-resistance genes are flanked by a pair of terminal inverted repeats: two IS50 insertion sequences (IS50L

and IS50R) that differ slightly from one another. Each IS50 sequence is flanked by a pair of 19-bp sequences referred to as the outer end (OE) and inner end (IE); the two OE sequences thus form the two ends of the transposon.

IS50R encodes two proteins: P1 (a *cis*-acting transposase, Tnp) and P2 (an inhibitor of the transposase, Inh) – P2 being encoded by the same reading frame as P1 but lacking the N-terminal 55 amino acids. (IS50L encodes two corresponding proteins, P3 and P4; however, IS50L contains an ochre codon so that P3 and P4 are non-functional proteins.)

Tnp can catalyse transposition of (i) the entire transposon (Tn5) or (ii) IS50; transposition of Tn5 involves the two OE sites, whereas transposition of IS50 involves one OE site and one IE site.

Tnp is characterized by a low level of activity which is further down-regulated by Inh; the relative levels of Tnp and Inh influence the frequency of transposition. In vivo, host factors tend to favour transposition from the OE sites (in preference to the IE sites). Other regulatory factors in vivo include *dam* methylation (see DAM GENE) which negatively affects the function of the P1 promoter (and also results e.g. in coupling transposition to DNA replication).

[Tn5 (review): ARM (1993) 47 945–963.]

Early studies suggested that transposition of Tn5 may involve a cut-and-paste (rather than a replicative) mechanism (see TRANSPOSABLE ELEMENT) [CSHSQB (1984) 49 215–226], but subsequent work suggested the involvement of cointegrates (i.e. a replicative mechanism) [JMB (1986) 191 75–84]. However, more recent evidence favours a cut-and-paste model [JBC (1998) 273 7367–7374].

The latter study [JBC (1998) 273 7367–7374] demonstrated that transposition could be achieved in an in vitro system consisting of: (i) transposase, (ii) DNA flanked by OE sequences, and (iii) target DNA. Such in vitro transposition is optimized by a 'hyperactive' form of transposase transcribed from IS50R containing three mutations – one of which blocks transcription of the inhibitor (Inh) while another enhances the binding of transposase to OE sequences.

**Tn7** A TRANSPOSON which can insert into the chromosome of *Escherichia coli* with a high degree of target specificity; the target site is designated *attTn7*. Insertion of Tn7 involves several Tn7-encoded proteins: TnsA, TnsB, TnsC and TnsD; TnsA and TnsB jointly provide transposase activity. Initially, TnsD binds to *attTn7* in a sequence-specific way, and such binding distorts the 5' end of the binding site; it has been suggested that this distortion of DNA acts as a signal for the recruitment of TnsC to the site [EMBO (2001) 20 924–932].

A second, distinct pathway of transposition of Tn7 involves the transposon-encoded TnsA, TnsB, TnsC and TnsE; TnsE, which binds DNA in a structure-dependent way, promotes insertion of Tn7 into (i) certain plasmids, and (ii) the chromosome of *E. coli* at sites proximal to double-stranded breaks in DNA and also at locations where DNA replication terminates [GD (2001) 15 737–747].

**Tn9** A 2638-bp composite TRANSPOSON which includes terminal, directly repeated IS1 elements and a gene (*cat*) for resistance to CHLORAMPHENICOL (*cat* encodes chloramphenicol acetyltransferase – an enzyme which also inactivates fusidic acid). Tn9 apparently transposes by a replicative process involving cointegrate formation, *recA* function being necessary for cointegrate resolution [JMB (1986) 191 75–84]. (cf. Tn3 and Tn5.) Tn9 occurs e.g. in the R plasmid pSM14 (= R14), a plasmid which also contains Tn10. Tn9-derived chloramphenicol resistance from Gram-negative bacteria can be cloned in, but not

phenotypically expressed in, *Bacillus subtilis* [PNAS (1982) 79 5886–5890]. (See also IS1.)

**Tn10** A 9.3-kb composite TRANSPOSON which carries a gene for tetracycline resistance; Tn10 occurs e.g. in the transmissible plasmid R100 (= R222). The mechanism of Tn10 transposition is distinct from that of Tn3 (q.v.); it apparently involves a non-replicative ‘cut-and-paste’ mechanism in which excision of the transposon from the donor molecule (by double-stranded breaks at each end) is followed by insertion of the transposon into the new target site. The remainder of the donor molecule is probably lost (‘donor-suicide’ model). [Genetic evidence for non-replicative Tn10 transposition: Cell (1986) 45 801–815.]

The two ends of Tn10 are IS elements (IS10, 1.4 kb) in opposite orientation; the two IS10 elements are similar but not identical, and are designated IS10-Right (IS10-R) and IS10-Left (IS10-L). IS10-R encodes at least one protein (transposase) which acts at the ends of Tn10 and is necessary for its transposition; the transposase is apparently preferentially *cis*-acting, possibly migrating along the DNA molecule rather than being freely diffusible in the cell cytoplasm. IS10-R can promote normal levels of transposition (e.g. ca.  $10^{-7}$  transpositions/TE/bacterial generation) even when IS10-L is inactive; however, IS10-L is functionally defective and can provide only ca. 1–10% of the transpositional activity of IS10-R. Insertion of Tn10 into a new target site – presumably recognized by the IS10-R transposase – results in the duplication of a 9-bp target sequence. The preferred (‘hot-spot’) target site for Tn10 contains a symmetrical 6-bp sequence within the 9-bp sequence (NGCTNAGCN) duplicated during insertion; insertion can also occur, less efficiently, at many other sites, with concomitant duplication of a different 9-bp sequence. (See also DAM GENE and MULTICOPY INHIBITION.)

**Tn21** A 19.3-kb Tn3-like transposon (see Tn3) present e.g. in plasmid R100 from *Shigella flexneri*; it encodes resistance to sulphonamides, streptomycin and mercuric ions. Tn21 transposition is regulated by a *modulator protein* encoded by a gene (*mpM*) located upstream of the Tn21 IRS. The *mpA*, *mpR* and *mpM* genes are all transcribed in the same direction (cf. Tn3). The Tn21 modulator apparently enhances Tn21 transposition and suppresses cointegrate resolution by Tn21 resolvase. A sequence homologous to the Tn21 *mpM* gene has been observed in an analogous site in Tn501. [Cell (1985) 42 629–638.]

**Tn501** An 8.2-kb Tn3-like transposon (see Tn3) from *Pseudomonas* spp (plasmid pUS1); it encodes resistance to mercury. The frequency of transposition and efficiency of cointegrate resolution are both substantially increased in the presence of low levels of mercury, suggesting that the *mpA* and *mpR* genes can be transcribed from the same promoter as the inducible gene for mercury resistance. Tn501 may encode a modulator protein similar to that of Tn21 (q.v.). Tn501 provides ‘hot-spots’ for Tn3 insertion.

**Tn551** See Tn3.

**Tn554** A site-specific, repressor-controlled TRANSPOSON from *Staphylococcus aureus*; it carries (inducible) genes for resistance to erythromycin and spectinomycin.

**Tn916** See CONJUGATIVE TRANSPOSITION.

**Tn925** See CONJUGATIVE TRANSPOSITION.

**Tn951** A defective transposon of the Tn3 group (see Tn3) which encodes genes for lactose metabolism (*lacZ* and *lacY*); its ends are perfect inverted repeats (40 bp), but it apparently lacks genes for its transposition – transposition requiring Tn3-encoded transposase and resolvase. (cf. IS101.) Tn951 contains an IS1 sequence [MGG (1980) 178 367–374].

**Tn1000** *Syn.*  $\gamma\delta$  (see Tn3).

**Tn1207.1** See MACROLIDE ANTIBIOTICS.

**Tn1545** See CONJUGATIVE TRANSPOSITION.

**Tn1681** A TRANSPOSON which carries a gene for the heat-stable enterotoxin STa of enterotoxigenic *Escherichia coli* (see ETEC); Tn1681 contains two copies of IS1 in inverted orientation.

**Tn1721** An 11.4-kb Tn3-like transposon (see Tn3) encoding resistance to tetracycline. In the presence of tetracycline the resistance gene is duplicated many times, resulting in increased levels of tetracycline resistance.

**Tn2410** An 18.5-kb (probably Tn3-like) TRANSPOSON derived from plasmid R1767 from *Salmonella typhimurium*; it carries genes encoding an OXA-2  $\beta$ -LACTAMASE and resistance to sulphonamides and mercury [JGM (1983) 129 2951–2957].

**Tn2603** See Tn3.

**Tn3701** See CONJUGATIVE TRANSPOSITION.

**Tn5253** See CONJUGATIVE TRANSPOSITION.

**Tn5397** A conjugative transposon (see CONJUGATIVE TRANSPOSITION) which is found e.g. in *Clostridium difficile* (and which is transferable to e.g. *Bacillus subtilis*); it encodes resistance to tetracycline. Although related to Tn916, Tn5397 encodes a dual-function protein, TndX, that mediates both insertion and excision (in contrast to the products of the *int* and *xis* genes of Tn916). Tn5397 contains a group II intron which has been shown to undergo splicing *in vivo* [JB (2001) 183 1296–1299].

**TnA** See Tn3.

***tna* operon** AN OPERON which includes the structural gene (*tnaA*) for TRYPTOPHANASE; *tnaA* is separated from the *tna* promoter by a long LEADER (*tnaL*) which contains several rho-dependent terminators [JB (1986) 166 217–223] (see TRANSCRIPTION) and a sequence (*tnaC*) encoding a 24-amino-acid leader peptide. The operon is subject to CATABOLITE REPRESSION and is inducible by tryptophan; translation of *tnaC* apparently plays an essential role in operon expression [JB (1986) 167 383–386]. In the absence of tryptophan, rho-dependent transcription termination occurs in the *tnaL* region, preventing expression of *tnaA*; however, in the presence of tryptophan, termination is prevented (see ANTITERMINATION), allowing *tnaA* gene expression. (cf. OPERON (attenuator control).)

**TNase** Thermonuclease (see DEOXYRIBONUCLEASE).

**TNF** Tumour necrosis factor: a pro-inflammatory cytokine (see CYTOKINES) synthesized by many types of cell on appropriate stimulation. The two forms of TNF, TNF- $\alpha$  and TNF- $\beta$ , are both encoded by three-intron, single-copy genes.

TNF- $\alpha$  (formerly ‘cachectin’) is produced e.g. by activated macrophages, by the Th1 subset of T lymphocytes, and by endothelial cells and leukocytes stimulated by lipopolysaccharides (see also CD14).

TNF- $\alpha$  appears to have a wide range of activities which include (i) induction of APOPTOSIS in target cells, (ii) cytolysis of certain types of tumour, (iii) regulation of proliferation and differentiation in lymphocytes, (iv) upregulation of CELL ADHESION MOLECULES (E-selectins, ICAM-1) on endothelial cells during INFLAMMATION, (v) promotion of ADCC activity in neutrophils, (vi) stimulation of monocytes and macrophages to synthesize e.g. TNF- $\alpha$ , IL-1 and IL-6, and (vii) induction of certain CHEMOKINES (e.g. IL-8).

Injection of TNF into animals gives rise to a syndrome indistinguishable from ENDOTOXIC SHOCK.

*In vitro* studies suggest that TNF- $\alpha$  may upregulate endothelial toxin receptors during EHEC infection and (thus) promote the vascular damage associated with HAEMOLYTIC URAEMIC SYNDROME

## ***tnpA* gene**

[TIM (1998) 6 228–233]. (See also DISSEMINATED INTRAVASCULAR COAGULATION and other cytokine-associated conditions listed under CYTOKINES.)

In some individuals, susceptibility to a severe form of MALARIA has been found to correlate with a variant form of the TNF- $\alpha$  promoter [Nature (1994) 371 508–510], and an increased susceptibility to endotoxic shock appears to correlate with enhanced synthesis of TNF [JAMA (1999) 282 561–568]. The apparent link between levels of TNF and pathogenesis has suggested that benefit may be obtained, in certain cases, from the use of ligands that sequester TNF and prevent its binding to specific cell-surface receptors; such anti-TNF ligands include *etanercept* and the monoclonal antibody *infliximab*.

TNF- $\alpha$  exists in both soluble (secreted) and membrane-associated forms, both forms being active.

TNF- $\beta$  (also called lymphotoxin  $\alpha$ ) is produced by activated lymphocytes, and is characteristic of the Th1 subset of T cells. TNF- $\beta$  resembles TNF- $\alpha$  in its activities – many of which coincide with the activities of INTERLEUKIN-1; unlike IL-1, however, TNF can trigger apoptosis in a target cell.

The cell-surface receptors of tumour necrosis factor are designated p55 (= CD120a) and p75 (= CD120b) and they occur on a wide range of cells. Each type of receptor can apparently serve as a binding site for both forms of TNF; however, the two receptors may have distinct roles in TNF activity, and p75 may have a subordinate role. Following endotoxaemia, the peripheral circulation contains raised levels of soluble (cell-free) TNF receptors; this may be a protective mechanism which down-regulates the effects of TNF on host cells.

The binding of TNF to its receptor may give rise to various effects ranging from stimulation to apoptosis – according to the particular signalling pathway which is activated within the target cell. Currently, these pathways (and the factors which influence the choice of pathway) are incompletely understood, but apoptosis seems to involve part of the cytoplasmic side of the TNF receptor – a region called the ‘death domain’. Following TNF–receptor binding, the death domain appears to associate with certain cytoplasmic factors – including TRADD (TNF receptor-associated death domain protein) and a serine threonine kinase called RIP (receptor interacting protein); RIP may activate caspase(s) such as IL-1 $\beta$ -converting enzyme (ICE) (leading to APOPTOSIS) or it may phosphorylate (and inactivate) the inhibitor I $\kappa$ B, thus activating the nuclear transcription factor NF- $\kappa$ B.

***tnpA* gene** See Tn3.

***TnphoA*** See TRANSPOSON MUTAGENESIS.

***tnpM* gene** See Tn21.

***tnpR* gene** See Tn3.

**toadstool** Any umbrella-shaped basidiocarp, but particularly one which is inedible or poisonous.

**tobacco diseases** For diseases of the tobacco plant see e.g. GRANVILLE WILT, PERONOSPORA (blue mould), POTATO VIRUS Y (e.g. veinal necrosis), TOBACCO MOSAIC VIRUS, TOBACCO NECROSIS VIRUS and WILDFIRE DISEASE.

**tobacco etch virus** See POTYVIRUSES.

**tobacco leafcurl virus** See GEMINIVIRUSES.

**tobacco mosaic virus (TMV)** The type member of the TOBAMOVIRUSES. The TMV virion is a tubular filament (ca. 300  $\times$  20 nm, central hole approx. 2 nm diam.,  $S_w^{20}$  ca. 194); it comprises coat protein subunits (MWt ca. 17500) arranged in a single right-handed helix with the ssRNA intercalated between the turns of the helix (ca. three nucleotides per protein subunit).

TMV infects tobacco (*Nicotiana tabacum*) and other plants. The common, ‘Vulgare’ or field strain (U1 strain) usually causes a systemic disease of tobacco in which leaves are distorted, blistered, and marked with a mosaic of light and dark green patches; intracellular crystalline arrays of virus particles are commonly visible by light microscopy. Other TMV strains may affect other plants (e.g. strain Cc affects legumes, TMV-L affects tomatoes). (See also PATHOGENESIS-RELATED PROTEINS.) TMV is transmitted mechanically; it may remain infective for a year or more in soil or dried leaf tissue. The virions may be inactivated e.g. at pH <3 or >8 or by formaldehyde, iodine, etc; TIP: ca. 95°C. Preparations of TMV may be obtained from plant tissues e.g. by (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> precipitation followed by differential centrifugation.

The TMV ssRNA genome is ca. 6400 nucleotides long [sequence: PNAS (1982) 79 5818–5822] and is capped at the 5' end (sequence: m<sup>7</sup>G<sup>5'</sup>ppp<sup>5'</sup>Gp) but is not polyadenylated. The genomic RNA can serve as mRNA for a protein of MWt ca. 130000 (130 K) and another, produced by readthrough, of MWt ca. 180000 (180 K); however, it cannot function as messenger for the synthesis of e.g. coat protein. Other genes are expressed during infection by the formation of monocistronic, 3'-coterminal SUBGENOMIC MRNAS, including one (LMC) encoding the 17.5 K coat protein and another (I<sub>2</sub>) encoding a 30 K protein. (Other putative subgenomic mRNAs may be artefacts generated during electrophoresis [Book ref. 80, pp. 69–72].) The 30 K protein has been detected in infected protoplasts [Virol. (1984) 132 71–78]; it may be involved in the cell-to-cell transport of the virus in an infected plant. The functions of the two large proteins are unknown.

Several dsRNA molecules – including dsRNAs corresponding to the genomic, I<sub>2</sub> and LMC RNAs – have been detected in plant tissues infected with TMV; these are presumably intermediates in genome replication and/or mRNA synthesis – processes which appear to occur by different mechanisms [Book ref. 80, pp. 84–87].

TMV assembly apparently occurs in the plant cell cytoplasm, although it has been suggested that some TMV assembly may occur in chloroplasts since transcripts of ctDNA have been detected in purified TMV virions [Book ref. 80, pp. 73–79]. Initiation of TMV assembly occurs by interaction between ring-shaped aggregates (‘discs’) of coat protein (each disc consisting of two layers of 17 subunits) and a unique internal nucleation site in the RNA: a hairpin region ca. 900 nucleotides from the 3' end in the common strain of TMV. (Any RNA – including e.g. subgenomic RNAs – containing this site may be packaged into virions.) The discs apparently assume a helical form on interaction with the RNA, and assembly (elongation) then proceeds in both directions (but much more rapidly in the 3'-to-5' direction) from the nucleation site. [Review of structure and assembly: JGV (1984) 65 253–279.]

**tobacco necrosis virus (TNV)** A PLANT VIRUS which can infect a range of angiosperms; transmission occurs via *Ophioidium* spp and can occur mechanically under experimental conditions. Symptoms of TNV infection range from severe necrosis (e.g. in Augusta disease of tulips) to local necrotic leaf lesions (e.g. in tobacco seedlings). Virion: icosahedral, ca. 28 nm diam., containing one polypeptide species (MWt ca. 22600); genome: a single molecule of linear positive-sense ssRNA (MWt ca. 1.3–1.6  $\times 10^6$ ) with the 5'-terminal sequence: ppApGpU...

TNV-infected plant cells may also contain a SATELLITE VIRUS: an icosahedral, ssRNA-containing virus [structure: JMB (1982) 159 93–108] which is completely dependent on the presence of

TNV for its replication. The satellite can be transmitted by the same mechanisms as TNV, and may influence the nature of the symptoms in the infected plant.

TNV (A strain) is the type member of a taxonomic group (the tobacco necrosis virus group); a possible member of this group is cucumber necrosis virus.

**tobacco necrotic dwarf virus** See LUTEOVIRUSES.

**tobacco rattle virus** See TOBRAVIRUSES.

**tobacco ringspot virus** See NEPOVIRUSES.

**tobacco streak virus** See ILARVIRUSES.

**tobacco vein distorting virus** See LUTEOVIRUSES.

**tobacco vein mottling virus** See POTYVIRUSES.

**tobacco vein necrosis disease** See POTATO VIRUS Y.

**tobacco yellow dwarf virus** See GEMINIVIRUSES.

**tobacco yellow net virus** See LUTEOVIRUSES.

**tobamoviruses** A group of PLANT VIRUSES in which the virion is a rigid filament consisting of one molecule of linear, positive-sense ssRNA associated with a single type of coat polypeptide. Type member: TOBACCO MOSAIC VIRUS; other members: e.g. cucumber green mottle mosaic virus, cucumber 4 virus, tomato mosaic virus. A group of morphologically similar viruses which are transmitted by members of the Plasmidiophoromycetes (*Polymyxa*, *Spongospora*) – including e.g. beet necrotic yellow vein virus, peanut clump virus, potato mop top virus, soil-borne wheat mosaic virus – were tentatively included in the tobamoviruses, but see SOIL-BORNE WHEAT MOSAIC VIRUS.

**tobramycin** 3'-DeoxyKANAMYCIN B.

**tobraviruses** (tobacco rattle virus group) A group of bipartite ssRNA-containing PLANT VIRUSES which have a wide host range (including monocots and dicots) and which are transmitted primarily by nematodes (*Paratrichodorus* and *Trichodorus* spp) but also via seeds and (sometimes) mechanically; the viruses persist in, but do not replicate in, the nematode vector. Type member: tobacco rattle virus (TRV) (PRN isolate); other member: pea early-browning virus. Possible member: peanut clump virus. Symptoms of tobnavirus infection typically include necrosis; TRV can cause e.g. SPRAING in potatoes.

Virion: tubular, consisting of a helix (pitch 2.5 nm) of protein-coated linear positive-sense ssRNA; two types of particle occur: one (L particle) is ca. 180–215 nm long and contains RNA1 (MWt ca.  $2.4 \times 10^6$ ), the other (S particle) is 46–114 nm long (depending on isolate) and contains RNA2 (MWt ca.  $0.6\text{--}1.4 \times 10^6$ ). RNA1 can be replicated in plant cells in the absence of RNA2, and L particles (but not S particles) can alone cause lesions in the host plant; however, both L and S particles are necessary for the formation of progeny virions (RNA2 encodes the coat protein).

**Todd–Hewitt broth** A medium used for the culture of certain *Streptococcus* spp. It contains an infusion of fat-free beef heart, peptone, glucose, sodium chloride, and a buffer system (sodium bicarbonate and disodium hydrogen phosphate); pH: 7.8.

**Todd unit** (TU) A unit used to express the antibody titre in an ANTISTREPTOLYSIN O TEST; it has been defined as the minimum amount of serum which can neutralize 2.5 minimum haemolytic doses of a standard preparation of streptolysin O.

**tofu** An intermediate in SUFU production. Tofu may itself be used as a food.

**Togaviridae** A family of enveloped ssRNA-containing VIRUSES, most of which can infect a wide range of vertebrates; most members also infect arthropods which act as VECTORS (cf. ARBOVIRUSES). The family includes a number of important pathogens of man and animals, some of which can be transmitted transplacentally and can cause abortion or abnormalities in the

infected fetus. Arthropod vectors (which remain infected for life) are apparently unharmed. The Togaviridae contains four genera (members of a genus being serologically related to each other but unrelated to those of other genera): ALPHAVIRUS, ARTERIVIRUS, PESTIVIRUS and RUBIVIRUS; possible members of the family include LACTATE DEHYDROGENASE VIRUS and carrot mottle virus. [Taxonomy: Intervirology (1985) 24 125–139.] (cf. FLAVIVIRIDAE.)

The togavirus virion is spherical (ca. 50–70 nm diam.) and consists of a nucleocapsid (ca. 28–35 nm diam.) – which is icosahedral in at least some species – surrounded by a lipoprotein envelope. The nucleocapsid is composed of a single type of core protein (C protein) associated with the RNA genome. The envelope bears surface projections (spikes) composed of two major glycoproteins, E1 and E2; in Semliki Forest virus a third glycoprotein, E3, is associated with the spikes, but in other alphaviruses E3 is released into the culture fluid in infected cell cultures. The nature of the glycosylation of these proteins is variable, depending at least in part on the nature of the host cell. The envelope glycoproteins are responsible for haemagglutinating activity and for virus infectivity. [Structure of alphaviruses: see e.g. Cell (2001) 105 5–8.]

The virus genome consists of a single molecule of linear positive-sense ssRNA (MWt ca.  $4 \times 10^6$ ); in those viruses which have been investigated, the RNA is capped and polyadenylated. In alphaviruses, at least, the gene sequence is 5'-nsP1–nsP2–nsP3–nsP4–C–E3–E2–E1-3', where nsP1–nsP4 are non-structural proteins (apparently RNA-dependent RNA polymerase components). [Nucleotide sequence of Sindbis virus: Virology (1984) 133 92–110.]

Togavirus replication occurs in the host cell cytoplasm; the process has been studied chiefly in the alphaviruses Semliki Forest virus and Sindbis virus. In these viruses, the non-structural proteins are synthesized directly from the (42S) genome-length (+)-strand RNA, while structural proteins are translated from capped and polyadenylated 26S subgenomic RNA which is initiated internally on a full-length (–)-strand template. (Rubella virus employs a similar strategy, producing 40S genome-length and 24S subgenomic RNAs [JV (1984) 49 403–408].) Translation is initiated at a single site, and the proteins are generally cleaved from the nascent polypeptide during translation. The synthesis of each type of viral RNA (full-length (–)-strand, full-length (+)-strand, and subgenomic) is apparently regulated independently; 26S RNA is produced in excess of 42S RNA, and genomic RNA is rapidly encapsidated, so that a large excess of structural over non-structural proteins is achieved. Virus maturation involves budding through the plasma membrane or through intracytoplasmic membranes. [Overview of the replication cycle: Book ref. 148, pp. 1021–1032.]

Many alphaviruses induce rapid and dramatic CPE in vertebrate cells (cf. RUBIVIRUS); host cell RNA and protein synthesis is rapidly arrested, and the cells eventually lyse. Some alphaviruses can establish persistent infections in vertebrate cells. [Effects of alphavirus infection on vertebrate cells: Book ref. 150, pp. 465–499.] Invertebrate cells are generally infected persistently with no apparent adverse effects.

**togaviruses** Viruses of the TOGAVIRIDAE.

**Tokophrya** See SUCTORIA.

**TOL plasmid** An IncP-9 *Pseudomonas* PLASMID (ca. 117 kb) which encodes the capacity to metabolize toluene and xylene. (cf. CAM PLASMID; OCT PLASMID; SAL PLASMID.) [Degradative plasmids of *Pseudomonas*: Book ref. 198, pp. 295–323.]

TOL encodes the enzymes of a two-stage catabolic pathway for the mineralization of toluene and xylene. Initially, these

## TolA protein

substrates are oxidized to their respective carboxylic acids. Such oxidation involves enzymes encoded by the *upper* operon of the TOL plasmid; the Pu promoter of the upper operon is regulated by an enhancer-dependent sigma factor ( $\sigma^{54}$ ; see SIGMA FACTOR) in association with the activator protein XylR. The *meta* operon of TOL encodes enzymes involved in aromatic ring fission and subsequent formation of pyruvate and acetaldehyde (which enter the TCA cycle). [Regulation of the *upper* and *meta* operons of the TOL plasmid; EMBO (2001) 20 1–11 (4–6).]

In strains of *Pseudomonas* carrying the Tol plasmid, the availability of iron may be an important factor in the oxidative metabolism of toluene [AEM (2001) 67 3406–3412].

**TolA protein** See COLICINS.

**TolB protein** See COLICINS.

**toleragen** See IMMUNOLOGICAL TOLERANCE.

**tolerance** (*immunol.*) See IMMUNOLOGICAL TOLERANCE.

**tolG gene** See OMP.

**tolnaftate** (2-naphthyl-*N*-methyl-*N*-(*m*-tolyl) thiocarbamate) An ANTIFUNGAL AGENT which is effective in the topical treatment of dermatophyte infections but which has little or no activity against most other fungi or bacteria.

**tolQ gene** See TONB PROTEIN.

**TolQ protein** See COLICINS.

**tolR gene** See TONB PROTEIN.

**TolR protein** See COLICINS.

**toluidine blue** A blue metachromatic basic thiazine DYE used e.g. in ALBERT'S STAIN and for VITAL STAINING.

**Tolypocladium** See HYPHOMYCETES; see also CYCLOSPORIN A.

**tolypomycins** See ANSAMYCINS.

**Tolyposporium** See USTILAGINALES.

**Tolyptothrix** See SCYTONEMA.

**tolZ gene** See FTSH.

**tomatine** A glycoalkaloid SAPONIN present in high concentrations in green tomatoes. It is toxic to many fungi; in mutant strains of *Fusarium solani* which are resistant to tomatine the cytoplasmic membrane has been found to have lower-than-normal levels of sterols.

**tomato apical stunt viroid** See VIROID.

**tomato aspermy virus** See CUCUMOVIRUSES.

**tomato black ring virus** See NEPOVIRUSES.

**tomato bunchy top viroid** See VIROID.

**tomato bushy stunt virus** See TOMBUSVIRUSES.

**tomato golden mosaic virus** See GEMINIVIRUSES.

**tomato mosaic virus** See TOBAMOVIRUSES.

**tomato (Peru) mosaic virus** See POTYVIRUSES.

**tomato planta macho viroid** See VIROID.

**tomato ringspot virus** See NEPOVIRUSES.

**tomato spotted wilt virus (TSWV)** A PLANT VIRUS which appears to be unrelated to other known viruses, although it has some properties resembling those of bunyaviruses. Virion: spherical, enveloped, ca. 82 nm diam., containing 4 major and up to 3 minor proteins. Genome: ssRNA (one negative-sense and two AMBISENSE pieces).

TSWV can infect a wide range of host plants. Infected cells contain granular cytoplasmic inclusion bodies. Immature virions are each surrounded by two lipoprotein membranes, but the mature virions each have a single envelope and occur in groups within membranous vesicles. Maturation resembles that of the BUNYAVIRIDAE. Transmission occurs (circulatively) via thrips (Thysanoptera); only the larval stage of the insect can acquire the virus from an infected plant, but once acquired the virus is retained by the insect for life. TSWV can also be transmitted mechanically under experimental conditions.

**tomato top necrosis virus** See NEPOVIRUSES.

**tomato yellow dwarf virus** See GEMINIVIRUSES.

**tomato yellow leafcurl virus** See GEMINIVIRUSES.

**tomato yellow mosaic virus** See GEMINIVIRUSES.

**tomato yellow net virus** See LUTEOVIRUSES.

**tomato yellow top virus** See LUTEOVIRUSES.

**tomaymycin** See ANTHRAMYCIN.

**tombusviruses** (tomato bushy stunt virus group) A group of ssRNA-containing PLANT VIRUSES which can infect a wide range of angiosperms. Transmission occurs mechanically and possibly via the soil. Type member: tomato bushy stunt virus (TBSV); other members: e.g. artichoke mottled crinkle virus, carnation Italian ringspot virus, *Cymbidium* ringspot virus, and eggplant mottled crinkle virus. (Other 'possible members' – e.g. carnation mottle virus, saguaro cactus virus, and turnip crinkle virus – appear on the basis of subgenomic dsRNA analysis to have a different genome organization and may constitute a separate group [Book ref. 80, pp. 80–83].) [Serological relationships among tombusviruses: JGV (1986) 67 75–82.]

Virion: icosahedral, 30 nm diam., containing one molecule of linear positive-sense ssRNA (MWt ca.  $1.5 \times 10^6$ ). The capsid is composed primarily of 180 molecules of a major coat protein. Each coat protein molecule (386 amino acid residues) is folded into three distinct domains (P, S and R): the S domains form the tightly bonded icosahedral shell, the P domains form surface projections, and the (N-terminal) R domains apparently project inwards and may bind the genomic RNA; the P and S domains are linked via a flexible hinge region. [Virion structure: Book ref. 81, pp. 43–50.] Within infected plant cells, the virus particles occur in the cytoplasm and nucleus (often associated with the nucleolus), sometimes forming crystalline arrays; compact membranous inclusion bodies ('multivesicular bodies') occur in the cytoplasm.

**tomentose** Downy; woolly.

**tomentum** (*lichenol.*) A downy or felted mat of hyphae which occurs (usually) on the lower surface of the thallus in certain foliose lichens.

**tomite** A typically small, motile, non-feeding stage in the life cycles of certain protozoa; it is generally formed, within a CYST, by the division of a cell called a *tomont*. In e.g. ICHTHYOPHTHIRIUS the tomite acts as a THERONT. In members of the Apostomatida the tomite itself eventually encysts at a site on a suitable host (becoming a *phoront*) and subsequently develops into a cell capable of feeding (a *trophont*) – which later develops into a tomont; in some apostomes a stage known as a *protomite* occurs between the tomont and tomite stages.

**tomont** See TOMITE.

**TonA protein** (FhuA protein) In *Escherichia coli*: an OUTER MEMBRANE protein encoded by the *tonA* gene; it acts as a receptor for e.g. colicin M and bacteriophages T1 and  $\phi 80$ , and is involved in the uptake of albomycin and ferrichrome.

**TonB protein** In e.g. *Escherichia coli*, a periplasmic protein that *shuttles* between the cytoplasmic membrane and outer membrane [Mol. Microbiol. (2003) 49 869–882], supplying energy (from pmf) to the outer membrane for the uptake of e.g. ferric iron–chelate complexes (see SIDEROPHORES); it is also involved e.g. in the uptake of VITAMIN B<sub>12</sub> by BINDING PROTEIN-DEPENDENT TRANSPORT.

The uptake of vitamin B<sub>12</sub> across the outer membrane in *E. coli* is pmf-dependent [JB (1993) 175 3146–3150]; it appears that maximum activity of this (and other) TonB-dependent systems requires the products of *exbB* and *exbD* (proteins in the cytoplasmic membrane) which may stabilize TonB. ExbB and

ExbD seem to be replaceable, to some extent, by the products of *tolQ* and *tolR*.

TonB is involved in the susceptibility of the cell to bacteriophage  $\phi$ 80. It is also required for the uptake of group B colicins: colicins B, D, Ia, Ib, M, V, 5 and 10 [colicin import into *Escherichia coli* cells: JB (1998) 180 4993–5002]. (See also FEPA PROTEIN and TSX PROTEIN.)

**tonoplast** The membrane which forms the boundary of an intracellular vacuole.

**tonsillitis** Inflammation of the tonsils, commonly caused by *Streptococcus pyogenes*. (See also OTITIS MEDIA, QUINSY, RHEUMATIC FEVER.)

**Tontonia** See OLIGOTRICHIDA.

**tooth diseases** See DENTAL CARIES and PERIODONTITIS.

**top-fermenting yeast** See BREWING.

**top necrosis** (*plant pathol.*) Necrosis (death) of the terminal bud or of the entire top of a plant.

**topical** (*med., vet.*) Local, i.e., restricted to a particular region of the body; not SYSTEMIC.

**topo I, topo II, etc.** *Syn.* TOPOISOMERASE type I, topoisomerase type II, etc.

**topoisomer** Topoisomers are molecules which differ from one another only in their topological properties. For example, a given dsDNA molecule may occur in a number of topologically distinct forms: linear, relaxed circular, or supercoiled circular (dscccDNA molecules with different linking numbers, but otherwise identical, are topoisomers); interconversion of topoisomers necessitates strand breakage and/or joining. (See also DNA.)

**topoisomerase** (DNA topoisomerase) Any enzyme which can convert one topological isomer of cccDNA to another; topoisomerases can e.g. alter the linking number (*Lk*) of a cccDNA molecule (see DNA) and (at least in vitro) can form and resolve knots and CATENANES – i.e. the reactions catalysed by a topoisomerase can be intermolecular or intramolecular. All such topological conversions involve transient breakage of either one or both strands of DNA.

*Type I* (= *type 1*) topoisomerases (also called untwisting, relaxing or nick-closing enzymes, or swivelases) break only one strand of DNA; in a dscccDNA molecule, the unbroken strand is passed through the break before re-sealing, thus changing the value of *Lk* by one for each such event.

*Type II* (= *type 2*) topoisomerases break both strands of DNA in a dscccDNA molecule; a (double-stranded) segment of DNA from elsewhere in the molecule is then passed through the break (without strand rotation) before re-sealing – each such event changing the value of *Lk* by two.

Both types of enzyme are found in both prokaryotic and eukaryotic cells.

Certain topoisomerases are the targets of QUINOLONE ANTIBIOTICS (q.v.).

An example of a type I topoisomerase is the  $\omega$  (omega) protein of *Escherichia coli* (*E. coli* topoisomerase I, or 'topo I'); in vitro, this enzyme can e.g. partially relax negatively (but not positively) supercoiled DNA, can introduce topological knots into sscccDNA, and can convert complementary sscccDNA circles into completely base-paired dscccDNA. The primary in vivo role of topo I appears to be the relaxation of negative supercoiling; topo I is necessary e.g. for chromosomal DNA REPLICATION. Topo III (encoded by gene *topB*) is another type I topoisomerase in *E. coli*; like topo I, this enzyme can relax negative supercoiling (and e.g. form and resolve knots) in vitro, but its in vivo role has not been established.

Type II topoisomerases include GYRASE, REVERSE GYRASE, bacteriophage T4 topoisomerase (gp39, 52, 60), and topoisomerase

II' (topo II', an enzyme from *E. coli* which contains gyrase subunit A and a part of gyrase subunit B). The T4 enzyme and topo II' have been reported to relax positively or negatively supercoiled DNA. In vitro, type II topoisomerases can form and resolve catenanes and can also form and resolve knots. In a model for the mechanism of type II topoisomerases, binding of the enzyme initially introduces a sharp bend in the DNA, the enzyme adopting a specific orientation with respect to the bend and subsequently promoting unidirectional passage of the strands through the break [PNAS (2001) 98 3045–3049].

Topoisomerase IV is a type II enzyme encoded by genes *parC* and *parE* in *E. coli*. This enzyme can e.g. relax more fully those negatively supercoiled molecules of DNA which have been partially relaxed by topo I; topo IV appears to be responsible – solely – for decatenation and for the resolution of knots in *E. coli* [GD (2001) 15 748–761].

**topological winding number** See DNA.

**topotaxis** A behavioural response in which a motile organism moves (directly or indirectly) towards or away from a directional stimulus. (cf. PHOBIC RESPONSE.)

**Torbal jar** See MCINTOSH AND FILDES' ANAEROBIC JAR.

**TORCH diseases** A group of diseases – comprising TOXOPLASMOSIS, RUBELLA, CYTOMEGALIC INCLUSION DISEASE, and HERPES SIMPLEX – each of which can cause abortion, stillbirth, severe neonatal disease, and sometimes fetal tissue damage with consequent developmental abnormalities.

**toroidal DNA** See DNA TOROID.

**Toroviridae** A family of enveloped RNA viruses proposed to include the BERNE VIRUS and serologically related viruses: e.g. BREDA VIRUS and some human gastroenteritis viruses.

**torr** See PASCAL.

**Torula** A genus of fungi of the HYPHOMYCETES. *T. herbarum* is common e.g. on dead grasses – forming dark, velvety colonies, and dark conidia in chains.

**torula yeast** A food yeast, *Candida utilis* (= *Torulopsis utilis*), grown e.g. on ethanol or sulphite liquor waste (see SINGLE-CELL PROTEIN); the yeast is pasteurized and dried before use. It is a rich source of protein and vitamins and is used medicinally and as a food additive.

**torularhodin** See CAROTENOIDS.

**Torulaspora** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are globose or ellipsoidal; vegetative reproduction occurs by multilateral budding. Pseudocellium is not formed. Vegetative cells are predominantly haploid (cf. SACCHAROMYCETES). Ascus formation is preceded by conjugation – usually between a cell and its bud, but sometimes between independent cells; asci are persistent. Ascospores: globose or ellipsoidal, smooth- or rough-surfaced, 1–4 per ascus. Glucose and certain other sugars are fermented vigorously; NO<sub>3</sub><sup>–</sup> is not assimilated. Species: *T. delbrueckii* (anamorph: *Candida colliculosa*), *T. globosa* (formerly e.g. *Saccharomyces kloeckerianus*), and *T. pretoriensis* (formerly e.g. *Saccharomyces pretoriensis*); strains have been isolated from fruit juice, wines, fermenting cucumber brines, soil, faeces, etc. [Book ref. 100, pp. 434–439.]

**Torulopsis** A genus of yeasts (class HYPHOMYCETES), now generally included within the genus CANDIDA [Book ref. 100, p. 841]. Hyphae and pseudohyphae are generally not formed.

**toruloposis** A MYCOSIS, now regarded as a form of CANDIDIASIS, caused by *Candida glabrata* (= *Torulopsis glabrata*). The disease (in man) is usually systemic, involving lungs, kidney, heart, CNS etc.

**torulosis** *Syn.* CRYPTOOCOCCOSIS.

**total cell count** See COUNTING METHODS.

## Totiviridae

**Totiviridae** See MYCOVIRUS.

**touchdown PCR** Repetition of a given PCR assay with a stepwise decrease in annealing temperature in each run; the object is to find the lowest annealing temperature (for the given assay) which will permit normal primer binding but avoid the problem of mispriming (i.e. binding of primers to inappropriate sequences). (The procedure thus seeks a level of stringency which promotes maximum specificity of primer binding.) [Examples of use: NAR (1991) 19 4008; JCM (1999) 37 1274–1279.]

**tower fermenter** See FERMENTER.

**toxaemia** (toxemia) The condition in which TOXINS are present in the blood. (cf. PYAEMIA; SEPTICAEMIA.)

**toxemia** *Syn.* TOXAEMIA.

**toxic** Poisonous; harmful. (cf. TOXIN.)

**toxic epidermal necrolysis** (TEN) A syndrome characterized by erythema followed by separation of the outer epidermis from the basal layer of the skin; it may be caused by ET-producing staphylococci (staphylococcal TEN – see SCALDED SKIN SYNDROME) or by a hypersensitivity reaction to certain drugs (allergic TEN).

**toxic food poisoning** See FOOD POISONING.

**toxic shock syndrome** (TSS) A severe, often fatal, illness characterized by fever, vomiting, diarrhoea and hypotension; late symptom: a sunburn-like rash with peeling of the skin, especially on palms and soles. In menstruating women, TSS is associated with the use of vaginal tampons. In children, TSS may follow burns or scalds etc.; encephalitic symptoms may occur in very young children in whom cytokines may cross the blood–brain barrier.

TSS is caused by certain of the toxins that are classified as SUPERANTIGENS: the B and C enterotoxins of *Staphylococcus aureus*, the toxic shock syndrome toxin 1 (TSST-1) of *S. aureus* (known earlier as enterotoxin F, pyrogenic exotoxin C and toxic shock toxin), and the superantigen A of *Streptococcus pyogenes*. The gene that encodes TSST-1 occurs on a *mobile PATHOGENICITY ISLAND* – possibly accounting for the spread of toxigenicity in *S. aureus* [Mol. Microbiol. (1998) 29 527–543].

Bacteraemia is uncommon in staphylococcal TSS, common in streptococcal TSS. In the acute phase of staphylococcal TSS there is a higher proportion of e.g. V $\beta$ 2 T cells, and raised levels of e.g. IL-2, IL-4, TNF- $\alpha$ , TNF- $\beta$  and IFN- $\gamma$ .

[Multiplex PCR for detection of the genes of *S. aureus* enterotoxins B and C, and TSST-1: JMM (1998) 47 335–340. Multiplex PCR for detection of genes for *S. aureus* enterotoxins, exfoliative toxins, toxic shock syndrome toxin 1 and methicillin resistance: JCM (2000) 38 1032–1035.]

**toxic shock syndrome toxin 1** (TSST-1) See TOXIC SHOCK SYNDROME AND SUPERANTIGEN.

**toxicoinfection** See *infant* BOTULISM.

**toxicosis** Any human or animal disease caused by poisoning (see e.g. MYCOTOXICOSIS).

**toxicyst** A type of tubular EXTRUSOME which occurs in many carnivorous ciliates (e.g. *Actinobolina*, *Didinium*, *Dileptus*); on activation, the tubular structure everts, penetrates the prey, and apparently introduces toxin(s) and proteolytic enzymes.

**toxigenic** (toxigenic) Refers to an organism which can produce one or more TOXINS.

**toxin** In a microbiological context: any of various microbial products or components which, at low concentrations, can act in a specific way on cells or tissues in a higher (multicellular) organism and cause local and/or systemic damage, or death – such an agent (alone, or with other toxin(s) and/or virulence factor(s)) being responsible, directly or indirectly, for at least some aspect

of pathogenesis. In many cases there is insufficient information on the role of a given agent in pathogenesis to decide whether or not it conforms to the above definition.

In some cases the known activity of a toxin is sufficient to account for all the observed features of pathogenesis in a given disease. For example, the zinc-endopeptidase activity of tetanus toxin, which blocks neuroexocytosis (see TETANOSPASMIN), adequately explains why inhibitory neurotransmitter is not released into the synaptic cleft.

In other cases, the activity of a toxin depends on one or more additional virulence factors. For example, toxigenic strains of *Bacillus anthracis* can cause ANTHRAX only if the cells have an antiphagocytic capsule. Again, the virulence of ETEC depends on plasmid-encoded fimbriae with which the bacteria adhere to the epithelium of the small intestine.

While tetanus toxin is involved *directly* in the mechanism of pathogenesis, the pathogenic role of some toxins is due partly or solely to their ability to behave as MODULINS – e.g. the B and C enterotoxins and TSST-1 of *Staphylococcus aureus* (see TOXIC SHOCK SYNDROME AND SUPERANTIGEN). Many types of bacterial toxin can induce cytokines, the exotoxins being particularly potent inducers.

Not all toxic microbial substances are called ‘toxins’. For example, generally *not* regarded as toxins are those products (e.g. lactic acid, hydrogen sulphide) which are significantly toxic to animals or plants only when present in relatively high concentrations (cf. ACIDOSIS *sense* 1 and SUFFOCATION DISEASE) – or which have an essentially physical role in causing or enhancing disease (e.g. alginate in CYSTIC FIBROSIS).

Also traditionally excluded from the category ‘toxin’ are those microbial products which, at low concentrations, are toxic to other *microorganisms* (e.g. ANTIBIOTICS, BACTERIOCINS).

The definition of a toxin may be based on criteria which differ in different disciplines. Thus, medical and veterinary workers may accept as toxins: (i) certain microbial enzymes which act as AGGRESSINS; (ii) substances toxic to cells *in vitro* but whose role in causing or exacerbating disease under natural conditions is unknown; (iii) substances produced at a site remote from the ‘target’ organism (see e.g. BOTULISM and *paralytic* SHELLFISH POISONING). Plant pathologists may not accept that *enzymes* can be toxins, and may not accept as toxins substances in categories (ii) and (iii) [discussion: Book ref. 58, pp 139–140].

A given toxin may be categorized according to the nature of the organism producing it (e.g. mycotoxin, phycotoxin), the nature of the organism affected by it (e.g. ichthyotoxin), the type of cell or tissue affected (e.g. ENTEROTOXIN, HAEMOLYSIN *sense* 2, hepatotoxin, LEUCOCIDIN, NEUROTOXIN) etc. (See also ENDOTOXIN and EXOTOXIN.) However, such categories are sometimes imprecise and may be misleading: e.g. an ‘ichthyotoxin’ may be toxic to organisms other than fish, and terms such as ‘hepatotoxin’ and ‘enterotoxin’ may be applied to toxins which can affect other types of cell and tissue.

For algal toxins see: PHYCOTOXIN.

For fungal toxins see: MYCOTOXIN.

For protozoal toxins see: *amoebic* DYSENTERY.

For bacterial toxins see: ANTHRAX TOXIN, BOTULINUM TOXIN, CHOLERA TOXIN, DELTA-ENDOTOXIN, DIPHTHERIA TOXIN, EPIDERMOLYTIC TOXIN, EXOTOXIN A, PERTUSSIS TOXIN, PHYTOTOXIN, RTX TOXINS, SHIGA TOXIN, TETANOSPASMIN. (See also HAEMOLYSIN *sense* 2), HYALURONATE LYASE, LEUCOCIDIN, THIOL-ACTIVATED CYTOLYSINS.)

[Bacterial protein toxins: Book ref. 206.]

**toxin co-regulated pili** (TCP) See CHOLERA, BACTERIOPHAGE CTX $\Phi$  and PATHOGENICITY ISLAND.

**toxinogenic** *Syn.* TOXIGENIC.

**toxoid** A TOXIN which has been modified (e.g. by treatment with formalin) so as to destroy its toxicity without affecting its specific immunogenicity. Thus, antibody formed against a toxoid can inactivate the corresponding toxin; toxoids are therefore useful in VACCINES.

**toxosome** A MICRONEME in *Toxoplasma*.

**Toxoplasma** A genus of parasitic, facultatively heteroxenous protozoa (suborder EIMERIORINA); the organisms have been classified by some authors [AP (1982) 20 403–406] in the genus ISOSPORA. *T. gondii* (= *I. gondii*) is an intracellular parasite and the causal agent of TOXOPLASMOSIS (q.v. for life cycle; see also PHAGOCYTOSIS); the sporozoites of *T. gondii* are uninucleate, banana-shaped, motile cells ca.  $5\text{--}8 \times 1\text{--}2 \mu\text{m}$ , but smaller, stumpy or ovoid cells occur within cysts. In the INTERMEDIATE HOST (birds, non-felines, man) only asexual reproduction occurs; in the FINAL HOST (members of the cat family) reproduction occurs asexually in extra-intestinal tissues as well as sexually in the intestinal tissues. *T. gondii* forms disporic, tetrazoic oocysts (10–15  $\mu\text{m}$ ) which undergo SPORULATION outside the (feline) host. Once sporulated, oocysts remain infective in soil for e.g. 1–2 years; they can be rendered uninfected e.g. by heating to 90°C for 30 sec [AP (1982) 20 310].

**Toxoplasma dye test** (Sabin–Feldman dye test) A serological test used to detect and quantify antibodies to *Toxoplasma gondii*. The patient's serum is heated (56°C/30 min) and a range of dilutions is prepared. To each dilution is added (i) live laboratory-cultured cells of *T. gondii*, and (ii) normal serum containing a known amount of 'accessory factor' – i.e., COMPLEMENT [JID (1980) 141 366–369]; each test dilution is then incubated. In the presence of antibodies (*positive test*) the cells are damaged and are unable to take up an indicator dye (alkaline methylene blue); this is determined by microscopy. In the absence of antibodies the (undamaged) cells take up the dye.

**Toxoplasmea** A class of parasitic protozoa (subphylum SPOROZOA); organisms of this class (e.g. *Sarcocystis*, *Toxoplasma*), together with those of the TELOSPOREA and PIROPLASMEA, have been incorporated in the class SPOROZOASIDA.

**toxoplasmosis** An acute or chronic disease of man and other animals (e.g. cat, goat, pig, sheep) caused by *Toxoplasma gondii* (see TOXOPLASMA). In man, infection occurs by ingestion of sporulated oocysts (present e.g. in infected cat faeces) or of 'tissue cysts' in raw or insufficiently cooked infected meats. Infection may be asymptomatic, there may be mild lymphadenopathy, or the disease may be generalized with e.g. hepatitis, pneumonia, myalgia, meningoencephalitis etc; latent infection may persist for years. In the acute phase of the disease the parasite multiplies endodyogenously in cells of various tissues (including e.g. macrophages), forming *pseudocysts*; a pseudocyst (= *group stage*) is the remains of a host cell packed with rapidly dividing cells (*endozoites*, *tachyzoites*) of the parasite. (See also PHAGOCYTOSIS.) If the host survives, the disease enters the chronic phase in which the parasite localizes in certain tissues (e.g. brain, eye, skeletal muscles, heart), forming *tissue cysts*; a tissue cyst (also called a *pseudocyst* or *meront*) is a structure (ca. 50–100  $\mu\text{m}$ ) containing cells of the parasite (*cystozoites*, *bradyzoites*) which are undergoing slow endodyogenous division. Toxoplasmosis may be transmitted transplacentally; the congenital disease often involves lesions in the brain and/or eyes and may lead to blindness, mental retardation, or death (cf. TORCH DISEASES). *Lab. diagnosis*: e.g. (i) inoculation of material from lesions into mice and examination of smears or sections post mortem; (ii) serological tests – e.g. a CFT and the TOXOPLASMA DYE TEST; (iii) an indirect immunofluorescence test (or

an ELISA-based test) for antibodies. A PCR-based assay for *T. gondii* (in HIV-positive patients) was reported to have a specificity of 100% but poor sensitivity (only 25%); it was nevertheless suggested that this assay may find use in differentiating between cerebral toxoplasmosis and clinically similar disease [JCM (1997) 35 2639–2641]. *Chemotherapy*: e.g. PYRIMETHAMINE with sulphonamides.

In the cat infection with *T. gondii* may occur on ingestion of mature oocysts (from other cats) or tissue cysts (in avian or mammalian prey); *T. gondii* develops in both extra-intestinal and intestinal tissues. In the intestine the parasite multiplies by endodyogeny, endopolygeny and schizogony and forms macrogametes and biflagellate microgametes. Macrogametes are fertilized in situ, and the zygote develops into an oocyst which is shed, unsporulated, in the faeces. Adult cats are usually symptomless; kittens may respond with diarrhoea and death or with anorexia and wasting. Congenital toxoplasmosis occurs e.g. in goats and sheep, and is one cause of abortion in sheep. [AP (1982) 20 296–332.]

**Toxothrix** A genus of colourless GLIDING BACTERIA which occur e.g. in cold, iron-containing springs; the trichomes give rise to bundles of thin, iron-oxide-containing inanimate filaments. [Habitat and culture: Book ref. 45, pp. 409–411.]

**ToxR, ToxS, ToxT** See BACTERIOPHAGE CTX $\Phi$ .

**TPA** 12-*O*-tetradecanoylphorbol-13-acetate. (See also ZEBRA.)

**TPB<sup>-</sup>** Tetraphenylborate: see CHEMIOSMOSIS.

**TPHA test** *Treponema pallidum* haemagglutination test. A TREPONEMAL TEST, involving passive haemagglutination, in which an *absorbed* serum (cf. FTA-ABS TEST) is tested for its ability to agglutinate tanned erythrocytes sensitized with antigens from the Nichol's strain of *Treponema pallidum*. In *primary* SYPHILIS the TPHA test is less sensitive than the FTA-ABS test, but these tests have similar sensitivities in other stages of the disease.

**TPI test** (*Treponema pallidum* immobilization test) A TREPONEMAL TEST previously used extensively as a confirmatory test in the diagnosis of SYPHILIS; the antibodies detected by the test are specific to *Treponema pallidum* and some other *Treponema* spp. Essentially, the test depends on the immobilization of living (motile) cells of *T. pallidum* in the presence of specific antibodies and COMPLEMENT. To the serum under test is added a standardized suspension of *T. pallidum* and a volume of fresh guinea-pig serum as a source of complement; the whole is incubated anaerobically for 18 hours at 37°C and examined microscopically. In a positive reaction a specified proportion of treponemes is immobilized.

**TPMP<sup>+</sup>** Triphenylmethylphosphonium: see CHEMIOSMOSIS.

**TPN** Triphosphopyridine nucleotide (NADP): see NAD.

**TPP** THIAMINE pyrophosphate.

**tra gene** See TRANSFER OPERON and F PLASMID.

**tra operon** See TRANSFER OPERON.

**traA gene** See F PLASMID.

**tracheal antimicrobial peptide** See DEFENSINS.

**tracheal cytotoxin** In WHOOPING COUGH: a toxin (apparently a fragment of PEPTIDOGLYCAN from the pathogen) which kills epithelial cells to which the pathogen is adherent.

**Trachelomonas** A genus of EUGLENOID FLAGELLATES in which the cells closely resemble those of EUGLENA except that each is enclosed within a yellowish to reddish-brown, round or ovoid LORICA composed mainly of ferric hydroxide and manganese oxides; the lorica is ornamented with spines in some species. The emergent flagellum protrudes through the lorica, and the organisms are free-swimming.

**Trachelophyllum** A genus of carnivorous ciliates (subclass GYMNOSTOMATIA) which occur e.g. in some SEWAGE TREATMENT

## **Tracheloraphis**

plants. Cells: elongated, with uniform body ciliature and a cytostome at the end of the narrower anterior region.

**Tracheloraphis** See KARYORELICTID GYMNOSTOMES.

**Trachelostyla** See HYPOTRICHIDA.

**Trachipleistophora** See MICROSPORIDIOSIS.

**trachoma** A potentially blinding disease of the eye which, in nature, affects only man; the causal agent is *Chlamydia trachomatis* (see CHLAMYDIA). Infection occurs contaminatively. Initially there is a follicular CONJUNCTIVITIS affecting particularly the margin of each upper eyelid (tarsal conjunctivae) – but also affecting the inner surfaces of the eyelids (palpebral conjunctive) and the (bulbar) conjunctiva on the anterior surface of the eyeball. Discharging follicles, containing accumulations of macrophages, polymorphs and lymphocytes, develop within the conjunctival tissues, the latter subsequently becoming scarred. The contraction of scarred tissues leads to intumed eyelids. The consequent abrasion of the cornea by the eyelashes causes ulceration, scarring and impairment/loss of vision. A thin fibrovascular membrane (*pannus*) develops on the surface of the cornea. Lymphoid follicles may develop at the cornea–sclera junction; on healing, these leave characteristic depressions (*Herbert's pits*). The mechanism of pathogenesis is not understood; it has been suggested that it may involve cell-mediated HYPERSENSITIVITY. Chemotherapeutic agents commonly used include e.g. TETRACYCLINES. Laboratory diagnosis typically involves the examination of specimens by e.g. IMMUNOFLUORESCENCE or enzyme immunoassay techniques.

[Book ref. 193, pp. 135–170.]

**Trachyspora** See UREDINIOMYCETES.

**trachytectum** *Syn.* EXOSPORIUM (sense 2).

**tractellum** A (eukaryotic) FLAGELLUM which 'pulls' the cell forwards.

**TRADD** See TNF.

**traffic ATPase** (1) *Syn.* ABC TRANSPORTER. (2) *Syn.* BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**Trager duck spleen necrosis virus** See AVIAN RETICULOENDOTHELIOSIS VIRUSES.

**traI gene** See F PLASMID.

**trailer** (*mol. biol.*) See MRNA.

**traJ gene** See F PLASMID.

**traM gene** See F PLASMID.

**trama** The sterile (i.e., non-generative) inner tissue of a LAMELLA or DISSEPIENT or of the 'teeth' of members of the Hydnaceae. (See also BILATERAL TRAMA.)

**Trametes** A genus of lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form basidiocarps in which the hymenophore is porous. *T. pini* is parasitic on certain trees. For *T. versicolor* see CORIOLUS. (See also XYLANASES.)

**trans-acting** See CIS-DOMINANCE.

**trans complementation** See CIS-TRANS TEST.

**transaldolase** See Appendix I(b) and RMP PATHWAY.

**transaminases** (of *Escherichia coli*) See AMMONIA ASSIMILATION.

**transcapsidation** See PHENOTYPIC MIXING.

**transcient** A cell which has received DNA from another cell.

**transconjugant** See CONJUGATION (1b) and CONJUGATIVE TRANSPOSITION.

**transcriptase** An RNA POLYMERASE involved in TRANSCRIPTION. (cf. RNA-DEPENDENT RNA POLYMERASE.)

**transcription** The synthesis of an RNA strand in a process in which ribonucleoside 5'-triphosphates (rNTPs) base-pair sequentially with nucleotides in a template strand and are polymerized in the 5'-to-3' direction (with elimination of PPI) by an RNA POLYMERASE; the template strand is DNA in cells and DNA viruses,

RNA in e.g. RNA viruses (see RNA-DEPENDENT RNA POLYMERASE). (cf. REVERSE TRANSCRIPTASE.)

(Until recently it has been observed that only one of the two strands of DNA in a gene acts as template in transcription. Interestingly, it has been reported that a certain gene in the fruitfly (*Drosophila*) contains protein-encoding information in *both* strands – RNAs synthesized on both template strands being subsequently joined to form a single molecule of mRNA [Nature (2001) 409 1000].)

In e.g. *Escherichia coli* (and other bacteria) *initiation* of transcription begins when the RNA POLYMERASE (RPase) holoenzyme binds to a PROMOTER. The polymerase core enzyme itself has a high affinity for dsDNA and can bind at (apparently) any site to form a stable, 'closed' enzyme–DNA complex in which the DNA strands are not unwound. Interaction of a SIGMA FACTOR with the core enzyme confers on it specificity for a particular class of PROMOTER while greatly reducing its affinity for other DNA sequences. The holoenzyme binds very tightly to its corresponding promoter; initially a 'closed' complex is formed, but this is subsequently converted to an 'open' complex in which a short region of the DNA bound by the enzyme becomes unwound. The first rNTP can then pair with a base on one of the DNA strands (the *start point* or *start site*). A few nucleotides are then incorporated, each being added to the 3'-OH of the preceding nucleotide; the  $\sigma$  factor then dissociates. (The first nucleotide retains its 5'-triphosphate group.) [Polymerase–promoter interactions: JB (1998) 180 3019–3025.]

*Elongation* is carried out by the RPase core enzyme (possibly in association with the product of the *nusA* gene, a protein which can bind to the core enzyme but not to the holoenzyme); the polymerase moves along the dsDNA, locally unwinding the strands to expose the ssDNA template, 'supervising' the correct base-pairing between incoming rNTPs and the template, and linking the nucleotides in the 5'-to-3' direction (antiparallel to the template) with elimination of pyrophosphate. In this way, a transient RNA–DNA hybrid duplex is formed in the region of the enzyme–DNA complex; as the enzyme proceeds, the RNA peels away from the template and the DNA duplex is restored. [Role of RNA polymerase in elongation: JB (1998) 180 3265–3275.]

In some cases, transcription of genes or operons occurs divergently (in opposite directions) from closely spaced promoters. This causes an increase in the level of negative supercoiling in the region between polymerases (negative supercoiling being generated behind each advancing polymerase). Such localized accumulation of negative superhelicity may affect the expression of genes/operons [Mol. Microbiol. (2001) 39 1109–1115].

Elongation continues until a specific *termination* signal (*terminator*, *t*) is reached. Terminators in bacteria vary in efficiency and in mechanism of action; secondary structure in the transcript itself appears to be important in effecting termination. In a *rho-independent* ('simple') terminator the RNA transcript of the termination region contains a GC-rich PALINDROMIC SEQUENCE (which can form a stem-and-loop structure) continuous with a run of consecutive uridine (rU) residues at the 3' end. The stem-and-loop structure causes the RPase to pause at the oligo-rU region, and the sequence of rU-dA base pairs (which is relatively unstable) may facilitate the release of the transcript and/or dissociation of the transcription complex. In a *rho-dependent* ('complex') terminator, the transcript may contain a stem-and-loop structure (which is not particularly GC-rich), but there is generally no oligo-rU sequence or any other apparent consensus sequence. In this case termination requires the participation of

a protein, the *rho* ( $\rho$ ) factor; the  $\rho$  factor is apparently active in hexameric form, has RNA-dependent NTPase activity (which is necessary for termination), and apparently interacts directly with the RNA transcript. The precise mode of action of  $\rho$  is unknown; it has been proposed that there is a  $\rho$  recognition site in the RNA, and that termination occurs at a relatively fixed distance downstream of this recognition site [Book ref. 188, pp. 155–178]. The NusA protein also appears to play some role in termination. [Review of transcription termination: Book ref. 60, pp. 123–161.]

The initial product of transcription (the *primary transcript*) may undergo extensive processing and/or modification to give the mature RNA product: see e.g. entries for mRNA, rRNA and tRNA.

Initiation and termination of transcription are important control points for gene expression: see e.g. ANTITERMINATION, CATABOLITE REPRESSION, OPERON. (See also POLAR MUTATION.)

**transcription antitermination** In certain Gram-positive bacteria (e.g. *Bacillus subtilis*): a control mechanism in which genes whose products are involved in the synthesis of amino acids (and in linking amino acids to tRNAs) are switched on when limiting amounts of those amino acids give rise to uncharged tRNAs. It appears that an uncharged tRNA interacts with the leader region of the gene's mRNA, causing reversal of a transcription terminator structure (formed when the cell has adequate amounts of the amino acid) to an antiterminator structure, thus enabling synthesis of the amino acid. [tRNA-directed transcription antitermination: Mol. Microbiol. (1994) 13 381–387.]

**transcription initiation factors** See RNA POLYMERASE.

**transcription-mediated amplification** See TMA.

**transcriptional coupling** Coupling between closely spaced promoters which results from *divergent* transcription from the promoters and the consequent transcription-dependent increase in negative superhelicity in the region between the active RNA polymerases; such local accumulation of negative superhelicity may activate or repress a promoter, or it may have little or no effect, depending on the intrinsic properties of the given promoter. [Possible role of transcriptional coupling in the *ilv* regulon of *Escherichia coli*: Mol. Microbiol. (2001) 39 1109–1115.]

**transcytosis** In certain Opa<sup>+</sup> strains of *Neisseria*: translocation through a layer of (mammalian) epithelial cells without disruption of the eukaryotic cell–cell junctions; transcytosis involves an initial phase in which the bacteria bind to specific receptors on the host cells and are then engulfed by the host cells [TIM (1998) 6 489–495]. (See also PARACYTOSIS.)

**transductant** See TRANSDUCTION.

**transduction** The virus-mediated transfer of host DNA (chromosomal or plasmid) from one host cell (the *donor*) to another (the *recipient*). Transduction was first observed in bacteriophage/bacterium systems, but has since also been found to be mediated by certain viruses infecting eukaryotic cells (see RETROVIRIDAE). The account below concerns only phage/bacterium systems.

Essentially, when a phage replicates in a (donor) cell, a few progeny virions encapsidate pieces of host DNA instead of – or in addition to – phage DNA; these virions can adsorb to a new host cell and introduce their DNA in the usual way. There are two basic types of phage-mediated transduction.

(a) *Generalized transduction*: any of a wide range of donor genes may be transduced, and the transducing phage particles contain *only* donor DNA. In some systems any of the host genes has a more or less equal chance of being transduced, but in

other systems some genes are transferred at higher frequencies than others. For example, in the BACTERIOPHAGE P22/*Salmonella* system, certain regions of the host chromosome resemble the P22 *pac* site, and packaging of chromosomal DNA may be initiated at and proceed from these sites [MGG (1982) 187 516–518]; thus, the probability of a given gene being transduced depends on its distance from a *pac*-like site. (Certain 'high-frequency transduction' (HT) mutants of P22 have been shown to be defective in *pac* recognition [JMB (1982) 154 551–563].)

The fate of the transduced DNA in the recipient cell (now called a *transductant*) depends on various factors. If the DNA is a complete replicon (e.g. a plasmid) it may be stably inherited by the transductant. If the DNA is a fragment of a chromosome or plasmid, it may undergo one of three possible fates. (i) It may be completely degraded by the recipient cell's RESTRICTION ENDONUCLEASE system. (ii) It may undergo RECOMBINATION with a homologous region of the recipient's chromosome (or plasmid), so that at least some of the genes it carries can be stably inherited (*complete transduction*). (iii) It may persist in the cell in a stable but non-replicating form (*abortive transduction*). (The transduced DNA in an abortive transductant may exist as a circular DNA–protein complex [Virol. (1980) 106 30–40].) Any donor genes present (and linked to promoters) may be expressed, and (if they are dominant alleles) the transductant may express the donor phenotype in respect of these genes. However, when an abortive transductant divides, only one of the daughter cells will receive the donor fragment; the other may nevertheless receive sufficient donor-gene products to permit expression of the donor phenotype for one or a few generations. Such abortive transduction is normally manifest by the formation of minute (often microscopic) colonies on medium selective for transductants; only one cell in the colony actually contains donor DNA.

The transduction of one particular donor gene is a rare event (e.g.  $10^{-7}$ – $10^{-5}$ , depending e.g. on phage). If two or more genes are transduced together (*cotransduction*) they are assumed to occur on the same fragment of DNA and are thus closely linked in the donor; generalized transduction has thus been used in the detailed mapping of donor chromosomes, distances between markers being estimated by determining their cotransduction frequencies.

(b) *Specialized (restricted) transduction* is mediated only by temperate phages which integrate into the host chromosome (see LYSOGENY); only bacterial genes immediately adjacent to the prophage can be transduced, and the transduced DNA is covalently linked to some or all of the phage genes. For example, when a population of *Escherichia coli* cells lysogenized by BACTERIOPHAGE  $\lambda$  is induced, a small proportion of the progeny virions may carry either *gal* or *bio* host genes – often at the expense of certain phage genes at the opposite end of the prophage (virion component genes in *gal*-containing particles, control genes in *bio*-containing particles); such virions (specialized transducing particles, STPs) arise as a result of rare aberrant excision events in which recombination occurs between sites other than the hybrid *att* sites (*attR* and *attL*). (A lysate from an induced lysogen will normally contain a heterogeneous population of STPs resulting from different aberrant excision events in different cells.) An STP can infect a recipient cell and introduce its DNA into the cell; however, if it lacks phage genes essential for replication (i.e., if it is *defective*) it will require the presence of a (non-defective) helper phage in order to produce progeny STPs. (cf. RETROVIRIDAE.)

A lysate obtained by induction of a lysogen contains only a small (and mixed) population of STPs (e.g. one STP per  $10^6$

## transductional shortening

wild-type particles); consequently, when the lysate is used to infect a culture of recipient cells only a few of the cells will be infected by an STP. Such lysates are therefore termed *low-frequency transducing* (LFT) lysates. If e.g. a *gal*<sup>-</sup> recipient culture is infected with an LFT lysate derived from a *gal*<sup>+</sup> donor population, a few recipients will become *gal*<sup>-</sup>/*λgal*<sup>+</sup> (merodiploid heterogenotes). In some of these cells homologous recombination may occur between the *gal*<sup>-</sup> and *gal*<sup>+</sup> regions to result in a stable, non-lysogenic *gal*<sup>+</sup> transductant ('replacement transduction'). Alternatively, the DNA of the STP may integrate, intact, into the host chromosome by homologous recombination, producing a lysogenic heterogenote ('addition transduction'). (Owing to the manner of its formation, an STP will normally contain a hybrid *attR* or *attL* site instead of the usual *attP*, and so integrates at *attB* only with low efficiency.) However, since non-transducing (wild-type) phage particles are present in great excess in an LFT lysate, at high multiplicities of infection a recipient is likely to be simultaneously infected with both wild-type and transducing phages. In this case both phage genomes can integrate into the recipient's chromosome to form a *double lysogen*; this probably occurs by normal site-specific integration of the wild-type genome, followed by homologous recombination between it and the defective phage genome. If the double lysogen is subsequently induced, both phages will replicate (the wild-type phage supplying the missing functions of the defective STP); the resulting lysate may thus contain approximately equal numbers of *λ* and *λgal*<sup>+</sup> particles. Furthermore, the population of STPs will be homogeneous, unlike that in an LFT lysate. Such a lysate can be used to infect another population of cells, and the *gal*<sup>+</sup> genes will be transduced with high frequency; the lysate is thus termed a *high-frequency transducing* (HFT) lysate.

Rarely, the genome of a wild-type *λ* integrates at sites other than *attB* in the host chromosome, and STPs from such lysogens will carry genes other than *gal* or *bio*.

(See also MINI-MU.)

**transductional shortening** The phenomenon observed in the TRANSDUCTION of a large plasmid: the transduced plasmid is smaller than the original donor plasmid, probably because the phage particles encapsidate deletion mutants of the plasmid (which arise spontaneously at low frequencies).

**transfection** Originally, the introduction of viral nucleic acid into an intracellular environment and the subsequent formation of normal virions.

Currently, the term is used for any *in vitro* procedure in which nucleic acid is introduced into cells in order to modify those cells genetically or to carry out intracellular experimentation. Transfection is also used to refer to the introduction of proteins or peptides into cells.

**transfer DNA synthesis** *Syn.* DCDS: see CONJUGATION (1b)(i).

**transfer operon** (*tra* operon) In a CONJUGATIVE PLASMID: an OPERON containing those genes which specify functions necessary for CONJUGATION (sense 1b). (cf. SEX FACTOR sense 2.) In some conjugative plasmids (see e.g. F PLASMID) the genes of the transfer operon encode e.g. PILI, certain proteins involved in DNA mobilization, and proteins involved in SURFACE EXCLUSION. Some conjugative plasmids (e.g. the F plasmid) are DEREPRESSED for conjugal transfer, but many or most are repressed. (See also FINOP SYSTEM.)

**transfer RNA** See TRNA.

**transferases** ENZYMES (EC class 2) which catalyse the transfer of a group from one molecule to another. Subclasses are recognized and numbered according to the nature of the group transferred

(e.g., subclass 1: one-carbon groups such as methyl, formyl, hydroxymethyl).

**transfersome** See CONJUGATION (1b)(i).

**transferrin** A SIDEROPHILIN which occurs in vertebrate plasma; its main function is to transport iron into cells. The iron–transferrin complex binds to a cell-surface receptor and is internalized via a coated vesicle (see PINOCYTOSIS); the iron is subsequently released, within the cell, and may be stored as an iron–FERRITIN complex. Although iron is tightly bound by transferrin it can be removed e.g. by certain bacteria or their products: see IRON. Interestingly, the intraerythrocytic stage of *Plasmodium falciparum* appears to obtain iron from iron–transferrin complexes by synthesizing transferrin receptors that become localized in the cell surface of the infected erythrocyte [Nature (1986) 324 388–391].

**transformant** A cell or organism which has undergone genetic TRANSFORMATION.

**transformation** (1) (*genetics*) A process in which exogenous DNA is taken up by a (*recipient*) cell, sphaeroplast or protoplast, in which it may be incorporated into the chromosome (or e.g. into a plasmid) by homologous RECOMBINATION or converted into an autonomous replicon. The DNA (*transforming* or *donor* DNA) may be e.g. a fragment of chromosomal DNA from a related strain, a plasmid, or a viral genome (see TRANSFECTION). Transformation can occur under natural conditions in some bacteria (e.g. *Bacillus*, *Haemophilus*, *Neisseria* and *Streptococcus* spp), but in many bacteria (including e.g. *Escherichia coli*) and in certain eukaryotic microorganisms it can occur only in cells 'permeabilized' to DNA by artificial methods.

It has been suggested that transformation (among other mechanisms) may contribute to the spread of antibiotic resistance in certain pathogenic bacteria [Science (1994) 264 375–382].

*Natural bacterial transformation systems.* Cells which are able to take up DNA are said to display *competence*. Competence is apparently constitutive in some species – e.g. *Neisseria gonorrhoeae* (in which it is reported to occur only in fimbriated cells [JGM (1984) 130 3165–3173]). However, in other species competence is a transient phenomenon that is dependent on certain factors – such as nutritional status and/or the phase of growth (in batch cultures). In *Haemophilus influenzae*, for example, competence is induced by growth-inhibiting conditions; in this species it is promoted by high levels of intracellular cAMP (cyclic AMP). In both *Bacillus subtilis* and *Streptococcus pneumoniae* competence is affected e.g. by the population density of the bacteria – an example of QUORUM SENSING. For example, when *B. subtilis* grows to a high density of cells, a secreted pheromone (designated ComX) accumulates in the extracellular environment; at an appropriate concentration, ComX activates a TWO-COMPONENT REGULATORY SYSTEM which, in turn, leads to the activation of certain genes (including *comS*) whose function is needed for the establishment of competence. In *S. pneumoniae*, competence has also been associated with the transmembrane transport of calcium [JB (1994) 176 1992–1996]. [Competence in transformation: TIG (1996) 12 150–155.]

To be effective in transformation, a fragment of chromosomal DNA must be double-stranded and larger than a certain minimum size – which depends on recipient. The DNA binds to the surface of a competent cell; initially binding is reversible and dependent on the concentration of the donor DNA, but subsequently a limited number of DNA molecules become irreversibly bound to specific cell-surface receptor sites. In *S. pneumoniae* and *B. subtilis* binding is non-specific with respect to the DNA, DNA from other species being bound

as readily as DNA from the same species. By contrast, in *Haemophilus* and *Neisseria* spp DNA binding is sequence-specific; *H. influenzae* takes up only dsDNA containing a 'DNA uptake site', a sequence (5'-A-A-G-T-G-C-G-G-T-C-A-3' [Gene (1980) 11 311–318]) which occurs frequently in the genomes of *H. influenzae* and *H. parainfluenzae* but much less so in DNA from other organisms.

In *B. subtilis* and *S. pneumoniae* the bound DNA is cleaved by an envelope-associated endonuclease. Subsequently, one strand of a fragment is internalized while its complement is degraded. It has been suggested that binding and uptake are achieved by a membrane-bound nuclease-containing protein complex, the nuclease processively degrading one strand of the DNA, thereby (possibly) driving the other through a pore in the membrane formed by other components of the complex. Within the recipient cell, the single-stranded fragment rapidly associates with cellular proteins to form a presynaptic *eclipse complex*; this probably protects the DNA from degradation. Synapsis between the donor (chromosomal) DNA and a homologous region of the recipient's chromosome rapidly ensues, and a single-stranded fragment of recipient DNA is effectively excised and replaced by the donor ssDNA to form a region of *hybrid DNA*; this could occur e.g. by invasion of the recipient duplex by the donor strand followed by 'strand assimilation' (cf. RECA PROTEIN). In *Haemophilus influenzae* and *H. parainfluenzae* a different type of uptake mechanism apparently occurs [PNAS (1982) 79 6350–6374], and dsDNA enters the recipient cell; however, recombination apparently still involves the pairing of a single donor strand with a complementary region of the resident DNA.

Resolution of the heteroduplex region may occur by separation of the strands during a subsequent round of semiconservative DNA synthesis, yielding some progeny resembling the donor, others the recipient, with respect to markers in this region. Alternatively, one of the strands may be corrected by a MISMATCH REPAIR system (*gene conversion*: cf. RECOMBINATION) to yield a homoduplex and hence a single type of progeny. In *S. pneumoniae* (but not in *B. subtilis*) some single-site mutations in the donor DNA are integrated into the recipient's chromosome more efficiently than others; it seems that this organism encodes a mismatch repair system (*hex* genes) which has different affinities for different mismatched base pairs, eliminating low-efficiency (LE) markers more efficiently than high-efficiency (HE) markers. (In *hex*<sup>-</sup> mutants all single-site mutations are integrated with the same high efficiency.) [*Hex* system in *S. pneumoniae*: MR (1986) 50 133–165.]

Plasmid DNA (ccc, ds) may also be taken up by competent cells; however, in natural systems transformation with plasmid monomers generally occurs only at very low frequencies, if at all, whereas plasmid oligomers (trimers or larger) can transform at high frequencies. Apparently the ccc dsDNA binds to the surface of a competent cell and undergoes cleavage and some degradation, and single strands enter the cell with the same polarity; if the plasmid is an oligomer, enough complementary ssDNA can eventually enter the cell to allow annealing and circularization and hence, with repair synthesis and ligation, regeneration of a plasmid monomer.

*Artificial transformation systems.* Non-competent cells of e.g. *Bacillus* or *Streptococcus*, or cells of those bacteria (e.g. *E. coli*) which cannot undergo transformation under natural conditions, may be induced to take up transforming DNA by various procedures involving laboratory-induced competence. For example, treatment of *E. coli* and other Gram-negative bacteria with high (millimolar) concentrations of calcium chloride, often in association with heat shock, induces artificial competence; calcium ions

may promote binding of DNA to the cell and increase the permeability of the cell envelope. In one scheme, calcium chloride solution (approx. 50 mM, 0.2 ml) containing 10<sup>8</sup>–10<sup>9</sup> washed, mid-log-phase cells of *E. coli* is chilled on ice, and a DNA suspension (10 µl) is added to give a final concentration of DNA of approx. 0.2 µg/ml; after further chilling at 0°C (15–30 minutes), the suspension is heat-shocked (42°C/1.5–2 minutes) and allowed to recover – e.g. returned to ice and then incubated in Luria–Bertani broth (1 ml) at 37°C for 1 hour.

The acquisition of competence by *E. coli* in ice-cold solutions of calcium is associated with the presence of a high concentration of poly-β-hydroxybutyrate/calcium polyphosphate complexes in the cytoplasmic membrane. It has been suggested that these complexes may form transmembrane channels which facilitate DNA transport, and that divalent cations may act as links between DNA and phosphate at the mouth of such channels [JB (1995) 177 486–490].

Small, circular plasmids tend to transform more readily than do larger ones. In wild-type *E. coli*, linear dsDNA transforms poorly (if at all) as it is degraded by the RecBC enzyme; linear dsDNA can transform some *recBC* mutants which lack a functional enzyme.

High-efficiency transformation of *E. coli* (and various other bacteria) with plasmids may be achieved by ELECTROPORATION.

Protoplasts from Gram-positive bacteria can be induced to take up DNA by treatment with POLYETHYLENE GLYCOL (PEG); viable cells can then be regenerated from the transformed protoplasts (and from certain types of sphaeroplast). (See also PROTOPLAST FUSION.)

PERMEAPLASTS have been used for the transformation of certain cyanobacteria. [DNA uptake by '*Anacystis nidulans*': MGG (1986) 204 243–248.]

In artificially competent cells, sphaeroplasts and protoplasts, DNA appears to be taken up intact.

[Methods for bacterial transformation by plasmid DNA: Book ref. 177, pp. 61–95.]

Certain fungi can be transformed artificially. In e.g. *Saccharomyces cerevisiae*, one method involves mixing sphaeroplasts (prepared e.g. with Zymolyase) with the DNA in the presence of Ca<sup>2+</sup>, and then adding PEG; in another method, whole cells are treated with alkali metal ions (usually lithium ions) and PEG, a method which is simpler but less efficient. [Transformation in fungi: Book ref. 179, pp. 161–195 (yeast) and pp. 259–278 (*Aspergillus*); Book ref. 178, pp. 468–472 (*Cephalosporium acremonium*).]

Certain unicellular green algae can also be transformed: e.g. *Chlamydomonas reinhardtii* has been transformed with yeast DNA [Nature (1982) 296 70–72].

(2) (of cells in tissue culture) See TISSUE CULTURE.

(3) (of lymphocytes) See BLAST TRANSFORMATION.

**transforming DNA** ('transforming principle') See TRANSFORMATION (1).

**transfusion-transmitted infection** Any infectious disease which can be transmitted via a transfusion of blood or blood-related products. Transfusion-transmissible agents include certain bacteria (e.g. *Treponema pallidum*), protozoa (e.g. *Plasmodium* spp) and viruses (e.g. hepatitis viruses B and C, human immunodeficiency virus (HIV) and, more recently, TT VIRUS). (See also CREUTZFELDT–JAKOB DISEASE.)

[Transfusion-associated hepatitis G virus infection: NEJM (1997) 336 747–754. Transfusion-transmitted malaria in the USA: NEJM (2001) 344 1973–1978.]

Other risks from transfused blood (apart from infection) include the possible presence of pro-inflammatory cytokines

## transgenesis

released from white blood cells during prolonged storage [e.g. Transfusion (1996) 36 960–965].

Avoidance of transfusion-transmitted infection is promoted e.g. by careful screening of donors and by appropriate tests on donated blood for specific infectious agents. Even so, infections still occur through transfusion. (*Autologous* blood transfusion involves re-infusion of the patient's own blood taken prior to anticipated requirement; one risk is that contamination may occur during donation, storage or use.)

For viral diseases, a major risk is that blood may be donated at a time when the donor has been recently infected with a given agent, is able to transmit that agent via blood, but has not yet become seropositive for the agent (i.e. the agent is still undetectable serologically). The period between initial infectivity and development of seropositivity (known as a diagnostic *window*) varies from one virus to another but is generally of the order of weeks/months. (In this context it is noteworthy that, normally, donor blood can be stored for a maximum of 35 days in the UK and 42 days in the USA.) To reduce the risk from window-phase blood, PCR-based tests have been used to detect the nucleic acid of hepatitis B and C viruses and the HIV-1 virus [Lancet (1999) 353 359–363]; nevertheless, transmission of hepatitis C virus via a blood donation negative in nucleic-acid-amplification tests has been reported [Lancet (2000) 355 41–42].

Other risk factors associated with transfused blood include the possibility that tests for a given agent may be insufficiently sensitive or may not detect genetically variant forms of an infectious agent. Additionally, human (laboratory) error, though rare, is always a possibility.

[Genome detection versus serology in blood screening for microbial agents: BCH (2000) 13 (4) chapter 8.]

**transgenesis** Incorporation of *alien* DNA, heritably, into living organisms by *in vitro* methods. [Book ref. 204.]

**transhydrogenase** Nicotinamide nucleotide transhydrogenase (EC 1.6.1.1): an enzyme which catalyses the (reversible) reduction of NADP<sup>+</sup> by NADH. *AB-transhydrogenases* are membrane-bound enzymes which occur e.g. in some bacteria and in mammalian mitochondria; *BB-transhydrogenases* are soluble flavoprotein enzymes found only in certain bacteria. Transhydrogenation of NADP<sup>+</sup> by AB-transhydrogenases appears to be regulated by pmf (see CHEMIOSMOSIS); transhydrogenation by BB-transhydrogenases is promoted e.g. by 2'-AMP and Ca<sup>2+</sup>.

**transition mutation** A type of POINT MUTATION in which one purine nucleotide is replaced by another, or one pyrimidine nucleotide is replaced by another. (cf. TRANSVERSION MUTATION.)

**transition state** (sporulation) See ENDOSPORE (sense 1).

**transketolase** See e.g. CALVIN CYCLE and Appendix I(b).

**translation** See PROTEIN SYNTHESIS.

**translational attenuation** A control mechanism in which the expression of certain genes is regulated by inhibition of their translation under given conditions. For example, in certain Gram-positive bacteria the *cat* gene (encoding chloramphenicol acetyltransferase) is induced by CHLORAMPHENICOL but normally remains unexpressed in the absence of this antibiotic. In the absence of chloramphenicol, the *cat* gene is transcribed but not translated; this is because the ribosome-binding site of the coding sequence is inaccessible owing to an inhibitory secondary structure in the mRNA formed by base-pairing between certain ribonucleotides. The presence of chloramphenicol inhibits development of the secondary structure, thus relieving repression of translation. (This mechanism operates with levels of chloramphenicol below those which inhibit protein synthesis.)

**translational enhancer** See DOWNSTREAM BOX.

**translational feedback regulation** See e.g. RIBOSOME (biogenesis).

**translational frame-shifting** A control mechanism in which the expression of certain genes is regulated during the *translocation* stage of PROTEIN SYNTHESIS. In this process, a specific sequence of nucleotides in the transcript acts as a signal that causes the ribosome to 'slip' along the mRNA; such a movement usually involves a '+1 slip' (i.e. a 1-nucleotide shift in the direction of translation) or a '-1 slip' (a 1-nucleotide shift in the opposite direction). Such a shift necessarily affects all subsequent codons. [Review: Mol. Microbiol. (1994) 11 3–8.]

**translational operator** See e.g. RIBOSOME.

**translesion synthesis** See SOS SYSTEM.

**translocase** *Syn.* translocon: see PROTEIN SECRETION (type II systems).

**translocation** (1) See PROTEIN SYNTHESIS. (2) Passage of viable bacteria across the epithelial barrier from the gut lumen [review: BCG (2003) 17 397–425].

**translocon** See PROTEIN SECRETION.

**transmissible disease** (1) Any disease which can be transmitted from one individual to another, or to a fetus, by any means, including experimental infection; 'transmissible disease' is therefore broader (more inclusive) than INFECTIOUS DISEASE. (2) Loosely, an infectious disease.

**transmissible gastroenteritis** (in pigs) An acute, typically non-febrile PIG DISEASE, characterized by diarrhoea and dehydration, which is often fatal in very young pigs; the causal agent is a coronavirus. The mode of transmission is uncertain. Incubation period: ca. 1–2 days. The virus replicates in distal regions of the villi, causing malabsorption and osmotically induced, typically yellowish-green diarrhoea.

**transmissible hypovirulence** See HYPOVIRULENCE.

**transmissible mink encephalopathy** A disease of mink which is probably a form of SCRAPIE; it appears to have arisen as a result of feeding farmed mink with scrapie-infected sheep meat. The disease can be transmitted experimentally to various other animals (but not to mice); in monkeys, infection results in a disease resembling experimental CREUTZFELDT-JAKOB DISEASE.

**transmissible spongiform encephalopathies** (TSEs) Fatal diseases of the nervous system characterized by spongiform degeneration of the brain without inflammation or specific immune response; in each disease the causal agent is a PRION (q.v.).

Unique features of TSEs include: (i) a novel mechanism of pathogenesis, (ii) manifestation in sporadic, inherited and transmitted forms, and (iii) (in contrast to e.g. Alzheimer's disease) manifestation in a range of histopathological patterns.

Human TSEs include CREUTZFELDT-JAKOB DISEASE, GERSTMANN-STRAUSSLER-SCHENKER SYNDROME (GSS syndrome) and KURU (all previously referred to as 'transmissible viral dementias'), and *fatal familial insomnia* (FFI; [NEJM (1992) 326 444–449]). FFI and GSS syndrome are both inherited diseases.

TSEs acquired by infection include kuru and (apparently) nvCJD (as well as the iatrogenic forms transmitted via medical/surgical treatment). Where infection involves ingestion of prion-contaminated food, it is believed that conversion of PrP to the prion form occurs initially within tissues of the gastrointestinal tract, and that such conversion continues to occur progressively in the lymphatic and/or peripheral nervous systems until it reaches the central nervous system. [Book ref. 215.]

The deposition of prions, in itself, may not be sufficient to cause neuropathy [Nature (1996) 379 339–343], suggesting that the development of disease may involve some kind of interaction between prions and the host's tissues.

Prions can be distinguished from the normal form of the protein by their ability to bind to plasminogen (a precursor of FIBRINOLYSIN), and this may be used as a basis for the development of a diagnostic test [Nature (2000) 408 479–483].

In animals, the TSEs include BOVINE SPONGIFORM ENCEPHALOPATHY (BSE; 'mad cow disease'), chronic wasting disease of elk and mule-deer, SCRAPIE, and TRANSMISSIBLE MINK ENCEPHALOPATHY.

Transmission of TSEs across species barriers has been demonstrated experimentally in a number of cases (e.g. sheep → mice; bovines → monkeys).

**transmissible viral dementias** See TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**transmission-blocking vaccine** See e.g. PLASMODIUM.

**transmission factor** (*plant virol.*) See NON-CIRCULATIVE TRANSMISSION.

**transovarial transmission** Transmission of a parasite from a host (or vector) to its offspring via the egg. (See e.g. BLACKHEAD and PULLORUM DISEASE; cf. VERTICAL TRANSMISSION.)

**transpeptidation** (in protein synthesis) See PROTEIN SYNTHESIS.

**transport medium** Any medium used specifically for the transportation and/or temporary storage of material (e.g. swabs) from which the isolation of particular organism(s) is subsequently to be attempted. The purpose of such a medium is to maintain the viability and/or infectivity of the organism(s) during the delay between collection and culture of the specimen. An effective transport medium is necessary e.g. for anaerobes (which may be killed by short or prolonged exposure to oxygen), for delicate organisms (e.g. *Neisseria gonorrhoeae*), and for certain viruses. The commonly used transport media are non-nutrient media which include STUART'S TRANSPORT MEDIUM and its modifications, e.g. Cary–Blair transport medium and Amies transport medium – the latter incorporating charcoal. (Charcoal-containing media obviate the need for collecting specimens on charcoal-impregnated swabs – the charcoal, in each case, serving to adsorb inhibitory substances in the medium and/or specimen.) Some transport media have been devised for particular organisms: see e.g. MONSIEUR TRANSPORT MEDIUM. For many types of virus, HANKS' BSS supplemented with protein (e.g. 0.5–2.0% bovine albumin) may be an effective transport medium; in such a medium some viruses can be rapidly frozen and stored at ca. –70°C.

**transport systems** Systems which permit the uptake or efflux of molecules or ions across membranes (e.g. ENERGY-TRANSDUCING MEMBRANES or the OUTER MEMBRANE in Gram-negative bacteria) – which are otherwise impermeable; the term 'transport' is used in a way which excludes transmembrane translocations concerned *exclusively* with energy conversion.

Some transport systems are specific for a particular substrate (or a few substrates) while others may be used for a range of substrates. Transport systems involved in the acquisition of essential component(s) are of course vital for the survival/growth of an organism. Such systems include e.g. the various IRON-uptake mechanisms in a range of organisms. Again, the inability of parasitic protozoa to synthesize their own purine nucleotides *de novo* means that these organisms must import pre-formed purines from their hosts; such uptake involves the operation of nucleoside transport systems which have been identified in various parasitic protozoa (including *Leishmania donovani*, *Plasmodium falciparum*, *Toxoplasma gondii* and *Trypanosoma brucei*) [see e.g. TIP (2001) 17 142–145].

Typically, transport requires energy (= active transport). Energy-independent transport may involve simple diffusion – for

example, uptake of small molecules or certain types of ion through a PORIN – or FACILITATED DIFFUSION (see also *glycerol facilitator* in MIP CHANNEL). In some cases transport and energy conversion are linked: see e.g. END-PRODUCT EFFLUX.

*Energy-dependent transport* may permit a cell or organelle to accumulate a substrate against a concentration gradient; this is necessary e.g. when a required molecule or ion occurs in low concentrations in the external environment. Such transport includes the following categories:

(a) *Group translocation*. In this form of transport the transmembrane translocation of substrate is obligatorily linked with chemical modification of that substrate. Transport systems of this type are commonly used e.g. for the uptake of sugars by bacteria: see PTS.

(b) *ATP hydrolysis-dependent transport*. The hydrolysis of ATP provides energy for various types of transport. For example, in *Escherichia coli*, ATP hydrolysis is needed for osmoregulatory uptake of potassium ions at a particular membrane ATPase (potassium pump). (See also ION TRANSPORT (b) and (d); TWO-COMPONENT REGULATORY SYSTEM.)

Uptake of IRON by the *E. coli* siderophore enterochelin involves initial binding of the iron–enterochelin complex by the FEPA PROTEIN. FepA is energized via the TONB PROTEIN (q.v.), and the iron–siderophore complex, released from FepA, passes through a system of proteins in the cytoplasmic membrane – transfer of the complex to the cytoplasm depending on ATP hydrolysis at a specific ATPase (FepC protein) in the cytoplasmic membrane.

ATP hydrolysis is also an essential feature of a large family of transport systems known as ABC TRANSPORTERS (q.v.) which include both importers and exporters.

Certain types of bacterial PROTEIN SECRETION involve energy derived from ATP hydrolysis.

(c) *Pmf-dependent transport*. Proton motive force (see CHEMIOSMOSIS) can be used, directly, for the transport of certain charged and uncharged species. Examples include the uptake of calcium ions by mitochondria (see ION TRANSPORT), and the proton–lactose symport system for lactose uptake in *Escherichia coli*. Such transport is inhibited by PROTON TRANSLOCATORS.

The uptake of vitamin B<sub>12</sub> across the outer membrane in *E. coli* is pmf-dependent [see JB (1993) 175 3146–3150].

As well as acting as a source of energy for transport, pmf can also *regulate* other transport systems. For example, by controlling the redox state of certain redox-sensitive membrane carrier proteins, pmf (as well as the redox potential of the environment) can control the transport of e.g. glucose by the PTS [AvL (1984) 50 545–555].

(d) *Smf-dependent transport*. See SODIUM MOTIVE FORCE and ION TRANSPORT.

*Transport in the control of metabolism*. The transport of a given substrate may be the rate-limiting step in the metabolism of that substrate; hence, the transport process itself may constitute an important control mechanism. According to the particular system involved, transport may be dependent on e.g. the level of pmf, the availability of a given ion species (for ion–substrate symport) or (as in the PTS) the availability of 'high-energy' compounds. In some cases, transport is reported to require the operation of the electron transport chain, i.e. to depend on electron flow rather than on pmf [AvL (1984) 50 545–555].

*Effect of transport on yield coefficient*. Differences in the YIELD COEFFICIENT of a given organism grown on different substrates may be attributed, at least partly, to differences in the energy costs of substrate transport. For example, in *E. coli* the transport

## transporter

of lactose by proton–lactose symport has been calculated to cost ca. 0.5 ATP per molecule transported, while maltose transport via a binding protein-dependent mechanism has been calculated to cost ca. 1.0–1.2 ATP per molecule transported [JB (1985) 163 1237–1242].

*Transport in other cell functions.* The above account refers primarily to transport involved in metabolism, secretion and osmoregulation. Transport is also required for e.g. PTS-dependent CHEMOTAXIS and for certain aspects of pathogenicity (see type III systems in PROTEIN SECRETION); it also appears to be involved in GLIDING MOTILITY in certain cyanobacteria [see e.g. JB (2000) 182 1191–1199 (1195–1196)].

**transporter** See PERMEASE.

**transposable element** (TE; ‘jumping gene’) A discrete DNA segment, within a larger DNA replicon, which can (actually or effectively) translocate to another (*target*) site in the same replicon, to a target site in another replicon in the same cell, or (see CONJUGATIVE TRANSPOSITION) to a target site in another cell; such translocation (termed *transposition*) does not require extensive DNA sequence homology between the TE and its target site. The following account refers to ‘classical’ transposable elements, i.e. TEs other than conjugative transposons.

TEs are normal components of e.g. chromosomes, plasmids and phage genomes. They are found in prokaryotes (see INSERTION SEQUENCE AND TRANSPOSON) and in eukaryotes – including yeasts (see e.g. TY ELEMENT), protozoa, *Drosophila* and higher plants. (See also INTRON HOMING.)

By convention, the presence of a TE in a given replicon is indicated by a double colon; for example, the presence of transposon Tn3 within a phage  $\lambda$  genome is designated  $\lambda::\text{Tn3}$ .

Different TEs employ different mechanisms for transposition. In bacteria, some TEs transpose by a *rec*-independent ‘replicative’ process, while others employ a non-replicative (‘simple’) mechanism – terms illustrated in the figure. (See also entries for Tn10 and Tn5.)

Some TEs can apparently employ different transposition mechanisms under different conditions: see e.g. BACTERIOPHAGE MU.

In eukaryotes, certain TEs appear to transpose via an RNA intermediate: see TY ELEMENT.

Transposition is normally a rare event, the actual frequency depending e.g. on the TE and on the physiological state of the cell (see e.g. entry for Tn501).

Functions necessary for transposition are usually encoded by the TE itself, although certain host cell functions may also be required – for example, in *Escherichia coli*, GYRASE has been implicated in the transposition of e.g. Tn5 [Cell (1982) 30 9–18]. Most TEs have a reading frame for at least one protein (e.g. a TRANSPOSASE), and each TE includes terminal INVERTED REPEAT sequences which apparently permit recognition of the TE by its transposase.

Target-site specificity is an intrinsic property of a TE. Some TEs (see entry for Tn7) are highly site-specific, while others appear to insert almost randomly; for example, Tn3 and IS1 show a preference for targets in (easily denaturable) AT-rich regions (cf. BACTERIOPHAGE MU), while IS5 inserts only at sites containing the sequence C(T/A)A(G/G/A). Nevertheless, even when insertion seems random, some kind of selective process is likely to be involved [ARB (1997) 66 437–474]. Studies on the transposition of IS903 into a large (55 kb) plasmid indicate that, while insertion can occur at many different sites, there are certain *preferred* regions into which IS903 will insert more than once on different occasions [JB (1998) 180 3039–3048].

Certain targets, termed ‘hot-spots’, are especially prone to insertion by particular TEs; for example, hot-spots for Tn3 insertion have been found to contain regions of homology with the Tn3 termini – although hot-spots for Tn10 insertion (see entry Tn10) bear no obvious relationship to the Tn10 termini.

Insertion of a TE at a target site results in the formation of direct repeats flanking the inserted TE; this is illustrated in the figure – which shows a scheme for the insertion of a TE by both ‘simple’ and ‘replicative’ mechanisms. The length of the target duplication is usually specific for the TE involved – for example, 5 bp for Tn3 and 9 bp for Tn10 (cf. IS1).

The transposition of some TEs (e.g. bacteriophage Mu, members of the Tn3/ $\gamma\delta$  family) is regulated by a *trans*-acting repressor (cf. Tn5); when a TE of this type enters a ‘naive’ host (i.e. a cell lacking a TE of the same type), transposition functions are expressed at a high level until repression of the TE has been established. (See also TRANSPOSITION IMMUNITY and MULTICOPY INHIBITION.) The transposition of e.g. Tn10 from a chromosomal location in *Escherichia coli* tends to be linked to the cell cycle; this is because Dam methylation inhibits transcription of the Tn10 transposase gene, and such inhibition is transiently relieved during chromosomal replication (immediately after the replication fork has passed the transposase gene but prior to Dam methylation of the gene).

TEs may be more or less ‘host-specific’; for example, IS1 appears to be limited mainly to strains of *Escherichia coli* K12.

[TEs in prokaryotes (review): ARB (1985) 54 863–896.]

The consequences of insertion of a TE at a new site depend on the TE and on the nature of the target site etc. If the insertion site is in a structural gene, an insertion mutation will result. If insertion occurs in an OPERON, strong polar effects may occur because TEs carry transcriptional and/or translational stop signals which prevent expression of all genes downstream of the insertion site. Insertion of a TE may also activate an operon – for example, the TE may carry a functional promoter, or may insert into, and inactivate, a sequence involved in the negative control of the operon. Precise excision of a TE from a site of insertion (an event that occurs at low frequency) leads to reversion of the corresponding mutation; however, imprecise excision (e.g. with deletion of adjacent host DNA) can also occur.

See also TRANSPOSON MUTAGENESIS.

TEs can also mediate a wide range of DNA rearrangements, including deletions and inversions of adjacent host DNA, formation and resolution of COINTEGRATES, gene fusion and amplification etc. These processes may be mediated by the mechanisms responsible for transposition per se; however, in some cases they may occur by transposition of a TE to another site in the same (or a different) replicon followed by *recA*-dependent recombination between the homologous sites thus created.

(See also entries for individual TEs under ‘IS’ and ‘Tn’.)

**transposase** An enzyme which is responsible for at least part of the process of transposition of a TRANSPOSABLE ELEMENT; a transposase (or a component of it) is usually encoded by the TE itself and is specific for that TE or for TEs with closely related terminal inverted repeats. (See e.g. Tn3; cf. IS101 and Tn951.)

**transposition** See TRANSPOSABLE ELEMENT.

**transposition (conjugative)** See CONJUGATIVE TRANSPOSITION.

**transposition immunity** A phenomenon in which a replicon containing a copy of Tn3 (or a Tn3-related transposon) is immune to the insertion of a second copy of the same transposon; the frequency of transposition of the transposon to other replicons in the same cell is unaffected. In the case of Tn3 the immunity

TRANSPOSABLE ELEMENT: a (diagrammatic) scheme for a transposon undergoing 'simple' and 'replicative' transposition.

(a) Two circular double-stranded DNA molecules. On the left, the donor molecule includes a transposon (dashed lines) – either side of which is an old 'target' site (●); the donor's target site was duplicated when the transposon was originally inserted into the donor molecule (see later). On the right, the molecule which will receive the transposon has a single target site (■) where the transposon will be inserted.

(b) An enzyme (a *transposase* – not shown) mediates at least the initial stages of transposition. A staggered break has been made at the target site. In the donor molecule, a nick has been made in each strand of the transposon (at opposite ends), and the free ends have been ligated to the target molecule, as shown. In 'simple' transposition (which occurs e.g. in transposon Tn10) the next (and final) stage is shown at (c).

(c) The result of 'simple' transposition. DNA synthesis has occurred from each free 3' end in the target molecule, using the (single-stranded) target site as template, to form the complementary strand of each target site (□). The remaining strand-ends of the transposon have been nicked and ligated as shown. Note that the target molecule's target site has been duplicated – compare with the donor molecule at (a). The rest of the donor molecule may be non-viable ('donor suicide').

(d) 'Replicative' transposition (which occurs e.g. in Tn3) involves stages (b), (d) and (e). At (d), new DNA synthesis (from each 3' end in the target molecule) has continued beyond the target site, using each strand of the transposon as template; that is, the transposon has been replicated. The end of each new strand has been ligated to a free strand-end in the donor molecule. The structure shown at (d) is called a *cointegrate*; the zigzag line represents newly synthesized DNA. Progress from stage (d) to stage (e) involves the activity of an enzyme called a *resolvase* (which is encoded by the transposon); this enzyme 'resolves' the cointegrate by promoting site-specific recombination between sites in the two copies of the transposon – forming the molecules shown at (e). (Continued on page 794.)

## transposon

is highly specific: a copy of Tn3 in a replicon confers immunity to insertion of a second copy of Tn3 but not to insertion of a closely related transposon such as Tn501. Apparently, only the terminal 38 bp of Tn3 need be present in a replicon to confer immunity. (cf. MULTICOPY INHIBITION.)

**transposon (Tn)** A TRANSPOSABLE ELEMENT (q.v.) which encodes not only those functions necessary for transposition but also functions that are unrelated to transposition – for example, resistance to antibiotics (see e.g. entries for Tn3, Tn5, Tn9, Tn10, Tn1721) or heavy metals (e.g. Tn501) or both (e.g. Tn2410), toxin production (e.g. ETEC heat-stable toxin; see Tn1681), and lactose metabolism (e.g. Tn951). (See also *conjugative transposons* in the entry CONJUGATIVE TRANSPOSITION.)

Some transposons (referred to as *class I, composite* or *compound* transposons) consist of a sequence containing structural genes flanked on either side by an INSERTION SEQUENCE – the two insertion sequences forming identical or non-identical, direct or inverted repeats; one or both IS elements mediate transposition of the entire transposon (see e.g. Tn10) and may also be able to transpose independently of each other and of the rest of the transposon.

Other transposons (*class II, simple* or *complex* transposons) consist of a sequence containing one or more structural genes flanked on either side by a short inverted repeat (see e.g. Tn3). *The use of transposons in laboratory studies.*

Transposons are valuable research tools that have many uses in the research laboratory. Depending on requirements, transposons can be inserted into the genomes of *living* cells (see e.g. TRANSPOSON MUTAGENESIS and SIGNATURE-TAGGED MUTAGENESIS) or inserted into isolated DNA molecules in an *in vitro* system.

The use of transposons has been facilitated e.g. by the development of a genetically modified form of a natural transposon, Tn5 (see TNS); this system can be used in the following approaches.

Transposons can be inserted, at random sites, into a population of plasmids (or other molecules) simply by incubating together the target DNA (i.e. population of plasmids), copies of the transposon and the relevant transposase; incubation is carried out at 37°C for a few hours in the presence of Mg<sup>2+</sup>. After incubation, the plasmids (most or all now containing a transposon inserted at a random location) are inserted into bacteria (e.g. *Escherichia coli*) by TRANSFORMATION or ELECTROPORATION; most or all of the bacteria will receive a transposon. If the transposon includes an antibiotic-resistance gene, plating the (transformed) bacteria on a medium containing the given antibiotic will select for those cells which contain a transposon. If, after incubating the plate, several colonies are chosen, each colony will contain cloned copies of the plasmid containing the transposon at a given, unique location.

How may such clones be used? If the plasmid is a large molecule, then each of a number of clones can be used for sequencing different parts of the molecule – using primers complementary to end-sequences in the transposon for bi-directional sequencing (see DNA SEQUENCING); as plasmids in different clones contain transposons in different (random) locations, sequencing can start from different sites around the molecule.

*In vitro* insertion of transposons, described above, may also be used for modifying a plasmid. Thus, the randomly inserting transposons may, in one or a few plasmids, insert into (and

inactivate) a particular gene, causing a *required* ‘knock-out’; such a mutant may be subsequently selected for in the population of transformed bacteria.

Transposons are also useful for carrying a specific gene into target cells; such a gene is inserted into the transposon.

*In vivo* insertion of transposons may be carried out with the same (Tn5-based) system: transposons, complexed with transposase in an Mg<sup>2+</sup>-free environment, are electroporated into living cells and insert (randomly) into the genome. This procedure may be used e.g. to insert a specific gene (carried by the transposon) and/or to create an insertional mutation in the genome.

**transposon mutagenesis** TRANSPOSON-MEDIATED MUTAGENESIS.

Various approaches involving transposon mutagenesis have been used e.g. for detecting/identifying potential virulence genes and/or gene products in pathogenic bacteria. One example is the detection of secreted and/or cell-surface-associated proteins – i.e. proteins which, because of their possible direct interaction with the host organism, are of interest as potential virulence-associated factors. To detect secreted/cell surface proteins, a population of the given pathogen is mutagenized with transposons that contain a promoter-less gene for alkaline phosphatase (*phoA*); these transposons (Tn*phoA*) insert randomly into the genome in cells of the bacterial population – inserting into different genes in different cells; the cells are then plated so that each cell forms an individual colony. Colonies are tested with a substrate for alkaline phosphatase which, if cleaved by the enzyme, generates colour. This substrate can be cleaved only if alkaline phosphatase has been secreted by the cells or if it is associated with the cell surface; hence, any colony which gives a positive (colour) reaction with the enzyme’s substrate indicates a secreted or cell-surface phosphatase. Because *phoA* (in the transposons) is promoter-less and lacks a signal sequence (see SIGNAL HYPOTHESIS), production of an extracellular alkaline phosphatase by cells in a given colony indicates that, in these cells, Tn*phoA* has inserted ‘in frame’ into the gene of a secreted or cell-surface protein, and that the signal sequence of the gene has enabled secretion of the phosphatase.

The gene containing Tn*phoA* is likely to have been inactivated by insertion of the transposon. If the gene is a virulence gene, the virulence of cells in the colony may be demonstrably reduced when the cells are tested in experimental animals; if so, the relevant (transposon-mutated) gene can be isolated, sequenced and characterized.

A system for transposon-mediated mutagenesis in *Haemophilus influenzae* takes advantage of the specific uptake-signal sequence which facilitates import of DNA by TRANSFORMATION [AEM (1998) 64 4697–4702].

Transposon mutagenesis, using *luxAB* genes (see BIOLUMINESCENCE) as a reporter system, has been used to identify genes induced in the COLD-SHOCK RESPONSE in *Sinorhizobium meliloti* [AEM (2000) 66 401–405].

(See also SIGNATURE-TAGGED MUTAGENESIS.)

**trans-stadial transmission** In a tick VECTOR (or, less commonly, an insect vector): the retention of infectious agents (e.g. viruses or bacteria) during the transition from larva to nymph, from nymph to adult, or throughout the entire period of transition from larva to adult. (See e.g. COWDRIA.)

TRANSPOSABLE ELEMENT (*continued*) (e) Donor and recipient molecules each contain a copy of the transposon; note that, in this model, each molecule contains parts of the original transposon (dashed lines) as well as newly synthesized DNA (zigzag lines).

Adapted from Fig. 11.29, p. 336, in *Molecular Biology of the Gene* 4th edn by Watson et al. Copyright 1965, 1970, 1976, 1987 by James D. Watson. Reprinted by permission of Addison Wesley Longman, Inc.

**transverse binary fission** See BINARY FISSION.

**transverse microtubules** (*ciliate protozoal*.) A ribbon of microtubules which arises at the left-hand anterior side of a kinetosome (near triplets 3–4(–5), GRAIN CONVENTION), extends upwards towards the pellicle, and then passes leftwards at right angles to the kineties, the wider face of the ribbon being parallel to the body surface. (See also RHABDOS.)

**transversion mutation** A type of POINT MUTATION in which a purine nucleotide is replaced by a pyrimidine nucleotide, or vice versa. (cf. TRANSITION MUTATION.)

**traO locus** See FINOP SYSTEM.

**Trapelia** See LECIDEA.

**traS gene** See F PLASMID and SURFACE EXCLUSION.

**traT gene** See F PLASMID and SURFACE EXCLUSION.

**travellers' diarrhoea** DIARRHOEA in persons outside their normal environment. Enterotoxigenic strains of *Escherichia coli* (see ETEC) are common causal agents, but almost any FOOD POISONING organism may be responsible.

**traY gene** See CONJUGATION (sense 1b).

**traZ gene** See CONJUGATION (sense 1b).

**treadmilling** See e.g. MICROTUBULES.

**Trebouxia** A genus of unicellular, coccoid, non-motile green algae (division CHLOROPHYTA); species are common photobionts in LICHENS, but they also occur (sparsely) in the free-living state e.g. on wood, bark, etc. The cells are variable in shape and size (up to ca. 35 µm diam.), free-living forms being larger than those in lichen thalli; each cell contains a single large central chloroplast with at least one central pyrenoid. 'Vegetative cell division' does not occur (cf. PSEUDOTREBOUXIA). Asexual reproduction involves the formation of biflagellate wall-less zoospores – at least in cells growing in liquid media; in lichen thalli zoospore formation is usually (but not always [Lichenol. (1980) 12 173–187]) suppressed, asexual reproduction occurring by autospore formation. [*Trebouxia* species from lichens: Lichenol. (1981) 13 65–86.]

*Trebouxia* has been placed – together with e.g. FRIEDMANNIA, MICROTHAMNION, PLEURASTRUM and PSEUDOTREBOUXIA – in an order, Pleurastrales, in the class Pleurostrophyceae (division Chlorophyta) [Book ref. 123, pp. 29–72]. (cf. TETRASELMI.)

**tree diseases** Decay of standing trees is generally due to fungal attack on the (dead) heartwood, the (living) sapwood being much less frequently attacked. Rotting of the heartwood generally does not affect the vital processes of the tree, but the tree eventually becomes structurally weakened and may be easily toppled in high winds. The fungi which attack heartwood (causing 'heart rots') normally gain access to it via wounds – e.g. damaged roots or broken branches. Important tree-rotting fungi include e.g. species of *Armillaria*, *Ganoderma*, *Heterobasidion*, *Piptoporus*, *Polyporus* and *Trametes*. (cf. TIMBER SPOILAGE; see also BROWN OAK; BROWN ROT; BUTT ROT and WHITE ROT.)

Other tree diseases include e.g. APPLE CANKER, BEECH BARK DISEASE, BLEEDING CANKER, BLISTER RUST, CHESTNUT BLIGHT, DUTCH ELM DISEASE, FIREBLIGHT, JARRAH DIEBACK, OAK WILT, PITCH CANKER, SOOTY BARK, SNOW BLIGHT, WATERMARK DISEASE and WETWOOD.

**tree lungwort** *Lobaria pulmonaria*.

**tree squirrel hepatitis B virus** See HEPADNAVIRIDAE.

**trehalose** ( $\alpha,\alpha$ -trehalose) A non-reducing disaccharide:  $\alpha$ -D-glucopyranosyl- $\alpha$ -D-glucopyranoside. It occurs e.g. in the haemolymph of insects, in certain algae (particularly red algae), in a few plants (commercial source: *Selaginella*), in actinomycetes and certain other bacteria (see e.g. CORD FACTOR), and as the major storage disaccharide in many fungi

and yeasts and some lichens. Trehalose is hydrolysed by an  $\alpha$ -glucosidase, *trehalase*, present in all trehalose-producing organisms. [Regulation of trehalose mobilization in fungi: MR (1984) 48 42–59.]

**Tremella** See TREMELLALES.

**Tremellales** An order of saprotrophic, lignicolous fungi (subclass PHRAGMOBASIDIOMYCETIDAE) which typically form gymnocarpous fruiting bodies in which the (usually) globose or clavate basidia each consist of a *longitudinally* septate metabasidium from which arise four elongated sterigmata. According to species, the basidiocarp may be e.g. crust-like, sheet-like and convoluted, or erect and stalked, it may be gelatinous (see JELLY FUNGI), waxy or leathery, and it may be e.g. orange, pink, brown or black. Genera include e.g. *Aporpium*, *Exidia* (*E. glandulosa* = 'witches' butter'), *Phlogiotis*, *Pseudohydnum*, *Tremella*. (See also TETRAGONIOMYCES.)

**tremorgenic** Capable of inducing tremors. (See e.g. PENITREMS.)

**trench fever** (Wolhynian fever) A louse-borne disease of man caused by *Bartonella quintana* (formerly called *Rochalimaea quintana*). The incubation period may be a few days or longer than a month. Symptoms include fever, severe muscular pain (particularly in the back and legs) and sometimes a maculopapular rash that occurs on the chest and abdomen; splenomegaly is common. Mortality rates are low, but complications (e.g. cardiac dysfunction) may occur, and relapses may occur in untreated patients. XENODIAGNOSIS has been used in the past, but diagnosis can now be achieved by culture and/or by complement-fixation tests and other serological approaches. The disease usually responds to chemotherapy with e.g. tetracyclines or chloramphenicol.

**trench mouth** *Syn.* VINCENT'S ANGINA.

**Trentepohlia** A genus of non-aquatic filamentous algae (division CHLOROPHYTA) which shares many features with e.g. CEPHALEUROS, PHYCOPELTIS and STOMATOCHROON [Book ref. 123, pp. 233–250]; the thallus is commonly heterotrichous (except in *Phycopeltis*), i.e., it is composed of more or less well-developed erect and prostrate systems of filaments; an orange-red pigment ('haematochrome') is stored in the cytoplasm; pyrenoids are absent; and zoospores and gametes are produced in specialized cells from which they are released via a single papillate exit pore. The flagella of the motile cells are characteristically bilaterally 'keeled' or 'winged'. In *Trentepohlia* spp. the erect system of orange-red filaments is well-developed, the prostrate system weakly developed. Species grow on rocks, wood or bark, or as photobionts in certain lichens (see e.g. OPEGRAPHA and ROCELLA). (See also ERYTHRITOL; PAINT SPOILAGE; RIBITOL.)

**Treponomas** See DIPLOMONADIDA.

**Treponema** A genus of Gram-negative bacteria (family SPIROCHAETACEAE) which occur as parasites or pathogens in the mouth, intestinal tract, and genital regions in man and other animals; some species are obligate anaerobes, but others (including *T. carateum* and *T. pallidum*) are now generally considered to be microaerophiles. The cells are helical, 0.1–0.4 × 5–20 µm, and motile; they stain poorly by the Gram stain but satisfactorily with silver deposition methods (see e.g. FONTANA'S STAIN). *T. pallidum*, *T. carateum* and *T. paraluisaniculii* have not been grown in cell-free media, and are propagated e.g. intratesticularly in rabbits (see also NICHOLS' TREPONEME). The other (obligately anaerobic) species have been grown in complex media and have a fermentative metabolism; isolation procedures are based e.g. on insensitivity to rifampicin, or on the ability of the cells to migrate through a membrane filter (pore size 0.2 µm) into, and through, a suitable agar medium. GC%: 25–54. Type species: *T. pallidum*. [Book ref. 22, pp. 49–57.]

## **Treponema pallidum immobilization test**

*T. bryantii*. Occurs in the bovine RUMEN; cells ca. 0.3 µm in diameter. Cultivable in media containing e.g. isobutyrate, pyridoxal, folic acid, biotin, thiamine and niacinamide. GC%: ca. 36.

*T. carateum*. The causal agent of PINTA. The cells are similar to those of *T. pallidum* (q.v.).

*T. denticola*. Occurs in the mouth (particularly the tooth – gum margin) in man and primates; cell diameter <0.2 µm. Cultivable in e.g. peptone–yeast extract–serum medium. GC%: 37–38.

*T. hyodysenteriae*. A pathogen of swine (see SWINE DYSENTERY). Cell diameter up to ca. 0.4 µm; 8 or 9 periplasmic flagella arise at each end of the cell. Cultivable in e.g. trypticase–soy broth containing 10% fetal calf serum and incubated under 10% CO<sub>2</sub>; produces a clear (‘β’) haemolysis. (cf. *T. innocens*.)

*T. innocens*. Occurs in the intestinal tract in dogs and swine but is apparently non-pathogenic. Cells are similar in size and structure to those of *T. hyodysenteriae*. Cultivable; weakly haemolytic. [Comparison of lipids in *T. hyodysenteriae* and *T. innocens*: IJSB (1984) 34 160–165.]

*T. minutum*. A non-pathogenic species which occurs on the genitals. Cells are 0.2 µm or less in diameter; 2 or 3 periplasmic flagella arise at each end of the cell. Cultivable on e.g. peptone–yeast extract–serum agar. GC%: 37.

*T. pallidum*. Cells helical, <0.2 µm (commonly 0.13–0.15 µm) in diameter, with pointed ends; 3 or 4 periplasmic flagella arise at each end of the cell. Motile. Apparently microaerophilic. GC%: 52–54. Three subspecies: *T. pallidum* subsp. *pallidum*, subsp. *pertenue* (formerly *T. pertenue*), and subsp. *endemicum*. *T. pallidum* subsp. *pallidum* is the causal agent of sexually- and congenitally-transmitted SYPHILIS which occurs worldwide. *T. pallidum* subsp. *pertenue* is the causal agent of YAWS. *T. pallidum* subsp. *endemicum* is the causal agent of human non-venereal endemic syphilis – which occurs in Africa, the Middle East, SE Asia and the former Yugoslavia, and which can be transmitted e.g. via fomites. All three subspecies (and *T. carateum*) give similar reactions in serological tests for syphilis.

*T. paraluiscuniculi*. The causal agent of a syphilis-like disease in rabbits. Cells are similar to those of *T. pallidum*.

*T. pertenue*. See *T. pallidum*.

*T. phagedenis*. A non-pathogenic species. Cells helical, 0.2–0.25 µm in diameter, with blunt ends; 3 to 8 periplasmic flagella arise at each end of the cell. Can be grown in e.g. peptone–yeast extract–serum media. Two biovars (*reiter* and *kazan*) are distinguishable antigenically and also by minor biochemical differences. (See also REITER TREPONEME.) GC%: 38–39.

*T. refringens*. A non-pathogenic species, occurring e.g. in the normal microflora of the human genitals; isolated from condyloma acuminatum and syphilitic lesions. Cells 0.2–0.25 µm in diameter, with 2–4 periplasmic flagella arising at each end. Cultivable in e.g. peptone–yeast extract–serum media. GC%: 39–43.

*T. saccharophilum*. See RUMEN.

*T. scoliodontum*. Occurs in the human mouth. Cells ≤0.2 µm in diameter. Cultivable in serum-enriched media.

*T. socranskii*. An oral species, three subspecies of which have been isolated from human periodontia [IJSB (1984) 34 457–462].

*T. succinifaciens*. Occurs in the intestine in swine. Cells up to 0.3 µm in diameter. GC%: 36.

*T. vincentii* (formerly *Borrelia vincentii*). Occurs in the human mouth and is associated with VINCENT'S ANGINA. Cells 0.2–0.25 µm in diameter, with 4–6 periplasmic flagella arising at each end. Cultivable in peptone–yeast extract–serum media.

[Pathogenesis and immunology of treponemal infection: Book ref. 78.]

**Treponema pallidum immobilization test** See TPI TEST.

**treponemal tests** Tests in which treponemal antigens or intact cells are used to detect specific anti-treponemal antibodies which occur in the serum of patients suffering from SYPHILIS (or PINTA or YAWS). These tests are more specific than STANDARD TESTS FOR SYPHILIS and are used as confirmatory tests (e.g., when results of STS are equivocal); however, as they remain positive for long periods after effective therapy, treponemal tests are less suitable than STS for assessing the progress of therapy. Treponemal tests include e.g. the FTA-ABS TEST, TPHA TEST, Reiter protein complement fixation test (RPCF test), and the TPI TEST.

**treponematosis** (*pl.* treponematoses) Any disease of man or animals in which the causal agent is a species of *Treponema* (see e.g. SYPHILIS, PINTA, YAWS).

**treitic development** See CONIDIUM.

**TRF** (*immunol.*) T cell replacing factor: a term originally used for the factor(s) which are present in the supernatant of cultures of activated T cells and which are necessary for the in vitro development of antibody-secreting B cells.

**trg gene** See CHEMOTAXIS (a).

**Triactinomyxon** See ACTINOSPORA and WHIRLING DISEASE.

**triadimefon** (trade name: e.g. Bayleton) An agricultural AZOLE ANTIFUNGAL AGENT which is particularly active against powdery mildews and rusts in e.g. cereals; it has both eradicant and protectant properties, and can apparently be translocated both acropetally and basipetally in the plant.

**triadimenol** An agricultural AZOLE ANTIFUNGAL AGENT used mainly as a seed treatment – sometimes mixed with e.g. fuberidazole – for the control of various cereal diseases (e.g. barley powdery mildew, rhynchosporium).

**Triangularia** See SORDARIALES.

**triangulation number** See ICOSAHEDRAL SYMMETRY.

**triarylmethane dyes** See TRIPHENYLMETHANE DYES.

**triatomine bugs** A category of obligate blood-feeding insects of the Hemiptera (true bugs); they include the vectors of CHAGAS' DISEASE. A major aspect of the control of Chagas' disease is the use of insecticidal sprays on bug-infected premises. Hence, characterization of triatomine populations and improvement in the accuracy of vector identification are likely to optimize control; in this context certain molecular methods (such as RAPD and SSCP) have contributed valuable information [molecular tools and triatomine systematics (a public health perspective): TIP (2001) 17 344–347].

**triazole antifungal agents** See AZOLE ANTIFUNGAL AGENTS.

**tribavirin** *Syn.* RIBAVIRIN.

**tribe** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**Tribonema** A genus of freshwater filamentous algae (class XANTHOPHYCEAE) in which the filaments consist of elongated cells joined end to end; each cell contains several parietal chloroplasts.

**tributyltin chloride** See PROTON ATPASE.

**tributyltin oxide** See TBTO.

**TRIC agents** Trachoma and inclusion conjunctivitis agents, i.e. strains of CHLAMYDIA which cause these diseases.

**tricarboxylic acid cycle** See TCA CYCLE and REDUCTIVE TRICARBOXYLIC ACID CYCLE.

**Triceratium** See DIATOMS.

**Trichamoeba** A genus of freshwater amoebae of the AMOEBIDA; cells are monopodial and commonly have a bulbous and/or filamentous UROID.

**Trichia** See MYXOMYCETES.

**Trichiales** See MYXOMYCETES.

**trichite** (1) Former name for NEMATODESMA. (2) Former name for a particular type of TRICHOCYST. (3) See PERANEMA.

**3,4,4'-trichlorocarbanilide** See CARBANILIDES.

**Trichochloris** See MICROMONADOPHYCEAE.

**trichocyst** A term formerly used to refer to many different types of EXTRUSOME but currently applicable to a particular type: a subpellicular, capsule-like extrusile organelle of the type which occurs e.g. in *Paramecium*; on appropriate stimulation (chemical, mechanical or electrical) the trichocyst rapidly extrudes a tipped thread (filament, shaft), ca. 15–25 µm in length, which has osmiophilic cross-striations of periodicity ca. 60 nm. Trichocysts may act as anchoring devices and/or as a form of defence, but their precise role is unknown. Electron microscopic studies of *Frontonia* and *Paramecium* indicate that trichocysts develop from minute membrane-bound vesicles within the cytoplasm, and that the developing structures (*pretrichocysts*) migrate to their final, subpellicular positions only shortly before reaching maturity. In *Paramecium aurelia* the mature trichocysts are ovoid, ca. 5 × 2 µm, orientated approximately perpendicular to the pellicle; the pointed, crystalline tip of the filament appears to be the only osmiophilic structure within the undischarged trichocyst. Trichocysts may be few to numerous, according to species. (See also FIBROCYST.)

**Trichoderma** A genus of fungi (class HYPHOMYCETES) which form septate mycelium and give rise to colourless or pigmented conidia from phialides on branched conidiophores; teleomorphs occur in the genus *Hypocrea*. *Trichoderma* spp grow rapidly and can use a wide range of substrates (see e.g. CELLULASES, XYLANASES); they are primarily saprotrophs, but some are MYCOPARASITES, and many are antagonistic to other fungi e.g. by forming antibiotics and/or by competing for nutrients. [Biology and potential for biological control: ARPPATH. (1985) 23 23–54.]

Species include e.g. *T. hamatum*, *T. harzianum*, *T. koningii* and *T. viride*. *T. viride* strain QM 6a has been called *T. reesei*, but its correct name is apparently *T. longibrachiatum* [discussion and references: MS (1986) 3 285–286].

Mutant strains of *Trichoderma*, resistant to heavy metal stress, have been isolated and may be suitable for development as biocontrol agents against plant-pathogenic fungi e.g. in the presence of heavy-metal-containing pesticides [LAM (2001) 33 112–116].

(See also GLIOTOXIN and TRICHOTHECENES.)

**trichodermin** See TRICHOTHECENES.

**Trichodesmium** A genus of filamentous planktonic marine CYANOBACTERIA which are closely related to – and regarded by some as congeneric with – *Oscillatoria*. The filaments contain phycoerythrin and may be red, purple or brown; they typically occur in well-defined sickle-shaped, spherical or fusiform colonies which are buoyed up by peripherally arranged, unusually strong GAS VACUOLES. Cells in the centre of a colony are less strongly pigmented; the immediate environment of these cells may be characterized by low levels of oxygen (at least in calm seas), and it has been suggested that this may permit the cells to carry out NITROGEN FIXATION, despite the absence of heterocysts. However, nitrogen fixation in culture apparently does not depend on colony formation, and nitrogenase activity appears to be light-dependent (and insignificant in the dark); the role of light may be either (i) to provide ATP and reductant (via photosynthesis) for nitrogen fixation, or (ii) to decrease intracellular levels of oxygen by promoting PHOTORESPIRATION [oxygen relationships in nitrogen fixation: MR (1992) 56 350–351].

*Trichodesmium* forms conspicuous, dense, floating blooms ('sea sawdust') covering vast areas of open ocean in tropical and subtropical regions (cf. RED TIDE).

Species that are sometimes distinguished on the basis of the arrangement of filaments in colonies include *T. contortum*, *T. erythraeum*, *T. hildenbrandtii* and *T. thiebautii*.

**Trichodina** See PERITRICHIA.

**Trichoglossum** See HELOTIALES.

**trichogyne** In certain eukaryotic organisms: a (typically) hair-like structure which arises from a female reproductive organ (e.g. gametangium) and which receives male nuclei or male reproductive cells.

**Tricholoma** See AGARICALES (Tricholomataceae).

**Tricholomataceae** See AGARICALES.

**Trichomarix invadens** See BLACK MAT SYNDROME.

**trichome** In many CYANOBACTERIA and in e.g. members of the CYTIPHAGALES, CARYOPHANON etc: a thread-like, usually uniseriate filament composed of closely juxtaposed cells which may or may not be surrounded by a common SHEATH. The cells in a trichome are separated by septa, the positions of which may or may not be marked by constrictions in the trichome; new septa arise by centripetal growth of the peptidoglycan layer from an annulus on the inside of the cell wall. In many cyanobacteria, at least, the contents of adjacent cells in a trichome communicate via small pores called microplasmodesmata (see also HETEROCYST).

**Trichomonadida** An order of protozoa of the ZOOMASTIGOPHOREA. Cells typically have 4–6 flagella, one of which is recurrent and may be associated with an undulating membrane; cysts are rarely formed. Reproduction occurs by binary fission. The organisms occur typically in the intestinal, respiratory and/or reproductive tracts in animals. Genera: e.g. DIENTAMOEBA, HISTOMONAS, *Monocercomonas*, TRICHOMONAS.

**Trichomonas** A genus of flagellate protozoa (order TRICHOMONADIDA) which are parasitic in man and other animals; some species can be pathogenic (see TRICHOMONIASIS). Cells: ovoid or pear-shaped, each having a single anteriorly located nucleus, a cytostome, endoskeletal structure(s), and several flagella which arise from the blunt anterior end of the cell. Cysts are not formed.

*T. foetus* ('*Tritrichomonas foetus*'). Cells: pear-shaped, ca. 20 × 10 µm, with well-developed COSTA and AXOSTYLE. Typically, three of the four flagella are directed anteriorly, while the fourth runs back along the margin of an undulating membrane and extends beyond the posterior limit of the body. The organism has a jerky form of motility. *T. foetus* is pathogenic in cattle (see TRICHOMONIASIS).

*T. gallinae*. Similar to *T. vaginalis* (see below) but smaller; it is pathogenic in birds.

*T. hominis* ('*Pentatrichomonas hominis*'). Cells: pear-shaped, ca. 8–20 µm in length, with 3–5 anteriorly directed flagella and one flagellum that forms the margin of an undulating membrane; the undulating membrane runs the entire length of the cell, and its associated flagellum extends beyond the posterior limit of the cell. The organism has a jerky form of motility. *T. hominis* is a common, non-pathogenic inhabitant of the human colon.

*T. tenax*. Occurs e.g. in the human mouth; it is normally non-pathogenic (but see TRICHOMONIASIS).

*T. vaginalis*. Cells: pear-shaped, ca. 15 × 10 µm, with costa and axostyle; there are four anteriorly directed flagella, and a short fifth flagellum that forms the margin of an undulating membrane extending approximately half the length of the cell. *T. vaginalis* apparently occurs only in the human genitourinary tract and may or may not cause disease (see TRICHOMONIASIS).

**trichomoniasis** Any disease in which the causal agent is a species of TRICHOMONAS.

In humans, the commonest form of trichomoniasis is that which affects the genitourinary tract and which is caused

## Trichomycetes

by *T. vaginalis*. Infection in men is often asymptomatic (but may result e.g. in epididymitis, prostatitis or NON-GONOCOCCAL URETHRITIS), but infection in women commonly results in VAGINITIS, with vaginal itching and burning, and sometimes a malodorous yellowish-green discharge. The infection can be transmitted sexually. [Cyto- and histopathological changes in the cervical epithelium in *T. vaginalis* infection: *Obstet. Gynec.* (1984) 64 179–184.]

**Diagnosis.** Wet mounts (of e.g. vaginal discharge) are reported to detect only ~60% of culture-positive specimens, while culture (a sensitive technique) may take up to 7 days. [Simplified diagnostic technique permitting both immediate examination and culture of the specimen: *JCM* (1992) 30 2265–2268. PCR-based diagnosis: *JCM* (1997) 35 132–138.]

**Chemotherapy:** e.g. METRONIDAZOLE, TRICHOMYCIN or furoxone (see NITROFURANS).

A pulmonary form of human trichomoniasis also occurs and is usually caused by aspirated *T. tenax* [*JMM* (1985) 20 1–10].

In cattle, *T. fetus* causes a sexually transmissible bovine trichomoniasis which can lead to early abortion; infection is usually self-limiting, the aborted fetus carrying with it all the parasites. Following abortion, the cow is usually immune to re-infection.

In young birds – particularly pigeons, but sometimes chickens and turkeys – *T. gallinae* causes an inflammatory and ulcerative condition of the upper digestive tract; 2-amino-5-nitrothiazole has been found to be an effective treatment.

**Trichomycetes** A class of fungi (subdivision ZYGOMYCOTINA) which typically live in the alimentary tract in aquatic or terrestrial arthropods. The thallus is commonly simple, branched or unbranched, with a basal holdfast – the thallus being septate in the orders Asellariales and Harpellales, aseptate in the Amoebidiales and Eccrinales. The cell wall appears to lack chitin. Asexual reproduction may involve the formation of sporangiospores (which may be amoeboid in the Amoebidiales) or arthrospores. (See also TRICHOSPORE.) Sexual reproduction is unknown in members of the Amoebidiales (e.g. *Amoebidium*) and Asellariales, and is known in only one genus (*Enteropogon*) in the Eccrinales. [Book ref. 64, p. 387.]

[Book ref. 172.]

**trichomycin** A MYCOSAMINE-containing heptaene POLYENE ANTI-BIOTIC produced by *Streptovorticillium hachijoense*; it has been used in the treatment of candidiasis and *Trichomonas vaginalis* infections.

**Trichonympha** A genus of cellulolytic protozoa (order HYPERMASTIGIDA) which occur in the gut of wood-eating termites. (See also CELLULASES and TERMITE–MICROBE ASSOCIATIONS.) The bell-shaped *T. campanula* (long axis ca. 100–300 µm) contains a single central nucleus and bears numerous flagella at the narrow (anterior) end of the cell; wood fragments are ingested at the naked posterior end.

**Trichophyton** See DERMATOPHYTES.

**Trichoplusia ni GV** See GRANULOSIS VIRUSES.

**Trichosida** An order of marine testate amoebae (class LOBOSEA) in which the test is fibrous with, in at least one stage of the life cycle, calcareous spicules and multiple apertures through which short, conical pseudopodia extend. The order includes the genus *Trichosphaerium*.

**Trichosphaerium** See TRICHOSIDA.

**trichospore** A dehiscient one-spored sporangium formed by fungi of the Harpellales.

**Trichosporon** A genus of fungi (class HYPHOMYCETES) which may form variously-shaped budding cells, scanty to well-developed pseudomycelium, and (usually abundant) septate

true mycelium which breaks up into arthrospores; blastospores may be formed, and some species (e.g. *T. capitatum*, *T. beigeli* [= *T. cutaneum*], *T. fermentans*) may form spherical or ellipsoidal asexual endospores. Most species are non-fermentative; only *T. terrestre* and *T. pullulans* can assimilate NO<sub>3</sub><sup>-</sup>. On the basis of e.g. CELL WALL structure, some species appear to have ascomycetous affinities (e.g. *T. capitatum*, *T. eriense*, *T. fermentans*, *T. sericeum*, *T. terrestre*, *T. variabile* [see PICHIA]), others to have basidiomycetous affinities (e.g. *T. aquatile*, *T. beigeli*, *T. pullulans*). Species have been isolated from a range of habitats, including e.g. water, plants, wood pulp, soil, human skin (see also WHITE PIEDRA), faeces, etc. [Book ref. 100, pp. 933–962; DNA relatedness among *Trichosporon* spp: *AvL* (1984) 50 17–32.]

(See also ACICULOCONIDIUM.)

**Trichostomatida** An order of protozoa (subclass VESTIBULIFERIA) in which the vestibular ciliature differs little from the somatic ciliature. In one suborder (Trichostomatina) the somatic ciliature covers the cell more or less completely; genera: e.g. BALANTIDIUM, DASYTRICHA, *Isotricha*, *Sonderia*. In the other suborder (Blepharocorythina) somatic ciliature is greatly reduced; these organisms (e.g. *Ochoterenaiia*) occur in herbivorous mammals, particularly horses.

**Trichostomatina** See TRICHOSTOMATIDA.

**trichothecenes** A group of sesquiterpenoid MYCOTOXINS produced by species of e.g. *Fusarium*, *Myrothecium*, *Trichothecium*. The parent compound is *scirpene* (12,13-epoxy-Δ<sup>9</sup>-trichothecene), produced e.g. by *Trichothecium roseum*. Other trichothecenes include e.g. calonectrin (produced e.g. by *Fusarium nivale*), crotoxin (e.g. *T. roseum*, ‘*Cephalosporium crotoxinigenum*’), deoxynivalenol (*Fusarium* spp), diacetoxyscirpenol (= anguidine) (*Fusarium* spp), fusarenon-X (*Fusarium* spp), HT-2 toxin (e.g. *F. solani*, *F. tricinctum*), neosolanol (*Fusarium* spp), nivalenol (e.g. *F. nivale*), T-2 toxin (*Fusarium* spp, e.g. *F. tricinctum*), trichodermin (*Trichoderma viride*), and trichothecin (*Trichothecium roseum*). The roridins and verrucarins (produced mainly by *Myrothecium roridum* and/or *M. verrucaria*) are trichothecenes which contain a (UV-absorbing) conjugated diene bridge.

Trichothecenes are toxic to a wide range of eukaryotic cells and are potent inhibitors of eukaryotic protein synthesis. In animals and man the toxins can, on contact with the skin, cause a severe local irritation with inflammation and desquamation. On ingestion (e.g. in contaminated mouldy cereals) they can cause a severe mycotoxicosis, involving haemorrhagic gastroenteritis with haemorrhages in other organs (‘haemorrhagic syndrome’ in animals; see also ALIMENTARY TOXIC ALEUKIA and STACHYBOTRYOTOXICOSIS). Trichothecenes are stable within the ranges of pH and temperature (including cooking) normally associated with foods.

[Book ref. 15.]

**trichothecin** See TRICHOTHECENES.

**Trichothecium** See HYPHOMYCETES; see also TRICHOTHECENES.

**trickle filter** See SEWAGE TREATMENT.

**trickling generator** See VINEGAR.

**trilocarban** See CARBANILIDES.

**triclosan** Irgasan DP 33; 5-chloro-2-(2,4-dichlorophenoxy phenol) A phenolic ANTISEPTIC (see PHENOLS) used in medicated soaps, hand cleansers and a wide range of other products; it is active against bacteria (particularly staphylococci) and certain fungi. Triclosan has been reported to act primarily by inhibiting fatty acid biosynthesis – specifically by inhibiting the enzyme enoyl-acyl carrier protein reductase (ENR) [Nature (1999)

398 383–384]. However, it appears that the relevant enzyme in *Streptococcus pneumoniae* is insensitive to triclosan, even though *S. pneumoniae* itself is sensitive; moreover, triclosan can be partially mineralized by a *Sphingomonas*-like organism [FEMS Ecol. (2001) 36 105–112].

**Tricornaviridae** A proposed family of PLANT VIRUSES which have tripartite, ssRNA genomes [Interviol. (1981) 15 198–203].

**tridemorph** (*N*-tridecyl-2,6-dimethylmorpholine) A MORPHOLINE ANTIFUNGAL AGENT used – either alone or mixed with e.g. carbendazim, maneb or propiconazole – against powdery mildew, rhynchosporium, eyespot and yellow rust in cereals; tridemorph apparently inhibits haustorium formation.

**trifluorothymidine** (F<sub>3</sub>T; trifluridine; 5-trifluoromethyl-2'-deoxyuridine; TFT; Viroptic) An ANTIVIRAL AGENT which is effective e.g. in the topical treatment of herpes simplex keratitis. It is too toxic for systemic use.

**trifluralin** See CHAGAS' DISEASE.

**trifluridine** *Syn.* TRIFLUOROTHYMIDINE.

**trifoliin A** A LECTIN found at the root surface of white clover (*Trifolium repens*); it binds e.g. 2-deoxy-D-glucosyl residues, and can agglutinate e.g. *Rhizobium leguminosarum* biotype *trifolii*. (See also ROOT NODULES and QUINOVOSAMINE.)

**triforine** (*N,N'*-bis(1-formamido-2,2,2-trichloroethyl)-piperazine) An agricultural systemic ANTIFUNGAL AGENT used e.g. as a seed dressing for the control of powdery mildew of barley, and – mixed with e.g. CARBENDAZIM and/or DITHIOCARBAMATES – as a broad-spectrum antifungal preparation against various other CEREAL DISEASES; it is also effective against powdery mildews of apples, cucurbits etc and against apple scab. Triforine inhibits haustorium formation in *Erysiphe graminis* f. sp. *hordei* and conidium germination in various ascomycetes and deuteromycetes.

**trigger hypothesis** See SIGNAL HYPOTHESIS.

**trigger mechanism** (bacterial uptake) See DYSENTERY.

**triglycollamic acid** *Syn.* NTA.

**Trigonopsis** A genus of yeasts (class HYPHOMYCETES) in which the cells are triangular or ellipsoidal, sometimes tetrahedral or rhombohedral, occurring singly or in pairs; cell shape is affected by growth conditions (e.g. nitrogen and carbon sources, growth temperature, presence of detergents). Vegetative reproduction occurs by budding – multilaterally in ellipsoidal cells, and from the angles in angular cells. Pseudomycelium is not formed. Metabolism is strictly respiratory; NO<sub>3</sub><sup>-</sup> is not assimilated. One species: *T. variabilis*, isolated from beer and from grape must. [Book ref. 100, pp. 963–965.]

**Triloculina** See FORAMINIFERIDA.

**Trilospora** See MYXOSPOREA.

**trimethoprim** (5-(3,4,5-trimethoxybenzyl)-2,4-diaminopyrimidine) A FOLIC ACID ANTAGONIST (q.v.) which has much higher affinity for bacterial dihydrofolate reductase than for the mammalian enzyme; it has a broad spectrum of (bacteriostatic) activity, being active against e.g. at least some enterobacteria, *Haemophilus* spp, staphylococci and streptococci, but not e.g. against mycoplasmas, *Pseudomonas aeruginosa* or *Treponema pallidum*. It is used – generally together with a sulphamide – mainly for treating infections of the upper respiratory tract and urinary tract.

**trimethylamine-*N*-oxide** See FISH SPOILAGE.

**trimethylene glycol** See ALCOHOLS.

**trimitic** See HYPHA.

**Trimitus** See DIPLOMONADIDA.

**trinactin** See MACROTETRALIDES.

**trinomial** A three-name designation such as *Puccinia graminis tritici*. (cf. TERNARY COMBINATION.)

**trioistins** See QUINOXALINE ANTIBIOTICS.

**trioxalen** 4,5',8-Trimethylpsoralen.

**triphenylmethane dyes** A family of DYES each of which may be regarded as an oxidation product of the corresponding colourless triarylmethane *leucobase*: C(Ar)<sub>3</sub>H; each dye contains a quinonoid ring (the chromophore). Triphenylmethane dyes include: *crystal violet* (*tris*(4-dimethylaminophenyl)methyl chloride), *malachite green* (4,4'-*bis*(dimethylamino)triphenylmethyl chloride), *pararosanilin* (*tris*(4-aminophenyl)methyl chloride), and *rosanilin* (4,4',4''-triamino-3-methyltriphenylmethyl chloride). Some triphenylmethane dyes are acidic, some basic (see also FUCHSIN). Some common stains (e.g. METHYL VIOLET) are mixtures of triphenylmethane dyes.

Many triphenylmethane dyes are used for STAINING. Some are used in media owing to their ability, at very low concentrations, to inhibit many Gram-positive bacteria; much higher concentrations are generally required to inhibit Gram-negative species, while acid-fast species are typically even more resistant. (See also BRILLIANT GREEN and BRUCELLA.) Some of the dyes are also fungistatic – e.g. for species of *Candida*, *Torula* and *Trichophyton*. (See also AURINTRICARBOXYLIC ACID.)

**triphenylmethylphosphonium** See CHEMOSMOSIS.

**triphenyltetrazolium chloride** See TETRAZOLIUM.

**triphosphopyridine nucleotide** NADP (see NAD).

**triple phosphate** See STRUVITE.

**triple-stranded DNA** See TRIPLEX DNA.

**triple-sugar-iron agar** See TSI AGAR.

**triple vaccine** A VACCINE containing diphtheria and tetanus TOXOIDS and killed cells of *Bordetella pertussis* (pertussis vaccine). (See also ANTIGENIC COMPETITION.)

**triple-vent Petri dish** See VENT.

**triplex DNA** (triple-stranded DNA) A triple-stranded structure in which pyrimidine or purine bases in a strand of nucleic acid, located within the major groove of a DNA duplex, bind to purine bases in the duplex; bases in the strand interact with purines in the duplex via *Hoogsteen hydrogen bonding*.

A DNA triplex may be formed by interaction between a duplex and a *triplex-forming oligonucleotide* (TFO). Alternatively, a DNA triplex may be formed by interaction between certain regions of a duplex and a single-stranded region from another part of the same (supercoiled) molecule; thus, e.g. in supercoiled plasmids, a homopurine–homopyrimidine tract may adopt a conformation (termed H-DNA) which depends primarily on the development of a triplex structure.

A triplex structure may also be formed by PNA; it has been found that two molecules of PNA can displace one strand of a DNA duplex – forming a triplex with the other strand.

[Triplex DNA structures: ARB (1995) 64 65–95.]

The specificity with which TFOs bind to DNA duplexes has suggested the use of these oligonucleotides as agents in GENE THERAPY. Thus, e.g. a TFO may inhibit transcription of a given gene by binding to a polypurine–polypyrimidine sequence in the promoter region. A triplex approach has been used successfully to downregulate expression of the *bcl-2* proto-oncogene in HeLa cells, suggesting that this technique may have value for oligonucleotide-based gene therapy [NAR (2001) 29 622–628].

**Triposporina** See HYPHOMYCETES and NEMATOPHAGOUS FUNGI.

**tripton** The non-living components of SESTON – e.g. organic detritus, mineral particles.

**TRIS** (THAM; Tris; tris; Tromethamine) Tris (hydroxymethyl) aminomethane; with e.g. HCl, TRIS forms the buffering system (CH<sub>2</sub>OH)<sub>3</sub>CNH<sub>2</sub>/(CH<sub>2</sub>OH)<sub>3</sub>CNH<sub>3</sub><sup>+</sup> which is effective between ca. pH 7 and pH 9 with a pK<sub>a</sub> (at 25°C) of 8. TRIS-buffered pH is significantly temperature-dependent.

## triskelion

**triskelion** (of clathrin) See PINOCYTOSIS.

**trisodium phosphonoformate** See PHOSPHONOFORMIC ACID.

**trisomic** See CHROMOSOME ABERRATION.

**trisporic acid** See PHEROMONE.

**tristeza disease** See CITRUS TRISTEZA VIRUS.

**Tritirachium** See HYPHOMYCETES; see also PROTEINASE K.

**Triton X-100** A non-ionic detergent of the polyoxyethylene *p*-*t*-octyl phenol series.

**Tritrichomonas** See TRICHOMONAS.

**Trk system** See ION TRANSPORT.

**tRNA** Transfer RNA: a type of RNA which, during PROTEIN SYNTHESIS, acts as an adaptor molecule, matching amino acids to their codons on mRNA. (tRNA is also involved in the priming of reverse transcription in viruses of the RETROVIRIDAE and in certain control functions.)

During protein synthesis, a given tRNA must be able to bind covalently to a specific amino acid, recognize the appropriate codon via an anticodon triplet (see GENETIC CODE), and fit into the ribosomal A and P sites – i.e. all tRNAs must be similar in size and shape. A given amino acid may be recognized by two or more different tRNAs (*isoaccepting tRNAs*).

A tRNA molecule is single-stranded, is ~74–95 nt long (ca. 4S), and contains a high proportion of ‘unusual’ (modified and hypermodified) nucleosides – e.g. dihydrouridine (D), pseudouridine ( $\psi$ ), QUEUOSINE (Q), 4-thiouridine ( $S^4U$ ), ribothymidine (T) – at specific positions in the chain. (See e.g. WOBBLE HYPOTHESIS.)

The 3'-OH end of a tRNA molecule always ends with the sequence pCpCpA (p = phosphate), the terminal residue being the site at which the amino acyl residue is bound. Base-pairing between short complementary regions in the chain results in the formation of a characteristic secondary structure, the *cloverleaf* structure; this structure generally comprises the *acceptor arm* (= CCA arm, the ‘stalk’ of the cloverleaf) and three stem-and-loop structures: (i) the *D arm* (which often contains dihydrouridine), (ii) the *anticodon arm* or *A arm* (which includes the anticodon), and (iii) the *T $\psi$ C arm* (the ‘common arm’ or ‘T arm’ which often includes the sequence ribothymidine–pseudouridine–cytidine) – together with a so-called *extra arm* (= variable arm) between the anticodon and T $\psi$ C arms.

Variation in size among different tRNA molecules occurs chiefly in the loop of the D arm and (particularly) in the extra arm – the latter generally containing either 4–5 nt (in *class I* tRNAs) or 13–21 nt (in *class II* tRNAs).

The positions of nucleotides in a tRNA molecule are given standardized numbers, 1–76, in the 5' → 3' direction; the additional nucleotides present in some tRNAs are numbered in relation to the preceding standard position: for example, nucleotides 20:1 and 20:2 occur between nucleotides 20 and 21. [Numbering system: Book ref. 186, pp. 518–519.] In the cloverleaf, nucleotides 1–7 pair with 72–66 to form the acceptor arm, the 3' end extending beyond the 5' end by (usually) 4 nt. Nucleotides 10–25 form the D arm (stem: 3 or 4 bp), 27–43 form the anticodon arm (stem: 5 bp; anticodon: nucleotides 34–36), and 49–65 form the T $\psi$ C arm (stem: 5 bp); nucleotides 47:1 to 47:n form the extra arm.

The cloverleaf structure is itself folded into a specific, compact, apparently L-shaped tertiary form which is essential for biological activity.

Variations in tRNA structure include e.g. the absence of dihydrouridine and ribothymidine in tRNAs from archaeans [tRNAs in archaeobacteria (archaeans): Book ref. 157, pp. 311–343], and

the absence of a D arm in tRNA<sup>Ser</sup> from mammalian mitochondria [Book ref. 84, pp. 259–278]. *Initiator* tRNAs are structurally distinct from those tRNAs which are involved in polypeptide chain *elongation* – for example, initiator tRNAs characteristically have three sequential G-C pairs in the stem of the anticodon arm (adjacent to the anticodon loop).

*tRNA synthesis*. TRANSCRIPTION of tRNA genes results in a large precursor molecule which is subsequently processed by cleavage and by modification of appropriate bases. (The primary transcript may contain sequences for several tRNA molecules.) In *Escherichia coli* (and most other organisms) the 5' end of a tRNA molecule is generated by the action of an endoribonuclease, RNASE P, on the precursor. Processing of the 3' end appears to involve exonucleolytic cleavage; in some tRNAs (apparently most or all in *E. coli*) the mature 3' end is generated by cleavage to the potential 3'-terminal CCA (possibly by the exoribonuclease RNase D), but in others (e.g. some tRNAs encoded by bacteriophage T4) there is no CCA – exoribonuclease action (possibly by RNase BN [PNAS (1983) 80 3301–3304]) being followed by the addition of CCA catalysed by *tRNA nucleotidyltransferase* (product of the *cca* gene in *E. coli*). (See also RNASE T.)

The organization of the tRNA genes differs in different organisms; for example, in *Bacillus subtilis* (but not in *E. coli*) tRNA genes are highly clustered. [tRNA genes in *B. subtilis*: MR (1985) 49 71–80.] (See also RRNA.) Some tRNA genes in archaeans [e.g. the tRNA<sup>Trp</sup> gene of *Halobacterium volcanii*: JBC (1985) 260 3132–3134] and in eukaryotes contain *introns* (see SPLIT GENE). (See also SUPPRESSOR MUTATION and PATHOGENICITY ISLAND.)

**tRNA-directed transcription antitermination** See TRANSCRIPTION ANTITERMINATION.

**trochal band** (locomotor fringe) A ring of cilia surrounding a TELEOTROCH, or encircling the basal disc of an adult mobile (see PERITRICHIA). (cf. PECTINELLA.)

**troleandomycin** See MACROLIDE ANTIBIOTICS.

**Tromethamine** See TRIS.

**Tropheryma** See WHIPPLE'S DISEASE.

**trophont** *Syn.* TROPHOZOITE.

**trophophase** In BATCH CULTURE, that phase in which primary (growth-directed) metabolism is dominant (cf. IDIOPHASE); it corresponds to the latter part of the lag phase and the early and middle periods of the log phase.

**trophosome** An organ which occurs in the giant tube worm, *Riftia pachyptila* (see HYDROTHERMAL VENT), and which may account for ca. 60% of the mass of the worm; it contains masses of (endosymbiotic) prokaryotic organisms of various types, including sulphide-oxidizing chemolithoautotrophs. Trophosome tissue contains two key enzymes of the CALVIN CYCLE (RuBisCo and phosphoribulokinase) as well as e.g. adenosine phosphosulphate reductase, ATP sulphurylase and RHODANASE.

**trophozoite** (trophont) A cell capable of (or specialized for) feeding.

**tropical canine pancytopenia** See EHRLICHIA.

**tropism** (1) A response to a directional stimulus exhibited by bending or growth of an organism – or of part of an organism – in an orientation dictated by that of the stimulus; growth towards the stimulus is called positive tropism, away from the stimulus negative tropism. (cf. TAXIS.) The stimulus may be e.g. a chemical gradient (*chemotropism*), gravity (*geotropism*), light (*phototropism*), water or air currents (*rheotropism*), etc. Examples: fruiting bodies of bracket fungi exhibit geotropism, developing horizontally in response to gravity; sporangiophores

of *Pilobolus* spp are positively phototropic; chemotropism is exhibited by certain fungi in response to PHEROMONES.

(2) The tendency of a parasite or pathogen to localize in a particular type of cell, tissue, or intracellular location. Thus, e.g., a virus may occur preferentially in lymphoid cells (*lymphotropism*), the skin (*dermotropism* or *epitheliotropism*), liver (*hepatotropism*), nerves (*neurotropism*) – and in the nucleus (*nucleotropism*) or cytoplasm (*cytotropism*) of the host cell. (cf. PANTROPIC.) A cell tropism may be due e.g. to the presence of specific cell-surface receptors on the target cell.

**tropocollagen** See COLLAGEN.

**trp operon** (tryptophan operon) An OPERON (mapping at ca. 27.5 min on the chromosome of *Escherichia coli*) which contains five contiguous structural genes encoding enzymes involved in the biosynthesis of tryptophan [Appendix IV(f)]. The operon is subject to both negative promoter control and attenuator control, and has the structure: promoter(–operator)–leader(–attenuator)–*trpE*–*trpD*–*trpC*–*trpB*–*trpA*–*t*–*t'*. The *trpE*...*trpA* genes are structural genes encoding enzymes for the conversion of chorismate to tryptophan; *t* is a rho-independent transcription terminator, *t'* a rho-dependent terminator (see TRANSCRIPTION).

An unlinked gene, *trpR*, encodes an aporepressor which, when activated by tryptophan (the corepressor), binds to the operator (*trpO*) and reduces (but does not abolish) transcription of the *trp* genes. The OPERATOR contains a palindromic sequence and occurs entirely within the PROMOTER, occupying (roughly) positions –23 to –3. The activated *trpR* repressor also represses the *trpR* gene itself (i.e., *trpR* is autoregulated) and the *aroH* gene (which encodes a 3-deoxyarabinoheptulosonate 7-phosphate (DAHP) synthase: see Appendix IV(f)). (In *E. coli* there are three DAHP synthases; one (the *aroH* gene product) is subject to feedback regulation by tryptophan, one by phenylalanine, and one by tyrosine.) The three operators recognized by the *trpR* repressor are closely related, having a consensus sequence which presumably reflects points of interaction with the repressor. (See also DAM GENE.)

Further reduction in *trp* gene transcription is achieved by attenuation (see OPERON); in the presence of tryptophan the attenuator in the leader region of the mRNA adopts the stem-and-loop structure characteristic of a rho-independent terminator, and transcription stops before *trpE*. However, in the absence of tryptophan, a ribosome beginning translation of the leader peptide stalls when it reaches two contiguous tryptophan codons, preventing the formation of the terminator stem-and-loop structure and allowing transcription to proceed into the *trp* structural genes. (Termination at the attenuator also occurs in the absence of ribosome binding at the leader sequence.)

(cf. TNA OPERON.)

**true slime moulds** See MYXOMYCETES.

**truffles** The typically hypogean, edible fruiting bodies of certain fungi – e.g. *Tuber aestivum* (summer truffle), *T. melanosporum* (Périgord truffle) and *T. uncinatum* (Burgundy truffle). 'False truffles' include the fruiting bodies of species of *Elaphomyces* (hart's truffles) and those of the gasteromycetes *Hymenogaster*, *Melanogaster* and *Rhizopogon*.

**trxA gene** See THIOREDOXIN.

**trypan blue** A blue acid diazo DYE used e.g. for VITAL STAINING.

**trypan red** A red acid diazo DYE formerly used for treating trypanosomiasis.

**trypanocide** Any agent which can kill trypanosomes – e.g. BERENIL, ETHIDIUM BROMIDE, PROPIDIUM, quinapyramine and SURAMIN. Pentamidine has been used for decades in the treatment of

SLEEPING SICKNESS (q.v.); it is a substituted dibenzamidine which appears to inhibit the trypanosomal enzyme *S*-adenosyl-L-methionine decarboxylase. (See also *melarsoprol* in ARSENIC (a) and *eflornithine* in SLEEPING SICKNESS; see also ANTIMONY.)

**Trypanosoma** A genus of parasitic flagellate protozoa (family TRYPANOSOMATIDAE); certain species cause human and animal TRYPANOSOMIASIS – primarily in parts of Africa and in Central and South America.

Most species have a life cycle which involves alternate phases of growth in a vertebrate and an invertebrate host; typically, trypomastigotes occur in the vertebrate while other forms develop in the invertebrate host (see illustrations in the entries TRYPANOSOMATIDAE and TRYPANOOZON). Cell sizes range from small intracellular amastigotes, ca. 3–6 µm in diameter, to the largest trypanosomes which measure over 1 mm in length; however, the cells are commonly ca. 10–100 µm in length.

In the vertebrate host, the trypomastigote is bounded by a typical unit-type membrane beneath which lies a layer of (apparently) cytoskeletal MICROTUBULES; often there is an external, electron-dense coat with which is associated the variant surface glycoprotein (see VSG) involved in ANTIGENIC VARIATION. The nucleus is rounded, and there is an elongated mitochondrion which runs most of the length of the body; within the mitochondrion is the KINETOPLAST which is situated close to the flagellar basal body. The FLAGELLUM arises from an invagination (*flagellar pocket*, or *reservoir*). In most species (cf. *Nannomonas*) there is a 'free flagellum' (i.e. that part of the flagellum which does not form the outer limit of the UNDULATING MEMBRANE) projecting anteriorly – that is, in the direction of locomotion; in the undulating membrane, the flagellar and cell body membranes are attached by desmosome-like structures. (Within the invertebrate host the flagellum can serve as a means of attachment; at the region of attachment the interior of the flagellum develops an electron-dense structure, the whole attachment complex being termed a *hemidesmosome*.)

The organisms are chemoorganotrophs. Soluble nutrients may be absorbed through the cell surface, and pinocytosis can occur via the cytoplasmic membrane in the region of the reservoir. In (at least) some stercorarian trypanosomes (e.g. *T. brucei*) the energy-yielding metabolism varies according to the phase of the life cycle – changes in this context being associated with changes in the structure of the mitochondrion. Some species can be cultured in blood-based media (e.g. NNN MEDIUM); see also SCHIZOTRYPANUM.

Within the vertebrate host, reproduction occurs asexually by longitudinal binary fission in the trypomastigote, and e.g. by multiple fission in certain other stages; binary fission involves duplication of the basal body and kinetoplast, nuclear division, and finally separation of the two daughter cells. A sexual process may occur. (See also METACYCLIC FORMS.) [Trypanosomatid genomes (special issue): *Science* (2005) 309 337–520.]

*Trypanosoma* spp parasitize a variety of animals, including birds, reptiles, amphibians and mammals; the invertebrate hosts include insects of the orders Diptera and Hemiptera, and are commonly involved (as VECTORS) in the cyclical transmission of *Trypanosoma* spp. Species parasitic in mammals are divided into the SALIVARIA and STERCORARIA.

For anti-trypanosomal agents see TRYPANOCIDE.

*Trypanosoma* spp include:

*T. brucei*: see TRYPANOOZON.

*T. congolense*: see NANNOMONAS.

*T. cruzi*: see SCHIZOTRYPANUM.

*T. equinum*: see TRYPANOOZON.

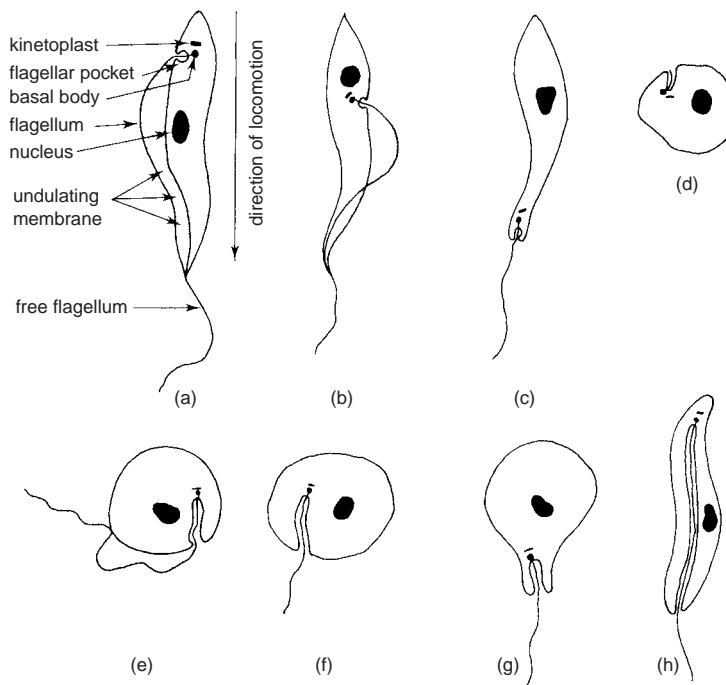

## trypanosomal form

- T. equiperdum*: see TRYPANOZOON.  
*T. evansi*: see TRYPANOZOON.  
*T. gambiense*: see TRYPANOZOON.

*T. rhodesiense*: see TRYPANOZOON.  
*T. platydictyli*: see LEISHMANIA.  
*T. simiae*: see NANNOMONAS.  
*T. suis*: see PYCNOMONAS.  
*T. theileri*: see MEGATRYPANUM.  
*T. theodori*: see MEGATRYPANUM.  
*T. uniforme*: see DUTTONELLA.  
*T. vivax*: see DUTTONELLA.  
*T. zapi*: see HERPETOSOMA.

**trypanosomal form** Obsolete *syn.* TRYPOMASTIGOTE.

**trypanosomatid** Any member of the family TRYPANOSOMATIDAE.

**Trypanosomatidae** A family of parasitic protozoa (suborder TRYPANOSOMATINA); constituent genera: BLASTOCRITHIDIA, CRITHIDIA, ENDOTRYPANUM, HERPETOMONAS, LEISHMANIA, LEPTOMONAS, PHYTOMONAS, RHYNCHOIDOMONAS and TRYPANOSOMA. (Monoxenous genera have been referred to as the 'Lower Trypanosomatidae'.) The diagram shows the range of types of cell which occur in the life cycles of species of the Trypanosomatidae.

TRYPANOSOMATIDAE. Some forms which occur in the life cycles of species of the Trypanosomatidae. (a) Trypomastigote. The undulating membrane extends for most of the length of the body with the flagellum forming its outer margin. (b) Epimastigote. (c) Promastigote. (d) Amastigote; amastigotes of the type shown (i.e., with a reduced, non-free flagellum) occur in *Leishmania* spp. (e) Sphaeromastigote. (f) Paramastigote. (g) Choanomastigote. (h) Opisthomastigote.

**Trypanosomatina** A suborder of (typically) uniflagellate parasitic protozoa (order KINETOPLASTIDA) which comprises one family: TRYPANOSOMATIDAE.

**trypanosome** Any member of the genus *Trypanosoma*. (cf. TRYPANOSOMATID.)

**trypanosome adhesion test** A serological test used for detecting the presence of antibodies homologous to particular species of trypanosomes. The test depends on the adhesion of erythrocytes or platelets (of certain species) to trypanosomes in the presence of homologous antibodies and complement.

**trypanosomiasis** Any human or animal disease in which the causal agent is a species of TRYPANOSOMA; such diseases include CHAGAS' DISEASE, DOURINE, SURRA, and the 'African trypanosomiasis' SLEEPING SICKNESS and NAGANA. [Human trypanosomiasis: BMB (1985) 41 103-194; TDB (1986) 83 R1-R60.]

**trypanothione** See ARSENIC (a).

**Trypanozoon** A subgenus of TRYPANOSOMA within the SALIVARIA; it includes cyclically transmitted species (vector: *Glossina*) and mechanically transmitted species – the latter, though not truly salivarian, exhibiting certain affinities with the former.

The cyclically transmitted members traditionally include *Trypanosoma (Trypanozoon) brucei* (= *T. (T.) brucei*), *T. (T.) gambiense*, and *T. (T.) rhodesiense*. Some authors regard these three species as subspecies of a single species, *T. (T.) brucei*; *Trypanosoma (Trypanozoon) brucei brucei* (= *T. (T.) b. brucei*), though not infective for man, is a causal agent of NAGANA, while *T. (T.) b. gambiense* and *T. (T.)*

TRYPANOSOM. The life cycle of *Trypanosoma (Trypanozoon) brucei gambiense*.

*b. rhodesiense* are both causal agents of SLEEPING SICKNESS. In the vertebrate host these organisms are 12–42  $\mu\text{m}$  in length; they may occur as *slender* trypomastigotes (commonly ca. 25  $\mu\text{m}$  in length), as short, *stumpy* trypomastigotes (which typically lack a *free* flagellum), and/or as some intermediate form. (See figure in the entry TRYPANOSOMATIDAE.)

Mechanically transmitted species include *T. (T.) evansi*, the causal agent of SURRA, and dyskinetoplastic trypanosomes formerly called '*T. equinum*' but now regarded as strains of *T. evansi*; bloodstream forms are trypomastigotes, 15–36  $\mu\text{m}$  in length. *T. equiperdum*, morphologically indistinguishable from *T. evansi*, causes DOURINE.

**tryparsamide** See ARSENIC.

**trypomastigote** A form assumed by the cells of species of *Endotrypanum*, *Rhynchoidomonas* and *Trypanosoma* during at least certain stages of their life cycles: see TRYPANOSOMATIDAE.

**trypsin** See PROTEASES.

**trypsinization** (in tissue culture) See TISSUE CULTURE.

**trypticase** *Syn.* TRYPTONE.

**trypticase–soy agar** (tryptone soya agar; tryptic soy agar; soybean casein digest agar; etc) An agar-based medium containing a pancreatic digest of casein (trypticase, tryptone), a papain digest of soybean meal (phytone), and NaCl (0.5% w/v). It is used e.g. as a general-purpose medium, as a BLOOD AGAR base, etc.

**trypticase–soy broth (TSB)** A general-purpose broth medium similar in composition to TRYPTICASE–SOY AGAR (without the agar), sometimes with the addition of D-glucose.

**tryptone** A tryptophan-rich PEPTONE: e.g. a pancreatic digest of casein.

**tryptone soya agar** *Syn.* TRYPTICASE–SOY AGAR.

**tryptone water** A MEDIUM containing 1–2% TRYPTONE and 0.5% NaCl in water.

**L-tryptophan biosynthesis** See AROMATIC AMINO ACID BIOSYNTHESIS, Appendix IV(f), and TRP OPERON.

**tryptophanase** L-Tryptophan indole-lyase (deaminating); EC 4.1.99.1. See e.g. Appendix IV(f), INDOLE TEST, and TNA OPERON.

**ts mutant** TEMPERATURE-SENSITIVE MUTANT.

**TSA** TRYPTICASE–SOY AGAR.

**TSB** TRYPTICASE–SOY BROTH.

**tSDA** See SDA.

**TSEs** TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**tsetse fly** See GLOSSINA and SODALIS.

**TSI agar** Triple-sugar–iron agar: a medium used e.g. in a SCREENING TEST (sense 2) for members of the Enterobacteriaceae. The medium is prepared as a slope with a deep BUTT; it contains peptone (2%), glucose (0.1%), lactose (1%), sucrose (1%), ferrous ammonium sulphate (0.02%), NaCl (0.5%), sodium thiosulphate (0.02–0.03%), PHENOL RED (0.0025%), and agar (ca. 1.5%). The strain under test is inoculated onto the surface of the slope and is also stab-inoculated (with a straight wire) deep into the butt. Following incubation the slope is examined for (a) acid/alkaline reaction at the (aerobic) surface of the slope; (b) acid/alkaline reaction in the (anaerobic or microaerobic) butt; (c) H<sub>2</sub>, CO<sub>2</sub> production – detectable as gas pockets, or splitting of the butt; (d) H<sub>2</sub>S production – detectable as blackening of the medium (due to ferrous sulphide formation). Thus, e.g. *Escherichia coli* (which typically attacks both glucose and lactose) commonly produces an acid slope and butt, and forms small amounts of H<sub>2</sub> and CO<sub>2</sub>, though (usually) no H<sub>2</sub>S. Non-lactose-fermenting strains of enterobacteria (e.g. most strains of *Salmonella*) form an acid butt and an alkaline slope – though some organisms (e.g. most strains of *Salmonella*) typically form large amounts of H<sub>2</sub>S which may obscure these reactions by blackening most or all of the medium. *S. typhi* typically forms an acid butt, an alkaline slope, and very small amounts of H<sub>2</sub>S. (cf. KLIGLER'S IRON AGAR.)

**tsr gene** See CHEMOTAXIS (a).

**TSS** TOXIC SHOCK SYNDROME.

**TSST-1** See TOXIC SHOCK SYNDROME and SUPERANTIGEN.

**tsutsugamushi disease** *Syn.* SCRUB TYPHUS.

**Tsx protein** In *Escherichia coli*: and OUTER MEMBRANE protein encoded by the *tsx* gene; it acts as a receptor for bacteriophage T6 and for COLICINS K, 5 and 10, and may be a channel-forming protein involved in the uptake of e.g. glycine, phenylalanine, serine and possibly nucleosides (cf. PORIN). Synthesis of the Tsx protein is subject to CATABOLITE REPRESSION.

## TT virus

**TT virus** A non-enveloped ssDNA virus, 30–50 nm diam., which has been associated with post-transfusion hepatitis of unknown aetiology. The sequence of the viral genome appears to be unlike that of other viruses; it has been suggested that the TT virus be classified in a new family (Circinoviridae) [PNAS (1999) 96 3177–3182]. A number of distinct genotypes of TT virus have been reported [JMV (1999) 57 252–258].

**TTC** See TETRAZOLIUM.

**TTFA** 2-Thenoyltrifluoroacetone (4,4,4-trifluoro-1-[2-thienyl]-1,3-butanedione): an inhibitor of reconstituted mitochondrial electron transport systems (see ELECTRON TRANSPORT CHAIN).

**TTGE** See DGGE.

**TU** (1) Tuberculin unit: 1 TU = 0.02 µg of PPD (see TUBERCULIN). (2) See TODD UNIT.

**tube dilution test** See DILUTION TEST.

**Tuber** A genus of fungi (order PEZIZALES) which form closed, hyaline ascocarps containing clavate to globose asci. (See also ASCOSPORE, ASCUS, MYCORRHIZA and TRUFFLES.)

**Tuberales** An order of fungi (recognized by some authors) which include certain hypogean ascomycetes, e.g. *Tuber* spp.

**tubercle** (1) (*med.*) See TUBERCULOSIS.

(2) A deposit formed on the inner surfaces of iron or steel water-pipes; tubercles may contain e.g. oxides and hydroxides of iron, as well as sulphate- and nitrate-reducing bacteria [AEM (1982) 44 761–764] and e.g. IRON BACTERIA such as *Crenothrix*, *Gallionella* and *Leptothrix* spp.

(3) (*lichenol.*) In the thallus of certain lichens (e.g. *Nephroma resupinatum*): a wart-like protuberance in which there may be a discontinuity in the cortex; it may be analogous in function to e.g. a CYPHELLA.

**tubercle bacillus** (1) *Mycobacterium tuberculosis*. (2) Any *Mycobacterium* sp which causes TUBERCULOSIS.

**tubercular** (1) Resembling, due (directly or indirectly) to, or pertaining to TUBERCULOSIS. (2) Consisting of or resembling a TUBERCLE (any sense). (cf. TUBERCOLOUS.)

**Tuberculariales** See HYPHOMYCETES.

**tuberculin** Any of various preparations, containing tuberculo-protein, obtained by filtration of a culture of tubercle bacilli. *Old tuberculin* (OT) is a filtrate of a steamed, evaporated, glycerol-broth culture. *Purified protein derivative* (PPD) is prepared from the filtrate of a steamed culture grown in a synthetic medium; the filtrate is treated with e.g. trichloroacetic acid to precipitate tuberculo-protein which is then washed and prepared in standard aqueous dilutions. ('Tuberculin' may refer specifically to PPD.) *Mammalian tuberculin* (used in the COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST) is PPD prepared from bovine tubercle bacilli; *avian tuberculin* is PPD prepared from the avian tubercle bacillus.

**tuberculin test** A SKIN TEST in which, typically, PPD (see TUBERCULIN) is injected intradermally; a positive test, indicated by induration and erythema (i.e. a hard, red bump at the site of injection), is given in ~24–48 hours and reflects DELAYED HYPERSENSITIVITY to PPD and/or to a cross-reactive entity. A positive test may indicate prior immunological contact with one or more of the following: (i) tubercle bacilli, (ii) BCG (through vaccination), (iii) certain other mycobacteria. Hence, a positive test is not proof of active infection by tubercle bacilli: sensitivity to PPD is induced not only by *Mycobacterium tuberculosis* and BCG but also by various non-tubercular mycobacteria – for example, positive tests have been recorded in some cases of cervical adenitis caused by members of the *M. avium* complex (see MAC). Nevertheless, reactivity to 'environmental' mycobacteria may be weaker than that induced

by tubercle bacilli, and the tuberculin test is still regarded as a useful diagnostic tool.

False-negative tests may be given by patients with overwhelming (e.g. miliary) tuberculosis or those with certain malignant conditions.

A negative test in an immunocompetent, healthy individual indicates a 'susceptible' who may benefit from vaccination with BCG.

Among the various forms of tuberculin test are the *Mantoux test*, in which PPD (commonly 5 TU) is injected intradermally; the HEAF TEST; the *Moro test*, in which tuberculin is smeared over a small area of skin; and the VOLLMER PATCH TEST. (cf. COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST.)

(See also ESAT-6.)

**tuberculin-type reaction** A DELAYED HYPERSENSITIVITY reaction similar to that seen in a positive TUBERCULIN TEST but involving a different antigen – see e.g. HISTOPLASMIN TEST.

**tuberculin unit** See TU.

**tuberculo-protein** Protein derived from tubercle bacilli – see TUBERCULIN.

**tuberculosis** (phthisis; TB) A chronic infectious disease of man and animals caused by certain species of MYCOBACTERIUM – commonly *Mycobacterium tuberculosis*, sometimes *M. bovis*; *M. africanum* causes tuberculosis primarily in Africa. Tuberculosis is responsible for several million human deaths each year, and the incidence is rising; the re-emergence of TB in the USA was associated with (i) changes in social structure, (ii) the spread of AIDS (creating many immunocompromised, highly susceptible, individuals), and (iii) failure of public health programmes [review: Science (1992) 257 1055–1064]. The problem of TB has been exacerbated by the appearance of multiply drug-resistant strains of the main causal agents; for example, one strain of *M. bovis*, resistant to 11 drugs, was reported to cause high mortality rates in HIV-positive patients [Lancet (1997) 350 1738–1742]. [Multiple drug resistance (review): BCID (1997) 4 77–96.]

*Tuberculosis in the human population.*

New infection arises commonly through inhalation of aerosols containing viable cells of the pathogen. In most immunocompetent people, the inhaled pathogen may remain viable but is constrained to quiescence by the body's immune system; such *latent* infection carries a life-time risk of active disease, this risk being increased e.g. by the use of immunosuppressive drugs or by infection with human immunodeficiency virus (HIV). The mechanism of latency is unknown. It is not known, for example, whether the pathogen survives in a non-acid-fast form or in a spore-like state, and the site(s) of (latent) infection within the body are also unknown; apparently, individuals with latent infection generally do not transmit the disease. [Latency in tuberculosis: TIM (1998) 6 107–112.]

Epidemiological investigation (contact tracing) may be facilitated by the use of assays for T lymphocytes (T cells) that react to the tuberculosis-associated antigen ESAT-6 [Lancet (2001) 357 2017–2021]. (See also ELISPOT ASSAY.)

In a proportion of cases infection leads to active disease; this may reflect a genetically based predisposition [BCID (1997) 4 207–229]. Within the lungs, some bacilli may be taken up by phagocytosis and killed by activated MACROPHAGES. However, some bacilli *invade* macrophages and survive within the phagosome. In such cases the phagosome fails to acidify and it also fails to fuse with a lysosome; moreover, the phagosomal membrane apparently becomes more permeable – allowing the pathogen access to the host cell's nutrients and, hence, permitting growth and reproduction [PNAS (1999) 96 15190–15195].

The ability of the pathogen to invade – and to survive and grow within – a macrophage may depend on factors such as (i) the cell-surface chemistry of the particular strain of pathogen; (ii) the site of infection (e.g. lung); and (iii) the timing of pathogen–macrophage contact (at initial infection, or subsequently). Opsonization of the pathogen via the COMPLEMENT system may involve one or more pathways of fixation [TIM (1998) 6 47–49, 49–50]. However, for the *initial* infection of lung tissue it has been suggested that *non*-opsonic binding of the pathogen to a macrophage may be important; thus, *M. tuberculosis* may invade macrophages when certain polysaccharides on the pathogen's surface bind to the *lectin*-binding site of macrophage receptor CR3 [*M. tuberculosis*–macrophage interactions: TIM (1998) 6 328–335].

[Pathogenesis of *Mycobacterium tuberculosis* (review): Cell (2001) 104 477–485.]

In *pulmonary* tuberculosis, lesion(s) develop in the lung tissue (although tubercle bacilli may be disseminated, via lymph and blood, to various parts of the body). In the lungs, each focus of infection develops to form a granulomatous lesion called a *tubercle*, such development reflecting the activity of the body's CELL-MEDIATED IMMUNITY; one important factor in this process is the involvement of antigen-specific T LYMPHOCYTES. A mature tubercle consists of a necrotic centre, containing dead macrophages and dead/viable tubercle bacilli, surrounded by a layer of epithelioid macrophages and an outer mantle of monocytes/macrophages and lymphocytes; GIANT CELLS are commonly present. The necrotic centre of a tubercle may subsequently calcify and remain quiescent, although it may still contain viable tubercle bacilli.

Necrotic degeneration within tubercles, seen in human (and guinea-pig) lung tissue, is uncommon in mice. In mice, the lesions are penetrated by lymphocytes – which may thus continue CYTOKINE-mediated stimulation of the macrophages. By contrast, in human and guinea-pig lesions the lymphocytes

remain peripherally distributed – so that macrophages in central parts of a lesion may remain unstimulated (and more likely to be killed by internalized tubercle bacilli); it has been suggested that this aspect of development may account for the large central region of necrosis observed in human and guinea-pig tubercles [TIM (1998) 6 94–97].

In pulmonary TB ('consumption') there is a persistent cough, initially unproductive but later productive of mucopurulent sputum (containing tubercle bacilli); in later stages there is typically dyspnoea and haemoptysis. In general, symptoms of TB include weakness, fever, night sweats and weight loss. (When infection spreads beyond the lungs, symptoms of disease depend on the tissues affected and may include e.g. lymphadenitis, pyuria/haematuria, MENINGITIS, OSTEOMYELITIS, pericarditis, peritonitis etc.; the pleura and skin are other sites which may be affected.) In some cases tubercles may rupture into a blood vessel, leading to massive dissemination of bacilli and the formation of many synchronously progressive tubercles in sites throughout the body (*miliary tuberculosis*).

Traditionally, tuberculosis has been classified into *primary* disease (which follows the initial infection) and *post-primary* disease (which may follow months, years or decades after the primary disease has resolved) – post-primary disease resulting from *re-activation* of the latent pathogen. These two categories of disease are sometimes distinguishable by features such as level of lymphatic involvement, cavity formation in lung tissue, and site affected (usually the upper lobes in post-primary disease); however, the distinction between primary and post-primary disease is not always clear-cut.

Infection, re-infection and re-activation are beginning to be studied with molecular tools that throw some light on the various manifestations of tuberculosis; these studies have indicated, for example, that more cases than previously thought are due to recent transmission (rather than re-activation) and that re-infection (following earlier active disease) is not a rare

TUBERCULOSIS – the number of cases of tuberculosis diagnosed between 1989 and 1996 in Hlabisa hospital, a district hospital in a rural location in South Africa. It was estimated that, in 1995, at least 44% of the cases were linked to infection with the human immunodeficiency virus (HIV).

## tuberculosis

occurrence, especially among HIV-positive individuals [BCID (1997) 4 173–183].

*Tuberculosis in the immunocompromised.* In AIDS, the fall in immunocompetence (particularly the lowered efficiency of cell-mediated immunity) is associated with susceptibility to various diseases, of which tuberculosis is one; moreover, in AIDS patients (particularly adults), clinical presentation of tuberculosis may be atypical and may include a higher proportion of cases of disseminated or extrapulmonary disease. It appears that infection with *M. tuberculosis* can promote HIV-mediated disease [J. Imm. (1996) 157 1271–1278], perhaps by stimulation of viral replication (see HIV).

For AIDS patients with a positive TUBERCULIN TEST, the drug ISONIAZID may be useful as a prophylactic measure against tuberculosis. [TB in the AIDS era (the role for preventive therapy): BCID (1997) 4 63–76.]

*Lab. diagnosis of tuberculosis* may include e.g. identification of the pathogen by acid-fast staining and culture from sputum, CSF, urine sediments, biopsy specimens etc. (See also BACTEC.) Sputum may be treated with a MUCOLYTIC AGENT prior to examination.

*Molecular methods of diagnosis.* Smear-positive respiratory specimens may be examined – for confirmation of the diagnosis – by methods that involve in vitro amplification of specific target sequences in the pathogen's nucleic acids. These methods include the PCR-based Amplicor™ system (Roche) which amplifies a DNA target in the pathogen's 16S rRNA gene, and AMTDT (Gen-Probe) (see TMA) which amplifies an rRNA target; both of these methods have been approved by the US Food and Drug Administration (FDA) for smear-positive respiratory specimens. (A further method, based on the ligase chain reaction (LCR), is being evaluated [JCM (1999) 37 229–232].) [Comparison of Amplicor with AMTDT for direct detection of *M. tuberculosis* in respiratory specimens: JCM (1997) 35 193–196.]

The molecular methods of diagnosis are useful, although some problems have arisen. For example, false-positive results in AMTDT were obtained when lung infections involved *M. avium* and/or *M. kansasii* – suggesting the need for an alteration in the interpretation of luminometer readings in the test [JCM (1999) 37 175–178]. Moreover, the original form of AMTDT suffered from low sensitivity; this problem was addressed in a later version by increasing the volume of sample used in the test. [Comparison of the new and original AMTDT: JCM (1998) 36 684–689. Clinical evaluation of the new-format AMTDT: JCM (1999) 37 1419–1425.]

AMTDT has been evaluated for the direct detection of *M. tuberculosis* in non-respiratory specimens [JCM (1997) 35 307–310]. [Evaluation of new and original forms of AMTDT for the detection of *M. tuberculosis* in respiratory and non-respiratory specimens: JCM (1998) 36 684–689.]

The simultaneous detection and TYPING of *M. tuberculosis* in clinical specimens may be achieved by SPOLIGOTYPING [JCM (1997) 35 907–914].

*Skin test.* See TUBERCULIN TEST.

*Antibiotic resistance testing of isolates.* Given the slow rate of growth of *M. tuberculosis* (and the inapplicability of routine tests) special methods have been devised. Isolates can be tested in liquid media using the BACTEC system. Alternatively, there are several molecular ('genotypic') methods; all of these are used to detect specific, resistance-conferring mutation(s) by initially amplifying the relevant sequence of genomic DNA and then testing the amplicons for the presence/absence of the given mutation(s).

Resistance to isoniazid, or streptomycin, can arise through mutation in more than one gene. However, resistance to rifampicin (= rifampin) is commonly due to one (or more) of several mutations within a single gene, *rpoB*, which encodes the  $\beta$  subunit of RNA polymerase; technically, therefore, resistance to rifampicin is easier to detect (by molecular methods), and most studies have concentrated on detecting mutations in *rpoB*. (In some regions, including the USA [JAMA (1994) 271 665–671], resistance to rifampicin commonly correlates with resistance to at least some other antituberculosis drugs, so that rifampicin resistance may be used as a marker for multidrug resistance.)

In *dideoxy fingerprinting*, amplicons of the target (*rpoB*) sequence are examined by a process resembling dideoxy sequencing (see DNA SEQUENCING) – mutation(s) in the target sequence being detected by variations in the nature of the chain-terminated products (compared with the products from wild-type amplicons) [JCM (1995) 33 1617–1623]. Another genotypic method is *line probe assay* (see PROBE), and a further method is SSCP analysis (see SSCP). (See also ANTIBIOTIC.)

*Chemotherapy.* A combination of drugs is used (i) for maximum effect and (ii) in order to discourage the emergence of drug-resistant strains. Major antituberculosis drugs include ETHAMBUTOL, ISONIAZID, PYRAZINAMIDE, rifampicin (see RIFAMYCINS) and STREPTOMYCIN. Given appropriate treatment, a patient whose disease is not caused by drug-resistant strains has an excellent prospect of cure.

In the mid-1990s the World Health Organization (WHO) initiated a comprehensive antituberculosis strategy known as *directly observed therapy, short-course* (DOTS). One aspect of DOTS involves direct supervision of patients during ingestion of medication – thus ensuring compliance (lack of which is a common cause of failed therapy). DOTS also promotes active searching for new cases among suspects, and requires short-course chemotherapy for all cases of smear-positive pulmonary TB.

The administration of antituberculosis drugs two or three times a week is reported to be as effective as daily treatment; this approach, combined with the DOTS strategy, is seen as a sensible therapeutic option in the treatment of tuberculosis [BCID (1997) 4 97–105, 107–109].

*Vaccines.* The BCG vaccine has been used for many years, although its efficacy against pulmonary TB in adults is variable, and it has also failed to prevent primary TB in some children.

More recently, DNA VACCINES (q.v.) have been used prophylactically and therapeutically against tuberculosis in mice, and this approach, combined with chemotherapy, may be applicable in human tuberculosis.

*Other mycobacteria causing pulmonary, extrapulmonary or disseminated disease.* Such species include members of the *M. avium* complex (see MAC), *M. kansasii* and *M. malmoense* (both of the latter being able to cause disease in damaged lungs and/or in immunocompromised patients). There is also a (growing) number of infrequently isolated mycobacteria among which are species whose pathogenic potential is still undetermined [RMM (1997) 8 125–135].

*Tuberculosis in animals.*

Many warm- and cold-blooded animals are susceptible to infection by one or more species of *Mycobacterium*. (See also SKIN TUBERCULOSIS.) *M. bovis* is the most important species among domestic animals, causing tuberculosis in cattle and pigs – less commonly in sheep, horses, dogs, cats etc.

Certain wild animals (e.g. the badger, *Meles meles*, in Great Britain [PTRSLB (1985) 310 327–381]) may provide a reservoir

for bovine tuberculosis; however, the role of the badger in this context is still controversial, and a cull of badgers in selected areas is now being conducted in the United Kingdom in an attempt to resolve this question. As of August, 2001, the question remains unresolved, and the recent outbreak of foot and mouth disease is one of the factors likely to extend the time to resolution [VR (2001) 149 162–163].

Where tuberculosis has been detected in cattle, a policy of extensive slaughter of infected animals has been successful in reducing the incidence of this disease in developed countries. (See also COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST.)

**tuberculous** (1) *Syn.* TUBERCULAR. (2) Infected with tubercle bacilli.

**Tubifera** See MYXOMYCETES.

**tubular loop fermenter** See AIRLIFT FERMENTER.

**tubulin** The acidic protein of which MICROTUBULES (q.v.) are composed; closely related (but not identical) tubulins have been isolated from a wide range of eukaryotic cells. The  $\alpha$  and  $\beta$  subunits of the (dimeric) protein each have a MWt of ca. 50000. Tubulin has binding sites for guanine nucleotides and  $\text{Ca}^{2+}$  (and e.g. for COLCHICINE).  $\text{Ca}^{2+}$  can bind at one high-affinity site and at several low-affinity sites; binding to the high-affinity site is inhibited by  $\text{Mg}^{2+}$ .

Under in vitro (and experimental in vivo) conditions, tubulin can assemble into microtubules and into structures such as rings, ribbons and flat sheets; sheet formation is promoted e.g. by high concentrations of glycerol.

[Molecular biology and genetics of tubulin: ARB (1985) 54 331–365.]

**tufA, tufB genes** In *Escherichia coli*: unlinked genes which encode the EF-Tu component of elongation factor T (see PROTEIN SYNTHESIS); the genes are nearly identical, the products differing in only the C-terminal amino acid (glycine in EF-TuA, serine in EF-TuB).

**tularaemia** (tularemia) A disease of rodents, rabbits and other animals, also transmissible to man (O'Hara's disease), caused by *Francisella tularensis*; it occurs in Europe and N. America. The pathogen varies in virulence apparently according to the composition of its capsule (and hence its ability to resist phagocytosis). In man, infection occurs via wounds or mucous membranes (e.g. by direct contact with an infected animal or carcass) or via the bite of any of various arthropod vectors (e.g., biting flies, ticks). Incubation period: 2–7 days. Onset is sudden, with chills and fever, headache, nausea and vomiting, and prostration. In the *ulceroglandular* form an ulcerative lesion develops at the site of infection, and there is regional lymphadenopathy. The *glandular* form closely resembles bubonic PLAGUE. Less commonly, there may be septicaemia or (following infection by ingestion) severe gastrointestinal symptoms – either of which may be fatal. Untreated infections may persist for months. Complications may result from the dissemination of *F. tularensis* to the heart, lungs or meninges, or from secondary infection of lesions by other bacteria. *Lab. diagnosis*: e.g. microscopic examination, culture, and/or inoculation into guinea pigs of material from lesions, lymph node aspirates etc. *Chemotherapy*: streptomycin, or e.g. tetracyclines or chloramphenicol.

*F. tularensis* can cause a fatal (usually tick-borne) septicaemia in sheep, pigs, and – to a lesser degree – calves. In horses, tularaemia involves e.g. fever and oedema of the limbs; in foals, dyspnoea and incoordination may also occur.

**Tulare apple mosaic virus** See ILARVIRUSES.

**Tulasnella** See TULASNELLALES.

**Tulasnellaceae** See TULASNELLALES.

**Tulasnellales** An order of fungi (subclass HOLOBASIDIOMYCETIDAE) that form thin, resupinate, often inconspicuous basidiocarps in which the basidia each have four relatively large sterigmata that are swollen and sometimes deciduous (Tulasnellaceae) or neither swollen nor deciduous (Ceratobasidiaceae). The organisms include saprotrophs and plant parasites, and some species form mycorrhizal associations with orchids (see MYCORRHIZA). Genera include *Ceratobasidium*, *Oncobasidium* (see also VASCULAR-STREAK DIEBACK), *Thanatephorus* and *Tulasnella*.

**tulip Augusta disease** See TOBACCO NECROSIS VIRUS.

**tulip breaking virus** See POTYVIRUSES and COLOUR-BREAKING.

**Tulostomatales** See GASTEROMYCETES.

**tumbling** See FLAGELLAR MOTILITY (a) and RANDOM WALK.

**tumor** See TUMOUR.

**tumorigenic** Causing or giving rise to tumours.

**tumour** (tumor) (1) (*med.*) See NEOPLASIA and CANCER. (2) (*plant pathol.*) See GALLS.

**tumour necrosis factor** See TNF.

**tunica** Any of various coat-like or enveloping structures – e.g. a LORICA.

**tunicamycin** An ANTIBIOTIC, obtained from *Streptomyces lysosuperificus*, which is structurally complex – consisting of uracil, *N*-acetylglucosamine (GlcNAc), and a complex amino sugar (tunicamine) linked at its amino group to an unsaturated fatty acid of variable length. Tunicamycin inhibits the synthesis of GlcNAc-containing macromolecules by preventing the transfer of GlcNAc 1-phosphate from its nucleotide derivative to BACTOPRENOL phosphate or DOLICHOL phosphate; it thus inhibits e.g. the synthesis of TEICHOIC ACIDS in bacteria, and the glycosylation step in the synthesis of GlcNAc-containing glycoproteins in eukaryotes (see PALADE PATHWAY) – and hence maturation of certain enveloped viruses.

**tuning-fork basidium** See DACRYMYCETALES.

**turanose** See MELEZITOSE.

**turbidimetry** (turbidometry) Any procedure in which the concentration of cells (or particles) in a suspension is estimated by passing a beam of light through the suspension and comparing the intensity of the *transmitted* light with that obtained with a different suspension or a cell-free control; light transmitted by a suspension is of lower intensity than that of the control due mainly to light scattering – although pigmented cells may absorb (as well as scatter) a significant amount of light of particular wavelength(s). A measure of the decrease in transmitted light is the *optical density* (OD) – given by  $\log_{10}(I_0/I)$  where  $I_0$  is the intensity of the incident light, and  $I$  the intensity of the transmitted light; for a given type of cell the relationship between OD and cell concentration is approximately linear over a certain range of values. Turbidimeters (e.g. the Klett–Summerson colorimeter) consist essentially of a colourless, transparent sample holder (*cuvette*), a means of passing a narrow beam of monochromatic light through the cuvette, and a photoelectric cell to measure the intensity of the transmitted light. (See also COUNTING METHODS.)

**turbidometry** *Syn.* TURBIDIMETRY.

**turbidostat** See CONTINUOUS CULTURE.

**Turbinaria** See PHAEOPHYTA.

**turimycin** See MACROLIDE ANTIBIOTICS.

**turkey bluecomb disease virus** See CORONAVIRIDAE.

**turkey diseases** See POULTRY DISEASES.

**turkey herpesvirus** See GAMMAHERPESVIRINAE and MAREK'S DISEASE.

**turkey X disease** An outbreak of AFLATOXICOSIS which occurred among turkey poults in England during the 1960s; the source of the aflatoxins was found to be contaminated groundnut feed.

## turkeypox virus

Symptoms: depression, anorexia, neurological symptoms, weakness and death; necrotic liver lesions were found postmortem. (See also POULTRY DISEASES.)

**turkeypox virus** See AVIPOXVIRUS.

**turnip crinkle virus** See TOMBUSVIRUSES.

**turnip mosaic virus** See POTYVIRUSES.

**turnip rosette virus** See SOBEMOVIRUSES.

**turnip yellow mosaic virus** See TYMOVIRUSES.

**turnip yellows virus** See LUTEOVIRUSES.

**tut gene** See OMP.

**Tw** Twist: see DNA.

**TWAR strains** Strains of bacteria isolated from patients with suspected trachoma and acute respiratory disease, and initially thought to be strains of the species *Chlamydia psittaci*; such strains were subsequently classified in a new species, *Chlamydia pneumoniae* (see CHLAMYDIA).

**Tween** Any of a range of non-ionic surfactants which are polyoxyalkylene derivatives of fatty acid esters of sorbitan: e.g., polyoxyethylene-sorbitan monolaurate (Tween 20), monopalmitate (Tween 40), monostearate (Tween 60), and mono-oleate (Tween 80).

**Tween hydrolysis** A TWEEN may be hydrolysed (with the liberation of free fatty acids) by certain LIPASES. A test of the ability of an organism to hydrolyse a Tween is used in the identification of certain bacteria. Essentially, the strain under test is grown in a liquid medium (pH 7) containing (usually) Tween 80 and NEUTRAL RED; the hydrolysis of Tween (a *positive* result) is indicated by a red coloration (due to the release of free fatty acids). For *Mycobacterium* spp, the test is read after e.g. 5 days for rapidly-growing strains, and after e.g. 10 days for slow-growing strains.

**twist** (of supercoiled DNA) See DNA.

**twitching motility** A jerky form of translocation exhibited by polarly (but not peritrichously) fimbriate bacteria in thin films of surface liquid – e.g. on freshly prepared plates incubated under high humidity. Formerly regarded as a passive form of locomotion, twitching motility (in *Neisseria gonorrhoeae*) is reported to involve retraction of type IV FIMBRIAE, at approx. 1 µm/sec, and to require protein synthesis and the PilT protein [Nature (2000) 407 98–102]. (cf. MOTILITY.) Twitching motility occurs in both flagellate and non-flagellate bacteria of various genera; for example, it has been seen in *Acinetobacter calcoaceticus*, *Moraxella* spp and certain species of *Pseudomonas*, including *P. aeruginosa*.

**two-component regulatory system** In bacteria: a system that regulates gene expression in response to environmental signals (e.g. changes in extracellular osmolarity). The signal acts via a *signal transduction pathway* in the cell. The first component of the pathway is a HISTIDINE KINASE (located in the cell envelope); an appropriate signal causes the kinase to undergo ATP-dependent autophosphorylation and to transfer phosphate to an aspartate-containing site in the second component, a ‘regulator protein’ (= ‘response regulator’). When the latter protein is phosphorylated, it regulates certain gene(s), e.g. by controlling their transcription, thus eliciting a response to the signal. [Histidine kinases in signal transduction: TIG (1994) 10 133–138.] (See also *phosphorelay* in the entry ENDOSPORE.)

A signal may regulate the kinase *directly*, the kinase then being the *sensor* – see e.g. EnvZ in OSMOREGULATION. A further example of a kinase sensor occurs in the *E. coli* Kdp (high-affinity) transport system for K<sup>+</sup> ions; on osmotic up-shift (in the medium), the sensor KdpD apparently responds to decreased turgor pressure and transfers phosphate to KdpE, a cytosolic

regulator protein. KdpE, in turn, promotes transcription of the Kdp operon; the product of gene *kdpB* is an ATPase at which ATP hydrolysis provides energy for the uptake of K<sup>+</sup> ions.

Alternatively, the sensor may be distinct from the kinase: signals act initially on the sensor which then regulates the kinase; thus, in CHEMOTAXIS in *Escherichia coli*, signals from the MCP sensor regulate the CheA kinase.

Two-component systems regulate a wide range of activities in bacteria. For example, in *Clostridium perfringens* a two-component system is involved in regulating transcription from toxin-encoding genes in GAS GANGRENE; the *virR/virS* operon encodes VirR (regulator) and VirS (histidine kinase), but the nature of the regulatory signal(s) is unknown [RMM (1997) 8 (suppl 1) S25–S27].

In *Salmonella typhimurium*, the SsrA–SsrB system regulates transcription of genes in the SPI-2 pathogenicity island; the products of these genes are needed for the pathogen’s intracellular growth [Mol. Microbiol. (1998) 30 175–188].

In *Bacillus subtilis*, growth to high-density populations promotes competence in TRANSFORMATION; this results from the accumulation of an extracellular peptide pheromone, ComX, which activates a two-component regulatory system. ComX causes autophosphorylation of the membrane-bound histidine kinase ComP; ComP, in turn, phosphorylates (activates) a transcription factor, ComA, that regulates the *comS* gene (whose expression is needed for competence) [TIM (1998) 6 288–294].

In *Staphylococcus aureus*, a two-component regulatory system designated ArlS–ArlR is involved in adhesion, autolysis and extracellular proteolytic activity [JB (2000) 182 3955–3964].

Another two-component system in *S. aureus* is reported to be involved in regulating the expression of certain virulence factors, including exotoxin, in response to environmental levels of oxygen [JB (2001) 183 1113–1123]. (See also AGR LOCUS.)

Certain two-component systems appear to be *essential* for viability; these systems are involved e.g. in regulating gene expression in cell cycle control. Examples of essential two-component systems: the *ycyF–ycyG* system in *Bacillus subtilis* [Microbiology (2000) 146 1573–1583] and the *mtrA–mtrB* system in *Mycobacterium tuberculosis* [JB (2000) 182 3832–3838].

Studies on the *pho* regulon in *Escherichia coli* have indicated that autoamplification of the (PhoR/PhoB) two-component regulatory system leads to a faster response in cells previously exposed to phosphate limitation (i.e. the cells exhibit ‘learning’ behaviour) [JB (2001) 183 4914–4917].

(See also *three-component* regulatory system in entry BACTERIOCIN.)

**two-dimensional electrophoresis** Any procedure which involves two stages (= dimensions) of ELECTROPHORESIS, the stages differing e.g. in the physical and/or chemical properties on which the electrophoretic separation of components is based. An example of such a procedure is the analysis of serum proteins by an initial stage of ISOELECTRIC FOCUSING and a second stage of IMMUNOELECTROPHORESIS at right-angles to the axis of focusing; *serological* procedures of this type are called *two-dimensional immunoelectrophoresis* or *crossed immunoelectrophoresis*.

**two-micron DNA plasmid** (2µ plasmid; 2µ circle; 2 µm circle) A 6318-bp ccc dsDNA PLASMID present in most strains of *Saccharomyces cerevisiae*; ca. 60–100 copies of the plasmid occur in the nucleus of a diploid cell. The plasmid *in vivo* occurs complexed with histones in a CHROMATIN-like structure. It appears to encode functions concerned only with its own partition and recombination, and has no known biological role in the yeast cell. The plasmid consists of two unique regions

(2774 bp and 2346 bp) separated by two 599-bp sequences which constitute a pair of INVERTED REPEATS. Intramolecular or intermolecular SITE-SPECIFIC RECOMBINATION between the inverted repeats results in, respectively, the inversion of one unique region with respect to the other (thus, the plasmid exists in two interconvertible monomeric forms) or the formation of plasmid multimers. Site-specific recombination is catalysed by a *trans*-acting recombinase encoded by the plasmid *FLP* gene (= *A* gene). Replication of the 2 $\mu$  plasmid apparently occurs only during S phase, each plasmid normally replicating only once per cell cycle. The plasmid contains two genes, *REP1* (= *B*) and *REP2* (= *C*), which encode proteins apparently concerned with partition of the plasmid during nuclear division [MGG (1986) 203 154–162]; the *REP1* protein is apparently associated with the NUCLEOSKELETON [JBC (1987) 262 883–891]. [Minireview: Mol. Microbiol. (1987) 1 1–4.]

(See also THREE-MICRON DNA PLASMID.)

**two-site model** (of translation) See PROTEIN SYNTHESIS.

**Ty element** A TRANSPOSABLE ELEMENT present in the genome of the yeast *Saccharomyces cerevisiae*. Ty elements show considerable sequence heterogeneity, but all known elements consist of an internal region ca. 5600 bp long, flanked by direct repeat sequences ( $\delta$  sequences) each ca. 330 bp long. The haploid yeast genome contains ca. 30–35 Ty elements as well as 100 or more 'solo'  $\delta$  sequences. Ty transposition involves non-homologous target sites and results in a 5-bp duplication of target DNA; transposition occurs via an RNA intermediate, apparently involving a reverse transcriptase encoded by the *tyb* gene of the Ty element [Cell (1985) 42 507–517] and a mechanism similar to that in retroviruses [TIBS (1986) 11 273]. (cf. RETROTRANSPOSON.)

**tyb gene** See TY ELEMENT.

**tylose** (tylosis; *pl.* tyloses) (*plant pathol.*) A balloon-like outgrowth from a xylem parenchyma cell which expands into, and blocks, the lumen of a xylem vessel or a tracheid; tyloses are typically impregnated with TANNINS, and their formation occurs during abscission and in response to wounding or infection. Tyloses may play a role in resistance to disease by restricting the translocation of the pathogen; however, they may be responsible for the symptoms of certain diseases such as vascular wilts due e.g. to species of *Fusarium* or *Ceratocystis* (see DUTCH ELM DISEASE).

**tylosin** A MACROLIDE ANTIBIOTIC (from *Streptomyces fradiae*) used e.g. in veterinary medicine.

**tylosis** (1) *Syn.* TYLOSE. (2) Tylose formation.

**tymoviruses** (turnip yellow mosaic virus group) A category of ssRNA-containing PLANT VIRUSES which generally have a rather narrow host range (e.g. turnip yellow mosaic virus (TYMV), the type member, can infect various crucifers, including turnip, swede, cauliflower, Chinese cabbage); transmission occurs mechanically and via beetles. Other tymoviruses include e.g. belladonna mottle virus, cacao yellow mosaic virus, eggplant mosaic virus, peanut yellow mottle virus, *Plantago* mottle virus. Virion: icosahedral, ca. 29 nm diam., containing a single species of coat protein (MWt ca. 20000). Genome: one molecule of linear, positive-sense ssRNA (MWt ca.  $2 \times 10^6$ ) with a capped 5' end (sequence: m<sup>7</sup>G<sup>5'</sup>ppp<sup>5'</sup>Gp...), and a 3' end which has a (valine-accepting) tRNA-like structure. (Subgenomic mRNAs may also be encapsidated.) Virus RNA replication appears to occur in small, flask-shaped vesicles, each bounded by a double membrane, which develop at the periphery of chloroplasts in infected cells. Coat protein may be synthesized and assembled into hexamers and pentamers in the cytoplasm,

virus assembly occurring at the necks of the vesicles. Clumping of the chloroplasts commonly occurs in infected cells.

**TYMV** Turnip yellow mosaic virus (see TYMOVIRUSES).

**tyndallization** ('fractional sterilization') A process sometimes used *with the aim of* sterilizing certain heat-labile materials (e.g. culture media which cannot be autoclaved). The material is heated to 80–100°C for periods of up to ca. 1 hour on each of three successive days, being incubated at room temperature, or 37°C, for the intervening periods. The first period of heating is intended to kill all vegetative cells initially present in the material. Incubation during the intervening periods is intended to permit germination of any spores which may be present; vegetative cells arising from such spores are killed during subsequent periods of heating. Tyndallization is based on the assumption that materials so treated are able to support the germination and outgrowth of any spores they may contain. (cf. STERILIZATION.)

**type** (*microbiol.*) (1) *Syn.* NOMENCLATORIAL TYPE. (2) The name (per se) of the nomenclatorial type of a given named taxon. (3) An infrasubspecific population (see VARIETY).

**type I fimbriae** See FIMBRIAE.

**type I fimbriae** See FIMBRIAE.

**type 1 killer strain** (of *Saccharomyces cerevisiae*) See KILLER FACTOR.

**type I protein secretion** See PROTEIN SECRETION.

**type I reaction** (anaphylaxis) A form of IMMEDIATE HYPERSENSITIVITY which involves the binding of ALLERGEN to homologous MAST CELL-bound REAGINIC ANTIBODIES and the consequent degranulation of the mast cells with release of HISTAMINE and other physiologically active agents; the reaction is complement-independent. Type I reactions, which develop within minutes of contact with the allergen, occur e.g. in hay fever and in ANAPHYLACTIC SHOCK.

**type I septum** See ACTINOMYCETALES.

**type II protein secretion** See PROTEIN SECRETION.

**type II reaction** (cytotoxic hypersensitivity) A form of IMMEDIATE HYPERSENSITIVITY which involves the binding of antibodies to antigenic sites on the surface of cells; such binding may result in (i) COMPLEMENT-dependent IMMUNE CYTOLYSIS or (ii) OPSONIZATION and phagocytosis of the target cells.

A type II reaction is involved e.g. in one form of haemolytic anaemia which may be associated with the continued use of certain drugs (e.g. chlorpromazine); in such cases the drug forms an antigenic complex at the surface of erythrocytes and thus renders these cells liable to complement-dependent cytolysis, or to phagocytosis, when homologous antibodies are formed. As a further example, haemolysis would occur if e.g. blood of group A or B were (incorrectly) transfused into a type O recipient; this is because type O individuals (normally) contain antibodies to antigens on type A and type B erythrocytes.

(See also ADCC.)

**type 2 septum** See ACTINOMYCETALES.

**type III protein secretion** See PROTEIN SECRETION.

**type III reaction** (complex-mediated hypersensitivity) A form of IMMEDIATE HYPERSENSITIVITY involving the development of complexes between soluble antigens and antibodies; the occurrence of COMPLEMENT FIXATION may cause local or systemic damage to tissues.

The effect of complex formation *in vivo* depends e.g. on the size and precipitability of the complexes. For example, if there are high levels of circulating complement-fixing antibodies, an intradermal injection of the corresponding antigen results in rapidly precipitating complexes which bring about a local

## type IV fimbriae

inflammatory response at the site of the injection (see ARTHUS REACTION). (See also FARMERS' LUNG.)

With low levels of circulating complement-fixing antibodies, the presence of antigen can result in ANTIGEN EXCESS so that small, soluble (non-precipitating) complexes are formed; these complexes may circulate in the body and give rise to systemic symptoms (see e.g. SERUM SICKNESS). (See also GLOMERULONEPHRITIS.)

**type IV fimbriae** See FIMBRIAE.

**type IV protein secretion** See PROTEIN SECRETION.

**type IV reaction** See DELAYED HYPERSENSITIVITY.

**type V protein secretion** See PROTEIN SECRETION.

**type V reaction** (stimulatory hypersensitivity) A form of IMMEDIATE HYPERSENSITIVITY in which humoral antibody reacts with a cell-surface component (e.g. a hormone receptor) with consequent stimulation of the cell; thus, e.g., in certain thyrotoxic patients a thyroid-stimulating antibody (an autoantibody) mimics thyroid-stimulating hormone (TSH) in stimulating thyroid cells.

**type B oncovirus group** (B-type particles) A genus of retroviruses of the ONCOVIRINAE. B-type particles are assembled throughout the host cell cytoplasm (cf. TYPE C ONCOVIRUS GROUP); the mature B-type particle has prominent surface spikes and an electron-dense core located eccentrically within the envelope. Prototype of the type B oncovirus group: MOUSE MAMMARY TUMOUR VIRUS. (cf. A-TYPE PARTICLES.)

**type C oncovirus group** (C-type particles) A genus of retroviruses of the ONCOVIRINAE. C-type particles are assembled just beneath the plasma membrane of the host cell. Initially, an electron-dense crescent-shaped structure is formed; subsequently, this structure becomes a spherical core (with an electron-lucent centre) which buds through the plasma membrane to form an extracellular enveloped particle. The extracellular particle has a centrally located core which is electron-lucent in the immature particle, electron dense in the mature particle. Some C-type particles have discernible surface spikes, some do not.

Type C oncoviruses may be subdivided into *mammalian type C oncoviruses*: e.g. bovine leukosis virus (but see BOVINE VIRAL LEUKOSIS), FELINE LEUKAEMIA VIRUS, GIBBON APE LEUKAEMIA VIRUS, MURINE LEUKAEMIA VIRUSES, MURINE SARCOMA VIRUSES, RAT LEUKAEMIA VIRUSES, SIMIAN SARCOMA VIRUS; *avian type C oncoviruses*: e.g. AVIAN ACUTE LEUKAEMIA VIRUSES, AVIAN LEUKOSIS VIRUSES, AVIAN RETICULOENDOTHELIOSES VIRUSES, AVIAN SARCOMA VIRUSES; *reptilian type C oncoviruses*: e.g. viper type C oncovirus, etc.

**type culture** (1) A culture of a TYPE STRAIN. (2) Any culture in a 'type culture collection' – whether or not a type strain.

**type D retrovirus group** (D-type particles) A proposed genus of the ONCOVIRINAE. 'Immature' intracellular D-type particles are ring-shaped (ca. 60–95 nm diam.) and occur most abundantly near the plasma membrane; the 'mature' extracellular particle (ca. 100–120 nm diam.) contains an electron-dense, eccentrically located nucleoid and bears surface spikes (shorter than those of the TYPE B ONCOVIRUS GROUP). Prototype of the type D retrovirus group: MASON-PFIZER MONKEY VIRUS. (See also SIMIAN AIDS.)

**type species** One of the species, or the sole species, included in the description of a newly proposed, validly published genus; the NOMENCLATORIAL TYPE of a given genus. The type species must remain permanently within the genus of which it is the nomenclatorial type; any other species removed from the genus must be given a different genus name. A type species is not necessarily typical (in characteristics) of those species which constitute the genus.

**type strain** One of the strains, or the sole strain, included in the description of a newly proposed, validly published species; the (viable) NOMENCLATORIAL TYPE of a given species. A type strain must remain permanently within the species whose name it bears; it is not necessarily typical (in characteristics) of those strains which constitute the species. Type strains are often designated by the culture number attached to the strain in an established culture collection; e.g. the type strain of *Escherichia coli* is ATCC 11775.

**typhoid fever** (typhoid) An acute infectious human disease caused by *Salmonella typhi*. Transmission occurs via the faecal–oral route, e.g. via contaminated food or water. Asymptomatic carriers are an important source of infection; *S. typhi* usually localizes in the gall bladder and may be excreted in the stools for years. Incubation period: usually 7–15 days. Symptoms include malaise, myalgia, headache, and fever that increases stepwise over several days; there may also be abdominal discomfort with constipation or diarrhoea, a transient macular rash ('rose spots'), delirium or stupor, and enlargement of the spleen and mesenteric lymph nodes. Inflammation of the lymphoid tissues in the ileum (Peyer's patches) is characteristic, and may lead to necrosis and bowel perforation or haemorrhage which may be fatal. *Lab. diagnosis*: *S. typhi* may be isolated by BLOOD CULTURE during the first 7–10 days, after which it may be cultured from urine or stools. The WIDAL TEST is rarely positive before 10 days after onset. *Chemotherapy*: e.g. chloramphenicol, ampicillin, amoxicillin. Elimination of *S. typhi* from carriers may necessitate large doses of ampicillin together with surgical removal of the gall bladder. Inactivated typhoid vaccines are available.

**typhoid Mary** A typhoid CARRIER, Mary Mallon, who was responsible for transmitting the disease to ca. 30 persons. The name is sometimes used to refer to a potential, suspected, or actual carrier in an outbreak of typhoid or other disease.

**Typhula** See APHYLLOPHORALES (Clavariaceae) and SNOW MOULD.

**typhula blight** See SNOW MOULD.

**typhus fevers** (a) *Epidemic (classical or louse-borne) typhus*.

In man: an acute systemic disease caused by *Rickettsia prowazekii*; infection occurs e.g. when louse faeces, containing *R. prowazekii*, contaminate a louse bite or other lesion. (Infection by inhalation of dried, contaminated louse faeces has also been reported.) The incubation period is 1–2 weeks. Typical symptoms include shivering, headache, muscular pains, malaise, and a sustained fever lasting 1–2 weeks – during which a macular rash develops on the trunk and limbs (rarely on the face); the lesions may become haemorrhagic. Delirium or stupor may occur. Mortality rates in untreated cases may be 5–70%. Diagnosis may involve a CFT and/or the WEIL–FELIX TEST. Tetracyclines and chloramphenicol have been used for treatment. Control measures include de-lousing and the use of prophylactic vaccines. (b) *Brill–Zinsser disease (Brill's disease; recrudescence typhus)*. A mild form of classical typhus which occurs some time after a previous attack; during the supervening period the pathogen remains latent in the body. [Brill–Zinsser disease (historical perspective): Lancet (2001) 357 1198–1200.] (c) *Murine typhus (endemic typhus; flea-borne typhus)*. In man, this disease is similar to, but less severe than, epidemic typhus. It is primarily a disease of the rat. The causal agent, *R. typhi* (= *R. mooseri*), is spread among rats by the rat flea, *Xenopsylla cheopis*; man becomes infected contaminatively. Diagnosis and treatment are as for epidemic typhus. (See also BOUTONNEUSE, SCRUB TYPHUS.)

**typhing** (of microorganisms) The process of (i) distinguishing between closely related strains of a microorganism on the basis

of specified criteria (i.e. a form of classification), and (ii) using the same criteria to characterize an unknown strain of the organism by matching it with a strain already classified in the typing process (i.e. a form of identification). An unknown strain which has been matched in this way is said to have been 'typed'.

In one approach to typing, all known strains of a given species are classified into categories according to specified criteria. If the classification includes a truly comprehensive range of strains, such a scheme should permit most newly isolated strains to be typed.

Another, distinct, form of typing is the *ad hoc* scheme used for non-inclusive populations of strains – for example, strains of a given pathogen isolated from patients in a geographically localized region. In typing systems of this kind, strains are differentiated by comparing each strain with other strains in the same limited population.

It should be noted that no system of typing can prove that an unknown strain is identical to a particular known strain (although non-identity can be demonstrated); this is because a given typing system reveals similarity, or otherwise, in respect of only one (or a few) characteristics, and even if the known and unknown strains match in *these* characteristic(s) they may well differ in others. For a given species, different typing systems categorize on the basis of different criteria and, for this reason, tend to give different results; thus, for example, a population of unknown strains may be divided into a small number of groups by one typing system but into many groups by another (the latter system being said to be more *discriminatory*, i.e. able to reveal a greater number of fine differences between the strains).

To be widely applicable, a typing system should satisfy certain basic requirements. First, the criteria used should enable all strains of the given organism to be typed. (However, in practice, it is not uncommon to find that some strains are 'untypable' in a given system.) Second, the typing system should clearly distinguish each strain from the other strains. Third, results should be reproducible.

*Applications of typing.* In a medical/veterinary context, typing has various uses – for example:

(a) *Detection of laboratory cross-contamination.* In a clinical laboratory, cross-contamination among pre-test specimens can lead e.g. to false-positive results and incorrect diagnoses. In one published episode, typing revealed that 60 specimens in a reference laboratory had been contaminated with *Mycobacterium tuberculosis* from one true-positive specimen [JCM (1999) 37 916–919].

(b) *Distinguishing between re-activation and new infection in tuberculosis.* DNA-based typing methods have been able to indicate the probable origins of strains isolated from patients with tuberculosis, and have indicated e.g. that recent transmission (as opposed to re-activation of a previous infection) is more common than previously supposed [BCID (1997) 4 173–183].

(c) *Epidemiology (community-based and global).* In epidemiology, typing permits the investigator to identify sources of infection and to follow the routes of transmission; such investigation is possible only if individual strains have been characterized (typed) and are distinguishable. The underlying rationale for the epidemiological use of typing is that all isolates of a given pathogen from a particular *outbreak* of disease, or from within the same *chain of infection*, will be progeny of the same ancestral cell and will therefore be recognizable by close genetic similarity (clonal relationship) compared with other, randomly acquired

isolates of the same pathogen. Thus, if strains of a pathogen have been stably typed, it is often possible to link a particular case or outbreak of disease with a known source of infection by comparing the causal strain with strains of the pathogen known to occur in specific locations. [Evaluation and use of epidemiological typing systems: CMI (1996) 2 2–11.] Tracking of virulent and antibiotic-resistant strains of pathogenic bacteria on a global scale, via the Internet, is possible by multilocus sequence typing (see MLST).

Typing *direct* from a clinical specimen (i.e. without prior culture) has been used for strains of *Neisseria meningitidis*; this can be advantageous when a specimen is culture-negative owing to pre-admission chemotherapy [JCM (1997) 35 1809–1812].

In a veterinary context, typing has been used e.g. to investigate outbreaks of *Pseudomonas aeruginosa* mastitis in dairy herds [AEM (1999) 65 2723–2729].

*Typing methods.* There are two main categories: conventional (phenotypic) methods, and nucleic-acid-based (genotypic) methods. Conventional methods include e.g. BACTERIOCIN TYPING, GRIFFITH'S TYPING, MULTILOCUS ENZYME ELECTROPHORESIS, PHAGE TYPING and SEROTYPING. Any of a range of characteristics may be suitable for typing purposes; for example, strains of *Pseudomonas aeruginosa* may be typable on the basis of variability in the siderophore *pyoverdine* [Microbiology (1997) 143 35–43].

Genotypic methods include AFLP FINGERPRINTING, ARBITRARILY PRIMED PCR, DNA FINGERPRINTING, DNA SEQUENCING, MLST, PFGE, RAPD, REP-PCR, RFLP, RIBOTYPING, SSCP and SPOLIGOTYPING.

[Nucleic-acid-based typing: Book ref. 221, pp 168–202.]

**tyrocidins** Cyclic decapeptide ANTIBIOTICS, produced by *Bacillus brevis*, which are bactericidal mainly for certain Gram-positive bacteria. The tyrocidin molecule contains one or more free amino groups, and includes at least one D-amino acid. Tyrocidins appear to disrupt the CYTOPLASMIC MEMBRANE, causing leakage of essential metabolites etc. (cf. GRAMICIDINS.)

**Tyromyces** See APHYLLOPHORALES (Polyporaceae).

**tyrosinase** See MELANIN and COPPER.

**L-tyrosine biosynthesis** See AROMATIC AMINO ACID BIOSYNTHESIS.

**tyrosine kinase** Commonly refers to a tyrosine-specific PROTEIN KINASE – see e.g. CYTOKINES.

**tyrothricin** A mixture of GRAMICIDINS (ca. 20%) and TYROCIDINS, produced by *Bacillus brevis*.

**tyvelose** (3,6-dideoxy-D-mannose) A sugar, first isolated from *Salmonella typhi*, which occurs in the O-specific chains of the LIPOPOLYSACCHARIDE in certain *Salmonella* serotypes and which contributes to the specificity of O antigen 9 in group D salmonellae (see KAUFFMANN-WHITE CLASSIFICATION).

**Tyzzeria** A genus of homoxenous coccidian protozoa (suborder EIMERIORINA) in which the oocysts contain 8 naked sporozoites (i.e. sporocysts are not formed). *T. perniciosa* causes an intestinal disease in ducks.

**Tyzzer's disease** A fatal disease which can affect e.g. rodents, cats, young foals and rhesus monkeys. The causal agent was reported to be an intracellular parasitic bacterium not cultivable in artificial media [JGM (1984) 130 1757–1763]; formerly referred to as '*Bacillus piliformis*', it is now designated *Clostridium piliforme* [IJSB (1993) 43 314–318]. In foals, onset is sudden, and death may occur within a few hours or days; the disease involves a necrotizing hepatitis and colitis with high fever and, in some cases, jaundice and diarrhoea. At post mortem the (greatly enlarged) liver exhibits miliary necrotic foci.

# U

**U** Uracil (or the corresponding nucleoside or nucleotide) in a nucleic acid.

**U-RNA** See SNRNA.

**U1–U6 snRNAs** See SNRNA.

**UACUAAC box** See SPLIT GENE (a).

**UAS** Upstream activation site: a sequence in the DNA of *Saccharomyces cerevisiae* which is involved in the regulation of transcription; it apparently resembles an ENHANCER except that it cannot function when located downstream of a promoter.

**ubiquinones** See QUINONES.

**ubiquitin** A polypeptide (containing 76 amino acids) present – either free or covalently bound to protein – in the cells of higher eukaryotes and in various microorganisms. Energy-dependent binding of ubiquitin to a protein is apparently an essential signal for the selective proteolysis of that protein in the cell.

The ubiquitin–PROTEASOME pathway has been reported to be essential for proteolysis during morphological changes in *Trypanosoma cruzi* [Biochem. (2001) 40 1053–1062].

**UDN** See ULCERATIVE DERMAL NECROSIS.

**Udotea** A genus of siphonaceous, usually calcified, fan-shaped green seaweeds related to HALIMEDA.

**UDP** Uridine 5'-diphosphate [see Appendix V(b)].

**UHT milk** See APPERTIZATION and CASEIN.

**ulcer** A localized break in an epithelial surface (e.g. the skin or mucous membrane), often accompanied by inflammation, formed as a result of the sloughing of necrotic tissue. Ulcers occur in certain infectious diseases or may result from physical damage (e.g. bed-sores), defective circulation, malignant tumours etc.

**ulcer disease** (in salmonids) A FISH DISEASE involving skin ulceration and septicaemia. Pathogen: '*Haemophilus piscium*' – now thought to be an atypical strain of *Aeromonas salmonicida*. (cf. FURUNCULOSIS.)

**ulceracin 378** A BACTERIOCIN produced by *Corynebacterium diphtheriae* var. *ulcerans*. [Purification and characterization: JGM (1985) 131 707–713.]

**ulcerative dermal necrosis** (UDN; salmon disease) An infectious FISH DISEASE of unknown aetiology affecting mature salmonid fish re-entering fresh water from the sea. Skin lesions range from small grey patches to deep haemorrhagic ulcers. Secondary SAPROLEGNIASIS is common.

**ulcerative enteritis** (of fowl) See QUAIL DISEASE.

**ulcerative lymphangitis** (ulcerative cellulitis) A chronic infectious disease, mainly of horses but also e.g. of cattle, caused by *Corynebacterium pseudotuberculosis*. Infection occurs via wounds; flies may be mechanical vectors [VR (1983) 113 496–497]. Progressive inflammation of the subcutaneous lymphatic vessels is typically accompanied by ulceration and/or induration; internal organs (e.g. lungs, kidneys) may be affected.

**Ulothrix** A genus of filamentous freshwater and marine green algae (division CHLOROPHYTA). The filaments are generally unbranched and attached to a substratum by a basal cell holdfast. Individual cells are uninucleate, and each contains a single chloroplast. Asexual reproduction occurs by fragmentation of filaments or by release of quadriflagellate zoospores. Sexual reproduction is isogamous; gametes are biflagellate.

**ultimate carcinogen** See CARCINOGEN.

**UITma™ DNA polymerase** See DNA POLYMERASE.

**ultracentrifugation** See CENTRIFUGATION.

**ultracytostome** *Syn.* MICROPORE.

**ultradian rhythms** In certain parameters of a eukaryotic cell or organism: innate rhythmical changes which occur with a periodicity of less than 24 hours. (cf. CIRCADIAN RHYTHMS.)

**ultrafiltration** See FILTRATION.

**ultramicrotome** See MICROTOME.

**ultrasonication** The use of sound waves of frequency ca. 16 kHz or higher (ultrasound) produced by a SONICATOR. Ultrasonication is used, in a *liquid* medium, e.g. for sphaeroplast lysis, for dispersing the fine particulate matter in centrifuge pellets, and for CELL DISRUPTION. Sphaeroplast lysis requires only a short exposure to ultrasound, resulting in minimal damage to liberated cell components; breakage of whole cells requires longer exposure, with concomitant risk of damage to cell components. The efficacy of ultrasonication increases with increasing frequency, and decreases with increasing viscosity. Ultrasonication causes *cavitation*: the formation of minute bubbles of gas or vapour in those regions of the liquid corresponding (at a given instant) to rarefactions in the sound waves; the shearing forces produced by fast-moving bubbles together with the abrupt pressure changes which occur in these microenvironments probably account for the main disintegrative effect. Ultrasonicated material is subject to oxidation – probably due to the formation of hydrogen peroxide and/or SINGLET OXYGEN during cavitation in an aerated medium; oxidation can be lessened by enveloping the sample with an inert gas.

**ultrasound** See ULTRASONICATION.

**ultraviolet microscopy** See MICROSCOPY (f).

**ultraviolet radiation (UVR)** (a) *Effects on DNA*. UVR of wavelength 240–300 nm is strongly absorbed by the bases in DNA and can induce the formation of a variety of photoproducts which may lead to mutation or cell death. A major product is the cyclobutyl pyrimidine (particularly thymine) dimer which arises by the formation of covalent bonds between the 5,6-positions of two adjacent pyrimidine residues (a cyclobutane ring being formed between the residues). The linked bases can no longer form Watson–Crick base pairs, and localized distortion of the DNA duplex occurs. Pyrimidine dimers prevent replication of the DNA and can be lethal unless acted upon by a DNA REPAIR mechanism (see e.g. EXCISION REPAIR, PHOTOREACTIVATION and RECOMBINATION REPAIR). (See also MAXICELL.)

In e.g. *Escherichia coli*, *mutagenesis* induced by UVR is apparently dependent on the induction of the SOS SYSTEM; many types of mutation occur, including base substitutions, frameshifts and deletions [JMB (1985) 182 45–68], and these are believed to result from *umuDC*-dependent error-prone repair of UV-induced lesions. The cyclobutyl pyrimidine dimers, although potentially lethal and capable of inducing the SOS response, are apparently not directly mutagenic. The main pre-mutagenic lesion is believed to be another UVR-induced product, the '(6–4) photoproduct' (Pyr(6–4)Pyo), formed between adjacent pyrimidines (usually 5'-T – C-3' or 5'-C – C-3') by covalent bonding between the 6-position of the 5' pyrimidine and the 4-position of the 3' pyrimidine [Cell (1983) 33 13–17; JMB (1985) 184 577–585; Mut. Res. (1986) 165 1–7]; the (6–4) photoproduct is not susceptible to enzymic photoreactivation but can be removed e.g. by excision repair. Apurinic sites may also be important pre-mutagenic lesions.

(b) *In disinfection*. UVR 'germicidal' lamps (emitting UVR at ca. 254 nm) are used in certain circumstances e.g. for the DISINFECTON of air and of exposed surfaces in enclosed areas. However, UVR (a non-IONIZING RADIATION) has poor powers of penetration: it is readily absorbed by solids, and can penetrate liquids only to a limited extent; furthermore, its effects on microorganisms may, depending e.g. on dose, be reversed by various DNA repair processes (see (a) above). (See also BROWN-BOVERI UV-C LAMP; cf. WOOD'S LAMP.)

**Ulva** A genus of green foliose seaweeds (division CHLOROPHYTA). The sheet-like irregularly shaped thallus is generally anchored to rocks by a perennial, rhizoid-like holdfast; it consists of two layers of uninucleate cells, each cell containing a single chloroplast with one or more pyrenoids. The cells of the holdfast are multinucleate. The life cycle involves an isomorphic alternation of generations; sporophytes produce quadriflagellate zoospores, gametophytes produce biflagellate gametes.

*U. lactuca* (the 'sea lettuce', 'green LAVER') is reputed to be edible; it is common in coastal and estuarine waters and may be particularly abundant near freshwater outfalls and in sewage-polluted waters (cf. ENTEROMORPHA). *U. lactuca* can have a detrimental effect on invertebrates which share its environment – due both to its production of toxic exudates and to its consumption of O<sub>2</sub> at night [JEMBE (1985) 86 73–83].

**Ulvophyceae** (Ulvophyceae) See CHLOROPHYTA.

**umber codon** See GENETIC CODE.

**Umbilicaria** A genus of LICHENS (order LECANORALES); photobiont: a green alga. The thallus is foliose, discoid, entire or lobed, attached to the substratum via a single, more or less central holdfast (umbilicus) on the underside. Apothecia: lecideine, smooth or gyrose according to species. Species occur mainly on acidic rocks in arctic–alpine regions. (cf. LASALLIA; see also IWATAKE and ROCK TRIPE.)

**umbilicate** (1) Having a localized central depression. (2) (of a lichen thallus) Attached to the substratum by an umbilicus (see UMBILICARIA).

**umbilicin** β-D-Galactofuranosyl-(1 → 3)-D-arabitol, a compound found in *Umbilicaria* spp.

**umbilicus** See UMBILICARIA.

**umbo** A discrete swelling at the centre of (e.g.) the upper part of a pileus, or of an otherwise flat bacterial colony.

**umbonate** Having an UMBO.

**umecyanin** See BLUE PROTEINS.

**UMP** Uridine 5'-monophosphate (= uridylic acid) [see Appendix V(b)].

**umuC, umuD genes** See SOS SYSTEM.

**UmuD'** See SOS SYSTEM.

**Una virus** See ALPHAVIRUS.

**unbalanced growth** See GROWTH.

**unc mutant** A mutant bacterium defective in the coupling between pmf (see CHEMIOSMOSIS) and PROTON ATPASE activity.

**Uncinula** See ERYSIPTHALES.

**uncoating** When a virus infects a host cell: the process in which the viral nucleic acid is released from the capsid or is exposed by modification of the capsid (depending on virus) prior to its expression and replication.

**unconventional slow virus infections** See SLOW DISEASE.

**uncoupling agents** Those chemical agents (e.g. PROTON TRANSLATORS) which can collapse (or prevent the formation of) a transmembrane electrochemical gradient (see CHEMIOSMOSIS) and which can thus uncouple the link between pmf-generating electron transport and the pmf-utilizing PROTON ATPASE. (See also RESPIRATORY CONTROL.) Even when a gradient has been collapsed, the electron transport chain which generated the gradient

may continue to operate, although no gradient develops in the continuing presence of the uncoupling agent. Uncoupling agents also tend to promote intracellular ATP hydrolysis ('uncoupler-stimulated ATPase activity'). (cf. OLIGOMYCIN.)

**Undaria** A genus of seaweeds of the PHAEOPHYTA. *U. pinnatifida* is widely used as food in Japan (where it is known as *wakame*) and in China (*qundai-cai*); in Japan it is cultivated by sowing spores on ropes which are submerged in the sea [Book ref. 130, pp. 690–692].

**undecaprenol** See BACTOPRENOL.

**undecenoic acid** *Syn.* UNDECYLENIC ACID.

**undecylenic acid** (undecenoic acid; CH<sub>2</sub>=CH(CH<sub>2</sub>)<sub>8</sub>COOH)

An antifungal ORGANIC ACID used (as the free acid or e.g. as the zinc salt) e.g. for the treatment of superficial dermatophyte infections.

**underwound DNA** See DNA.

**undulant fever** See BRUCELLOSIS.

**undulating membrane** (1) (*ciliate protozool.*) See PARORAL MEMBRANE. (2) In some flagellates (e.g. species of TRICHOMONAS and TRYPANOSOMA): a membranous structure which spans the region between the FLAGELLUM or the proximal part of the flagellum (according to species) and the cell body – see e.g. figure under TRYPANOSOMATIDAE. In e.g. *Trypanosoma* the undulating membrane is a double membrane.

**ung gene** See URACIL-DNA GLYCOSYLASE.

**UNG method** (decontamination) See PCR.

**ungulate** (*adj.*) Shaped like a hoof.

**unialgal** Of e.g. an algal culture: containing only one species of alga.

**unicell** A single autonomous cell.

**unicellular** Consisting of a single cell.

**unifactorial heterothallism** See HETEROTHALLISM.

**unilocular** Consisting of or having a single LOCULE: see e.g. FORAMINIFERIDA.

**uniport** The transmembrane transport of one type of solute (e.g. a given ion) by a carrier. (cf. ANTIPORT, SYMPORT; see also e.g. VALINOMYCIN and ION TRANSPORT.)

**uniseriate** Arranged in or forming a single row; also used to refer to e.g. a filament or chain composed of a single row of cells or spores.

**unit membrane** A conceptual structure, proposed in the 1930s by Danielli and Davson, for biological membranes. Essentially, a membrane was supposed to consist of a bilayer of lipid molecules (orientated with their fatty acid side-chains perpendicular to the plane of the membrane, and their hydrophilic portions forming the surfaces of the bilayer) with a layer of protein coating each surface of the bilayer. The model has been superseded by the fluid mosaic model (see CYTOPLASMIC MEMBRANE), but *unit-type membrane* refers to any membrane based on a lipid bilayer.

**unitunicate ascus** An ASCUS whose wall consists of a functionally single layer, i.e., if the wall is bi- or multilayered the layers do not move relative to one another during the discharge of ascospores. Ascospores are discharged e.g. via an apical pore or an operculum. (cf. BITUNICATE ASCUS.)

**univalent** (*noun*) An unpaired chromosome at meiosis.

**univalent bottle** A cylindrical, shoulderless, screw-cap glass jar of capacity ca. 25 ml. (cf. MCCARTNEY BOTTLE.)

**universal conjugation system** See PILL.

**universal genetic code** See GENETIC CODE.

**universal nucleotide** See PCR.

**universal primers** See BROAD-RANGE PRIMERS.

## universal veil

**universal veil** (*mycol.*) In certain agarics (e.g. *Amanita* spp): a membranous tissue which entirely covers the immature fruiting body; as the fruiting body develops, the universal veil tears – leaving a VOLVA and (sometimes) fragments of the membrane (*scales*) adhering to the upper surface of the pileus. (cf. PARTIAL VEIL.) (For some authors ‘universal veil’ refers also to the PERIDIUM of gasteromycetes.)

**unlinked gene** See LINKAGE.

**Unna–Pappenheim stain** *Syn.* METHYL GREEN–PYRONIN STAIN.

**untwisting enzyme** A type I TOPOISOMERASE.

**unwinding angle** See INTERCALATING AGENT.

**unwinding protein** See DNA UNWINDING PROTEIN.

**up mutation** (up-promoter mutation) A MUTATION in a PROMOTER which results in an increased level of transcription from that promoter. (cf. DOWN MUTATION.)

**UPEC** Uropathogenic *Escherichia coli*: strains of *E. coli* associated with a high proportion of human urinary tract infections. (See also CYSTITIS and PYELONEPHRITIS.)

Strains of UPEC typically encode a range of virulence factors which include a cytotoxic agent, a haemolysin and a number of ADHESINS such as type I FIMBRIAE, DR ADHESINS and P FIMBRIAE. In at least some strains of UPEC, virulence factors (including the haemolysin) are encoded by a 70 kb chromosomal PATHOGENICITY ISLAND, designated PAI-1, which is reported to be inserted downstream of the *selC* gene.

Effective adhesion of UPEC to uroepithelium is an essential first step in pathogenesis as there is a need to combat the flushing action of the urine flow. Type I fimbriae (the FimH adhesin) can bind to certain UROPLAKINS (UPIa, UPIb); moreover, the type I fimbria can act as an INVASIN, promoting uptake of the bacterial pathogen by bladder epithelial cells. (This role appears to be specific to type I fimbriae; adhesion mediated by the PapG adhesin of P fimbriae did not promote uptake [EMBO (2000) 19 2803–2812].)

In the mouse model, strains of UPEC are able to persist within bladder tissue; if this reflects the human situation it could at least partly explain recurrent infections of the urinary tract.

[Interplay between uropathogenic *E. coli* and the innate host defences: PNAS (2000) 97 8829–8835.]

[Disseminated multidrug-resistant clonal group A: Lancet (2002) 359 2249–2251.]

**UPGMA** In NUMERICAL TAXONOMY, unweighted pair group method with averages: a method in which two groups (‘clusters’) unite (coalesce) at a similarity level determined by the arithmetical average of the similarities which exist between inter-cluster OTU pairs.

**uphill electron transport** See REVERSE ELECTRON TRANSPORT.

**upstream** (*mol. biol.*) See DOWNSTREAM.

**upstream activation site** See UAS.

**uptake hydrogenase** See NITROGENASE.

**UQ** Ubiquinone: see QUINONES.

**uracil-DNA glycosylase** (uracil-*N*-glycosylase) An enzyme (the product of the *ung* gene in *Escherichia coli*) which removes uracil from a dUMP residue in ssDNA or dsDNA (but not from dUMP itself); removal of uracil from dsDNA is followed by BASE EXCISION REPAIR of the AP SITE. The enzyme is believed to function primarily in protecting against mutation resulting from the deamination of cytosine to uracil in DNA (see SPONTANEOUS MUTATION).

In PCR, this enzyme is used in one approach for preventing the contamination of apparatus and environment by ‘carryover’ amplicons from previous amplifications.

**uracil-*N*-glycosylase** *Syn.* URACIL-DNA GLYCOSYLASE.

**uranil acetate** See ELECTRON MICROSCOPY.

**urea** (as an antimicrobial agent) Urea (carbamide: (NH<sub>2</sub>)<sub>2</sub>CO) has mild antibacterial properties against certain bacteria (but see UREASES), as do certain of its derivatives (e.g. urethanes: RNH.CO.OC<sub>2</sub>H<sub>5</sub>). (See also CARBAMIC ACID DERIVATIVES; CARBANILIDES; *N*-NITROSO COMPOUNDS (nitrosoureas); THIOUREA DERIVATIVES.)

**Ureaplasma** A genus of urease-positive, microaerophilic bacteria (family MYCOPLASMATACEAE) which occur e.g. in the mouth and in the respiratory and urogenital tracts in man and other animals. Cells: non-motile, coccoid (ca. 0.1–0.85 μm diam.) in young cultures, or pleomorphic. *Ureaplasma* spp (formerly called T-strain mycoplasmas) resemble *Mycoplasma* spp in their general properties, and they can be cultured in serum- and yeast extract-containing media; however, colonies are small (ca. 15–60 μm diam.) and may lack the zone of surface growth (and hence the ‘fried egg’ appearance) typical of *Mycoplasma* spp. Infection with ureaplasmas has been associated with various diseases – e.g. chorioamnionitis, urethritis – although the causal role of ureaplasmas in at least some of these diseases remains uncertain. GC%: ca. 27–30. Type species: *U. urealyticum* (which includes strains isolated from man); other species: *U. diversum* (which includes bovine strains). [Book ref. 22, pp. 770–775. Ovine and caprine ureaplasmas: JGM (1983) 129 3197–3202.]

**urease** An enzyme (EC 3.5.1.5) which hydrolyses UREA to ammonia and carbon dioxide; ureases occur e.g. in certain bacteria (e.g. *Helicobacter pylori*, *Proteus* spp, some other enterobacteria, and *Ureaplasma*), in some plants (e.g. soybean) and in certain invertebrates. [Bacterial ureases (structure, regulation of expression, and role in pathogenesis): Mol. Microbiol. (1993) 9 907–913.]

Urease activity in enterobacteria can be detected by growing the organisms on Christensen’s urea agar: a phosphate-buffered medium containing glucose, peptone, urea and PHENOL RED; the medium is inoculated heavily, incubated at 37°C, and examined after 2–4 hours, 18 hours, and daily for 4 days. In a positive reaction (urea hydrolysed) the resulting alkalinity causes the pH indicator to turn red.

**Uredinales** See UREDINIOMYCETES.

**Uredinella** See SEPTOBASIDIALES.

**Urediniomycetes** (rust fungi; rusts) A class of plant-parasitic fungi (subdivision BASIDIOMYCOTINA), all of which are placed in the order Uredinales; the rusts form sexual organs but do not form macroscopic basidiocarps (cf. USTILAGINOMYCETES). Some rusts cause economically important plant diseases: see RUSTS (sense 2). Rust fungi often exhibit a high degree of host specificity, and a given species of rust may consist of many PHYSIOLOGICAL RACES. Some rusts are HOMOXENOUS, others are HETEROXENOUS. Many rusts exhibit HETEROETHALLISM. Many species of rust have been grown in axenic culture.

*Morphology and life cycles of the rust fungi.* The vegetative (somatic) form is a hyaline, septate mycelium which generally occurs intercellularly in the host plant; haustoria are commonly formed.

The life cycle involves a series of distinct spore stages which occur in a definite sequence; some species exhibit up to five stages, while other exhibit four or fewer stages. The rust life cycle may be exemplified by that of *Puccinia graminis tritici*, a heteroxenous, heterothallic rust which exhibits all five spore stages and which causes black stem rust of wheat; wheat is the *primary host* (i.e., that host of a heteroxenous rust in which arise the (BASIDIUM-forming) *teliospores* – see later), while the secondary host of *P. graminis tritici* is an appropriate species of

the barberry (*Berberis*). The complete life cycle of *P. graminis tritici* (not always exhibited in nature) is as follows.

**Stage 0.** A basidiospore germinates on a barberry leaf and gives rise, subsequently, to a mononucleate, haploid, intercellular, HAUSTORIUM-forming mycelium. After several days, erumpent, flask-shaped structures (*pycnia*) develop as small, raised, yellowish lesions on the upper surface of the leaf. A *pycnium* (= *spermogonium*, *spermatogonium* or *spermogonium*) is a wholly fungal structure lined with a layer of elongated cells or hyphae from the ends of which are produced minute, mononucleate, haploid cells – *pycniospores* (= *pycnospores* or *spermatia*) – that are exuded in drops of sweet, sticky nectar from the ostiole (opening) of the *pycnium*. Extending from the ostiole is a tuft of stiff, sterile, orange filaments, and a number of thin-walled *flexuous hyphae* (= *receptive hyphae*). The *pycniospores* function as male reproductive cells, while the *flexuous hyphae* function as female structures; however, in *P. graminis tritici* (and other heterothallic rusts) fertilization does not occur between *pycniospores* and *flexuous hyphae* from the same *pycnium* because both are of the same MATING TYPE. Fertilization occurs when *pycniospores* from another *pycnium* (of different mating type) fuse with the *flexuous hyphae*; the nucleus of the *pycniospore* then travels down the *flexuous hypha* and subsequently undergoes repeated division.

**Stage I.** Within the barberry leaf the mycelium forms a number of differentiated regions near the lower epidermis; these spheroidal regions are aecial initials (= *protoaecia* or *protoaecidia*). A *protoaecium* (= *protoaecidium*) does not develop further unless it receives nuclei of appropriate mating type – either via the *flexuous hyphae* or by fusion of hyphae of compatible strains which occupy adjacent regions in the leaf. On DIKARYOTIZATION each *protoaecium* develops into an *aecium* (= *aecidium*) (*pl. aecia* and *aecidia*, respectively). An *aecium* consists of a basal layer of sporogenous cells which gives rise to a mass of parallel, basipetally-formed chains of binucleate spores (*aeciospores*, *aecidiospores*) arranged perpendicularly to the leaf surface; the entire mass of spores is contained within a thin wall (*peridium*) of fungal origin. The mature *aecium* later breaks through the leaf's lower epidermis, and the exposed *peridium* ruptures to form a cup-like structure (*aecial cup* or *cluster cup*) from which the orange *aeciospores* are discharged.

**Stage II.** *Aeciospores* cannot re-infect the barberry; they can infect suitable strains of wheat, giving rise to a binucleate, intercellular mycelium. Later, fungal structures termed *uredia* (= *uredinia* or *uredosori*) develop subepidermally in stem and leaf tissues, and eventually become erumpent. A *uredium* (= *uredinium* or *uredosorus*) bears a layer of single-celled, binucleate, rust-coloured spores – *uredospores* (= *uredinospores* or *urediospores*) – each spore being borne on a thin stalk (*pedicel*); in this species the *uredium* is not bounded by a *peridium*. After the spore mass has ruptured the host's epidermis the *uredospores* are dispersed e.g. by wind. Heavy infection of stems can cause LODGING. *Uredospores* cannot infect the barberry; they can infect wheat (and may re-infect the original host plant), giving rise to a binucleate mycelium. Several crops of *uredospores* may be formed during the summer; *uredospores* are thus the main dispersal agents of this rust. (See also AMPHISPORE; for dormancy in *uredospores* see SPORE.)

**Stage III.** In late summer/early autumn the fungus (still within wheat) ceases to form *uredia* and gives rise to *telia* (= *teleutosori*). A *telium* (= *teleutosorus*) resembles a *uredium* in that it is an erumpent mass of stalk-borne spores unbounded by a *peridium*; it differs, however, in that each *teliospore*

(= *teleutospore*) is a very dark, two-celled structure (each cell binucleate) with a wall much thicker than that of a *uredospore*. By the time the spore has reached maturity karyogamy has occurred in both cells. *Teliospores* are RESTING SPORES. The telial stage is regarded as the sexual stage of rust fungi – which are classified mainly on the basis of the characteristics of this stage.

**Stage IV.** In spring, *teliospores* germinate to form basidia (see BASIDIUM) which give rise to haploid, unicellular, thin-walled BASIDIOSPORES (= *sporidia*). Of the four basidiospores formed on each basidium, two are of one mating type, and the other two are of a different mating type. Basidiospores are dispersed e.g. by wind.

In some parts of the world (e.g. the eastern USA) *P. graminis tritici* overwinters on barberry. In e.g. Great Britain, however, outbreaks of black stem rust are commonly due to the arrival of wind-borne *uredospores* from southern Europe. In warm regions the pathogen can overwinter as *uredospores* and can re-infect wheat in the following year.

**Characteristics of other rust fungi.** Rusts may be classified according to the range of types of spore they produce: see e.g. DEMICYCLIC RUSTS, MACROCYCLIC RUSTS, MICROCYCLIC RUSTS. According to species, the *pycnium* may be any of twelve different morphological types; the *aecium* may be e.g. AECIDIOD, CAEMATOID, PERIDERMIOID or ROESTELIOID; and the *uredium* may be non-peridiate (e.g. *Puccinia*) or peridiate (e.g. *Melampsora*). (The *uredium* of *Pucciniastrum agrimoniae* has a persistent peridium, the *uredospores* escaping via a pore.) *Teliospores* may be sessile or pedicellate, and may be one-celled (e.g. *Uromyces*), two-celled (e.g. *Puccinia*) or multicelled (e.g. *Xenodochus*).

The genera of rust fungi include e.g. *Arthuria*, *Coleosporium*, *CRONARTIUM*, *Cystomyces*, *Dasyscypha*, *Endophyllum*, *GYMNOSPORANGIUM*, *Hemileia* (see also COFFEE RUST), *Hyalospora*, *Intraptes*, *MELAMPSORA*, *Peridermium*, *Phragmidium*, *PUCCINIA*, *Pucciniastrum*, *Trachyspora*, *Uredinopsis*, *Uromyces* and *Xenodochus*.

**uredinospores** See UREDINIOMYCETES stage II.

**uredinium** See UREDINIOMYCETES stage II.

**Uredinopsis** See UREDINIOMYCETES.

**urediospores** See UREDINIOMYCETES stage II.

**uredium** See UREDINIOMYCETES stage II.

**uredosorus** See UREDINIOMYCETES stage II.

**uredospores** See UREDINIOMYCETES stage II.

**urethanes** See UREA.

**urethritis** Inflammation of the urethra. Symptoms: frequent and painful micturition, sometimes with a purulent discharge. Urethritis may be caused by any of a range of organisms – see e.g. GONORRHOEA and NON-GONOCOCCAL URETHRITIS. (See also URINARY TRACT INFECTION.)

**uridine** See NUCLEOSIDE and Appendix V(b).

**uridylic acid** See UMP.

**urinary mucoprotein** *Syn.* TAMM-HORSFALL PROTEIN.

**urinary tract infection (UTI)** Infection of the human urinary tract (which is generally more frequent in women than in men) may involve any of a range of organisms. UTI is common as a nosocomial infection following catheterization; in these cases, causal organisms are usually endogenous faecal bacteria – frequently *Escherichia coli*, species of *Klebsiella* or *Proteus*, or enterococci. (See also CATHETER-ASSOCIATED INFECTION.)

Infection by strains of UPEC is believed to involve initial adhesion of the pathogen to the bladder UROPLAKINS [PNAS (2000) 97 8829–8835].

## urinogenital tract flora

The examination of a urine sample typically includes (i) microscopy of a WET MOUNT (to assess the likelihood of urinary tract infection from the numbers of leukocytes present), and (ii) a semi-quantitative form of culture, to determine whether the urine contains potential pathogen(s) in numbers high enough to be consistent with a pathogenic role (see SIGNIFICANT BACTERIURIA). The sample usually consists of a *mid-stream* urine (MSU) – this method of sampling tending to minimize contamination from e.g. the urethra.

In a murine model of an *E. coli* urinary tract infection, the PROBIOTIC *Lactobacillus casei* strain Shirota, administered intraurethrally, was reported to exhibit potent therapeutic activity [AAC (2001) 45 1751–1760].

For 'stones' (calculi) in the urinary tract see UROLITHIASIS.

(See also CYSTITIS, PYELONEPHRITIS, URETHRITIS and GENITOURINARY TRACT FLORA.)

**urinogenital tract flora** See GENITOURINARY TRACT FLORA.

**urkaryote** A hypothetical evolutionary forerunner of eukaryotic cells.

**urkingdom** (1) A taxonomic category comprising the ARCHAEABACTERIA – from which the EUBACTERIA and eukaryotes were supposed to have evolved independently [Book ref. 157, pp. 561–564].

(2) A taxonomic category used for any of several ancient 'primary' groups of organisms [see e.g. PNAS (1985) 82 3716–3720]. (See also PHOTOCYTA.)

**urocanate** See HISTIDINE DEGRADATION.

**Urocystis** See UTILAGINALES.

**urogenital tract flora** See GENITOURINARY TRACT FLORA.

**Uroglena** A genus of freshwater colonial CHRYSOPHYTES. The colony is motile and consists of cells arranged around the periphery of a ball of clear mucilage; the posterior end of each cell is drawn out into a long 'tail' which reaches the centre of the colony.

**uroid** (*protozool.*) The posterior end (relative to the direction of locomotion) of an amoeba. According to species, a uroid may or may not be clearly differentiated; it may have a knobby appearance (e.g. in some *Mayorella* spp), and/or trailing filaments may extend from it as a result of adhesion of small areas of its surface to the substratum during locomotion. In *Trichamoeba* the uroid is typically bulbous and usually bears short, fine, fairly rigid filaments (a *villous-bulb* uroid). In e.g. *Pelomyxa* food (e.g. non-motile algae) is ingested at the uroid.

**urolithiasis** The presence of mineral-based bodies ('stones'; calculi) within the urinary tract. 'Infectious stones' are commonly associated with certain infections (involving e.g. *Proteus* spp) that lead to the formation of alkaline urine: see STRUVITE. It has been suggested that calculi in urine of near-neutral pH may be associated with the presence of nanobacteria [PNAS (1998) 95 8274–8279].

Urinary calculi may also be associated with reduced numbers of oxalate-degrading organisms (e.g. *Oxalobacter formigenes*) in the intestinal tract; these organisms seem to be important for regulating the absorption of oxalate. For example, loss of activity of *O. formigenes* has been associated with hyperoxaluria and possible urolithiasis. The population of *O. formigenes* in human faecal specimens has been assessed with a PCR-based method [JCM (1999) 37 1503–1509].

**uromucoid** *Syn.* TAMM-HORSFALL PROTEIN.

**Uromyces** See UREDINIOMYCETES.

**Uronema** (1) A genus of filamentous freshwater and marine green algae related to CHAETOPHORA; the filaments are uniseriate, erect and unbranched. Quadriflagellate zoospores are formed. (2) A genus of protozoa of the SCUTICOCILLATIDA.

**uronic acids** Compounds with the general formula CHO(CHOH)<sub>n</sub>COOH, formed e.g. by the oxidation of the primary alcohol group of an aldose; the uronic acid corresponding to glucose is glucuronic acid.

**Uronychia** See HYPOTRICHIDA.

**uropathogenic *E. coli*** See UPEC.

**uroplakin** Any of four types of membrane protein (designated UPIa, UPIb, UPII and UPIII) that form hexagonal complexes on the luminal surface of the mammalian bladder; such complexes occur on the lumen-facing surface of the multinucleate *facet* cells that line the bladder. These complexes form plaques that cover most of the luminal surface. Thus, the lumen of the bladder is delimited by a uroplakin-studded membrane which is referred to as the *asymmetric unit membrane* (AUM); the AUM is believed to have the dual function of acting as a permeability barrier and stabilizing the facet cells during their stretching in an active bladder.

UPIa and UPIb can bind the type I FIMBRIAE of *Escherichia coli*, apparently via the FimH adhesin; such binding, which is inhibited by D-mannose, is believed to be important in the initial colonization of the bladder by UPEC [PNAS (2000) 97 8829–8835].

**Urosoma** See HYPOTRICHIDA.

**Urospora** (1) A genus of unbranched, filamentous, siphonocladous green algae (division CHLOROPHYTA). (2) See GREGARINASINA.

**Urosporidium** See STELLATOSPOREA.

**Urostyla** See HYPOTRICHIDA.

**Urotricha** See GYMNOSTOMATIA.

**URTI** Upper respiratory tract infection.

**urticaria** (hives) A condition, due e.g. to an allergy, in which swellings (wheals) appear (usually) in the skin; the wheals are typically redder than the surrounding skin and they characteristically itch or burn.

**use-dilution** For a given DISINFECTANT: that dilution which can be regarded as effective under specified conditions of usage.

**use-dilution test** Any test which, for a given DISINFECTANT, determines the USE-DILUTION – e.g. the KELSEY-SYKES TEST or the AOAC USE-DILUTION TEST.

**usher protein** See FIMBRIAE.

**Usnea** A genus of fruticose LICHENS (order LECANORALES); photobiont: a green alga. The thallus is greenish-grey, filamentous, extensively branched, usually pendulous, with a tough, whitish axial strand (cf. ALECTORIA). Isidia, soredia or papillae may be formed, according to species. *Usnea* spp occur chiefly on trees in regions of high humidity (particularly mountain woodlands). (See also USNIC ACIDS.)

**usnic acids** Yellow pigments (acetylphloroglucinol derivatives) which occur in the cortex in many lichens (e.g. *Cetraria islandica*, *Usnea* spp). Usnic acids have antibiotic activity against many Gram-positive bacteria (including *Mycobacterium tuberculosis*) and some fungi; they also have antitumour activity. Usnic acids have been used e.g. in the treatment of certain fungal diseases of plants, and in ointments for the topical treatment of burns or skin infections; they are relatively non-toxic to man, although they can cause an allergic skin reaction in sensitive individuals.

**USR test** Unheated serum reagin test: a qualitative STANDARD TEST FOR SYPHILIS in which samples of serum are tested without prior heating (cf. VDRL TEST).

**Ussing chamber** An in vitro arrangement of intestinal epithelium, or relevant cultured cells, used to examine changes in (energy-dependent) transmembrane ion flux promoted by enteric

bacterial toxins. [Description and references: MR (1996) 60 167–215 (p. 170).]

**ustilagic acids** Insoluble extracellular glycolipids produced by *Ustilago* spp e.g. when cultured in aerated liquid media; they are  $\beta$ -D-cellobiosides of ustilic acids (di- and trihydroxyhexadecanoic acids). Ustilagic acids inhibit e.g. Gram-positive and Gram-negative bacteria, and may be toxic to plants infected with *Ustilago* spp; they have been used in the perfume industry for preparing macrocyclic musks.

**Ustilaginaceae** See USTILAGINALES.

**Ustilaginales** (smut fungi; smuts) An order of characteristically plant-parasitic fungi of the class USTILAGINOMYCETES. Most species are parasitic only on flowering plants, infection usually being confined to the sexual organs, flowers, leaves and/or stem of the host plant (cf. ENTORRHIZA, MELANOETAENIUM); some smuts cause economically important plant diseases: see SMUTS (sense 2). Some species of smut fungi have been grown in vitro.

*Morphology and life cycles of the smut fungi.* The vegetative (somatic) form is a hyaline, septate, usually annual mycelium which generally occurs intercellularly in the plant host (intracellular hyphae are formed e.g. by *Ustilago maydis*), and which, according to species, may exhibit CLAMP CONNECTIONS and/or haustoria. Ballistoconidia (asexual spores) are formed by some smut fungi.

Basidiospores (= 'sporidia') are formed by most species of smut fungi (cf. e.g. *Ustilago nuda*); the life cycle from the basidiospore stage onwards appears to vary according to species. In some species the germination of a basidiospore can give rise to a hypha which is able to infect a host; some authors believe that such a hypha is monokaryotic and haploid, and that it subsequently undergoes DIKARYOTIZATION (by hyphal fusion) within the host, while others believe that the basidiospores which give rise to infective hyphae are themselves binucleate or diploid. In many other smuts, however, the mycelium derived from a basidiospore cannot infect a plant host; in such species dikaryotization must precede infection, and it may occur e.g. by the fusion of a basidiospore with a hypha, or by the fusion of buds formed by different basidiospores. Many smuts exhibit HETEROTHALLISM, and in such species the hyphae and/or basidiospores must be of appropriate MATING TYPES for fusion to occur.

Within an infected plant, the dikaryotic mycelium gives rise to TELIOSPORES (also called e.g. brand spores, chlamydospores, pseudospores, smut spores, teleutospores, ustilospores and ustospores); individual hyphal cells round up, each developing a thick wall and becoming a (typically dark-coloured) teliospore. Teliospores develop in masses (sori), a sorus being composed of numbers of individual teliospores (e.g. in *Tilletia* and *Ustilago*) or of pairs or clusters of teliospores (a cluster being called a *spore ball*). A spore ball is a definite structure composed of a characteristic arrangement of teliospores, or of teliospores and sterile cells; such arrangements are often genus-specific. Smut sori may occur on leaves, stems etc according to the species of smut fungus and host plant.

Teliospores may germinate immediately or behave as RESTING SPORES; those of some species can remain viable for many years. When the mature (uninucleate, diploid) teliospore germinates it

generally gives rise to a basidium bearing basidiospores laterally and/or apically; the basidiospores are STATISMOSPORES.

The order contains three families [Book ref. 64, pp. 397–398]: Graphiolaceae, Tilletiaceae and Ustilaginaceae. Tilletiaceae: species characteristically form basidiospores apically on aseptate or uniseptate basidia; genera include e.g. ENTORRHIZA, ENTYLOMA, *Melanotaenium*, *Neovossia*, TILLETIA and *Urocystis*. Ustilaginaceae: species characteristically form transversely septate basidia bearing lateral basidiospores; genera include e.g. *Sphacelotheca*, *Tolyposporium* and USTILAGO.

[Ustilaginales of the British Isles: Mycol. Pap. (1984) Nr 154.]

**Ustilaginomycetes** A class of typically plant-parasitic or saprotrophic fungi (subdivision BASIDIOMYCOTINA) which do not form sexual organs or give rise to macroscopic basidiocarps (cf. UREDINIOMYCETES); most species form phragmobasidia (cf. FILOBASIDIACEAE and SPORIDILOBUS). Two orders [Book ref. 64, pp. 398–399]: SPORIDIALES and USTILAGINALES.

**Ustilago** A genus of plant-parasitic fungi (order USTILAGINALES) which include some important pathogens of cereals (see e.g. SMUTS sense 2).

In a typical life cycle, the teliospore germinates to give rise to a septate promycelium from which bud (laterally and apically) a number of haploid basidiospores ('sporidia'); subsequent DIKARYOTIZATION may occur in various ways (see USTILAGINALES). In species which do not form basidiospores (e.g. *U. nuda*) the teliospores germinate to form hyphae between which dikaryotization occurs prior to infection of a fresh host.

[Ultrastructure of meiosis, postmeiotic mitosis, basidiospore development, and septation in *U. maydis*: Mycol. (1984) 76 468–502.]

**Ustilago maydis virus** See MYCOVIRUS.

**ustilic acids** See USTILAGIC ACIDS.

**ustilospores** See USTILAGINALES.

**ustospores** See USTILAGINALES.

**uterotropic** Having an affinity for the uterus.

**UTI** URINARY TRACT INFECTION.

**utricle** Any of various sac-like structures: e.g., a former term for an ASCUS. (See also CODIUM.)

**Uukuniemi virus** See UKUVIRUS.

**Uukuvirus** A genus of viruses of the BUNYAVIRIDAE. Host range: various vertebrates (including birds and rodents); vectors: ticks. MWts of L, M and S RNAs: ca. 2.0–2.5, 1.0–1.3, and 0.4–0.6  $\times 10^6$ , respectively. MWts of proteins L, G1, G2 and N: ca. 180–200, 70–75, 65–70, and 20–25  $\times 10^3$ , respectively. The genus comprises a single serological group which includes the Uukuniemi virus (type species).

**UV radiation** See ULTRAVIOLET RADIATION.

**uveitis** Inflammation affecting part(s) of the *uvea* – the pigmented, vascular layer within the eyeball. There are various causes which include e.g. the varicella-zoster virus. (See also HTLV.)

**uvr genes** Genes involved in the repair of DNA damaged by ULTRAVIOLET RADIATION (see EXCISION REPAIR); mutation in a *uvr* gene results in extreme sensitivity to UV radiation.

**UvrABC-mediated repair** See EXCISION REPAIR.

**UWO** University of Western Ontario Culture Collection, Department of Plant Sciences, London, Ontario N6A 587, Canada.

# V

**V** Valine (see AMINO ACIDS).

**V-DNA** An in vitro form of ds cccDNA produced by annealing two complementary ss cccDNA molecules without strand breakage; V-DNA is thus characterized by a linking number of zero (see DNA). Any regions of right-handed double-helical conformation must be compensated for by negative supercoils and/or by regions of left-handed double-helical conformation. There is evidence that V-DNA of natural base sequence can adopt a combination of right-handed (B-DNA) and left-handed (Z-DNA) conformations [Nature (1982) 300 545–546].

**V factor** A growth factor required by certain *Haemophilus* spp; the requirement is satisfied by NAD<sup>+</sup> or NADP<sup>+</sup> (or, minimally, by nicotinamide mononucleotide). 'V factor' occurs e.g. in yeast extract and in blood, although it is not available in whole blood since it occurs within the RBCs (which also contain NADase); heating of blood, as in the preparation of CHOCOLATE AGAR, releases the NAD(P)<sup>+</sup> and destroys the NADase. (V factor is destroyed e.g. by 121°C/30 min.) (See also X FACTOR and SATELLITE PHENOMENON.)

**V forms** See V–W TRANSITION.

**v-*onc*** See ONCOGENE.

**V region** (*immunol.*) See VARIABLE REGION.

**v strand** (V strand) (*virol.*) An ssDNA viral genome, or a strand homologous to it. (cf. C STRAND.)

**V3 loop** (of HIV) See AIDS.

**VA mycorrhiza** Vesicular-arbuscular MYCORRHIZA.

**VA RNAs** See SPLIT GENE (e).

**vaccination** (1) IMMUNIZATION (sense 1) by the parenteral administration of a VACCINE. (2) IMMUNIZATION (sense 1) by the oral or parenteral administration of a vaccine (cf. INOCULATION (2)). (3) *Syn.* IMMUNIZATION (1).

**vaccine** Any preparation administered with the object of stimulating the recipient's protective immunity to specific pathogen(s) and/or toxin(s). Until quite recently, all vaccines consisted of preparations of pathogen(s) or specific antigen(s); although many such vaccines are currently in use, there are now also vaccines which consist of the DNA which encodes relevant antigen(s): DNA VACCINES (q.v.).

Some vaccines (e.g. SABIN VACCINE) are given orally [oral vaccines: Microbiology (1994) 140 215–224], while others (e.g. BCG) are administered parenterally.

A vaccine should elicit antibodies and/or a cell-mediated response to PROTECTIVE ANTIGENS. Antibodies must be formed in those parts of the body where they can efficiently counteract the specific pathogen or toxin (see, for example, SABIN VACCINE); moreover, antibodies must be present when required, and in sufficient quantity. Optimal protection against bacterial *enteric* pathogens is obtained when antigens act via the immune system of the gut mucosa; thus, for example, development of effective vaccines against enterotoxigenic *E. coli* (ETEC) depends on oral administration [RMM (1996) 7 165–177].

(cf. *active* and *passive* IMMUNIZATION; see also VACCINATION.)

Vaccines may be categorized as follows:

(a) INACTIVATED VACCINES (see e.g. SEMPLE VACCINE and JAPANESE B ENCEPHALITIS). Inactivated vaccines against cholera (killed cells of *Vibrio cholerae* administered parenterally) give poor protection; currently they are rarely recommended.

(b) ATTENUATED VACCINES (see e.g. BCG and YELLOW FEVER). One problem with attenuated vaccines is their potential to cause

active disease in immunocompromised patients. Moreover, such vaccines should not normally be given to pregnant women. [*Salmonella* vaccines: FEMS Reviews (2002) 26 339–353.]

(c) TOXOIDS – used e.g. in the TRIPLE VACCINE.

(d) Synthetic vaccines and CONJUGATE VACCINES. The synthetic vaccines include synthetic peptides which correspond to antigenic determinants of toxins or pathogens (see INFLUENZA, FOOT AND MOUTH DISEASE, PLASMODIUM). Conjugate vaccines have been used against *Streptococcus pneumoniae*, but they are useful for only a limited range of serotypes; vaccines based on cell-surface proteins may offer better protection against this pathogen [TIM (1998) 6 85–87]. Conjugate vaccines have been successful against *Haemophilus influenzae* type b [RMM (1996) 7 231–241].

(e) Solutions/suspensions of particular antigen(s) or antigenic extracts from specific pathogen(s) – e.g. acellular vaccines (ACVs) against pertussis (whooping cough); these ACVs show reduced side-effects compared with the whole-cell vaccines (WCVs), but they may be less effective against *Bordetella parapertussis* than against *B. pertussis* [RMM (1996) 7 13–21].

A pathogen's absolute requirement for IRON has prompted research on new vaccines which elicit antibodies against the pathogen's receptors for SIDEROPHILINS. For example, transferrin-receptor proteins (TbpA, TbpB) in *Neisseria meningitidis* are potential antigens for a new anti-meningitis vaccine, although problems exist with antigenic heterogeneity among strains of this pathogen [RMM (1998) 9 29–37].

(f) Genetically engineered vaccines (e.g. VACCINIA VIRUS). A vaccine produced by recombinant DNA technology is used against hepatitis B.

(g) DNA vaccines: see DNA VACCINES.

Vaccines containing preservatives (for example, thiomersal, i.e. sodium ethylmercurithiosalicylate), or antibiotics, may cause allergic reactions in some patients.

(See also ARD; AUTOGENOUS VACCINE; CAPRINIZED VACCINE; KILLED VACCINE; LAPINIZED VACCINE; LIVE VACCINE; MIXED VACCINE; POLYVALENT VACCINE.)

[Vaccines, coming of age after 200 years: FEMS Reviews (2000) 24 9–20.]

**vaccinia subgroup** See ORTHOPOXVIRUS.

**vaccinia virus** A virus of the genus ORTHOPOXVIRUS. Vaccinia virus has been used for many years as a 'live' vaccine against SMALLPOX (q.v.). It is usually assumed to have derived from the COWPOX VIRUS, but its evolutionary origin is uncertain. It could have resulted from genetic recombination between different orthopoxvirus strains, or from genetic changes occurring during serial passage of the cowpox (or variola) virus; alternatively, it could be a surviving representative of a virus now extinct in nature [Book ref. 148, p. 663]. Vaccinia virus has a broad host range and can replicate in many types of cell. On the CAM it typically produces large, opaque, white or haemorrhagic pocks; it is highly lethal for mice and for chick embryos. A-type inclusion bodies are not formed in infected cells. Genome MWt: ca. 120–124 × 10<sup>6</sup> (ca. 186000 bp). (See POXVIRIDAE for structure and replication cycle.)

Vaccinia virus is a useful vector for inserting foreign DNA into animal cells. It can infect a wide range of cells in culture, and even cell lines which do not allow completion of the viral replication cycle (and which are therefore not lysed by

the virus) may be infected and may allow expression of viral early genes. Thus, e.g., a recombinant vaccinia virus containing a cDNA encoding Sindbis virus structural proteins has been used to infect cultured mosquito cells; infected cells were not lysed, and Sindbis virus proteins were synthesized and processed in their cytoplasm [JGV (1985) 66 2761–2765]. Recombinant vaccinia viruses which can express antigens from unrelated pathogens (e.g. hepatitis B virus surface antigen [Nature (1983) 302 490–495], or the circumsporozoite protein of a malarial parasite [Parasitol. (1986) 92 S109–S117]) have been suggested as 'live' vaccines against diseases caused by those pathogens [commentary: Nature (1986) 319 549–550]. (See also AIDS.)

**Vacuolaria** See CHLOROMONADS.

**vacuolating agent** SIMIAN VIRUS 40.

**vacuole** Any of various membrane-delimited compartments within a cell: see e.g. CONTRACTILE VACUOLE, FOOD VACUOLE, GAS VACUOLE. In yeasts such as *Saccharomyces cerevisiae*, vacuoles function e.g. as repositories for the storage of e.g. POLYPHOSPHATE and certain amino acids, and apparently also function as LYSOSOMES, sequestering e.g. proteases and other hydrolytic enzymes. In mycelial fungi, vacuoles occupy a large proportion of the interior of older parts of the mycelium, possibly serving e.g. to concentrate the bulk of the cytoplasm at the growing hyphal tip (see GROWTH (b)).

**vacuum autoclave** See AUTOCLAVE.

**vacuumizing** See CANNING.

**vagina microflora** In adult women (post-puberty, pre-menopause) the vagina harbours a varied microflora in which species of *Lactobacillus* (particularly *L. acidophilus*) typically predominate; these bacteria metabolize glycogen and/or its breakdown products (present in the vaginal secretions), thus maintaining a low pH (< ca. 4.5) in the vagina – which helps to protect against CANDIDIASIS, TRICHOMONIASIS, and other vaginal infections (see also BACTERIAL VAGINOSIS). Other organisms which may be present in the vagina in a high proportion of healthy women include e.g. species of *Acinetobacter*, *Bacteroides*, *Bifidobacterium*, *Corynebacterium*, members of the Enterobacteriaceae, *Moraxella*, *Peptococcus*, *Peptostreptococcus*, *Staphylococcus*, *Streptococcus*, *Ureaplasma*, etc. [Changes in the vagina microflora during the menstrual cycle: AJRIM (1985) 9 1–5.] Before puberty and after the menopause, the vagina is less acidic and it harbours a microflora which may include e.g. corynebacteria, enterobacteria, streptococci, etc. (See also GENITOURINARY TRACT FLORA.)

**Vaginicola** See PERITRICHIA.

**vaginitis** Inflammation of the vagina; it may involve any of a range of organisms: see e.g. CANDIDIASIS, TRICHOMONIASIS. (cf. BACTERIAL VAGINOSIS.) In *vulvovaginitis* both the vulva and vagina are affected. (See also ZEARALENONE.)

**vaginosis** See BACTERIAL VAGINOSIS.

**Vahlkampfia** A genus of amoebae (order SCHIZOPYRENIDA) in which flagellate stages are unknown. Cysts are commonly formed. Species are mainly free-living in freshwater, soil and marine habitats; *V. patuxent* is parasitic in the alimentary tract in oysters. (See also BEE DISEASES.)

**VAHS** (virus-associated haemophagocytic syndrome) See HAEMOPHAGOCYTIC SYNDROME.

**valaciclovir** An ANTIVIRAL AGENT used in the treatment of alpha-herpesvirus infections; valaciclovir is the L-valyl ester of ACYCLOVIR.

**valency** (*immunol.*) The number of COMBINING SITES per monomeric or polymeric ANTIBODY; the term is sometimes also used to refer to the number of DETERMINANTS per antigen. (See also POLYVALENT ANTISERUM; POLYVALENT VACCINE.)

**valid publication** See NOMENCLATURE.

**L-valine biosynthesis** See Appendix IV(b).

**valinomycin** A DEPSIPEPTIDE ANTIBIOTIC, produced by *Streptomyces* sp, which can act as a mobile carrier IONOPHORE for the UNIPORT of Rb<sup>+</sup>, K<sup>+</sup>, Cs<sup>+</sup>, or NH<sub>4</sub><sup>+</sup> across mitochondrial, thylakoid, bacterial or artificial membranes; valinomycin has a ca. 10<sup>4</sup>-fold lower selectivity for Na<sup>+</sup> than for K<sup>+</sup>. Valinomycin is a cyclic molecule containing 12 residues: (–D-valine–L-lactic acid–L-valine–D-α-hydroxyisovaleric acid–)<sub>3</sub>; a single ion can be carried at the centre of the molecule – any ion being carried having, of necessity, previously lost its water of hydration. Valinomycin can be used e.g. to alter or abolish a membrane potential (see CHEMIOSMOSIS).

**valley fever** *Syn.* COCCIDIOIDOMYCOSIS.

**Valonia** A genus of marine, mainly tropical, siphonocladous green algae (division CHLOROPHYTA) in which the cells are inflated to form macroscopic vesicles.

**VAMP** See TETANOSPASMIN.

**Vampirovibrio** A genus of Gram-negative bacteria which are predatory on viable cells of *Chlorella*; a predatory bacterium attaches to the prey cell and grows without penetration (cf. BDELLOVIBRIO). The organisms are vibrioid, 0.3–0.6 μm in diameter, and each cell has a single, polar, non-sheathed flagellum. GC%: ca. 50. Type species: *V. chlorellavorus*.

**Vampyrella** See FILOSEA.

**van genes** (*vanA*, *vanB*) See ENTEROCOCCUS.

**vancomycin** A complex glycopeptide ANTIBIOTIC produced by certain actinomycetes. Vancomycin inhibits PEPTIDOGLYCAN biosynthesis by binding to the D-alanyl-D-alanine of the pentapeptide in the bactoprenol-bound disaccharide–pentapeptide – thus preventing transfer of the disaccharide–pentapeptide from the membrane to the periplasmic site of incorporation.

Vancomycin is active against many Gram-positive bacteria; it is used clinically e.g. in the treatment of pseudomembranous colitis and infections involving MRSA. (Most Gram-negative bacteria are resistant as they are impermeable to the drug.)

Structurally related antibiotics (also obtained from actinomycetes) with apparently similar modes of action include actaplanin, actinoidin, AVOPARCIN, RISTOCETIN and TEICOPLANIN.

[Enterococci resistant to vancomycin: Drugs (1996) 51 (supplement 1) 6–12. Screening for vancomycin-resistant enterococci with multiplex PCR: JCM (1999) 37 2090–2092. Reduced susceptibility of MRSA to vancomycin: JAC (1997) 40 135–136; Lancet (1999) 353 1587–1588.]

**vanillin** 3-Methoxy-4-hydroxybenzaldehyde.

**Vannella** See AMOEBA and PSEUDOPODIUM.

**vapam** *Syn.* METHAM SODIUM.

**var.** VARIETY (q.v.).

**variable region** (V region) (*immunol.*) Any of the four regions of a given type of (monomeric) Ig molecule (see IMMUNOGLOBULINS) in which compositional variation is most marked among antibodies of different specificity; one V region occurs (as a DOMAIN) at the N-terminal end of each heavy chain and light chain. (See also COMBINING SITE; HYPERVARIABLE REGION.)

**variant** A strain which differs from other related strains in a (specified or unspecified) way. (cf. VARIETY.)

**variant antigen type** See VSG.

**variant surface glycoprotein** See VSG.

**varicella** *Syn.* CHICKENPOX.

**varicella-zoster virus** See ALPHAHERPESVIRINAE.

**variegation** (*plant pathol.*) Patchy – or otherwise irregular – colour variation in leaves, petals etc; variegation may be genetically based or may result from e.g. virus infection. (cf. COLOUR-BREAKING; MOSAIC; MOTTLE.)

## variety

**variety** (var.) In mycology: a rank between subspecies and subvariety. In bacteriology: formerly a rank equivalent to subspecies; currently an infrasubspecific rank which has no official standing in nomenclature. A variety may be distinguished from other varieties within a given subspecies by e.g. metabolic and/or physiological properties; it is then called a *biovar* (= *biotype*). Other criteria used include e.g. morphological feature(s) (*morphovar*; *morphotype*); pathogenicity for specific host(s) (*pathovar*, abbreviated pv.; *pathotype*); susceptibility to lysis by specific bacteriophage(s) (*phagovar*; *phagotype*); serological (antigenic) characteristics (*serovar*; *serotype*).

N.B. All of the above terms are often used, loosely, in a non-taxonomic sense.

**variola major** See SMALLPOX.

**variola minor** See SMALLPOX.

**variola ovina** Syn. SHEEP POX.

**variola sine eruptione** See SMALLPOX.

**variola virus** A virus of the genus ORTHOPOXVIRUS; it has a narrow host range (apparently only man), and forms small, opaque, white pocks on the CAM. Two main types of variola virus are distinguished: variola major virus (causal agent of classical SMALLPOX), which can form pocks on CAM at 38.5°C, and variola minor virus (causal agent of alastrim), which does not form pocks on CAM at temperatures >38°C. Variola virus is not highly lethal in mice or in chick embryos; variola major virus is more lethal than variola minor virus for chick embryos. A-type inclusion bodies are not formed in infected cells. Genome MWt: ca.  $120 \times 10^6$ .

**Varney jar** A type of ANAEROBIC JAR within which O<sub>2</sub> is removed by the combustion of phosphorus.

**vascular cell adhesion molecule-1** See CD106.

**vascular-streak dieback** A CACAO DISEASE which occurs e.g. in Papua-New Guinea; the aerial parts of the plant are affected, and the causal agent is believed to be *Oncobasidium theobromae*.

**vascular wilt** (wilt) (*plant pathol.*) Any of various plant diseases in which infection of the vascular system by a fungal or bacterial pathogen results in wilting (flaccidity) of the plant. Many fungi which cause wilts – e.g. *Fusarium* spp (see FUSARIUM WILT), *Verticillium* spp (e.g. *V. albo-atrum*, *V. dahliae*) – are soil-borne pathogens which infect via the roots and become established in the vascular system of the plant; these fungi can also be seed-borne. Other wilt pathogens – e.g. ERWINIA spp, *Pseudomonas solanacearum*, and the causal agents of DUTCH ELM DISEASE and OAK WILT – gain entry to the vascular system via wounds in the aerial parts of the plant. Factors which may be involved in pathogenesis include e.g. the formation of high-MWt gummy polysaccharides which block the vessels, blockage of vessels by the pathogen itself, TYLOSE formation, and the collapse of infected vessels – all of which cause water losses to exceed water uptake; in at least some cases TOXINS produced by the pathogen may also be involved (see e.g. FUSARIC ACID, LYCOMARASMIN).

**vasculotoxin** See SHIGA TOXIN.

**Vaspar** A mixture of Vaseline and paraffin wax, used e.g. to make an airtight seal in vessels used for anaerobic culture.

**VAT** Variant antigen type: see VSG.

**Vaucheria** A genus of siphonaceous algae (class XANTHOPHYCEAE). The vegetative organism consists of long, irregularly branched filaments (diam. ca. 50–200 µm) within which a thin peripheral layer of cytoplasm (containing numerous chloroplasts and nuclei) forms a 'tube' surrounding a large central vacuole; the vacuole extends the length of the filament, stopping short of the tip. The organisms may be terrestrial, being anchored

to e.g. moist soil by rhizoid-like branches, or aquatic, forming bright-green mats e.g. in stagnant/slow-moving fresh waters.

*Vaucheria* spp differ from other xanthophytes in many respects: e.g., they form a unique type of zoospore, their sexual reproduction is oogamous, and the spermatozoid is the only cell to resemble the 'typical' xanthophycean heterokont cell. In zoospore formation, the swollen tip of a filament is closed off by a septum to form a zoosporangium within which the (multinucleate) protoplast develops one pair of flagella for each nucleus it contains. The resulting multinucleate, multiflagellate zoospore is released and remains (sluggishly) motile for a short time, after which it withdraws its flagella and germinates to form a new thallus. In terrestrial organisms, the entire contents of the sporangium may develop into a single aplanospore. Sexual reproduction involves the formation of antheridia and oogonia on lateral branches, each being separated from the rest of the thallus by a septum. After release of the spermatozooids and fertilization, the zygote develops a thick wall and remains dormant for some time; meiosis is believed to occur on germination.

**Vauchomia** See PERITRICHIA.

**VBNC** See VNC.

**VCAM-1** See CD106.

**VCN agar** Syn. THAYER–MARTIN AGAR.

**VD** VENEREAL DISEASE.

**VD-1827** SULTAMICILLIN.

**VDAC** Voltage-dependent anion channel: a PORIN channel in the mitochondrial outer membrane.

**VDRL test** (Venereal Disease Research Laboratory test) A qualitative or quantitative STANDARD TEST FOR SYPHILIS. A fixed volume of the test antigen is added to a fixed volume of the patient's INACTIVATED SERUM (or a known dilution of it) on a slide; mixing is conducted under standard conditions for a fixed period of time. Flocculation (aggregation of the antigen particles into clumps) occurs in the presence of reagins, and is detected under the microscope ( $\times 100$ ); large clumps are reported as 'reactive', small clumps as 'weakly reactive', and a regular or finely granular suspension of antigen as 'non-reactive'. Strongly positive sera may exhibit a PROZONE.

**vector** (1) (*med., vet., plant pathol.*) Any living organism – conventionally, an invertebrate, or a microorganism (see e.g. PLASMIDIOPHOROMYCETES) – which effects the transmission of a parasite (e.g. a pathogenic bacterium, fungus, protozoon or virus) from one individual (man, animal or plant) to another. (cf. CARRIER; VEHICLE.) In many cases a parasite can be transmitted by only one or a few species of vector; in other cases there may be little or no parasite–vector specificity. Common vectors of human and animal parasites include flies, lice, mosquitoes and ticks, while vectors of plant parasites include insects such as aphids, leafhoppers, and whiteflies, as well as mites, fungi (see e.g. OLPIDIUM), nematodes, etc. (See also TRIATOMINE BUGS.)

In a *biological vector* the parasite replicates and/or undergoes one or more stages of development in the vector (see e.g. CYCLICAL TRANSMISSION and *propagative* CIRCULATIVE TRANSMISSION). In a *mechanical vector* the parasite is transported more or less passively by the vector (cf. NON-CIRCULATIVE TRANSMISSION).

(See also TRANSOVARIAL TRANSMISSION and TRANS-STADIAL TRANSMISSION.)

(2) (*mol. biol.*) See e.g. CLONING, EXPRESSION VECTOR, PHAGE-MID, SHUTTLE VECTOR.

**vectorial electron transfer** See EXTRACYTOPLASMIC OXIDATION.

**vectorial group translocation** Directional translocation of given molecular or ionic species across a membrane as a consequence of the presence of fixed pathways across the membrane; in

this concept, translocation of the species does not involve conformational changes in the membrane proteins – the latter merely providing, passively, suitable transmembrane routes. This concept is exemplified in the LOOP MODEL of proton translocation by the respiratory chain (see ELECTRON TRANSPORT CHAIN and CHEMIOSMOSIS).

**VEE** VENEZUELAN EQUINE ENCEPHALOMYELITIS.

**vegetable spoilage** See e.g. CANNING; GANGRENE (2); PECTIC ENZYMES; PICKLING; SOFT ROT (2).

**vegetative** (1) (assimilative; somatic; trophic) Refers to a cell or organism, or to a stage in an organism's life cycle, in which nutrition and growth (as opposed to e.g. sexual reproduction or dormancy) predominate.

(2) (*virol.*) Refers to the 'growth phase' of a virus (i.e., the phase in which progeny virions are formed), or to a virus in the 'growth phase'.

**vegetative mycelium** (in actinomycetes) *Syn.* SUBSTRATE MYCELIUM.

**vehicle** (1) (*epidemiol.*) An inanimate medium in or on which a (usually pathogenic) microorganism may be transmitted: e.g., unpasteurized milk. (cf. VECTOR.)

(2) (*mol. biol.*) *Syn.* cloning vector (see CLONING).

(3) (*mol. biol.*) The organism in which a recombinant DNA molecule is replicated during CLONING experiments.

**veil** (*mycol.*) See PARTIAL VEIL and UNIVERSAL VEIL.

**Veillon tube** A glass tube (e.g. 25 cm long, internal diam. 1 cm) which can be sealed at both ends with rubber bungs; it is used for SHAKE CULTURE (sense 1).

**Veillonella** A genus of Gram-negative bacteria (family VEILLONELLACEAE) which occur e.g. in the mouth and in the intestinal and respiratory tracts of man and other animals. Cells: cocci, 0.3–0.5 µm diam., often in pairs. Some species (*V. criceti*, *V. dispar*, *V. ratti*) form a pseudocatalase. Colonies fluoresce red under ultraviolet light (360 nm). The organisms ferment e.g. lactate (forming acetate, propionate, CO<sub>2</sub> and H<sub>2</sub>), fumarate and pyruvate; in general, carbohydrates are attacked weakly or not at all. GC%: (Bd) ca. 40–44. Type species: *V. parvula*. Other species: *V. atypica*, *V. caviae*, *V. rodentium*. (*V. alcalescens* has been included within *V. parvula*.)

**Veillonellaceae** A family of Gram-negative, oxidase-negative, chemorganotrophic, anaerobic bacteria which occur e.g. in the intestinal tract in man, ruminants and other animals. Cells: non-motile cocci, ca. 0.3–2.5 µm diam., which usually occur in pairs (adjacent sides of cells may be flattened); cells may resist decolorization in the Gram stain. No species forms catalase, but some strains form a PSEUDOCATALASE. Genera: ACIDAMINOCOCCUS, MEGASPHAERA, VEILLONELLA. [Book ref. 22, pp. 680–685.]

**vein-banding** (*plant pathol.*) A narrow band of tissue of altered coloration on each side of the main vein(s) of a leaf – a symptom of certain plant diseases.

**vein-clearing** (*plant pathol.*) Increased transparency of the veins in a leaf – a symptom of certain plant diseases.

**velar** (*mycol.*) Of or pertaining to a VELUM.

**velleral** See LACTARIUS.

**velum** (*mycol.*) *Syn.* veil (see e.g. UNIVERSAL VEIL).

**velvet disease** A FISH DISEASE caused by *Oodinium* species; affected fish appear 'dusty' and gills may be heavily infested. *O. ocellatum* attacks marine fish, *O. limneticum* attacks freshwater fish. The disease may be fatal in aquaria.

**velvet tobacco mottle virus** (VTMoV) A PLANT VIRUS which infects plants of the Solanaceae; it is transmitted by insects (e.g. coccinellid beetles) and can be transmitted mechanically.

Virion: icosahedral, ca. 30 nm in diam., containing one major polypeptide species. Genome: a linear ssRNA, RNA1 (ca. 4.5 kb), and a circular ssRNA, RNA2 (also known as a VIRUSOID q.v.); both RNA1 and the virusoid are necessary for infectivity. Closely related viruses include lucerne transient streak virus (LTSV), *Solanum nodiflorum* mottle virus (SNMV), and subterranean clover mottle virus (SCMoV).

**venereal disease** (VD) (1) Any disease transmissible by sexual intercourse. The 'classical' venereal diseases are CHANCROID, GONORRHOEA, GRANULOMA INGUINALE, LYMPHOGRANULOMA VENEREUM and SYPHILIS. (cf. SEXUALLY TRANSMITTED DISEASE.) (2) *Syn.* SEXUALLY TRANSMITTED DISEASE.

**venereal wart** See PAPILOMA.

**Venezuelan equine encephalomyelitis** (VEE; Venezuelan equine encephalitis; Venezuelan encephalitis) An acute disease of man and horses caused by an ALPHAVIRUS; it occurs in epidemics and epizootics in northern South America, Central America, the West Indies, and southern USA. Small mammals appear to be a reservoir of infection; transmission occurs via mosquitoes (e.g. *Aedes* and *Psorophora* spp). In horses, the disease may be rapid and fulminating with high mortality rates. In man, the disease is usually benign; symptoms include fever, chills, headache, nausea, and pains in muscles, bones and joints. (Symptoms of encephalitis are uncommon in man.)

**vent** In a PETRI DISH: a small projection on the periphery of the inner surface of the lid; a Petri dish may have one or three vents ('single-vent' or 'triple-vent'). Vent(s) slightly raise the lid of the (closed) Petri dish, thus facilitating equilibration between the air/gas(es) inside and outside the Petri dish. (A non-vented plastic Petri dish can be vented by pressing a red-hot wire on the edge of the wall to make two or three vertical 2-mm slits at different locations.)

**Venturia** A genus of fungi (order DOTHIDEALES) which include plant parasites and pathogens.

*V. inaequalis* causes APPLE SCAB (q.v.). Within the host the mycelium gives rise to a subcuticular stroma from which arise numerous, short, erumpent conidiophores – each bearing a single, terminal, flask-shaped conidium. Conidia continue to be formed until early autumn when the ascocarps – individual pseudoperithecia – start to develop in stromata within the dead and dying leaves. During ascocarp formation, fertilization (which involves GAMETANGIAL CONTACT) occurs via a trichogyne which projects through the stromal initial; since *V. inaequalis* exhibits HETEROTHALLISM, male nuclei must be derived from an antheridium of appropriate mating type. Each pseudoperithecium contains a layer of asci and pseudoparaphyses, and it bears several setae around the rim of its ostiolar pore; the yellowish ascospores each have a septum which divides the spore into two cells of unequal sizes.

**vermicule** (1) The ookinete of PLASMODIUM. (2) A uninucleate, motile cell of *Babesia* or *Theileria* formed in the gut of the tick vector.

**vernamicins** See STREPTOGRAMINS.

**Vero** An ESTABLISHED CELL LINE derived from the kidney of an African green monkey (*Cercopithecus aethiops*); the cells are heteroploid and fibroblast-like.

**Vero cell cytotoxin** See SHIGA TOXIN.

**verocytotoxins** See SHIGA TOXIN and EHEC.

**veronal** *Syn.* BARBITAL.

**verotoxin** See SHIGA TOXIN.

**Verpa** A genus of fungi (order PEZIZALES) in which the ascocarp, an APOTHECIUM, consists of a stipitate, bell-shaped pileus – the tip of the stipe being attached to the inside of the pileus at its centre; the hymenium develops on the outer surface of the pileus.

## verruca

**verruca** *Syn.* wart – see PAPILLOMA.

**Verrucaria** A genus of crustose LICHENS (order VERRUCARIALES).

The thallus may be white, grey, brown or black, and may be epilithic or ENDOLITHIC (e.g. *V. hochstetteri* in calcareous rocks). The pseudothecia may be superficial or immersed in the thallus. Some species are aquatic (e.g. *V. aquatilis* occurs on rocks in streams), while e.g. *V. maura* forms an extensive, thin, black thallus covering rocks on the seashore in the intertidal and supratidal zones.

**Verrucariales** An order of (mainly lichenized) fungi of the ASCOMYCOTINA. Most members are crustose saxicolous LICHENS; some are foliose or squamulose lichens, and a few are lichenicolous or saprotrophic fungi. Bitunicate asci are formed in pseudothecia (often termed 'perithecia'). Genera include e.g. CATAPYRENIUM, DERMATOCARPON, *Endocarpon*, *Placidiopsis*, *Staurrothele*, *Thelidium*, VERRUCARIA.

**verrucarins** See TRICHOTHECENES.

**verrucologen** A tremorgenic MYCOTOXIN produced e.g. by *Penicillium piscarium* and *P. estinogenum*.

**verrucose dermatitis** *Syn.* CHROMOBLASTOMYCOSIS.

**verrucose** (verrucose) Of or pertaining to warts (see PAPILLOMA); wart-like; bearing wart-like elevations.

**verruca peruana** See BARTONELLOSI.

**Versene** A sodium salt of EDTA.

**vertical illumination** See MICROSCOPY (g).

**vertical resistance** (*plant pathol.*) In a given cultivar: the existence of significantly higher levels of resistance to some races of a given pathogen than to others. A cultivar which is resistant to an existing race of a pathogen may become susceptible when a new race of the pathogen emerges, i.e., resistance to the pathogen tends to be temporary. (cf. HORIZONTAL RESISTANCE.)

**vertical transmission** The transmission of a disease or parasite from a parent to its offspring via the egg (TRANSOVARIAL TRANSMISSION), via the placenta (transplacental transmission), or by genetic inheritance (see RETROVIRIDAE). (cf. HORIZONTAL TRANSMISSION.)

**verticil** Chains of spores arranged in a whorl, or a number of structures arranged in a whorl.

**verticillate** Whorled.

**Verticillium** A genus of fungi (class HYPHOMYCETES) which include some important plant-pathogenic species – see e.g. COTTON WILT and VASCULAR WILT; an entomopathogenic species, *V. lecanii* ('*Cephalosporium lecanii*'), has been used successfully against various insect pests under both glasshouse and field conditions [AEE (1985) 12 151–156]. (See also BUBBLE DISEASES.) The mycelium is septate; colourless or pale, non-septate conidia (sometimes in slimy masses) are formed (from phialides) at the tips of whorled branches on the conidiophores.

**verticillium wilt** See VASCULAR WILT.

**vesicle** (*med., vet.*) In skin or mucous membranes: a raised lesion containing a clear watery fluid. (cf. PUSTULE.)

**vesicle-associated membrane protein** See TETANOSPASMIN.

**vesicular-arbuscular mycorrhiza** See MYCORRHIZA.

**vesicular exanthema** (of swine) An acute, febrile PIG DISEASE clinically indistinguishable from FOOT AND MOUTH DISEASE; outbreaks have occurred mainly in the USA. The causal agent is a calicivirus (see CALICIVIRIDAE).

**vesicular stomatitis** (*vet.*) An acute, infectious disease which affects e.g. cattle, horses and pigs. The causal agent is a VESICULOVIRUS; infection appears to occur via skin lesions or insect bites. Clinically, vesicular stomatitis can resemble FOOT AND MOUTH DISEASE but vesicles may or may not occur in the mouth and are very uncommon on the feet; in milking cows

extensive lesions may occur on the teats and the milk yield is appreciably decreased.

*In man*, infection results in influenza-like symptoms.

**Vesiculovirus** A genus of viruses of the RHABDOVIRIDAE; type species: vesicular stomatitis virus (VSV), Indiana serotype. VSV can infect a very wide range of animals (including man) and birds; the principal natural hosts appear to be horses, cattle and pigs – see VESICULAR STOMATITIS. The virus can replicate rapidly in many types of cultured cells. The RNA genome (MWt ca.  $3.6\text{--}4.2 \times 10^6$ ) contains 5 genes in tandem and a leader sequence of 47 nucleotides: 3'-leader-N-NS-M-G-L-5'. The RNA-N protein nucleocapsid functions as the template for transcription; it is associated with the L protein (which appears to be the transcriptase) and the NS protein (which may function in transcriptional control) [JGV (1985) 66 1011–1023]. [The transcription complex of VSV (minireview): Cell (1987) 48 363–364.] Transcription occurs in a linear and sequential manner from the 3' end, generating a transcript of the leader sequence and 5 monocistronic mRNAs. The mRNAs are all capped and polyadenylated. The leader transcript is neither capped nor polyadenylated; it appears to be responsible for the inhibition ('shut-off') of host cell DNA, RNA and protein synthesis characteristic of VSV infection [review: MS (1985) 2 152–156]. (However, host protein synthesis is apparently also necessary for inhibition of host RNA synthesis – possibly indicating that the active inhibitor is a nucleoprotein complex containing the leader RNA transcript [Virology (1985) 140 91–101].) VSV nucleocapsids are synthesized in the cytoplasm; budding occurs mainly through the plasma membrane.

**Vestibulifera** A subclass of ciliates (class KINETOFRAGMINOPHOREA) in which the cytostome is at the base of a VESTIBULUM located apically, subapically or laterally. Cilia may cover the entire body or may be restricted to particular regions; oral ciliature is characteristically somatic in origin. The cytopharyngeal apparatus resembles the RHABDOS type. Orders: COLPODIDA, ENTODINIOMORPHIDA, TRICHOSTOMATIDA.

**vestibulum** (vestibule) (1) In ciliates of the VESTIBULIFERIA: a depression in the body surface leading to the CYTOSTOME; the ciliature is characteristically somatic in origin but may include distinctive membranelles. (2) *Syn.* PREBUCCAL AREA.

**Vexillifera** See AMOEBIDA.

**V<sub>H</sub> region** See IMMUNOGLOBULINS.

**v<sub>H</sub>2 gene** (v<sub>H</sub>2 gene) See PHASE VARIATION.

**VHF** VIRAL HAEMORRHAGIC FEVER.

**Vi antigens** Polysaccharide cell-surface (microcapsular) antigens which occur in some enterobacteria – e.g. certain strains of *Escherichia coli*, *Citrobacter freundii* (see also PHASE VARIATION), and *Klebsiella*, and three (of ca. 2000) serotypes of *Salmonella* (certain strains of *S. typhi*, *S. paratyphi-C*, and *S. dublin*); in *S. typhi* the Vi antigen is a (1 → 4)-α-linked polymer of N-acetylgalactosaminuronic acid. Vi antigens may play a role in the virulence of a pathogen for a particular host(s).

Vi antigens are detected in the serological characterization of certain enterobacteria (see e.g. KAUFFMANN-WHITE CLASSIFICATION). Cells with Vi antigens are agglutinated by homologous Vi-antisera. However, the (cell-surface) Vi antigens may, to a variable extent, mask the O ANTIGENS and inhibit agglutination by O-antisera; the Vi antigens are generally destroyed by heat-treating the cells (100°C/10–30 min) which may then be agglutinated by homologous O-antiserum.

**Vi phage typing** See PHAGE TYPING.

**viable** In microbiology: refers to an organism capable of reproducing (or, in the case of a virus, replicating) under appropriate conditions.

**viable but non-cultivable** See VNC.

**viable cell count** See COUNTING METHODS.

**vial** (ampoule) (1) Any of a range of types of tubular glass vessel, closed at one end, in which (e.g.) a cell suspension can be freeze-dried (see FREEZE-DRYING) or frozen (see FREEZING) for storage. Before use, a vial is stoppered with a cotton wool plug and sterilized in a hot-air oven. (2) A vial as in (1) together with its freeze-dried or frozen contents.

**vibramycin** See TETRACYCLINES.

**vibrio** (1) A bacterium of the genus *Vibrio*. (2) Any curved, rod-shaped bacterial cell, regardless of taxon.

**Vibrio** A genus of Gram-negative bacteria of the family VIBRIONACEAE; the genus has been classified in the gamma group of Proteobacteria. The cells are straight or curved rods, 0.5–0.8 × 1.4–2.6 µm; INVOLUTION FORMS are common under appropriate conditions. In liquid media most species are motile with one sheathed polar flagellum; the sheath is continuous with – but compositionally somewhat different from – the OUTER MEMBRANE of the cell. On solid media, some species (e.g. *V. alginolyticus*, *V. campbellii*, *V. harveyi*, *V. parahaemolyticus*, some strains of *V. fluvialis*) form additional, unsheathed, lateral flagella (L-flagella); lateral and polar flagella are structurally and antigenically distinct and differ in wavelength (ca. 0.9 µm and ca. 1.4–1.8 µm, respectively). On solid complex media, *V. alginolyticus*, *V. parahaemolyticus* and *V. proteolyticus* form elongated cells capable of SWARMING (apparently involving the L-flagella). [Regulation of transcription of L-flagella genes in *V. parahaemolyticus*: JB (1986) 167 210–218.]

At least low concentrations of NaCl (Na<sup>+</sup>) are essential for growth in all species of *Vibrio* except *V. cholerae* and some strains of *V. metschnikovii* – although NaCl stimulates growth even in these species; *V. costicola* requires a minimum concentration of 600–700 mM NaCl.

All species can grow at 20°C, most at 30–35°C, some at 40°C; *V. logei* and *V. marinus* grow only at or below 20°C and can grow at 4°C.

Many species can tolerate moderately high pH (*V. cholerae* and *V. metschnikovii* can grow at pH 10). Enrichment media for clinical use include APW and various tellurite-containing media (see e.g. MONSUR MEDIUM). Selective media include e.g. TCBS AGAR. [Medium for differentiating *V. alginolyticus* and *V. parahaemolyticus*: AEM (1983) 45 310–312.]

*V. fischeri* and *V. logei* form a cell-associated yellow-orange pigment after 3–4 days on complex solid media. *V. gazogenes* forms PRODIGIOSIN, and *V. nigrapulchritudo* forms a characteristic insoluble blue-black pigment, crystals of which accumulate in colonies on basal media.

Most species are oxidase +ve. Glucose is fermented by the MIXED ACID FERMENTATION with the formation of acid but (usually) without gas. Various sugars can be fermented, but lactose is usually not fermented (exceptions: strains of *V. metschnikovii* and *V. vulnificus*). Most species do not require organic growth factors. PHB is usually not accumulated. Most strains are sensitive to O/129 (q.v.). Some species exhibit BIOLUMINESCENCE (e.g. *V. splendidus* biotype I, *V. fischeri*, *V. logei*, some strains of *V. harveyi* and *V. cholerae*); a strain of *V. logei* emits an unusual yellow light at temperatures <18°C but emits blue-green light at temperatures >23°C. Some strains have been reported to be capable of nitrogen fixation [e.g. *V. diazotrophicus*: IJSB (1982) 32 350–357].

*Vibrio* spp are primarily aquatic, occurring in freshwater, estuarine and marine habitats and in association with aquatic organisms – including e.g. planktonic copepods (*V. cholerae*,

*V. parahaemolyticus*). Some strains are pathogenic in man (*V. cholerae*, *V. parahaemolyticus*) and in shellfish (e.g. *V. tubiashii*, a pathogen of bivalve molluscs [IJSB (1984) 34 1–4], *V. alginolyticus*, *V. logei*). The species formerly known as *V. anguillarum* (see LISTONELLA) is a pathogen of eels. The bioluminescent *V. fischeri* (see also PHOTOBACTERIUM) occurs e.g. in specialized luminous organs in certain teleost fish and squid. Most vibrios are CHITINOLYTIC and may be important in the primary degradation of chitin in aquatic ecosystems. Vibrios also occur in salted foods and brines (see e.g. MEAT SPOILAGE and CURING sense 1).

The genus includes species formerly classified in the genera *Beneckea*, LUCIBACTERIUM and PHOTOBACTERIUM (q.v. in respect of *V. fischeri* and *V. logei*). (See also LISTONELLA and WOLINELLA.)

GC%: 38–51. Type species: *V. cholerae*.

*V. alginolyticus* is commonly isolated from temperate and tropical coastal and estuarine waters and seafoods; it has also been isolated from (human) wounds, from the stools of gastroenteritis patients, and from diseased and dead shellfish. L-flagella and swarming occur on complex solid media. Growth occurs at 30°C and 40°C but not at 4°C. Oxidase +ve. VP +ve. Sucrose +ve. D-Gluconate +ve. Arginine dihydrolase –ve. Respiration can be coupled to the development of SODIUM MOTIVE FORCE, smf being used e.g. for the uptake of amino acids.

*V. anguillarum*. See LISTONELLA.

*V. cholerae*. CHOLERA-causing strains produce two main virulence factors: (i) CHOLERA TOXIN (encoded by BACTERIOPHAGE CTXφ) and (ii) so-called ‘toxin co-regulated pili’ – appendages which mediate adhesion to the intestine (and which are encoded by a chromosomal PATHOGENICITY ISLAND). (Strains of *V. cholerae* which do not produce cholera toxin may produce the Ace and Zot toxins; such strains may give rise to a less severe form of disease.)

The cells do not form L-flagella; rotation of the polar flagellum is energized by SODIUM MOTIVE FORCE [JB (1999) 181 1927–1930]. Growth can occur in the absence of NaCl, and at 30°C and 40°C but not at 4°C. Oxidase +ve. Sucrose +ve. D-Gluconate +ve. Arginine dihydrolase –ve. Nitrate is reduced.

The genome consists of two (dissimilar) chromosomes [Nature (2000) 406 477–483].

Colonies on nutrient agar are round, entire, glossy and translucent, 1–2 mm in 24 hours. A thin PELLICLE is formed in peptone water.

*V. cholerae* may be killed e.g. by heating to 60°C for 15 minutes (although it is preferable to boil unsafe water.)

Serotypes are distinguished on the basis of O antigens (H antigens appear to be common to all strains and are therefore not suitable for typing.)

Prior to 1992, all cholera-causing strains of *V. cholerae* were of the O1 serogroup (also referred to as serovar 1, O1, O:1, O-1 etc.). The O1 strains include two biotypes: (i) El Tor (also called Eltor, or *eltor*) and (ii) *cholerae* (= classical biotype); the El Tor biotype is more resistant than the classical biotype to adverse conditions. The original El Tor isolates were strongly haemolytic for sheep blood, but strains subsequently isolated were less strongly haemolytic, or even non-haemolytic. Typical El Tor strains are VP +ve, agglutinate chicken erythrocytes, and are resistant to group IV phages and to polymyxin B; typical *cholerae* strains have the opposite characteristics.

O1 strains can be subdivided into variants designated Ogawa, Inaba and Hikojima [Book ref. 46, p 1280].

Multiple-drug-resistant O1 strains have been reported [Lancet (1997) 349 924].

## vibriocins

In 1992 non-O1 cholerae strains were isolated in India; these strains are designated O139 Bengal [RMM (1996) 7 43–51]. Vaccines against O1 strains do not protect against O139 strains; in one approach to the development of anti-O139 vaccines, genes for certain of the pathogen's virulence factors have been deleted [see e.g. JID (1994) 170 278–283]. [A rapid screening test for O139 strains based on monoclonal antibodies: JCM (1998) 36 3595–3600.]

Strains other than those of serogroups O1 and O139 may cause gastrointestinal/diarrhoeal disease – sometimes mild, but in some cases of cholera-like severity.

*V. cholerae* is believed to be a member of the autochthonous flora of estuarine and other brackish environments – e.g. in association with planktonic copepods [AEM (1983) 45 275–283]. So-called 'viable but non-cultivable' (see VNC) strains of *V. cholerae* may retain virulence [Science (1996) 274 2025–2031].

*V. fischeri*. This organism is now commonly classified within the genus PHOTOBACTERIUM as *P. fischeri*. It produces blue-green bioluminescence, and is associated e.g. with the luminous organs of certain fish. The development of bioluminescence in high-density populations (e.g. in the luminous organs of fish) is a manifestation of so-called QUORUM SENSING – the autoinducer being a member of the *N*-acyl-L-homoserine lactones [TIBS (1996) 21 214–219].

*V. metschnikovii* (formerly *V. cholerae* biotype *proteus*) differs from *V. cholerae* e.g. in that it is oxidase –ve, lactose +ve (some strains), and is unable to reduce nitrate. It occurs in marine habitats and may cause gastroenteritis in man.

*V. parahaemolyticus* occurs (worldwide) in coastal and estuarine waters during the warmer months, apparently spending the winter in marine sediments; it also occurs in fresh and brackish waters rich in organic material.

L-flagella and swarming are seen on complex media. The organism grows with 1–8% NaCl (opt. 2–4%) but not with 0% or 10% NaCl. Growth occurs at 30°C and 40°C but not at 4°C. Oxidase +ve. VP –ve. Sucrose –ve. D-Gluconate +ve. Arginine dihydrolase –ve. Nitrate reduction +ve. Colonies on TCBS agar: large, and blue to green.

The organism may be killed e.g. by heating to 60°C/15 minutes, by acidity, and by desiccation.

*V. parahaemolyticus* can cause gastroenteritis: see FOOD POISONING (h). It is also associated with wound infection in swimmers and fish handlers, and with diseased shellfish.

[Molecular typing: JCM (1999) 37 2473–2478; genome sequence: Lancet (2003) 361 743–750.]

*V. succinogenes*. See WOLINELLA.

*V. vulnificus* (= '*Vibrio* sp biovar 6330'). A marine species [distribution: AEM (1983) 45 985–998]. *V. vulnificus* can be pathogenic in man, causing fatal septicaemia, particularly in debilitated or immunosuppressed individuals; infection may occur via wounds or by ingestion of contaminated seafood. For the detection of *V. vulnificus* in environmental samples, an optimal approach is reported to be the combined use of a selective medium and a species-specific PROBE [JAM (2001) 91 322–327].

L-flagella are not formed. Growth can occur at 30°C and 40°C but not at 4°C, and not in peptone water containing 8% NaCl. Oxidase +ve. VP –ve. Sucrose –ve. Lactose (commonly) +ve. D-Gluconate +ve. Arginine dihydrolase –ve. Nitrate reduction +ve.

[RAPD analysis of *V. vulnificus*: AEM (1999) 65 1141–1144.]

Other species include: *V. aestuarianus*, *V. mimicus*, *V. natrie-gens*, *V. nereis*, *V. orientalis* and *V. pelagius*.

**vibriocins** BACTERIOCINS produced by *Vibrio* spp. Vibriocin production (by cells in the mid- or late-logarithmic phase) can be induced e.g. by anaerobiosis, UV radiation, or mitomycin C. A vibriocin is a tubular structure which resembles the tail section of certain phages; it has a contractile sheath. Vibriocins are active against e.g. strains of *Vibrio*, *Escherichia coli* and other enterobacteria, *Pseudomonas aeruginosa* – and certain mammalian cells (e.g. HeLa cells). In bacteria, vibriocins cause (bactericidal) changes in the permeability of the cytoplasmic membrane and/or inhibition of DNA synthesis; the lethal activity of vibriocins can be inhibited by the action of trypsin added within ca. 10 min of adsorption. [Review: AVR (1984) 29 298–312.]

**vibrioid** *Vibrio*-like; curved with a twist, i.e., not in one plane, as in an incomplete turn of a helix.

**Vibrionaceae** A family of Gram-negative, asporogenous, facultatively anaerobic bacteria. Cells: straight or curved rods, coccobacilli, short filaments, etc. Most strains are motile with one or more polar flagella; lateral flagella may be formed on solid media. Metabolism is chemoorganotrophic (respiratory or fermentative); most strains can grow on media containing only salts, NH<sub>4</sub><sup>+</sup> and glucose, although a few require organic growth factors. Most strains are oxidase +ve and can reduce NO<sub>3</sub><sup>-</sup> to NO<sub>2</sub><sup>-</sup>. Species occur mainly in marine and freshwater habitats and in association with aquatic animals; some are pathogenic in man and/or animals (e.g. fish). GC%: 38–63. Genera: AEROMONAS, ALLOMONAS; PHOTOBACTERIUM; PLESIOMONAS; VIBRIO. [Book ref. 22, pp. 516–550.]

[Phylogeny and reorganization of the Vibrionaceae: SAAM (1985) 6 171–182.]

**vibriosis** Any disease of man or animals (e.g. fish) caused by a VIBRIO sp; the term usually refers to diseases other than cholera.

**vibriostatic** Refers to any agent bacteriostatic for *Vibrio* spp.

**vibunazole** See AZOLE ANTIFUNGAL AGENTS.

**Victoria blight** (of oats) A seed- and soil-borne CEREAL DISEASE which affects the Victoria and related cultivars of oats (*Avena* spp); causal agent: see VICTORIN. Symptoms: necrosis and reddening of seedling leaves, and later rotting of stem bases.

**victorin** A TOXIN, synthesized by *Drechslera* (= *Helminthosporium*) *victoriae*, which is responsible for the symptoms of VICTORIA BLIGHT of oats; victorin causes leakage of electrolyte through the plasmalemma.

**vidarabine** (adenine arabinoside; 9-β-D-arabinofuranosyladenine; ara-A; Vira-A) An ARABINOSYL NUCLEOSIDE used e.g. as an ANTIVIRAL AGENT for the treatment of certain herpesvirus infections (e.g. topically for herpes simplex keratitis, systemically for varicella-zoster virus infections in immunocompromised patients). In vivo, vidarabine is readily converted to the less active arabinosylhypoxanthine by adenosine deaminase (an enzyme widely distributed in host cells); its antiviral activity can be potentiated by the adenosine deaminase inhibitor *pentostatin*. (Vidarabine was originally synthesized chemically, but was subsequently found to be produced e.g. by *Streptomyces antibioticus*.)

**vignafuran** A PHYTOALEXIN, 2-(2'-methoxy-4'-hydroxyphenyl)-6-methoxybenzofuran, produced by the cowpea (*Vigna unguiculata*).

**vilia** (viili, filia, filli) A Finnish food made by fermenting milk with capsulated ('rope-forming') strains of *Lactococcus lactis* which give the product flavour (LACTIC ACID and DIACETYL) and a stringy texture. A surface growth of *Geotrichum candidum* may be present; this organism lowers the acidity by utilizing some of the lactic acid. (See also DAIRY PRODUCTS.)

**villin** See ACTIN.

**vimentin** See INTERMEDIATE FILAMENTS.

**vinblastine** See VINCA ALKALOIDS.

**Vinca alkaloids** (*Cantharanthus* alkaloids) A group of iridoid indole alkaloids obtained from the periwinkle *Cantharanthus roseus* (formerly *Vinca rosea*). Some are used in anticancer therapy; they include e.g. vinblastine (= vincalukoblastine), vincristine and vindesine – each of which can combine with TUBULIN, inhibiting the assembly of MICROTUBULES (and, hence, inhibiting MITOSIS). The *Vinca* alkaloids can precipitate tubulin, in paracrystalline form, intracellularly.

**vincalukoblastine** See VINCA ALKALOIDS.

**Vincent's angina** (trench mouth; Vincent's disease) An ulcerative disease of the mouth and pharynx, believed to be caused by *Treponema vincentii* together with (uncharacterized) anaerobic fusiform bacteria.

**Vinckeria** A subgenus of PLASMODIUM.

**vinclozolin** See DICARBOXIMIDES.

**vincristine** See VINCA ALKALOIDS.

**vinculin** See ACTIN.

**vindesine** See VINCA ALKALOIDS.

**vinegar** A condiment made by the ACETIFICATION (by *Acetobacter* spp) of various fermented liquors – e.g. beer, wine, cider, or distilled alcohol (for malt, wine, cider and spirit vinegars, respectively). *Slow processes* of manufacture involve the bulk acetification of naturally fermented liquor on exposure to air. The *Orleans process*, still used in some regions, is a continuous slow process in which vinegar (serving as an inoculum) is mixed with the fermented liquor which is allowed to acetify in partially filled kegs; acetifying bacteria form a film on the liquid surface. As vinegar is withdrawn it is replaced with fresh liquor. *Quick processes* are of two types. (a) In *trickling generators* the liquor trickles through a tank packed with e.g. twigs, corn-cobs, or wood-shavings which are coated with a film of *Acetobacter* spp. The commonest, the Frings trickling generator, is packed with beechwood shavings; the liquor is pumped from a reservoir at the base to the top of the tank and allowed to trickle back to the reservoir through the coated shavings. Air is forced in at the bottom and up through the shavings. Cooling is necessary to maintain a temperature of ca. 29–35°C. Trickling generators can become blocked by growth of the slime-producing *Acetobacter xylinum*, especially if acidity levels are low. (b) *Submerged culture generators* are becoming more widely used. The commonest is the Frings Acetator: a fermenter with a high-speed rotor that distributes fine air-bubbles which rise through the agitated liquor. Temperature control, aeration etc can be fully automated. Vinegar produced by any of these processes may be aged prior to filtration, bottling and pasteurization. ('Vinegar' made chemically, e.g. by the carbonylation of methanol at high temperature and pressure, is referred to in Europe as 'non-brewed condiment'; it is cheaper than microbially-produced vinegar.)

In Japan, one type of rice vinegar (*komesu*) is made from polished rice, while another type (*kurosus*) is made from unpolished rice – *Acetobacter pasteurianus* being important in both production processes. [Characterization of acetic acid bacteria in the traditional production of rice vinegar in Japan: AEM (2001) 67 986–990.]

**viniferins** The ( $\alpha$ - and  $\epsilon$ -) viniferins are stilbene oligomer PHYTOALEXINS produced by the grapevine (*Vitis vinifera*).

**Vioform** See 8-HYDROXYQUINOLINE.

**violacein** A purple, water- and chloroform-insoluble pigment formed from tryptophan by species of *Chromobacterium* and *Janthinobacterium*; it consists of two substituted indole nuclei

linked via a pyrrolone residue. An ethanolic solution of violacein has an absorption maximum at 579 nm and a minimum at 430 nm; it becomes green when acidified with H<sub>2</sub>SO<sub>4</sub>.

The synthesis of violacein may be used as an indicator system in the study of QUORUM SENSING (q.v.).

**violaxanthin** See CAROTENOIDS.

**viomycin** A peptide ANTIBIOTIC which inhibits PROTEIN SYNTHESIS in bacteria; it apparently binds to the ribosome at a site identical to the binding site of the 2-deoxystreptomine-containing AMINOGLYCOSIDE ANTIBIOTICS, inhibiting the initiation of translation and the translocation step of elongation. Viomycin has little or no activity against at least some archaeans (methanogens).

**viper type C oncovirus** See TYPE C ONCOVIRUS GROUP.

**vir loci** See CROWN GALL.

**Vira-A** See VIDARABINE.

**viraemia** (viremia) The condition in which virions are present in the bloodstream.

**viral haemorrhagic fevers** A group of clinically similar diseases in which characteristic features are increased capillary permeability, leukopenia and thrombocytopenia; causal agents include arenaviruses (e.g. Argentinian and Bolivian haemorrhagic fevers and LASSA FEVER), flaviviruses (e.g. Omsk haemorrhagic fever), Ebola virus (see FILOVIRIDAE), Marburg virus (see MARBURG FEVER), and bunyaviruses (Crimean–Congo haemorrhagic fever – a tick-borne disease [ARE (1981) 26 77–80]). (See also HANTAVIRUS; KOREAN HAEMORRHAGIC FEVER.)

The incubation period may be 7–14 days. Onset is insidious, with chills and fever, myalgia, headache, conjunctivitis, anorexia and vomiting; exanthem and oedema of the face, neck and upper thorax may occur. After a few days, hypotension and haemorrhages develop, and death may follow uraemic coma or hypovolaemic shock.

(See also DENGUE and SIMIAN HAEMORRHAGIC FEVER VIRUS.)

**viral haemorrhagic septicaemia** (of trout) See EGTVED DISEASE.

**viral hepatitis** See e.g. HEPATITIS A, HEPATITIS B, HEPATITIS C.

**viral infectivity** See END-POINT DILUTION ASSAY.

**viral pneumonia of calves** See CALF PNEUMONIA.

**Virazole** *Syn.* RIBAVIRIN.

**Virchow cells** See LEPROSY.

**viremia** *Syn.* VIRAEMIA.

**virulence** (*plant pathol.*) An abnormal greening (e.g. of petals): a symptom of certain plant diseases.

**VirG protein** See DYSENTERY.

**virginiamycins** Antibiotics (see STREPTOGRAMINS), produced by a strain of *Streptomyces virginiae*, which are active against primarily Gram-positive bacteria; they have been used e.g. as FEED ADDITIVES for pigs, poultry and ruminants.

**viricidal** *Syn.* VIRUCIDAL.

**viridans streptococci** Streptococci which are typically  $\alpha$ -haemolytic (see STREPTOCOCCUS), which do not contain Lancefield grouping antigens, and which are characteristically found in the upper respiratory tract in man and other animals; they include e.g. *S. acidominimus*, some strains of *S. mutans* (*sensu lato*), *S. oralis*, *S. pneumoniae*, *S. salivarius* and *S. sanguis*. [Classification of some viridans streptococci as *S. oralis*: IJSB (1985) 35 482–488.]

**viridigrisein** An antibiotic structurally related to streptogramin B (see STREPTOGRAMINS).

**virino** A hypothetical infectious particle consisting of a host-encoded protein complexed with a small nucleic acid which does not encode any protein but which can serve as a template for its own replication (catalysed by host enzymes). (cf. VIROID.) The nucleic acid could play a regulatory role by inducing

## virion

the synthesis of host-encoded structural protein(s). It was once suggested that a virino could be the causal agent of SCRAPIE and other (PRION-mediated) diseases.

**virion** A single complete VIRUS particle.

**virigenes** Viral genes integrated in a (eukaryotic) host cell chromosome. (cf. PROVIRUS.)

**virogenic** Virus-producing.

**viroid** A plant-pathogenic infectious agent comprising small, naked (i.e., protein-free), circular ssRNA (240–380 nucleotides); the RNA appears not to code for any protein and depends entirely on the host cell for its replication. (cf. VIRUSOID; SATELLITE RNA.) Viroids currently known include: avocado sunblotch viroid (ASBV); burdock stunt viroid (BSV); chrysanthemum chlorotic mottle viroid (CCMV); chrysanthemum stunt viroid (CSV); *Citrus exocortis* viroid (CEV); COCONUT CADANG-CADANG VIROID (CCCV); cucumber pale fruit viroid (CPFV) – closely homologous with, and probably a strain of, hop stunt viroid (HSV); potato spindle tuber viroid (PSTV); tomato apical stunt viroid (TASV); tomato bunchy top viroid (TBTV); and tomato ‘planta macho’ viroid (TPMV). (A viroid-like RNA apparently related to HSV has been isolated from grapevine leaves [JGV (1985) 66 333–338].) Many of these viroids cause commercially important losses among crop plants. Symptoms of viroid infection range from mild (e.g. discoloration and malformation of leaves) to severe and even lethal (e.g. in the case of CCCV). Transmission typically occurs mechanically, particularly by vegetative propagation (e.g., grafting has been an important mode of spread of CEV); PSTV transmission via seed and pollen has been recorded in certain host plants, and PSTV may also be transmitted at low frequencies by the aphids *Macrosiphum euphorbiae* and *Myzus persicae*.

All viroids seem to be essentially similar in structure. They are covalently closed circular ssRNA molecules that form highly base-paired rigid rods in which short double-stranded segments are separated by small unpaired internal loops; a small loop also occurs at each end of the rod. This secondary structure is highly conserved among the viroids and is apparently necessary for replication and possibly also for pathogenicity.

Since viroid RNA appears not to encode proteins, it must rely on host enzymes for its replication. Replication occurs in the host cell nucleus, where the viroid RNA is apparently associated with the nucleolus. Evidence from studies using *in vitro* systems and  $\alpha$ -amanitin suggests that DNA-dependent RNA polymerase II may be involved, although a role for the RNA-dependent RNA polymerase present in many plants has not been excluded. Initially, infectious (+) viroid RNA is transcribed – apparently by a ROLLING CIRCLE MECHANISM – into an oligomeric complementary (–) RNA several times the unit length of the viroid RNA. The (–) RNA oligomers may serve as templates for the synthesis of (+) RNA oligomers which are then presumably cleaved into unit-length linear strands; processing and ligation of the linear molecules is then necessary to yield ‘mature’, infectious viroid RNA.

It has been demonstrated that viroids show some homology with group I introns (see SPLIT GENE), leading to the suggestion that they may have evolved from group I introns and/or that cleavage of viroid oligomers to form monomers may require structural features similar to those of group I introns [see e.g. PMB (1986) 7 129–142]. It has been proposed that viroids may exert their pathogenic effects by interfering with pre-rRNA processing in host cells [see e.g. BBA (1986) 868 190–197].

[General reviews: Book ref. 81, pp. 281–334; Interviol. (1984) 22 1–16.]

**viropexis** The uptake by a cell of virus particle(s) (bound to cell surface receptors) by a non-specific phagocytic process. (See e.g. REOVIRUS.)

**viroplasm** (*syn.* factory area; viroplasmic matrix; viroplast; virus factory; X body) A type of INCLUSION BODY which is – or is presumed to be – the site of virus replication and/or assembly in a virus-infected cell. A viroplasm generally consists of or contains accumulations of virions and/or virus components.

**viroplasmic matrix** *Syn.* VIROPLASM.

**viroplast** *Syn.* VIROPLASM.

**Viroptic** *Syn.* TRIFLUOROTHYMININE.

**virosome** A LIPOSOME which incorporates viral (usually ENVELOPE) proteins.

**viroidal** (viricidal) Able to inactivate viruses. (See also ANTIVIRAL AGENTS.)

**virulence** (of pathogenic microorganisms) The capacity of a PATHOGEN to cause disease – defined broadly in terms of the severity of symptoms in the host; thus, a highly virulent strain may cause severe symptoms in a susceptible individual, while a less virulent strain would produce relatively less severe symptoms in the same individual. The severity of the disease which actually develops may be regarded as the result of the joint expression of the degree of INFECTIVITY (sense 1) and virulence of the pathogen and the state of immunity (either natural or acquired) of the host in relation to that pathogen.

**virulent bacteriophage** A BACTERIOPHAGE which causes lysis of its host cell. (cf. TEMPERATE BACTERIOPHAGE.)

**virulon** In *Yersinia* spp: a system, encoded by a set of plasmid-borne genes, which consists essentially of (i) a number of virulence proteins (Yops), and (ii) a type III transport system (see PROTEIN SECRETION) for delivering Yops into the cytoplasm of a eukaryotic cell [Mol. Microbiol. (1997) 23 861–867]. Analogous systems (i.e. effector molecules and a type III secretion system) occur in certain other bacteria (e.g. species of *Salmonella* and *Shigella*).

The 70-kb *Yersinia* virulence plasmid (pYV) which encodes the virulon is found in *Y. enterocolitica* and *Y. pseudotuberculosis* as well as in *Y. pestis*.

The type III secretion system is constructed from a number of different Ysc proteins. Thus, at least four of these proteins (YscDRUV) are known to span the cytoplasmic membrane, while YscC is a SECRETIN. YscN is believed to function as an ATPase. (See figure.)

Some of the Yop proteins are effector molecules that are secreted into the eukaryotic cell. Others (e.g. YopBD) are ‘translocators’ which mediate translocation of effectors through the cytoplasmic membrane of the host cell. In some cases, an effector or translocator has a specific CHAPERONE – a given chaperone being designated SycD, SycE etc. (Syc = specific Yop chaperone); translocation of effector molecules would be inefficient, or absent, in the absence of specific chaperones. The chaperones of the effector molecules may also be involved in determining the order in which Yops are delivered to the eukaryotic cell [JB (2000) 182 4811–4821].

Among effector Yops, YopH (a phosphatase) can inhibit phagocytosis by de-phosphorylating certain macrophage proteins. YopE and YopT can disrupt eukaryotic actin-based structures. YopJ can down-regulate certain kinases in macrophages, thus inhibiting release of the pro-inflammatory cytokine TNF- $\alpha$  [Mol. Microbiol. (1998) 27 953–965].

[The Yop virulon in the context of plague: PNAS (2000) 97 8778–8783.]

**viruria** The presence of viruses in urine.

**VIRULON:** the Yop virulon of *Yersinia*. When cells of *Yersinia* are placed in a rich environment at 37°C, the Ysc secretion channel is installed. Proteins YscD, -R, -S, -T, -U and -V are localized in the inner membrane (IM), whereas YscC and YscP are exposed at the bacterial surface. Lipoprotein YscW stabilizes YscC. YscN belongs to the family of ATPases. A stock of Yop proteins is synthesized, and some of them are capped with their specific Syc chaperone. As long as there is no contact with a eukaryotic cell, a stop-valve, possibly made of YopN, YopE, YopT, YopM, YopH, YopP/J and YopO/YpkA, blocks the Ysc secretion channel. On contact with a eukaryotic target cell, the bacterium attaches tightly by interaction between its YopN and Inv adhesins and  $\beta$ -integrins, and the secretion channel opens. The Yops are then transported through the Ysc channel, and the Yop effectors are translocated across the plasma membrane, guided by the translocators YopB, YopD and LcrV.

Cornelis, Christian de Duve Institute of Cellular Pathology and Faculté de Médecine, Université catholique de Louvain, Brussels.

**virus** A non-cellular MICROORGANISM (q.v.) which consists minimally of protein and nucleic acid (DNA or RNA) and which can replicate only within particular (animal, microbial or plant) cells; the viral nucleic acid (genome) encodes viral structural proteins and (usually) one or more types of molecule necessary e.g. for viral gene expression, genome replication, etc. (cf. SUBVIRAL AGENTS.) A virus has no intrinsic metabolism, relying entirely on its host cell for energy, for precursor molecules (nucleotides, amino acids etc), and for all essential enzymes not encoded by the virus; host cell macromolecule synthesis is often inhibited by the infecting virus. Infection of an organism by a virus may or may not result in disease, depending e.g. on virus, host, and/or conditions. (See also ANIMAL VIRUSES, BACTERIOPHAGE, CYANOPHAGE, MYCOVIRUS, PHYCOVIRUS, PLANT VIRUSES.)

Depending on virus, an individual virus particle (*virion*) may be e.g. isometric, rod-shaped, filamentous, or pleomorphic, or it may consist of an isometric 'head' with a rod-shaped or filamentous 'tail'. Virions vary in structural complexity from relatively simple, with only one or a few types of major structural protein, to highly complex, with many components – including glycoproteins and various enzymes (see e.g. POXVIRIDAE and T-EVEN PHAGES). Nevertheless, in the majority of viruses the virion conforms essentially to one of two basic types of construction: the genome occurs either (a) within a shell-like, isometric CAPSID (see e.g. ADENOVIRIDAE, MICROVIRIDAE, TOMBUSVIRUSES), or (b) complexed with protein in a structure (often rod-shaped or filamentous) with helical symmetry (see e.g. TOBACCO MOSAIC

VIRUS). (cf. NUCLEOCAPSID.) Virions of either type may have an external lipoprotein ENVELOPE.

In size, virions range from ca. 20–25 nm diam. or less (PARVOVIRIDAE, PICORNAVIRIDAE) to ca. 200–450 nm maximum dimension (POXVIRIDAE); filamentous viruses may reach lengths of ca. 2000 nm (CLOSTERVIRUSES). Thus, some virions are larger than some bacteria: cf. CHLAMYDIA and MYCOPLASMA.

The virus *replication cycle* begins with the *attachment* (*adsorption*) of the virion to a specific receptor on the host cell surface, followed by *penetration* of the cell by the virion or by part of the virion (including at least its genome). (See e.g. BACTERIOPHAGE  $\phi$ 6; BACTERIOPHAGE T4; ENVELOPE; VIROPEXIS.) After partial or complete UNCOATING of the genome, viral *gene expression* begins. Viral genes are often expressed in a particular temporal sequence: 'early genes', the first to be expressed, commonly encode enzymes necessary for genome replication and/or for subsequent ('middle' and/or 'late') gene expression; 'late genes' generally encode virion structural proteins, and their expression is often coupled to or preceded by replication of the genome. (See e.g. ADENOVIRIDAE, BACTERIOPHAGE SPO1 and BACTERIOPHAGE T4.) *Genome replication* generally requires at least some virus-encoded enzymes: e.g. RNA viruses generally encode an RNA-DEPENDENT RNA POLYMERASE. *Virion assembly* may occur e.g. in the host cell cytoplasm or nucleus, depending on virus, and culminates in *maturation* which may involve e.g. elimination of SCAFFOLDING PROTEIN, acquisition of an ENVELOPE, conformational changes or cleavages of certain virion proteins (see e.g. RETROVIRIDAE), etc. *Release* of the progeny virions from

## virus-associated haemophagocytic syndrome

the host cell may occur e.g. by host cell lysis, by exocytosis, or by budding of the virions through the plasma membrane. Hundreds or thousands of progeny virions may be formed per cell. For details of replication cycles see separate entries for virus families/groups (see ANIMAL VIRUSES, PLANT VIRUSES, BACTERIOPHAGE). (See also ONE-STEP GROWTH EXPERIMENT.)

The strategy for viral gene expression and replication depends largely on the nature of the viral genome – which may be DNA (ss or ds, linear or circular) or RNA (ss or ds linear, or ss circular), and may consist of one or more pieces of nucleic acid (i.e., it may be monopartite, bipartite, etc). In viruses with single-stranded genomes, the genome is said to be *positive-sense* or *negative-sense* according to whether it is *homologous with or complementary to*, respectively, the viral mRNA (which is arbitrarily defined as positive-sense, = plus- or(+)-strand). Thus, e.g., a virus with a *positive-sense ssDNA genome* (e.g. SSDNA PHAGES, GEMINIVIRUSES) must synthesize a complementary negative-sense DNA strand before mRNA can be transcribed. A *negative-sense ssDNA genome* (see e.g. PARVOVIRIDAE) can – at least theoretically – be transcribed directly into mRNA. *Positive-sense ssRNA genomes* can generally act directly as mRNA; however, since in eukaryotes translation cannot usually be initiated at internal initiation sites, internal genes in an ssRNA genome must be expressed e.g. by the synthesis of SUBGENOMIC MRNAs on a complementary (–) strand and/or by the synthesis of a POLYPROTEIN on a polycistronic mRNA. Viruses with *negative-sense ssRNA* (e.g. ORTHOMYXOVIRIDAE, RHABDOVIRIDAE) generally carry their own RNA-DEPENDENT RNA POLYMERASE in the virion, since a (+)-strand must be synthesized before any gene expression can occur; negative-strand RNA viruses may e.g. synthesize subgenomic mRNAs and/or have segmented genomes. (See also AMBISSENSE RNA.) Viruses of the RETROVIRIDAE carry a REVERSE TRANSCRIPTASE which synthesizes a DNA strand complementary to the RNA genome; mRNA is transcribed from the (ds) DNA provirus. Viruses with *dsDNA genomes* may synthesize mRNA on only one strand, the (–)-strand (see e.g. HEPADNAVIRIDAE), or on both strands (e.g. in the ADENOVIRIDAE and BACTERIOPHAGE LAMBDA); in the latter case neither strand can be designated ‘+’ or ‘–’. Most known *dsRNA viruses* have SEGMENTED GENOMES (cf. MYCOVIRUS), one strand (the (+)-strand) of each segment functioning as mRNA. (cf. BALTIMORE CLASSIFICATION; see also INFECTIONOUS NUCLEIC ACID.)

**Classification of viruses.** Current classification schemes are based on features such as the composition, morphology and anatomy of the virion, the nature of the genome, replication strategy, etc. The ANIMAL VIRUSES and some BACTERIOPHAGES have been classified into families (names ending in -viridae), occasionally subfamilies (names ending in -virinae), genera (names ending in -virus), and species (corresponding to individual viruses) [Book ref. 23]; however, the species concept in virology has not been universally accepted [debate: Intervirology. (1985) 24 61–98]. (cf. PLANT VIRUSES.) Strains or types of a given virus are recognized e.g. on the basis of virulence, antigenic determinants, etc.

**Assay of viruses.** See COUNTING METHODS (b).

**Inactivation of viruses.** Viruses may be inactivated e.g. by extremes of pH (cf. ENTEROVIRUS), by relatively mild heat treatment (e.g. 50–80°C for some viruses), and by UV and ionizing radiation; some viruses are sensitive to desiccation and to various ANTISEPTICS and DISINFECTANTS. Enveloped viruses (and some non-enveloped viruses) are generally inactivated by organic solvents (e.g. ether, chloroform) and by detergents. (See also ANTIVIRAL AGENTS and STERILIZATION.)

**virus-associated haemophagocytic syndrome (VAHS)** See HAEMOPHAGOCYTIC SYNDROME.

**virus factory** *Syn.* VIROPLASM.

**virusoid** A type of small (ca. 300–400-nucleotide) ccc ssRNA present (as ‘RNA2’) within the virions of VELVET TOBACCO MOTTLE VIRUS (VTMoV) and related viruses. In VTMoV and *Solanum nodiflorum* mottle virus the virusoid is an integral part of the genome, both RNA1 and the virusoid being necessary for infectivity. (However, the RNA1 of lucerne transient streak virus (LTSV) can replicate in the absence of its ‘virusoid’; the LTSV ‘virusoid’ may thus be a SATELLITE RNA [JGV (1983) 64 1167–1173].) A virusoid resembles a VIROID, at least superficially, in its secondary structure (which is apparently more flexible than that of a viroid), in its apparent lack of coding capacity, and possibly also in its mode of replication (concatemeric forms have been detected in infected plant cells); however, virusoids differ from viroids in being encapsidated and in being incapable of infecting plant cells in the absence of RNA1.

**visceral leishmaniasis** LEISHMANIASIS of man and other animals in which the pathogen, typically *Leishmania donovani*, infects the internal organs; *L. donovani* is transmitted by the bites of sandflies. The disease occurs primarily in Africa, Asia and South America: in India the disease in man is called *kala-azar*. In man, the incubation period may be 3–6 months (range: weeks–years); typically, there is a recurrent low-grade fever, splenomegaly, hepatomegaly, leucopenia and cachexia – with high mortality rates in untreated cases. Diagnosis may involve e.g. an indirect fluorescent antibody test; the Montenegro test is usually negative. Chemotherapeutic agents used for treatment include pentavalent ANTIMONY compounds; however, resistance to pentavalent antimony is now found e.g. in the Bihar region of India – where almost half of the world’s cases occur, and where therapeutic use is being made of e.g. AMPHOTERICIN B.

[Clinical and experimental advances in the treatment of visceral leishmaniasis: AAC (2001) 45 2185–2197.]

(See also POST-KALA-AZAR DERMAL LEISHMANIASIS.)

**viscotaxis** A TAXIS in which the stimulus is a change in viscosity; a positively viscotactic organism swims towards regions of higher viscosity.

**visna** A chronic, progressive, fatal meningoencephalitis of sheep; the causal agent is a virus of the LENTIVIRINAE (cf. MAEDI). Incubation period: months or years. Symptoms – which include e.g. abnormal gait, tremor of facial muscles, increasing emaciation and paralysis – are associated with inflammation and subsequent demyelination of tissues in the central nervous system. [Antigenic variation in the visna virus: JMB (1982) 158 415–434.]

**vital staining** The STAINING of *living* cells or their components by dyes whose presence is tolerated by the cells for varying periods of time; ‘vital staining’ may also refer to the uptake of minute insoluble particles (e.g. carbon, carmine) by certain types of cell. Vital dyes include Bismarck brown, brilliant cresyl blue, Janus green, METHYLENE BLUE, NEUTRAL RED and NILE BLUE A; most vital dyes are basic dyes – EOSIN is an exception. (See also FLUORESCENT BRIGHTENER.) Some vital dyes (e.g. Janus green) are more toxic than others, neutral red being one of the least toxic; all vital dyes are used in low concentrations (e.g. less than 0.01% w/v). Vital staining has been used e.g. for studying differentiation in the pseudoplasmodium of cellular slime moulds, and is involved e.g. in the TOXOPLASMA DYE TEST; Janus green is used e.g. for staining mitochondria and for following redox changes in mitochondria (see also RHODAMINE). In animals, *intra vitam* (= *intravital*) staining involves the

injection or ingestion of a dye which is taken up by certain types of cell in the (living) animal; thus, e.g. on injection into a mammal, TRYPAN BLUE is taken up by macrophages. Trypan blue stains some types of cell only when they are dead or damaged; hence, this dye is used to determine the proportion of dead/damaged cells in a cell suspension used to prepare a TISSUE CULTURE. The staining of living cells after their removal from the host has been referred to as *supervital* or *supravital* staining when the cells remain viable during the staining process.

**vitamin** In microbiology: a generic term for any of a range of unrelated organic compounds, many of which are necessary – in small quantities – for the normal metabolism and growth of certain microorganisms; they typically function as COENZYMES (sense 2) or as components of coenzymes. Most microorganisms can synthesize the vitamins they require. Those which cannot synthesize a particular vitamin must obtain it – or sometimes one or more of its precursors – from the growth medium; such organisms can be used in the BIOASSAY of that vitamin. Some microorganisms are important natural and/or commercial sources of certain vitamins. See also ASCORBIC ACID, BIOTIN, BIOPTERIN, FOLIC ACID, LIPOIC ACID, NICOTINIC ACID, PANTOTHENIC ACID, PYRIDOXINE, RIBOFLAVIN, THIAMINE, VITAMIN B<sub>12</sub>.

**vitamin A** See RETINAL.

**vitamin B<sub>1</sub>** *Syn.* THIAMINE.

**vitamin B<sub>2</sub>** *Syn.* RIBOFLAVIN.

**vitamin B<sub>6</sub>** See PYRIDOXINE.

**vitamin B<sub>12</sub>** A photolabile, water-soluble VITAMIN. The term ‘vitamin B<sub>12</sub>’ may refer specifically to cyanocobalamin or to any of its various analogues (see below). These compounds are *corrinoids*, i.e. they contain a tetrapyrrole ring system (the corrin ring) which is highly substituted and which contains a central cobalt atom linked to the four pyrrole nitrogen atoms to form *cobinamide*; 3-phosphoribose linked to a side-chain on one of the pyrrole rings forms *cobamide*. In the *cobalamins*, 5,6-dimethylbenzimidazole forms a bridge between the cobalt atom and the  $\alpha$ -1-position of the ribose residue; the sixth coordination position of the cobalt may be occupied by e.g. cyanide (in *cyanocobalamin*), hydroxyl (in *hydroxycobalamin*) etc. (cf. HAEM).

*Cobamide coenzymes* (= coenzymes B<sub>12</sub>) typically consist of a cobalamin in which a 5'-deoxyadenosyl residue has been linked, through its 5' position, to the cobalt atom, forming 5'-deoxyadenosylcobalamin. These coenzymes are involved in various intramolecular re-arrangements: e.g. glutamate/ $\beta$ -methylaspartate and methylmalonyl-CoA/succinyl-CoA interconversions, dehydration of 1,2-diols (e.g. glycerol  $\rightarrow$   $\beta$ -hydroxypropionaldehyde) etc. [Mechanism of coenzyme B<sub>12</sub>-dependent re-arrangements: *Science* (1985) 227 869–875.] (See also NUCLEOTIDE.)

*Methylcobalamin*, in which a methyl group occurs in place of the 5'-deoxyadenosyl group, functions as a coenzyme e.g. in the synthesis of methionine from homocysteine [see Appendix IV(d)], apparently acting as a methyl carrier.

In certain methanogens, a corrinoid-containing enzyme (methanol:corrinoid methyltransferase) is involved in the biosynthesis of methane from methanol (see METHANOGENESIS).

Vitamins of the B<sub>12</sub> group are apparently synthesized primarily or solely by bacteria, and are obtained commercially from e.g. *Streptomyces* spp as a by-product of antibiotic production. In man, B<sub>12</sub> synthesized by bacteria in the small intestine may – in at least some cases – be an important source of the vitamin [Nature (1980) 283 781–782], but B<sub>12</sub> synthesized by bacteria in the large intestine cannot be absorbed and is voided

with the faeces. In ruminants, the microflora of the RUMEN is an important source of this vitamin for the animal; a ‘wasting disease’ of ruminants grazing cobalt-deficient pastures is due to the inability of the rumen microflora to synthesize adequate amounts of B<sub>12</sub>.

B<sub>12</sub> vitamins are required as growth factors e.g. by many algae, by certain protozoa, and by *Lactobacillus* spp; *Euglena gracilis* has been used for the BIOASSAY of B<sub>12</sub>. (See also BLOOM.)

In *Escherichia coli*, B<sub>12</sub> is taken up by (i) pmf-dependent transport across the OUTER MEMBRANE (see also BTUB PROTEIN and TONB PROTEIN) and (ii) a BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM in which the binding protein BtuF [PNAS (2002) 99 16642–16647] transfers B<sub>12</sub> to BtuCD (see ABC TRANSPORTER); negatively charged (glutamate) residues on BtuF may interact with positive (arginine) residues on BtuCD.

**vitamin C** *Syn.* ASCORBIC ACID.

**vitamin H** *Syn.* BIOTIN.

**vitamins K** See QUINONES.

**Vitreoscilla** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur in e.g. soil, fresh water, and decaying vegetation. The organisms are chemoorganotrophs which resemble BEGGIATO A spp but differ e.g. in the width of the trichome (ca. 1–4  $\mu$ m) and in that sulphur is not deposited intracellularly.

**vitrification** See ELECTRON MICROSCOPY (d).

**Vittiforma** See MICROSPORIDIOSIS.

**vivotoxin** (*plant pathol.*) A substance in a diseased plant – produced either by the pathogen or by the host – which causes damage to the plant tissues and is thus responsible for at least some of the symptoms of the disease.

**VL region** See IMMUNOGLOBULINS.

**VLP** Virus-like particle.

**VNC** (VBNC) Viable but non-cultivable: refers to normally-cultivable bacteria which have become non-cultivable owing to stress (e.g. starvation) – but which still show features of living cells (e.g. metabolic activity and maintenance of structure). VNC pathogens (e.g. *Vibrio cholerae*) may retain virulence. Some view the VNC state as a kind of ‘dormancy’ adopted by non-spore-forming bacteria as a normal response to stress [FEMS Ecol. (1998) 25 1–9]. Others believe that failure to culture may, in at least some cases, reflect inappropriate media/conditions; for example, starved cells transferred to a nutrient-rich aerobic medium may be damaged/killed by *endogenous* toxic radicals (e.g. SUPEROXIDE) which normal (adapted) cells can detoxify [Microbiology (1998) 144 1–3].

VNC strains of enterotoxigenic *Escherichia coli* (ETEC) can produce toxin [AEM (1996) 62 4621–4626].

VNC enterococci are reported to have changes in peptidoglycan, lipoteichoic acid and penicillin-binding proteins [AEM (2000) 66 1953–1959] and to maintain resistance to vancomycin when division is resumed [AAC (2003) 47 1154–1156].

**vodka** See SPIRITS.

**Vogelbusch IZ fermenter** See JET LOOP FERMENTER.

**Voges–Proskauer test** (VP test) An IMVIC TEST used to determine the ability of an organism to form acetoin and/or DIACETYL (formed e.g. during the BUTANEDIOL FERMENTATION) in a phosphate-buffered glucose–peptone medium. (For *Bacillus* spp the medium should not contain phosphate as this may prevent the formation of acetoin.) The test medium is inoculated and then incubated at 37°C for 48 h or at 30°C for 5 days or more. In *Barritt's method* 5% alpha-naphthol in ethanol (0.6 ml) and 40% KOH (0.2 ml) are added to ca. 1 ml of the culture; the (stopped) tube is shaken vigorously and left in a sloping position. A positive reaction (acetoin/diacetyl present) is

## Vollmer patch test

indicated by the development of a red coloration within 5–60 minutes. In *O'Meara's method* (which is somewhat less sensitive) 2 drops of creatine (1% in 0.1 N HCl) are used in place of the alpha-naphthol, and 1 ml of KOH is used; a positive reaction is indicated by a pink coloration.

In e.g. the *Westerfeld modification*, both creatine and alkaline alpha-naphthol are used – this combination of reagents apparently detecting aliphatic compounds (of minimum chain length 4 carbons) which have vicinal carbonyl groups in the 2- and 3-positions; acetoin gives a positive reaction because it is apparently oxidized by the alpha-naphthol to diacetyl [AEM (1982) 44 40–43].

**Vollmer patch test** A form of TUBERCULIN TEST in which a patch of tuberculin-impregnated gauze is fastened to the skin with adhesive tape.

**volunteer plant** A self-propagated plant, i.e., a (normally cultivated) plant which is growing as a result of natural propagation.

**volutin** *Syn.* POLYPHOSPHATE.

**volva** The cup-shaped lower part of the UNIVERSAL VEIL or PERIDIUM surrounding, respectively, the base of the stipe in certain mature agarics (e.g. *Amanita* spp) or the base of the receptacle in certain mature gasteromycetes (e.g. *Mutinus* spp).

**Volvariella** See AGARICALES (Pluteaceae) and PADI-STRAW MUSHROOM.

**Volvocida** See PHYTOMASTIGOPHOREA.

**Volvox** A genus of motile, coenobial, freshwater green algae (division CHLOROPHYTA). (cf. PHYTOMASTIGOPHOREA.) The coenobium consists of a spherical or ovoid gelatinous matrix (up to ca. 1.0 mm diam. in certain species) in which ca. 500–20000 cells (depending on species) are arranged in a single peripheral layer. The individual cells are biflagellate and resemble CHLAMYDOMONAS; in the coenobium they are orientated with their flagella projecting outwards, and are often interconnected by fine cytoplasmic threads. The coenobium has a characteristic rolling motility.

*Asexual reproduction.* Certain cells within a vegetative coenobium enlarge to become *gonidia*; each gonidium divides many times to form a hollow sphere of progeny cells oriented such that their flagellated ends face towards the centre of the sphere. Subsequently the sphere of cells everts via a pore (the *phialopore*) such that the flagellated ends of the cells face outwards, thus forming a daughter coenobium. Daughter coenobia may not be released until the parental coenobium disintegrates.

*Sexual reproduction* is oogamous; male and female gametes may be formed in the same coenobium or in different coenobia, according to species. In dioecious species such as *V. carteri* male coenobia may be formed spontaneously, but female coenobia may be produced only in the presence of male coenobia which produce a highly potent glycoprotein sexual inducer. (This inducer can be produced in response to heat shock in *V. carteri* [Science (1986) 231 51–54].) In some species (e.g. *V. carteri*) the male gametes (produced in male coenobia) are released as 'sperm bundles'. A sperm bundle is attracted towards, and adheres to, a female coenobium; the bundle then breaks down, an adjacent region of the female coenobium is also lysed, and individual sperm cells penetrate the female coenobium and fuse with female gametes. The resulting zygotes subsequently develop thick walls, are released by disintegration of the parent coenobium, and undergo a period of dormancy. On germination (during which meiosis occurs) a small 'juvenile' coenobium develops in a manner similar to that in which a vegetative coenobium develops from a gonidium. Subsequent daughter coenobia, produced asexually, have increased numbers of cells, so that eventually full-sized coenobia are formed.

(See also e.g. ASTREPHOMENE and PANDORINA.)

**vomiting and wasting disease** A PIG DISEASE, which affects suckling piglets, caused by porcine haemagglutinating encephalitis virus (a coronavirus). Symptoms: vomiting, constipation, and subsequent unthriftiness; an encephalitic form also occurs. Mortality rates may be high.

**vomitoxin** Deoxynivalenol: see TRICHOTHECENES.

**von Economo's encephalitis** (epidemic encephalitis) A rare form of ENCEPHALITIS believed to be of viral aetiology.

**von Willebrand factor** (vWF) A large, multimeric glycoprotein which normally occurs (i) in plasma, in which e.g. it stabilizes blood clotting factor VIII, (ii) in the  $\alpha$ -granules of platelets, and (iii) in cytoplasmic granules (called *Weibel–Palade bodies*) in endothelial cells. vWF is named after a Finnish doctor, Erik von Willebrand.

When vascular endothelium is damaged, vWF binds to ligands (collagen?) in subendothelial connective tissue; platelets can then bind to the vWF via their membrane glycoprotein GPIb. Platelets thus adhere to subendothelial tissue, and to one another, forming a plug.

vWF also binds to coagulase-negative staphylococci [JMM (2000) 49 217–225].

[vWF (biochemistry and genetics): ARB (1998) 67 395–424.]

**Vorticella** A genus of sedentary ciliate protozoa (subclass PERITRICHIA) which occur in fresh, brackish and marine waters; some species (e.g. *V. convallaria*) are common in SEWAGE TREATMENT plants. (See also SAPROBITY SYSTEM.) The zooid is commonly bell-shaped or goblet-shaped, ca. 50–150  $\mu$ m in length, the buccal cavity being at the wider (distal) end, and the narrow end being attached, by a stalk, to the substratum; both the zooid and stalk are contractile, the stalk (usually several hundred micrometres in length) being tubular and containing a SPASMONEME. Unlike CARCHESIUM, *Vorticella* is a solitary organism, only one zooid being carried on each (unbranched) stalk. The macronucleus is curved or U-shaped, and the micronucleus is spherical. One or more contractile vacuoles are usually present. Bacteria appear to be the main component of the diet for most species.

**VP test** See VOGES–PROSKAUER TEST.

**VPI technique** See ROLL-TUBE TECHNIQUE.

**VRE** Vancomycin-resistant enterococci (see ENTEROCOCCUS).

**VSG** Variant surface glycoprotein: in certain species of *Trypanosoma*, the material which forms the electron-dense cell-surface layer (the 'surface coat'); by periodically switching from the synthesis of one VSG to another of different antigenic specificity, pathogens of a given species can evade the host's immunological defence mechanisms.

A given trypanosome contains an estimated 1000 different VSG-specifying genes (VSG genes) of which only *one* can be expressed at any given time. (Earlier reports of the simultaneous expression of two VSG genes are now believed to be erroneous.)

To be expressed, a given VSG must be located within a specialized *expression site* situated in a TELOMERE; the genome appears to contain an estimated 20–40 copies of such expression sites, only one of which is functional at any given time. Some of the expression sites are used *specifically* by the bloodstream stage of the organism (i.e. the stage found within the vertebrate host); other expression sites are used *specifically* by METACYCLIC FORMS of the organisms (which occur within the tsetse fly).

Different trypanosomes expressing different VSGs are said to be different *variant antigenic types* (VATs).

Switching from one VSG to another appears to occur by two distinct mechanisms. The (apparently) less common mechanism

is one in which transcription is switched from one expression site (containing the resident *VSG*) to another expression site (containing the 'new' *VSG*), the first expression site being inactivated. In the alternative switching mechanism, the resident *VSG*, within the active expression site, is replaced by a new *VSG* – the mechanism apparently involving homologous RECOMBINATION and gene conversion; such *duplicative transposition* seems to be the common form of switching mechanism.

[Antigenic variation in trypanosomes (*VSG* switching mechanisms): TIP (2001) 17 338–343.]

**VSL#3** A PROBIOTIC (Yovis; Sigma-Tau, Pomezia, Italy) consisting of strains of *Lactobacillus*, *Bifidobacterium* and *Streptococcus*. Results of a double-blind, placebo-controlled trial suggest that oral administration of VSL#3 is effective in preventing flare-up in *chronic pouchitis*, a complication following surgery for ulcerative colitis. [Oral bacteriotherapy with VSL#3 in chronic pouchitis: Gastroenterology (2000) 119 305–309.]

**VSV** See VESICULOVIRUS.

**VT1, VT2** See EHEC.

**VTEC** See EHEC.

**vulvovaginitis** See VAGINITIS.

**VW antigens** Surface antigens present in virulent strains of *Yersinia pestis*, *Y. pseudotuberculosis*, and some virulent strains of *Y. enterocolitica*. The V (protein) and W (lipoprotein) components together confer on the cells the ability to resist phagocytic digestion. The formation of VW antigens is plasmid-mediated (*Vwa* plasmid) and is associated with certain other features – e.g. colony morphology [FEMS (1983) 17 121–126], autoagglutinability at 37°C [JB (1984) 158 1033–1036], production of specific OMPs, requirement for Ca<sup>2+</sup> for growth at 37°C.

**V–W transition** In certain strains of *Citrobacter*: a form of PHASE VARIATION which involves a reversible loss or re-establishment of the ability to synthesize VI ANTIGEN; cells which synthesize the antigen are called *V forms*, those which do not are called *W forms*.

**Vwa plasmid** See VW ANTIGENS and YERSINIA (*Y. pestis*).

**vWF** See VON WILLEBRAND FACTOR.

**VZV** Varicella-zoster virus (see ALPHAHERPESVIRINAE).

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# W

**W** Tryptophan (see AMINO ACIDS).

**W forms** See V-W TRANSITION.

**W-reactivation** WEIGLE REACTIVATION.

**Wagatsuma agar** A medium containing human or horse RBCs added to a basal medium of yeast extract, peptone, NaCl (7%), D-mannitol, crystal violet, and agar [recipe: Book ref. 46, p. 1284]; see KANAGAWA PHENOMENON.

**wakame** See UNDARIA.

**Waldhof fermenter** A type of FERMENTER in which aeration and agitation are provided by a hollow-bladed wheel-type impeller.

**walking** (*mol. biol.*) See CHROMOSOME WALKING.

**wall-forming body** A granule, present in a coccidian macrogamete, which subsequently contributes to the structure of the oocyst wall.

**Wallal subgroup** See ORBIVIRUS.

**Wallemia** A genus of osmophilic fungi which form reddish-brown mycelial growth e.g. on jams and salted fish; chains of spores develop acropetally. *W. sebi* may be related to the FILOBASIDIACEAE [AvL (1986) 52 183–187].

**Wangiella** A genus of fungi of the class HYPHOMYCETES. *W. dermatitidis* (sometimes called '*Hormiscium dermatitidis*', '*Hormodendrum dermatitidis*' or '*Phialophora dermatitidis*') can grow saprotrophically in e.g. soil, but it can also act as a dermatropic and/or neurotropic pathogen in man (see PHAEOHYPHOMYCOSIS); dark, budding, yeast-like cells are formed in culture, but in tissues the organism occurs predominantly in the form of dark hyphae. Non-septate, spherical to ovoid, smooth conidia are produced from flask-shaped to cylindrical, smooth, brown phialides which lack collarettes (see CONIDIUM). [Human isolates of *W. dermatitidis*: Mycol. (1984) 76 232–249.]

**Warburg–Dickens pathway** *Syn.* HEXOSE MONOPHOSPHATE PATHWAY.

**Warburg effect** The inhibition of CO<sub>2</sub> fixation and O<sub>2</sub> evolution during oxygenic PHOTOSYNTHESIS by the presence of high levels of O<sub>2</sub>; the effect is due at least in part to the competitive inhibition of the carboxylase function of RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE–OXYGENASE by O<sub>2</sub> and an increased rate of PHOTORESPIRATION.

**warhead delivery** A mechanism whereby an antimicrobial compound which does not itself readily cross the cell envelope of a potentially susceptible cell can be made to do so by attachment to a carrier component (e.g. a peptide) which can be recognized and transported by a specific TRANSPORT SYSTEM in the target cell; once inside the cell, the active component is released from the carrier component by cellular enzymes. See e.g. ALAFOFSALIN and BACILYSIN. [Review: Book ref. 153, pp. 219–266.]

**Warrego subgroup** See ORBIVIRUS.

**wart** (*med., vet.*) A skin PAPILLOMA (q.v.).

**wart disease** (black wart disease) (of potato) A soil-borne POTATO DISEASE, caused by *Synchytrium endobioticum* (see SYNCHYTRIUM), characterized by cauliflower-like outgrowths (GALLS) from the tubers and lower stem; entire tubers may be converted into warty masses, the warts subsequently blackening. The warts may continue development during storage of the harvested tubers.

**wash-out** (in continuous culture) See DILUTION RATE.

**washing powders** (biological) See SUBTILISINS.

**Wassermann antibody** See WASSERMANN REACTION.

**Wassermann reaction** (WR) A STANDARD TEST FOR SYPHILIS carried out as a COMPLEMENT-FIXATION TEST in which the antibody

(reagin, 'Wassermann antibody') undergoes a complement-fixing reaction with the cardiolipin–lecithin–cholesterol antigen. (The term 'Wassermann reaction' may be used loosely to refer to any STS or to any serological test used for the diagnosis of syphilis.)

**wastewater treatment** *Syn.* SEWAGE TREATMENT.

**wasting disease** (1) (of ruminants) See VITAMIN B<sub>12</sub>. (2) (of eel-grass) See LABYRINTHULAS. (3) (of elk) See TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**watchglass organelle** *Syn.* LIEBERKÜHN'S ORGANELLE.

**water activity** (*a<sub>w</sub>*) The amount of 'free' or 'available' water in a given substrate – e.g. a foodstuff or a medium; it may be defined as 1/100th the relative humidity (RH%) of the air in equilibrium with the substrate. Thus, e.g. an RH of 95% corresponds to an *a<sub>w</sub>* of 0.95. Temperature variation between 0°C and 37°C has little effect on *a<sub>w</sub>*; however, freezing lowers the *a<sub>w</sub>* of water: for pure water the values are ca. 0.95 at –5°C, 0.90 at –10°C, 0.84 at –15°C, and 0.82 at –20°C. The presence of solutes also lowers the *a<sub>w</sub>*.

For many species of bacteria the optimum *a<sub>w</sub>* for growth is above ca. 0.99; for e.g. staphylococci it is ca. 0.93, and for some halophiles it is ca. 0.75. Many bacteria (e.g. species of *Escherichia*, *Clostridium*, *Pseudomonas*) may fail to grow at *a<sub>w</sub>* below 0.95; staphylococci have a minimum of ca. 0.87. For many yeasts the minimum *a<sub>w</sub>* for growth is ca. 0.88–0.92, but the xerophilic yeast *Zygosaccharomyces rouxii* has a minimum of ca. 0.65. A number of filamentous fungi have *a<sub>w</sub>* minima between ca. 0.80 (e.g. *Aspergillus*, *Penicillium* spp) and ca. 0.90 (e.g. *Mucor* spp). Most algae have a minimum *a<sub>w</sub>* of about 0.95, although for *Dunaliella salina* it is ca. 0.75. (See also FOOD PRESERVATION (c).)

**water bath** A covered glass or metal tank containing water at a thermostatically-controlled temperature; in microbiology, water baths are used for INCUBATION – the material to be incubated being placed in a vessel suspended in the water. A motor-driven propeller ensures rapid mixing of the water and the maintenance of a given temperature in all parts of the tank; far greater temperature stability can be achieved in a water bath (e.g. ±0.1°C) than in a hot-air incubator. A refrigerated water bath is used for maintaining temperatures below the ambient temperature; it includes a cooling coil (which operates continually) and maintains a steady temperature by means of the thermostat and heater of the water bath.

**water bloom** *Syn.* BLOOM.

**water-immersion objective** See RESOLVING POWER.

**water moulds** Traditionally, the aquatic, mycelial members of the orders Saprolegniales and Leptomitales, though the term is sometimes used to include all aquatic mycelial fungi.

**water net** See HYDRODICTYON.

**water supplies** Supplies of fresh (non-saline) water are obtained mainly from surface waters (rivers, streams, lakes) and underground layers of water-bearing rock (*aquifers*); water from aquifers is called *groundwater*. Typically, surface waters are more polluted. (Some supplies are obtained by desalination of seawater.)

To be made potable, i.e. drinkable, water from any natural source must be suitably treated – primarily to make it microbiologically safe. The type of treatment needed will depend on (i) the initial quality of the water (the lower the quality the more extensive the treatment), and (ii) the quantity of water

involved – different approaches being used for small-scale (low-volume) supplies and large-scale (urban) supplies (see below).

[Microbiological safety of drinking water (emerging pathogens, cyanobacterial toxins, microbial ecology): ARM (2000) 54 81–127.]

[Developments in microbiological risk assessment for drinking water (with particular reference to *Cryptosporidium parvum*, rotavirus and bovine spongiform encephalopathy): JAM (2001) 91 191–205.]

*Small-scale water supplies.* Supplies in rural areas (e.g. for isolated houses) are often obtained from groundwater (wells) or from streams. Treatment may involve passing the water through an efficient fibre filter and then through a ‘chlorinator’ – i.e. a chamber containing tablets of calcium hypochlorite; the tablets gradually dissolve, releasing chlorine. Alternatively, the filtered water may be disinfected by ultraviolet radiation.

Small supplies (on expeditions etc.) can be disinfected by boiling or by using *halazone* tablets (*p*-carboxy-*N,N*-dichlorobenzenesulphonamide).

Novel methods have been used to improve the microbiological quality of drinking water in rural areas in some developing countries. For example, in Bangladesh, multi-layered local fabric has been used as a filter to retain a high proportion of plankton-associated *Vibrio cholerae*, and this may reduce the incidence/severity of cholera [AEM (1996) 62 2508–2512]. In Kenya, water has been disinfected by exposure to solar radiation [AEM (1996) 62 399–402; JMM (1999) 48 785–787].

*Large-scale (urban) water supplies.* Water for use as a public supply must be adequately treated in order to (i) eliminate those pathogens capable of causing the major water-borne diseases (such as CHOLERA), and (ii) eliminate, or reduce to safe levels, any harmful substance (e.g. nitrate) which may be present. A further aim is to achieve a final product which is acceptable in terms of clarity, taste and odour. Note that treated water entering an urban distribution system is not necessarily sterile; moreover, treatment may fail to remove taints caused by certain microbial products: see e.g. GEOSMIN, METHYLISOBORNEOL and SYNURA.

The suitability of *raw water* (i.e. water to be made potable by treatment) is assessed according to various standards (including bacteriological, chemical) which are recommended by the World Health Organization and other bodies.

Some regions (e.g. Scotland, British Columbia) depend on surface waters; others (e.g. Austria, Denmark, Portugal) use mainly groundwater.

The type of treatment varies according to the origin (groundwater/surface water) and quality of the raw water.

(i) *Treatment of groundwater.* Groundwater is obtained via bore-holes and springs. Generally it is of good quality; however, because it derives from an underground source it commonly needs aeration, rapid sand filtration and disinfection (see later). Extra treatment may be necessary if it contains e.g. excess nitrates (see later).

(ii) *Treatment of surface water.* Initial storage of raw water for a number of days can be useful e.g. for allowing sedimentation of some particulate (suspended) matter. (In some cases, raw water is seeded with coagulant and left in a *sedimentation basin* until the coagulated matter has formed a sediment.) The water may then be microstrained through rotating stainless-steel mesh drums of pore size ~30 µm.

If the water contains little dissolved oxygen it may be aerated by a cascade or fountain process.

Most of the remaining fine particulate matter can be removed by adding a coagulant such as aluminium sulphate – which

causes the particles to aggregate, forming *flocs*. Flocs can be removed (*clarification*) by passing the water upwards through a *floc blanket clarifier* – a tank within which the flocs form a ‘sludge blanket’ below a layer of clarified water; water is continually passed upwards through the blanket, clear water overflowing at the top of the tank and passing to the next stage of treatment.

Fine particles can be removed by allowing the water to flow downwards through a *rapid sand filter*: a bed of sand (grain size ~1 mm) which functions essentially as a mechanical sieve; when the filter begins to clog (lowering the filtration rate), air is blown upwards through the sand to dislodge particulates – this being followed by water (*back-washing*) to flush away the solids.

A *slow sand filter* is a bed of finer sand, the upper layer supporting a film of microorganisms – including bacteria and protozoa; it acts not only as a mechanical sieve but also (by virtue of the BIOFILM) as a means of mineralizing some of the dissolved organic matter and of removing some nitrogen and phosphorus as biomass. Moreover, a slow sand filter can remove certain taste- and odour-causing substances, and may also reduce the levels of any cyanobacterial toxins that may be present; dangerous levels of such toxins can be formed by BLOOMS of e.g. *Anabaena*, *Aphanizomenon*, *Microcystis*, *Nodularia* and/or *Oscillatoria* which may develop in reservoirs (and other bodies of water) if conditions are suitable. These toxins may cause gastroenteritis, liver disease and other conditions in man and various animals [see e.g. RMM (1994) 5 256–264]. [Ecological and molecular investigations of cyanotoxin production (review): FEMS Ecol. (2001) 35 1–9.]

The biofilm in a slow sand filter operates under *aerobic* conditions – essential e.g. for the activity of the (obligately aerobic) nitrifying bacteria (see NITROBACTERACEAE) which form part of the biofilm. Hence, water entering the slow sand filter must be adequately aerated. Unlike rapid sand filters, a slow sand filter is not back-washed; instead, the uppermost layer is periodically skimmed off (and replaced with new sand to maintain the depth of the filter).

Water leaving a slow sand filter is disinfected before entering the distribution system; disinfection usually involves chlorination and, because the activity of chlorine is affected by pH, the pH of the water may need to be adjusted (chemically).

*Disinfection.* CHLORINE, the common disinfecting agent, is very effective (at suitable concentrations) against vegetative pathogenic bacteria of faecal origin – e.g. *Escherichia coli* and species of *Campylobacter*, *Clostridium*, *Salmonella*, *Shigella* and *Vibrio*; chlorination is therefore an excellent measure against cholera, typhoid and other water-borne diseases.

Because chlorine reacts with impurities in the water, some chlorine is initially lost in satisfying this *chlorine demand*. Addition of further chlorine to the water leaves so-called ‘residual chlorine’ or *free residuals*; free residuals include elemental chlorine, hypochlorous acid (HClO) and ClO<sup>-</sup> ions. The recommended level of free residuals is usually about 0.5–2 parts per million (p.p.m.) (= 0.5–2 mg/litre). Disinfection by chlorine is maximally effective at pH <7 because acidic conditions tend to depress the dissociation of hypochlorous acid.

If water contains ammonia, chlorine combines with it to form *chloramines* (*combined residuals*). Chloramines decompose slowly, releasing chlorine; as disinfectants, they are less effective – but more persistent – than chlorine. Ongoing addition of chlorine raises the concentration of chloramines to a maximum level – which depends on the initial concentration of ammonia. Further chlorine begins to oxidize the chloramines;

## Waterhouse–Friderichsen syndrome

levels of combined residuals therefore begin to fall. On continued addition of chlorine, the combined residuals reach their lowest level (the *breakpoint*), and any further chlorine added will form free residuals in the water. Hence, to achieve free residuals, the amount of chlorine added must be beyond the breakpoint (*breakpoint chlorination*).

*Superchlorination* uses higher concentrations of chlorine in order to eliminate undesirable odours and/or tastes; excess chlorine is later removed by adding sulphur dioxide (*sulphonation*) until the desired level of free residuals is achieved.

(OZONE, compared with chlorine, is a stronger disinfectant, but it lacks residual activity. If ozone is used it is followed by low-level chlorination in order to provide residual disinfection.)

*Testing for free residuals.* With tablets of DPD (*N,N*-diethyl-*p*-phenylenediamine), chlorine levels can be determined by the level of coloration which develops; the intensity of coloration (and, thus, the level of chlorine) is indicated by comparison with a colour chart or ‘comparator’.

*Tests for the efficiency of disinfection.* Certain bacteria, particularly faecal coliforms and ‘faecal streptococci’ (the latter including *Enterococcus faecalis* and related organisms) are used as indicators of faecal pollution; their presence in treated drinking water points to a failure of the treatment process or to contamination subsequent to treatment. Coliforms and ‘faecal streptococci’ are used as indicator organisms because they are common intestinal bacteria; their presence in water points to the potential presence of water-borne faecal pathogens. Usually, pathogens are not tested for directly as they may occur only intermittently; moreover, the indicator bacteria greatly outnumber pathogens (e.g.  $\sim 10^8$  *E. coli* cells per gram faeces), and it is possible to detect very low levels of faecal pollution.

Indicator bacteria are detected/counted by the MULTIPLE-TUBE METHOD and by membrane filtration. In membrane FILTRATION, a known volume of water is filtered through a membrane filter (pore size  $\sim 0.2 \mu\text{m}$ ); the membrane is then incubated, face upwards, on a pad saturated with appropriate growth medium. Indicator bacteria, if present, form colonies on the membrane; this allows enumeration from (i) the number of colonies, and (ii) the volume filtered. Confirmation of *E. coli* (a thermotolerant ‘faecal’ coliform) is obtained by two further tests carried out at  $44^\circ\text{C}/24$  hours: the INDOLE TEST and the EIJKMAN TEST. (The medium used for the Eijkman test includes an agent that inhibits endospore-formers; this is particularly important when testing chlorinated water because spore-formers are more resistant than *E. coli* to chlorine.)

Note that fully treated water may still contain pathogens. For example, certain viruses (e.g. the NORWALK VIRUS [AEM (1985) 50 261–264]) and thick-walled oocysts of CRYPTOSPORIDIUM can survive routine levels of chlorination. (The cysts of *Entamoeba histolytica* may survive chlorination but are likely to be retained by an efficient sand filter.) [Cysts of GIARDIA in raw and chlorinated water in Canada: AEM (1996) 62 47–54.] Studies on the resistance of *Mycobacterium avium* to disinfectants (including chlorine and ozone) have suggested that resistance to these agents may be a factor which promotes persistence of *M. avium* in drinking water [AEM (2000) 66 1702–1705].

*Problems with nitrates, pesticides etc.* Nitrates are common in surface waters and, increasingly, in groundwater; a major source is agricultural fertilizer. The upper limit recommended by the EC is 50 mg of nitrate ion per litre; the USEPA value is 44.29 mg/litre (= 10 mg/l as N). Water containing high levels of nitrate may be blended with low-nitrate waters. Alternatively, water may be stored for long periods to permit DENITRIFICATION. Nitrate can also be removed by ion-exchange.

Pesticides etc. may be removed by adsorption to activated charcoal.

*Problems in the distribution system.* Microbial growth/slime in pipelines may lower water quality and pumping efficiency. This problem has been linked to the presence of organic carbon, but a more stringent removal of phosphorus might offer a cost-effective method for control [Nature (1996) 381 654–655]. [Drinking water biofilms: FEMS Ecol. (1997) 22 265–279.]

**Waterhouse–Friderichsen syndrome** See MENINGITIS.

**watermark disease** A disease of willows (*Salix* spp) caused by *Erwinia salicis*; symptoms: leaves wither and become reddish, a watery liquid is discharged from infected shoots, and the wood is stained brown or black and may be rendered unfit for use as timber.

**watery stipe** (La France disease) A MUSHROOM DISEASE of viral causation. A consistent symptom is cessation of growth leading to a serious reduction in yield. The stipe is often long, slightly bent, and watery, and the cap may be very small and may fail to open. [Review: Book ref. 180, pp. 239–324.]

A disease known as *hard gill* has also been attributed to viral infection.

[Properties of two viruses from *Agaricus brunnescens*: JGV (1979) 42 231–240.]

**Watson–Crick base pair** See BASE PAIR.

**Watson–Crick double helix** See DNA.

**wax caps** See AGARICALES (Hygrophoraceae).

**wax D** A peptidoglycolipid component of the cell wall in *Mycobacterium* spp. Wax D is a branched arabinogalactan which is esterified with MYCOLIC ACIDS and linked, via an acid-labile phosphodiester bridge, to an *N*-glycolylmuramic acid residue in the PEPTIDOGLYCAN. The glycolipid is soluble in chloroform or ether, but not in acetone, and can be hydrolysed by KOH; it appears to be released by autolysis in old cultures. Wax D can replace whole mycobacteria in Freund’s complete adjuvant. (cf. MYCOSIDE C.)

**Wb phage** WEYBRIDGE PHAGE.

**WBC** White blood cell.

**WCVs** See VACCINE.

**weal-and-flare** See WHEAL-AND-FLARE.

**wedeloside** An analogue of ATRACTYLOSIDE which occurs in the Australian weed, *Wedelia asperima*; it inhibits the mitochondrial ADP/ATP carrier system [FEBS (1985) 189 245–249].

**WEE** WESTERN EQUINE ENCEPHALOMYELITIS.

**Weibel–Palade bodies** See VON WILLEBRAND FACTOR.

**Weigle mutagenesis** See WEIGLE REACTIVATION.

**Weigle reactivation** (W-reactivation) A phenomenon in which certain bacteriophages (e.g.  $\lambda$ ) containing UV-damaged DNA show much higher survival rates in host cells which have been irradiated with UV before infection than in non-irradiated host cells. Furthermore, the mutation frequency in the UV-damaged phage is higher when the phage is grown in pre-irradiated host cells (*Weigle mutagenesis*). These observations are at least partly explicable on the basis that irradiation of the host cells induces the SOS SYSTEM which can bring about high levels of repair, including *umuDC*-dependent error-prone repair, of the UV-damaged phage DNA (the damaged phage DNA is apparently not an effective signal for SOS induction in non-irradiated cells). However, W-reactivation depends on UV irradiation of the host cells even when the cells are mutants in which the SOS genes are fully derepressed, implicating the involvement of another factor – possibly the ‘active’ form of the RecA protein [MGG (1985) 201 329–333].

**Weil–Felix test** A serological test which is used for the presumptive diagnosis of certain rickettsial diseases; the test is based on

the fact that antibodies against certain rickettsial antigens can agglutinate cells of *Proteus vulgaris* strains OX19, OX2 and OXK. In the test, a suspension of a given strain of *P. vulgaris* is mixed with the patient's serum, and the tube is subsequently examined for agglutination. OX19 and OX2 generally give positive results in cases of epidemic and murine typhus and spotted fevers, but negative results in cases of scrub typhus, Q fever, rickettsialpox, and (usually) Brill–Zinsser disease. OXK generally gives positive results *only* in cases of scrub typhus.

**Weil's disease** See LEPTOSPIROSIS.

**Wenyonella** See EIMERIORINA.

**Wescodyne** See IODINE (a).

**Wesselsbron virus** See FLAVIVIRIDAE.

**West Nile virus** See FLAVIVIRIDAE.

**Westerfeld modification** See VOGES–PROSKAUER TEST.

**Western blot** See BLOTTING.

**western duck disease** A type of BOTULISM which affects waterfowl that feed on decaying vegetation in shallow, alkaline waters harbouring *C. botulinum* type C<sub>α</sub>. The disease occurs in the western USA, often in extensive epidemics.

**western equine encephalomyelitis** (WEE; western equine encephalitis; western encephalitis) An acute ENCEPHALITIS (or encephalomyelitis) of man and horses, caused by an ALPHAVIRUS. The WEE virus is widely distributed in North America in wild birds and can be transmitted from bird to bird by the mosquitoes *Culex tarsalis* and *Culiseta melanura*; however, WEE occurs chiefly in western regions, reflecting the distribution of *C. tarsalis* (common west of the Mississippi river) which bites mammals as well as birds. (*C. melanura* occurs in remote swamps and feeds primarily on birds.) In horses, WEE may have a high mortality rate. In man, WEE is usually benign but may be fatal; it can cause serious sequelae (e.g. mental impairment, paralysis) in young infants.

**wet bubble** See BUBBLE DISEASES.

**wet mount** (wet preparation) In microscopy: a temporary preparation in which the specimen is present in a thin layer of liquid sandwiched between a SLIDE and COVER-GLASS.

**wet rot** (of timber) A BROWN ROT of softwood and hardwood timbers which have a high moisture content (e.g. 40–60% – see TIMBER SPOILAGE); the common cause is *Coniophora puteana*. Infected timbers usually exhibit a dark, branching, surface mycelium. Wet rot may be controlled by effective ventilation and drying of the timbers. (See also TIMBER PRESERVATION.)

**wettable powder** (wp) A form in which water-insoluble antifungal agents (e.g. CAPTAN) etc may be prepared for agricultural use. The active ingredient, usually mixed with a filler (e.g. fine clay, diatomaceous earth) is finely ground, and a surface-active 'wetter' is added – usually a soluble salt of an organic acid. The filler permits the active ingredient to be ground into fine particles and prevents caking during storage in an aqueous medium; the wetter allows rapid dispersion of the powder in water.

**wetwood** A disease of living trees, common e.g. in elms and cottonwoods, associated with the presence of dense populations of hydrolytic, methanogenic and nitrogen-fixing prokaryotes in moist, alkaline, anaerobic dead xylem tissue. Within a given tree, the disease appears to spread as a result of the degradation of xylem vessel-to-ray pit membranes by pectinolytic bacteria; anaerobic cellulolytic bacteria have also been detected [AEM (1985) 50 807–811]. Holes bored into the trunk of an infected tree yield methane and a fetid liquid. Organisms isolated from wetwood include species of *Bacteriodes*, *Clostridium*, *Erwinia*, *Lactobacillus* and *Propionispira*, and *Methanobrevibacter arboriphilus*. [Microbial populations in wetwood of European white fir (*Abies alba*): FEMS Ecol. (1986) 38 141–150.]

(See also TREE DISEASES.)

**Weybridge phage** (Wb phage) A group 3 *Brucella* phage which can replicate in smooth strains of *B. abortus*, *B. neotomae* and *B. suis*.

**WGA** WHEAT GERM AGGLUTININ.

**Whataroa virus** See ALPHAVIRUS.

**WHBV** See WOODCHUCK HEPATITIS VIRUS.

**wheat-and-flare** A localized oedematous swelling (wheat) and reddening (flare) on the body surface: a manifestation of certain forms of immediate hypersensitivity which is brought about by the release of histamine from degranulated mast cells (see e.g. PRAUSNITZ–KÜSTNER TEST).

**wheat** (nitrogen fixation) See NITROGEN FIXATION.

**wheat chlorotic streak virus** See RHABDOVIRIDAE.

**wheat diseases** See CEREAL DISEASES.

**wheat dwarf virus** See GEMINIVIRUSES.

**wheat germ agglutinin** (WGA) A non-mitogenic LECTIN from wheat, *Triticum vulgare*; it binds to oligosaccharides which contain *N*-acetylglucosamine.

**wheat scab** (*Fusarium* scab; *Fusarium* blight) A disease of wheat caused by *Fusarium graminearum* (see FUSARIUM). Consumption of grain harvested from infected plants ('scabby wheat') is a cause of TRICHOHECENE poisoning.

**wheat soil-borne mosaic virus** *Syn.* SOIL-BORNE WHEAT MOSAIC VIRUS.

**wheat spindle streak mosaic virus** See POTYVIRUSES.

**wheat spindle streak virus** See POTYVIRUSES.

**wheat streak mosaic virus** See POTYVIRUSES.

**wheat streak virus** See POTYVIRUSES.

**wheat striate mosaic virus** See RHABDOVIRIDAE.

**wheat yellow leaf virus** See CLOSTEROVIRUSES.

**wheat yellow mosaic virus** See POTYVIRUSES.

**wey** The liquid by-product of CHEESE-MAKING; it contains ca. 4–5% lactose, 0.8% protein, and 0.2–0.6% lactic acid. It has been intensively investigated as a source of substrates for various commercial microbial products – e.g. INDUSTRIAL ALCOHOL and SINGLE-CELL PROTEIN.

**wey proteins** In MILK: non-CASEIN proteins which are not precipitated under acidic conditions.

**whiplash flagellum** See FLAGELLUM (b).

**Whipple's disease** Intestinal lipodystrophy: in man, a malabsorption syndrome characterized e.g. by diarrhoea, steatorrhoea, lymphadenopathy, CNS involvement, and infiltration of the intestinal mucosa by macrophages containing PAS-positive material. It is linked to a Gram-positive bacterium, *Tropheryma whipplei* (formerly *T. whippelii*) [culture in fibroblasts: NEJM (2000) 342 620–625; genome: Lancet (2003) 361 637–644].

Diagnosis of Whipple's disease has been based primarily on histology [VA (1996) 429 335–343] with PCR-based confirmation using e.g. duodenal tissue or cerebrospinal fluid (CSF) [diagnosis and treatment: Drugs (1998) 55 699–704]. PCR-positive tests for *T. whipplei* in patients with no clinical signs of Whipple's disease suggest that diagnosis of this disease should not be based solely on the results of PCR-based tests [Lancet (1999) 353 2214].

*Treatment* (e.g.): parenteral penicillin + streptomycin for 2 weeks, or (long-term) trimethoprim–sulphamethoxazole.

[Whipple's disease (review): Lancet (2003) 361 239–246.]

**whirling disease** A FISH DISEASE which affects salmonid fish; it is caused by a protozoan (see below). The pathogen causes little harm to the European brown trout (*Salmo trutta*), apparently its original host, but in the rainbow trout (*S. gairdneri*) it causes a severe infection, migrating to and developing in cartilaginous

## whisky

tissue and causing cartilage destruction and skeletal deformities; affected fish commonly swim with a whirling, 'tail-chasing' motion.

The causal agent of whirling disease is *Myxosoma cerebralis* (class Myxosporidia). However, the spores released from an infected fish cannot infect another fish, but can infect certain tubificid oligochaete worms; an infected worm in turn produces a distinct stage of the pathogen – a stage previously regarded as belonging to the genus *Triactinomyxon*, class Actinosporidia (see MYXOZOA). The '*Triactinomyxon*' stage cannot reinfect other worms but can infect salmonid fish, thus completing the life cycle. [Science (1984) 225 1449–1452.]

**whisky** (whiskey) See SPIRITS.

**white blister disease** See ALBUGO.

**white clover mosaic virus** See POTEXVIRUSES.

**white fluids** Commercial disinfectants consisting of oil-in-water emulsions of certain phenolic coal tar fractions; emulsifying agents used include e.g. animal glue, casein. White fluids are more stable than BLACK FLUIDS in the presence of electrolyte.

**white membrane** See PURPLE MEMBRANE.

**white piedra** A chronic human MYCOSIS in which hair of the scalp, beard and/or pubic region is infected by *Trichosporon beigeli* (= *T. cutaneum*). Soft, gelatinous, white or fawn nodules, composed of a dense mycelial network, adhere to infected hairs; the hair shaft may be penetrated and may break in the vicinity of the nodule, but skin is not infected. (cf. BLACK PIEDRA.)

**white pine blister rust** *Syn.* BLISTER RUST.

**white precipitate** See MERCURY.

**white rot** (1) (of timber) A form of fungal TIMBER SPOILAGE in which the CELLULOSE, HEMICELLULOSES and LIGNIN are decomposed, leaving the wood soft, whitish and fibrous. The hyphae of at least some white-rot fungi (e.g. *Coriolus versicolor*, *Phanerochaete chrysosporium*) penetrate the wood cell lumen and lie in contact with the inner surface of the cell wall; degradation of the wall then occurs in the vicinity of the hypha, often resulting in the formation of a trough with a central ridge upon which the hypha rests. The enzymes (see CELLULASES) appear to be retained in a mucilaginous sheath surrounding the hyphae. [Book ref. 39, pp. 59–61; microstructural changes in wood due to white rot basidiomycetes: CJB (1986) 64 905–911.] (cf. BROWN ROT; POCKET ROT.)

(2) (of onions) See ONION ROT.

**white rust** (1) See ALBUGO. (2) See CHRYSANTHEMUM WHITE RUST.

**white scours** Scouring in young calves caused by strains of *Escherichia coli*. (cf. CALF SCOURS.)

**white smoker** See HYDROTHERMAL VENT.

**white spot** May refer to ICHTHYOPHTHRIASIS or to a similar disease of marine fish caused by the ciliate *Cryptocaryon irritans*.

**whitehead** (1) (*plant pathol.*) The dead and bleached upper part of a plant; in cereals: a white, narrow ear which is empty or contains only shrivelled grains. Whiteheads are formed as a result of certain diseases. (cf. SILVER-TOP.)

(2) (*med.*) See e.g. ACNE.

**whitlow** (felon) (1) *Syn.* PARONYCHIA. (2) An abscess affecting the pulp of a fingertip.

**WHO plate** A rectangular block of plastic (e.g. 18 × 15 × 1.5 cm), one face of which bears a number of rows of indentations (wells) – each well being approximately semicircular in (vertical) cross-section and having a capacity of e.g. 1.5 ml. WHO plates are used e.g. in various quantitative serological procedures which involve the preparation of serial dilutions of serum etc.

**whole mount** Any specimen mounted whole on a SLIDE for microscopical examination.

**whooping cough** (pertussis) An acute infectious disease which affects mainly children; it may be caused by *Bordetella pertussis* or *B. parapertussis* – the latter pathogen commonly (though not invariably) causing a less severe form of the disease ('parapertussis'). (*B. bronchiseptica* causes disease in dogs and other animals, and may also cause respiratory disease in humans, particularly the immunocompromised.)

Infection occurs by droplet inhalation. The incubation period is ~7–10 days. Early symptoms may resemble those of a common cold. The characteristic paroxysmal stage occurs ~7–14 days later; this involves paroxysms of coughing, each ending in a prolonged, audible inspiratory effort (the 'whoop') as air is forcibly drawn through the narrowed glottis. The whoop is often followed by vomiting. (In infants, the whoop may be replaced by cyanosis.) Complications include e.g. secondary infections (otitis media, pneumonia etc.) and CNS involvement (e.g. ENCEPHALITIS). The disease may be fatal, especially in infants. Recovery is usually followed by long-term immunity.

*Pathogenesis.* The pathogen does not invade respiratory epithelium. It adheres to the mucosa; adhesion to ciliated epithelium is apparently mediated primarily by (i) the pathogen's (non-fimbrial) *filamentous haemagglutinin* (FHA), and (ii) certain B subunits of PERTUSSIS TOXIN. Pathogenesis apparently involves the combined effects of several toxins: PERTUSSIS TOXIN, CYCLOLYSIN, TRACHEAL CYTOTOXIN (cf. DERMONECROTIC TOXIN).

*Lab. diagnosis.* In preference to the earlier COUGH PLATE method, a pernasal swab is (i) plated on either BORDET-GENGOU AGAR or CHARCOAL BLOOD AGAR, and (ii) used to prepare a smear for detecting the pathogen by an IMMUNOFLOUORESCENCE test. (Improved isolation of *B. parapertussis* has been reported on Moredun medium [JCM (1996) 34 638–640].) For serology, emulsified growth from several colonies is examined with specific antisera in a SLIDE AGGLUTINATION TEST.

A nested duplex PCR is able simultaneously to detect both *B. pertussis* and *B. parapertussis* [JCM (1999) 37 606–610].

*Chemotherapy.* Antibiotics do not alter the clinical course once the paroxysmal stage has begun; erythromycin may reduce disease severity if given before this stage (and may reduce infectivity).

*Vaccines.* Whole-cell VACCINES (WCVs) do not confer complete immunity to pertussis, and have been associated with side-effects. Acellular pertussis vaccines (ACVs) are reported to have fewer side-effects but may give less protection against disease caused by *B. parapertussis* [RMM (1996) 7 13–21].

**WHV** WOODCHUCK HEPATITIS VIRUS.

**WI-38** (Wistar Institute 38) A diploid cell line derived from female embryonic lung tissue.

**Wickerhamia** A genus of yeasts (family SACCHAROMYCETACEAE). Cells: oval to elongate or lemon-shaped, occurring singly, in pairs, or in very short chains; vegetative reproduction occurs by bipolar budding. Ascus formation is not preceded by conjugation. Ascospores: sporting-cap-shaped, usually 1–2 per ascus. Glucose and other sugars are fermented; NO<sub>3</sub><sup>-</sup> is not assimilated. One species: *W. fluorescens* (formerly *Kloeckera fluorescens*); only one strain has been isolated (from dung of a wild squirrel in Japan). [Book ref. 100, pp. 440–442.]

**Wickerhamiella** A genus of yeasts (family SACCHAROMYCETACEAE). Cells: spheroidal, ovoid or ellipsoidal; vegetative reproduction occurs by multilateral budding. Pseudomycelium is not formed. Ascus formation is preceded by conjugation. Ascospores: oblong with obtuse ends, minutely rugose (appearing smooth by light microscopy). Non-fermentative; NO<sub>3</sub><sup>-</sup> is

assimilated. One species: *W. domercqii* (anamorph: *Candida domercqii*), isolated e.g. from a wine vat and from effluent from a cane-sugar factory. [Book ref. 100, pp. 443–445.]

**Widal test** An AGGLUTINATION TEST used for detecting serum antibodies to salmonellae which cause human ENTERIC FEVERS (including TYPHOID FEVER). Serial dilutions of serum are tested for the presence of agglutinins to the O and H antigens of these salmonellae – suspensions of (killed) bacteria of each species or serotype being used as the test antigens. A rising titre in paired sera is indicative of infection. (Anti-H, but not anti-O, agglutinins may persist for years after infection.)

**wide groove** *Syn.* major groove (see DNA).

**WIGA bacterium** *Legionella bozemanii*.

**Wigglesworthia** A genus of endosymbiotic, Gram-negative bacteria of the family Enterobacteriaceae which occur within BACTERIOCYTES in the anterior midgut of the tsetse fly (GLOSSINA). (See also SODALIS and WOLBACHIA.)

**wild type** Refers to a given strain of organism – or to a genotypic or phenotypic trait in a given organism – which is characteristic of the majority of naturally occurring members of its kind, i.e., a *non-mutant* strain or trait.

**wildfire disease** (of tobacco) A disease of the tobacco plant that involves severe chlorosis of the leaves; symptoms are caused by a toxin, TABTOXIN, secreted by the pathogen, *Pseudomonas syringae* pv. *tabaci*. (See also TOBACCO DISEASES.)

**Wilson and Blair's agar** (bismuth sulphite agar) A medium containing peptone, beef extract, glucose, disodium phosphate, ferrous sulphate, brilliant green, bismuth sulphite (as indicator) and agar [recipe: Book ref. 53, p. 1393]. The medium is used for the primary isolation of *Salmonella* strains (e.g. from faeces); typically, coliforms and some strains of *Shigella* are inhibited. Isolated colonies of *Salmonella* are black, but heavy or confluent growth may not exhibit blackening.

**wilt** (1) (*plant pathol.*) A disease (or symptom) characterized by a loss of turgidity in a plant: see e.g. VASCULAR WILT. (2) (*entomopathol.*) Any viral INSECT DISEASE.

**Wimmera grass poisoning** Poisoning of sheep and cattle following consumption of e.g. Wimmera ryegrass (*Lolium rigidum*) bearing galls (which resemble ergot sclerotia) induced by larvae of the nematode *Anguina lolii*; it appears that galls responsible for the poisoning contain a yellow-pigmented *Corynebacterium* sp [Australian Vet. J. (1976) 52 242, cited in Book ref. 33, pp. 1168–1169]. Symptoms: ataxia, convulsions, sometimes with haemorrhages and abortion; the toxicosis is an important cause of death among livestock in western Australia.

**window-phase blood** See TRANSFUSION-TRANSMITTED INFECTION.

**wine-making** Wine is made by the ALCOHOLIC FERMENTATION of grapes or grape-juice by special strains of yeast – usually strains of *Saccharomyces cerevisiae* var. *ellipsoideus* ('*S. ellipsoideus*'). Grapes contain ca. 10–25% fermentable sugars (mainly glucose and fructose) together with organic acids (mainly tartaric and malic) and small amounts of nitrogenous compounds (e.g. amino acids), tannins, pigments, vitamins, minerals etc. The grapes are crushed and SULPHUR DIOXIDE is added to inhibit 'wild' yeasts and bacteria (wine yeasts are relatively resistant to SO<sub>2</sub>). For white wines either black or white grapes may be used, the juice being extracted from the pulp by pressing before fermentation. For red wines black grapes are used, and pressing does not occur until after fermentation; during fermentation anthocyanin pigments are leached from the grape skins by the alcohol. Rosé wines may be made from black grapes (the skins being removed before all the pigment has been extracted), from less strongly pigmented grapes, or by blending red and white wines.

Before the grape-juice/pulp (*must*) is inoculated with the yeast, its composition may be adjusted e.g. by the addition of sugar, water, and/or traces of ammonium salts (to stimulate fermentation). Some musts may be excessively acidic. Levels of L-malic acid may be reduced either by the bacterial MALOLACTIC FERMENTATION or by the fermentation of malic acid to ethanol and CO<sub>2</sub> by species of *Schizosaccharomyces*; either fermentation may occur during or after the alcoholic fermentation. (Acidity may also be reduced by adding CaCO<sub>3</sub>.) Alcoholic fermentation of the must is generally initiated by the addition of a starter culture of wine yeast (pre-grown e.g. in sterile grape-juice). The fermentation temperature is important; it affects the flavour of the finished product – lower temperatures favouring the formation of aromatic compounds (and hence bouquet) – and also the time necessary for fermentation to be completed (several days or longer). For white wines the starting temperature is ca. 7–16°C, rising to 20–23°C; red wines are fermented at e.g. 21–27°C. (Since fermentation generates heat, cooling is necessary.)

Fermentation is complete when all the fermentable sugars have been used or when the level of alcohol is high enough to inhibit further yeast action. Particulate matter is allowed to settle and the wine is drawn off as early as possible after fermentation to avoid the effects of yeast autolysis; autolysis can cause off-flavours, and the amino acids, vitamins etc released can encourage the growth of spoilage bacteria. (However, if a malolactic fermentation is required, some yeast autolysis may be desirable to encourage growth of the fastidious malolactic bacteria.) The wine is then clarified e.g. by centrifugation and/or 'fining' (e.g. by the addition of the adsorbent bentonite) and/or filtration; lower quality wines may be pasteurized. Finally, the wine is allowed to age (for several months or more) either in the bottle or in oak casks prior to bottling.

*Table wines* have an alcohol content of ca. 9–14% by volume and may be *dry* (i.e. with little or no remaining sugar) or *sweet*. Sweet wines may be made from musts with a high sugar content (see e.g. NOBLE ROT), fermentation being stopped (e.g. by chilling) before all the sugar has been used; alternatively, fermentation may be stopped by fortification (see below). *Sparkling wines* (e.g. champagne) contain CO<sub>2</sub> under pressure (ca. 2–5 atmospheres); cheaper wines may be carbonated directly, but quality wines undergo a secondary fermentation of added sugar either in the bottle or in large closed tanks prior to bottling under pressure.

*Fortified wines* (e.g. port, sherry) are made by adding wine spirit (brandy) to the primary fermentation at a stage determined by the level of sugar required in the finished product. The alcohol content of a fortified wine is usually ca. 16–20%. *Flor sherries* (e.g. Spanish fino sherries) are made by a more complex process. The primary fermentation resembles that for other wines and is carried out to completion; the required final alcohol content is ca. 15%. A secondary 'flor fermentation' (FERMENTATION sense 2) is then carried out in oak barrels and requires the presence of air. A thick film of special 'flor' yeasts (including various species and strains of *Saccharomyces*) forms on the surface of the wine; these yeasts slowly oxidize a small proportion of the ethanol to acetaldehyde which, together with acetal (a product of its reaction with ethanol), is an important flavour component. Completion of the traditional surface flor fermentation takes one to several years; however, more rapid methods have been developed in which the flor yeast is submerged in the wine in pressure tanks. Finally the sherry is fortified to the required alcohol content before bottling.

## wine spoilage

[Selection and modification of microorganisms used in wine-making: Food Mic. (1984) 1 315–332.]

(See also PULQUE, SAKE; cf. BREWING, CIDER, SPIRITS.)

**wine spoilage** Microbial spoilage of wines may be due to various yeasts (e.g. species of *Saccharomyces*, *Pichia*, *Brettanomyces*) which may cause turbidity and off-flavours; off-flavours may also result from autolysis of the wine yeast itself (see WINE-MAKING) and from the reduction during fermentation of elemental sulphur (sprayed onto the grapes as a fungicide) to H<sub>2</sub>S. Spoilage bacteria include e.g. *Acetobacter* spp (which may cause ACETIFICATION) and lactobacilli (which may cause off-flavours due e.g. to the production of DIACETYL from citric acid); *Leuconostoc mesenteroides* may cause ROPINESS if enough sugar is present for dextran formation. The MALOLACTIC FERMENTATION may be regarded as spoilage in wines already low in acid.

**Wingea** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are spheroidal to ellipsoidal; vegetative reproduction occurs by multilateral budding. Pseudomycelium is not formed. Prior to ascus formation, cells with ‘copulatory’ protuberances are formed; asci (which are persistent) develop from these cells either directly or following fusion between two cells via their protuberances. Ascospores: lentiform, light brown, smooth, 1–4 per ascus. Glucose, sucrose, maltose and raffinose are fermented; NO<sub>3</sub><sup>-</sup> is not assimilated. One species: *W. robertsii*, isolated e.g. from soil. [Book ref. 100, pp. 446–448.]

**winter coccidiosis** See COCCIDIOSIS (b).

**winter dysentery** (*syn.* black scours) An acute, sometimes fatal disease of (primarily) adult (and particularly housed) cattle; symptoms: fever and dark, watery diarrhoea, or sometimes DYSENTERY. Aetiology is uncertain: strains of *Campylobacter* may be the primary cause or may play a secondary role to a viral agent. Infection occurs via faecally-contaminated feed or water. A carrier state occurs.

**winter mushroom** *Syn.* ENOKITAKE.

**winter spore** (*mycol.*) *Syn.* RESTING SPORE.

**winter vomiting disease** See FOOD POISONING (i).

**Winterbottom’s sign** Following infection from a bite on the head by a tsetse fly carrying the causal agent of SLEEPING SICKNESS: enlargement of the post-auricular or occipital lymph nodes.

**wire stem** See DAMPING OFF.

**Wisconsin mastitis test** See CALIFORNIA MASTITIS TEST.

**Wiskott–Aldrich syndrome** A primary immunodeficiency which affects young children and which is characterized e.g. by susceptibility to recurrent bacterial infections (meningitis, otitis media etc.). Mutation in the WASP gene has been found in cases of Wiskott–Aldrich syndrome, although mutant forms of this gene are also associated with e.g. X-linked thrombocytopenia.

[Primary immunodeficiency diseases: Lancet (2001) 357 1863–1869.]

**WISH** An ESTABLISHED CELL LINE derived from human amnion; the cells are heteroploid and epithelioid.

**witches’ broom** An abnormal form of plant growth, most common in woody plants, in which there is a profuse outgrowth of lateral buds to give a ‘witches’ broom’ appearance; the shoots may be thickened and may bear abnormal leaves. Witches’ brooms may result from infection by various microorganisms – e.g. *Taphrina* spp (e.g. *T. deformans* in the hairy birch, *Betula pubescens*, and *T. turgida* in the silver birch, *B. pendula*), *Crimipellis perniciosus* in cacao plants, and various rust fungi. Many of these organisms produce auxins in vitro, but the mechanism of witches’ broom formation in vivo remains unclear.

**witches’ butter** See TREMELLALES.

**WL 28325** A fungicide (2,2-dichloro-3,3-dimethyl-cyclopropane carboxylic acid) which causes an increase in the amount of MOMILACTONE produced by rice plants infected with *Pyricularia oryzae*.

**wobble hypothesis** A hypothesis originally proposed by Crick [JMB (1966) 19 548–555] to account for the observed pattern of degeneracy in the 3rd base of a codon (see GENETIC CODE), i.e., it explains how certain tRNAs can recognize more than one codon when the codons differ only in the 3rd position (the base at the 3’ end). According to this hypothesis, normal base-pairing can occur between bases in positions 1 and 2 of the codon and their complementary bases (3rd and 2nd, respectively) in the anticodon; however the base in the 1st position of the anticodon (the ‘wobble position’) can undergo non-Watson–Crick base-pairing with the corresponding (3rd) base in the codon: G in the wobble position can pair with either C or U in the 3rd position of the codon, and similarly U can pair with either A or G. These recognition patterns can be affected by modification of the bases in the anticodon. For example, A seems never to occur in the wobble position in an anticodon, being always modified (by deamination) to inosine (I) in this position; I can pair with A, C or U. Similarly, unmodified U rarely occurs in the wobble position; 2-thiouridine in this position can pair with A but does not allow ‘wobble pairing’ with G. (See also QUEUOSINE.)

The wobble hypothesis is applicable to most, but not all, tRNAs; the decoding potential of a tRNA may be influenced e.g. by the conformation of its anticodon arm. (See also SUPPRESSOR MUTATION.)

**Wolbachia** A genus of Gram-negative bacteria of the tribe WOLBACHIEAE; the organisms grow intra- or extracellularly in various invertebrate hosts but are apparently not overtly pathogenic. The cells are coccoid or rod-shaped, morphologically similar to those of e.g. *Rickettsia*.

*W. melophagi* grows in the gut lumen of e.g. sheep keds (*Melophagus ovinus*) and in certain flies.

*W. persica* grows e.g. in ticks of the genera *Argas*, *Dermacentor* and *Rhipicephalus*.

*W. pipiens* grows in certain mosquitoes and in the almond moth.

Strains of *Wolbachia* also occur in reproductive tissues of the tsetse fly (GLOSSINA). (See also SODALIS and WIGGLESWORTHIA.)

Certain strains of *Wolbachia* have been found as obligate endosymbionts in the filarial nematode *Onchocerca volvulus*; *O. volvulus* causes human onchocerciasis – one manifestation of which is the disease known as *river blindness*. Onchocerciasis is transmitted to man via a blood-sucking insect (black fly). The adult forms of *O. volvulus* are characteristically found in subcutaneous tissues, where they give rise to nodular lesions, while the (juvenile) microfilariae (which are approx. 300 × 8 μm) may be isolated from the skin or bloodstream (those in the bloodstream potentially localizing in the eyes and causing river blindness).

Treatment of onchocerciasis with ivermectin, while effective against juvenile forms, does not affect the adult stage. However, treatment with a tetracycline (doxycycline) has been found to deplete the *Wolbachia* endosymbiont, causing long-term sterility in the nematode and inhibition of the worm’s development and viability; a potential advantage of this treatment is interruption of the transmission of *O. volvulus*.

[Endosymbiotic bacteria in worms as targets for a novel chemotherapy in filariasis: Lancet (2000) 355 1242–1243. Depletion of *Wolbachia* endobacteria in *Onchocerca volvulus*

by doxycycline: Lancet (2001) 357 1415–1416. Comment: TIP (2001) 17 358. Onchocerciasis: BMJ (2003) 326 207–210.]

**Wolbachiae** A tribe of bacteria of the family RICKETTSIACEAE; species are parasites or pathogens in invertebrate hosts. The genera: RICKETTSIELLA; WOLBACHIA. [Book ref. 22, pp. 711–717.]

**Wolhynian fever** *Syn.* TRENCH FEVER.

**Wolinella** A genus of oxidase-positive, Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN and in the human gingival crevice, and which have been isolated from dental root canal infections. Cells: straight, curved or helical rods, 0.5–1.0 × 2.0–6.0 μm; monotrichously (polarly) flagellated. Energy is obtained by the anaerobic oxidation of formate and/or H<sub>2</sub> using e.g. fumarate as electron acceptor (see FUMARATE RESPIRATION); fumarate reductase, which appears to receive electrons from a menaquinone via a *b*-type cytochrome, catalyses the reduction of fumarate to succinate. L-Aspartate, L-malate or nitrate may be used instead of fumarate – although in at least some cases succinate must be supplied if nitrate is used as electron acceptor. Carbohydrates are not utilized. The organisms grow e.g. in complex or synthetic media supplemented with haemin, sodium formate and sodium fumarate. GC%: ca. 42–48. Type species: *W. succinogenes* (formerly *Vibrio succinogenes*). Other species: *W. curva* [a species of human origin: IJSB (1984) 34 275–282], and *W. recta* (predominantly straight rods).

**Woloszynskia** See DINOFLAGELLATES.

**wood blewit** See BLEWIT.

**wood-boring beetles** See SCOLYTIDAE.

**wood mushroom** See AGARICUS.

**wood pulp spoilage** See PAPER SPOILAGE.

**wood spoilage** See TIMBER SPOILAGE.

**wood sugar** XYLOSE.

**Wood–Werkman reaction** (1) The carboxylation of pyruvate to yield oxaloacetate [see Appendix II(b)]. (2) Any carboxylation reaction which yields oxaloacetate, e.g., carboxylation of phosphoenolpyruvate [see Appendix II(b)].

**woodchuck hepatitis virus** (WHV; woodchuck hepatitis B virus, WHBV) A virus of the HEPADNAVIRIDAE which infects woodchucks (*Marmota monax*) and which closely resembles the human HEPATITIS B VIRUS (HBV); like HBV, WHV can cause chronic liver disease and hepatocellular carcinoma (HCC) in its host, HCC developing after ca. 2–4 years in up to 90% of chronically infected woodchucks. The chromosomes of HCC tumour cells contain integrated, extensively rearranged WHV DNA sequences (cf. HEPATITIS B VIRUS).

**wooden tongue** See ACTINOBACILLOSIS.

**Woodruffia** See COLPODIDA.

**Wood's lamp** (Wood's light) A lamp in which ultraviolet radiation (emitted from a mercury vapour source) is transmitted through a nickel oxide-containing soda-glass filter (Wood's filter) that allows passage of radiation of wavelength ca. 365 nm only. The lamp is used e.g. in the diagnosis of certain infectious diseases (see e.g. ERYTHRASMA and RINGWORM) and for detecting porphyrins (see PORPHYRIN TEST) or other fluorescent materials.

**woodwasp fungi** Fungi (usually species of *Amylostereum*, *Daedalea* or *Stereum*) which line the tunnels of the wood-boring larvae of woodwasps (Siricidae and Xiphydriidae). Adult wasps harbour fungal oidia in a pair of pouches (mycetangia, mycangia) at the base of the ovipositor; during egg-laying, fungal oidia are deposited with the eggs. The fungi degrade many of the components of wood (including cellulose and lignin). The wasp larvae feed on fungal and fungal mycelium. Siricid larvae, at least, require fungal enzymes (cellulases, xylanases etc) for

the digestion of wood components, and they acquire these enzymes by ingestion of the fungal mycelium [Book ref. 77, pp. 161–163]. (See also AMBROSIA FUNGI and INSECT–MICROBE ASSOCIATION.)

**wool spoilage** Raw wool is relatively resistant to microbial attack owing to its content of antimicrobial fatty acids. However, woollen textiles – especially when kept under humid conditions – are susceptible to attack by various bacteria (including actinomycetes) and fungi (e.g. *Microsporum* and *Trichophyton* spp) which may cause loss of strength of the wool fibres, discolouration (e.g. due to pigment production), odour production, etc. Preservatives for woollen goods may include e.g. phenolics (e.g. pentachlorophenyl laurate, *o*-phenylphenol), salicylanilide, sodium fluorosilicate. (See also TEXTILE SPOILAGE.)

**woolly monkey sarcoma virus** *Syn.* SIMIAN SARCOMA VIRUS.

**woolsorters' disease** Pulmonary ANTHRAX.

**working distance** In MICROSCOPY: the distance between the specimen (or upper surface of the cover-glass, when present) and the nearest face of the objective lens when the specimen is sharply in focus.

**Woronin bodies** In certain mycelial fungi: spheroidal, refractile and electron-dense, membrane-limited bodies (ca. 0.2 μm) located in the cytoplasm – commonly around septal pores; they may act as plugs, sealing the pores e.g. following hyphal damage. [Review: FEMS Reviews (1987) 46 1–11.]

**Woronin granules** *Syn.* WORONIN BODIES.

**Woronina** See PLASMIDIOPHOROMYCETES.

**wort** See BREWING.

**wound botulism** See BOTULISM (a).

**wound tumour virus** (WTV; clover wound tumour virus) A virus of the genus PHYTOREOVIRUS. WTV was originally isolated from the leafhopper *Agalliopsis novella*, but has never again been isolated from a natural source; the natural plant hosts (if any) are therefore unknown. Experimentally, WTV can infect a wide range of dicotyledonous plants; infection spreads systemically, and tumours are produced irregularly – mainly on the veins of leaves and stems and on the roots. (In e.g. *Melilotus alba* (sweet clover) and *M. officinalis* the number of tumours can be greatly increased by artificial wounding.) The virus also replicates in the insect vector. Prolonged culture of WTV in plant cells tends to result in a reduction in or loss of WTV's ability to infect insects, and vice versa; this is due to the deletion of one or more dsRNA segments or parts of segments. Such mutants are termed *subvectorial* and *exvectorial* according to whether the loss of ability to infect insect vectors is partial or complete, respectively. [Molecular biology: AVR (1984) 29 57–93.]

**wp** WETTABLE POWDER.

**Wr** Writhe: see DNA.

**WR** WASSERMANN REACTION.

**WR238605** See MALARIA.

**Wright's stain** See ROMANOWSKY STAINS.

**writhe** (of supercoiled DNA) See DNA.

**wyerol** See WYERONE.

**wyerone** A furanoacetylene PHYTOALEXIN produced by the broad bean (*Vicia faba*); other furanoacetylene phytoalexins produced by *Vicia faba* include wyerone acid, wyerone epoxide, wyerol, dihydrowyerone, dihydrowyerone acid, and dihydrowyerol. Wyerone and its derivatives can be metabolized to less fungitoxic compounds e.g. by *Botrytis fabae* (causal agent of CHOCOLATE SPOT). (cf. MEDICARPIN.)

**wyosine** See Y BASES.

# X

**X adhesin** An ADHESIN, distinct from both mannose-sensitive adhesins and P fimbriae, which occurs on a proportion of pyelonephritic strains of *Escherichia coli*; some of these 'X-specific' strains of *E. coli* bind specifically to neuraminyl  $\alpha$ -(2  $\rightarrow$  3)-galactosides [BBRC (1983) 111 456–461].

**X-bacteria** Gram-negative endosymbiotic bacteria which occur in the cytoplasm of certain strains of *Amoeba proteus*; they do not confer a killer characteristic. Amoebae may be dependent on their endosymbionts. X-bacteria are sensitive to e.g. chloramphenicol, and are killed at temperatures above ca. 26°C. [Book ref. 22, p. 799.]

**X-band** (in ESR) See ELECTRON SPIN RESONANCE.

**X body** (virol.) Syn. VIROPLASM.

**X factor** A growth factor required for aerobic growth by certain *Haemophilus* spp; the requirement is usually satisfied by haemin or by protoporphyrin IX (essential for the synthesis of e.g. CYTOCHROMES and CATALASE). Some strains (e.g. of *H. aegyptius*) lack ferrochelatase and thus cannot insert iron into protoporphyrin IX; these strains therefore require haemin. 'X factor' is available in media containing lysed RBCs (e.g. chocolate agar). (See also PORPHYRIN TEST.)

**X-gal** See XGAL.

**X-linked lymphoproliferative syndrome** See XLP SYNDROME.

**X-Press** An apparatus for CELL DISRUPTION similar in principle to the HUGHES PRESS.

**X-ray spectrochemical analysis** A method used e.g. to determine the *in vivo* location of certain types of atom within a specimen. When the electron beam irradiates a specimen, atoms of a given element give rise to a characteristic X-ray emission spectrum; the specimen, as a whole, also responds with a non-specific background continuum radiation of X-rays (*Bremsstrahlung*). The emitted X-rays are analysed (in terms of either energy or wavelength) and their source(s) within the specimen can be mapped with an accuracy which depends e.g. on the diameter and energy of the electron beam and on the thickness of the specimen.

**X-rays** See IONIZING RADIATION.

**xanthan gum** An extracellular heteropolysaccharide produced by strains of *Xanthomonas campestris*. It consists of a linear backbone chain of (1  $\rightarrow$  4)-linked  $\beta$ -D-glucosyl residues in which alternate residues are substituted at the O-3 position with a trisaccharide side-chain (D-mannose – D-glucuronic acid – D-mannose); typically, at least some of the proximal mannosyl residues are acetylated, and ca. 50% of the terminal mannosyl residues bear a pyruvic acid acetal group bridging the O-4 and O-6 positions. (Structural details differ in gums from different strains of *X. campestris*.)

Xanthan gum has many commercial applications: e.g. in the food industry it is used as a gelling agent, gel stabilizer, thickener, and crystallization inhibitor in various foods; it is generally resistant to microbial degradation and is stable at temperatures up to ca. 120°C. In nature, xanthan gum may mediate adhesion of *X. campestris* to its plant host. (See also CAPSULE.)

**Xanthidium** A genus of placoderm DESMIDS; the cells resemble those of COSMARIUM except in that they bear conspicuous spines.

**Xanthobacter** A genus (*incertae sedis*) of aerobic, catalase-positive, Gram type-negative bacteria which occur e.g. in soil and water. Cells: straight or curved, pleomorphic, non-motile or

peritrichously flagellated rods (0.4–1.0  $\times$  0.8–6.0  $\mu$ m), cocci, or filaments – cell shape depending primarily on the carbon source used for growth. The cells give a positive or variable reaction in the Gram stain, but have Gram-negative type cell walls which contain LPS, *meso*-DAP-linked peptidoglycan, and a water-insoluble yellow carotenoid pigment (zeaxanthin dirhamnoside). An  $\alpha$ -polyglutamine capsule is formed during chemoorganotrophic growth; the  $\alpha$ -polyglutamine can apparently be used by the cells e.g. under conditions of nitrogen limitation. Large amounts of polysaccharide slime are also produced during growth on e.g. lactate or carbohydrates. Metabolism is respiratory (oxidative), with oxygen as terminal electron acceptor. NITROGEN FIXATION occurs (usually only under microaerobic conditions). All strains can grow as chemolithoautotrophs with mineral salts and a mixture of H<sub>2</sub>, O<sub>2</sub> and CO<sub>2</sub>, or as chemoorganotrophs using e.g. methanol (see METHYLOTROPHY), ethanol, *n*-propanol, or some organic acids; some strains can use certain carbohydrates (e.g. fructose and/or sucrose). Carbohydrates and gluconate are metabolized via the ENTNER–DOUDOROFF PATHWAY and the HEXOSE MONOPHOSPHATE PATHWAY; CO<sub>2</sub> is assimilated via the CALVIN CYCLE. Optimum growth temperature: 25–30°C; optimum pH: 5.8–9.0. GC%: 66–68. Type species: *X. autotrophicus* (formerly known as *Corynebacterium autotrophicum*); other species: *X. flavus* (formerly known as *Mycobacterium flavum*). [Book ref. 22, pp. 325–333.]

**xanthochroic** (*mycol.*) Refers to a hymenomycete basidiocarp in which the context is yellowish brown but becomes dark brown or olive-brown with KOH (10% aqueous).

**xanthomegnin** A naphthoquinone pigment and hepatotoxic MYCOTOXIN produced e.g. by species of *Aspergillus*, *Penicillium* and *Trichophyton*. It gives rise to an electron transport shunt from NADH dehydrogenase to cytochrome *c* in the mitochondrial ELECTRON TRANSPORT CHAIN.

**xanthomonadins** Water-insoluble pigments which occur in *Xanthomonas* spp; they were once thought to be carotenoids but are now known to be brominated aryl polyenes.

**Xanthomonas** A genus of Gram-negative, obligately aerobic, chemoorganotrophic, plant-pathogenic bacteria within the family PSEUDOMONADACEAE. The cells are straight, monotrichously (polarly) flagellated rods, usually 0.4–0.7  $\times$  0.7–1.8  $\mu$ m; most strains contain water-insoluble, yellow (non-carotenoid) pigment(s) (see e.g. XANTHOMONADINS) and some strains form extracellular ('capsular') polysaccharides (see e.g. XANTHAN GUM). Growth requirements typically include factors such as glutamic acid and methionine. In pathovars of *X. campestris* (the only strains investigated) glucose is metabolized mainly via the ENTNER–DOUDOROFF PATHWAY and to a lesser extent via the HEXOSE MONOPHOSPHATE PATHWAY; the TCA CYCLE and the glyoxylate cycle are reported to be present. Degradative enzymes produced by *Xanthomonas* spp may include e.g. carboxymethylCELLULASES, mannanases, PECTIC ENZYMES (e.g. endopectate lyase, pectin methylesterase) and XYLANASES. No species can carry out nitrate respiration (cf. *Pseudomonas*). Growth in some strains may be slow, visible colonies being formed only after a week or more; young colonies are typically round, smooth, entire and butyrous. Optimum growth temperature: usually 25–30°C. Growth is inhibited by 0.1% triphenylTETRAZOLIUM chloride. Catalase +ve; oxidase –ve or weakly +ve. GC%: 63–71. Type species: *X. campestris*.

*X. albilineans*. Hosts: certain species of the Gramineae. The causal agent of leaf scald of sugar cane. Growth is non-mucoid on nutrient agar containing 5% glucose. NaCl tolerance is low (0.5%).

*X. ampelina*. The causal agent of bacterial blight and canker of the grape vine (*Vitis vinifera*). Growth is non-mucoid on nutrient agar containing 5% glucose. NaCl tolerance: 1%. Urease +ve. Pigments are apparently not xanthomonadins; a brown, water-soluble pigment is formed in cultures on yeast extract-galactose-calcium carbonate agar.

*X. axonopodis*. The causal agent of gummosis in species of *Axonopus* (Gramineae). Growth is non-mucoid on nutrient agar containing 5% glucose. Starch is hydrolysed. H<sub>2</sub>S is formed from peptone. NaCl tolerance: 1%.

*X. campestris*. The repository for a large number of nomen-species, each distinguished on the basis of pathogenicity for particular host(s), and each now classified as a pathovar within the species. Typically, *X. campestris* pathovars form mucoid growth on nutrient agar containing 5% glucose, cause proteolysis in milk, form H<sub>2</sub>S from peptone, and tolerate 2–5% NaCl. The pathovars (with examples of hosts) include e.g. *X. campestris* pv. *badrii* (members of the Compositae and Leguminosae, e.g. *Pisum sativum*); pv. *campestris* (*Brassica* spp); pv. *cassavae* (*Manihot* spp); pv. *cerealis* (Gramineae, e.g. *Hordeum* spp); pv. *fici* (*Ficus carica*); pv. *glycines* (Leguminosae, e.g. *Glycine* spp); pv. *mangiferaeindicae* (mango: see BLACK SPOT sense 3); pv. *musacearum* (*Musa* spp); pv. *oryzae* (Gramineae, e.g. *Oryza* spp); pv. *phaseoli* (Leguminosae, e.g. *Phaseolus vulgaris*).

*X. fragariae*. The causal agent of a leaf spot disease of strawberry. Growth is mucoid on nutrient agar containing 5% glucose. Milk protein is not hydrolysed, and H<sub>2</sub>S is not formed from peptone. NaCl tolerance: 0.5–1%.

*X. maltophila* See PSEUDOMONAS (*P. maltophila*).

[Book ref. 22, pp. 199–210. Host range of the genus *Xanthomonas*: Bot. Rev. (1984) 50 308–356.]

**Xanthophyceae** (yellow-green algae) A class of ALGAE characterized by the formation – during at least some stage of the life cycle – of motile biflagellated (heterokont) cells which have one long tinsel flagellum directed anteriorly, and one much shorter whiplash flagellum directed posteriorly; the flagella arise at or near the anterior end of the cell. The chloroplasts are yellow-green and contain chlorophyll *a* (*Vaucheria geminata* apparently also contains chlorophyll *c*); each is surrounded by two membranes of chloroplast endoplasmic reticulum, the outer membrane typically being continuous with the nuclear envelope. The EYESPOT, when present, occurs within a chloroplast. The cell wall in e.g. *Botrydium* and *Vaucheria* contains cellulose.

The vegetative organisms may be unicellular and either solitary (e.g. OPHIOCYTIUM) or colonial (e.g. GLOEOCHLORIS, MISCHOCOCCUS), multicellular and filamentous (e.g. TRIBONEMA), or siphonaceous and either vesicular (e.g. BOTRYDIUM) or tubular (e.g. VAUCHERIA). Certain unicellular xanthophytes (e.g. *Chloramoeba*, *Heterochloris*) form vegetative cells which are flagellated and/or amoeboid, and these organisms are sometimes classified as protozoa of the PHYTOMASTIGOPHOREA.

Asexual reproduction occurs by fragmentation (in filamentous species) or by the formation of zoospores and/or aplanospores; some members can form thick-walled resistant resting cells (akinetes), and some can form cysts (statospores) intracellularly in certain cells.

Sexual reproduction has been observed in *Botrydium*, *Tribonema* and *Vaucheria*, and is oogamous in *Vaucheria*, isogamous or anisogamous in other genera.

Xanthophytes occur mainly in freshwater habitats; a few are marine, while e.g. *Botrydium* and some *Vaucheria* spp can grow on damp soil.

**xanthophylls** See CAROTENOIDS.

**xanthophytes** Algae of the XANTHOPHYCEAE.

**Xanthoria** A genus of foliose LICHENS (order TETRASTICHIALES).

Photobiont: *Trebouxia/Pseudotreboouxia*. [Evidence for free-living photobiont and mycobiont of *X. parietina*: New Phyt. (1984) 97 455–462.] The thallus contains parietin and is yellow or orange (sometimes greenish-yellow when growing in shade – see PARIETIN); it consists of small to large lobes which in some species (e.g. *X. parietina*) are radially arranged to form a rosette. Apothecia: lecanorine, orange, abundant (e.g. in *X. parietina*) or scarce (e.g. in *X. fallax*); ascospores: polarilocular. Species are nitrophilous (ornithocoprophilous), growing primarily on rocks (e.g. *X. elegans*), on bark (e.g. *X. fallax*), or on any of a wide range of substrata (e.g. *X. parietina*). *X. parietina* can tolerate moderate levels of air pollution.

**xanthosine 5'-monophosphate** See e.g. Appendix V(a).

**xanthosomes** Granules present in the cytoplasm of certain foraminifera – believed to be waste products of digestion.

**XbaI** A RESTRICTION ENDONUCLEASE from *Xanthomonas campestris* pv. *badrii*; T/CTAGA.

**xcp genes** See PROTEIN SECRETION (type II systems).

**xenoantibody** Any antibody, raised in one species, whose homologous antigen derives from a different species.

**xenobiotic** Any chemical which is present in a natural environment but which does not normally occur in nature: e.g. a pesticide, industrial pollutant, drug, etc. (See also BIOREMEDIATION and CO-METABOLISM.)

**Xenococcus** A genus of unicellular CYANOBACTERIA (section II) in which the vegetative cells are rounded and variable in size; bacocytes are non-motile and have a fibrous outer cell wall layer at the time of their release. GC%: ca. 44.

**xenodiagnosis** A method for diagnosing a vector-transmitted disease (e.g. CHAGAS' DISEASE). A laboratory-bred, pathogen-free strain of the vector is allowed to suck blood from the patient; after e.g. several weeks the vector (or its faeces) is examined for the presence of the pathogen.

**Xenodochus** See UREDINIOMYCETES.

**xenogenic** Derived from a different species. (cf. ALLOGENEIC and SYNGENEIC.)

**xenoma** A tumour-like lesion which develops in animal tissues infected with certain parasites; it consists of hypertrophied host tissue within which the parasite lives. (See e.g. GLUGEAE.) [Morphogenesis of *Glugea*-induced xenomas: JP (1985) 32 269–275.]

**Xenophyphorea** A class of marine organisms (superclass RHIZOPODA) which form a multinucleate plasmodium enclosed within a system of transparent, organic, branching tubes; barite crystals occur in the cytoplasm. Genera include *Psammitta*, *Psammitta*, *Stannophyllum*.

**Xenorhabdus** A genus of motile bacteria of the ENTEROBACTERIACEAE [Book ref. 22, pp. 510–511]; species have been isolated from parasitic nematodes and their (insect larva) hosts. Growth is poor (or absent) at 36°C, optimum at ca. 25°C; results are negative in most of the biochemical tests used for enterobacteria. *X. luminescens* is weakly bioluminescent, *X. nematophilus* is non-luminescent. [DNA relatedness and phenotypic study of the genus: IJSB (1984) 34 378–388.]

**xenosaprobic zone** See SAPROBITY SYSTEM.

**xenosome** (1) A bacterium-like endosymbiont in certain marine scuticociliates (e.g. *Parauronema*). [Characterization of xenosome DNA in *P. acutum*: JGM (1983) 129 1317–1325.]

## xenotropic

(2) In certain testate amoebae (e.g. *Diffugia*), 'xenosomes' are the sand particles in the (agglutinated) test that are acquired from the environment, the spaces between the 'xenosomes' being filled with apparently endogenously formed 'idiosomes' [Book ref. 137, pp. 272–275].

**xenotropic** Refers to an ENDOGENOUS RETROVIRUS which, although transmitted genetically in its host of origin, cannot replicate in that host, but can infect and replicate in cells of another species. An example is a xenotropic C-type murine retrovirus which cannot infect other mouse cells but which can infect and replicate in human, rabbit or duck cells. (cf. ECOTROPIC; AMPHOTROPIC.)

**xero-** A prefix meaning *dry*.

**xerophilic** Refers to organisms which grow best at low  $a_w$  (see WATER ACTIVITY) and which may not grow at all at high  $a_w$ .

**Xgal** (XGal) 5-Bromo-4-chloro-3-indolyl- $\beta$ -D-galactoside. Hydrolysis of Xgal by  $\beta$ -GALACTOSIDASE yields a blue-green substance which adheres to bacterial cells; thus, cells which produce  $\beta$ -galactosidase form blue-green colonies on Xgal-containing plates. (cf. XP.)

**XhoI** See RESTRICTION ENDONUCLEASE (table).

**xid mice** (*immunol.*) Genetically deficient mice which do not form Lyb 5<sup>+</sup> B LYMPHOCYTES.

**xis gene** See e.g. BACTERIOPHAGE  $\lambda$ .

**XLD agar** XYLOSE-LYSINE-DEOXYCHOLATE AGAR.

**XLP syndrome** (Duncan disease) An inherited (X-linked recessive) lymphoproliferative syndrome in which infection with EPSTEIN-BARR VIRUS (EBV) leads to a fatal INFECTIOUS MONONUCLEOSIS; a genetically determined failure of specific T cell and other cellular immune responses results in a massive, uncontrolled proliferation of EBV-infected B cells.

**XMP** (1) Xanthosine 5'-monophosphate [see Appendix V(a)]. (2) Xylulose monophosphate (xylulose 5-phosphate).

**XMP pathway** (dihydroxyacetone pathway; XuMP pathway; xylulose monophosphate pathway) A cyclic metabolic pathway for the assimilation of formaldehyde by yeasts growing on methanol (see METHYLOTROPHY). The regenerated intermediate xylulose 5-phosphate (Xu5P) transfers a glycolaldehyde group to formaldehyde to yield glyceraldehyde 3-phosphate (G3P) and dihydroxyacetone (DHA); the reaction is catalysed by DHA synthase [properties of DHA synthase: JGM (1983) 129 935–944]. DHA is phosphorylated, and DHAP condenses with G3P to form fructose 1,6-bisphosphate which is converted to fructose 6-phosphate (F6P); F6P and G3P undergo 'rearrangement reactions' (involving e.g. transketolase, transaldolase, epimerase – cf. RMP PATHWAY) to regenerate Xu5P. Some of the G3P is assimilated into cell biomass. The XMP pathway is energetically more efficient than the (icl) serine pathway but less efficient than the more economical routes of the RMP pathway.

**xonA gene** (*sbcB* gene) See RECF PATHWAY.

**XP** 5-Bromo-4-chloro-3-indolylphosphate-*p*-toluidine: a reagent used e.g. for detecting alkaline PHOSPHATASE activity. (cf. XGAL.)

**XSCID** See SEVERE COMBINED IMMUNODEFICIENCY.

**xseA gene** See EXONUCLEASE VII.

**xthA gene** See EXONUCLEASE III.

**XuMP pathway** XMP PATHWAY.

**xylan** See XYLANS.

**xylanases** Enzymes which degrade XYLANS. There are several distinct types – differing in specificities and end-products.  $\beta$ -Xylosidases, produced by many fungi (e.g. *Aspergillus*, *Penicillium*, *Rhizopus*, *Trichoderma*) and bacteria (e.g. *Agrobacterium*, *Erwinia*, *Xanthomonas*, rumen bacteria), release xylose from

short xylo-oligosaccharides from the non-reducing end. *Exo-xylanases* (formed e.g. by *Bacillus pumilus*, *Aspergillus niger*) can act on xylans to yield xylose and xylo-oligosaccharides. *Endo-xylanases* (from e.g. *Stereum*, *Trametes*, *Streptomyces*) cleave bonds within xylan chains to form xylose and/or xylo-oligosaccharides; some can also cleave L-arabinose–xylose branch points. [Book ref. 26, pp. 111–129.]

**xylans** Polysaccharides consisting largely or solely of xylosyl residues (see XYLOSE). In angiosperms, xylans form the bulk of the HEMICELLULOSE component of the cell wall; they consist essentially of (1 → 4)- $\beta$ -linked D-xylopyranosyl residues with side-chains of other sugars – commonly single residues of (4-*O*-methyl)- $\alpha$ -D-glucopyranosyluronic acid (in dicots and gymnosperms) or one or more  $\alpha$ -L-arabinofuranosyl residues (e.g. in grasses).

In hardwoods, 4-*O*-methylglucuronoxylans are partially acetylated.

In many members of the Chlorophyta (e.g. *Caulerpa*, *Halimeda*, *Udotea*) a linear (1 → 3)- $\beta$ -xylan replaces cellulose as the main structural component of the CELL WALL. A major polysaccharide in the red alga *Palmaria palmata* is a linear xylan containing a random sequence of (1 → 3)- and (1 → 4)- $\beta$ -D-xylosidic linkages.

(See also XYLANASES.)

[Molecular biology of xylan degradation: FEMS Reviews (1993) 104 65–82.]

**Xylaria** A genus of fungi (order SPHAERIALES) which occur e.g. on tree stumps and fallen timber. The organisms form an erect, branched or unbranched, prosenchymatous stroma (commonly ca. 1–8 cm high) which is initially covered, or partly covered, with conidiophores; perithecia subsequently develop in the superficial layer of the same stroma with their ostiolar pores at the surface.

*X. hypoxylon* (the 'candle-snuff fungus') forms branched, antler-like, somewhat flattened stromata which are black and velvety except at the distal end – which is initially covered with chalk-white conidia. Ascospores: black, bean-shaped, ca. 12 × 6  $\mu$ m.

*X. polymorpha* ('dead man's fingers') forms clavate, typically unbranched, black stromata, each on a short, cylindrical stipe; the tissue inside the stromata is white.

**xynolens** (as disinfectants) See PHENOLS.

**xylitol** An optically inactive PENTITOL formed e.g. by the reduction of XYLOSE. [See also Appendix III(d).]

**xylobiose**  $\beta$ -D-Xylopyranosyl-(1 → 4)-D-xylose: a common product of enzymic degradation of XYLANS.

**Xylohypha** A genus of fungi of the HYPHOMYCETES. *X. bantiana* (formerly *Cladosporium bantianum*) is an important causal agent of cerebral PHAEOHYPHOMYCOSIS; the organism forms conidiophores that are indistinguishable from vegetative hyphae, and gives rise to aseptate (rarely two-celled), smooth-walled conidia in long, sparsely branched chains. [Reclassification of *C. bantianum* as *X. bantiana*: JCM (1986) 23 1148–1151.]

**xylomycetophagous** See AMBROSIA FUNGI.

**xylophagous** Wood-eating.

**xylophilous** Having an affinity for wood.

**xylose** (wood sugar) An aldopentose (see PENTOSE) which occurs e.g. in XYLANS. Xylose can be metabolized by some bacteria [see e.g. Appendix III(d)] but by few yeasts; xylose is heat-labile, and solutions for use in media (e.g. XLD agar) should be sterilized by filtration. (cf. XYLULOSE; see also INDUSTRIAL ALCOHOL.)

## xylulose monophosphate pathway

**xylose isomerase** See GLUCOSE ISOMERASE.

**xylose–lysine–deoxycholate agar** (XLD agar) An agar medium containing e.g. xylose, L-lysine, lactose, sucrose, deoxycholate, thiosulphate, NaCl, ferric ammonium citrate, phenol red; pH 7.4. [Recipe: Book ref. 47, p. 671.] On XLD agar, *Shigella* ferments no sugars (i.e. forms no acid) and give rise to red colonies (phenol red: pH 6.8 yellow → pH 8.4 red). *Salmonella* ferments xylose (forms acid) – but also decarboxylates lysine, giving a *net* alkaline reaction (red colonies); unlike *Shigella*, *Salmonella* usually gives rise to *black-centred* red colonies because it produces hydrogen sulphide that reacts with the ferric

salt. *Escherichia* typically ferments all three sugars; it gives rise to *yellow* colonies, but tends to be inhibited by deoxycholate.

**β-xylosidase** See XYLANASES.

***Xylosphaera*** Former name of XYLARIA.

**xylulose** A pentulose (see PENTOSES). Xylulose 5-phosphate is an important intermediate in various metabolic pathways: see e.g. CALVIN CYCLE, HEXOSE MONOPHOSPHATE PATHWAY [Appendix I(b)], HETEROLACTIC FERMENTATION [Appendix III(b)], pentose metabolism [see e.g. Appendix III(d)], XMP PATHWAY.

**xylulose monophosphate pathway** XMP PATHWAY.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# Y

**Y** Tyrosine (see AMINO ACIDS).

**Y** YIELD COEFFICIENT.

**Y bases** Bases formed by the modification of guanine in tRNA; an example is *wyosine*, in which an additional ring is fused with the purine ring of guanine, the additional ring itself bearing a substituted hydrocarbon side-chain. Y bases occur e.g. in tRNA<sup>Phe</sup> in bacteria and yeasts. (cf. Q BASES.)

**Yaba monkey tumour poxvirus** (Yaba virus) A virus of the POXVIRIDAE which can cause benign tumours in monkeys. Monkey handlers may become infected, infection typically resulting in the formation of a small nodular lesion which eventually regresses. Yaba virus replicates in the CAM and in certain types of cell culture. (cf. TANAPOX VIRUS.)

**YadA protein** See FOOD POISONING (*Yersinia*).

**yakult** A 'health food' marketed in Japan and in other countries; skim-milk containing glucose and an extract of *Chlorella* is inoculated with *Lactobacillus casei* and allowed to ferment at 37° C for several days. Sweeteners and flavourings may be added. (See also PROBIOTIC.)

**Yamaguchi-73 sarcoma virus** See AVIAN SARCOMA VIRUSES.

**yaourt** *Syn.* YOGHURT.

**Yarrowia** See SACCHAROMYCOPSIS.

**Y<sub>ATP</sub>** See YIELD COEFFICIENT.

**yaws** (framboesia; frambesia; pian) A chronic infectious human disease caused by *Treponema pallidum* subsp. *pertenue*; it occurs e.g. in tropical regions of America, Africa and the Far East, chiefly in areas where standards of hygiene are poor. Transmission occurs mainly by direct contact with infected persons or fomites; infection occurs via wounds and abrasions. An ulcerative lesion develops at the site of infection, and after a few weeks open sores appear all over the body. After several years tissue destruction becomes extensive, involving skin, bones and joints. *Chemotherapy*: e.g. penicillins. (cf. PIAN BOIS.)

**YDC agar** *Syn.* YGC AGAR.

**yeast** A name often used specifically for *Saccharomyces cerevisiae* (see SACCHAROMYCES) – cf. YEASTS. (See also BAKERS' YEAST and BREWERS' YEAST.)

**yeast extract** Yeast extracts are water-soluble preparations (liquid, paste, powder or granules) obtained from e.g. brewers' or BAKERS' YEAST (*Saccharomyces cerevisiae*), *Kluyveromyces marxianus* var. *lactis*, *K. marxianus* var. *marxianus*, or *Candida utilis* (TORULA YEAST). Yeast extracts are rich in amino acids and peptides, B vitamins, trace elements, etc; they are used as condiments and food additives and as nutritional supplements in industrial fermentations, microbial growth media etc. (See also SINGLE-CELL PROTEIN.)

*Yeast autolysates* are made by subjecting yeast cells to ca. 40–60° C. Endogenous enzymes degrade many of the yeast cell components to soluble amino acids, peptides etc; some of the cell wall polymers and some glycogen remain insoluble. Autolysis can be accelerated by plasmolysing agents such as NaCl or sucrose, or by organic solvents such as ethanol (which also serve to inhibit bacterial putrefaction).

*Yeast hydrolysates* are made by treating a suspension of yeast cells with strong acid at ca. 100° C followed by neutralization and concentration; while yields are higher than those for autolysates in terms of hydrolysis of cell components, the product tends to be inferior in terms of amino acid content (tryptophan is destroyed, levels of tyrosine, methionine and cysteine are greatly reduced),

vitamin content, salt content (hydrolysates contain up to 50% NaCl), and flavour.

**yeast phase** See DIMORPHIC FUNGI.

**yeasts** A non-taxonomic category of FUNGI defined in terms of morphological and physiological criteria. The 'typical' yeast (e.g. *Saccharomyces cerevisiae*) is a unicellular saprotroph which can metabolize carbohydrates by FERMENTATION (sense 1) and in which asexual reproduction occurs by BUDDING. However, some yeasts (e.g. *Schizosaccharomyces* spp) divide by fission, and some can form a pseudomycelium and/or a true mycelium; some (e.g. *Hansenula canadensis*, *Lipomyces* spp, *Sporobolomyces* spp) are non-fermentative, and some (e.g. *Candida albicans*) can be pathogenic. (cf. DIMORPHIC FUNGI; see also SACCHAROMYCETACEAE and SPOROBOLOMYCETACEAE.)

**yellow-brown algae** CHRYSOPHYTES.

**yellow fever** (yellow jack) An acute infectious disease of man and other primates, endemic in parts of Africa and S. America; it is caused by a flavivirus (see FLAVIVIRIDAE). In the *urban cycle* ('urban yellow fever') the virus is transmitted among humans by *Aedes aegypti*. The *jungle* or *sylvatic cycle* ('jungle yellow fever') involves mainly wild primates, the principal vectors being *Aedes simpsoni* or *A. africanus* (in Africa) or *Haemagogus* spp (in S. America). Man is incidental in the natural sylvan cycle. In man, the incubation period is 2–6 days. Onset is sudden, with fever, headache, myalgia and prostration; the fever abates but then recurs. Other symptoms typically include vomiting, jaundice, albuminuria, and haemorrhages (e.g. 'black vomit'); death (due usually to liver or kidney failure) may occur 6–10 days after onset. Long-term immunity follows recovery. *Lab. diagnosis*: identification of the virus from blood samples; detection of rising antibody titres; histological examination of the liver (see COUNCILMAN BODIES). *Prevention*: vaccination with attenuated virus (17D strain); control of mosquito vectors (where feasible).

[History of yellow fever research by the US Army: *Lancet* (2001) 357 1772.]

**yellow-green algae** See XANTHOPHYCEAE.

**yellow rice** (1) Rice grains yellowed as a result of the growth and pigment formation of *Penicillium islandicum*. Consumption of such rice can lead to a MYCOTOXICOSIS ('yellow rice disease') due to the hepatotoxic, carcinogenic, anthraquinone pigment luteoskyrin and other toxins (e.g. CHLOROPEPTIDE).

(2) Rice yellowed by any of several pigment-forming *Penicillium* spp – e.g., *P. islandicum*, *P. citreoviride* (see CITREOVIRIDIN), *P. citrinum* (see CITRININ).

**yellow rust** (stripe rust) A CEREAL DISEASE caused by *Puccinia striiformis*. On wheat the disease is characterized by lines of lemon-yellow uredial pustules which occur between the veins on the upper (adaxial) surface of the leaf. On barley the symptoms are similar; in severe infections the pustules can also occur on the ears.

**yellow** (*plant pathol.*) Any of a wide variety of plant diseases in which a major symptom is a uniform or non-uniform (e.g. striped or mottled) yellowing of leaves and/or other plant components. (cf. CHLOROSIS.) Yellows may be caused by fungi (e.g. one form of CELERY YELLOWS), viruses (diseases in many plants – see e.g. SUGAR BEET YELLOWS VIRUS), bacteria (e.g. COCONUT LETHAL YELLOWING), or protozoa (e.g. HARTROT, PHLOEM NECROSIS).

(See also CORN STUNT DISEASE.) In yellows caused by wall-less prokaryotes (SPIROPLASMA spp, MLOS) the pathogen grows (intracellularly) within the sieve tubes; *Spiroplasma* gives rise e.g. to stunting and yellowing, while MLOs, in addition, may cause VIRESCENCE and PHYLLODY or WITCHES' BROOM formation. Some yellows previously attributed to viruses (e.g. aster yellows, and the 'viral' form of celery yellows) are now known to be caused by MLOs.

**Yersinia** A genus of Gram-negative bacteria of the family ENTEROBACTERIACEAE (q.v.). *Yersinia* spp are parasites and pathogens in man (see e.g. FOOD POISONING (j) and PLAGUE) and in other animals, including fowl and fish; some species are also found in food and water etc.

Cells: bacilli or coccobacilli, 0.5–0.8 × 1–3 µm; the cells (particularly those of *Y. pestis*) tend to show bipolar staining.

Phenotypic characteristics are largely dependent on temperature. For example, most species are motile below 30°C but non-motile at 37°C (*Y. pestis* is always non-motile). The VP test is always negative at 37°C but may be positive in some species at 25°C. The optimum growth temperature is ~28°C. The organisms can grow on unenriched nutrient agar, but generally grow better on e.g. blood agar. Colonies (after 24–30 hours at 28–37°C) may be ≤1 mm diam. (*Y. pestis*) or 2–3 mm (most other species); after 48 hours colonies may become umbonate.

MR +ve. Acid (little or no gas) from glucose. Typically lactose –ve, but ONPG TEST +ve. (Rarely, strains may harbour a Lac plasmid.) Urease –ve (e.g. *Y. pestis*) or +ve (e.g. *Y. enterocolitica*, *Y. pseudotuberculosis*). Oxidase –ve. Catalase +ve.

The major human pathogens (*Y. enterocolitica*, *Y. pestis* and *Y. pseudotuberculosis*) each encode a VIRULON (q.v.) which e.g. helps the organisms to evade phagocytosis. Invasion of intestinal tissue by *Y. enterocolitica* is described in FOOD POISONING (j).

GC%: ~46–47. Type species: *Y. pestis*.

*Y. aldovae*. (Formerly 'Y. enterocolitica-like group X2'.) [JJSB (1984) 34 166–172.]

*Y. enterocolitica*. Urease +ve. Rhamnose –ve, maltose +ve, sucrose +ve. VP test may be +ve at 25°C. A causal agent of adenitis and diarrhoea (mainly in children) (see FOOD POISONING (j)), and of e.g. arthritis and erythema nodosum in adults). VW ANTIGENS may be present.

*Y. enterocolitica* is psychrotrophic and can be selected by cold enrichment (4°C); it occurs e.g. in meat (see MEAT SPOILAGE and DFD MEAT) and also in milk (but is usually destroyed by pasteurization [AEM (1982) 44 517–519]).

*Y. frederiksenii*. Urease +ve. Rhamnose +ve, sucrose +ve, raffinose –ve. VP (25°C)+ve. May cause diarrhoea [GE (1984) 86 1237 (abstr.)].

*Y. intermedia*. Urease +ve. Rhamnose +ve, sucrose +ve, raffinose +ve. VP (25°C) +ve. May be an opportunist pathogen.

*Y. kristensenii*. Urease +ve. Rhamnose –ve, sucrose –ve, raffinose –ve. VP –ve.

*Y. pestis* (formerly *Pasteurella pestis*). Urease –ve. Rhamnose –ve, sucrose –ve, glucose (acid, no gas) +ve. ONPG +ve. Non-motile.

The causal agent of PLAGUE (q.v.). (See also VIRULON.)

On primary isolation from an animal host, or on incubation in protein-rich media at 37°C, virulent strains have been associated with certain antigens: (i) a heat-labile (100°C/10 min) water-soluble capsular antigen (the Fraction 1 antigen, serofactor 1, F1 antigen) which comprises glycoprotein (F1A) and protein (F1B) components; (ii) heat-stable somatic VW ANTIGENS (encoded by plasmid Vwa); the Vwa plasmid is readily lost on subculture in

nutrient media at 37°C, and such loss has been associated with a loss of virulence.

In some strains of *Y. pestis* COAGULASE activity (evident only in rabbit or guinea-pig plasma) and fibrinolytic activity are correlated with the production of a bacteriocin (PESTICIN 1).

*Y. philomiragia*. See PHILOMIRAGIA BACTERIUM.

*Y. pseudotuberculosis* (formerly *Pasteurella pseudotuberculosis*). Urease +ve. Rhamnose +ve, sucrose –ve, salicin +ve. VP –ve. ONPG +ve. VP –ve. Virulent strains possess the F1 and VW antigens (see *Y. pestis*). *Y. pseudotuberculosis* is the causal agent of PSEUDOTUBERCULOSIS. It has been proposed that, on the basis on DNA homology, *Y. pseudotuberculosis* and *Y. pestis* be reclassified, respectively, as *Y. pseudotuberculosis* subsp *pseudotuberculosis* and *Y. pseudotuberculosis* subsp *pestis* [Curr. Micro. (1980) 4 225–230], but this proposal was rejected [JJSB (1985) 35 540].

*Y. ruckeri*. Urease –ve. Rhamnose –ve, sucrose –ve, raffinose –ve. VP variable. Pathogenic in fish, causing ENTERIC REDMOUTH. This organism may be sufficiently distinct from other yersiniae to warrant a separate genus.

**yersiniosis** Any disease of man or animals caused by a species of YERSINIA.

**yes** See AVIAN SARCOMA VIRUSES and ONCOGENE.

**Y<sub>G</sub>** See YIELD COEFFICIENT.

**YGC agar** (YDC agar) An agar medium containing yeast extract, D-glucose, and precipitated chalk; it is used e.g. as a general-purpose medium for plant-pathogenic bacteria (e.g. *Erwinia* spp). [Recipe: Book ref. 46, p. 1267.]

**yield coefficient** (growth yield coefficient; *Y*) The amount of biomass (grams, dry weight) formed per mass (grams) of a given substrate; this 'observed' or 'overall' relationship may be designated e.g. *Y*, *Y<sub>0</sub>*, *Y<sub>s</sub>* or *Y<sub>x/s</sub>*, and the theoretical or maximum yield coefficient may be written e.g. *Y<sub>x/s(MAX)</sub>* or *Y<sub>MAX</sub>*. If the amount of substrate is expressed in moles (so that the growth-supporting potential of different substrates can be compared) the coefficient may be designated e.g. *Y<sub>x/m</sub>* and is referred to as the *molar growth yield* or the *molar yield coefficient*. *Y<sub>x/ATP</sub>* (= *Y<sub>ATP</sub>*) refers to the amount (grams) of biomass (or of a given metabolic product) formed per mole of ATP synthesized by the biomass. *Y<sub>x/O<sub>2</sub></sub>* (= *Y<sub>O<sub>2</sub></sub>*) refers to the amount of biomass (or product) formed per mole of oxygen consumed.

The observed yield coefficient (*Y*) differs from the 'true' yield coefficient (*Y<sub>G</sub>*; *growth-specific yield coefficient*) in that *Y<sub>G</sub>* is calculated from the amount of the given substrate which is actually incorporated into biomass – i.e., a quantity which excludes the amount of that substrate used for MAINTENANCE ENERGY. *Y* and *Y<sub>G</sub>* are related:

$$\frac{1}{Y} = \frac{m}{\mu} + \frac{1}{Y_G}$$

where  $\mu$  is the SPECIFIC GROWTH RATE and *m* is the *maintenance coefficient*; *m* can be calculated by plotting 1/*Y* (ordinate) versus 1/ $\mu$  (abscissa), the slope of the straight-line graph being numerically equal to *m*. (The intercept on the 1/*Y* axis gives the value of 1/*Y<sub>G</sub>*.) The maintenance coefficient gives a measure of the proportion of the total energy requirements needed to satisfy maintenance energy during periods of slow growth, i.e., high values of *m* indicate that maintenance energy is a relatively high proportion of the total energy requirements, and conversely.

Although widely used, parameters such as *Y<sub>ATP</sub>* should be interpreted with care. Thus, for example, while in some species growth seems to be stoichiometrically related to the amount of ATP synthesized, this relationship is dependent on certain

## YM broth

conditions: e.g. growth must be 'energy-limited', i.e., limited by the supply of the energy source, and none of the energy source must be incorporated into biomass. Moreover, some organisms can carry out 'energy-spilling' reactions and FUTILE CYCLES which necessarily affect parameters such as  $Y_{ATP}$ . [ $Y_{ATP}$  and maintenance energy as biologically interpretable phenomena: ARM (1984) 38 459–486.] The growth yield can also be significantly influenced by the amount of energy needed to transport and phosphorylate a given exogenous substrate [JB (1985) 163 1237–1242].

**YM broth** Yeast extract–malt extract broth, a medium for the culture of yeasts; it contains yeast extract, malt extract, peptone and glucose. YM agar is YM broth solidified with 2% agar. [Recipes: Book ref. 100, p. 51.]

**YMA** Yeast extract–mannitol agar, used e.g. for the culture of *Rhizobium* spp. [Recipe: Book ref. 45, p. 826.]

**yoghurt** (yogurt, yaourt) A food made by fermenting milk with a mixed culture of *Lactobacillus bulgaricus* and *Streptococcus thermophilus*; the bacteria produce lactic acid and other flavour components (traces of acetaldehyde, DIACETYL and acetic acid – see Appendix III(c)). Neither species can be used successfully without the other. Initially, *L. bulgaricus* breaks down milk proteins to amino acids and small peptides which stimulate the growth of *S. thermophilus*; formic acid produced

by *S. thermophilus* stimulates growth of *L. bulgaricus* which produces most of the lactic acid and acetaldehyde. The mixed culture is sufficiently stable for the production of yoghurt by a continuous process [AvL (1983) 49 84–85.] (See also PROTOCO-OPERATION.)

MILK used for yoghurt-making is high in milk solids, usually low in fat, and may be treated with a stabilizer (e.g. gelatin); it is pasteurized, homogenized, cooled, and inoculated with roughly equal numbers of the two species of bacteria. Incubation is carried out at ca. 35–45°C for a few hours, during which the pH falls to about 4.2–4.6 and the milk proteins coagulate. The product is then cooled rapidly to ca. 4°C and stored at this temperature. Additional flavourings or whole fruit, pasteurized separately, may be added before fermentation.

(See also DAIRY PRODUCTS.)

**Yop virulon** See VIRULON.

**Yops** See VIRULON.

**yscIV** See PHEROMONE.

**yscF** See PHEROMONE.

**YscN protein** See VIRULON.

**Yst** See FOOD POISONING (*Yersinia*).

**YZ endonuclease** See MATING TYPE.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# Z

**Z** The factor 2.3(RT/F); see e.g. CHEMOSMOSIS.

**Z-DNA** A left-handed helical form of dsDNA (cf. DNA) first observed in oligomers of alternating deoxycytidine (dC) and deoxyguanosine (dG) in the presence of high salt concentrations or ethanol. In these oligomers the strands are connected by Watson-Crick BASE PAIRING, the sugar-phosphate backbones form an irregular zig-zag (hence Z-DNA), there are ca. 12 bp/turn, and the bases are relatively peripheral with the N7 and C8 positions of guanine exposed; there is a single very deep helical groove corresponding to the minor groove of B-DNA (see DNA). Stretches of alternating dC and dG in a plasmid can undergo transition from right- to left-handed helical form under physiological levels of ionic strength and superhelical density; the transition is driven by the torsional strain of negative supercoiling and is facilitated by C5-methylation of cytidine [Nature (1982) 299 312–316].

Whether or not Z-DNA occurs in vivo remains controversial. Unlike B-DNA, Z-DNA is strongly immunogenic, and monoclonal antibodies have been used for its detection in cells; however, the specificity of these antibodies for Z-DNA is uncertain. The isolation of proteins which preferentially bind Z-DNA rather than B-DNA provides circumstantial evidence for the existence of Z-DNA in vivo.

(See also V-DNA.)

**Z ring** See CELL CYCLE (b).

**Z scheme** See PHOTOSYNTHESIS.

**z value** The increase in temperature (°C) required for a 10-fold decrease in the D VALUE.

**Zadoks' code** (Zadoks, Chang and Konzak decimal code) (*plant pathol.*) A code, designed primarily for computer use, in which the various growth stages of cereals are represented by numbers between 0 and 100: 0–9, germination; 10–19, seedling growth; 20–29, tillering; 30–39, stem elongation; 40–49, 'booting' (swelling of the leaf sheath enclosing the developing ear); 50–59, ear emergence; 60–69, flowering; 70–79, 'milky' stage of grain development; 80–89, 'doughy' stage of grain development; 90–99, grain ripening. [Review (with illustrations): Ann. Appl. Biol. (1987) 110 441–454.] (cf. FEEKES' SCALE.)

**zalcitabine** See NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS.

**Zalieron** See HYPHOMYCETES; see also TEXTILE SPOILAGE.

**zanamivir** (Relenza™, Glaxo Wellcome) An anti-INFLUENZA drug: a sialic acid analogue which can inhibit the viral neuraminidase in influenza virus types A and B; the drug is inhaled. [Efficacy and safety of zanamivir: NEJM (1997) 337 874–880; Lancet (1998) 352 1877–1881.]

**ZAP** Zoster-associated pain: see HERPES ZOSTER.

**zaragozic acids** Metabolites of certain fungi which are potent inhibitors of the enzyme squalene synthase; they have potential uses as antifungal agents and/or as therapeutic agents for lowering the levels of plasma cholesterol. [Zaragozic acids: ARM (1995) 49 607–639.]

**ZDV** Zidovudine (see AZT).

**α-zearalenol** See ZEARALENONE.

**zearalenone** (F-2 toxin) A MYCOTOXIN produced by *Gibberella zeae* (*Fusarium graminearum*) growing e.g. on damp cereal feedstuffs. It has oestrogenic activity and can cause hyperoestrogenism (manifest by vulvovaginitis and infertility) in sows; cattle and poultry can be affected, though to a lesser extent.

Zearalenone can also act as a regulatory hormone in the sexual cycle of *Gibberella*. Chemical reduction of zearalenone yields α-zearalenol, which is 4.8 times more oestrogenic than zearalenone and has anabolic properties; it is used to promote rapid weight gain in cattle and as an oestrogen substitute in postmenopausal women. [RIA of zearalenone and zearalenol in human serum: AEM (1983) 45 16–23.]

**zeatin** A naturally occurring CYTOKININ: 6-(4-hydroxy-3-methylbut-2-enyl)-aminopurine. Its derivatives (e.g. zeatin riboside) also function as cytokinins.

**zeaxanthin** See CAROTENOIDS.

**zeaxanthin rhamnoside** See XANTHOBACTER.

**ZEBRA** (Zta) Z EBV replication activator: the protein product of (immediate-early) viral gene *bzlf-1* which promotes replication of the EPSTEIN-BARR VIRUS in latently infected B lymphocytes. ZEBRA can be induced by treating latently infected B cells with e.g. anti-immunoglobulin, corticosteroids or 'phorbol ester' (12-O-tetradecanoylphorbol-13-acetate, TPA).

The lytic cycle in latently infected B cells is also promoted by another transcription factor, Rta, encoded by the immediate-early viral gene *brlf-1*; it has been reported that the promoter of *brlf-1* is activated by acetylation of histones [NAR (2000) 28 3918–3925].

**Zelleriella** See OPALINATA.

**Zenker's fluid (modified)** A FIXATIVE: mercuric chloride (5 g) and potassium dichromate (2.5 g) in distilled water (100 ml) supplemented immediately before use with glacial acetic acid (5 ml).

**Zephiran** See QUATERNARY AMMONIUM COMPOUNDS.

**Zeta Plus filter** See FILTRATION.

**ζ-potential** (zeta potential; electrokinetic potential) Of e.g. a bacterial cell, or a charged colloid particle: the electrical potential at the surface of shear – i.e., the surface of the cell or particle, including adherent counterions and water molecules – which tends to move relative to the surrounding medium when an external electrical field is applied; it is a determinant of the electrophoretic migration rate of a cell etc.

In media of neutral or alkaline pH most bacteria carry a surface charge of negative polarity – due to the ionization of surface groups. In many cases the ISOELECTRIC POINT of a bacterium is ca. 3.0; at or near this pH such bacteria tend to agglutinate spontaneously.

[Electrical properties and topochemistry of bacteria: Adv. Coll. Int. Sci. (1982) 15 171–221.]

(See also ADHESION.)

**Zetapor membrane filter** See FILTRATION.

**zeugite** An early term for a cell or structure in which KARYOGAMY ends DIKARYOPHASE.

**zicai** See LAVER.

**zidovudine** Syn. AZT (q.v.).

**Ziehl-Neelsen's stain** An ACID-FAST STAIN. A heat-fixed smear is flooded with concentrated CARBOLFUCHSIN, heated and kept steaming (not boiling) for 5 min, allowed to cool, and rinsed in running water; the slide is then passed through several changes of acid-alcohol (e.g. 3% v/v conc. HCl in 95% ethanol), washed in water, and counterstained with e.g. 0.5% aqueous malachite green. After a final washing in water the smear is dried and examined by microscopy. Acid-fast organisms stain red, others green.

## Ziemann's dots

**Ziemann's dots** In erythrocytes infected with *Plasmodium malariae*: fine dots sometimes observed on heavy staining with Romanowsky stains. (cf. SCHÜFFNER'S DOTS.)

**Zika virus** See FLAVIVIRIDAE.

**zinc** (a) (microbial requirement) Zinc is a HEAVY METAL which is needed, in trace amounts, for the activity of a number of microbial enzymes – e.g. alcohol dehydrogenase; de-acetylase (encoded by gene *IpxC* in *Escherichia coli*, and involved in lipid A synthesis); some  $\beta$ -lactamases and superoxide dismutases; the UvrA protein involved in DNA repair; the zinc-endopeptidase TETANOSPASMIN; and CARBONIC ANHYDRASE. (See also FTSH.)

(b) (as an antimicrobial agent) In effective concentrations, zinc, and certain of its compounds, are useful antimicrobial agents. For example, zinc undecylenate (see UNDECYLENIC ACID) and zinc oxide have been used for treating certain superficial mycoses (e.g. athlete's foot), and zinc oxide is used as a mould inhibitor in paints. Zinc naphthenate can replace copper naphthenate as a wood preservative but is apparently less effective. Zinc dimethyldithiocarbamate (see DMDC) has been used as a preservative in rubber (it also serves as a vulcanization catalyst) and as an agricultural antifungal agent (*ziram* – see also ZINEB).

The precise mechanism of antimicrobial action may vary with organism; thus, e.g. zinc appears initially to cause membrane damage in *Saccharomyces cerevisiae* but may act by inhibiting intracytoplasmic proteins in another yeast, *Sporobolomyces roseus* [JGM (1983) 129 3421–3425].

(c) (zinc chelation) The mammalian protein CALPROTECTIN is a zinc-chelating agent whose bacteriostatic action presumably reflects its ability to sequester zinc ions [see RMM (1997) 8 217–224].

**zinc-endopeptidase** See TETANOSPASMIN.

**zinc sulphate flotation** See FLOTATION.

**zinc undecylenate** See UNDECYLENIC ACID.

**ziconazole** See AZOLE ANTIFUNGAL AGENTS.

**zineb** (dithane Z-78) Zinc ethyleneBISDITHIOCARBAMATE; this important agricultural antifungal agent is used to control a wide range of plant pathogens, e.g. *Botrytis* spp., *Fulvia fulva* (*Cladosporium fulvum*), *Peronospora* spp., *Phytophthora infestans*; it may be prepared as a WETTABLE POWDER – or may be prepared in the field by mixing NABAM, zinc sulphate and lime.

**ZipA protein** See CELL CYCLE (b).

**zippering** See FOOD POISONING (*Yersinia*).

**ziram** See DMDC.

**zoite** In coccidia: any of a range of stages in the life cycle – e.g. cystozoite, endozoite, sporozoite etc.

**zonal centrifugation** See CENTRIFUGATION.

**Zonaria** See PHAEOPHYTA.

**zone centrifugation** See CENTRIFUGATION.

**zone lines** In decaying wood: dark lines which are the edges of sheets of pigmented fungal tissues in the wood [see e.g. Book ref. 39, pp. 109–128 (122–124)]. In wood rotted by e.g. *Phellinus weirii* the coloration is due to a melanin-like pigment which apparently inhibits the growth of microorganisms antagonistic to *P. weirii* [Mycol. (1983) 75 562–566].

**zooibiont** An animal symbiont. (cf. PHYCOZOAN.)

**zoochlorellae** Green endosymbiotic algae present in various PHYCOZOAN associations. For example, *Chlorella* occurs e.g. in certain protozoa (e.g. foraminifera, *Mayorella viridis*, *Paramecium bursaria*, *Stentor polymorphus*), the freshwater sponge *Spongilla* sp, the coelenterate *Hydra viridis*, the freshwater flatworm *Dalryllia viridis* (see also CONVOLUTA), and the freshwater clam *Anodonta*. The phycobiont generally supplies the zooibiont

with products of photosynthesis (e.g. MALTOSE in *Hydra* and *Paramecium*, glucose in *Spongilla*), although the zooibiont may continue to feed. (See also ELYSIA; cf. ZOOXANTHELLAE.)

**zooflagellates** Flagellates of the ZOOMASTIGOPHOREA.

**zoogloea** (zooglea) A mass or film of cells embedded in a slimy matrix; zoogloea are formed e.g. by *Zoogloea ramigera*.

**Zoogloea** A genus of Gram-negative, aerobic, chemoorganotrophic bacteria (family PSEUDOMONADACEAE) which occur e.g. in organically polluted freshwater habitats, and in aerobically treated sewage (see also SEWAGE TREATMENT). Cells: straight or slightly curved, monotrichously (polarly) flagellated, non-pigmented rods, 1.0–1.3  $\times$  2.1–3.6  $\mu$ m, typically embedded, in masses, within an extracellular polysaccharide matrix – forming flocs or surface films (branching or amorphous zoogloea); polysaccharide (and floc) formation tends to be enhanced when the carbon:nitrogen ratio is high, and may be inhibited by high levels of carbon and nitrogen – conditions which favour increased biomass production [AEM (1982) 44 1231–1237]. Metabolism is respiratory (oxidative); the organisms can carry out nitrate respiration. Major carbon sources can include e.g. fumarate, lactate, pyruvate, dicarboxylic amino acids (e.g. aspartate, glutamate), and certain alcohols. PHB is accumulated. Optimum growth temperature: 28–37°C; optimum pH: 7.0–7.5. Growth is inhibited by 3% NaCl. Oxidase +ve. Catalase +ve (weak). Most strains are urease +ve. GC%: ca. 65. Type species: *Z. ramigera*. [Book ref. 22, pp. 214–219.]

**zoid** (*microbiol.*) (1) A motile spore. (2) Of a stalked ciliate (e.g. *Vorticella*): the cell body, as opposed to the stalk.

**zoom microscope** A compound microscope in which magnification can be varied continuously over a range of values.

**Zoomastigophorea** A class of flagellate protozoa (subphylum MASTIGOPHORA) which lack chloroplasts and which are non-photosynthetic. Orders: CHOANOFLAGELLIDA, DIPLOMONADIDA, HYPERMASTIGIDA, KINETOPLASTIDA, OXYMONADIDA, PROTETOMONADIDA, RETORTAMONADIDA, TRICHOMONADIDA.

**zoonosis** Any infectious disease which can be contracted by man and in which the pathogen is normally maintained in a reservoir consisting of animal (i.e. non-human) population(s). (cf. ANTHROPNOSIS.)

**zoonotic** Pertaining to ZOONOSIS.

**Zoopagales** An order of fungi (class ZYGOMYCETES) which occur e.g. in soil and water, and which are parasitic on e.g. certain amoebae, nematodes, and fungi; the organisms form zygospores and give rise to asexual spores which are not forcibly discharged (cf. ENTOMOPHTHORALES). Genera: e.g. *Bdellospora*, *Cochlonema*, PIPTOCEPHALIS, *Rhopalomyces*, and *Stylopage* (see also NEMATOPHAGOUS FUNGI).

**Zoophagus** A genus of fungi of the PERONOSPORALES; *Z. insidians* is an aquatic species which captures and feeds on rotifers.

**zoophilic** Refers to a parasite or pathogen which preferentially infects animals (cf. ANTHROPOPHILIC).

**Zoophthora** See ENTOMOPHTHORALES.

**zooplankton** See PLANKTON.

**zoosporangium** A SPORANGIUM in which motile spores are formed.

**zoospore** A motile (flagellated) SPORE.

**Zoothamnium** See PERITRICHIA.

**Zooxanthella** See ZOOXANTHELLAE.

**zooxanthellae** Endosymbiotic DINOFLAGELLATES found in various marine invertebrates, including sea anemones (e.g. *Anthopleura*), giant clams (*Tridacna*), jellyfish (*Cassiopeia*), reef-forming tropical corals [Book ref. 129, pp. 19–35], and members of the FORAMINIFERIDA and RADIOLARIA. (The loss of zooxanthellae from corals is a useful indicator of stress due e.g. to pollution

[AMB (1985) 22 1–63.] All such endosymbiotic dinoflagellates have been regarded as belonging to a single species, variously called *Symbiodinium microadriaticum*, *Gymnodinium microadriaticum*, or *Zooxanthella microadriatica*, but according to one report [see Science (1985) 229 656–658] there are probably several distinct species. (See also PHYCOZOAN.) [Evidence for heterotrophy by zooxanthellae in the sea anemone *Aiptasia pulchella*, and its detrimental effects on the host under certain conditions: Biol. Bull. (1986) 170 267–278.]

**zoster** *Syn.* HERPES ZOSTER.

**zoster-associated pain (ZAP)** See HERPES ZOSTER.

**Zot toxin** (*Vibrio cholerae*) See BACTERIOPHAGE CTXΦ.

**Zovirax** *Syn.* ACYCLOVIR.

**Zschokkella** See MYXOSPORA.

**Zta** *Syn.* ZEBRA.

**Zwischenferment** Glucose 6-phosphate dehydrogenase (see HEXOSE MONOPHOSPHATE PATHWAY).

**zwogerziekte virus** (zwogerziekte virus) See LENTIVIRINAE.

**Zygnema** A genus of freshwater, unbranched filamentous green algae related to SPIROGYRA; each cell contains two stellate chloroplasts. Akinetes may be formed.

**Zygoascus** A genus of filamentous, heterothallic fungi that include the teleomorphic stages of *Candida hellenica*, *C. inositolophila* and *C. steatolytica*; type species: *Z. hellenicus*. [AvL (1986) 52 25–37.]

**Zygocecos** See DIATOMS.

**Zygonium** A genus of filamentous green algae related to SPIROGYRA. The filaments contain a purple pigment and grow e.g. on damp peaty soils; some species are thermophilic, forming dense purple mats near hot springs.

**Zygomycetes** A class of fungi of the ZYGOMYCOTINA; most zygomycetes are terrestrial saprotrophs, but some are parasites or pathogens of animals (including insects), plants, and other fungi. (See also ZYGOMYCOSIS.) The typical thallus is a well-developed, branched, coenocytic (aseptate) mycelium, but some species form a septate mycelium, and some (see MUCORALES) are DIMORPHIC FUNGI (sense 1); the CELL WALL contains CHITIN and/or CHITOSAN. Characteristic asexual reproductive structures include the SPORANGIUM and the SPORANGIOLUM (cf. CONIDIUM). Sexual reproduction typically involves ZYGOSPORE formation by the fusion of two morphologically similar gametangia; some species exhibit HOMOTHALLISM, some HETEROTHALLISM. (See also PHEROMONE.)

Orders [Book ref. 64, pp. 411–412]: Dimargaritales (members form merosporangia each containing two spores arranged end-to-end); ENDOGONALES; ENTOMOPHTHORALES; KICKXELLALES; MUCORALES; ZOOPAGALES.

**zygomycosis** Any of a range of human and animal diseases caused by fungi of the ZYGOMYCETES; the term currently includes diseases formerly called phycomycosis (caused by 'phycomycetes'), mucormycosis (caused by fungi of the MUCORALES), and entomophthoromycosis (caused by fungi of the ENTOMOPHTHORALES). In all zygomycoses the invasive form of the pathogen is an aseptate or sparsely septate, broad (e.g. 6–25 μm diam.), hyaline mycelium; the hyphae may be branched and may assume bizarre forms.

*Zygomycosis in man.* *Subcutaneous* zygomycosis, in which a sharply delineated, pain-less nodule develops and grows to form a tumour-like mass, is caused usually by *Basidiobolus haptosporus* (= *B. meristosporus*). *Nasofacial* zygomycosis is caused by *Conidiobolus coronatus* and involves the development of tumefactions in the nasal mucosa and adjacent tissues. *Rhinocerebral* zygomycosis is caused by *Rhizopus oryzae* and

is associated specifically with acidosis due to acute uncontrolled diabetes; infection occurs mainly via the nasal turbinates and paranasal sinuses, spreading rapidly to the eyes and brain, and the condition is rapidly fatal if untreated. *Systemic* zygomycosis may involve an initial pulmonary infection which, if untreated, may spread to other internal organs; causal agents include *Absidia corymbifera*, *Conidiobolus incongruus*, *Cunninghamella bertholletiae* (= *C. elegans*), *Rhizomucor pusillus*, *Rhizopus microsporus*, *R. oryzae*, and *Saksenaeva vasiformis* [identification of *S. vasiformis*: SAB (1985) 23 137–140].

*Zygomycosis in animals.* Causal agents include some human pathogens as well as species apparently non-pathogenic in man (e.g. *Mortierella* spp). Infection may lead e.g. to placentitis followed by abortion (in cattle), or to the formation of granulomatous, tuberculosis-like lesions in lymph nodes, intestines etc (e.g. in pigs and cattle). (See also EQUINE PHYCOMYCOSIS.)

**Zygomycotina** A subdivision of fungi (division EUMYCOTA) which form non-flagellate asexually derived spores and which typically reproduce sexually by gametangial copulation with the formation of ZYGOSPORES (q.v.). Classes: TRICHOMYCETES and ZYGOMYCETES.

**zygophore** A short hyphal branch which develops into a PROGAMETANGIUM.

**Zygorhynchus** See MUCORALES.

**Zygosaccharomyces** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are globose, ellipsoidal or cylindrical; vegetative reproduction occurs by multilateral budding. Pseudomycelium may be formed. The vegetative cells are predominantly haploid (cf. SACCHAROMYCETES). Ascus formation is preceded by conjugation between individual cells (occasionally between a cell and its bud); asci are persistent. Ascospores: globose to ellipsoidal, 1–4 per ascus. Sugars are fermented vigorously; NO<sub>3</sub><sup>-</sup> is not assimilated. Eight species are recognized: *Z. bailii* (formerly e.g. *Saccharomyces elegans*), *Z. bisporus*, *Z. cidri*, *Z. fermentati*, *Z. florentinus*, *Z. microellipsoides*, *Z. mrakii*, and *Z. rouxii* (anamorph: *Candida mogii*; numerous synonyms, including e.g. *Saccharomyces rouxii*). [Book ref. 100 pp. 393–395 and 449–465.]

(See also e.g. MISO and SOY SAUCE.)

**zygosporangium** See ZYGOSPORE.

**zygospore** A thick-walled, sexually-derived resting spore characteristic of fungi of the ZYGOMYCOTINA. (Zygospores are apparently not formed by e.g. members of the Saksenaaceae or of the Amoebidiales.) The fusion of two gametangia (see PROGAMETANGIUM) gives rise to a *prozygosporangium* which develops into a *zygosporangium* having a thick, multilayered, often highly ornamented wall; in at least some zygomycetes the zygospore is known to develop as a separate structure *within* the zygosporangium [CJB (1978) 56 1061–1073]. The term 'zygospore' has been traditionally used to refer to the zygosporangium together with its enclosed zygospore.

**zygote** A single diploid cell formed by the fusion of two gametes.

**zygotene stage** See MEIOSIS.

**zygotic induction** The induction of a prophage when a chromosome containing that prophage is transferred from a lysogenic conjugal donor (see LYSOGENY and bacterial CONJUGATION) to a recipient not lysogenized by the same (or a closely related) bacteriophage; the induction occurs as a result of the absence of a phage repressor protein in the recipient cell.

**zygotic meiosis** MEIOSIS, in a zygote, preceding the formation of haploid vegetative cells in a life cycle in which HAPLOPHASE predominates. (cf. GAMETIC MEIOSIS.)

## zymase

**zymase** Old term for the enzyme fraction isolated from disrupted yeast cells which is capable of catalysing ALCOHOLIC FERMENTATION.

**zymodeme** A subpopulation within a given taxon (e.g. genus) distinguished on the basis of one or more isoenzymes.

**zymogen** (proenzyme) An inactive enzyme precursor that is usually converted to the active form of the enzyme by proteolytic cleavage. (See e.g. FIBRINOLYSIN.)

**zymogenous** Refers to those (predominantly transient or alien) microorganisms in a given environment (e.g. soil) which exhibit an upsurge in growth (and hence in numbers or biomass) on those occasions when the levels of nutrients increase, or when a particular substrate becomes available; in the absence of suitable levels of nutrients, relatively small numbers of such organisms may be capable of existence, in that environment, in a dormant or starvation-resistant stage. (cf. AUTOCHTHONOUS sense 1.)

**zymogram** (1) A medium (e.g. a starch gel strip) which has been used for the ELECTROPHORESIS of a cell homogenate and which has been subsequently stained to detect or quantify a given enzyme. (2) A table showing the results of tests which determine the ability of one or more organisms to ferment each of a range of carbohydrates.

**Zymolyase** A commercial enzyme preparation obtained from culture filtrates of *Arthrobacter luteus*. It contains endo-(1→3)-β-glucanase activity ('Z-glucanase') – which is active against most (1→3)-β-glucans – and also some protease activity ('Z-protease') [JB (1984) 159 1018–1026]. Zymolyase is used e.g. for investigating fungal (particularly yeast) CELL WALL structure, for preparing yeast sphaeroplasts, etc.

**Zymomonas** A genus (*incertae sedis*) of oxidase-negative, catalase-positive, chemoorganotrophic, Gram-negative bacteria which occur e.g. as spoilage organisms in alcoholic beverages

(see e.g. CIDER spoilage) and which are used in specific fermentations (see e.g. PULQUE). [*Zymomonas* ethanol fermentations: MS (1984) 1 133–136.] The genus includes obligately anaerobic and facultatively aerobic strains. Cells: round-ended rods, ca. 1.0–1.4 × 2.0–6.0 μm, non-motile or with 1–4 polar flagella. Metabolism: primarily fermentative. Glucose or fructose is fermented, via the ENTNER–DOUDOROFF PATHWAY, to ethanol, CO<sub>2</sub> and lactic acid with smaller amounts of acetaldehyde, acetoin and glycerol. Ethanol tolerance: at least ca. 5%. Under aerobic conditions, some strains metabolize glucose (in glucose–yeast extract medium) to ethanol, the latter then being oxidized to acetate; during such growth glucose provides only about 50% of the carbon, the remainder being supplied by the yeast extract. All strains need biotin and pantothenate. Nitrate is not reduced. Optimum growth temperature: 25–30°C. Many or all strains can grow at or below pH 4.0. Colonies (2 days, 30°C) on glucose–yeast extract agar: smooth, white to cream, 1–2 mm diam. GC%: ca. 47.5–49.5. Type species: *Z. mobilis*. *Z. mobilis* subsp *mobilis* (which includes e.g. strains previously named *Z. anaerobia* var. *anaerobia*) can grow in glucose–yeast extract broth at 36°C. *Z. mobilis* subsp *pomacii* (which includes e.g. strains previously named *Z. anaerobia* subsp *pomaceae*) cannot grow in glucose–yeast extract broth at 36°C.

[Book ref. 22, pp. 576–580.]

**zymosan** An insoluble polysaccharide, found in the cell wall in certain yeasts, which promotes COMPLEMENT FIXATION via the alternative pathway.

**zymotype** A BIOTYPE characterized on the basis of a ZYMOGRAM.

**Zythia** A genus of fungi (order SPHAEROPSIDALES) which include *Gnomonia (Zythia) fragariae*, a pathogen of the strawberry plant. Elongated conidia are formed in light-coloured pycnidia.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

## Appendices

- Appendix I (a) Embden–Meyerhof–Parnas pathway  
(b) Hexose monophosphate pathway  
(c) Entner–Doudoroff pathway
- Appendix II (a) Tricarboxylic acid cycle  
(b) Tricarboxylic acid cycle – showing some anaplerotic sequences and catabolic and anabolic interactions
- Appendix III (a) Lactose metabolism in some bacteria  
(b) Heterolactic fermentations: ‘classical’ pathway and *Bifidobacterium* pathway  
(c) Some anaerobic fates of pyruvate in lactic acid bacteria  
(d) Pentose and pentitol dissimilation in lactic acid bacteria  
(e) Mixed acid fermentation  
(f) Butanediol fermentation  
(g) Butyric acid fermentation and acetone–butanol fermentation  
(h) Propionic acid fermentation (in *Propionibacterium*)
- Appendix IV (a) Biosynthesis of arginine, glutamate, glutamine, proline  
(b) Biosynthesis of alanine, leucine, valine  
(c) Biosynthesis of cysteine, glycine, serine  
(d) Biosynthesis of asparagine, aspartate, isoleucine, methionine, threonine  
(e) Biosynthesis of lysine: diaminopimelic acid pathway and aminoadipic acid pathway  
(f) Biosynthesis of aromatic amino acids: the shikimate pathway  
(g) Biosynthesis of histidine
- Appendix V (a) Biosynthesis of purine nucleotides  
(b) Biosynthesis of pyrimidine nucleotides
- Appendix VI The Greek alphabet

## Abbreviations and Conventions used in the Appendices

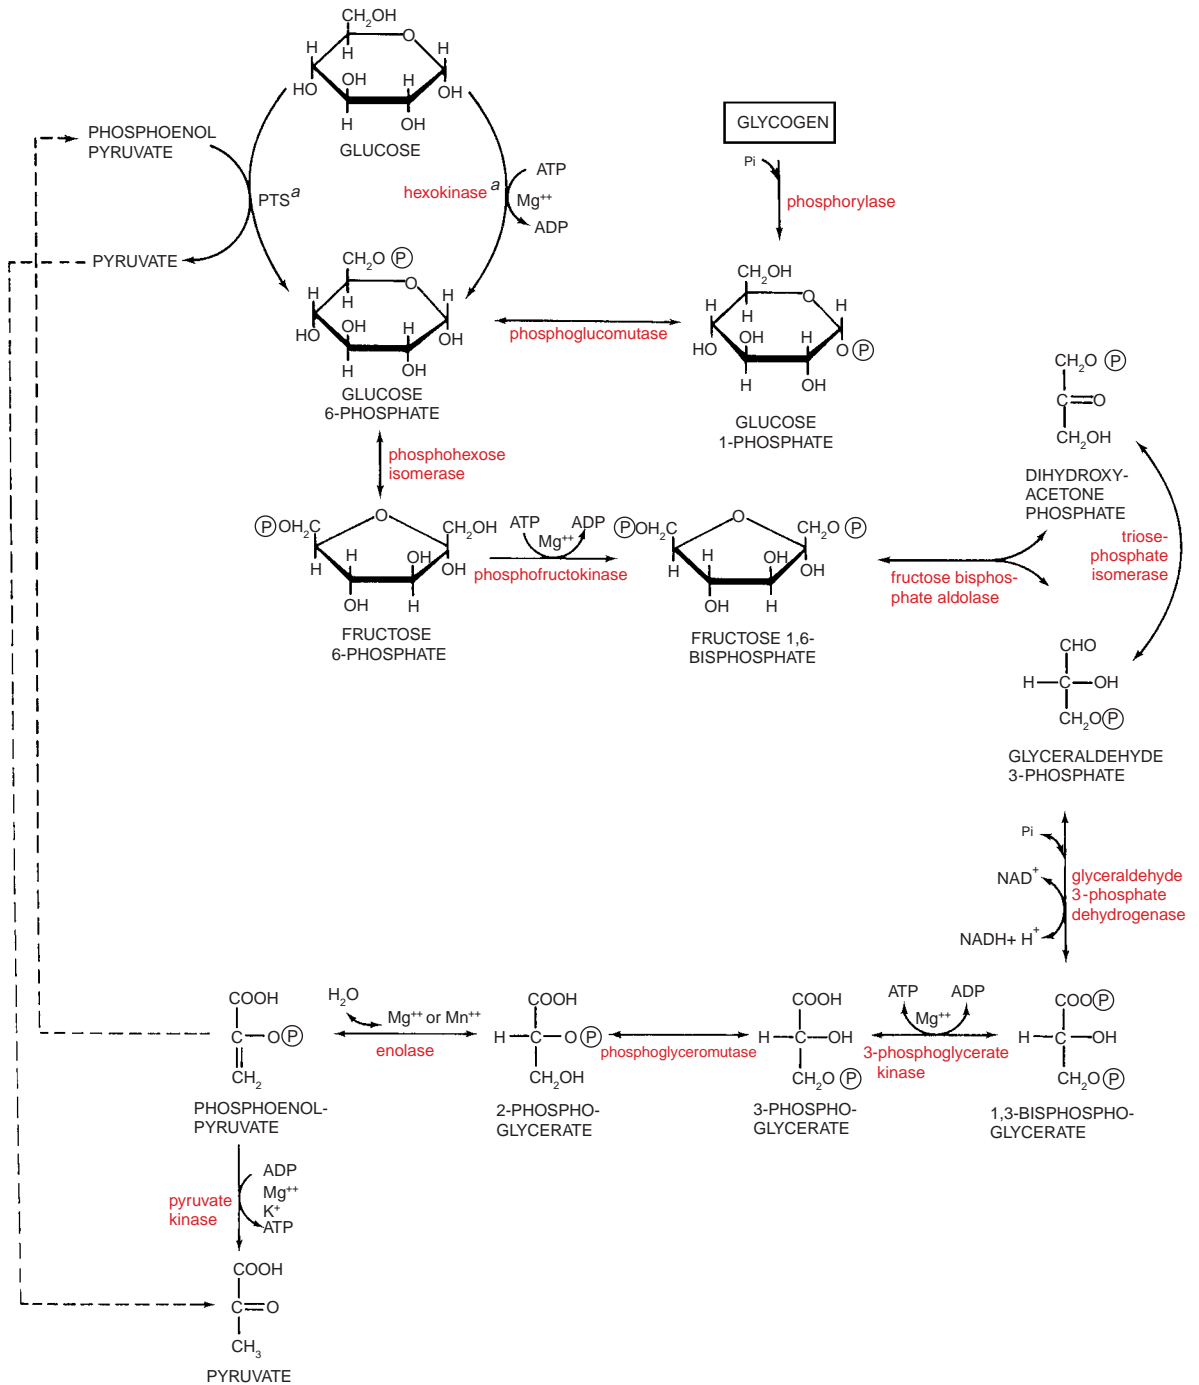

ADP	adenosine 5'-diphosphate
AMP	adenosine 5'-monophosphate
ATP	adenosine 5'-triphosphate (see entry ATP)
CoASH	coenzyme A (see entry COENZYME A)
e <sup>-</sup>	electron
FAD	flavin adenine dinucleotide (see entry RIBOFLAVIN)
GDP	guanosine 5'-diphosphate
GTP	guanosine 5'-triphosphate
NAD	nicotinamide adenine dinucleotide; NAD <sup>+</sup> = oxidized form, NADH + H <sup>+</sup> = reduced form (see entry NAD)
NADP	nicotinamide adenine dinucleotide phosphate; NADP <sup>+</sup> = oxidized form, NADPH + H <sup>+</sup> = reduced form
Ⓟ	-PO <sub>3</sub> <sup>2-</sup>
PEP	phosphoenolpyruvate
Pi	inorganic phosphate (PO <sub>4</sub> <sup>3-</sup> )
PPi	inorganic pyrophosphate (P <sub>2</sub> O <sub>7</sub> <sup>4-</sup> )
PTS	phosphoenolpyruvate-dependent phosphotransferase system (see entry PTS)
TPP	thiamine pyrophosphate

A *bisphosphate* is a compound containing two phosphate groups which are not linked to one another (as in e.g. fructose 1,6-bisphosphate); in a *diphosphate* the two phosphate groups are linked to each other (as in e.g. adenosine 5'-diphosphate).

A *synthetase* is an enzyme belonging to EC class 6 (see entry ENZYME); a *synthase* may belong to any other EC class.

For simplicity and visual clarity we have followed the usual practice of giving the *formula* for an organic acid in the unionized form but *naming* it as the salt: e.g., CH<sub>3</sub>COOH = acetate.

**EMBDEN-MEYERHOF-PARNAS PATHWAY**

<sup>a</sup>Depending on organism (see entry EMBDEN-MEYERHOF-PARNAS PATHWAY).  
 PTS = phosphoenolpyruvate-dependent phosphotransferase system (see entry PTS).

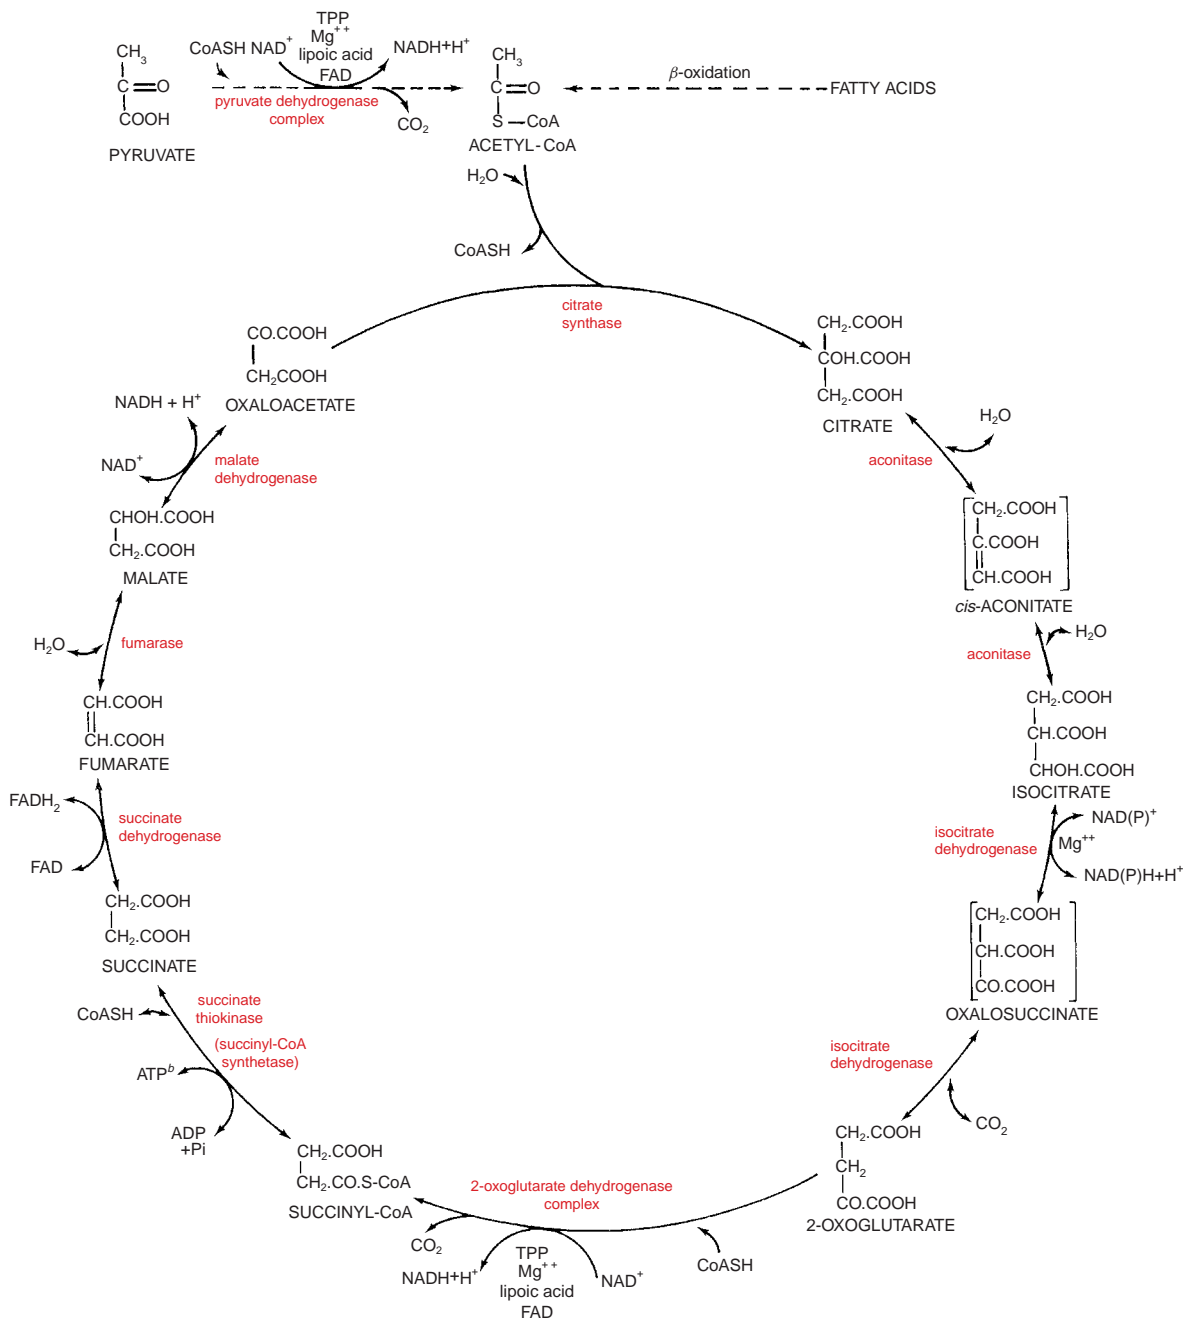

ENTNER-DOUDOROFF PATHWAY<sup>a</sup><sup>a</sup>See entry ENTNER-DOUDOROFF PATHWAY.

Appendix II(a)

TRICARBOXYLIC ACID CYCLE<sup>a</sup>

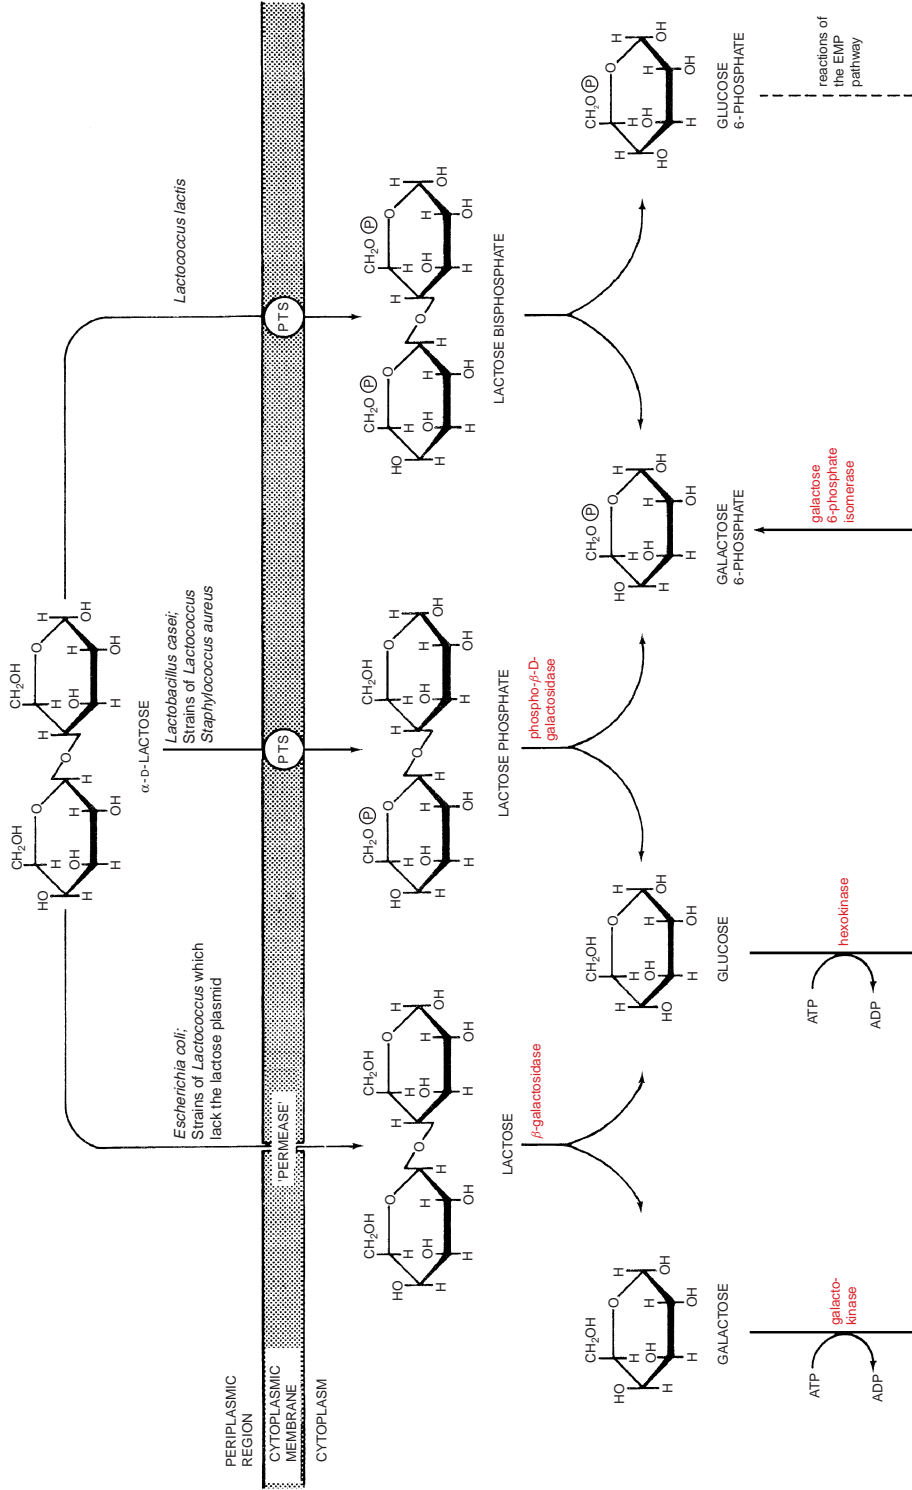

<sup>a</sup>See entry TCA CYCLE.

<sup>b</sup> $\text{ATP} \longrightarrow \text{ADP} + \text{P}_i$  in e.g. *Escherichia coli*;  $\text{GTP} \longrightarrow \text{GDP} + \text{P}_i$  in e.g. mammalian systems; either reaction in some bacteria. Square brackets indicate an enzyme-bound intermediate.

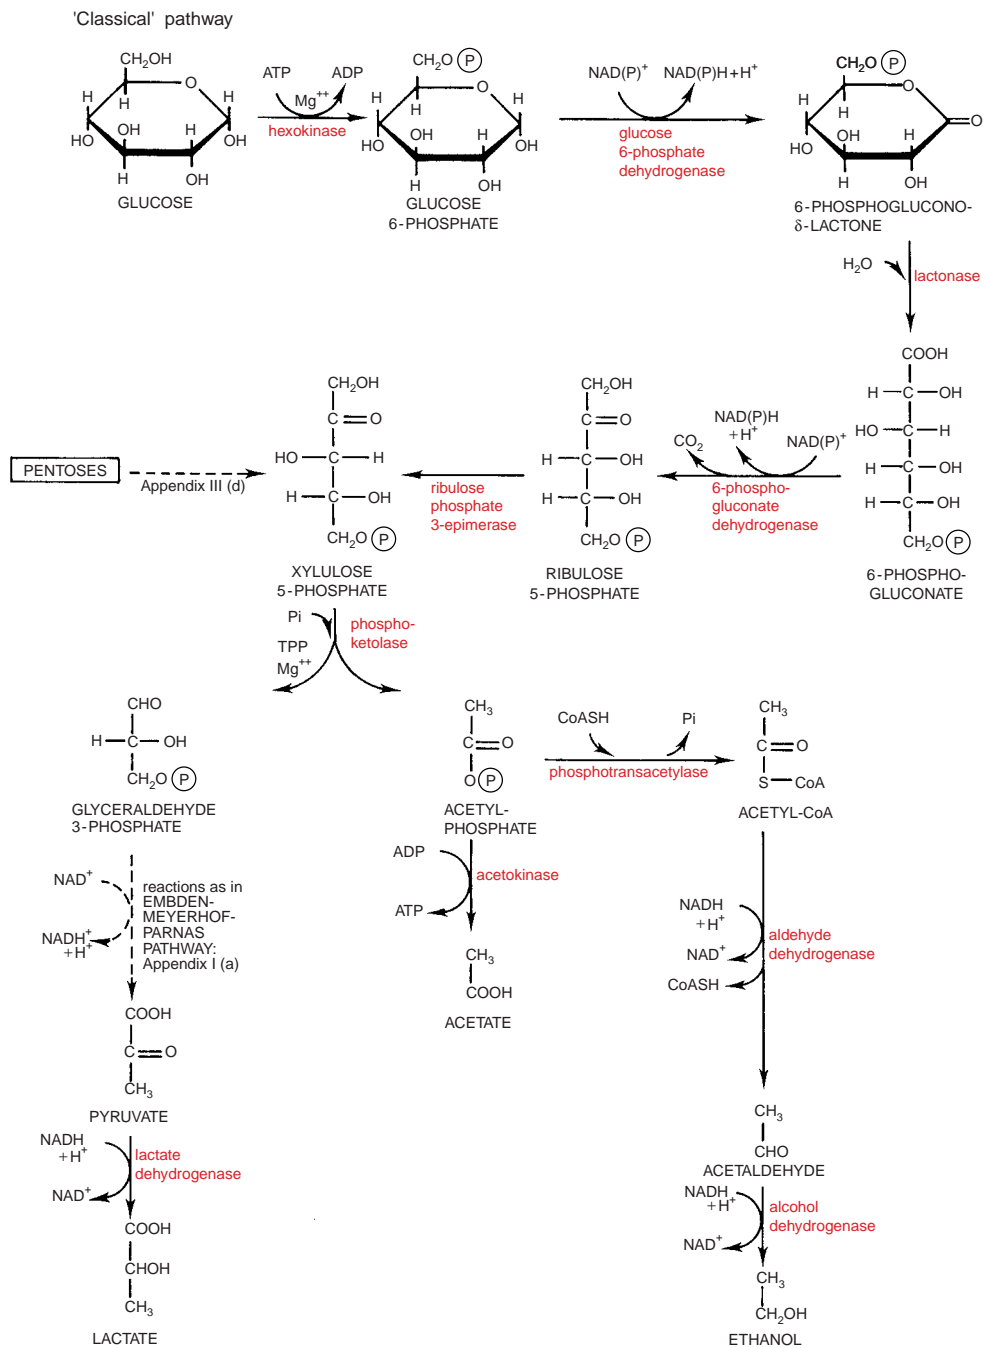

Appendix III(a)

LACTOSE METABOLISM IN SOME BACTERIA<sup>a</sup>

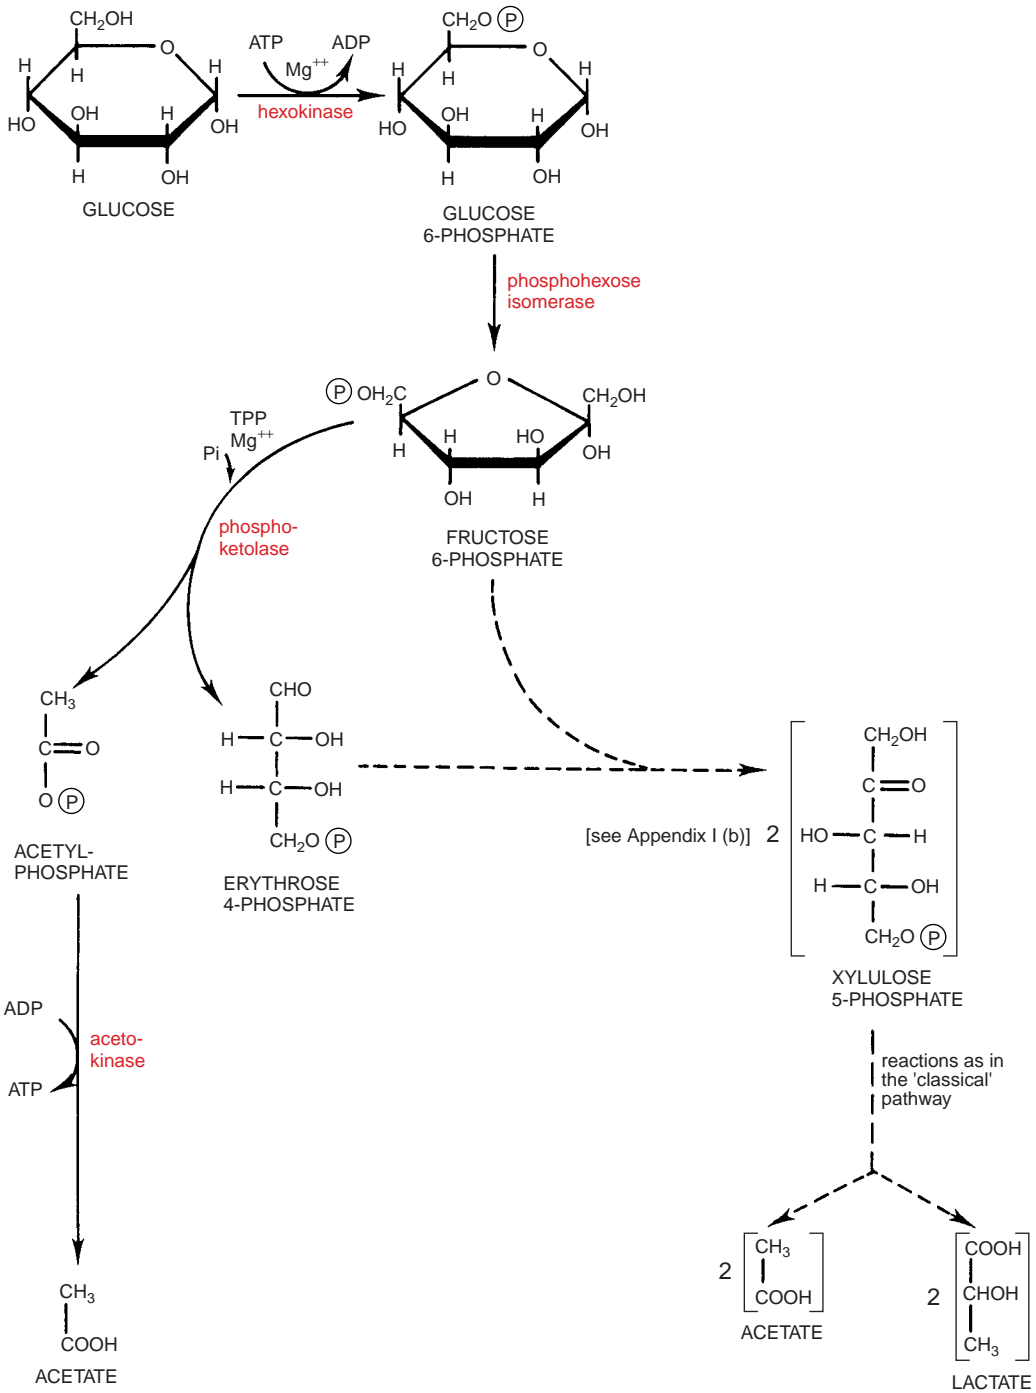

### HETEROLACTIC FERMENTATIONS<sup>a</sup>

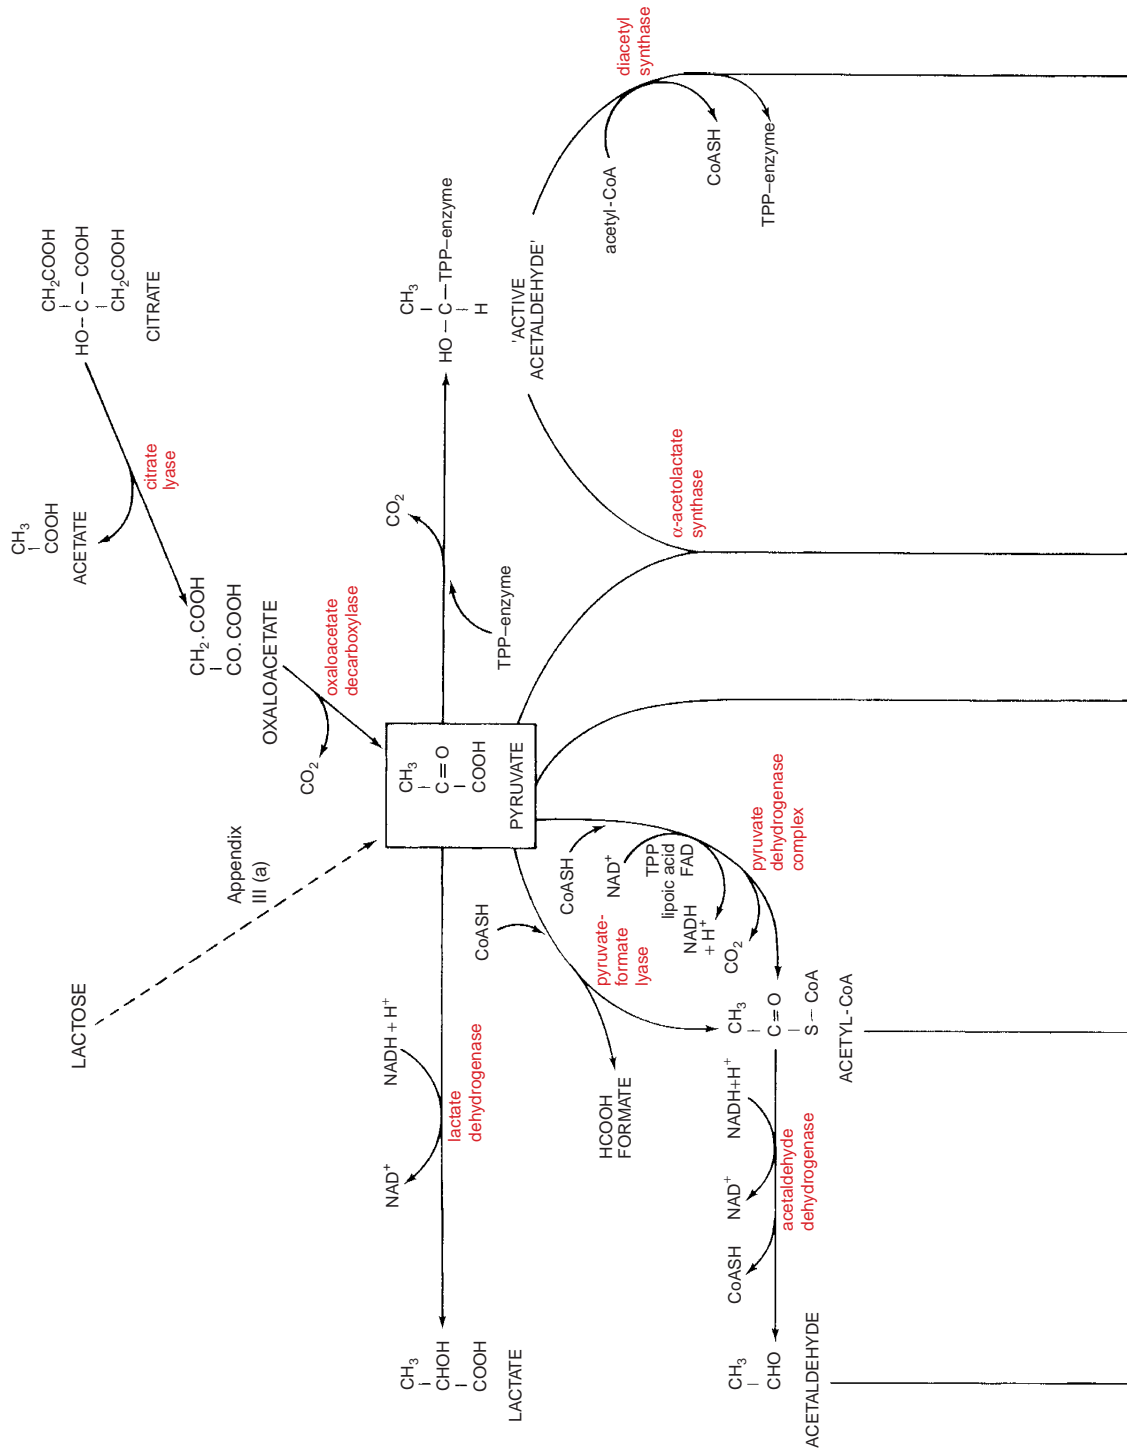

<sup>a</sup>See entry HETEROLACTIC FERMENTATION.

*Bifidobacterium* pathway

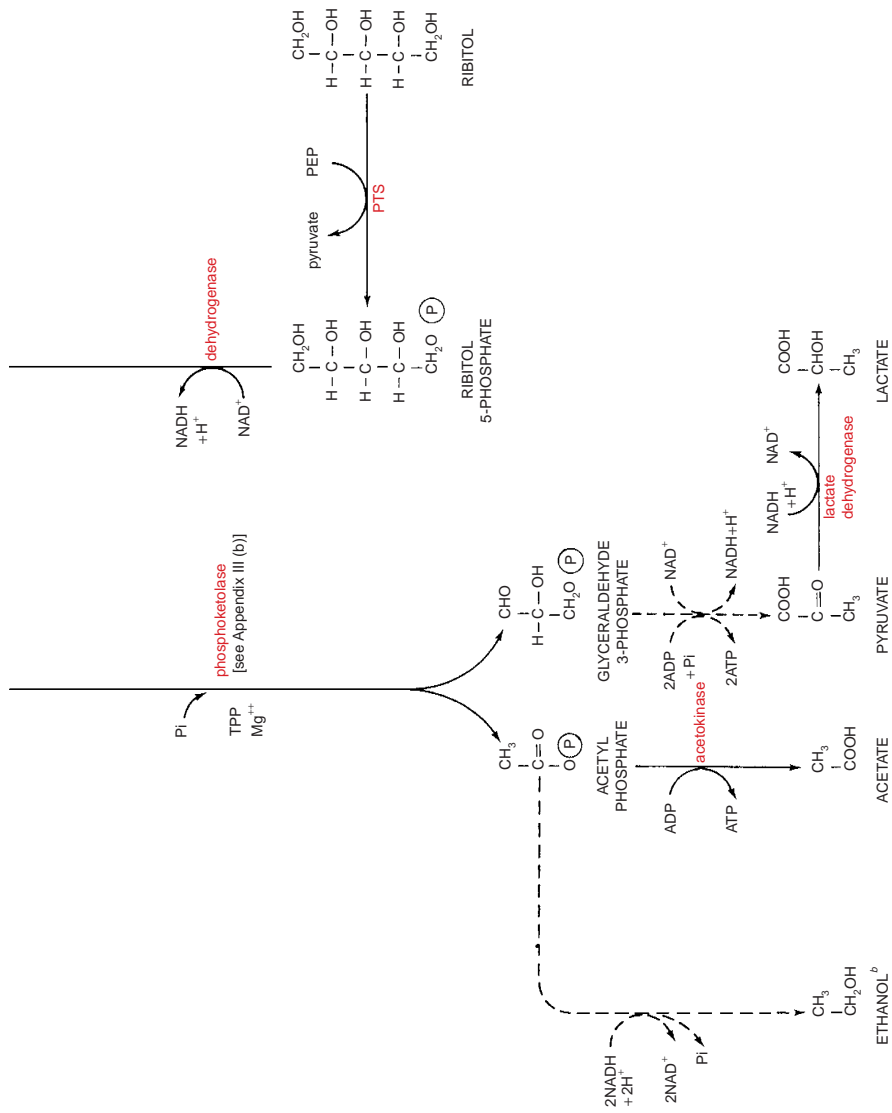

SOME ANAEROBIC FATES OF PYRUVATE IN LACTIC ACID BACTERIA<sup>a</sup>

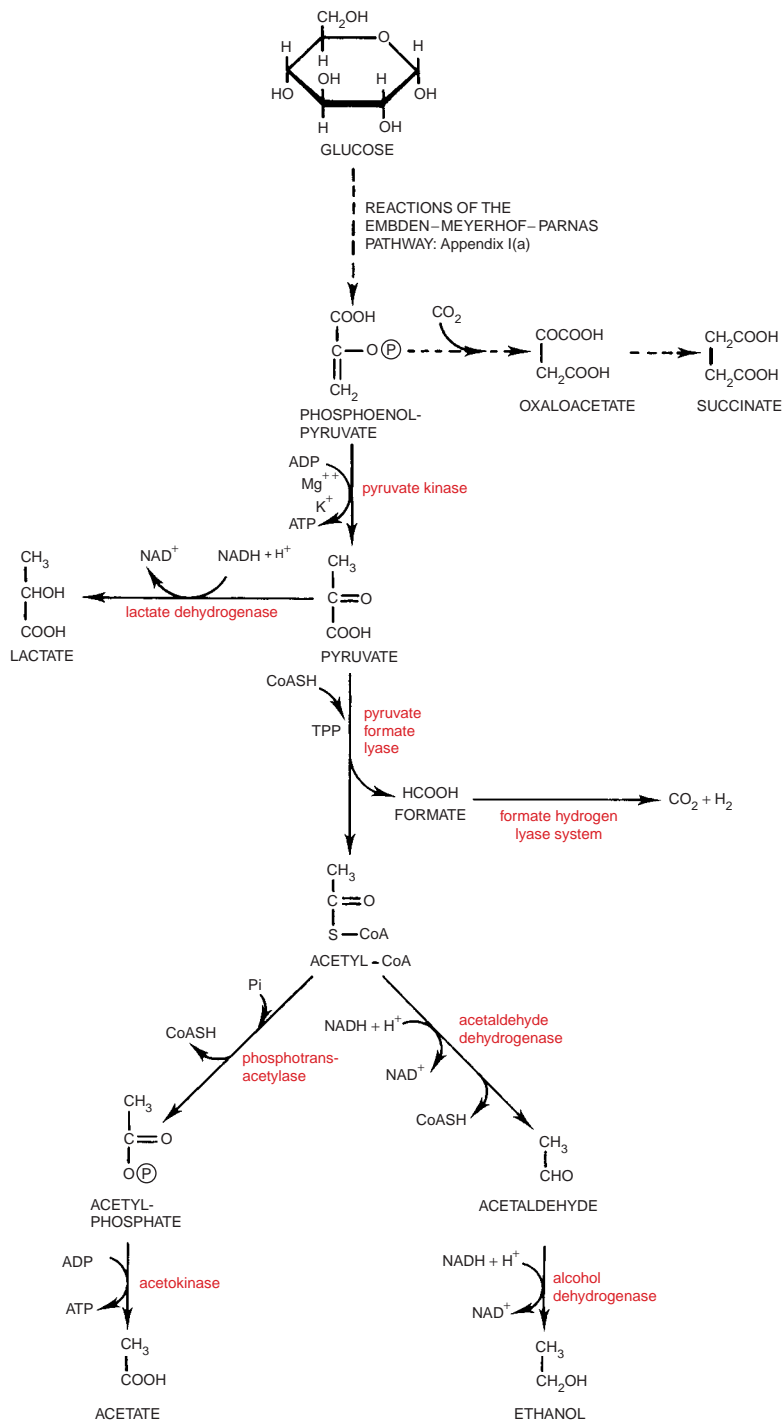

<sup>a</sup>Not all lactic acid bacteria carry out all of these conversions, and many of the pentose/pentulose/pentitol interconversions occur in other microorganisms: see entries PENTOSSES and PENTITOLS.

<sup>b</sup>Ethanol is produced only when the substrate is a pentitol, the NADH formed by the pentitol phosphate dehydrogenase reaction being reoxidized by this means. PTS = phosphoenolpyruvate-dependent phosphotransferase system (see entry PTS).

### MIXED ACID FERMENTATION<sup>a</sup>

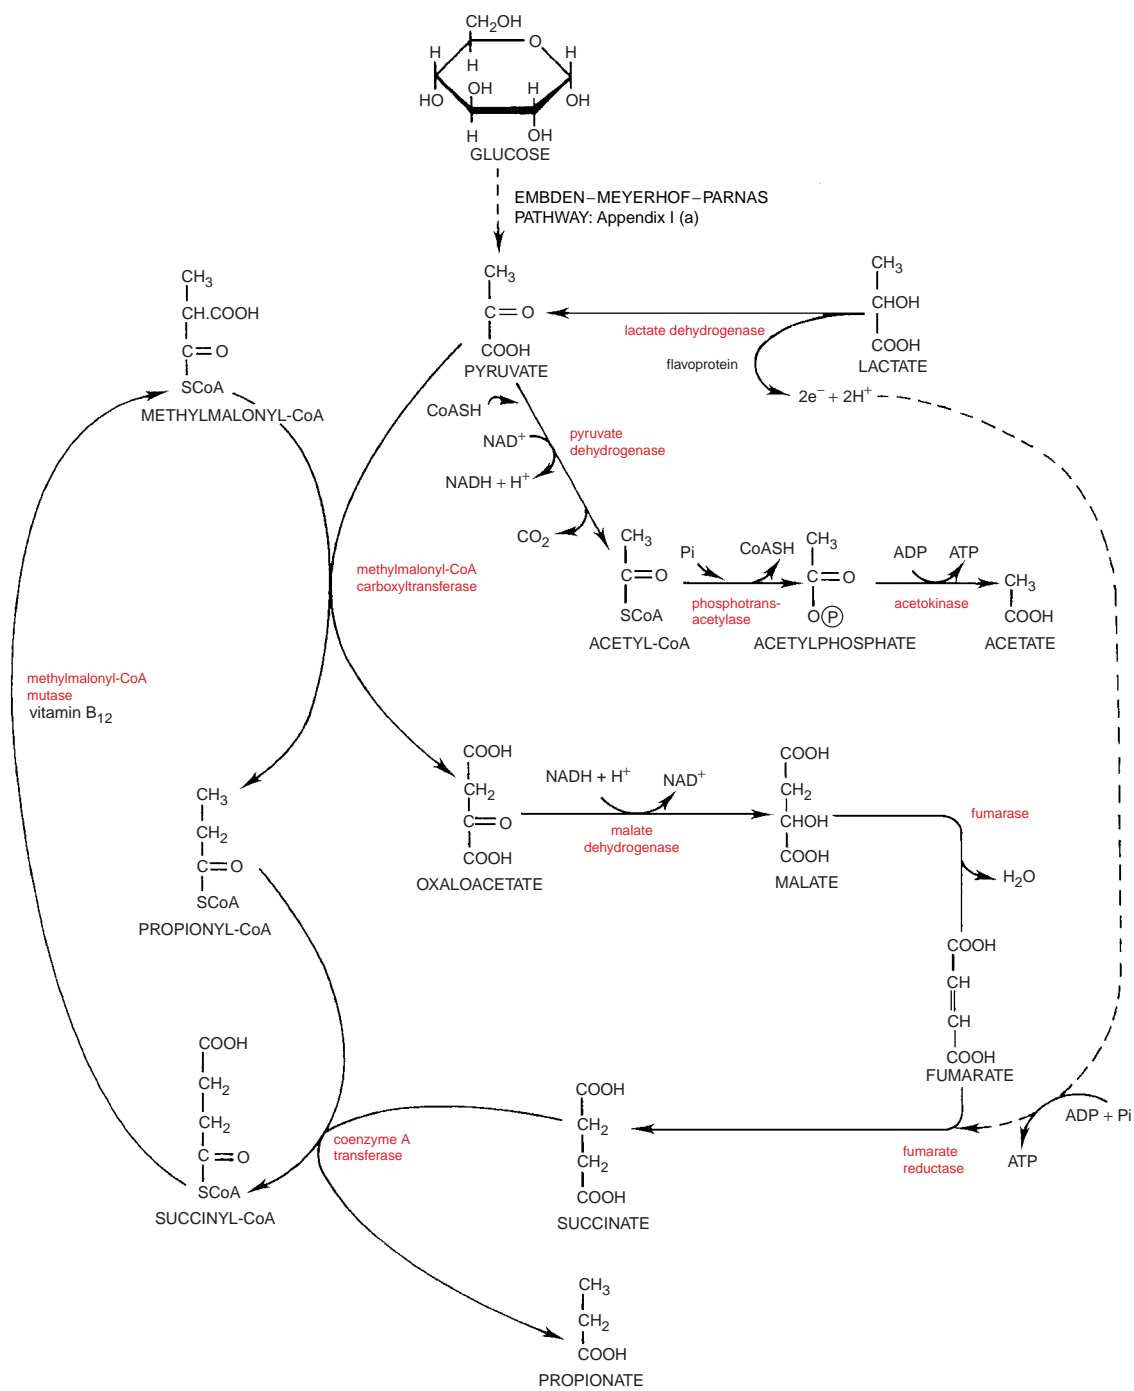

<sup>a</sup>See entry MIXED ACID FERMENTATION.

BUTANEDIOL FERMENTATION<sup>a</sup><sup>a</sup>See entry BUTANEDIOL FERMENTATION.

## PROPIONIC ACID FERMENTATION (in *Propionibacterium*)<sup>a</sup>

<sup>a</sup>See entry PROPIONIC ACID FERMENTATION.

Appendix IV(a)

**BIOSYNTHESIS OF ARGININE<sup>a</sup>, GLUTAMATE<sup>b</sup>, GLUTAMINE<sup>c</sup>, PROLINE**

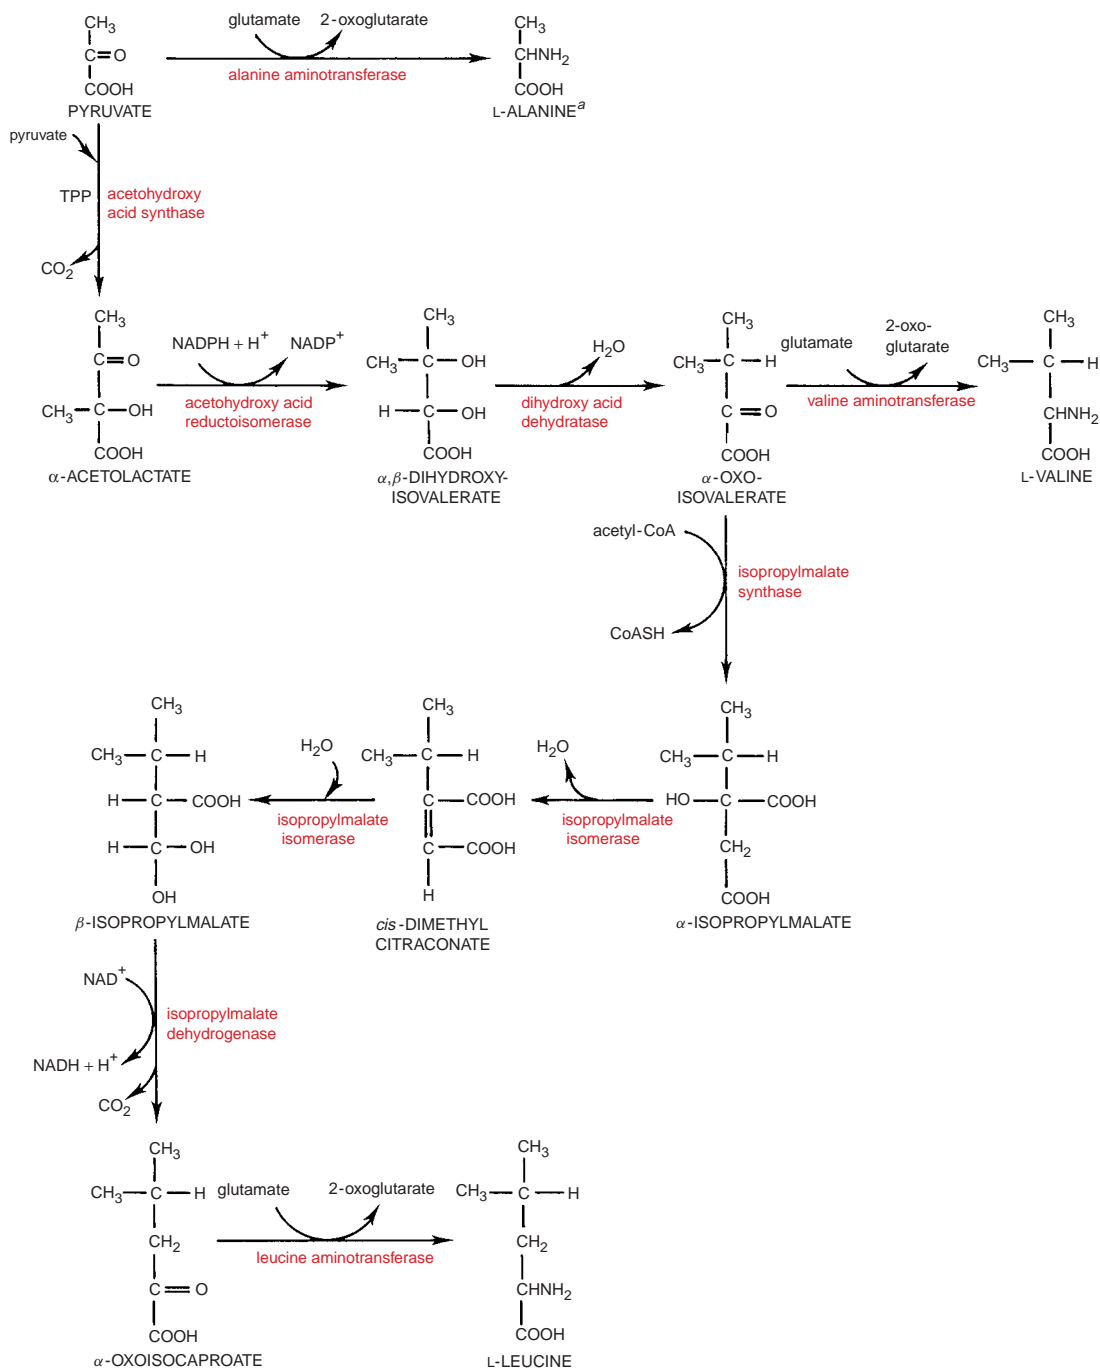

<sup>a</sup>See entry ARGININE BIOSYNTHESIS for reference.

<sup>b</sup>See entry GLUTAMIC ACID.

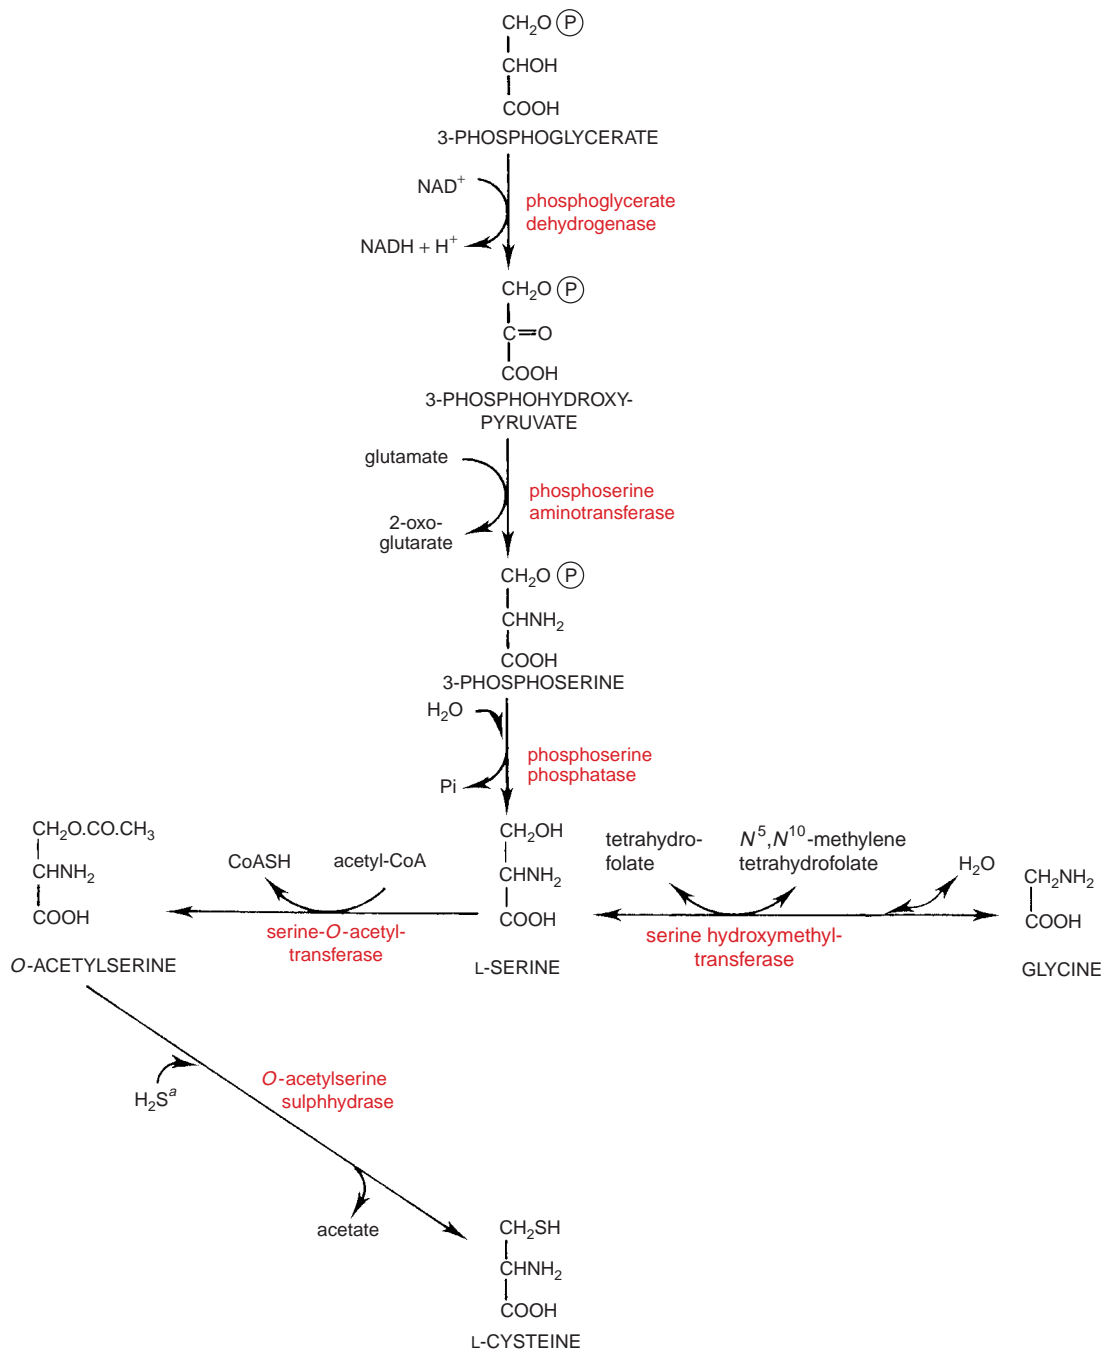

<sup>c</sup>See entry GLUTAMINE.

## BIOSYNTHESIS OF ALANINE, LEUCINE, VALINE

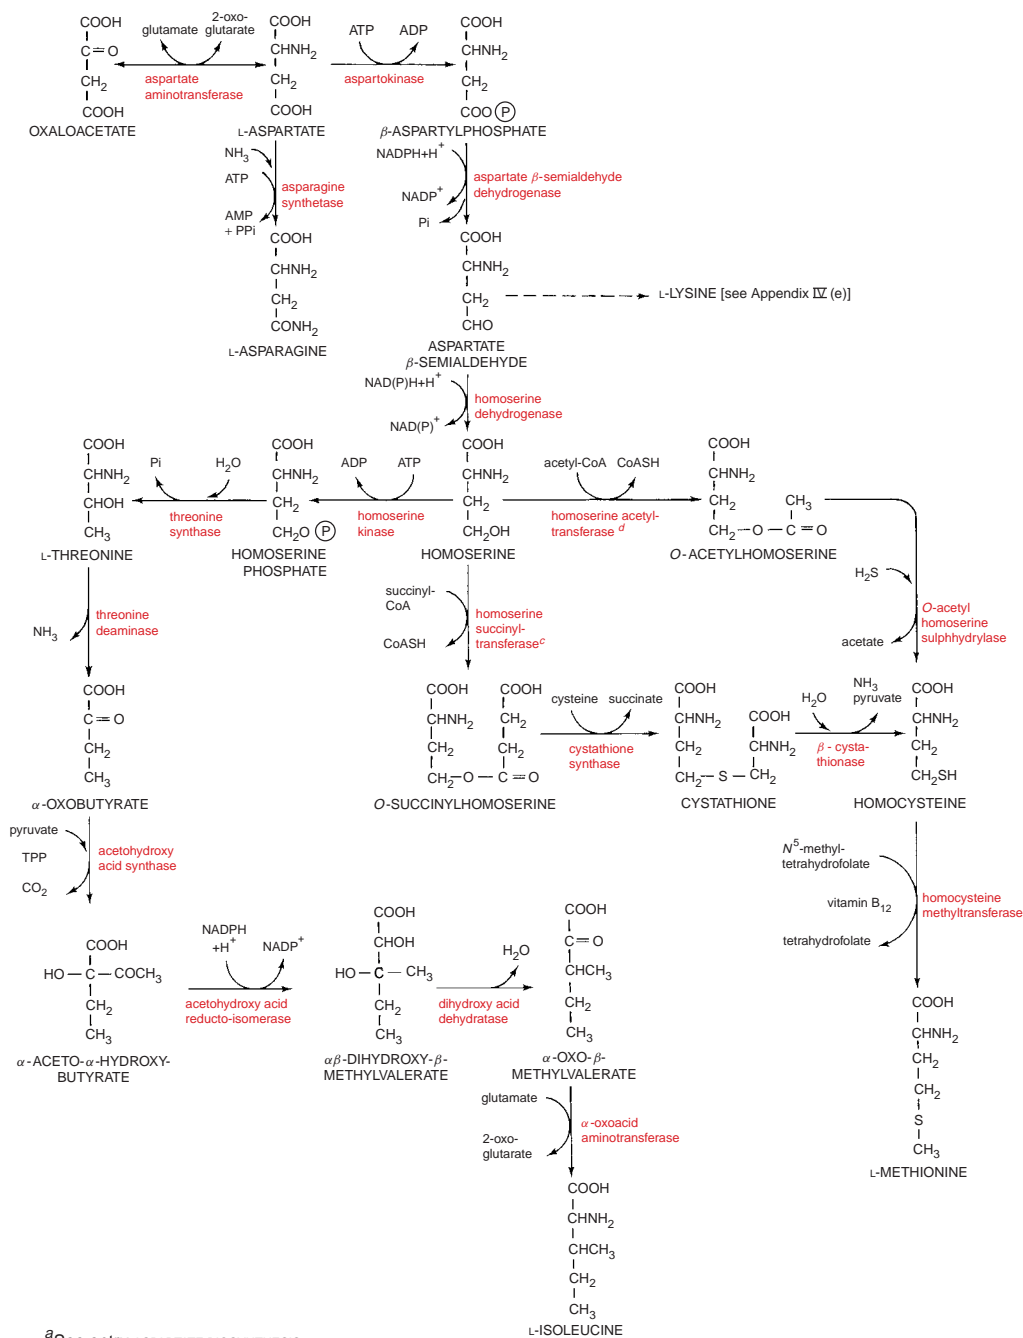

<sup>a</sup>cf. entry AMMONIA ASSIMILATION.

### BIOSYNTHESIS OF CYSTEINE, GLYCINE, SERINE

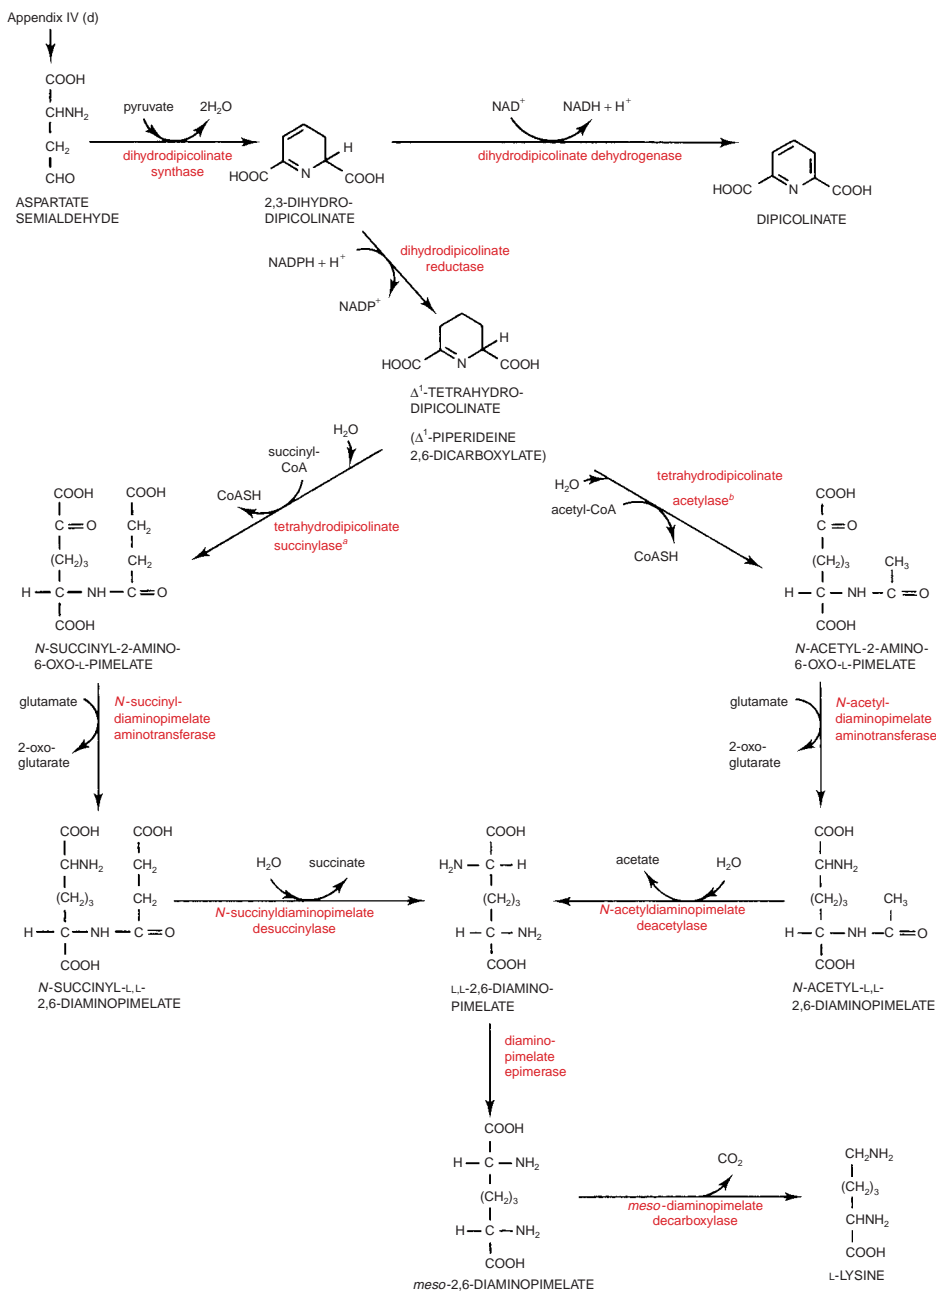

<sup>a</sup>Formed by ASSIMILATORY SULPHATE REDUCTION (q.v.).

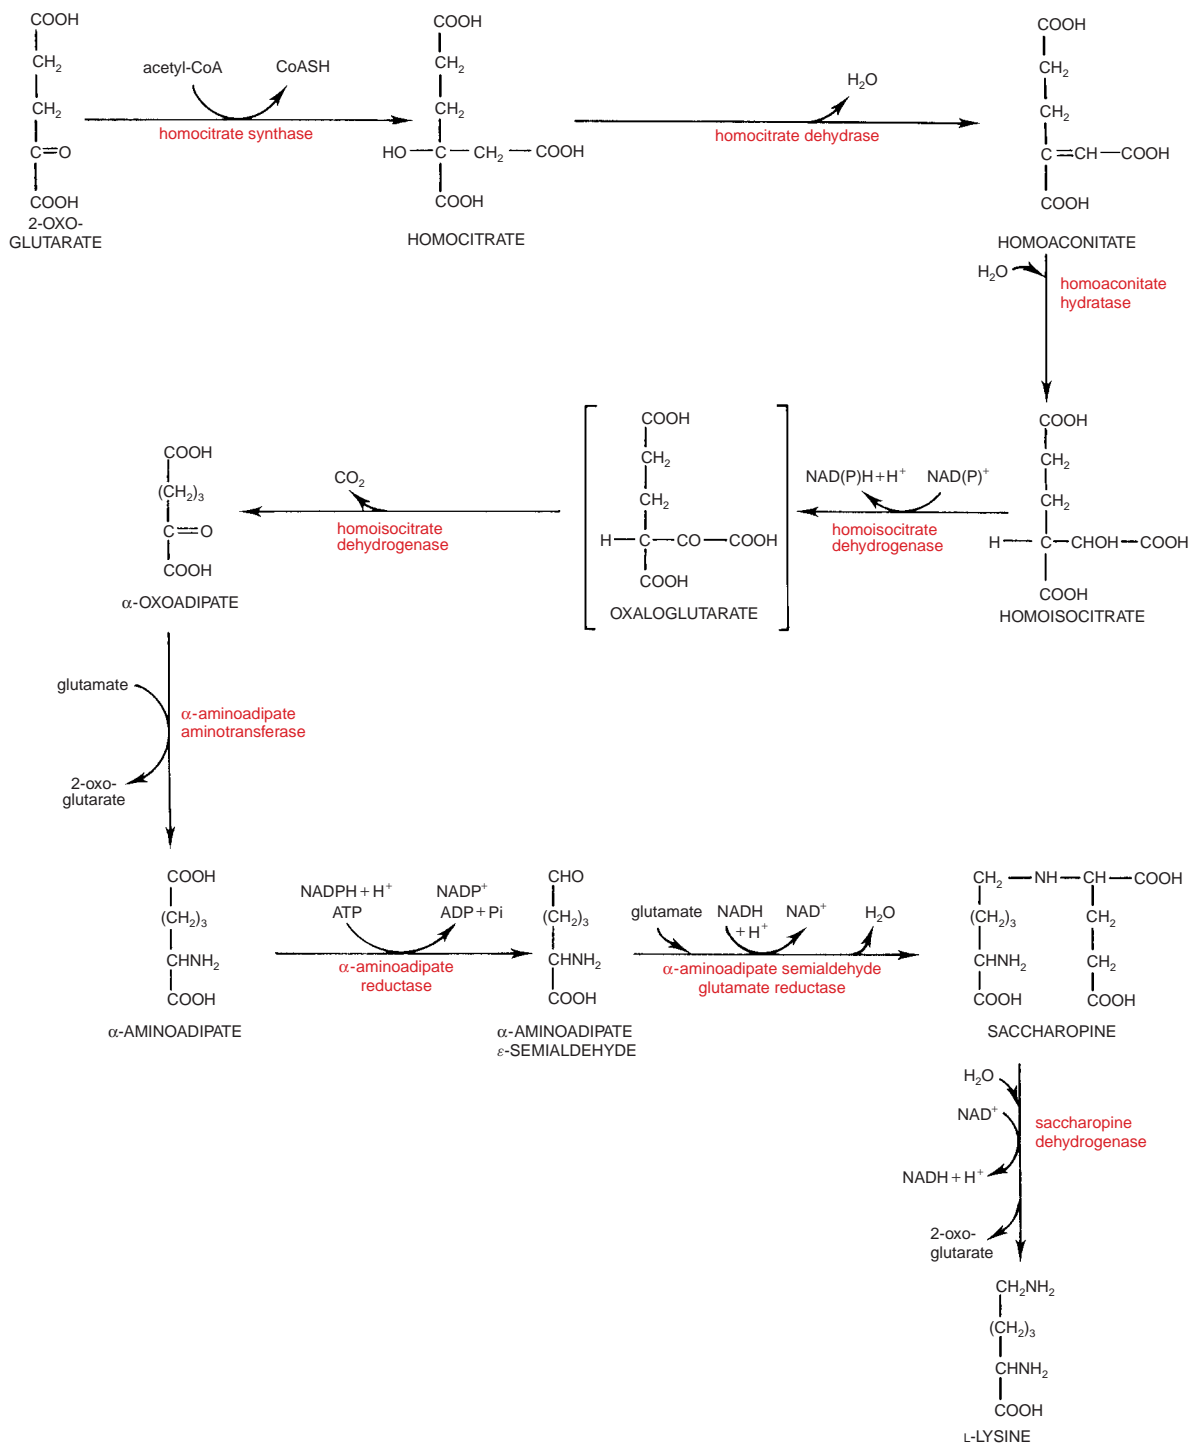

BIOSYNTHESIS OF ASPARAGINE, ASPARTATE<sup>a</sup>, ISOLEUCINE<sup>b</sup>, METHIONINE, THREONINE<sup>a</sup>See entry ASPARTATE BIOSYNTHESIS.<sup>b</sup>See entry ISOLEUCINE BIOSYNTHESIS.<sup>c</sup>In e.g. enterobacteria.<sup>d</sup>In certain bacteria and fungi.

## BIOSYNTHESIS OF LYSINE

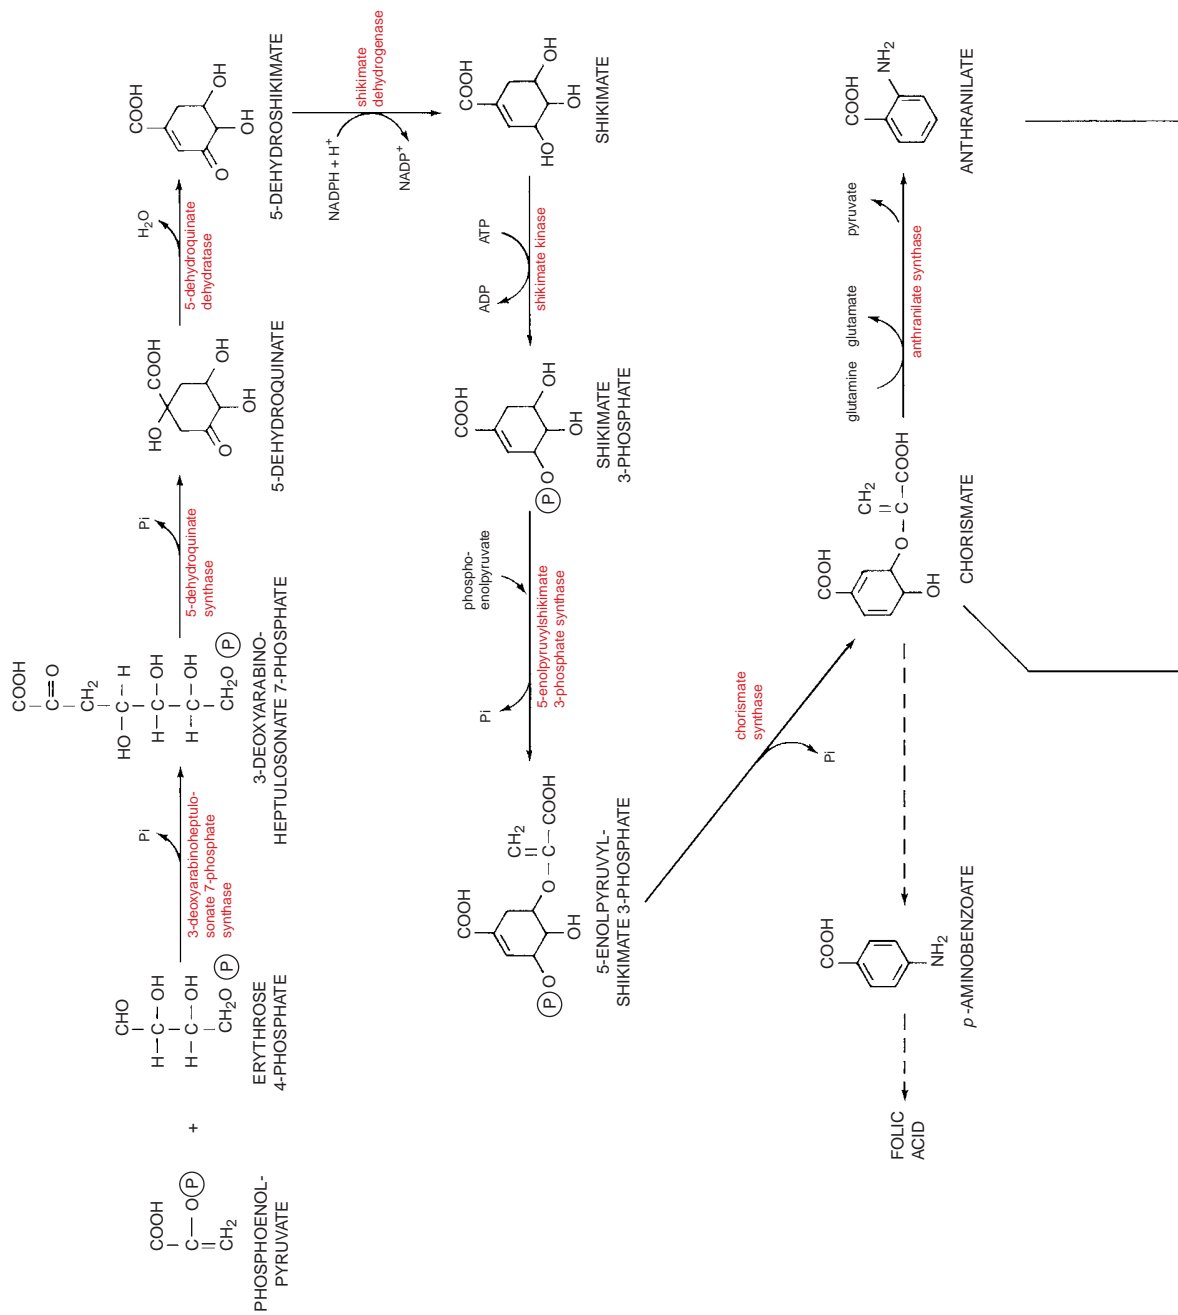

Diaminopimelic acid pathway (see entry)

<sup>a</sup>In e.g. *Escherichia coli*.<sup>b</sup>In e.g. *Bacillus megaterium* [JGM (1982) 128 1073-1081].

Aminoacidic pathway (see entry)

**BIOSYNTHESIS OF AROMATIC AMINO ACIDS: THE SHIKIMATE PATHWAY<sup>a</sup>**

**BIOSYNTHESIS OF HISTIDINE**

Appendix V(a)

BIOSYNTHESIS OF PURINE NUCLEOTIDES<sup>a</sup>

<sup>a</sup>See entry NUCLEOTIDE.

BIOSYNTHESIS OF PYRIMIDINE NUCLEOTIDES<sup>a</sup><sup>a</sup>See entry NUCLEOTIDE.

## THE GREEK ALPHABET

A	$\alpha$	alpha	N	$\nu$	nu
B	$\beta$	beta	$\Xi$	$\xi$	xi
$\Gamma$	$\gamma$	gamma	O	o	omicron

190. *The Genus Coelomomyces*, Couch, J. N. & Bland, C. E. (eds); Academic Press, 1985.

191. *Microbes in Extreme Environments*, Herbert, R. A. & Codd, G. A. (eds); Academic Press, 1986.
192. *Alkalophilic Microorganisms*, Horikoshi, K. & Akiba, T.; Japan Scientific Societies Press (Tokyo)/Springer-Verlag (Berlin), 1982.
193. *Chlamydial Infections*, Oriel, D. et al (eds); Cambridge University Press, 1986.
194. *Evolution of Prokaryotes*, Schleifer, K. H. & Stackenbrandt, E. (eds); Academic Press, 1985.
195. *The Biochemistry of Silage*, McDonald, P.; John Wiley, 1981.
196. *Thermophiles*, Brock, T. D. (ed.); John Wiley, 1986.
197. *Chrysophytes: Aspects and Problems*, Kristiansen, J. & Anderson, R. A. (eds); Cambridge University Press, 1986.
198. *The Bacteria*, Volume X: *The Biology of Pseudomonas*, Sokatch, J. R. (ed.); Academic Press, 1986.
199. *Molecular Cloning and Gene Regulation in Bacilli*, Ganesan, A. T., Chang, S. & Hoch, J. A. (eds); Academic Press, 1982.
200. *Molecular Cloning: a Laboratory Manual*, Maniatis, T., Fritsch, E. F. & Sambrook, J.; Cold Spring Harbor Laboratory, 1982.
201. *The Bacteria*, Volume IX: *Antibiotic-producing Streptomyces*, Queener, S. W. & Day, L. E. (eds); Academic Press, 1986.
202. *Ecology of Microbial Communities* (41st Symposium of the Society for General Microbiology), Fletcher, M., Gray, T. R. G. & Jones, J. G. (eds); Cambridge University Press, 1987.
203. *Structure and Function of Biofilms*, Characklis, W. G. & Wilderer, P. A. (eds); Wiley, 1989.
204. *Transgenesis*, Murray, J. A. H. (ed.); Wiley, 1992.
205. *Secondary Metabolites: their Function and Evolution*, CIBA Foundation Symposium 171; Wiley, 1992.
206. *Sourcebook of Bacterial Protein Toxins*, Alouf, J. E. & Freer, J. H. (eds); Academic Press, 1991.
207. *Gene Regulation: Biology of Antisense RNA and DNA*, Erickson, R. P. & Izant, J. G. (eds); Raven Press (New York), 1992.
208. *Antisense RNA and DNA*, Murray, J. (ed.); Wiley, 1992.
209. *Prospects for Antisense Nucleic Acid Therapy of Cancer and AIDS*, Wickstrom, E. (ed.); Wiley, 1991.
210. *PCR Protocols* (Current methods and applications), White, B. A.; Humana Press, 1993 (ISBN 0-89603-244-2).
211. *PCR* (Essential data), Newton, C. R. (ed.); John Wiley, 1995.
212. *PCR* (Essential techniques), Burke, J. (ed.); John Wiley, 1996.
213. *Antimicrobial Drug Action*, Williams, R. A. D., Lambert, P. A. & Singleton, P.; βios Scientific Publishers, Oxford, 1996 (ISBN 1-872748-81-3).
214. *Cystic Fibrosis*, Shale, D. J. (ed.); BMJ Publishing Group, 1996 (ISBN 0-7279-0826-X).
215. *Progress in Pathology*, Volume 4. Kirkham, N. & Lemoine, N. R. (eds); Churchill-Livingstone, 1998 (ISBN 0-443-06032-0).
216. *Environmental Health Engineering in the Tropics*, 2nd edn, Cairncross, S & Feachem, R; John Wiley, 1993 (ISBN 0-471-93885-8).
217. *Low-cost Sewerage*, Mara, D. (ed.); John Wiley, 1996 (ISBN 0-471-96691-6).
218. *Cellular Microbiology*, Henderson, B., Wilson, M., McNab, R. & Lax, A. J.; John Wiley, 1999 (ISBN 0-471-98681-X).
219. *Practical Medical Microbiology*, 14th edn, Collee, J. G., Fraser, A.G., Marmion, B.P. & Simmons, A.; Churchill-Livingstone, 1996 (ISBN 0-443-047219).
220. *Therapy with Botulinum Toxin*, Jancovic, J. & Hallett, M. (eds); Marcel Dekker (New York), 1994.
221. *DNA Methods in Clinical Microbiology*, Singleton, P.; Kluwer Academic Publishers (Dordrecht), 2000 (ISBN 07923-6307-8).
222. *DNA Methylation: Molecular Biology and Biological Significance*, Jost, J. P. & Saluz, H. P. (eds); Birkhäuser, 1993 (ISBN 3-7643-2778-2).
223. *Bacteria in Biology, Biotechnology and Medicine*, 5th edn, Singleton, P.; John Wiley, 1999 (ISBN 0-471-98880-4).
224. *External Eye Diseases: a Colour Atlas*, Watts, M. T. & Nelson, M. E. (eds); Churchill-Livingstone, 1992 (ISBN 0-443-04446-5).
225. *Plasmids for Therapy and Vaccination*, Schleef, M. (ed.); Wiley-VCH, 2000/2001 (ISBN 3527-30269-7).
226. *The Molecular Biology of Cytokines*, Meager, T.; John Wiley, 1998 (ISBN 0-471-98272-5).
227. *Immunology*, 3rd edn, Benjamini, E., Sunshine, G. & Leskowitz, S.; Wiley-Liss, 1996 (ISBN 0-471-59791-0).
228. *Tempe*, Baumann, U. & Bisping, B. (eds); Wiley-VCH, 2001 (ISBN 3527-30090-2).
