**ethylene** (*plant pathol.*) A PHYTOHORMONE which, in higher plants, can induce e.g. germination, flowering, fruit ripening, senescence – depending on the plant and its stage of development. Ethylene is also produced by plant tissues in response to stress, damage, or infection by certain pathogens, and large quantities are produced by plant tissues exhibiting HYPERSENSITIVITY; it may give rise to certain symptoms of disease – e.g. EPINASTY, premature ripening of fruit or leaf-fall.

**ethylene glycol** See ALCOHOLS.

**ethylene oxide** A colourless, highly reactive, water-soluble cyclic ether (b.p. 10.8°C) used (as a vapour) for the DISINFECTANT or STERILIZATION of e.g. medical equipment and certain heat-labile materials. The vapour forms explosive mixtures with air in a wide range of proportions and is commonly diluted with carbon dioxide, nitrogen or fluorohydrocarbons: e.g. *Carboxide* contains 10% ethylene oxide, 90% CO<sub>2</sub> (see also e.g. CRYOXICIDE,

PENNOXIDE). Ethylene oxide is an ALKYLATING AGENT which reacts with e.g. proteins and nucleic acids. Antimicrobial activity depends e.g. on temperature, concentration, duration of action, water content of the target organisms (dried spores etc can be highly resistant), and relative humidity. The use of ethylene oxide as a STERILANT thus requires careful control of conditions. For reliable sterilization the optimum relative humidity is variously reported as 35–60% [Book ref. 2, pp. 481–483] and ca. 100% [Book ref. 12, pp. 548–568]. The vapour has moderate powers of penetration, and sterilization usually necessitates exposure for at least several hours. Ethylene oxide is often used in an apparatus resembling a vacuum autoclave to allow conditions to be controlled and to reduce sterilization time. Ethylene oxide is absorbed by, or reacts with, substances such as hessian, rubber, and certain plastics; this may significantly reduce the effective concentration of the vapour. Ethylene oxide is readily hydrolysed to ethylene glycol; the toxic substance ethylene chlorohydrin (b.p. 129°C) is formed by hydrolysis in the presence of chloride ions. (N.B. Ethylene oxide is irritant and may be carcinogenic.)

The sterilizing activity of ethylene oxide at a given location can be monitored by a *Royce indicator sachet*: a small plastic bag containing MgCl<sub>2</sub>, HCl and the pH indicator BROMPHENOL BLUE; under sterilizing conditions ethylene oxide penetrates the sachet and is hydrolysed to ethylene chlorohydrin, causing a rise in pH. Bacterial endospores may be used as biological monitors [see e.g. JAB (1983) 55 39–48].

**ethylenediaminetetraacetic acid** See EDTA.

**ethyleneane sulphonate** A mutagenic ALKYLATING AGENT.

**ethylhydrocupreine hydrochloride** See OPTOCHIN.

**ethylmethane sulphonate** See ALKYLATING AGENTS.

**etiology** See AETIOLOGY.

**etioplast** An achlorophyllous PLASTID formed e.g. in dark-grown (etiolated) seedlings of most types of angiosperm; most algae, mosses and ferns can synthesize chlorophylls in the dark. (See also PROLAMELLAR BODY.)

**etioporphyrins** See PORPHYRINS.

**ETP** (electron-transport particle; sub-mitochondrial particle, SMP)

A type of vesicle formed by the ultrasonic disruption of mitochondria (see MITOCHONDRION and ULTRASONICATION). An ETP consists of *inverted* mitochondrial membranes containing electron-transport and H<sup>+</sup>-ATPase functions (although the actual composition varies considerably depending e.g. on the mode of preparation); ATP synthesis in an ETP thus correlates with the *outward* passage of protons. (cf. KABACKOSOME.)

**etridiazole** (trade names: Aaterra, DWELL, Pansoil, Terrazole) 5-Ethoxy-3-trichloromethyl-1,2,4-thiadiazole, a NITRIFICATION INHIBITOR which is also used as a seed and soil fungicide – e.g. for the control of damping off caused by *Phytophthora* and *Pythium*. [Review: Book ref. 121, pp. 45–62.]

**etruscomycin** A MYCOSAMINE-containing tetraene POLYENE ANTI-BIOTIC structurally very similar to PIMARICIN.

**Euascomycetes** A class of fungi comprising most or all ascomycetes other than the HEMIASCOMYCETES. The class is not recognized in modern taxonomic schemes.

**Euastrum** A genus of placoderm DESMIDS.

**Eubacteria** (*taxon.*) A kingdom (now obsolete) which included all those prokaryotes which were not classified in the kingdom ARCHAEBACTERIA. [The major eubacterial taxa defined: SAAM (1985) 6 143–151.] Members of the Eubacteria are now included in the domain BACTERIA (q.v.).

**Eubacterium** An ill-defined genus of Gram-positive, asporogenous, anaerobic, rod-shaped bacteria consisting of those species

## Eubenangee subgroup

which are excluded from the genera ACTINOMYCES, ARACHNIA, BIFIDOBACTERIUM, LACTOBACILLUS and PROPIONIBACTERIUM on the basis of the nature of the products of fermentation. *Eubacterium* spp typically form butyric and other fatty acids; some species produce acetic and formic acids (and ethanol), and some do not form acids. The organisms occur e.g. in the human gut and in the RUMEN. [Book ref. 46, pp. 1903–1911.]

**Eubenangee subgroup** See ORBIVIRUS.

**Eucapsis** A phycological genus of unicellular 'blue-green algae' (Chroococcales) in which the cells occur (in nature) in cubical packets. See SYNECHOCYSTIS.

**eucarpic** Refers to those organisms in which only part of the thallus is involved in the formation of reproductive organs. (cf. HOLOCARPIC.)

**eucaryote** *Syn.* EUKARYOTE.

**Eucheuma** A genus of tropical marine algae (division RHODOPHYTA). The organisms are used as a source of CARRAGEENAN.

**euchromatin** See CHROMATIN.

**euchrysin** *Syn.* ACRIDINE ORANGE.

**Eucoccida** An order of protozoa (subclass Coccidia) later incorporated – together with organisms of the TOXOPLASMEA – in the order EUCCIDIORIDA.

**Eucocciida** An order of protozoa [JP (1980) 27 37–58] equivalent to the EUCCIDIORIDA.

**Eucoccidiorida** An order of protozoa (subclass COCCIDIASINA), parasitic in vertebrates and invertebrates, in which both schizogony and sexual reproduction occur. Suborders: ADELEORINA, EIMERIORINA, HAEMOSPORORINA.

**Eucoronis** See RADIOLARIA.

**euendolith** See ENDOLITHIC.

**eulflavin** *Syn.* ACRIFLAVINE.

**eu-form rusts** *Syn.* MACROCYCLIC RUSTS.

**Euglena** A genus of photosynthetic EUGLENOID FLAGELLATES (q.v. for general features). Most species are green, but some (e.g. *E. rubra*) contain a bright red pigment which may mask the green colour under certain conditions. The vegetative cell is typically elongated and fusiform (ca. 15–400 µm long, according to species) but can vary its shape extensively. There is only one emergent flagellum; this bears a single helical row of fine hairs along its length, as well as a coating of shorter hairs. A lateral swelling (the *paraflagellar body*) is present on the long flagellum in the region within the reservoir, and this swelling lies opposite an EYESPOT present in the cytoplasm. A contractile vacuole empties into the reservoir. Other cell contents include the chloroplasts, a single large nucleus, paramylon granules etc.

*Euglena* spp exhibit two distinct types of motility: a spiral swimming motion (see FLAGELLAR MOTILITY (b)) and 'euglenoid movement' (*metaboly*) – a type of crawling motility involving progressive waves of swelling and constriction of the cell body; metaboly is the main type of motility in *E. deses*. [Regulation of cell shape in *E. gracilis* – localization of actin and myosin in the region of the pellicle: JCS (1985) 77 197–208.]

Most *Euglena* spp (e.g. *E. gracilis*, *E. rubra*, *E. spirogyra*) occur in freshwater habitats, particularly those rich in organic matter (e.g. farm ponds) where they may form dense green or red blooms. (See also SAPROBITY SYSTEM.) *E. cyclopicola* frequently occurs attached by its anterior end to microscopic crustacea (*Cyclops*, *Daphnia* etc), when it resorbs its flagellum. Some species occur in brackish waters (e.g. in estuarine mudflats), a few occur in the sea. *E. deses* is common in soil.

**Euglenamorpha** See EUGLENOID FLAGELLATES.

**Euglenida** See PHYTOMASTIGOPHOREA.

**euglenids** *Syn.* EUGLENOID FLAGELLATES.

**euglenoid flagellates** (euglenids; euglenoids) A group of unicellular organisms regarded either as algae (class Euglenophyceae, division Euglenophyta) or as protozoa (see PHYTOMASTIGOPHOREA). The vegetative cell has no cell wall, but has a *pellicle* consisting of spirally arranged, interlocking, proteinaceous strips beneath the plasmalemma. The pellicle may be flexible (in e.g. *Astasia*, *Distigma* and *EUGLENA*) or rigid (in e.g. *Menoidium*, *Phacus* and *Rhodomonas*). Mucilage-secreting *muciferous bodies* occur in helical rows beneath the pellicle. In some genera (e.g. *Klebsiella*, TRACHELOMONAS) the cell is partly or totally enclosed in a mineralized LORICA. At the anterior end of the cell is an invagination, the *reservoir* (also called the 'gullet' although it does not function in feeding), which opens to the exterior via a narrow *canal*. A contractile vacuole commonly empties into the reservoir. In most genera two flagella arise from basal bodies at the base of the reservoir, but in some genera (e.g. *Astasia*, *Colacium*, *Euglena*, *Phacus*) only one flagellum (containing a PARAXIAL ROD) actually emerges from the cell via the canal; in e.g. *Distigma*, *Eutreptia*, PERANEMA and HETERONEMA two flagella are emergent, one of which is directed anteriorly, the other laterally or posteriorly. (Parasitic euglenids may have 3 or more emergent flagella.)

Many euglenids are photosynthetic, possessing green chloroplasts containing chlorophylls *a* and *b* and various carotenoids. However, photosynthetic species can apparently also grow heterotrophically on e.g. acetate or ethanol in the dark, and many genera (e.g. *Astasia*, *Khawkinea*, *Rhodomonas*) are colourless and obligately heterotrophic; PERANEMA and related genera are holozoic. A storage compound characteristic of both photosynthetic and heterotrophic euglenids is PARAMYLON.

Euglenids reproduce chiefly by longitudinal binary fission; MITOSIS occurs within the nuclear membrane and does not involve a spindle. Palmelloid phases are common in some species. (cf. COLACIUM.) Desiccation-resistant cysts are formed in e.g. *Distigma* and *Euglena* under adverse conditions. Sexual reproduction is virtually unknown.

Euglenoid flagellates are mainly free-living aquatic organisms, occurring in fresh water (e.g. most *Euglena* spp, *Phacus*) or in brackish or sea water (e.g. some *Euglena* spp, *Eutreptia*, *Klebsiella*). Some species are parasitic (e.g. *Euglenamorpha* in the gut of tadpoles).

**euglenoid movement** See EUGLENA.

**Euglenophyceae** See EUGLENOID FLAGELLATES.

**Euglypha** A genus of testate amoebae (order Gromiida, class FILOSEA) in which the test (ca. 30–160 µm diam.) is composed of siliceous scales which are synthesized within the cytoplasm before incorporation into the test. Pseudopodia are generally narrow, filamentous, and sometimes anastomosing. Species occur in fresh water, activated sludge, anaerobic regions in acidic bogs, etc. (cf. PAULINELLA.)

**eugonic** Refers to a strain of e.g. *Mycobacterium* which, on culture, produces growth which is more luxuriant than that produced by other (*dysgonic*) strains; the growth itself may also be described as eugonic (or dysgonic).

**eugregarines** See GREGARINASINA.

**eukaryote** (eucaryote) A type of CELLULAR (sense 2 or 3) organism in which the CHROMOSOMES are separated from the cytoplasm by a membrane (see NUCLEUS) and usually contain HISTONES (cf. DINOFLAGELLATES); the CYTOPLASMIC MEMBRANE contains sterols; mitochondria are commonly present; chloroplasts occur in photosynthetic species; RIBOSOMES in the *cytoplasm* are of the 80S type; the CELL WALL (when present) contains e.g. CELLULOSE or CHITIN; storage compounds apparently never include poly-β-hydroxybutyrate; flagella or cilia (when present) are structurally

relatively complex (see FLAGELLUM (b) and CILIUM). Eukaryotic MICROORGANISMS include ALGAE, FUNGI, LICHENS and PROTOZOA.

Eukaryotes may have arisen some 2–3.5 billion years ago [Science (1996) 271 470–477] from an energy-based symbiotic relationship between cells of the ARCHAEA and BACTERIA [the hydrogen hypothesis: Nature (1998) 392 37–41].

(cf. PROKARYOTE.)

**eumycetoma** See MADUROMYCOSIS.

**Eumycetozoa** See EUMYCETOZOA.

**Eumycetozoa** According to one protozoal classification scheme [JP (1980) 27 37–58]: a class of SLIME MOULDS of the RHIZOPODA. Members of the class typically form myxamoebae with filose pseudopodia or subpseudopodia; flagella, when formed, lack mastigonemes. Aerial fruiting bodies are produced. Subclasses: Protosteliia (equivalent to the PROTOSTELIOMYCETES together with CERATIOMYXA); Dictyosteliia (equivalent to the DICTYOSTELIOMYCETES); Myxogastria (equivalent to the MYXOMYCETES). According to another classification scheme [Book ref. 147, pp. 4–5], equivalent taxa are the class Eumycetozoa (subphylum MYCETOZOA) and its constituent subclasses Protostelia, Dictyostelia and Myxogastria.

**Eumycota** In some mycological classification schemes [e.g. Book ref. 64]: a division which includes the 'true fungi' (subdivisions ASCOMYCOTINA, BASIDIOMYCOTINA, DEUTEROMYCOTINA, MASTIGOMYCOTINA and ZYGOMYCOTINA). (cf. MYXOMYCOTA.)

**Euphorbia mosaic virus** See GEMINIVIRUSES.

**euphotic zone** See PHOTIC ZONE.

**euploid** (1) Having the basic haploid number of chromosomes or any *exact* multiple of the haploid number. (cf. ANEUPLOID.)

(2) Having a chromosome complement characteristic of the species. (cf. HETEROPLLOID.)

**Euplotes** A genus of highly evolved ciliate protozoa (order HYPOTRICHIDA); species occur in freshwater, brackish and marine habitats, and some (e.g. *E. moebiusi*) are common in some SEWAGE TREATMENT plants. Cells: roughly ovoid, ca. 50–150 µm in length, with a flattened ventral side and a dorsal side which is often markedly ridged; the cytostome is anterior and ventral, the distal part of the AZM forming a conspicuous, protruding fringe. The ventral surface carries a number of cirri which occur in localized groups and on which the organism is capable of 'creeping' or 'walking' movements; other forms of somatic ciliature are absent. The macronucleus is typically band-like and curved, the micronucleus small and spherical. [Macronuclear development in *E. crassus*: JCB (1985) 101 79–84.] Some strains contain endosymbionts (see OMICRON). A contractile vacuole is present. Asexual reproduction occurs by binary fission. CONJUGATION occurs (see SYNGEN). TRANSLATIONAL FRAME-SHIFTING seems common [Cell (2002) 111 763–766]. Food: algae, bacteria, other protozoa.

**European bat lyssavirus** See LYSSAVIRUS.

**European blastomycosis** *Syn.* CRYPTOCOCCOSIS.

**European foulbrood** A BEE DISEASE which affects larvae (ca. 4–5 days old) of *Apis mellifera* and *A. cerana*; infected larvae die, turn brown and putrefy. The causal agent is *Melissococcus pluton* (formerly called *Streptococcus pluton*) [JAB (1983) 55 65–69]; infection occurs by ingestion, and the bacteria multiply within – and sometimes fill – the midgut. Secondary invaders may include e.g. *Enterococcus faecalis* and *Bacillus alvei*. (cf. AMERICAN FOULBROOD.)

**European swine fever** *Syn.* SWINE FEVER.

**Eurotiales** An order of mainly saprotrophic fungi of the sub-division ASCOMYCOTINA; anamorphs occur e.g. in the genera ASPERGILLUS and PENICILLIUM. Ascocarp: cleistothecoid,

sometimes (e.g. in *Talaromyces*) very loosely constructed of interwoven hyphae, with no appendages; the development of the ascocarp may involve intertwining of the ascogonium and antheridium. Asci: unitunicate, thin-walled, formed at various levels in the ascocarp. Ascospores: unicellular, dark or colourless. Genera: e.g. BYSSOCHLAMYS, EMERICELLA, *Emerickloppsis* (see also ACREMONIUM), EUROTIIUM, *Pleuroascus*, SARTORYA, TALAROMYCES, THERMOASCUS.

**Eurotium** A genus of fungi (order EUROTIALES) which include the teleomorph of *Aspergillus glaucus*. The ascocarp is a globose, commonly yellow, cleistothecium containing globose to pyriform, evanescent asci.

**eury-** A prefix signifying 'wide' or 'extensive' – e.g. a *euryhaline* organism is one able to tolerate a wide range of salt concentrations. (cf. STENO-.)

**Euryarchaeota** See ARCHAEA.

**euryxenus** Having a broad host range.

**euseptum** See SEPTUM (b).

**Eutreptia** See EUGLENOID FLAGELLATES.

**eutrophic** Of lakes rivers etc: rich in nutrients, particularly those which support the growth of aerobic photosynthetic organisms. (cf. OLIGOTROPHIC; see also EUTROPHICATION.)

**eutrophication** The enrichment of a habitat or environment with inorganic materials – in particular those substances (e.g. nitrogen and phosphorus compounds) which encourage the growth of plants and algae. In rivers and lakes, eutrophication may occur as a result of SELF PURIFICATION.

**evanescent** Having a transient existence.

**EVE** See IPN VIRUS.

**Everglades virus** See ALPHAVIRUS.

**Evernia** A genus of LICHENS (order LECANORALES); photobiont: a green alga. The thallus is strap-like, dichotomously branched, typically hanging in festoons from trees; that of *E. prunastri* (oak-moss), a species used commercially in the perfume industry, is greenish-grey above, whitish below.

**evernic acid** A depside LICHEN substance which has antibacterial properties; it occurs e.g. in *Evernia prunastri*.

**evernimicin** (SCH 27899) An antibiotic with good in vitro activity against various Gram-positive bacteria [JAC (2001) 47 15–25].

**Ewingella** A genus of bacteria of the ENTEROBACTERIACEAE. *E. americana* (formerly 'enteric group 40') produces acid but no gas from glucose, is VP +ve, DNase –ve, lipase –ve, LDC and ODC –ve. [Ann. Mic. (1983) 134A 39–52.]

**exanthem** A skin rash, or a disease characterized by a skin rash (cf. ENANTHEM).

**exanthem subitum** (roseola infantum; sixth disease; pseudo-rubella) A benign disease, of infants and young children, in which high fever (for 3–4 days) is followed by a rubelliform rash on the trunk, spreading to the limbs and face. Human (beta) herpesvirus 6 has been recognized as a causal agent. (cf. ERYTHEMA INFECTIOSUM.)

**exbB gene** See TONB PROTEIN.

**exbD gene** See TONB PROTEIN.

**Excillospora** A genus of thermophilic soil bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes). The organisms form both substrate and aerial mycelium, both of which give rise to spores. Type species: *E. viridilutea*. [Ecology, isolation, cultivation: Book ref. 46, pp. 2103–2117.]

**exchange diffusion** *Syn.* ANTIPORT.

**exciple** *Syn.* EXCIPULUM.

**excipulum** (1) See APOTHECIUM. (2) The peridium (wall) of a PERITHECIUM.

## excipulum proprium

**excipulum proprium** See PROPER MARGIN.

**excipulum thallinum** See THALLINE MARGIN.

**excision repair** Any DNA REPAIR process which can repair lesions affecting only a single strand of dsDNA (not, for example, inter-strand cross-linking) and which involves removal and replacement of one or more nucleotides. Excision repair in *Escherichia coli* can be considered under three main headings:

(i) BASE EXCISION REPAIR, i.e. repair of an AP SITE after preliminary cleavage of a base (see ADAPTIVE RESPONSE and URACIL-DNA GLYCOSYLASE).

(ii) MISMATCH REPAIR, used mainly for errors that escape proof-reading during DNA replication.

(iii) UvrABC-mediated repair (nucleotide excision repair; *short patch repair*). This common excision repair mechanism recognizes and repairs DNA which has been damaged/distorted by ultraviolet radiation or by certain other causes; damage may consist e.g. of a thymine dimer or a Pyr(6-4)Pyo photoproduct (see ULTRAVIOLET RADIATION). The ATP-dependent enzyme system UvrABC (also called 'ABC excinuclease') consists of three proteins encoded by genes *uvrA*, *uvrB* and *uvrC*. Initially a UvrA dimer binds to the damaged DNA. UvrB then binds to the dimer, and the complex UvrA<sub>2</sub>B translocates to the precise site of damage; such translocation is apparently ATP-dependent (the zinc-binding protein UvrA being an ATPase). UvrC displaces UvrA, and the UvrBC complex nicks the damaged strand on either side of the lesion, the 3' nick being made first. UvrD (= helicase II) then displaces UvrC together with the short sequence of nucleotides containing the site of damage. DNA polymerase I fills the single-stranded gap, displacing UvrB, and the repair is completed by a ligase. In *E. coli* only about 10 nucleotides in and around the damaged site are excised (thus accounting for the name 'short patch repair'). (See also PHOTOLYASE.)

The UvrABC system is enhanced during the SOS RESPONSE. Another repair system, the so-called 'error-prone repair' system (involving *translesion synthesis* of DNA), appears to operate only during the SOS RESPONSE (q.v.).

**excisionase** See e.g. BACTERIOPHAGE  $\lambda$ .

**exciter filter** See MICROSCOPY (e).

**exclusion limit** See PORIN.

**exclusion zone** See MICROTUBULES.

**exconjugant** A cell which has separated from another following CONJUGATION.

**excystation** *Syn.* EXCYSTMENT.

**excystment** (excystation) The release of one or more vegetative (or other) cells from a CYST.

**exergonic reaction** Any reaction which is accompanied by the liberation of energy. (cf. ENDERGONIC REACTION.)

**exflagellation** See PLASMODIUM.

**exfoliatin** *Syn.* EPIDERMOLYTIC TOXIN.

**Exidia** See TREMELLALES.

**Exiguobacterium** A genus of Gram-positive, asporogenous, facultatively anaerobic, rod-shaped or coccoid, motile bacteria [JGM (1983) 129 2037–2042]. *E. aurantiacum* is an ALKALOPHILE which has been isolated from potato processing effluent.

**exine** See CYST (a).

**Exo** Abbr. for exonuclease; for example, Exo III is EXONUCLEASE III.

**Exobasidiales** An order of plant-endoparasitic, characteristically GALL-inciting fungi (subclass HOLOBASIDIOMYCETIDAE) which form hymenia that emerge through the epidermis in parasitized plants. Genera include *Exobasidium* (see also BLISTER BLIGHT) and *Kordyana*. (cf. BRACHYBASIDIALES.)

**Exobasidium** See EXOBASIDIALES and BLISTER BLIGHT.

**exobiology** Extraterrestrial biology.

**exocellular** *Syn.* EXTRACELLULAR (sense 1 or 2).

**exocellulase** See CELLULASES.

**exochelins** Low MWt (<ca. 1000) iron-solubilizing peptides secreted by *Mycobacterium* spp – particularly in iron-deficient media. 'MB-type' exochelins (formed e.g. by *M. bovis* BCG and by *M. tuberculosis*) are compounds which can be extracted by chloroform after they have chelated ferric iron. 'MS-type' exochelins (formed e.g. by *M. smegmatis*) are not extractable by organic solvents.

**exocyst** See CYST (b).

**exocytosis** The secretion of material by a cell in a process which resembles ENDOCYTOSIS in reverse. (See also TETANOSPASMIN.)

**exoenzyme** (1) An ENZYME which sequentially removes units from one end of a polymer. (See e.g.  $\beta$ -AMYLASES; cf. ENDOENZYME.)

(2) Sometimes used as a synonym of 'extracellular enzyme'.

**exoenzyme S** An enzyme produced by strains of *Pseudomonas aeruginosa*; it appears to be capable of ADP-ribosylation of eukaryotic proteins (cf. EXOTOXIN A), but its role in virulence – if any – is unknown.

**exoerythrocytic schizogony** (in *Plasmodium*) See PLASMODIUM.

**exogenote** See MEROZYGOTE.

**exogenous retrovirus** A retrovirus (see RETROVIRIDAE) which infects a cell from a source outside that cell – e.g. a retrovirus transmitted horizontally from another animal, or one which has spread from another site in the same animal. Such a virus is absent from normal host cells (cf. ENDOGENOUS RETROVIRUS).

**exoglucanase** See CELLULASES.

**exon** See SPLIT GENE.

**exonuclease** A NUCLEASE which sequentially removes nucleotides from one end of a strand of NUCLEIC ACID. (cf. ENDONUCLEASE.)

**exonuclease I** See RECF PATHWAY.

**exonuclease III** An enzyme of *Escherichia coli* (product of the *xthA* gene) which degrades either strand of a dsDNA molecule from the 3' end, leaving single-stranded 5' ends.

**exonuclease V** See RECBC PATHWAY.

**exonuclease VII** An enzyme of *Escherichia coli* (product of the *xseA* gene) which degrades ssDNA processively from either end but leaves dsDNA intact.

**exonuclease VIII** See RECF PATHWAY.

**exopeptidase** See PECTIC ENZYMES.

**exopeptidase** See PROTEASES.

**exoperidium** See LYCOPERDALES.

**Exophiala** See HYPHOMYCETES.

**exopolysaccharuronase** See PECTIC ENZYMES.

**exoribonuclease** See RNASE.

**exospore** (1) A type of SPORE formed from the parent organism by budding or by septum formation and fission (cf. ENDOSPORE sense 1); see e.g. ACTINOMYCETALES and RHODOMICROBIUM. (See also CHAMAESIPHON and METHYLOCOCCACEAE.)

(2) *Syn.* EXOSPORIUM (sense 2).

**exosporium** (1) (*bacteriol.*) See ENDOSPORE (sense 1(a)). (2) (*mycol.*) (exospore; epitunica; trachytectum) The layer external to the two innermost layers (the endosporium – see ENDOSPORE sense 2 – and episporium) of a fungal spore wall.

**exotoxin** An extracellular TOXIN, i.e., a toxin which is secreted by a living cell. (cf. ENDOTOXIN sense 2.)

**exotoxin A** A protein exotoxin (MWt ca. 66000) produced by strains of *Pseudomonas aeruginosa*; it is believed to be an important virulence factor in *P. aeruginosa* infections in patients suffering from extensive burns, immunosuppressive therapy, etc.

The mode of action of exotoxin A appears to be identical with that of DIPHTHERIA TOXIN, although the two proteins differ in other respects: they show no immunological cross-reactivity; they are toxic for different cell lines (e.g. Vero cells are resistant to exotoxin A, murine cells are sensitive); they bind to different cell-surface receptors; they appear to be taken up by sensitive cells via different mechanisms; fragment A of exotoxin A is heat-labile. [Review: MR (1984) 48 199–221; structure: PNAS (1986) 83 1320–1324.] (See also IMMUNOTOXIN.)

**exotoxin A** (streptococcal) See SUPERANTIGEN.

**exoxy lanase** See XYLANASES.

**exp-1 protein** See PLASMODIUM.

**expanded gold standard** See GOLD STANDARD.

**exponential growth rate constant** See GROWTH (a).

**exponential phase** (of growth) See BATCH CULTURE.

**exponential silencing** Downregulation of activity at a given gene promoter as a consequence of exponential growth in a rich medium [see e.g. EMBO (2001) 20 1–11 (5)].

**export** (of a protein) The transmembrane translocation of a protein, towards the cell's exterior, without eventual release to the external environment. (cf. SECRETION.)

**export apparatus** See FLAGELLUM (a).

**expression vector** (*mol. biol.*) A CLONING vector that encodes functions for the transcription/translation of an inserted fragment of DNA. In addition to an origin of replication and a marker gene (e.g. an antibiotic-resistance gene), an expression vector includes e.g. (i) a promoter, commonly a strong, hybrid promoter (e.g. the TAC PROMOTER); (ii) a ribosome-binding site to ensure that, following transcription of the insert, the mRNA contains a Shine–Dalgarno sequence (needed for binding to the ribosome); (iii) a multiple cloning site (MCS) – a POLYLINKER with a range of restriction sites that permit flexibility in the preparation of the insert; (iv) a transcription terminator to inhibit unwanted readthrough.

Using an expression vector, a given insert can be initially cloned and then expressed. The insert is expressed by initiating transcription, and this can be achieved in various ways – for example, by a specific change in temperature. In an alternative mode of control, the vector incorporates a *lac* operator (see LAC OPERON) which regulates transcription of the insert and which is itself regulated by the host cell's LacI protein; activity of the promoter can be switched on e.g. by adding IPTG to the medium. (For cells which do not synthesize LacI, use can be made of a vector which incorporates a *lacI* gene.)

If required, a gene can be cloned in bacteria and then expressed in eukaryotic cells, a single vector carrying a prokaryotic origin of replication and control functions suitable for expression in eukaryotes.

**extein** See INTEIN.

**extended batch culture** See FED BATCH CULTURE.

**extended-spectrum  $\beta$ -lactamases** See  $\beta$ -LACTAMASES.

**external guide sequence** See SPLIT GENE (a).

**extracellular** (1) Refers to enzymes or structures etc which are external to the cells that produced them – whether or not they remain attached to, or form part of, the surface of the cell.

(2) Refers to enzymes or structures etc which are released by the cell into the surrounding medium. (cf. EPICELLULAR.)

**extrachromosomal genes** *Syn.* CYTOPLASMIC GENES.

**extrachromosomal inheritance** *Syn.* CYTOPLASMIC INHERITANCE.

**extract broth** See NUTRIENT BROTH.

**extracytoplasmic** Of a bacterial enzyme or redox carrier: located in the periplasmic region, either free or attached to the outer face of the cytoplasmic membrane [MR (1985) 49 140–157 (141)].

**extracytoplasmic oxidation** In certain bacteria: the oxidation of a substrate at the external face of the cytoplasmic membrane, or within the periplasmic region, giving rise to (or augmenting) a proton motive force (pmf: see CHEMOSMOSIS). During such oxidations, protons formed at the extracytoplasmic site contribute to pmf, while electrons (derived from the substrate) pass through the cytoplasmic membrane (a process sometimes called 'vectorial electron transfer') and are involved in electron- and proton-consuming reactions. [Early review: MR (1985) 49 140–157.]

Substrates oxidized extracytoplasmically include e.g. (depending on species): hydrogen, formate, methanol, glucose and various ions – particularly ferrous ions. Intracellular terminal electron acceptors include e.g. oxygen, fumarate, sulphate ions and nitrate ions.

Oxidations carried out extracytoplasmically include e.g. the oxidation of hydrogen by *Desulfovibrio* spp, *Escherichia coli* and by those HYDROGEN-OXIDIZING BACTERIA containing an NAD-independent membrane-bound HYDROGENASE. In *E. coli* the hydrogenase is located on the external surface of the cytoplasmic membrane, while in *Desulfovibrio* spp a soluble hydrogenase is located in the periplasmic region.

In *Beggiatoa*, sulphide appears to be oxidized extracytoplasmically to elemental sulphur. It has been proposed that *Thiobacillus thiooxidans* can oxidize insoluble (colloidal) sulphur extracytoplasmically.

In *Thiobacillus ferrooxidans*, the oxidation of ferrous to ferric ions occurs extracytoplasmically; it appears to involve e.g. an oxidase, *c*-type and *a*-type cytochromes and RUSTICYANIN [see e.g. MR (1994) 58 39–55 (47–48)].

In some bacteria, ions such as  $Mn^{2+}$  or  $U^{4+}$  may be oxidized extracytoplasmically.

Some bacteria (e.g. *Pseudomonas aeruginosa*) can generate pmf by extracytoplasmic oxidation of glucose to gluconate by glucose dehydrogenase (a QUINOPROTEIN) [JB (1985) 163 493–499]; in these organisms the enzyme glucose dehydrogenase, with its cofactor pyrroloquinoline quinone (PQQ), occurs on the outer surface of the cytoplasmic membrane. The gluconate formed can then be transported across the membrane, phosphorylated to 6-phosphogluconate, and fed into the ENTNER–DOUDOROFF PATHWAY.

*E. coli* (and some related bacteria) normally form a membrane-bound glucose dehydrogenase which lacks the cofactor (PQQ); such organisms can carry out extracytoplasmic oxidation only if they are supplied with exogenous PQQ [IJSB (1989) 39 61–67]. However, a mutant strain of *E. coli* with a non-functional PTS system is able to synthesize PQQ and to carry out extracytoplasmic oxidation; this has suggested that PQQ-encoding genes are normally present but not expressed [JGM (1991) 137 1775–1782].

**extranuclear genes** *Syn.* CYTOPLASMIC GENES.

**extravasation** See INFLAMMATION.

**extremophile** See ARCHAEA.

**extrinsic allergic alveolitis** (EAA; hypersensitivity pneumonitis)

A form of pneumonitis, which appears to involve an ARTHUS-TYPE REACTION and a DELAYED HYPERSENSITIVITY (type IV) reaction, caused by the inhalation of certain allergen(s). Examples of EAA include e.g. BAGASSOSIS, CHEESE-WASHERS' LUNG, FARMERS' LUNG, MAPLE BARK STRIPPERS' DISEASE, SUBEROSIS. [CIA (1984) 4 173–192.]

**extrusome** A generic term for an extrusile organelle (function often unknown), various types of which occur near the cell surface in many ciliates and in some other organisms. Examples:

## exudative dermatitis

conocyst, EJECTOSOME, FIBROCYST, haptocyst, kinetocyst (see AXOPODIUM), PEXICYST, rhabdocyst, TOXICYST, TRICHOCYST (cf. *polar filament* in MICROSPOREA and MYXOSPOREA).

**exudative dermatitis** *Syn.* GREASY PIG DISEASE.

**EYA** See EGG-YOLK AGAR.

**eye microflora** The surface of the eye and the conjunctival membranes normally bear only a sparse microflora owing to the constant flushing action of the secretions of the lacrimal glands; these secretions contain certain antimicrobial agents – e.g. LACTOFERRIN, LYSOZYME, and immunoglobulins (see IGA). Organisms which may be isolated from the eye surfaces include certain members of the SKIN MICROFLORA, e.g. staphylococci. (See also BODY MICROFLORA and CONJUNCTIVITIS.)

**eyepiece micrometer** See MICROMETER.

**eyespot** (1) (sigma) In certain algae: a body consisting of a group, layer or layers of closely-packed lipid globules which, according to species, occurs within the CHLOROPLAST (e.g. in members of the Chlorophyta) or outside it (e.g. in euglenoid flagellates). In most or all cases an eyespot contains orange or red CAROTENOID pigments. In certain dinoflagellates (e.g.

*Nematodinium armatum*) there is a large complex eyespot (termed an *ocellus*) which incorporates a lens and cup-shaped structure containing one or more rows of pigment granules. In at least some algae the eyespot is believed to be involved in PHOTOTAXIS.

[The eyespot in green algae: Book ref. 167, pp. 193–268.]

(2) A CEREAL DISEASE which affects mainly winter wheat and barley; causal agent: *Pseudocercospora herpotrichoides* (which can overwinter in stubble). (cf. HALO SPOT.) Pale oval spots, each with a diffuse dark margin, develop in the spring on leaf sheaths and stalks of the tillers – usually close to soil level; each eyespot lesion has a greyish centre and may contain one or more black dots. A grey mycelium develops within the stem; lodging may occur. Control: e.g. use of resistant varieties, or early foliar spray with e.g. BENOMYL or THIOPHANATE-METHYL. In *sharp eyespot* (caused by *Rhizoctonia solani*) the eyespot lesions have sharper margins, and they are more numerous – and develop further up the stem – than those of ‘true’ eyespot; mycelium does not develop within the stem.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see ‘Notes for the User’ at the front of the Dictionary.

# F

**f.** See **FORMA SPECIALIS**.

**F** Phenylalanine (see **AMINO ACIDS**).

**F-actin** See **ACTIN**.

**F antigens** Fimbrial antigens – see **FIMBRIAE**. (cf. **K ANTIGENS**.)

**F<sup>+</sup> donor** See **F PLASMID**.

**F-duction** See **SEXDUCTION**.

**F factor** See **F PLASMID**.

**F layer** See **CYANOBACTERIA** (section II).

**F-like pili** See **PILI**.

**F pili** See **PILI**.

**F plasmid** (formerly F factor, ‘fertility factor’) An IncFI PLASMID which occurs e.g. in *Escherichia coli* with a COPY NUMBER of usually 1 or 2; it consists of a ccc dsDNA molecule (ca. 95 kilobases) which includes two copies of the INSERTION SEQUENCE IS3, one each of IS2 and IS1000, and sequences relating to replication, incompatibility and CONJUGATION (sense 1b). An F plasmid confers on the host cell the characteristics of a conjugal donor, and it can also affect the cell’s phenotype in other ways: see e.g. FEMALE-SPECIFIC PHAGE. (See also PIF.)

Within the host cell, an F plasmid exists either in the autonomous (extrachromosomal) state, i.e. as a free, circular plasmid, or integrated in the host’s chromosome. (cf. EPISOME.) Integration occurs by homologous RECOMBINATION between an insertion sequence in the plasmid and one in the chromosome (see CAMPBELL MODEL); copies of insertion sequences IS2 and IS3 are common in the chromosome of *E. coli*. An integrated F plasmid may undergo aberrant excision from the chromosome: see PRIME PLASMID.

*Conjugation mediated by the F plasmid.* The F plasmid can mediate conjugation either in the autonomous state or in the integrated state.

In the autonomous (extrachromosomal) state an F plasmid can efficiently promote its own intercellular transfer by CONJUGATION (sense 1b). A cell containing an autonomous F plasmid is called an F<sup>+</sup> donor, while a cell lacking an F plasmid (but able to receive one by conjugation) is called an F<sup>-</sup> recipient. (Such cells are sometimes referred to as ‘male’ and ‘female’ cells, respectively.) In a mixed population of F<sup>+</sup> and F<sup>-</sup> cells, a copy of the F plasmid is transferred at high frequency, i.e. all, or nearly all, of the F<sup>-</sup> cells receive a copy (and hence become F<sup>+</sup> donors themselves); in such F<sup>+</sup> × F<sup>-</sup> crosses, chromosomal genes are usually not transferred.

Integration of an F plasmid into the chromosome gives rise to an HFR DONOR (q.v.) – in which the chromosome is mobilized for transfer by the integrated plasmid (see CONJUGATION).

Whether conjugation is mediated by an autonomous or integrated F plasmid, the mechanism of transfer depends on an extensive (ca. 33 kilobase) region of the plasmid – the transfer region – containing over 30 genes. This region is commonly referred to as ‘the transfer operon’, although it contains more than one promoter; however, most of the *tra* genes are found in a single large operon (*traY-I*). The *traJ* and *traM* genes (both located immediately downstream of *oriT*) are outside the *traY-I* operon; *traJ* has one promoter, *traM* has two. *traY*, the first gene of the *traY-I* operon, is adjacent to *traJ*. The *traY-I* operon is transcribed by the Eσ<sup>70</sup> holoenzyme; activation of the *traY* promoter is dependent on TraJ, but other factors appear to be needed for full activation. Apparently some genes within the

*traY-I* operon (e.g. *traS*, *traT*) have their own promoters, and their expression seems to be independent of TraJ.

About 15 genes are needed for synthesis and assembly of the F pilus. The *traA* gene encodes the precursor molecule that is processed to form the subunit, pilin, from which PILI are assembled; the initial product of *traA* (MWt ca. 13000) is processed to a final size of MWt ca. 7000. Genes *traQ* and *traX* are reported to be involved in processing the *traA* gene product.

Products of the *traG* and *traN* genes have been associated with stabilization of donor–recipient mating contacts.

The *tral* gene product is a HELICASE which is needed for site- and strand-specific nicking at *oriT* (the origin of transfer) and for unwinding DNA during conjugal transfer [JBC (1991) 266 16232–16237].

The *traM* gene product has binding sites in the *oriT* region (one of which, *sbmC*, is associated with DNA transfer); it is also linked with the cytoplasmic membrane, possibly via TraD. The role of TraM in conjugation has not been clarified, but it is apparently essential for transfer of DNA. In a related IncF plasmid (R1), TraM stimulated nicking at *oriT* by TraI [JMB (1998) 275 81–94]; in the F plasmid, TraY and the INTEGRATION HOST FACTOR were reported to stimulate nicking at *oriT* in vitro [JBC (1995) 270 28374–28380]. TraM may have a role in relaying the (currently unknown) ‘mating signal’ on establishment of stable cell–cell contact.

The products of *traS* and *traT* are involved in SURFACE EXCLUSION.

*traM* is autoregulated but needs TraY for full expression; expression is affected by external factors, and is negligible in stationary phase cells. Most genes in the *traY-I* operon are positively regulated by TraJ, and in most IncF plasmids, expression of *traJ* is under negative control of the FINOP SYSTEM (q.v.) so that the transfer genes are normally repressed. The F plasmid lacks a functional *finO* gene, i.e. in this particular plasmid, *traJ* is not under negative control; consequently, the transfer genes are constitutively derepressed (that is, permanently ‘switched on’). (See also FERTILITY INHIBITION.)

[Control of transfer genes in F-like transfer systems: FEMS Reviews (1998) 21 291–319 (291–295).]

*Replication of the F plasmid.* In wild-type F plasmids replication occurs bidirectionally from an origin and is under stringent control (see PLASMID). The F plasmid has two origins of replication: *oriV* (= *ori1*) and *oriS* (= *ori2*); in wild-type F plasmids, a PRIMOSOME assembly site is present near *ori2* [PNAS (1983) 80 7132–7136]. (In MINI-F PLASMIDS containing both origins, replication occurs preferentially, and bidirectionally, from *ori1*.) Host factors needed for F plasmid replication include the products of genes *dnaB*, *dnaC* and *dnaE*; replication of the plasmid is independent of the *dnaA* product. (See also INTEGRATIVE SUPPRESSION.)

Control of replication involves the (plasmid-encoded) RepE protein (= E protein). Molecules of the E protein (MWt ca. 29000) initiate replication by binding to two sequences of 19-bp DIRECT REPEATS (ITERONS), designated *incB* and *incC*, located either side of the E-encoding gene (close to the origin of replication); the bound molecules of E protein contribute to a nucleoprotein complex which is a pre-requisite for replication. Control of replication (and, hence, of COPY NUMBER) is achieved by controlling the intracellular level of E protein to that

## F' plasmid

which will permit only one (sometimes two) rounds of plasmid replication prior to division of the bacterial cell. When a plasmid enters a daughter cell, subsequent binding of E protein molecules by the iterons 'titrates' the E protein, tending to lower its intracellular concentration; this promotes synthesis of E protein and restoration of an appropriate intracellular level. Lowering the concentration of E protein stimulates its synthesis because the gene encoding E protein is autorepressible at the level of transcription, i.e. the E protein represses its own transcription by binding to a sequence in, or overlapping, the gene's promoter.

Interestingly, *monomers* of E protein bind to iterons whereas *dimers* are involved in the autorepression of its own gene.

*Incompatibility.* The *incB* and *incC* sequences are determinants of INCOMPATIBILITY in IncFI plasmids.

*Partition.* As in other low-copy-number plasmids, an efficient system for PARTITION must be present during cell division to ensure stable maintenance of the F plasmid.

To ensure stability of inheritance in bacterial populations, the F plasmid also encodes another system (*ccd* – coupled cell division) involving the genes *ccdA* and *ccdB* (formerly *letA* and *letB*, respectively); this system results in the death of any cell which does *not* contain a plasmid following cell division. CcdB, a lethal toxin for the host cell, is a stable molecule. CcdA neutralizes CcdB, but this antidote is gradually degraded by the host's Lon protease – so that its protective role is available only while it is being synthesized from the (plasmid-encoded) *ccdA* gene, i.e. only in those cells containing the plasmid. Following cell division, a plasmid-less cell will be killed by CcdB as there is no *ccdA* gene from which CcdA can be synthesized.

CcdB induces the SOS SYSTEM, and it kills cells by inhibiting DNA gyrase. Interestingly, CcdB has been considered for development as a possible therapeutic agent [TIM (1998) 6 269–275].

**F' plasmid** See PRIME PLASMID.

**F-prime plasmid** See PRIME PLASMID.

**F<sup>-</sup> recipient** See F PLASMID.

**f. sp.** See FORMA SPECIALIS.

**F<sub>0</sub> component** (of ATPase) See PROTON ATPASE.

**F<sub>0</sub> value** The time (in minutes) required, at 121.1°C, to inactivate a population of cells or spores of a given species *calculated from* the time required for inactivation at another temperature, assuming a z VALUE of 10°C. The F<sub>0</sub> value, sometimes written F<sub>121.1</sub><sup>10</sup>, is one particular value in a range of F values; thus, e.g., if the inactivation time at 121.1°C is calculated assuming a z value of 9°C, the relevant F value is indicated by F<sub>121.1</sub><sup>9</sup>. (See also D VALUE.)

**(F<sub>0</sub>F<sub>1</sub>)-type H<sup>+</sup>-ATPase** See PROTON ATPASE.

**F1 antigen** See YERSINIA (*Y. pestis*).

**F1 component** (of ATPase) See PROTON ATPASE.

**F1 fimbriae** Type I FIMBRIAE.

**F2 fimbriae** *Syn.* CFA I (see ETEC).

**F-2 toxin** *Syn.* ZEARALENONE.

**F3 fimbriae** *Syn.* CFA II (see ETEC).

**F<sub>3</sub>T** TRIFLUOROTHYIMIDINE.

**F4 fimbriae** K88 FIMBRIAE.

**F5 fimbriae** K99 FIMBRIAE.

**F6 fimbriae** (987P fimbriae) FIMBRIAE which occur on certain strains of ETEC which are pathogenic for newborn piglets. [Organization and expression of genes involved in biosynthesis of 987P fimbriae: MGG (1986) 204 75–81.]

**F41 fimbriae** FIMBRIAE which occur on some strains of ETEC which are pathogenic for piglets; they promote MRHA.

**F420** See METHANOGENESIS.

**F430** See METHANOGENESIS.

**Fab portion** (Fab fragment) Either of two identical portions of an IMMUNOGLOBULIN monomer which can be released by certain enzymes (e.g. PAPAINE); the remainder of the molecule is termed the Fc portion (q.v.). Each Fab portion consists of a light chain linked via a disulphide bond to the N-terminal part of a heavy chain, i.e., it is one of the two limbs of the Y-shaped Ig molecule. Each Fab portion of an antibody contains a single COMBINING SITE and behaves as a non-precipitating univalent antibody. Under acid conditions, MERCAPTOETHANOL splits the Fab portion into the heavy chain segment (the *Fd portion*) and the light chain.

**F(ab')<sub>2</sub> portion** Part of an IMMUNOGLOBULIN monomer released by the proteolytic action of PEPSIN (which also degrades at least part of the remainder of the Ig molecule); it includes both FAB PORTIONS connected by the HINGE REGION. The F(ab')<sub>2</sub> portion of an antibody behaves as a bivalent, precipitating, non-complement-fixing antibody.

**facial eczema** (*vet.*) See SPORIDESMINS.

**facilitated diffusion** An energy-independent TRANSPORT SYSTEM in which the diffusion of a substance across a membrane is facilitated by a membrane-bound protein carrier system; in facilitated diffusion a substance necessarily passes *down* a concentration gradient. Unlike simple diffusion, facilitated diffusion exhibits Michaelis–Menten saturation kinetics, it is relatively substrate-specific, and it is subject to competitive inhibition – the uptake of one substance being inhibited by the presence of another, structurally similar, substance. In e.g. *Saccharomyces cerevisiae* various sugars, amino acids and vitamins can be taken up by facilitated diffusion – although, depending on conditions, the same substances may also (or alternatively) be taken up by other transport mechanisms. In *Escherichia coli*, glycerol can cross the cytoplasmic membrane by facilitated diffusion, the membrane containing a specific *facilitator protein* (see also MIP CHANNEL); once inside the cell the glycerol is phosphorylated.

**FACS** Fluorescence-activated cell sorter: an instrument used for analysing and/or sorting cell populations by FLOW MICROFLUOROMETRY. Essentially, the cells (in suspension) move down a thin, open-ended tube and, in doing so, each cell passes momentarily through a laser beam which crosses the liquid column at right angles. As each cell passes through the beam it gives rise to a scatter signal (scattered laser light), and also – if labelled with a FLUOROCHROME (e.g. TEXAS RED) – a FLUORESCENCE signal. By using antibody-conjugated fluorochromes it is possible e.g. to determine the presence or number of homologous antigens or receptor sites on the cell surface, since the strength of the fluorescence signal is proportional to the amount of fluorochrome bound to the cell surface. In the 'dual parameter' mode, cells may be pre-treated, simultaneously, with antibodies of two different specificities – each being conjugated with a different fluorochrome; each cell passes through two separate laser beams (of wavelengths dependent on the fluorochromes chosen) and the two fluorescence signals are interpreted separately.

The FACS can also be used e.g. to monitor the proportion of proliferating lymphocytes in a population, measurement being based on the increased content of DNA in proliferating cells; cells are initially permeated with an agent (e.g. mithramycin) which can interact with intracellular DNA to form a complex which fluoresces on irradiation.

Cell *sorting* involves the physical separation of cells into subpopulations. Essentially, ultrasonic energy is applied to the nozzle through which the stream of liquid (i.e. cell suspension) passes, thus breaking up the stream into a series of very

small droplets – each droplet (ideally) containing a single cell. Immediately before each droplet is discharged from the nozzle, the fluorescence (or scatter) signal received from the cell is interpreted (electronically) and the droplet is charged positively or negatively according to the nature of the signal received. As each (charged) droplet falls under gravity it passes between a pair of deflector plates – one positively charged, the other negatively charged; each droplet is therefore deflected to the right or left and subsequently falls into one of two collecting vessels.

**factor 420** See METHANOGENESIS.

**factor 430** See METHANOGENESIS.

**Factor B** (*immunol.*) A  $\beta$ -globulin (MWt ca. 93000) found in normal plasma; during COMPLEMENT FIXATION by the alternative pathway, Factor B is cleaved to fragments Ba and Bb.

**Factor D** (*immunol.*) A glycoprotein (MWt ca. 23000) found in very low concentrations in normal plasma; it circulates as an active enzyme whose substrate is C3b-bound FACTOR B.

**Factor H** (*immunol.*) A protein (MWt ca. 150000) present in normal serum; it regulates (inhibits) the C3 convertase in the alternative pathway of COMPLEMENT FIXATION, and also acts as an essential cofactor for FACTOR I.

**Factor I** (KAF; C3bina; C3bINA; conglutinin-activating factor; C3b/C4b inactivator) A protein (a  $\beta$ -globulin, MWt 90000), present in normal plasma, involved in regulating the sequence of reactions in COMPLEMENT FIXATION. Together with an essential co-factor, FACTOR H, Factor I cleaves (inactivates) C3b and C4b. A cleavage product of C3b is involved in *conglutination*: see CONGLUTININ.

**factory area** (*virol.*) *Syn.* VIROPLASM.

**factumycin** See POLYENE ANTIBIOTICS (b).

**facultative** 'Optional', referring to the ability of an organism to adopt an alternative life style, mode of nutrition etc; thus, e.g. an AEROBE may be a facultative ANAEROBE. The word 'facultative' is often followed by the mode *not* normally adopted; thus, e.g. 'facultative anaerobe' often refers to an organism which normally grows aerobically but which *can* grow anaerobically. (cf. OBLIGATE.)

**facultative heterochromatin** See CHROMATIN.

**FAD** See RIBOFLAVIN.

**faecal coliform test** See COLIFORM TEST.

**faecal streptococci** A general term for certain Gram-positive cocci which occur primarily in human and animal intestines and faeces; they include *Enterococcus faecalis* and *E. faecium* (both formerly classified in the genus *Streptococcus*) and species such as *Streptococcus bovis* and *S. equinus*.

**faecapentaenes** *Syn.* FECAPENTAENES.

**faeces** See e.g. GASTROINTESTINAL TRACT FLORA; INDICATOR ORGANISMS; SEWAGE TREATMENT.

**Faenia** See MICROPOLYSPORA.

**FAIDS** See FELINE LEUKAEMIA VIRUS.

**falcarindiol** A polyacetylenic PHYTOALEXIN produced by tomato plants.

**false branching** In certain sheathed filamentous bacteria (particularly CYANOBACTERIA, sections III–V): apparent branching which results from the protrusion through the sheath of the broken end(s) of a trichome, or of a loop of trichome which subsequently breaks to generate a pair of false branches.

**false neisseriae** Bacteria regarded either as species *incertae sedis* in the genus *Neisseria* (*N. caviae*, *N. cuniculi*, *N. ovis*) or as members of the subgenus *Branhamella* (see MORAXELLA).

**false tinder fungus** *Fomes ignarius*.

**false truffle** See TRUFFLES.

**falx** A specialized pellicular region in opalinids.

**famciclovir** An oral ANTIVIRAL AGENT that resembles ACYCLOVIR in mode of action and antiviral activity; famciclovir is the 6-deoxy diacetyl ester prodrug of the guanine nucleoside analogue *peniclovir*. After absorption in the intestine, famciclovir is rapidly converted to penciclovir; within cells, the half-life of the active form (penciclovir triphosphate) is much longer than that of acyclovir triphosphate. Famciclovir is used e.g. for the treatment of herpes zoster.

**FAME** Fatty acid methyl ester: a methylated fatty acid derivative prepared for use in a microbial identification scheme; in such a scheme, identification is based on differences in the fatty acid content of *whole cells* of different species and strains of microorganism. Cells (grown under standard conditions) are harvested, and their fatty acids are initially saponified e.g. by heating in a solution of NaOH containing methanol. The product is then methylated (to increase volatility) e.g. by heating to ca. 80°C with an HCl–methanol mixture. FAMES are then extracted with organic solvent(s); the resulting solution is washed by agitation with aqueous NaOH, and its FAME content is then analysed by gas chromatography.

**family** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**Fansidar** See MALARIA (*chemotherapy*).

**farcy** (*vet.*) (1) (in equines) See GLANDERS. (2) (in cattle) *Bovine farcy* is a chronic condition involving purulent lymphangitis and lymphadenitis, and the development of hard, subcutaneous lesions with thickening of the associated lymph nodes and ducts; the causal agent can be either *Mycobacterium farcinogenes* or *M. senegalense* [Book ref. 54, pp. 508–509]. The disease occurs mainly in the tropics. (cf. EPIZOOTIC LYMPHANGITIS.)

**farcy buds, farcy pipes** See GLANDERS.

**farmers' lung** AN EXTRINSIC ALLERGIC ALVEOLITIS associated with inhalation of the spores of certain actinomycetes (e.g. *Microsporysphaera faeni*) and/or other bacteria (e.g. *Thermoactinomyces vulgaris*) present e.g. in mouldy hay; 4–8 hours after inhalation of these spores there is severe pulmonary dysfunction due to an intrapulmonary TYPE III REACTION. [CIA (1984) 4 175–184.]

**Farr technique** A RADIOIMMUNOASSAY used for quantifying antibody. Essentially, the antiserum under test is added to excess radiolabelled antigen, and the antigen–antibody complex is separated from uncombined antigen by precipitation with ca. 50% ammonium sulphate; the antibody is measured (indirectly) by determining the amount of radiolabelled antigen in the precipitate. (The method can be used only for antigens which remain soluble in the ammonium sulphate.)

**Fas** (CD95, APO-1) On mammalian cells: the cell-surface receptor for Fas ligand (Fas L). Fas ligand is a membrane-anchored cytokine which occurs on CD8<sup>+</sup> T cells. The effect of binding between Fas ligand and its receptor depends on the specific signals triggered; in some cases, binding activates caspases and leads to APOPTOSIS.

**fasciation** An abnormal type of plant growth resembling a flattened bundle of coalesced shoots – a symptom of certain plant diseases. Fasciation may be caused in certain plants (e.g. sweet peas) by *Rhodococcus fascians*, and may result from cytokinin production by the pathogen.

**fast blue B** *Syn.* DIANISIDINE.

**fast death factor** See MICROCYSTIS.

**FAT** FLUORESCENT ANTIBODY TECHNIQUE.

**fat spoilage** See e.g. RANCIDITY.

**fat stain** See e.g. BURDON'S STAIN.

**fatal familial insomnia** See TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**fatty acid methyl ester** See FAME.

## Faulschlamm

**Faulschlamm** *Syn.* SAPROPEL.

**favus** (*tinea favosa*) A severe form of RINGWORM (usually *tinea capitis*) caused by *Trichophyton schoenleinii*. It is characterized by a spreading alopecia with pathognomonic lesions called *scutula* (sing. *scutulum*): round or oval, cup-shaped, sulphur-yellow crusts which develop from infected hair follicles. Hyphae, but few arthrospores, occur within the hair shaft, as may fine tubular canals left by the disintegration of hyphae. A bluish-white fluorescence may be observed in infected hairs under Wood's lamp.

The term *favus* also refers to a POULTRY DISEASE caused by *Trichophyton gallinae*. White powdery spots appear on the unfeathered parts of the head and develop to form wrinkled crusts or scabs; in severe cases feathered parts of the body are affected, with resulting loss of feathers.

**FBJ osteosarcoma virus** Finkel-Biskis-Jenkins murine sarcoma virus: a retrovirus complex consisting of a replication-competent murine leukaemia virus (FBJ-MuLV) and a replication-defective transforming murine sarcoma virus (FBJ-MSV); FBJ-MSV carries the oncogene *v-fos* and induces osteosarcomas in mice after a latent period of ca. 3 weeks. The *v-fos* product does not have tyrosine kinase activity. Homologues of *c-fos* have been identified in the genomes of various vertebrates as well as in *Drosophila*. [Organization and expression of *fos*: Book ref. 113, pp. 309–321.]

**FBP** Ferrous sulphate–sodium metabisulphite–sodium pyruvate; FBP destroys H<sub>2</sub>O<sub>2</sub> and superoxide anions and, when added to culture media (0.025%), can increase aerotolerance in certain microaerophilic and anaerobic organisms.

**Fc portion** (Fc fragment) A portion of an IMMUNOGLOBULIN monomer which can be released by certain enzymes (e.g. PAPAINE). (cf. FAB PORTION.) The Fc portion corresponds to the stem of the Y-shaped Ig molecule and consists of the C-terminal sections of the two heavy chains linked by one or more disulphide bonds; it is e.g. the site of complement fixation in COMPLEMENT-FIXING ANTIBODIES. (See also PROTEIN A.)

**FCA** Freund's complete adjuvant.

**FCCP** See PROTON TRANSLOCATORS.

**FcyRIII** *Syn.* CD16.

**Fd** FERREDOXIN.

**Fd portion** (Fd fragment) See FAB PORTION.

**Fe protein** See NITROGENASE.

**fecapentaenes** A group of mutagens, each having a highly unsaturated conjugated enol ether structure, produced by certain bacteria. It has been proposed that they act as alkylating agents as a result of the formation of carbocations [Science (1984) 225 521–523].

**feces** See FAECES.

**fed batch culture** A modified form of BATCH CULTURE in which a solution of nutrient(s) is added at specific time(s) in order e.g. to optimize the production of particular metabolite(s). If volumes of culture are periodically removed to permit repeated feeding, the process is called *extended batch culture*.

**feed additives** Substances, such as certain antibiotics, that are added to the feedstuffs of domestic animals (including poultry, pigs and/or ruminants) in order to increase growth rates and/or increase feed conversion efficiency. Ideally, feed additives should not be absorbed from the alimentary tract at the dosages used (e.g. ca. 10–60 mg/kg dry-weight feedingstuff, according to additive); absorption may necessitate a 'withdrawal period' prior to slaughter in order to allow elimination of the additive. Feed additives include e.g. AVOPARCIN, LASALOCID, MONENSIN, NARASIN, SALINOMYCIN and VIRGINIAMYCINS. [Antibiotics as feed additives for ruminants: Book ref. 121, pp. 331–347.]

**feedlot bloat** See BLOAT.

**Feekes' scale** (*plant pathol.*) A scale of numbers which indicate the various growth stages of wheat and barley: 1–5, shoot emergence and tillering; 6–10, stem elongation; 10.1–10.5, heading (ear development); 11.1–11.4, grain ripening. Feekes' scale does not allow as detailed a designation of plant development as does ZADOKS' CODE, and is limited to wheat and barley.

**felid herpesvirus 1** *Syn.* FELINE RHINOTRACHEITIS VIRUS.

**feline AIDS** See FELINE LEUKAEMIA VIRUS.

**feline calicivirus** (FCV; cat flu virus; 'feline rhinotracheitis virus'; 'feline picornavirus') A virus (family CALICIVIRIDAE) which infects the respiratory tract (occasionally also the gastrointestinal tract) of cats, causing e.g. rhinitis, conjunctivitis, oral ulceration, and pneumonia; the disease ranges from mild to fatal. An attenuated strain of FCV is used as a vaccine. FCV can be propagated in feline cell cultures. (cf. FELINE RHINOTRACHEITIS.)

**feline coronavirus** See CORONAVIRIDAE.

**feline immunodeficiency virus** (FIV) A retrovirus of the subfamily LENTIVIRINAE, originally isolated as a 'T-lymphotropic virus' from domestic cats with an immunodeficiency-like syndrome [Science (1987) 235 790–793]; the virus can give rise to illness resembling AIDS in humans and FAIDS (see FELINE LEUKAEMIA VIRUS) in cats.

The FIV virion, ~120–150 nm in size, contains a characteristic lentivirus-type nucleocapsid. The genome – ~9.5 kb – contains some open reading frames (as well as *gag*, *pol* and *env* regions) within terminal LTRs; the ORFs apparently encode regulatory function(s).

Horizontal transmission is believed to occur typically as a result of fighting and biting (cf. FeLV). Vertical transmission by asymptomatic, chronically infected mothers has not been reported, but the virus can be transmitted via milk following experimental infection.

[Haematological disorders associated with feline retrovirus infections (FeLV and FIV): BCH (1995) 8 73–112.]

**feline infectious peritonitis virus** See CORONAVIRIDAE.

**feline leukaemia virus** (FeLV) A retrovirus (subfamily ONCOVIRINAE, type C), strains of which cause important diseases in cats; there are many exogenous and some endogenous strains of the virus.

The FeLV virion is roughly spherical and is ~110–120 nm in diameter. The proviral DNA (of replication-competent strains) – approximately 8.4 kb in length – includes the usual retroviral *gag*, *pol* and *env* regions between 5' and 3' LTRs; the expression of proviral genes is under the regulation of *cis*-acting promoter and enhancer regions located in the U3 sequence of the LTR.

FeLV is transmitted horizontally, apparently via the oronasal route, by repeated social contact; transmission also occurs vertically, by intrauterine infection of the developing embryo. Animals which develop chronic viraemia are sources of high-titre infectious FeLV virions (which occur in plasma and in nasal secretions and saliva).

In over one half of the cats exposed to FeLV, the humoral and cell-mediated defence systems succeed in abolishing detectable virus in plasma. Nevertheless, in at least a proportion of animals the virus can remain latent for a period of time in myelomonocytic precursors in the bone marrow and in stromal fibroblasts; however, it is thought that spontaneous reactivation of latent virus in nature occurs only rarely.

FeLV causes neoplastic, degenerative and immunosuppressive forms of disease, the latter including a syndrome resembling human HIV-AIDS (*feline AIDS* or *FAIDS*); other conditions

include myeloid leukaemias, anaemia, marrow aplasia, and lymphosarcomas. (A FAIDS-like syndrome can also be caused by the FELINE IMMUNODEFICIENCY VIRUS.)

Typically, *chronic* infection with FeLV involves a gradual decrease in the numbers of lymphocytes and a reduction in the function of both T and B cells, thus leading to clinical immunodeficiency. Certain strains of FeLV, however, cause an *acute* immunodeficiency syndrome (FAIDS).

Isolates of FeLV are often replication-competent and *v-onc<sup>-</sup>*, but ONCOGENE-containing sarcoma-inducing recombinant viruses ('feline sarcoma viruses') have been isolated from FeLV-associated tumours. Several oncogenes (e.g. FES, *abl*, *sis*) have been reported to confer on FeLV the ability to induce sarcomas.

Insertional mutagenesis by FeLV of the host cell's *c-myc* oncogene is found in a significant proportion of spontaneous and experimentally induced lymphomas.

In some experimentally induced lymphomas, the location at which the provirus integrates in the cell's genome suggests that enhancer activity associated with the proviral LTR region may stimulate expression of *c-myc* and, in this way, contribute to pathogenesis.

The exogenous, replication-competent FeLVs are divided into subgroups A, B and C on the basis of (i) differences in the viral envelope glycoprotein, (ii) the interference pattern *in vitro*, and (iii) susceptibility of the viruses to neutralization by specific antibodies; differences in the envelope glycoprotein are associated with differences in the host cell range of the various strains of FeLV.

Subgroup A strains of FeLV are widespread and readily transmissible – although apparently not highly pathogenic. Subgroup B strains may arise through *in vivo* recombination and may be more pathogenic than the A strains; in infected animals, B strains are reported to be invariably accompanied by A strains. C strains are said to be comparatively rare, and are associated with pure red cell aplasia.

Various germ-line-transmissible endogenous retroviruses may be detectable in the genome of uninfected animals. In some cases the endogenous virus contains sequences homologous to FeLV (enFeLV strains); in other cases (RD-114 viruses) there is no apparent genetic relationship with FeLV. Although enFeLV proviral DNA may not give rise to infectious virions, it may nevertheless contribute to pathogenicity; thus, e.g. expression of enFeLV genes has been detected in both FeLV-positive and FeLV-negative lymphomas. Moreover, enFeLV-encoded product(s) may represent the entity referred to as FOCMA.

*Diagnosis of persistent infection by FeLV.* In cells that harbour a replication-competent strain of FeLV, viral proteins and virions are commonly produced at a high rate. One particular protein, the Pr65 *gag* precursor protein, is produced in excess and can be easily detected in the blood of infected cats by immunoassay techniques.

[Haematological disorders associated with feline retrovirus infections (FeLV and feline immunodeficiency virus): BCH (1995) 8 73–112.]

**feline panleukopenia virus (FPV)** A subspecies of feline parvovirus (genus PARVOVIRUS). Like CANINE PARVOVIRUS (CPV), the ssDNA genome (~5100 nt) encodes two structural proteins (VP1, VP2: the mRNAs transcribed from overlapping sequences) and two non-structural proteins. DNA from FPV and CPV isolates is almost identical; the host range of these viruses depends on small differences in the composition of the capsid: less than 10 amino acids determine whether a given virus can replicate in dogs *or* cats. The virion retains infectivity for days/weeks in the environment.

Feline panleukopenia virus causes disease in cats, raccoons and some of their relatives. The main targets for viral replication include dividing cells in lymphoid tissues and in the intestinal epithelium.

Infection probably occurs via the nasopharyngeal route and/or via lymphoid tissues.

In the adult animal, generalized infection of lymphoid tissues follows viraemia. Levels of erythrocytes (red blood cells) are not affected. Often, infection leads to PANLEUKOPENIA, the total leukocyte count sometimes falling to ~1000 per cubic millimetre, with neutrophils <200 per cubic millimetre; the fall in lymphocyte numbers is less marked, and there is minimal change in numbers of eosinophils, basophils and monocytes.

Intestinal infection (in adult animals) involves viral replication in the rapidly dividing epithelial cells of the ileum and jejunum – with consequent diarrhoea (often with blood/mucus).

In neonatal kittens there is no manifestation of enteritis. Infection characteristically affects the cerebellum, leading to cerebellar hypoplasia and, typically, to ataxia in surviving animals.

[Pathogenesis of FPV: BCH (1995) 8 57–71.]

**feline parvovirus** See PARVOVIRUS.

**feline picornavirus** *Syn.* FELINE CALCIVIRUS.

**feline rhinotracheitis** (feline viral rhinotracheitis) A severe upper respiratory tract disease of cats caused e.g. by felid herpesvirus 1 (see ALPHAHERPESVIRINAE). This virus replicates mainly in the oral and nasal mucous membranes; symptoms include fever and discharge from the eyes and nose. Latent infection generally follows recovery from the acute disease; latently infected animals may periodically shed virus either spontaneously or after stress. The virus has been isolated from the trigeminal ganglia of latently infected cats [JGV (1985) 66 391–394]. (cf. FELINE CALCIVIRUS.)

**feline rhinotracheitis virus** FELINE CALCIVIRUS or felid herpesvirus 1 (see FELINE RHINOTRACHEITIS).

**feline sarcoma viruses** See FELINE LEUKAEMIA VIRUS.

**feline syncytial virus** See SPUMAVIRINAE.

**feline T-lymphotropic lentivirus** See FELINE IMMUNODEFICIENCY VIRUS.

**felon** *Syn.* WHITLOW.

**FeLV** FELINE LEUKAEMIA VIRUS.

**fem genes** See MRSA.

**female-specific phage** Any phage whose EOP on bacteria containing certain plasmid(s) is significantly lower than that on plasmid-free strains of the same bacteria. For example, phages of the T7 group (e.g. T7,  $\phi$ I, W31) are inhibited in cells of *Escherichia coli* K12 which contain the F plasmid; in the case of T7, the presence of the plasmid inhibits translation of the intermediate and late phage proteins. In some cases phage DNA is the target of plasmid-encoded restriction endonucleases; e.g., phages F116 and G101 are restricted in cells of *Pseudomonas aeruginosa* containing the plasmid pMG7 [Plasmid (1977) 1 115–116]. (cf. ANDROPHAGE.)

**FeMo protein** See NITROGENASE.

**FeMoco** The FeMo cofactor of NITROGENASE.

**fenpropimorph** A MORPHOLINE ANTIFUNGAL AGENT used e.g. to control yellow rust, brown rust, and powdery mildew on wheat and barley.

**Fenticlor** See BISPHENOLS.

**fenticonazole** See AZOLE ANTIFUNGAL AGENTS.

**fentin** Triphenyltin; two derivatives, fentin acetate ((C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>SnO.CO.CH<sub>3</sub>) and fentin hydroxide ((C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>SnOH), are used (sometimes in conjunction with MANEB) as antifungal agents e.g. for the control of late blight of potato and powdery mildew of sugar-beet. (See also TIN.)

## FepA protein

**FepA protein** In *Escherichia coli*: an OUTER MEMBRANE protein encoded by the *fepA* gene; it acts as a receptor for B and D colicins, and is involved in the uptake of  $\text{Fe}^{3+}$ -enterobactin (see SIDEROPHORES).

**ferbam** See DMDC.

**FERM** Fermentation Research Institute of the Agency of Industrial Science and Technology, Tsukuba, Japan.

**ferment** (1) (*noun*) An archaic name for an enzyme. (2) (*verb*) To carry out FERMENTATION.

**fermentation** (1) Energy-yielding metabolism in which an energy substrate is metabolized without the involvement of an *exogenous* electron acceptor; fermentation characteristically occurs under anaerobic or microaerobic conditions (cf. e.g. CRABTREE EFFECT). The absence of an exogenous electron acceptor (= oxidizing agent, 'electron sink') necessarily means that the products of fermentation – collectively – have the same oxidation state as that of the substrate, the oxidation of any intermediate in the fermentation pathway being balanced by equivalent reduction of other intermediate(s) in the pathway; since the substrate undergoes no *net* oxidation, energy derived from the fermentation of a given substrate is less than that obtainable by the RESPIRATION of that substrate. Until the 1980s it was believed that all fermentable substrates were organic compounds; it is now known that inorganic sulphur compounds (such as sulphite) can be fermented e.g. by *Desulfovibrio sulfodisimutans* and by some other SULPHATE-REDUCING BACTERIA [Nature (1987) 326 891–892]. Although the synthesis of ATP during fermentative metabolism commonly involves SUBSTRATE-LEVEL PHOSPHORYLATION, ATP synthesis by ELECTRON TRANSPORT PHOSPHORYLATION can occur (e.g. when lactate is fermented via the succinate–propionate pathway of the PROPIONIC ACID FERMENTATION); in some organisms, proton motive force can also be generated by excreting the end products of fermentation: see END-PRODUCT EFFLUX. (See also e.g. ACETONE–BUTANOL FERMENTATION; ALCOHOLIC FERMENTATION; BUTANEDIOL FERMENTATION; BUTYRIC ACID FERMENTATION; homoacetate fermentation (in ACETOGENESIS); LACTIC ACID FERMENTATION; MIXED ACID FERMENTATION; PROPIONIC ACID FERMENTATION.)

(2) As commonly used in industrial microbiology: *any* of a wide range of processes carried out by microorganisms, regardless of whether fermentative or respiratory metabolism is involved. (See e.g. DIHYDROXYACETONE FERMENTATION; flor fermentation in WINE-MAKING; MALOLACTIC FERMENTATION; SORBOSE FERMENTATION. See also FERMENTER.)

**fermentative nitrate reduction** See NITRATE RESPIRATION.

**fermented foods** See e.g. BREAD-MAKING, DAIRY PRODUCTS, DOSA, GARI, IDLI, MISO, NATTO, OGI, ONCOM, PICKLING, SALAMI, SAUERKRAUT, SOY SAUCE, TEMPEH, TOFU. (cf. ANG-KAK, COFFEE, COCOA, FOOD PRESERVATION (e).) (See also SILAGE.)

**fermenter** (fermentor) A vessel in which an aerobic or anaerobic FERMENTATION (sense 2) can be carried out either in BATCH CULTURE or in CONTINUOUS CULTURE. (cf. BIOREACTOR.) Fermenters are typically vertical, essentially closed, cylindrical steel vessels. The traditional STIRRED TANK REACTOR is a squat vessel, but other types are 'column' (= 'tower') fermenters in which the vessel (the 'column') has a height-to-diameter ratio of up to ca. 10 (e.g. the typical AIRLIFT FERMENTER, BUBBLE COLUMN FERMENTER, JET LOOP FERMENTER, and PROPELLER FERMENTER). Important features of fermenter design include provision for: (i) Adequate heat transfer from the culture. (The heat produced from a given substrate can be estimated from the value of 110 kcal/mole  $\text{O}_2$  taken up – a value obtained empirically using various substrates and organisms [Book ref. 11, p. 32].) (ii) Efficient mixing of the culture. (iii) Efficient oxygen-to-liquid transfer. (iv) Adaptability to a range of operating conditions. (v) Ease of scale-up from the laboratory or pilot stage to industrial use. These factors largely determine the economics of a fermentation and the type of fermenter required for a particular purpose; thus, e.g., an STR – but not a bubble column or airlift fermenter – would generally be considered suitable for the fermentation of a (viscous) mycelial culture since only the STR (which has a greater input energy) would be able to ensure adequate mixing.

**Fernández–Morán particles** The stalked particles (the  $F_1$  parts of ( $F_0F_1$ )-type PROTON ATPASES) on the inner surface of the mitochondrial inner membrane.

**Fernandez reaction** See LEPROMIN TEST.

**ferredoxins** A category of simple IRON–SULPHUR PROTEINS which are involved only in electron transfer processes; a given ferredoxin may contain one or more iron–sulphur centres of the type  $[2\text{Fe}–2\text{S}]$ ,  $[3\text{Fe}–3\text{S}]$  and/or  $[4\text{Fe}–4\text{S}]$ . Ferredoxins typically have low-potential (i.e., highly negative)  $E_m$  values; thus, e.g. a  $[4\text{Fe}–4\text{S}]$  ferredoxin (Fd I) in *Desulfovibrio gigas* has an  $E_m$  of  $-455$  mV, and a  $(2[4\text{Fe}–4\text{S}])$  ferredoxin in *Clostridium pasteurianum* has an  $E_m$  of  $-400$  mV. However, a  $[2\text{Fe}–2\text{S}]$  ferredoxin in *Pseudomonas putida* (putidaredoxin) has an  $E_m$  of  $-240$  mV. (See also HIPIP; cf. FLAVODOXINS.)

**ferrichrome** See SIDEROPHORES.

**ferrimycins** See SIDEROMYCINS.

**ferrioxamines** See SIDEROPHORES.

**ferritin** An iron-storage protein which occurs e.g. within various mammalian, plant and fungal cells; iron is stored within the large, hollow ferritin molecule. (cf. SIDEROPHILINS; see also IMMUNOELECTRON MICROSCOPY.)

**ferrocene monocarboxylic acid** See BIOFUEL CELL.

**ferrochelatae** See HAEM.

**ferruginous** Rust-coloured.

**fertility factor** *Syn.* F PLASMID.

**fertility inhibition** (of the F plasmid) Inhibition of expression of the *traJ* gene (and, hence, inhibition of the TRANSFER OPERON)

FERMENTATION (diagrammatic): the fermentation of an organic substrate showing intermediates undergoing mutual oxidation and reduction.

by the intracellular presence of an IncF plasmid which encodes a functional *finO* product (see FINOP SYSTEM); a plasmid which encodes such a *finO* product is designated *fi*<sup>+</sup> (fertility inhibition positive) or *fin*<sup>+</sup>. Compatible plasmids which do not encode a functional *finO* product are designated *fi*<sup>-</sup>.

**ferulate** 3-Methoxy-4-hydroxycinnamate.

**Fervidobacterium** See BACTERIA (taxonomy).

**fes** An ONCOGENE present in the Snyder–Theilen and Gardner–Arnstein strains of feline sarcoma virus (see FELINE LEUKAEMIA VIRUS); *v-fes* is closely related to *v-fps* (present in Fujinami AVIAN SARCOMA VIRUS) and may be derived from a related *c-onc* sequence. The products of *v-fes* and *v-fps* have tyrosine-specific protein kinase activity.

**Fe–S protein** (Fe/S protein) See IRON–SULPHUR PROTEINS.

**fescue foot** (fescue toxicity syndrome) A condition which affects animals (mainly cattle) grazing pastures dominated by tall fescue grass (*Festuca arundinacea*); symptoms: lameness, followed by dry gangrene of the extremities (tail tip, hooves, ears). It appears to be caused by a vasoconstrictive mycotoxin produced by fungi parasitic or pathogenic in the grasses; fungi which have been implicated include *Aspergillus terreus* and biotypes of *Epichloë typhina* [AEM (1977) 34 576–581].

**Festuca necrosis virus** See CLOSTEROVIRUSES.

**Feulgen reaction** A specific staining reaction for DNA in situ. Mild acid hydrolysis of DNA (e.g. with 1 N HCl) removes purine bases and makes available the aldehyde group of the deoxyribose; aldehyde groups react with SCHIFF'S REAGENT to give a purple coloration.

**fever blister** *Syn.* COLD SORE.

**Ff phages** F-specific filamentous phages (e.g. fd, f1, M13, ZJ/2); see INOVIRUS.

**ff. sp.** See FORMA SPECIALIS.

**Ffh** See PROTEIN SECRETION.

**FH<sub>4</sub>** TetrahydroFOLIC ACID.

**FHA** See WHOOPING COUGH.

**FhuA protein** *Syn.* TONA PROTEIN.

**fhuB–fhuD genes** See SIDEROPHORES.

**FhuE** See IRON.

**fi<sup>-</sup> plasmid** See FERTILITY INHIBITION.

**fi<sup>+</sup> plasmid** See FERTILITY INHIBITION.

**FIAC** (2'-deoxy-2'-fluoro-5-iodo-1-β-D-arabinosylcytosine) An ARABINOSYL NUCLEOSIDE which has antiviral activity against herpes simplex viruses 1 and 2, varicella-zoster virus and cytomegaloviruses in cell cultures; its mode of action resembles that of ACYCLOVIR. In trials, FIAC gave better control of progressive herpes zoster than did vidarabine; it can be administered orally.

**fibrillae** See FIMBRIAE.

**fibrillum** See FIMBRIAE.

**fibrin** A fibrous, insoluble protein present e.g. in blood clots; during normal blood-clotting, fibrin is formed from the plasma protein FIBRINOGEN by the action of thrombin in the presence of Ca<sup>2+</sup>. (See also COAGULASE.)

**fibrinogen** The soluble glycoprotein precursor of FIBRIN. It consists of two identical monomers – each comprising three chains designated α, β and γ; the chains and monomers are held together by disulphide bridges. [Review of fibrin and fibrinogen: ARB (1984) 53 195–229.]

**fibrinolysin** (plasmin) An enzyme which, in mammals, is responsible for dissolving blood clots by the proteolytic degradation of fibrin. Fibrinolysin is formed from an inactive precursor (profibrinolysin, plasminogen) normally present in the blood. The term fibrinolysin has also been applied to various microbial enzymes capable of direct or indirect FIBRINOLYSIS.

**fibrinolysis** The degradation of FIBRIN, and, hence, the lysis of blood clots (see FIBRINOLYSIN). Various microbial enzymes have fibrinolytic activity; such activity may be (i) direct, due to proteolytic activity on fibrin itself (see e.g. BRINASE), or (ii) indirect, due to the activation of plasminogen (profibrinolysin) (see e.g. STREPTOKINASE). The production of plasminogen activators by certain bacteria has been linked to invasiveness [TIM (1997) 5 466–467].

**fibrinolytic** Capable of FIBRINOLYSIS.

**Fibrobacter** See BACTERIA (taxonomy).

**fibrocyst** (compound trichocyst) (*protozool.*) A type of TRICHOCYST formed by certain hypostome ciliates; the filament carries an umbrella-like tip.

**fibroma** A benign tumour of connective tissue. (cf. SARCOMA.)

**fibronectin** A heterodimeric glycoprotein, produced e.g. by fibroblasts and macrophages, which is found e.g. in extracellular matrix material and in plasma; it binds e.g. to various INTEGRINS, and its major roles include that of an adhesive molecule.

**fibrosarcoma** A SARCOMA arising from collagen-producing fibroblasts.

**Ficoll** A synthetic, water-soluble, non-ionic co-polymer of sucrose and epichlorhydrin, used e.g. in the preparation of density gradients for CENTRIFUGATION. It is also used for increasing the viscosity of a medium in order to slow down rapidly-motile organisms – a technique useful in certain COUNTING METHODS and in studies of ciliar and flagellar motility; in this context Ficoll has been reported to be superior to e.g. methylcellulose in that Ficoll causes less perturbation of hydrodynamic characteristics [Nature (1979) 278 349–351].

**FID** Free induction decay: see NUCLEAR MAGNETIC RESONANCE.

**fide** In a literature citation: an indication that a given reference has not been read by the author citing that reference.

**field blewit** See BLEWIT.

**field diaphragm** (in MICROSCOPY) (1) See KÖHLER ILLUMINATION. (2) (*Syn.* field stop) A metal annulus attached to the inside of an eyepiece at the focal plane of the eyepiece lens.

**field mushroom** See AGARICUS.

**Field's stain** A water-based staining procedure for detecting e.g. *Plasmodium* spp and trypanosomes in thick blood smears. The smear is immersed in a solution of azure, rinsed, immersed in a solution of eosin, rinsed, and allowed to dry in air; the water used for staining and rinsing should have a pH of 7.0–7.2. Any parasites present will not be obscured by erythrocytes since the latter are lysed during the procedure; lysis occurs because a methanol fixation stage is omitted.

**fièvre boutonneuse** *Syn.* BOUTONNEUSE.

**fifth disease** *Syn.* ERYTHEMA INFECTIONOSUM.

**figwort mosaic virus** See CAULIMOVIRUSES.

**Fiji disease** A SUGARCANE DISEASE, caused by a FIJIVIRUS and transmitted by planthoppers (*Perkinsiella* spp), which is characterized by stunting and the formation of GALLS on the underside of leaves. *Pseudo-Fiji* diseases of sugarcane include one similar to MAIZE WALLABY EAR DISEASE.

**Fijivirus** (plant reovirus subgroup 2) A genus of plant viruses of the REOVIRIDAE. Genome: 10 dsRNA molecules. Members infect plants of the Gramineae, and some can cause important diseases of crop plants; symptoms typically include stunting, excessive tillering, enations, and unnaturally dark-green leaves. Transmission occurs propagatively via plant-hoppers (*Perkinsiella* spp) in which transovarial transmission may occur. Type member: Fiji disease virus. Three serotypes of fijiviruses are recognized (host and geographical range in parentheses):

Group I: cereal tillering disease virus (CTDV) (barley, oats, maize, wheat; Sweden); maize rough dwarf virus (MRDV)

## filament

(maize, oats, wheat and other grasses; Europe); pangola stunt virus (PSV) ('pangola grass' – *Digitaria decumbens* – and other *Digitaria* spp; S. America, Taiwan etc); rice black-streaked dwarf virus (RBSDV) (rice, oats, maize, wheat; Japan, China).

Group II: Fiji disease virus (FDV) (sugarcane – *Saccharum officinarum*; Australia, Fiji, etc).

Group III: *Arrhenatherum* blue dwarf virus (ABDV) (*Arrhenatherum elatius*; Germany); *Lolium* enation virus (LEV) (ryegrass – *Lolium* spp; Germany); oat sterile dwarf virus (OSDV) (oats, *Lolium* spp; *Arrhenatherum elatius* etc; Europe).

MRDV, CTDV, RBSDV and PSV may be strains of the same virus or closely related viruses, as may OSDV, ABDV and LEV. (cf. RICE RAGGED STUNT VIRUS; LEAFHOPPER A VIRUS.)

[Review: Book ref. 83, pp. 505–563.]

**filament** (1) (*bacteriol.*) An elongated bacterial cell, i.e., one in which the length exceeds the width by ca. 10 times or more. (2) (*bacteriol.*) A (sheathed or unsheathed) chain of cells. (3) *Syn.* TRICHOME.

**filament pyrolyser** See PYROLYSIS.

**filamentous haemagglutinin** See WHOOPING COUGH.

**filamentous phages** *Syn.* INOVIRUS.

**filamin** See ACTIN.

**filar micrometer** See MICROMETER.

**Fildes' enrichment agar** (Fildes' digest agar) A medium which contains the X FACTOR and the V FACTOR; it is used for isolating *Haemophilus* spp. A peptic digest of blood is made by mixing 1 volume of defibrinated sheep blood with 3 volumes of physiological saline (0.87% NaCl) and adding conc. HCl (3 ml/100 ml) and granular pepsin (0.5 g/100 ml); after incubation (56°C/ca. 4 hours, with occasional shaking), the pH is adjusted to 7 with conc. NaOH. The digest is stored at 4°C; chloroform (0.25% v/v) may be added as preservative. Before use, any chloroform present should be driven off by heating (56°C/30 min); 2–5% (v/v) of the digest is then added to e.g. molten nutrient agar which has been autoclaved and cooled to 56°C.

**Fildes' peptic digest of blood** See FILDES' ENRICHMENT AGAR.

**filia** *Syn.* VILIA.

**Filibacter** A genus of Gram-negative, strictly aerobic, filamentous gliding bacteria; *F. limicola* has been isolated from the sediment of a eutrophic lake [JGM (1984) 130 2943–2959].

**Filifactor** See CLOSTRIDIUM.

**filiform** Thread-like.

**filipin** A pentaene POLYENE ANTIBIOTIC produced by *Streptomyces filipinensis*. It has a higher affinity for cholesterol than for ergosterol, and is more toxic to mammalian cells than to fungi; it appears not to form pores in cytoplasmic membranes but can cause disruption of membranes in sensitive cells.

**filli** *Syn.* VILIA.

**film** See SMEAR.

**film and spots** A test used for differentiating species of *Mycoplasma*. The organisms are grown on a medium containing egg yolk or ca. 20% horse serum. Species which give a positive reaction (e.g. *M. gallinarum*, *M. synoviae*) give rise to a wrinkled, pearly surface film, and to minute dark or black spots in the medium under and around the colonies; these cultural features indicate lipolytic activity: the film contains cholesterol and phospholipids, and the spots are small deposits of Ca<sup>2+</sup> and Mg<sup>2+</sup> salts of fatty acids liberated by lipolysis. A negative test is given e.g. by *M. meleagridis*, *M. mycoides* and *M. pneumoniae*. (See also LIPASE.)

**Filobasidiaceae** A family of basidiomycetous fungi characterized by the formation of long, slender, non-septate basidia with

terminal sessile basidiospores; blastospores may be formed, teliospores are not. Members have a yeast-like vegetative phase, with globose, oval, apiculate or elongate cells which reproduce by budding. Conjugation between two haploid cells is followed by the formation of a dikaryotic mycelium on which the basidia develop. Most strains are heterothallic. The family includes the genera CHIONOSPHAERA, FILOBASIDIELLA, and FILOBASIDIUM. (See also WALLEMIA.)

The taxonomic position of the family is unsettled. It has been included e.g. in the Ustilaginales, and in a separate order (Filobasidiales) [discussion and refs: Book ref. 100, pp. 468–469]; some authors [Book ref. 64] include the above three genera in the SPORIDIALES.

**Filobasidiella** A genus of fungi (see FILOBASIDIACEAE). The yeast-like vegetative cells have CAPSULES, the size of the capsule depending on environmental conditions. The dikaryotic hyphae have clamp connections and dolipore septa which lack parentheses. Basidiospores are formed in long chains by basipetal budding from 4 sites on the apex of the basidium. The sole species, *F. neoformans*, has two varieties – *F. neoformans* var. *neoformans* (anamorph: *Cryptococcus neoformans* var. *neoformans*) and *F. neoformans* var. *bacillispora* (anamorph: *Cryptococcus neoformans* var. *gattii*) – and four serotypes (A–D). Strains have been isolated from pigeon excreta, soil, and humans (see CRYPTOCOCCOSIS). [Book ref. 100, pp. 472–482.]

**Filobasidium** A genus of fungi (see FILOBASIDIACEAE). The dikaryotic hyphae have clamp connections and dolipore septa with or without parentheses. Basidia are produced laterally and terminally on the hyphae, and sessile basidiospores are produced on a whorl at the apex of the metabasidium. Species: *F. capsuligenum* (anamorph: *Candida japonica*), isolated e.g. from cider and saké; *F. floriforme* (anamorph: possibly *Cryptococcus albidus* var. *albidus* on the basis of physiological characteristics), isolated from plants; and *F. uniguttulatum* (anamorph: *Cryptococcus uniguttulatus*), isolated from clinical specimens. [Book ref. 100, pp. 483–491.]

**filoplasmodium** See LABYRINTHULAS.

**filopodium** See PSEUDOPODIUM.

**filose** Thread-like.

**Filosea** A class of amoebae (superclass RHIZOPODA) which form long, tapering, hyaline filopodia that often branch and sometimes anastomose, and that are used for trapping prey. Spores and flagellated stages are not formed. Orders: Aconchulinida (cell naked, i.e., non-testate: e.g. NUCLEARIA, *Vampyrella*) and Gromiida (cell enclosed by a siliceous or proteinaceous and membrane-like test: e.g. EUGLYPHA, *Gromia*).

**Filoviridae** A family of viruses originally proposed to accommodate Marburg virus and Ebola virus [Interviol. (1982) 18 24–32], causal agents of clinically similar VIRAL HAEMORRHAGIC FEVERS in man (see MARBURG FEVER). The viruses occur in various parts of Africa; man is presumed to be infected only incidentally. Monkeys and rodents can be infected experimentally, infection usually resulting in fatal disease.

Marburg and Ebola viruses are morphologically similar and genetically related but serologically distinct. The virions are pleomorphic filaments of uniform width (~80 nm) but variable in length (up to ~14000 nm); the unit length (i.e. the shortest length with maximum infectivity) is ~790 nm for Marburg virus, ~970 nm for Ebola virus. Ring-shaped or branched structures are sometimes seen.

The virion consists of a helical nucleocapsid surrounded by an envelope bearing surface spikes. [Ebola virus proteins: Virol. (1985) 147 169–176]. The genome is one molecule of negative-sense ssRNA. Virions are stable at room temperature but can

be inactivated by heat (e.g. 60°C/30 min), ultraviolet radiation and gamma radiation, organic solvents, phenolic disinfectants, hypochlorite and  $\beta$ -propiolactone.

Virus replication occurs in the host cell's cytoplasm; maturation involves budding of preformed nucleocapsids through the plasma membrane.

Marburg and Ebola viruses can be grown in various types of cell culture (e.g. Vero cells). Infected cells exhibit CPEs such as intracytoplasmic vesiculation, swelling of mitochondria and degeneration of organelles.

[Book ref. 148, pp 1111–1118.]

Attempts to elicit protective immunity to Ebola virus in the traditional way have not been successful. However, an approach termed *genetic vaccination* (= *genetic immunization*), in which plasmid DNA (encoding viral proteins) is injected into the host, has achieved some success in an animal model: when vaccinated in this way, guinea pigs were protected against a lethal challenge of Ebola virus, protection correlating with both antibody titre and the antibody-specific T cell response [Nature Medicine (1998) 4 37–42]. (See also DNA VACCINES.)

The Ebola virus glycoprotein is reported to be the main viral determinant of vascular cell cytotoxicity and damage [Nature Medicine (2000) 6 886–889]. The synthesis of increased amounts of glycoprotein by a mutant virus was associated with a higher level of cytotoxicity [Science (2001) 291 1965–1969].

A combination of 'DNA immunization' and boosting with an adenoviral vector (encoding relevant antigenic proteins) has been successful in generating protective immunity against the Ebola virus in non-human primates (cynomolgus macaques) [Nature (2000) 408 605–609].

[Asymptomatic Ebola infection (in contacts of symptomatic patients): Lancet (2000) 355 2210–2215. On the trail of Ebola and Marburg viruses: Science (2000) 290 923–925.]

**filter-paper cellulose** See FP-CELLULOSE.

**filterable virus** An obsolete term originally applied to any infectious agent which could pass through the early microbiological filters (e.g. the Berkefeld candle). Such agents included viruses but also e.g. *Chlamydia* and mycoplasmas.

**filtration** Filtration can be used to separate microorganisms from a liquid or gas in which they are dispersed; it is used e.g. for the following purposes. (a) The sterilization of e.g. heat-labile liquids (known to be free of small viruses or virioids) by passing them through a filter capable of retaining all other microorganisms. (b) The preparation of cell-free culture filtrates for the recovery of extracellular enzymes, antibiotics etc. (c) The counting of small numbers of bacteria in a large volume of liquid – used e.g. in water bacteriology. A measured volume of the sample is passed through a membrane filter (pore size e.g. 0.45  $\mu\text{m}$  – see below) and the membrane is subsequently incubated, face upward, on a pad of absorbent material which has been saturated with a suitable liquid culture medium. The number of bacteria per unit volume is calculated from the number of colonies which develop on the membrane. Membranes overprinted with a grid facilitate colony counting. (See also DEFT and COUNTING METHODS.) (d) Estimation of particle size in a monodisperse system. The suspension is filtered through a series of membranes of progressively smaller pore size; assuming minimal adsorption, particle size corresponds approximately to the pore size of the first membrane to effect significant retention of the particles. (See also *sand filter* in WATER SUPPLIES.)

Many different types of filtering apparatus have been devised. In the majority of these, liquid is drawn through the filter

as a result of reduced pressure in the receiving vessel. The *candle filter* type consists essentially of a thick-walled test tube-shaped structure made either of unglazed earthenware (e.g. the *Chamberland candle* or *Doulton filter*) or wholly or partly of DIATOMACEOUS EARTH (e.g. the *Berkefeld candle* or *Mandler filter*); when assembled, the cavity of a candle filter communicates with the receiving vessel, and the liquid sample is contained in a jacket which surrounds the exterior of the candle. Such filters may be used repeatedly, but should be cleaned and sterilized after each use. The *Seitz filter* consists of a flat pad of asbestos (or asbestos and cellulose) suitably mounted between the sample container and the receiving vessel; the filter is used once and then discarded. In *sintered glass filters* the filter proper consists of a layer of minute glass particles which have been fused together ('sintered', 'fritted') to form a porous mass; such filters may be re-used after having been cleaned (e.g. in acid and/or hypochlorite solutions), washed, dried, and sterilized e.g. in a HOT-AIR OVEN.

*Membrane filters* are thin films of e.g. cellulose nitrate (*collodion*), cellulose acetate, nylon, polycarbonate, polytetrafluoroethylene (PTFE, *Teflon*), or polyvinylidene; they are manufactured in a range of pore sizes – commonly used membrane filters having a mean pore diameter of 0.45  $\mu\text{m}$  or 0.22  $\mu\text{m}$ . (Filtration through membranes with such small pores is often referred to as *ultrafiltration*.) Pores may be tortuous (as in Gelman- or Millipore-type membranes) or cylindrical (as in Nuclepore membranes). In order to avoid blocking the fine pores of a membrane filter with coarse particulate matter it may be necessary to use one or more stages of *prefiltration*; this may involve e.g. passing the sample through a Seitz filter or through pads of matted glass-fibre before filtering it through the membrane. Hydrophobic membranes (made e.g. of PTFE) are used e.g. for the filtration of air in the brewing industry. Membranes with hydrophobic rims can filter aqueous fluids in the central region and air in the annular region; these membranes can prevent air-locks forming upstream of the filter. The physical integrity of a membrane filter can be monitored e.g. by the BUBBLE POINT TEST or the DIFFUSION TEST; the presence of surfactants in a membrane can affect the results of the former test.

Although filtration depends largely on a mechanical sieving action, suspended particles, organisms and macromolecules may also be adsorbed to the material of the filter as a result of electrostatic or other forces. [Adsorption of poliovirus to membrane filters: AEM (1983) 45 526–531.] Some filters (e.g. the Seitz filter) are highly adsorptive, while others (such as the modern porcelain filters) are relatively non-adsorptive. The charge-modified filters such as Zetapor and Zeta Plus, which carry a net positive charge, combine a sieving action with electrostatic adsorption; such filters are used e.g. for the concentration of viruses from water samples [AEM (1983) 45 232–237]. Some membranes are markedly anisotropic in that the two faces of the membrane have different pore characteristics; an effect of this is that flow rate is higher when filtration is carried out in one particular direction.

In some cases substances can be leached from a filter during the filtration process: e.g., Seitz filters tend to enrich the filtrate with magnesium ions. In the manufacture of some types of membrane, additives such as glycerol and surfactants are incorporated to improve flexibility and wettability, respectively; unless such substances are leached out prior to use (e.g. during sterilization) they can subsequently contaminate the filtrate.

(See also HEMMING FILTER and HEPA FILTER.)

**fim operon** See FIMBRIAE.

## fimbriae

**fimbriae** (*singular*: fimbria) Thin, proteinaceous filaments which extend from the surface of some types of microbial cell; fimbriae may be sparse, or they may occur in large numbers on a given cell. More than one type of fimbria may be present on a given cell. Fimbriae are functionally distinct from both flagella (see FLAGELLUM) and PILI.

*Note.* A number of authors use the two terms *fimbriae* and *pili*, interchangeably, to refer to the appendages described in this entry. By contrast, appendages described in the entry PILI (which, unlike fimbriae, are concerned with the transfer of DNA between cells) are referred to consistently by all authors as 'pili'. A logical, scientific use of terminology would require that different entities be referred to by different terms; for this reason, the terms 'fimbriae' and 'pili' are used here with distinct and mutually exclusive meanings.

Fimbriae are quite common on Gram-negative bacteria (including cyanobacteria) but less common on Gram-positive species; they occur on various fungi – including the yeasts *Candida albicans* and *Saccharomyces cerevisiae* [fimbriae of yeasts and yeast-like organisms: Bot. Gaz. (1982) 143 534–541] and some SMUTS.

The account below refers specifically to fimbriae of Gram-negative bacteria.

Fimbriae may be distributed over the entire surface of a given cell or they may occur only in particular region(s) of the cell surface.

Fimbriae may promote cell-to-cell adhesion, or adhesion between the cell and substratum. The adhesive fimbriae of some pathogenic bacteria are important virulence factors which play a critical role in the process of infection.

Some polar fimbriae – i.e. fimbriae located at the pole (end) of a rod-shaped bacterium – are associated with TWITCHING MOTILITY.

A fimbria is essentially a rod-like structure with a uniform width (typically 2–8 nm) and a length between ~100 nm and several micrometres; although it may contain more than one type of component, the main structure is composed of a single type of protein subunit. In at least some cases (type I fimbriae of *Escherichia coli* – see below), the individual fimbria has been seen as a tightly coiled *helical* filament under the electron microscope, the filament itself comprising a linear sequence of protein subunits.

Short fimbriae (e.g. K88) may be seen as a tangled mass on the cell surface, appearing as an amorphous layer under low-power magnification in the electron microscope; such fimbriae have been referred to as 'capsular material' or *fibrillae* (but see later for an alternative use of 'fibrillae'). It has been suggested that such short fimbriae may in fact represent broken fimbriae [FEMS Reviews (1996) 19 25–52 (35)].

A fimbria is constructed essentially of linearly repeating molecules of the main protein subunit. Protein subunits have been termed *fimbrillins* or *pilins*, the latter term being used more commonly. (The subunits have also been called *fimbrins*, but this may cause confusion because 'fimbrins' are involved in the formation of actin bundles in eukaryotic cells.) (See also PSEUDOPILINS.) Pilins frequently contain a high proportion of non-polar amino acids, so that fimbriate cells are commonly (not always) more hydrophobic than afimbriate cells. (In this context hydrophobicity may be indicated by the tendency of cells to congregate at an air–water or oil–water interface.)

The occurrence, number and composition of fimbriae on a cell depend on various factors which include e.g. genetic switching mechanisms (see later) and temperature; for example, K88 and K99 fimbriae are not formed below ~18°C.

*Classification of fimbriae.* The different types of fimbria on Gram-negative bacteria can be grouped into categories on the basis of e.g. (i) homology in the amino acid sequences in major subunit proteins; (ii) physical, antigenic and adhesive characteristics; and (iii) the mechanism of secretion and assembly.

One group comprises the type I fimbriae (also called type 1 fimbriae); these include: (i) the 'common' type I fimbriae of *Escherichia coli*, (ii) the P FIMBRIAE and (iii) the K88 and K99 'fibrillae'.

Another well-studied category of fimbriae, the type IV (= type 4) fimbriae, are found on a range of pathogenic bacteria; these fimbriae occur e.g. on strains of EPEC and ETEC, on *Neisseria* spp and *Pseudomonas aeruginosa*, and on *Vibrio cholerae* ('toxin co-regulated pili' (TCP) which constitute an important virulence factor in CHOLERA).

*Type I fimbriae* (type 1 fimbriae; F1 fimbriae; 'common pili'). These fimbriae are chromosomally encoded and are common e.g. on *Escherichia coli* and other enterobacteria. Each fimbria consists primarily of the main rod-shaped region, about 7 nm in diam., which comprises several thousand copies of the major pilin subunit, FimA (encoded by the *fimA* gene). The distal end of the fimbria consists of a short (~16 nm) and narrow (2–3 nm diam.) flexible structure – the *fibrillum* (plural: *fibrillae*) – which is composed of the minor pilin subunits FimF, FimG and FimH; FimH is a mannose-binding ADHESIN which appears to be the most distal pilin in the fibrillum.

Type I fimbriae can adhere to various cells and surfaces, including guinea-pig and horse erythrocytes – causing HAEMAGGLUTINATION; such adhesion is inhibited by D-mannose, or by methyl- $\alpha$ -D-mannoside, i.e. binding is 'mannose-sensitive', and type I fimbriae are said to cause 'mannose-sensitive haemagglutination' (MSHA). Fimbriae whose adhesion is not inhibited in this way are said to cause 'mannose-resistant haemagglutination' (MRHA).

Type I fimbriae can also bind to UROPLAKINS (see also UPEC), such adhesion being a preliminary step in the development of many URINARY TRACT INFECTIONS (such as CYSTITIS). Moreover, type I fimbriae can promote the *invasion* of human urinary tract epithelium [EMBO (2000) 19 2803–2812].

*Genetics of type I fimbriae.* In *Escherichia coli*, type I fimbriae are encoded by the *fimA–fimH* operon; *fimA* and *fimFGH* are structural genes (see above), while the *fimCD* products are involved in assembly (see later).

The *fimBE* genes have a regulatory role, being involved in PHASE VARIATION: the on/off switching of fimbrial synthesis. Switching involves inversion of a 314-bp sequence that contains the promoter of the first structural gene in the operon, *fimA*. When the control sequence is in one orientation the promoter is located correctly for transcription of *fimA* and of the other genes (so that fimbriae are synthesized); when the control sequence is in the opposite orientation, *fimA* is promoter-less (so that fimbriae are not synthesized) (cf. flagellar PHASE VARIATION in *Salmonella*). The products of the *fimBE* genes are recombinases which mediate inversion of the control sequence; FimB can bring about inversion in either direction (i.e. it can switch synthesis from on to off and from off to on), whereas FimE can mediate only the on-to-off switch. (Under in vivo conditions, switching also requires other (intracellular) factors, including INTEGRATION HOST FACTOR and the H-NS PROTEIN.)

Interestingly, there is evidence of regulatory cross-talk between the *fim* operon and the *pap* operon (which encodes P FIMBRIAE) – this resulting in inhibition of expression of type I fimbriae. In this cross-talk, PapB, a *pap* regulatory protein, is

reported to (i) increase the expression of FimE (thus promoting the on-to-off switch), and (ii) inhibit the activity of FimB (thus blocking an off-to-on reversal of FimE activity) [EMBO (2000) 19 1450–1457].

**Secretion and assembly of type I fimbriae.** The individual protein subunits are synthesized in the cytoplasm; each protein has a signal sequence (see SIGNAL HYPOTHESIS) and is transported across the cytoplasmic membrane in a *sec*-dependent manner (see type II PROTEIN SECRETION). In the periplasm, each protein is bound by a 'chaperone', FimC. FimC folds the protein and prevents it from forming abortive contacts with other subunits; the chaperone also appears to target its subunit to the outer membrane.

In the OUTER MEMBRANE, the *usher protein*, FimD, forms an oligomeric ring structure with a central pore (of ~2 nm diam.) through which the oligomerized subunits of the nascent fimbria are translocated as a linear (not helical) filament. The first subunits to be externalized are those of the fibrillum; FimG is thought to have a critical role in 'nucleating' the fibrillum [PNAS (2000) 97 9240–9245]. Subsequently, the FimA subunits, bound together in linear sequence, are translocated through the usher pore and added to the base of the growing fimbria; only when the FimA subunits have reached the extracellular side of the usher pore do they adopt a helical form.

The order in which the various types of subunit are externalized via the usher pore may depend on the affinity with which each type of subunit binds to the pore structure; thus, e.g., under in vitro conditions, the FimH adhesin has the highest affinity for the usher.

[Secretion and assembly of type I fimbriae: FEMS Reviews (2000) 24 21–44 (27–31).]

**P fimbriae.** The 11 genes encoding P FIMBRIAE occur in the (chromosomal) *pap* operon, which is quite similar to the *fim* operon. PapA is the major subunit; PapC is the usher protein; PapD is the chaperone; PapKEFG form the fibrillum, PapG being the adhesin. PapH binds at the base of the fimbria, forming an anchor and signalling the end of fimbrial growth. (In mutant cells lacking the PapD chaperone, the subunits are degraded by a periplasmic protease, DegP; in *papD degP* mutants, subunits accumulate in the periplasm.)

**K88 (F4) fimbriae.** These (plasmid-encoded) fimbriae occur on strains of *E. coli* pathogenic for piglets. The major fimbrial subunit, FaeG, also functions as an adhesin; the binding sites for K88 fimbriae contain Gal- $\alpha$ (1–3)Gal.

**K99 (F5) fimbriae.** These (plasmid-encoded) fimbriae occur on strains of *E. coli* pathogenic for calves and lambs. The major subunit, FanC, has adhesive properties.

[Chromatographic purification of K99 fimbriae: JGM (1983) 129 1975–1982. Production of K88, K99 and F41 fimbriae in relation to growth phase: FEMS (1985) 26 15–19. K88, K99 and 987P fimbrial antigens used in a vaccine against porcine colibacillosis: VR (1985) 117 408–413.]

**Type II fimbriae (type 2 fimbriae).** These fimbriae occur on some strains of *Salmonella* and other enterobacteria; they lack the adhesive and haemagglutinating properties of type I fimbriae but are otherwise similar.

**Type III fimbriae (type 3 fimbriae)** occur on various members of the Enterobacteriaceae [JMM (1985) 20 113–121]; their adhesive properties are not inhibited by mannose. These fimbriae promote haemagglutination of ox erythrocytes only when the latter have been treated with tannic acid (the so-called 'tanned ox' haemagglutination). [Comparative study of type 3 fimbriae in *Klebsiella* spp: JMM (1985) 20 203–214.]

**Type IV fimbriae (type 4 fimbriae).** All the fimbriae placed in this category are secreted and assembled in a similar way. These fimbriae include important (adhesive) virulence factors in a range of Gram-negative pathogens such as *Neisseria gonorrhoeae* and *N. meningitidis*, *Pseudomonas aeruginosa*, *Vibrio cholerae* and certain strains of *Escherichia coli* (e.g. the 'bundle-forming pili' of EPEC). (See also LONGUS.)

The type IV fimbriae of e.g. *N. gonorrhoeae* are subject to PHASE VARIATION (on/off switching) as well as to extensive ANTIGENIC VARIATION.

Most type IV fimbriae are encoded chromosomally (see also PIL GENES). The 'bundle-forming pili' of EPEC are an exception, being encoded by a virulence plasmid (see also PATHOGENICITY ISLAND).

Type IV fimbriae are typically flexible, rod-like appendages, ~5–6 nm in diam. and 1–2  $\mu$ m in length; constituent pilins are apparently organized in a helical fashion.

In a recent model for the assembly of type IV fimbriae in *N. gonorrhoeae* [FEMS Reviews (2000) 24 21–44 (31–35)], the assembly of these appendages (unlike the assembly of type I fimbriae) begins at a protein complex in the cytoplasmic membrane; that is, the base of the fimbria is linked to the cytoplasmic membrane – a column of *assembled* subunits passing from this origin, through the periplasm, through the outer membrane (see later), and into the extracellular environment.

The adhesive properties of type IV fimbriae are due, at least partly, to the major (structural) pilins – in contrast to type I fimbriae, in which there are minor pilins specialized for adhesion in the distal fibrillum. Exceptionally, tip adhesins (encoded by the *pilC* gene) have been identified in the two major pathogenic species of *Neisseria* [Nature (1995) 373 357–359; Mol. Microbiol. (1997) 23 879–892].

**Secretion and assembly of type IV fimbriae.** In the model for assembly of type IV fimbriae in *N. gonorrhoeae*, the major pilin subunit, PilE, is translocated across the cytoplasmic membrane but initially remains attached to the membrane by an N-terminal hydrophobic sequence; this sequence is subsequently cleaved, so that the PilE subunits can be incorporated, sequentially, into the nascent fimbria – incorporation being mediated by a complex of proteins (including PilFGT) located within the cytoplasmic membrane. A SECRETIN, PilQ, forms a pore (~5.5 nm diam.) in the outer membrane through which the developing fimbria extends to the exterior; the pore is stabilized by PilP. In *N. gonorrhoeae* (and *N. meningitidis*), the distal end of the fimbria has an adhesive subunit, PilC (which is synthesized with a *sec*-dependent signal sequence); the incorporation of PilC is one of the initial steps in the assembly process.

[Type IV fimbriae (review): ARM (1993) 47 565–596.]

**PSA fimbriae ('PSA pili')** occur as a polar tuft in many strains of *Pseudomonas aeruginosa*; they are apparently chromosomally encoded, retractable filaments, ca. 6 nm in diam. and <1 to several micrometres in length. PSA fimbriae act as receptors for a range of bacteriophages.

[Secretion and assembly of regular surface structures (fimbriae, flagella and S layers) in Gram-negative bacteria: FEMS Reviews (2000) 24 21–44.]

**fimbriate** (1) Having FIMBRIAE. (2) Having a fringed edge.

**fibrillum** See FIMBRIAE.

**fimbrin** See ACTIN.

***fin*<sup>+</sup> plasmid** See FERTILITY INHIBITION.

**fin rot** See BACTERIAL FIN ROT.

**final host** (definitive host) In heteroxenous coccidia: the host in which the sexual phase occurs (see EIMERIORINA).

## finger-and-toe disease

**finger-and-toe disease** See CLUBROOT.

**finger millet mosaic virus** See RHABDOVIRIDAE.

**fingerprinting** Any procedure which gives a strain-specific pattern of products when a given organism is examined; the products commonly consist of fragments of DNA (or RNA) distributed electrophoretically in a gel. A fingerprint may be generated e.g. by restriction of chromosomes followed by ELECTROPHORESIS of the products (see e.g. DNA FINGERPRINTING) or by electrophoresis of the products formed in TYPING procedures that involve nucleic acid amplification (e.g. AFLP).

**Finkel–Biskis–Jinkins murine sarcoma virus** See FBI OSTEOSARCOMA VIRUS.

**FinOP system** In most IncF plasmids: a system in which the plasmid's *finO* and *finP* products act, jointly, to inhibit translation of the *traJ* gene (the gene which exerts a positive regulatory influence on the transfer genes); as a consequence of this activity, the transfer function of such plasmids is repressed.

The FinO products of most IncF plasmids are interchangeable but the FinP products of different plasmids are commonly not interchangeable. [Nucleotide sequences of *finP* alleles of five IncF plasmids: JB (1986) 167 754–757.]

The *finP* product is an antisense RNA molecule which binds to the 5' end of *traJ* mRNA (including the ribosome-binding sequence), thus inhibiting translation; the *finO* product (a polypeptide) binds to, and promotes the stability of, the FinP–mRNA duplex – resulting in repression of the *traJ* gene and (therefore) repression of transfer (so-called fertility inhibition). (The FinOP binding site was formerly designated *fisO*, *O<sub>1</sub>* or *traO*.)

Mutant (defective) *finO* and/or *finP* products may fail to inhibit the expression of *traJ* – in which case the negative regulation of the transfer genes is abolished, and the transfer function is expressed constitutively. Plasmids containing mutant *finO* genes include R1*drd*19 and R100-1.

It was originally thought that the (constitutively derepressed) F PLASMID lacked a *finO* locus [Book ref. 161, p 605]. *finO* is now known to be present but is inactivated by an INSERTION SEQUENCE (IS<sub>3</sub>) located within the coding region of the gene.

(See also FERTILITY INHIBITION.)

**fireblight** A disease which can affect many members of the Rosaceae, e.g. apple and pear trees, cotoneaster and hawthorn; it is characterized by wilting and by browning and necrosis of blossoms, fruit, leaves and twigs. The causal agent, *Erwinia amylovora*, infects e.g. via blossoms and/or wounds; virulent strains of *E. amylovora* form AMYLOVORIN. [Review: Book ref. 58, pp. 45–63.]

**firefly luciferin** See BIOLUMINESCENCE. (See also CHEMILUMINESCENCE.)

**Firmibacteria** A proposed class of bacteria comprising all organisms of the FIRMICUTES other than the THALLOBACTERIA.

**Firmicutes** A proposed division of the PROCARYOTAE comprising bacteria in which the CELL WALL is of the Gram-positive type; classes: FIRMIBACTERIA; THALLOBACTERIA.

**Fis protein** See CELL CYCLE (b).

**Fischerella** A genus of filamentous, thermophilic CYANOBACTERIA (section V) in which some of the cells in a mature trichome divide in more than one plane, resulting in a partly multiserial trichome with lateral uniseriate branches. Hormogonia are formed from the ends of the trichomes or from lateral branches, and are composed of small cylindrical cells which enlarge and become rounded; heterocysts initially develop mainly in intercalary positions, and are mainly intercalary or lateral in mature trichomes. Akinetes may be formed. GC%: 42–49.

The genus includes '*Mastigocladus laminosus*', an organism found in hot springs; it has an upper temperature limit for growth of ca. 58°C (cf. CHLOROGLOEOPSIS) and is capable of nitrogen fixation. [Cell division and branching in *M. laminosus*: JGM (1984) 130 2079–2088.]

**FISH** See PROBE.

**fish diseases** Marine and freshwater fish are susceptible to a wide range of infectious diseases, the severity and spread of which tend to be enhanced under high-density fish farming conditions. (a) *Bacterial diseases* include e.g. BACTERIAL FIN ROT, BACTERIAL GILL DISEASE, COLD WATER DISEASE, COLUMNARIS DISEASE, ENTERIC REDMOUTH, ENTERIC SEPTICAEMIA, FURUNCULOSIS, KIDNEY DISEASE, RED MOUTH, RED PEST, tuberculosis, ULCER DISEASE, vibriosis (see VIBRIO). [Book ref. 9; control of bacterial diseases by antimicrobial compounds: Book ref. 121, pp. 255–268.] (b) *Fungal diseases* include e.g. GILL ROT, ICHTHYOPHONOSIS, SAPROLEGNIASIS. (See also APHANOMYCES.) [Book ref. 10.] (c) *Protozoal diseases* include e.g. COSTIASIS, ICHTHYOPHTHIRIASIS, PROLIFERATIVE KIDNEY DISEASE, VELVET DISEASE, WHIRLING DISEASE; see also GLUGEA, HENNEGUYA and MYXOBOLUS. (d) *Viral diseases* include e.g. CARP POX, CHANNEL CATFISH VIRUS DISEASE, EGTVD DISEASE, INFECTIOUS HAEMATOPOIETIC NECROSIS, INFECTIOUS PANCREATIC NECROSIS, LYMPHOCYSTIS, SPINNING DISEASE, SPRING VIRAEMIA OF CARP.

Fish may also be affected or killed by algal or cyanobacterial BLOOMS due to the production of toxins (see e.g. RED TIDE) and/or to oxygen depletion resulting from the sudden decomposition of vast numbers of algae or cyanobacteria.

**fish spoilage** Freshly caught, gutted, iced fish and crustacea (shrimps etc) are susceptible to spoilage by a mixed psychrotrophic flora derived from the fish itself and/or from equipment, handlers etc [Book ref. 29, pp. 283–294]. Common spoilage organisms include *Photobacterium* spp (from the fish's intestine) and *Alteromonas putrefaciens*. These organisms are facultative anaerobes which can reduce trimethylamine-*N*-oxide (TMAO) – present in the flesh of the fish – to the strongly malodorous substance trimethylamine (TMA); TMAO may function as the terminal electron acceptor for anaerobic electron transport [JGM (1983) 129 3689–3696]. Other malodorous products of bacterial spoilage include ammonia and hypoxanthine. In certain types of fish (e.g. mackerel) dangerously high – but often organoleptically undetectable – levels of HISTAMINE may accumulate, during storage, as a result of the decarboxylation of histidine by contaminating bacteria (e.g. *Clostridium* spp, *Escherichia coli*, Proteaceae); consumption of such fish causes 'scombroid poisoning' [Food Mic. (1984) 1 263–267]. Fish spoilage may be delayed by the addition of preservatives (usually zeonic acid) and/or by irradiation.

Off-flavours and taints in fish may be due to substances produced by certain actinomycetes and cyanobacteria present in the aquatic environment (see e.g. GEOSMIN and 2-METHYLLISOBORNEOL).

**fish-eye spoilage** (of olives) See PICKLING.

***fisO* locus** See FINOP SYSTEM.

**fiSSION** Cell division in which overall (i.e., not localized) cell growth is followed by septum formation which typically divides the fully grown cell into two similar or identical cells. (See also BINARY FISSION; cf. BUDDING.)

**fissitunicate ascus** *Syn.* BITUNICATE ASCUS.

**Fistulina** See APHYLLOPHORALES (Fistulinaceae).

**Fistulinaceae** See APHYLLOPHORALES.

**FITC** Fluorescein isothiocyanate: a reactive derivative of FLUORESCENIN used e.g. for labelling proteins in IMMUNOFLUORESCENCE techniques. FITC fluoresces greenish-yellow.

**Fite–Faraco stain** An acid-fast stain used for detecting *Mycobacterium leprae* in tissue sections; the procedure resembles that for the ZIEHL–NEELSEN STAIN but haematoxylin is used as counterstain.

**Fitz–Hugh–Curtis syndrome** See CURTIS–FITZ-HUGH SYNDROME.

**FIV** FELINE IMMUNODEFICIENCY VIRUS.

**five-five-five test** (5-5-5 test) A quantitative SUSPENSION TEST in which a test organism is exposed for 5 min to each of a range of dilutions of the test disinfectant; after neutralization of the disinfectant, surviving bacteria are counted by subculturing to pour plates. To be considered effective, a disinfectant must give a minimum 5-log ( $10^5$ -fold) reduction in cell numbers. Sporicidal activity is assessed by using a suspension of endospores of *Bacillus cereus* ATCC 9139 preheated at 80°C for 60 sec; an ‘effective’ sporicidal disinfectant must produce a minimum 1-log decrease in viable spores.

**five-kingdom classification** See KINGDOM.

**five-three-two symmetry** (5-3-2 symmetry) See ICOSAHEDRAL SYMMETRY.

**fixation** The process of killing cells while preserving their structure and organization in as life-like a condition as possible (cf. CRYOFIXATION). Fixation involves the inactivation of enzymes, particularly AUTOLYSINS; ideally, it also hardens cellular structures and renders cell components compatible with particular stains. Most or all methods of fixation create ARTEFACTS. (a) *Heat fixation* can be used for the fixation of smears of bacteria prior to staining. The SMEAR is passed *rapidly* through a flame two or three times; such *heat-fixed smears* are suitable e.g. for the GRAM STAIN but are not suitable for observations on cell structure or morphology. (b) *Chemical fixation*. A chemical *fixative* permeates cells and stabilizes their components by binding to them or denaturing them. Some fixatives (e.g. ethanol, mercuric chloride, picric acid) precipitate proteins and thus considerably disturb cellular organization. Others (e.g. FORMALDEHYDE, GLUTARALDEHYDE, OSMIUM TETROXIDE, potassium dichromate) tend to preserve proteins in situ. Osmium tetroxide and potassium dichromate are also important lipid fixatives. For ELECTRON MICROSCOPY osmium tetroxide and glutaraldehyde are often used in e.g. alkaline phosphate buffer or cacodylate buffer. Glutaraldehyde may be used first to fix proteins (*pre-fixation*), and osmium tetroxide used subsequently for the *post-fixation* of lipids. (See also BOUIN’S FLUID, CARNOY’S FLUID, POLYVINYL ALCOHOL FIXATIVE, SCHAUDINN’S FLUID, ZENKER’S FLUID.)

**fixative** A substance used for FIXATION.

**fixative virus** A strain of rabies virus attenuated by serial passage e.g. through rabbits. (cf. FLURY VIRUS; STREET VIRUS; SEMPLE VACCINE.)

**FkpA** See PROTEIN SYNTHESIS (protein folding).

**fla genes** In e.g. enterobacteria: genes involved in the synthesis and function of bacterial flagella. [ARBB (1984) 13 51–83.]

**flabelliform** (flabellate) Fan-shaped.

**Flabellula** See AMOEBIDA.

**flacherie** An economically important disease of silkworms caused by a small RNA virus resembling a picornavirus (see PICORNAVIRIDAE).

**flagella** Plural of FLAGELLUM.

**flagellar motility** (a) (bacterial) MOTILITY produced by the rotation of a FLAGELLUM, or the rotation of a number of flagella.

In peritrichously flagellated bacteria (such as *Escherichia coli* and *Salmonella typhimurium*), the flagella rotate independently of one another [Cell (1983) 32 109–117]. For most (95%) of the time, each flagellum rotates counterclockwise (CCW). When the majority of flagella are rotating CCW they bunch

together at one pole of the cell – this propelling the cell forward with the opposite pole leading. Within a uniform medium, such ‘smooth swimming’ is interrupted at intervals of ca. 1 second by *tumbling*: a random, chaotic movement (lasting ca. 0.1 second) resulting from a switch from CCW to clockwise (CW) in some of the bunched flagella; when this happens the flagellar bundle is disrupted, causing the random movement. (The timing of the switch from CCW to CW in a given flagellum is apparently not related to the timing of the switch in the other flagella.) Smooth swimming is resumed when the majority of the flagella are again rotating CCW.

The pattern of alternate smooth swimming and tumbling results in a three-dimensional RANDOM WALK. Certain environmental stimuli can influence the pattern of motility – leading to a TAXIS (see e.g. CHEMOTAXIS).

Peritrichously flagellated bacteria generally reach speeds of ca. 10–30  $\mu\text{m}/\text{second}$  – although peritrichously flagellated cells of *Thiovulum majus* have been reported to swim at  $\sim 600 \mu\text{m}/\text{second}$  [Microbiology (1994) 140 3109–3116].

Speeds reported in monotrichously flagellated bacteria include 70  $\mu\text{m}/\text{second}$  (*Pseudomonas aeruginosa*) and 100  $\mu\text{m}/\text{second}$  (*Bdellovibrio*). In these organisms, flagellar rotation may occur for approximately equal periods of time in the CCW and CW modes; during rotational reversal, conformational changes in the filament and/or hook may bring about randomization of direction (equivalent to tumbling in peritrichous cells) – thus permitting responses to environmental stimuli.

In amphitrichously flagellate bacteria the two flagella rotate in opposite directions.

In bacteria of the order SPIROCHAETALES, motility is associated with rotation of the periplasmic flagella – this generating a helical waveform in the outer membrane which enables the cells to ‘screw’ their way through the medium. Thus, CCW flagellar rotation in *Leptonema illini* causes the anterior (i.e. forward directed) end of the cell to assume a helical shape and the cell to rotate clockwise about its longitudinal axis – moving forward with a screw-like action. Spirochaetes can reverse direction and flex – the latter movement perhaps being a means of randomizing direction. The cells can swim through media which are too viscous to permit motility of cells which rely on external flagella. (‘Creeping’ or ‘crawling’ movements have also been recorded for spirochaetes in contact with solid surfaces.)

[Structure/motility of spirochaetes: JB (1996) 178 6539–6545.]

(b) (eukaryotic) The eukaryotic FLAGELLUM commonly beats in an undulatory manner (usually in one plane, but sometimes – e.g. in *Euglena* – in a spiral) or in an oar-like manner (as in *Chlamydomonas*). Undulations commonly originate at the base of the flagellum and travel towards the tip.

The beating of a smooth flagellum generates forces which act on the surrounding medium in the direction of the propagated waves, so that the cell moves in the opposite direction (i.e. the flagellum ‘pushes’ the cell from behind). Conversely, if waves travel from the tip to the base of the flagellum (as e.g. in *Trypanosoma*), the cell swims with the flagellum leading.

In *tinsel* flagella, the mastigonemes appear to act as rigid, passive structures which lie in the plane of the beat and generate forces which act on the surrounding medium in a direction *opposite* to that of the propagated waves; thus, a *tinsel* flagellum undulating from base to tip will ‘pull’ the cell from the front (as e.g. in *Ochromonas*, and in zoospores of *Phytophthora*).

In some species the pattern of flagellar beating can be changed e.g. in response to environmental conditions. For example, in *Trypanosoma* the flagellum normally propagates waves from tip

## flagellar motor

to base, but during an 'avoiding reaction' (PHOBIC RESPONSE) the direction of wave propagation can be reversed. *Chlamydomonas* normally swims with an oar-like 'breast stroke' ('ciliary-type' action), but in an avoiding reaction the two flagella extend forwards and propagate waves from base to tip ('flagellar-type' action).

In many species the flagellum is apparently capable of only one type of movement; in these organisms changes in direction may be achieved by a temporary cessation of beating, the flagellum remaining bent during this period. [Dynamics of eukaryotic flagellar movement: SEBS (1982) 35 289–312.]

Flagellar movements appear to be regulated by the levels of  $\text{Ca}^{2+}$  in the flagellum; some environmental stimuli appear to cause changes in the permeability of the flagellar membrane to calcium ions, and consequent changes in motility patterns. In at least some species, levels of calcium ions within the flagellum may be regulated by a  $\text{Ca}^{2+}$ -ATPase located in the flagellar membrane. In *Chlamydomonas reinhardtii* the photophobic response is apparently initiated by  $\text{Ca}^{2+}$ -stimulated phosphorylation of certain axonemal proteins [JCB (1985) 101 1702–1712].

**flagellar motor** See FLAGELLUM (a).

**flagellar phase variation** See PHASE VARIATION.

**flagellar stain** See FLAGELLUM (a).

**flagellate** (1) (*adj.*) Bearing one or more flagella (see FLAGELLUM). (2) (*noun*) A protozoan of the MASTIGOPHORA.

**flagellin** The protein subunit of the filament of a bacterial FLAGELLUM. The composition of flagellin (MWt ca. 30000–55000) varies with species, and determines e.g. the shape of the flagellum, its antigenic specificity (see H ANTIGEN and PHASE VARIATION), and susceptibility to FLAGELLOTROPIC PHAGES. Typically, flagellins are relatively rich in glutamate and aspartate but poor in aromatic amino acids; cysteine is usually absent. Flagellins from the alkalophile *Bacillus firmus* have a lower content of basic amino acids [JGM (1983) 129 3239–3242]; the 'complex' flagella of *Rhizobium* spp have a higher content of hydrophobic amino acids. A flagellar filament may be dissociated into its flagellin subunits e.g. by treatment with detergents or acid; under appropriate conditions, and given a primer (e.g. a small fragment of flagellum), the flagellin subunits can re-assemble spontaneously.

**flagellotropic phage** Any BACTERIOPHAGE which adsorbs to a host cell flagellum and hence is specific for flagellated host cells (see also FLAGELLIN). Flagellotropic phages include e.g. bacteriophage  $\chi$  (see STYLOVIRIDAE) in enterobacteria, BACTERIOPHAGE PBS1 (q.v.) in *Bacillus subtilis*, and bacteriophage 7-7-1 in '*Rhizobium lupini*'. In e.g. phage  $\chi$ , the tip of the phage tail bears a fibre which appears to wrap around the flagellum, and the phage then appears to move down to the base of the flagellum to infect the cell.

**flagellum** (*plural*: flagella) (a) (bacterial) A thread-like appendage which (commonly) projects from the surface of the cell and which is responsible for MOTILITY in most types of motile bacteria; such flagella may occur e.g. singly, in groups or tufts, or distributed over the surface of the cell (see AMPHITRICHOUS, HELICOTRICHOUS, LOPHOTRICHOUS, MONOTRICHOUS and PERITRICHOUS).

By contrast, in bacteria of the SPIROCHAETALES the flagella occur *between* layers of the cell envelope. This entry refers primarily to flagella which project from the cell surface – although the structural and mechanistic features of spirochaete flagella are apparently similar.

Flagella can be detected by dark-field MICROSCOPY – but not by bright-field microscopy unless suitably stained (see e.g.

LEIFSON'S FLAGELLA STAIN). [Simple method for staining bacterial flagella: JCM (1989) 27 2612–2615.]

The bacterial flagellum consists essentially of three parts: (i) a protein *filament* which projects from the cell surface and which, by *rotating*, provides the thrust for FLAGELLAR MOTILITY; (ii) a curved protein structure, the *hook*, contiguous with the proximal end of the filament, and (iii) the *flagellar motor* (*basal body*) – a structure which anchors the hook in the cell envelope and incorporates the energy-converting apparatus.

The *filament* (ca. 5–10  $\mu\text{m} \times 20 \text{ nm}$ ) is a semi-rigid, left-handed *helix* (of periodicity  $\sim 2 \mu\text{m}$ ) composed of eleven longitudinally arranged fibrils, each fibril being a chain of FLAGELLIN subunits; the fibrils are closely associated (like the strands of a rope) to form a structure with an axial channel. (In some species the cells may have two types of flagellum which have different periodicities, a phenomenon known as *biplicity* – see e.g. VIBRIO.) In some Gram-negative species the filament is *sheathed*, i.e. covered by an extension of the OUTER MEMBRANE. Yet further variation in the filament occurs e.g. in strains of *Rhizobium* which have 'complex' flagella that differ e.g. in their fine structure [JMB (1986) 190 569–576] and in their greater fragility.

The *hook* is a tightly coiled right-handed helix, with an axial channel, which is curved through  $\sim 90^\circ$ ; its protein subunits are distinct from flagellin.

The *flagellar motor* (= *basal body*) is a cylindrical structure which spans the width of the cell envelope; its composition varies with species. In *Escherichia coli* the components include a stack of three protein rings and a hollow, axial protein *rod* (*shaft*) – together with a fourth protein ring which projects into the cytoplasm (see figure). The L (for 'lipopolysaccharide') ring is coplanar with the OUTER MEMBRANE, the P (for 'peptidoglycan') ring is coplanar with the PEPTIDOGLYCAN layer of the cell envelope, and the MS ring (once believed to be two distinct rings – the M ring and the S ring) lies within the cytoplasmic membrane; the C (for 'cytoplasm') ring, which is associated with the MS ring, carries the components of a switching mechanism which allows the direction of rotation to be reversed.

A different number of rings has been reported in other bacteria – e.g. two in *Bacillus subtilis* and five in *Caulobacter crescentus*. In *Campylobacter* a 'cartwheel structure' with eleven 'spokes' appears to be associated with the basal body [JGM (1984) 130 1307–1310].

In a current model of flagellar rotation (in e.g. *Escherichia coli*, *Salmonella typhimurium* and related species) the MS ring and the C ring jointly rotate relative to the stationary L and P rings; this rotation causes the axial shaft (and hence the filament) to rotate, the filament converting torque into thrust.

Flagellar rotation needs energy in the form of an ion gradient across the cytoplasmic membrane. In *E. coli* and *S. typhimurium* energy is supplied by proton motive force (pmf) (see CHEMIOSMOSIS), and rotation is driven by an inward flow of protons through the flagellar motor (perhaps via a channel in the MotA/MotB protein assembly); torque generation appears to involve interaction between the rotor (MS ring) and the stator (MotA/MotB assembly) – specifically, between the FliG protein, associated with the MS ring, and MotA. [Models for the flagellar motor (theoretical considerations): PTRSLB (2000) 355 491–501.]

The C ring (apparently the FliM component of the C ring – see later) plays a pivotal role in the switching mechanism in CHEMOTAXIS.

The speed of rotation of a flagellum varies linearly with the level of the cell's pmf. The minimum (threshold) value of pmf

FLAGELLUM: the origin of a flagellum in the cell envelope of *Escherichia coli*, *Salmonella typhimurium* and related Gram-negative bacteria (diagrammatic, not drawn to scale; see entry).

(a) An earlier model.

(b) A current view based on several sources [e.g. JB (1996) 178 4582–4589; JMB (1996) 255 458–475]. As in the earlier model, the L and P rings are associated with the outer membrane and peptidoglycan layer, respectively. The MS ring – previously regarded as two distinct structures (the M and S rings) – lies in the cytoplasmic membrane. The C ring, which includes proteins FliM and FliN (see table, text), is in the cytoplasm; it is associated with the MS ring and is believed to rotate with the MS ring when the flagellar motor is running. The C ring is involved in switching between counterclockwise and clockwise rotation of the flagellum in chemotaxis.

The annular region of the cytoplasmic membrane which encircles the MS ring contains the MotA and MotB proteins; this region acts as the stator of the flagellar motor. It appears that MotA and MotB form a complex, with MotB bound to peptidoglycan, and MotA interacting with molecules of the FliG protein (which are bound to the periphery of the MS ring); the latter interaction (details currently unknown) generates torque and, hence, flagellar rotation.

The *flagellar motor* (= *basal body*) includes the L, P and MS rings, the axial rod (shaft) and the MotA/MotB complex. The C ring is included by some authors; other authors include the C ring as part of an 'extended' basal body.

The dotted line enclosed by the C ring represents a structure which has been termed the *export apparatus* (see entry) – and which now appears to be a form of type III PROTEIN SECRETION system.

Reproduced from *Bacteria* 5th edition, Figure 2.8, page 28, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

(below which rotation does not occur) appears to vary with species; it has been reported to be ~30 mV for *E. coli* and *Bacillus subtilis* but less for e.g. streptococci.

Although flagellar rotation is commonly driven by pmf, SODIUM MOTIVE FORCE is used in some species – e.g. smf is used to drive the polar flagellum in *Vibrio cholerae* [JB (1999) 181 1927–1930].

*Assembly of the flagellum.* Assembly is a highly organized process in which the components are added in strict sequence. The following refers to flagellar assembly in *E. coli*, *S. typhimurium* and related organisms.

First, the MS ring – consisting of about 25 molecules of the *fliF* gene product (FliF protein) – is inserted into the cytoplasmic membrane. Then the FliG, FliM and FliN proteins are incorporated; it appears that molecules of FliG bind around the periphery of the MS ring (on the cytoplasmic side), while FliM and FliN jointly form the C ring, with FliN being more distal to the membrane [JB (1997) 179 813–817].

At this stage an *export apparatus* assembles within the C ring (see figure). The purpose of the export apparatus is to permit the operation of a functional channel through the MS ring without compromising the cell's structural integrity; this channel allows

## flagellum

specific components subsequently to pass through the MS ring when required. The export apparatus is a multiprotein structure that includes FlhA, FlhB, FliH, FliI, FliO, FliP, FliQ and FliR.

Interestingly, some of the proteins of the basal body exhibit homology with proteins of type III secretion systems (see PROTEIN SECRETION), and the group of proteins involved in transport of the flagellar components has been referred to as a type III secretion system.

In addition to these proteins, FliJ is needed for the export of components – and may be part of the transport apparatus; this protein also appears to act as a ‘chaperone’, preventing intracellular aggregation of various export substrates [JB (2000) 182 4207–4215].

FlgB, FlgC and FlgF are translocated via the export apparatus and form the proximal part of the hollow rod (shaft); FlgG then forms the distal part of the rod.

The L and P rings are formed by molecules of FlgH and FlgI, respectively; these proteins, which have a signal sequence (see SIGNAL HYPOTHESIS), are secreted through the cytoplasmic membrane into the periplasmic space, i.e. unlike rod components, they do not pass through the MS ring.

Molecules of FlgE exit via the MS ring and give rise to the hook. When the hook has reached an appropriate length, annuli of hook-associated proteins FlgK and FlgL, and a terminal ‘cap’ of FliD protein, are added, in that order, at the distal end. (The mechanism which regulates the length of the hook is unknown, but it appears to involve FliK.) FliD forms a permanent distal cap while the flagellin subunits (FliC protein) pass through the axial channel of the rod and hook and are polymerized at the FlgL–FliD junction to form the growing filament. Incorporation of FliC may be promoted by rotation of the flagellar cap [Science (2000) 290 2148–2152]. Growth of the filament thus occurs at the distal end (‘tip growth’ – compare archaeal flagella in (c), below); during growth, the FliC subunits are incorporated by self-assembly.

*Genetic regulation of flagellar assembly.* The first genes to be expressed – class I genes – are those in the *flhCD* operon; these genes encode transcriptional activators, and their expression is essential for the expression of all other flagellar genes. (The *flhCD* genes are expressed at peak levels in synchrony with the cell cycle [JB (1997) 179 5602–5604].)

FlhC and FlhD promote the expression of class II genes, including: *fliF* (MS ring), *fliG* (switch), *fliMN* (switch/C ring), *flgE* (hook) and genes from two operons, *flhAB* and *fliHIOPQR*, whose products are required for the export apparatus.

Another class II gene, *fliA*, encodes a SIGMA FACTOR ( $\sigma^{28}$ ) which activates class III genes, but FliA is temporarily inactivated by the binding of FlgM (FlgM is an ANTI-SIGMA FACTOR); however, completion of the hook serves as a signal for the release of FlgM (which is externalized via the axial canal) – thus allowing FliA to mediate expression of the class III genes.

The class III genes include *fliC* (the flagellin subunit of the filament) and the *motAB* genes (which encode components of the stator).

Some of the genes and gene products involved in the assembly of the flagellum are listed in the table.

[Genetics and assembly of flagella in Gram-negative bacteria: FEMS Reviews (2000) 24 21–44 (22–27).]

(b) (eukaryotic) A thread-like appendage (ca. 0.15–0.3  $\mu\text{m}$  in diam., up to  $\sim 40 \mu\text{m}$  in length), one or more of which extend from vegetative and/or reproductive cells of certain algae, fungi and protozoa. Eukaryotic flagella typically act as locomotory organelles but may be involved e.g. in mating (see

FLAGELLUM (bacterial): some of the genes and gene products involved in the assembly of the flagellum in *Escherichia coli*, *Salmonella typhimurium* and related species

Gene (product)	Function of gene product

e.g. CHLAMYDOMONAS) or attachment (see e.g. TRYPANOSOMA) (cf. HAPTONEMA).

The eukaryotic flagellum is completely different from the bacterial flagellum in both structure and mechanism of action. The main structural component of the eukaryotic flagellum is the *axoneme*: a system of longitudinally arranged MICROTUBULES (each ca. 25 nm diam.) which extend the length of the flagellum. These microtubules are arranged in a characteristic ‘9 + 2’ pattern: two adjacent tubules (enclosed by a membranous sheath in some species) run through the centre of the axoneme and are surrounded by a circular arrangement of nine *pairs* of tubules (*doublets*). Each doublet consists of an A-tubule (= ‘A-subfibre’) and a B-tubule (‘B-subfibre’); the A-tubules are complete microtubules, but the B-tubules are incomplete, sharing part of the wall of the A-tubule (giving the B-tubules a somewhat D-shaped appearance in cross-section). The A-tubule in each doublet bears a series of paired (inner and outer) ‘arms’ composed of high-MWt,  $\text{Ca}^{2+}$ - and  $\text{Mg}^{2+}$ -activated ATPase called *dynein*. The A-tubules are linked to the central

tubules (or to the sheath surrounding them) by radial 'spokes'; protein (*nexin*) links also occur between the peripheral doublets. [Axoneme substructure: JBC (1985) 100 2008–2018.]

The axoneme is embedded in a flagellar *matrix*, the whole being enclosed by a sheath-like *flagellar membrane* which is apparently continuous with the cytoplasmic membrane. The proximal end of the flagellum is connected to a *BASAL BODY* via a more or less distinct region, the *transition region* (cf. *CILIUM*).

Although most eukaryotic flagella conform to the basic structure described above, there are differences in detail among the species. For example, many eukaryotic flagella bear characteristic surface structures attached to the flagellar membrane – structures such as minute scales (see PRASINOPHYCEAE); a fine *tomentum* of minute hairs; or larger, more distinct hairs called *mastigonemes* (or *flimmer*) which are commonly arranged in two longitudinal rows, one on each side of the flagellum. (See also TRENTIPOHLIA.) (A distinction is sometimes made between the terms 'mastigoneme' and 'flimmer': mastigonemes are shorter and more rigid, while flimmer are longer, finer, and more flexible.) A flagellum which lacks obvious scales or mastigonemes is said to be of the *smooth, simple, whiplash* or *peitschengeissel* type, while a flagellum bearing mastigonemes is said to be of the *tinseel, flimmergeissel* or *hispid* type.

The nature and number of a cell's flagella, and the sites and orientation of the flagella, are important taxonomic features. (See also HETEROKONT, ISOKONT and STEPHANOKONT.) Ultrastructural details of flagella may also be of taxonomic value: e.g. in flagellated cells of the green algae (CHLOROPHYTA) the A-tubule of *one* of the nine peripheral doublets in the axoneme lacks an outer dynein arm – a characteristic apparently universal in, and unique to, green algae. The flagellum of green algae also has a microfibrillar structure in the transition region which gives a characteristic stellate pattern in cross-section. [Review of flagellar ultrastructure in green algal classification: Book ref. 123, pp 73–120.] (See also PARAXIAL ROD.)

The eukaryotic flagellum can move independently of the basal body: flagella which have been severed from the cell are capable of independent movement, and in e.g. *Chlorogonium* the cells remain motile when the basal bodies have detached from the flagella prior to cell division [JCB (1985) 100 297–309]. Movement is thus a property of the flagellar shaft itself – cf. *bacterial* flagellum (a), above. The movement involves sliding of axonemal microtubules relative to one another, the energy being supplied by dynein-catalysed hydrolysis of ATP; movement is apparently regulated by  $Ca^{2+}$ : see FLAGELLAR MOTILITY (b).

(c) (archaeal) The archaeal flagellum differs from the bacterial flagellum in composition, structure and apparent mode of assembly. Thus, the subunits (flagellin) of the archaeal filament are typically glycosylated proteins, and the filament itself is typically much thinner than the bacterial filament. Moreover, archaeal flagellins have a signal sequence – suggesting passage through the cytoplasmic membrane rather than through an export apparatus; this feature, together with certain similarities between archaeal flagellins and bacterial type 4 fimbriae, have suggested that the archaeal flagellum is assembled from the *base* – in contrast to the 'tip growth' of the bacterial flagellum [JB (1996) 178 5057–5064].

Interestingly, genes homologous to those which encode bacterial flagellar structures have not been detected in the genomes of archaeans, even in those whose complete genome sequence is known; this has suggested that the archaeal flagellum is a unique form of organelle [FEMS Reviews (2001) 25 147–174].

**Flagyl** See METRONIDAZOLE.

**flaming** Brief exposure of an object (or part of an object) to the hottest part of a flame – usually for the STERILIZATION of the surface thus treated. Flaming is part of the ASEPTIC TECHNIQUE. Objects such as the LOOP and STRAIGHT WIRE are flamed for ca. 3–5 sec; somewhat shorter exposures are used for the rims of e.g. bottles from which sterile (non-flammable!) substances are to be poured. Flaming for very short times may be used for the heat FIXATION of bacterial smears.

**Flammulina** See AGARICALES (Tricholomataceae) and ENOKI-TAKE.

**flash-freezing** *Syn.* QUENCH-FREEZING.

**flash pasteurization** See PASTEURIZATION.

**flask fungi** PERITHECIUM-forming fungi.

**flat-field objective lens** An objective lens (see MICROSCOPY) which can give an image in which all parts of the field are simultaneously in focus. Flat-field objectives are denoted by the prefix *plan-* or *plano-* (see e.g. ACHROMAT).

**flat sour** A can (see CANNING) which appears normal (i.e. the ends are flat or slightly concave – cf. SWELL) but whose contents have been soured as a result of microbial growth; *Bacillus stearothermophilus* is one of several common causal agents in low-acid foods. (See also SOFT CORE HAM.)

**flavacol** A compound produced by *Aspergillus flavus*: 3-hydroxy-2,5-diisobutylpyrazine.

**flavin adenine dinucleotide** See RIBOFLAVIN.

**flavin mononucleotide** See RIBOFLAVIN.

**Flaviviridae** ('arbovirus group B') A family of enveloped ssRNA-containing VIRUSES [Intervirol. (1985) 24 183–192] formerly regarded as a genus within the family TOGAVIRIDAE. Flaviviruses infect a wide range of vertebrates, and many also infect invertebrates (mosquitoes or ticks) which act as VECTORS. Some flaviviruses are important pathogens of man or animals. The family contains a single genus, *Flavivirus*; type species: yellow fever virus.

The flavivirus virion is more or less spherical (ca. 40–50 nm diam.); it consists of a core (comprising a single type of core protein, C, associated with the genome), a 'membrane-like' protein, M, which surrounds the C–RNA complex, and a lipoprotein envelope containing one type of virus-specific glycoprotein, E, which acts as a haemagglutinin (e.g. with chick RBCs) and is the target of neutralizing antibodies. The genome is a single linear positive-sense ssRNA molecule (MWt ca.  $4 \times 10^6$ ) which is capped at the 5' end but is apparently not polyadenylated at the 3' end. Subgenomic mRNA is not produced; the genome-length RNA functions as the sole messenger and contains only one long open reading frame – at least in West Nile virus [Virology (1986) 149 10–26] and in yellow fever virus [Science (1985) 229 726–733] – suggesting that viral proteins are formed by post-translational cleavage of a polyprotein. The genes encoding structural proteins are located at the 5' end (5'-C–M–E...); several non-structural proteins are also produced. A region at the 3' end is not translated and has the potential for forming a stem-and-loop secondary structure [JGV (1986) 67 1183–1188]. Viral RNA synthesis (which involves the formation of both replicative intermediates and replicative forms) apparently occurs in the perinuclear region; maturation may involve a process of 'condensation' rather than budding, and appears to occur within cisternae of the endoplasmic reticulum.

Flaviviruses can replicate in various types of vertebrate cells in culture, often causing CPE and plaque-formation; infected cells typically exhibit extensive proliferation of the endoplasmic reticulum. Host protein synthesis is not significantly inhibited. Invertebrate cells may also be infected, with or without CPE.

## Flavivirus

Most flaviviruses can be classified in 7 serologically defined complexes (subgroups); most of those of greatest medical and veterinary importance belong to one of three such subgroups. (YELLOW FEVER virus is serologically distinct from other flaviviruses.) The *dengue virus subgroup* includes DENGUE viruses types 1–4. The *West Nile virus subgroup* includes e.g. Kunjin virus, JAPANESE B ENCEPHALITIS virus, MURRAY VALLEY FEVER virus, Rocio virus, ST LOUIS ENCEPHALITIS virus, and West Nile virus. The *tick-borne encephalitis virus subgroup* includes e.g. KYASANUR FOREST DISEASE virus, LOUPING-ILL virus, Negishi virus, Omsk haemorrhagic fever virus, POWASSAN ENCEPHALITIS virus, and tick-borne encephalitis (TBE) virus – including the eastern subtype (RUSSIAN SPRING-SUMMER ENCEPHALITIS virus) and the European subtype (Central European encephalitis virus). Other flaviviruses which are occasionally responsible for human disease include e.g. Banzi virus, Bussuquara virus, Ilheus virus, Rio Bravo virus, Sepik virus, Spondweni virus, Wesselsbron virus and Zika virus.

Possible members of the Flaviviridae include *Aedes albopictus* cell-fusing agent and SIMIAN HAEMORRHAGIC FEVER VIRUS.

[Medical aspects: Book ref. 148, pp. 955–1004.]

**Flavivirus** See FLAVIVIRIDAE.

**Flavobacterium** A genus (*incertae sedis*) of aerobic, chemoor-ganotrophic, Gram-negative bacteria which occur e.g. in soil, water, raw meats, milk and in some clinical specimens (*F. meningosepticum* is a causal agent of neonatal MENINGITIS). Cells: non-motile, round-ended rods, ca.  $0.5 \times 1.0$ – $3.0 \mu\text{m}$ , which typically contain orange or yellow non-fluorescent, water-insoluble pigments; in *F. breve* and *F. odoratum* (at least) the pigments may be of the flexirubin type. *F. meningosepticum* is typically weakly pigmented or non-pigmented. Metabolism is respiratory (oxidative). Acid (but no gas) is formed from carbohydrates in media which have a low content of peptone. Most species (not *F. aquatile*) grow well in nutrient broth and on nutrient agar; *F. aquatile* requires media enriched with e.g. casein digest, glucose, and yeast extract. *F. meningosepticum* is non-haemolytic on blood agar. Catalase +ve. Oxidase +ve. GC%: ca. 31–42. Type species: *F. aquatile*; other species: *F. breve*, *F. balustinum*, *F. meningosepticum*, *F. multivorum*, *F. odoratum*, *F. spiritivorum* [Book ref. 22, pp. 353–361], and *F. gleum* [JSB (1984) 34 21–25]. (See also SPHINGOBACTERIUM.)

**flavodoxins** A category of flavoproteins which have low (i.e. highly negative)  $E_m$  values which can replace FERREDOXINS as electron carriers in various reactions – though their efficiency as electron carriers is less than that of ferredoxins. Flavodoxins contain 1 FMN per molecule but do not contain metal or labile sulphur. In many organisms (e.g. *Clostridium* spp, certain algae) flavodoxins are synthesized in place of ferredoxins in response to iron deficiency. Algal flavodoxin is also known as *phytoflavin*. In *Azotobacter vinelandii* a flavodoxin, *azotoflavin*, acts as electron carrier in NITROGEN FIXATION.

**Flavomycin** *Syn.* MOENOMYCIN.

**flavoproteins** See RIBOFLAVIN.

**flavour microorganisms** Microorganisms which form metabolic products ('flavour compounds') that contribute to the flavour and/or aroma of certain foods: see e.g. DIACETYL. (See also GLUTAMIC ACID and YEAST EXTRACT.) [Review: AAM (1983) 29 29–51.]

**flax retting** See RETTING.

**flax rust** (linseed rust) A disease of the flax plant (*Linum usitatissimum*) caused by the macrocyclic, homoxenous rust *Melampsora lini*. Symptoms include the presence of orange

uredia on both sides of the leaf and, later, dark-coloured telia on the stems.

**flax wilt** See FUSARIUM WILT.

**Flectobacillus** A genus of pink-pigmented bacteria (family SPIROSOMACEAE). The cells are typically C-shaped,  $0.3$ – $1.0 \times 1.5$ – $5.0 \mu\text{m}$ , but spiral forms occur – as do filaments up to  $50 \mu\text{m}$ ; 'ring-shaped' structures may be apparent due to overlap of the ends of curved cells. Acid is formed from many carbohydrates. GC%: 34–40. Type species: *F. major*.

**Flexibacter** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur in aquatic habitats; some species are pathogenic for fish (see e.g. COLD WATER DISEASE and COLUMNARIS DISEASE). The cells are short, non-motile rods in old cultures but are thin, thread-like and motile in young cultures; typically, they contain pigments ranging from yellow to red. Metabolism: chemoorganotrophic.

**Flexibacteriae** A class of non-photosynthetic GLIDING BACTERIA comprising the orders CYTOPHAGALES and MYXOBACTERIALES [ARM (1981) 35 339–364].

**flexible pouch** *Syn.* RETORT POUCH.

**flexirubins** Polyene pigments found e.g. in members of the CYTOPHAGALES.

**flexuous hyphae** (receptive hyphae) Hyphae which project from a pycnium and which function as female (receptive) structures. (cf. TRICHOGYNE.)

**flgM gene** See SIGMA FACTOR.

**fljA gene** See SIGMA FACTOR.

**flimmer** See FLAGELLUM (b).

**flimmergeissel flagellum** See FLAGELLUM (b).

**flip–flop** (of membrane lipids) See CYTOPLASMIC MEMBRANE.

**flippase** See CYTOPLASMIC MEMBRANE.

**flipper** A can (see CANNING) which appears normal but in which one end 'flips out' (i.e. becomes convex) if the can is struck (cf. SWELL).

**fl<sub>St</sub> gene** See FLORFENICOL.

**floc blanket clarifier** See WATER SUPPLIES.

**flocculation** (1) (*serol.*) A term used with different meanings by different authors and for different phenomena: e.g., (i) the development of a flaky or fluffy precipitate in certain precipitin tests; (ii) any form of precipitate; (iii) any form of agglutination, but particularly the agglutination of bacteria by antflagellar antibodies.

(2) The aggregation of (initially separate) cells to form flocs. Spontaneous flocculation occurs e.g. in certain sewage bacteria (see e.g. ZOOGLOEA and CELLULOSE) and in strains of BREWERS' YEAST during the stationary phase of batch culture (e.g. at the end of the fermentation stage of BREWING). Flocculation of brewers' yeast aids in the separation of the yeast cells from the fermented wort. (Yeast cells which remain dispersed in all phases of batch culture are called 'powdery yeasts'.) Prior to flocculation, the cells are presumed to remain dispersed because of their mutually repulsive (usually negative) surface charge (see ZETA POTENTIAL); flocculation is thought to be initiated by a change in the surface structure of the cells, and  $\text{Ca}^{2+}$  appears to play a role by bridging the negative charges on adjacent cells [review: Book ref. 108, pp. 323–335]. (cf. COAGGREGATION.)

**flood plate** A PLATE in which the surface has been flooded with liquid inoculum and the excess drawn off with a sterile Pasteur pipette. (See also LAWN PLATE.)

**flor sherry, flor yeast** See WINE-MAKING.

**florfenicol** A synthetic, broad-spectrum antibiotic which has been used e.g. against *Mycoplasma bovis* in the treatment of calf pneumonia. In vitro tests on field isolates of *M. bovis*

indicate that significant levels of resistance have developed against florfenicol [VR (2000) 146 745–747]. In *Salmonella typhimurium* DT104 (an emergent multidrug-resistant pathogen), mutation in gene *flos<sub>r</sub>* can result in resistance to both florfenicol and chloramphenicol [JCM (1999) 37 1348–1351].

**Florida horse leech** *Syn.* EQUINE PHYCOMYCOSIS.

**floridean starch** An amylopectin-like D-glucan: the main storage carbohydrate in members of the Rhodophyta. [Book ref. 37, pp. 475–478.]

**floridoside** 2-O-Glycerol- $\alpha$ -D-galactopyranoside: a glycoside found in members of the Rhodophyta; it serves as a reserve carbohydrate and as an osmoregulatory compound. (cf. ISOFLORIDOSIDE.)

**flotation** A method for concentrating e.g. protozoan cysts in a sample of faeces; the sample is dispersed in a concentrated solution of e.g. ZnSO<sub>4</sub> or NaCl such that any cysts present in the sample float to the surface. (cf. FORMALIN-ETHER METHOD.)

*Zinc sulphate flotation.* The faecal sample (ca. 1 g) is mixed with about ten times its volume of water, centrifuged (ca. 350 g/3 min), and all the supernatant discarded. The sediment is re-suspended in ca. 10 ml of a solution of ZnSO<sub>4</sub> of S.G. 1.18 (made by adding water to 331 g ZnSO<sub>4</sub>·7H<sub>2</sub>O to give a final volume of 1 litre) and filtered through a double layer of wet gauze; the filtrate is centrifuged (ca. 350 g/3 min) – the centrifuge being allowed to stop naturally to avoid turbulence within the liquid. A loopful of liquid from the surface is transferred to a drop of iodine solution on a slide; a cover-glass is added, and the preparation is examined under the microscope.

*Salt flotation.* A solution of NaCl (70–100% saturated) is often used for the concentration of coccidian cysts in faecal samples. The sample is subjected to several cycles of centrifugation in water (each ca. 350 g/2–3 min), the supernatant being discarded each time. The sediment is then dispersed in salt solution and centrifuged at ca. 200 g/5 min. The surface layer of supernatant is transferred, by pipette, to ten times its volume of water; this suspension is centrifuged and the sediment collected for study. Prolonged contact with saturated salt solution causes plasmolysis; however, oocysts generally remain viable, and they regain their original appearance on transfer to water.

**flotation form** (of an amoeba) See PSEUDOPODIUM.

**flow cytometry** Any procedure in which individual cells in a suspension are counted, sorted, or otherwise analysed by the use of an apparatus in which the cells pass, individually, through a small hole or tube; the term is commonly used to refer specifically to those techniques in which cell populations are analysed by detecting fluorescence or FLUOROCHROME-labelled antigens or other structures on/in the cell (see e.g. FACS and FLOW MICROFLUOROMETRY; cf. COULTER COUNTER).

**flow microfluorometry** Any procedure in which populations of cells, or of other particles, are counted, sorted, or otherwise analysed by passing them individually through a small hole or tube and detecting specific fluorescence or FLUOROCHROME labels. (See e.g. FACS; cf. FLOW CYTOMETRY.)

**flowers of tan** See FULIGO.

**FLP gene** See TWO-MICRON DNA PLASMID.

**flu** *Syn.* INFLUENZA.

**flucloxacillin** See PENICILLINS.

**fluctuation test** A test devised by Luria and Delbrück in 1943 for investigating the mode in which bacterial populations respond to changes in the environment. At that time two hypotheses co-existed. (i) Genetic changes occur *adaptively*, i.e., as a result of environmental influences on the cells; those cells which adapt to the environment survive and proliferate. (ii) Genetic changes

occur *spontaneously*, i.e., independently of the environment; those cells which have become particularly well suited to certain environmental conditions proliferate (preferentially) if such conditions arise.

If bacteria adapted to a new environment, a similar proportion of adapted cells should arise in each of a number of independent cultures. If, however, mutants arose spontaneously and randomly, the number of mutant cells should vary considerably from culture to culture.

In the original test, a measurement was made of the statistical variance among the numbers of bacteriophage-resistant cells in samples from each of a number of separate cultures of phage-sensitive bacteria; the very high variance could not be attributed to sampling error since a very much lower variance was obtained for the numbers of resistant cells in each of a number of samples taken from a single (bulk) culture. (Phage-resistant cells were counted by plating each sample on a separate plate, subjecting the plate to virulent phage, and incubating; resistant cells formed colonies.) The wide fluctuation (high variance) in mutant numbers among the separate cultures indicated that mutant clones had been initiated in some cultures much earlier than in others – i.e., resistant cells had appeared at different times; this indicated that mutant (resistant) cells had arisen *before* the cells had been exposed to phage – thus supporting hypothesis (ii).

**flucytosine** (5-fluorocytosine) An ANTIFUNGAL AGENT which is active mainly against yeasts and yeast-like fungi; it is used (usually with AMPHOTERICIN B) in the treatment of e.g. candidiasis and cryptococcosis. It functions as a pyrimidine analogue. After uptake by the yeast cell, it is deaminated to 5-fluorouracil by cytosine deaminase; 5-fluorouracil may then be phosphorylated and incorporated into RNA, or converted to 5-fluorodeoxyuridine monophosphate which inhibits thymidylate synthase (see Appendix V(b)), thereby inhibiting DNA synthesis.

**fluid mosaic model** See CYTOPLASMIC MEMBRANE.

**fluid-phase pinocytosis** See PINOCYTOSIS.

**fluidized-bed fermenter** A FERMENTER in which a nutrient solution is pumped upwards through a vertical column of small particles (e.g. stainless steel balls) coated with cells. The upward flow of liquid causes the particles to exhibit small, rapid movements which (a) facilitate interaction between the adherent cells and the medium, and (b) result in the removal (by friction) of a proportion of the adherent cells; a steady state is achieved when the loss of cells is balanced by cell growth.

**flunidazole** See NITROIMIDAZOLES.

**fluor** *Syn.* FLUOROCHROME.

**FluoReporter<sup>®</sup>** See PROBE.

**fluorescein** A pale-yellow FLUOROCHROME which fluoresces greenish-yellow; it is a substituted xanthene used e.g. in IMMUNOFLUORESCENCE techniques. (See also FITC.) Solubility in water is very low; in ethanol it is ca. 2% w/v. (cf. PYOVERDIN.)

**fluorescence** The emission of light which occurs when certain substances absorb radiation; emission occurs as electrons excited to the singlet state (S<sub>1</sub>) are returning to the (unexcited) ground state (S<sub>0</sub>). The light emitted is of wavelength longer than that of the exciting radiation, and emission typically lasts for ca. 10<sup>-9</sup> sec (cf. PHOSPHORESCENCE). In fluorescence microscopy (see MICROSCOPY (e)) the exciting radiation is usually UV light, but blue light is used in some cases ('blue-light fluorescence'). *Primary* fluorescence (= autofluorescence) is that produced by a substance which is inherently fluorescent – e.g. chlorophyll fluoresces red under UV radiation. *Secondary* fluorescence is

## fluorescence-activated cell sorter

that produced by a non-fluorescent substance which has been dyed with a FLUOROCROME.

**fluorescence-activated cell sorter** See FACS.

**fluorescence *in situ* hybridization (FISH)** See PROBE.

**fluorescence microscopy** See MICROSCOPY (e).

**fluorescence resonance energy transfer** See PCR.

**fluorescent antibody technique (FAT)** Any procedure in which IMMUNOFLOUORESCENCE is used (e.g. for clinical lab. diagnosis, for counting or detecting specific microorganisms in water samples, etc).

**fluorescent brightener** (brightener; optical bleach; optical brightener) A compound which exhibits FLUORESCENCE under ultraviolet radiation, and which may be used e.g. to treat (white) paper or textiles etc in order to enhance their 'whiteness' in normal daylight (by effectively enhancing the blue end of the visible spectrum); fluorescent brighteners which are absorbed by – and are non-toxic (or selectively toxic) for – microorganisms have also been used e.g. for STAINING microorganisms, the presence of the brightener being demonstrated by fluorescence MICROSCOPY.

Type A brighteners (e.g. CALCOFLUOR WHITE) are (anionic) derivatives of 4,4'-diamino-2,2'-stilbene disulphonic acid. Type N brighteners (e.g. TINOPAL AN) are (cationic) oxacyanine compounds which tend to be more inhibitory than type A brighteners for microorganisms.

**fluorescent dye** Any dye capable of FLUORESCENCE.

**Fluoribacter** See LEGIONELLACEAE.

**fluorides** The fluoride ion is inhibitory to a wide range of organisms, inhibiting many enzymes; it inhibits e.g. the fermentation of sugars by streptococci – apparently chiefly by (competitively) inhibiting enolase and thereby preventing the formation of phosphoenolpyruvate (necessary for uptake of PTS sugars) from 2-phosphoglycerate. (See also PEP POTENTIAL.) The inhibitory effect of fluoride is greater at lower pH; the cytoplasmic membrane may be impermeable to F<sup>-</sup>, and fluoride may enter the cell as HF.

Fluorides are used e.g. in the prevention of DENTAL CARIES; they act primarily by becoming incorporated into the tooth enamel, thereby decreasing its susceptibility to acid demineralization; oral bacteria are apparently relatively insensitive to fluoride in the presence of saliva [Inf. Immun. (1986) 51 119–124]. Sodium and ammonium fluorides have also been used e.g. as antifungal wood PRESERVATIVES; their efficacy is said to be greater than that of zinc or copper compounds.

**fluorite objective** (semiapochromatic objective) An objective lens (see MICROSCOPY) in which chromatic and spherical aberrations are each corrected for two colours (cf. ACHROMAT, APOCHROMAT). A FLAT-FIELD OBJECTIVE LENS of this type is called a *planofluorite*.

**fluorochrome** Any fluorescent dye – e.g. ACRIDINE ORANGE, EOSIN, FITC, FLUORESCENIN.

**5-fluorocytosine** *Syn.* FLUCYTOSINE.

**fluoroquinolone antibiotics** See QUINOLONE ANTIBIOTICS.

**5-fluorouracil** See e.g. PHENOTYPIC SUPPRESSION.

**Flury virus** An avianized strain of the rabies virus used e.g. for anti-rabies vaccination in animals. The Flury LEP strain has been passaged (see SERIAL PASSAGE) in chick embryos ca. 40–60 times; the Flury HEP strain has been passaged >180 times.

**flutriafol** An agricultural AZOLE ANTIFUNGAL AGENT which is active against certain cereal diseases: e.g. powdery mildew, leaf blotch, septoria, net blotch, rusts, and MBC-sensitive and -resistant eyespot.

**fly agaric** See AMANITA and MUSCARINE.

**FMAU** (2'-deoxy-2'fluoro-5-methyl-1-β-D-arabinosyluracil) An ARABINOSYL NUCLEOSIDE which has antiherpetic and antileukaemia activity; its mode of antiviral action resembles that of ACYCLOVIR.

**FMDV** FOOT AND MOUTH DISEASE VIRUS.

**FMN** See RIBOFLAVIN.

***fms*** An ONCOGENE present in the McDonough strain of feline sarcoma virus (see FELINE LEUKAEMIA VIRUS); the *v-fms* product appears not to have tyrosine kinase activity. The *c-fms* gene probably encodes the receptor for the macrophage-specific colony-stimulating factor 1 (CSF-1).

**foamy viruses** See SPUMAVIRINAE.

**FOCMA** Feline oncornavirus-associated cell-membrane antigen, an antigen on the surface of feline lymphosarcoma cells which reacts with sera from cats exposed to FELINE LEUKAEMIA VIRUS (or from cats having recovered from feline sarcoma virus infection). Anti-FOCMA antibodies do not neutralize FeLV, but may protect against the development of lymphosarcoma by exerting a cytotoxic effect on feline leukaemia cells in the presence of complement.

**focus-forming viruses** Viruses which form foci of morphologically transformed cells in cell cultures or in tissues – see e.g. FRIEND VIRUS and MCF VIRUSES.

**Foettingeria** See HYPOSTOMATIA.

**fog fever** (acute bovine pulmonary emphysema and oedema) An acute ATYPICAL INTERSTITIAL PNEUMONIA in adult cattle, characterized by a sudden onset within ca. 1 week of being moved to new, lush green pasture; death may occur quickly, without warning, or animals may exhibit laboured breathing and fail to graze. Movement or exertion may cause death within minutes. The cause of fog fever is unknown. One hypothesis is that fog fever may result from an increased intake of tryptophan; in the rumen, tryptophan is metabolized to 3-methylindole – a substance which, when administered experimentally, produces a syndrome clinically indistinguishable from fog fever. The conversion of tryptophan to 3-methylindole in the rumen is inhibited e.g. by MONENSIN.

**foliaceus** *Syn.* FOLIOSE.

**folic acid** (pteroylglutamic acid) A water-soluble, photolabile VITAMIN. (See figure for structure.) Some microorganisms form pteroylpolyglutamic acid derivatives (typically containing 3–7 glutamic acid residues), certain of which may be specifically required for particular reactions.

The coenzyme form of folic acid (coenzyme F) is 5,6,7,8-tetrahydrofolic acid (THF, FH<sub>4</sub>), formed by the reduction of folic acid (via 7,8-dihydrofolic acid) by dihydrofolate reductase and NADPH. THF functions as a carrier of one-carbon units (e.g. formyl, methyl, methylene or hydroxymethyl groups); such groups are carried at the N<sup>5</sup> or N<sup>10</sup> positions (e.g. N<sup>5</sup>,N<sup>10</sup>-methylene-THF) or bridge these two positions (e.g. N<sup>5</sup>,N<sup>10</sup>-methylene-THF). THF is involved e.g. in glycine–serine interconversion [see Appendix IV (c)], in methionine biosynthesis [Appendix IV (d)], in the biosynthesis of purines and deoxythymidine [Appendix V], in the catabolism of e.g. histidine, in ACETOGENESIS, etc.

An exogenous source of folic acid is necessary for the growth of certain microorganisms: e.g. *Enterococcus faecalis* and *Lactobacillus casei* (both used for folic acid BIOASSAY), *Crithidia fasciculata*, *Tetrahymena* spp, and *Trypanosoma platydictyli* (formerly *Leishmania tarentolae*); most fungi can synthesize folic acid, although a few require the precursor *p*-AMINOBENZOIC ACID. *Leuconostoc cremoris* (formerly *L. citrovorum*) requires N<sup>5</sup>-formyl-THF (= citrovorum factor, folinic acid, leucovorin).

## FOLIC ACID (pteroylglutamic acid)

Drugs which interfere with folic acid metabolism include e.g. FOLIC ACID ANTAGONISTS, PAS and SULPHONAMIDES.

(cf. BIOPTERIN and *tetrahydromethanopterin* under METHANOGENESIS.)

**folic acid antagonist** (antifol) A synthetic drug (typically a diaminopyrimidine derivative) which acts as a structural analogue of FOLIC ACID and which binds to and inhibits the enzyme dihydrofolate reductase (DHFR) – preventing the reduction of dihydrofolate (or folic acid) to tetrahydrofolate (THF) and thereby inhibiting THF-dependent reactions (e.g. synthesis of deoxythymidine and hence of DNA). The folic acid antagonists *aminopterin* and *methotrexate* have high affinities for mammalian DHFRs, and are used e.g. as anti-cancer and anti-leukaemia drugs. (See also HYBRIDOMA and IMMUNOSUPPRESSION.) PYRIMETHAMINE and TRIMETHOPRIM are more effective against microbial DHFRs, and are used in the treatment of certain infectious diseases. A microorganism may become resistant to a folic acid antagonist e.g. by acquiring a plasmid encoding a drug-resistant DHFR (see e.g. O/129), or by a mutation resulting in the overproduction of (normal) DHFR.

The action of a folic acid antagonist is often synergistic – at least in laboratory tests – with that of a SULPHONAMIDE, each type of drug inhibiting folic acid-dependent reactions but by different mechanisms; an antifol–sulphonamide mixture (e.g. *cotrimoxazole*: a mixture of trimethoprim and sulphamethoxazole) is often microbicidal, even though each drug is microbistatic when acting independently. However, sulphonamide–diaminopyrimidine combinations have a wide variety of toxic effects in humans, and their continued clinical use is open to question [JAC (1986) 17 694–696].

**foliicolous** Living or growing on leaves.

**folinic acid** See FOLIC ACID.

**foliose** (foliaceous) Leaf-like or leafy. Of a LICHEN: having a thallus which is ‘leaf-like’ (i.e., flattened and dorsiventral) and either lobed, with part or most of its lower surface being more or less firmly attached to the substratum (e.g. by RHIZINES), or disc-like, attached to the substratum by a holdfast in the centre of the lower surface (see e.g. UMBILICARIA). (cf. CRUSTOSE and FRUTICOSE.)

**folpet** (*N*-(trichloromethylthio)phthalimide) An agricultural ANTI-FUNGAL AGENT closely related to CAPTAN – with which it shares a similar antifungal spectrum.

**Fomes** (1) A genus of lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form woody, hoof-like, perennial fruiting bodies (with porous, stratified hymenophores) on both wood and living trees; the context is trimitic and has clamp connections. Some species have been transferred to other genera – e.g. *F. annosus* to HETEROBASIDIUM.

(2) *Fomes* is sometimes used as a form genus to include all polypores which form hard (corky or woody) perennial fruiting bodies. (cf. POLYPORUS sense 2.)

**fomites** Objects or materials which have been associated with infected persons or animals and which potentially harbour pathogenic microorganisms.

**Fonsecaea** See HYPHOMYCETES.

**Fontana’s stain** (for spirochaetes) An air-dried smear on a clean, grease-free slide is fixed for 2 min in 2% aqueous formalin containing 1% acetic acid, and washed for 3 min in absolute ethanol. The smear is then flooded with 5% aqueous tannic acid containing 1% phenol, and heated so that the solution steams (not boils) for 30 sec. The smear is washed with distilled water and flooded with a solution prepared by adding 10% w/v aqueous ammonium hydroxide, drop by drop, to 0.5% w/v aqueous silver nitrate until the precipitate which forms just dissolves; the solution is made to steam (not boil) until the smear becomes brown. The slide is washed in distilled water and dried. Spirochaetes appear dark brown.

**Fonticula** See ACRASIOMYCETES.

**food cup** (in *Amoeba*) See PSEUDOPODIUM.

**food microbiology** For examples of the use of microorganisms as food or in the manufacture of foods see ALCOHOLIC BEVERAGES; COCOA; COFFEE; DAIRY PRODUCTS; FERMENTED FOODS; LAYER; MUSHROOM (senses 3 and 4); SINGLE-CELL PROTEIN; UNDARIA; VINEGAR; YAKULT. Microbial products used as food additives include e.g. ALGINATE; CARRAGEENAN; CITRIC ACID; GLUTAMIC ACID; NISIN; XANTHAN GUM; YEAST EXTRACT.

(See also FOOD PRESERVATION and FOOD SPOILAGE.)

**food poisoning** ‘Food poisoning’ generally refers to acute GASTROENTERITIS caused by ingestion of food contaminated with certain pathogenic bacteria and/or their toxins, or contaminated with certain viruses; clinically distinct conditions that may be food-borne (e.g. CHOLERA) are generally excluded, although, traditionally, BOTULISM has been included. (cf. e.g. GIARDIASIS, MYCOTOXICOSIS.)

Bacterial food poisoning may involve infection of the intestine (‘food-borne infection’) and/or the action of bacterial toxin(s) produced either in the food, prior to ingestion, or in the intestine (‘food-borne intoxication’, ‘toxic food poisoning’). Food that is contaminated with pathogens often shows no organoleptic signs of deterioration. (See also FOOD SPOILAGE and FISH SPOILAGE.)

Some of the common types of food poisoning are described below (under causal agent).

(a) *Bacillus cereus* can cause two distinct syndromes. (i) *Diarrhoeal form*. After an incubation period of ~8–16 hours: diarrhoea, abdominal pain and nausea, but little or no vomiting. The (heat-labile) diarrhoeagenic enterotoxin causes a watery

## food poisoning

diarrhoea by stimulating adenylate cyclase (cf. CHOLERA TOXIN). Foods implicated: unrefrigerated meat and vegetable dishes, contaminated spices. (ii) *Vomiting form*. The incubation period (~1–7 hours) is followed by nausea, vomiting and abdominal pain, but little or no diarrhoea. The pathogen may produce a (heat-stable) emetic toxin in association with sporulation. Foods commonly implicated in this type of illness include cooked rice which has been stored unrefrigerated. (Other species of *Bacillus*, e.g. *B. subtilis* and *B. megaterium*, have been associated with food poisoning.)

(b) *Campylobacter*. Strains of *C. jejuni* or *C. coli* are usually involved: see CAMPYLOBACTERIOSIS; these organisms do not grow at 25°C but survive refrigeration and freezing – although they are killed by moderate heating (e.g. PASTEURIZATION).

(c) *Clostridium*. Strains of *C. perfringens* type A are the commonest causal agents of clostridial food poisoning. Most frequently isolated are type A2 strains (non-haemolytic/weakly haemolytic on horse-blood agar; endospores especially resistant to heat); isolated less often are type A1 strains ( $\beta$ -haemolytic; endospores relatively sensitive to heat). After an incubation period of ~8–24 hours: abdominal pain and diarrhoea, usually with little vomiting and no fever; symptoms last ~12–24 hours. Food (especially meat and poultry) may be contaminated with spores present in dust or in human or animal faeces etc.; the spores may survive cooking and, if the food is allowed to cool slowly or is stored without refrigeration, may germinate and grow rapidly. A large number of cells must be ingested in order to initiate infection as many are killed by stomach acidity. In the gut, the surviving organisms multiply and sporulate, releasing an enterotoxin which is distinct from the four major clostridial toxins ( $\alpha$ ,  $\beta$ ,  $\epsilon$ ,  $\iota$ ) formed by *C. perfringens*; this toxin damages the tips of villi of the epithelial cells, inhibiting absorption of glucose and causing an efflux of sodium ions, chloride ions and water.

(See also ENTERITIS NECROTICANS.)

(d) *Escherichia*. Certain strains of *E. coli* can cause gastroenteritis after ingestion of e.g. raw or improperly cooked foods, unpasteurized milk or water which has been contaminated from a faecal source. See e.g. ETEC (travellers' diarrhoea) and EPEC.

(e) *Salmonella*. Food-poisoning strains include a range of serotypes – e.g. *S. typhimurium*, *S. hadar*, *S. virchow*, *S. agona*.

Infection commonly occurs by consumption of contaminated foods of animal origin: undercooked meat/poultry, meat products, eggs, raw milk etc. Foods may become faecally contaminated during preparation – e.g. via the hands of the cook – but in some cases (e.g. eggs) contamination may be present at source. Infection from pets has been reported. In meat, salmonellae compete poorly with the normal meat flora (cf. MEAT SPOILAGE); the meat flora is destroyed by cooking, so that salmonellae subsequently introduced are likely to thrive. Salmonellae can survive deep freezing but are killed by adequate cooking.

After an incubation period of ~12–48 hours there is a sudden onset with diarrhoea, abdominal pain, vomiting and fever; the stools may contain blood/mucus.

The pathogen multiplies in the gut, adheres to microvilli, and then invades the epithelial cells. Invasiveness in salmonellae depends on a type III secretory system (see PROTEIN SECRETION) encoded by the *inv-spa* complex of genes located on a chromosomal PATHOGENICITY ISLAND. The initial attachment of a bacterial cell may be mediated by type I fimbriae; attachment appears to promote the formation of *invasomes*: bacterial appendages which resemble very short, thick flagella and which are believed to be essential for invasion. *Salmonella* induces its

own uptake – which occurs by the 'trigger mechanism'. Effector molecules (secreted via the type III system) are translocated into the epithelial cell where they bring about certain changes (e.g. actin polymerization). During uptake, extrusions of the host cell membrane (supported e.g. by actin elements) engulf the bacterium – which is thus internalized in a vacuole containing extracellular fluid. Unlike *Shigella* (see DYSENTERY), *Salmonella* invades via the *apical* (lumen-facing) surface of gut epithelial cells.

*Salmonella* multiplies within the vacuole.

Although much is now known about the way in which salmonellae invade the epithelium, less is known about the mechanism(s) by which infection induces intestinal secretion. Two mechanisms have been considered: (i) the action of toxin(s), and (ii) the effect of invasion *per se*. *S. typhimurium* is known to produce at least one toxin: Stn, a 25 kDa protein, encoded by gene *stn*, which is predicted to function as an ADP-ribosylating agent; however, only low levels of this toxin are formed, and its significance in pathogenesis is uncertain. It has been suggested that invasion may stimulate certain host cell secretory pathways, although invasion and secretion are not always correlated. (In a veterinary context, the cattle pathogen *Salmonella dublin* has been reported to secrete an effector protein, SopB, via a type III secretory system encoded by the *inv-spa* genes; SopB is believed to mediate enteropathogenicity by being translocated into epithelial cells and inducing both inflammation and fluid secretion [Mol. Microbiol. (1997) 25 903–912].)

Recovery from *Salmonella* food poisoning commonly begins within a few days, but a carrier state may persist. Complications include sepsis and abscess formation in the meninges (in small children), arteries (leading to arteritis and e.g. rupture of the artery), bones and joints (cf. OSTEOMYELITIS).

(f) *Shigella*. See DYSENTERY.

(g) *Staphylococcus*. Staphylococcal food poisoning usually follows ingestion of food containing one or more ENTEROTOXINS (q.v.) formed by toxigenic, coagulase-positive strains of *S. aureus*. Commonly implicated are cooked foods eaten cold (e.g. hams, poultry), and prepared foods such as sandwiches, custards etc. The source of staphylococcal contamination is man (typically a food-handler); the organisms derive from the nares or skin, or from skin lesions (e.g. boils). [Detection of staphylococcal enterotoxins: RMM (1994) 5 56–64.]

Incubation period: 1–6 hours. Onset is abrupt, with nausea, vomiting, abdominal pain and prostration, sometimes with diarrhoea. Symptoms may last for about 12 hours, but weakness and malaise may persist.

Vomiting may result from stimulation, by the toxin, of neural receptors in the upper intestinal tract – this being suggested by abolition of the emetic reflex (in monkeys) following vagotomy and sympathectomy. The superantigenic nature of the enterotoxins suggests that cytokines may play an important role in generating at least some of the symptoms of staphylococcal food poisoning.

(h) *Vibrio parahaemolyticus*. Gastroenteritis due to *V. parahaemolyticus* (see VIBRIO) is associated with the consumption of raw or inadequately cooked seafoods (fish, shellfish etc.). Most outbreaks occur during warm months. The pathogen may be concentrated in the gut of filter-feeding shellfish (cf. SHELLFISH POISONING) and may proliferate in contaminated seafoods stored without refrigeration.

Incubation period: often 12–24 hours, but may be less than 2 hours (a shorter period typically correlating with more severe symptoms). Gastroenteritis: diarrhoea commonly watery,

sometimes explosive and dysenteric; other symptoms include nausea, abdominal cramps, vomiting, fever and chills. The illness may last ~3–6 days.

The main diarrhoeagenic factor of the pathogen is a 23 kDa protein, TDH; TDH is the haemolysin responsible for the KANAGAWA PHENOMENON. The binding site for this haemolysin (in the rabbit) is probably a trisialoganglioside designated GT1<sub>b</sub>; in vitro studies indicate that the toxin promotes the secretion of chloride.

*V. parahaemolyticus* is reported to be usually sensitive to tetracycline, chloramphenicol, nalidixic acid and gentamicin but resistant to a number of  $\beta$ -lactam antibiotics, including ampicillin.

[*V. parahaemolyticus* in humans (review): RMM (1995) 6 137–145.]

(i) *Viruses*. Strains of ROTAVIRUS are common causal agents of viral gastroenteritis in infants; they infect the mucosa of the jejunum and ileum, causing desquamation and villous atrophy. Infection occurs by ingestion of faecally contaminated food or water. Incubation period: ~2–3 days. Onset is abrupt, with vomiting and diarrhoea (often associated with an upper respiratory tract infection). Recovery may occur in ~2–3 days, or the disease may be fatal. Infection in adults seems to be largely asymptomatic.

The SMALL ROUND STRUCTURED VIRUSES (also called e.g. 'parvo-like viruses' or 'parvovirus-like agents') are major causes of gastroenteritis in both children and adults; these infections have been called e.g. 'epidemic vomiting disease', while outbreaks during the winter months have been designated 'winter vomiting disease'. Immunity following infection may be short-lived. Infection is thought to occur by consumption of faecally contaminated food (see e.g. SHELLFISH POISONING) or water. Incubation period: ~1–2 days. Onset is sudden, with nausea and vomiting, sometimes with mild diarrhoea, fever, myalgia, malaise etc.

(j) *Yersinia enterocolitica* is associated with gastroenteritis mainly in children. The condition is often mild, with fever, a watery diarrhoea, vomiting and abdominal pain, usually resolving in 1–2 days. However, severe cases may involve ileitis – often in association with mesenteric lymphadenitis; in these cases the severe abdominal pain may mimic acute appendicitis ('pseudoappendicitis').

Various foods have been implicated as vehicles for the pathogen (e.g. meat, especially pork, and milk); large numbers of cells of *Y. enterocolitica* have been reported in certain vacuum-packed meats (see DFD MEAT). The pathogen can grow at, and below, 4°C (i.e. even under refrigeration).

Strains of the pathogen secrete a heat-stable enterotoxin (designated Yst) apparently similar to the ST-I of ETEC in both structure and activity; this toxin may be responsible for the diarrhoeal symptoms.

*Y. enterocolitica* invades the intestinal mucosa – studies in animals indicating that initial entry occurs (as in *Shigella*) via the M cells of Peyer's patches. [Invasion by *Y. enterocolitica*: e.g. Book ref. 218, pp 225–228.] In one model, cells of the pathogen pass through the M cells – so that they gain access to the basolateral surfaces of adjacent epithelial cells on which are found the receptors (*integrins*) of several bacterial adhesins. Adhesins of *Y. enterocolitica* include the outer membrane protein *invasin* (chromosomally encoded by the *inv* gene), and the YadA protein (encoded by plasmid pYV) which forms a cell-surface fibrillar matrix. Invasion via the basolateral surfaces of epithelial cells is likely to resemble the process seen in vitro. In vitro, the

bacterial adhesin *invasin* binds to  $\alpha_5\beta_1$  integrins, such binding inducing the development of further integrin molecules at the binding site – leading to multiple points of attachment between bacterium and epithelial cell (*zippering*); this induces uptake in a close-fitting vacuole (within which the pathogen apparently survives). As well as consolidating bacterial attachment (*zippering*), the greater concentration of integrins also induces tyrosine kinase activity within the epithelial cell; this is necessary for the invasion process, but the precise details are not known.

Various invasive pathogens – including e.g. *Shigella dysenteriae* and EIEC – induce secretion of certain CYTOKINES by the gut epithelial cells; one of these, IL-8 (a chemoattractant for inflammatory leukocytes), probably represents a host response aimed at overcoming invasion. However, virulent strains of *Y. enterocolitica* have been found to induce significantly less IL-8 compared with non-virulent strains.

Virulent strains of *Y. enterocolitica* also encode various effector molecules ('Yops') and an associated type III secretory system (see PROTEIN SECRETION) [the *Yersinia* Yop virulon: Mol. Microbiol. (1997) 23 861–867]; the genes for this system are located on plasmid pYV. An important function of the Yop system is to avoid phagocytosis by disrupting the phagocyte's uptake mechanism.

[Infections with enteropathogenic *Yersinia* species (review): RMM (1998) 9 191–205.]

(k) Various other organisms have been linked with gastroenteritis/diarrhoea – e.g. species of *Aeromonas* [RMM (1997) 8 61–72], *Citrobacter*, *Enterobacter*, *Klebsiella*, *Proteus*, *Pseudomonas* and *Streptococcus*.

**food preservation** The various methods of food PRESERVATION aim to prevent or delay microbial and other forms of FOOD SPOILAGE, and to guard against FOOD POISONING; such methods therefore help to retain the nutritive value of the product, extend its shelf-life, and keep it safe for consumption. It is generally considered preferable to use physical methods of preservation (e.g. refrigeration) when possible.

(a) *Heat treatment*. See e.g. APPERTIZATION; CANNING; PASTEURIZATION.

(b) *Low-temperature preservation*. Low temperatures delay or prevent spoilage e.g. by reducing the metabolic activities of contaminating organisms and/or the activity of endogenous enzymes in the food; spoilage by PSYCHROTROPHS may nevertheless still occur. (i) *Above 0°C*. Refrigeration between 0°C and 5°C is often used for the short-term storage of foods; however, spoilage may occur at these temperatures (see e.g. MEAT SPOILAGE). (ii) *Below 0°C*. FREEZING may kill a proportion of contaminating organisms, and it also lowers the food's WATER ACTIVITY – thus making it a less hospitable environment for surviving contaminants. Nevertheless, spoilage may still occur (see e.g. BLACK SPOT (1)); care must therefore be taken to exclude or reduce contamination before freezing.

(c) *Dehydration*. If the WATER ACTIVITY of a food is progressively decreased, a point is reached at which the food will not support the growth of contaminating organisms. The  $a_w$  of foods may be reduced by evaporation through heating (e.g. dried milk) or e.g. by the addition of sodium chloride (salting – e.g. fish products) or sugar syrups (e.g. fruits). FREEZE-DRYING has been used e.g. for coffee. (See also CURING (1) and SMOKING.)

(d) *Acidification* – see PICKLING.

(e) *Fermentation*. Fermentation of certain types of raw food not only enhances the keeping qualities of the food, it may also improve the flavour and (often) the nutritive value of the food, and avoids the need for expensive heat treatment,

## food spoilage

freezing etc. The preservative effect of fermentation may be due e.g. to (i) the lowering of pH, usually by the formation of lactic or acetic acids (see e.g. PICKLING); (ii) production of antimicrobial substances – e.g. ethanol (as in ALCOHOLIC BEVERAGES), CARBON DIOXIDE, antibiotics (e.g. NISIN, DIPLOCOCCIN in DAIRY PRODUCTS), H<sub>2</sub>O<sub>2</sub> (see e.g. LACTIC ACID BACTERIA; cf. LACTOPEROXIDASE–THIOCYANATE–HYDROGEN PEROXIDE SYSTEM); (iii) the metabolism of readily utilizable substrates (e.g. simple sugars) which would otherwise be available to potential spoilage organisms or pathogens. (See also FERMENTED FOODS.)

(f) *Preservatives*. The addition of PRESERVATIVES to particular foods is generally subject to governmental control; a preservative permissible in one country may be banned in another. A preservative should ideally be innocuous to the consumer and should not be an allergen; it should be microbicidal, rather than microbistatic, to a range of possible contaminants; it should not be inactivated by constituents of the food or by the products of microbial contaminants. Food preservatives include e.g. BENZOIC ACID; nitrites (see e.g. CURING (1)); PARABENZOATES; SORBIC ACID; SULPHUR DIOXIDE (including e.g. metabisulphite e.g. in SAUSAGES). Antibiotics, particularly those which have a medical use, have limited application in food preservation (cf. NISIN and PIMARICIN).

(g) IONIZING RADIATION has been used in some countries e.g. for chicken and for fish fillets, strawberries, onions and spices. Toxicological testing of foods irradiated with doses <10 kGy is regarded as unnecessary, and this may lead to an increase in the use of this form of preservation [Book ref. 50, pp. 145–171].

(h) A PULSED ELECTRIC FIELD technique has been able e.g. to reduce significantly the concentration of viable cells of *Mycobacterium paratuberculosis* in milk [AEM (2001) 67 2833–2836].

**food spoilage** Any change in the condition of food which causes it to become less palatable (and sometimes toxic); such changes may involve alterations in taste, smell, appearance or texture. (Foods contaminated with pathogens and/or microbial toxins (see e.g. FOOD POISONING and MYCOTOXINS) do not necessarily exhibit obvious deterioration.) Spoilage organisms include a variety of bacteria and fungi – although particular foods may be susceptible to only a limited range of species; the nature of the spoilage flora is determined e.g. by the types of nutrient present in the food, its WATER ACTIVITY and pH, the conditions of storage (particularly temperature and accessibility of air), and the presence or absence of PRESERVATIVES (see also FOOD PRESERVATION). For examples see BEER SPOILAGE; BREAD SPOILAGE; BUTTER; CANNING; CHEESE SPOILAGE; CIDER; FISH SPOILAGE; MEAT SPOILAGE; MILK SPOILAGE; PICKLING; RANCIDITY; ROPINESS; WINE SPOILAGE. (See also BIODETERIORATION.)

**food vacuole** (gastrole) A closed, membrane-limited intracellular sac which contains particle(s) of food; food vacuoles are formed e.g. by certain protozoa as a consequence of PHAGOCYTOSIS. One or more food vacuoles may be present in a given cell at any given time. Soon after its formation, a food vacuole coalesces with a LYSOSOME, and its contents become acidic and enzyme-rich; the food is digested by lysosomal enzymes (which include e.g. acid phosphatases, nucleases, amylases and esterases) and the digested food appears to enter the cytoplasm by pinocytosis – pinocytotic vesicles developing in the vacuolar membrane. Undigested food is voided when the vacuole subsequently coalesces with the cytoplasmic membrane at the cytoproct.

Under certain conditions, e.g. starvation, a cell may digest some of its own internal structures (a process called autophagy);

such structure(s) are initially enclosed within membranous vesicles to form food vacuoles.

**food yeast** See SINGLE-CELL PROTEIN.

**foolish seedling disease** *Syn.* BAKANAE DISEASE.

**foot** (*mycol.*) In fungi of the Laboulbeniales: a dark, basal cell which anchors the thallus to the host organism. (cf. FOOT CELL.)

**foot and mouth disease** (aphthous fever) An acute, highly infectious disease which can affect all cloven-hoofed animals – e.g. cattle, goats, pigs, sheep – and e.g. hedgehogs and rodents; horses are immune, and man is affected only rarely. The causal agent is an APHTHOVIRUS. Infection may occur by ingestion of contaminated food or inhalation of virus-bearing aerosols; the incubation period is usually several days to a week, but may be up to ca. 20 days. Symptoms include fever and the formation of vesicles (fluid-filled blister-like lesions) on the mucous membranes of the mouth and on the feet – particularly where the horny material and skin are contiguous; the copious saliva contains viruses derived from the ruptured vesicles. Vesicles may also appear on the teats, and viruses may also be found in the milk, blood, urine and faeces. In adult animals the disease is usually not fatal; however, it causes serious economic losses in terms of meat and milk production. *Control*: in countries where outbreaks occur only sporadically, control may be effected by slaughter of infected and suspect animals; vaccination has been used in some cases. [Protection of cattle using a synthetic peptide vaccine: *Science* (1986) 232 639–641.] A carrier state occurs in cattle, goats and sheep (but not pigs). *Disinfection*. The virus may persist for months in infected premises, stability being promoted e.g. by low temperatures. The virus may be destroyed e.g. by extremes of pH – citric acid solution or a 1% solution of sodium hydroxide (caustic soda) being effective disinfectants. Other disinfectants which have been used include iodophors (see IODINE) and hypochlorites; phenolics are apparently effective only if used in concentrated solutions (e.g. 1:6, 1:8). *Laboratory diagnosis*: e.g. culture of the virus (from pharyngeal swabs etc) and/or a CFT.

In February, 2001, the first cases of a major outbreak of foot and mouth disease were confirmed in the United Kingdom; during the period February–May the number of reported cases was particularly high in Cumbria, Dumfries and Galloway, County Durham and Devon. (A flare-up in Northumberland occurred in late August.) [Epidemiology (diagram of links between confirmed cases as at March 14th, 2001): VR (2001) 148 322–325.] Government policy involved timely slaughter of both infected and suspect animals, including those on adjacent farms (the ‘contiguous cull’). Large numbers of carcasses were burnt or buried, but burial was considered inappropriate for cattle over a certain age owing to the presumed risk of environmental contamination with prions of BOVINE SPONGIFORM ENCEPHALOPATHY.

Despite the availability of vaccines, vaccination was resisted; an important factor in this decision was the desire to maintain the UK’s ‘disease-free status’ (thus protecting the export trade).

In this outbreak, some veterinary inspections revealed lesions of unknown aetiology which could complicate the diagnosis of foot and mouth disease [photographs of oral lesions in sheep and cattle in Dumfries and Galloway that could complicate the diagnosis of foot and mouth disease: VR (2001) 148 720–723].

Currently, work is ongoing to improve the performance of ELISA-based serological tests that distinguish between (i) antibodies to whole virus particles (such as those in inactivated vaccines), and (ii) antibodies to viral proteins exposed only during replication of the virus; tests that could (reliably) distinguish

between infected, vaccinated and 'carrier' animals could lead to the possibility of vaccination compatible with 'disease-free status' [see Nature (2001) 410 1012].

In *man*, the disease involves fever, malaise, and the formation of vesicles in the mouth and on the lips, hands and feet; infection may occur via wounds or by ingestion of contaminated dairy products. Complete recovery usually occurs. (cf. HAND, FOOT AND MOUTH DISEASE.)

(See also SWINE VESICULAR DISEASE; VESICULAR EXANTHEMA; VESICULAR STOMATITIS.)

**foot cell** (1) (*mycol.*) A foot-shaped terminal cell in a macroconidium of FUSARIUM. (2) (*mycol.*) A hyphal cell which gives rise to a conidiophore. (cf. FOOT.)

**foot-rot** (foot rot; footrot) (1) (*vet.*) In cattle and sheep: a disease involving infection and inflammation of the skin–horn junction and adjacent sensitive areas of the foot, frequently resulting in severe lameness; in sheep the causal agent is *Bacteroides nodosus* (cf. SCALD), while in cattle the condition may be caused by *Fusobacterium necrophorum* and/or *Bacteroides* (or other) species. Foot-rot occurs typically in warm, wet weather. (Some breeds are more susceptible than others. *Bos taurus* cattle appear to be much more susceptible than *Bos indicus* (Zebu-type, Brahman) breeds, and the Australasian Merino sheep tend to be more susceptible than British breeds.) *Symptoms*: the foot is tender and inflamed and has a characteristic necrotic odour, but pus is generally not formed in large amounts. Fever may be present. *Treatment*: parenteral administration of antibiotics and/or topical application (to the cleaned, prepared foot) of e.g. a 5% w/v CuSO<sub>4</sub> solution; foot-baths of e.g. 5% CuSO<sub>4</sub>, 5% formalin, or 10% ZnSO<sub>4</sub> are useful for control.

In pigs, foot-rot is not unlike that found in cattle and sheep, but the condition appears to be more obviously linked to mechanical damage to the feet, and the causal agent(s) appear to include a wider range of species (e.g. *F. necrophorum*, staphylococci); a dietary deficiency of biotin predisposes towards foot lesions in the pig. Topical treatment and foot-baths can be effective.

(2) (*plant pathol.*) Any of various plant diseases in which the base of the stem rots as a result of microbial infection; causal agents include species of e.g. FUSARIUM, *Pythium*, *Rhizoctonia*, *Sclerotium*, *Thielaviopsis*, etc. These fungi commonly soften the stem tissue by producing pectinolytic – and possibly cellulolytic – enzymes, causing the plant to collapse. (cf. DAMPING OFF.)

**footprinting** In the context of protein–DNA interactions: any of various methods used to determine the particular sequence of DNA to which a given protein binds; essentially, the binding site of the protein is determined by identifying that region of the DNA molecule in which the presence of bound protein protects ('shields') the DNA from cleavage by a nuclease (e.g. DNase I) or by certain chemical agents.

In one approach, two sets of homologous, end-labelled DNA fragments – one set carrying the bound protein – are exposed to a particular nuclease, or a chemical agent, under conditions in which, ideally, each fragment is cut at only one of a number of potential cleavage sites. The result is a number of labelled sub-fragments in a range of different sizes – reflecting cleavage at different sites in different fragments. If, in *protein-bound* fragments, the presence of protein obscures one or more cleavage sites, then no sub-fragment will terminate at such protected site(s). Consequently, if the two sets of sub-fragments are compared by gel electrophoresis, the *absence* of certain size(s) of sub-fragment from the protein-bound set will be seen as a gap in the gel; this gap, resulting from shielding of corresponding cleavage site(s) by the protein, is the protein's *footprint*.

The use of DNase I as the DNA-cleavage agent commonly gives a large, clear footprint because it tends not to cut at sites close to the bound protein. The binding site of the protein may be determined with greater resolution by employing chemically mediated cleavage e.g. with *in vitro*-generated hydroxyl radical; this agent can cut at all unprotected phosphodiester bonds, so that the electrophoretic pattern in this case includes a band for each unshielded position in the sequence – a relatively narrow range of missing bands in the gel indicating a protein-binding site.

[Example of DNase I-mediated footprinting to investigate protein binding to the regulatory region of the *gal* operon in *Escherichia coli*: NAR (1994) 22 4375–4380.]

An entirely *unrelated* procedure has been termed GENETIC FOOTPRINTING (q.v.).

**forage poisoning** A form of BOTULISM in horses caused by *C. botulinum* type C<sub>β</sub> (cf. MIDLAND CATTLE DISEASE); it may occur in epizootics.

**foramen** (*pl.* foramina) A perforation or aperture in a structure: see e.g. FORAMINIFERIDA.

**foramina** See FORAMEN.

**Foraminiferida** An order of free-living (mainly marine), testate, amoeboid protozoa (class GRANULORETICULOSEA). The nature of the test (<0.2 mm to >5 mm diam., depending on species) is an important taxonomic criterion. In the suborder Allogromiina (genera: e.g. *Allogromia*, *Iridia*, *Myxotheca*) the test is predominantly organic. In the suborder Fusulinina (e.g. *Fusulina*, *Schwagerina*) the test may be composed of microgranular calcite or may consist of two or more differentiated layers. Members of the suborder Miliolina (e.g. *Quinqueloculina*, *Triloculina*) form smooth, shiny, porcellanous (porcelain-like) tests which may or may not be perforated. In the suborder Rotaliina (e.g. *Ammonia*, *Elphidium*, *Rosalina*) the test is hyaline and calcareous. Members of the suborder Textularina (e.g. *Saccamina*, *Textularia*) form 'agglutinated' tests, i.e., tests composed of foreign matter (sand, small shells etc) incorporated into a (commonly calcareous) matrix. [JP (1980) 27 37–58.]

In a few foraminifera (e.g. *Allogromia*) the test is *unilocular*, i.e., it consists of a single chamber (*locule*), but in the majority the test is *multiloculate*, new locules being added sequentially to the first-formed chamber (the *proloculus*) as the organism grows. The arrangement of locules in multiloculate species may be e.g. rectilinear and uniserial (i.e., arranged in a single row, as e.g. in *Dentalina*, *Nodosaria* and *Orthocerina*), rectilinear and biserial (i.e., in two adjacent rows, as in e.g. *Cribrostomum* and *Textularia*), planispiral (i.e., in a flat coil, as in e.g. *Ammodiscus* and *Discorbis*) or conical (i.e., in a cone-shaped spiral, as in e.g. *Elphidium* and *Glomospira*). Adjacent locules communicate via an opening (the *foramen*) between them, and the reticulopodium extends from the distal opening (*aperture*) of the most recently formed locule. In some genera reticulopodia also emerge from perforations in the test, and in some a thin layer of cytoplasm covers the outer surface of the test.

The life cycle in foraminifera is unique among protozoa in that it generally involves an ALTERNATION OF GENERATIONS. In e.g. *Elphidium* spp. meiosis occurs in the mature, multiloculate, diploid organism (*agamont*) and haploid, amoeboid cells (young gamonts) are liberated; each cell secretes a test and grows to form a mature, multiloculate, haploid *gamont* which eventually releases numerous biflagellate isogametes. Following fertilization, each zygote (young agamont) secretes a test and grows to form a mature agamont. In e.g. *Allogromia* the mature gamonts and agamonts are morphologically indistinguishable, while in e.g. *Elphidium crispum* the proloculus in the agamont test is

## foreign body giant cell

smaller than that in the gamont test. Variations may occur in this generalized life cycle: e.g., in *Glabratella sulcata* the gametes are exchanged directly between two gamonts in contact, rather than being released into the sea.

Most foraminifera are marine benthic organisms, although some (e.g. GLOBIGERINA, GLOBIGERINOIDES) are pelagic (planktonic), and a few (e.g. *Nonion germanicum*) occur in brackish waters. The organisms are typically holozoic and omnivorous, feeding on bacteria, small protozoa, microalgae, etc. [Invasive activity of *Allogromia* pseudopodial networks: JP (1985) 32 9–12.] Photosynthetic endosymbionts occur in many foraminifera, including most or all of the large forms (e.g. *Amphistegina*) which occur – often abundantly – in shallow tropical and subtropical seas; depending on species, these endosymbionts may be dinoflagellates (e.g. *Amphidinium*, ‘*Symbiodinium*’), green algae (e.g. *Chlamydomonas*, *Chlorella*), frustule-less diatoms (which can reconstitute their frustules in culture), or a unicellular red alga (*Porphyridium?*). The endosymbionts seem able to satisfy at least a significant proportion of the carbon and energy requirements of the protozoon, but ingestion of prey is apparently necessary to supply adequate levels of e.g. nitrogen and phosphorus [e.g. in *Globigerinoides sacculifer*: Limn. Ocean. (1985) 30 1253–1267]. In *Nonion germanicum* chloroplasts from ingested algae appear to survive digestion for long enough to supply the protozoon with some photosynthate. [Symbiosis: Book ref. 129, pp. 37–68; potential symbionts in bathyal species: Science (2003) 299 861.]

Fossil foraminiferan tests occur abundantly in certain oceanic deposits and sedimentary rocks, sometimes being a major component of thick deposits of chalk (such as the white cliffs of Dover and Normandy). (See also COCCOLITH.) Numerous genera and species of fossil foraminifera have been documented, the earliest dating from the late Precambrian to early Cambrian (primitive globular tests with a single aperture). Fossil tests are commonly ca. 0.2–2.0 mm in diam., but some ‘fusulinids’ (Carboniferous to Permian) and ‘nummilitids’ (Eocene to Oligocene) are much larger: e.g. the discoid multiloculate tests of *Nummilites gizehensis* may be >120 mm. A rapid succession of distinctive species of fossil foraminifera has occurred through the geological ages, making them ideal markers in the biostratigraphy of sedimentary rocks e.g. for oil prospecting. [Stratigraphy of planktonic foraminifera: Book ref. 136, pp. 11–328.]

**foreign body giant cell** See GIANT CELL.

**forespore** See ENDOSPORE (sense 1 (a)).

**forest yaws** Syn. PIAN BOIS.

**form genus** (*mycol.*) A non-phylogenetic category, equivalent to ‘genus’, which is distinguished on the basis of one or more (typically) morphological features. Form species within a form genus are referred to by Latin binomials (see NOMENCLATURE). (The prefix ‘form’ – although taxonomically correct – is frequently omitted.)

In the DEUTEROMYCOTINA, form genera are used to classify e.g. those fungi which have no known sexual stage; such form genera are based primarily on the characteristics (including mode of development) of the conidia. If the sexual stage of a form species is discovered, the name of the form species – based on the anamorph – can continue to be used, but the taxonomically valid name is that of the teleomorph.

Form genera are also used for certain members of the Aphyllophorales: see e.g. FOMES, POLYPORUS and PORIA.

**form species** See FORM GENUS.

**forma specialis** (special form; f. sp., sometimes written f.; plural: *formae speciales*, ff. sp.) An intraspecific taxonomic

rank in which the taxa are distinguished on a physiological basis – particularly on the basis of adaptation to (or pathogenicity for) one or more specific hosts. In mycology, *forma specialis* is a taxonomic rank lower than (in ascending order) form, subvariety, VARIETY and SUBSPECIES, and higher than PHYSIOLOGICAL RACE [Book ref. 64, p. 83].

**formaldehyde** (HCHO; methanal) (a) (as an antimicrobial agent)

A colourless, water-soluble and ethanol-soluble, pungent gaseous aldehyde which functions as an ALKYLATING AGENT, substituting amino and other groups (in proteins and nucleic acids) with hydroxymethyl groups (cf. GLUTARALDEHYDE); it can be mutagenic and is a presumed carcinogen. Formaldehyde is used e.g. for FIXATION, as a DISINFECTANT, as a biocide in a low-temperature STERILIZATION process, and as an inactivating agent in certain INACTIVATED VACCINES. It is active against a wide range of bacteria and fungi and some viruses; activity against bacterial endospores is very slow and can involve reversible inhibition of germination. For maximum antimicrobial activity, gaseous formaldehyde requires a high relative humidity (>60%); the gas has poor powers of penetration and is used e.g. as an indoor surface disinfectant or sterilant (cf. FUMIGATION). An aqueous solution of formaldehyde (*formalin*) is used e.g. as a preservative for biological specimens and as a general disinfectant; alcoholic solutions have been used e.g. for disinfecting surgical instruments. Antimicrobial activity is inhibited by organic matter. *Formaldehyde-releasing agents* include e.g. HEXAMINE, NOXYTHIOLIN, PARAFORMALDEHYDE, TAUROLIN. (See also LOW-TEMPERATURE STEAM-FORMALDEHYDE STERILIZATION.)

(b) (as a metabolite) See METHYLOTROPHY.

**formalin** See FORMALDEHYDE.

**formalin–ether method** (formol–ether method) A method for concentrating protozoan cysts (and e.g. parasite larvae) in a sample of faeces. The sample (e.g. 1–2 g faeces) is emulsified in ca. 10 ml physiological saline containing 10% formalin, and left for 30 min; the suspension is then filtered through a double layer of wet gauze and the filtrate is centrifuged (ca. 350 g/2–3 min). The supernatant is discarded, and the sediment is shaken in a stoppered tube with 10 ml formalin–saline and 3 ml diethyl ether. The tube is then centrifuged (ca. 350 g/2–3 min). Cysts, if present, are found in the sediment. This method is unsuitable for the concentration of coccidian cysts if the latter are subsequently to be sporulated. (cf. FLOTATION.)

**formate hydrogen lyase** An enzyme system which splits formic acid into carbon dioxide and hydrogen (see e.g. MIXED ACID FERMENTATION and BUTANEDIOL FERMENTATION). The system includes a *formate dehydrogenase* (which eliminates CO<sub>2</sub> from formic acid) and a HYDROGENASE; electrons derived from the first reaction appear to be transferred to hydrogenase via one or more electron carriers. Anaerobically, *Escherichia coli* (and certain other bacteria) can oxidize formate using nitrate or fumarate as terminal electron acceptor; a different formate dehydrogenase is involved, and hydrogen is not evolved.

**N-formimidoylthienamycin** See THIENAMYCIN.

**formol–ether method** See FORMALIN–ETHER METHOD.

**Formvar** Polyvinyl formal: a substance, soluble in e.g. chloroform, used in the preparation of support films for ELECTRON MICROSCOPY.

**Forssman antigen** (1) Any HETEROPHIL ANTIGEN. (2) Any heterophil antigen which can elicit antibodies capable of combining with determinant(s) on sheep RBCs. (The first-described Forssman antigen is an antigen found e.g. on sheep RBCs and on certain guinea-pig cells.)

**Fort Bragg fever** (pretibial fever) Human LEPTOSPIROSIS, caused by *Leptospira interrogans* serotype *autumnalis*, which is characterized by a pretibial rash, malaise, coryza and fever; it occurs in SE Asia, Japan, and the USA.

**Fort Morgan virus** See ALPHAVIRUS.

**fortimicin** An AMINOGLYCOSIDE ANTIBIOTIC which contains neither streptidine nor deoxystreptamine.

**forward mutation** A MUTATION which results in a *mutant* phenotype, i.e., a phenotype which differs from that of the WILD-TYPE organism; a forward mutation typically involves the inactivation of e.g. a structural gene. (cf. BACK MUTATION.)

**forward primer** In the context of a given gene whose nucleotides are numbered: a primer whose sequence of nucleotides corresponds to a sequence within the gene which reads in a numerically ascending order in the 5'-to-3' direction; thus, a forward primer may have a sequence which corresponds to e.g. nucleotides 10 → 25 (5'-to-3') of a given gene. The nucleotides of a *reverse primer* read in a numerically descending order in the 5'-to-3' direction – e.g. nucleotides 350 → 335 in the other strand.

**fos** See FBJ OSTEOSARCOMA VIRUS.

**Foscarnet sodium** See PHOSPHONOFORMIC ACID.

**fosfomycin** (phosphonomycin; *cis*-1,2-epoxypropyl-1-phosphonic acid) A broad-spectrum ANTIBIOTIC (obtained from *Streptomyces* strains) which blocks PEPTIDOGLYCAN biosynthesis by binding (irreversibly) and inhibiting phosphoenolpyruvate: UDP-GlcNAc enolpyruvyl transferase – thus preventing the synthesis of *N*-acetylmuramic acid; other reactions involving PEP are apparently not inhibited. Fosfomycin is taken up by the glycerolphosphate transport system in susceptible cells, and resistance to the drug develops readily by alteration or loss of this transport system; plasmid-borne resistance involving intracellular modification of the drug also occurs [JGM (1985) 131 1649–1655].

**Fosfonet sodium** See PHOSPHONOACETIC ACID.

**Foshay test** A SKIN TEST in which the antigen is a suspension of (or a protein extract from) killed cells of *Francisella tularensis*.

**Foshay's vaccine** An anti-TULARAEMIA vaccine prepared from killed cells of *Francisella tularensis*.

**fossil microorganisms** See e.g. COCCOLITH; CYANOBACTERIA; DASYCLADALEAN ALGAE; FORAMINIFERIDA; GYROGONITES; RADIOLARIA; STROMATOLITES. (See also BIOSTRATIGRAPHY.) [Microfossils of the Proterozoic/Phanerozoic periods in China: Nature (1985) 315 655–658.]

**foulbrood** See AMERICAN FOULBROOD and EUROPEAN FOULBROOD.

**Fourier transform** See NUCLEAR MAGNETIC RESONANCE.

**foveate** Pitted with small holes or depressions.

**foveolate** Minutely pitted.

**fowl adenovirus** See AVIADENOVIRUS.

**fowl cholera** (avian pasteurellosis) A POULTRY DISEASE (affecting e.g. chickens, turkeys, ducks, game birds) caused by *Pasteurella multocida*. Symptoms of the acute form of the disease may include anorexia, bloody diarrhoea, discharge from nostrils, eyes and mouth, and haemorrhages of internal organs and mucous membranes; death may occur within hours or days. In the chronic form the disease mainly affects the respiratory system.

**fowl paralysis** *Syn.* MAREK'S DISEASE.

**fowl pest** (1) *Syn.* FOWL PLAGUE. (2) *Syn.* NEWCASTLE DISEASE.

**fowl plague** A POULTRY DISEASE caused by strains of influenza-virus A. Symptoms resemble those of NEWCASTLE DISEASE; mortality rates may be high. Wild birds may be an important source of infection.

**fowl pox** A POULTRY DISEASE caused by an AVIPOXVIRUS. Infection occurs via wounds (particularly in unfeathered regions such as

the comb, wattles etc) or mucous membranes. Greyish-white or yellow eruptions form and may develop into large wart-like growths, and/or yellowish, caseating vesicles develop in the throat, forming a characteristic diphtheritic membrane. Live attenuated vaccines are available.

**fowl typhoid** An acute infectious POULTRY DISEASE caused by *Salmonella gallinarum*; it affects mainly adult chickens and turkeys. Symptoms: e.g. lethargy, anorexia, yellow or greenish diarrhoea; the liver is enlarged and has a typical bronzed appearance post-mortem. Death may occur within days, or the disease may become chronic with severe, progressive emaciation and anaemia. Survivors become chronic carriers. Transmission occurs via the faecal–oral route or transovarially. Wild birds (e.g. rooks, pigeons) may provide a reservoir of infection. *Lab. diagnosis and treatment*: as for PULLORUM DISEASE; antisera which are positive for *S. pullorum* cross-react with *S. gallinarum*.

**fowlpox subgroup** See AVIPOXVIRUS.

**foxfire** BIOLUMINESCENCE in decaying wood.

**FP-cellulose** 'Filter-paper cellulose'; filter paper may be used as a substrate for determining the ability of an organism or enzyme to degrade crystalline CELLULOSE.

**FP2 plasmid** See INCOMPATIBILITY.

**fps** See FES.

**fractalkine** See CHEMOKINES.

**Fraction 1 antigen** See YERSINIA (*Y. pestis*).

**fraction I protein** See CHLOROPLAST.

**fractional sterilization** *Syn.* TYNDALLIZATION.

**fractionation** See CELL FRACTIONATION.

**Fragilaria** See DIATOMS.

**fragilis yeast** See SINGLE-CELL PROTEIN.

**fragmin** See ACTIN.

**framboesia** (frambesia) *Syn.* YAWS.

**frameshift mutation** (phase-shift mutation) A type of MUTATION in which a number of nucleotides *not* divisible by three is inserted into or deleted from a coding sequence, causing an alteration in the reading frame of the entire sequence downstream of the mutation. For example, if a wild-type gene containing a sequence UUG-GAG-UGU-AGU (encoding Leu-Glu-Cys-Ser; see GENETIC CODE) suffers an insertion mutation in the UUG codon which generates the sequence UAUG (a +1 frameshift), the reading frame will be shifted backwards by one nucleotide, and the sequence will read UAU-GGA-GUG-UAG-U (encoding Tyr-Gly-Val-*stop*, UAG being a nonsense codon). Similarly, deletion of one nucleotide (a –1 frameshift) will shift the reading frame forwards; e.g., if the second U is deleted, the above sequence becomes UGG-AGU-GUA-GU, encoding Trp-Ser-Val. A –1 frameshift may suppress the effects of a +1 frameshift: see SUPPRESSOR MUTATION.

Frameshift mutations may occur spontaneously (see SPONTANEOUS MUTATION) and are induced by certain types of mutagen (e.g. certain INTERCALATING AGENTS).

**framycetin** An AMINOGLYCOSIDE ANTIBIOTIC produced by a strain of *Streptomyces lavendulae*; it may be identical to one form of neomycin.

**Francisella** A genus (*incertae sedis*) of aerobic, chemoorganotrophic, Gram-negative bacteria which occur e.g. as parasites and pathogens in man and other animals. Cells (when actively growing): non-motile cocci, coccobacilli or rods, according to species and growth conditions; subsequently filamentous and pleomorphic. The cells stain poorly and often bipolarly; a bipolarly stained rod may give the false impression of two cocci. Metabolism: respiratory (oxidative). One species (*F. tularensis*)

## frange

is nutritionally fastidious (requiring e.g. cysteine for growth), while the other (*F. novicida*) can grow e.g. on nutrient gelatin. Carbohydrates are metabolized slowly and anaerogenically. Optimum growth temperature: ca. 37°C. Oxidase -ve. Catalase test: weakly positive. GC%: ca. 33–36. Type species: *F. tularensis*.

*F. novicida*. Cells: non-capsulated, ca. 0.2–0.3 × 0.3 µm in tissues, 0.5 × 0.5–0.9 µm on solid media, 0.7 × 1.7 µm in liquid media. Unlike *F. tularensis*, *F. novicida* does not require cysteine for growth. *F. novicida* is apparently not pathogenic for man but can produce tularaemia-like lesions, experimentally, in e.g. guinea pigs and white mice.

*F. tularensis* (formerly *Pasteurella tularensis*). The causal agent of TULARAEMIA. Cells: ca. 0.2 × 0.2–0.7 µm; virulent strains have a non-immunogenic capsule, ca. 0.02–0.04 µm in thickness. *F. tularensis* can be grown e.g. on glucose–cysteine–blood agar; colonies (2–4 days, 37°C) are 1–4 mm diam., typically smooth, grey, easily emulsifiable, each being surrounded by a zone of greenish discoloration. *F. tularensis* is generally sensitive to e.g. kanamycin, streptomycin and tetracyclines.

[Book ref. 22, pp. 394–399.]

**frange** A band of perioral ciliature characteristic of some members of the HYPOSTOMATIA.

**Frankia** A genus of bacteria (order ACTINOMYCETALES, wall type III) which form ACTINORRHIZAE but which can also occur as free-living soil saprotrophs that appear not to fix nitrogen. (At least some of the *nif* genes have been found to be located on a large plasmid in one strain of *Frankia* [MGG (1986) 204 492–495].) The organisms form branching, septate hyphae, and give rise to non-motile spores in sporangia which develop on the hyphae. GC%: ca. 68–72. Type species: *F. alni*. [Media and methods: Book ref. 46, pp. 1991–2003.]

**Frateuria** A genus of Gram-negative, obligately aerobic, chemoorganotrophic bacteria (family PSEUDOMONADACEAE) which occur e.g. on the fruit of the raspberry (*Rubus parvifolius*). Cells: polarly flagellate or non-motile rods, 0.5–0.7 × 0.7–3.5 µm. Round, entire, dark brown colonies are formed on glucose–yeast extract–CaCO<sub>3</sub> agar; optimum growth temperature: 25–30°C. Growth can occur at pH 3.6. Acid is formed from various carbon sources, including ethanol. Catalase +ve. Oxidase -ve. GC%: 62–64. Type species: *F. aurantia*. [Book ref. 22, pp. 210–213.]

**Frazier's medium** An agar medium containing 0.4% GELATIN; it is used to detect gelatin hydrolysis. Following culture of the test organism on the medium, the plate is flooded with a solution of mercuric chloride in dilute HCl; unhydrolysed gelatin rapidly becomes opaque – clear zones indicating gelatin hydrolysis.

**frd genes** See FUMARATE RESPIRATION.

**free cell formation** See ASCUS.

**free electrophoresis** See ELECTROPHORESIS.

**free induction decay** (FID) See NUCLEAR MAGNETIC RESONANCE.

**free-living** Living without being directly dependent on other organisms. (cf. SYMBIOSIS.)

**free residuals** See WATER SUPPLIES.

**freeze-cleaving** *Syn.* FREEZE-FRACTURING.

**freeze-drying** (lyophilization) A process used e.g. for the long-term preservation of certain microorganisms, certain foodstuffs etc; in this process volatile substances (mainly water) are removed from the deep-frozen specimen or material by sublimation under high vacuum (cf. CRITICAL POINT DRYING).

*Freeze-drying of bacterial cultures.* A fresh broth culture of e.g. 10<sup>8</sup> cells/ml is gently centrifuged and the cells resuspended

in a cryoprotectant (e.g. 20% skim milk) to a cell density of ca. 10<sup>8</sup> cells/ml. An aliquot of the suspension (ca. 0.1 ml) is put into a sterile VIAL. (This account assumes the use of a vial 10 cm long, 6 mm internal diameter.) The COTTON WOOL plug is replaced and pressed into the vial to a position ca. 2–3 cm above the suspension. With precautions to avoid heating the suspension, a region of the vial 2–3 cm from its open end is heated and drawn out into a capillary neck. The suspension is then frozen (see FREEZING) at –60 to –80°C, e.g. by placing the closed end of the vial in a mixture of solid CO<sub>2</sub> ('dry ice') and ethanol. The vial is transferred to a freeze-drying machine (where the low temperature is maintained) and subjected to a high vacuum for a period of 18 hours to several days, depending on temperature. The vial is removed, fitted to a vacuum line, and sealed by melting the capillary neck. Vials are best stored at 5°C or below. (For many species, viability is retained for 10–30 years or longer.) When a culture is required, a vial is opened and the contents reconstituted with broth or distilled water. A sealed vial can be opened (preferably in a SAFETY CABINET) by 'nicking' the glass over the centre of the cotton wool plug and momentarily applying a red-hot glass rod to the nick; the vial (usually) cracks around its circumference, permitting the slow ingress of air – which is filtered through the cotton wool.

In the double-vial method, the material is freeze-dried in a vial which is sealed only with a cotton wool plug; this vial is placed in an outer vial, containing a desiccant, which is evacuated and sealed by fusion of the glass.

**freeze-etching** A technique used for examining the topography of surface(s) exposed by the fracture (cleavage) of e.g. a deep-frozen cell. The specimen is frozen rapidly (see FREEZING). While at ca. –100 to –196°C (depending on apparatus), the specimen is fractured: it may be split with a knife-blade in a microtome-based apparatus, or, in one form of the 'snapped tube' apparatus, a capillary tube containing a homogenate is deep-frozen and snapped at a pre-scored position. During fracture, part of the cleavage generally follows the boundaries of internal structures (e.g. organelles), and membranes may be split to expose their hydrophobic faces. Surfaces exposed by cleavage are then 'etched' by sublimation of volatiles (mainly water) from the surfaces at a temperature of ca. –100°C under high vacuum; organelles and non-volatiles are thus thrown into relief. A thin replica of the etched surface is then prepared (see ELECTRON MICROSCOPY (a)) and examined under the TEM. [Book ref. 4, pp. 279–341. For nomenclature of freeze-etched surfaces see Science (1975) 190 54–56. For potential artefacts see JUR (1983) 82 123–133.]

**freeze-fracturing** The process of FREEZE-ETCHING omitting the etching step.

**freeze pressing** The operation of a HUGHES PRESS.

**freeze-sectioning** (cryosectioning) The preparation of sections, for MICROSCOPY or ELECTRON MICROSCOPY, by cutting a FROZEN-HYDRATED SPECIMEN with a *cryotome* (a modified MICROTOME which maintains the specimen in a frozen state).

**freeze-substitution** A procedure for preparing a specimen e.g. for X-RAY SPECTROCHEMICAL ANALYSIS. Essentially, the specimen is rapidly frozen and then immersed for e.g. 14 days in anhydrous ethanol or acetone at e.g. –70°C; during this time the ice is gradually replaced by ethanol or acetone. This method helps to maintain the positions of e.g. water-soluble ions within the specimen – thus facilitating subsequent determination of the *in vivo* locations of these ions.

**freezing** Sub-zero (°C) freezing is used for the preservation (*cryopreservation*) of certain microorganisms, foods etc, and

e.g. in FREEZE-DRYING and FREEZE-ETCHING techniques (see also CRYOFIXATION).

(a) *Cryopreservation of living cells.* Cryopreservation may be used to preserve viability in many species of bacteria, fungi and protozoa, many viruses, and tissue cultures; this method of preservation (or freeze-drying) is generally preferable, when practicable, to preservation by repeated subculture (see STABILATE). However, unless precautions are taken, cells may be killed or (reversibly) damaged when they are frozen. Damage or death may be due to one (or both) of two main causes. First, the formation of intracellular and extracellular ice crystals may result in e.g. mechanical or osmotic damage. (Even after water freezes, ice crystals continue to grow at temperatures above a certain *critical temperature*; the temperature range between the freezing point and the critical temperature is called the *critical temperature zone*.) Secondly, as the temperature continues to fall below 0°C, the ongoing formation of crystals of pure ice results in the development of concentrated intracellular solutions of salts as the eutectic temperature is approached; these concentrated solutions are believed to damage certain cell components (e.g. enzymes). The continued presence of these solutions at temperatures found in certain types of commercial freezer (e.g. -10 to -20°C) precludes the use of such equipment for effective microbial preservation.

Cell damage can be minimized if, prior to freezing, the cells are equilibrated with a *cryoprotectant*: an antifreeze which, by depressing the freezing point, reduces the time that cells are subjected to temperatures in the critical temperature zone. Cryoprotectants may be used in both rapid and slow freezing (see below); they include e.g. glycerol (widely used e.g. for bacteria and yeasts) and DIMETHYLSULPHOXIDE (DMSO) (used e.g. for protozoa and tissue cultures). These agents are used e.g. at 10% v/v in growth medium; they can penetrate cell membranes and permeate the cytoplasm. Other cryoprotectants (e.g. skim milk, dextran, polyvinylpyrrolidone) appear to function extracellularly.

*Rapid freezing* (e.g. ca. 100 to 1000 centigrade degrees per second) tends to prevent ice crystal formation by encouraging *vitrification*, i.e. the non-crystalline (amorphous) solidification of water; it is commonly used to preserve viability in eukaryotes (e.g. *Saccharomyces cerevisiae*). The use of a cryoprotectant encourages vitrification by compressing the critical temperature zone. The specimen (e.g. one drop of suspension) may be initially quench-frozen in e.g. FREON 22 at ca. -150°C and then transferred to liquid nitrogen (-196°C). Liquid nitrogen may be used as the sole cryogen (despite the LEIDENFROST PHENOMENON) if the specimen is frozen in subcooled nitrogen (at ca. -200 to -210°C); heat transferred from the specimen raises the temperature of the nitrogen - but not as far as its boiling point. [Instruments which facilitate rapid freezing: JM (1982) 126 221-229; relative efficiency of cryogens used for plunge-cooling biological specimens: JM (1987) 145 89-96.]

*Slow freezing* is often used e.g. for bacteria; it may permit extracellular ice formation and intracellular dehydration by osmosis. A cell suspension is equilibrated with a cryoprotectant, and aliquots are placed in vials; vials containing non-pathogens are usually sealed. Freezing may be carried out at a rate of ca. one degree/min down to ca. -30°C, then at 30 degrees/min down to -150°C; vials are then stored in liquid nitrogen or in the vapour phase above liquid nitrogen (ca. -150°C).

*Tissue culture cells* may be initially equilibrated for 1 hour at 4°C in a mixture of growth medium, serum and ca. 10% v/v DMSO to permit penetration of DMSO. The cells, in sealed

vials, are then transferred to the 'freezing chamber' of a liquid nitrogen apparatus for 20-30 min, and subsequently placed in liquid nitrogen.

Thawing should be rapid to preserve viability [Nature (1980) 286 511-514]. Vials in liquid nitrogen may be equilibrated in solid CO<sub>2</sub> (-78°C) before being transferred to a 37°C water-bath.

When working with liquid nitrogen, thawing vials etc. it is usual to wear a protective face-shield and gloves.

(b) See FOOD PRESERVATION (b).

**Frei test** A SKIN TEST, analogous to the TUBERCULIN TEST, used in the diagnosis of LYMPHOGRANULOMA VENEREUM; it involves the intradermal injection of antigen derived from a chick embryo culture of *Chlamydia trachomatis*.

**Fremyella** See RIVULARIACEAE.

**French moult** See BUDGERIGAR FLEDGLING DISEASE.

**French press** (French pressure cell) An apparatus for CELL DISRUPTION. A suspension or paste of cells is put into a cooled steel cylinder, and a piston is forced into the cylinder by hydraulic pressure (ca. 10 tons/inch<sup>2</sup>, i.e., ca. 160 MPa). Cells emerge from a small hole in the cylinder and are broken by the high shear forces during their exit; they tend to explode owing to the sudden drop in pressure. The process readily breaks most Gram-negative bacteria but not Gram-positive cocci or endospores.

**Frenching disease** See COTTON WILT.

**Frenkelia** A genus of coccidian protozoa (suborder EIMERIORINA) parasitic in rodents (intermediate hosts) and birds (final hosts); the organisms closely resemble species of SARCOCYSTIS.

**Freon** (trade name) Any of a range of halogenated hydrocarbons. For example, Freon 22 (= halocarbon 22; CHClF<sub>2</sub>) melts at -160°C and boils at -41°C; it is used e.g. as a CRYOGEN. Freon 113 (= halocarbon 113; CCl<sub>2</sub>F.CClF<sub>2</sub>) melts at -35°C and boils at +48°C; it is used e.g. as an intermediate fluid in CRITICAL POINT DRYING.

**FRET** See PCR.

**Freund's adjuvant** Freund's *incomplete* ADJUVANT is a water-in-oil emulsion made with a mineral oil. Freund's *complete* adjuvant consists of the incomplete adjuvant together with dead mycobacteria dispersed in the oil phase; in a modified form, MDP (q.v.) is used instead of the mycobacteria. In both types of adjuvant the antigen is dispersed in the water phase. (cf. ADJUVANT 65.)

**fried egg colony** See MYCOPLASMA.

**Friedländer's bacillus** A species of *Klebsiella* isolated by Friedländer (in 1883) from the lungs of postmortem cases of PNEUMONIA.

**Friedländer's pneumonia** See PNEUMONIA (d).

**Friedmannia** A genus of sarcinoid, soil-inhabiting green algae related to TREBOUXIA.

**Friend virus** (FV) A virus complex consisting of a mixture of a replication-competent MURINE LEUKAEMIA VIRUS (F-MuLV or Fr-MuLV) and a replication-defective component designated 'spleen focus-forming virus' (SFFV) because of its ability to induce macroscopic foci of erythroid cell proliferation in the spleen of an infected mouse. (FV does not transform cells in vitro.) The F-MuLV component alone can induce erythroleukaemia only in newborn mice of certain strains, or in adult mice after a long latent period; the F-MuLV-SFFV complex can cause disease in both adult and neonatal mice of most inbred strains, causing anaemia (variant FV-A, containing SFFV<sub>A</sub>) or polycythaemia (variant FV-P, containing SFFV<sub>P</sub>) after a short latent period. Both SFFV variants are believed to have arisen by recombination between F-MuLV and an endogenous xenotropic

## Frings Acetator

virus sequence; the glycoprotein product of the recombinant *env* gene has been implicated in the enhanced oncogenicity of FV as compared with that of F-MuLV alone. (cf. MCF VIRUSES; RAUSCHER VIRUS.)

**Frings Acetator** See VINEGAR.

**Frings trickling generator** See VINEGAR.

**Fritschiella** See CHAETOPHORA.

**frog virus 3 (FV3)** A virus (genus RANAVIRUS) originally isolated from a leopard frog (*Rana pipiens*); it is apparently non-pathogenic in adult leopard frogs, but is lethal for tadpoles and for Fowler toads. FV3 can replicate in a wide range of cells in culture, including amphibian, avian, mammalian and piscine cells. Growth temperature: ca. 12–32°C.

The virion (ca. 160–200 nm diam.) apparently contains ca. 29 structural proteins and at least six enzymic activities. An envelope may or may not be present; enveloped virions, which are more infective than naked virions, enter the host cell by endocytosis (see ENVELOPE), while the naked virions usually enter by fusion between the virion shell and the host cell plasmalemma [JGV (1985) 66 283–293]. Initial rounds of viral DNA replication occur in the host cell nucleus, resulting in DNA molecules up to twice the length of the viral genome. The DNA is then transferred to the cytoplasm where subsequent rounds of replication occur; concatemers >10 times the genome length are formed – apparently by recombination (as in e.g. BACTERIOPHAGE T4). The virion DNA and cytoplasmic viral DNA – but not the viral DNA synthesized in the nucleus – is highly methylated, >20% of the cytosine residues being methylated at the C-5 position; methylation is carried out in the cytoplasm by a viral early-gene product (a methyltransferase), and may protect the DNA from virus-encoded endonucleases. Virus assembly occurs in morphologically distinct regions of the cytoplasm delimited by aggregated host-cell INTERMEDIATE FILAMENTS [JGV (1986) 67 915–922].

[Review: AVR (1985) 30 1–19.]

**frond twist disease** See ALGAL DISEASES.

**front focal plane** Of a convex lens: the focal plane nearest the light source.

**Frontonia** See HYMENOSTOMATIDA.

**frost damage** (in plants) See e.g. ICE NUCLEATION BACTERIA.

**frosty pod** (of cacao) See POD ROT.

**frozen-hydrated specimen** A specimen which has been frozen hard without prior dehydration – as e.g. in FREEZE-SECTIONING.

**fructan** (fructosan) A polysaccharide composed mainly or solely of fructosyl residues (see e.g. INULIN and LEVAN). Fructans are synthesized by the addition of fructose residues to SUCROSE, and hence each fructan chain ends in a (non-reducing) sucrose residue. Fructans can be hydrolysed by a wide range of microorganisms.

**fructification** (1) *Syn.* FRUITING BODY. (2) The formation or development of a fruiting body.

**fructosan** *Syn.* FRUCTAN.

**fructose** ('fruit sugar') A ketohexose found e.g. in plants (e.g. in sweet fruits), in honey (with glucose and sucrose), and as a component of many oligo- and polysaccharides (e.g. MELEZITOSE, RAFFINOSE, SUCROSE; see also FRUCTAN). D-Fructose ('laevulose') can be metabolized by a wide range of microorganisms.

Fructose is sweeter than sucrose and is being used on an increasing scale as a sweetener in foods (see e.g. HIGH FRUCTOSE CORN SYRUP). (See also INULINASE.)

**fructose bisphosphatase** See GLUCONEOGENESIS.

**β-fructosidase** See INVERTASE and INULINASE.

**fruit** (*verb*) To produce a FRUITING BODY.

**fruit spoilage** See e.g. CANNING; GREY MOULD; PECTIC ENZYMES; PICKLING; SOFT ROT (2).

**fruiting body** (fructification; fruit body; sporocarp) Any specialized structure (plectenychmatous in fungi) which bears or contains sexually- or asexually-derived spores. Examples include e.g. APOTHECIUM, PYCNIDIUM, pycnium and the resting structures of the MYXOBACTERIALES. Some fruiting bodies (e.g. those formed by species of *Heterobasidion* and *Poria*) are perennial.

**frustule** See DIATOMS.

**fruticose** Shrub-like. Of a LICHEN: having a thallus which is thread-like (terete) or strap-like (more or less flattened) and either erect and shrubby or pendulous; the thallus may be attached to the substratum by a holdfast or may be unattached. The mechanical strength of the thallus may derive from a dense axial strand (in USNEA) or from the cortex; thalli of the latter type may or may not be hollow. (cf. CRUSTOSE; FOLIOSE.)

**FTA-ABS test** (fluorescent treponemal antibody-absorption test)

A TREPONEMAL TEST used in the diagnosis of SYPHILIS. Initially, the patient's serum is absorbed with an extract of Reiter treponemes to remove non-specific anti-treponemal antibodies, and the absorbed serum is applied to a slide on which there is a film of killed, fixed cells of *Treponema pallidum*; the slide is then briefly incubated to allow any specific antibodies in the serum to combine with the surface antigens of *T. pallidum*. The slide is rinsed free of serum and briefly re-incubated with fluorescent conjugate (anti-human globulin conjugated with a fluorescent dye); uncombined conjugate is rinsed off and the slide is examined by fluorescence MICROSCOPY. Antibodies which combine with *T. pallidum* combine also with the conjugate – their presence being indicated by fluorescent treponemes.

**FTO agar** A selective medium used for the culture of *Micrococcus* spp. It consists of trypticase–soy agar containing 0.1% yeast extract, 0.5% Tween 80, and small amounts of furoxone and Oil Red O. [Preparation and use: Book ref. 46, p. 1542.]

**ftsA gene** (*Caulobacter*) See CAULOBACTER.

**FtsH** An ATP- and zinc-dependent protease within the cytoplasmic membrane of *Escherichia coli* and many other bacteria; it is encoded by gene *ftsH* (also called *hflB* and *tolZ*). In *E. coli*, FtsH is involved e.g. in the degradation of certain membrane and regulatory proteins (including the HEAT-SHOCK PROTEIN  $\sigma^{32}$ ), and it may also act as a chaperone. [FtsH (review): FEMS Reviews (1999) 23 1–11.]

**ftsI gene** See PENICILLIN-BINDING PROTEINS.

**ftsQ gene** (*Caulobacter*) See CAULOBACTER.

**FtsY protein** See PROTEIN SECRETION (type II systems).

**ftsZ gene** See SOS SYSTEM.

**FtsZ protein** See CELL CYCLE (b) and SOS SYSTEM.

**5-FU** 5-Fluorouracil (see e.g. PHENOTYPIC SUPPRESSION).

**fuberidazole** (2-(2'-furyl)-benzimidazole) An agricultural antifungal agent (see BENZIMIDAZOLES); it is particularly useful as a seed treatment for the control of *Fusarium* infections (e.g. *F. nivale* in cereals).

**Fucales** See FUCUS and PHAEOPHYTA.

**fucan** A polymer of FUCOSE. (See also FUCOIDIN.)

**fuchsin** (fuchsine) *Basic* fuchsin is a red-purple DYE consisting mainly of pararosanilin and rosanilin (see TRIPHENYLMETHANE DYES). (See also CARBOLFUCHSIN and BRUCELLA.) *Acid* fuchsin, derived from basic fuchsin by sulphonation, is used e.g. in ANDRADE'S INDICATOR.

**fucidin** See FUSIDIC ACID.

**fucoidin** (fucoidan; fucan) A group of complex, branched, sulphated heteropolysaccharides present in phaeophyceal algae; fucoidins contain fucose (usually sulphated), xylose, glucuronic

acid, and – in some species – galactose and/or mannose, and they may be linked to protein. Fucoidins occur in the algal CELL WALLS and intercellular matrix and in the mucilage exuded from the surfaces of the fronds. They appear to play a role in preventing desiccation of the alga when it is exposed by tides: algae which are permanently submerged contain much less fucoidin than those growing in the intertidal zone.

**fucosans** See PHAEOPHYTA.

**L-fucose** 6-Deoxy-L-galactose.

**fucosterol** See PHAEOPHYTA.

**fucoxanthin** See CAROTENOIDS.

**Fucus** A genus of algae (division PHAEOPHYTA) which occur primarily in marine and intertidal zones. The vegetative organism consists typically of dichotomously branched, flat leathery blades, each having a pronounced central midrib; according to species, the blade may have entire or serrated edges. The stipe is attached to rocks etc by a holdfast. Some species, e.g. *F. vesiculosus* (bladder wrack), have PNEUMATOCYSTS. As in other members of the Fucales, the haploid phase of the life cycle is represented only by the gametes of the sexual organs in diploid individuals.

**fuel biodeterioration** See PETROLEUM.

**fuel cell** See BIOFUEL CELL.

**fuel ethanol** See INDUSTRIAL ALCOHOL.

**Fujinami sarcoma virus** See AVIAN SARCOMA VIRUSES.

**Fuligo** A genus of slime moulds (class MYXOMYCETES) which form aethalia containing both capillitium and pseudocapillitium; the capillitium threads bear nodes of lime. *F. septica* – a common species on rotting wood, humus, manure, etc. – forms aethalia measuring up to 70 cm across (the largest sporocarp of any myxomycete); the aethalia (sometimes known as ‘flowers of tan’) are initially brownish-yellow, and have a thick calcareous covering which eventually breaks open to reveal the black spores.

**Fulvia** A genus of fungi of the HYPHOMYCETES. *F. fulva*, formerly *Cladosporium fulvum*, is the causal agent of leaf mould of the tomato plant.

**fumagillin** An ANTIBIOTIC produced by *Aspergillus fumigatus*; it has a complex structure which includes two epoxide rings and is an ester of decatetraenedioic acid. Fumagillin apparently has no activity against bacteria or fungi but it is a potent AMOEBOCIDIC; it also inhibits the development of certain bacteriophages, and may show some antiviral activity in tissue cultures.

**fumarase** See Appendix II(a).

**fumarate reductase** See e.g. FUMARATE RESPIRATION and PROPIONIC ACID FERMENTATION [Appendix III(h)].

**fumarate respiration** A type of ANAEROBIC RESPIRATION, carried out by a range of bacteria and by certain eukaryotic microorganisms, in which exogenous fumarate acts as the terminal electron acceptor for re-oxidation of reduced pyridine nucleotides, for oxidative phosphorylation, etc; fumarate is reduced to succinate, the  $E_0'$  for the succinate/fumarate redox couple being +30 mV. (cf. e.g. PROPIONIC ACID FERMENTATION.)

In *Escherichia coli*, fumarate respiration occurs during anaerobic growth in the presence of a non-fermentable carbon source (e.g. glycerol) and fumarate; the respiratory chain involved comprises fumarate reductase (EC 1.3.99.1), menaquinone, dehydrogenases (e.g. formate, NADH and lactate dehydrogenases), and possibly a *b*-type cytochrome. Fumarate reductase is distinct from succinate dehydrogenase (which catalyses the same reaction): fumarate reductase is repressed in the presence of  $O_2$  and  $NO_3^-$  but is expressed under anaerobic conditions in the presence of fumarate, whereas succinate dehydrogenase is induced

under aerobic conditions and repressed under anaerobic conditions. Fumarate reductase is bound to the cytoplasmic face of the cytoplasmic membrane [JGM (1984) 130 2851–2855]; fumarate respiration thus requires a fumarate transport system. Fumarate reductase in *E. coli* consists of an FAD-containing protein subunit (*frdA* gene product), an iron–sulphur protein subunit (*frdB* gene product), and two small, hydrophobic ‘anchor proteins’ (*frdC* and *frdD* gene products) which anchor the enzyme in the membrane; these four cistrons occur in an operon with a promoter–operator region and a transcriptional terminator. The energy yield of fumarate respiration in *E. coli* is uncertain, but has been calculated to be ca. 0.66 ATP/fumarate [MR (1984) 48 222–271].

In *Wolinella succinogenes*, fumarate is used as an electron acceptor for the oxidation of formate ( $HCOO^- + H^+ + \text{fumarate} \rightarrow \text{succinate} + CO_2$ ) or  $H_2$ , yielding, by oxidative phosphorylation, 1–2 ATP per fumarate reduced.

**fumigant** See FUMIGATION.

**fumigation** The exposure of an enclosed space (e.g. a horticultural glasshouse, a hospital room) to a gaseous or vapour-phase DISINFECTANT or STERILANT. Control of humidity is commonly important for effective fumigation. Agents used for fumigation (*fumigants*) include e.g. DAZOMET, ETHYLENE OXIDE, FORMALDEHYDE, SULPHUR DIOXIDE.

**fumitremorgin** A tremorgenic MYCOTOXIN produced e.g. by *Aspergillus fumigatus* and *Penicillium piscarium*.

**functional immunity** Syn. IMMUNITY (3).

**fungaemia** (fungemia) The presence of fungi in the bloodstream.

**fungemia** See FUNGAEMIA.

**fungi** (*sing.* fungus) Unicellular, multicellular or coenocytic, heterotrophic, eukaryotic MICROORGANISMS which do not contain chlorophyll (cf. ALGAE) and which characteristically form a rigid CELL WALL containing CHITIN and/or CELLULOSE (cf. PROTOZOA). In some taxonomic schemes [see e.g. Book ref. 64] the fungi are divided into two divisions: EUMYCOTA (‘true fungi’) and MYXOMYCOTA; since members of the Myxomycota are commonly regarded as protozoa, the following account refers specifically to the ‘true fungi’.

In most fungi the vegetative form (thallus) consists of hyphae (see HYPHA), while in e.g. many YEASTS the thallus is predominantly or exclusively unicellular (cf. DIMORPHIC FUNGI). (See also GROWTH (fungal).) The majority of fungi are non-motile; however, flagellated reproductive/disseminative forms are produced by many of the LOWER FUNGI. (Phylogenetically, motility is regarded as a ‘primitive’ feature among the fungi.)

Most fungi can reproduce asexually – often by the formation of conidia (see CONIDIUM). In sexual reproduction, interaction between individuals may involve e.g. anisogamy, GAMETANGIAL CONTACT, isogamy, oogamy (see MONOBLEPHARIDALES), or SOMATOGAMY. (See also PARASEXUAL PROCESSES.) Specialized asexual and/or sexual SPORE-bearing structures (see e.g. FRUITING BODY) are formed by most fungi; many are macroscopic, and some (e.g. the mushrooms and puffballs) may be several centimetres or more in size.

Fungi are osmotrophic chemoheterotrophs which, collectively, utilize substrates ranging from simple sugars to e.g. cellulose (see CELLULASES), HYDROCARBONS, LIGNIN, pectins (see PECTIC ENZYMES) and xylans (see XYLANASES). Energy-yielding metabolism may involve RESPIRATION and/or FERMENTATION. Although fungi are typically aerobic organisms, some are facultative or obligate anaerobes (see e.g. RUMEN).

The fungi are widespread in nature; most species are terrestrial, but some (see e.g. NIA, OOMYCETES, SPATHULOSPORALES) are

## Fungi Imperfecti

primarily or exclusively aquatic. [Review of marine fungi: Biol. Rev. (1983) 58 423–459.] The terrestrial species include free-living saprotrophs which occur e.g. in soil and dung; parasites and pathogens of man and other animals – see e.g. INSECT DISEASES, MYCOSIS, NEMATOPHAGOUS FUNGI (see also MYCOTOXINS); plant-pathogenic species – see e.g. DOWNY MILDEWS, POWDERY MILDEWS, RUSTS (sense 2) and SMUTS (sense 2); MYCOPARASITES; and fungi involved in other associations – see e.g. AMBROSIA FUNGI, FUNGUS GARDENS, LICHENS, MYCETOCYTE, MYCORRHIZA, TERMITE–MICROBE ASSOCIATIONS. Some of the aquatic fungi are pathogenic – see e.g. BLACK MAT SYNDROME, BURNED SPOT DISEASE, FISH DISEASES and OSTRACOBLABE IMPLEXA. (See also ANTI-FUNGAL AGENTS.)

Certain fungi are used commercially e.g. in the production of antibiotics (e.g. some PENICILLINS), enzymes (see e.g. PROTEASES), FERMENTED FOODS, INDUSTRIAL ALCOHOL and SINGLE-CELL PROTEIN. Fungi may also be important agents in the BIODETERIORATION of certain materials.

**Fungi Imperfecti** See DEUTEROMYCOTINA.

**fungicidal** Able to kill at least some types of fungus. (cf. FUNGISTATIC.)

**fungicide** See ANTIFUNGAL AGENTS.

**fungicidin** *Syn.* NYSTATIN.

**fungicole** Any organism which grows on or in fungi; hence *adj.* fungicolous.

**fungimycin** *Syn.* PERIMYCIN.

**fungistatic** Able to inhibit the growth and reproduction of at least some types of fungus. (cf. FUNGICIDAL.)

**fungitoxic** Toxic to fungi.

**fungus** See FUNGI.

**fungus ball** *Syn.* MYCETOMA (sense 2).

**fungus combs** See TERMITE–MICROBE ASSOCIATIONS.

**fungus gardens** Subterranean ‘gardens’ of fungi cultivated by parasol ants (Formicidae, subfamily Myrmicinae, tribe Attini). The ants cut leaf fragments or collect other organic particles and carry them to the nest, where the fragments are pulped, treated with faecal material, inserted into the garden, and inoculated with fungal mycelium acquired from established parts of the garden or – if a new garden is being started – from a small pellet of the fungus carried in an infrabuccal pocket at the back of the mouth. Hyphae growing in the garden commonly develop terminal swellings (variously called *bromatia*, *gongylidia* or *staphyla*), and these are eaten by adult ants and fed to the larvae; the fungi are the sole source of food for the larvae, but the adults may also feed on plant juices. The fungi appear to occur only in fungus gardens; they generally appear to be basidiomycetes of the genera *Auricularia*, *Agaricus* or *Lepiota*. The fungal hyphae contain proteases (as well as cellulases, pectic enzymes etc), but proteases are not secreted to any significant extent, and the fungi grow slowly if supplied with polypeptides as sole source of nitrogen. When the fungus is ingested by the ants, the enzymes pass through the ants’ gut and are still active in the faecal material. Thus, treatment of plant fragments with faecal material increases availability of amino acids by proteolysis, augmenting growth of the fresh inoculum of fungi, and probably also facilitates fungal penetration of the plant material by pectinolysis. [Book ref. 77, pp. 163–166.] The fungus is maintained in almost pure culture by the activities of the ants, although it is not clear how this is achieved. (See also INSECT–MICROBE ASSOCIATIONS.)

**fungus gnats** Small flies (family Mycetophilidae) whose larvae feed on fungal mycelium and fruiting bodies; fungus gnats (particularly *Sciara* spp) can cause severe damage in mushroom beds.

**funicular cord** See CYATHUS.

**funiculus** See CYATHUS.

**funoran** A mucilaginous sulphated galactan produced by *Gloiopeltis furcata*; it consists mainly of D-galactose and 3,6-anhydro-L-galactose residues, with some L-galactose residues. In Japan, funoran is used as an adhesive and sizing agent.

**Fur protein** A multifunctional regulatory protein encoded by the *fur* gene. In many bacteria, Fur is involved e.g. in the control of ferric iron uptake (hence ferric uptake regulator); for example, after uptake of adequate ferric iron in *Escherichia coli*, accumulated intracellular ferrous ions cause the Fur protein to repress transcription from various genes (e.g. *fep* genes) which encode cell envelope proteins involved in ferric iron uptake. Repression involves the binding of Fe<sup>2+</sup>–Fur to an operator sequence (the ‘iron box’) upstream of the coding region in the affected genes. (See also OPERATOR.) Fur has many functions other than iron regulation – e.g. in *Salmonella typhimurium* it is involved in the acid tolerance response [JB (1996) 178 5683–5691].

**furacin** Nitrofurazone: see NITROFURANS.

**furadantin** Nitrofurantoin: see NITROFURANS.

**furalexyl** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**furaltadone** See NITROFURANS.

**furamide** See DILOXANIDE.

**furazlocillin** A β-LACTAM ANTIBIOTIC which binds exclusively to PBP-3 (see PENICILLIN-BINDING PROTEINS).

**furazolidone** See NITROFURANS.

**furcellaran** (Danish agar) A sulphated galactan, similar to κ-CARRAGEENAN, isolated from *Furcellaria fastigiata*; it has been used as a gelling agent in the food industry.

**Furcellaria** See RHODOPHYTA.

**furfuraceous** Scuffy; covered with small scales.

**furcoumarin** *Syn.* PSORALEN.

**fuoviruses** See SOIL-BORNE WHEAT MOSAIC VIRUS.

**fuoxone** Furazolidone: see NITROFURANS.

**furuncle** *Syn.* BOIL.

**furunculosis** (1) A FISH DISEASE affecting mainly freshwater fish, particularly salmonids. Pathogen: *Aeromonas salmonicida*. The typical disease occurs in two forms. In the acute form external symptoms are usually absent; internal organs become inflamed and haemorrhagic, and death is usually rapid. In the subacute form furuncle-like swellings (containing necrotic tissue, blood and bacteria) appear on the body. A chronic, subclinical carrier state is also known. Infection may occur via gills or wounds; high temperature (12–19°C) is a predisposing factor. Atypical forms of the disease (‘ulcerative furunculosis’), caused by atypical strains of *A. salmonicida*, occur in salmonids and non-salmonids (e.g. goldfish) and involve progressive ulceration of skin and underlying muscle. (cf. ULCER DISEASE.)

*A. salmonicida* produces several extracellular toxins, including a leucocytolytic factor, proteases (‘caseinase’ and ‘gelatinase’), and two haemolysins: H-lysin and T-lysin; H-lysin is a broad-spectrum haemolysin [purification and properties: JGM (1985) 131 1603–1609], while T-lysin appears to be active specifically against trout RBCs. These products may, together, play a role in the pathogenicity of *A. salmonicida*.

(2) (*med.*) The (simultaneous or sequential) formation of a number of BOILS.

**furylfuramide** (AF-2) See NITROFURANS.

**fusarenon-X** See TRICHOETECENES.

**fusaric acid** (2-carboxyl-5-*n*-butylpyridine) A TOXIN produced – sometimes together with dehydrofusaric acid and 10-hydroxyfusaric acid – by several species of *Fusarium*. It apparently

damages plant cell membranes and may play a role in the pathogenesis of FUSARIUM WILT; the toxin can also inhibit plant polyphenol oxidases, thus possibly interfering with the host defence mechanisms. Some plants can convert fusaric acid to the less toxic *N*-methyl derivative.

**fusarotoxicosis** A MYCOTOXICOSIS due to toxins produced by FUSARIUM spp.

**Fusarium** A genus of economically important fungi (class HYPHOMYCETES) which form a septate mycelium and produce macroconidia and, in some species, microconidia and/or chlamydospores. The macroconidia are produced from phialides which are generally borne on sporodochia; they are hyaline, usually crescent-shaped and multiseptate, and each has a characteristically shaped *foot cell* (forming one pole of the macroconidium) in which a 'heel' is present. Microconidia are also formed from phialides and are usually single-celled and spherical or ovoid. Conidia intermediate in form between macro- and microconidia may be produced. Fusaria are notoriously variable in culture, often making identification difficult. Many species have teleomorphs in the Hypocreales (e.g. GIBBERELLA, NECTRIA), but some – e.g. *F. culmorum*, *F. oxysporum* – have no known teleomorph.

*Fusarium* spp have a world-wide distribution and occur e.g. in soil, decaying organic materials, etc. Some strains may be wholly saprotrophic, but the majority can also be weakly to highly pathogenic – mainly in plants and invertebrates; no strain appears to be obligately parasitic.

Examples of plant-pathogenic species: *F. avenacearum* (*Gibberella avenaceae*) and *F. culmorum* cause seedling blight, foot and root rot, and head blight in cereals; *F. coeruleum* causes DRY ROT (sense 2) in potatoes; *F. decemcellulare* causes gall formation on cacao pods; *F. graminearum* (*Gibberella zeae*) causes seedling blight and foot and root rots in small-grain cereals (cf. WHEAT SCAB), and stalk and ear rot of maize; *F. lateritium* (*Gibberella baccata*) causes wilt, dieback and canker in woody plants, bud rot in apples, etc; *F. moniliforme* (*Gibberella fujikuroi*) causes ear and stalk rot of maize, BAKANAE DISEASE of rice, PITCH CANKER of pines, etc; *F. nivale* causes pre-emergence blight, root rot and head blight of cereals (see also SNOW MOULD); *F. oxysporum* causes e.g. FUSARIUM WILT, a form of CELERY YELLOWS, and basal rots of bulbs and corms (e.g. *Narcissus*, tulips, gladioli); *F. poae* causes SILVER TOP in grasses; *F. solani* (*Nectria haematococca*) causes root rots in a wide range of plants; *F. sulphureum* (*Gibberella cyanogena*) can cause dry rot of stored potatoes. Many plant-pathogenic fusaria produce non-host-specific TOXINS (see e.g. FUSARIC ACID, LYCOMARASMIN, NAPHTHAZARINS), although the significance of these in pathogenesis is uncertain (cf. GIBBERELLINS). In chlamydospore-forming species the chlamydospores are believed to be the main agents of infection [Book ref. 131, pp. 71–93].

*Fusarium* spp can be important pathogens in e.g. crustacea (see e.g. BLACK GILL DISEASE and BURNED SPOT DISEASE) and insects – e.g. strains of *F. solani* can be pathogenic in larvae and adults of the Southern pine beetle *Dendroctonus frontalis*, and in the larvae of the elm beetle *Scolytus scolytus*, while *F. larvarum* and *F. lateritium* have been reported to be pathogenic in scale insects. Toxins such as the naphthazarin pigments may account for at least some of the insecticidal activity of these fungi. (See also AMBROSIA FUNGI.)

In man and other mammals, *Fusarium* spp are rarely pathogenic, although they may indirectly cause disease by producing mycotoxins in foodstuffs (see e.g. TRICHOTHECENES and ZEAREALONONE). Certain strains have been associated with e.g.

eye infections and skin lesions in man and animals; such infections are usually or always secondary to trauma or debilitation in the host.

In immunocompromised patients, invasive infection by *Fusarium* may mimic aspergillosis; a PCR-based examination may be useful for detecting this organism in clinical specimens [JCM (1999) 37 2434–2438].

*Fusarium* spp have been used commercially as sources of ENNIATINS, GIBBERELLINS for horticultural use, ZEAREALONONE derivatives for medical and veterinary use, and in the production of single-cell protein. (See also PAPER SPOILAGE and TIMBER STAINING.)

[Applied aspects: Book ref. 131.]

**fusarium wilt** A VASCULAR WILT caused by a *Fusarium* sp – usually *F. oxysporum* ('oxysporum wilt'). Strains of *F. oxysporum* may have a narrow, intermediate or wide host range: e.g. *F. oxysporum* f. sp. *cubense* infects banana plants ('Panama disease'); f. sp. *lini* infects flax; f. sp. *lycopersici* infects tomatoes (cf. LYCOMARASMIN); f. sp. *conglutinans* infects cruciferous plants; f. sp. *vasinfectum* infects e.g. coffee, cotton, cowpea, rubber (*Hevea*), soybean, and many other plants. Typical symptoms of fusarium wilts include brown or black vascular discoloration and wilting, sometimes preceded by e.g. epinasty, vein-clearing and leaf chlorosis; affected plants generally die.

**fusarubin** See NAPHTHAZARINS.

**Fuscidea** See LECIDEA.

**fusel oil** A mixture of higher alcohols (mainly amyl, isoamyl, isobutyl, and propyl alcohols) formed in small quantities as by-products of ALCOHOLIC FERMENTATION; the alcohols are formed by deamination, decarboxylation and reduction of amino acids, and from keto acid precursors of amino acids.

**fusicoffin** A toxin, produced by *Fusicoccum amygdali*, which can affect a range of plants. Fusicocin can increase the rate at which a plant loses water, e.g. by promoting the opening of stomata. It can also stimulate H<sup>+</sup> efflux across the plasmalemma, thus facilitating uptake of e.g. K<sup>+</sup> and certain energy-yielding substrates; this may at least partly account for the observed growth-promoting activity of fusicocin.

**Fusicoccum** A genus of fungi of the COELOMYCETES.

**fusidic acid** An ANTIBIOTIC synthesized e.g. by *Cylindrocarpum* spp (= *Fusidium coccineum*) and *Acronium* (*Cephalosporium*) spp; it is a steroid structurally related to cephalosporin P1 – with which it exhibits cross-resistance. Sodium fusidate (fucidin) is active (bacteriostatic) against Gram-positive bacteria, particularly staphylococci; it inhibits PROTEIN SYNTHESIS by binding to EF-G, preventing the dissociation of EF-G and GDP from the ribosome following translocation. The EF-Gs (= EF-2s) of certain archaeans (e.g. methanogens, halobacteria) are sensitive to fusidic acid, whereas those from e.g. *Desulfurococcus mobilis*, *Sulfolobus solfataricus*, *Thermococcus celer* and *Thermoplasma acidophilum* are insensitive [JB (1986) 167 265–271].

**Fusidium** See CYLINDROCARPON.

**fusiform** Spindle-shaped; tapered at both ends.

**Fusiformis** An obsolete bacteria genus. (See BACTEROIDES and FUSOBACTERIUM.)

**fusigen** A SIDEROPHORE produced by e.g. *Aspergillus* spp.

**fusion protein** (1) In e.g. viruses of the genus PARAMYXOVIRUS (e.g. Sendai virus): a protein which promotes fusion between host cells, as well as between virus envelope and cell membrane.

(2) (*biotechnol.*) A protein containing amino acid sequences from each of two distinct proteins; it is formed by the expression of a recombinant genetic construct prepared by joining together

## **Fusobacterium**

two coding sequences with their reading frames in phase. (See also GENE FUSION.) Fusion proteins are constructed for various purposes.

A fusion protein may be constructed e.g. in order to facilitate identification/detection/assay of a given gene product which (for any reason) may be difficult to identify, detect or assay on its own. In such cases, the gene in question may be fused with a (*partner* or *carrier*) gene such as the *lacZ* gene of *Escherichia coli*; this results in a fusion protein with the properties of  $\beta$ -galactosidase – which can be readily detected/assayed e.g. on media containing XGAL. Another type of partner gene is that encoding glutathione *S*-transferase (GST); the resulting fusion protein can be isolated e.g. by affinity chromatography (using glutathione in the stationary matrix). In this latter example GST is the *affinity tail* on the protein of interest.

If a given gene encodes an intracellular protein, the product may be made secretable by fusing the gene to a partner gene whose product is secreted; this may facilitate isolation of the required gene product.

Fusion may also be used to determine the intracellular location of a given gene product. For example, the location of the FtsZ protein during cell division in *Escherichia coli* has been studied by fusing *ftsZ* with the gene encoding GREEN FLUORESCENT PROTEIN – the (fluorescent) fusion protein being detected by fluorescence microscopy [PNAS (1996) 93 12998–13003]. Again, the gene for GFP has been fused with *smc* in a study on chromosome partitioning [GD (1998) 12 1254–1259]. [Other GFP fusions: TIM (1998) 6 234–238.]

Another use of fusion is to obtain the product of a gene which is normally not highly expressed – the gene of interest being fused downstream of a highly expressed partner gene in an expression vector. A well-chosen partner gene may also confer the additional benefit of greater solubility and/or stability.

If a fusion protein has been isolated it may be cleaved to yield separate products for each of the two genes. One method is to use a site-specific protease. An alternative approach is to use a chemical agent such as cyanogen bromide (which cleaves at methionine residues) or hydroxylamine (which cleaves between asparagine and glycine residues); potential problems with chemical agents include (i) possible cleavage at sites *within* the required protein, and (ii) unwanted chemical modification of the required protein.

Fusion is also useful for studying the *regulation* of gene expression. If the expression of a gene is difficult to monitor (owing, e.g. to difficulty in assaying the gene product) the activity of the gene's *promoter* may be studied separately by fusing it upstream of a promoter-less *reporter gene* – i.e. a gene whose product can be readily monitored and whose expression reflects the activity of the promoter. Reporter genes include those encoding e.g. galactokinase, chloramphenicol acetyltransferase (CAT) and green fluorescent protein. While this is generally a

useful experimental approach, certain reporter genes have been found to influence the activity of some promoters [JB (1994) 176 2128–2132].

(‘Fusion protein’ is also used to refer to the products of certain viral ONCOGENES – e.g. MYC.)

**Fusobacterium** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the human mouth and intestine, and in the RUMEN, and which include human and animal pathogens (see NECROBACILLOSIS and FOOT-ROT; see also SWINE DYSENTERY). Cells: typically fusiform or non-fusiform rods or filaments; all species are non-motile. Fermentation of peptone or carbohydrates yields butyric acid as a major product; isobutyric and isovaleric acids are not formed, but small amounts of acetic, formic, lactic or propionic acids may be formed. Optimum growth temperature: ca. 37°C. GC%: ca. 26–34. Type species: *F. nucleatum*.

*F. necrophorum* (formerly *Fusiformis necrophorus*, *Sphaerophorus necrophorus*). Fusiform or round-ended cells. Propionate is formed from both threonine and lactate; aesculin is not hydrolysed; indole +ve; copious gas is usually formed from glucose.

*F. nucleatum* (formerly *Fusiformis fusiformis*, *Fusobacterium polymorphum*, *Sphaerophorus fusiformis*). Cells: typically fusiform rods or filaments. Propionate is formed from threonine but not from lactate; aesculin is not hydrolysed; indole +ve; typically, little gas is formed from glucose.

Other species: *F. gonidiaformans*, *F. mortiferum*, *F. naviforme*, *F. necrogenes*, *F. perfoetens*, *F. prausnitzii*, *F. russii* and *F. varium*.

**Fusulina** See FORAMINIFERIDA.

**fusulinids** See FORAMINIFERIDA.

**Fusulinina** See FORAMINIFERIDA.

**futile cycle** The cyclic interconversion of two compounds by irreversible reactions catalysed by two or more enzymes which are active at the same time within a given cell, the result being an apparently useless dissipation of energy. For example, in e.g. *Escherichia coli* phosphofructokinase catalyses ATP-dependent phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate [see Appendix I(a)], and fructose bisphosphatase hydrolyses fructose 1,6-bisphosphate to fructose 6-phosphate and inorganic phosphate (Pi) (see GLUCONEOGENESIS); if both enzymes were to be active simultaneously, the net result would be the hydrolysis of ATP to ADP + Pi. Presumably, futile cycles are normally prevented by control of the presence/activity of enzymes with opposing functions; however, they may have a role under certain conditions: e.g., it has been suggested that a futile cycle that results in ATP hydrolysis could provide Pi from endogenous ATP when the exogenous supply of Pi is interrupted [ARM (1984) 38 459–486 (471–473)].

**FV3** FROG VIRUS 3.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see ‘Notes for the User’ at the front of the Dictionary.

# G

**G** (1) Guanine (or the corresponding nucleoside or nucleotide) in a nucleic acid. (2) Glycine (see AMINO ACIDS).

**G-actin** See ACTIN.

**(G + C)% value** See GC%.

**G loop** If the DNA of BACTERIOPHAGE MU is extracted from virions obtained by induction of a lysogenic population of bacteria and is then denatured and re-annealed, a proportion of the resulting dsDNA molecules show a 'bubble' or loop of unpaired strands in the G region of the DNA; this loop – the *G loop* – reflects localized non-homology generated by inversion of the G segment during lysogeny. (G loops are rarely observed in phage DNA derived from lytic infections.)

**G phases** (of cell cycle) See CELL CYCLE.

**G proteins** (GTP-binding proteins) In eukaryotic cells: GTP-binding proteins involved mainly in intracellular signalling. There are two main types of G protein: (i) the heterotrimeric type (each G protein consisting of  $\alpha$ ,  $\beta$  and  $\gamma$  subunits), and (ii) the (smaller) proteins of the Ras superfamily (= p21 family).

Heterotrimeric G proteins are characteristically associated with the cytoplasmic domain of certain transmembrane receptors (e.g. the receptors for CHEMOKINES). (See also ADENYLATE CYCLASE.) In the inactive state, a GDP residue binds to the  $\alpha$  subunit of the protein. During activation of the G protein (through receptor–ligand binding), the  $\alpha$  subunit separates from the other two subunits (which stay together), and GDP on the  $\alpha$  subunit is exchanged for GTP; when activated in this way (i.e. when binding GTP), the  $\alpha$  subunit can behave as an effector molecule in the signalling pathway – as can the  $\beta + \gamma$  entity. During de-activation of the G protein, GTPase activity (inherent in the  $\alpha$  subunit) cleaves the terminal phosphate from GTP – so that the  $\alpha$  subunit is then bound to GDP; the  $\alpha$  subunit (with bound GDP) then re-associates with  $\beta + \gamma$  to form the inactive G protein.

G proteins of the Ras superfamily interact with several factors during their cycle of activation and de-activation. During activation, a guanosine nucleotide exchange factor promotes the exchange of (bound) GDP for GTP; the activated G protein (i.e. with bound GTP) can then act as an effector molecule in the signalling pathway. During de-activation, a GTPase-activating factor stimulates the latent GTPase activity of the G protein, thus giving rise to the inactive (GDP-bound) state. Another factor – guanosine nucleotide dissociation inhibitor – inhibits the exchange of GDP for GTP.

**G<sub>1</sub>-event model** See CELL CYCLE.

**Gaeumannomyces** A genus of fungi of the order DIAPORTHALES. *G. graminis* (formerly *Ophiobolus graminis*), the causal agent of TAKE-ALL, forms dark, thick-walled perithecia which occur immersed in leaf sheaths and stem bases with their beaks (i.e., necks) protruding; the ascospores are septate, filiform or fusiform. (See also MYCOVIRUS.)

**Gaeumannomyces graminis virus** See MYCOVIRUS.

**gaffkaemia** (gaffkemia) A fatal septicaemic disease of lobsters (*Homarus* spp) caused by *Aerococcus viridans* (formerly *Gaffkya homari*); infection occurs via breaks in the integument.

**Gaffkya** An obsolete bacterial genus [*nom. rejic.* IJSB (1971) 21: 104–105]. (See also AEROCOCCUS and PEPTOSTREPTOCOCCUS.)

**gag gene** See RETROVIRIDAE.

**gal operon** See OPERON and OPERATOR.

**galactan** A polymer of GALACTOSE: see e.g. AGAR; AMYLOVORIN; CARRAGEENAN; FUNORAN; FURCELLARAN; GALACTOCARULOSE; PECTIC POLYSACCHARIDES.

**galactitol** (dulcitol) The POLYOL corresponding to galactose. It occurs in certain HONEYDEWS, in two red algae (*Iridaea laminarioides* and *Bostrychia scorpioides*), in certain yeasts and other fungi, and in certain higher plants. Galactitol can be metabolized e.g. by a number of fungi.

**galactocarolose** An extracellular polysaccharide from *Penicillium charlesii*; it consists of (1 → 5)-linked D-galactofuranosyl residues.

**galactose** An aldohexose; both D- and L-forms occur naturally. Galactose is found e.g. in GALACTANS, LACTOSE, MELIBIOSE, RAFFINOSE and STACHYOSE. Many bacteria can metabolize galactose; uptake may involve a PEP-PTS or permease transport system, and subsequent metabolism may involve the tagatose 6-phosphate or Leloir pathways, respectively – see Appendix III(a).

**galactose 1-phosphate pathway** *Syn.* Leloir pathway: see LACTOSE and Appendix III(a).

**$\beta$ -galactosidase** (lactase;  $\beta$ -D-galactoside galactohydrolase; EC 3.2.1.23) An ENZYME which hydrolyses LACTOSE to glucose and galactose. (cf. ALLOLACTOSE.)  $\beta$ -Galactosidases are produced by a range of microorganisms and are obtained commercially mainly from yeasts (e.g. *Kluyveromyces marxianus*) or moulds (e.g. *Aspergillus* spp). The commercial enzyme is used mainly to hydrolyse the lactose in milk and milk products (to make them acceptable to lactose-intolerant consumers, to increase their sweetness, and to avoid crystallization of lactose in frozen or condensed milk products) and in WHEY (to make it more amenable as a microbial substrate). (See also ONPG TEST and XGAL.)

**galacturonan** A polysaccharide composed of galacturonic acid residues – see PECTINS.

**galacturonic acid** The URONIC ACID corresponding to galactose. (See also PECTINS.)

**Galerina** See AGARICALES (Cortinariaceae).

**gall** See GALLS.

**Gallego's solution** See BROWN–HOPPS MODIFICATION.

**gallid herpesviruses 1 and 2** See GAMMAHERPESVIRINAE.

**gallid herpesvirus 3** See HERPESVIRIDAE.

**Gallionella** A genus of Gram-negative, microaerophilic IRON BACTERIA. The cells are stalked and are coccoid to kidney shaped; they divide by binary fission, the non-stalked daughter cell being flagellated. The stalk consists of a bundle of (apparently inanimate) fibrils. Metabolism is apparently chemolithoautotrophic; energy appears to be obtained by the oxidation of Fe<sup>2+</sup> (thus accounting for the deposition of ferric hydroxide during growth). (See also EXTRACYTOPLASMIC OXIDATION.) Type species: *G. ferruginea*.

**galls** (cecidia) (*plant pathol.*) Abnormal plant structures formed e.g. in response to parasitic attack by certain insects or microorganisms. Galls may develop either by localized cell proliferation or increase in cell size. In at least some cases gall-formation involves a PHYTOHORMONE imbalance. Gall-inducing organisms often exhibit considerable host specificity; the host plant is rarely killed.

## galvanotaxis

Bacterium-induced galls include e.g. CROWN GALL, FASCIATION (some instances), HAIRY ROOT, and OLIVE KNOT; galls can also be induced by *Erwinia herbicola*. (See also ROOT NODULES.)

Fungus-induced galls (*mycoecidia*) include e.g. CLUBROOT, WART DISEASE and WITCHES' BROOM; galls are also induced by e.g. *Albugo candida* on certain crucifers, by some smut fungi (see SMUTS sense 2), and by members of the EXOBASIDIALES. (See also 'cedar apples' under GYMNOSPORANGIUM.)

Virus-induced galls include those caused by the RICE GALL DWARF VIRUS and the WOUND TUMOUR VIRUS. (See also ENATIONS and FIJI DISEASE.)

**galvanotaxis** A TAXIS in which the stimulus is an electrical potential gradient. An organism may move (with its anterior end pointing in the direction of motion as in normal motility) towards the cathode (negative galvanotaxis) or anode (positive galvanotaxis). *Paramecium* is said to be negatively galvanotactic, but with a higher potential difference it may move towards the anode with its (normally) posterior end leading. Some protozoa are positively galvanotactic.

**Gambierdiscus** See CIGUATERA.

**gametangial contact** (gametangy) A process in which one or more male nuclei pass from a male gametangium to a female gametangium either (according to species) via a pore which develops at the point of contact of the two gametangia, or via a TRICHOGYNE which grows between the gametangia.

**gametangial copulation** The occurrence of plasmogamy and karyogamy in a process which may involve either the complete fusion of two gametangia ('gametangial fusion') or the transfer of the contents of one gametangium into the other.

**gametangial fusion** See GAMETANGIAL COPULATION.

**gametangium** A structure which gives rise to gametes or which, in its entirety, functions as a gamete.

**gametangy** *Syn.* GAMETANGIAL CONTACT.

**gamete** A haploid cell or nucleus involved in sexual reproduction – during which two gametes fuse to form a zygote. (See also ANISOGAMY; ISOGAMY; OOGAMY.)

**gametic meiosis** MEIOSIS, in a meiocyte other than a zygote, preceding gamete formation in a life cycle in which DIPLOPHASE predominates. (cf. ZYGOTIC MEIOSIS.)

**gametocytaemia** The presence in the bloodstream of gametocyte stages of a parasite.

**gametocyte** Any cell which gives rise to gamete(s); a gametocyte may be haploid (see ALTERNATION OF GENERATIONS) or diploid (see GAMETIC MEIOSIS).

**gametogony** (gamogony) (1) The formation of gametocytes and gametes. (2) The formation of gametes from gametocytes.

**gametophyte** See ALTERNATION OF GENERATIONS.

**gametothallus** See ALTERNATION OF GENERATIONS.

**gamma chain** (*immunol.*) See HEAVY CHAIN.

**gamma-delta** ( $\gamma\delta$ ) See entry Tn3.

**gamma globulins** A subclass of serum globulins (which includes the IMMUNOGLOBULINS) characterized by low electrophoretic mobility towards the anode – or, under certain conditions, movement towards the cathode (see ELECTROENDOSMOSIS).

**gamma interferon** See INTERFERONS.

**gamma particle** (1) See PSEUDOCAEDIBACTER. (2) (*mycol.*) In the zoospores of some members of the Chytridiomycetes (e.g. *Blastocladiella emersonii*): an ovoid particle, one or more of which appear to play a role in cyst wall formation; in *B. emersonii* the gamma particles (each ca. 500 nm diam.) exhibit chitin synthase activity. [Book ref. 175, pp. 544–545.]

**gamma-rays** ( $\gamma$ -rays) See IONIZING RADIATION.

**Gammacell** A laboratory apparatus used as a source of gamma-radiation. (See also IONIZING RADIATION.)

$\gamma\delta$  See entry Tn3.

**Gammerferon**<sup>TM</sup> See INTERFERONS.

**Gammaherpesvirinae** ('lymphotropic or lymphoproliferative group') A subfamily of viruses of the HERPESVIRIDAE (q.v.).

The prototype virus of the subfamily is the EPSTEIN-BARR VIRUS (human (gamma) herpesvirus 4; human herpesvirus 4, HHV4; type species of the genus *Lymphocryptovirus* [Inter-virol. (1986) 25 141–143]). Other herpesviruses which have been either accepted or proposed as members of the subfamily include *Herpesvirus saimiri* (main natural host: squirrel monkeys, *Saimiri sciureus*), equine herpesvirus 2 (EHV2); *Herpesvirus ateles* (main natural host: spider monkeys, *Ateles* spp.), gallid herpesvirus 1 (MAREK'S DISEASE VIRUS), gallid herpesvirus 2 (turkey herpesvirus) and leporid herpesvirus 1 (rabbit herpesvirus).

These gammaherpesviruses vary in the duration of their replication cycles and in the type of CPEs which they produce. They are generally able to replicate in lymphoblastoid cells, and some can also lyse epithelioid and fibroblastoid cells. In either B or T lymphocytes (according to virus), infection often does not result in the production of progeny virions; the viral genome may persist in the cells with minimal viral gene expression and no cell lysis, or cells may lyse without formation of complete virions. Latent infection in vivo appears to occur commonly in lymphoid cells.

Gammaherpesviruses are associated with the formation of tumours either in their natural hosts (see e.g. EPSTEIN-BARR VIRUS and MAREK'S DISEASE) or in experimental animals; for example, neither *Herpesvirus saimiri* nor *Herpesvirus ateles* are pathogenic in their main natural hosts but are highly oncogenic in marmosets (*Saguinus* spp) and in other New World primates, causing malignant tumours of the lymphatic system [review: Book ref. 139, pp 253–332].

The most recent addition to the subfamily is human (gamma) herpesvirus 8 (human herpesvirus 8, HHV8). The genome is reported to be ~170 kb but to vary in size in different isolates (owing to duplication events); it includes sequences which resemble those of various human regulatory genes (e.g. those encoding a CYCLIN and a CYTOKINE). HHV8 has a tropism for B lymphocytes (and also infects endothelial cells) and it has been associated with B-cell lymphomas and with KAPOSI'S SARCOMA. [HHV8 (review): Lancet (1997) 349 558–563. PCR-based study on specimens of biopsy-proven Kaposi's sarcoma: Am. J. Path. (1997) 150 147–153.]

Activation of latent HHV8 in vitro has been achieved by demethylation of the promoter region of a transactivator [PNAS (2001) 98 4119–4124].

**gamogony** *Syn.* GAMETOLOGY.

**gamone** A name used for various types of sex PHEROMONE.

For example, the two mating types of *Blepharisma japonicum* (types I and II) form, respectively, gamone 1 (= blepharmon; a glycoprotein) and gamone 2 (= blepharismone or blepharismin: calcium 3-(2'-formylamino-5'-hydroxybenzoyl)-lactate) [Book ref. 28, pp. 339–340].

**gamont** (1) *Syn.* GAMETOCYTE. (2) See ALTERNATION OF GENERATIONS.

**ganciclovir** A nucleoside analogue used as an ANTIVIRAL AGENT; it is activated by phosphorylation, intracellularly, and inhibits viral DNA synthesis. Ganciclovir is used mainly for the treatment of cytomegalovirus infections; it has a number of side-effects and is contraindicated in pregnancy.

**gangliosides** See SPHINGOLIPID.

**gangrene** (1) (*med., vet.*) Death of tissues or organs in the body owing to a deficiency in or loss of local blood supply. *Dry*

*gangrene* results from a gradual reduction in local blood supply, with darkening, drying and shrivelling of the tissues. *Moist gangrene* is sudden in onset, resulting e.g. from injury followed by bacterial infection and putrefaction; it may spread very rapidly. (cf. GAS GANGRENE; see also e.g. ERGOTISM.)

(2) (*plant pathol.*) A disease of stored potato tubers, caused by *Phoma exigua* (e.g. var. *foveata* in the UK), in which the tubers become decayed and hollow. Surface contamination of the tubers occurs during harvesting, an important source of the pathogen being pycnidia from senescent potato stems; infection occurs via wounds made during or after harvesting. The disease may be controlled with e.g. benomyl or thiabendazole. (See also POTATO DISEASES.)

**gangrenous coryza** *Syn.* MALIGNANT CATARRHAL FEVER.

**Ganoderma** See APHYLLOPHORALES (Ganodermataceae).

**Ganodermataceae** See APHYLLOPHORALES.

**gap** (in dsDNA) See NICK.

**GAR-936** See TETRACYCLINES.

**Gardner–Arnstein feline sarcoma virus** See FES.

**Gardnerella** A genus (*incertae sedis*) of catalase-negative, oxidase-negative, chemoorganotrophic, apparently Gram type-negative bacteria which occur in the human genital and urinary tracts and which are commonly associated with BACTERIAL VAGINOSIS. Cells: pleomorphic rods, ca.  $0.5 \times 1.5$ – $2.5 \mu\text{m}$ . The genus includes both obligately anaerobic and facultatively anaerobic strains. The organisms are nutritionally fastidious: little or no growth occurs on nutrient agar. Neither X FACTOR nor V FACTOR is required. Growth occurs e.g. on certain blood-containing media and on peptone–starch–D-glucose medium; most strains can grow aerobically on blood agar at  $35^\circ\text{C}$ . Clear ( $\beta$ ) haemolysis occurs on human (but not sheep) blood plates. Most strains ferment maltose (and some ferment lactose) forming acid but not gas. Nitrate is not reduced. Optimum growth temperature:  $35$ – $37^\circ\text{C}$ . GC%: ca. 42–44. Type species: *G. vaginalis* (formerly *Haemophilus vaginalis*). [Book ref. 22, pp. 587–591.]

**Gardneriella** See RHODOPHYTA.

**gari** A West African food made by the fermentation of cassava pulp. The essential organisms appear to be *Leuconostoc* and *Candida* spp.

**gas bladder** (*algol.*) *Syn.* PNEUMATOCYST.

**gas gangrene** A type of acute, rapidly spreading GANGRENE (sense 1) which typically results from the infection of a wound with certain anaerobic bacteria, particularly *Clostridium* spp (e.g. *C. perfringens* type A, *C. septicum*, *C. novyi*); these organisms produce a variety of extracellular enzymes (see CLOSTRIDIUM) which promote tissue destruction. The  $\alpha$ -toxin of *Clostridium perfringens* (which hydrolyses lecithin and also has sphingomyelinase activity) appears to be the major lethal toxin [Mol. Microbiol (1995) 15 191–202]. Gas gangrene may occur in e.g. subcutaneous tissues (clostridial CELLULITIS), muscle (clostridial myonecrosis), or internal organs. Infected tissues become necrotic, discoloured, and swollen with serosanguinous fluid and pockets of gas (hydrogen, carbon dioxide) produced by the clostridia; the gas exerts pressure on adjacent tissues, further disrupting the blood supply to these tissues and promoting spread of the gangrene. *Treatment*: e.g. surgery; antibiotic therapy; treatment with hyperbaric oxygen. (Other organisms occasionally implicated in gas gangrene include anaerobic streptococci and *Escherichia coli*; mixed infections also occur.)

**gas–liquid chromatography** See CHROMATOGRAPHY.

**gas vacuole** A subcellular organelle, found only in prokaryotes, which consists of clusters of hollow, cylindrical, gas-filled vesicles (*gas vesicles*). Gas vacuoles appear bright and refractile

under the light microscope. They occur in planktonic cyanobacteria, particularly bloom-forming species (e.g. *Anabaena flos-aquae*, *Trichodesmium*), and in certain archaeans and bacteria (e.g. strains of *Halobacterium*, *Methanosarcina*, *Pelodictyon* and *Rhodospseudomonas*).

In cyanobacteria, gas vacuole formation is usually constitutive, but it may be inducible in hormogonia (see HORMOGONIUM).

The gas vesicles of cyanobacteria are hollow cylinders with conical ends; they are ca. 60–250 nm in diameter and of variable length (e.g. 300 nm); they have a ribbed construction. Vesicles from other prokaryotes (including *Methanosarcina*) are generally similar in both morphology and construction (although they may differ in size), but those of *Halobacterium* are usually spindle-shaped.

Vesicles are composed of a rigid monolayer of a single type of protein (*gas vesicle protein* – GVP); they are permeable to gases but not to water. GVPs from e.g. cyanobacteria and halobacteria show some homology [JGM (1984) 130 2709–2715].

The primary function of a gas vacuole is to give buoyancy to the (free-floating) organism. Gas vesicles collapse when subjected to pressure (ca. 5 atmospheres for many freshwater cyanobacteria, ca. 50 atmospheres for *Trichodesmium*). The vesicles in some freshwater species can be collapsed by high turgor pressures within the cells, thus providing a mechanism whereby these cells can regulate their buoyancy and, hence, their position in the water: an increase in light intensity causes an increase in turgor pressure in the cell (due to light-stimulated accumulation of potassium ions and the accumulation of photosynthate), resulting in the collapse of part of the gas vacuole and hence loss of buoyancy. New gas vesicles form when the light intensity is low, thus increasing buoyancy. (There is some evidence that the GVP of collapsed vesicles disaggregates and may be re-used in the assembly of new vesicles [JGM (1984) 130 1591–1596].)

Another mechanism for the regulation of buoyancy occurs e.g. in *Oscillatoria agardhii* and in a strain of *Microcystis* [JGM (1985) 131 799–809]: when the intensity of light is high, gas vesicles do not collapse – but existing vesicles are ‘diluted out’ by cell growth and division.

**gas vesicle** (1) See GAS VACUOLE. (2) *Syn.* PNEUMATOCYST.

**gasohol** A mixture of gasoline and (up to ca 20% v/v) ethanol which is used as a fuel. (See also INDUSTRIAL ALCOHOL.)

**GasPak** An ANAEROBIC JAR which consists of a strong, cylindrical, transparent plastic (polycarbonate) chamber with a flat, gas-tight lid which is secured by means of a screw clamp. The jar is loaded (with e.g. plates), and an indicator of anaerobiosis (e.g. a pad soaked with a METHYLENE BLUE solution) is placed inside the jar. Water is then added to a small foil sachet containing (i) sodium borohydride and (ii) a mixture of powdered sodium bicarbonate and citric acid – which (with water) yield  $\text{H}_2$  and  $\text{CO}_2$ , respectively; the sachet is quickly placed in the jar in an upright position and the lid is clamped in place. Attached to the inside of the lid is a ‘cold’ catalyst (see MCINTOSH AND FILDES’ ANAEROBIC JAR) which promotes the elimination of  $\text{O}_2$ . Anaerobiosis within the jar develops within a few hours. Since this type of jar does not require evacuation, plates can be incubated upside down (i.e. lid-side down); this avoids the problem (which can arise with the McIntosh and Fildes’ jar) in which water of condensation drops from the inside of the Petri dish lid onto the agar surface.

**gasteroid** Refers to the type of fruiting body which is characteristic of fungi of the GASTEROMYCETES: angiocarpic, forming STATISMOPORES. (cf. AGARICOID.)

## **gasteroid basidiospore**

**gasteroid basidiospore** A term proposed for a BASIDIOSPORE which is *not* forcibly discharged from the basidium [BBMS (1983) 17 82–94 (86)]. (cf. STATISMOSPORE.)

**Gasteromycetes** A class of fungi (subdivision BASIDIOMYCOTINA) characterized by the formation of epigeal or hypogean, sessile or stipitate basidiocarps which undergo ANGIOCARPIC DEVELOPMENT and give rise to STATISMOSPORES. The typical basidiocarp consists of e.g. fleshy or cartilaginous fertile tissue (the GLEBA) enclosed by a limiting wall (PERIDIUM); in some species the basidiocarp contains a definite hymenium, while in others the fertile cells are scattered, singly or in groups, throughout the spore-bearing tissue. (See also CAPILLITIUM.) The dispersal of mature basidiospores depends e.g. on the disintegration or perforation of the peridium. Gasteromycetes occur typically as saprotrophs on soil, dead wood and dung; some species form mycorrhizal associations.

The orders [Book ref. 64, p. 160] are:

Gautieriales. Hymenium-forming, hypogean saprotrophs or mycorrhizal fungi.

Hymenogastrales. Hymenium-forming, typically hypogean saprotrophs, mycorrhizal fungi and parasites. Some authors include gasteroid members of the Russulales in this order. Genera include e.g. *Hymenogaster* and *Rhizopogon* (which forms mycorrhizal associations with conifers).

LYCOPERDALES (q.v.).

Melanogastrales. Hypogean or marine; mature gleba mucilaginous, lacking a true hymenium. Genera include *Melanogaster* and *NIA*.

NIDULARIALES (q.v.).

PHALLALES (q.v.).

Podaxales. An order which includes some of the SECOTIOD FUNGI.

SCLERODERMATALES (q.v.).

Tulostomatales. An order which includes the stipitate puffballs (e.g. *Battarrea*, *Calostoma*).

**gastric flu** A term sometimes used to refer to the syndrome caused by infection with *Influenzavirus* type B – in which some studies have recorded involvement of the gastrointestinal tract.

**gastroile** *Syn.* FOOD VACUOLE.

**gastroenteritis** Inflammation of the lining of the stomach and intestine (usually the small intestine), usually resulting in DIARRHOEA and vomiting. (cf. ENTERITIS.) It may be due e.g. to allergic reactions, chemical poisoning (e.g. by excessive alcohol consumption), or to microbial infection or toxins (see e.g. FOOD POISONING).

**gastrointestinal tract flora** The mammalian gastrointestinal tract is normally sterile at birth, but thereafter becomes rapidly colonized by a range of bacteria. The gut flora of the human infant initially includes *Lactobacillus* and *Bifidobacterium* spp, coliforms and clostridia, but the flora depends to some extent on diet: the gut of breast-fed infants contains a higher proportion of bifidobacteria and lactobacilli – and fewer coliforms – than that of infants bottle-fed on cows' milk [Book ref. 107, pp 1–26]. Acid production by the lactic acid bacteria is believed to discourage the growth of enterobacteria, including enteric pathogens. On weaning, the gut flora becomes more complex and soon resembles that of the adult.

In adult humans, many of the bacteria ingested with food (and oral bacteria swallowed with saliva) are killed by the acidity in the stomach. However, despite the normal acidity of the stomach, it appears that this region of the gut is colonized by *Helicobacter pylori* (see HELICOBACTER) in a high proportion of the human population. (A greater number and variety of organisms may be present in the stomach in cases of achlorhydria.)

Bacterial numbers (in colony-forming units/gram) increase from about  $10^3$  in the duodenum to about  $10^{11}$  in the colon. Anaerobes such as *Bacteroides* and *Fusobacterium* generally predominate but many other organisms are usually present – e.g. species of *Clostridium* and *Peptostreptococcus*, enterobacteria, various yeasts (e.g. *Blastocystis hominis*, *Candida* spp), protozoa (e.g. *Endolimax nana*, *Entamoeba* spp, *Trichomonas hominis*) and viruses such as enteroviruses.

The numbers and nature of the gut microorganisms may be affected by e.g. the nature of the diet, malnutrition, local immune responses, antibiotic therapy etc. Under certain conditions – e.g. abnormal peristalsis, trauma, diminished gut secretions – abnormally high numbers of bacteria may develop in the small intestine; symptoms of such 'bacterial overgrowth' include steatorrhoea, malabsorption of carbohydrates, and symptoms of iron and vitamin B<sub>12</sub> deficiencies. TRANSLOCATION (sense 2) of gut bacteria may occur normally but may sometimes lead to extraintestinal disease; however, the importance of translocation in pathogenesis has been questioned [Critical Care Medicine (2003) 31 598–607].

The microflora has various roles: (i) production of short-chain fatty acids – e.g. butyric acid (a nutrient for epithelial cells); (ii) recycling of BILE ACIDS. (iii) production of vitamin K (see QUINONES); (iv) stimulation of the gut immune system – helping to maintain a normal immune response; (v) inhibition of pathogens by competing for nutrients and space, and by producing antimicrobial agents (e.g. BACTERIOCINS) [Lancet (2003) 360 512–519]. (The gut epithelium also secretes antimicrobial peptides (e.g. *defensins*) [Nature (2002) 415 389–395, (2003) 422 478–479].)

However, a possible role for gut bacteria in the aetiology of carcinoma of the colon has been postulated: certain substances (particularly bile acids) in the gut may be metabolized by gut bacteria to potential carcinogens or co-carcinogens [Book ref. 107, pp 347–363]; the bacteria implicated include the so-called 'nuclear dehydrogenating clostridia' (NDC) which can desaturate the A-ring in various bile acid derivatives to form 4-ene-3-one structures [JMM (1985) 20 233–238]. (See also LIGNANS.) Certain gut parasites (e.g. *Entamoeba histolytica*) appear to require the presence of gut bacteria (as food) in order to establish infection.

**GATC** Dam methylation site: see DAM GENE.

**gatifloxacin** A QUINOLONE ANTIBIOTIC (q.v.).

**gating** The switching on or off of a function or facility as a consequence of the value of a given parameter reaching a critical level. Thus, e.g., certain transport systems and membrane PROTON ATPASE activity are inhibited when proton motive force falls below a certain level.

**Gäumannomyces** *Syn.* GAEUMANNOMYCES.

**Gautieriales** See GASTEROMYCETES.

**Gazdar murine sarcoma virus (Gz-MSV)** A MURINE SARCOMA VIRUS originally isolated from a spontaneous tumour in a (NZB × NZW)F1 mouse. Gz-MSV resembles MOLONEY MURINE SARCOMA VIRUS (Mo-MSV) in containing *v-mos*, but the *mos* sequence is inserted at a different location in the genome. The pathologies of Gz-MSV and Mo-MSV infections are similar.

**Gb<sub>3</sub>** See SHIGA TOXIN and STARFISH.

**GC%** (GC value; %GC value; %G + C value; mol% G + C; etc) Of (usually chromosomal) DNA: the ratio (G + C)/(A + T + G + C) in which G, C, A and T represent the relative molar amounts of guanine, cytosine, adenine and thymine, respectively, in a given organism; the ratio is expressed as a percentage. (cf. BASE RATIO.) GC% values vary according to genus and species,

and provide a useful criterion in microbial TAXONOMY; however, a similarity in GC% values, by itself, does not necessarily indicate a close taxonomic relationship. The possession of a PLASMID (particularly one with a high copy number) may affect the observed GC% value of a cell unless the method used for extracting chromosomal DNA discriminates against extrachromosomal nucleic acids.

The GC% of a DNA sample may be obtained, indirectly, by determining its 'melting point' ( $T_m$ : see THERMAL MELTING PROFILE), since  $T_m$  is linearly related to GC% (i.e., a high  $T_m$  correlates with a high GC%). Alternatively, an indirect determination of GC% may be achieved by buoyant density (Bd) measurement (e.g. in a CsCl density gradient – see CENTRIFUGATION) since Bd is also linearly related to GC%.

GC% values in bacteria fall within the approximate range 25–75; as a guideline, intra-species variation should be not more than 4–5% and intra-genus variation not more than 10% [Book ref. 59, p. 14].

[Methods for determining DNA base composition: Book ref. 138, pp. 1–31.]

**GC type** See BASE RATIO.

**GDP** Guanosine 5'-diphosphate.

**Geastrum** See LYCOPERDALES.

**gel diffusion** In serology: gel diffusion (= immunodiffusion) refers to any procedure in which antibodies (usually in an antiserum) and/or antigens diffuse through a gel medium (e.g. AGAR or agarose) – forming a precipitate in the gel where homologous (or cross-reacting) antigens and antibodies meet in OPTIMAL PROPORTIONS. (Agar/agarose at concentrations of ca. 0.5% to 1.5% allows the diffusion of antibody-sized molecules but hinders random mechanical and thermal movements in the medium.) Lines, bands or haloes of whitish precipitate are obtained (within hours or a day or two) in number(s) and position(s) which depend on the number and nature of the homologous (or cross-reacting) pairs of antigens and antibodies within the diffusing system. The precipitate may or may not be visible to the naked eye; visibility may be enhanced by washing the gel free of uncombined antigen and antibody, and staining the precipitate in situ with a protein stain (e.g. COOMASSIE BRILLIANT BLUE).

Gel diffusion may involve SINGLE DIFFUSION or DOUBLE DIFFUSION of the single- or double-DIMENSION type. (See also IMMUNOELECTROPHORESIS and ELEK PLATE.)

**gel electrophoresis** See ELECTROPHORESIS.

**gel filtration** (molecular sieving) A method for separating molecules from a mixture by passing the mixture through a column of e.g. Sephadex, polyacrylamide, or agarose gel; molecules are separated primarily according to their size and shape.

**gelatin** The product obtained by boiling COLLAGEN. Gelatin is soluble in water at temperatures above ca. 40°C, and a solution of concentration >ca. 1–2% (w/v) forms a gel on cooling below ca. 28–35°C; gels of ca. 4–12% are used e.g. to test the ability of certain microorganisms to liquefy (i.e., hydrolyse) gelatin (see GELATINASE). (See also FRAZIER'S MEDIUM.)

**gelatinase** A GELATIN-hydrolysing enzyme. Gelatin can be hydrolysed (to soluble oligopeptides) by clostridial COLLAGENASES and by any of a range of extracellular proteolytic enzymes produced e.g. by various bacteria and fungi. The activity of many gelatinases requires, or is stimulated by, calcium ions.

**Gelbstoff** Collectively, the various dissolved and colloidal organic substances which occur e.g. in lakes and coastal waters and which may absorb significant amounts of light – particularly at the blue end of the spectrum.

**Geleia** See KARYORELICITID GYMNOSTOMES.

**Gelidium** See RHODOPHYTA.

**gellan gum** An extracellular polysaccharide produced by '*Pseudomonas elodea*'. Gellan gum is a linear polymer containing residues of glucose, rhamnose and glucuronic acid which may be mainly (1 → 4)-β-linked; the polymer may be O-acetylated. In water containing monovalent or divalent cations, gellan gums form gels on heating and cooling; the nature of the gel depends on the degree of acetylation – the more de-acetylated the polymer the firmer and more brittle the gel.

A clarified, de-acetylated form of gellan gum (*Gelrite*; Kelco, San Diego, USA) can be used as a substitute for AGAR in bacteriological media; the setting temperature varies from 35°C to >50°C, depending on the concentrations of *Gelrite* and cations. The gels can be re-melted under standard autoclaving conditions. *Gelrite* gels containing 0.1% calcium chloride are not prone to SYNERESIS at high temperatures (unlike agar gels) and may thus be suitable for use in media for thermophiles. *Gelrite* may also be used e.g. as a substitute for agarose in gel electrophoresis (*Gelrite* gels are clearer than agar gels).

*Gelrite* has been investigated for use as a gelling agent, in place of agar, in transport media used for PCR-based studies. This investigation was prompted by the finding that agar inhibits PCR in a concentration-dependent manner [JCM (1998) 36 275–276], an observation suggesting that detection of pathogens by PCR can be inhibited by the use of an agar-containing transport medium (such as STUART'S TRANSPORT MEDIUM). These studies yielded superior results from gellan gum, inhibition of PCR occurring with agar [JMM (2001) 50 108–109].

In industry, the polymer may be useful e.g. as a substitute for pectins or gelatin in jams, jellies etc. or as a matrix for the IMMOBILIZATION of cells or enzymes. [Book ref. 62, pp 231–253.]

**Gelman filter** See FILTRATION.

**Gelrite** See GELLAN GUM.

**gelsolin** See ACTIN.

**Gemella** A genus of Gram-type-positive bacteria of the family Streptococcaceae; the organisms occur e.g. in the mammalian respiratory tract. Cells: cocci (diam. <1 μm), which occur singly or in pairs. Colonies on rabbit- or horse-blood agar are each surrounded by a zone of clear haemolysis. GC%: ca. 33. Type species: *G. haemolysans*.

**gemifloxacin** A QUINOLONE ANTIBIOTIC (q.v.).

**geminiviruses** A group of small, ssDNA-containing PLANT VIRUSES in which the virions have a unique morphology: each consists of a pair of isometric particles (incomplete icosahedra, each ca. 18 × 20 nm), composed of a single type of protein (MWt ca. 2.7–3.4 × 10<sup>4</sup>). The group includes: MAIZE STREAK VIRUS (MSV; type member), BEAN GOLDEN MOSAIC VIRUS (BGMV), cassava latent virus (CLV), *Chloris* striate mosaic virus (CSMV), tomato golden mosaic virus (TGMV; possibly = tomato yellow mosaic virus). Probable members include: beet curly top virus (BCTV), *Euphorbia* mosaic virus, mung-bean yellow mosaic virus, *Paspalum* striate mosaic virus, tobacco leafcurl (= tomato yellow dwarf) virus, tobacco yellow dwarf virus (TYDV; = bean summer death virus), tomato yellow leafcurl virus, wheat dwarf virus. Each virus has a narrow host range; some cause economically important diseases in cultivated plants, symptoms including e.g. curling and distortion of the leaves (e.g. BCTV) or chlorosis (e.g. BGMV). Depending on virus, transmission occurs via leafhoppers or whitefly – in which the viruses are persistent (circulative).

Each geminivirus virion contains one molecule of circular, positive-sense ssDNA, MWt ca. 7–8 × 10<sup>5</sup> (<2.6 kb). In

## gemma

some (whitefly-transmitted) members (e.g., CLV, BGMV, TGMV) the genome appears to be bipartite, i.e., two ssDNA molecules – similar in size but differing in nucleotide sequence – are present in a given population of virions [nucleotide sequence of CLV genome: *Nature* (1983) 301 260–262, and of BGMV: *PNAS* (1985) 82 3572–3576]; however, the (leafhopper-transmitted) members CSMV and (possibly) TYDV seem to have only one type of ssDNA [Book ref. 80, pp. 59–62]. Virus replication occurs in the plant cell nucleus, where large aggregates of virus particles accumulate. There is evidence (at least in the case of BGMV and TGMV) that replication may involve a supercoiled ccc dsDNA intermediate (which may also act as a template for transcription), and that a rolling circle mechanism may be involved [Book ref. 80, pp. 49–58]. [Model for gene regulation in geminiviruses: *PNAS* (1985) 82 3572–3576.]

[Review: *ARPPATH*. (1985) 23 55–82; *AVR* (1985) 30 139–177.]

**gemma** A thick-walled, irregularly-shaped or spheroidal, asexually derived spore formed by certain fungi (e.g. *Saprolegnia* spp) from a portion of a somatic hypha; gemmae may be formed singly or in chains.

**Gemmata obscuriglobus** A species of freshwater BUDDING BACTERIA; the life cycle includes a multitrifid swarmer stage. GC%: ca. 64. [*AvL* (1984) 50 261–268.]

**Gemmiger** A genus of Gram-variable, anaerobic, budding bacteria which can ferment carbohydrates to butyric acid. Cells: cocci, occurring in pairs or chains. GC%: ca. 59. [*G. formicilis* in the avian caecum: *JAB* (1983) 54 7–22.]

**gen. nov.** See GENUS NOVUM.

**gene** A sequence of nucleotides in a genetic nucleic acid (chromosome, plasmid etc) which encodes a functional polypeptide chain or RNA molecule (rRNA, tRNA, etc). In certain cases a gene may share a sequence with another gene (see OVERLAPPING GENES); some genes contain non-coding sequences (see e.g. MRNA and SPLIT GENE). (See also ALLELE; CISTRON; GENETIC CODE; PSEUDOGENE.)

**gene amplification** The generation of multiple copies of one or more genes in a cell or nucleus – e.g. as an arrangement of tandemly repeating genes within a chromosome, or in the form of extrachromosomal elements (see e.g. RRNA). (See also GENE DOSAGE.) Amplification occurs in both eukaryotic and prokaryotic cells. For example, in some mammalian cells in culture (and in bacteria) resistance to certain drugs involves the amplification of genes specifying enzymes which either detoxify or bypass the effects of the drug. [Gene amplification in eukaryotes: *ARB* (1984) 53 447–491.]

In bacteria, amplification occurs spontaneously at frequencies which depend e.g. on the location of the amplified sequences, and is generally readily reversible. Amplification of particular genes may help the organism to adapt to particular environmental conditions: e.g., a substrate normally used inefficiently by a given strain may be used more effectively following amplification of genes specifying the appropriate catabolic enzymes. Amplified regions are generally found to be flanked by directly repeated sequences, and amplification commonly appears to involve RecA-dependent homologous RECOMBINATION (e.g. between daughter molecules). [Possible mechanism: *CSH-SQB* (1984) 49 443–451.]

**gene bank** *Syn.* LIBRARY.

**gene cloning** See CLONING.

**gene cluster** A cluster of functionally related genes, each of which encodes a separate protein. (cf. CLUSTER GENE.)

**gene conversion** See RECOMBINATION.

**gene dosage** The number of copies of a given gene per cell or nucleus. Increased gene dosage may cause higher levels of gene product if the gene is not autogenously regulated.

**gene-for-gene concept** (*plant. pathol.*) See AVIRULENCE GENE.

**gene fusion** In genetic engineering: the fusion of two DNA sequences from different genes to form a ‘hybrid’ gene (see FUSION PROTEIN, sense 2). The term is sometimes used synonymously with OPERON FUSION. (See also MUDLAC SYSTEM.)

[Gene fusions (commentary): *JB* (2000) 182 5935–5938.]

**gene gun** A device for inoculating a DNA VACCINE directly into the epidermis; it bombards the surface with gold particles (~ 1 µm) that are coated with the target DNA. [Example of use: *Inf. Immun.* (2005) 73 2974–2985.]

**gene library** See LIBRARY.

**gene therapy** Genetic modification of certain cells specifically to correct an inherited disorder or to treat some infectious diseases; it has been successful e.g. with adenosine deaminase deficiency but has apparently caused leukaemia-like illness in one patient [*Nature* (2002) 420 116–118].

In the *ex vivo* mode, cells from the patient are modified *in vitro* and then re-introduced. For example, in ADENOSINE DEAMINASE DEFICIENCY the patient’s stem cells are supplemented with the normal, wild-type gene before re-introduction; lymphocytes – derived from the stem cells – can then develop normally. (In some cases stem cells from a normal (histocompatible) donor are introduced into the patient.) For selecting stem cells the CD34 marker can be used in immunomagnetic enrichment techniques (see DYNABEADS). In the *in vivo* mode, modification takes place within the patient.

Viruses used as vectors (for carrying genetic material into cells) include adenoviruses (see ADENOVIRIDAE), adeno-associated viruses (see DEPENDOVIRUS) and certain retroviruses (RETROVIRIDAE), e.g. lentiviruses. Viral vectors are genetically modified to be replication-deficient and non-pathogenic; the gene (etc.) to be introduced into cells is inserted into the viral genome and enters cells during infection.

Sequences/transgenes can be inserted into various types of dividing or non-dividing cell e.g. by AAVs (small sequences), adenoviruses (larger sequences) and lentiviruses.

With some viruses the broad range of host cells is problematic when specific type(s) of cell are to be targeted. In such cases a virus can be modified by PSEUDOTYPING – e.g. adenovirus type 5 was modified to produce a more specifically targeted vector [*JV* (2001) 75 2972–2981].

In CYSTIC FIBROSIS, respiratory epithelial cells have been targeted (via an inhaler) by LIPOSOMES containing the normal gene. [*Bioch. J.* (2005) 387 1–15.]

*Gene therapy against infectious diseases*

For this type of disease a wider range of modalities may be employed. For example, RIBOZYMES can be targeted to specific pathogen-associated RNA; useful activity was reported for the anti-*pol* ribozyme in infection by simian immunodeficiency virus (SIV) [*JGV* (2004) 85 1489–1496].

Intrabodies (= single-chain antibodies) are engineered antibodies that remain intracellular [see *NAR* (2003) 31 e23].

DNA VACCINES are being developed against e.g. *Mycobacterium tuberculosis* [*Inf. Immun.* (2005) 73 5666–5674] and *Leishmania donovani* [*Inf. Immun.* (2005) 73 812–819].

RNA INTERFERENCE (RNAi) has shown promise *in vitro* but pathogens may escape RNAi by mutation [e.g. *JV* (2004) 78 2601–2605; *Blood* (2005) 106 818–826].

Transdominant negative proteins (TNPs) – encoded e.g. in the genome of a viral vector – can be expressed in infected or pre-infected cells; TNPs may be engineered anti-function versions of particular pathogen-associated proteins which are necessary e.g. for the completion of a given phase of replication. A TNP may be inhibitory e.g. by forming an inactive complex with its wild-type counterpart or by competing with it for specific binding site(s).

One anti-AIDS concept is to modify CD34<sup>+</sup> bone marrow stem cells or CD4<sup>+</sup> T cells so that they inhibit HIV replication. In one *in vitro* study the TNP consisted of a modified form of the Rev protein (see HIV) whose functions include facilitating export of viral transcripts from the nucleus; HIV-1 replication was strongly inhibited [JV (2001) 75 3590–3599].

(See also TRIPLEX DNA.)

**gene transfer agent** See CAPSDUCTION.

**GeneAmp<sup>®</sup> *In situ* PCR System 1000** See IN SITU PCR.

**genera** Plural of *genus* (see TAXONOMY).

**general export pathway** See PROTEIN SECRETION.

**general recombination** See RECOMBINATION.

**general secretory pathway** See PROTEIN SECRETION.

**generalized transduction** See TRANSDUCTION.

**generation time** (of bacteria) *Syn.* doubling time – see GROWTH (b).

**generative hyphae** See HYPHA.

**generic** Of a genus; e.g. *generic name* (see BINOMIAL).

**genetic code** The ‘code’ in which information for the synthesis of proteins is contained in the nucleotide sequence of a DNA molecule (or, in certain viruses, of an RNA molecule). During PROTEIN SYNTHESIS, the coded information in DNA is initially transmitted to mRNA (q.v.), i.e., the deoxyribonucleotide sequence is transcribed into a complementary sequence of ribonucleotides. (In RNA viruses the viral RNA may itself function as mRNA, or may need to be transcribed into complementary RNA: see VIRUS.) The mRNA is then translated into one or more polypeptides, each amino acid of a polypeptide being encoded by a particular sequence of three nucleotides (called a *codon*) in the mRNA; an mRNA molecule contains a series of non-overlapping nucleotide triplets (codons) which, together, specify the amino acid sequence of a polypeptide. Polypeptide synthesis begins at a specific *initiator codon* in the mRNA (see PROTEIN SYNTHESIS), and the translating machinery reads the triplets sequentially from this point; thus, although (theoretically) triplets in a sequence of nucleotides could be read in three different ways (*reading frames*) – e.g. AUC-AUC-AUC-AUC or A-UCA-UCA-UCA-UC or AU-CAU-CAU-CAU-C – in practice the correct reading frame is determined by the fixed starting point. (cf. FRAMESHIFT MUTATION.) (N.B. The term *codon* is also applied to the corresponding triplet in the coding or non-coding strand of DNA.)

A codon does not interact directly with its corresponding amino acid; the amino acid must be linked to an adaptor molecule, tRNA (q.v.), which contains a triplet of nucleotides (the *anticodon*) complementary to the codon for that amino acid. For example, a codon ACG is recognized by a tRNA containing the anticodon CGU. (Codons and anticodons, like other nucleotide sequences, are conventionally written in the 5'-to-3' direction: hence, the *first* base in a codon pairs with the *third* base in the anticodon.)

The four bases (A, C, G and U) in mRNA can generate 64 possible triplet combinations; 61 of these encode 20 amino acids: i.e., in most cases an amino acid is encoded by two or more (*synonymous*) codons, a phenomenon called *degeneracy* (see table). The remaining three codons – UAA (*ochre codon*), UAG (*amber codon*) and UGA (*opal* or *umber codon*) – are *nonsense*

GENETIC CODE: the ‘universal’ code

First base (5' end)	Second base				Third base (3' end)
	U	C	A	G	
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	<i>ochre</i>	<i>opal</i>	A
	Leu	Ser	<i>amber</i>	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	Glu	Gly	G

*codons* (‘stop codons’, termination codons) which specify the termination of polypeptide chain synthesis. (cf READTHROUGH.)

The three bases of a codon do not contribute equally to the specificity of the codon: the 2nd base contributes maximally, the 3rd minimally; thus, certain codons which specify the same amino acid differ from each other only in the 3rd base (see table). (See also WOBBLE HYPOTHESIS.) There is some relationship between codons which specify related amino acids: e.g. all codons in which U is the 2nd base specify hydrophobic amino acids. [Hypothesis on the physicochemical rationale of the genetic code: FEBS (1985) 189 159–162.]

The frequency with which synonymous codons occur in mRNAs is believed to parallel the population sizes of the corresponding tRNAs in the cell, i.e., the most commonly used codons correspond to the most abundant of the isoaccepting tRNA molecules. The codons in a given gene may thus affect the rate of translation of that gene; e.g., it has been suggested that the presence of rare codons in sequences encoding signal peptides (see SIGNAL HYPOTHESIS) may serve – or may have served at some evolutionary stage – to delay translation, allowing time for the ribosome–polypeptide complex to become associated with the cell membrane [FEBS (1985) 189 318–324]. (See also CODON BIAS.)

The genetic code as shown in the table is often said to be ‘universal’, i.e., applicable to all living systems. However, there are exceptions. For example in at least some plant, animal and fungal mitochondria – and apparently also in *Mycoplasma capricolum* [PNAS (1985) 82 2306–2309] – UGA functions not as a stop codon but as a sense codon specifying tryptophan; in mammalian mitochondria AUA specifies methionine, while AGA and AGG function as stop codons. In the ciliate MACRONUCLEUS, UAA and UAG specify glutamine, UGA apparently acting as the sole stop codon. It is believed that these distinct codes must have evolved from a common, more primitive code rather than one from another. [Evolutionary aspects: MR (1992) 56 229–264.]

**genetic drift** Changes in the genotype of a species or strain which are due not to selection pressures but to the persistence of neutral mutations, i.e., mutations which appear to be neither

## genetic engineering

advantageous nor disadvantageous to the organism. (cf. ANTI-GENIC DRIFT.)

**genetic engineering** The in vitro manipulation of nucleic acid molecules e.g. to generate new combinations of genes or sequences (see e.g. FUSION PROTEIN), to place a given gene or genes under the control of a different regulatory system (see e.g. OPERON FUSION), to introduce specific mutations into a molecule (see SITE-SPECIFIC MUTAGENESIS), etc. The 'engineered' DNA may be produced in quantity by any of various CLONING techniques. (See also BIOTECHNOLOGY.)

**genetic footprinting** A procedure which may be used to determine the need for expression of each of a range of specific genes during growth under particular, chosen conditions. (cf. FOOTPRINTING.) The procedure involves three stages. Initially, a population of cells is subjected to transposon mutagenesis, transposons inserting randomly and extensively in the genome; from this mutagenized population, a sample (labelled T0, for time zero) is taken and set aside for subsequent analysis. The remainder of the mutagenized cells are then grown for many population doublings under conditions that repress further transposition. Finally, genomic DNA is isolated from (i) cells of the T0 population and (ii) cells of the cultured mutagenized population, and PCR is used to amplify sequences from specific genes from each of these two groups of cells. If a given gene is necessary for viability under particular growth conditions, then transposon insertions may be detected in that gene from the T0 population, but fewer (or none) will be found in that gene from cultured populations of the cells. [Genetic footprinting in bacteria (*Escherichia coli*): JB (2001) 183 1694–1706.]

(See also IVET.)

**genetic immunization** The use of a DNA VACCINE. (See also FILOVIRIDAE.)

**genetic reactivation** See REACTIVATION.

**genetic vaccination** The use of a DNA VACCINE. (See also FILOVIRIDAE.)

**genital herpes** See HERPES SIMPLEX.

**genital wart** See PAPILLOMA.

**genitourinary tract flora** The distal part of the human urethra (in either sex) may harbour any of a range of organisms which include various Gram-positive cocci (e.g. *Staphylococcus* spp), Gram-negative bacteria (e.g. species of *Acinetobacter*, *Escherichia*), and yeasts (e.g. *Candida albicans*); in the female, the urethral microflora is generally influenced by the resident vaginal flora (see VAGINA MICROFLORA). The microflora of the external genitalia in both sexes may include those organisms mentioned above together with e.g. various coliform bacteria and *Mycobacterium smegmatis*. (See also UREAPLASMA.) Other regions of the genitourinary tract (e.g. urinary bladder, ureters) do not normally have a resident microflora. (See also BODY MICROFLORA and URINARY TRACT INFECTION.)

**genome** A term which is used with various meanings, including the following:

(1) The genetic material of an organism. For example: (i) the chromosome in a bacterial cell (or one of each type of chromosome if more than one type is present – e.g. both the small and large chromosomes in *Vibrio cholerae* [Nature (2000) 406 477–483]); (ii) the DNA or RNA in a virion; (iii) the chromosome(s) together with any associated plasmids – for example, the chromosome and the two small plasmids in the bacterium *Buchnera* [Nature (2000) 407 81–86].

(2) All the (different) genes in a cell or virion.

(3) The *haploid* set of chromosomes or genes in a cell.

The 'complete genome sequence' (i.e. the complete sequence of nucleotides in the genome) has been published for a number of

bacterial species – references for some of them can be found in the entry BACTERIA. Sequences have also been published e.g. for the genome of the plant *Arabidopsis thaliana* [Nature (2000) 408 791–826] and the human genome [Nature (2001) 409 813–958].

**genomic library** See LIBRARY.

**genomic masking** See PHENOTYPIC MIXING.

**genophore** A nucleic acid which carries genetic information; the term is usually applied to a prokaryotic chromosome, viral genome, ctDNA or mtDNA.

**genospecies** Any given group of strains among which genetic exchange can occur.

**genotoxin** Any DNA-damaging agent (e.g. a MUTAGEN).

**genotype** The genetic constitution of an organism: i.e., the organism's content of genetic information, either in total or with respect to one or more particular named alleles, regardless of whether or not that information is being – or can be – expressed under a given set of conditions. (cf. GENOME; PHENOTYPE.)

**gentamicin** Any of several (related) AMINOGLYCOSIDE ANTIBIOTICS (gentamicins A, B, C<sub>1</sub>, C<sub>1a</sub>, C<sub>2</sub> etc) produced by *Micromonospora* spp. The drug 'gentamicin' used clinically contains gentamicins C<sub>1</sub>, C<sub>1a</sub>, and C<sub>2</sub>; it is active against e.g. some strains of *Pseudomonas aeruginosa*.

**gentian violet** A mixture of dyes which includes CRYSTAL VIOLET and METHYL VIOLET.

**gentiobiose** A reducing disaccharide: β-D-glucopyranosyl-(1 → 6)-D-glucose. It occurs naturally in several plant glycosides (e.g. AMYGDALIN) and as a degradation product of glucans containing (1 → 6)-β-D-glucosyl linkages.

**genus** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**genus novum** (gen. nov.; gen. n.; n. gen.) A designation used to indicate a newly proposed genus at the time of its initial publication.

**Geodermatophilus** A genus of aerobic, catalase-positive bacteria (order ACTINOMYCETALES, wall type III) which occur in soil. The organisms form a simple substrate mycelium of thick strands, each a mass of cuboid cells formed by repeated division in both transverse and longitudinal modes; the mycelium gives rise to zoospores and to non-motile cuboid or coccoid cells. Budding occurs in zoospores and in young mycelia. GC%: ca. 73–75. Type species: *G. obscurus*. (cf. DERMATOPHILUS.)

**Geoglossum** See HELOTIALES.

**geophilic** Living or growing in or on the earth. (cf. DERMATOPHYTES.)

**geosmin** (*trans*-1,10-dimethyl-*trans*-9-decalol) A substance which is produced by certain aquatic actinomycetes and cyanobacteria (e.g. *Anabaena*, *Lyngbya* and *Oscillatoria* spp) and which imparts an 'earthy' or 'musty' taste and odour to the water and to fish living in the water. (cf. METHYLISOBORNEOL.)

**geotaxis** A TAXIS in which the stimulus is gravity; a negatively geotactic organism moves upwards.

**Geotoga** See BACTERIA (taxonomy).

**Geotrichum** A genus of fungi of the class HYPHOMYCETES; teleomorphs occur in the genus *Dipodascus*. [DNA relatedness between *Geotrichum* and *Dipodascus*: CJB (1985) 63 961–966.] The mycelium is septate, each septum having a single, central pore; pores as small as 50 nm (*micropores*) have been reported e.g. in *G. candidum*. Conidiogenesis is thallic-arthric (see CONIDIUM). In e.g. *G. candidum* the septa which separate adjacent conidia are multiperforate. (See also CHEESE SPOILAGE, PAPER SPOILAGE, SEWAGE FUNGUS, VILIA.)

**geotropism** See TROPISM (sense 1).

**GEP** See PROTEIN SECRETION.

**GERL** Part of the GOLGI APPARATUS from which LYSOSOMES are derived.

**germ sporangium** (*mycol.*) A SPORANGIUM produced at the distal end of a germ tube formed by a germinating zygospore.

**germ tube** (*mycol.*) A short, hypha-like structure which develops from certain types of spore on germination, or – in e.g. *Candida albicans* – from yeast cells undergoing yeast-to-mycelium transition. A germ tube usually develops into a hypha.

**germ warfare** See BIOLOGICAL WARFARE.

**Germall 115** A water-soluble imidazolidinyl urea compound with antibacterial and antifungal properties; it is used as a PRESERVATIVE in e.g. cutting oil emulsions.

**German measles** *Syn.* RUBELLA.

**germicide** (1) A general term for any antimicrobial chemical agent used for disinfection, antiseptics or sterilization – regardless of whether its action is microbicidal or microbistatic. (2) Any microbicidal disinfectant, antiseptic or sterilant.

**germinal centres** See ANTIBODY FORMATION.

**germinant** See ENDOSPORE (sense 1(a)).

**germination** (1) The process in which a spore gives rise to a vegetative cell or hypha. (2) (of bacterial endospores) See ENDOSPORE (sense 1(a)).

**germination by repetition** (*mycol.*) On the germination of a spore: the formation of a secondary spore (rather than a germ tube).

**Gerstmann–Sträussler–Scheinker syndrome** A human, inherited, autosomal-dominant TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHY (one of a number of inherited prion diseases). Characteristically, PrP-amyloid plaques in the cerebellar cortex are associated with pyramidal tract degeneration. Onset occurs in the third–seventh decade, and the mean duration of the illness is 5 years; clinical features (including the presence/absence of dementia) appear to depend on genotype.

**Getah virus** An ALPHAVIRUS which is closely related to ROSS RIVER VIRUS; it is apparently non-pathogenic in man, but in horses it can cause a febrile disease with e.g. oedema of the limbs.

**GF stain** GRIDLEY FUNGUS STAIN.

**GFP** GREEN FLUORESCENT PROTEIN.

**ghost** (1) An empty phage capsid (i.e., a capsid devoid of its genome).

(2) An empty vesicle, composed of cytoplasmic membrane, obtained e.g. from a bacterial cell by removal of its peptidoglycan followed by cell lysis.

**G<sub>i</sub> protein** See ADENYLATE CYCLASE.

**giant cells** Large multinucleate cells found in the tissues in certain diseases – e.g. CHICKENPOX, MEASLES, TUBERCULOSIS (cf. GRANULOMA); they are formed by the fusion of MACROPHAGES. *Langhans* giant cells contain relatively few nuclei which are situated at the periphery of the cytoplasm; *foreign body* giant cells contain many nuclei distributed throughout the cytoplasm.

**giant condylooma acuminatum** *Syn.* BUSCHKE–LÖWENSTEIN TUMOUR.

**Giardia** A genus of parasitic flagellate protozoa of the DIPLOMONADIDA. Strains occur in the intestinal tract in a wide range of vertebrates; the organisms are transmitted as cysts.

*G. lamblia* (= e.g. *G. intestinalis*, *Lamblia intestinalis*) occurs in the small intestine of man (causing GIARDIASIS), other primates, and pigs. Morphologically, the trophozoite resembles one half of a longitudinally-bisected pear, the flat side being ventral; it is commonly ca. 10–20 × 5–10 μm. The two nuclei occur symmetrically in the broad anterior region. The 8 flagella arise ventrally between, and slightly anterior to, the nuclei; three pairs emerge laterally, and the distal ends of the fourth pair become free at the extreme posterior end of the cell. The anterior ventral surface of the cell body bears a large ‘sucking

disc’ or ‘sucker’ by means of which the parasite is believed to adhere to the intestinal wall of its host (see also GIARDIASIS). The cell contains a pair of AXOSTYLES, and one or two deeply staining, rod- or comma-shaped bodies (median or ‘parabasal’ bodies) which occur in the centre of the cell and are orientated more or less perpendicularly to the long axis of the cell. The trophozoites reproduce by binary fission; they stain well with e.g. iron–haematoxylin. [Culture of *G. lamblia* in serum-free medium: J. Parasitol. (1983) 69 1181–1182. Lipid metabolism in *Giardia*: TIP (2001) 17 316–319.]

*G. lamblia* forms ovoid cysts (ca. 11–15 × 7–10 μm) in the gut lumen, and these are expelled with the faeces. Mature cysts generally contain 4 nuclei which are commonly clustered at one pole. The nuclei and portions of the median bodies and flagella can be seen in cysts stained with e.g. iodine.

The classification of *Giardia* strains into species remains controversial. Strains are often named according to the host in which they are found – e.g. *G. canis* (from dogs) – but such speciation may not be justified. It has been proposed that only three species be recognized on the basis of morphology and host range: *G. agilis* (from frogs and tadpoles), *G. muris* (from rodents and birds), and *G. duodenalis* (from mammals); strains currently known as ‘*G. lamblia*’ would thus be included in the species *G. duodenalis*.

**giardiasis** (lambliasis) A human disease caused by *Giardia lamblia*. Infection occurs by ingestion of cysts; transmission may occur by person-to-person contact or via contaminated food or drinking water (cysts can survive levels of chlorination used for treating WATER SUPPLIES).

Incubation period: ~4–7 days. Infection may be asymptomatic, or there may be acute or chronic diarrhoea, often with nausea, weight loss, fatty stools and flatulence. Symptoms are believed to be due to mechanical obstruction of the intestinal mucosa; tissue invasion does not occur. Although adhesion of *G. lamblia* to the mucosa of the small intestine is generally believed to depend on the organism’s ‘sucker’ (see GIARDIA), adhesion may involve a specific giardial LECTIN which is activated by gut proteases [Science (1986) 232 71–73].

**Diagnosis.** Trophozoites may be detected by microscopy in (fresh) saline-mounted specimens of diarrhoea; cysts, rather than trophozoites, may be found in specimens of formed stool. An ELISA-based method, using polyclonal antibodies, may be used to detect *Giardia* antigens in faeces.

**Chemotherapy:** e.g. METRONIDAZOLE, QUINACRINE.

[*Giardia* in drinking water supplies (cyst levels, parasite viability, health impact): AEM (1996) 62 47–54.]

**Gibberella** A genus of fungi (order HYPOCREALES) which include plant-pathogenic species (see e.g. BAKANAE DISEASE); anamorphs occur in the genus FUSARIUM. *Gibberella* spp form blue- or violet-coloured superficial perithecia, and ovoid to fusiform ascospores. (See also GIBBERELLINS and ZEARELENONE.)

**gibberellic acid** GIBBERELLIN A<sub>3</sub>.

**gibberellins** A class of PHYTOHORMONES which are synthesized e.g. in the leaves of plants and which regulate stem elongation, seed germination, etc; gibberellins were originally discovered as products of the fungus *Gibberella fujikuroi* (*Fusarium moniliforme*). Many gibberellins have now been identified and designated gibberellins A<sub>1</sub>, A<sub>2</sub> etc (or GA<sub>1</sub>, GA<sub>2</sub> etc); all share a common tetracyclic structure, but differ in the position and nature of their substituents.

The production of gibberellins by *G. fujikuroi* is believed to play an important role in the pathogenesis of BAKANAE DISEASE; another example of a plant pathogen which produces

## **gibbon ape leukaemia virus**

a gibberellin (A<sub>4</sub>) is *Sphaceloma manihoticola*, causal agent of 'superelongation disease' in cassava [BBRC (1979) 91 35–40]. Stunting of plants infected with certain viruses may be reversed by the application of gibberellins; it has been suggested that such viruses may affect the functioning of endogenous plant gibberellins.

Gibberellins obtained commercially from *G. fujikuroi* have been used e.g. for controlling premature fruit-drop, improving fruit setting, improving the quality and yield of grapes, and inducing rapid and uniform germination in malting barley (e.g. for BREWING).

**gibbon ape leukaemia virus (GALV)** A C-type retrovirus (subfamily ONCOVIRINAE) first isolated from a female gibbon with disseminated lymphosarcoma; GALV can be transmitted horizontally and can cause a substantial incidence of leukaemia in gibbon colonies. GALV is infectious for a wide range of host cells, including e.g. human, monkey, cat, mink, rabbit, rat (but not mouse), and various avian (but not chicken) cells. [Book ref. 114, pp. 130–137.] (cf. SIMIAN SARCOMA VIRUS.)

**Giemsa's stain** See ROMANOWSKY STAINS.

**Gigartacon** See ACANTHAREA.

**Gigartina** A genus of marine algae (division RHODOPHYTA). The organisms, which attach to rocks etc by means of a holdfast, vary widely in form according to species – often being flat (ribbon-like) and more or less branched; the surface frequently bears numerous papillate outgrowths. *Gigartina* spp are used e.g. as a source of CARRAGEENAN.

**Gigaspora** See ENDOGONALES.

**Gilbertella** See MUCORALES.

**Gilchrist's disease** Syn. BLASTOMYCOSIS.

**gill (mycol.)** Syn. LAMELLA.

**gill disease** (in fish) See BACTERIAL GILL DISEASE.

**gill fungi** Fungi which form lamellae: see LAMELLA.

**gill rot** A FISH DISEASE caused by *Branchiomyces sanguinis* or *B. demigrans*. The fungus grows on and into the gills, obstructing capillary circulation and leading to necrosis; the fish soon dies from suffocation. Gill rot is encouraged by high temperatures and the presence of decaying organic matter.

**Gilpinia hercyniae NPV** See BACULOVIRIDAE.

**Jiménez stain** A procedure for staining rickettsiae. Add 4% aqueous phenol (250 ml) and distilled water (650 ml) to 10% basic fuchsin in 95% ethanol (100 ml); allow to stand for 2 days at 37°C, and then add 2 volumes to 5 volumes of phosphate buffer (0.2 M, pH 7.45), mix, and filter immediately before use. A heat-fixed smear is stained for 1–2 min and washed with tap water; the smear is then stained for 5–10 sec with 0.8% w/v malachite green oxalate, washed in tap water, stained again for 5–10 sec with malachite green oxalate, washed thoroughly in tap water, and blotted dry. Rickettsiae stain red, background green.

**gin** See SPIRITS.

**gin gene** See BACTERIOPHAGE MU.

**ginger blotch** A MUSHROOM DISEASE caused by a distinct strain of the *Pseudomonas fluorescens* complex; superficial pale-brown to ginger-coloured lesions develop on the caps [JAB (1982) 52 43–48]. (cf. BROWN BLOTCH.)

**gingivitis** An acute or chronic inflammation of the gingiva (i.e., the gums) affecting areas of gum tissue (the 'attached gingiva') other than those immediately adjacent to the tooth–gum junction (which are referred to as the 'free gingiva'); unlike PERIODONTITIS, gingivitis does not bring about a permanent loss of periodontal structures.

*Acute herpetic gingivostomatitis* occurs most commonly in children and generally lasts about two weeks. It involves reddening of the gingiva and the formation of vesicular lesions

on various tissues within the mouth; systemic symptoms may include anorexia, fever, and the involvement of the submandibular and cervical lymph nodes. The causal agent is the type 1 HERPES SIMPLEX VIRUS.

*Acute necrotizing ulcerative gingivitis* occurs principally in young adults and is apparently stress-linked. It involves necrosis of the gingiva and the development of ulcers which usually become secondarily infected by spirochaetes. The primary aetiological agents are believed to include *Bacteroides intermedius*.

In *chronic (non-specific) gingivitis* the gingiva may show signs of oedema, hyperplasia or atrophy.

The severity of gingivitis often appears to correlate with stress and/or with hormonal influences; thus, e.g. the severity of the disease may increase during puberty or pregnancy.

**Giovannolaia** A subgenus of PLASMODIUM.

**girdle** See e.g. DINOFLAGELLATES.

**girdle bands** See DIATOMS.

**Glabatella** See FORAMINIFERIDA.

**glabrous** Hairless; smooth.

**glanders** An acute or chronic, often fatal disease which affects mainly equines (horse, mule, donkey), although some other animals – including man – are susceptible; the causal agent, *Pseudomonas mallei*, appears to enter the body mainly via the mouth or, less commonly, via the nose or skin lesions. Among equines, the acute form of the disease (more common in mules and donkeys) typically involves fever, coughing, a highly infectious nasal discharge, ulceration of the nasal mucosa, and nodular skin lesions on the limbs or abdomen; death from septicaemia may occur within days. Chronic glanders (more common in horses) may be largely pulmonary, with coughing, dyspnoea and epistaxis; alternatively, the prominent features may include ulcerating nasal lesions and/or subcutaneous ulcerating nodules (often in the hock region) which discharge a dark-honey-coloured pus. In *farcy*, a cutaneous manifestation of glanders, ulcerating lesions occur in cutaneous and subcutaneous tissues, and the regional lymph nodes and ducts become swollen and hard (the so-called *farcy buds* and *farcy pipes*, respectively). *Lab. diagnosis*: e.g. a CFT and/or the MALLEIN TEST. *Treatment*: e.g. sulphonamides together with a formalinized vaccine prepared from *P. mallei*. (cf. EPIZOOTIC LYMPHANGITIS.)

In man, the disease (which can be fatal) affects mainly the respiratory tract and/or cutaneous tissues, but the viscera, muscles or bones may also be affected.

**glandular fever** Syn. INFECTIOUS MONONUCLEOSIS.

**Glanzmann's thrombasthenia** See INTEGRINS.

**glass** (biodegradation of) In warm, humid conditions certain fungi (e.g. *Aspergillus glaucus*, *A. fumigatus*, *Cladosporium* spp, *Penicillium* spp) can grow on glass surfaces (e.g. microscope lenses), deriving nutrients either from adjacent substrates (e.g. lens sealing compounds) or from the film of material which tends to condense and collect on the glass; the surface of the glass may be etched by the extracellular products of such fungi. Certain lichens can grow on and etch stained glass windows etc. Damage to glass may be avoided by frequent cleaning, storage under dry conditions (where possible), use of fungicides, etc.

**Glasser's disease** (infectious polyarthritis and polyserositis) An acute disease of young pigs, often fatal within days. Onset is sudden, with fever, anorexia, dyspnoea, and lameness with swollen joints; the causal agent is a species of *Haemophilus* – often *H. parasuis* – although *Mycoplasma* spp can also be isolated in some cases. *Treatment*: e.g. tetracyclines, given early.

**glaucescent** Becoming GLAUCOUS.

**Glaucozystis** See GLAUCOPHYTA.

**Glaucoma** A genus of ciliates (order HYMENOSTOMATIDA). *G. scintillans* is ovoid, ca. 40–80 µm, with uniform somatic ciliature; it is common in freshwater habitats containing decomposing organic matter (see also SAPROBITY SYSTEM). *G. dragescui* also is ovoid, but *G. frontata* is elongate with a pointed posterior end.

**Glaucochyta** A phylum of 'algae' which includes those species that contain CYANELLES instead of CHLOROPLASTS. The phylum contains wall-less organisms (e.g. the flagellated, cryptomonad-like *Cyanophora*) and species which have a cell wall (e.g. *Glaucozystis*). In *Cyanophora* the (cyanobacterial) endosymbiont is a species of *Cyanocyta*; synthesis of phycocyanin by the endosymbiont is apparently partially dependent on the host's ribosomes.

**glaucous** Bluish-green, or covered with a bluish-green powdery or waxy bloom.

**GLC** Gas-liquid CHROMATOGRAPHY.

**GlcNAc** N-ACETYL-D-GLUCOSAMINE.

**gleba** In the fruiting bodies of e.g. fungi of the GASTEROMYCETES: the spore-bearing tissue which is (at least initially) enclosed by the PERIDIUM (or by the wall of the peridiole in members of the NIDULARIALES).

**Glenodinium** See DINOFAGELLATES.

**gliding bacteria** A non-taxonomic group of bacteria and cyanobacteria which exhibit GLIDING MOTILITY during at least some stage in their life cycles; gliding bacteria typically occur in soil and in freshwater and marine habitats. The group comprises the genera listed under CYTOPHAGALES, the MYXOBACTERIALES, the CHLOROFLEXACEAE, members of the cyanobacteria – both unicellular (e.g. *Synechococcus*) and filamentous (e.g. *Anabaena*, *Oscillatoria*, *Phormidium*, *Spirulina*) – and e.g. *Capnocytophaga* and *Desulfonema*.

Although not formally included among the gliding bacteria, some species of *Mycoplasma* exhibit a form of surface-associated locomotion referred to as gliding.

**gliding motility** A continuous-type (i.e. smooth, non-jerky) MOTILITY which occurs in some prokaryotes (GLIDING BACTERIA), algae (e.g. some diatoms and desmids) and protozoa (e.g. *Toxoplasma gondii*) which have no obvious locomotory organelles; gliding motility appears to occur only on a solid surface.

In the diatom *Amphora coffeaeformis*, some studies have suggested a possible mechanism that involves actin- and tubulin-based structures; this is compatible with the theory that gliding results from the translocation of membrane proteins along the raphe canal – the outermost part of such proteins being attached to the immobile slime secretion which has adhered to the substratum [Cell Mot. (1985) 5 103–122].

In the gregarine *Gregarina garnhami* (which apparently does not contain actin) it has been suggested that gliding may involve two sets of filaments which run longitudinally in the pellicle [JUR (1984) 88 66–76].

Gliding motility has been extensively investigated in prokaryotes [early review: ARM (1981) 35 497–529]. In some species, individual cells glide quite slowly (a few micrometres per minute) while in other species the cells may achieve speeds of up to ca. 150 micrometres per minute; some gliding bacteria can also perform other types of movement (e.g. flexing, twitching – see e.g. SPIRULINA). The path of a gliding cell is marked by a slime trail, and on an agar surface the path may be 'etched' into the agar; at least some gliding bacteria can penetrate agar gels. Gliding is also exhibited by trichomes and by aggregates of cells ('swarms').

Typically, gliding bacteria glide when nutrient levels are low; high levels can suppress gliding. Gliding appears to require the presence of calcium ions and is inhibited by EGTA

in a number of bacteria and cyanobacteria. In bacteria of the *Cytophaga*–*Flexibacter* group, sulphonolipids in the cell envelope appear to be necessary for gliding motility [Nature (1986) 324 367–369].

In some gliding bacteria certain stages in the life cycle (e.g. the myxospore in myxobacteria) are non-motile. In *Flexibacter elegans* (cells ca. 1–50 µm) gliding occurs only in those cells which are longer than ca. 5 µm.

In some cyanobacteria, motility has been associated with the *junctional pore complex* (JPC): a channel in the cell envelope through which mucilage (carbohydrate) is secreted; each organism has a number of JPCs, and secretion via these channels is believed to provide the thrust that is necessary for locomotion [JB (2000) 182 1191–1199].

Results of studies on *Myxococcus xanthus* (involving shock-freezing and freeze-drying) have indicated that the motility apparatus in this organism resembles a helical 'continuum' or band (~170–380 nm wide) that is wrapped around the protoplast (i.e. within the periplasmic space) to form a closed loop; 'nodes', associated with the continuum, may travel along the trichomes in a wave-like fashion (but with variable internode distance), each node possibly corresponding to a region of close contact, or adhesion, between the trichome and substratum [Microbiology (2001) 147 939–947].

**Gliocladium** See HYPHOMYCETES and GLIOTOXIN.

**gliotoxin** An epidithiapiperazinedione MYCOTOXIN (see EPIPOLYTHIAPIPERAZINEDIONES) obtained from *Trichoderma viride* and from species of *Aspergillus*, *Gliocladium* and *Penicillium*; it inhibits replication of polioviruses, echoviruses and measles virus, and also has antibacterial, antifungal and antitumour activity. In eukaryotic cells an early effect of gliotoxin is apparently disruption of microfilaments [JCS (1986) 85 33–46].

**glmM gene** In *Helicobacter pylori*: a gene (formerly *ureC*) which encodes phosphoglucosamine mutase.

**gln genes** See e.g. NTR GENES.

**global regulatory system** *Syn.* REGULON.

**global warming** See GREENHOUSE EFFECT.

**Globigerina** A genus of pelagic foraminifera (order FORAMINIFERIDA). The test is calcareous and multiloculate, the rounded locules being spirally arranged. *G. bulloides* may reach ca. 800 µm diam., and numerous fine calcareous spines radiate from the test; *G. bulloides* and e.g. *G. inflata*, *G. pachyderma* and *G. quinqueloba* occur in subpolar and cold temperate seas.

**Globigerinoides** A genus of pelagic foraminifera (order FORAMINIFERIDA). *G. sacculifer* is often abundant in tropical and subtropical seas, occurring in the upper euphotic zone; it is ca. 0.5–1.0 mm diam., bears radial spines 1–2 mm long, and contains numerous zooxanthellae.

**globomycin** See e.g. BRAUN LIPOPROTEIN.

**globose** Spherical.

**globoside** (parvovirus receptor) See ERYTHROVIRUS.

**Gloeobacter** A genus of unicellular CYANOBACTERIA (section I) in which the rod-shaped cells divide by equal binary fission in one plane and occur in colonial aggregates surrounded by a sheath; the cells are characterized by their lack of THYLAKOIDS – photosynthesis and respiration apparently being associated with the cytoplasmic membrane. Phycobiliproteins occur as an electron-dense layer of characteristically shaped phycobilisomes (apparently composed of bundles of rods) beneath the cytoplasmic membrane [Arch. Micro. (1981) 129 181–189]. GC% (one strain): 64.

**Gloeocapsa** A genus of unicellular CYANOBACTERIA (section I) in which the cells are coccoid and divide by equal binary

## **Gloeochloris**

fission in two or three planes, giving rise to clusters of cells enclosed in a sheath. GC%: 40–46. The organisms grow – often in masses – on wet rocks e.g. in the supralittoral zones of rocky coasts. (cf. GLOEOTHECE.)

**Gloeochloris** A genus of algae of the XANTHOPHYCEAE. The vegetative cells occur in a spherical palmelloid colony; asexual reproduction occurs by the formation and release of biflagellate zoospores.

**Gloeodinium** A genus of DINOFAGELLATES which form palmelloid colonies and reproduce by zoospore formation. One species (*G. montanum*), found in freshwater peaty marshes.

**Gloeotheca** A genus of unicellular CYANOBACTERIA (section I); the cells are rod-shaped (ca. 5–6 µm wide), possess thylakoids (cf. GLOEOBACTER), divide by equal binary fission in one plane (cf. GLOEOCAPSA), and occur in colonial aggregates surrounded by a well-defined sheath (cf. SYNECHOCOCCUS). The function of the sheath seems not to include the protection of nitrogenase from oxygen [oxygen relationships in nitrogen fixation: MR (1992) 56 346–347]. Strains of *Gloeotheca* can carry out NITROGEN FIXATION aerobically, despite the absence of heterocysts, and were formerly regarded as nitrogen-fixing strains of GLOEOCAPSA. GC%: 40–43.

**Gloeotrichia** A phycological genus of the RIVULARIACEAE (now included in the genus CALOTHRIX). '*G. echinulata*' is a gas-vacuolate, freshwater planktonic species which may form blooms; in nature, it forms characteristic spherical urchin-like colonies in which the terminal heterocysts occur in the centre of the colony and the trichomes radiate outwards. Hair cells may be formed e.g. under phosphorus-deficient conditions.

**Gloiopeltis** See RHODOPHYTA.

**glomerulonephritis** Inflammation of the kidney glomeruli. Acute glomerulonephritis is characterized by blood and red cell casts in the urine, and a reduced glomerular filtration rate leading to oliguria, oedema and hypertension. It may be due to deposition in the glomeruli of antigen-antibody complexes formed during certain infectious diseases, e.g., SYPHILIS (see also POST-STREPTOCOCCAL GLOMERULONEPHRITIS); in mice it may be induced e.g. by the LCM VIRUS. (See also PYELONEPHRITIS.)

**Glomospira** See FORAMINIFERA.

**Glomus** See ENDOGONALES.

**glorin** See POLYSPHONDYLUM.

**Glossina** (tsetse fly) A genus (22 species) of haematophagous (blood-sucking) flies (order Diptera) which include vectors of salivarian trypanosomes; they occur in sub-Saharan Africa in a belt approximately 15°N–15°S, and in SE Africa, including Mozambique. *Glossina* spp are distinguished from other dipterans e.g. by the chopper-shaped 'hatchet cell' in the wing venation. Both the male and female flies suck blood.

**glove box** A cabinet, the interior of which is accessible via gloves attached to openings in the front panel. (See also SAFETY CABINET.)

**glove juice test** A test used (in the USA) to determine the efficacy of a given antimicrobial agent used as a surgical hand scrub [Book ref. 65, pp. 958–961].

**GlpF** See MIP CHANNEL.

**glucan** A homoglycan (see POLYSACCHARIDE) consisting of glucose residues – see e.g. CELLULOSE, GLYCOGEN, LUTEOSE, NIGERAN, PARAMYLON, STARCH. (See also CELL WALL (fungal).)

**glucitol** *Syn.* SORBITOL.

**glucoamylases** *Syn.* γ-AMYLASES.

**glucobrassicin** See CLUBROOT.

**glucocorticoids** Steroid hormones, produced in the adrenal cortex, whose activity includes regulation of carbohydrate and protein metabolism. Glucocorticoids also have anti-inflammatory

activity; thus, e.g. they inhibit the ability of IFN-γ and lipopolysaccharides to induce the synthesis of CYTOKINES in macrophages.

**glucogenesis** *Syn.* GLUCONEOGENESIS.

**glucomannans** See MANNANS.

**gluconate** See GLUCONIC ACID.

**gluconeogenesis** (glucogenesis) The synthesis of glucose (and hence other hexoses) from non-carbohydrate substrates such as acetate, glycerol, pyruvate, succinate etc. Essentially, this may be achieved by conversion (where necessary) of the substrate to an intermediate of the EMBDEN-MEYERHOF-PARNAS PATHWAY [Appendix I(a)], followed by reversal of reactions of the EMP pathway – the three irreversible reactions in this pathway being bypassed by other enzymes. Thus, e.g., in *Escherichia coli* phosphoenolpyruvate can be synthesized from pyruvate or from the TCA CYCLE intermediates oxaloacetate and malate [see Appendix II(b)]; phosphoenolpyruvate is then converted to fructose 1,6-bisphosphate by reversal of reactions of the EMP pathway. Fructose 1,6-bisphosphate is hydrolysed by *fructose biphosphatase* to fructose 6-phosphate which can in turn be converted to glucose 6-phosphate by phosphohexose isomerase.

**gluconic acid** Gluconic acid and its salts are metabolized by various microorganisms (see e.g. ENTNER-DOUDOROFF PATHWAY), and are synthesized (by the oxidation of glucose) e.g. by *Aspergillus niger* and other hyphomycetes and by *Gluconobacter oxydans*. *A. niger* and *G. oxydans* are used as commercial sources of these compounds which have a range of uses in the food and pharmaceutical industries; for example, gluconic acid (a chelating agent) is used for sequestering metal ions; sodium gluconate is used for cleaning glassware and for removing rust from metals; calcium and iron gluconates are used therapeutically for the treatment of calcium and iron deficiencies.

**Gluconobacter** A genus of Gram-type-negative bacteria of the ACETOBACTERACEAE; the organisms occur e.g. on certain fruits and flowers, and are used e.g. for the production of MONOBACTAMS and in the SORBOSE FERMENTATION. Cells: typically ovoid to rod-shaped, 0.5–0.8 × 0.9–4.2 µm, non-motile or lophotrichously flagellate. Catalase-positive. Typically, ethanol is oxidized to acetic acid on e.g. CARR MEDIUM; neither acetate nor lactate is oxidized to CO<sub>2</sub>. Ketogenic growth occurs on polyalcohol substrates, and all strains form 2-ketogluconic acid (and most form 5-ketogluconic acid) from D-glucose. Substrates utilized include e.g. D-mannitol, sorbitol, glycerol (see DIHYDROXY-ACETONE FERMENTATION), D-fructose and D-glucose; all strains require growth factors (which may include e.g. pantothenate, niacin, thiamine, PABA) when D-mannitol is used as the sole carbon source. The organisms lack a complete TCA cycle; the breakdown of sugars and polyols to CO<sub>2</sub> occurs mainly via the HEXOSE MONOPHOSPHATE PATHWAY. Optimum growth temperature: 25–30°C. GC%: ca. 56–64. Type species: *G. oxydans* – which incorporates strains previously referred to as *Acetobacter suboxydans*.

**glucose dehydrogenase** See QUINOPROTEIN and EXTRACRYTOPLASMIC OXIDATION.

**glucose effect** (glucose repression) (1) *Syn.* CATABOLITE REPRESSION. (2) *Syn.* CRABTREE EFFECT.

**glucose isomerase** (xylose isomerase; D-xylose ketolisomerase; EC 5.3.1.5) An intracellular enzyme which converts D-glucose to D-fructose, although its main function in vivo is probably the conversion of D-xylose to D-xylulose; the enzyme is typically induced in the presence of xylose. Glucose isomerase, obtained e.g. from *Bacillus coagulans* (see IMMOBILIZATION (1)) or *Streptomyces* spp, is used commercially on a large scale for the

conversion of D-glucose to D-fructose e.g. in the manufacture of HIGH-FRUCTOSE CORN SYRUP. (See also ENZYMES.)

**glucose oxidase** ( $\beta$ -D-glucose: oxygen 1-oxidoreductase, EC 1.1.3.4)

An enzyme (produced e.g. by *Aspergillus* and *Penicillium* spp) which oxidizes glucopyranose in the presence of oxygen to D-glucono- $\delta$ -lactone and H<sub>2</sub>O<sub>2</sub> – the former rapidly hydrolysing to D-gluconic acid. Glucose oxidase from e.g. *Aspergillus niger* (a glycoprotein containing 2FAD/molecule) is widely used in clinical tests for the detection of glucose in urine, blood etc; in general, such tests rely on a colour change resulting from the oxidation of a chromogen by H<sub>2</sub>O<sub>2</sub> released by glucose oxidase in the presence of glucose and oxygen. Glucose oxidase is also used in the food industry e.g. for removing glucose from foods (e.g. eggs preparatory to drying) to prevent browning, and for removing oxygen from e.g. beer, wine, mayonnaise etc. (See also ENZYMES.)

**$\beta$ -glucosidase** See CELLULASES.

**$\beta$ -glucoside permease** (in *Escherichia coli*) See CATABOLITE REPRESSION.

**glucosinolase** See CLUBROOT.

**Glugea** A genus of protozoa (class MICROSPOREA) which are parasitic in fish; tumour-like cysts (XENOMAS, 'glugea cysts') ca. 2–4 mm diam. develop in the gut mucosa and liver of the infected fish.

**glume blotch** A CEREAL DISEASE, caused by *Leptosphaeria nodorum* (*Septoria nodorum*), which can affect e.g. wheat and barley. Leaf lesions are initially yellow, later becoming golden-brown and sometimes coalescing. Lesions on glumes (usually spreading from the tip) are a dark purplish-brown, and they later exhibit dark or black pycnidia. Control: e.g. CARBENDAZIM or PROCHLORAZ with a DITHIOCARBAMATE.

**L-glutamate** See GLUTAMIC ACID.

**glutamate dehydrogenase** See AMMONIA ASSIMILATION.

**glutamate synthase** See AMMONIA ASSIMILATION.

**L-glutamic acid** An amino acid synthesized by the reductive amination of 2-oxoglutarate – see Appendix IV(a). It is produced commercially on a large scale for use in the food industry – mainly as a flavour enhancer (monosodium glutamate) – and is obtained from strains of bacteria (e.g. *Corynebacterium glutamicum*, 'glutamic acid bacteria') grown aerobically on e.g. molasses or starch hydrolysates. (Some strains can be grown e.g. on acetic acid.) The strains used require biotin for growth and have little or no 2-oxoglutarate dehydrogenase activity (so that metabolism of 2-oxoglutarate via the TCA cycle is limited or cannot occur). Production of glutamic acid is maximal under suboptimal growth conditions (achieved e.g. by limiting biotin). The glutamic acid must be secreted by the cells to avoid feedback inhibition of its synthesis; permeability of the cells may be increased e.g. by biotin deficiency, by treatment with fatty acid derivatives or antibiotics (e.g. penicillin), or by using strains auxotrophic for glycerol or oleic acid grown on low levels of glycerol and oleic acid, respectively.

Some L-glutamine is also formed during glutamic acid production; the proportion of glutamine formed can be increased by adjusting conditions of pH, nutrient availability etc.

**L-glutamine** An amino acid synthesized from GLUTAMIC ACID: see Appendix IV(a). It is an important intermediate in various metabolic pathways, being involved e.g. in some types of AMMONIA ASSIMILATION and in various transamination reactions – e.g. in the biosynthesis of tryptophan and of purine nucleotides [see Appendixes IV(f) and V(a)].

**glutamine synthetase** See AMMONIA ASSIMILATION.

**glutaraldehyde** (CHO(CH<sub>2</sub>)<sub>3</sub>CHO) A dialdehyde whose two aldehyde groups can substitute amino and other groups in proteins and nucleic acids and which can thus form cross-links in

and between molecules (cf. FORMALDEHYDE); it is used e.g. for pre-FIXATION (e.g. 1–10% in phosphate or cacodylate buffer) and as a DISINFECTANT or STERILANT (e.g. for medical and other equipment). Glutaraldehyde (e.g. 2% aqueous) is rapidly lethal for a wide range of vegetative microorganisms and viruses, but activity may be slow against e.g. *Mycobacterium tuberculosis* and bacterial ENDOSPORES: the dried spores of *Bacillus subtilis*, for example, have been reported to need up to 10 hours in 2% glutaraldehyde for complete inactivation (cf. STERILANT). The antimicrobial activity of glutaraldehyde is much greater (but stability is reduced) under alkaline or neutral conditions than under acidic conditions. [For antimicrobial activity and uses of glutaraldehyde see JAB (1980) 48 161–190.]

**glutarimide antibiotics** A group of ANTIBIOTICS characterized by two structural components: a  $\beta$ -(2-hydroxyethyl)-glutarimide and a cyclic or non-cyclic ketone. They include e.g. CYCLOHEXIMIDE and *inactone*.

**glutathione peroxidase** (glutathione:hydrogen peroxide oxidoreductase; EC 1.11.1.9) An enzyme which catalyses the oxidation of reduced glutathione by hydrogen peroxide. (See also CATALASE.)

**glycan** *Syn.* POLYSACCHARIDE.

**glyceollin** Any of four isoflavonoid PHYTOALEXINS (glyceollins I–IV) formed by the soybean plant.

**glycerate pathway** See TCA CYCLE.

**glycerokinase** (ATP:glycerol 3-phosphotransferase; EC 2.7.1.30)

An enzyme which catalyses the ATP-dependent phosphorylation of glycerol. It is obtained commercially from e.g. '*Candida mycoderma*' and *Escherichia coli*, but a more stable enzyme is obtained from *Bacillus stearothermophilus*. It is used in diagnostic kits for the determination of serum triglyceride levels [PTRSLB (1983) 300 399–410]. (See also ENZYMES.)

**glycerol** (CH<sub>2</sub>OH.CHOH.CH<sub>2</sub>OH) Glycerol is produced by various organisms as a (usually minor) product of e.g. ALCOHOLIC FERMENTATION and other fermentations; it is formed by the reduction of dihydroxyacetone phosphate (DHAP, an intermediate of the EMBDEN-MEYERHOF-PARNAS PATHWAY) to glycerol 3-phosphate, followed by hydrolysis to yield free glycerol. (See also NEUBERG'S FERMENTATIONS.)

Some bacteria can use glycerol as a growth substrate: e.g. *Escherichia coli* can use glycerol (taken up by FACILITATED DIFFUSION) as sole source of carbon and energy in the presence of an external electron acceptor such as O<sub>2</sub>, NO<sub>3</sub><sup>-</sup>, or fumarate. Glycerol is phosphorylated by an ATP-dependent kinase, the resulting glycerol 3-phosphate being oxidized by an NAD-dependent dehydrogenase to yield DHAP which can be further metabolized via the EMP pathway. (See also DIHYDROXYACETONE FERMENTATION.) *Klebsiella pneumoniae* and certain lactobacilli can ferment glycerol: some glycerol is converted to DHAP as above, and the NADH thus formed is reoxidized by a parallel pathway in which glycerol is converted to  $\beta$ -hydroxypropionaldehyde (by a coenzyme B<sub>12</sub>-dependent glycerol dehydrase) which is in turn reduced to 1,3-propanediol by an NADH-dependent reductase.

(See also ALCOHOLS (as antimicrobial agents) and COMPATIBLE SOLUTE.)

**glycerol facilitator** See MIP CHANNEL.

**glycerol fermentation** See NEUBERG'S FERMENTATIONS and GLYCEROL.

**glycine betaine** See OSMOREGULATION.

**glycine biosynthesis** See e.g. Appendix IV(c).

**glycobiarsol** See ARSENIC.

**glycocalyx** In eukaryotic cells: a layer of polysaccharide and/or glycoprotein that surrounds many types of cell. In bacterial

## glycocholic acids

cells: a CAPSULE – of either a polysaccharide or S LAYER type [ARM (1981) 35 299–324] – or, specifically, a *polysaccharide* capsule.

**glycocholic acids** See BILE ACIDS.

**glycogen** A highly branched D-glucan formed as a storage polysaccharide in animal cells, in many bacteria, fungi (excluding oomycetes) and protozoa, and in certain plants. Glycogen resembles amylopectin (see STARCH) but the average chain length is generally shorter (average 10–12 glucose residues) and the molecule is more extensively branched. It forms reddish-brown complexes with iodine and may be stained (non-specifically) e.g. by the PAS REACTION.

*Biosynthesis* of glycogen involves the successive transfer of glucose residues from UDP-glucose (in eukaryotes) or ADP-glucose (in bacteria) to a (1 → 4)- $\alpha$ -D-glucan acceptor in the presence of glycogen synthase; the branches are then introduced by a branching enzyme: an enzyme that transfers a segment of a (1 → 4)- $\alpha$ -glucan chain from a 4-OH to a 6-OH position. (ADP/UDP-glucose is formed from ATP/UTP and glucose 1-phosphate, the latter being formed from glucose 6-phosphate by phosphoglucomutase.) In bacteria, at least, initiation of glycogen synthesis may involve the addition of glucosyl residues to a protein acceptor [BBA (1978) 540 190–196]; different enzymes may be necessary for the synthesis of the glucoprotein primer and the glycogen molecule. [Book ref. 62, pp. 171–178; ARM (1984) 38 419–458.]

*Degradation* of glycogen typically involves the transfer of glucose residues from the non-reducing end of a chain to inorganic phosphate, a reaction catalysed by glycogen phosphorylase. (See also AMYLASES and DEBRANCHING ENZYMES.)

**glycolate metabolism** (glycollate metabolism) See e.g. entry TCA CYCLE.

**glycolate pathway** See PHOTORESPIRATION.

**glycols** (as antimicrobial agents) See ALCOHOLS.

**glycolysis** *Syn.* EMBDEN–MEYERHOF–PARNAS PATHWAY.

**glycomacropeptide** See CASEIN.

**glycosaminoglycan** *Syn.* MUCOPOLYSACCHARIDE.

**glycosaminopeptide** *Syn.* MUCOPEPTIDE.

**glycosome** A MICROBODY which contains glycolytic enzymes and which occurs in members of the KINETOPLASTIDA; in e.g. *Trypanosoma brucei* most of the enzymes involved in the glycolytic pathway from glucose to 3-phosphoglycerate occur exclusively in glycosomes. [BBA (1986) 866 179–203 (190–193).]

**glycosylase** (DNA glycosylase) See ADAPTIVE RESPONSE and URACIL-DNA GLYCOSYLASE.

**glyodin** (2-heptadecyl-2-imidazole acetate) An ANTIFUNGAL AGENT used e.g. for the control of apple scab and various fungal diseases of cherries and ornamental plants.

**glyoxalase** See METHYLGlyoxal BYPASS.

**glyoxylate cycle** A pathway which occurs in a variety of organisms, including some bacteria and fungi: see entry TCA CYCLE and Appendix II(b); a key enzyme in the cycle is isocitrate lyase. The glyoxylate cycle permits the use of 2-carbon compounds and e.g. fatty acids as sources of carbon. (See also PHOTORESPIRATION.)

Following phagocytosis, the persistence of *Mycobacterium tuberculosis* within macrophages is reported to require the activity of the (bacterial) isocitrate lyase [Nature (2000) 406 735–738].

The glyoxylate cycle is reported to be required for the expression of virulence in certain fungi [Nature (2001) 412 83–86].

**glyoxylate metabolism** See TCA CYCLE.

**glyoxylate shunt** See TCA CYCLE.

**glyoxysome** A type of MICROBODY which occurs in plant cells, and in some eukaryotic microorganisms, and which contains enzymes of the glyoxylate cycle.

**glypiated protein** A protein which is anchored to a component of the eukaryotic cell membrane (glycosylphosphatidylinositol) via a carbohydrate chain (to which the protein is attached).

**Gm allotype** See ALLOTYPE.

**GM-CSF** See COLONY-STIMULATING FACTORS.

**GM gangliosides** See SPHINGOLIPID.

**GMP** Guanosine 5'-monophosphate: see Appendix V(a).

**GMS** Gomori METHENAMINE–SILVER STAIN.

**GN broth** 'Gram-negative enrichment broth' (used e.g. for the enrichment of shigellae from food or faeces); it contains enzymic digest of casein and animal tissue, D-glucose, citrate, deoxycholate, NaCl, phosphate buffer (pH 7.0). [Recipe: Book ref. 47, p. 652.]

**Gnomonia** See DIAPORTHALES.

**gnatobiotic** Refers to a microbiologically monitored environment or animal, i.e., one in which the identities of all microorganisms present are known. (cf. SPECIFIC PATHOGEN FREE.)

**goat pox** A goat disease, clinically similar to SHEEP POX, caused by a *Capripoxvirus* which is antigenically distinguishable from the sheep pox virus.

**GOGAT** See AMMONIA ASSIMILATION.

**gold leaching** See LEACHING.

**gold standard** (*lab. microbiol.*) Any well-established procedure (e.g. a diagnostic test) which is generally regarded as the superior and definitive method, and which is used as a reference against which other, proposed or alternative methods may be compared (often in terms of sensitivity and/or specificity).

In many cases *culture* is regarded as the gold standard for diagnostic purposes. However, with the advent of nucleic-acid-based methods, some authors refer to an *expanded* or *combined* gold standard; using such a standard, a true-positive result is one that is positive by the gold standard method (usually culture) and by one nucleic-acid-amplification test [example of use of the term *expanded/combined* gold standard: JCM (1997) 35 957–959].

For diagnostic tests on *Chlamydia trachomatis*, some authors have used an *aggregate* gold standard in which a sample is deemed to give a true-positive result if it is either culture-positive or positive in two non-culture assays.

**Goldberg–Hogness box** See PROMOTER.

**golden algae** CHRYSOPHYTES.

**Golgi apparatus** An intracellular organelle consisting typically of a number of stacks of flattened membranous vesicles (*cisternae*); at least one Golgi apparatus occurs in most types of eukaryotic cell (cf. e.g. DIPLOMONADIDA). Within the cell the Golgi apparatus is characteristically orientated such that one end of the stacked cisternae (the proximal or 'forming' end) is nearer the nucleus; the opposite end is called the distal or 'maturing' end. Functions of the Golgi apparatus include the formation of LYSOSOMES and the formation of secretory vesicles within which e.g. macromolecules or cell envelope substructures can be transported to the cell surface (see e.g. PALADE PATHWAY and CELL WALL (a)). Secretory molecules reach the Golgi apparatus primarily from the ENDOPLASMIC RETICULUM; thus, e.g., a portion of smooth ER forms a vesicle which encloses molecules from the lumen of the ER, and the vesicle passes through the cytoplasm and fuses with a similar vesicle or with a cisterna at the 'forming' end of the Golgi apparatus. Presumably as a result of repeated budding and fusion, the contents of a vesicle eventually reach the 'maturing' end of the Golgi apparatus and are finally enclosed within a secretory vesicle which

fuses with the cytoplasmic membrane. During transit through the Golgi apparatus a molecule characteristically increases its degree of glycosylation – fucose, galactose and/or neuraminic acid residues typically being added.

(See also DICTYOSOME.)

**Gomori stain** *Syn.* METHENAMINE–SILVER STAIN.

**Gomphonema** A genus of pennate DIATOMS. In e.g. *G. olivaceum* the cell adheres to the substratum by a 'stalk' of secreted mucilage.

**gonal nucleus** See CONJUGATION (1)(c).

**Gonapodya** See MONOBLEPHARIDAE.

**Gonatobotrys** See HYPHOMYCETES and CONIDIUM.

**Gonatobotryum** See HYPHOMYCETES.

**gongylidia** (*sing.* gongyliidius) Nodular fungal structures which develop in the FUNGUS GARDENS of parasol ants or in the fungus combs of termites (see TERMITE–MICROBE ASSOCIATIONS).

**gonidium** A cell which is involved in asexual reproduction: see e.g. LEUCOTHRIX and VOLVOX. (The term was once applied to a photobiont cell in a lichen in the mistaken belief that such cells served a reproductive function.)

**Gonimochaete** See ENTOMOPHTHORALES.

**gonococcal ophthalmia** See GONORRHOEA.

**gonococcus** *Neisseria gonorrhoeae*.

**Gonometa virus** See PICORNAVIRIDAE.

**gonorrhoea** (gonorrhoea) An acute or chronic VENEREAL DISEASE which in nature affects only man; it is caused by *Neisseria gonorrhoeae* (the 'gonococcus' – see NEISSERIA). Incubation period: 2–5 days or longer. Gonococci adhere to the urethral epithelium by means of fimbriae; they penetrate the mucosa, causing an acute inflammatory response, and the infection spreads readily to adjacent tissues. In males, infection may be asymptomatic or may involve URETHRITIS, with painful urination and a yellowish mucopurulent discharge; prostatitis and epididymitis may occur. In females, infection may be asymptomatic or there may be a purulent vaginal discharge; infection may spread via the endometrium, fallopian tubes and ovaries to the pelvic peritoneum (*pelvic inflammatory disease*, PID). (See also CURTIS–FITZ-HUGH SYNDROME.) In either sex, sterility may result. Some strains of gonococci may become disseminated: bacteraemia, associated with e.g. fever, may be followed by skin lesions, arthritis, and (sometimes fatal) endocarditis and/or meningitis. Gonococcal contamination of the eyes may lead to conjunctivitis (*gonococcal ophthalmia*) which can cause blindness if untreated; infants may be infected during birth (*ophthalmia neonatorum*), and neonates may therefore be prophylactically treated with eye-drops containing e.g. 1% w/v silver nitrate (*Credé procedure*) or penicillin. *Lab. diagnosis*: smears of the discharge are stained (e.g. by the Gram stain or fluorescent antibody techniques) to reveal large numbers of diplococci in PMNs. Culture (e.g. on THAYER–MARTIN AGAR) may be necessary, especially for diagnosing females. A PROBE-based test (the PACE 2C test) has been used for detecting *N. gonorrhoeae* and *Chlamydia trachomatis* in a single assay (particularly useful because co-infection with these two pathogens is quite common) [evaluation of the PACE 2C test with endocervical specimens: JCM (1995) 33 2587–2591]. A test for detecting *N. gonorrhoeae* based on the ligase chain reaction (see LCR) reported results superior to those obtained by culture [JCM (1997) 35 239–242].

*Chemotherapy* depends on (changing) patterns of antibiotic resistance in the pathogen; penicillins (with probenecid), tetracycline, erythromycin and spectinomycin have been used.

**Gonyaulax** See DINOFLAGELLATES; BIOLUMINESCENCE; RED TIDE.

**gonyautoxins** Toxins produced by *Gonyaulax* spp and other RED TIDE dinoflagellates. The toxins are sulphonated derivatives of SAXITOXIN and neosaxitoxin; they have a low toxicity, but can be converted to saxitoxin/neosaxitoxin by low pH (e.g. in the stomach).

**Gonyostomum** See CHLOROMONADS.

**Good buffers** Zwitterionic pH buffers, e.g. BICINE and HEPES.

**goose parvovirus** See PARVOVIRUS.

**Gordona** An obsolete genus of bacteria currently included in the genus RHODOCOCCUS.

**Gorgonzola cheese** See CHEESE-MAKING.

**Gouda cheese** See CHEESE-MAKING.

**Gower coefficient** See entry  $S_G$ .

**gp** (1) Gene product. For example, gp6 = the polypeptide product of gene 6. (2) In retroviruses, gp designates a *glycoprotein* gene product (see RETROVIRIDAE).

**Gracilaria** See RHODOPHYTA. (See also HOLMSELLA.)

**Gracilicutes** A proposed division of the PROCARYOTAE comprising bacteria in which the CELL WALL is typically of the Gram-negative type; classes: ANOXYPHOTOBACTERIA; OXYPHOTOBACTERIA; SCOTOBACTERIA.

**gradient differential centrifugation** See CENTRIFUGATION.

**gradient elution** Elution during which the eluent, *A*, is progressively diluted with another solvent or solution, *B*, until it is finally pure *B*.

**gradient plate** An agar plate within which a given antibiotic is distributed such that its concentration varies, in gradient fashion, from one side of the plate to the other; the plate is used to isolate antibiotic-resistant mutants. To prepare a gradient plate, a volume of antibiotic-free agar is allowed to set in a Petri dish – one side of which is raised ca. 5 mm above the horizontal during setting; with the Petri dish level, an equal volume of antibiotic-agar is then added and allowed to set. Plates are left for ca. 1 day before inoculation; this permits equilibration of antibiotic concentrations in a vertical (but not lateral) direction.

A two-dimensional gradient plate may be prepared in a square dish; two wedge-shaped layers are prepared as described above, and a further two layers are added perpendicular to the first two. A given layer may incorporate a specific electrolyte, acid etc [JGM (1985) 131 2865–2869].

**Gradocol filter** A type of membrane filter. (See also FILTRATION.)

**gradostat** An apparatus used for a specialized form of CONTINUOUS CULTURE in which two different solutions flow, simultaneously but in opposite directions, through each of a number of serially-linked chemostats; under steady-state conditions the concentration of each of the given solutes exhibits a stepped gradient along the line of chemostats. In one type of gradostat five chemostats are arranged at progressively higher levels so that one of the solutions can flow through the system under gravity – i.e., overflowing a weir in each chemostat and passing down to the chemostat below it; the other solution is pumped into the lowest chemostat, and pumped from each chemostat to the one above it. In this type of gradostat organisms as well as solutes are transferred between chemostats. By contrast, in the *diffusion-coupled gradostat* (Herbert model) several chemostats (each with its own independent inflow and outflow of medium) are connected in a horizontal row such that the medium in one chemostat is separated from that in the next by a membrane filter; thus, solutes can diffuse between chemostats but the organisms in a given chemostat remain in that chemostat. Such a system can be used e.g. to investigate metabolic interactions between different species [FEMS Ecol. (1985) 31 239–247].

[Gradostats and other novel growth systems: MS (1985) 2 53–60.]

## Graff–Reinet disease

**Graff–Reinet disease** *Syn.* MAEDI.

**Grahamella** A genus of Gram-negative bacteria (family BARTONELLACEAE); the organisms occur worldwide and are parasitic (though rarely, if ever, pathogenic) in various small mammals (e.g. rodents) but not in man. *Grahamella* spp (*G. talpae*, the type species; *G. peromysci*) are non-flagellated bacilli or coccobacilli, commonly ca. 1 µm long; the organisms are transmitted e.g. by fleas and occur in the erythrocytes of the infected vertebrate host.

**grain bloat** See BLOAT.

**Gram convention** A system for numbering the microtubular triplets in a kinetosome. Looking at a cross-section of a ciliary kinetosome from the direction of the *interior* of the cell, the number 1 triplet is that which is aligned with the axis of the KINETY and which is near the posterior side of the kinetosome (relative to the cell's anterior–posterior axis); triplets 2–9 follow in a clockwise sequence from number 1. (cf. PITELKA CONVENTION.)

**Gram-negative** See GRAM STAIN.

**Gram-negative enrichment broth** See GN BROTH.

**Gram-positive** See GRAM STAIN.

**Gram reaction** The result (positive, negative, or variable) of the GRAM STAIN; the Gram reaction does not *necessarily* indicate the chemical nature of the cell envelope (cf. GRAM TYPE). In a non-staining method for determining Gram reaction, bacterial growth is emulsified with one drop of aqueous KOH (3%); Gram-negative bacterial growth becomes viscid, or gels, in 5–60 sec [AEM (1982) 44 992–993].

**Gram stain** An important bacteriological STAINING procedure discovered empirically in 1884 by the Danish scientist Christian Gram. When bacteria are stained with certain basic dyes the cells of some species (*Gram-negative* species) can be easily decolorized with organic solvents such as ethanol or acetone; cells of *Gram-positive* species resist decolorization. The ability of bacteria to either retain or lose the stain generally reflects fundamental structural differences in the CELL WALL, and is an important taxonomic feature; the Gram stain is therefore used as an initial step in the identification of bacteria.

*Procedure* (one of many variations). A heat-fixed smear of bacteria on a slide is stained for ca. 1 min with one of certain basic TRIPHENYLMETHANE DYES (commonly crystal violet); most bacteria take up the dye. The smear is then rinsed briefly under running water, treated for 1 min with LUGOL'S IODINE, and again rinsed with water. Decolorization is then attempted by treating the smear with ethanol, acetone, or iodine–acetone. This is the critical step: solvent is allowed to run over the tilted slide until dye no longer runs *freely* from the smear (ca. 1–3 sec), and the smear is *immediately* rinsed under running water; at this stage any Gram-negative bacteria in the smear will be colourless, while any Gram-positive cells will still be violet. The smear is then counterstained for ca. 30 sec (e.g. with dilute carbolfuchsin) to stain any Gram-negative bacteria present in the smear. Finally, the slide is rinsed briefly under the tap, blotted dry, and examined under the microscope. (In *Hucker's method* the dye solution is made by adding 20 ml crystal violet (10% w/v in 95% ethanol) to 80 ml of 1% w/v aqueous ammonium oxalate, and filtering after 24 h. The decolorizing agent is 95% ethanol. The counterstain is safranin O.) (See also BROWN–HOPPS MODIFICATION and KOPELOFF MODIFICATION.)

The mechanism of Gram-staining is still not understood. The integrity of the CELL WALL is necessary for Gram-positivity; disrupted Gram-positive cells do not retain the dye. It may be that Gram-positive cells retain the dye–iodine complex owing

to the lower permeability of their cell walls: the PEPTIDOGLYCAN of Gram-positive cell walls is more extensively cross-linked than that in Gram-negative species. (N.B. *Mammalian* cells are uniformly Gram-negative.)

The cells of some bacteria (e.g. *Bacillus* spp) are strongly Gram-positive when young, but tend to become Gram-negative in ageing cultures; this may reflect degenerative changes in the cell wall. Some bacteria give a *Gram-variable* reaction, i.e., they are sometimes Gram-positive, sometimes Gram-negative; this could reflect e.g. minor variations in staining technique. To avoid the taxonomic problems of Gram-variable bacteria it has been suggested that classification be based on GRAM TYPE rather than on GRAM REACTION.

**Gram type** A taxonomically useful designation (either *Gram type positive* or *Gram type negative*) which is based on biochemical and anatomical properties of a bacterial cell (see e.g. CELL WALL) rather than on GRAM REACTION; designation on this basis avoids the taxonomic problems caused by a Gram-variable reaction in the GRAM STAIN. [JGM (1982) 128 2261–2270.]

**Gram-variable** See GRAM STAIN.

**gramicidins** A group of linear peptide ANTIBIOTICS, each of which has a formyl group at the N-terminal and an ethanolamine residue at the C-terminal. ('Gramicidin J', also called 'gramicidin S', is misnamed: it is a TYROCIDIN.) Gramicidins act as channel-forming IONOPHORES, forming transient ion-conducting dimers in lipid bilayers; such channels permit the passage of a range of hydrated monovalent cations as well as protons. Against Gram-positive bacteria gramicidins may be bacteriostatic or (at higher concentrations) bactericidal; most Gram-negative bacteria tend to be resistant.

**grana** See CHLOROPLAST.

**granulin** See BACULOVIRIDAE.

**granulocyte** See PMN.

**granuloma** A type of lesion resulting from a local inflammatory response to a persistent antigen or toxin at a given site in the body; the lesion consists of a hard mass composed mainly of macrophages and strands of fibrous connective tissue – although other types of cell (e.g. lymphocytes, plasma cells, polymorphs etc) may also be present, and the lesion may also contain GIANT CELLS. Granuloma formation involves a T cell-dependent immune response. (See also DELAYED HYPERSENSITIVITY.)

**granuloma inguinale** (donovanosis) A chronic human disease, occurring mainly in the tropics and subtropics, in which granulomatous ulcers develop chiefly on the genitals; the causal agent, *Calymmatobacterium granulomatis*, is transmitted by intimate contact. In smears (stained e.g. with Wright's stain) the pathogen appears as clusters of blue or black 'Donovan bodies' in the cytoplasm of large mononuclear cells.

**granuloplasm** See e.g. SARCODINA.

**Granuloreticulosea** A class of protozoa (superclass RHIZOPODA) which form delicate, finely granular or hyaline reticulopodia (or, rarely, finely pointed, granular, non-anastomosing pseudopodia). Orders: Athalamida (amoebae naked: e.g., *Arachnula*, *Biomyxa*); Monothalamida (amoebae enclosed in a single-chambered organic or calcareous test, not exhibiting an alternation of generations: e.g., *Lieberkuehnia*); FORAMINIFERIDA.

**granulose** (1) (*noun*) A (1 → 4)- $\alpha$ -glucan which accumulates in the cells of *Clostridium* spp prior to sporulation; it is rapidly degraded during sporulation, and may thus function as an endogenous reserve of carbon and energy for sporulation.

(2) (*adj.*) Having a granular appearance.

**granulosis** An INSECT DISEASE caused by a GRANULOSIS VIRUS.

**granulosis viruses (GVs)** Viruses belonging to subgroup B of the BACULOVIRIDAE (q.v.). The viruses replicate mainly in the

nucleus, but some replication can also occur in the cytoplasm. The virion contains a single nucleocapsid within the envelope. Type species: *Trichoplusia ni* (cabbage looper) GV (TnGV); other members: *Plodia interpunctella* (Indian meal moth) GV, *Cydia pomonella* (codling moth) GV, and viruses isolated from a wide range of other lepidopteran insects.

**granum** (*pl.* grana) See CHLOROPLAST.

**Granville wilt** (Southern bacterial wilt) A soil-borne TOBACCO DISEASE, involving wilting and yellowing of leaves, caused by *Pseudomonas solanacearum*. (See also SCOPOLETIN.)

**granzymes** See APOPTOSIS.

**Graphidales** An order of fungi of the ASCOMYCOTINA; members include crustose LICHENS (photobiont generally trentepohlioid). Ascocarp: APOTHECIOID, or immersed and ostiolate, with paraphyses. Asci: unitunicate and cylindrical with a thickened apex. Genera: e.g. *Diploschistes*, *GRAPHIS*, *Phaeographis*, *Thelotrema*.

**Graptolaceae** See UTILAGINALES.

**Graphis** A genus of crustose LICHENS (order GRAPHIDALES); photobiont: a green alga. Thallus: thin, smooth or wrinkled. Apothecia: black LIRELLAE; ascospores: colourless, multiseptate. Species occur mainly on bark.

**graphitization** An early term for the anaerobic corrosion of iron by sulphate-reducing bacteria.

**Grarium** A synnema-forming genus of the HYPHOMYCETES. (See also SAP-STAIN.)

**GRAS** 'Generally recognized as safe' – a category of food additives (including some food PRESERVATIVES) recognized in the USA.

**grass diseases** Diseases which can affect non-cereal grasses include e.g. CHOKE, DOLLAR SPOT, SILVER TOP, SNOW MOULD, and ophiobolus patch disease (see TAKE-ALL). (See also FIJIVIRUS, CEREAL DISEASES and SUGARCANE DISEASES.)

**Grasseella** See EIMERIORINA.

**graticule** See MICROMETER.

**gratuitous inducer** See OPERON.

**gravity slide sampler** *Syn.* DURHAM SHELTER.

**gray** (Gy) A unit of absorbed radiation equal to 1 joule of energy absorbed by 1 kg of material. (1 Gy = 100 RAD; 10<sup>3</sup> Gy = 1 kGy.)

**gray mold** See GREY MOULD.

**greasy pig disease** (exudative dermatitis) An acute, often fatal disease of piglets characterized by a non-pruritic dermatitis, the presence of a greasy exudate on the skin, dehydration and emaciation; aetiology: uncertain, but a Gram-positive coccus (*Staphylococcus hyicus*) and/or a virus may be involved.

**green algae** Algae of the CHLOROPHYTA.

**green bacteria** (green sulphur bacteria) (1) Bacteria of the sub-order CHLOROBIIINEAE. (2) Bacteria of the family CHLOROBIAEAE.

**green ear disease** See PHYLLODY.

**green fluorescent protein** (GFP) A fluorescent protein, found in jellyfish of the genus *Aequorea*, which emits green light ( $\lambda = 508$  nm) when irradiated with blue light ( $\lambda = 395$  nm). The gene for GFP has been widely used as a partner in gene fusion experiments (see FUSION PROTEIN sense 2).

[Green fluorescent protein (review): ARB (1998) 67 509–544.]

**green laver** See LAVER and ULVA.

**green manure** See *Azolla* in NITROGEN FIXATION.

**green monkey fever** *Syn.* MARBURG FEVER.

**green oak** Oak wood which has been stained green as a result of infection by *Chlorociboria aeruginascens* (= *Chlorosplenium aeruginascens*, often called *Chlorosplenium aeruginosum*). Green oak is valued as a medium for inlay work etc. (cf. BROWN OAK.)

**green spot disease** See ALGAL DISEASES.

**green sulphur** See SULPHUR.

**green sulphur bacteria** See GREEN BACTERIA.

**Greenberg–Smith sampler** An ALL-GLASS IMPINGER.

**greenhouse effect** The warming of the planet due to rising levels of CO<sub>2</sub>, methane and certain other gases (which effectively 'trap' some of the radiant energy reaching the Earth's surface).

In the CARBON CYCLE, large amounts of CO<sub>2</sub> are produced by animals, plants and microbes during respiration or fermentation, but large amounts are used ('fixed') during PHOTOSYNTHESIS; globally, the important balance between biological production and uptake of CO<sub>2</sub> is being upset e.g. by the burning of vast amounts of fossil fuel (gas, petroleum etc.). (See also METHANOTROPHY.)

It might be thought that raised levels of CO<sub>2</sub> would stimulate growth in plants, and, thereby – due to greater sequestration of CO<sub>2</sub> by photosynthesis – tend to offset the rise in CO<sub>2</sub>. Some agricultural, crop-type plants do respond to increased CO<sub>2</sub> by improved growth. However, experimental tropical ecosystems under increased CO<sub>2</sub> have shown, in addition to increased root growth, an increased efflux of CO<sub>2</sub> from soil to atmosphere; this efflux was apparently due to stimulated metabolic activity of microorganisms in the RHIZOSPHERE. Thus, an increased uptake of CO<sub>2</sub> by plants may itself be offset by increased efflux of CO<sub>2</sub> from the soil [Science (1992) 257 1672–1675].

More recently it was suggested that certain pasture grasses in the South American savannas may offer a useful sink for carbon in their particularly massive and deep root systems [Nature (1994) 371 236–238].

It has been pointed out that global warming may itself result in increased levels of greenhouse gases – i.e. a potential positive feedback effect [BC (1996) 5 1069–1083].

It has been assumed that the avoidance of deforestation is of major importance in the context of global warming because such a policy preserves a valuable means for controlling levels of atmospheric carbon dioxide [Nature (2001) 410 429]. However, recent experiments have indicated that the ability of forest systems to sequester carbon dioxide may be limited by shortages of nutrients and water and/or by the relatively rapid turnover of organic carbon in the litter layer [Nature (2001) 411 469–472; Nature (2001) 411 466–469; commentary: Nature (2001) 411 431–433].

**greening** (1) See HAEMOLYSIS. (2) See MEAT SPOILAGE and DFD MEAT.

**gregarin** The trophozoite form of a gregarine.

**Gregarina** A genus of the GREGARINASINA.

**Gregarinasina** (Gregarinidia) A subclass of protozoa (class SPOROZOASIDA) parasitic in invertebrates (e.g. annelids, insects). In members of this subclass the mature gametocytes occur extracellularly in the host (cf. COCCIDIASINA); the mature organism generally has a MUCRON or an EPIMERITE. In the *cephaline* gregarines (e.g. *Gregarina* spp) the mature organism is septate – the nucleus usually being in the DEUTOMERITE; in *acephaline* gregarines (e.g. MONOCYSTIS) the mature organism is aseptate. Species whose life cycles do not include schizogony (the *eugregarines*) are commonly non-pathogenic; species which undergo schizogony as well as sexual reproduction (the *schizogregarines*) are commonly pathogenic. Some authors divide the schizogregarines into the *archigregarines* (parasitic in annelids) and the *neogregarines* (parasitic in insects). Genera include *Actinocephalus*, *Stenophora*, *Urospora*.

**gregarine** A member of the GREGARINASINA.

**gregarine movement** See MOTILITY.

## Gregarinia

**Gregarinia** (1) A subclass of protozoa (class Telosporea) later classified as the subclass GREGARINASINA. (2) A subclass of protozoa (class Sporozoa [JP (1980) 27 37–58]) equivalent to the GREGARINASINA.

**Gregarinidia** *Syn.* GREGARINASINA.

**grepaffloxacin** See QUINOLONE ANTIBIOTICS.

**grex** See DICTYOSTELIUM.

**grey mould** ('botrytis') A disease, caused by *Botrytis cinerea*, which can affect a wide range of plants as well as stored fruits and vegetables (e.g. beans, peas, raspberries and strawberries); the disease is encouraged by cool, damp conditions, and is characterized by a grey, fluffy surface mould overlying a soft, commonly brown, rot. (See also DAMPING OFF.)

**grid** See ELECTRON MICROSCOPY (a).

**Gridley fungus stain** A staining procedure that depends on the oxidation (by chromic acid) of adjacent hydroxyl groups in fungal cell wall polysaccharides, followed by the reaction of the resulting aldehyde groups with e.g. SCHIFF'S REAGENT. [Method: Book ref. 53, p. 2207.]

**Griffith's tube** An apparatus used for grinding tissues. It consists of a stout, large-diameter glass tube which is closed at the bottom; the lower, inner part of the tube has a roughened surface – against which the tissue is ground by means of a close-fitting pestle-like glass rod.

**Griffith's typing** (of group A streptococci) A serological (slide agglutination) TYPING method based on strain differences in the M and/or T antigens.

**Griffithsia** See RHODOPHYTA.

**Grifola** See APHYLLOPHORALES (Polyporaceae).

**grippe** *Syn.* INFLUENZA.

**griseofulvin** (7-chloro-4,6-dimethoxycoumaran-3-one-2-spiro-1'-(2'-methoxy-6'-methylcyclohex-2'-en-4'-one)) An antifungal ANTIBIOTIC produced by *Penicillium griseofulvum*. It is inhibitory for actively growing dermatophytes and certain other filamentous fungi but is inactive against e.g. yeasts and bacteria. Griseofulvin acts primarily as a MICROTUBULE inhibitor, preventing the assembly of tubulin dimers into microtubules and thereby inhibiting e.g. mitosis. Additionally, the antibiotic interferes with the pattern of glucan and glycoprotein deposition in the fungal cell wall; as a result the tips of the hyphae become characteristically curled (hence the early name for the antibiotic: 'curling factor').

Griseofulvin is widely used in the treatment of dermatophyte infections of the skin, hair and nails. It is administered orally (it is not effective topically) and accumulates in keratinized tissues; it apparently forms a complex with keratin which may decrease the susceptibility of the keratin to fungal keratinases. Griseofulvin-resistant dermatophytes occur [Arch. Derm. (1981) 117 16–19].

Griseofulvin is active against certain plant-pathogenic fungi (e.g. *Botrytis* spp, *Alternaria solani*). It can be taken up by plant roots and has low phytotoxicity; it has limited use as a systemic ANTIFUNGAL AGENT in plants.

**griseoviridin** An antibiotic structurally related to streptogramin A (see STREPTOGRAMINS).

**gRNAs** See RNA EDITING.

**Grocott–Gomori stain** *Syn.* METHENAMINE–SILVER STAIN.

**groEL gene** See HEAT-SHOCK PROTEINS.

**groES gene** See HEAT-SHOCK PROTEINS.

**Gromia** See FILOSEA.

**Gromiida** See FILOSEA.

**groove** (in DNA) See DNA.

**Grossglockneria** See CILIOPHORA.

**ground squirrel hepatitis virus** (GSHV; ground squirrel hepatitis B virus, GSHBV) A virus of the HEPADNAVIRIDAE which infects

Beechey ground squirrels (*Spermophilus beecheyi*); infected animals show little or no evidence of hepatitis and appear not to develop hepatocellular carcinoma. (cf. WOODCHUCK HEPATITIS VIRUS.)

**groundnut crinkle virus** See CARLAVIRUSES.

**groundnut eyespot virus** See POTYVIRUSES.

**groundwater** See WATER SUPPLIES.

**group I/II introns** See SPLIT GENE (b) and (c).

**group-phase antigens** See PHASE VARIATION.

**group stage** See TOXOPLASMOSIS.

**group translocation** (1) See TRANSPORT SYSTEMS. (2) *Syn.* VECTORTIAL GROUP TRANSLOCATION.

**group treponemal antigens** *Syn.* REITER ANTIGENS.

**grouping antiserum** Any antiserum which can agglutinate all the members of a particular group of serotypes within a given genus, i.e., serotypes which have in common one or more antigens which are not found in serotypes outside the group (see e.g. KAUFFMANN–WHITE CLASSIFICATION).

**growth** In a single living cell: a *coordinated* increase in the mass of essential cell components leading, typically, to progress through the CELL CYCLE; in a population of cells or a mycelium: a coordinated increase in biomass, or an increase in the number of cells in the population. (An increase in mass does not necessarily signify growth since it may be due e.g. to the accumulation of an intracellular storage compound.)

Growth is said to be *balanced* when the increase in mass of all essential cell components occurs exponentially and is coincident with the rate of increase in total biomass or in cell numbers. In *unbalanced* growth there is a change in the rate of synthesis of some cell component(s) relative to that of other components; under these conditions (which occur e.g. during the adaptive changes in the lag phase of BATCH CULTURE) changes in biomass are not directly proportional to changes in cell numbers. (See also CONTINUOUS CULTURE.)

Growth may be measured e.g. by monitoring cell numbers (see COUNTING METHODS), by measuring the increase in dry weight of biomass formed in a given time interval, by monitoring the uptake and metabolism (or release) of particular substances, or by measuring the amount of a radioactive metabolite incorporated in biomass in a given time. Growth may be expressed in the form of a *growth curve*: a graph in which the number of cells, or the biomass, is plotted against time.

(a) *Bacterial growth.* Growth in individual bacterial cells commonly leads to (asexual) reproduction (i.e., cell division) – usually by BINARY FISSION, but sometimes by BUDDING or by MULTIPLE FISSION; the events which occur during growth in a single cell are described under CELL CYCLE. In some species, growth may be followed by differentiation, e.g. the formation of a dormant cell (see e.g. ENDOSPORE).

*The growth of a bacterial population.* When cells divide by binary fission, each individual cell gives rise to 2, 4, 8, 16, 32, ... cells after 1, 2, 3, 4, 5, ... generations (i.e. rounds of division). Hence, the number of cells (N) derived from a single cell after *n* generations is given by:

$$N = 2^n$$

Similarly, after *n* generations, the number of cells derived from an initial cell population of  $N_0$  is given by:

$$N = 2^n N_0$$

For bacteria dividing by binary fission, a growth curve can be prepared by plotting cell numbers on a  $\log_2$  scale; this permits the number of generations per unit time to be read off directly

(since each unit on the  $\log_2$  scale is equal to one generation), and the graph also indicates clearly any changes in the growth rate. (The  $\log_2$  and  $\log_{10}$  of any number can be interconverted by use of the formula:  $\log_{10} N = 0.301 \log_2 N$ .)

The rate of growth may be expressed in terms of the SPECIFIC GROWTH RATE,  $\mu$ . When  $\mu$  is constant (e.g. during exponential growth in batch culture), the relationship between  $\mu$  and the doubling time (i.e. the time taken for the biomass – or population – to double) is given by:

$$t_d = \frac{0.693}{\mu}$$

in which  $t_d$  is the doubling time. For some cells (including those of e.g. *Escherichia coli*) the minimum doubling time (= minimum generation time) is of the order of minutes, while for others (e.g. those of certain *Mycobacterium* spp) it may be many hours. (Variation may occur among the doubling times of individual cells in a single-species population – see also SYNCHRONOUS CULTURE.)

Provided that  $\mu$  is constant, the number of generations (= number of doublings of biomass, or of cell numbers) per unit time is given by k:

$$k = \frac{(\log_2 N_t - \log_2 N_0)}{t}$$

– k being the exponential growth rate constant (sometimes, confusingly, symbolized by  $\mu$  instead of k), and  $N_t$  and  $N_0$  being the populations at time t and time zero, respectively. The quantity  $1/k$  is the mean generation time (= mean doubling time).

(b) *Fungal growth.* According to species and conditions, growth may involve or lead to (i) an increase in cell size or (in mycelial fungi) an increase in hyphal length and/or hyphal branching; (ii) vegetative differentiation – e.g. a phase change in DIMORPHIC FUNGI; (iii) asexual reproduction; (iv) sexual reproduction.

*Hyphal growth.* Linear hyphal growth occurs by the incorporation of new materials at the extreme distal end of the hypha (i.e., ‘tip growth’); precursors of the CELL WALL and CYTOPLASMIC MEMBRANE are assembled in the GOLGI APPARATUS and then transported, in vesicles, to the hyphal apex where fusion occurs between the vesicles and the cytoplasmic membrane. The unidirectional flow of vesicles to the hyphal apex appears to be related to a phenomenon observed in growing (but not in non-growing) hyphae: the continual circulation of positive charges through the terminal region of the hypha; thus, positive charges from the environment pass into the hypha at, and close to, the hyphal apex, and pass out into the environment a short distance proximal to the apical region. Such transhyphal currents of positive charge have been observed in several fungi [JGM (1984) 130 3313–3318] and may be common to all growing fungal hyphae. (Axially aligned currents of positive charge also occur e.g. in zygotes of the brown algae *Fucus* and *Pelvetia* and in growing plant roots and pollen tubes.) In the water mould *Achlya bisexualis* the current consists of protons; the proton current is apparently due to the preferential distribution of proton–amino acid symporters in the apical region of the hypha, and PROTON ATPASES in the adjacent region. (In e.g. *Pelvetia* the circulating current appears to consist primarily of calcium ions.) The way in which these circulating currents contribute to the unidirectional flow of intracellular cell-building vesicles is not clear; it has been suggested e.g. that currents of charge may promote the ‘electrophoretic’ translocation of vesicles, or (in *Achlya*

*bisexualis*) that the localized decrease in pH in the hyphal tip may affect vesicle–cytoskeleton interaction, thereby regulating the translocation and localization of vesicles. Interestingly, the polarity of growth of various filamentous fungi can be manipulated experimentally by applied electrical fields [JGM (1986) 132 2515–2525].

The development of a hyphal branch is apparently preceded by the commencement of charge influx at the given location. Branching can be enhanced by CYTOCHALASINS A and E (which may affect microfilament systems involved in vesicle transport) and by IONOPHORES such as A23187 and CCCP (thus implicating cytoplasmic ions in the control of branch initiation) [JGM (1986) 132 213–219].

Hyphal growth (both linear and branching) requires the coordinated action of autolytic and synthetic enzymes in the region of growth – together with an intracellular turgor pressure to act as driving force for surface expansion. Antibiotics which inhibit cell wall formation (e.g. POLYOXINS) cause the development of bulbous hyphae and distorted germ tubes in isotonic media; hyphal tips (and budding yeasts) burst in hypotonic media.

[Cell wall synthesis in apical hyphal growth: Int. Rev. Cytol. (1986) 104 37–79.]

*Growth in unicellular fungi.* Growth may involve BUDDING or BINARY FISSION. BATCH CULTURES of unicellular fungi exhibit lag, exponential, stationary and death phases of growth.

*Growth in dimorphic fungi.* Whether growth occurs in the unicellular or mycelial phase may be determined by temperature (e.g. in *Paracoccidioides brasiliensis*), by the availability of particular nutrients (e.g. in *Candida albicans*, *Mucor rouxii*), or by a combination of factors which include temperature and redox potential (e.g. in *Histoplasma capsulatum*). In a given organism the composition of the CELL WALL (q.v.) may differ in the unicellular and mycelial phases. In *C. albicans* the distribution of ACTIN in a growing bud differs from that in a growing hypha [JGM (1986) 132 2035–2047].

(See also SECONDARY METABOLISM.)

**growth curve** See GROWTH and BATCH CULTURE.

**growth cycle** (1) *Syn.* CELL CYCLE. (2) A term used by some authors to refer to the (non-cyclical) sequence of phases in BATCH CULTURE (i.e. lag phase to death phase).

**growth precursor cell** (shut-down cell) A cell which differs from its parent cell in that it proceeds through the CELL CYCLE only under (presumably) favourable environmental conditions. Cells conforming to this description include e.g. the swarmer cells of *Caulobacter crescentus*, *Hyphomicrobium* sp. and *Rhodospirillum rubrum* – cells which are characterized by low levels of endogenous metabolism, no synthesis of DNA or rRNA, and the apparent ability to respond to external growth-triggering stimuli. It has been suggested that a growth precursor cell may function as a survival cell and/or as a stage from which one of various cell types may develop according to particular environmental stimuli. [Review: Book ref. 28, pp. 187–247.]

**growth rate constant** (1) *Syn.* SPECIFIC GROWTH RATE. (2) The exponential growth rate constant – see GROWTH (a).

**growth-specific yield coefficient** See YIELD COEFFICIENT.

**growth yield coefficient** *Syn.* YIELD COEFFICIENT.

**Grunstein–Hogness procedure** *Syn.* COLONY HYBRIDIZATION.

**Gruyère cheese** See CHEESE-MAKING.

**G<sub>s</sub> protein** See ADENYLATE CYCLASE.

**GS/GOGAT** See AMMONIA ASSIMILATION.

**GSHBV** See GROUND SQUIRREL HEPATITIS VIRUS.

**GSHV** GROUND SQUIRREL HEPATITIS VIRUS.

## GSP

**GSP** See PROTEIN SECRETION.

**GSR** Generalized SHWARTZMAN REACTION.

**GT** ... **AG rule** See SPLIT GENE (a).

**GT1<sub>b</sub>** See FOOD POISONING (*Vibrio*).

**GTA** Gene transfer agent: see CAPSDUCTION.

**GTP** Guanosine 5'-triphosphate. (See also ATP and NUCLEOTIDE.)

**GTP-binding proteins** *Syn.* G PROTEINS.

**GU** ... **AG rule** See SPLIT GENE (a).

**guanidine** ((H<sub>2</sub>N)<sub>2</sub>C=NH) Guanidine salts (e.g. guanidine hydrochloride: (H<sub>2</sub>N)<sub>2</sub>C=NH<sub>2</sub><sup>+</sup>Cl<sup>-</sup>) act as ANTIVIRAL AGENTS against a number of picornaviruses (e.g. polioviruses) by inhibiting viral RNA synthesis. Although cytotoxicity is low, guanidine is not used clinically since resistant mutants arise rapidly; guanidine-dependent mutants have also been isolated.

**guanidine antifungal agents** See e.g. DODINE and GUAZATINE.

**guanosine** See NUCLEOSIDE and Appendix V(a).

**guanosine tetraphosphate** (guanosine 5'-diphosphate 3'-diphosphate) See STRINGENT CONTROL (sense 1).

**guanylate cyclase** See ETEC (ST-I).

**guanylin** See EAST1 and ETEC (ST-I).

**guanylyl transferase** See MRNA (b).

**Guanieri bodies** (B-type inclusion bodies) Eosinophilic INCLUSION BODIES, each surrounded by a clear non-staining 'halo', characteristically formed in the cytoplasm of cells infected with vaccinia, variola or cowpox viruses (see POXVIRIDAE).

**guazatine** A guanidine ANTIFUNGAL AGENT used e.g. as a seed treatment for the control of bunt of wheat, and – mixed with e.g. imazalil – as a spray against cereal smuts, net blotch, etc.

**Guepiniopsis** See DACRYMYCETALES.

**guide RNAs** (gRNAs) See RNA EDITING.

**guide sequence** See SPLIT GENE.

**Guillain–Barré syndrome** (GBS) An immune-mediated disorder of the peripheral nerves involving e.g. a progressive motor weakness in at least two limbs. In the majority of patients GBS is preceded by an infectious disease – e.g. a (very) small proportion of patients with a *Campylobacter* infection may develop GBS.

**Guilliermondella** A genus of fungi (family SACCHAROMYCETACEAE) which form budding yeast cells as well as a true septate mycelium. One species: *G. selenospora*. [Book ref. 100, pp. 151–153.]

**guinea-pig agent** *Legionella micdadei*.

**guinea-pig cytomegalovirus** See BETAHERPESVIRINAE.

**gullet** (1) The BUCCAL CAVITY in certain ciliates. (2) See EUGLENOID FLAGELLATES.

**gularonic acid** See ALGINATE.

**gum xanthan** *Syn.* XANTHAN GUM.

**Gumboro disease** *Syn.* infectious bursal disease (see INFECTIOUS BURSAL DISEASE VIRUS).

**gumma** See e.g. SYPHILIS.

**gummosis** Any plant disease in which the lesions exude a sticky liquid; examples: gummosis of cucumber (caused by *Cladosporium cucumerinum*), of *Axonopus* spp (Gramineae) (caused by *Xanthomonas axonopodis*), and of sweet orange (*Citrus sinensis*) (caused by *Phytophthora parasitica*).

**Gunflintia** See STROMATOLITES.

**Gunnera** See NOSTOC.

**gut flora** (human) See GASTROINTESTINAL TRACT FLORA.

**guttulate** Containing one or more GUTTULES.

**guttule** (*mycol.*) A globule or droplet (of oil?) within a spore.

**Guttulina** See ACRASIOMYCETES.

**Guttulinopsis** See ACRASIOMYCETES.

**GV** GRANULOSIS VIRUS.

**Gy** See GRAY.

**Gyalecta** See GYALECTALES.

**Gyalectales** An order of mainly lichenized fungi of the ASCOMYCOTINA. Ascocarp: APOTHECIOID; hamathecium; paraphyses. Asci: clavate or cylindrical. Genera: e.g. *Dimerella*, *Gyalecta*, *Petractis*.

**GYC agar** See ACETOBACTER.

**Gymnamoebia** A subclass of naked (non-testate) amoebae (AMOEBIDA, PELOBIONTIDA and SCHIZOPYRENIDA). (cf. TESTACEALOBOSIA.)

**Gymnoascales** An order of mainly keratinophilic fungi of the subdivision ASCOMYCOTINA; many species have anamorphs among the DERMATOPHYTES. Ascocarp: cleistothecoid, with or without appendages, sometimes insubstantial (consisting e.g. of a loose hyphal network); sessile or stipitate. Asci: unitunicate. Ascospores: unicellular, spherical, discoid or fusiform, sometimes forming a mazaedial mass at maturity. Genera: e.g. AJELLOMYCES, *Aphanoascus*, ARTHRODERMA, *Gymnoascus*, *Myxotrichum*, NANNIZZIA and *Onygena* (see also MAZAEDIUM); of these, *Aphanoascus* and *Onygena* belong in the family Onygenaceae, and the others in the family Gymnoascaleaceae.

**Gymnoascus** See GYMNOASCALES.

**gymnocarpic development** (also: gymnocarpous development) (*mycol.*) The mode of development of a fruiting body in which the spores are exposed to the environment throughout their differentiation and maturation. (See e.g. APHYLLOPHORALES; cf. ANGIOCARPIC DEVELOPMENT.)

**Gymnodinioides** See HYPOSTOMATIA.

**Gymnodinium** See DINOFLAGELLATES; RED TIDE; ZOOXANTHELLAE.

**Gymnomyxa** A protistan phylum (equivalent to the mycological division MYXOMYCOTA) comprising the subphyla MYCETOZOA, Plasmodiophorina (equivalent to PLASMIDIOPHOROMYCETES), and Labyrinthulina (equivalent to LABYRINTHULOMYCETES). [Book ref. 147, pp. 4–5.]

**Gymnosphaera** See CENTROHELIDA.

**Gymnosporangium** A genus of typically heteroxenous rust fungi (class UREDINIOMYCETES) whose primary and secondary hosts are commonly members of the families Juniperaceae and Rosaceae, respectively. Most species are DEMICYCLIC RUSTS. The aecial and telial stages often form on GALLS which develop on the host plant as a response to infection by the rust; thus, e.g. *G. juniperi-virginianae*, which parasitizes the juniper (*Juniperus*) and apple (*Malus*), produces telia which develop in (and later project from) spherical galls ('cedar apples') which form on the juniper. (The cedar (*Cedrus*) is not susceptible to this rust.)

**Gymnostomatia** A subclass of ciliates (class KINETOFRAGMINOPHOREA) in which the cytostome is superficial (i.e., it does not occur at the base of an organized buccal cavity or vestibulum), and the cytopharyngeal apparatus is of the RHABDOS type. Somatic ciliature is commonly uniform. The organisms are typically large and carnivorous. Genera include e.g. *Acaryophrya*, *Acineria*, ACTINOBOLINA, COLEPS, *Didesmis*, DIDINIUM, DILEPTUS, *Holophrya*, *Lacrymaria*, KENTROPHOROS, LOXODES, *Loxophyllum*, *Mesodinium*, *Metacystis*, *Nanophrya*, PRORODON, STEPHANOPOGON, TRACHELOPHYLLUM and *Urotricha*.

(See also KARYORELICHTID GYMNSTOMES; PRIMOCILLIATID GYMNSTOMES.)

**gymnostome** A ciliate of the GYMNSTOMATIA.

**gyrA, gyrB genes** See GYRASE.

**gyrase** (DNA gyrase) A type II TOPOISOMERASE which catalyses the negative supercoiling of relaxed or positively supercoiled

ds cccDNA (see DNA) in an ATP-dependent process. (In the absence of ATP, the gyrase from *Escherichia coli* can relax negative, but not positive, supercoils.) Gyrase functions as a tetramer consisting of two of each of two types of subunit, A and B (i.e. A<sub>2</sub>B<sub>2</sub>); subunits A and B are the products of genes *gyrA* (= *nalA*) and *gyrB* (= *cou*), respectively. The enzyme binds to dsDNA at specific (but apparently non-homologous) sites. The DNA becomes wrapped around the surface of the enzyme in a positive supercoil; this necessarily introduces a compensating negative supercoil elsewhere in the molecule. The remaining steps effectively remove the positive supercoil. The B subunits bind ATP, a step which alters the functional (conformational?) state of the enzyme, and the A subunits bring about a staggered break in the dsDNA, the resulting 5' ends each projecting beyond the 3' ends by four bases. [Determinants of site-specific DNA breakage by gyrase: EMBO (1986) 5 1411–1418.] Each 5' end is covalently bound to one of the A subunits via a phosphotyrosine bond; this allows conservation of the energy of the phosphodiester bond for later use in re-sealing. A length of DNA from elsewhere in the molecule (possibly from the region wrapped around the enzyme) is passed through the (double-stranded) break while both ends of the break are held so that they cannot rotate; the break is then re-sealed. This decreases the linking number of the molecule by two. (If the translocated length of DNA belongs to a second molecule, rather than to another part of the same molecule, the result is a CATENANE.) Finally, the ATP bound to the B subunits is hydrolysed and the original conformation of the enzyme is restored; the whole cycle can then begin again. (Note: ATP *binding* allows a single round of supercoiling, but ATP *hydrolysis* is necessary for subsequent rounds.) The

ability of gyrase to introduce negative supercoiling appears to decrease with increasing levels of negative supercoiling. In *E. coli*, the appropriate level of supercoiling in vivo is apparently achieved/maintained by the opposing activities of gyrase, on the one hand, and topoisomerases I and IV (see TOPOISOMERASE) on the other hand.

Gyrase is apparently essential in vivo for e.g. DNA REPLICATION, recombination, transposition (see TRANSPOSABLE ELEMENT), and some cases of TRANSCRIPTION; this requirement seems to be due, at least in part, to the need for supercoiled DNA in these processes, and implies that gyrase has an important role in generating and maintaining the correct level of supercoiling of DNA in the cell. (cf. ILLEGITIMATE RECOMBINATION.) There is also evidence for a more direct role for gyrase at the replication forks during DNA replication. (cf. REVERSE GYRASE; see also COUMERMYCINS; NALIDIXIC ACID; NOVIOBIACIN; OXOLINIC ACID.)

[QUINOLONE ANTIBIOTICS and other gyrase-targeted antibiotics: TIM (1997) 5 102–109.]

Some candidate antibiotics affect gyrase at sites distinct from those targeted by quinolone antibiotics (and do not exhibit cross-resistance with the quinolones) [TIM (1998) 6 269–275].

**Gyrodinium** See DINOFLAGELLATES.

**Gyrodontium** See APHYLLOPHORALES (Coniophoraceae).

**gyrogonites** Fossilized charophyte oogonia.

**Gyromitra** See PEZIZALES.

**gyrose** Sinuous; curving; marked with undulating lines. In lichenology: refers to a type of apothecium (e.g. in some *Umbilicaria* spp) in which there is a spiral or maze-like pattern of fertile ridges and sterile furrows.

**Gyrosigma** See DIATOMS.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# H

**H** Histidine (see AMINO ACIDS).

**H antigens** Bacterial flagellar antigens. H antigens are detected in the serological characterization of certain enterobacteria (see e.g. KAUFFMANN-WHITE CLASSIFICATION). Agglutination of cells with homologous H antiserum occurs rapidly, is characteristically floccular, and the agglutinated cells can be readily dispersed by shaking (since flagella are easily broken). H antigens are heat-labile and are destroyed by alcohol but not by dilute formalin. (See also IMMOBILIZATION TEST.)

In a few *Salmonella* serotypes (e.g. *S. typhi*) and other enterobacteria the flagella exhibit only one type of antigenic pattern, i.e. the H antigens are *monophasic*. However, most salmonellae can produce either of two different patterns of H antigens, i.e. in these organisms the H antigens are *diphasic* (see PHASE VARIATION).

**H<sup>+</sup>-ATPase** See PROTON ATPASE.

**H<sup>+</sup>/2e<sup>-</sup> ratio** During the operation of an ELECTRON TRANSPORT CHAIN: the number of protons translocated across the membrane during the passage of two electrons along the chain.

**H-lysin** See FURUNCULOSIS (sense 1).

**h mutant** HOST-RANGE MUTANT.

**H<sup>+</sup>/O ratio** During the operation of an ELECTRON TRANSPORT CHAIN with oxygen as terminal electron acceptor: the number of protons translocated across the membrane per oxygen atom reduced. (cf. P/O RATIO.)

**H<sup>+</sup>/P ratio** The number of protons passing through a PROTON ATPASE per molecule of ATP released at the catalytic site.

**H<sup>+</sup>-PPase** PROTON PHASE.

**H strand** 'Heavy strand': that strand of a dsDNA molecule which exhibits the higher buoyant density (owing to a higher content of thymine and guanine) when the dsDNA is denatured and subjected to CsCl density gradient CENTRIFUGATION; the other ('light') strand is designated the *L strand*. The designation 'heavy' or 'H' is also used to refer to a strand labelled with a heavy isotope such as <sup>15</sup>N, the unlabelled strand being designated 'light' or 'L'.

**H1 protein** *Syn.* H-NS PROTEIN.

**H-1 virus** See PARVOVIRUS.

**H<sub>II</sub> phase** See CYTOPLASMIC MEMBRANE.

**HAA** See HEPATITIS B VIRUS.

**HAART** Highly active antiretroviral therapy: a form of chemotherapy, used for HIV-positive and AIDS patients, involving a combination of different kinds of ANTIRETROVIRAL AGENT; such treatment should, theoretically, inhibit completely the replication of HIV, and in some studies HIV is reported to be undetectable in plasma.

One example of HAART is the combination of (i) efavirenz (a non-nucleoside reverse transcriptase inhibitor), (ii) nelfinavir (a protease inhibitor) and (iii) a nucleoside reverse transcriptase inhibitor [NEJM (1999) 341 1874–1881].

Even with effective HAART, low-level replication can occur. This may involve (i) long-lived HIV-infected cells and (ii) selection of drug-resistant mutants [JV (2005) 79 9625–9634].

**Haber-Weiss reaction** See HYDROXYL RADICAL.

**HACCP** Hazard analysis critical control point system: detailed appraisal of a production process and control of known/potential hazards at certain critical points in the process. ('Hazard' refers to any influence or factor which would, unless avoided, affect

adversely the integrity of the process and/or the quality of the final product.)

Initially, an objective assessment of known and potential hazards is carried out using a flow-chart which shows all aspects of the process – details that may include e.g. source(s) of raw materials, a step-wise coverage of all stages of processing, route(s) of distribution of the product, and the movement of product to the point of sale (if applicable).

Central to the HACCP system is the identification of a number of *critical control points* (CCPs) – specific stages in the process at which effective action can be taken to prevent or counteract the effects of particular hazard(s). Monitoring is carried out at CCPs to ensure that processing continues within pre-determined tolerance limits (in terms of quality, contamination etc.).

Microbiological monitoring at CCPs may aim to detect specific organism(s) or it may assess the level of general microbial contamination. Monitoring tests should give rapid results so that corrective action, if necessary, can be taken swiftly; the traditional approach to monitoring, based on colony counting, may be too slow to permit timely intervention in a modern production process.

In the food industry, many of the microbiological tests are designed to detect contamination by non-specific organisms; these tests monitor factors such as carbon dioxide (produced by contaminating organisms) and/or the presence of ATP (released, *in vitro*, from contaminating organisms). An example of such tests is the screening of UHT milk for microbial contamination by the Lumac<sup>®</sup> Autobiocounter M 4000 (manufactured by Perstorp Analytical LUMAC, Landgraaf, The Netherlands); in this system, samples of UHT milk are examined for their content of (intracellular) ATP – the presence of which indicates contamination with metabolizing (living) organisms. The Autobiocounter M 4000 is used e.g. for testing samples derived from a continuous production process that operates on a batch system (see below). Before testing, each sample is pre-incubated (at e.g. 30°C for 48 hours) to allow the growth of any contaminants that may be present. After incubation, an aliquot (e.g. 50 µl) of sample is transferred to an ATP-free cuvette (container) and is treated first with ATPase to hydrolyse (destroy) any background ATP in the sample. Subsequently, the aliquot is treated with a reagent that degrades (permeabilizes) the cytoplasmic membrane of any contaminating cells – allowing leakage of ATP from such cells. ATP, if present, is then detected by the luciferin–luciferase system (see BIOLUMINESCENCE) which produces light in the presence of even minute quantities of ATP; emitted light is measured by a photomultiplier (light meter), the result being shown digitally. Measurement of ATP is a fully automated procedure that is completed in about 15–20 minutes. Each batch of product is held back until the test results on samples from that batch become available – being released for distribution when tested samples are found to be satisfactory; despite the delay for sample preparation (incubation), the manufacturing process itself can be continuous, each batch of product being held only for the period required to examine samples.

The LIMULUS AMOEBOCYTE LYSATE TEST, which detects and/or quantifies LIPOPOLYSACCHARIDE (LPS), can be used to monitor contamination by Gram-negative bacteria; any LPS-containing cell, and even isolated LPS, can give a positive test, so that this approach can detect both living and dead cells in the sample.

A particular type of microbial contaminant (e.g. a specific pathogen) may be detectable by using a PROBE-based approach. Moreover, PCR may provide a useful test system given organism-specific primers.

**HACEK** Acronym for a group of bacteria which occur in the mouth and upper respiratory tract and which are sometimes responsible for lesions on heart valves: *Haemophilus* spp, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella* spp.

**hadacidin** (CHO.NOH.CH<sub>2</sub>.CO<sub>2</sub>H) An ANTIBIOTIC and antitumour agent. It is an analogue of L-aspartic acid and blocks adenylosuccinate synthetase (and hence adenine nucleotide synthesis: see Appendix V(a)) but not other aspartic acid-requiring reactions. (cf. AZASERINE.)

**HaeII** A RESTRICTION ENDONUCLEASE from *Haemophilus aegyptius*; PuGCGC/Py.

**HaeIII** A RESTRICTION ENDONUCLEASE from *Haemophilus aegyptius*; GG/CC.

**Haeckel's theory** See ONTOGENY.

**haem** (heme) (1) A generic term for any compound in which iron is coordinately bound to a PORPHYRIN or related compound (e.g. a CHLORIN); the four pyrrole nitrogen atoms each contribute an electron pair to form coordinate bonds with the iron atom – which may be in the ferrous or ferric state. The 5th and 6th coordination positions of the iron may be filled by electron pairs donated e.g. from water, chloride, or – in a *haemoprotein* – basic amino acid residues in the protein. Iron–protoporphyrin IX (= *protohaem IX*, ‘protohaem’) is the prosthetic group in haemoproteins such as CATALASE and certain CYTOCHROMES. Biosynthesis of protohaem IX involves the insertion of an iron atom into the porphyrin, catalysed by *ferrochelatase*. (See also X FACTOR.)

(2) The term ‘haem’ is often used to refer specifically to protoporphyrin IX–ferrous iron – cf. HAEMIN.

**haemadsorption** The adherence of RBCs to cells which are infected with certain types of virus (e.g. paramyxoviruses); thus, if a tissue culture is infected by such viruses infection may be detected by the cells’ ability to adsorb the RBCs of certain species (e.g. guinea pig) under appropriate conditions.

**haemadsorption-inhibition test** Any test used to detect serum antibodies homologous to HAEMADSORPTION-promoting viruses. Essentially, the patient’s INACTIVATED SERUM (in various dilutions) is incubated (e.g. for 1 hour) with a suspension of such a virus – the whole then being used to inoculate a tissue culture; after ca. 5 days’ incubation the (washed) tissue culture is tested for haemadsorption by the addition of RBCs. In a positive test at least some dilutions of the patient’s serum will have neutralized the virus – thus preventing viral infection of the cells and (hence) preventing subsequent haemadsorption.

**haemagglutination** The AGGLUTINATION of red blood cells (RBCs). Haemagglutination may result from any of the following. (a) Combination between RBCs and antibodies homologous to their surface antigens. (b) Combination between certain types of virus (e.g. orthomyxoviruses, paramyxoviruses) and specific cell membrane receptor sites on the RBCs of certain species – the viruses acting as links between the RBCs. After a period of time (which depends e.g. on temperature) some viruses may subsequently elute, spontaneously, owing to their NEURAMINIDASE activity which destroys the neuraminic acid-containing receptor sites. RBCs from which such viruses have eluted cannot again be agglutinated by viruses of the same strain, and are said to be ‘stabilized’. (Sometimes RBCs stabilized by one strain of virus can be agglutinated by a different strain.)

Spontaneous elution (e.g. of influenza viruses) can be inhibited by carrying out haemagglutination tests at 4°C. (c) Passive haemagglutination: see PASSIVE AGGLUTINATION. (d) The action of certain LECTINS. (e) Combination between RBCs and bacterial fimbrial haemagglutinins (see FIMBRIAE).

**haemagglutination-inhibition test** (HAI or HI test) Any test in which specific antibody or antigen is detected or quantified by its ability to inhibit HAEMAGGLUTINATION. HI tests are used e.g. as clinical diagnostic tests to detect serum antibodies to haemagglutinating viruses (e.g. influenza and rubella viruses); essentially, such tests determine the ability of a patient’s serum to neutralize the haemagglutinating properties of a suspension of the given virus – neutralization (a positive test) being indicated by the failure of the serum–virus mixture to agglutinate added RBCs. In many cases the serum used in such tests must be pre-treated to (i) abolish its ability to inhibit haemagglutination *non-specifically*, and/or (ii) to abolish its ability to *promote* haemagglutination. For example, serum may be pre-absorbed with kaolin (to sequester certain non-specific inhibitors of haemagglutination) and/or pre-treated with RBCs (of the type used in the test) in order to absorb HETEROEPHIL ANTIBODIES; serum used in HI tests for e.g. influenza viruses is pre-treated with e.g. the enzyme RDE, and is then heated (prior to the test) in order to destroy RDE activity. [Book ref. 53, pp. 2034–2048.]

HI tests for soluble antigens may involve inhibition of *passive haemagglutination* (see PASSIVE AGGLUTINATION) – antigen being preabsorbed to RBCs. Thus, the amount of antigen in a sample can be measured by the amount of homologous antibody it can complex (sequester) when mixed with a fixed volume of antibody; the amount of free (uncombined) antibody remaining in the mixture (an indirect measure of antigen) is determined by the addition of antigen-coated RBCs (see BOYDEN PROCEDURE.) To ensure antigen-specificity in the test, the antiserum should be preabsorbed with (non-coated) RBCs of the type used in the test.

**haemagglutinin** Any agent or substance which can bring about HAEMAGGLUTINATION.

**Haemamoeba** A subgenus of PLASMODIUM.

**haematein** A red amphoteric DYE prepared by atmospheric oxidation of an aqueous solution of the colourless compound haematoxylin; haematein is usually referred to as ‘haematoxylin’.

**haematin** Protoporphyrin IX–Fe(III) hydroxide. (cf. HAEMIN.)

**haematogenous** (hematogenous) Produced by or derived from the blood, or disseminated via the bloodstream.

**haematophagous** Feeding on blood.

**haematotropic** *Syn.* HAEMOTROPIC.

**haematoxylin** See HAEMATEIN.

**haematuria** The presence of blood in the urine.

**haemin** (1) Any protoporphyrin IX–ferric iron complex: cf. HAEM sense 2. (2) Specifically: protoporphyrin IX–Fe(III) chloride. (cf. HAEMATIN.)

**Haemobartonella** A genus of Gram-negative bacteria of the family ANAPLASMATACEAE. Cells: cocci, coccobacilli or rods (range 0.1–1.5 µm) which occur tightly bound to, or within, erythrocytes in the infected host. *Haemobartonella* spp (*H. canis*, *H. felis* and *H. muris*) have a wide host range and occur worldwide; they are transmitted e.g. by biting insects.

**haemocytometer** See COUNTING CHAMBER.

**haemoglobinuria** The presence of free haemoglobin in the urine.

**Haemogregarina** See ADELEORINA.

**haemogregarines** An imprecise name for those protozoa of the suborders ADELEORINA and EIMERIORINA which infect red and/or white blood cells in the vertebrate host.

**haemolysin** (1) Any antibody homologous to the surface antigens of red blood cells (RBCs). (See also IMMUNE HAEMOLYSIS.)

## haemolysis

(2) (*Syn.* haemolytic toxin) Any of various microbial products which cause HAEMOLYSIS by damaging the cytoplasmic membrane of RBCs.

(a) *Aeromonas salmonicida* haemolysins. See e.g. FURUNCULOSIS (H-lysin and T-lysin).

(b) *Bacillus* haemolysins. See e.g. SURFACTIN.

(c) *Clostridium* haemolysins. See CLOSTRIDIUM.

(d) *Escherichia coli* haemolysins.

$\alpha$ -Haemolysin is an extracellular haemolysin (MWt ca. 107000) specified by either chromosomal or plasmid-borne genes (*hly* genes); chromosomal and plasmid-borne *hly* genes are closely homologous, and identical *hly* genes can occur on plasmids of different incompatibility groups. In cultures of *E. coli*, production of  $\alpha$ -haemolysin occurs under aerobic and anaerobic conditions, but is enhanced by aerobiosis and inhibited by  $>100 \mu\text{M}$  iron.  $\alpha$ -Haemolysin can lyse the RBCs of e.g. sheep, rabbits and man – causing clear haemolysis on blood agar plates; it is cytotoxic for human leucocytes and is lethal when injected into mice.  $\alpha$ -Haemolysin appears to insert into lipid bilayers, generating hydrophilic transmembrane pores of effective diameter ca. 3 nm [Inf. Immun. (1986) 52 63–69]. [Review: MR (1984) 48 326–343; role of  $\alpha$ -haemolysin in the pathogenesis of experimental *E. coli* infection in mice: JGM (1985) 131 395–403.]

$\beta$ -Haemolysin is a cell-bound haemolysin active against e.g. rabbit and human RBCs; it causes clear haemolysis on blood agar plates.

$\gamma$ -Haemolysin has been reported in nalidixic acid-resistant *E. coli* mutants, and its production is stimulated by nalidixic acid; it is not lytic for human or rabbit RBCs.

(e) *Staphylococcus* haemolysins are produced by both coagulase-positive and -negative strains; the best known are the protein EXOTOXINS  $\alpha$ -,  $\beta$ -,  $\gamma$ - and  $\delta$ -haemolysins, although others also occur. No particular pattern of haemolysin production has been associated with virulence.

$\alpha$ -Haemolysin ( $\alpha$ -toxin) is a hydrophobic, surface-active protein with (apparently) no enzymic activity. It shows the Arrhenius effect: it is inactivated on heating to  $60^\circ\text{C}$  but is partly reactivated on further heating to ca.  $100^\circ\text{C}$ .  $\alpha$ -Haemolysin is  $>100$  times more effective against rabbit RBCs than human RBCs. It appears to bind to the cell membrane, causing release of  $\text{K}^+$  – possibly due to the formation of transmembrane pores by amphiphilic hexamers of the haemolysin.  $\alpha$ -Haemolysin can be lethal for man and animals; depending on animal species, it can be leucocidal (= the Neisser–Wechsberg LEUCOCIDIN), can aggregate and lyse blood platelets, and has a range of toxic effects e.g. on the nervous and vascular systems (e.g. it increases vascular permeability). When injected subcutaneously it can have dermonecrotic effects which may be due to direct necrotizing activity or to prolonged vasospasm.  $\alpha$ -Haemolysin has been shown to play a major role in the pathogenesis of gangrenous mastitis in sheep and cattle.

$\beta$ -Haemolysin ( $\beta$ -toxin) is a SPHINGOMYELINASE C specific for sphingomyelin (or lysolecithin); it is inactivated at  $60^\circ\text{C}$ , requires  $\text{Mg}^{2+}$  for activity, and is inhibited e.g. by  $\text{Zn}^{2+}$  and chelating agents. It can hydrolyse the sphingomyelin in sphingomyelin-rich RBCs (e.g. those from sheep or ox) without causing haemolysis; however, lysis can subsequently be induced by chilling (see HOT–COLD LYSIS) or by the addition of the CAMP factor (see CAMP TEST).  $\beta$ -Haemolysin is most frequently produced by staphylococci isolated from animals other than man. Reports that it can be lethal are controversial. It is not dermonecrotic (although it may cause necrosis in lactating mammary gland), but it can show toxic effects on the cardiovascular

system and can lyse platelets and guinea-pig macrophages (but not human PMNs). Its role in pathogenesis, if any, is unknown.

$\gamma$ -Haemolysin ( $\gamma$ -toxin) consists of two protein components which appear to act synergistically in bringing about haemolysis. Rabbit RBCs are more susceptible than human or sheep RBCs; horse RBCs are insensitive.  $\gamma$ -Haemolysin can also increase membrane permeability in cultured fibroblasts, and may have some leucocidal activity. It is inactivated at  $60^\circ\text{C}$  and by certain acidic polymers – including agar, heparin, and dextran sulphate (but not e.g. agarose, hyaluronic acid or chondroitin sulphate), by various lipids (e.g. cholesterol, fatty acids), and by EDTA and citrate.

$\delta$ -Haemolysin ( $\delta$ -toxin) is a heat-stable, hydrophobic, strongly surface active peptide containing 26 amino acid residues. It can lyse RBCs from many (possibly all) species; it is also active on a wide range of natural and synthetic membranes, lysing e.g. leucocytes, all kinds of mammalian cells in culture, certain bacteria, mitochondria, protoplasts, liposomes, etc. At relatively high concentrations, it probably exerts its effect by non-specific solubilization of membrane lipids and/or proteins; at low concentrations it may act by forming transmembrane pores and/or by activating endogenous phospholipase  $\text{A}_2$ . It is inhibited by various phospholipids and serum lipoproteins, and is poorly antigenic. Different  $\delta$ -haemolysins are produced by different biotypes of *S. aureus*.

[Reviews: Book ref. 44, pp. 619–744.]

(f) *Streptococcus* haemolysins. See e.g. STREPTOLYSIN O and STREPTOLYSIN S.

(g) *Vibrio parahaemolyticus* haemolysin. See KANAGAWA PHENOMENON.

**haemolysis** The lysis of erythrocytes (red blood cells). Haemolysis may occur in any of the following ways. (a) By the action of a COMPLEMENT-dependent or -independent HAEMOLYSIN. (b) By a complement-fixing union between an antibody and an erythrocyte-bound particulate antigen (*passive haemolysis*). (c) By REACTIVE LYSIS. (d) By osmotic lysis in a hypotonic medium. (e) By viral activity: certain viruses (e.g. the mumps virus) can lyse the erythrocytes of certain species.

The ability of certain microorganisms to cause haemolysis can be detected e.g. by growing the organisms on a suitable BLOOD AGAR; an extracellular haemolysin causes the development of a differentiated zone around each colony. Some types of haemolysin bring about a glass-clear, colourless zone. Such *clear haemolysis* is often called ' $\beta$ -haemolysis'; however, ' $\beta$ -haemolysis' can be a misleading term since clear haemolysis can be caused e.g. by the  $\alpha$ -haemolysin of staphylococci or by the  $\alpha$ - or  $\beta$ -haemolysins of *Escherichia coli*. A zone in which the blood is greenish, but still opaque, is often called ' $\alpha$ -haemolysis'; such *greening* can be caused by various types of haemolysin. The *absence* of haemolysis is sometimes called (confusingly) ' $\gamma$ -haemolysis'.

**haemolytic immune body (HIB; amboceptor)** Antibody to the surface antigens of erythrocytes. (See also HAEMOLYTIC SYSTEM.)

**haemolytic system** In a COMPLEMENT-FIXATION TEST: a suspension of *sensitized* erythrocytes, i.e. erythrocytes (commonly sheep erythrocytes) which have been exposed to a subagglutinating dose of antibodies homologous to their surface antigens. The system exhibits no HAEMOLYSIS in the absence of COMPLEMENT, and almost complete haemolysis (ca. 90% of the erythrocytes lysed) when exposed to the maximum concentration of complement used in a CFT; with amounts of complement between these extremes, the proportion of erythrocytes which lyse is dependent on the amount of free (i.e. unfixed) complement. Thus, the

haemolytic system indicates the amount of complement (if any) remaining unfixd in each dilution at the end of the first stage in a CFT. (See also EAC.)

**haemolytic uraemic syndrome (HUS)** A potentially fatal disease (of children and adults) involving renal impairment/acute renal failure (see also TNF). An early stage of (bloody) diarrhoea is common, though not invariably present. Most cases with prodromal diarrhoea appear to be caused by O157 strains of *Escherichia coli* (see EHEC) or by *Shigella dysenteriae*.

The major symptoms of HUS are toxin-dependent; attempts are being made to sequester toxins in the gut (see SYNSORB P<sup>k</sup>). Complications may include e.g. CNS involvement. Antibiotics have not been found useful, and may be actually harmful.

Non-diarrhoeal HUS is sometimes associated with EHEC but may be induced by certain drugs (e.g. mitomycin C, quinine), and there are several other distinct causes.

**haemophagocytic syndrome (HS)** A syndrome which is characterized by fever and e.g. (commonly) cytopenia, coagulopathy, hepatosplenomegaly and *haemophagocytosis* – i.e. phagocytosis of haemopoietic cells by HISTIOCYTES. Primary HS is associated with inherited conditions. Secondary HS may be associated with certain infections, malignancy or non-malignant conditions (e.g. autoimmune disease), or may be drug-associated (phenytoin).

Infection-associated HS (IAHS) includes virus-associated HS (VAHS) and bacterium-associated HS (BAHS).

The pathogenesis of HS is not understood but it appears to involve unregulated T lymphocytes, monocytes, macrophages and cytokines; elevated levels of e.g. IFN- $\gamma$  (interferon- $\gamma$ ) and IL-18 (interleukin-18) have been found in serum, and an imbalance in Th1/Th2 cells has also been reported. Some 60% of cases have been reported to occur in patients with pre-existing immunodeficiency, suggesting that immune status may be important as a predisposing factor.

Diagnosis includes demonstrating phagocytosis of erythrocytes (red blood cells), leukocytes and platelets by examination of bone marrow.

Microorganisms associated with HS include: Epstein-Barr virus (apparently responsible for most cases of VAHS) and other herpesviruses (e.g. cytomegalovirus, HHV6 and HHV8); species of *Borrelia*, *Brucella*, *Mycobacterium*, *Rickettsia*, *Staphylococcus* and *Streptococcus*; *Cryptococcus*; and *Leishmania donovani*.

[Haemophagocytic syndrome associated with infections: BCH (2000) 13 163–178.]

**Haemophilus** A genus of Gram-negative bacteria of the PASTEURACEAE. Cells: pleomorphic coccobacilli, rods (often ca.  $0.4 \times 1-2 \mu\text{m}$ ) or – especially under suboptimal growth conditions – filaments. Some strains have capsules. Fimbriae occur in haemagglutinating strains (*H. parasuis*, *H. paragallinarum*, strains of *H. aegyptius*). Optimum growth temperature: 35–37°C. Growth may require the X FACTOR and/or the V FACTOR (see PORPHYRIN TEST and SATELLITE PHENOMENON). Media for primary isolation include e.g. CHOCOLATE AGAR, FILDES' ENRICHMENT AGAR, or LEVINTHAL'S MEDIUM; some species (e.g. *H. ducreyi*, *H. parasuis*) require serum. Growth in some species (e.g. *H. aphrophilus*, *H. paragallinarum*) requires, or is enhanced by, incubation with 5–10% CO<sub>2</sub>. Colonies on rich media are usually non-pigmented or slightly yellowish, 0.5–2.0 mm diameter (48 hours/37°C); those of capsulated strains are more mucoid and may appear iridescent in obliquely transmitted light. Most species produce acetic, lactic and succinic acids (usually without gas) from glucose. Most strains do not ferment lactose. NO<sub>3</sub><sup>-</sup> is reduced to NO<sub>2</sub><sup>-</sup>; NO<sub>2</sub><sup>-</sup> may also be reduced. GC%: 37–44. Type species: *H. influenzae*.

*Haemophilus* spp are parasitic on the mucous membranes (particularly of the respiratory tract) in man and other animals. Some species are pathogenic; others can be opportunist pathogens, causing e.g. dental abscesses, ENDOCARDITIS etc. Some strains form IgA1 proteases (q.v.). Plasmid-mediated antibiotic resistance has become common in some species (e.g. *H. influenzae*).

*H. actinomycetemcomitans*. See ACTINOBACILLUS.

*H. aegyptius*. Causes e.g. PINK-EYE, mainly in hot climates. Requires X FACTOR (q.v.) and V factor. Indole –ve; urease +ve; non-haemolytic; usually forms acid (no gas) from glucose but not from xylose; catalase +ve.

*H. ducreyi*. Causes CHANCROID. Requires X factor but not V factor. Indole –ve; urease –ve; non-capsulated; some strains weakly haemolytic; sugars are generally not metabolized (acid from glucose may be delayed +ve); peptidases are produced; catalase –ve.

*H. influenzae*. Parasitic and pathogenic in man. Requires V and X factors; non-haemolytic; acid (no gas) from glucose and xylose; catalase +ve. Eight biotypes (I–VIII) are distinguished e.g. on indole, urease and ODC reactions. Some strains have

*Haemophilus influenzae*: differentiation of biotypes

Biotype	Indole	Urease	ODC <sup>a</sup>
I	+	+	+
II	+	+	–
III	–	+	–
IV	–	+	+
V	+	–	+
VI	–	–	+
VII	+	–	–
VIII	–	–	–

<sup>a</sup> Ornithine decarboxylase test (see DECARBOXYLASE TESTS).

capsules, and six serotypes are distinguished on the basis of capsular antigens (polysaccharides, at least some of which contain ribosyl groups). Strains of serotype b (usually biotype I) may cause acute diseases such as CELLULITIS, EPIGLOTTITIS, MENINGITIS (in children), and PNEUMONIA (caused also by other serotypes). Antisera to serotype b cross-react with antigens from a wide range of bacteria – e.g. staphylococci, streptococci, *Bacillus* spp. Non-capsulated strains (usually biotypes II or III) occur as commensals (e.g. in the nasopharynx) but can occasionally cause chronic conditions such as BRONCHITIS, CONJUNCTIVITIS, OTITIS MEDIA and SINUSITIS. [Conjugate vaccine against *H. influenzae* type b (for protection against e.g. meningitis and epiglottitis); RMM (1996) 7 231–241.]

*H. paragallinarum* (including strains formerly called *H. gallinarum*). Causes coryza in fowl. Requires V factor but not X factor. Indole –ve; urease –ve; non-haemolytic; acid (no gas) from glucose and (some strains) xylose; catalase –ve.

*H. parainfluenzae*. Commensal in man, occasionally implicated in e.g. endocarditis. Requires V factor but not X factor. Indole –ve; urease –ve (biotype I) or +ve (biotypes II and III); non-haemolytic; acid ( $\pm$ gas; biotype III: no gas) from glucose but not from xylose; catalase +ve/–ve.

*H. parasuis* (including most strains formerly called *H. suis* or *H. influenzae-suis*). Causes GLASSER'S DISEASE in pigs. Requires

## haemoproteins

V factor but not X factor. Indole -ve; urease -ve; non-haemolytic; acid (no gas) from glucose but not from xylose; catalase +ve.

*H. piscium*. A fish pathogen (see ULCER DISEASE) now regarded as an atypical strain of *Aeromonas salmonicida*.

*H. vaginalis*: see GARDNERELLA.

Other species: *H. aphrophilus*, *H. avium*, *H. haemoglobinophilus*, *H. haemolyticus*, *H. paracuniculus*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. paraphrophilus*, *H. pleuropneumoniae*, *H. segnis*. Species *incertae sedis*: '*H. somnus*', '*H. agni*' and '*H. equigenitalis*', pathogenic in cattle, sheep and horses, respectively.

[Book ref. 22, pp. 558–569.]

**haemoproteins** See HAEM.

**Haemoproteus** A genus of protozoa of the HAEMOSPORORINA. Species are parasitic in e.g. birds; the vectors are hippoboscids flies.

**haemorrhagic colitis** COLITIS associated with bloody diarrhoea; when caused by EHEC it usually occurs without fever.

**haemorrhagic enteritis of turkeys** An acute disease of turkeys (particularly turkey poults 6–12 weeks of age) caused by an AVIADENOVIRUS. Symptoms: depression, loss of appetite, bloody faeces; haemorrhages also occur in the muscles and internal organs. The disease may be fatal. [Book ref. 116, pp. 537–539.] (cf. MARBLE SPLEEN DISEASE.)

**haemorrhagic fever with renal syndrome** See HANTAVIRUS.

**haemorrhagic fevers** See VIRAL HAEMORRHAGIC FEVERS.

**haemorrhagic nephrosonephritis** *Syn.* KOREAN HAEMORRHAGIC FEVER.

**haemorrhagic septicaemia** (1) (in fish) See INFECTIOUS DROPSY and EGTVED DISEASE. (2) (barbone) An acute, often fatal, septicemic CATTLE DISEASE which appears to be a primary PASTEURILLOSIS caused by strains of *Pasteurella multocida*. Onset is sudden, with fever, profuse salivation, and petechial haemorrhages in submucosal tissues; death may occur within ca. 1 day. A carrier state occurs. A vaccine is available.

**haemorrhagic syndrome** See TRICHOTHECENES.

**Haemosporina** See HAEMOSPORORINA.

**Haemosporina** A suborder of protozoa (order EUCCOCCIDIORIDA) previously classified as the suborder Haemosporina (*sic*) of the order Eucoccida [JP (1964) 11 7–20] or Eucoccidiida [JP (1980) 27 37–58]. In this suborder the organisms lack a conoid, syzygy does not occur, and motile zygotes are formed (cf. ADELEORINA, EIMERIORINA); some species form pigment from host cell haemoglobin (cf. PIROPLASMASINA). The organisms are heteroxenous, the asexual phase taking place in a vertebrate host and the sexual phase occurring in a blood-sucking insect. Genera: e.g. HAEMOPROTEUS, LEUCOCYTOZON, PLASMODIUM.

**haemotropic** (haematotropic; hemotropic; hematotropic) Having an affinity for the blood. (Used e.g. of blood parasites such as *Plasmodium*.)

**haemozoin** (malarial pigment) A brown or black pigment which occurs in the intraerythrocytic schizont of *Plasmodium* spp (see PLASMODIUM and MALARIA). Haemozoin derives from the erythrocyte's haemoglobin; the parasite ingests haemoglobin, uses the protein part, and (normally) detoxifies the remaining ferriprotoporphyrin IX (FP) by polymerizing it to haemozoin. (Unless detoxified by polymerization, FP can lyse the parasite's membranes.)

Haemozoin remains behind in the parasitized erythrocyte following release of merozoites.

Quinoline-type antimalarial agents (see AMINOQUINOLINES, QUININE) appear to act by blocking the parasite's 'haem polymerase' activity, thus killing the parasite by inhibiting detoxification of FP [Acta Tropica (1994) 56 157–171].

In order to facilitate studies on (i) the mechanism by which *Plasmodium* detoxifies FP, and (ii) the mode of action of quinoline-type antimalarials, the crystal structure has been determined for a synthetic compound,  $\beta$ -haematin, which is chemically identical to haemozoin [Nature (2000) 404 307–310].

**Hafnia** A genus of (usually non-capsulated) Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Most strains are motile at 25–30°C, but many are non-motile at 35°C. MR and VP reactions are variable at 35–37°C but MR -ve, VP +ve at 22–25°C. Lactose -ve (but Lac plasmids may occur); lysine and ornithine decarboxylases +ve; arginine dihydrolase -ve. Growth occurs e.g. on DCA and in KCN media.

One species: *H. alvei* (formerly e.g. *Enterobacter alvei* or *E. hafniae*); many biotypes. *H. alvei* occurs in man, animals and birds, and in soil, sewage and water. *H. alvei* has been associated with diarrhoeal disease [JCM (1994) 32 2335–2337]; strains of *H. alvei* can produce A/E lesions (see entry EPEC). *H. alvei* has also been associated with liver abscesses, septicaemia, peritonitis and pneumonia [characterization of *H. alvei* isolates from human clinical extra-intestinal specimens: JMM (2001) 50 208–214].

(cf. KOSERELLA and OBESUMBACTERIUM.)

**hag gene** In enterobacteria: the structural gene for FLAGELLIN.

**HAI test** HAEMAGGLUTINATION-INHIBITION TEST.

**haidai** See LAMINARIA.

**hair cell** A narrow, elongated, apparently non-pigmented cell present at the ends of trichomes in certain filamentous CYANOBACTERIA. In 'rivularian' species (e.g. GLOEOTRICHIA), at least, hair cells seem to be formed under conditions of phosphorus or fixed nitrogen limitation; their function, if any, is unknown.

**hairpin** In a single strand of DNA or RNA: a double-stranded region formed by base-pairing between sequences in the strand which are complementary and opposite in polarity (e.g., 5'...GGCATG...CATGCC...3'). (cf. CRUCIFORM; see also STEM-AND-LOOP STRUCTURE.)

**hairy-cell leukaemia** (1) A T cell LEUKAEMIA (see HTLV-II in HTLV). (2) A B cell leukaemia. Both diseases are rare, and in each the cells have fine, hair-like projections.

**hairy leukoplakia** (oral hairy leukoplakia) In e.g. HIV-infected individuals: whitish areas, typically found on the sides of the tongue, associated with replication of the EPSTEIN-BARR VIRUS; it may resemble oral candidiasis but, unlike candidiasis, it cannot be removed. A high proportion of patients with hairy leukoplakia subsequently develop AIDS. Hairy leukoplakia has been treated with e.g. high-dose ACYCLOVIR but it tends to recur on cessation of treatment.

[Opportunistic oral infections in patients infected with HIV-1: RMM (1996) 7 151–163 (hairy leukoplakia: 157–158).]

**hairy root** A disease which can affect various dicotyledonous plants; it is characterized by the proliferation of adventitious roots from the site of a wound infected with *Agrobacterium rhizogenes* (see AGROBACTERIUM). Pathogenesis appears to be analogous to that in CROWN GALL, involving the transfer, integration, and expression in plant host cells of a segment of an Ri (root-inducing) plasmid. (Ri and Ti plasmids belong to different incompatibility groups.) Conjugal transfer of Ri plasmids appears to occur constitutively at rather high frequencies, and induction of conjugal transfer by opines or other compounds has not been observed. Two types of Ri plasmid are known: the agropine type and the mannopine type; some of the catabolic

functions of the agropine strains are carried not by the Ri plasmid but by another plasmid which can cointegrate with it [MGG (1983) 190 204–214].

[Book ref. 55, pp. 271–286.]

**hairy shaker disease** *Syn.* BORDER DISEASE.

**halazone** See CHLORINE.

**half-a-Gram stain** A non-specific staining procedure used e.g. for detecting cells of *Legionella* in smears of sputum or aspirates etc. The slide is flooded for 0.5–1 min with a solution of crystal violet, drained, and flooded with Gram's iodine solution for 1–2 min. The slide is then rinsed well in tap-water and dried in air. (cf. GRAM STAIN.)

**half-chiasma** See RECOMBINATION.

**half-reduction potential** See REDOX POTENTIAL.

**Halicystis** See DERBESIA.

**Halidrys** See PHAEOPHYTA.

**Halimeda** A genus of siphonaceous, mainly tropical or subtropical green seaweeds (division CHLOROPHYTA). The thallus is segmented and calcified, and contains both chloroplasts and amyloplasts. The cell wall contains a xylan (see XYLANS) as the main structural component, and is more or less heavily calcified with aragonite. When mature, the entire thallus is converted to gametangia, after which it dies. Related holocarpic, usually calcified algae include species of CAULERPA, PENICILLUS and UDOTEA.

**Haliscomenobacter** A genus of Gram-negative, rod-shaped bacteria which occur e.g. in activated sludge. Individual cells are apparently non-motile; they commonly occur in sheathed trichomes. The organisms can utilize a range of carbon and nitrogen sources; PHB is not formed. *H. hydrossis* has a GC% of ca. 49. [Book ref. 45, pp. 425–440 (436–439).]

**hallucinogenic mushrooms** Certain agarics whose fruiting bodies contain hallucinogenic compounds; they include certain species of *Conocybe*, *Psilocybe* (e.g. *P. mexicana*, *P. semilanceata*) and *Stropharia*. At least some of these fungi contain *psilocybin* and/or *psilocin*, hallucinogenic tryptamine derivatives related to serotonin. Some species of *Lycoperdon* also contain hallucinogenic substance(s).

**halo blight** A typically seed-borne disease of beans (*Phaseolus*) caused by *Pseudomonas phaseolicola*. Small, translucent lesions on leaves later darken, each becoming surrounded by a yellowish 'halo'; leaves later exhibit interveinal yellowing, and brownish spots may develop on pods.

**halo spot** A CEREAL DISEASE, caused by *Selenophoma donacis* (*Septoria oxyspora*) which can affect e.g. barley, wheat and rye. Small, pale lesions, each with a purplish-brown margin, occur mainly on the leaves, and rows of dark-coloured pycnidia develop in line with the veins. (Halo spot is called 'eyespot' in some parts of the world: cf. EYESPOT sense 2.)

**halobacteria** (1) Strains or species of *Halobacterium*. (2) Members of the family Halobacteriaceae.

**Halobacteriaceae** A family of extremely halophilic archaeans which occur e.g. in salt lakes, evaporated brines, and salted fish (in which they can cause spoilage). Cells: rods, cocci or discs, containing orange, red or mauve carotenoid pigments (predominantly bacterioruberins). Division occurs by binary fission. The Gram reaction is negative. (See also CELL WALL, GAS VACUOLE and S LAYER.)

Growth requires a minimum concentration of 1.5 M NaCl, good growth typically needing 3–4 M NaCl; cells accumulate electrolyte (mainly KCl) to an intracellular concentration at least equivalent to that in the environment. High concentrations of electrolyte are required to maintain the structural integrity of e.g. the cytoplasmic membrane and the ribosomes; in dilute solutions

some species lyse (owing to weakening of the cell envelope rather than to an osmotic effect per se).

The organisms are chemoorganotrophs which use amino acids and/or carbohydrates as principal sources of carbon, and which typically grow aerobically; metabolism is respiratory (oxidative). The organisms form menaquinones rather than ubiquinones. Under microaerobic or anaerobic conditions some strains can use light energy (see PURPLE MEMBRANE; see also PHOTOTAXIS).

Two genera: HALOBACTERIUM (the type genus) and HALOCOCUS.

**Halobacterium** A genus of catalase-positive, oxidase-positive archaeans of the HALOBACTERIACEAE. The cells are lophotrichously flagellated (or non-motile) frequently pleomorphic rods or filaments, or discs; they often contain gas vacuoles (which are plasmid-encoded in at least some strains), and they lyse in dilute solutions (e.g. NaCl ~ca. 0.8–1.5 M). Binary fission occurs by constriction.

Most strains can be cultured in e.g. well-aerated tryptone – yeast extract – salt media. Optimum growth temperature: 40–50°C.

Some strains form a PURPLE MEMBRANE under microaerobic or anaerobic conditions.

The DNA in *Halobacterium* spp is often composed of a major component (ca. 60–90% of the total DNA) with a GC% of ca. 66–68, and a minor component ('satellite DNA' or plasmid DNA) with a GC% of ca. 57–60. Type species: *H. salinarium*.

*H. halobium*. See *H. salinarium*.

*H. pharaonis*. Motile, alkalophilic (optimum pH: 8.5) rods which do not use sugars; substrates include e.g. formate, fumarate, pyruvate. Growth occurs optimally in 3.5 M NaCl.

*H. saccharovorum*. Motile rods which form acid (mainly acetic acid) from sugars. Growth occurs optimally in 3.5–4.5 M NaCl.

*H. salinarium* (= *H. halobium*). Motile, typically rod-shaped cells which grow aerobically or (strains with a purple membrane) anaerobically in the light. Amino acids are used for carbon and energy, although growth may be stimulated by carbohydrates (without acid formation). Growth occurs optimally in 4–5 M NaCl.

*H. vallismortis*. Motile, very pleomorphic rods which use sugars, often with the formation of acid. Facultatively anaerobic. Growth occurs optimally in 4.3 M NaCl.

*H. volcanii*. Mainly discoid or cup-shaped cells which are (apparently) non-flagellated but which are sometimes capable of a rotatory movement. Sugars are used for carbon and energy. Growth occurs optimally in 1.5–2.5 M NaCl.

**halocarbon** See FREON.

**halocins** See BACTERIOCINS.

**Halococcus** A genus of catalase-positive and oxidase-positive archaeans of the HALOBACTERIACEAE. The cells are non-motile, orange- or red-pigmented cocci (diameter ca. 0.8–1.5 µm) which occur in pairs or in regular or irregular groups. At least 2.5 M NaCl is needed for growth; growth occurs optimally in 3.5–4.5 M NaCl. The organisms are much more resistant than are *Halobacterium* spp to hypotonic solutions. Amino acids are used for carbon and energy. Optimum growth temperature: 30–37°C. GC%: ca. 61–66. Type species: *H. morrhuae* [Book ref. 22, pp. 266–267].

**halofantrine** See MALARIA.

**halogens** (as antimicrobial compounds) See entries CHLORINE, FLUORIDES, IODINE.

**Halomonas** A genus (*incertae sedis*) of aerobic, facultatively anaerobic, chemoorganotrophic, halotolerant, Gram-negative

## halonitrosoureas

bacteria which occur e.g. in salterns and (presumably) in salt lakes etc. Cells: non-pigmented or yellow-pigmented, polarly or laterally flagellated rods, 0.6–0.8 × 1.6–1.9 µm, sometimes pleomorphic or filamentous. Metabolism may be respiratory (oxidative), with O<sub>2</sub> or nitrate (anaerobic respiration) as terminal electron acceptor, or fermentative; anaerobic growth, without nitrate, can occur with glucose but not with other carbohydrates. Carbon sources include a wide range of alcohols, amino acids, organic acids and sugars. Salt (NaCl) tolerance: 0.1–32.5% w/v. Catalase +ve. Oxidase +ve. GC%: ca. 60. Type species: *H. elongata*. [Book ref. 22, pp. 340–343.]

**halonitrosoureas** See *N*-NITROSO COMPOUNDS.

**halo-opsin** See OPSIN.

**halophile** An organism which grows optimally only in the presence of electrolyte (commonly NaCl) at concentrations above ca. 0.2 M, and which typically grows poorly, or not at all, in low concentrations of electrolyte; examples include e.g. species of ACTINOPOLYSPORA, DACTYLOCOCCOPSIS, HALOBACTERIUM, HALOCOCCUS, PARACOCCUS and VIBRIO. (cf. HALOTOLERANT.)

A number of authors have accepted the following categories: slightly halophilic (optimum growth in the presence of 0.2–0.5 M electrolyte); moderately halophilic (optimum growth in 0.5–2.5 M electrolyte); extremely halophilic (optimum growth in >2.5 M electrolyte).

[Halophilic and halotolerant organisms: Book ref. 157, pp. 171–214, and Book ref. 191, pp. 55–81.]

**Halopteris** See PHAEOPHYTA.

**halorhodopsin** A RETINAL-containing protein pigment (MWt ca. 25000) which occurs in the PURPLE MEMBRANE of *Halobacterium salinarium* and which is involved in transmembrane ion translocation. Maximum absorption appears to occur at ca. 580 nm, the absorption characteristics being stabilized by anions (primarily Cl<sup>-</sup>). On illumination, halorhodopsin undergoes cyclical changes in its absorption characteristics with a periodicity of ca. 5–10 msec; several photointermediates appear to be involved. Halorhodopsin undergoes bleaching when illuminated in the presence of hydroxylamine. Some strains of *Halobacterium salinarium* (e.g. JW-5, W-296), which cannot synthesize retinal, produce bacterio-opsin but are repressed in the synthesis of halo-opsin.

**Halothrix** See PHAEOPHYTA.

**halotolerant** Refers to the ability of a *non*-HALOPHILE to grow in the presence of high concentrations of electrolyte (e.g. up to ca. 2.5 M); examples of halotolerant organisms include e.g. HALOMONAS and strains of *Staphylococcus*.

**Halteria** A genus of freshwater ciliates (order OLIGOTRICHIDA). Cells: roughly spherical, with very conspicuous oral ciliature and a number of groups of 'cirri' or 'bristles' forming an equatorial band. *H. grandinella* is ca. 25–50 µm in diam., has a 'bouncing' type of movement, and occurs e.g. in ponds and organically polluted waters (see SAPROBITY SYSTEM) where it feeds on bacteria; the organism is fairly tolerant of low O<sub>2</sub> levels, but is sensitive to NH<sub>3</sub> and H<sub>2</sub>S.

**ham** See CURING (1); MEAT SPOILAGE; SOFT CORE HAM.

**hamanatto** (black beans) An oriental food made by fermenting whole soybeans with strains of *Aspergillus oryzae*. Beans are steamed, coated with wheat flour, inoculated with *A. oryzae*, and incubated 1–2 days. Brine and spices are added and incubation is continued 6–12 months; the beans are then dried.

**hamathecium** A term which refers, collectively, to the various types of structure which may occur between and around the asci in an ASCOCARP: see e.g. PARAPHYSIS, PARAPHYSOID, PSEUDOPARAPHYSIS and PERIPHYSES.

**Hamigera** See TALAROMYCES.

**Hammondia hammondi** *Syn. Isospora datusi*.

**hamycin** A heptaene POLYENE ANTIBIOTIC produced by *Streptomyces pimprina*; it is effective against only a limited range of fungi, but is particularly effective against *Candida albicans*.

**hand, foot and mouth disease** An acute, highly infectious, self-limiting disease (mainly of children) characterized by the development of vesicular-ulcerative lesions in the mouth with similar lesions scattered on the soles of the feet and on the palms of the hands. The causal agent is usually coxsackievirus A16, but A4, A5, A9, A10, B2 and B5 have also been implicated. (cf. FOOT AND MOUTH DISEASE.)

**hanging drop** A direct, visual procedure used for determining the MOTILITY of microorganisms in a fluid medium. A COVERGLASS is placed flat on the bench, and a drop of fluid (e.g. from a broth CULTURE) is transferred (e.g. by a LOOP) from the culture to the centre of the cover-glass. A plasticine ring (diam. ca. 1.5 cm, ca. 4 mm thick) is gently pressed onto one face of a SLIDE; the ring (attached to the slide) is then gently pressed onto the cover-glass so that the ring becomes sandwiched between the (parallel) faces of slide and cover-glass. The whole is then inverted, so that the drop hangs *freely* beneath the cover-glass, and can be examined under the microscope. This method avoids microcurrents which could give a false impression of motility.

**Hanks' BSS** Hanks' BALANCED SALT SOLUTION; it contains (g/l): NaCl (8.0), KCl (0.4), CaCl<sub>2</sub>·2H<sub>2</sub>O (0.185), MgSO<sub>4</sub>·7H<sub>2</sub>O (0.1), MgCl<sub>2</sub>·6H<sub>2</sub>O (0.1), Na<sub>2</sub>HPO<sub>4</sub>·H<sub>2</sub>O (0.06), KH<sub>2</sub>PO<sub>4</sub> (0.06), NaHCO<sub>3</sub> (0.35), glucose (1.0), and phenol red (0.01); pH: 7.0–7.2.

**Hanseniaspora** A genus of fungi (family SACCHAROMYCETACEAE). The genus contains the teleomorphs of KLOECKERA spp. Ascospores may be bowler-hat-shaped, 1–4 per ascus, and released at maturity, or they may be spherical, with or without an equatorial ridge, smooth or warty, and not released at maturity. [Book ref. 100, pp. 154–164.]

**Hansen's bacillus** *Mycobacterium leprae*.

**Hansen's disease** *Syn.* LEPROSY.

**Hansenula** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are generally spheroidal, ellipsoidal or elongate; vegetative reproduction occurs by multilateral budding. Pseudomycelium or true mycelium may be formed. Asci are generally dehiscent, occasionally persistent. Ascospores: hemispheroidal, Saturn-shaped, or bowler-hat-shaped. Species may be homothallic or heterothallic. Most species can ferment glucose, some can also ferment other sugars, and some (e.g. *H. canadensis*) are non-fermentative. NO<sub>3</sub><sup>-</sup> is assimilated. Thirty species are recognized, including e.g. *H. anomala* (anamorph: *Candida pelliculosa*), *H. canadensis* (conspecific with *H. wingei*), *H. capsulata*, *H. jadinii* (anamorph: *Candida utilis*), *H. polymorpha* (see also METHYLOTROPHY), *H. wickerhamii*. Species have been isolated from tree exudates, soil, insect larvae and frass, etc. [Book ref. 100, pp. 165–213.]

**Hantaan virus** See HANTAVIRUS.

**Hantavirus** A genus of viruses of the family BUNYAVIRIDAE [taxonomic proposal: *Virology* (1983) 131 482–491]. The enveloped, spherical virions each contain a negative-sense ssRNA genome consisting of three fragments.

Approximately half of the >20 known species are associated with human disease – either (i) the hantavirus pulmonary syndrome (HPS), or (ii) haemorrhagic fever with renal syndrome (HFRS).

Unlike other members of the Bunyaviridae (which are maintained in arthropods) hantaviruses are found in populations of

(persistently infected) rodents – including rats (Seoul virus), mice (Sin Nombre virus, Dobrava-Belgrade virus, Hantaan virus) and voles (Puumala virus); human infection appears to occur mainly by inhalation of aerosols of the infected urine, faeces etc. of rodents.

Species of *Hantavirus* include: Hantaan virus (HFRS; see also KOREAN HAEMORRHAGIC FEVER), Seoul virus (HFRS), Puumala virus (HFRS), Dobrava-Belgrade virus (HFRS), Sin Nombre virus (HPS), Andes virus (HPS), Black Creek Canal Virus (HPS) and Laguna Negra virus (HPS).

[Hantaviruses (persistence in rodent reservoirs): TIM (2000) 8 61–67. Hantaviruses (review): JMM (2000) 49 587–599.]

**Haploangium** See MYXOBACTERIALES.

**haploid** Having a ploidy of *one*. (cf. DIPLOID, POLYPLOID.)

**haploidization** (*mycol.*) See PARASEXUAL PROCESSES.

**haplokinety** (1) The infraciliary base (only) of a *stichodyad* PARORAL MEMBRANE. (2) A stichodyad paroral membrane.

**haplomycosis** *Syn.* ADIASPIROMYCOSIS.

**haplont** (1) (*noun*) An organism in whose life cycle only the zygote is diploid. (cf. DIPLONT.) (2) The haploid form of an organism, e.g. a gametophyte (see ALTERNATION OF GENERATIONS). (3) (haplontic) (*adj.*) Refers to either (1) or (2) above.

**haplophase** In organisms which reproduce sexually: the haploid phase of the life cycle. In many higher fungi haplophase and DIPLOPHASE are separated by DIKARYOPHASE.

**Haplospora** See PHAEOPHYTA.

**Haplosporangium** See ADIASPIROMYCOSIS.

**Haplosporidium** A genus of protozoa (class STELLATOSPOREA) which are parasitic in various aquatic invertebrates (including annelids and molluscs). The spores are operculate and characteristically bear filamentous extensions which arise from the outer spore coat and are typically coiled around the spore. [Spore ultrastructure in *H. lusitanicum*: J. Parasitol. (1984) 70 358–371.] The vegetative stage is plasmodial.

**haplosporosomes** See STELLATOSPOREA.

**hapten** A substance which can elicit an immune response only when combined with another molecule or particle (*carrier*); if administered on its own it fails e.g. to stimulate antibody production (but cf. autocoupling hapten, below). The free hapten can, however, combine with antibodies raised against the hapten–carrier complex; such combination may or may not result in the precipitation of the hapten–antibody complex. A substance which acts as a hapten in one species may act as a complete antigen in another – e.g. the pneumococcal capsular polysaccharides are haptenic in the rabbit but antigenic in man. A hapten may be artificially bound to a protein in order to increase the immunological specificity of that protein. *Autocoupling* haptens bind spontaneously to tissue carriers *in vivo*, thus becoming antigenic. (See also ALLERGEN.)

**hapteron** See CYATHUS.

**haptocyst** An EXTRUSOME in the tentacles of suctorian ciliates.

**haptonema** A thread-like appendage present on unicellular algae of the PRYMNESIOPHYCEAE. Structurally, a haptonema bears some resemblance to a eukaryotic FLAGELLUM but contains fewer microtubules (which are arranged differently from those in a flagellum) and has a sheath composed of several concentric membranes, the innermost enclosing the microtubules. Haptonemata range from relatively short (e.g. in *Prymnesium parvum*) to very long (>80 µm in *Chrysochromulina* spp); most haptonemata (but not that of *Prymnesium*) can coil and uncoil: e.g., in *Chrysochromulina* spp the haptonema remains coiled while the organism is swimming and becomes extended when the cell comes to rest. The haptonema is believed to function as an attachment organelle.

**Haptophyceae** *Syn.* PRYMNESIOPHYCEAE.

**hard cider** (American) *Syn.* CIDER.

**hard gill** See WATERY STIPE.

**hard-pad** A form of CANINE DISTEMPER which begins with tenderness and keratinization of the feet, usually followed by CNS involvement and death.

**hard swell** See SWELL.

**hare fibroma virus** See LEPORIPOXVIRUS.

**Harpellales** See TRICHOMYCETES.

**harpin** (*plant. pathol.*) Any of certain types of glycine-rich protein, encoded by plant-pathogenic bacteria, which (at least in culture) can be secreted via a type III PROTEIN SECRETION system and which are able to elicit a heat-stable HYPERSENSITIVITY reaction in the leaves of tobacco and certain other plants [see e.g. JB (1997) 179 5655–5662].

(See also AVIRULENCE GENE.)

**Harpochytriales** See CHYTRIDIOMYCETES.

**Harpophyrium** See HYPHOMYCETES and NEMATOPHAGOUS FUNGI.

**Hartig net** See MYCORRHIZA.

**Hartmannella** A genus of amoebae which are similar to ACANTHAMOEBA spp except that they do not produce acanthopodia from the (usually well-defined) hyaline cap of the pseudopodium.

**Hartmannula** See HYPOSTOMATIA.

**hartrot** (bronze leaf wilt; Coronie wilt) A disease of the coconut palm (*Cocos nucifera*) caused by a species of PHYTOMONAS which invades the phloem. Symptoms: yellowing and falling of leaves and blackening of inflorescences; unripe, internally blackened coconuts fall prematurely. Trees may die within three months of the initial signs.

**hart's truffle** See TRUFFLES.

**Harvey murine sarcoma virus** (Ha-MSV) A replication-defective, *v-onc*<sup>+</sup>, fibroblast-transforming MURINE SARCOMA VIRUS which was isolated from BALB/c mice inoculated neonatally with rat-passaged MOLONEY MURINE LEUKAEMIA VIRUS (Mo-MuLV). Ha-MSV carries the oncogene *v-ras* (*v-Ha-ras*) and apparently arose by recombination between Mo-MuLV and a rat cellular *ras* sequence (Ha-*ras*: see RAS). Infection of newborn rodents with Ha-MSV results in anaemia, splenomegaly (resulting from proliferation of erythroblasts) and erythroleukaemia, as well as sarcomas. (cf. KIRSTEN MURINE SARCOMA VIRUS.)

**HAT medium** See HYBRIDOMA.

**haustorium** A specialized hyphal structure formed e.g. by certain plant-parasitic fungi (e.g. *Erysiphe*, *Peronospora*) in order to obtain nutrients from the host plant; it develops *within* a host cell after a small hyphal branch has penetrated the host cell wall, but it remains external to the host cell's cytoplasmic membrane. A haustorium may be spherical, club-shaped or elongated (branched or unbranched) according to the species of fungus which forms it. (Haustoria are also formed by the mycobionts of certain lichens.)

**Haverhill fever** See RAT-BITE FEVER.

**Hawii virus** See SMALL ROUND STRUCTURED VIRUSES.

**hay fever** See TYPE I REACTION.

**Hayflick medium** A medium used for the culture of *Mycoplasma* spp. It consists of heart infusion broth supplemented with membrane-filtered horse serum (which provides sterols), fresh yeast extract solution, calf thymus DNA solution, thallium acetate and benzylpenicillin; the pH is adjusted to 6.8–7.8 according to strain. The solid medium is made by using a purified agar (e.g. Noble agar) as gelling agent.

**HBB** (2-( $\alpha$ -hydroxybenzyl)-benzimidazole) An ANTIVIRAL AGENT which selectively inhibits the replication of a number of picornaviruses in cell cultures; it inhibits the initiation of viral

## HBcAg

RNA synthesis. HBB-resistant mutants emerge rapidly; HBB-dependent mutants have also been isolated.

**HBcAg** See HEPATITIS B VIRUS and HEPATITIS B.

**HBsAg** See HEPATITIS B VIRUS and HEPATITIS B.

**HBsAg** See HEPATITIS B VIRUS and HEPATITIS B.

**HBV** HEPATITIS B VIRUS.

**HCAM** *Syn.* CD44.

**HCC** HEPATOCELLULAR CARCINOMA.

**HCMV** Human cytomegalovirus; see BETAHERPESVIRINAE.

**HCV** HEPATITIS C VIRUS.

**HCVs** (human caliciviruses) See SMALL ROUND STRUCTURED VIRUSES.

**HD protein** Helix-destabilizing protein (see SINGLE-STRAND BINDING PROTEIN).

**HD<sub>50</sub>** (CH<sub>50</sub>; C/H<sub>50</sub>) Haemolytic dose (50%): the quantity of COMPLEMENT needed to lyse 50% of a standardized suspension of sensitized erythrocytes. In a COMPLEMENT-FIXATION TEST the HD<sub>50</sub> may be used as the unit in place of MHD (q.v.); this gives a more accurate end-point (since the graph '%lysis of cells versus quantity of complement' is sigmoidal).

**HDAg** See DELTA VIRUS.

**HDCV** Human diploid cell vaccine (see RABIES).

**hDNA** Hybrid DNA. (See e.g. CLONING.)

**H-DNA** See TRIPLEX DNA.

**HE-cellulose** (HEC) Hydroxyethylcellulose: a neutral cellulose derivative sometimes used in preference to CM-CELLULOSE in CELLULOSE assays.

**HE markers** See TRANSFORMATION (1).

**headful mechanism** A mechanism of genome packaging during virion assembly: packaging is initiated by insertion into a prohead (or provirion) of one end of a concatemeric form of the genome (which, at or before insertion, may be cut at a particular sequence); incorporation of the genome then continues until the head is full. Thus, termination of packaging is determined only by the length of the nucleic acid packaged, and not by a specific sequence in the nucleic acid. (See e.g. BACTERIOPHAGE MU and BACTERIOPHAGE P22; cf. e.g. BACTERIOPHAGE λ.)

**Heaf test** A form of TUBERCULIN TEST. PPD is spread over a small area of skin and is then pressed into the skin with a 'Heaf gun': an instrument which punctures the skin with several small needles.

**heart rot** See TREE DISEASES.

**heartwater** See COWDRIA.

**heat-fixed smear** See FIXATION.

**heat-shock proteins** (HSPs) Proteins which are synthesized at greatly (but transiently) increased levels in an organism in response to a sudden rise in temperature or to certain other types of stress (e.g. ultraviolet radiation, virus infection, ethanol, or the intracellular accumulation of abnormal proteins); HSPs may be necessary for survival of the organism at higher temperatures, and they are produced at the expense of 'normal' proteins. Such a *heat-shock response* has been observed in a wide range of species – from bacteria and yeasts to plants and animals; at least some HSPs have been highly conserved through evolution, but the response is regulated differently in different organisms.

In *Escherichia coli* there are at least 17 HSPs which include the products of genes *dnaJ*, *dnaK*, *groEL*, *groES*, *rpoD*, *lysU* and *lon*. Synthesis of these proteins reaches a peak ca. 5–10 min after a rise in temperature (for example, 30 → 42°C), and subsequently declines to a new steady state which is greater than that at the lower temperature. Some HSPs apparently cope with stress-induced damage – for example, the molecular *chaperones*

GroES, GroEL and DnaK seem to prevent misfolding or aggregation of unfolded proteins, while the Lon protease degrades abnormal proteins.

The heat-shock genes constitute a REGULON composed of several unlinked operons (for example: promoter–*dnaK*–*dnaJ* and promoter–*groES*–*groEL*). The heat-shock regulon is under the control of a positive transcriptional activator encoded by gene *rpoH* (previously called *htpR*). RpoH (MWt ca. 32000) is a SIGMA FACTOR ( $\sigma^{32}$ ) which interacts with RNA POLYMERASE, producing a holoenzyme ( $E\sigma^{32}$ ) that promotes transcription from heat-shock promoters more efficiently than does  $E\sigma^{70}$ . (Transcription of the *rpoH* gene itself requires  $E\sigma^{70}$  [JB (1986) 166 380–384].)

Following heat shock, the increased levels of RpoH are due mainly to increased translation of the protein – rather than increased transcription of *rpoH*. The heat-induced translation from *rpoH* mRNA involves an effect of temperature on a secondary structure formed in the mRNA by base-pairing between a site immediately downstream of the start codon (a *downstream box*) and another region in the coding sequence. This secondary structure normally inhibits translation, but on temperature upshift it is destabilized so that translation can occur; thus, the mRNA acts as a thermosensor (an *RNA thermometer*) for expression of  $\sigma^{32}$  [GD (1999) 13 633–636].

Although synthesized under normal conditions,  $\sigma^{32}$  has a short half-life (about 1 min); it appears that, within the cell,  $\sigma^{32}$  forms complexes with DnaK, DnaJ and GrpE and is subsequently degraded by the FtsH protease. During heat shock DnaK binds preferentially to denatured proteins – leaving RpoH free to function as a sigma factor [EMBO (1996) 15 607–617].

*The heat-shock response in other bacteria.* In some bacteria the mechanism for regulating the heat-shock response differs from that in *E. coli*. In some cases there is a regulatory sequence upstream of heat-shock genes; this inverted repeat sequence, termed CIRCE (controlling inverted repeat of chaperone expression), occurs e.g. in strains of *Bacillus* and *Clostridium* and is also found in some Gram-negative bacteria. In *Bradyrhizobium japonicum* the control mechanism includes at least two distinct regulatory systems involving CIRCE and a  $\sigma^{32}$ -like sigma factor [JB (1996) 178 5337–5346].

More recently it has been reported that control of the heat-shock response involves negative regulation by repressor proteins (in conjunction with *cis*-acting DNA sequences) which inhibit transcription of the HSP genes under normal physiological conditions [Mol. Microbiol. (1999) 31 1–8].

(See also SOS SYSTEM.)

Strains of *E. coli* mutant in the *rpoH* gene have been useful in the OVERPRODUCTION of recombinant proteins.

**heated lid cyclor** See THERMOCYCLER.

**heavy chain** A class-specific polypeptide IMMUNOGLOBULIN component (MWt ca. 50000–70000, depending on Ig class). The various types of heavy chain are designated *alpha*, *gamma*, *delta*, *epsilon* and *mu* – corresponding to Ig classes IgA, IgG, IgD, IgE and IgM, respectively. In IgM, different C-terminal sequences occur in the heavy chains of the membrane-associated and pentameric forms. Certain Ig classes can be divided into subclasses on the basis of minor differences in their heavy chains.

**heavy metals** (and their compounds) (as antimicrobial agents) Although trace amounts of certain heavy metal ions are essential for the growth of microorganisms, higher concentrations may exhibit antimicrobial activity. Heavy metal ions bind to certain groups (particularly thiol groups) and appear to exert antimicrobial activity largely by inactivating proteins, nucleic acids and

other microbial constituents; their activity is often microbistatic, and they typically have little or no activity against bacterial endospores. The antimicrobial activity of e.g. mercury ions may be reversed by the presence of substances such as cysteine, glutathione etc which presumably complex free ions. In some cases the antimicrobial activity of one metal can be antagonized by another; thus, e.g., the inhibition of *Lactobacillus* spp by zinc can be reversed by the addition of manganese. Some ions appear to have antimicrobial activity only when they are in a particular redox state (see e.g. ANTIMONY and ARSENIC). (See also OLIGODYNAMIC EFFECT.)

Among bacteria, resistance to heavy metals and their compounds can be PLASMID-borne. Thus, e.g., some bacteria can synthesize an inducible, plasmid-encoded, NADPH-linked mercuric ion reductase which can reduce  $Hg^{2+}$  to (relatively non-toxic) metallic mercury which is readily lost from the cell; such cells may also synthesize an organomercurial lyase which cleaves the carbon–mercury bond in organomercurials such as phenylmercuric acetate. [Microbial resistance to mercury and organomercurials: MR (1984) 48 95–124.] In *Staphylococcus aureus*, plasmid-encoded resistance to cadmium may involve a pmf-dependent efflux of cadmium ions (via a cadmium–proton antiporter) which prevents intracellular accumulation of  $Cd^{2+}$ . [Reviews on bacterial resistance to metal ions: Book ref. 160, pp. 345–367; FEMS Reviews (1985) 32 39–54.] (See also MET-ALLOTHIONEIN; TN501.)

Heavy metals and their compounds have been used e.g. as agricultural antifungal agents, as antiseptics, as chemotherapeutic agents for the treatment of diseases of bacterial, fungal and protozoal aetiology, as preservatives for e.g. textiles and wood, and in the disinfection of water.

(See also ANTIMONY; ARSENIC; COPPER; MERCURY; SILVER; TIN; ZINC; and TELLURITE MEDIA.)

**heavy strand** (*mol. biol.*) See H STRAND.

**HEC** See HE-CELLULOSE.

**hedgheg fungus** *Hydnum repandum* (see APHYLLOPHORALES).

**Hektoen medium** A medium selective for certain enterobacteria; it contains lactose, sucrose, salicin, bromthymol blue, Andrade's indicator, ferric citrate, and deoxycholate. Strains (e.g. most salmonellae) which do not ferment sucrose, lactose or salicin form blue-green colonies; those which can ferment one or more of these substrates form salmon-pink colonies.  $H_2S$ -producing colonies have black centres.

**HeLa** AN ESTABLISHED CELL LINE derived, in 1952, from a human cervical carcinoma; the cells are heteroploid and epithelioid. HeLa cultures support the replication of a wide range of viruses.

**Helber chamber** See COUNTING CHAMBER.

**helicases** (DNA unwinding proteins) Proteins with ssDNA-dependent ATPase activity which can unwind and separate the strands of dsDNA given a single-stranded 'leader sequence' or gap.

*Escherichia coli* has several types of helicase: the Rep protein (encoded by the *rep* gene), the DnaB protein (see DNAB GENE), helicases II and III, and the F PLASMID-specified helicase I.

The Rep protein binds to a region of ssDNA in a dsDNA molecule, moving along (3'-to-5') into the double-stranded region and unwinding it processively; the separated strands may be stabilized by SINGLE-STRAND BINDING PROTEIN. Two molecules of ATP are hydrolysed for each base pair separated. The Rep protein is required for RF replication in certain phages (see SSDNA PHAGES), but its role in the host cell is unknown.

Helicase II (*uvrD* gene product) is involved in EXCISION REPAIR. This enzyme may act processively in the 3'-to-5' direction [see e.g. JBC (1987) 262 2066–2076].

Helicases I and III both act processively and move in the 5'-to-3' direction along the strand to which they are bound. Helicase I is encoded by the *tral* gene of the F plasmid [PNAS (1983) 80 4659–4663]; it seems to be responsible for nicking at *oriT* in the F plasmid [JBC (1991) 266 16232–16237], and may be involved in unwinding the plasmid DNA for transfer during CONJUGATION (sense 1b). Helicase III cannot replace either the Rep protein or helicase II.

Some bacteriophages encode their own helicases; for example, the *dda* gene product of phage T4 is a helicase, while the gp4 of phage T7 is a protein with both helicase and PRIMASE activities.

The DnaB helicase, which is active e.g. in DNA replication, is a ring-shaped hexamer of DnaB proteins [see e.g. Cell (1996) 86 177–180].

**Helicobacter** A genus of asporogenous Gram-negative bacteria classified within the  $\epsilon$  (epsilon) subdivision (= rRNA superfamily VI) of the taxon Proteobacteria (which also includes the family CAMPYLOBACTERACEAE). The cells are typically curved/helical rods with one or more sheathed flagella (unsheathed e.g. in *H. pullorum*). Currently there are ~20 named species, many of which have been isolated from the intestines (and often liver) of animals (e.g. dogs, sheep, pigs, rodents, chickens). However, attention has been focused primarily on the species *H. pylori* owing to its association with e.g. gastritis and peptic-ulcer disease in humans.

*H. pylori* was formerly classified within the genus *Campylobacter*, but was re-classified [IJSB (1989) 39 397–405]. Cells: curved/helical, ca. 0.5–0.9  $\mu m$  wide and up to ~3  $\mu m$  in length; motile (several flagella). Genome: circular, approx. 1700 kb; GC%: average 39, but significant differences occur in specific regions – one such region including the *cag* PATHOGENICITY ISLAND [*H. pylori* strain 26695 (complete genome): Nature (1997) 388 539–547].

Chemooorganoheterophilic. Microaerophilic. Culture on enriched media (e.g. blood, chocolate agar) needs high humidity (freshly poured, undried plates) and a gaseous phase of e.g. oxygen/carbon dioxide/nitrogen (5%/10%/85%); grey, translucent colonies (<2 mm in diam.) are obtained after 3–7 days at 35–37°C. The medium may be made selective for *H. pylori* by adding e.g. amphotericin, nalidixic acid and vancomycin (to which the organism is resistant).

Oxidase +ve, catalase +ve, urease +ve.

The pathogenesis of *H. pylori*-associated gastric disease is not understood. One suggestion was based on the presence of lipopolysaccharide antigens identical to the Lewis x and Lewis y antigens found e.g. in human gastric mucosa; it was postulated that these antigens might provoke an antibody response and give rise to autoimmune inflammation [molecular mimicry of *H. pylori*: TIM (1997) 5 70–73]. However, this idea was questioned because the predominant anti-LPS antibodies found in a number of infected patients were unrelated to the given LPS antigens [Inf. Immun. (1998) 66 3006–3011].

Pathogenesis seems likely to involve the *cag* pathogenicity island and an unlinked gene, *vacA*, which is often jointly expressed. The joint expression of *cag* and *vacA* (in 'type I' clinical strains) appears to correlate with severe gastrointestinal disease, while type II strains (which lack *cag*, and do not express *vacA*) are generally not associated with severe disease.

The reason why infection with *H. pylori* gives rise to gastric cancer in only some individuals may depend on host genetic factors such as polymorphisms which affect levels of the pro-inflammatory cytokine interleukin-1 $\beta$  (IL-1 $\beta$ ) [Nature (2000) 404 398–402].

## **Helicobasidium**

Species of *Helicobacter* have also been detected in liver tissue from patients with primary sclerosing cholangitis and primary biliary cirrhosis [JCM (2000) 38 1072–1076].

[*H. pylori* infection (diagnosis, treatment): Lancet (1997) 349 265–269. Vaccines against *H. pylori*: Drugs (1996) 52 799–804; BCID (1997) 4 413–433. E test (susceptibility to antibiotics): JCM (1997) 35 1842–1846. Electroporation of *H. pylori*: AEM (1997) 63 4866–4871. *H. pylori* epidemiology, metabolism, genetics, pathogenesis, diagnosis, therapy etc.: BCID (1997) 4 239–484. *H. pylori* (detection by PCR): JCM (1999) 37 772–774.]

**Helicobasidium** See AURICULARIALES.

**helicosporae** See SACCARDOAN SYSTEM.

**helicotrichous** Refers to flagella inserted in a helical zone on the cell surface of *Centipeda periodontii* [JGM (1984) 130 185–191].

**Helio bacterium** A genus of photosynthetic bacteria; *H. chlorum* contains a novel bacteriochlorophyll (Bchl *g*: see CHLOROPHYLLS) which, when in situ, shows a long-wavelength absorption peak at 788 nm. From 16S rRNA sequence analysis, *H. chlorum* is apparently related more closely to the Gram-positive bacteria than to other photosynthetic bacteria [Science (1985) 229 762–765].

**Heliozoa** A class of protozoa (superclass ACTINOPODA) in which numerous separate axopodia or filopodia radiate from the (more or less spherical) cell body, giving rise to the popular name of ‘sun animalcules’. The cells lack a central capsule (cf. RADIO-LARIA); some species have a ‘skeleton’ of siliceous scales or spines. The cytoplasm is more or less clearly differentiated into a highly vacuolated (‘frothy’) ectoplasm and a less vacuolated endoplasm which contains e.g. one or more nuclei, contractile vacuole(s), food vacuoles, etc. The ectoplasmic vacuoles appear to aid flotation. In general, the axopodia are not effective locomotory organelles, serving mainly to capture prey; however, in some members a type of rolling motility can be achieved by the sequential retraction of the axopodia. (See also TAXOPODIDA.)

Reproduction occurs by binary fission or (in some uninucleate species) by budding. Sexual processes have been recorded in some species.

Most heliozoa are free-floating freshwater organisms; however, some occur attached to a substratum by a stalk, and some are marine. They feed on other protozoa, microalgae, etc.

Orders: ACTINOPHYRIDA, CENTROHELIDA, DESMOTHORACIDA, TAXOPODIDA.

**helix–coil transition** In proteins or nucleic acids: the transition from an ordered, helical conformation to a disordered ‘random coil’ conformation. When used of double-helical DNA the term usually means simply *strand separation* (‘melting’).

**helix destabilizing protein** *Syn.* SINGLE-STRAND BINDING PROTEIN.

**Helminthosporium** A genus of fungi (class HYPHOMYCETES) which form septate mycelium and pigmented, septate conidia; conidiogenesis is tretic. The organisms occur e.g. on woody plants. (See also SILVER SCURF.) Some species have been transferred from *Helminthosporium* to the genus DRECHSLERA.

**Helminthosporium maydis virus** See MYCOVIRUS.

**Helmstetter–Cooper model** (*I* + *C* + *D* model) A model which relates chromosome replication (in bacteria) to the (prokaryotic) CELL CYCLE. Essentially, the cell cycle is divided into a linear sequence of three main periods designated *I*, *C* and *D*. Chromosome replication starts at the beginning of the *C* period and finishes at the end of the *C* period. Septum formation begins, and is completed, during the *D* period – at the end of which the cell divides. The *I* period is the inter-initiation period, that is,

the period between successive initiations of DNA replication; it is equal to the doubling time. As each *I* period ends, another *I* period begins.

The principle of the Helmstetter–Cooper model is illustrated in the figure. Some of the factors that may influence or determine the length of the *I* period are indicated in the entry CELL CYCLE.

**Helotiales** An order of fungi (subdivision ASCOMYCOTINA) which are typically saprotrophs or plant parasites. Ascocarp: APOTHECIUM with paraphyses, sessile or stipitate, sometimes setose. Asci: unitunicate, typically cylindrical; inoperculate, but with an apical pore. Ascospores: typically *not* elongated. Genera: e.g. *Ascocoryne*, *Botryotinia*, *Bulgaria*, *Chlorociboria* (see also GREEN OAK), *Chlorosplenium*, *Ciboria*, *Dasyyscyphus*, DIPLOCARPON, *Geoglossum*, *Korfia*, *Microglossum*, *Mitrula* (see also MYCOPARASITE), *Monilinia*, *Pezizella* (see also MYCORRHIZA), *Phacidium* (see also SNOW BLIGHT), SCLEROTINIA, *Spathularia*, *Trichoglossum*.

**helotism** (*mycol.*) Literally: *serfdom*. The term has been used to refer to the (supposedly) subservient role of the photobiont in a LICHEN.

**helper component** (*plant virol.*) See NON-CIRCULATIVE TRANSMISSION.

**helper T cell** See T LYMPHOCYTE.

**helper virus** Any virus which can provide functions necessary for the replication of a DEFECTIVE VIRUS or e.g. of a SATELLITE RNA.

**Helvella** A genus of fungi (order PEZIZALES) in which the ascocarp is a stipitate APOTHECIUM which is typically saddle-shaped (‘saddle fungi’); the smooth to warty, guttulate ascospores are commonly colourless or pale brown.

**helveticin J** See BACTERIOCINS.

**heme** See HAEM.

**Hemiascomycetes** A class of ascomycetes characterized by the formation of naked asci (i.e., asci not formed on or in an organized ascocarp) which do not develop from a system of ascogenous hyphae; the hemiascomycetes include most of the yeasts (e.g. *Saccharomyces* spp) and e.g. *Taphrina* spp. The class is not recognized in most modern taxonomic schemes; most of the hemiascomycetes are now placed in the ENDOMYCETALES.

**Hemiaulus** See DIATOMS.

**Hemibasidiomycetes** See TELIOMYCETES.

**hemicelluloses** The non-cellulosic polysaccharide fraction obtained from isolated plant cell walls by extraction with alkali after the PECTIC POLYSACCHARIDES have been extracted. Hemicelluloses are closely (but non-covalently) associated with CELLULOSE and occur in the matrix of the plant cell wall; they include e.g. galactomannans, glucomannans (see MANNANS), mixed  $\beta$ -glucans, XYLANS, xyloglucans etc.

**hemidesmosome** See TRYPANOSOMA.

**Hemidiscus** A genus of DIATOMS which are generally regarded as centric, although the valves are often markedly asymmetric. Blooms of *H. hardmannianus* in estuarine and neritic waters in India have been associated with high mortalities of fish and invertebrates [Limn. Ocean. (1985) 30 910–911].

**Hemileia** See UREDINIOMYCETES and COFFEE RUST.

**hemimethylated DNA** dsDNA in which only one of the strands is methylated (see DNA METHYLATION).

**Hemitrichia** A genus of slime moulds (class MYXOMYCETES). *H. serpula* forms conspicuous, yellowish, sessile, reticulate plasmodiocarps (up to several centimetres across) on humus or on rotting wood.

**Hemming filter** An apparatus used for FILTRATION. Two bijou bottles are clamped together, mouth-to-mouth, with a filter

HELMSTETTER-COOPER MODEL (see entry). (a) Chromosome replication during growth at different rates (cells and chromosomes are represented diagrammatically). Replication begins at a specific location in the chromosome, the *origin*, which is shown here as a small circle. During slow growth (*upper sequence*) each new daughter cell has exactly one chromosome because, following duplication of the parental chromosome, a new round of replication does not begin before the parent cell has divided fully.

During faster growth (*lower sequence*), a new round of replication has begun before the previous round has been completed – well before cell division; as a result, each new daughter cell has fractionally more than one chromosome.

(b) The cell division cycle may be represented as a linear sequence of three periods: *I*, *C* and *D*. *C* is the period during which chromosome replication occurs. *D* is the period in which the septum forms – cell division occurring at the end of the *D* period. *I* is the period between each successive *initiation* of chromosomal replication. Each *I* period starts when the previous one ends. (*Continued on page 362.*)

## hemp retting

between them; one bijou contains the sample, the other acts as the receiving vessel. On centrifugation, liquid passes through the filter into the receiver.

**hemp retting** See RETTING.

**Henneguya** A large genus of protozoa (class MYXOSPOREA) which are important histozoic parasites in various fish. Species are commonly specific for a given host and for a particular tissue within that host: e.g. the Channel catfish (*Ictalurus punctatus*) may be parasitized by *H. adiposa* (adipose fin), *H. diversis* (liver and kidney), or *H. exilis* (gills), while the Pacific salmon (*Oncorhynchus* spp) can be infected by *H. salmonicola* (muscles). Typically, conspicuous spore-filled cysts (up to 15 mm across in e.g. salmon infected with *H. salmonicola*) are formed. Heavy infestations may kill the fish (particularly when the gills are affected).

**HEP** High egg passage: refers to the number of times that a given strain of virus has undergone SERIAL PASSAGE in eggs. (See e.g. FLURY VIRUS; cf. LEP.)

**Hep-2** (H.Ep2, Hep-2, hep-2 etc) An ESTABLISHED CELL LINE derived from a human laryngeal carcinoma; the cells are heteroploid and epithelioid. HEP-2 cultures support the replication of a wide range of viruses.

**HEPA filter** High-efficiency particulate air filter, used e.g. in a SAFETY CABINET.

**Hepadnaviridae** A family of enveloped DNA-containing animal viruses which can cause hepatitis in man, animals or birds; the family includes HEPATITIS B VIRUS (HBV) of man, GROUND SQUIRREL HEPATITIS VIRUS (GSHV), DUCK HEPATITIS B VIRUS (DHBV), and WOODCHUCK HEPATITIS VIRUS (WHV) [Inter-virol. (1986) 25 14–29], and probably tree squirrel (*Sciurus carolinensis pennsylvanicus*) hepatitis B virus (THBV) [PNAS (1986) 83 2994–2997]. These viruses closely resemble one another in structure and genetic organization, but differ e.g. in their interactions with their hosts. The host's immune response to hepadnavirus infection has been implicated in the pathology of the virus-induced liver disease. Although all of the hepadnaviruses are highly hepatotropic, HBV DNA has also been detected in e.g. pancreatic, spleen and kidney cells, and DHBV can apparently infect duck pancreatic and kidney cells.

The infectious hepadnavirus virion (ca. 42 nm diam.) consists of a nucleocapsid (an internal core containing the viral genome) surrounded by a lipoprotein envelope. The core contains a major protein (designated P22<sup>C</sup> in HBV) and is associated with a DNA polymerase and a protein kinase which can phosphorylate the major core protein. In HBV, at least, the envelope contains three proteins: a 'major protein' (glycosylated form: GP27<sup>S</sup>, non-glycosylated form: P24<sup>S</sup>), the 'middle protein' (two glycosylated forms: GP33<sup>S</sup> and GP36<sup>S</sup>), and the 'large protein' (glycosylated form: GP42<sup>S</sup>; non-glycosylated form: P39<sup>S</sup>).

The genome, as present in hepadnavirus virions isolated from the blood of an infected host, has a characteristic structure:

it consists of a circular (but not covalently closed), partially double-stranded DNA molecule in which one strand (the L, 'long', or (–) strand) is of fixed length (ca. 3000–3300 nucleotides long) and has unique 3' and 5' ends and a protein (the 'DNA-linked protein') covalently attached to the 5' end. The other strand (the S, 'short', or (+) strand) has a fixed 5' end but a variable 3' end, and varies in length from 50 to 100% of that of the L(–) strand. (The 3' end of the S(+) strand can be extended by the endogenous viral polymerase, the L(–) strand acting as template.) The circularity of the molecule is maintained by base-pairing between the 5' ends of the two strands (the 'cohesive overlap'); in all hepadnaviruses there is an 11-bp direct repeat sequence on either side of the cohesive overlap.

In mammalian hepadnaviruses, the L(–) strand has four open reading frames, orientated in the same direction, designated S, C, P and X regions. The S region comprises the S gene, the pre-S1 region and the pre-S2 region; it encodes the 'major protein' (S gene), 'middle protein' (pre-S2 + S gene) and 'large protein' (pre-S1 + pre-S2 + S gene) of the viral envelope. The C region comprises the C gene (which encodes the major core protein) and the pre-C region. The product of the P region (which overlaps the whole of the S region and parts of the C and X regions) is a large histidine-rich protein (MWt ca. 90000) which is a DNA polymerase with REVERSE TRANSCRIPTASE activity. The X region includes the cohesive overlap sequence and encodes a polypeptide of unknown function. (DHBV lacks an X region.) The viral genes are expressed via at least two unspliced primary transcripts. No known viral protein is encoded by the S(+) strand.

Hepadnavirus DNA replication occurs by a characteristic mechanism involving reverse transcription of an RNA intermediate (see RETROID VIRUSES). When a virion infects a host cell, the viral DNA enters the nucleus and is converted to a supercoiled ccc dsDNA molecule. The L(–) strand is transcribed to form multiple copies of a 3.5-kb RNA called the *pre-genome*; this RNA is then encapsidated with the viral DNA polymerase and 'DNA-linked protein', and an L(–) strand of DNA is synthesized by reverse transcription of the *pre-genome*. The *pre-genome* is then apparently degraded by an RNase H activity, and an S(+) strand is synthesized on the L(–) strand template. The 'DNA-linked protein' may act as primer for L(–) strand DNA synthesis, while a small fragment of RNA may be the primer for S(+) strand synthesis. (cf. RETROVIRIDAE.) The assembly of the virions and their release from the cell can occur before S(+) strand synthesis is complete, accounting for the partially double-stranded nature of the genome in virions liberated into the bloodstream.

[Review (mainly of HBV): Nature (1985) 317 489–495; Book ref. 110, pp. 23–41.]

**heparin** A highly sulphated proteoglycan present e.g. in MAST CELLS and other cells. Heparin varies in MWt according e.g.

## HELMSTETTER–COOPER MODEL (continued)

In a given set of  $I + C + D$  sequences, the relationship between a particular sequence and the one immediately above it is that of a daughter cell to its parent cell. The upper set of  $I + C + D$  sequences represents successive cell cycles during slow, steady growth. Notice that, when  $I = C + D$ , a new round of chromosome replication does not start until after the  $D$  period, i.e. after completion of cell division.

The lower set of  $I + C + D$  sequences represents successive cell cycles during faster steady growth. Here, with  $I$  shorter than  $C$ , chromosome replication is initiated before the previous round has been completed. Hence, at the end of  $D$  the new round of replication is already well advanced. Thus, in cells growing rapidly, the chromosome in a new daughter cell will have reached a stage of replication which is determined by the timing of initiation (i.e. start of the  $C$  period) in the parent cell.

In *Escherichia coli*,  $C$  and  $D$  increase linearly in generation times >60–70 minutes [Microbiology (2003) 149 1001–1010].

Reproduced from *Bacteria*, 5th edition, Figure 3.2, pages 44–45, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

to the methods used for its isolation; that used as an ANTICOAGULANT (heparin inhibits thrombin activity) has a MWt of ca. 25000. In addition to anticoagulant activity, heparin can e.g. modify (limit) delayed hypersensitivity reactions in mice and guinea pigs (mechanism unknown), stimulate phagocytosis, inhibit the alternative pathway of complement fixation (by enhancing the activity of Factor H), and inhibit eosinophil-mediated ADCC. Heparin is cleaved by heparinases, and its activity can be neutralized by e.g. protamines.

**hepatitis** Inflammation of the liver. Hepatitis is often caused by viruses (e.g. HEPATITIS A, HEPATITIS B, HEPATITIS C); hepatitis D and hepatitis E viruses are less-common causal agents. The significance of infection with hepatitis G virus is currently uncertain [transfusion-associated hepatitis G virus infection: NEJM (1997) 336 747–754; RMM (1998) 9 207–215]. Hepatitis may also occur as a symptom of non-viral infectious diseases (see e.g. amoebic DYSENTERY). [Diagnostic perspective of viral hepatitis: RMM (1997) 8 197–207.]

**hepatitis A** (infectious hepatitis; epidemic hepatitis; short-incubation hepatitis) A viral HEPATITIS caused by the hepatitis A virus (HAV, = ENTEROVIRUS type 72); it tends to occur in epidemics among children and young adults, particularly in closed institutions (e.g. mental hospitals). Man is probably the only natural host, but certain other primates (e.g. chimpanzees) can be infected. A carrier state is not known. Infection occurs mainly by consumption of water, milk or food contaminated with human faeces – e.g. shellfish harvested from sewage-polluted waters. HAV replicates in hepatocytes and is presumed to reach the intestine (and hence faeces) via the bile duct. The peak excretion of virus occurs during the latter half of the incubation period (2–6 weeks). Symptoms: fatigue, anorexia, low-grade fever, some abdominal pain, and sometimes jaundice. The disease is usually self-limiting within a few weeks; rarely, a severe, fulminant, often fatal hepatitis develops. *Lab. diagnosis*: demonstration of HAV in faeces; serological tests for anti-HAV IgM antibodies in serum.

**hepatitis B** (serum hepatitis; homologous serum jaundice; long-incubation hepatitis) A viral HEPATITIS caused by the HEPATITIS B VIRUS (HBV). Incubation period: 2–6 months (but occasionally as short as 2 weeks). Infection occurs by direct inoculation or by contamination of mucous membranes. The virus is present in the blood and body fluids (saliva, semen, mucus, wound exudates etc) of an infected person. Transmission may thus occur by the transfusion of blood or blood products from infected donors; by tattooing, ear-piercing, vaccination, renal dialysis, etc, using contaminated needles; by sexual contact; or (in infants) during birth. (Intrauterine infection is uncommon since HBV does not normally cross the placenta.) HBV reaches the liver via the blood and replicates in the hepatocytes. The disease may be mild or subclinical, and a carrier state is recognized (see HEPATITIS B VIRUS). In clinical cases, onset is gradual with jaundice and e.g. nausea, malaise, pains in muscles and joints, with or without fever; occasionally acute hepatic failure occurs. (See also DELTA VIRUS.) Pathogenesis appears to involve the host's immune response to viral antigens in the plasma membranes of infected hepatocytes. The condition may be self-limiting, or chronic liver disease may develop; chronic infection is associated with an increased risk of hepatocellular carcinoma (HCC: see HEPATITIS B VIRUS) and possibly other tumours, including KAPOS'S SARCOMA [JAMA (1984) 251 1007–1008]. HCC is a major cause of death in regions where HBV is endemic and neonatal infection is common (e.g. in regions of China and tropical Africa).

*Lab. diagnosis* involves detection of HBV antigens in the serum. HBsAg (see HEPATITIS B VIRUS) appears in the serum during the incubation period and persists through the symptomatic phase of the disease. It usually begins to disappear ca. 2–3 months after the onset of symptoms; if it persists for >6 months, the patient has become a carrier and may develop chronic liver disease. Anti-HBsAg antibodies appear only late in convalescence; the high levels of HBsAg present in the blood may induce immune tolerance to this antigen. HBeAg appears in the serum just before symptoms begin; its appearance is associated with high infectivity and the presence of whole (infectious) virions ('Dane particles') in the blood. HBcAg does not appear in the serum, but anti-HBcAg antibodies can be detected as symptoms begin. Anti-HBcAg IgM antibodies disappear late in the convalescence phase, but anti-HBcAg IgG antibodies may persist for years (possibly for life), and detection of the latter is a useful indicator of previous infection. [Screening blood samples for HBV by PCR: Lancet (1999) 353 359–363.]

*Treatment.* There is no specific treatment for the clinical disease. Antiserum may be used for pre- or post-exposure prophylaxis. Vaccines containing HBsAg are available [PM (1984) 75 199–211].

**hepatitis B virus** (HBV) A virus of the HEPADNAVIRIDAE (q.v.) which causes HEPATITIS B in man, and which is also apparently a causal agent of human hepatocellular carcinoma (HCC). (HBV can also infect chimpanzees, but does not cause chronic hepatitis or HCC in these animals.) (cf. WOODCHUCK HEPATITIS VIRUS.)

On infection of a new host (see HEPATITIS B), the HBV virion attaches to the surface of a hepatocyte and penetrates the cell by endocytosis or by fusion of the viral envelope with the host cell plasma membrane. HBV surface (envelope) antigen (HBsAg) and core antigen (HBcAg) become associated with the plasma membrane of the infected cell, and subsequently large amounts of HBsAg are released into the circulation in the form of non-infectious (DNA-free), spherical or tubular lipoprotein particles (ca. 22 nm diam.). HBsAg (formerly known e.g. as 'Australia antigen', Au antigen, or hepatitis-associated antigen, HAA) is a dimer of two molecules, linked by disulphide bonds, of the envelope 'major protein' (see HEPADNAVIRIDAE). HBcAg is the major capsid polypeptide (P22<sup>C</sup>). The soluble e antigen (HBeAg) is a product of proteolytic cleavage of HBcAg. The appearance in the serum of infected individuals of antibodies to these antigens provides a useful means of monitoring disease development (see HEPATITIS B).

HBV strains can be serotyped on the basis of their HBsAg. HBsAg contains a group-specific determinant (designated *a*), common to all subtypes, together with subtype-specific determinants (designated *d*, *y*, *w* and *r*); strains typically contain either *d* or *y* with either *w* or *r*. The four principal serotypes, which differ in geographical distribution, are *adw*, *adr*, *ayw* and *ayr*. The subtype determinants are useful epidemiological markers.

In ca. 5–10% of individuals infected with HBV, HBsAg persists in the circulation for >6 months, and a carrier state is established which may persist for life. The carrier state may be asymptomatic (latent infection) or symptomatic (with e.g. chronic active hepatitis, cirrhosis, and/or HCC), and is most likely to develop in e.g. perinatally-infected or immunodeficient individuals. In HBV carriers, viral DNA may integrate at one or more (apparently random) sites in the host cell genome; the integrated sequences may be complete genomes or subgenomic fragments, and in HCC cells they are often extensively rearranged, with e.g. multiple deletions, inversions, duplications, etc. Rearrangements also occur in the flanking cellular sequences.

## hepatitis C

[Duplications of flanking cellular sequences and model for HBV DNA integration: PNAS (1985) 82 4458–4462.] Integrated viral DNA may continue to be expressed, resulting in the continued synthesis of e.g. HBsAg; however, in HCC cells virus replication and gene expression appear generally to be absent. Integrated HBV DNA has been found in the majority of HCC cells examined, and integration is generally assumed to precede carcinogenesis; however, the relationship between viral DNA integration and the induction of HCC is unknown. HCC generally does not develop for many years after the establishment of the carrier state; in at least some cases additional factors – such as genetic predisposition, immunological factors, or exposure to chemical co-carcinogens (e.g. AFLATOXINS) – may be involved.

[Biology and epidemiology of HBV: Book ref. 110, pp. 43–65; molecular biology of HBV: Nature (1985) 317 489–495.]

**hepatitis C** A viral HEPATITIS caused by the HEPATITIS C VIRUS (HCV); most cases of hepatitis formerly referred to as NANB (non-A-non-B) hepatitis are now believed to have been hepatitis C. In nature, hepatitis C is limited to humans (chimpanzees can be infected experimentally). The route of transmission of HCV is commonly parenteral (including blood transfusion); sexual and perinatal transmission also occur.

The incubation period (4–12 weeks) may be followed by non-specific symptoms that resolve within weeks or months. Infection is often asymptomatic; jaundice is uncommon. HCV RNA is detectable in serum (e.g. by rtPCR) before seroconversion. In a high proportion of patients infection becomes chronic (indicated e.g. by the continuing presence of HCV RNA in serum); usually asymptomatic, the chronic disease may nevertheless give rise to e.g. hepatocellular carcinoma or cirrhosis in a proportion of cases after 20–30 years. (Preliminary data have suggested that there is a cerebral effect (altered cerebral metabolism) in patients chronically infected with HCV [Lancet (2001) 358 38–39].)

*Lab. diagnosis:* e.g. screening (with a third-generation ELISA) for specific antibodies; antigens used in the assay consist of synthetic peptides/recombinant proteins representing products which are encoded by particular regions of the HCV genome. Any specimen positive in this assay is re-tested by a supplemental assay such as the *recombinant immunoblot assay* (RIBA). In a RIBA test, a nitrocellulose strip is coated with peptides/recombinant proteins similar to those used in the ELISA, each type of peptide and protein forming a separate band on the strip. The strip is exposed to a sample of serum (permitting antibody–antigen binding) and then to an anti-human IgG–enzyme conjugate. After washing, bound antibodies are detected by adding the enzyme's substrate and examining the strip for the (coloured) product of hydrolysis; the presence of particular antibodies in the serum is deduced from the development of colour at particular band(s) on the strip. Nucleic-acid-based tests are useful for the early detection of HCV – and also for following the efficacy of antiviral therapy. [Quantification of hepatitis C virus by bDNA assay: JCM (1997) 35 187–192; rtPCR-based screening for HCV in a blood bank: Lancet (1999) 353 359–363.]

**hepatitis C virus** (HCV) A small, enveloped, positive-sense ssRNA virus which causes HEPATITIS C in man. A population or sample of HCV from a given source exists as a QUASISPECIES. HCV has not been cultured.

The 5' non-coding end of the HCV genome is followed (5' → 3') by sequences which encode: core protein, envelope proteins, membrane-binding function, helicase and protease, membrane-binding function, RNA polymerase and a 3' non-coding region. One of the envelope protein genes includes a hypervariable region designated HVR-1.

Six major genotypes and >60 subtypes of HCV have been distinguished. Treatment of hepatitis C is apparently influenced by the specific genotype involved and the level of viraemia; disease caused by genotype 2 or 3, in conjunction with low-level viraemia, is reportedly more likely to respond in a sustained fashion to treatment with IFN- $\alpha$ , while disease caused by genotype 1 or 4 is apparently more refractory.

[Quantification of HCV in plasma samples: JCM (1997) 35 187–192.]

In many cases HCV causes persistent infection. Persistence may be facilitated by the relatively poor immunogenicity of the virus and the low-level viraemia. Changes in viral antigens, due e.g. to mutations in HVR-1, may also contribute to persistence; however, genetic drift in HCV may be independent of the host's (weak) immune pressure [JV (2000) 74 2541–2549].

(See also CD81.)

**hepatitis D, E** See HEPATITIS.

**hepatitis D virus** *Syn.* DELTA VIRUS.

**hepatitis delta virus** *Syn.* DELTA VIRUS.

**hepatitis G virus** See HEPATITIS.

**hepatitis X** Hepatitis in dogs caused by ingestion of food contaminated with AFLATOXINS; the liver becomes necrotic and congested, with haemorrhagic oedema of the gall bladder mucosa.

**hepatocellular carcinoma** (HCC) A CARCINOMA of liver cells. Primary HCC can be caused e.g. by HEPATITIS B VIRUS and WOODCHUCK HEPATITIS VIRUS. (See also HEPATITIS C.)

**hepatotoxin** A TOXIN which acts on the liver.

**hepatotropism** See TROPISM (sense 2).

**HEPES** A zwitterionic pH buffer: *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulphonic acid. HEPES is widely used e.g. in TISSUE CULTURES, and has also been used in bacterial cultures; it is readily soluble in water, and does not bind divalent cations such as Ca<sup>2+</sup>, Mg<sup>2+</sup> or Cu<sup>2+</sup>. At 37°C the pK<sub>a</sub> of HEPES is ca. 7.3; at 25°C it is ca. 7.5. (cf. BICINE.)

**Herbert's pits** See TRACHOMA.

**herbicin A** An acyl peptide antibiotic produced by *Erwinia herbicola*. It can inhibit the growth of yeasts and filamentous fungi, and can kill sterol-requiring molluscs [JAC (1985) 16 449–455]; it is inactive against other bacteria.

**herbivorous** Refers to protozoa which feed on bacteria and/or algae. (cf. CARNIVOROUS.)

**herd immunity** See EPIDEMIOLOGY.

**herd structure** See EPIDEMIOLOGY.

**Heribaudiella** See PHAEOPHYTA.

**Hericium** A genus of fungi of the APHYLLOPHORALES.

**hermaphroditism** The phenomenon in which an individual has both male and female sexual organs; such an individual may exhibit HOMOTHALLISM or HETEROTHALLISM.

**herpangina** An acute (usually self-limiting) infectious PHARYNGITIS, occurring mainly in children and young adults, caused by coxsackieviruses A2–A6, A8 and A10. Small, vesicular, ulcerating lesions develop in the pharyngeal region, and there may be varying degrees of fever and/or prostration.

**herpes** (1) Any disease caused by a herpesvirus (especially HERPES SIMPLEX but also e.g. HERPES ZOSTER) and characterized by the formation of small vesicular lesions on skin and mucous membranes. (2) Used increasingly as a synonym of genital herpes (see HERPES SIMPLEX).

**herpes genitalis** See HERPES SIMPLEX.

**herpes gladiatorum** See HERPES SIMPLEX.

**herpes labialis** See HERPES SIMPLEX.

**herpes simplex** An infectious disease, caused by herpes simplex virus (HSV) type 1 or 2 (see ALPHAHERPESVIRINAE), which

(typically) involves the formation of thin-walled vesicles that ulcerate, crust and heal; vesicles occur, often in clusters, on skin and/or mucous membranes. Transmission occurs mainly by person-to-person contact – e.g. sexual contact, kissing, contact sports such as wrestling ('herpes gladiatorum').

Infection may occur at any of a range of body sites; in general, HSV type 2 is associated with genital (and hence neonatal) infections; HSV type 1 accounts for most of the other forms.

Incubation period: 2–12 (average 6) days. The disease varies from subclinical to severe, and is occasionally fatal. HSV can remain latent in nerve cells near the site of infection; reactivation may occur spontaneously or in response to other infections, stress, immunosuppression etc. In general, recurrent episodes become progressively less severe and less frequent. In neonates and immunodeficient individuals HSV may become disseminated and may involve e.g. the liver, adrenal glands, brain etc.

*Cutaneous herpes.* Skin lesions may occur on any part of the body, often in clusters which may coalesce. Other symptoms of primary infection may include pain, fever, oedema etc. HSV type 1 tends to be associated with skin lesions above the waist, type 2 with those below the waist. (See also ECZEMA and PARONYCHIA.)

*Encephalitis.* HSV type 1 is a common cause of non-epidemic viral ENCEPHALITIS. Onset is acute, with headache, nausea, vomiting, fever, myalgia, mental deterioration, convulsions, coma etc.; the fatality rate is typically >50%. Neurological sequelae are common in survivors. (See also aseptic MENINGITIS.)

*Genital herpes* (herpes genitalis) is a SEXUALLY TRANSMITTED DISEASE which usually involves HSV type 2. It may be mild and self-limiting. Lesions occur in the genital region and may spread to adjacent areas of skin (e.g. buttocks, thighs). Other symptoms may include e.g. fever, dysuria, pain, malaise. In women the cervix may be the main site of genital infection (*herpetic cervicitis*); this may be asymptomatic, or there may be ulceration with hyperplasia. (HSV type 2 infection in women is associated with an increased risk of abortion and of cervical cancer.) Genital infections may give rise to subclinical shedding of virus, with associated risk of transmission.

*Labial herpes* (herpes labialis) is typically a recurrent lip lesion (cf. COLD SORE) which usually crusts and heals in 3–10 days. Labial herpes may be associated with lip cancer.

*Neonatal herpes* is usually acquired (during birth) from a mother with genital herpes – hence HSV type 2 is commonly responsible. Herpetic vesicles or ulcers, or keratoconjunctivitis, may or may not be present. Fatality rates may be 50% or more in untreated cases; surviving infants commonly exhibit neurological and/or ocular sequelae. (See also TORCH DISEASES.)

*Ocular herpes.* HSV infection of the eye is a recurrent, usually unilateral, keratitis, sometimes with conjunctivitis; corneal scarring can lead to blindness. The characteristic lesion is a dendritic (branching) corneal ulcer with can be readily stained with either FLUORESCIN or ROSE BENGAL [photograph of stained lesion: Book ref. 224, pp 67–68].

*Oral herpes* (herpetic stomatitis) occurs as a manifestation of initial HSV infection in adults and children. Primary herpetic gingivostomatitis involves shallow vesicular and ulcerative lesions on the labial and buccal mucosa, and tongue, with GINGIVITIS, fever and regional lymphadenopathy. The lesions usually heal in 7–10 days. Reactivation rarely involves the oral mucosa (except in immunocompromised individuals, in whom the oral lesions may be atypical in appearance). (Oral lesions may also be due to infection with the varicella zoster virus (VZV); in

chickenpox, such lesions may appear before development of the characteristic skin lesions.) [Virology of the mouth (including HSV infections): RMM (1994) 5 209–216.]

*Lab. diagnosis.* For infections other than encephalitis: scrapings from the edges of lesions, or biopsies from skin or liver, are examined microscopically for multinucleate giant cells with eosinophilic intranuclear inclusion bodies; HSV can be demonstrated e.g. by immunofluorescence techniques, ELISA etc.

For encephalitis, laboratory diagnosis may be made e.g. by PCR-based examination of cerebrospinal fluid (CSF), thus avoiding the risks of brain biopsy [see e.g. JCM (1997) 35 691–696]. The PCR-based detection of HSV (types 1 and 2) may be facilitated by a commercial system involving the use of MOLECULAR BEACON PROBES that hybridize to amplicons of both HSV type 1 and HSV type 2 (HSVision™; Stratagene). (HSV type 2 is not a common cause of viral encephalitis; it may be a causal agent e.g. in immunocompromised individuals.)

*Chemotherapy.* A number of antiviral agents (e.g. ACYCLOVIR, IDOXURIDINE, PENCICLOVIR, trifluorothymidine, VIDARABINE) are active against HSV and are useful in some cases; for example, vidarabine has been used in cases of HSV encephalitis, while acyclovir, or penciclovir, is used in creams for the topical treatment of lesions on skin and mucous membranes. In general, such agents are not effective in preventing recurrence or transmission.

**herpes simplex virus group** See ALPHAHERPESVIRINAE.

**herpes zoster** A human disease resulting from the reactivation of a latent human (alpha) herpesvirus 3, present in a dorsal nerve ganglion, subsequent to an attack of CHICKENPOX that may have occurred (many) years earlier. The virus replicates in the ganglion, and in adjacent nervous tissue, and is transported, within the axon, to nerve endings in the corresponding region of skin; viral replication is believed to account for pain experienced during the acute phase of the disease – the pain being accompanied by an eruption of characteristic clusters of vesicular lesions. (Lesions may develop in areas not served by the affected nerves; this is thought to be due to viral dissemination in the bloodstream.) (See also RAMSAY HUNT SYNDROME.) Reactivation of the virus may occur spontaneously or may be provoked e.g. by immunosuppression, certain drugs, or other diseases.

Post-herpetic neuralgia (PHN) is prolonged pain which appears to be due to damage sustained by the peripheral nervous system as a result of viral replication. Some regard PHN as pain which persists following the disappearance of the rash, while others have defined PHN as e.g. pain which persists for at least 30 days from the onset of the rash. In an attempt to provide a usable definition (for clinical trials of antiviral agents), the concept of *zoster-associated pain* (ZAP) has been introduced; ZAP includes the continuum of acute and chronic pain.

*Chemotherapy.* The use of antiviral agents in the acute phase of herpes zoster is generally beneficial, and is particularly important in immunocompromised patients in whom herpes zoster may become a life-threatening condition; in the latter patients, intravenous ACYCLOVIR is the first-choice therapy (which may decrease the risk of dissemination).

For immunocompetent patients with moderate to severe pain during the acute phase, systemic antiviral therapy should reduce the duration of the rash and pain if given immediately after the onset of the rash (within a maximum of 72 hours after onset); useful drugs: ACYCLOVIR, FAMCICLOVIR, VALACICLOVIR (each of which can be administered orally). Acyclovir should be given intravenously if severe complication (e.g. encephalitis) develop.

[Treatment of zoster: RMM (1995) 6 165–174.]

## Herpesviridae

**Herpesviridae** A large family of enveloped viruses containing a linear dsDNA genome. All herpesviruses are structurally similar: the virion (ca. 120–200 nm diam.) contains a core, i.e. a DNA–protein complex, within an icosahedral capsid (ca. 100–110 nm diam.; 12 pentameric and 150 hexameric capsomers) [capsid protein (structure): EMBO (2003) 22 757–765]; the nucleocapsid is enclosed by a lipoprotein envelope (bearing glycoprotein projections at the surface) – the (apparently) amorphous region (*tegument*) between capsid and envelope containing virus-encoded proteins. Virions are readily inactivated by lipid solvents, lipases or heat.

Herpesviruses have been isolated from a wide range of animals, including mammals, birds, reptiles, amphibians and fish; some of the viruses have a narrow host range.

Many herpesviruses can cause disease in their primary host(s). Many (possibly all) can remain latent in the host's tissues, often for the lifetime of the host.

The transmission of herpesviruses commonly occurs by direct contact between mucosal surfaces – but some can be transmitted via body fluids, such as milk, or via the placenta etc. (See also DNA TUMOUR VIRUSES.)

The herpesvirus genome ranges from ~125 to ~240 kb in length and it characteristically contains repeated terminal and/or internal sequences which can take part in recombinational events (and which may therefore allow the development of variant forms of the genome). In the large genome (e.g. ~80 genes in EPSTEIN–BARR VIRUS), most of the genes encode structural or regulatory functions; relatively few genes are expressed during viral latency.

Interestingly, in some human herpesviruses the genome contains sequences that are partially homologous to certain CYTOKINES and/or cytokine receptors.

Herpesviruses may be typed (fingerprinted) by techniques such as RFLP for epidemiological and other purposes [e.g. molecular epidemiology of herpes simplex virus type 1: RMM (1998) 9 217–224].

**Replication cycle.** Initially, the virion attaches to a host cell and the viral envelope then fuses with the cell membrane (see ENVELOPE). The nucleocapsid is transported across the cytoplasm to the nuclear membrane where the DNA is released into the nucleus via a nuclear pore. Within the nucleus, the viral immediate–early genes are transcribed, and the transcripts enter the cytoplasm for synthesis of viral polypeptides. Products of the immediate–early genes include proteins that serve regulatory functions and which are necessary for the expression of early genes (encoding e.g. a DNA polymerase) and late genes (encoding e.g. components of the capsid). Viral DNA is replicated, and the nucleocapsids are assembled, in the nucleus, with various structural proteins that enter the nucleus from the cytoplasm. Nucleocapsids can leave the nucleus in two ways. They can bud through the inner lamella of the nuclear membrane, thus acquiring an envelope; in this case, the mature virions are transported to the cell surface within membrane-bounded vacuoles and are then released to the exterior. Alternatively, nucleocapsids may enter the cytoplasm in an immature form which, only later, acquires an envelope by budding into a cytoplasmic vacuole.

**Classification and nomenclature.** Some of the (many) known herpesviruses have been allocated to one of three subfamilies: ALPHAHERPESVIRINAE, BETAHERPESVIRINAE and GAMMAHERPESVIRINAE [Book ref. 23, pp 47–51] – mainly on the basis of biological characteristics.

The naming of individual herpesviruses has been complicated by the widespread use of common names which are based on a

variety of criteria – such as the disease caused by the virus (e.g. Marek's disease virus, herpes simplex virus); CPEs induced by the virus (e.g. cytomegalovirus); host species (e.g. *Herpesvirus saimiri*); names of pioneer workers (e.g. Epstein–Barr virus, Lucké virus).

It has been recommended [Book ref. 139, pp 1–23] that the name of a herpesvirus should usually be based on the family or subfamily to which its primary host belongs (subfamily for bovine and primate viruses, family in other cases) – viruses isolated from humans being prefixed by 'human'; the name may, where applicable, indicate the subfamily of herpesviruses to which the virus belongs (alpha, beta or gamma), and is followed by a number – numbers being allocated sequentially as new viruses are discovered. Thus, e.g. Marek's disease virus becomes gallid herpesvirus 1; herpes simplex type 1 virus becomes human (alpha) herpesvirus 1; Epstein–Barr virus becomes human (gamma) herpesvirus 4.

Many herpesviruses, including some important pathogens of animals, were not listed in an earlier (1982) classification scheme [Book ref. 23, pp 47–51]. These viruses include e.g. bovine herpesvirus 1 (causal agent of various cattle diseases, such as INFECTIOUS BOVINE RHINOTRACHEITIS, encephalitis in newborn calves, infectious pustular vulvovaginitis and abortion in cows etc.); anadid herpesvirus 1 (= anserid herpesvirus 1, causal agent of DUCK VIRUS ENTERITIS); gallid herpesvirus 3 (causal agent of AVIAN INFECTIOUS LARYNGOTRACHEITIS); herpesviruses of amphibians (e.g. Lucké virus, causal agent of renal adenocarcinoma in frogs, *Rana pipiens*) [review: Book ref. 140, pp 367–384]; and herpesviruses of reptiles and fish (see e.g. CARP POX and CHANNEL CATFISH VIRUS DISEASE) [review: Book ref. 140, pp 319–366].

**Herpesvirus ateles** See GAMMAHERPESVIRINAE.

**herpesvirus B** *Syn.* B VIRUS.

**Herpesvirus saimiri** See GAMMAHERPESVIRINAE.

**Herpesvirus simiae** *Syn.* B VIRUS.

**herpetic** Pertaining to or caused by a herpesvirus – see e.g. HERPES SIMPLEX.

**herpetic cervicitis** See HERPES SIMPLEX.

**herpetic stomatitis** See HERPES SIMPLEX.

**Herpetomonas** A genus of homoxenous parasitic protozoa (family TRYPANOSOMATIDAE) which occur (typically in the gut) in flies, bugs and hymenopterous insects. Promastigote, paramastigote and opisthomastigote forms occur during the life cycle; biflagellate organisms may result from rapid division of promastigotes.

**Herpetosiphon** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur in aquatic (freshwater to marine) habitats. The organisms are gliding filaments (up to ca. 2 µm wide) which may be sheathed; they typically contain carotenoid glycoside pigments ranging from yellow or orange. Metabolism appears to be chemoorganotrophic. GC%: ca. 44–53.

**Herpetosoma** A subgenus of TRYPANOSOMA within the STERCORARIA; species include parasites of rodents and man. The trypomastigote form typically has a subterminal kinetoplast, a pointed posterior end, and a free flagellum.

*T. (H.) lewisi*, a parasite in rats, is transmitted cyclically and contaminatively by fleas, e.g. *Xenopsylla cheopis*; it is cultivable e.g. in NNN medium at 25–27°C. In the vertebrate host, the reproductive forms (epimastigotes) undergo multiple fission or unequal binary fission, resulting eventually in the production of non-dividing trypomastigotes.

*T. (H.) rangeli* is parasitic in man (and in e.g. cats, dogs etc) in Central and South America, and is transmitted cyclically – mainly by bugs of the genus *Rhodnius*. Although classified in the Stercoraria, this species is transmitted by bite: the

organism develops both in the gut and (as epimastigotes and trypomastigotes) in the salivary glands of the vector, but forms which develop in the gut are not infective for mammals. In man, bloodstream forms are trypomastigotes, ca. 25–35 µm in length. *T. (H.) rangeli* appears to be non-pathogenic. It can be cultivated e.g. in NNN medium.

Other species include *T. microti*, *T. nabiasi* and *T. zapi*.

**Herpomyces** See LABOULBENIALES.

**Herxheimer reaction** *Syn.* JARISCH–HERXHEIMER REACTION.

**Hessea** See MICROSPOREA.

**Hesseltinella** See MUCORALES.

**heteroantibody** Any antibody formed in one species against an antigen derived from another species. (cf. ISOANTIBODY.)

**heteroauxin** See AUXINS.

**Heterobasidion** A genus of fungi of the APHYLLOPHORALES (family Polyporaceae). *H. annosum* (formerly *Fomes annosus*) forms perennial, bracket-shaped or resupinate, typically corky or woody fruiting bodies in which the context is dimitic and lacks clamp connections; the bracket-shaped fruiting body typically has a rust-coloured upper surface and a pale, porous, lower surface. Fruiting bodies of several years' standing consist of vertically stacked ('stratified') layers of vertically orientated tubules. Basidiospores: spheroidal, colourless, ca. 5 × 4 µm. *H. annosum* grows on felled timbers, and is parasitic on conifers and e.g. red oak (*Quercus borealis*); in e.g. parts of the United Kingdom, the stumps of freshly-felled trees are inoculated with *Peniophora gigantea* which colonizes the cut surface, inhibiting infection by *H. annosum*. (See also TIMBER SPOILAGE.)

**heterocaryon** *Syn.* HETEROKARYON.

**Heterochlorida** See PHYTOMASTIGOPHOREA.

**Heterochloris** See XANTHOPHYCEAE.

**heterochromatin** See CHROMATIN.

**heteroclicity** The phenomenon in which a cross-reactive antigen binds an antibody with an AFFINITY greater than that shown by the homologous antigen; the cross-reactive antigen, and the antibody, are described as *heteroclitic*.

**heteroclitic** See HETEROCLICITY.

**heterococcolith** See COCCOLITH.

**heterocyst** A type of cell, morphologically and functionally distinct from a vegetative cell, which occurs under certain conditions in some filamentous CYANOBACTERIA (members of sections IV and V); heterocysts function as specialized anaerobic compartments within which NITROGEN FIXATION can occur in aerobic environments. (cf. AKINETE.) Heterocysts differentiate from vegetative cells (intercalary or terminal, depending on species) in response to limiting levels of combined nitrogen; differentiation is inhibited in the presence of e.g. nitrate and ammonia.

Mature heterocysts apparently cannot divide.

Differentiation from a vegetative cell involves e.g. (i) the formation of a thick, multilayered envelope – whose thickness (in *Anabaena flos-aquae*) has been found to increase with increased partial pressure of oxygen [JGM 1992] 138 2673–2678; (ii) rearrangement of thylakoid membranes (heterocysts are filled with contorted membranes); (iii) inactivation of photosystem II, resulting in the cessation of oxygen evolution – cyclic photophosphorylation (which involves photosystem I) apparently continues to occur; (iv) degradation of phycocyanin (see PHYCOBILIPROTEINS); (v) cessation of carbon dioxide fixation (e.g. by inactivation of RuBP carboxylase); (vi) synthesis of NITROGENASE (see NIF GENES). [Role of transcription in differentiation: JGM (1984) 130 789–796]. Respiratory activity apparently

helps to maintain the anaerobic state. [Protection of nitrogenase from oxygen in heterocystous cyanobacteria: MR (1992) 56 352–362.]

In *Anabaena* strain PCC 7120, which forms heterocysts in both terminal and intercalary locations, differentiation of heterocysts depends on a functional *hetR* gene. In genetically engineered cells of this strain, controlled expression of *hetR* can induce differentiation of heterocysts even under conditions that would normally repress their formation. However, in cells with a mutant *patA* gene – which form heterocysts almost exclusively at *terminal* locations – the expression of *hetR* did not induce the formation of intercalary heterocysts; this was interpreted to mean that, while raised levels of HetR are necessary to promote the formation of heterocysts, PatA may play a role in regulating the expression of *hetR* [PNAS (2001) 98 2729–2734].

During nitrogen fixation, the heterocysts and vegetative cells are metabolically interdependent. The vegetative cells supply heterocysts with e.g. fixed carbon, reduced sulphur, and glutamate; in the heterocyst, fixed nitrogen is transferred to glutamate by glutamine synthetase (see AMMONIA ASSIMILATION), and the resulting glutamine is passed back to vegetative cells to supply their nitrogen requirements. Communication between a heterocyst and adjacent vegetative cell(s) occurs via fine pores (*microplasmodesmata*) in their juxtaposed cytoplasmic membranes; juxtaposition of these membranes occurs at the vegetative-cell end of a channel (the *pore channel*) which passes through the thick heterocyst envelope. (Microplasmodesmata are also found between vegetative cells.) [Heterocyst differentiation and function: Book ref. 75, pp. 219–242, 265–280.]

**heterocytotropic antibodies** CYTOPHILIC ANTIBODIES (particularly REAGINIC ANTIBODIES) which can attach to the cells of two or more different host species. (cf. HOMOCYTOTROPIC ANTIBODIES.)

**heteroduplex** Any double-stranded nucleic acid in which some, or many, of the bases in one strand are not complementary to bases in the corresponding positions in the other strand; such mismatching of base pairs is reflected in the thermal stability of the duplex. (See also DNA HOMOLOGY and HOMODUPLEX.) The term 'heteroduplex' is also used for any duplex in which each strand originates from a different parent duplex (see e.g. RECOMBINATION), even though such strands may in some cases be strictly complementary.

**heteroecious** *Syn.* HETEROXENOUS.

**heterofermentation** (1) Any fermentation in which there is more than one major end-product. (2) *Syn.* HETEROLACTIC FERMENTATION.

**heterogeneous nuclear RNA** See HNRNA.

**heterogenote** See MEROZYGOTE.

**heteroglycan** See POLYSACCHARIDE.

**heteroimmune phages** See SUPERINFECTION IMMUNITY.

**heteroimmunization** The stimulation of an immune response to antigens derived from another species. (cf. ISOIMMUNIZATION.)

**heterokaryon** (heterocaryon) (*mycol.*) A hyphal cell, mycelium, organism, or spore which contains genetically different nuclei. (cf. HOMOKARYON.)

**heterokaryosis** (*mycol.*) The condition in which genetically different nuclei exist in the same cell, mycelium or spore; it may arise e.g. by the entry of a genetically different nucleus into a HOMOKARYON (e.g. by hyphal fusion) or by mutation in a binucleate or multinucleate homokaryotic cell or mycelium. Heterokaryosis is important e.g. in PARASEXUAL PROCESSES.

**heterokont** Refers to a pair of flagella (on a biflagellate cell) in which one flagellum differs from the other in length and often also in type: see e.g. XANTHOPHYCEAE. (cf. ISOKONT.)

## Heterokontae

**Heterokontae** Former taxon for the xanthophytes.

**heterolactic fermentation** A type of LACTIC ACID FERMENTATION in which sugars (e.g. lactose, glucose) are fermented to a range of products. There are two distinct pathways, *phosphoketolase* being a key enzyme in each. The 'classical' (6-phosphogluconate) pathway occurs in certain LACTIC ACID BACTERIA (e.g. *Leuconostoc* spp, betabacteria – e.g. *Lactobacillus brevis*): glucose is fermented to lactic acid, CO<sub>2</sub>, and acetic acid and/or ethanol (the ratio of acetic acid to ethanol depending e.g. on the redox potential of the system); PENTOSEs are fermented to lactic and acetic acids [Appendix III(b)]. In the *Bifidobacterium* ('bifidus') pathway the products of glucose fermentation are lactic and acetic acids in the molar ratio 2:3 [Appendix III(b)].

**heterologous** (1) Derived from or associated with a species different from that being referred to (cf. HOMOLOGOUS (2)). (2) See ALTERNATION OF GENERATIONS. (3) (*immunol.*) Of an antibody (or antigen): one which is not HOMOLOGOUS (sense 4) to a given antigen (or antibody). A heterologous antibody, for example, may be a CROSS-REACTING ANTIBODY or may not combine at all with the given antigen. A heterologous vaccine is a vaccine prepared against one organism but capable of giving protective immunity against another.

**heterologous interference** See INTERFERENCE (1).

**Heteromastix** See MICROMONADOPHYCEAE.

**heteromeros** (1) (*lichenol.*) Refers to a lichen thallus in which the photobiont is confined to a distinct layer within the thallus (see LICHEN). (2) (*mycol.*) In an agaric: refers to a pileus and stipe composed of two distinct types of cell: SPHAEROCYSTS and hyphae (see RUSSULALES). (3) (*ciliate protozool.*) See MACRONUCLEUS. (cf. HOMOIMEROUS.)

**heteromixis** Collectively: DIMIXIS, DIAPHOROMIXIS and *secondary* HOMOTHALLISM.

**heteromorphic** Morphologically dissimilar.

**heteromorphic alternation of generations** See ALTERNATION OF GENERATIONS.

**Heteronema** A genus of EUGLENOID FLAGELLATES, closely related to PERANEMA, in which the second emergent flagellum is not attached to the pellicle. *H. acus* occurs e.g. in activated sludge.

**heterophil antibodies** (heterophile antibodies) Antibodies which can combine with specific HETEROPHIL ANTIGENS. Such antibodies may occur in a host which has not had immunological contact with the corresponding antigen; e.g., patients with INFECTIOUS MONONUCLEOSIS usually develop heterophil antibodies which agglutinate the red blood cells of the sheep, horse and ox – species whose RBCs share a common heterophil antigen (see PAUL–BUNNELL TEST).

**heterophil antigen** (heterophile antigen) Any antigen which occurs (in an identical or closely related form) in several or many widely differing species (e.g. sheep, horse). If introduced into a species in which it is normally absent, a heterophil antigen elicits the synthesis of HETEROPHIL ANTIBODIES. (See also FORSSMAN ANTIGEN.)

**heterophilic binding** (of cell adhesion molecules) See IMMUNOGLOBULIN SUPERFAMILY.

**Heterophrys** See CENTROHELIDA.

**heteroplasmon** See CYTODUCTION.

**heteroploid** Having a complement of chromosomes differing from that characteristic of the species. (cf. EUPLOID sense 2.) A heteroploid cell may be EUPLOID (sense 1) – e.g. a polyploid cell arising in a haploid or diploid population – or it may be ANEUPOID.

**heteropolysaccharide** See POLYSACCHARIDE.

**heteroresistance** (1) The resistance (of an organism) to two or more *related* antibiotics – e.g. two or more  $\beta$ -lactam antibiotics.

(2) See MRSA.

**heterothallism** The phenomenon in which sexual reproduction requires the involvement of two different thalli – an individual thallus being self-sterile even when (as is common) it is hermaphroditic; gametes etc which can unite sexually are said to be *compatible*. (cf. HOMOTHALLISM; see also COMPATIBILITY sense 2.)

In *morphological heterothallism* (= *dioecism*) compatibility is determined solely on a sexual basis: there are separate male and female thalli, and sexual reproduction can occur between any male thallus and any female thallus of the same species. Dioecism is uncommon among fungi; it occurs e.g. in some species of *Achlya* and of *Laboulbenia*.

In *physiological heterothallism* male and female organs generally occur on the same thallus, and in these cases compatibility is determined not only on a sexual (male–female) basis: sexual union can occur between male and female gametes etc only if each has appropriate *mating type allele(s)* (see MATING TYPE); gametes etc which have the same mating type allele(s) cannot unite sexually and are said to be *incompatible*. In e.g. many zygomycetes, male and female organs are not distinguishable; in such cases sexually compatible thalli are often designated 'plus' and 'minus'.

In *bipolar physiological heterothallism* compatibility is determined at *one* mating type locus which may contain either of 2 alleles; if these alleles be designated *A* and *a*, then mating can occur between one individual (mating type) which has the *A* allele and another which has the *a* allele. Bipolar heterothallism is also called one-locus two-allele heterothallism, *unifactorial* heterothallism (since only one locus is involved), or DIMIXIS (since two alleles are involved).

In *tetrapolar physiological heterothallism* compatibility is determined at *two* mating type loci, each locus containing one of two alleles. If these loci be designated *A, B* (with alleles *a, b*, respectively), four mating types can be distinguished: *AB, Ab, aB* and *ab*. Mating can occur only between individuals which contain complementary alleles at *both* loci; thus, e.g. mating can occur between *AB* and *ab* individuals, and between *Ab* and *aB* individuals. Tetrapolar heterothallism is also called *bifactorial* heterothallism.

In some cases of one- and two-locus heterothallism, a locus may be occupied by any allele of an allelomorphous series; in such cases there can be many mating types. (See also DIAPHOROMIXIS.)

Heterothallism provides a constraint on inbreeding, and consequently increases the potential for genetic reassortment within a species.

**Heterotrichida** An order of free-living and parasitic ciliate protozoa (class POLYHYMENOPHOREA) in which the organisms are typically large, often contractile (see MYONEME), and sometimes pigmented, and in which somatic ciliature is commonly abundant and oral ciliature is well developed. Genera include e.g. *Balan-tidioides*, BLEPHARISMA, *Brachonella*, *Bursaria*, *Condylostoma*, *Metopus*, SPIROSTOMUM and STENTOR.

**heterotrichous** (1) Having different types of cilia or flagella. (2) Of certain filamentous algae: having a vegetative thallus consisting of both prostrate and erect systems of filaments (as e.g. in CHAETOPHORA).

**heterotroph** An organism which uses organic compounds for most or all of its carbon requirements. (cf. AUTOTROPH; ORGANOTROPH.) The term 'heterotroph' is often used to refer specifically to CHEMOORGANOHETEROTROPHS – although chemolithotrophs and phototrophs may also be heterotrophic.

**heteroxenous** (heteroecious) Refers to a parasite which carries out part of its life cycle in each of two or more different host species. (cf. HOMOXENOUS.)

**heterozygote** A HETEROZYGOUS cell or organism.

**heterozygous** Refers to a cell or organism (e.g. a diploid eukaryote or a bacterial MEROZYGOTE) in which one or more specified genes, or all of the genes, are present in the form of different ALLELES. (cf. HOMOZYGOUS.)

**hex genes** See TRANSFORMATION (1).

**Hexacapsula** See MYXOSPOREA.

**hexachlorophane** (hexachlorophene) See BISPHENOLS.

**hexagonal II phase** See CYTOPLASMIC MEMBRANE.

**hexamer** See ICOSAHEDRAL SYMMETRY.

**hexamethylenetetramine** See HEXAMINE.

**hexamine** (hexamethylenetetramine; methenamine) A condensation product of ammonia and formaldehyde used as a urinary antiseptic. It has no intrinsic antimicrobial activity, but under acid conditions it slowly releases FORMALDEHYDE. It is not effective against urea-splitting bacteria since these produce ammonia which raises the pH of the urine. Hexamine is usually used with MANDELIC ACID (hexamine mandelate, Mandelamine) or with hippuric acid (Hiprex).

**Hexamita** A genus of protozoa of the DIPLOMONADIDA. *H. meleagridis* is an important pathogen of turkeys (see HEXAMITIASIS); cells are pear-shaped, ca. 10  $\mu\text{m}$  in length, with two anteriorly located nuclei, two clearly separate, parallel, longitudinal axostyles, and 8 flagella – two pairs orientated anteriorly, one pair laterally, and the fourth pair projecting posteriorly. *H. intestinalis* is a cyst-forming species which occurs e.g. in the cloaca of the frog.

**hexamitiasis** An acute infectious disease of e.g. turkeys and pheasants (but not affecting chickens, ducks or geese); it is caused by *Hexamita meleagridis*. Infection occurs by ingestion of food, water etc contaminated with faeces from infected or carrier birds. Symptoms: listlessness; anorexia; passage of watery, frothy, foul-smelling stools; coma. Mortality rates are often very high in young birds. Survivors commonly become carriers. Treatment: e.g. furazolidone. (See also POULTRY DISEASES.)

**hexokinase** An enzyme which phosphorylates various hexoses in the 6-position (see e.g. EMBDEN–MEYERHOF–PARNAS PATHWAY).

**hexon** See ADENOVIRIDAE.

**hexose bisphosphate pathway** *Syn.* EMBDEN–MEYERHOF–PARNAS PATHWAY.

**hexose monophosphate pathway** (HMP pathway; HMP shunt; oxidative pentose phosphate pathway; pentose phosphate pathway/cycle; phosphogluconate pathway; Warburg–Dickens pathway) A metabolic pathway present in a wide range of prokaryotic and eukaryotic microorganisms as well as in plants and animals; it involves the oxidative decarboxylation of glucose 6-phosphate, via 6-phosphogluconate, to ribulose 5-phosphate, followed by a series of reversible, non-oxidative interconversions whereby hexose and triose phosphates are formed from pentose phosphates. The generally accepted scheme for the HMP pathway is shown in Appendix I(b).

The HMP pathway can serve various functions, the major ones probably being to provide NADPH (2 molecules per molecule of glucose converted to ribulose 5-phosphate) necessary for biosyntheses (e.g. of fatty acids), and to provide precursors for various biosynthetic pathways (e.g. pentoses for histidine and nucleotide biosynthesis [Appendices IV(g) and V], erythrose 4-phosphate for aromatic amino acid biosynthesis [Appendix IV(f)]). Fructose 6-phosphate may be converted to glucose 6-phosphate and re-enter the pathway, or may be converted to pyruvate via

reactions of the EMBDEN–MEYERHOF–PARNAS PATHWAY; similarly, glyceraldehyde 3-phosphate may be converted to pyruvate via the latter part of the EMP pathway. In organisms with a functional TCA CYCLE, pyruvate can be oxidized to yield energy via the TCA cycle and a respiratory chain. In organisms which lack a complete TCA cycle, pyruvate may be converted to acetyl-CoA and thence to acetic acid (as in some acetic acid bacteria). Alternatively, under certain conditions, glyceraldehyde 3-phosphate can be converted to glucose 6-phosphate (by reactions of GLUCONEOGENESIS) which can then re-enter the HMP pathway; in this case, for every six molecules of glucose entering the pathway, one molecule is effectively completely oxidized. If reducing equivalents from NADPH can be transferred to  $\text{NAD}^+$  (see TRANSHYDROGENASE) and thence to an electron acceptor via a respiratory chain, the pathway can be used to generate energy even in the absence of a TCA cycle. Other functions of the HMP pathway include the metabolism of those pentoses which can be converted to intermediates of the pathway. (See also RMP PATHWAY.)

**hexulose phosphate pathway** *Syn.* RMP PATHWAY.

**hexuronic acids** URONIC ACIDS corresponding to hexoses.

**hexylresorcinol** See PHENOLS.

**hfl genes** (in *E. coli*) See BACTERIOPHAGE  $\lambda$ .

**hflB gene** See FTSH.

**Hfr donor** High frequency recombination donor: a conjugal donor (see CONJUGATION sense 1b) created by the insertion of a CONJUGATIVE PLASMID (sense 1) into a bacterial chromosome. The chromosome of an Hfr donor can be mobilized by the plasmid so that chromosomal genes can be transmitted to a recipient during conjugation; thus, in a mixed population of recipients and Hfr donors, recombination between recipient and (transferred) donor DNA will occur at high frequency in the recipient population. The (relatively few) conjugative plasmids which can give rise to Hfr donors include the  $F^+$  PLASMID.

A conjugative plasmid which cannot normally integrate into the bacterial chromosome may be able to do so if it first integrates e.g. with the genome of an  $A^+B^-$  strain of BACTERIOPHAGE MU, integration of the plasmid–Mu complex into the chromosome then being mediated by Mu; a recipient mated with such an Hfr donor must be lysogenic for a  $c^+$  strain of Mu to avoid ZYGOTIC INDUCTION when the Mu prophage is transferred to the recipient.

(See also PRIME PLASMID and INTERRUPTED MATING.)

**HFRS** Haemorrhagic fever with renal syndrome (see HANTAVIRUS).

**HFT** (of plasmids) See EPIDEMIC SPREAD.

**HFT lysate** See TRANSDUCTION.

**HGV** Hepatitis G virus (see HEPATITIS).

**HHV1** Human (alpha) herpesvirus 1 (see ALPHAHERPESVIRINAE).

**HHV2** Human (alpha) herpesvirus 2 (see ALPHAHERPESVIRINAE).

**HHV3** Human (alpha) herpesvirus 3 (see ALPHAHERPESVIRINAE).

**HHV4** Human (gamma) herpesvirus 4 (see GAMMAHERPESVIRINAE).

**HHV5** Human (beta) herpesvirus 5 (see BETAHERPESVIRINAE).

**HHV6** Human (beta) herpesvirus 6 (see BETAHERPESVIRINAE).

**HHV7** Human (beta) herpesvirus 7 (see BETAHERPESVIRINAE).

**HHV8** Human (gamma) herpesvirus 8 (see GAMMAHERPESVIRINAE).

**HI test** HAEMAGGLUTINATION-INHIBITION TEST.

**HIB** HAEMOLYTIC IMMUNE BODY.

**Hibitane** See CHLORHEXIDINE.

**high-dry objective** Any objective lens which has a numerical aperture between 0.65 and 0.95, and which is *not* used as an immersion lens.

## high-fructose corn syrup

**high-fructose corn syrup** A sweetening agent produced industrially from glucose by GLUCOSE ISOMERASE (see also IMMOBILIZATION).

**high-mobility group proteins** See NON-HISTONE PROTEINS.

**high mutability gene** *Syn.* MUTATOR GENE.

**high-performance liquid chromatography** See CHROMATOGRAPHY.

**high-potential iron-sulphur protein** See HIPIP.

**high-pressure liquid chromatography** See CHROMATOGRAPHY.

**high zone tolerance** See IMMUNOLOGICAL TOLERANCE.

**higher fungi** Fungi of the subdivisions ASCOMYCOTINA, BASIDIOMYCOTINA and DEUTEROMYCOTINA. (cf. LOWER FUNGI.)

**Highlands J virus** See ALPHAVIRUS.

**highly active antiretroviral therapy** See HAART.

**HIGM** See RNA EDITING.

**Hikojima variant** See VIBRIO (*V. cholerae*).

**hilar appendix** A small protuberance on a basidiospore near its region of attachment to the sterigma.

**Hildenbrandia** See RHODOPHYTA.

**Hill reaction** In PHOTOSYNTHESIS: light-dependent evolution of oxygen by isolated CHLOROPLASTS in the absence of CO<sub>2</sub> but in the presence of e.g. ferric oxalate which acts as an electron acceptor for PS-II.

**hilum** The mark, scar or small projection on a spore corresponding to the region at which it was formerly attached to the spore-bearing structure.

**him genes** (in *E. coli*) See BACTERIOPHAGE  $\lambda$ .

**Himantalia** See PHAEOPHYTA.

**Himmelweit pipette** A PASTEUR PIPETTE with a hole in the side of the capillary end; it is used e.g. in the harvesting of allantoic fluid from an EMBRYONATED EGG.

**hin gene** See PHASE VARIATION.

**HindII** A RESTRICTION ENDONUCLEASE from *Haemophilus influenzae*; GTPy/PuAC.

**HindIII** A RESTRICTION ENDONUCLEASE from *Haemophilus influenzae*; A/AGCTT.

**HinfI** See RESTRICTION ENDONUCLEASE (table).

**hinge region** In the heavy chain of an IMMUNOGLOBULIN: the amino acid sequence at the junction of the Fd portion and the Fc portion; it appears to confer conformational flexibility on the molecule. Structurally, the hinge region is the most variable part of the 'constant' region of the heavy chain. In *alpha* and *gamma* chains (but not in *mu* chains) the hinge region is rich in proline.

**Hinozan** (edifenphos; *O*-ethyl-*S,S*-diphenyl phosphorodithioate) An antifungal ORGANOPHOSPHORUS COMPOUND used as a protectant against rice blast disease; it can act e.g. as a powerful cutinase inhibitor (see CUTIN).

**hip gene** (in *E. coli*) See BACTERIOPHAGE  $\lambda$ .

**HiPIP** High-potential iron-sulphur protein: a type of IRON-SULPHUR PROTEIN which has a single [4Fe-4S] centre and a highly positive E<sub>m</sub>; the HiPIP in *Chromatium vinosum* has an E<sub>m</sub> of +350 mV.

**hippurate hydrolysis** Certain bacteria (e.g. *Streptococcus* spp. *Campylobacter* spp) produce a hippuricase which hydrolyses hippurate (C<sub>6</sub>H<sub>5</sub>.CO.NH.CH<sub>2</sub>.CO<sub>2</sub><sup>-</sup>) to benzoate and glycine. Hippuricase activity may be detected by adding a calculated amount of acid FeCl<sub>3</sub> to a 4-day culture of the organism in a medium containing 1.0% sodium hippurate; the FeCl<sub>3</sub> forms a persistent precipitate with benzoate (positive test). (A precipitate is also formed with hippurate, but this is more soluble with excess FeCl<sub>3</sub>; the amount of FeCl<sub>3</sub> used in the test is that which just dissolves the hippurate precipitate initially formed in an uninoculated control tube on dropwise addition of the

reagent.) In a quicker method, a solution of sodium hippurate is heavily inoculated with the test organism; after incubation (37°C/2hours), ninhydrin reagent is added. A deep purple colour indicates the presence of glycine (positive test). [Methods: Book ref. 2, p. 416.]

**Hiprex** See HEXAMINE.

**hircinol** A dihydroxyphenanthrene PHYTOALEXIN produced by the orchid *Loroglossum hircinum* in response to infection with e.g. *Rhizoctonia* spp. (cf. ORCHINOL.)

**Hirst spore trap** (automatic volumetric spore trap) An instrument used e.g. for sampling the airborne microflora. (See also AIR.) Air, drawn in through a vertical slit in an upright cylindrical housing, strikes a slowly-moving greased microscope slide or, in the modern version (*Burkard trap*), a slowly-rotating drum coated with transparent adhesive tape; the slit is kept facing into the wind by a vane attached to the housing.

**Hirsutella** A genus of fungi of the HYPHOMYCETES. Most species are entomopathogenic; *H. thompsonii* infects mites.

**his operon** (histidine operon) AN OPERON (located at ca. 44 min on the chromosome of *Escherichia coli*) which contains 9 structural genes (*hisGDCBHAFIE*) encoding enzymes necessary for the biosynthesis of histidine [Appendix IV(g)]. The transcription of the *his* structural genes is inversely related to the level of histidyl-tRNA in the cell. Regulation is apparently achieved solely by attenuation (see OPERON, cf. TRP OPERON); the sequence encoding the leader peptide contains seven successive histidine codons.

**HisJ, HisM, HisP, HisQ** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**hispid** Bearing hairs, bristles or spines. *Hispid flagellum*: see FLAGELLUM (b).

**Hiss serum water** A medium made by mixing 1 volume of serum (horse, ox or sheep) with 3 volumes of water, and adding phenol red and a sugar (final concentrations ca. 0.0025% and 1.0%, respectively).

**histamine** An amine formed by the decarboxylation of histidine; it occurs e.g. in MAST CELLS and is involved in ANAPHYLACTIC SHOCK and INFLAMMATION. (See also ANAPHYLATOXINS.) Histamine causes contraction of e.g. tracheobronchial and intestinal smooth muscle, and increases vascular permeability in the skin and other regions by acting as a vasodilator of terminal arterioles and as a vasoconstrictor of postcapillary venules. [Agents that release histamine from mast cells: ARPT (1983) 23 331-351.]

The microbial production of toxic amounts of histamine in certain foods has been implicated as a cause of food poisoning: for example, *Lactobacillus buchneri* can produce histamine in Swiss cheese [AEM (1985) 50 1094-1096] (see also FISH SPOILAGE).

**histamine-sensitizing factor** *Syn.* PERTUSSIS TOXIN.

**histidase** See HISTIDINE DEGRADATION.

**L-histidine biosynthesis** See Appendix IV(g); see also HIS OPERON.

**histidine degradation** Histidine can be used as a substrate by various bacteria; in e.g. *Pseudomonas aeruginosa* histidine is initially deaminated by histidase to urocanate which is eventually degraded to glutamate and formate. Some bacteria can decarboxylate histidine to histamine: see e.g. FISH SPOILAGE. (See also BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.)

**histidine kinase** A KINASE whose active site contains a histidine residue. (See also CHEMOTAXIS and TWO-COMPONENT REGULATORY SYSTEM.) [Histidine kinases and signal transduction (review): TIG (1994) 10 133-138.]

**histidine operon** *Syn.* HIS OPERON.

**histidine permease** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**histiocyte** A MACROPHAGE which occurs in extravascular tissues.

**histocompatibility restriction** (MHC restriction) The restriction on (physical) cell–cell interaction, involving cells of the immune system, imposed by the need for such cells to have, or to recognize, particular MHC-specified cell-surface antigens as a prerequisite for interaction.

**histolyticolysin** See THIOL-ACTIVATED CYTOLYSINS.

**Histomonas** A genus of protozoa of the TRICHOMONADIDA. *H. meleagridis* is the causal agent of BLACKHEAD in turkeys. Intracellular cells of *H. meleagridis* are spherical to ovoid, non-flagellate (though they contain kinetosomes), ca. 10–15 µm; they exhibit amoeboid motility. Within the caecal lumen of the turkey, cells of *H. meleagridis* (ca. 10–25 µm) may exhibit both amoeboid and flagellar motility, each cell having 1–4 flagella (commonly one).

**histomoniasis** *Syn.* BLACKHEAD.

**histone-like proteins** Bacterial DNA-binding proteins believed to resemble the HISTONES associated with eukaryotic DNA. (Compare HU PROTEIN.)

**histones** Basic proteins, rich in arginine and/or lysine, which are major components of CHROMATIN in most eukaryotes. (cf. DINOFLAGELLATES.) The main classes of histones are designated H1 ('lysine-rich'), H2A and H2B ('slightly lysine-rich'), and H3 and H4 ('arginine-rich'). Histones interact with DNA primarily via salt bridges between the positively-charged arginine/lysine residues and the negatively-charged phosphate groups of the DNA.

Constitutive histone *variants* can effect changes in chromatin structure and dynamics that affect e.g. DNA replication, repair and transcription [GD (2005) 19 295–316].

**Histoplasma** A genus of fungi of the HYPHOMYCETES; teleomorph: AJELLOMYCES. *H. capsulatum*, the causal agent of HISTOPLASMOSIS, is a dimorphic fungus which occurs e.g. in soil that is contaminated with the droppings of birds, bats and other animals. At room temperature or e.g. 25°C, *H. capsulatum* forms white to golden, cottony, septate mycelium, but at 37°C it forms ovoid, budding, yeast-like cells 2–4 µm (var. *capsulatum*) or 8–15 µm (var. *duboisii*); in vivo, grape-like clusters of cells may occur in macrophages or in regions of caseation. *H. capsulatum* gives rise to microconidia (2–5 µm) and macroconidia (ca. 8–15 µm), the latter (also called 'chlamydoconidia') typically bearing short, finger-like projections.

*H. farciminosum*. See EPIZOOTIC LYMPHANGITIS.

(See also ENDOCARDITIS and PAS REACTION.)

**histoplasmin test** A SKIN TEST, analogous to the TUBERCULIN TEST, used in the diagnosis of HISTOPLASMOSIS; it involves the intradermal injection of *histoplasmin* (a filtrate of a mycelial culture of *Histoplasma capsulatum*). The skin usually becomes reactive to histoplasmin within one to two months of the onset of disease, and reactivity may persist for many years; cross-reactions with other fungal antigens (e.g. coccidioidin) occur.

**histoplasmosis** (Darling's disease) A disease of man and animals, found worldwide, caused by *Histoplasma capsulatum* (cf. EPIZOOTIC LYMPHANGITIS). Infection occurs by inhalation of spores (e.g. from disturbed soil). The disease may be subclinical, acute or chronic. The acute condition may resemble a common cold or influenza. In the chronic condition, granulomatous, inflamed lesions occur in the lungs; the primary lesion may become inactive and calcify on healing. The primary infection is usually self-limiting, but occasionally progressive lung disease occurs and may eventually be fatal due e.g. to loss of

lung function or to secondary bacterial infection. Infrequently, histoplasmosis becomes disseminated (usually in young children or in the elderly, debilitated or immunocompromised); lesions may occur in lymph nodes, liver, spleen, intestine, skin, heart, kidneys, CNS etc. Disseminated histoplasmosis is often rapidly fatal. *Lab. diagnosis*: serological tests (e.g. a CFT); microscopic and cultural examination of clinical specimens. *Chemotherapy*: e.g. amphotericin B, ketoconazole.

**histotope** A site on an MHC class I or II antigen recognized by a T lymphocyte.

**histozoic** Living (parasitic) within tissues. (cf. COELOZOIC.)

**Histiculus** See HYPOTRICHIDA.

**hit-and-run oncogenesis** Oncogenesis which is initiated by a particular agent (e.g. a virus) but, once initiated, can proceed in the absence of the initiating agent.

**HIV** Human immunodeficiency virus, infection with which can give rise to AIDS (q.v.). HIV is a retrovirus (family RETROVIRIDAE) classified within the subfamily LENTIVIRINAE. HIV was previously referred to as AIDS-associated retrovirus (ARV), 'HTLV-III' (cf. HTLV), immunodeficiency-associated virus (IDAV) and lymphadenopathy-associated virus (LAV).

Evidence for the involvement of HIV in AIDS was obtained in 1983 [Science (1983) 220 868–871]. Subsequently a distinct, but related, retrovirus was detected in AIDS patients in West Africa [Nature (1987) 326 662–669]. These two viruses are now designated HIV-1 and HIV-2 respectively. HIV-1 and HIV-2 are similar in both structure and genome.

The origin of HIV is unknown. One hypothesis supposes that the major (M) strain of HIV arose through the use of an anti-polio myelitis vaccine that had been prepared by culturing polio virus in non-human primate cells; it is proposed that a simian strain of immunodeficiency virus (initially present in the culture cells) contaminated the vaccine and (thus) entered the vaccinated human population (located mainly in the Congo) in the late 1950s. Subsequent studies on viruses from the Congo area do not support this hypothesis [Nature (2001) 410 1047–1048].

The HIV virion is ~100 µm in diameter. Its innermost region consists of a cone-shaped core that includes (i) two copies of the (positive-sense) ssRNA genome, (ii) the enzymes REVERSE TRANSCRIPTASE, integrase and protease, (iii) some minor proteins, and (iv) the major core protein. The core is surrounded by a protein matrix, and the whole is enclosed within an envelope (a lipid bilayer); the envelope is penetrated by a number of 'spikes' (gp41), each spike bearing a distal (outermost) trimeric glycoprotein (gp120). [Fine structure of HIV: Virol. (1987) 156 171–176.]

The genome (~9.2 kb) includes sequences corresponding to the *gag*, *pol* and *env* regions of other exogenous retroviruses (see RETROVIRIDAE).

The *gag* region encodes structural proteins, including the major core protein (p24) and the matrix protein (p17).

The *pol* region encodes regulatory proteins: REVERSE TRANSCRIPTASE, protease (involved in the maturation of virions), RNASE H and integrase. (The enzymes reverse transcriptase and protease are major targets for antiretroviral drugs.)

The *env* region encodes the envelope-associated proteins, gp120 (required for initial binding of virus to target cell) and gp41 (involved in fusion of the viral envelope with the membrane of the target cell).

Other HIV genes include: *tat* and *rev* (whose products are needed for viral replication); *vif* ('viral infectivity factor'); and *vpr* (whose product promotes efficient budding of the (HIV-1) virion during productive infection of a cell). (See also Rev in GENE THERAPY.)

## HIV-positive

### *Attachment of the virion to a target cell.*

The principal high-affinity binding site for viral gp120 glycoprotein is the CD4 antigen (see CD4) (formerly referred to as OKT4); target cells for HIV therefore include the CD4<sup>+</sup> ('T helper') subset of T LYMPHOCYTES, monocytes, macrophages and dendritic cells. CD4<sup>+</sup> cells also occur in the central nervous system (microglial cells), and infection of these cells by HIV may account for neurological symptoms in HIV-positive patients; multinucleate (syncytial) cells have been observed in brain tissue from such patients.

For *infection* of a cell by HIV, the cell must express not only CD4 antigen but also receptors for particular CHEMOKINES – e.g. those for certain CXC-type and CC-type chemokines (the CXCR4 and CCR5 receptors) [JLB (1999) 65 552–565]. Some (T-cell-tropic) strains of HIV require the co-receptor CXCR4 while other (M-tropic) strains require CCR5; M-tropic strains can infect macrophages and monocytes as well as T cells. Yet other (dual-tropic) strains of HIV can use both co-receptors. On the basis of their use of particular co-receptors, strains of HIV have been categorized as X4, R5 and R5X4 respectively.

Some CD34<sup>+</sup> haemopoietic stem cells co-express the CD4 antigen (and co-receptors) but these cells are apparently not susceptible to infection by pathogenic strains of HIV; however, such cells are susceptible to infection by genetically engineered viral 'constructs' (based on HIV) which may be of use in GENE THERAPY. Although stem cells may not be susceptible to natural strains of HIV, inhibition of haemopoiesis may nevertheless occur in HIV<sup>+</sup> patients owing to perturbation of the cytokine milieu in bone marrow. [Haematological aspects of HIV infection: BCH (2000) 13 215–230.]

### *Internalization and integration of HIV.*

Fusion between viral envelope and cell membrane is achieved in a gp41-dependent manner; the viral core then enters the target cell's cytoplasm. On (intracellular) release of viral RNA and enzymes, a dsDNA form of the genome is synthesized using viral reverse transcriptase and RNase H (see: RETROVIRIDAE). [HIV entry inhibitors: PNAS (2002) 99 16249–16254.]

The 3' and 5' LTRs of the dsDNA are involved in circularization of the molecule (forming a plasmid-like structure); this structure enters the nucleus and is integrated into the host's genome in a process involving the viral integrase. In some cases the integrated (provirus) form of HIV remains latent (inactive), or weakly active, for some time (e.g. ~10 years), the patient remaining essentially asymptomatic; in other cases disease progresses rapidly.

### *Replication of HIV.*

Replication is apparently an inefficient process in which a high proportion of progeny virions are defective.

Transcription of the integrated viral genome appears to depend on various (viral and host) regulatory proteins which have binding sites on the LTR. For example, the viral *tat* gene product, with a binding site designated Tat-responsive region (TAR), has an important transactivation role; the activity of this protein is essential in the upregulation of replication.

The host's nuclear transcription factor, NF- $\kappa$ B (see CYTOKINES), is also important as a (positive) regulator of viral gene expression and it, too, has a binding site on the LTR; it is therefore possible that expression of viral genes may be promoted by superinfection with certain opportunist pathogens that activate NF- $\kappa$ B by inducing synthesis of appropriate cytokines. (This suggests a possible mechanism for the exacerbation of HIV-mediated disease that may be seen during opportunist infections.)

The LTR also includes a regulatory region for polyadenylation of transcripts.

Synthesis of viral mRNA, and of genomic RNA, is carried out by the host's RNA polymerase. Viral envelope proteins are translocated to, and insert into, the cell membrane (with gp120 located at the outer surface). The assembled core acquires an envelope by budding through the cell membrane.

### *Culture.*

Culture may be useful e.g. for diagnosis of HIV infection in neonates; in these young patients the presence of anti-HIV antibody may simply reflect acquisition from an HIV-positive mother.

Cultures of HIV characteristically exhibit CPE (cytopathic effects), including the formation of giant multinucleated cells and cell lysis. Culture can be carried out in CD4<sup>+</sup> T cells; the virus can also infect other types of cell such as monocytes and promyelocytes [Virology (1985) 147 441–448]. HIV may give rise to a persistent, non-cytopathic and productive (virion-producing) infection of human CD4<sup>+</sup> T cells in culture [Science (1985) 229 1400–1402].

### *Inactivation of HIV by disinfection.*

Hypochlorite (effective conc. 10000 parts per million available chlorine) is a useful disinfectant. Glutaraldehyde (dangerous chemical!!!) has been used for disinfecting surfaces in a well-ventilated environment; safety regulations must be observed.

Phenolics and ethanol are unsuitable.

In serum, inactivation of HIV may require more than 30 minutes at 56°C [e.g. Book ref. 219, p 814].

### *Genetic variability of HIV isolates.*

Isolates of HIV from different patients tend to be genetically heterogeneous, particularly in the *env* sequence [mini-review: Cell (1986) 46 1–4], and variation may also be observed in isolates obtained sequentially from the same patient over a period of time [Science (1986) 232 1548–1553]. As *env* encodes the (antigenic) viral surface protein gp120, such ANTIGENIC VARIATION presents a problem for the development of an effective anti-HIV vaccine; in this context, studies have been carried out to determine the effect of genetic variation on the immunogenic potential of gp120 [Arch. Virol. (2000) 145 2087–2103].

**HIV-positive** Refers to an individual who is infected with the human immunodeficiency virus (see HIV). (See also AIDS.)

**hives** *Syn.* URTICARIA.

**Hjärre's disease** (coli-granuloma) A POULTRY DISEASE in which granulomatous lesions are formed in the wall of the intestine (particularly in the caecum); the causal agent is *Escherichia coli*.

**HLA-A, HLA-B etc.** See MAJOR HISTOCOMPATIBILITY COMPLEX.

**Hly plasmid** See ESCHERICHIA.

**HlyA** (of *Escherichia coli*) See RTX TOXINS.

**HMA** Hydroxymethionine analogue: DL- $\alpha$ -hydroxy- $\gamma$ -methionolbutyrate; HMA is used in animal feedstuffs as a sulphur amino acid supplement [ARB (1983) 52 215–216]. (See also SINGLE-CELL PROTEIN.)

**HMG box** That region, in certain types of protein, which can e.g. interact with sharply angular or kinked DNA (in eukaryotic cells); it consists of a sequence of about 80 amino acid residues (including a high proportion of aromatic amino acids) with a net positive charge. HMG boxes are found in certain NON-HISTONE PROTEINS. (See also HU PROTEIN.)

**HMG proteins** See NON-HISTONE PROTEINS.

**HMP pathway** HEXOSE MONOPHOSPHATE PATHWAY.

**HMS-1  $\beta$ -lactamase** See  $\beta$ -LACTAMASES.

**HMT toxin** A long-chain polyketide host-specific toxin produced by *Drechslera* (*Helminthosporium*) *maydis* race T; it has been suggested that HMT toxin acts as an ionophore.

**hnRNA** Heterogeneous nuclear RNA: the high-MWt RNA synthesized by RNA polymerase II in the nucleus of a eukaryotic cell; hnRNA occurs in the form of ribonucleoprotein (hnRNP) and includes pre-mRNA (i.e., mRNA before the generation of 3' ends, polyadenylation and splicing).

**H-NS protein** (*syn.* H1 protein) In bacteria (e.g. *Escherichia coli*), a small protein (136 amino acids, 15.6 kDa) encoded by the *hns* gene. H-NS protein is able to (i) regulate the expression of various unrelated genes (e.g. *bgl*, *proU*), (ii) constrain negative supercoiling, and (iii) contribute to the physical organization of the bacterial nucleoid.

In uropathogenic strains of *E. coli* (UPEC) the H-NS protein has been implicated in the temperature-dependent expression of P FIMBRIAE: at the non-permissive temperature of 25°C, the H-NS protein is reported to act as a methylation-blocking factor, repressing transcription [Mol. Microbiol. (1998) 28 1121–1137]. In *Proteus mirabilis* it is reported to act as a repressor of the transcriptional activator gene, *ureR*, in the absence of urea induction [JB (2000) 182 2649–2653].

H-NS has also been implicated in the regulation of DNA repair in *Shigella* [JB (1998) 180 5260–5262].

H-NS protein is able to condense supercoiled plasmid DNA, and appears to play a major part in condensing DNA in the nucleoid. H-NS-mediated condensation of DNA has been investigated by studying the structure of H-NS–DNA complexes by atomic force microscopy [NAR (2000) 28 3504–3510].

**Hoarella** A genus of protozoa (suborder EIMERIORINA) which form dizoic oocysts each containing 16 sporocysts.

**Hoechst 33258** A bis-benzimidazole derivative: a FLUOROCHROME used e.g. for staining chromosomes.

**hog cholera** *Syn.* SWINE FEVER.

**hog diseases** See PIG DISEASES.

**Hogness box** See PROMOTER.

**holdfast** An organ or organelle by means of which an organism or cell attaches to the substratum or to another organism. Examples include the root-like region of LAMINARIA, and the specialized regions in SPORICHTHYA and members of the ASTOMATIDA.

**holding-flush jar procedure** In the culture of anaerobes: a procedure which minimizes the exposure of plates to O<sub>2</sub>; essentially, uninoculated plates, or inoculated plates awaiting incubation, are held in an anaerobic jar (with unclamped lid) while a stream of O<sub>2</sub>-free gas (e.g. N<sub>2</sub> or CO<sub>2</sub>) is continually directed through a tube to the bottom of the jar.

**holin** See LYSIS PROTEIN.

**Hollandina** See SPIROCHAETALES.

**Holliday junction** See RECOMBINATION.

**Holliday model** See RECOMBINATION (Figure 1).

**Holliday structure** See RECOMBINATION.

**Holmsella** A genus of algae (division RHODOPHYTA). *H. pachyderma* is a colourless organism which is parasitic on the red alga *Gracilaria*; PIT CONNECTIONS have been observed between *H. pachyderma* and *Gracilaria*.

**Holobasidiomycetidae** A subclass of fungi (class HYMENOMYCETES) characterized by the formation of *holobasidia* (see BASIDIUM). Orders [Book ref. 64, p. 189]: AGARICALES, APHYLLOPHORALES, BOLETALES, BRACHYBASIDIALES, CANTHARELLALES, DACRYMYCETALES, EXOBASIDIALES, RUSSULALES and TULASNELLALES.

**holobasidium** See BASIDIUM.

**holoblastic development** See CONIDIUM.

**holocarpic** Refers to those organisms in which the entire thallus takes on a reproductive function. (cf. EUCARPIC.)

**holocellulose** A complex of cellulose and hemicelluloses (formed e.g. by the removal of lignin from lignocellulosic plant material).

**holocentric** (holokinetic) Refers to a chromosome in which the CENTROMERE is diffuse, being distributed along the length of the chromosome; the kinetochores are correspondingly long, and microtubules are attached along the whole length of the chromosome.

**holococcolith** See COCCOLITH.

**holoenzyme** A 'whole' enzyme – i.e., an enzyme in its complete, active form – consisting either of an apoenzyme plus PROSTHETIC GROUP or of two or more distinct protein subunits (see e.g. DNA POLYMERASE).

**holokinetic** *Syn.* HOLOCENTRIC.

**holomictic lake** A lake in which the entire water mass undergoes a complete turnover. (cf. MEROMICTIC LAKE.)

**holomorph** (*mycol.*) Any fungus considered in its entirety, i.e., including all latent or expressed (sexual and/or asexual) forms and potentialities. (cf. ANAMORPH; ANA-HOLOMORPH; TELEOMORPH.)

**Holophrya** See GYMNOSTOMATIA.

**holophytic nutrition** Plant-type nutrition, i.e., the endogenous formation of nutrients by photosynthesis. (cf. HOLOZOIC NUTRITION.)

**Holospira** A genus of Gram-negative bacteria which are obligate endosymbionts in the micronucleus (*H. elegans*, *H. undulata*) or the macronucleus (*H. caryophila*, *H. obtusa*) of *Paramecium* spp; *Holospira* spp do not confer a killer characteristic (cf. CAEDIBACTER). Cells: non-motile rods or filaments. Type species: *H. undulata*. [Book ref. 22, pp. 802–803; *H. obtusa* in *P. caudatum* (infection and maintenance): JCS (1985) 76 179–187.]

**Holosticha** See HYPOTRICHIDA.

**holothallic conidium** See CONIDIUM.

**holotoxin** The form in which an exotoxin is secreted by a pathogen. After uptake by a eukaryotic cell, the holotoxin may be processed (e.g. by proteolytic cleavage) to release the active component (see e.g. DIPHTHERIA TOXIN and SHIGA TOXIN).

**holotrich** Any of the relatively primitive ciliate protozoa previously classified in the subclass Holotrichia [JP (1964) 11 7–20] but now classified in the classes KINETOFRAGMINOPHOREA and OLIGOHYMENOPHOREA.

**holotype** The actual specimen which an author has designated as the NOMENCLATURE TYPE of a new taxon.

**holozoic nutrition** Animal-type nutrition, i.e., nutrition involving the ingestion of other organisms or components of other organisms. (cf. HOLOPHYTIC NUTRITION.)

**homing** (intron, bacterial) See INTRON HOMING.

**homing-associated cell adhesion molecule** *Syn.* CD44.

**homooacetate fermentation** See ACETOGENESIS.

**homocaryon** *Syn.* HOMOKARYON.

**homocysteine** See e.g. Appendix IV(d).

**homocytotropic antibodies** (1) *Syn.* REAGINIC ANTIBODIES. (2) Antibodies which bind only to cells of the species in which they were formed. (cf. HETEROCYTOTROPIC ANTIBODIES.)

**homodiaphoromixis** See HOMOTHALLISM.

**homodimixis** See HOMOTHALLISM.

**homoduplex** Any double-stranded nucleic acid in which each strand is completely complementary to the other. (cf. HETERODUPLEX.)

**homooimerous** *Syn.* HOMOIOIMEROUS.

**homoofermentation** (1) Any fermentation in which there is only one major end-product. (2) *Syn.* HOMOLACTIC FERMENTATION.

**homogeneous immersion** See IMMERSION OIL.

**homogenization** (of milk) See MILK.

**homogenote** See MEROZYGOTE.

## homoglycan

**homoglycan** See POLYSACCHARIDE.

**homoheteromixis** See HOMOTHALLISM.

**homoimmune phages** See SUPERINFECTION IMMUNITY.

**homoimerous** (homoeomerous) (1) (*Lichenol.*) Refers to a lichen thallus in which the photobiont is more or less evenly distributed throughout the thallus (see LICHEN). (2) (*mycol.*) In an agaric: refers to a pileus or stipe composed of hyphae only. (3) (*ciliate protozool.*) See MACRONUCLEUS. (cf. HETEROMEROUS.)

**homoisocitrate pathway** See  $\text{icl}^-$  SERINE PATHWAY.

**homokaryon** (homocaryon) (*mycol.*) A hyphal cell, mycelium, organism or spore in which all the nuclei are genetically identical. (cf. HETEROKARYON.)

**homokaryotic** (1) (*mycol.*) Refers to a HOMOKARYON. (2) (*ciliate protozool.*) Having only one type of nucleus: see PRIMOCILLIATID GYMNSTOMES.

**homolactic fermentation** A type of LACTIC ACID FERMENTATION in which e.g. glucose is converted entirely, or almost entirely, to lactic acid. Many LACTIC ACID BACTERIA (e.g. *Lactococcus lactis*, thermobacteria and streptobacteria) carry out a homolactic fermentation of glucose (or lactose) under conditions of glucose (or lactose) excess (cf. LACTIC ACID STARTERS); glucose is metabolized by the EMBDEN-MEYERHOF-PARNAS PATHWAY, and most or all of the pyruvate thus formed is converted to lactic acid. (See also LACTOSE.) However, under glucose or lactose limitation, or with different substrates (e.g. PENTOSSES), the same organisms may form other products, sometimes with little or no lactic acid; for example, many strains of *L. lactis* produce mainly formic and acetic acids and ethanol when grown in glucose- or lactose-limited continuous culture (see Appendix III(c)). (See also DIACETYL.)

**homologous** (1) Similar in form or structure, but not necessarily in function; homology suggests evolutionary relatedness. (2) Derived from or associated with the same species as that being referred to. (cf. HETEROLOGOUS (1).) (3) See ALTERNATION OF GENERATIONS. (4) (*immunol.*) The antibody elicited by a given antigen is said to be *homologous* to that antigen; similarly, the antigen is said to be homologous to the antibody. (cf. HETEROLOGOUS (3).) (5) (*genetics*) Of chromosomes or chromatids: containing the same sequence of genes – but not necessarily identical alleles. (6) (*genetics*) Of nucleic acids: see e.g. DNA HOMOLOGY.

**homologous interference** See INTERFERENCE (1).

**homologous recombination** See RECOMBINATION.

**homologue** (of chromosomes) In a diploid eukaryotic nucleus: each of a pair of CHROMOSOMES which encode the same types of characteristics and which are usually morphologically similar; in general, homologous chromosomes carry the same sequences of genes, though not necessarily the same alleles.

**homology** (of DNA) See DNA HOMOLOGY.

**homomixis** See HOMOTHALLISM.

**homonym** Any name used to refer to each of two (or more) different microbial taxa; a name of a higher animal or plant which is identical to that of a microorganism is not considered to be a homonym. The name published first is the senior homonym, while any name published later is a junior homonym; junior homonyms are usually suppressed.

**homophilic binding** (of cell adhesion molecules) See IMMUNOGLOBULIN SUPERFAMILY.

**homoplasmid segregant** See INCOMPATIBILITY.

**homopolymer tailing** See TAILING.

**homopolysaccharide** See POLYSACCHARIDE.

**homoserine** See e.g. Appendix IV(d).

**homothallism** (homomixis) Self-fertility: the phenomenon in which sexual reproduction can involve the fusion of e.g. gametes

derived from the same individual (as well as the fusion of those derived from different individuals); no 'mating types' are involved (cf. HETEROTHALLISM).

*Secondary homothallism* (= *homoheteromixis*) occurs in some fungi which are basically heterothallic; it can arise e.g. when nuclei of compatible mating types are incorporated in the same spore – the thallus developing from such a spore being self-fertile. (This occurs regularly in e.g. *Neurospora tetrasperma*.) If secondary homothallism involves nuclei whose compatibility is determined on a one-locus two-allele basis the phenomenon is called *homodimixis*; if it is determined on a one- or two-locus *multi-allele* basis the phenomenon is called *homodiaphoromixis*.

**homothetogenic** Refers to the type of cell division typical of ciliate protozoa: transverse (PERKINETAL) BINARY FISSION in which the daughter cells (the PROTER and OPISTHE) are not mirror images of one another – although they may be similar or identical. For example, when *Tetrahymena* divides, the anterior end of the opisthe is near the plane of division. (cf. SYMMETROGENIC; see also INTERKINETAL.)

**homoxenous** (monoxenous, autoecious) Refers to a parasite which completes its life cycle in a single host species. (cf. HETEROXENOUS.)

**homozygote** A HOMOZYGOUS cell or organism.

**homozygous** Refers to a cell or organism (e.g. a diploid eukaryote or a bacterial MEROZYGOTE) in which one or more specified genes, or all of the genes, are present in the form of identical ALLELES. (cf. HETEROZYGOUS.)

**honey-bee diseases** See BEE DISEASES.

**honey fungus** See ARMILLARIA.

**honeydew** A sugary secretion produced e.g. by sap-sucking insects such as aphids. Sap-sucking insects feed on phloem sap which is rich in sugars but low in nitrogen; thus, large quantities of sap must be ingested to satisfy the insect's nitrogen requirements, the excess sugars being excreted as honeydew. Insect honeydews vary in composition (depending e.g. on insect); some contain e.g. melezitose (rare in nature), and some are rich in polyols (galactitol, ribitol, etc). Certain fungi – particularly SOOTY MOULDS – may grow abundantly on insect honeydews, and it has been suggested that honeydews falling on soil below insect-infested plants may enhance nitrogen-fixation by free-living bacteria in the soil [SBB (1984) 16 203–206]. (See also CLAVICEPS.)

**Hong Kong flu** See INFLUENZAVIRUS.

**Hoogsteen hydrogen bonding** See TRIPLEX DNA.

**hook** (flagellar) See FLAGELLUM (a).

**hop latent virus** See CARLAVIRUSES.

**hop mosaic virus** A member of the CARLAVIRUSES which can cause severe to lethal disease in certain (Golding-type) cultivars of hops (*Humulus lupulus*); symptoms include chlorotic vein-banding, curling of leaf-margins, stunting etc. Transmission occurs via aphids. Weeds (e.g. *Urticaria urens*, *Chenopodium album*, *Plantago major*) may be important reservoirs of the virus. Sensitive hop cultivars have been replaced by tolerant cultivars in endemic areas.

**Hop protein** (*plant pathol.*) Hrp-dependent outer protein: a proposed designation for proteins secreted via the Hrp system (see AVIRULENCE GENE) – some of which may lack an avirulence function (and are therefore inappropriately referred to as avr proteins) [JB (1997) 179 5655–5662 (5659–5660)].

**hop stunt viroid** See VIROID.

**hopanes** See *bacterial* CYTOPLASMIC MEMBRANE.

**HOQNO** HYDROXYQUINOLINE-N-OXIDE.

**hordeiviruses** (barley stripe mosaic virus group) A group of multicomponent PLANT VIRUSES in which the virions are elongated,

rigid particles (ca. 100–150 × 20 nm) composed of ssRNA and helically-arranged subunits of a single type of coat protein (MWt ca. 21000). The genome appears to consist of 2–4 molecules (depending on strain) of linear positive-sense ssRNA, two or three of which are necessary for infection. The 3' end of the RNA has an internal poly(A) sequence and a 3'-terminal tRNA-like structure which can be amino-acylated with tyrosine *in vitro* [Virology (1982) 119 51–58]. Viruses accumulate mainly in the cytoplasm but also in the nuclei of infected cells. Type member: barley stripe mosaic virus (BSMV), an important pathogen of barley in many regions of the world; some strains of BSMV can also infect wheat, oats etc. Transmission is mechanical and seed-borne. Seeds from BSMV-infected plants may show increased frequencies of triploidy and aneuploidy, and some BSMV strains induce a heritable genetic anomaly ('aberrant ratio phenomenon' [ARPPath (1984) 22 77–94]) characterized by abnormal segregation ratios for one or more genetic markers.

**hordeolum** *Syn.* STYE.

**horizontal resistance** (*plant pathol.*) In a given cultivar: the existence of similar levels of resistance to each of the races of a given pathogen. Unlike VERTICAL RESISTANCE, horizontal resistance tends to be a permanent (though not necessarily complete) form of resistance which does not readily break down when genetic changes occur in the pathogen; it is commonly inherited polygenically.

**horizontal transmission** (lateral transmission) Transmission of a disease or parasite from one individual to another *contemporary* individual. (cf. VERTICAL TRANSMISSION.)

**Hormidium** *Syn.* KLEBSORMIDIUM.

**Hormiscium dermatitidis** See WANGIELLA.

**Hormoconis** A genus of fungi of the HYPHOMYCETES. *H. resinae* (formerly *Cladosporium resinae*, the 'creosote fungus' or 'kerosene fungus') can utilize e.g. creosote and various hydrocarbons as sources of carbon (see also PETROLEUM). [Mechanism of dodecane uptake by *H. resinae*: JGM (1986) 132 751–756.] The teleomorph of *H. resinae* is the ascomycete *Amorphotheca resinae*. [Discussion and references on re-naming of *C. resinae*: MS (1986) 3 169.]

**hormocyst** In certain cyanobacteria: short filaments – composed of granular cells surrounded by a common, condensed sheath – formed in intercalary or terminal positions in the vegetative trichome; hormocysts become detached from the parent trichome and appear to function as propagules (cf. AKINETE and HORMOGONIUM). (See also LEMPHOLEMMA.)

**Hormodendrum dermatitidis** See WANGIELLA.

**Hormodendrum resinae** *Syn.* *Hormoconis resinae*.

**hormogonium** A short filament of undifferentiated cells (i.e., lacking heterocysts or akinetes) formed by filamentous CYANOBACTERIA (members of sections III, IV and V) and by e.g. *Beggiatoa*; hormogonia may be formed by the fragmentation of whole filaments (e.g. in *Oscillatoria* and *Cylindrospermum*) or may develop from the tips of trichomes (e.g. in *Scytonema*). (See also NECRIDIUM.) Hormogonia may differ from the parent trichome e.g. in having smaller cells; they are typically motile (by gliding) and usually move some distance before developing into mature filaments, thus functioning as propagules. In some cyanobacteria (e.g. *Nostoc muscorum* [JGM (1983) 129 263–270], *Calothrix* spp), GAS VACUOLES are formed only in the hormogonia, the increased buoyancy they confer presumably aiding in the dispersal of the hormogonia.

**hormone** A substance which is released from specialized cells in specific part(s) of a multicellular organism and which, in small quantities, can bring about one or more specific responses when translocated to other part(s) of the same individual.

**hormone A** See PHEROMONE.

**hormone B** See PHEROMONE.

**horse diseases** Horses may be affected by a wide range of diseases, some of which are specific to equines. (a) *Bacterial diseases*: see e.g. CONTAGIOUS EQUINE METRITIS; CONTAGIOUS PUSTULAR DERMATITIS (sense 2); GLANDERS; PARATYPHOID FEVER; POTOMAC HORSE FEVER; SLEEPY FOAL DISEASE; STRANGLES; TULARAEMIA; TYZZER'S DISEASE; ULCERATIVE LYMPHANGITIS. (See also RHODOCOCCLUS (*R. equi*)). (b) *Fungal diseases*: see e.g. ASPERGILLOSIS; EPIZOOTIC LYMPHANGITIS; EQUINE PHYCOMYCOSIS; SPOROTRICHOSIS. (See also PASPALUM STAGGERS and PENITREMS.) (c) *Protozoal diseases*: see e.g. DOURINE; EQUINE PROTOZOAL MYELOENCEPHALITIS; SURRA. (d) *Viral diseases*: see e.g. AFRICAN HORSE SICKNESS; BORNA DISEASE; EASTERN EQUINE ENCEPHALOMYELITIS; EQUINE COITAL EXANTHEMA; SWAMP FEVER (equine infectious anaemia); VENEZUELAN EQUINE ENCEPHALOMYELITIS; VESICULAR STOMATITIS; WESTERN EQUINE ENCEPHALOMYELITIS.

**horse mushroom** See AGARICUS.

**horse sickness fever** See AFRICAN HORSE SICKNESS.

**horseradish peroxidase** A haemin-containing PEROXIDASE, used e.g. in the IMMUNOPEROXIDASE METHODS.

**host-controlled modification** The modification of bacteriophage DNA by its host's modification enzymes (see RESTRICTION – MODIFICATION SYSTEM). If a given phage replicates in a particular bacterial strain, the DNA of the progeny phages will carry the modification pattern characteristic of that strain; such phages will be able to infect other cells of the same strain with high efficiency. If these phages infect another strain of bacteria in which there is a *different* R-M system, a low efficiency of plating is generally observed since, in most of the cells, infection is followed by restriction of the phage DNA; however, in a few cells restriction may fail to occur, and the phage DNA then acquires the modification pattern characteristic of the new strain. The modified DNA can replicate, the daughter strands being modified by the host enzymes; the progeny phages can efficiently infect cultures of the new strain, but will infect cultures of the original strain with low efficiency.

**host-dependent mutant** A CONDITIONAL LETHAL MUTANT bacteriophage which contains e.g. an amber mutation in an essential gene and can thus replicate only in a (permissive) host which contains an intergenic amber SUPPRESSOR MUTATION.

**host-range mutant** (*h* mutant; *hr* mutant) A mutant virus in which the mutation alters the host range of the virus (i.e. the type(s) of cell which it can infect).

**hot-air oven** An apparatus used for the dry-heat STERILIZATION of e.g. clean glassware and those materials (such as mineral oils) which cannot be sterilized in an AUTOCLAVE owing to their impermeability to steam. It consists of an electrically heated, thermostatically controlled, heat-insulated cabinet which, ideally, incorporates an internal fan to prevent temperature stratification. Typical sterilizing conditions are 160–170°C/1 hour.

**hot-cold lysis** A phenomenon in which incubation of susceptible red blood cells (RBCs) with e.g. staphylococcal β-HAEMOLYSIN at 37°C causes little or no haemolysis, but subsequent chilling to 0–4°C causes rapid and extensive haemolysis. The sensitivity of RBCs from different species depends on the SPHINGOMYELIN content of their membranes, those from sheep, goat and ox being the most sensitive. Hot-cold lysis is still not fully understood; it may reflect the combined effects of degradation of sphingomyelin in the outer leaflet of the cell membrane (with consequent condensation of the resulting ceramide into droplets in the outer layer) and the weakening of hydrophobic forces

## hot-spot

on cooling [Book ref. 44, pp. 721–725]. Hot–cold lysis with staphylococcal  $\beta$ -toxin is most easily demonstrated in the test-tube; blood agar plates may give less consistent results.

Hot–cold lysis can also occur with the  $\alpha$ -toxin of *Clostridium perfringens*.

**hot-spot** (*mol. biol.*) A region of DNA which is particularly prone to e.g. transposition (see TRANSPOSABLE ELEMENT) or mutation (see SPONTANEOUS MUTATION).

**hot-start PCR** A form of PCR in which an essential component of the reaction mixture is withheld, or blocked, until the temperature of the mixture has, for the first time, risen above the primer-binding temperature; the object of this procedure is to avoid mis-priming (i.e. binding of primers to inappropriate sequences) – which, in the standard form of PCR, tends to occur primarily in the initial pre-cycling stage, i.e. when all components are present but the mixture is still at room temperature. By avoidance (or minimization) of mis-priming, the hot-start technique promotes the specificity of a PCR assay; it can also promote the sensitivity of an assay by concentrating the full potential of the system on amplification of the required target sequence. Avoidance or minimization of non-specific products also serves to reduce the background against which the legitimate target is to be detected.

In one commercial procedure, a chemically modified form of the polymerase (AmpliTaQ Gold™ DNA polymerase; Perkin-Elmer) is initially inactive (when added to the reaction mixture) but is thermally activated at 95°C when the temperature first rises to the denaturation level.

In another commercial system, the reaction mixture is prepared with all components except the polymerase; a layer of molten wax (AmpliWax™; Perkin-Elmer) is allowed to set on the surface of the mixture, and the polymerase is then added above the wax barrier. Once cycling begins, the wax melts when the temperature first exceeds ~75–80°C; the reactants then mix, and PCR proceeds normally.

[See also *Nature* (1996) 381 445–446.]

**housefly virus** (HFV) A virus pathogenic in the housefly (*Musca domestica*); it resembles viruses of the REOVIRIDAE in having a dsRNA genome (10 genes), but is apparently not serologically related to reoviruses. [Book ref. 83, p 5.]

**Howell–Jolly body** In some erythrocytes in a stained blood smear: a small, dark, rounded body generally considered to be a fragment of the precursor cell's disintegrating nucleus.

**Hoyer's medium** (Frature's modification) A medium in which ethanol is the sole source of carbon, and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> the sole source of nitrogen; it includes K<sub>2</sub>HPO<sub>4</sub>, KH<sub>2</sub>PO<sub>4</sub>, MgSO<sub>4</sub>, FeCl<sub>3</sub>, biotin, calcium pantothenate, thiamine, folic acid, PABA, vitamin B<sub>12</sub>, pyridoxal-HCl, niacin and riboflavin. (See e.g. ACETOBACTER.)

**HpaI** A RESTRICTION ENDONUCLEASE from *Haemophilus parainfluenzae*; GTT/AAC.

**HpaII** A RESTRICTION ENDONUCLEASE from *Haemophilus parainfluenzae*; C/CGG.

**HPI layer** See DEINOCOCCUS.

**HPLC** High-pressure liquid CHROMATOGRAPHY.

**HPr** See PTS.

**HPr kinase** See CATABOLITE REPRESSION.

**hprK gene** (in *Staphylococcus xylosum*) See CATABOLITE REPRESSION.

**HPUra** (Hpura) 6-(*p*-Hydroxyphenylazo)uracil: an inhibitor of DNA polymerase III in e.g. Gram-positive bacteria.

**HPV** Human papillomavirus – see PAPILLOMA and PAPILLOMAVIRUS. (*Note.* ‘Human parvovirus’ was formerly referred to as HPV

but is now referred to as ‘parvovirus B19’ or ‘B19 parvovirus’ (see ERYTHROVIRUS).)

**HQNO** HYDROXYQUINOLINE-N-OXIDE.

**hr mutant** HOST-RANGE MUTANT.

**HR756** *Syn.* cefotaxime (see CEPHALOSPORINS).

**Hrp secretion pathway** (*plant pathol.*) See AVIRULENCE GENE.

**HRP-2 protein** See MALARIA.

**HS** HAEMOPHAGOCYTIC SYNDROME.

**HSA** (*serol.*) Human serum albumin.

**hsp genes** Genes encoding HEAT-SHOCK PROTEINS.

**HSV** HERPES SIMPLEX VIRUS.

**HT-2 toxin** See TRICHOTHECENES.

**HTF** *Mastigocladus* See CHLOROGLOEOPSIS.

**HTLV** Human T-lymphotropic virus (= human T-cell leukaemia virus, human T-cell leukaemia/lymphoma virus): a generic term for exogenous, replication-competent human retroviruses (see RETROVIRIDAE) which (at least HTLV-I and HTLV-II) can infect and transform CD4<sup>+</sup> T LYMPHOCYTES; other types of cell (including macrophages) can also be infected.

HTLV-I (formerly ‘HTLV’) was first identified in the neoplastic T cells of patients with ADULT T CELL LEUKAEMIA (ATL) and is now regarded as a causal agent of that disease; this virus has also been associated with some non-malignant diseases which include spastic paraparesis and uveitis.

Infection with HTLV-I is permanent (i.e. life-long). A carrier state is recognized. Transmission of the virus appears to occur mainly via breast-feeding, sexual contact and blood transfusion. Endemic areas include Japan, the Caribbean, parts of Africa and Latin America.

The virion of HTLV-I is ~75  $\mu$ m in diameter.

The genome of HTLV-I integrates at random sites in the host's DNA; transformed T cells from ATL patients contain only one, or a few, copies of the viral genome per cell.

The genome of HTLV-I (~9–10 kb) includes the genes *gag*, *pol* and *env* (analogous to those of other retroviruses). A further gene, *pro*, encodes a protease. Near the 3' end of the genome (the pX region) are several genes that include *rex* and *tax*, both of which are involved in viral replication. The genome lacks a viral oncogene.

In addition to its role in viral replication, the Tax protein induces the expression of a number of host genes – including that encoding INTERLEUKIN-2 and the ONCOGENE *c-fos*. Expression of such host proteins may promote leukaemogenesis. (In vitro, HTLV-I is reported to transform normal human peripheral blood T cells, the transformed cells continuing to proliferate in the absence of exogenous interleukin-2.)

HTLV-I is closely related to SIMIAN T-CELL LEUKAEMIA VIRUS (strains of which are >85% homologous with HTLV-I in terms of nucleotide sequence); it is also related to bovine leukosis virus (BLV).

HTLV-II has been rarely isolated – initially from a T cell line derived from a case of (T cell) HAIRY CELL LEUKAEMIA [Science (1982) 218 571–573]. The nucleotide sequence of HTLV-II is 70% homologous with that of HTLV-I. The pathogenic potential of HTLV-II is uncertain, although one report described a patient with disease closely resembling HTLV-I-associated myelopathy in a patient infected with HTLV-II.

‘HTLV-III’ was a former name for the human immunodeficiency virus (HIV).

Another human T-cell lymphotropic retrovirus – related to but distinct from other HTLVs – was detected in some cases of MULTIPLE SCLEROSIS (MS), but an aetiological role (if any) for such a virus in MS has yet to be determined [Nature (1985) 318 154–160].

[Early review (HTLV-I -II -III): Nature (1985) 317 395–403. Human T-cell leukaemia virus: BCH (1995) 8 131–148. Detection of HTLV-I and HTLV-II by multiplex PCR: PNAS (1999) 96 6394–6399. Human T-lymphotropic virus type I infection: BCH (2000) 13 231–243.]

**hspR gene** See HEAT-SHOCK PROTEINS.

**HTST** See APPERTIZATION and PASTEURIZATION.

**HU** HYDROXYUREA.

**HU protein** A small, basic protein, abundant in *Escherichia coli*, which binds strongly to angular/kinked dsDNA and which can inhibit cruciform extrusion from PALINDROMIC SEQUENCES in vitro. It functions e.g. in replication from *oriC* in *E. coli*, in some SITE-SPECIFIC RECOMBINATION systems, and in Tn10 transposition. It resembles mammalian HMG1 protein (whose DNA-binding is more structure- than sequence-dependent) [Mol. Microbiol. (1993) 7 343–350].

The HU protein is reported to be involved in regulating the expression of gene *rpoS* (encoding SIGMA FACTOR  $\sigma^S$ ) [Mol. Microbiol. (2001) 39 1069–1079].

**Hucker's method** See GRAM STAIN.

**Huffia** A subgenus of PLASMODIUM.

**Hugh and Leifson's test** OXIDATION-FERMENTATION TEST.

**Hughes press** An apparatus for CELL DISRUPTION. A frozen suspension or paste of cells in a cylinder is forced by hydraulic pressure (up to ca. 30 tons/inch<sup>2</sup>, i.e., ca. 480 MPa) through a small hole in the containing vessel; as the cells emerge they are broken by the solid shear forces due to the presence of intracellular ice crystals. The frozen sample may incorporate an abrasive (e.g. finely powdered glass) for more efficient cell breakage.

**Huilia** See LECIDEA.

**hülle cell** See EMERICELLA.

**human (alpha) herpesviruses** See ALPHAHERPESVIRINAE.

**human (beta) herpesviruses** See BETAHERPESVIRINAE.

**human caliciviruses** See SMALL ROUND STRUCTURED VIRUSES.

**human coronavirus** See CORONAVIRIDAE.

**human cytomegalovirus** See BETAHERPESVIRINAE.

**human diploid cell vaccine** (HDCV) See RABIES.

**human enteric coronavirus** See CORONAVIRIDAE.

**human foamy viruses** See SPUMAVIRINAE.

**human (gamma) herpesviruses** See GAMMAHERPESVIRINAE.

**human genome** (sequence) See GENOME.

**human herpesvirus** (HHV) Any virus of the family HERPESVIRIDAE which can infect humans; HHVs occur in each of the three subfamilies ALPHAHERPESVIRINAE, BETAHERPESVIRINAE and GAMMAHERPESVIRINAE. (See also HHV.)

**human immunodeficiency virus** See HIV.

**human papilloma virus** See PAPILLOMAVIRUS.

**human parvovirus** See PARVOVIRUS.

**human T-cell leukaemia/lymphoma virus** See HTLV.

**human T-lymphotropic virus** See HTLV.

**Humicola** See HYPHOMYCETES; see also COMPOSTING and SOFT ROT (sense 1).

**humicolous** Growing in or on soil or humus.

**humoral antibodies** Antibodies present (free) in plasma and in other body fluids.

**humoral immunity** (1) ANTIBODY-dependent IMMUNITY; humoral immunity can be transferred to a non-immune individual by the transfer of cell-free plasma or serum. (cf. CELL-MEDIATED IMMUNITY; see also IMMUNIZATION (sense 1); ADCC; JONES-MOTE SENSITIVITY.) (2) Immunity derived from any factor(s) in the body fluids – e.g. antibodies, LYSOZYME, COMPLEMENT.

**humus tank** See SEWAGE TREATMENT.

**Hungate technique** See ROLL-TUBE TECHNIQUE.

**Hungate tube** A gas-tight, tube-shaped glass vessel with a rubber stopper which is held in place by a screw cap; it is used in the ROLL-TUBE TECHNIQUE.

**hupA, hupB genes** In *Escherichia coli*, the genes which encode the two subunits of the HU PROTEIN.

**Huroniospora** See STROMATOLITES.

**HUS** See HAEMOLYTIC URAEMIC SYNDROME.

**hut genes** Genes involved in histidine utilization (see HISTIDINE DEGRADATION).

**Hutchinson's teeth** See SYPHILIS.

**HUVEC** Human umbilical vascular endothelial cell.

**HVR-1** (in hepatitis C virus) See HEPATITIS C VIRUS.

**hyaline** Transparent, translucent, or colourless.

**hyaline cap** See PSEUDOPODIUM.

**hyalodendrins** See EPIPOLYTHIAPIPERAZINEDIONES.

**hyalodidymae** See SACCARDOAN SYSTEM.

**hyaloplasm** (1) *Syn.* CYTOSOL. (2) See SARCODINA.

**Hyalospora** See UREDINIOMYCETES and AMPHISPORE.

**Hyalotheca** A genus of filamentous placoderm DESMIDS. The filaments are composed of chains of cylindrical, flat-ended cells; each cell has only a slight median constriction.

**hyaluronan** *Syn.* HYALURONIC ACID.

**hyaluronate lyase** ('spreading factor'; EC 4.2.2.1) A LYASE which cleaves HYALURONIC ACID at the (1 → 4)- $\beta$ -linkages; the end product is a disaccharide containing a 4,5-unsaturated uronic acid residue. (cf. HYALURONIDASE). It is produced e.g. by most coagulase +ve staphylococci, *Streptococcus pneumoniae*, *S. pyogenes* and *Clostridium perfringens* ( $\mu$  toxin); it may promote invasiveness. It can be assayed by its ability to reduce viscosity in a solution of hyalauronic acid. [Action of enzyme from *S. pneumoniae*: EMBO (2000) 19 1228–1240.]

**hyaluronic acid** A linear polysaccharide in which repeating disaccharide units of  $\beta$ -D-glucuronopyranosyl-(1 → 3)-*N*-acetyl-D-glucosamine are connected by (1 → 4)- $\beta$ -linkages. Hyaluronic acid occurs e.g. as an intercellular constituent of various animal tissues, in synovial fluid, and in the capsules of certain group A streptococci. Hyaluronic acid forms highly viscous solutions in water and readily forms gels.

**hyaluronidase** Any enzyme which cleaves HYALURONIC ACID; they include HYDROLASES and LYASES. The hydrolases include hyaluronate 4-glucanhydrolase (EC 3.2.1.35) – present e.g. in testicular extracts and produced e.g. by certain streptomycetes. The name 'hyaluronidase' is often used (erroneously) as a synonym for the enzyme HYALURONATE LYASE.

**hybrid antibody** See CONJUGATION (2).

**hybrid-arrested translation** A method for identifying a protein encoded by a given cDNA. mRNAs from the cell are translated in the presence of cloned, single-stranded copies of the cDNA. mRNAs which do not bind cDNA yield proteins incorporating a *labelled* amino acid. Translation is repeated *without* cDNAs, allowing translation of the mRNA previously blocked by hybridization to cDNA. The protein of interest is the *extra* protein formed in the second translation.

**hybrid plasmid** (1) Any recombinant PLASMID (see e.g. CLONING). (2) A recombinant plasmid containing sequences derived from organisms which can normally exchange genetic information. (cf. CHIMERIC PLASMID.)

**hybridization** (1) The formation of a double-stranded nucleic acid by base-pairing between single-stranded nucleic acids derived (usually) from different sources; some authors use the term specifically for the association of ssRNA with ssDNA. (See also DNA HOMOLOGUE and SOUTHERN HYBRIDIZATION.)

## hybridization protection assay

(2) The formation of e.g. a HYBRID PLASMID.

(3) The formation of a hybrid cell (see e.g. HYBRIDOMA), or of a hybrid organism (e.g. by a cross between genetically dissimilar organisms).

## hybridization protection assay See TMA.

**hybridoma** The product and/or progeny of cell fusion ('somatic cell hybridization') between a tumour cell and a non-tumour cell; the in vitro production of hybridomas is carried out to provide continuously replicating (hybrid) cells which exhibit some or all of the characteristics of the non-tumour cell. Hybridomas have been formed, for example, between normal B LYMPHOCYTES and MYELOMA cells; such hybridomas are used e.g. as sources of MONOCLONAL ANTIBODIES.

In one method of *B cell hybridoma* formation, spleen (or lymph node) cells are mixed with similar numbers of myeloma cells and centrifuged. The cell pellet is briefly exposed to polyethylene glycol (PEG) which promotes cell fusion. (Lysolecithin or inactivated Sendai virus has been used in place of PEG.) (cf. ELECTROFUSION.) The PEG is diluted out, and the fusion mixture is then centrifuged; the pellet is re-suspended in a growth medium, divided into aliquots, and incubated. Small cluster(s) of hybridoma cells appear in the aliquots after ca. 1 week. (The number of hybridomas depends e.g. on the initial cell density: the fusion rate may be e.g. 1 in  $10^4$ .)

In order to prevent the culture from being overgrown by the myeloma cells, use is made of (pre-selected) mutant myeloma cells which are blocked in one of their two (normal) pathways for nucleotide synthesis; such mutants lack either thymidine kinase (TK<sup>-</sup> mutants) or hypoxanthine-guanine-phosphoribosyltransferase (HGPRT<sup>-</sup> mutants) so that they cannot use the ancillary ('salvage') pathway for nucleotide synthesis and (hence) cannot use exogenous thymidine or hypoxanthine (or guanine). Accordingly, to suppress the growth of non-fused myeloma cells, the fusion mixture is incubated in a medium (HAT medium) which contains aminopterin (a folic acid analogue which blocks the *main* pathway of nucleotide synthesis) together with hypoxanthine and thymidine; thus, the main pathway for nucleotide synthesis is blocked in both myeloma and non-myeloma cells, while *fused* (hybridoma-forming) myeloma cells can continue to grow by using TK or HGPRT supplied by their non-mutant partner cells.

In order to prevent the formation of hybrid Ig (molecules which contain heavy and/or light chains from each of both partner cells), use is made of mutant myeloma cells which do not secrete Ig components.

Activated or proliferating B cells fuse to myeloma cells more readily than do quiescent B cells; hence, prior to hybridoma formation, B cells of the required antibody specificity should be activated e.g. by antigenic challenge. (The consequent expansion of particular B cell clone(s) will also increase the incidence with which the cells of such clones participate in hybridoma formation.)

*T cell hybridomas* have been used e.g. in the study of cytokines, and for characterization of the different T LYMPHOCYTE subsets.

**Hydnaceae** See APHYLLOPHORALES.

**Hydnum** See APHYLLOPHORALES (Hydnaceae).

**Hydra viridis** See ZOOCHLORELLAE.

**Hydramoeba** A genus of amoebae (order AMOEBIDA) which occur both free-living and as parasites in the gastrodermis of Hydra sp.

**hydrocarbon inclusions** See HYDROCARBONS.

**hydrocarbons** Compounds which contain only carbon and hydrogen; they occur e.g. in PETROLEUM. Many types of hydrocarbon can be used as substrates for growth by various microorganisms. Such organisms are ecologically important e.g. in the degradation of petroleum pollutants, and some may be commercially useful e.g. in the production of SINGLE-CELL PROTEIN from hydrocarbons; however, certain hydrocarbon-utilizing organisms can cause spoilage of hydrocarbon products such as fuels (see PETROLEUM). Hydrocarbon metabolism is strictly aerobic and appears always to involve the introduction of oxygen into the molecule in a process requiring a monooxygenase (= hydroxylase) or dioxygenase (see OXYGENASE).

*Aliphatic hydrocarbons.* Straight-chain paraffins (*n*-alkanes) can be utilized by bacteria (e.g. strains of *Acinetobacter*, *Corynebacterium*, *Mycobacterium*, *Nocardia*, *Pseudomonas*), by yeasts (e.g. species of *Candida*), and by mycelial fungi (e.g. species of *Aspergillus*, *Botrytis*, *Fusarium*, *Helminthosporium*, *Hormoconis*, *Penicillium*). Some organisms can use only short-chain alkanes, some can use only long-chain alkanes. In most cases *n*-alkane metabolism appears to occur by  $\omega$ -oxidation, i.e., a terminal methyl group of the alkane is oxidized by a monooxygenase to form a primary alcohol which is in turn (apparently) oxidized, via the aldehyde, to the corresponding fatty acid by alcohol dehydrogenase and aldehyde dehydrogenase activities; the fatty acid can then be degraded by conventional  $\beta$ -oxidation. In e.g. *Pseudomonas* strains the alkane-oxidizing enzyme system is complex, involving an  $\omega$ -monooxygenase, a rubredoxin (see IRON-SULPHUR PROTEINS), and an NADH-rubredoxin oxidoreductase; in eukaryotes, and possibly in certain bacteria (e.g. *Acinetobacter* strains [FEMS (1981) 11 309-312]), the alkane monooxygenase is linked to the cytochrome P-450 electron-carrier system (see CYTOCHROMES). (See also METHANOTROPHY.)

In some organisms an alkane may be oxidized at *both* ends, resulting in the formation of a dicarboxylic acid. Subterminal oxidation may also occur.

Branched-chain alkanes (alkylalkanes) and unsaturated hydrocarbons (alkenes, olefins) are generally somewhat less susceptible to microbial degradation than are *n*-alkanes; they may be oxidized in the same way as *n*-alkanes, but alkenes may also be oxidized at the double bond, resulting in the formation of a diol.

Organisms growing on alkanes have certain characteristic structural features. For example, yeasts growing on hydrocarbons generally contain numerous PEROXISOMES which are apparently involved in fatty acid metabolism rather than in alkane oxidation per se. Alkane-utilizing bacteria generally contain intracytoplasmic membranes together with 'hydrocarbon inclusions': electron-translucent, spherical bodies (ca. 0.2  $\mu$ m diam.) limited by a non-unit-type (monolayer) membrane; the inclusions occur at the cell periphery or in close association with the intracytoplasmic membranes, and apparently contain unmodified alkane, protein, phospholipid and neutral lipid.

Since alkane metabolism occurs intracellularly, the hydrocarbon must be taken into the cell. Uptake may occur by different mechanisms in different organisms, and in at least some cases may require prior emulsification of the hydrocarbon by an extracellular BIOSURFACTANT or bioemulsifier.

*Alicyclic hydrocarbons* (cycloparaffins, cycloalkanes) are cyclic, non-aromatic hydrocarbons; they are generally less susceptible to microbial attack than either aliphatic or aromatic compounds. A suggested pathway for the degradation of e.g. cyclohexane by strains of *Nocardia* or *Pseudomonas* involves oxidation of the cyclohexane to cyclohexanol by a cyclohexane monooxygenase; cyclohexanol is oxidized to cyclohexanone,

and then an oxygen atom is introduced into the ring (forming a lactone) by a cyclohexanone monooxygenase. The lactone can then be hydrolysed to form a (non-cyclic) dicarboxylic acid.

**Aromatic hydrocarbons** (benzene, naphthalene, anthracene etc) are present in e.g. petroleum and are formed by the incomplete combustion of almost any organic material; they are therefore common pollutants, and many are recognized carcinogens. Bacteria (e.g. *Pseudomonas* spp) metabolize aromatic hydrocarbons by initially incorporating two atoms of oxygen into the substrate to form a *cis*-dihydrodiol; the reaction is catalysed by a multicomponent enzyme system comprising a dioxygenase, a flavoprotein, and IRON-SULPHUR PROTEINS. The *cis*-dihydrodiol is oxidized to a catechol which is in turn a substrate for another dioxygenase system which breaks open the aromatic ring. In contrast, fungi oxidize aromatic hydrocarbons using a cytochrome P-450-dependent monooxygenase to form a reactive arene oxide; this can either undergo isomerization to form a monohydric phenol, or enzymic hydrolysis to form a *trans*-dihydrodiol.

[Reviews on microbial hydrocarbon metabolism: Book ref. 155.]

**Hydroclathrus** See PHAEOPHYTA.

**Hydrodictyon** A genus of freshwater green algae (division CHLOROPHYTA) which form free-floating net-like colonies ('water nets') composed of large, coenocytic cells.

**hydrogen** (as a metabolite) Gaseous (molecular) hydrogen is produced e.g. in various types of FERMENTATION (sense 1), and is formed during NITROGENASE activity. Gaseous hydrogen may be consumed e.g. during METHANOGENESIS and may be used for lithotrophic metabolism by e.g. HYDROGEN-OXIDIZING BACTERIA and some SULPHATE-REDUCING BACTERIA. [Production and uptake of molecular hydrogen by unicellular cyanobacteria: JGM (1985) 131 1561–1569.] (See also FORMATE HYDROGEN LYASE and INTERSPECIES HYDROGEN TRANSFER.)

**hydrogen bacteria** *Syn.* HYDROGEN-OXIDIZING BACTERIA.

**hydrogen dehydrogenase** *Syn.* HYDROGENASE.

**hydrogen hypothesis** See EUKARYOTE.

**hydrogen-oxidizing bacteria** (the 'hydrogen bacteria'; knallgas bacteria) A phrase sometimes used to refer specifically to a (non-taxonomic) category of aerobic bacteria which can grow chemolithoautotrophically by obtaining energy from the oxidation of gaseous hydrogen by oxygen via an electron transport chain (see KNALLGAS REACTION); most species can also grow chemoorganoheterotrophically and/or mixotrophically. [Details of the obligately chemolithoautotrophic hydrogen-oxidizing species *Hydrogenobacter thermophilus* (gen. nov., sp. nov.): IJSB (1984) 34 5–10.] The hydrogen-oxidizing bacteria, *sensu stricto*, are distinct from those bacteria which can oxidize H<sub>2</sub> without autotrophic CO<sub>2</sub> fixation and/or which can carry out anaerobic oxidation of H<sub>2</sub> coupled to the reduction of e.g. SO<sub>4</sub><sup>2-</sup>, CO<sub>2</sub> or fumarate. The hydrogen-oxidizing bacteria (which include most or all CARBOXYDOBACTERIA) include e.g. those strains of *Alcaligenes denitrificans* formerly called *A. ruhlandii*; *Aquaspirillum autotrophicum*; *Bacillus schlegelii* [JGM (1979) 115 333–341]; *Paracoccus denitrificans*; *Pseudomonas facilis* and *P. saccharophila*; and bacteria referred to as *Alcaligenes eutrophus*, *Nocardia autotrophica*, and *N. opaca*.

Most hydrogen-oxidizing bacteria (including e.g. *Paracoccus denitrificans*) have only a membrane-bound, NAD-independent HYDROGENASE (see also EXTRACRYTOPLASMIC OXIDATION); some strains have only a soluble (cytoplasmic), NAD-reducing hydrogenase ('hydrogen dehydrogenase'), while others (e.g. strains of '*Alcaligenes eutrophus*') have both forms of the enzyme.

[Habitats, culture, and descriptions of individual hydrogen-oxidizing bacteria: Book ref. 45, pp. 865–893.]

**hydrogen peroxide** (a) (as an antimicrobial agent) Hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) is an OXIDIZING AGENT which can be an effective disinfectant at low concentrations (e.g. 0.1% or less) and can act as a sterilant (for inanimate objects) at high concentrations (e.g. 10–25%); sporicidal activity at high concentrations is enhanced by ultrasonic energy and by certain metal ions, particularly Cu<sup>2+</sup>. Dilute aqueous solutions of H<sub>2</sub>O<sub>2</sub> are used for the treatment of wounds; here, antimicrobial activity may be largely mechanical – tissue CATALASE causing a rapid evolution of oxygen which can dislodge contaminating foreign matter, thus facilitating its removal. However, the strongly oxygenated environment thus created in the wound can inhibit the development of anaerobic pathogens.

The antimicrobial action of H<sub>2</sub>O<sub>2</sub> may be due to its reduction to the highly reactive HYDROXYL RADICAL which can react e.g. with membrane lipids and nucleic acids. [Book ref. 65, pp. 240–244.]

*Escherichia coli* and *Salmonella typhimurium*, when exposed to sublethal concentrations of H<sub>2</sub>O<sub>2</sub>, acquire resistance to higher doses of H<sub>2</sub>O<sub>2</sub> and other oxidants; in *S. typhimurium* this 'adaptation' to oxidative stress involves the induction of various proteins, some of which are apparently encoded by a regulon under the positive control of a locus designated *oxyR* [Cell (1985) 41 753–762]. [Toxicity, mutagenesis and stress responses induced in *E. coli* by H<sub>2</sub>O<sub>2</sub>: JCS (1987) Supplement 6 289–301.]

Peracids (acids containing the peroxy group, –O–O–) – which can be regarded as derivatives of H<sub>2</sub>O<sub>2</sub> – are oxidizing agents whose activity is greater than that of H<sub>2</sub>O<sub>2</sub>. *Peracetic acid* (CH<sub>3</sub>.COO.OH) is the most active antimicrobial agent of the organic peracids, and can act as a sterilant at quite low concentrations (e.g. 1% or less). An aqueous solution of *sodium perborate* (NaBO<sub>3</sub>) acts as a mixture of borate and hydrogen peroxide; a paste of sodium perborate in water or glycerol has been used for the treatment of oral infections involving anaerobes (e.g. Vincent's angina).

[H<sub>2</sub>O<sub>2</sub> and peracetic acid as antimicrobial agents: JAB (1983) 54 417–423.]

(b) (as a metabolite) H<sub>2</sub>O<sub>2</sub> is produced e.g. by the spontaneous or enzymatic dismutation of SUPEROXIDE (see also SUPEROXIDE DISMUTASE). Endogenously formed H<sub>2</sub>O<sub>2</sub> may be inactivated, intracellularly, by e.g. CATALASE or GLUTATHIONE PEROXIDASE, thus preventing the toxic effects of H<sub>2</sub>O<sub>2</sub> (H<sub>2</sub>O<sub>2</sub> can inactivate some types of superoxide dismutase, and can give rise to HYDROXYL RADICAL and SINGLET OXYGEN). However, extracellular H<sub>2</sub>O<sub>2</sub>, produced by the activities of certain organisms, may be important e.g. in LIGNIN degradation and in BROWN ROT (sense 1). (See also DIANISIDINE and LACTOPEROXIDASE-THIOCYANATE-HYDROGEN PEROXIDE SYSTEM.)

**hydrogen sulphide** (H<sub>2</sub>S) Certain bacteria can produce H<sub>2</sub>S e.g. by the reductive degradation of sulphur-containing amino acids (e.g. cysteine) or by DISSIMILATORY SULPHATE REDUCTION; H<sub>2</sub>S production can be plasmid mediated – see e.g. Hys plasmid in ESCHERICHIA. (See also KLIGLER'S IRON AGAR and TSI AGAR.) H<sub>2</sub>S can be formed from sulphite by *Saccharomyces cerevisiae* [JGM (1985) 131 1417–1424].

H<sub>2</sub>S can be used by some bacteria as an electron donor in lithotrophic metabolism; these bacteria include e.g. species of *Beggiatoa* and *Thiobacillus*, members of the Rhodospirillaceae and other photosynthetic bacteria, and the cyanobacterium *Oscillatoria*.

(See also SULPHUR CYCLE.)

**hydrogen swell** A SWELL caused by hydrogen production due to internal corrosion of the can (see also TIN). Hydrogen swells,

## hydrogenase

characterized by a high proportion of hydrogen in the headspace, may take months to develop; they are commonly associated with certain acidic fruits and with foods containing curing salts.

**hydrogenase** An OXIDOREDUCTASE (EC 1.12.-.-) which catalyses the reaction:  $H_2 \leftrightarrow 2H^+ + 2e^-$ . Hydrogenases occur in various algae (see e.g. PHOTOREDUCTION) and e.g. in HYDROGEN-OXIDIZING BACTERIA, some SULPHATE-REDUCING BACTERIA, some nitrogen-fixing bacteria (see NITROGENASE), *Chloroflexus aurantiacus* [FEMS (1985) 28 231–235], and *Escherichia coli* (e.g. as part of the FORMATE HYDROGEN LYASE system). Hydrogenases are IRON-SULPHUR PROTEINS, and in many species of bacteria they have been shown to contain nickel. Hydrogen-oxidizing bacteria may contain a membrane-bound NAD-independent hydrogenase (see also EXTRACYTOPLASMIC OXIDATION) and/or a soluble NAD<sup>+</sup>-reducing hydrogenase ('hydrogen dehydrogenase'). [Hydrogenases – their structure and applications in hydrogen production: Book ref. 132, pp. 75–102.] (See also KNALLGAS REACTION.)

**Hydrogenobacter** See HYDROGEN-OXIDIZING BACTERIA.

**hydrogenogen** See ACETOGEN.

**Hydrogenomonas** An obsolete bacterial genus which included certain species of HYDROGEN-OXIDIZING BACTERIA (e.g. *H. facilis*, now *Pseudomonas facilis*).

**hydrogenosome** A membrane-limited intracellular organelle present in certain eukaryotic microorganisms – e.g. trichomonads (but not e.g. *Entamoeba histolytica*); in trichomonads it contains various IRON-SULPHUR PROTEINS and flavoproteins as components of an electron transport chain that is used in the oxidation of pyruvate to acetate, CO<sub>2</sub> and H<sub>2</sub> (protons being used as electron acceptors). In isolated hydrogenosomes of *Trichomonas vaginalis*, METRONIDAZOLE is reduced, anaerobically, to an active (cytotoxic) derivative [JGM (1985) 131 2141–2144]; in vivo such active product(s) may damage the hydrogenosome itself and/or may leave the hydrogenosome and affect other target(s). (cf. MICROBODY.)

**hydrolases** ENZYMES (EC class 3) which catalyse the hydrolytic cleavage of bonds, including C–O, C–N and C–C bonds. The names of such enzymes are commonly formed by adding '-ase' to the name of the substrate (e.g. esterase, glycosidase, peptidase); the systematic name has the form *substrate hydrolase*.

**hydrophobia** *Syn.* RABIES.

**hydrops fetalis** (non-immune) A condition in which the fetus develops e.g. anaemia and oedema; death may result from severe anaemia. In a proportion of cases hydrops fetalis is due to infection by parvovirus B19 (see ERYTHROVIRUS).

**hydroresorufin** See RESAZURIN TEST.

**hydrothermal vent** In certain geographical locations: a region of the ocean floor where seawater, which has permeated the earth's crust for several kilometres, emerges as a warm (5–25°C) or hot (270–380°C) hydrothermal fluid which is particularly rich in sulphide; vents which discharge hot fluids ≤300°C are called 'white smokers', while those discharging fluids at ca. 350°C are called 'black smokers' – an allusion to the clouds of black metal sulphides formed when these fluids meet the cold (2°C) ambient seawater. One of the best-studied vents is situated at the Galápagos Rift (near the equator at 86°W).

The sulphide (and e.g. hydrogen, methane and ferrous iron) in hydrothermal fluids supports the chemolithotrophic growth of various bacteria (e.g. species of THIOBACILLUS and THIOMICROSPIRA) – thus permitting chemosynthetic PRIMARY PRODUCTION; these bacteria form the basis of a food chain which supports communities of e.g. giant clams, limpets, mussels and tube worms in and around the vents. Some of the lithotrophic prokaryotes form symbiotic associations with some of the invertebrates;

thus, e.g. prokaryotes occur in the gill cells of the giant clam (*Calypotgena magnifica*) and in the TROPHOSOME tissue of the giant tube worm, *Riftia pachyptila*. A living community at a given vent appears to last for several years to several decades.

[Biology and microbiology of hydrothermal vents: Science (1985) 229 713–725; evidence for chemosynthetic primary production in hydrothermal vents: Book ref. 202, pp. 319–360.]

**hydroxamates** (in iron uptake) See SIDEROPHORES.

**hydroxyapatite** (hydroxylapatite; Ca<sub>10</sub>(PO<sub>4</sub>)<sub>6</sub>(OH)<sub>2</sub>) A mineral which is used as a stationary phase in adsorption CHROMATOGRAPHY e.g. for separating ssDNA from dsDNA or RNA. Under certain ionic conditions the mineral adsorbs dsDNA; the dsDNA is desorbed at higher ionic concentrations.

**hydroxycobalamin** See VITAMIN B<sub>12</sub>.

**hydroxyethylcellulose** See HE-CELLULOSE.

**hydroxyl radical** (OH· or ·OH) A hyper-reactive radical formed e.g. during a reaction involving SUPEROXIDE and HYDROGEN PEROXIDE (the 'Haber–Weiss reaction'); this reaction can be catalysed by iron complexes (e.g. Fe–EDTA, Fe–transferrin) and may be represented in two phases: (i) the reduction of ferric complexes by O<sub>2</sub><sup>−</sup> (with the formation of ferrous complexes and SINGLET OXYGEN), and (ii) the oxidation of ferrous complexes by H<sub>2</sub>O<sub>2</sub> (with the formation of ferric complexes, OH<sup>−</sup> and OH·) [FEBS (1978) 86 139–142]. (Hydroxyl radical is also reported to be formed e.g. in a reaction involving superoxide and hypochlorite, and by the action of ultraviolet radiation on hydrogen peroxide.) During PHAGOCYTOSIS, LACTOFERRIN from activated NEUTROPHILS may catalyse the formation of OH·, thus enhancing antimicrobial activity. Scavengers of OH· used in experimental systems include e.g. benzoate, dimethyl sulphoxide, mannitol and salicylate.

**hydroxylamine** (as a MUTAGEN) Hydroxylamine (NH<sub>2</sub>OH) reacts mainly with cytosine residues (and, much more slowly, with adenine residues) in DNA (particularly ssDNA), replacing the amino group with a hydroxyamino group (–NHOH); this favours tautomerization of the base such that, during subsequent DNA replication, mispairing occurs (resulting predominantly in G·C to A·T transitions). Although hydroxylamine is an effective mutagen when used to treat certain viruses or e.g. transforming DNA, any mutagenic effect it may have in living cells is generally masked by its toxic or lethal effects. The related compound *methoxyamine* (NH<sub>2</sub>OCH<sub>3</sub>) acts in a similar way.

**hydroxylapatite** *Syn.* HYDROXYAPATITE.

**hydroxylase** *Syn.* MONOOXYGENASE.

**hydroxymethionine analogue** See HMA.

**6-(p-hydroxyphenylazo)uracil** See HPURA.

**hydroxypyrimidine antifungal agents** A group of agricultural systemic ANTIFUNGAL AGENTS which have a highly selective action against powdery mildews; resistance to these fungicides tends to develop rapidly. Hydroxypyrimidines include e.g. DIMETHIRIMOL and ETHIRIMOL.

**8-hydroxyquinoline** (oxine; 8-quinolinol) (as antimicrobial agent) A chelating agent which, in the presence of Cu<sup>2+</sup> or Fe<sup>2+</sup>, has antifungal and antibacterial activity; Gram-positive bacteria are much more susceptible than Gram-negative bacteria. The potentiating effects of Cu<sup>2+</sup> and Fe<sup>2+</sup> are antagonized by trace amounts of Co<sup>2+</sup>, while Ni<sup>2+</sup> acts as a competitive inhibitor. COPPER-oxine has been used in agricultural antifungal sprays and as a rot-proofing agent for e.g. textiles.

Some halogenated derivatives of oxine are used e.g. for the treatment or prophylaxis of amoebic dysentery. They include

7-iodo-8-hydroxyquinoline-5-sulphonate (chiniofon); 5,7-diiodo-8-hydroxyquinoline (diiodohydroxyquin; Diodoquin); 5-chloro-7-iodo-8-hydroxyquinoline (iodochlorohydroxyquin; Enterovioform; Vioform). (Some of these derivatives also have useful antibacterial and antifungal properties.)

**hydroxyquinoline-*N*-oxide** (HOQNO; HQNO) 2-Alkyl-4-hydroxyquinoline-*N*-oxides (e.g. 2-*n*-heptyl-4-HOQNO) act as RESPIRATORY INHIBITORS in mitochondria and in certain bacteria – some bacteria are apparently impermeable to HOQNOs; HOQNOs appear to resemble ANTIMYCIN A (q.v.) in their mode of action. HOQNOs also inhibit the Na<sup>+</sup> pump in *Vibrio alginolyticus* (see SODIUM MOTIVE FORCE).

**2-hydroxystilbamidine** An aromatic DIAMIDINE which has trypanocidal and antifungal activity; it has been used e.g. in the treatment of blastomycosis and African trypanosomiasis.

**5-hydroxytryptamine** *Syn.* SEROTONIN.

**hydroxyurea** (HU; HONH.CO.NH<sub>2</sub>) A reagent which prevents the synthesis of deoxyribonucleotides by specifically inhibiting ribonucleoside diphosphate reductase.

**Hyella** See PLEUROCAPSA GROUP.

**Hygrocybe** See AGARICALES (Hygrophoraceae).

**hygrocytin B** AN AMINOGLYCOSIDE ANTIBIOTIC which, like STREPTOMYCIN, appears to act at a single ribosomal site.

**hygrophilic** (hygrophilous) Requiring a moist habitat for optimum growth.

**Hygrophoraceae** See AGARICALES.

**Hygrophorus** See AGARICALES (Hygrophoraceae).

**hymenium** (*mycol.*) A layer of ascospore- or basidiospore-forming tissue – e.g. that lining an APOTHECIUM or that forming the surface of a LAMELLA; a hymenium may also contain sterile structures – see e.g. PARAPHYSIS and PSEUDOPARAPHYSIS.

**Hymenochaetaceae** See APHYLLOPHORALES.

**Hymenochaete** See APHYLLOPHORALES (Hymenochaetaceae).

**Hymenogaster** See GASTEROMYCETES (Hymenogastrales).

**Hymenogastrales** See GASTEROMYCETES.

**Hymenomomas** See COCCOLITHOPHORIDS.

**Hymenomycetes** A class of fungi (subdivision BASIDIOMYCOTINA) in which the typical fruiting body is a well-developed, macroscopic, gymnocarpous or semiangiocarpous structure containing BALLISTOSPORE-bearing basidia in a HYMENIUM. Subclasses: HOLOBASIDIOMYCETIDAE and PHRAGMOBASIDIOMYCETIDAE.

**hymenophore** That part of a fruiting body which bears a HYMENIUM or SUBHYMENIUM, or the entire (hymenium-bearing) fruiting body. (cf. SPOROPHORE.)

**Hymenostomatia** A subclass of (mostly) freshwater ciliates (class OLIGOHYMENOPHOREA) in which somatic ciliature is often uniform, the buccal cavity (when present) is ventral, and kinetodesmata are usually conspicuous; sedentary and colonial types are not common. Orders: ASTOMATIDA, HYMENOSTOMATIDA, SCUTICOCILIATIDA.

**Hymenostomatida** An order of protozoa (subclass HYMENOSTOMATIA) in which the buccal cavity is well defined and contains characteristic membranelles. A SCUTICA does not appear during stomatogenesis. Genera (which may be distinguished e.g. by the number of post-oral kineties) include e.g. COLPIDIUM, *Frontonia*, GLAUCOMA, ICHTHYOPHTHIRIUS, LAMBORNELLA, *Ophryoglena*, PARAMECIUM and TETRAHYMENA.

**hyperauxinic** Containing or producing abnormally high levels of AUXINS.

**hyperchromic shift** A change in the amount of ultraviolet radiation absorbed by a nucleic acid during changes from the double-stranded to the single-stranded condition, or vice versa (see e.g. THERMAL MELTING PROFILE).

**hypericin** See STENTORIN.

**hyper-IgM syndrome** See RNA EDITING.

**hyperimmune** Refers to the condition of an individual whose plasma contains a high titre of a particular antibody following repeated exposure of the individual to the homologous antigen. *Hyperimmune serum* is serum derived from such an individual.

**Hypermastigida** An order of protozoa (class ZOOMASTIGOPHOREA) which have numerous flagella, the kinetosomes being arranged in complete or incomplete circles; the organisms are associated with insects. Genera: e.g. *Barbulanympha*, *Lophomonas*, *Microjoenia*, *Spirotrichonympha*, TRICHONYMPHA.

**hyperparasite** A parasite of a parasite.

**hyperplasia** The enlargement of an organ or tissue owing to an increase in the number of cells. (Hence *adj.* hyperplastic.) (cf. HYPERTROPHY and NEOPLASIA.)

**hypersensitivity** (1) (*immunol.*) The state of a PRIMED individual who, on further exposure to the relevant antigen, gives an exaggerated immune response that causes varying degrees of harm – ranging from a mild local inflammatory reaction to death. (See IMMEDIATE HYPERSENSITIVITY and DELAYED HYPERSENSITIVITY; see also BRUCELOSIS.)

(2) (*plant pathol.*) The expression of extreme reactivity by a plant in response to a potential parasite or pathogen, the plant's response commonly serving to limit or prevent parasitization/disease. Hypersensitivity typically involves rapid cell death at the (localized) site of infection and the concomitant induction of e.g. PHYTOALEXIN(s) by microbial elicitors; the induction of phytoalexins by microbial elicitors involves the expression of new host genes and the formation of new species of mRNA and new enzymes. (In addition to phytoalexin production, microbial elicitors can also apparently e.g. stimulate the formation of ETHYLENE and bring about the accumulation of LIGNIN.) (See also PATHOGENESIS-RELATED PROTEINS.) In many cases the combination of cell death and accumulation of phytoalexin(s) at the site of infection appears to provide the level of resistance needed to prevent disease development. When the challenging microorganism is an obligate parasite (i.e., a BIOTROPH), the death of host cells may, in itself, be sufficient to prevent the spread of the parasite to uninfected tissues.

**hypersensitivity pneumonitis** *Syn.* EXTRINSIC ALLERGIC ALVEOLITIS.

**hypertrophy** Enlargement of an organ or tissue owing to an increase in the size of pre-existing cells. (cf. HYPERPLASIA.)

**hypervariable region** (*immunol.*) Any of several amino acid sequences, located in the VARIABLE REGIONS of the heavy chain and light chain of IMMUNOGLOBULINS, which exhibits a degree of variability (in composition) greater than that found in other parts of the variable region. (See also COMPLEMENTARITY-DETERMINING REGIONS.)

**hypha** (*pl.* hyphae) (1) (*bacteriol., mycol.*) In many (mycelial) fungi and in some bacteria (see ACTINOMYCETALES): a branched or unbranched filament, many of which together constitute the vegetative form of the organism and (in some species) form the sterile portion of a fruiting body; a mass of vegetative hyphae is referred to as a MYCELIUM.

*Fungal hyphae.* Each hypha has a tubular CELL WALL which, in many species, is divided into compartments or cells by cross-walls (see SEPTUM (b)); in both septate and aseptate species, the cell wall is external to the CYTOPLASMIC MEMBRANE which encloses the cytoplasm, NUCLEUS or nuclei, and other components typical of eukaryotic organization. (See also VACUOLE.) The diameter of a hypha ranges from about 1 μm to macroscopic dimensions, depending e.g. on species. Hyphae grow mainly by apical extension – see GROWTH (fungal).

## hyphal body

In basidiomycetes the *primary* hyphae are uninucleate haploid hyphae which develop when basidiospores germinate; the *secondary* (dikaryotic) hyphae develop following DIKARYOTIZATION.

A *basidiocarp* may, according to species, consist of one, two or three distinct types of hypha – corresponding, respectively, to a *monomitic*, *dimitic* or *trimitic* sporocarp. A monomitic sporocarp contains only *generative hyphae*: typically thin-walled, branched, septate hyphae which give rise to basidia; generative hyphae may contain CLAMP CONNECTIONS if the organism normally forms clamps on its vegetative mycelium. A dimitic sporocarp contains generative hyphae together with either skeletal hyphae or binding hyphae (both of which originate from generative hyphae). *Skeletal hyphae* are typically thick-walled and unbranched; they are sterile (i.e., do not form basidia) and do not form clamps. *Binding* (= *ligative*) *hyphae* are sterile, highly branched, and do not form clamps; in trimitic sporocarps they bind together the generative and skeletal hyphae.

(2) (*bacteriol.*) See PROSTHECA.

**hyphal body** In some species of the ENTOMOPHTHORALES: a piece of fragmented mycelium which can germinate to form a spore-bearing structure.

**hyphenated dyad symmetry** See e.g. PALINDROMIC SEQUENCE.

**Hyphochytriaceae** See HYPHOCHYTRIOMYCETES.

**Hyphochytriales** See HYPHOCHYTRIOMYCETES.

**Hyphochytridiomycetes** See HYPHOCHYTRIOMYCETES.

**Hyphochytriomycetes** A class of fungi (subdivision MASTIGOMYCOTINA) which form zoospores having one anteriorly-directed tinsel flagellum. The organisms include terrestrial species as well as aquatic saprotrophs and parasites of other fungi and of freshwater and marine algae; they closely resemble members of the CHYTRIDIALES in morphology and life cycle, but they apparently do not carry out sexual processes. One order: Hyphochytriales; three families: Anisolpidiaceae, Hyphochytriaceae and Rhizidiomycetaceae (e.g. RHIZIDIOMYCETES).

This class has been called 'Hyphochytridiomycetes' by many authors. [Validation of the name 'Hyphochytriomycetes': Book ref. 174, p. 285.]

**Hypholoma** See AGARICALES (Strophariaceae).

**Hyphomicrobium** A genus of PROSTHECATE BACTERIA found in soils and in freshwater, estuarine and marine habitats. Morphologically, *Hyphomicrobium* resembles RHODOMICROBIUM, and its cell cycle is very similar to the 'simplified' cell cycle of *R. vannielii*; it differs from *R. vannielii* e.g. in the absence of pigments and in that its swarm cells bear a single subpolar flagellum. (Phages specific for developing daughter cells have been isolated [JGV (1979) 43 29–38].) The organisms are chemoorganotrophs which can use one-carbon compounds (e.g. methanol, methylamine) as sole sources of carbon and energy (see METHYLOTROPHY); one-carbon compounds are metabolized via the  $icl^-$  serine pathway. Growth occurs either aerobically or anaerobically with nitrate (which is reduced to nitrogen via nitrite); optimum growth temperature: 25–30°C. GC%: ca. 59–67. [Review: ARM (1981) 35 567–594.]

**Hyphomonas** A genus of Gram-negative, aerobic, asporogenous, non-photosynthetic, heterotrophic, PROSTHECATE BACTERIA which reproduce by budding; daughter cells are motile (swarm cells), having one or more flagella according to species. The cell body may vary in size and shape during the cell cycle, and usually has a single polar prostheca ('hypha'). Iron and manganese salts are not deposited on the cell surface (cf. PEDOMICROBIUM). Amino acids are the preferred substrates for growth; one-carbon compounds are not used (cf. HYPHOMICROBIUM). Species:

*H. neptunium* (isolated from seawater) and *H. polymorpha* (type species, isolated from nasal mucus from a patient with sinusitis) [IJSB (1984) 34 71–73]. Proposed species: *H. hirschiana*, *H. janmaschiana* and *H. oceanitis* [IJSB (1985) 35 237–243].

**Hyphomycetales** See HYPHOMYCETES.

**Hyphomycetes** A class of fungi of the subdivision DEUTEROMYCOTINA; most of the conidium-forming species do not form conidiomata (order Hyphomycetales), while the others form sporodochia (order Tuberculariales) or synnemata (order Stilbellales) – and some species do not form conidia at all (order AGONOMYCETALES). (cf. COELOMYCETES.) The vegetative form of the organisms is commonly a well-developed mycelium, but the class includes some fungi which can grow as unicellular organisms and which are sometimes classified in the class BLASTOMYCETES.

The class Hyphomycetes (ca. 1000 genera) includes e.g. ACICULOCONIDIUM, ACREMONIUM, ALTERNARIA, ARTHROBOTRYTS, ASPERGILLUS, AUREOBASIDIUM, BEAVERIA, BLASTOMYCETES, BOTRYTIS, BRETTANOMYCETES, CALCARISPORIUM, CANDIDA, CERCOSPORA, *Chalara*, CHRYSOSPORIUM, *Cladobotryum*, CLADOSPORIUM, COCCIDIOIDES, CRYPTOCOCCUS, CRYPTOSTROMA, CULICINOMYCETES, *Curvularia*, CYLINDROCARPON, DACTYLARIA, DACTYLELLA, DRECHSLERA, *Exophiala*, *Fonsecaea*, FULVIA, FUSARIUM, GEOTRICHUM, *Gliocladium*, *Gonatobotryts*, *Gonatobotryum*, GRAPHIUM, HARPOSPORIUM, HELMINTHOSPORIUM, HIRSUTELLA, HISTOPLASMA, HORMOCOENIS, HUMICOLA, HYPHOZYMA, KLOECKERA, MADURELLA, MALASSEZIA, MERIA, METARHIZIUM, MONACROSPORIUM, *Monodictys*, *Mycocentrospora*, MYCOGONE, MYROTHECIUM, NOMURAEA, *Oidiosis*, *Oidium*, OOSPORIDIUM, *Ovulariopsis*, PAECILOMYCETES, PARACOCCIDIOIDES, PENICILLIUM, *Periconia*, *Pesotia*, PHAFFIA, PHIALOPHORA, PITHOMYCETES, PSEUDOCERCOSPORELLA, PYRICULARIA, *Ramularia*, RHINOCLADIELLA, RHODOTORULA, RHYNCHOSPORIUM, *Scedosporium*, SCHIZOBLASTOSPORIUM, *Scopulariopsis*, *Sphaclia*, SPOROTHRIX, SPOROTRICHUM, STACHYBOTRYTS, STENELLA, STERIGMATOMYCETES, THERMOMYCETES, THIELAVIOPSIS, *Tolyopcladium*, TORULA, TRICHODERMA, TRICHOSPORON, TRICHOTHECIUM, TRIGONOPSIS, *Triposporina*, *Tritirachium*, VERTICILLIUM, WANGIELLA, XYLOHYPHA, ZALERION.

**hyphomycosis destruens** *Syn.* EQUINE PHYCOMYCOSIS.

**hyphopodium** In the mycelium of the BLACK MILDEWS: a short, one- or two-celled branch on a somatic hypha. In a *capitate hyphopodium* the distal cell is enlarged; this type of hyphopodium may act as an appressorium and give rise to a haustorium.

**Hyphozyma** A genus of yeast-like fungi of the HYPHOMYCETES. [Key to species: AvL (1986) 52 39–44.]

**hyphospore** A thick-walled resting cell.

**hyphozite** A dormant form of a parasite in a living host. (See e.g. PLASMIDIUM.)

**Hypocnemosis** See DORMANCY.

**Hypocnemosyce** See LECIDEA.

**hypochlorites** (as antimicrobial agents) Hypochlorites (and hypochlorous acid) are strong OXIDIZING AGENTS which are microbicidal e.g. for many bacteria (including endospores) and viruses; their antimicrobial activity is not inhibited by most anionic and non-ionic detergents, but they are readily inactivated by organic matter and they have a tendency to decompose, forming e.g. chlorate ( $ClO_3^-$ ) and HCl. (Decomposition is enhanced by e.g. heavy metal ions, acidity, light, and heat.) In solution, hypochlorites occur in equilibrium with hypochlorous acid, HOCl. The highly microbicidal *undissociated* form of HOCl is favoured by low pH; however, low pH reduces the stability of hypochlorites, so that commercial

sodium hypochlorite solutions are often stabilized with sodium hydroxide. Sodium hypochlorite is used in a range of DISINFECTANTS and bleaches (e.g. Chlorox, Domestos, Milton). Aerosols of hypochlorite solutions have been used for the disinfection of air. (N.B. Hypochlorite solutions react with formaldehyde to form the carcinogen *bis*-chloromethylether.) (See also DICHLOROISOCYANURATE.)

**hypocone** See DINOFLAGELLATES.

**Hypocrea** See HYPOCREALES.

**Hypocreales** An order of mainly saprotrophic, plant-parasitic or fungicolous fungi of the subdivision ASCOMYCOTINA; anamorphs occur e.g. in the genera ACREMONIUM, CYLINDROCARPON and FUSARIUM. Ascocarp: perithecioid or closed, frequently on or within a stroma and often brightly coloured. Asci: cylindrical to clavate. Ascospores: usually colourless, aseptate to multiseptate or muriform. Some genera in the order have traditionally been distinguished on the basis of the number of septa in their ascospores; spore septation has not been recognized as a valid taxonomic criterion [Mycol. Pap. (1983) Nr 150]. Genera: e.g. *Calonectria*, GIBBERELLA, *Hypocrea*, NECTRIA.

**Hypocrella** See CLAVICIPITALES.

**Hypoderma** See RHYTISMATALES.

**hypogean** Occurring underground (cf. EPIGEAN).

**Hypogymnia** A genus of LICHENS (order LECANORALES). The thallus is foliose, with often hollow, inflated lobes, grey to greyish-brown above, black beneath; rhizines are absent. *H. physodes* is very common e.g. in the UK; it is tolerant of air pollution and is often the only macrolichen to be found in and around towns and cities.

**hypolimnion** In a lake: the layer of water between the METALIMNION and the lake bottom; characteristically, it is anaerobic and rich in sulphide.

**Hypomyces** A genus of mainly fungicolous fungi of the order CLAVICIPITALES; anamorph: *Cladobotryum*. (See also COBWEB DISEASE.)

**hyponeuston** See NEUSTON.

**hypophloeodal** *Syn.* ENDOPHLOEODAL.

**Hypopylaria** A category ('section') of LEISHMANIA species which develop in the midgut and hindgut of the arthropod vector; it includes '*L. agamae*' and '*L. ceramodactyli*'. (cf. PERIPYLARIA, SUPRAPYLARIA.)

**hyposensitization** (immunol.) *Syn.* DESENSITIZATION.

**Hyposter exiguae virus** See POLYDNAVIRIDAE.

**hypostatic allele** See EPISTASIS.

**Hypostomatia** A subclass of ciliates (class KINETOFRAGMINOPHOREA) in which the cytostome (when present) generally occurs on the ventral surface, and the cytopharyngeal apparatus is of the CYRTOS type; the body is typically cylindrical or dorsoventrally flattened, and the somatic ciliature is often reduced. The orders are:

Apostomatida. Cytostome inconspicuous or absent; rosette (secretory organelle?) commonly present in the oral area; somatic ciliature spirally arranged in mature organisms; cysts common (see also TOMITE); often associated with marine

crustacea. Genera: e.g. *Chromidina*, *Foettingeria*, *Gymnodinoides*, *Polyspira*.

Chonotrichida. Typically vase-shaped and sedentary with a non-contractile stalk, attached to crustacea; reproduction by budding, producing motile ciliated forms (see also BROOD POUCH); ciliature in adult cell restricted to atrial region. Genera: e.g. *Actinichona*, CHILODOCHONA, *Spirochona*, *Stylochona*.

Cyrtophorida. Body flattened, FRANGE absent or vestigial. Genera: e.g. CHILODONELLA, *Chlamydonon*, *Dysteria*, *Hartmannula*.

Nassulida. Frange typically limited and restricted to left side of ventral surface. Genera: e.g. *Microthorax*, NASSULA, *Pseudomicrothorax*.

Rhynchodida. Cells with a single, TOXICYST-bearing anterior tentacle, typically associated with the gills of marine bivalve molluscs. Genera: e.g. *Ancistrocoma*.

Synhymeniida. Body commonly cylindrical and completely ciliated; frange extensive. Genera: e.g. *Orthodonella*.

**hypothallus** (1) (prothallus) (*lichenol.*) A pale or black layer of non-lichenized (i.e. photobiont-free) hyphae which extends from the periphery of the thallus in certain crustose (or squamulose) lichens; a hypothallus may also be evident between the areolae of certain areolate species (see e.g. RHIZOCARPON).

(2) (of myxomycetes) A thin, often transparent, sometimes calcified deposit which is secreted by the plasmodium during fruiting, and which forms a base for the fruiting bodies, remaining on the substratum following fruiting body formation. In some cases the hypothallus may be simply a remnant of the plasmodial slime sheath.

**hypotheca** (1) See DINOFLAGELLATES. (2) See DIATOMS.

**hypothecium** See APOTHECIUM.

**Hypotrichida** An order of typically free-living ciliate protozoa (class POLYHYMENOPHOREA). Cells: typically ovoid to elongate and dorsoventrally flattened, with a conspicuous oral ciliature and a number of groups of cirri on the ventral side; the dorsal side often carries pairs of short cilia ('sensory bristles'). Genera include e.g. ASPIDISCA, EUPLOTES, *Histiculus*, *Holosticha*, *Isosticha*, *Klonotricha*, *Oxytricha*, *Psammomitra*, *Strongylidium*, *Stylonychia*, *Trachelostyla*, *Uronychia*, *Urosoma*, *Urostyla*.

**hypovalve** See DIATOMS.

**hypovirulence** A reduced level of virulence in a strain of pathogen due e.g. to genetic changes in the pathogen, or to the effects on the pathogen of an infectious agent (*contagious* or *transmissible hypovirulence*: see e.g. CHESTNUT BLIGHT and DUTCH ELM DISEASE).

**hypoxanthine** The base in the nucleoside *inosine* [see Appendix V(a) for structure]. (See also NITROUS ACID and WOBBLE HYPOTHESIS.)

**hypoxanthine-DNA glycosylase** See NITROUS ACID.

**Hypoxylon** See SPHAERIALES.

**Hys plasmid** See ESCHERICHIA.

**hystrichosphaerids** (hystrichospheres; hystricospores) Fossil resting spores of DINOFLAGELLATES; they date from the late Triassic onwards. [Book ref. 136, pp. 847-964.]

**Hyuga fever** See EHRLICHIA.

# I

**I** Isoleucine (see AMINO ACIDS).

**(I + C + D) model** *Syn.* HELMSTETTER-COOPER MODEL.

**I-like pili** See PILI.

**I period** See HELMSTETTER-COOPER MODEL.

**Ia antigens** Class II antigens of the murine MAJOR HISTOCOMPATIBILITY COMPLEX. (See also IR GENES.)

**Ia protein** The *Escherichia coli* OmpF PORIN.

**IAA** Indole 3-acetic acid (see AUXINS).

**IAEA** International Atomic Energy Agency.

**IAHS** Infection-associated haemophagocytic syndrome: see HAEMOPHAGOCYTIC SYNDROME.

**IAM** Institute of Applied Microbiology, University of Tokyo, Yayoi, Bunko-Ku, Tokyo, Japan.

**IAP** Intracisternal A-TYPE PARTICLE.

**iatrogenic** Refers to any disease or infection which is caused or exacerbated, unintentionally, as a result of medical intervention – e.g. examination or treatment.

**IAVI** International AIDS Vaccine Initiative.

**Ib protein** The *Escherichia coli* OmpC PORIN.

**ibotenic acid** See AMATOXINS.

**IBV** Infectious bronchitis virus (CORONAVIRIDAE).

**ICAD** See APOPTOSIS.

**ICAM-1** *Syn.* CD54.

**ICAM-2** See CD102.

**ICAM-3** See IMMUNOGLOBULIN SUPERFAMILY.

**ICDH** Isocitrate dehydrogenase: see TCA CYCLE.

**ICE** (*syn.* caspase-1) See APOPTOSIS.

**ice algae** See DIATOMS.

**ice nucleation bacteria** Those bacteria which, at temperatures just below 0°C, promote water-to-ice transition by acting as nuclei around which ice crystals can form. Such bacteria (e.g. strains of *Erwinia herbicola*, *Pseudomonas fluorescens*, *P. syringae* and *Xanthomonas campestris*) – which include some common epiphytes – have been implicated as contributory factors in frost damage in various agricultural crops.

A DNA fragment from *P. fluorescens*, when cloned in *Escherichia coli*, can confer the ice-nucleation phenotype; the fragment may encode an OUTER MEMBRANE protein of MWt ca. 180000 [EMBO (1986) 5 231–236]. When grown at 15°C, most ice-nucleation-positive strains of *Erwinia herbicola* shed into the medium vesicles composed of outer membrane; these vesicles ('cell-free ice nuclei') can behave as ice-nucleation centres which are active at –2°C to –10°C [JB (1986) 167 496–502].

Some plant tissues survive, without damage, when 'super-cooled' to several degrees below 0°C – but may suffer frost damage if ice-nucleation bacteria are present. Above (approx.) –5°C, the incidence of frost injury can be decreased by reducing the size of the populations of plant-contaminating ice-nucleation bacteria. This can be done e.g. by treatment of plant surfaces with antibiotics such as streptomycin or oxytetracycline; an alternative method is to treat plant surfaces with non-ice-nucleating bacteria (a form of BIOLOGICAL CONTROL). A combination of antibiotic treatment and biological control has been found to act additively in the control of frost injury in pear trees [Phytopathol. (1996) 86 841–848].

**Iceland moss** See CETRARIA.

**ich** See ICHTHYOPHTHIRIASIS.

**ichthyo-** Prefix denoting fish – e.g. ichthyopathology: the study of FISH DISEASES; ichthyotoxic: toxic to fish.

**ichthyophonus** A systemic, granulomatous FISH DISEASE caused by *Ichthyophonus hoferi* (see ICHTHYOPHONUS); external symptoms vary in nature and severity (cf. TAUMELKRANKHEIT). *I. hoferi* occurs in various host tissues, mainly as spherical, thick-walled, multinucleate cells ('cysts', 'resting spores') up to 200 µm or more in diameter; immediately after the death of the host the 'cysts' germinate to form branching hyphae. The disease can affect e.g. mackerel and salmonids, and has caused mass fatalities in Atlantic herring; infected fish are, or rapidly become, unsuitable for human consumption as the muscles rapidly degenerate after the death of the fish. [Review: Book ref. 1, pp. 243–269.]

**Ichthyophonus** A genus of fungi (or protozoa? – taxonomic affinity unknown) parasitic in fish. Species: *I. hoferi* (see ICHTHYOPHONOSIS) and *I. gasterophilum*. (cf. ICHTHYOSPORIDIUM.)

**ichthyophthiriasis** (white spot, ich, ick) A freshwater FISH DISEASE caused by the ciliate *Ichthyophthirius multifiliis*. White spots 1 mm or so across, each containing one or more ciliates, appear on skin and fins; affected fish are weakened and may die. Secondary SAPROLEGNIASIS is common. *I. multifiliis* needs well-oxygenated waters and may be controlled e.g. by raising the temperature to diminish dissolved oxygen levels.

**Ichthyophthirius** A genus of ciliates (order HYMENOSTOMATIDA); *I. multifiliis* is the causal agent of ICHTHYOPHTHIRIASIS in freshwater teleost fish. (cf. CRYPTOCARYON.) The life cycle of *I. multifiliis* involves three stages. The stage infective for fish is an ovoid or fusiform cell (called a *tomite* or *theront*), ca. 15 × 40 µm, which is covered with cilia, and which has a filamentous projection at the anterior end. Within the fish's epidermis the tomita becomes spherical and develops an oral apparatus – becoming a *trophozoite* (= *trophont*) which grows to ca. 100–1000 µm diam. When free of the host, the trophozoite forms a gelatinous exocyst, loses its oral apparatus, and undergoes schizogony. Cysts, each several hundred micrometres in size, may contain up to ca. 1000 tomites which are released to complete the life cycle.

[SEM of stages in the life cycle of *I. multifiliis*: J. Parasitol. (1985) 71 218–226; development of *I. multifiliis* in gill epithelium: JP (1986) 33 369–374.]

**Ichthyosporidium** A genus used by some to include members of the genus ICHTHYOPHONUS, and by others to include microsporidean protozoa parasitic in fish.

**ichthyotoxin** A TOXIN which is active against fish.

**ick** See ICHTHYOPHTHIRIASIS.

**icl** See SERINE PATHWAY.

**ICL** Isocitrate lyase: see TCA CYCLE and SERINE PATHWAY.

**icm genes** (of *Legionella pneumophila*) See end of section (a) in PHAGOCYTOSIS.

**ICMSF** International Commission on Microbiological Specifications for Foods, an organization of the International Union of Microbiological Societies.

**ICNV** International Committee on Nomenclature of Viruses, superseded by the ICTV.

**icosahedral symmetry** (5-3-2 symmetry) The symmetry exhibited by an ICOSAEDRON and by the capsid of certain types of virus: 5-fold rotational symmetry through each of the 12 apices; 3-fold rotational symmetry about an axis through the centre of each of the 20 triangular faces; and 2-fold rotational symmetry about an axis through the centre of each of the 30 edges.

A viral capsid having *strict* icosahedral symmetry would be constructed from exactly 60 identical building units arranged in positions of exact equivalence on the surface of a hypothetical sphere, the units being held together via identical (strictly equivalent) interunit contacts throughout. In most viruses, however, the genome is too large to fit into a capsid composed of 60 reasonably sized units, and in many 'icosahedral' viruses the number of units which form the capsid is a *certain* multiple of 60 (n60); in some viruses (e.g. polioviruses) the n60 units include units of more than one type, while in other viruses all the units are identical. The construction of a symmetrical capsid with n60 units requires that the units be arranged in 60-unit sets, the members of each set being distributed throughout the capsid. In such an arrangement of (n60) units, the interunit contacts are not precisely identical throughout the capsid; however, since all interunit bonding involves the same general type of contact, the interunit bonds in such a capsid are described as 'quasi-equivalent'.

In the smaller icosahedral capsids consisting of n60 units, the units are (of necessity) arranged into 5- and 6-membered rings, each ring forming a tight cluster – referred to as a PENTAMER or *hexamer*, respectively – that may be distinguishable in electron micrographs; the clustering of units in this way maximizes contact between the units. In such capsids a pentamer occupies each of the 12 apexes. (The existence of 5- or 6-membered clusters does not necessarily mean that members of a given cluster are bound more strongly to each other than they are to adjacent units; thus, e.g. many viruses which have 180-unit capsids yield dimers (2-unit particles) when gently disrupted.) In some cases a pentamer or hexamer may appear, under the electron microscope, as a single entity – which may be referred to as a *morphological unit* or *capsomer* (= *capsomere*).

In those icosahedral viruses whose capsids comprise up to 240 building units, the value of *n* (in n60) can be 1, 3 or 4 (depending on virus); in these viruses, *n* (i.e., the number of 60-unit sets in the capsid) corresponds to the *triangulation number* (T number, or T). The large icosahedral viruses (e.g. adenoviruses) deviate from the geometrical and structural criteria obeyed by the smaller icosahedral viruses.

[Principles of virus structure: Book ref. 148, pp. 27–44.]

**icosahedron** A solid figure contained by 20 plane faces, all the faces being equilateral triangles of the same size. Many viruses have ICOSAHEDRAL SYMMETRY.

**ICP** (insecticidal crystal protein) See BIOLOGICAL CONTROL.

**ICPB** International Collection of Phytopathogenic Bacteria, Department of Bacteriology, University of California, Davis, California 95616, USA.

**ICR compounds** See ACRIDINES.

**IcsA protein** See DYSENTERY and PROTEIN SECRETION (type IV systems).

**icteroanaemia** (porcine) See EPERYTHROZONOSIS.

**icterus** Jaundice.

**ICTV** International Committee on Taxonomy of Viruses. (cf. ICNV.)

**id reaction** The formation of skin lesions at sites remote from a focus of infection; such lesions are commonly sterile, and they may represent a local HYPERSENSITIVITY response to the infection. If the infecting organism is e.g. *Trichophyton* the reaction is termed trichophytid.

**ID<sub>50</sub>** Infectious dose (50%): that dose of a given infectious agent which, when given to each of a number of experimental test systems or animals, brings about the infection of 50% of the systems/animals under given conditions.

**IDAV** See HIV.

**idiogram** See KARYOTYPE.

**idiolite** A product of SECONDARY METABOLISM.

**idiopathic** (of a disease) Of unknown cause.

**idiophase** In BATCH CULTURE, that phase in which SECONDARY METABOLISM is dominant (cf. TROPHOPHASE); it corresponds to the latter part of the log phase together with the stationary phase.

**idiosome** (*protozool.*) See XENOSOME (2).

**idiotope** See IDIOTYPE.

**idiotype** An Ig molecule defined by the sum total of antigenic determinants (*idiotopes*) on its variable (V<sub>H</sub> and/or V<sub>L</sub>) domains.

**idli** A type of steamed bread from India. It is made from a batter of milled rice and black gram (*Phaseolus mungo*) which is left to ferment overnight. The fermentation is carried out mainly by *Leuconostoc mesenteroides* which produces acid and gas; *Enterococcus faecalis*, and sometimes *Pediococcus cerevisiae*, contribute acidity, and yeasts may also be involved. The leavened batter is then steamed.

**idling** During DNA replication: repeated cycles of addition and excision of nucleotides at a 3' terminal with no net synthesis or degradation of DNA. [Idling as a mechanism in lagging strand synthesis: GD (2004) 18 2764–2773.]

**idoxuridine** (IDU; 5-iodo-2'-deoxyuridine; IUDR) An ANTIVIRAL AGENT which acts as an analogue of thymidine (5-methyl-2'-deoxyuridine). Selective toxicity is poor, and the drug is too toxic for systemic use; it may be used topically for the treatment of e.g. herpes simplex keratitis, but is being superseded by more recent antiviral drugs.

**IDU** IDOXURIDINE.

**IEF** ISOELECTRIC FOCUSING.

**IEM** IMMUNOELECTRON MICROSCOPY.

**IEP** (1) ISOELECTRIC POINT. (2) IMMUNOELECTROPHORESIS.

**IF** INTERMEDIATE FILAMENT.

**IF-1, IF-2, IF-3** See PROTEIN SYNTHESIS.

**IF<sub>1</sub> protein** See PROTON ATPASE.

**IFA test** *Syn.* IFAT.

**IFAT** See indirect IMMUNOFLOUORESCENCE.

**IFN** INTERFERON.

**IFO** Institute for Fermentation, 17–85 Juso-Honmachi, 2-Chome, Yodogawa-Ku, Osaka, Japan.

**IFT** *Syn.* IFAT.

**Ig** IMMUNOGLOBULIN.

**IgA** Immunoglobulin A, the predominant IMMUNOGLOBULIN in saliva, tears, colostrum and other body fluids, but comprising only ca. 10% of the total plasma Igs. The IgA monomer (MWt ca. 160000; S<sub>20</sub><sup>0</sup> 7) contains *alpha* HEAVY CHAINS, *kappa* or *lambda* LIGHT CHAINS, and ca. 8% carbohydrate. Most IgA at mucosal surfaces (secretory IgA, sIgA, SIgA) is in dimeric form: two monomers are linked via a J CHAIN, and the whole is linked to the SECRETORY COMPONENT. Polymers larger than dimers are also formed. IgA can fix complement via the alternative pathway. There are two subclasses: IgA1 and IgA2. (See also entry IgA1 proteases.)

**IgA1 proteases** Various extracellular bacterial enzymes which specifically cleave the human IgA1 antibody at the heavy-chain hinge region – but which do not affect IgA2; some are sensitive to EDTA. These enzymes are synthesized by e.g. *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *N. meningitidis* and *Streptococcus pneumoniae* – bacteria which are typically pathogenic at or via the mucosal surfaces; presumably, IgA1 proteases counteract the host's IgA1 defences, but the role of these enzymes in pathogenesis has not been established.

At least some IgA1 proteases are secreted by a type IV system (see PROTEIN SECRETION).

## IgD

**IgD** Immunoglobulin D, an IMMUNOGLOBULIN present in very low concentrations in plasma; it occurs mainly as a surface receptor for antigen on the membranes of B LYMPHOCYTES. The IgD molecule (MWt ca. 175000;  $S_{\text{W}}^{20}$  7) contains *delta* HEAVY CHAINS, *kappa* or *lambda* LIGHT CHAINS, and ca. 12–13% carbohydrate.

**IgE** Immunoglobulin E, an IMMUNOGLOBULIN found in minute quantities in plasma. The IgE molecule (MWt ca. 190000;  $S_{\text{W}}^{20}$  8) contains *epsilon* HEAVY CHAINS, *kappa* or *lambda* LIGHT CHAINS, and ca. 12% carbohydrate. IgE binds to basophils and mast cells via its Fc portion, causing degranulation in the presence of specific allergen and thus effecting a TYPE I REACTION; cytophilic activity is abolished e.g. by heating (56°C/3–4 hours).

**IgG** Immunoglobulin G, the predominant IMMUNOGLOBULIN in plasma (ca. 9–16 mg/ml, 75% of total plasma Ig). The IgG molecule (MWt ca. 150000;  $S_{\text{W}}^{20}$  7) contains *gamma* HEAVY CHAINS, *kappa* or *lambda* LIGHT CHAINS, and ca. 3% carbohydrate. There are four subclasses – IgG1, IgG2, IgG3 and IgG4 – distinguished by differences in amino acid sequences and by serology; human IgG subclasses are numbered in order of their concentrations in plasma: IgG1 comprises ca. 65% of plasma IgG. IgG1 and IgG3 are bivalent COMPLEMENT-FIXING ANTIBODIES (half-life ca. 21 and 7 days, respectively) which are important e.g. as opsonins and antitoxins in extravascular regions as well as in the bloodstream; in humans, they can cross the placenta and are important in the protection of the fetus and neonate. (Efficient binding of complement component C1 appears to require an IgG doublet, i.e. two molecules side by side; a single IgG molecule binds C1 only weakly.) IgG antibodies generally appear to predominate in the secondary (anamnestic) humoral response to antigen. (See also ALLOTYPE.)

**IgG protease** See e.g. ELASTASE.

**IgM** (macroglobulin) Immunoglobulin M, a minor plasma IMMUNOGLOBULIN (comprising ca. 5–10% of total plasma Ig); phylogenetically, IgM is apparently the most primitive class of Igs. The IgM monomer (MWt ca. 180000) contains *mu* HEAVY CHAINS, *kappa* or *lambda* LIGHT CHAINS, and ca. 12% carbohydrate; monomeric IgM occurs as a surface receptor for antigen on the B LYMPHOCYTE membrane. The typical form of IgM is a pentamer ( $S_{\text{W}}^{20}$  19) in which the five monomers are arranged radially (Fc portions directed towards the centre) and connected via disulphide bonds, with a J CHAIN at the centre of the polymer; in the free (uncombined) form, an IgM antibody is therefore stellate, but pentameric IgM is sufficiently flexible to assume a spider-like conformation in order to combine with multiple-repeating antigens on a surface. (IgM antibodies are thus particularly good agglutinators of those antigens, e.g. bacteria, which display a pattern of repeated antigenic determinants.) IgM antibodies are COMPLEMENT-FIXING ANTIBODIES with a theoretical valency of 10. Maximum valency is generally exerted only with small haptens; with larger antigens the effective valency is often only 5. (It appears that an IgM antibody must bind antigen at more than one of its combining sites in order to be able to fix complement [Mol.Immunol. (1981) 18 863–868, cited in Book ref. 42, p. 647].) In man, IgM does not pass through blood vessel walls into the tissues, and does not cross the placenta; its half-life is ca. 5 days. IgM antibodies are often the first to be formed in the humoral response to antigen; the humoral response to THYMUS-INDEPENDENT ANTIGENS (such as purified pneumococcal polysaccharides) generally involves, almost exclusively, the formation of IgM antibodies. The Wassermann antibody (see WASSERMANN REACTION) and the rheumatoid factor (see RHEUMATOID ARTHRITIS) are largely or exclusively IgM antibodies.

**IGS** (*mol. biol.*) Internal guide sequence: see SPLIT GENE (b).

**IHF** INTEGRATION HOST FACTOR.

**IκBα** See CYTOKINES.

**IL** Abbreviation for interleukin. See separate entries for INTERLEUKIN-1 (IL-1), INTERLEUKIN-2 (IL-2) etc.

**IL-1** INTERLEUKIN-1.

**IL-1γ** *Syn.* INTERLEUKIN-18.

**IL-2** INTERLEUKIN-2.

**ilarviruses** ('isometric labile ringspot viruses'; tobacco streak virus group) A group of tripartite ssRNA-containing PLANT VIRUSES which have a wide host range; transmission occurs via seeds and pollen and can readily occur mechanically. Type member: tobacco streak virus; other members include e.g. apple mosaic virus, *Citrus* leaf rugose virus, *Citrus* variegation virus, *Prunus* necrotic ringspot virus, spinach latent virus, Tulare apple mosaic virus.

Virions: quasi-isometric, occasionally bacilliform; several types occur, differing in size (ca. 26–35 nm diam.) and in  $S_{\text{W}}^{20}$ . Genome: three molecules of linear positive-sense ssRNA: RNA1 (MWt ca.  $1.1 \times 10^6$ ), RNA2 (MWt ca.  $0.9 \times 10^6$ ) and RNA3 (MWt ca.  $0.7 \times 10^6$ ); the coat protein mRNA ('RNA4') is also encapsidated. RNAs 1, 2 and 3, together with coat protein or RNA4, are required for infectivity (cf. ALFALFA MOSAIC VIRUS).

**ileocaecal syndrome** *Syn.* NEUTROPENIC ENTEROCOLITIS.

**Ilheus virus** See FLAVIVIRIDAE.

**illegitimate name** In NOMENCLATURE: a validly published name which contravenes any rule(s) of the relevant nomenclatural code.

**illegitimate recombination** Fortuitous RECOMBINATION which occurs between DNA sequences which are non-homologous or which have very short regions of homology. In *Escherichia coli* illegitimate recombination is *recA*-independent and may be mediated by GYRASE: strands cleaved during gyrase action at different sites may undergo crossing over by the exchange of gyrase subunits covalently bound to the cut ends [model: PNAS (1983) 80 2452–2456].

**imazalil** An agricultural systemic ANTIFUNGAL AGENT, an imidazolyl derivative which acts as an inhibitor of sterol biosynthesis, thereby disrupting the cytoplasmic membrane in susceptible fungi. Imazalil is used – mixed with e.g. guazatine or thiophanate-methyl – as a seed treatment against many seed-borne pathogens of cereals (e.g. *Ustilago* and *Pyrenophora* spp). It is also effective against *Penicillium* diseases of citrus fruits.

**imbricated** Overlapping, like tiles on a roof.

**ImD unit** See MICROCOMPLEMENT FIXATION.

**IMF** INTERMEDIATE FILAMENT.

**imf phosphorylation** See ELECTRON TRANSPORT PHOSPHORYLATION.

**Imhoff tank** A large tank formerly widely used for SEWAGE TREATMENT. Essentially, crude sewage flows into a sludge settlement chamber located within a larger tank; sludge falls from a slot in the settlement chamber into the main digester compartment where it undergoes ANAEROBIC DIGESTION. The tank is vented for the escape of gases.

**IMI** Imperial Mycological Institute, the former name of the Commonwealth Mycological Institute, Kew, UK.

**imidazole antifungal agents** See AZOLE ANTIFUNGAL AGENTS.

**imipenem** See THIENAMYCIN.

**immediate hypersensitivity** (*immunol.*) HYPERSENSITIVITY mediated by humoral antibodies: see TYPE I REACTION, TYPE II REACTION, TYPE III REACTION, TYPE V REACTION (cf. DELAYED HYPERSENSITIVITY). Immediate hypersensitivity reactions typically occur within minutes or hours of contact with specific

antigen; they are also referred to as *immediate-type* hypersensitivity reactions to include those which require hours or days to develop.

**immediate-type hypersensitivity** See IMMEDIATE HYPERSENSITIVITY.

**Immersion filter** See SEWAGE TREATMENT.

**immersion lens** See RESOLVING POWER.

**immersion oil** Cedarwood or synthetic oil (refractive index ca. 1.5) used with oil-immersion objectives (see RESOLVING POWER). In *homogeneous immersion* the immersion oil, objective lens, and cover-glass all have the same refractive index. Oil should be removed from the objective with a lens tissue immediately after use; unless otherwise recommended, a suitable solvent is 1,1,1-trichloroethane, but benzene or xylene can be used. Prolonged contact with solvents may damage lens mountings.

**immobilization** (1) (*biotechnol.*) Microbial, plant or animal cells, or macromolecules, may be 'immobilized' by attachment to solid structures, incorporation in gels etc for use in e.g. BIOCONVERSIONS (sense 1) – in some cases on an industrial scale. Various immobilized macromolecules are used e.g. in procedures involving affinity CHROMATOGRAPHY.

*Enzymes* are immobilized because soluble enzymes are difficult to separate from substrates or products (and, hence, cannot be re-used in industrial processes), and most are unstable under conditions of use. The main methods of enzyme immobilization are: (a) Binding to a solid carrier or support. Supports used for covalent binding include e.g. cellulose, ceramic, glass, steel and synthetic polymers; usually, the support is 'activated' (see e.g. CYANOGEN BROMIDE), and the enzyme is then allowed to bind (commonly via its amino or carboxyl groups) to the activated support. The active site of the enzyme can be protected by allowing binding to occur in the presence of the enzyme's substrate. Supports used for *ionic* binding include ion exchangers such as DEAE-cellulose. (b) Cross-linking with bifunctional reagents to form insoluble aggregates. Reagents used include GLUTARALDEHYDE (which binds enzymes via their amino groups), or diamines (e.g. hexamethylenediamine) which bind enzymes via their carboxyl groups after these groups have been 'activated' with carbodiimides; e.g., immobilized glucose isomerase is manufactured by treating pellets of homogenized cells of *Bacillus coagulans* with glutaraldehyde, yielding water-insoluble aggregates containing glucose isomerase and other proteins. (c) Encapsulation. Enzymes are enclosed within LIPOSOMES or hollow fibres which are permeable to low-MWt substrates and products. (d) Entrapment within polymeric gels such as calcium ALGINATE,  $\kappa$ -CARRAGEENAN and polyacrylamide. Enzymes are added to a solution of the polymer which is then gelled e.g. by the addition of a gelling agent. Leakage of enzymes from the gel may be counteracted by cross-linking them e.g. with glutaraldehyde. Entrapment is suitable primarily for bioconversion of low-MWt substrates which can diffuse through the gel.

Immobilized enzymes are used for simple one-step or two-step bioconversions in which there is no need for regeneration of coenzymes. [Potential for immobilization of coenzyme-dependent enzymes: PTRSLB (1983) 300 335–367.] In some cases immobilization can improve the stability of enzymes which may otherwise be inadequate under operational conditions; e.g. immobilization of proteases inhibits their mutual degradation, and multipoint binding of an enzyme to its support helps to retain the conformational integrity of the enzyme – protecting it from inactivation by various denaturing agents (e.g. heat).

*Immobilized cells* can be used for bioconversions which are not possible with isolated enzymes; the use of cells saves the cost

and labour of preparing purified immobilized enzymes. Cells can be immobilized by the methods used for enzymes (see above), but entrapment is the most commonly used method; gels used include e.g. agar, alginate,  $\kappa$ -carrageenan, polyacrylamide, and polyurethane. Dead cells may be used for simple one-step or two-step reactions (provided they retain specific enzymic activity), but living cells are necessary for multistep transformations in which several enzymes act sequentially and/or in which there is a need for the regeneration of cofactors. Examples of the industrial use of dead immobilized cells include e.g. *Escherichia coli* in a  $\kappa$ -carrageenan gel for the production of L-aspartic acid from ammonium fumarate, and '*Brevibacterium flavum*' in a  $\kappa$ -carrageenan gel for the production of L-malic acid from fumaric acid. High cell densities can be achieved with immobilized living cells. Thus, e.g., in one process used for the production of ethanol, *Saccharomyces cerevisiae* ('*S. carlsbergensis*') is immobilized in carrageenan, and 'beads' of the gel (containing  $3.5 \times 10^6$  cells/ml) are incubated in a shaken nutrient medium for 60 hours: cell density rises to over  $5 \times 10^9$  cells/ml – ca. 10 times higher than that possible in a conventional broth culture – with the yeast cells densely packed within the surface layer of each bead. When such beads are packed into a column and fed with a glucose-containing nutrient medium they produce ethanol efficiently for long periods of time. Other uses of immobilized living cells include the production of hydrogen from cells of *Anabaena cylindrica* bound to glass beads, and the production of an extracellular  $\alpha$ -amylase by *Bacillus subtilis* immobilized in a polyacrylamide gel.

[Book ref. 3, pp. 203–222, and PTRSLB (1983) 300 369–389 (cells); Book ref. 31, pp. 331–367 (enzymes); Science (1983) 219 722–727.]

(2) The inhibition of MOTILITY in a microorganism – e.g. by a specific antiserum (see IMMOBILIZATION TEST).

**immobilization test** Any test which involves the inhibition of MOTILITY in a microorganism. Immobilization tests can be used e.g. to detect specific antibodies (see e.g. TPI TEST) or organisms (e.g. a given strain of *Vibrio cholerae* may be identified by determining which types of specific antibody inhibit its motility). Antibodies may immobilize a motile organism e.g. by mediating the adhesion of flagella, or by promoting IMMUNE CYTOLYSIS.

**immune** (1) (*adj.*) Refers to the state of IMMUNITY (sense 2 or 3). (2) (*noun*) See EPIDEMIOLOGY.

**immune adherence** A phenomenon in which antigen–antibody complexes that have triggered COMPLEMENT FIXATION adhere firmly to receptors on phagocytes; the enhanced adhesion (which adds to that due to direct antigen–antibody–phagocyte interaction) is due mainly to component C3b.

The phrase 'immune adherence' is sometimes used also to refer to the totality of pathogen–phagocyte adherence, i.e. including both antibody-mediated and complement-mediated adhesion.

**immune complex** An antigen–antibody complex. Small, soluble (i.e. non-precipitating) immune complexes are formed e.g. under ANTIGEN EXCESS conditions. (See also TYPE III REACTION.)

**immune cytotoxicity** The lysis of a cell which has been sensitized (SENSITIZATION sense 3) and which has triggered COMPLEMENT FIXATION; lysis may result directly or indirectly from the formation of a pore, in the membrane, created by the membrane attack complex. (cf. REACTIVE LYSIS.)

**immune deficiency-associated virus** See AIDS.

**immune electron microscopy** IMMUNOELECTRON MICROSCOPY.

**immune globulin** Antiserum (or its immunoglobulin fraction) containing antibodies to a particular antigen or antigens.

## immune haemolysis

**immune haemolysis** IMMUNE CYTOLYSIS of erythrocytes.

**immune lysis** *Syn.* IMMUNE CYTOLYSIS.

**immune response** The response(s) of a person or animal to immunological contact with an antigen; such responses may involve e.g. priming (see PRIMED), ANTIBODY FORMATION, AN ANAMNESTIC RESPONSE, a HYPERSENSITIVITY reaction, or IMMUNOLOGICAL TOLERANCE. (See also ANTIGENIC COMPETITION.)

**immune serum** *Syn.* ANTISERUM.

**immune surveillance** *Syn.* IMMUNOSURVEILLANCE.

**immune tolerance** See IMMUNOLOGICAL TOLERANCE.

**immunity** (1) A state characterized by the tendency of the body to reject, eliminate or otherwise counteract foreign ('non-self') or seemingly foreign materials, or organisms, on or within its tissues; in this (broadest) sense immunity includes AUTOIMMUNITY, HYPERSENSITIVITY and IMMUNOLOGICAL TOLERANCE as well as other forms of SPECIFIC IMMUNITY, and NON-SPECIFIC IMMUNITY. (2) The state of an individual who, having had prior contact with a given antigen, can react to further contact with that antigen more vigorously than can a non-immune individual; in this sense immunity includes all the (beneficial and harmful) manifestations of HUMORAL IMMUNITY and CELL-MEDIATED IMMUNITY, including HYPERSENSITIVITY. (3) (protective immunity; functional immunity) Relative insusceptibility to specific harmful agents (e.g. pathogens) involving only the beneficial effects of humoral immunity and/or cell-mediated immunity.

**immunity breakdown** See COLICINS.

**immunity groups** See e.g. COLICIN E.

**immunity protein** See e.g. COLICIN PLASMID; COLICINS; KILLER FACTOR.

**immunization** (1) Any procedure in which specific microorganisms and/or antigenic materials (see VACCINE), or pre-formed antibodies, are introduced into the body in order to bring about specific *protective* IMMUNITY. (cf. INOCULATION (2) and VACCINATION.) Stimulation of the body's own immune response (by administration of a vaccine) is referred to as *active immunization*; the (parenteral) administration of pre-formed antibodies is called *passive immunization* (see also PASSIVE IMMUNITY). (2) The administration of antigen to elicit any form of SPECIFIC IMMUNITY. (See also ISOIMMUNIZATION; HETEROIMMUNIZATION; NON-SPECIFIC IMMUNIZATION.)

**immunoadjuvant** See ADJUVANT (1).

**immunoassay** Any procedure in which the specificity of the antigen-antibody reaction is used for detecting and quantifying antigens, antibodies, or substance(s). (See e.g. ELISA; ERYTHROIMMUNOASSAY; ENZYME IMMUNOASSAY; IMMUNORADIOMETRIC ASSAY; PREGNANCY TEST; RADIOIMMUNOASSAY.)

**immunoblotting** See BLOTTING.

**immunocompromised** Unable to exhibit a normal immune response.

**immunoconglutinins** Autoantibodies homologous to certain bound components of COMPLEMENT, particularly C3b; titres of serum immunoconglutinins are raised in long-term autoallergic conditions and in some diseases of microbial aetiology. Immunoconglutinins possibly play a role in the agglutination and phagocytosis of small, C3b-containing complexes. (cf. CONGLUTININ.)

**immunocyte** Any functional cell of the immune system.

**immunocyte adherence technique** (rosette technique) A method used e.g. for detecting cells which form specific antibodies. When such cells are incubated with homologous particulate antigen (or with erythrocytes coated with homologous soluble antigens) the antigenic particles adhere to specific receptor sites on the surfaces of the antibody-forming cells, forming rosettes. (See also PROTEIN A.)

**immunodeficiency** The inability to respond with a normal immune response to antigenic stimulation. (See also e.g. AIDS.)

**immunodepression** *Syn.* IMMUNOSUPPRESSION.

**immunodiffusion** See GEL DIFFUSION.

**immunodominant** See DETERMINANT and ANTIGENIC COMPETITION.

**immunolectron microscopy** A procedure used e.g. for locating particular antigens in cells or tissues. Essentially, the given antigen is isolated and an antiserum is raised against it. The homologous antibodies are labelled with e.g. FERRITIN and then allowed to combine with the antigen in the cells or tissue; on examination by transmission ELECTRON MICROSCOPY the location of the given antigen is indicated by the ferritin label. (The use of ferritin in this way is called the *immunoferritin technique*.) (cf. IMMUNOSORBENT ELECTRON MICROSCOPY; see also IMMUNOGOLD TECHNIQUE.)

**immuno-electrophoresis** (IEP) Any procedure in which antibodies (or other serum proteins) and/or antigens are subjected to ELECTROPHORESIS prior to their detection, characterization, or quantification (e.g. by means of specific antigen-antibody precipitation or staining). In one form of IEP the serum (or other) sample is first subjected to electrophoresis in a strip of agarose (or other) gel. This separates components into discrete zones – each zone containing one or more proteins characterized by a specific electrophoretic mobility. (Some proteins migrate in an unexpected direction – see ELECTROENDOSMOSIS.) A rectangular slot ('trough'), cut into the gel strip parallel to the line of electrophoretic migration, is filled with antiserum containing antibodies to some or all of the proteins in the sample; the proteins and their homologous (and/or cross-reacting) antibodies diffuse through the agar and form lines or arcs of precipitate where they meet in OPTIMAL PROPORTIONS (see GEL DIFFUSION). (See also CHARGE-SHIFT IMMUNOELECTROPHORESIS; COUNTERCURRENT IMMUNOELECTROPHORESIS; ROCKET IMMUNOELECTROPHORESIS; TWO-DIMENSIONAL ELECTROPHORESIS.)

**immunoferritin technique** See IMMUNOELECTRON MICROSCOPY.

**immunofluorescence** The use of a fluorescent antibody (i.e. antibody conjugated with a FLUOROCHROME such as FITC, FLUORESCIN, or RHODAMINE isothiocyanate) for the detection and/or quantification of a specific antigen (or antibody). In the simplest (*direct*) immunofluorescence techniques, used to detect antigen, the specimen (tissue section, smear etc) is exposed to the conjugate (i.e. dye-linked antibody) for an appropriate time, washed free of conjugate, and examined by fluorescence MICROSCOPY; antigens homologous to the fluorescent antibodies are readily identified by regions of fluorescence in the specimen. In the *indirect* immunofluorescence technique (e.g. the indirect fluorescent antibody test, IFAT) the presence of a given antigen can be determined by first exposing the specimen to *unstained* antibodies (e.g. a serum containing antibodies homologous to the given antigen); the specimen is then washed free of uncombined antibodies, exposed to fluorescent anti-Ig antibodies, washed, and examined by fluorescence microscopy. Any antigen-antibody combination on the specimen can thus be detected by the presence of fluorescent antibodies (which bind to the unstained antibodies); if particular antigens are known to be present in the specimen, the test can be used to detect homologous antibodies in the serum. Another type of indirect immunofluorescence technique is referred to as the SANDWICH TECHNIQUE.

In all immunofluorescence techniques adequate controls are necessary to preclude an interpretation based on the non-specific localization of conjugate, and to take into account any *primary* FLUORESCENCE.

(See also FLOW MICROFLUOROMETRY.)

**immunogen** (1) *Syn.* ANTIGEN. (2) An antigen which can stimulate *protective* immunity.

**immunogenicity** The capacity to function as an IMMUNOGEN. (Hence *adj.* immunogenic.)

**immunoglobulin superfamily** A category of CELL ADHESION MOLECULES characterized by a molecular structure homologous to that of immunoglobulins – i.e. a number of immunoglobulin domains, each containing an intra-domain disulphide bond. These molecules are involved e.g. in calcium-independent cell–cell adhesion and antigen-specific interaction.

The first member of the family to be isolated was the neural cell adhesion molecule (NCAM) which appears early in ontogeny and is important e.g. in the development of the central nervous system; binding is *homophilic*, i.e. NCAM binds to NCAM – in contrast to most members of the superfamily which bind to dissimilar molecules (i.e. *heterophilic* binding).

Other members are important in the immune system – e.g. the T CELL RECEPTOR and the CD4 and CD8 molecules. Interactions between T cells and other cells also involve the *leukocyte function-associated antigens* LFA-2 (= CD2) and LFA-3 (= CD58); CD2 occurs on T cells, while CD58 occurs on many types of cell. CD2 and CD58 bind to one another. (N.B. LFA-1 is a member of the integrin family: see CD11a/CD18.)

The *intercellular adhesion molecules* (ICAMs) have important roles in cell–cell adhesion. ICAM-1 (= CD54), ICAM-2 (CD102) and ICAM-3 (CD50) – widely distributed (e.g. on endothelium, monocytes, lymphocytes) – bind to integrin ligands (see CD11a/CD18). In at least some circumstances, cell-surface expression of ICAMs can be upregulated or down-regulated.

(See also CD31 and CD106.)

**immunoglobulins** (Igs) A class of proteins present e.g. in plasma, colostrum, tears and other body fluids; all antibodies are immunoglobulins (see ANTIBODY and ANTIBODY FORMATION). The (monomeric) form of an immunoglobulin consists of four polypeptide chains: two identical HEAVY CHAINS and two identical LIGHT CHAINS which are linked by interchain disulphide bonds to form a Y-shaped macromolecule. The two heavy chains are adjacent for part of their length, their N-terminal ends diverging (at the HINGE REGION) to form the two limbs of the Y; two or more disulphide bonds connect the heavy chains at the hinge region. One light chain runs alongside each of the two limbs of the Y, and is attached to it by a disulphide bond. The distal (N-terminal) end of each limb of the Y is, compositionally, a highly *variable region* –  $V_H$  and  $V_L$  referring to the so-called variable (distal) DOMAINS (*V regions*) of the heavy and light chains, respectively. The composition of the rest of the molecule is relatively constant, and is therefore termed the constant region (*C region*). The C region of each heavy chain comprises several DOMAINS which are designated  $C_H1$ ,  $C_H2$  etc (numbering from the V region end), while the constant region of the light chain consists of a single domain designated  $C_L$ .

Certain enzymes, e.g. PAPAINE, cleave the Ig monomer at the hinge region, producing two identical FAB PORTIONS and an FC PORTION. Pepsin cleaves monomeric Ig to form an  $F(ab')_2$  portion (q.v.).

Five Ig classes are distinguished: see entries for IgA, IgD, IgE, IgG and IgM.

[Book ref. 42, pp. 131–219.]

**immunogold technique** A form of IMMUNOELECTRON MICROSCOPY in which the specific antibodies (or PROTEIN A molecules) are complexed with gold prior to use – the gold serving as an electron-dense marker.

**immunoliposome** See LIPOsome.

**immunological drift** *Syn.* ANTIGENIC DRIFT.

**immunological paralysis** IMMUNOLOGICAL TOLERANCE – particularly that induced by pneumococcal polysaccharides.

**immunological surveillance** *Syn.* IMMUNOSURVEILLANCE.

**immunological tolerance** Inability to respond normally to a given antigen (by humoral and/or by cell-mediated mechanisms) as a consequence of prior exposure to that antigen; unrelated antigens may elicit normal responses in the same individual. (cf. SELF TOLERANCE.) Tolerance may be total (i.e. no detectable response to antigen) or may involve e.g. failure to produce certain class(es) of antibody or some type(s) of immune response. Failure to react normally to some antigens may be beneficial in that harmful HYPERSENSITIVITY reactions may be avoided.

The extent, duration, and type of acquired tolerance is influenced e.g. by the size of dose of the inducing antigen (the *toleragen*), the nature of the antigen, the route of administration, and the state of immunological maturity of the individual when tolerance is induced; the induction of tolerance is inhibited e.g. by adjuvants and is favoured e.g. by ANTIGENIC COMPETITION and by non-specific immunosuppression.

Typically, thymus-dependent antigens (e.g. proteins) can induce tolerance when administered in doses higher than the normal immunizing dose (*high-zone tolerance*) or lower than the normal immunizing dose (*low-zone tolerance*); in high-zone tolerance both specific B cell and T cell clones are unresponsive (*clonal deletion*), while in low-zone tolerance only the helper T cell clone is unresponsive. Thymus-independent antigens usually induce only high-zone tolerance. Direct access of antigens to the gastrointestinal tract favours the induction of tolerance (see also SULZBERGER–CHASE PHENOMENON). In general, tolerance to a given antigen is more readily induced in the fetus or neonate than in the adult, and in a naive subject than in a primed one. The duration of tolerance may be extended by repeated administration of antigen.

Diverse mechanisms of tolerance induction have been suggested (including e.g. enhancement of suppressor T cell activity), and different types of tolerance may involve different mechanisms. Exposure of *immature* B lymphocytes to specific antigen or to anti-Ig makes them subsequently unresponsive (i.e., unable to secrete antibody) when exposed to specific antigen (*clonal abortion*); this suggests a reason why tolerance can be induced more easily in the fetus or neonate than in adults.

**immunological unresponsiveness** (1) *Syn.* IMMUNOLOGICAL TOLERANCE. (2) Inability, or reduced ability, to respond to antigens in general, due e.g. to IMMUNOSUPPRESSION.

**immunomagnetic separation** See DYNABEADS.

**immunomodulation** Specific or generalized alteration of the immune response (see IMMUNOSTIMULATION; IMMUNOSUPPRESSION; IMMUNOLOGICAL TOLERANCE).

**immunopathogenesis** The development of pathological effects as a direct result of the immune response.

**immunoperoxidase method** Any method in which antibody-conjugated, or otherwise complexed, peroxidases (e.g. horseradish peroxidase) are used to locate specific antigens on cells or tissues (see e.g. ABC IMMUNOPEROXIDASE METHOD and PAP TECHNIQUE).

**immunopotential** (1) *Syn.* IMMUNOSTIMULATION. (2) Non-specific immunostimulation.

**immunoprecipitable** Capable of being precipitated by homologous antibodies.

**immunoradiometric assay** A highly sensitive IMMUNOASSAY by which specific antigens are quantified using radioactive antibodies – which may be prepared as follows. Antigen is adsorbed

## immunorecessive

to an inert carrier (e.g. cellulose) and exposed to purified immunoglobulins obtained from an antiserum containing the homologous antibody; uncombined antibodies are removed by washing, and the combined antibodies are radiolabelled (e.g. with  $^{125}\text{I}$ ). The radioactive antibodies are then eluted for use in the assay. In one form of assay, excess radioactive antibody is added to the sample containing antigen at an unknown concentration; the reaction mixture is then exposed to fresh, cellulose-bound antigen which adsorbs the uncombined antibodies and permits their separation from the reaction mixture. The amount of combined antibody can then be measured by determining the level of radioactivity remaining in the reaction mixture; this allows the concentration of antigen in the sample to be determined from a previously prepared standard curve (radioactivity versus antigen concentration). (cf. RADIOIMMUNOASSAY.)

**immunorecessive** See DETERMINANT.

**immunosilent** See DETERMINANT.

**immunosorbent assay** Any IMMUNOASSAY in which antigen or antibody is immobilized by adsorption to a solid surface – see e.g. ELISA.

**immunosorbent electron microscopy (ISEM)** ELECTRON MICROSCOPY in which particulate antigens (e.g. specific viruses) are detected or examined by first complexing them with homologous antibodies; prior to antigen–antibody interaction the antibodies may be e.g. fixed to an electron microscope grid (Derrick's method, antibody-coated grid technique, A-CGT), adsorbed to a PROTEIN A-coated grid (Shukla's method, protein A-coated grid technique, PA-CGT), or adsorbed directly to the protein A of cells of *Staphylococcus aureus* (protein A-coated bacteria technique, PA-CBT). [Review: AVR (1984) 29 169–194.] (cf. IMMUNOELECTRON MICROSCOPY.)

**immunostaining** The staining of a specific antigen or structure by any method in which the stain (or stain-generating system) is complexed with specific antibody (e.g. ABC IMMUNOPEROXIDASE METHOD).

**immunostimulation** Specific or non-specific potentiation of the immune response – e.g. by the administration of a VACCINE or by the use of an ADJUVANT. (cf. IMMUNOPOTENTIATION.)

**immunosuppression** (immune suppression) Complete or partial suppression of normal IMMUNE RESPONSES – either in respect of specific antigen(s) (see also IMMUNOLOGICAL TOLERANCE) or in respect of all antigens (generalized suppression). Immunosuppression can be induced e.g. by ionizing radiation; specific antimetabolites (e.g. the folic acid antagonist methotrexate); a variety of antimetabolic/antitumour agents (e.g. 6-mercaptopurine, prednisone, CYCLOSPORIN A, cyclophosphamide, azathioprine); antilymphocyte serum. Immunosuppression induced by radiation or by drugs tends to be generalized.

**immunosurveillance** The continual monitoring of the tissues for abnormal antigens (e.g. on tumour cells) by cells of the immune system.

**immunotoxin** An antibody–toxin conjugate intended to destroy specific target cells (e.g. tumour cells) which bear antigens homologous to the antibody. [Anti-CD22 immunotoxin BL22, which uses a fragment of EXOTOXIN A, in chemotherapy-resistant HAIRY-CELL LEUKAEMIA: NEJM (2001) 345 241–247.]

**Imotest** A form of TUBERCULIN TEST in which a disposable plastic unit is used. The tuberculin is contained in a sealed plastic tube which is first broken and then squeezed to inoculate the nine points used to penetrate the skin.

**IMP** Inosine 5'-monophosphate: see Appendix V(a).

**impactor** See AIR.

**impedimetry** A technique in which microbial growth and activity are measured in terms of changes in the electrical impedance

of the growth medium due to the effects of metabolism. [JAB (1982) 53 423–426.]

**imperfect stage** (*mycol.*) See ANAMORPH.

**impetigo** A superficial, highly infectious skin disease, common in children, caused by *Streptococcus pyogenes* and/or *Staphylococcus aureus*. In the streptococcal form, spreading, inflamed pustules develop, rupture, and form thick brownish-yellow crusts; lesions may be secondarily infected by staphylococci. In the staphylococcal form (*bullous impetigo*) the lesions contain watery fluid rather than pus, and a thin crust forms over the centre of the lesion. Bullous impetigo occurs most commonly in very young infants; superinfection with streptococci is rare. *Chemotherapy*: e.g. oral penicillin (for streptococcal impetigo) or erythromycin. [Book ref. 17, pp. 341–346.]

**impinger** See AIR.

**IMS** See DYNABEADS.

**IMVEC tests** IMVIC TESTS plus the EIJKMAN TEST.

**IMViC tests** Tests used for the identification of bacteria e.g. of the family Enterobacteriaceae: INDOLE TEST, METHYL RED TEST, VOGES–PROSKAUER TEST, CITRATE TEST. (cf. EIJKMAN TEST.)

**in-block staining** See ELECTRON MICROSCOPY (a).

**in situ gene amplification** See IN SITU PCR.

**in situ hybridization** See PROBE.

**in situ PCR** PCR-based amplification of a target inside intact cells.

The cells may be initially attached to glass slides (e.g. with AAS in acetone) and are fixed (e.g. with a formalin-based solution). The cells are then treated (*permeabilized*) so as to allow entry of PCR reagents without encouraging the exit of PCR products. The reaction mixture is added to the cell layer (or tissue section), and is held in place with a cover slip. Temperature cycling may be carried out in a specialized form of THERMOCYCLER in which each slide is processed in a close-fitting slot that ensures good thermal contact (e.g. the GeneAmp® *In situ* PCR System 1000; Perkin-Elmer). After amplification, another phase of fixation promotes intracellular retention of the products.

Detection of products may be direct or indirect. Direct detection involves the use of labelled nucleotides or primers in the reaction mixture, and detection of the label histochemically. One disadvantage of this approach is that *all* amplified products will be labelled – even those resulting from mis-priming; as a consequence, the specificity of the assay is reduced. Improved specificity is obtained by the indirect mode of detection which involves the use of a labelled probe that is complementary to an internal sequence in the amplicon; the use of such a probe is equivalent to adding a stage of *in situ* hybridization (ISH), and procedures which involve indirect detection of products in this way have been referred to as PCR-ISH ('*in situ* PCR' being reserved for those procedures involving direct detection of products). Collectively, *in situ* PCR and PCR-ISH have been referred to as *in situ gene amplification* (IS-GA) [RMM (1997) 8 157–169].

This approach has been widely used for studying virus-infected cells, and may be particularly useful e.g. for those viruses which remain latent in tissues in small numbers. One early study detected intracellular lentiviral DNA [PNAS (1990) 87 4971–4975]. PCR-ISH has been used e.g. in studies on  $\gamma$ -herpesvirus type 8 [AJP (1997) 150 147–153].

**in vitro complementation assay** An assay based on the COMPLEMENTATION of a defective (mutant) protein by an active (wild-type) form of that protein; such assays are used e.g. to determine which of several proteins is/are involved in a particular process. For example, to identify a protein involved in DNA synthesis, a cell-free DNA-synthesizing system is initially prepared

from cells which have a temperature-sensitive mutation in a gene essential for DNA synthesis; such a system can synthesize DNA at permissive temperatures but not at restrictive temperatures. Proteins purified from a wild-type strain of the same species can then be added, separately, to the system to determine which of them can restore DNA-synthesizing activity at restrictive temperatures.

**in vivo expression technology** See IVET.

**Inaba variant** See VIBRIO (*V. cholerae*).

**inactivated serum** Serum which has been heated to 56°C for 30 min; heating inactivates COMPLEMENT in the serum.

**inactivated vaccine** (killed vaccine) Any VACCINE consisting of microorganisms which have been treated (e.g. with formalin) so that they are no longer capable of multiplying, although their PROTECTIVE ANTIGENS remain effective. (See e.g. SALK VACCINE; SEMPLE VACCINE.)

**inactivation** (of a microorganism) (1) The killing of a microorganism. (2) The temporary (reversible) inhibition of growth (or other activity) of a microorganism.

**inactone** See GLUTARIMIDE ANTIBIOTICS.

**inaequihymeriferous** See LAMELLA.

**Inc group** See INCOMPATIBILITY.

**incB locus** See F PLASMID.

**IncC group** See INCOMPATIBILITY.

**incC locus** See F PLASMID.

**incertae sedis** Of uncertain taxonomic position.

**IncF groups** See INCOMPATIBILITY.

**Incl groups** See INCOMPATIBILITY.

**incident light microscopy** See MICROSCOPY (e) and (g).

**inclusion blennorrhoea** See OPHTHALMIA NEONATORUM.

**inclusion bodies** ('inclusions') Discrete structures of various types present (normally or abnormally) within cells.

In *virology*, the term generally refers to those structures which develop in certain virus-infected cells; such structures consist of virions and/or viral components and/or cellular material, and may be characteristic in form and location for a given type of virus. (See also CYTOPATHIC EFFECT; GUARNIERI BODIES; NEGRI BODIES; POLYHEDRA; VIROPLASM.)

In *bacteriology*, the term may refer to structures within a bacterial cell (e.g. granules of GLYCOGEN, POLY- $\beta$ -HYDROXYBUTYRATE or POLYSULPHATE; 'hydrocarbon inclusions' (see HYDROCARBONS); CARBOXYSOMES; GAS VACUOLES; R BODY) or to bacterial cells within a (parasitized) eukaryotic host cell (see e.g. ANAPLASMA and CHLAMYDIA).

(See also OVERPRODUCTION.)

**inclusion body hepatitis** A POULTRY DISEASE apparently caused by certain strains of AVIADENOVIRUS (e.g. the 'Tipton' strain). The liver of an infected bird is enlarged, yellowish, with haemorrhagic patches; haemorrhages may also occur in the muscles. The disease may be associated with INFECTIOUS BURSAL DISEASE VIRUS infection.

**inclusion body rhinitis** A common, generally mild disease of young pigs, caused by suid herpesvirus 2 (see BETAHERPESVIRINAE). Infection occurs by inhalation; symptoms: e.g. sneezing, nasal discharge etc. The disease may become generalized, resulting in anaemia and sudden death.

**inclusion conjunctivitis** In adults: CONJUNCTIVITIS caused by *Chlamydia trachomatis*, commonly serotype D, E, F, G, H, I, J or K; if untreated, the disease (which is also called *paratrachoma*) typically resolves spontaneously after some months. (cf. TRACHOMA.) In newborn infants: see OPHTHALMIA NEONATORUM.

**IncN group** See INCOMPATIBILITY.

**incompatibility** (in plasmids) The inability of PLASMIDS to co-exist, stably, within the same cell when they have similar or identical systems for replication (see PLASMID) and/or PARTITION. Two incompatible plasmids which occupy the same cell will (in the absence of a selective pressure for both plasmids) tend to segregate to different cells during cell division. The stable intracellular co-existence of one plasmid with another requires that each plasmid be able to control, independently of the other, its own replication/partition such that it can establish and maintain a stable COPY NUMBER; the inability of a given plasmid to maintain a stable copy number in the presence of another plasmid is the characteristic feature of incompatibility.

In many cases, incompatibility arises from the synthesis of plasmid-encoded *trans*-acting elements involved in the negative control of plasmid replication. Since plasmids with identical replication systems form identical *trans*-acting elements, the elements synthesized by one plasmid will affect the replication of other plasmids (in the same cell) which have an identical replication system. In this case, plasmid replication initially occurs randomly – e.g., two (incompatible) plasmids will each have an equal chance of being replicated. Once replicated, however, a plasmid of one type will be present at a higher copy number and will then be more likely to be involved in subsequent rounds of replication; this effect tends to be cumulative and to give rise to progeny cells that contain only one type of plasmid ('homoplasmid segregants').

In plasmids which have similar but not identical replication systems, incompatibility may result in the preferential exclusion of one particular plasmid; for example, in a cell containing certain derivatives of the COLE1 PLASMID and of plasmid pMB1, the COLE1 derivative is rapidly excluded – possibly owing to differential sensitivity of the two plasmids to RNA I. (See also DISLODGEMENT and ONE-WAY INCOMPATIBILITY.)

In a number of plasmids the negative control elements which govern incompatibility are small RNA molecules: see e.g. RNA I under COLE1 PLASMID, and CopA under R1 PLASMID. In the pT181 family of *Staphylococcus aureus* plasmids, too, replication is regulated by negative control elements (countertranscripts – see ANTISENSE RNA); however, in the pT181 family of plasmids incompatibility is not governed by such elements because the negative control elements of different plasmids in this group are not interchangeable. Among pT181 plasmids incompatibility is due to the existence of a common (interchangeable) Rep protein (an initiator protein which promotes replication by binding to the origin) [MGG (1986) 204 341–348].

*Incompatibility and the classification of plasmids.* The expression of incompatibility or compatibility between plasmids provides a useful criterion for classifying them. Thus, plasmids are classified into so-called *incompatibility groups* (Inc groups) in such a way that all the plasmids in a given Inc group express mutual incompatibility. Inc groups exist e.g. for plasmids which occur in enterobacteria, and separate Inc groups exist for plasmids which occur in other bacteria; some ('promiscuous') plasmids can occur e.g. in both enterobacteria and *Pseudomonas* spp, and some of these plasmids have been allocated to an Inc group in both the enterobacterial and pseudomonad grouping schemes.

*Enterobacterial Inc groups* are designated by the prefix 'Inc' followed by a letter and, sometimes, by a Roman numeral or a Greek letter – e.g. IncFII, IncI $\alpha$ . The letter (e.g. F, I) indicates the type of *conjugation* system specified by the TRANSFER OPERON; thus, e.g. an IncF plasmid specifies a conjugative system like that of the F PLASMID or of an F-like plasmid, and encodes either F pili or F-like pili (see PILI). The Roman

## incompatible

numerical or Greek letter indicates a particular type of plasmid replication system; thus e.g. IncFI and IncFII plasmids have different replication systems (i.e., they are compatible) though they specify similar conjugation systems. Some examples of enterobacterial Inc groups are given below.

IncFI includes the F PLASMID, the COLICIN PLASMID ColV-K94, and the R PLASMID R386.

IncFII includes the R1 PLASMID, R6 and R100.

IncI $\alpha$  (sometimes written IncI1 or IncI<sub>1</sub>) includes ColIb-P9, the delta plasmid (see DELTA), and R64.

IncI $\gamma$  includes R621a.

IncN includes N3, R46, and R269N-1.

IncX includes the R6K PLASMID.

*Pseudomonas Inc groups* are designated IncP-1 to IncP-13, the numbers referring to each of the 13 different types of replication system. The conjugation systems of *Pseudomonas* plasmids are less well known than those of enterobacterial plasmids, but the pili encoded by *Pseudomonas* plasmids have been characterized. [Pili encoded by *Pseudomonas* plasmids: JGM (1983) 129 2545–2556; *Pseudomonas* R plasmids: Book ref. 198, pp. 265–293.] Some of the *Pseudomonas* Inc groups are given below.

IncP-2 includes the CAM PLASMID, the OCT PLASMID, and the R plasmid pMG1.

IncP-6 includes the R plasmid Rms149.

IncP-7 includes Rms148.

IncP-8 includes plasmid FP2 (which encodes resistance to mercury).

IncP-9 includes R2, the SAL PLASMID, and the TOL PLASMID.

IncP-10 includes R91.

IncP-11 includes RP8 and R151.

IncP-12 includes R716.

IncP-13 includes pMG25.

*Shared enterobacterial and pseudomonad Inc groups.* Some of the shared groups are given below, the enterobacterial Inc group being given first.

IncC ( $\equiv$  IncP-3) includes R55.

IncP ( $\equiv$  IncP-1) includes R68, R751, RK2, RP1 and RP4.

IncQ ( $\equiv$  IncP-4) includes RSF1010. (A plasmid apparently related to this group, pFM739, has been isolated from *Neisseria sicca* [JGM (1986) 132 2491–2496].)

**incompatible** (non-compatible) (*plant pathol.*) Refers to an interaction between a plant and a microorganism (e.g. an avirulent strain of a pathogen) which does not result in the development of disease in the plant. (cf. COMPATIBLE.)

**incomplete antibodies** (1) *Syn.* BLOCKING ANTIBODIES (sense 1). (2) FAB PORTIONS.

**incomplete Freund's adjuvant** See FREUND'S ADJUVANT.

**IncP groups** See INCOMPATIBILITY.

**IncQ group** See INCOMPATIBILITY.

**incubation** The maintenance of e.g. inoculated media or other types of material at a particular ambient temperature over a period of hours, days, weeks, or longer; the purpose of incubation is to provide conditions suitable for growth etc. Incubation is commonly carried out within closed, thermally insulated, thermostatically controlled chambers (*incubators*) or within vessels suspended in a WATER BATH; refrigerated incubators maintain the lower range of temperatures. Specialized incubation permits control of humidity, light, radiation etc as well as temperature. (cf. PHYTOTRON.)

Cultures or specimens are sometimes left outside the incubator, i.e., they are exposed to the (often variable) conditions within the laboratory – a procedure known as 'incubation at room temperature'.

**incubation period** (*med., vet.*) The time interval between INFECTION (sense 1), or e.g. exposure to a TOXIN, and the appearance of the first symptoms of disease. (cf. PREPATENT PERIOD.)

**incubator** See INCUBATION.

**IncX group** See INCOMPATIBILITY.

**independent assortment** (*genetics*) During e.g. MEIOSIS: the chance distribution of unlinked genes (see LINKAGE) among progeny cells. Thus, e.g., if the (diploid) parent cell contained the unlinked allelic pairs *A/a* and *Z/z*, any one of the four possible allele combinations (*A* and *Z*, *A* and *z*, *a* and *Z*, *a* and *z*) may occur, with equal probability, in a given (haploid) progeny cell.

**indicator** (pH) See PH INDICATOR.

**indicator organism** Any organism whose presence and/or numbers serve to indicate the condition or quality of a material or environment. For example, in studies on faecal pollution in rivers, counts of the faecal bacteria *Escherichia coli* and *Enterococcus faecalis* are often used to indicate the degree of sewage pollution at given sites. The same organisms are also used for testing the efficiency of disinfection in treated drinking water, their presence in treated water supplies indicating a failure of the treatment process or contamination by sewage effluent subsequent to treatment. These organisms are used as indicators because they are common intestinal bacteria: their presence in water signals the *potential* presence of enteric pathogens. Water samples are not routinely tested for each of the (many) different types of enteric pathogen because, even in sewage-contaminated water, a given pathogen may occur only intermittently. Moreover, in sewage-contaminated water the indicator bacteria greatly outnumber pathogens so that they permit detection of very low levels of faecal pollution. Endospores of *Clostridium perfringens*, which remain viable for long periods of time, have been used to indicate *previous* contamination. *Bifidobacterium* spp may specifically indicate *human* faecal pollution [JAB (1983) 55 349–357], while faecal pollution from human and animal sources may be differentiated by differences in the antibiotic resistance patterns of 'faecal streptococci' [AEM (1996) 62 3997–4002].

Traditional tests for faecal indicator bacteria include the MULTIPLE-TUBE METHOD (for *E. coli*) and membrane FILTRATION for FAECAL STREPTOCOCCI.

Indicator organisms are also monitored in the assessment of food-handling conditions/hygiene [indicator organisms in meat: J. Food Protect. (1984) 47 672–677].

(See also SAPROBITY SYSTEM and *lichens and pollution* in the entry LICHEN.)

**indigoidine** See ERWINIA (*E. chrysanthemi*).

**indinavir** See ANTIRETROVIRAL AGENTS.

**indirect agglutination** *Syn.* PASSIVE AGGLUTINATION.

**indirect fluorescent antibody test** (IFAT) See indirect IMMUNOFLUORESCENCE.

**indirect immunofluorescence** See IMMUNOFLUORESCENCE.

**individual quick blanch** (IQB) In the preparation of certain foods for CANNING: blanching by exposure of individual items of food to steam for a short period of time.

**indole 3-acetic acid** See AUXINS.

**indole test** An IMVIC TEST used to determine the ability of an organism to produce indole from tryptophan [see Appendix IV(f)]. The organism is grown in PEPTONE WATER or TRYPTONE WATER at 37°C. (N.B. The presence of carbohydrate (which may repress TRYPTOPHANASE) or nitrite in the medium can give false-negative results.) Test procedures vary. (a) KOVÁCS' INDOLE REAGENT (0.5 ml) is added to ca. 5 ml of e.g. a 48-hour culture with gentle shaking; the reagent forms a floating layer which,

in a positive test (i.e. indole produced), becomes pink or red. (b) Xylene (ca. 1 ml) is added to ca. 5 ml of e.g. a 48-hour culture with vigorous shaking (to extract the indole). EHRLICH'S REAGENT (ca. 0.5 ml) is then allowed to run down the side of the slanted tube and forms a layer beneath the (floating) xylene; in a positive test a red colour develops in the reagent layer. (c) An oxalic acid-impregnated paper strip is inserted between the tube and stopper *before* incubation; during incubation (up to 7 days) indole (volatile at 37°C) reacts with the test strip to give a pink or red colour.

**indophenol oxidase test** See OXIDASE TEST.

**indoxyl acetate** (3-acetoxyindole) A reagent used in identification tests for e.g. species of *Arcobacter* and *Campylobacter*. Growth (from a non-selective medium) is suspended in distilled water, and a paper disc, impregnated with indoxyl acetate, is added; on incubation at room temperature for 20 minutes, a blue coloration indicates hydrolysis of indoxyl acetate.

**inducer exclusion** (catabolite inhibition) The inhibition by glucose (or certain other readily metabolizable, 'preferred' substrates) of the uptake of certain substrates by bacteria; for example, if the bacteria are growing in a medium containing two substrates, one of the substrates is preferentially taken up and metabolized, and this substrate prevents the uptake of the other.

There are several mechanisms for inducer exclusion; for exclusion of e.g. lactose in enterobacteria see CATABOLITE REPRESSION. Uptake of other (structurally unrelated) non-PTS sugars – e.g. maltose, melibiose – is inhibited in a similar way.

In other cases, inducer exclusion may be due to competition between structurally related substrates for the same transport system or for shared components of the PTS; for example, in enterobacteria glucose can directly inhibit the uptake of galactose via a transport system common to both sugars.

In certain Gram-positive bacteria (e.g. *Streptococcus* spp, *Lactobacillus casei*), accumulated sugar phosphates are actually expelled from the cell when e.g. glucose is added (*inducer expulsion*); this involves a two-step mechanism in which intracellular dephosphorylation of the sugar is followed by efflux of the free sugar. In these organisms regulation of sugar accumulation has been associated with the CcpA system (see CATABOLITE REPRESSION); phosphorylation of HPr at the Ser-46 site reduces its ability to be phosphorylated at the (routine) His-15 site by enzyme I, and this should reduce phosphate transfer to the PTS permeases and (hence) inhibit the uptake of sugars.

**inducer expulsion** See INDUCER EXCLUSION.

**inducer protein** *Syn.* activator: see OPERON.

**induction** (1) (of enzymes, gene expression) See e.g. OPERON. (2) (of bacteriophage) See LYSOGENY.

**industrial alcohol** (microbiological aspects) Large amounts of ethanol are produced commercially by the microbial fermentation of carbohydrates; ethanol is used primarily as a fuel (e.g. in GASOHOL), as a solvent, and as a feedstock in the chemical industry. 'Fermentation ethanol' (= 'fuel ethanol') may be produced by the ALCOHOLIC FERMENTATION of substrates such as MOLASSES and STARCH hydrolysates by strains of the yeast *Saccharomyces*; laboratory- and pilot-scale evaluations have been made of the economics of ethanol production from materials as diverse as cassava, Jerusalem artichoke, LIGNOCELLULOSE, sweet sorghum and WHEY – using various yeasts, certain bacteria, and mixtures of organisms.

Since many organisms can utilize only mono- or disaccharides, polymers such as cellulose and starch must be subjected to acid or enzyme-catalysed hydrolysis before they can be fermented; strains of e.g. *Clostridium thermocellum* (which form

extracellular CELLULASES) can use lignocellulose without prior hydrolysis, but the potential of this organism for ethanol production is limited by its poor tolerance of ethanol. On hydrolysis, most usable polysaccharides yield mainly hexoses – from which ethanol can be formed as a major product by various yeasts (including e.g. species of *Candida*, *Kluyveromyces*, *Saccharomyces* and *Schizosaccharomyces*) and by some bacteria (e.g. *Zymomonas mobilis*). The hydrolysis of HEMICELLULOSES yields significant quantities of PENTOSEs, e.g. xylose; some organisms (e.g. *Fusarium oxysporum*) can convert xylose to xylulose, and can ferment the latter to ethanol via reactions of the HEXOSE MONOPHOSPHATE PATHWAY and the EMBDEN-MEYERHOF-PARNAS PATHWAY. Certain other organisms (e.g. *Candida tropicalis*, *Pachysolen tannophilus*) can also form ethanol from xylose, while a number of organisms (e.g. *Saccharomyces*, *Schizosaccharomyces* spp) can form ethanol from xylulose. A strain of *Paecilomyces* can give good yields of ethanol from a range of hexoses and pentoses [Nature (1986) 321 887–888].

**industrial microbiology** For examples of microorganisms and/or microbial products used on an industrial or commercial scale see e.g. AGAR, ALCOHOLIC BEVERAGES, ALGINATE, ASCORBIC ACID, BIOLOGICAL CONTROL, BIOMIMETIC TECHNOLOGY, BIOPOL, CARAGEENAN, CITRIC ACID, COCOA, COFFEE, DAIRY PRODUCTS, DEXTRANS, DIATOMACEOUS EARTH, ENZYMES, ERGOT ALKALOIDS, FERMENTED FOODS, FUNORAN, FURCELLARAN, GELLAN GUM, GLUCONIC ACID, GLUTAMIC ACID, INDUSTRIAL ALCOHOL, INTERESTERIFICATION, KELP, LEACHING, MUSHROOM (senses 3 and 4), OVERPRODUCTION, RETTING, RIBOFLAVIN, SILAGE, SINGLE-CELL PROTEIN, STEROID BIOCONVERSIONS, VINEGAR, VITAMIN B<sub>12</sub>, XANTHAN GUM and ZEARALENONE.

**infant botulism** See BOTULISM (a).

**infantile gastroenteritis** See EPEC.

**infantile paralysis** *Syn.* POLIOMYELITIS.

**infection** (1) The initial entry of a pathogen into a host. (2) The condition in which a pathogen has become established in or on the cells or tissues of a host; such a condition does not necessarily constitute or lead to disease. (3) Synonymous with disease of microbial aetiology. (See also CATHETER-ASSOCIATED INFECTION and TRANSFUSION-TRANSMITTED INFECTION.) (4) The establishment of a microbial symbiont in a host organism (see e.g. ROOT NODULES).

**infection-associated haemophagocytic syndrome (IAHS)** See HAEMOPHAGOCYTIC SYNDROME.

**infection court** (*plant pathol.*) The site at which a pathogen or parasite initiates infection of a plant (e.g. a wound).

**infection immunity** *Syn.* PREMUNITION.

**infection peg** See APPRESSORIUM.

**infection thread** See ROOT NODULES.

**infectious abortion** (*vet.*) See e.g. BRUCELLOSIS, CAMPYLOBACTERIOSIS, ENZOOTIC ABORTION.

**infectious ascites** (of fish) See INFECTIOUS DROPSY.

**infectious bovine keratoconjunctivitis** See INFECTIOUS KERATITIS.

**infectious bovine rhinotracheitis** (red nose) A highly infectious CATTLE DISEASE caused by strains of bovine herpesvirus 1 (see HERPESVIRIDAE). (Rarely, pigs may be affected.) Infection occurs mainly by droplet inhalation. Incubation period: 3–7 days or longer. Onset is sudden, with anorexia, fever, necrotic lesions on the mucous membranes of the nasal septum, serous discharge from the eyes and nose, increased salivation etc; sudden death may result from obstructive bronchiolitis. Abortion is a common sequel. [Book ref. 33, pp. 798–804.]

**infectious bronchitis** See AVIAN INFECTIOUS BRONCHITIS.

## infectious bulbar paralysis

**infectious bulbar paralysis** *Syn.* AUJESZKY'S DISEASE.

**infectious bursal disease virus** (IBDV) A virus which causes severe inflammation of the BURSA OF FABRICIUS in chickens. IBDV closely resembles IPN VIRUS in morphology, genome etc.

**infectious centre** See ONE-STEP GROWTH EXPERIMENT.

**infectious disease** (communicable disease) Any disease which, under natural conditions, can be transmitted from one individual to another by a causal agent which passes either directly (by physical contact) or indirectly (e.g. by DROPLET INFECTION or via FOMITE or VECTOR) from the infected to the non-infected individual (i.e. HORIZONTAL TRANSMISSION); diseases passed on by VERTICAL TRANSMISSION include some which are normally 'infectious' (e.g. AIDS) as well as others (e.g. certain TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES) which are hereditary, i.e. not considered 'infectious'.

A *transmissible* disease may be transmitted from the affected individual to another individual, or to a fetus, by any means, including those processes that are involved in horizontal and vertical transmission as well as those involved in experimental infection (the latter form of transmission may or may not occur naturally in any given instance).

TETANUS is an example of a non-infectious disease.

(cf. CONTAGIOUS DISEASE; see also IATROGENIC.)

[The transmission of infection (review): RMM (1995) 6 217–227.]

**infectious dropsy** (of carp) (*syn.* rubella; infectious ascites; also: haemorrhagic septicaemia) An 'umbrella term' for at least two distinct FISH DISEASES affecting carp (*Cyprinus* spp); see SPRING VIRAEMIA OF CARP and CARP ERYTHRODERMATITIS; abdominal distension with generalized oedema are common to both diseases.

**infectious endocarditis** See ENDOCARDITIS.

**infectious enterohepatitis** *Syn.* BLACKHEAD.

**infectious equine arteritis virus** *Syn.* equine arteritis virus; see ARTERIVIRUS.

**infectious foot-rot** See FOOT-ROT.

**infectious haematopoietic necrosis** (IHN) A FISH DISEASE characterized by massive destruction of the blood-forming tissues; the causal agent is a virus (see RHABDOVIRIDAE).

**infectious hepatitis** *Syn.* HEPATITIS A.

**infectious jaundice** See LEPTOSPIROSIS.

**infectious keratitis** (infectious bovine keratoconjunctivitis; pink-eye) In cattle: KERATITIS or KERATOCONJUNCTIVITIS which occurs world-wide, particularly in young animals, usually in summer and autumn. The common causal agent is apparently *Moraxella bovis*. [Microbial flora of the bovine eye: VR (1986) 118 204–206.] (See also CATTLE DISEASES.)

**infectious mononucleosis** (*syn.* glandular fever) An acute, self-limiting infectious disease of the lymphatic system which primarily affects children and young adults; it is caused by the EPSTEIN-BARR VIRUS (EBV). Transmission occurs by direct oral contact ('kissing disease') and may also occur by droplet infection.

The incubation period is 1–7 weeks. In the typical 'glandular fever' syndrome (the anginose form), common in young adults, there is fever, pharyngitis (often with exudative tonsillitis) and swollen tender lymph nodes (with or without rash); jaundice and/or hepatosplenomegaly occur less commonly. Infrequently, the disease develops with fulminant hepatitis and VAHS (see HAEMOPHAGOCYTIC SYNDROME). Therapeutic approaches to the severe form of the disease may involve the use of agents such as ACYCLOVIR, CYCLOSPORIN A and corticosteroids.

*Lab. diagnosis* may include demonstration of (a) increased levels of heterophil antibodies (see PAUL-BUNNELL TEST); (b)

mononucleosis and lymphocytosis; (c) the presence of atypical lymphocytes (enlarged, with foamy, vacuolated cytoplasm). (The atypical lymphocytes are not virus-infected B cells; they are T cells expressing the CD3 molecule.)

[Haematology and cell-mediated immunity in infectious mononucleosis: BCH (1995) 8 165–199 (170–175).]

(See also XLP SYNDROME; cf. CYTOMEGALIC INCLUSION DISEASE and EHRLICHIA.)

**infectious necrotic hepatitis** (*vet.*) *Syn.* BLACK DISEASE.

**infectious nucleic acid** (*virol.*) A nucleic acid which, when extracted from virions, can infect a host cell and give rise to progeny virions. Such a nucleic acid must be capable of being expressed and replicated in the cell in the absence of *virion* enzymes. Examples include DNA genomes which can gain access to the cell nucleus and which can be recognized and transcribed by host enzymes, and positive-sense ssRNA genomes which can be recognized and translated by host protein-synthesizing machinery. Negative-sense ssRNA genomes are not infectious since an RNA-dependent RNA polymerase (present in the virion) is necessary for the synthesis of positive-sense mRNA. An infectious nucleic acid (e.g. that from polioviruses) may be able to infect cells not normally susceptible to the intact virion since the nucleic acid does not depend on the presence of a specific cell-surface receptor to initiate the infection process. (See also TRANSFECTION.)

**infectious pancreatic necrosis** (IPN) A FISH DISEASE affecting hatchery-reared salmonid fry during the onset and early stages of feeding. Pancreatic tissue degenerates and becomes necrotic; mortality is often high. The causal agent is the IPN VIRUS.

**infectious polyarthritis** (of pigs) *Syn.* GLASSER'S DISEASE.

**infectious spread** (of plasmids) See EPIDEMIC SPREAD.

**infectious stunting syndrome** (of chickens) See STUNTING SYNDROME.

**infective endocarditis** See ENDOCARDITIS.

**infectivity** (1) (of pathogenic microorganisms) The ability of a pathogen to become established on or within the tissues of a host. (See also VIRULENCE.)

(2) (of a disease) The ease with which an infectious disease may be contracted under given conditions.

(3) (viral) See END-POINT DILUTION ASSAY.

**inflammation** In man and other animals: an acute or chronic response to tissue damage or to the presence of an allergen, or certain types of microorganism, within the tissues; inflammation may be initiated and sustained by microbial components and/or products. Inflammation is a protective response which commonly enables the body to overcome infection and return to normal function.

*Acute inflammation* is characterized by redness, swelling, warmth (in the affected region), pain and loss of function. This manifestation of the body's innate response to infection involves a diverse range of intercellular and intracellular signalling events – illustrated in the following generalized account of inflammation triggered by a Gram-negative bacterial pathogen which has breached the epithelial barrier. For convenience only, events mediated by complement and those mediated by cytokines are considered below under separate headings; the events described are representative of a process which is much more complex and which is still not understood fully.

*Complement-mediated events in inflammation.* Activation of COMPLEMENT by LIPOPOLYSACCHARIDES (LPS) gives rise to (among other products) the fragments C3a and C5a; these fragments are anaphylatoxins which elicit HISTAMINE from e.g. MAST CELLS; C5a also acts as a chemotactic factor which attracts MONOCYTES and NEUTROPHILS to the infected site.

Histamine increases the permeability of small blood vessels, allowing efflux of plasma (hence the swelling) and exposing the pathogen to (i) increased amounts of antimicrobial agents (e.g. complement and antibodies) and (ii) cells of the immune system attracted by C5a. Histamine is also reported to stimulate the early expression of SELECTIN molecules (specifically P-selectins) on local vascular endothelium (apparently within minutes of stimulation).

*Cytokine-mediated events in inflammation.* CYTOKINES (e.g. IL-1, IL-8, TNF- $\alpha$ ) are produced by local cells on stimulation by the pathogen. IL-1 and TNF- $\alpha$  promote the expression of E-selectins on local vascular endothelium.

Leukocytes in local blood vessels bind weakly to endothelial selectins; binding involves certain carbohydrate ligands in the leukocyte membrane – e.g. sialyl-Lewis x (= CD15). This (labile) selectin-CD15 binding causes leukocytes to slow down and *roll* along the vascular endothelium in the direction of blood flow, bonds being continually made and broken; this is referred to as *tethering*. As well as CD15, the leukocyte cell membrane also contains adhesion molecules of the INTEGRIN family – although, in the absence of infection, these molecules are normally inactive; an example is the *leukocyte function-associated antigen 1* (LFA-1; CD11a/CD18). Chemokines, e.g. IL-8 (see above), promote the activation of LFA-1 (via phosphorylation), so that LFA-1 can then bind (strongly) to counter-receptors (e.g. ICAM-1, ICAM-2) on vascular endothelium. [Leukocyte rolling and firm adhesion (biophysical view): PNAS (2000) 97 11262–11267.] The captured leukocytes flatten, and then ‘crawl’ over the endothelium to a cell–cell junction – subsequently migrating *between* endothelial cells (a process called *diapedesis* or *extravasation*) into the affected area (apparently guided by the chemokine gradient). The mechanism of extravasation is not known, but *platelet-endothelial cell adhesion molecule-1* (PECAM-1) appears to be required.

As indicated, cytokines are important for the recruitment of immune cells to the local site of infection. (Neutrophils are commonly the dominant type of cell in the early stages of acute inflammation; macrophages often become prominent after ~8 hours, and their ability to secrete FIBRONECTIN may be an important factor in tissue repair [wound healing (review): Science (1997) 276 75–81].) The importance of leukocyte recruitment to infected tissues is emphasized by those genetic disorders in which this process is inhibited (e.g. LEUKOCYTE ADHESION DEFICIENCY).

Cytokines are also involved in the production of ACUTE-PHASE PROTEINS (q.v.).

Antigen-stimulated T lymphocytes release  $\gamma$ -interferon (IFN- $\gamma$ ) which activates MACROPHAGES.

The pain associated with inflammation may be due e.g. to pressure on nerves and/or to PROSTACYCLIN.

*Chronic inflammation*, which occurs e.g. in some persistent intracellular infections, is characterized by the formation of new connective tissue and by the presence of concentrations of macrophages; it often leads to the formation of a GRANULOMA.

**infliximab** See TNF.

**influenza** (flu; grippe) An acute, highly infectious human disease caused by influenza virus A (often widespread epidemics, occasionally pandemics) or influenza viruses B or C (typically sporadic outbreaks, often among children and young adults). (See INFLUENZAVIRUS for details of strains, including those in the 1997 bird flu in Hong Kong, the 1999 outbreak in Guangdong (China), and the 2004–2006 problem with strain H5N1; see also INFLUENZA VIRUS C, GASTRIC FLU and COMMON COLD.)

Infection generally occurs by inhalation of virus-containing aerosols, virions being deposited onto alveolar membrane or (larger droplets) onto mucous membrane lining the respiratory tract; in the latter case, virions may bind to sialic acid residues in mucoproteins (rather than to receptors on respiratory epithelium) – but such (abortive) binding can be broken by the viral neuraminidase.

Incubation period: typically 1–3 days. Infection may be asymptomatic, or there may be a sudden onset with chills, fever, headache, muscular aches, anorexia, malaise etc.; fever subsides after 1–5 days, and respiratory symptoms (coryza, cough etc.) then become prominent. Recovery is usually rapid, although cough and malaise may persist for several weeks.

Viral infection damages ciliated epithelium in the trachea and bronchi; loss of cilia predisposes to secondary bacterial infection and development of e.g. bronchial pneumonia involving organisms such as *Streptococcus pneumoniae* and/or *Haemophilus influenzae*. Secondary infections are particularly problematic e.g. in the elderly, debilitated and immunocompromised; apart from pneumonia, secondary infections may lead to complications such as tracheo-bronchitis, sinusitis, otitis media etc. (One early report indicated that, in mice, the severity of disease can be reduced by ozone [AEM (1982) 44 723–731].)

*Chemotherapy.* Drugs such as AMANTADINE and rimantadine may afford some protection against influenza virus type A if administered before or soon after infection. (See also ZANAMIVIR.)

*Vaccines.* The original, formalin-inactivated, whole-virus vaccines produce local and systemic side-effects. *Split-product* (*split-virus*) vaccines, containing H and N components of the virus (as opposed to entire virions), are tolerated better.

Various alternative approaches to vaccines have been tried. For example, attempts have been made to prepare attenuated ‘live’ vaccines by using REASSORTANT VIRUSES containing e.g. surface glycoproteins from a currently epidemic strain and internal components from an attenuated strain. In some cases the attenuated strain was a temperature-sensitive (cold-adapted) virus, while in other cases it was a strain from another species with low virulence for man [e.g. avian strains: Book ref. 86, pp 395–405]. Vaccines have been prepared from synthetic oligopeptides that mimic glycoprotein epitopes [oligopeptide vaccines: MS (1984) 1 55–58] and with virosomes [Lancet (1994) 344 160–163].

Owing to the effects of antigenic variation, the components of influenza vaccines must be regularly reviewed to ensure that, when used, a given vaccine will generate protection relevant to the existing strain(s) of virus.

[Efficacy of influenza vaccines: RMM (1996) 7 23–30.]

**influenza virus A** See INFLUENZAVIRUS.

**influenza virus B** See INFLUENZAVIRUS.

**influenza virus C** A virus of the ORTHOMYXOVIRIDAE. It is physicochemically and morphologically similar to members of the genus INFLUENZAVIRUS, but differs in containing only 7 RNA segments (total MWt ca. 4–5  $\times 10^6$ ) and in having only one type of surface glycoprotein (HA) which has both haemagglutinating and receptor-destroying activities, but apparently no neuraminidase activity. It has been shown that, contrary to previous assumptions, sialic acid may nevertheless be an essential component of the host cell-surface receptor [Virol. (1985) 141 144–147]. Influenza virus C primarily infects man, although it has been isolated from pigs in China; it generally causes only mild or subclinical disease of the upper respiratory tract. Antigenic drifting occurs slowly, but antigenic shift has not been observed (cf. INFLUENZAVIRUS).

## Influenzavirus

**Influenzavirus** A genus of viruses (family ORTHOMYXOVIRIDAE) which includes influenza virus type A and influenza virus type B; both viruses cause sporadic or epidemic INFLUENZA in man, but type A strains also cause epizootics in pigs, horses or birds (see e.g. FOWL PLAGUE and SWINE INFLUENZA) and (occasionally) pandemics in humans. (See also INFLUENZA VIRUS C.)

Influenzaviruses are transmitted via aerosols or water, or by direct contact.

**Virions.** The enveloped virions are pleomorphic, ca. 80–120 nm across; ‘filamentous’ forms of up to several micrometres in length are common. The genome consists of eight molecules of linear, negative-sense ssRNA (total MWt ca.  $5 \times 10^6$ ); these RNA segments form a helical ribonucleoprotein complex with the (virus-encoded) NP protein. Associated with the RNA–NP complex are the viral proteins P1, P2 and P3 (also called PA, PB1 and PB2) which, together, constitute a *transcriptase* (i.e. an RNA-dependent RNA polymerase) which is required for synthesis of viral mRNA and for replication of the RNA genome. [Function of transcriptase (model): Book ref. 86, pp 73–84.]

The ribonucleoprotein is surrounded by a layer of (virus-encoded) *matrix protein* M1; this layer of M1 protein is wholly enclosed by the viral envelope.

The viral M2 protein forms part of the envelope. It is encoded by genome segment 7 (as is M1); M2 (MWt ca.  $13 \times 10^3$ ) is translated from a spliced transcript.

The viral envelope (containing lipids derived from host cell membrane) forms the outermost layer of the virion.

Two types of structure arise from the surface of the envelope. These structures are usually referred to as *spikes* and *mushroom-shaped projections* (names which reflect their appearance under the electron microscope).

**Spikes.** Each spike (~10–15 nm long) consists of three identical glycoproteins. Because these glycoproteins can bind to red blood cells (and cause HAEMAGGLUTINATION) they are referred to as haemagglutinins (HA). However, the glycoproteins can bind to any type of cell which has a suitable sialic acid (= *N*-acetylneuraminic acid, NANA) receptor – e.g. cells of the respiratory epithelium.

Each molecule of HA glycoprotein consists of two dissimilar polypeptide subunits which are linked by a disulphide bond; these subunits are termed HA1 (the larger subunit) and HA2. (The HA protein is encoded by segment 4 of the viral genome. It is synthesized as a single polypeptide chain which undergoes post-translational cleavage: an N-terminal signal sequence is removed, and the molecule is commonly cleaved to form HA1 (328 amino acid residues) and HA2 (221 amino acid residues) – which remain linked by a disulphide bond.) In each spike, the proximal HA molecule is attached to the envelope via a site in the HA2 subunit.

**Mushroom-shaped projections.** Each individual mushroom-shaped projection is a tetramer of another glycoprotein, NEURAMINIDASE (NA) (q.v.); each protein in the tetramer has a functional enzymic site.

**Propagation of influenzaviruses in vitro.** The influenzaviruses can be propagated in embryonated hens’ eggs and e.g. in chick embryo cell cultures. Some authors prefer monkey kidney or human embryo kidney cells for primary isolation. (Eggs are used for vaccine virus production.)

**Inactivation of virions.** Virions are rapidly inactivated by low pH (<5), by mild heat (e.g. 60°C/30 min), by lipid solvents, detergents and soaps, by formaldehyde and ultraviolet radiation, and by phenolic disinfectants and other agents; they

are apparently resistant to drying at room temperature, and survive at low temperatures in water. The virions can be preserved for long periods at –70°C.

**Infection of host cells; replication.** The virion binds, via the HA protein, to specific cell surface receptors containing sialic acid residues; it is then internalized in a vesicle (endocytosis). Low pH within the vesicle promotes cleavage of the HA protein (by a host protease), and this leads to fusion of the viral envelope with the vesicle’s membrane; as a result, viral ribonucleoprotein and transcriptase are released into the cytoplasm of the host cell. (See also ENVELOPE.)

The infectivity of a virion is abolished if antibodies have bound to the globular HA1 portion of the HA glycoprotein.

Transcription of the (negative-sense) viral RNA occurs in the nucleus; it involves viral transcriptase but depends on the priming activity of the host’s ( $\alpha$ -AMANITIN-sensitive) RNA polymerase II. (See also RIBAVIRIN.) Transcription gives rise to ten molecules of mRNA (two from each of genome segments 7 and 8 – each of which have two reading frames). Viral mRNAs are polyadenylated in the nucleus.

Replication of the viral genome also occurs in the nucleus and involves viral transcriptase and the host’s RNA polymerase II. The progeny ribonucleoprotein structures are assembled in the nucleus, but details of the mode of assembly are not available.

HA and NA proteins are synthesized on rough endoplasmic reticulum and subsequently migrate to localized sites in the plasma membrane.

The type B influenzaviruses (but apparently not type A viruses) encode another glycoprotein, NB, whose reading frame overlaps that of NA; NB does not occur in the virion. Other non-structural (NS) proteins are produced in cells infected with A- or B-type viruses; their role(s) are unknown.

Maturation of the virion occurs by budding through the cell membrane at sites containing HA and NA.

**Classification/nomenclature of influenzaviruses.** Influenzaviruses are classified as subtypes on the basis of their HA antigens (15 different subtypes) and NA antigens (9 different subtypes). A given strain of virus is designated by a formula which indicates the following data: (i) type (i.e. A, B or C); (ii) the animal from which the strain was first isolated (omitted if the host was human); (iii) the place where the strain was first isolated; (iv) the strain number; (v) the year of isolation; and (vi) the particular HA (= H) and NA (= N) antigens. Example:

A/duck/Ukraine/1/63(H3N8)

The pandemic of 1957 – so-called Asian flu – was caused by a strain formerly referred to as ‘strain A2’ but now designated:

A/Singapore/1/57(H2N2)

The 1968 pandemic – so-called Hong Kong flu – was due to:

A/Hong Kong/1/68(H3N2)

It appears that these two strains of influenzavirus were circulating human strains which had acquired novel antigens through genetic reassortment with avian strains (see REASSORTANT VIRUS). The sudden acquisition of new antigens (‘antigenic shift’ – see below) meant that radically new strains of virus had appeared in a human population which, immunologically, was completely naive.

It was previously assumed that if a ‘new’ subtype appears then the ‘old’ strain ceases to circulate. However, subtype H1N1, which was active early in the 20th century, re-appeared in 1977 and was involved in the pandemic of so-called Russian flu.

The surface glycoproteins of influenzaviruses undergo ANTI-GENIC VARIATION; by this means, the virus may avoid the host's immune response and give rise to new outbreaks of influenza. New strains of virus are generally not inactivated by antibodies induced by a previous strain – i.e. antibody-based protection tends to be strain-specific.

Variation in surface antigens may involve ANTIGENIC DRIFT or ANTIGENIC SHIFT.

Antigenic drift involves relatively small changes in the surface antigens, and this is associated with the regular occurrence of epidemic influenza.

Antigenic shift involves major (and abrupt) changes in the surface antigens, and it happens infrequently. It has been recorded only in type A influenzaviruses; this apparently reflects the fact that type A strains can infect animals as well as man, and that, in mixed infections (involving viruses from different species), segments of the genome may undergo reassortment – resulting in the formation of novel hybrid subtypes containing genome segments from different co-infecting parent virions.

In recent times, human strains typically displayed H1, H2 or H3, and N1, N2 or N3 antigens. Many other types of H and N antigens occur in animal strains, suggesting scope for the formation of new pandemic strains by reassortment. Fortunately, influenzaviruses are generally highly species-specific – so that transfer across the species barrier is assumed to occur only rarely. Transfer occurred when American harbour seals were infected by an avian H7N7 virus in 1980 [Virology (1981) 113 712–724] and pigs were infected by avian strains [JV (1996) 70 8041–8046].

Transfer across the species barrier may occur in a two-step process; for example, transmission of the human H3N2 subtype to avian hosts can be achieved after reassortment in pigs.

The 1997 outbreak of *bird flu* in Hong Kong, which caused six deaths, resulted from avian-to-human transmission of a fowl plague strain (H5N1). Subsequently, no deaths from this strain were reported following large-scale slaughter of poultry.

In 1999, two children in Hong Kong were infected with influenza A subtype H9N2 (strains A/Hong Kong/1073/99; A/Hong Kong/1074/99); these strains closely resemble a strain isolated from quail in 1997 (A/quail/Hong Kong/G1/97). Also in 1999, H9N2 viruses were isolated from patients with influenza-like illness in Guangdong province (China).

The H5N1 and (Hong Kong) H9N2 human isolates are similar in the six genes that encode *internal* components of the virion, suggesting that H9N2 arose from reassortment of H5N1. Avian strains with these six genes might have a tendency to infect humans and may therefore have the potential to give rise to a novel human pathogen. [Relationship between H9N2 and H5N1 human isolates: PNAS (2000) 97 9654–9658].

H5N1 caused over 50 human deaths in East Asia in 2004–2005. Isolates from humans and those from birds consisted of two distinct clades. In all isolates the genes were of avian influenzaviruses, indicating that they were not derived through reassortment with human strains. Human-to-human transmission was described. [Evolution of H5N1 avian influenza viruses in Asia: EID (2005) 11(10). Influenza (special issue): EID (2006) 12(1) (January).]

**informational suppressor** See SUPPRESSOR MUTATION.

**informosome** See MRNA (b).

**infracliaature** (*ciliate protozool.*) The subpellicular system which includes the kinetosomes and all the various associated microfillicular and microtubular structures (see e.g. KINETODESMA; POST-CILIARY MICROTUBULES; TRANSVERSE MICROTUBULES).

**infradian rhythms** In certain parameters of a eukaryotic cell or organism: innate rhythmical changes which occur with a periodicity >24 hours. (cf. CIRCADIAN RHYTHMS.)

**infrared radiation** See dry-heat STERILIZATION.

**infrasubspecific rank** Any rank below subspecies (see e.g. VARIETY).

**infundibulum** (1) In some ciliates: the lower or inner (often tubular) region of the BUCCAL CAVITY; in peritrichs it corresponds to that part of the buccal cavity which excludes the PERISTOME (sense 1). (2) Any funnel-shaped structure.

**infusion agar** Infusion broth (see NUTRIENT BROTH) gelled with 1.5–2.0% w/v AGAR.

**infusion broth** See NUTRIENT BROTH.

**infusoria** An archaic term for the various microscopic organisms – particularly ciliates – found in aqueous infusions of vegetable matter.

**INH** Isonicotinic acid hydrazide: ISONIAZID.

**inhibitory medium** See MEDIUM.

**initial(s)** (*microbiol.*) Any part of a cell or organism which subsequently develops and/or differentiates to become a distinct and characteristic structure; the earliest or early stage(s) of a given structure.

**initial body** See CHLAMYDIALES.

**initiation complex** See PROMOTER.

**initiation mass** See CELL CYCLE.

**initiator** (of an operon) See OPERON.

**ink-cap fungi** Species of COPRINUS whose autodigesting lamellae form a black, basidiospore-containing, ink-like liquid.

**Inkoo virus** See BUNYAVIRUS.

**inlA gene** See LISTERIOSIS.

**innate** (*mycol.*) Refers to any fungal structure which is embedded in a substratum, or in the fungal thallus, such that its outer surface is more or less level with the surface of the substratum or thallus.

**inner primers** See NESTED PCR.

**inner veil** (*mycol.*) *Syn.* PARTIAL VEIL.

**inoculation** (1) The placing of material (the INOCULUM) on or into a MEDIUM, TISSUE CULTURE, animal etc using an ASEPTIC TECHNIQUE. If the purpose of inoculation is to initiate a CULTURE, the inoculated medium must be incubated (see INCUBATION). (2) (*immunol.*) *Syn.* VACCINATION (1) or (2).

**inoculative infection** (*parasitol.*) Infection in which a pathogen is introduced into the vertebrate host from the ANTERIOR STATION. (cf. CONTAMINATIVE INFECTION.)

**inoculum** (1) Material used for the INOCULATION of a MEDIUM, TISSUE CULTURE, animal etc; it typically comprises or contains viable microorganisms. (2) (*plant pathol.*) Pathogenic microorganisms which have become established within a plant and which may give rise to disease.

**inoculum effect** In the in vitro testing of bacteria for resistance to antibiotic(s): the phenomenon in which the MIC increases when the size of the test inoculum (cells/ml) is increased; for a given strain of bacteria the inoculum effect may differ greatly with different antibiotics.

**Inocybe** See AGARICALES (Cortinariaceae).

**Inonotus** A genus of fungi of the APHYLLOPHORALES (family Hymenochaetaceae) which form basidiocarps in which the context is reddish-brown and fibrous. *I. dryadeus* (formerly *Polyporus dryadeus*) forms bracket-type basidiocarps (context: monomitic) with a pale grey (later darkening) upper surface and a porous underside; basidiospores: whitish, spheroidal, ca. 7 µm diameter. It is parasitic on various types of oak (*Quercus*). (See also BUTT ROT and POCKET ROT.)

## inoperculate

**inoperculate** Lacking an OPERCULUM.

**inorganic pyrophosphate** See PYROPHOSPHATE.

**iNOS** See NITRIC OXIDE.

**inosine** See NUCLEOSIDE and Appendix V(a).

**inositol** Hexahydroxycyclohexane. Theoretically there are nine stereoisomers; of these, *meso*-inositol (= *myo*-inositol), scyllitol, *d*-inositol and *l*-inositol occur naturally, and only *meso*-inositol is common. *Meso*-inositol occurs widely e.g. in the phospholipids of microorganisms; it is required, in small amounts, for the growth of a number of microorganisms – including many yeasts (see e.g. BREWING). Inositol is used as a substrate in biochemical characterization tests for bacteria; it is attacked e.g. by *Klebsiella pneumoniae*. (See also CYCLITOL ANTIBIOTICS.)

**Inoue–Melnick virus** A virus which has been isolated from patients with chronic CNS disease (including MULTIPLE SCLEROSIS) [JCM (1985) 21 698–701].

**Inoviridae** A family of ssDNA PHAGES in which the virions are rod-shaped or filamentous, the capsid subunits being arranged helically around one piece of ss cccDNA; the virions are chloroform-sensitive. On entry into a host cell the ssDNA is converted into a double-stranded replicative form from which progeny ssDNA can be synthesized. Mature phages are extruded through the host cell envelope. The host remains viable but grows more slowly than an uninfected cell. There are two genera: INOVIRUS and PLECTROVIRUS. [Book ref. 23, pp. 78–79.]

**Inovirus** (filamentous phages) A genus of non-lytic ssDNA PHAGES of the INOVIRIDAE. Hosts: enterobacteria (for e.g. phages fd, f1, M13, If1, If2, IKE, ZJ/2), *Pseudomonas* (phages Pf1, Pf2), *Xanthomonas* (phages Xf, Xf2, Cf), and *Vibrio* (phage v6); most or all inoviruses can infect only 'male' cells (i.e. those containing CONJUGATIVE PLASMIDS). Proposed type member: bacteriophage fd; f1 and M13 are very similar to fd. The inovirus virion is a flexible filament (760–1950 × 6 nm, according to phage) comprising ss cccDNA (MWt ca. 1.9–2.7 × 10<sup>6</sup>), one major coat protein (gp8, B-protein), and minor coat proteins A (gp3), C (gp9) and D (gp6) at 5, 10 and 5 copies/virion, respectively. Proteins A and D occur at one end of the virion; C seems to occur at the opposite end. The A-protein (gp3) is necessary for adsorption; the roles of C and D are unknown. The DNA loop fits inside the capsid (internal diam. ca. 2 nm) such that the two adjacent (antiparallel) strands of the loop are wound around each other in a type of double helix (pitch ca. 2.7 nm) despite the lack of homology between them; the helix seems to be stabilized by the coat protein [JMB (1982) 157 321–330].

The following refers to fd, f1 and M13; other inoviruses seem to be generally similar. Phages fd, f1 and M13 adsorb specifically to the *tips* of F and F-like pili (cf. BACTERIOPHAGE IKE, BACTERIOPHAGE IF1, LEVIVIRIDAE). During penetration of the host (which may involve pilus retraction) the capsid proteins (at least gp3 and gp8) become localized asymmetrically in the cell membrane. At it penetrates the cell, the phage DNA becomes coated with host SSB protein, initiating stage I (see ssDNA PHAGES). A unique 508-nucleotide intergenic (IG) region between genes 2 and 4 may remain uncoated; this region binds host RNA POLYMERASE holoenzyme which may recognize the secondary or tertiary structure of DNA in the IG region (which can form several hairpin loops). The RNA polymerase synthesizes an RNA primer at a specific site (*ori*) in the IG region. The complementary (*c*) strand, and hence RF, is completed as in other ssDNA phages (q.v.). RF is supercoiled by GYRASE to become RFI (see RF). The *c* strand of RFI functions as template for transcription of phage genes. An early product is an endonuclease (gp2) which initiates stage II by cleavage of the

RFI *v* strand at a specific site in the IG region; the free 3' end is elongated as in other ssDNA phages (q.v.). Genome lengths of displaced *v* ssDNA are cleaved by gp2, and each is circularized to form *v* ss cccDNA. At first, new *v* strands are converted to RFs. However, a phage-coded SSB protein (gp5) gradually accumulates, eventually coating the newly formed *v* strands and blocking their conversion to RFs (stage III). Phage coat proteins (at least gp8 and gp3) are synthesized as soluble cytoplasmic precursors with a 'signal peptide' at the amino end (see SIGNAL HYPOTHESIS); these proteins become inserted asymmetrically into the cytoplasmic membrane, the signal peptides are removed, and the proteins are 'anchored' within the membrane [PNAS (1982) 79 5200–5204]. Phage assembly – which requires THIOREDIXIN [PNAS (1985) 82 29–33] – occurs (in f1) at zones of adhesion between the cytoplasmic and outer membranes, f1 gp1 possibly being involved in the formation of these adhesion zones [JB (1985) 163 1270–1274] (cf. ADHESION SITE); gp8 displaces gp5, and the mature virion is finally extruded through the host cell envelope.

**insect diseases** *Bacterial* pathogens of insects include e.g. *Bacillus* spp (see e.g. AMERICAN FOULBROOD, DELTA-ENDOTOXIN, MILKY DISEASE), *Melissococcus pluton* (see EUROPEAN FOULBROOD), and species of RICKETTSIELLA, SERRATIA and SPIROPLASMA. (See also CECROPINS and SARCOTOXINS.)

*Fungal* entomopathogens include species of e.g. *Ascospaera* (see CHALK-BROOD); ASCHERSONIA; *Aspergillus* (see e.g. STONE-BROOD); BEAUVERIA; *Coelomomyces* (see BLASTOCLADIALES); CORDYCEPS; CULICINOMYCES; ENTOMOPHTHORA, ERYNIA and other fungi of the ENTOMOPHTHORALES; FUSARIUM; HIRSUTELLA; METARHIZIUM; NOMURAEA; SEPTOBASIDIALES; TERMITARIA; VERTICILLIUM.

*Protozoal* entomopathogens include e.g. species of MALPIGHA-MOEBA, NOSEMA and THELOHANIA. (See also CRITHIDIA, HERPETOMONAS and LEPTOMONAS.)

For *viral* entomopathogens see e.g. BACULOVIRIDAE; CYTOPLASMIC POLYHEDROSIS VIRUS GROUP; DENSOVIRUS; DROSOPHILA X VIRUS; ENTOMOPOXVIRINAE; FLACHERIE; HOUSEFLY VIRUS; NODAVIRIDAE; NUDAURELIA  $\beta$  VIRUS GROUP; PICORNAVIRIDAE; POLYDNVIRIDAE; SIGMA VIRUS.

(See also INVERTEBRATE DISEASES and BIOLOGICAL CONTROL.)

**insect iridescent viruses** See CHLORIRIDOVIRUS and IRIDOVIRUS.  
**insect–microbe associations** See e.g. AMBROSIA FUNGI; DUTCH ELM DISEASE; FUNGUS GARDENS; FUNGUS GNATS; INSECT DISEASES; MYCETOCYTE; TERMITES–MICROBE ASSOCIATIONS; WOOD-WASP FUNGI.

**insecticidal crystal protein (ICP)** See BIOLOGICAL CONTROL.

**insertion mutation** (addition mutation) A type of MUTATION in which one or more nucleotides are inserted into the genome; if the number of nucleotides inserted is not divisible by 3, the mutation will be a FRAMESHIFT MUTATION. Insertion mutations commonly result from the insertion of a TRANSPOSABLE ELEMENT or prophage (see also BACTERIOPHAGE CONVERSION). (cf. DELETION MUTATION.)

**insertion sequence (IS element)** A TRANSPOSABLE ELEMENT which contains no genetic information other than that necessary for its transposition. (cf. TRANSPOSON.) An IS element may transpose independently, when it may be detectable by the effect(s) of its insertion at a new site, or it may occur as a terminal part of a composite (class I) TRANSPOSON. An IS element is defined by its ends: an INVERTED REPEAT sequence of ca. 10–40 bp has been found to occur at both ends in every IS element so far analysed; these inverted repeats are apparently necessary for transposition and are probably the recognition sites for the

corresponding transposition enzymes. Most IS elements also have the potential for encoding 1–3 polypeptides, presumed to include TRANSPOSASE component(s). In many IS elements a small open reading frame occurs within the larger open reading frame but in the opposite orientation; IS50 has overlapping genes (see Tn5).

IS elements (designated IS1, IS2 etc) may be classified according to their terminal inverted repeats and the number of base pairs duplicated at the target site on insertion. Different IS elements transpose with different frequencies depending e.g. on the structure of the donor and target sequences, on the physiological state of the host cell, etc; frequencies of transposition range from ca.  $10^{-9}$  to  $10^{-5}$  per IS element per cell division. (See also e.g. IS1, IS5, IS101.)

[Review: Book ref. 20, pp. 159–221.]

**insertion vector** A CLONING vector which has a single site at which a sequence of exogenous DNA can be inserted (cf. REPLACEMENT VECTOR).

**inside-to-outside model** A model which describes the mode of incorporation of PEPTIDOGLYCAN into the CELL WALL of a growing Gram-positive bacillus [FEMS Reviews (1986) 32 247–254; J. Theor. Biol. (1985) 117 137–157]. Essentially, layers of newly formed peptidoglycan are laid down just external to the cytoplasmic membrane – a region in which they are subject to minimal hydrostatic stress; as growth continues, the layers move outwards towards the cell surface (being replaced by new layers) and accordingly bear an increasing proportion of the hydrostatic pressure. Finally, near the region of maximum stress, the peptidoglycan becomes increasingly susceptible to autolysins, the (older) layers of peptidoglycan commonly being shed in fragments.

**inspissation** The process of thickening. In microbiology: a process in which certain heat-coagulable substances (e.g. serum, homogenized hens' eggs) – or media containing such substances – are solidified by heating to ca. 85°C for ca. 1 hour. (See e.g. LÖWENSTEIN–JENSEN MEDIUM.)

**instructive theories of antibody-formation** Theories (now untenable) which hold that the ability to produce specific antibodies develops in antibody-producing cells only *after* their initial exposure to the antigen, i.e., it is assumed that pre-existing specificity does not occur. In such theories antigen is supposed to act as a template for the production of specific antibodies or for the formation of an antibody-specifying nucleic acid. (cf. CLONAL SELECTION THEORY.)

**int** (1) See e.g. BACTERIOPHAGE LAMBDA and BACTERIOPHAGE P22.  
(2) See MOUSE MAMMARY TUMOUR VIRUS.

**integral membrane protein** See CYTOPLASMIC MEMBRANE.

**integrase** See e.g. BACTERIOPHAGE  $\lambda$ .

**integrase-type recombinase** See SITE-SPECIFIC RECOMBINATION.

**integration host factor** (IHF) In e.g. *Escherichia coli*: a heterodimeric protein consisting of polypeptide chains of apparent MWt 11000 and 9500 [JBC (1981) 256 9246–9253]; IHF, which has the ability to induce bends in DNA, has been associated with various roles that include e.g. stimulating the transcription of nitrogen-fixing operons [Cell (1990) 63 11–22], promoting expression of the *tra* operon in the F plasmid [JB (1990) 172 4603–4609], stimulating helicase-catalysed nicking of the F plasmid at *oriT* [JBC (1995) 270 28374–28380] and promoting gene specificity for a given sigma factor [EMBO (2000) 19 3028–3037].

IHF is also one of the factors needed for the on–off switching of type I fimbriae in *Escherichia coli*.  
(See also SIDD.)

**integrative suppression** The phenomenon in which the integration of a plasmid into a bacterial chromosome suppresses the effect of a chromosomal mutation which has inhibited the initiation of chromosome replication; replication of the joint plasmid–chromosome replicon is apparently initiated at a site within the plasmid. Thus, e.g., as a result of integrative suppression, a temperature-sensitive *dnaA* mutant of *Escherichia coli* can carry out limited chromosome replication at a non-permissive temperature.

**integrins** A family of CELL ADHESION MOLECULES found on various types of cell and involved in many aspects of cell physiology; the molecule is a heterodimer of proteins consisting of an  $\alpha$  subunit non-covalently linked to a  $\beta$  subunit – the particular combination of  $\alpha$  subunit (many types) and  $\beta$  subunit (few types) determining the biological activity of each integrin.

Integrins of the  $\beta_1$  subfamily are found e.g. on various types of epithelial cell – either on the basolateral surface or (e.g.  $\alpha_6\beta_1$ ) on the basal surface (i.e. adjacent to the basement membrane) [integrins (review): HJ (1993) 25 469–477]. These integrins have a major role in cell–cell and cell–matrix interaction – binding to ligands that include collagen, fibronectin and laminin; however, such interaction involves more than cell position and maintenance of tissue structure: integrin–ligand binding can also trigger signals that modulate a wide range of cell functions, including aspects of the cell cycle.

The  $\beta_1$  integrins are also implicated as receptors for the adhesins of invasive pathogenic bacteria; for example, adhesins of *Yersinia enterocolitica* have been found to bind (in vitro) to the  $\alpha_5\beta_1$  integrin of epithelial cells.

The  $\beta_2$  integrins are found primarily on leukocytes; their expression on a given cell is apparently dependent on activation – e.g. cytokine-stimulated cells may exhibit the *leukocyte function-associated antigen-1* (LFA-1; = CD11a/CD18; =  $\alpha_L\beta_2$ ) and the Mac-1 integrin (= CD11b/CD18; =  $\alpha_M\beta_2$ ); both of these integrins can bind to ICAM ligands (see IMMUNOGLOBULIN SUPERFAMILY and INFLAMMATION).

The  $\beta_2$  integrins can also serve as receptors for bacterial adhesins. Thus, many integrins bind (via their  $\alpha$  subunit) to ligands that contain the amino acid sequence Arg-Gly-Asp (RGD), and this sequence is mimicked by the adhesin *filamentous haemagglutinin* (FHA) of *Bordetella pertussis*; the binding between FHA (RGD sequence) and Mac-1 ( $\alpha_M\beta_2$ ) of an activated macrophage assists bacterial invasion of the phagocyte.

The  $\beta_3$  integrin  $\alpha_{IIb}\beta_3$  (gpIIb/IIIa; = CD41b/CD61) is found on platelets and megakaryocytes; its ligands include fibrinogen, VON WILLEBRAND FACTOR and fibronectin. Failure to synthesize adequate amounts of this integrin results in deficient platelet aggregation (*Glanzmann's thrombasthenia*).

(See also LEUKOCYTE ADHESION DEFICIENCY.)

[Defects in human integrins: Lancet (1999) 353 341–343.]

**integron** A region of DNA which includes (i) a gene encoding a site-specific recombinase (see SITE-SPECIFIC RECOMBINATION) and (ii) a corresponding site for recombination into which one or more genes may be inserted [see e.g. JAC (1999) 43 1–4]. Integrons may have a role as a general gene-capture mechanism in bacterial evolution [PNAS (2001) 98 652–657].

**intein** In certain types of protein: an internal sequence of amino acids apparently capable of catalysing a self-splicing reaction in which the intein is excised (forming a separate protein) and the terminal parts of the original polypeptide (the two *exteins*) are joined to form a functional protein. [Review: TIBS (1995) 20 351–356. Intein sequences (review): NAR (1997) 25 1087–1093.]

## interallelic complementation

**interallelic complementation** See COMPLEMENTATION TEST.

**intercalary** Not apical or terminal: e.g. formed or situated between apex and base of a given structure or between two cells in a chain of cells.

**intercalating agent** Any dye possessing a planar chromophore which can insert (intercalate) *between* adjacent base pairs in dsDNA or in base-paired regions in ssDNA (e.g. HAIRPIN loops); *bifunctional* (*bis*) intercalating agents have two such chromophores per molecule (see e.g. QUINOXALINE ANTIBIOTICS). Intercalation forces the base pairs apart and causes (a) local unwinding of the helix, the degree of unwinding (*unwinding angle*,  $\phi$ ) depending on the nature of the dye, and (b) an increase in the length of the DNA. In linear dsDNA these effects lead to an increase in viscosity and a decrease in sedimentation coefficient (*s*) of the DNA in proportion to the amount of dye intercalated. Intercalative binding is limited to a maximum of one dye molecule per 2–3 bp; the binding of a dye molecule at one site precludes binding of others at the adjacent sites (the *neighbour exclusion principle*).

In circular dsDNA intercalation causes a local increase in pitch and thus a decrease in local (and hence average overall) twist. It follows from  $Wr = Lk - Tw$  (see DNA) that, as increasing amounts of dye intercalate in a *negatively* supercoiled molecule, the amount of writhe progressively decreases to zero (molecule behaves as relaxed), and then increases again as the molecule becomes *positively* supercoiled. The changes in writhe are accompanied by changes in viscosity of the DNA solution (increase to a maximum, then decrease) and in sedimentation coefficient of the DNA (decrease, then increase). Since intercalation relieves the strain of negative supercoiling, a negatively supercoiled cccDNA molecule has a higher affinity for intercalating agents than does the equivalent nicked or linear DNA, while a relaxed or positively supercoiled cccDNA has a lower affinity than the equivalent nicked or linear DNA. However, a cccDNA molecule has a limited capacity to unwind, and can therefore bind fewer molecules of intercalating agent than can equivalent linear or nicked circular DNA molecules (see e.g. ETHIDIUM BROMIDE).

Many intercalating agents have antimicrobial and antitumour activity, inhibiting e.g. transcription, DNA replication etc, and inducing FRAMESHIFT MUTATIONS. In vivo, intercalation is often followed by DNA strand breakage, possibly due to the action of nucleases which recognize distortion of the helix at the intercalation sites. At lower concentrations some intercalators (e.g. aminoACRIDINES, ETHIDIUM BROMIDE) can cause the selective loss of small cccDNAs such as plasmids (see CURING (2)), mtDNA (see PETITE MUTANT), ctDNA, and kinetoplast DNA. (See also ACTINOMYCIN D; ANTHRACYCLINE ANTIBIOTICS; QUINOXALINE ANTIBIOTICS; TILORONE. cf. MITOMYCIN C and PSORALENS.)

[Review of DNA-binding drugs: *Bioch. J.* (1987) 243 1–13.]

**intercistronic complementation** See COMPLEMENTATION TEST.

**intercrines** *Syn.* CHEMOKINES; thus,  $\alpha$ -intercrines =  $\alpha$ -chemokines,  $\beta$ -intercrines =  $\beta$ -chemokines.

**interesterification** An industrial process in which fatty acyl residues are interchanged among the various triglycerides in a mixture of lipids; the process, which is catalysed e.g. by sodium methoxide, is carried out in order to modify the composition (and hence properties) of oils and fats. Interesterification can be carried out using certain microbial LIPASES for the production of useful mixtures of triglycerides which cannot be made by conventional chemical processes. [Enzyme-catalysed modification of oils and fats: PTRSLB (1985) 310 227–233.]

**interference** (1) (*virolog.*) The phenomenon in which the replication of one virus (the *challenge virus*) is partially or completely

inhibited by the presence in the host cells of another (*interfering*) virus. In *homologous interference* the challenge and interfering viruses are of similar or identical types, while in *heterologous interference* they are unrelated (see e.g. RUBIVIRUS). Interference may result e.g. from competition between the viruses for components of the replication apparatus, etc. (See also DEFECTIVE INTERFERING PARTICLE.)

(2) (genetics) The phenomenon in which the occurrence of one recombinational event affects the chances of another occurring between adjacent regions of the same molecules of nucleic acid. In *chiasma interference* (= *positive interference*) the occurrence of a cross-over tends to prevent the occurrence of a second cross-over between nearby regions in the same duplexes; this effect decreases with increasing distance from the cross-over. In markers which are closely linked, a localized *negative interference* is sometimes observed: the occurrence of one recombinational event promotes recombination in an adjacent region; this can be due to the correction of adjacent sequences in hybrid DNA during gene conversion (co-conversion – see RECOMBINATION).

**interference-contrast microscopy** See MICROSCOPY (d).

**interfering virus** See INTERFERENCE (1).

**interferons** (IFNs) A category of CYTOKINES which are able to inhibit the replication of many types of virus in (i) the IFN-producing cell, and (ii) cells exposed to exogenous IFNs; IFNs also have other important roles in host defence mechanisms (see later).

Human interferons are divided into two main groups that are designated types I and II.

The type I interferons (stable at pH 2) include IFN- $\alpha$  (~17–26 kDa), IFN- $\beta$  (~21 kDa) and IFN- $\omega$ ; these interferons appear to be related – their genes (all of which are intron-less) may have developed from a common ancestral gene. The IFN- $\alpha$  gene exists in many allelic forms (subtypes).

The type II (acid-labile) interferon IFN- $\gamma$  (~25 kDa) exhibits little homology with type I interferons in terms of amino acid sequence; even so, the three-dimensional structure of the molecule has features in common with IFN- $\beta$ . The gene encoding IFN- $\gamma$  contains three introns.

Distinct types of interferon are found in other animals; for example, IFN- $\tau$  (structurally related to IFN- $\omega$ ) occurs in cows and sheep. These animals also form e.g. interferons related to IFN- $\beta$ . (A given type of interferon from one species may or may not be active in another species.)

Human interferons of both types have antiviral activity, although this function appears to be of major importance primarily in type I interferons. The type II interferon (IFN- $\gamma$ ) plays a major role in various immune defence mechanisms.

*Alpha interferon* (IFN- $\alpha$ ). IFN- $\alpha$  is produced by leukocytes. At least 14 subtypes of IFN- $\alpha$  occur in humans; these are designated IFN- $\alpha$ 1, IFN- $\alpha$ 2 etc.

*Beta interferon* (IFN- $\beta$ ). IFN- $\beta$  is produced by fibroblasts. Compared with IFN- $\alpha$ , the amino acid sequence of IFN- $\beta$  exhibits only 30% homology; the two IFNs are antigenically distinct.

Both IFN- $\alpha$  and IFN- $\beta$  can induce intracellular antiviral effects that include degradation of viral RNA and inhibition of protein synthesis (described later). These IFNs also upregulate MHC class I molecules at the surface of virus-infected cells; this is of value in that class I molecules act as binding sites for CD8<sup>+</sup> cytotoxic T cells (which kill virus-infected cells).

*Gamma interferon* (IFN- $\gamma$ ). IFN- $\gamma$  is produced by antigenically and/or mitogenically stimulated T lymphocytes. (See also

INTERLEUKIN-18.) The active form of IFN- $\gamma$  is a non-covalently-bound dimer.

Like type I interferons, IFN- $\gamma$  can upregulate class I MHC molecules. It can also upregulate class II MHC molecules on certain types of cell (including fibroblasts and endothelial cells); class II molecules promote the ability of cells to present antigen to CD4<sup>+</sup> T cells (for which MHC class II molecules are binding sites).

IFN- $\gamma$  is categorized as a pro-inflammatory cytokine (see CYTOKINES). In addition to its ability to upregulate MHC molecules, IFN- $\gamma$  can also e.g. (i) activate macrophages, (ii) stimulate the synthesis of NITRIC OXIDE, and (iii) promote class switching in B cells – upregulating e.g. IgG1 (and murine IgG2a) antibodies.

**Induction of interferons.** Agents which induce the synthesis of interferons include many types of virus, certain bacteria and protozoa, mitogens, lipopolysaccharides, and double-stranded nucleic acids (e.g. poly(I:C) – a polymer consisting of one strand each of polyinosinic acid and polycytidylic acid). (See also TILORONE.)

Many of the studies on induction of interferons have investigated transcriptional regulation of the gene encoding IFN- $\beta$  – apparently because this gene lacks the many subtypes of IFN- $\alpha$  and because, unlike IFN- $\gamma$ , it lacks introns.

Induction of the gene encoding IFN- $\beta$  during viral infection appears to involve activation of the transcription factor NF- $\kappa$ B; this seems to depend on phosphorylation of I $\kappa$ B by a dsRNA-dependent kinase designated PKR [PNAS (1994) 91 6288–6292]. (I $\kappa$ B normally inhibits NF- $\kappa$ B by binding to it; phosphorylation (and hence degradation) of I $\kappa$ B therefore results in the activation of NF- $\kappa$ B.) Viral infection also appears to promote synthesis of ‘interferon regulatory factor-1’ (IRF-1) which, together with activated NF- $\kappa$ B, may promote transcription from the regulatory region of the IFN- $\beta$  gene.

**Antiviral activity of interferons.** Exogenous interferons initially bind to specific cell-surface receptors. There are various kinds of receptor for type I interferons; some (not all) are common to IFN- $\alpha$ , IFN- $\beta$  and IFN- $\omega$ . The receptor for IFN- $\gamma$  is distinct from those that bind type I interferons. In all cases, however, the receptor for an interferon consists of a heterodimeric structure associated with tyrosine kinases on the cytoplasmic side; the kinases are involved in initiating the intracellular signal that leads to transcriptional upregulation of certain genes.

A generalized account of antiviral activity is as follows. The binding of interferon to a specific receptor activates a JAK-STAT signalling pathway (see JAK and STATs in CYTOKINES); this promotes transcription of certain genes encoding antiviral proteins. The type of interferon-inducible protein produced in any given case will depend on the type of cell and the type of interferon. Proteins induced by interferons include e.g. receptors for TNF; class I and II MHC antigens; nitric oxide synthetase; CD54 (inducible only by IFN- $\gamma$ ); Mx protein (an inhibitor of influenza virus replication inducible only by type I interferons); PKR (a protein kinase); and 2–5A synthetase. The two latter proteins are involved in generalized antiviral activity, as follows.

When activated by dsRNA, the PKR kinase phosphorylates (and therefore inactivates) the  $\alpha$  subunit of the protein synthesis initiation factor 2; this inhibits formation of initiation complexes and, hence, inhibits the synthesis of both viral and cellular proteins.

The 2–5A synthetase (activated by dsRNA) catalyses the synthesis of 2–5A (= 2,5-oligoadenylate). The 2–5A activates

an enzyme, RNase L (also called RNase F), which can cleave viral and cellular RNA; however, 2–5A is unstable, being enzymically degraded by 2',5'-phosphodiesterase.

The antiviral activity of interferons has been assayed *in vitro* by a plaque-reduction method in which cultured cells are treated with IFN and subsequently challenged with virus; the titre of IFN may be taken as the reciprocal of the highest dilution of IFN that produces a 50% decrease in the number of plaques.

**Therapeutic uses of interferons.** Both natural and recombinant forms of interferon (types I and II) have been evaluated for clinical use in a range of diseases, including various types of malignancy, Kaposi's sarcoma (IFN- $\alpha$ ), multiple sclerosis (IFN- $\beta$ ), diseases of viral aetiology, and disease caused by *Mycobacterium tuberculosis* (IFN- $\gamma$ ). Commercial products include Alferon N (multicomponent IFN- $\alpha$ ; Interferon Sciences, USA); Betaferon and Betaseron (recombinant IFN- $\beta$ ; Schering AG); Gammaferon (recombinant IFN- $\gamma$ ; Rentschler, Germany).

[Clinical uses of interferons: Book ref. 226, pp 237–271.]

The enhanced capacity of lymphocytes to secrete IFN- $\gamma$  when thalidomide is used for adjuvant therapy may offer an explanation for the ability of thalidomide to bring about clinical improvement in patients infected with e.g. *Mycobacterium tuberculosis* and HIV [AAC (2000) 44 2286–2290].

(See also ELISPOT ASSAY (for TB).)

**intergenic complementation** See COMPLEMENTATION TEST.

**intergenic repeat unit** *Syn.* ERIC SEQUENCE.

**intergenic spacer region** See RIBOTYPING.

**intergenic suppression** See SUPPRESSOR MUTATION.

**intergenote** A partial zygote formed by heterologous TRANSFORMATION (i.e., transformation in which the donor DNA is derived from a species different from that of the recipient).

**intergranal frets** See CHLOROPLAST.

**interkinesis** See MEIOSIS.

**interkinetal** Refers e.g. to the plane of cell division typical of members of the OPALINATA: longitudinal, between the rows of kineties. (cf. HOMOTHETOGENIC.)

**interleukin-1 (IL-1)** A cytokine (see INTERLEUKINS) secreted by various types of cell, including monocytes, fibroblasts, dendritic cells and endothelial cells. There are several forms of IL-1: IL-1 $\alpha$  (previously called lymphocyte activating factor, LAF) and IL-1 $\beta$  (both pro-inflammatory cytokines with similar or identical functions) and IL-1 $\gamma$ ; IL-1 $\alpha$  binds to the cognate receptor of IL-1 $\alpha$  and IL-1 $\beta$  but, having no agonist activity, it functions as an antagonist of the  $\alpha$  and  $\beta$  forms of IL-1. (There are two types of receptor for IL-1 but only one is functional; the other ('decoy') receptor does not initiate intracellular signals when IL-1 $\alpha$  or IL-1 $\beta$  binds to it.)

For IL-1 $\gamma$  see INTERLEUKIN-18.

The mature forms of IL-1 $\alpha$  and IL-1 $\beta$  are produced by intracellular cleavage of precursor pro-proteins. IL-1 $\beta$  is cleaved (activated) by a cysteine protease referred to as IL-1 $\beta$ -converting enzyme (ICE). (ICE also has a role in APOPTOSIS.)

Cells stimulated to produce IL-1 generally form both the  $\alpha$  and  $\beta$  types; however, in at least some cases (e.g. a monocyte responding to LPS), the amount of IL- $\beta$  produced is much greater than that of IL-1 $\alpha$ .

The known or presumed functions of IL-1 $\alpha$  and IL-1 $\beta$  *in vivo* include:

Activation, and induction of cytokine synthesis in macrophages.

Induction of ACUTE-PHASE PROTEINS in the liver.

Stimulation of activated B cells to proliferate and form antibody (and possibly stimulation of T cells).

## interleukin-2

Induction of synthesis of endothelial adhesion molecules during INFLAMMATION; induction of e.g. IL-1 and colony-stimulating factors in endothelial cells.

Induction of fever (apparently by stimulation of prostaglandins in the temperature regulatory region of the brain).

The biological activities of IL-1 overlap with those of tumour necrosis factor (TNF); IL-1 $\beta$  and TNF- $\alpha$  have been found to be synergistic when jointly administered to animals. Moreover, IL-1 $\beta$  and TNF- $\alpha$  stimulate the production of each other (as well as their own synthesis). However, despite the overlap in activities, it appears that, unlike TNF- $\alpha$ , IL-1 cannot promote cytotoxic activity via apoptosis.

**interleukin-2** (IL-2; killer helper factor, KHF; T cell growth factor, TCGF) A cytokine (see INTERLEUKINS) produced by T lymphocytes. In vitro, IL-2 can stimulate proliferation of antigenically or mitogenically activated T cells; in vivo, it appears to promote the growth/differentiation of T cells and to enhance the cytotoxicity of CD8<sup>+</sup> T cells and NK cells. (See also CD28 and ANTIBODY FORMATION.)

IL-2 promotes development of the Th1 subset of T lymphocytes, and is one of the cytokines secreted by these pro-inflammatory cells.

The gene encoding IL-2 (like that encoding IFN- $\gamma$ ) contains three introns.

(See also SEVERE COMBINED IMMUNODEFICIENCY.)

**interleukin-4** (IL-4) A cytokine (see INTERLEUKINS) produced by lymphocytes of the Th2 subset. IL-4 promotes differentiation of Th0 to Th2 cells, and in antigenically stimulated B cells it seems to e.g. induce class switching to IgG4 and IgE (IgG1 and IgE in mice). IL-4 is also involved in the formation of eosinophils – probably through its ability to promote the Th2 subset and (consequent) secretion of interleukin-5 (a cytokine required for the normal development of eosinophils).

The ability of naive CD4<sup>+</sup> T cells to secrete IL-4 is inhibited when ICAM-1 is co-expressed with antigen on the antigen-presenting cell [PNAS (1999) 96 3023–3028].

**interleukin-5** (IL-5) A cytokine (see INTERLEUKINS) produced by the Th2 subset of T lymphocytes (see also INTERLEUKIN-4). IL-5 appears to be the main stimulus for eosinophilia in certain parasitic infections. [Eosinophilia and helminthic infections: BCH (2000) 13 301–317.]

**interleukin-6** (IL-6) A cytokine (see INTERLEUKINS) produced by a variety of cells, including monocytes/macrophages, fibroblasts, endothelial cells and the Th2 subset of T lymphocytes. Synthesis of IL-6 in monocytes/macrophages can be induced by LPS (lipopolysaccharides) or by cytokines (TNF- $\alpha$  or IL-1); the  $\rho$  FIMBRIAE of uropathogenic *Escherichia coli* are reported to be potent inducers of IL-6.

IL-6 appears to have many roles in vivo. These roles include stimulation of growth, differentiation and antibody production in B cells, and induction of ACUTE-PHASE PROTEINS; in at least some cases IL-6 may contribute to the development of fever.

**interleukin-8** (IL-8) A cytokine (see INTERLEUKINS) produced by many types of cell, including monocytes/macrophages, neutrophils, fibroblasts, epithelial and endothelial cells, keratinocytes, NK cells and T cells. Agents that stimulate production of IL-8 include LPS and the cytokines IL-1 and TNF; production of IL-8 is inhibited by certain cytokines (e.g. IFN- $\gamma$  and IL-4) and by glucocorticoids.

IL-8 acts as a chemoattractant and activator primarily for neutrophils (see CHEMOKINES), and its main role in vivo is believed to be the recruitment of leukocytes to sites of infection/INFLAMMATION. IL-8 is found in many inflammatory diseases

but, unlike e.g. TNF, it does not induce shock when administered experimentally.

**interleukin-10** (IL-10) A cytokine (see INTERLEUKINS) produced e.g. by the Th2 subset of T cells and by monocytes stimulated by LPS. IL-10 has anti-inflammatory activity; for example, it inhibits proliferation and release of cytokines in antigen-stimulated Th1 cells, it inhibits release of pro-inflammatory cytokines from monocytes and macrophages, and it promotes proliferation and synthesis of antibodies in activated B cells.

**interleukin-12** (IL-12; natural killer stimulatory factor) A cytokine (see INTERLEUKINS) produced by B cells and also by macrophages acting as antigen-presenting cells. IL-12 appears to be essential for development of the Th1 subset of T cells from naive T cells; it also stimulates cytotoxicity in NK cells and enhances the release of cytokines from NK cells, macrophages and T cells. IL-12 also has anti-angiogenic activity (it inhibits development of new blood vessels).

The ability of macrophages to synthesize IL-12 is inhibited by the binding of measles virus to the complement receptor CD46.

**interleukin-18** (*syn.* interleukin-1 $\gamma$ ) An INTERLEUKIN produced e.g. by macrophages, keratinocytes and (murine) Kupffer cells. IL-18 is a pro-inflammatory cytokine which induces IFN- $\gamma$  in T cells (and murine spleen cells), enhances cytotoxicity in NK cells, and promotes the Th1 (rather than Th2) immune response. IL-18 also triggers activation of NF- $\kappa$ B and synthesis of e.g. IL-1 $\beta$ , TNF- $\alpha$  and Fas ligand.

IL-18 is synthesized in a biologically inactive form; it is activated by IL-1 $\beta$  converting enzyme (ICE; also referred to as caspase-1).

IL-18-mediated induction of IFN- $\gamma$  can be inhibited by the binding of poxvirus-encoded proteins to IL-18 [PNAS (1999) 96 11537–11542 (correction: PNAS (2000) 97 11673)].

**interleukin-21** An INTERLEUKIN which, in vitro, influences the proliferation/maturation of NK cells from bone marrow, the proliferation of B cells co-stimulated with anti-CD40, and the proliferation of T cells co-stimulated with anti-CD3. IL-21 is synthesized by activated CD4<sup>+</sup> T cells. [Nature (2000) 408 57–63.]

**interleukins** Certain CYTOKINES which are secreted by, and effective on, *leukocytes* (white blood cells) – but which, in some cases, can also be secreted by other types of cell (e.g. endothelial cells). It should be noted that the nomenclature is inconsistent in that some cytokines which conform to this description (e.g. tumour necrosis factor) are not formally referred to as interleukins; moreover, some interleukins are also classified in other named categories (e.g. interleukin-8 is a chemokine).

Each interleukin (IL) is designated by a number – e.g. IL-4, IL-6, IL-21.

(See also separate entries for individual interleukins.)

**intermediate filaments** (IFs; IMFs) In most types of eukaryotic cell: protein filaments, ca. 7–11 nm thick, which form part of the CYTOSKELETON. IMFs appear to be much more stable than either microfilaments or microtubules, and their roles are believed to include the strengthening of the cytoskeleton. IMFs differ e.g. according to cell type and species, and the monomers of different IMFs vary widely in size; the monomer *vimentin* (MWt ca. 55000) occurs in many types of cell.

**intermediate host** In heteroxenous coccidia: the host in which the asexual phase occurs (see EIMERIORINA).

**internal guide sequence** See SPLIT GENE (b).

**internalin A** See LISTERIOSIS.

**interphase** (1) See MITOSIS. (2) See DICTYOSTELIOMYCETES.

**interrupted gene** *Syn.* SPLIT GENE.

**interrupted mating** A technique used for studying gene transfer during bacterial CONJUGATION. For example, a population of cells of an Hfr strain of *Escherichia coli* is mixed with an F<sup>-</sup> (recipient) population (time zero). At regular intervals of time, a sample is taken from the mating mixture, agitated to separate mating cells, diluted to reduce the probability of further mating contacts, and plated on a medium which will support the growth of particular recombinant(s) but not of the parent Hfr or recipient cells. Samples taken within ca. 5 min of time zero generally do not contain recombinants; samples taken after increasing periods of time will contain recombinants with an increasing number of donor genes. Since donor genes are transferred sequentially, a given donor gene will appear in a recombinant after a characteristic time interval which depends on the distance of the gene from the origin of transfer and on the efficiency with which the gene recombines with the recipient's chromosome. Thus, the time of transfer of a gene gives an indication of the position of that gene in the donor chromosome, and interrupted mating can be a useful means of genetic mapping. (In practice, the further a gene is from the origin of transfer, the less frequently will it be transferred owing to the increased chances of strand breakage during the longer conjugation times; thus, the *yield* of recombinants expressing a given donor gene is also indicative of the position of that gene.) In *E. coli* the time taken to transfer the entire chromosome is typically ca. 100 min at 37°C (estimated using several Hfr strains differing in the position of the origin of transfer). The position of any gene can be given in terms of the time (in *minutes*) of transfer of that gene relative to a given origin of transfer – arbitrarily standardized at the *thr* (threonine synthesis) locus (zero minutes).

**interspecies hydrogen transfer** The mutually beneficial, unidirectional transfer of H<sub>2</sub> from H<sub>2</sub>-producing to H<sub>2</sub>-utilizing organisms in a given ecosystem (see e.g. ANAEROBIC DIGESTION).

**interstitial pneumonia** See PNEUMONIA.

**intervening sequence** See SPLIT GENE.

**intestinal tract flora** See GASTROINTESTINAL TRACT FLORA.

**intimin** See EPEC AND PATHOGENICITY ISLAND.

**intine** See CYST (a).

**Intoshellina** See ASTOMATIDA.

**intoxication** Poisoning. See e.g. FOOD POISONING and MYCOTOXICOSIS.

**intra-epithelial lymphocytes (IELs)** See T LYMPHOCYTE.

**intra vitam staining** See VITAL STAINING.

**intracisternal A-type particles** See A-TYPE PARTICLES.

**intracistronic complementation** See COMPLEMENTATION TEST.

**intracytoplasmic membranes** (also: cytomembranes) (*bacteriol.*)

Membranous systems or structures present within the cytoplasm in certain bacteria; according to type, the membranes may or may not be continuous with the CYTOPLASMIC MEMBRANE. Intracytoplasmic membranes occur e.g. in members of the METHYLOCOCCACEAE and NITROBACTERACEAE, in HYDROCARBON-utilizing bacteria, in photosynthetic bacteria (see CHLOROSOMES, CHROMATOPHORE (sense 2), THYLAKOIDS), etc. (See also MESOSOME and POLAR MEMBRANE.)

**intragenic complementation** See COMPLEMENTATION TEST.

**intragenic suppression** See SUPPRESSOR MUTATION.

**Intrapes** See UREDINIOMYCETES.

**Intrasporangium** A genus of aerobic bacteria (order ACTINOMYCETALES, wall type I). The organisms form branching substrate mycelium (hyphae: 0.4–1.2 μm in diam.) but no aerial hyphae; intercalary or subterminal swellings ('sporangia') occur in old cultures. Type species: *I. calvum*.

**intravital staining** See VITAL STAINING.

**intrinsic resistance** (to antibiotics) See ANTIBIOTIC.

**intron** See SPLIT GENE.

**intron homing** (in bacteria) The process in which introns (of either group I or group II) spread, in replicative fashion, to *allelic* intron-less genes. The mechanism of intron homing differs in the two types of intron.

Intron homing in group I introns is initiated when a DNA endonuclease (*homing endonuclease*), encoded within the intron sequence, acts at the potential insertion site in an intron-less allele, typically making a double-stranded cut. The lesion is repaired by enzymes which use the intron-containing gene as a template; in this way, a copy of the intron is synthesized in the insertion site of the intron-less allele.

In group II introns, the process begins with an intron-encoded protein which forms a complex with an RNA copy of the intron. This RNA-protein (RNP) complex is able to recognize the insertion site in an intron-less allele. The RNP complex can then (i) cut both strands at the target site, covalently inserting the RNA into one strand, and (ii) form a cDNA copy of the RNA (by virtue of the protein's reverse transcriptase function); the RNA is then replaced by DNA. The involvement of a reverse-transcribed copy of the intron (cf. group I introns) is reflected in the term *retrohoming* for the process in bacterial group II introns. Intron homing (in both group I and II bacterial introns) is outlined in a recent minireview [JB (2000) 182 5281–5289 (5281–5282)].

**inulin** A linear FRUCTAN consisting of (2 → 1)-β-linked fructofuranose residues. Inulins occur e.g. as storage polysaccharides in certain plants (e.g. in dahlia tubers).

**inulinase** An enzyme (β-fructosidase, 2,1-β-D-fructan-fructanohydrolase, EC 3.2.1.7) which hydrolyses INULIN to FRUCTOSE. Many microbial inulinases also show INVERTASE activity, and some can hydrolyse bacterial LEVAN. Microbial inulinases may prove useful in the commercial production of fructose from plant inulins [AAM (1983) 29 139–176].

**inv gene** (*Yersinia*) See FOOD POISONING (*Yersinia*).

**inv-spa genes** See PATHOGENICITY ISLAND and FOOD POISONING (*Salmonella*).

**invasin** In certain pathogenic bacteria: a type of cell-surface molecule which promotes uptake of the pathogen by (eukaryotic) host cells. Examples of invasins include 'invasin' (see FOOD POISONING (*Yersinia*)) and 'internalin A' (see LISTERIOSIS). In strains of UPEC (q.v.), the FimH adhesin appears to function as an invasin.

**invasion** (of phagocytes by pathogens) See end of section (a) in PHAGOCYTOSIS.

**invasiveness** (of a pathogenic microorganism) The ability of a pathogen to spread through a host's tissues; the degree of invasiveness reflects the relative insusceptibility of the pathogen to the host's defense mechanisms. (See also AGGRESSIN.)

**invasomes** See FOOD POISONING (*Salmonella*).

**inversion** (*mol. biol.*) See e.g. CHROMOSOME ABERRATION and RECOMBINATIONAL REGULATION.

**invert sugar** See INVERTASE.

**invertase** (1) (saccharase; sucrose; β-fructosidase; β-D-fructofuranoside fructohydrolase; EC 3.2.1.26) An enzyme which hydrolyses SUCROSE to glucose and fructose; it can also hydrolyse raffinose to fructose and melibiose. Invertase occurs in many yeasts and other fungi and in higher plants; it is obtained commercially mainly from BAKERS' YEAST in which it occurs in the cell wall as a mannoprotein containing ca. 50% mannose. Invertase is used chiefly in the conversion of sucrose to 'invert

## invertebrate diseases

sugar' (a mixture of glucose and fructose) used as a sweetening agent. (See also ENZYMES.)

(2) (*mol. biol.*) A recombinase responsible for the inversion of a segment of DNA: see RECOMBINATIONAL REGULATION.

**invertebrate diseases** See e.g. CRUSTACEAN DISEASES; INSECT DISEASES; NEMATOPHAGOUS FUNGI; OYSTER DISEASES.

**inverted repeat (IR)** In a double-stranded nucleic acid molecule: either of two regions in which the sequences of base pairs are similar or identical and have the same polarity but are opposite in orientation, e.g.:

(The repeated sequences may or may not be contiguous.)

In a single-stranded nucleic acid, IRs are sequences which are complementary and opposite in polarity, i.e., equivalent to one of the strands of a double-stranded IR.

(cf. DIRECT REPEAT; see also HAIRPIN and PALINDROMIC SEQUENCE.)

**invertible DNA** See RECOMBINATIONAL REGULATION.

**invJ gene** (*Salmonella typhimurium*) See NEEDLE COMPLEX.

**involution forms** (of bacteria) Morphologically or otherwise aberrant cells often seen in old cultures or among organisms cultured under harsh or hostile conditions (e.g. in the presence of sub-lethal concentrations of antibiotics). Involution forms are generally regarded as degenerate cells, degeneracy commonly being ascribed to the action of autolysins, failure of cell wall synthesis, or failure of cell division without cessation of macromolecule synthesis. (cf. L-FORM.)

**Iodamoeba** A genus of protozoa of the AMOEBIDA. *I. bütschlii* occurs in the human intestine; it is non-pathogenic. Trophozoites (ca. 9–20 µm diam.) contain numerous vacuoles and form blunt pseudopodia slowly; the single nucleus lacks peripheral chromatin and contains a large karyosome which is variable in shape and location and which is surrounded by clusters of granules. Cysts are irregular in shape, ca. 5–16 µm in diam., containing (usually) a single nucleus and a large persistent glycogen granule which stains a characteristic dark-brown with iodine; chromatoid bodies are usually absent.

**iodinated density-gradient media** Media used e.g. for the separation of macromolecules and sub-cellular fractions by isopycnic ultracentrifugation. High-density, non-ionic media in this category include e.g. a tri-iodinated benzamido derivative of glucose (*Metrizamide*), and a tri-iodinated derivative of benzoic acid (substituted with three highly hydrophilic aliphatic side chains) having a MWt of 821 and a density of 2.1 g/ml (*Nycodenz* – trade mark of Nyegaard & Co., Oslo, Norway).

**iodine** (a) (as an antimicrobial agent) Iodine has microbicidal activity against a wide range of bacteria (including endospores), fungi, and viruses; in many cases its antimicrobial activity appears to be due to the combination of molecular iodine with proteins (e.g. tyrosine is irreversibly iodinated). Iodine is readily soluble in organic solvents; *tincture of iodine* (used as an ANTI-SEPTIC) contains ca. 2.5% iodine in an ethanol–water solution of potassium iodide. The (low) solubility of iodine in water is increased by the presence of iodide, when the tri-iodide ( $\text{I}_3^-$ ) is formed;  $\text{I}_3^-$  itself is not antimicrobial, but it readily decomposes to release free iodine. For skin antiseptics aqueous solutions are generally preferred since they are less irritant than alcoholic solutions; the latter have been used e.g. for the disinfection of thermometers. The antimicrobial activity of aqueous iodine solutions is sometimes said to be maximal under acid conditions (pH 6 or below) – when dissolved iodine is present largely in the

molecular form ( $\text{I}_2$ ); however, an iodine solution was reported to inactivate poliovirus (at 25°C) more efficiently at pH 10 than at pH 6 (at pH 10 iodine occurs mainly as hypoiodous acid, HIO) [AEM (1982) 44 1064–1071]. Both  $\text{I}_2$  and HIO are strongly microbicidal; the ratio  $\text{I}_2$ :HIO in a solution of iodine is affected not only by pH but also by the total concentration of dissolved iodine and by the presence of organic matter [Book ref. 65, pp. 183–196]. The staining, corrosive and irritant properties of iodine can be overcome by complexing the element with certain high-MWt surface-active compounds – e.g. polyvinyl pyrrolidone, certain quaternary ammonium compounds; such complexes are referred to as *iodophores* (or iodophors). Iodophores have the antimicrobial properties of iodine together with the detergent properties of the surfactant, but only ca. 80% of the bound iodine is released; their response to pH is similar to that of iodine. Iodophores have been used e.g. for the disinfection of swimming-pool water and dairy equipment; polyvinyl pyrrolidone–iodine (*povidone–iodine*, *PVP–iodine*) has been used for treating skin and mucous membrane infections involving species of *Streptococcus*, *Staphylococcus* and *Candida*. *Betadine* and *Wescodyne* are iodophores used as antiseptics/disinfectants. (cf. IODOFORM; IODONIUM COMPOUNDS; see also CHLORINE.)

(b) (as a stain) See e.g. LUGOL'S IODINE.

**iodinin** A red, water-soluble pigment: 1,6-phenazinediol-5,10-dioxide; crystals of iodinin are formed in the culture medium e.g. by *Microbispora parva*.

**iodochlorohydroxyquin** See 8-HYDROXYQUINOLINE.

**5-iodo-2'-deoxyuridine** *Syn.* IDOXURIDINE.

**iodoform** ( $\text{CHI}_3$ ) A compound once widely used as an antiseptic; its antimicrobial activity is poor compared with that of IODINE.

**iodonium compounds** Compounds of the form  $\text{R}_2\text{IX}$ , in which R is an organic group and X is an inorganic ion; such compounds (e.g. diphenyliodonium chloride) contain trivalent iodine, are strongly basic, and possess antimicrobial properties, but their activity against spores is doubtful.

**iodophores** (iodophors) See IODINE (a).

**ion-exchange chromatography** See CHROMATOGRAPHY.

**ion-motive force phosphorylation** See ELECTRON TRANSPORT PHOSPHORYLATION.

**ion transport** Ion fluxes across ENERGY-TRANSDUCING MEMBRANES are involved e.g. in certain types of energy conversion (see e.g. PROTON ATPASE, PROTON PMPASE, END-PRODUCT EFFLUX), in the ion-linked uptake of certain substrates, in the regulation of intracellular osmotic pressure and pH, in the generation of electrochemical gradients of specific ions, and (apparently) in morphogenetic processes (see GROWTH (fungal)). Since ions cannot pass freely across such membranes (cf. OUTER MEMBRANE) their transmembrane translocation requires a driving force and more or less specific TRANSPORT SYSTEMS which may involve UNI-PORT, ANTI-PORT or SYM-PORT processes. The energy needed for transmembrane ion translocation may be provided, directly, by (a) a concentration gradient of the ion itself; (b) a gradient of another ion – e.g.  $\text{H}^+$  (see pmf in CHEMIOSMOSIS) or  $\text{Na}^+$  (see SODIUM MOTIVE FORCE); (c) ATP hydrolysis (see e.g. PROTON ATPASE); (d) the direct coupling of metabolism to ion transport (see ELECTRON TRANSPORT CHAIN and SODIUM MOTIVE FORCE); or (e) light (see PHOTOSYNTHESIS and PURPLE MEMBRANE).

*Ion electrochemical gradients as driving forces in ion transport.* A difference in the concentrations of a given ion on either side of a membrane constitutes an electrochemical gradient which may be able to provide a driving force for the transmembrane transfer of the ion itself or of other types of ion. However, the presence of such a gradient, and the existence of transmembrane route(s) for a given ion, does not necessarily mean that

the ion will be translocated: ion transport is subject to various intracellular and extracellular regulatory factors; moreover, the transmembrane route taken by a given ion may vary according e.g. to the extracellular concentration of that ion.

The potential energy of a transmembrane gradient of ions can be considered in terms of the change in Gibbs free energy which occurs when a charged species is transferred down an electrochemical gradient. Thus, e.g., if one mole of an ion,  $X^{m+}$ , is transferred down an electrical potential gradient of  $\Delta\psi$  millivolts, from concentration  $[X^{m+}]'$  to  $[X^{m+}]''$ , the net change in Gibbs free energy ( $\Delta G$ ) can be obtained from the general electrochemical equation:

$$\Delta G = -mF\Delta\psi + 2.3RT \log_{10} \frac{[X^{m+}]''}{[X^{m+}]'} \quad (1)$$

in which  $R$  is the gas constant,  $T$  is the absolute temperature,  $F$  is the Faraday constant, and  $m$  is the charge on the ion. This expression can be readily converted to the ion electrochemical potential gradient,  $\Delta\tilde{\mu}_{X^{m+}}$ :

$$\Delta\tilde{\mu}_{X^{m+}} = m\Delta\psi - Z \log_{10} \frac{[X^{m+}]''}{[X^{m+}]'} \quad (2)$$

where  $Z$  is the constant  $2.3RT/F$ . When applied to the gradient of an ion which crosses the membrane by electrogenic or electrophoretic uniport, equation 2 gives a measure of the driving force (due to the gradient itself) tending to cause movement of that ion across the membrane. (When an ion is translocated across a membrane by antiport or symport mechanisms equation 2 must be modified so as to accommodate the additional forces acting on the ion.)

If a proton gradient is maintained (imposed) across an energy-transducing membrane (e.g. by the use of metabolic energy) it will influence the electrochemical equilibria of each of the various types of ion distributed across the membrane. A given cation which crosses the membrane by electrical uniport will tend to redistribute across the membrane so as to reach an electrochemical equilibrium with the membrane potential of the pmf. For example, in the case of the bacterial cytoplasmic membrane (interior negative) a given cation which, initially, is largely extracellular will tend to be accumulated within the cytoplasm; if the cation reaches electrochemical equilibrium, the Gibbs free energy associated with its gradient becomes zero (i.e.,  $\Delta\tilde{\mu}_{X^{m+}} = 0$ ), and the relationship of the imposed membrane potential to the intracellular and extracellular concentrations of the given cation is then given by the Nernst equation:

$$\Delta\psi = \frac{Z}{m} \log_{10} \frac{[X^{m+}]_{\text{int}}}{[X^{m+}]_{\text{ext}}} \quad (3)$$

Equation 3 is obtained by re-arranging equation 2 in the special case when  $\Delta\tilde{\mu}_{X^{m+}} = 0$ .

In living cells, transmembrane ion translocation may affect either or both components of pmf. When ions are translocated by antiport or symport processes, the effect of such translocation on pmf depends e.g. on the stoichiometry of the process. For example, under some conditions the  $\text{Na}^+/\text{H}^+$  antiporter in *Escherichia coli* consumes pmf,  $\text{H}^+$  influx exceeding  $\text{Na}^+$  efflux. (Since the  $\text{H}^+/\text{Na}^+$  ratio is  $>1$ , operation of the antiporter in this mode consumes  $\Delta\psi$  as well as  $\Delta\text{pH}$ .) However, with high extracellular pH and  $\text{Na}^+$  the antiporter operates in such a way that  $\text{H}^+$  efflux is greater than  $\text{Na}^+$  influx – with consequent augmentation of pmf.

Ion uptake or extrusion commonly leads to compensatory ion fluxes. Thus, e.g. in mitochondria the effects of pmf-dependent

$\text{Ca}^{2+}$  uptake are modified by the operation of  $\text{Ca}^{2+}$  efflux systems, and a steady-state level of intramitochondrial  $\text{Ca}^{2+}$  is maintained by the continual cycling of  $\text{Ca}^{2+}$  across the membrane.

Modes of ion transport include:

(a) *Uniport driven by pmf*. Examples include pmf-mediated ATP synthesis (see PROTON ATPASE) and the uptake of  $\text{Ca}^{2+}$  by mitochondria [Book ref. 126, pp. 251–255].

(b) *Uniport coupled to ATP hydrolysis*. One example is the so-called Kdp transport system for  $\text{K}^+$  uptake in *Escherichia coli*. In this system, ATP hydrolysis (rather than pmf) at a membrane-bound  $\text{K}^+$ -ATPase (' $\text{K}^+$ -dependent ATPase', ' $\text{K}^+$ -stimulated ATPase', ' $\text{K}^+$ -pump') brings about the transmembrane translocation of  $\text{K}^+$  into the cell against a concentration gradient; the Kdp system becomes derepressed under conditions of  $\text{K}^+$  starvation. [ $\text{K}^+$  pathway in *E. coli*: Book ref. 126, pp. 653–666.] *Enterococcus faecalis* has been reported to use an  $\text{Na}^+$ -ATPase for  $\text{Na}^+$  extrusion [JB (1984) 158 844–848], and appears to use a  $\text{Ca}^{2+}$ -ATPase for  $\text{Ca}^{2+}$  extrusion.

(c) *Antiport driven by pmf or smf*. A  $\text{Ca}^{2+}/\text{H}^+$  antiporter has been reported to operate in membrane vesicles of *Bacillus subtilis* for  $\text{Ca}^{2+}$  extrusion [JB (1985) 164 1294–1300]. Similar systems appear to function in *E. coli* and *Azotobacter vinelandii* for  $\text{Ca}^{2+}$  extrusion, while a  $\text{Ca}^{2+}/\text{Na}^+$  antiporter may occur in halophilic organisms (e.g. *Halobacterium* spp.). Under some conditions the  $\text{Na}^+/\text{H}^+$  antiporter in *E. coli* can be driven by pmf, extruding  $\text{Na}^+$  and thus generating a SODIUM MOTIVE FORCE which can be used e.g. for melibiose uptake ( $\text{Na}^+/\text{melibiose}$  symport) and/or for the regulation of intracellular pH. However, in media of high pH, containing high concentrations of  $\text{Na}^+$ , the  $\text{Na}^+/\text{H}^+$  antiporter can generate pmf by proton extrusion [JB (1985) 163 423–429]. The  $\text{K}^+/\text{H}^+$  antiporter in *E. coli* is believed to function e.g. for the prevention of over-alkalinization of the cytoplasm in respiring cells.

(d) *Antiport coupled to ATP hydrolysis*. An  $\text{Na}^+/\text{K}^+$ -ATPase ('sodium pump') occurs in eukaryotic cells but not in prokaryotic cells or in mitochondria; energy derived from ATP hydrolysis at this ATPase is used to pump  $\text{Na}^+$  out and  $\text{K}^+$  in – the  $\text{Na}^+/\text{K}^+$  exchange ratio probably being ca. 3:2. The sodium pump is used e.g. to maintain intracellular osmotic stability, and to generate the smf needed for the uptake of certain substrates; it is inhibited by ouabain.

(e) *Symport systems*. In *E. coli*, LACTOSE is generally taken up by an  $\text{H}^+/\text{lactose}$  symport, while melibiose uptake involves an  $\text{Na}^+/\text{melibiose}$  symport. *Bacillus subtilis*, grown aerobically on citrate-containing media, can accumulate  $\text{Ca}^{2+}$  by a  $\text{Ca}^{2+}/\text{citrate}$  symport. An electrogenic  $\text{H}^+/\text{lactate}$  symport is used by some fermentative bacteria for energy conversion (see END-PRODUCT EFFLUX). In mitochondria, phosphate ( $\text{P}_i$ ) uptake occurs by electroneutral symport with  $\text{H}^+$ .

(f) *Other ion transport systems*. The so-called Trk system is responsible for much of the uptake of  $\text{K}^+$  in *E. coli*, and its activity is influenced by extracellular osmotic pressure. Trk is apparently not an ATPase, but it may be regulated by ATP or by a related compound [JGM (1985) 131 77–85].

**ionizing radiation** (in sterilization) Ionizing radiations (e.g. gamma-rays, beta-rays (electrons), X-rays) are used e.g. for the STERILIZATION of pre-packed medical and biological equipment such as surgical sutures, syringes, plastic Petri dishes, etc; currently they are not used to any great extent for the treatment of foodstuffs because they can cause toxicity and a deterioration in organoleptic properties in foods (but see FOOD PRESERVATION (g)). (See also SEWAGE TREATMENT.)

## $\beta$ -ionone ring

Ionizing radiations sterilize by supplying energy which permits a great variety of lethal chemical reactions to occur in contaminating organisms. In general, resistance to ionizing radiation increases in the order: multicellular organisms; Gram-negative bacteria; Gram-positive bacteria and moulds; bacterial endospores, viruses and viroids. Exceptions include e.g. *Deinococcus radiodurans*, which is more resistant than most or all bacterial endospores. Low (sublethal) doses of radiation can be mutagenic: e.g., in *Escherichia coli* the SOS SYSTEM – and hence error-prone (mutagenic) repair – may be induced. (In some cases, susceptibility to ionizing radiation is enhanced by the presence of water and/or oxygen.) Typically, toxins and other microbial products are more resistant than cells to ionizing radiations. Ionizing radiation may affect the materials being sterilized – e.g., a sterilizing dose of radiation can damage certain plastics.

Large-scale industrial sterilization is generally carried out with either a source of *gamma*-rays or a source of high-energy electrons. In a *gamma*-radiation plant the source of radiation is  $^{60}\text{Co}$  (cobalt-60): a radioactive isotope (half-life ca. 5.3 years) which provides both *gamma*-rays and (relatively) low-energy electrons. High-energy electrons (ca. 5–10 MeV) are produced in electron accelerators. The high-energy electron radiation used for sterilization carries more energy than does the *gamma*-radiation, although it has poorer powers of penetration; sterilization processes using high-energy electrons require exposures of the order of seconds, while those using *gamma*-rays require minutes or hours. The actual sterilizing dose used should, ideally, take into account e.g. the numbers and types of contaminants. In many countries the recommended minimum sterilizing dose is ca. 2.5 Mrad (25 kGy, see GRAY); a higher minimum is recommended in Scandinavia.

X-rays (a form of electromagnetic radiation) have been used e.g. for sterilizing items of high density which are impermeable to a beam of high-energy electrons.

[Quality assurance in radiation sterilization (theoretical treatment): JAB (1985) 58 303–313.]

(See also ULTRAVIOLET RADIATION.)

## $\beta$ -ionone ring See CAROTENOIDS.

**ionophore** Any substance which actually or effectively increases the permeability of biological membranes (or of artificial lipid bilayers) to one or more types of ion. *Channel-forming* ionophores (e.g. GRAMICIDINS) form pores in the membrane; such ionophores typically exhibit little discrimination between different ions, and may allow the passage of up to ca.  $10^7$  ions per pore per second. *Mobile carrier* ionophores (e.g. PROTON TRANSLOCATORS) diffuse within the membrane; they can exhibit a high degree of specificity for ions. Mobile carriers may effect ion UNIPORT (see e.g. VALINOMYCIN) or ion ANTIPORT (see e.g. A23187 and NIGERICIN). (See also ENNIATINS, LASALOCID, MACROTETRALIDES, SALINOMYCIN and ION TRANSPORT.)

**Iotech process** A process, involving explosive depressurization, in which the lignin–hemicellulose–cellulose complex from plant material is disrupted to release CELLULOSE for use as a feedstock in certain biotechnological processes (e.g. SINGLE-CELL PROTEIN or INDUSTRIAL ALCOHOL production).

**IP10** (chemokine) See CHEMOKINES.

**IpaA protein** See DYSENTERY.

**IpaB protein** See APOPTOSIS, DYSENTERY and PROTEIN SECRETION (type III systems).

**IPNV virus** (IPNV) The causal agent of INFECTIOUS PANCREATIC NECROSIS disease of salmonid fish. The virion has an unenveloped, icosahedral capsid (ca. 59 nm diam.) containing a

genome of two linear pieces of dsRNA (MWts ca.  $2.3 \times 10^6$  and  $2.5 \times 10^6$ ). Each strand of both RNA molecules is covalently linked by its 5' end to a protein – the first known case of genome-linked protein in a dsRNA virus. A minor protein component (VP105) is reputed to have dsRNA-dependent RNA transcriptase activity. [Review: CJM (1983) 29 377–384.] Virus transmission occurs vertically and horizontally.

IPNV is representative of a family of bisegmented dsRNA animal viruses, Birnaviridae [approved: Interviol. (1986) 25 141–143], which includes the INFECTIOUS BURSAL DISEASE VIRUS of chickens, DROSOPHILA X VIRUS, and various 'IPNV-like' viruses isolated from freshwater and marine fish (e.g. Eel Virus European, EVE, isolated from Japanese eels: *Anguilla japonica*; see also SPINNING DISEASE) and from marine bivalve molluscs (e.g. oysters – *Ostrea* and *Crassostrea* spp – and *Tellina tenuis*).  
**ipomeamarone** The (+)-enantiomer of 2-methyl-2-(4-methyl-2-oxopentyl)-5-(3-furyl) tetrahydrofuran: a PHYTOALEXIN produced by the sweet potato (*Ipomoea batatas*) in response to infection by certain fungal pathogens (e.g. the 'black rot' fungus *Ceratocystis fimbriata*). Ipomeamarone and its (–)-enantiomer ngaione (a normal constituent of certain trees and shrubs) are both hepatotoxic and can cause liver disease in livestock. (See also 4-IPOMEANOL.)

**4-ipomeanol** A substance, (1-(3-furyl)-4-hydroxy-1-pentane), produced by the sweet potato (*Ipomoea batatas*) in response to infection by certain fungal pathogens. It is toxic to animals, causing pulmonary oedema and massive pleural effusion. Together with e.g. ipomeanine (a dihydro derivative of 4-ipomeanol) it may be the 'lung oedema factor' responsible for the fatal respiratory disease in livestock (especially cattle) which follows ingestion of mould-damaged sweet potatoes. (cf. IPOMEAMARONE.)

**iprodione** See DICARBOXIMIDES.

**IPTG** Isopropyl- $\beta$ -D-thiogalactoside: a gratuitous inducer of the LAC OPERON.

**IQB** INDIVIDUAL QUICK BLANCH.

**IR** INVERTED REPEAT.

**Ir genes** Immune response genes: genes, associated with the MHC, which determine the ability of a mouse to make humoral and cell-mediated immune responses to a wide range of antigens; certain of these genes encode the IA ANTIGENS.

**Irgasan DP 33** *Syn.* TRICLOSAN.

**Iridaea** See RHODOPHYTA.

**iridescence** Coloured light formed by interference when white light is reflected from both surfaces of a thin film.

**iridescent insect viruses** See CHLORIRIDOVIRUS and IRIDOVIRUS.

**Iridia** See FORAMINIFERIDA.

**Iridoviridae** A family of icosahedral dsDNA-containing VIRUSES which infect invertebrates (mainly insects) and poikilothermic vertebrates. The family contains four genera: CHLORIRIDOVIRUS, IRIDOVIRUS, LYMPHOCYSTIVIRUS and RANAVIRUS. (cf. AFRICAN SWINE FEVER.)

Virion: icosahedral (ca. 120–300 nm diam.) and complex in structure, consisting of a nucleoprotein core surrounded by a layer composed of a lipoprotein membrane beneath an icosahedral protein lattice. Some virions may have an additional lipoprotein ENVELOPE derived from the host cell plasmalemma or endoplasmic reticulum; the envelope is apparently not essential for infectivity. Virions are generally stable at pH 3–10 and at 4°C; they can be inactivated e.g. at 55°C for 15–30 min. Members of the genera *Ranavirus* and *Lymphocystivirus* are sensitive to ether and non-ionic detergents.

Genome: one molecule (possibly two in some cases) of linear dsDNA (MWt ca. 100–250  $\times 10^6$ ); in at least some iridoviruses

(Chilo iridescent virus, frog virus 3, lymphocystis virus) the DNA is circularly permuted and terminally redundant – features unique among animal viruses (but quite common among bacteriophages). The molecular biology of iridoviruses has been studied mainly in FROG VIRUS 3.

**Iridovirus** (small iridescent insect virus group) A genus of viruses (family IRIDOVIRIDAE) which infect insects; infected larvae – and purified virus pellets – exhibit a blue iridescence. Virions (ca. 120 nm diam.) are ether-resistant. Type species: Chilo iridescent virus (insect iridescent virus type 6) [Intervirol. (1986) 25 141–143]. Other members include e.g. *Tipula* iridescent virus, which infects e.g. craneflies (*Tipula* spp) and many other insects, and insect iridescent viruses 1, 2, 9, 10 and 16–29. Probable member: *Chironomus plumosus* iridescent virus (*C. plumosus* is a type of non-biting midge, with haemoglobin-containing larvae known as ‘blood-worms’). Possible member: *Octopus vulgaris* disease virus.

**Irish moss** See CHONDRUS.

**iron** Most microorganisms need iron to form e.g. CATALASE, various oxidases, IRON-SULPHUR PROTEINS, ribonucleotide reductase, certain SUPEROXIDE DISMUTASES and/or CYTOCHROMES. Rarely – as e.g. in the type strain of *Lactobacillus plantarum* [FEMS (1983) 19 29–32] – iron is not an absolute requirement for growth. In many cases microorganisms synthesize and export SIDEROPHORES (q.v.) specifically for the sequestration and uptake of iron, particularly when iron is scarce.

Theoretically, siderophores could behave simply as shuttles – remaining extracellular and delivering iron from the environment to the cell surface for internalization by a membrane TRANSPORT SYSTEM. However, in *Escherichia coli*, the siderophore *enterochelin* (= enterobactin) carries (ferric) iron into the cytoplasm in an energy-dependent uptake process – binding initially at the cell-surface FEPA PROTEIN; within the cytoplasm, cleavage of the siderophore (by an esterase) releases the iron. Fe<sup>3+</sup> is reduced to Fe<sup>2+</sup>.

Some strains of *E. coli* produce *aerobactin*, a siderophore whose outer membrane receptor is the Iut protein.

Interestingly, *E. coli* can also use iron-coprogen and iron-ferrichrome complexes (receptors: FhuE and FhuA (= TonA) proteins, respectively) – even though *E. coli* produces neither coprogen nor ferrichrome. *E. coli* can also take up iron-citrate complexes.

**Iron uptake: regulation.** In e.g. *E. coli*, accumulation of intracellular Fe<sup>2+</sup> results in binding of ferrous ions to the regulator FUR PROTEIN which then represses the expression of a number of genes (including *fep*).

**Iron in pathogenicity.** Pathogens in animals must compete successfully with the host for available iron. [Iron in pathogenicity: RMM (1998) 9 171–178.] Thus, many pathogenic strains of *E. coli* secrete aerobactin; this promotes bacterial growth in extracellular concentrations of iron ca. 500-fold lower than those needed by the enterochelin system [Inf. Immun. (1986) 51 942–947]. Aerobactin seems able to compete successfully with the SIDEROPHILIN *transferrin* [Mol. Microbiol. (1994) 14 843–850].

For extracellular growth, *Mycobacterium tuberculosis* uses EXOCHELINS (which may obtain iron from siderophilins) and cell-surface ferric iron chelators: MYCOBACTINS (which internalize iron transferred from the exochelin).

Some pathogens obtain iron *directly* from siderophilins; thus, e.g. *Neisseria gonorrhoeae* and *N. meningitidis* have receptors for human TRANSFERRIN.

*Listeria monocytogenes* uses siderophores from other bacteria and various iron-chelating agents in the environment and mammalian hosts; a cell-surface ferric reductase may recognize all of these agents.

A pathogen's absolute need for iron has prompted the search for new vaccines that stimulate protective antibodies against the cell-surface receptors for iron-chelating agents.

*Pseudomonas aeruginosa* can reduce PYOCYANIN to leucopyocyanin which, in turn, can reduce the (ferric) iron in iron-transferrin complexes [Inf. Immun. (1986) 52 263–270]; iron thus released from transferrin may be available to iron-limited bacteria.

Virulence in the fish pathogen *Vibrio anguillarum* (see VIBRIO) depends partly on a plasmid-encoded siderophore, *anguibactin*. [Plasmid-mediated iron transport and bacterial virulence: ARM (1984) 38 69–89.]

In plant-pathogenic *Erwinia chrysanthemi*, mutants defective in iron transport were non-pathogenic [JB (1985) 163 221–227].

[Iron metabolism in pathogenic bacteria: ARM (2000) 54 881–941.]

**Applied aspects.** Siderophore-producing strains of *Pseudomonas putida* used for the BACTERIALIZATION of seed potatoes apparently increase the yield in short-rotation crops [NJPP (1986) 92 249–256]; thus, siderophores may modify the RHIZOSPHERE microflora in favour of the potato plant. Interestingly, some microbial ferrisiderophores are taken up by plants [see for example FEBS (1986) 209 147–151].

**iron bacteria** Bacteria whose growth is associated with the extracellular deposition of oxides or hydroxides of iron and/or manganese; such deposits usually cover or impregnate the bacterial capsule, sheath or stalk. Iron bacteria occur e.g. in various iron- and manganese-containing soils and waters, and in water distribution systems (see also TUBERCLE (sense 2)). Evidence that the deposition of metal oxides/hydroxides is a *direct* result of microbial metabolism has not been obtained for the majority of the iron bacteria (cf. GALLIONELLA) – many of which have not even been grown in pure culture; the opportunity for biological oxidation of Fe<sup>2+</sup> is relatively poor under aerobic conditions (in which Fe<sup>2+</sup> undergoes rapid autoxidation) but becomes significant under microaerobic conditions, particularly at pH 5–6, in which autoxidation is slow. (Autoxidation of Mn<sup>2+</sup> is slow below pH 9.) The iron bacteria include e.g. CLONOTHRIX, CRENOTHRIX, GALLIONELLA, LEPTOTHRIX, METALLOGENIUM, OCHROBIUM and SIDEROCAPSA; some authors include the acidophilic iron oxidizers, e.g. *Thiobacillus ferrooxidans*.

[Review: ARM (1984) 38 515–550.]

**iron box** See OPERATOR.

**iron corrosion** See CATHODIC DEPolarIZATION THEORY.

**iron-sulphur centre** See IRON-SULPHUR PROTEINS.

**iron-sulphur proteins** (Fe-S proteins) A category of iron- and sulphur-containing proteins which are widely distributed in cells of all types and which participate e.g. in electron transfer processes (see e.g. ELECTRON TRANSPORT CHAIN and NITROGENASE); except in rubredoxins (see later) each iron-sulphur protein contains two or more iron atoms linked to one another by an equal number of (acid-labile) sulphur atoms, the entire complement of iron and acid-labile sulphur forming one or more discrete *iron-sulphur centres* (= *iron-sulphur clusters*) linked to the protein typically by thiolate side-chains of cysteine residues. (See also RHODANESE.)

*Rubredoxins* are traditionally included with the Fe-S proteins, although they contain only one iron atom and no acid-labile sulphur; the iron is linked to the protein via four thiolate

## ironophores

ligands. A rubredoxin with an  $E_m$  of ca.  $-60$  mV occurs in *Clostridium pasteurianum*. (See also HYDROCARBONS.)

Other iron–sulphur proteins contain, per molecule, one or more of the following types of centre: [2Fe–2S] (see also RIESKE PROTEIN), [3Fe–3S] (found e.g. in *Azotobacter vinelandii*), and/or [4Fe–4S]; 2S, 3S and 4S refer specifically to *acid-labile* sulphur.

Iron–sulphur proteins can be classified as either *simple* (e.g. rubredoxins, FERREDOXINS) or *complex* (= *conjugated*), the latter having additional prosthetic groups such as a flavin or haem or a non-iron metal atom (e.g. molybdenum). Complex iron–sulphur proteins include e.g. the sulphite reductase of *Escherichia coli* (EC 1.8.7.1), which includes four [4Fe–4S] centres together with molecules of FAD, FMN and sirohaem, and a chloroplast nitrate reductase (EC 1.7.7.1) containing one [4Fe–4S] centre and sirohaem.

[Review: Book ref. 146, pp. 79–120.]

**ironophores** *Syn.* SIDEROPHORES.

**Irpex** See APHYLLOPHORALES (Polyporaceae).

**IRS** Internal resolution site: see Tn3.

**IS element** See INSERTION SEQUENCE.

**IS1** A 768-bp INSERTION SEQUENCE present e.g. in R plasmids (see also Tn9), the genome of BACTERIOPHAGE P1, the chromosome of *Escherichia coli* K12 (in multiple copies), etc. IS1 seems to transpose preferentially to target sites which are rich in AT, frequently cleaving at a GC pair within such a region. Transposition can apparently generate either 9- or 8-bp duplications of target DNA [PNAS (1985) 82 839–843]. IS1 encodes two genes, *insA* and *insB*, which are required for IS1-mediated transposition and cointegration.

**IS5** A 1195-bp INSERTION SEQUENCE present in the chromosome of *Escherichia coli* K12 strains; it has a high target specificity (see TRANSPOSABLE ELEMENT).

**IS10** An INSERTION SEQUENCE that has been found only in association with Tn10 (q.v.).

**IS50** See Tn5.

**IS101** A 209-bp INSERTION SEQUENCE which is defective and carries no genes; its transposition depends entirely on  $\gamma\delta$ -encoded transposase and resolvase functions (see Tn3). (cf. Tn951.) Its inverted repeat sequences are closely related to, but not identical with, those of  $\gamma\delta$ .

**IS900** An INSERTION SEQUENCE reported to be specific to *Mycobacterium paratuberculosis*. IS900 has been used e.g. as a target for PCR-based detection of *M. paratuberculosis* in milk [AEM (1998) 64 3153–3158].

**IS1000** *Syn.*  $\gamma\delta$  (see Tn3).

**IS6110** An INSERTION SEQUENCE regarded as specific to members of the *Mycobacterium tuberculosis* complex (i.e. *M. tuberculosis*, *M. bovis*, BCG, *M. africanum* and *M. microti*). The number of copies of IS6110 per genome varies with strain; a few strains of *M. tuberculosis* apparently lack the sequence, while most strains of *M. bovis* appear to contain only a single copy. Some 16 copies of IS6110 occur in the genome of the H37rv reference strain of *M. tuberculosis* [Nature (1998) 393 537–544].

Some authors have questioned the specificity of IS6110, indicating that a central region of the sequence is similar to a sequence in non-tuberculous mycobacteria [JCM (1997) 35 799–800]; others have affirmed the specificity of this sequence for members of the *M. tuberculosis* complex [JCM (1997) 35 800–801].

IS6110 has been widely used for TYPING isolates of *M. tuberculosis*. However, using SPOLIGOTYPING, some authors have found that, in a particular subset of multidrug-resistant

strains, the rate of transposition of IS6110 within the genome may be too high for reliable RFLP-based typing even over a period of a few years [JCM (1999) 37 788–791]. By contrast, others have reported that IS6110-based typing gives insufficient discrimination [JCM (1999) 37 3022–3024].

**isatin- $\beta$ -thiosemicarbazone (IBT)** An ANTIVIRAL AGENT. IBT and some of its derivatives (e.g. methisazone: *N*-methyl-IBT) inhibit the replication of poxviruses, apparently acting at a late stage in the replication cycle. Methisazone has been used prophylactically in cases of exposure to smallpox, and in the treatment of complications of smallpox vaccination. (See also THIOSEMICARBAZONES.)

**ISEM** IMMUNOSORBENT ELECTRON MICROSCOPY.

**IS-GA** See IN SITU PCR.

**ISH** See PROBE.

**isidiate (lichenol.)** Bearing or consisting of isidia (see ISIDIUM).

**isidium (lichenol.)** A small protuberance (ca.  $0.01$ – $0.3 \times 0.5$ – $3.0$  mm) which arises from the surface of the thallus in certain lichens; it consists of photobiont cells and medullary tissue, typically covered by a cortex, and may be e.g. spherical, flattened, cylindrical, branched ('coralloid'), according to species. In many isidiate lichens the isidia are easily broken off and probably serve as propagules; in other cases they may serve to increase the surface area – and hence the assimilative capacity – of the thallus.

**islandic acid** A water-soluble, acidic, extracellular, (1  $\rightarrow$  6)- $\beta$ -linked glucan containing malonic acid residues; it is produced by *Penicillium islandicum*.

**islet-activating protein** *Syn.* PERTUSSIS TOXIN.

**isoaccepting tRNA** See TRNA.

**isoamylase** See DEBRANCHING ENZYMES.

**isoantibody** Any antibody formed against an antigen derived from a genetically different individual of the same species.

**isocitrate dehydrogenase** See TCA CYCLE.

**isocitrate dehydrogenase kinase–phosphatase** See TCA CYCLE.

**isocitrate lyase** See TCA CYCLE and SERINE PATHWAY.

**isiconazole** See AZOLE ANTIFUNGAL AGENTS.

**isodiametric** Rounded or polyhedral: having roughly the same diameter in all directions.

**isoelectric focusing (IEF)** A type of ELECTROPHORESIS in which amphoteric molecules (e.g. proteins) are separated from one another on the basis of their differing ISOELECTRIC POINTS (IEPs). In principle, a column of gel (e.g. polyacrylamide) containing a mixture of AMPHOLYTES (each with a different IEP) is subjected to an electrical potential difference until the ampholytes are distributed (according to their IEPs) to form a stable pH gradient. The sample (e.g. mixture of proteins) is then added and subjected to an electrical potential difference so that each protein migrates to the region corresponding to its IEP; proteins may then e.g. be stained in situ or removed from the gel.

**isoelectric point (IEP; pI)** In substances (e.g. proteins) whose charge depends on the pH of the medium: the pH at which the molecule has no *net* charge and hence zero electrophoretic mobility.

**isoelectrofocusing** *Syn.* ISOELECTRIC FOCUSING.

**isoenzyme (isozyme)** One of a number of ENZYMES which catalyse the same reaction(s) but differ from each other e.g. in primary structure and/or electrophoretic mobility. (See also ZYMODEME.)

**isofloridoside** 1-*O*-Glycerol- $\alpha$ -D-galactopyranoside: a storage and osmoregulatory glycoside in e.g. *Poteroichromonas malhamensis* and also (often with FLORIDOSIDE) in members of the Rhodophyta.

**isogamy** The union of gametes which are alike in form and physiology. (cf. ANISOGAMY.)

**isogenic** Refers to two or more organisms or cells which have identical genotypes.

**isoimmunization** The stimulation of an immune response to antigens derived from another individual of the same species. (cf. HETEROIMMUNIZATION.)

**isokont** Refers to a pair of flagella (on a biflagellate cell) which are similar in length and type. (cf. HETEROKONT.)

**isolation** (1) (*microbiol.*) Any procedure in which a given species of organism, present in a particular sample or environment, is obtained in pure CULTURE. According to organism, isolation may involve e.g. culture on a selective MEDIUM, ENRICHMENT, and/or the use of techniques such as FILTRATION or MICROMANIPULATION.

(2) (*med., vet.*) The separation of patient(s) or animal(s) from others in order e.g. to prevent the spread of disease. (See also QUARANTINE.)

**L-isoleucine biosynthesis** Many microorganisms synthesize isoleucine by the pathway shown in Appendix IV(d). Certain bacteria generate  $\alpha$ -oxobutyrate by alternative pathways: e.g., from L-glutamate in *Escherichia coli*, from L-methionine in obligately anaerobic bacteria, from pyruvate in *Leptospira* sp, and from propionate in *Clostridium sporogenes* [JGM (1984) 130 309–318, q.v. for refs].

**isolichenin** A linear  $\alpha$ -D-glucan containing (1  $\rightarrow$  3) and (1  $\rightarrow$  4) linkages; it occurs in certain lichens (e.g. *Cetraria islandica*). (cf. LICHENIN.)

**isomaltose** A reducing disaccharide:  $\alpha$ -D-glucopyranosyl-(1  $\rightarrow$  6)-D-glucopyranose. (cf. GENTIOBIOSE.)

**isomarticin** See NAPHTHAZARINS.

**isomerases** ENZYMES (EC class 5) which catalyse isomerizations (i.e., intramolecular rearrangements). They include e.g. *epimerases* (e.g. that catalysing the interconversion of D-ribulose 5-phosphate and D-xylulose 5-phosphate), *racemases* (e.g. those catalysing L- and D-amino acid interconversions), etc.

**isometric labile ringspot viruses** *Syn.* ILARVIRUSES.

**isometric ssDNA phages** *Syn.* MICROVIRIDAE.

**isometric virus** A virus in which the virion is more or less spherical, usually exhibiting ICOSAHEDRAL SYMMETRY.

**isomorphic** Morphologically similar or identical.

**isomorphic alternation of generations** See ALTERNATION OF GENERATIONS.

**isoniazid** A synthetic ANTIBIOTIC, isonicotinic acid hydrazide (INH), bactericidal for actively growing cells of *Mycobacterium tuberculosis*, *M. bovis* and, to a lesser extent, other *Mycobacterium* species. INH is an important anti-TUBERCULOSIS drug whose function depends on prior activation by a catalase (KatG; *katG* gene product) within the bacterium; the activated drug apparently inhibits enzymic step(s) in the synthesis of essential cell-wall MYCOLIC ACID (Microbiology (2000) 146 289–296].

Resistance to isoniazid can follow mutation in any of several genes, including *katG* and *ahpC*; isoniazid is used in combination therapy for the treatment of tuberculosis. (See also RISE-RESISTANT TUBERCULOSIS.)

In *M. tuberculosis*, susceptibility to isoniazid, oxidative stress response and iron regulation are related features, but precise details of relationships remain to be elucidated [see TIM (1998) 6 354–358].

**isopanose**  $\alpha$ -Maltosyl-(1  $\rightarrow$  6)-D-glucose.

**isopenicillin N** See PENICILLIN N.

**isopropanol** See ALCOHOLS.

**isopropyl- $\beta$ -D-thiogalactoside** A gratuitous inducer of the LAC OPERON.

**isoporalen** See PCR.

**isopycnic centrifugation** See CENTRIFUGATION.

**isorenieratene** See LIGHT-HARVESTING COMPLEX.

**isoschizomers** RESTRICTION ENDONUCLEASES which recognize the same sequence in DNA but which are derived from different species. [Restriction endonucleases and their isoschizomers: NAR (1991) 19 2077–2109.]

**Isosphaera** See BACTERIA (taxonomy).

**Isospora** A genus of parasitic protozoa (suborder EIMERIORINA) which form disporic, tetrazoic oocysts (cf. e.g. EIMERIA); the genus, as originally defined, includes only homoxenous species, but it has been expanded by some authors [see AP (1982) 20 403–406] to include heteroxenous species which form disporic, tetrazoic oocysts (typically shed unsporulated) and which may form tissue cysts in the intermediate host. The expanded genus thus includes e.g. organisms otherwise placed in the genera BESNOITIA and TOXOPLASMA, as well as the obligately heteroxenous *Isospora datusi* (= *Hammondia hammondi*).

For generalized homoxenous and heteroxenous life cycles see EIMERIORINA; see also COCCIDIOSIS (q.v. for refs).

**Isosticha** See HYPOTRICHIDA.

**isosulfazecin** See MONOBACTAMS.

**isotopic labelling** (probe) See PROBE.

**Isotricha** A genus of ciliates related to DASYTRICHA.

**isotype** (class) Each of the five main variant forms (classes) of IMMUNOGLOBULIN (IgA, IgD, IgE, IgG and IgM); isotypes differ in the amino acid sequence in the constant region of their heavy chains. Immunoglobulins of all five isotypes occur in every normal individual (cf. ALLOTYPE).

A given isotype may be divided into subclasses (distinguishable serologically). For example, there are several subclasses of IgG (designated IgG1, IgG2 etc.).

**isotype switching** See ANTIBODY FORMATION.

**isovelleral** See LACTARIUS.

**IsoVitaleX** A commercial preparation – containing e.g. vitamin B<sub>12</sub>, amino acids, purines, D-glucose, thiamine and TPP, NAD<sup>+</sup>, Fe(NO<sub>3</sub>)<sub>3</sub>, PABA – used for the enrichment of media for isolating and/or cultivating fastidious bacteria (e.g. *Haemophilus spp.*).

**isozyme** *Syn.* ISOENZYME.

**Issatchenkia** A genus of yeasts (family SACCHAROMYCETACEAE) which reproduce by multilateral budding; pseudomycelium is formed. Asci are persistent. Ascospores: spheroidal, rough-surfaced. Cells contain ubiquinone-7 (Q-7). Sugars may be fermented; NO<sub>3</sub><sup>-</sup> is not assimilated. A pellicle develops on liquid cultures. Species – *I. occidentalis* (anamorph: *Candida sorbosa*), *I. orientalis* (anamorph: *Candida krusei*), *I. scutulata*, *I. terricola* – have been isolated from soil, fruit, etc. [Book ref. 100, pp. 214–223.]

**isthmus** (*biol.*) Any narrow region connecting two structures in an organism or cell: see e.g. *placoderm* DESMIDS.

**iteron** One of a number of repeated ('reiterated') nucleotide sequences which occur in and/or near the replication origin(s) in certain plasmids – e.g. the F PLASMID and the R6K PLASMID.

**Itersonilia** A genus of fungi *incertae sedis*; the organisms form mycelium containing CLAMP CONNECTIONS, and it has been suggested that *I. perplexans* forms a one-spored basidium [TBMS (1983) 80 365–368].

**itraconazole** A clinically useful AZOLE ANTIFUNGAL AGENT (a triazole); it has a high MWt and is highly lipophilic. Itraconazole has a broad spectrum of activity, inhibiting yeasts, dimorphic fungi and filamentous fungi; it appears to be less toxic to mammalian tissues than e.g. miconazole or ketoconazole owing

## IUB

to its much higher selectivity for the fungal rather than the mammalian cytochrome P-450. [Review: Arch. Derm. (1986) 122 399–402.]

[Pharmacology of itraconazole (review): Drugs (2001) 61 (supplement 1) 27–37.]

**IUB** International Union of Biochemistry.

***iucA–iucD* genes** See SIDEROPHORES.

**IUDR** See IDOXURIDINE.

**IUPAC** International Union of Pure and Applied Chemistry.

***iutA* gene** See SIDEROPHORES.

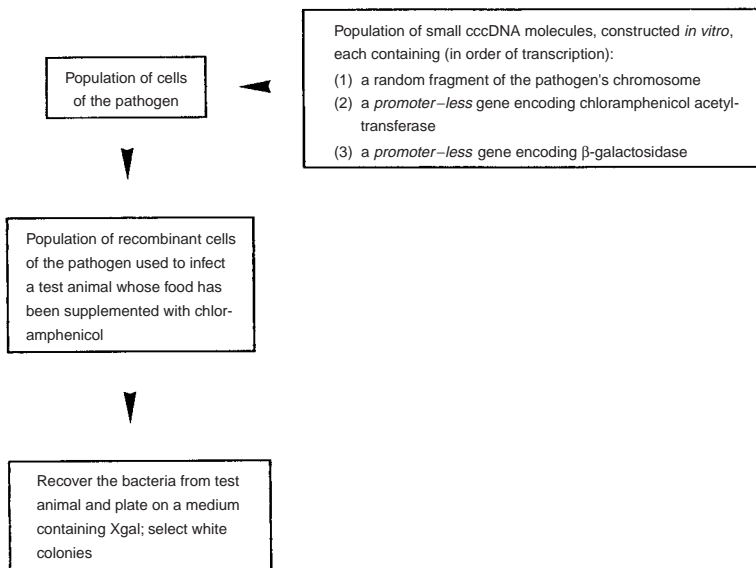

**ivanolysin** See THIOL-ACTIVATED CYTOLYSINS.

**IVET** (in vivo expression technology) A technique used for detecting those genes (of a pathogen) which are transcribed only during infection of the host; such genes *may* be virulence genes, and this can be studied further e.g. by animal tests involving strains of the pathogen which are mutant for the given gene. IVET is outlined in the figure.

[Some examples of IVET: TIM (1997) 5 509–513. Behaviour of bacteria in the host, and the methodology for studying it: TIM (1998) 6 239–243.]

**IVS** (*mol. biol.*) Intervening sequence (= *intron*); see SPLIT GENE.

**iwatake** The edible lichen *Umbilicaria esculenta*.

IVET (in vivo expression technology): the principle (diagrammatic). The figure shows one of several forms of IVET.

IVET detects those genes of a pathogen whose expression is induced *during* (and *only* during) infection of the host animal.

Vector molecules (see *top, right*) are inserted, by transformation, into a population of cells of the pathogen. In each transformed cell, the (random) fragment of chromosome in the vector inserts into the corresponding part of the pathogen's chromosome (by an 'insertion–duplication' mechanism); because the vector molecules contain different fragments of the chromosome they will insert into different chromosomal sites in different cells – forming a heterogeneous population of recombinant cells.

In some recombinant cells, the vector's two promoter-less genes will have been inserted 'in frame' with an upstream promoter. In such cells, *both* of these genes will be transcribed *if the promoter is active*.

The recombinant cells of the pathogen are used to infect a test animal whose food contains the antibiotic chloramphenicol (to which the pathogen is normally susceptible). Under these conditions, a recombinant cell can grow only if it produces chloramphenicol acetyltransferase (CAT), i.e. only if the CAT gene (in the vector molecule) is controlled by an *active* promoter; thus, the fact that a given recombinant cell *grows* within the animal indicates that its CAT gene is controlled by a promoter *which is active within the test animal*. (Because synthesis of CAT points to an active promoter, the CAT gene is sometimes called a 'reporter' gene.) Cells producing CAT can form large populations which greatly outnumber cells that do not form CAT.

We need to know whether the promoter controlling an expressed CAT gene is active *only* when the pathogen is in the test animal – or whether it is also active when the pathogen is cultured (e.g. on agar media). If active only in the test animal, this indicates that the gene *normally* controlled by that promoter is induced during infection; such a gene is of interest because of its possible association with virulence. To study promoter activity further, the recovered bacteria are plated on a medium which lacks chloramphenicol but which contains the agent XGAL (q.v.); all the cells will grow. If a given promoter is active in culture then  $\beta$ -galactosidase will be formed and will give rise to a *blue-green* colony; such a colony tells us that activation of the given promoter does not occur *only* within the test animal. A *white* (*lac*<sup>-</sup>) colony indicates that  $\beta$ -galactosidase (and CAT) can be formed *only* within the test animal, i.e. the relevant promoter is active only when the pathogen is actually infecting the animal. The gene which is normally controlled by this promoter can be isolated, cloned and sequenced and examined for its role in virulence.

Reproduced from *Bacteria*, 5th edition, Figure 11.3, pages 304–305, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

# J

**J chain** A cystine-rich polypeptide (MWt ca. 15000) involved in the formation of dimeric and polymeric forms of both IgA and IgM (q.v.). In an IgA dimer the J chain forms a link between cystine residues situated near the C-terminal ends of the heavy chains in the two monomers.

**jaagsiekte** (pulmonary adenomatosis) A SHEEP DISEASE characterized by chronic progressive pneumonia in which the alveolar spaces become occluded by adenomatous ingrowths of the epithelium; the causal agent(s) appear to be viral (a herpesvirus and/or a retrovirus), but the causal agent of MAEDI is not involved. Incubation period: 1–3 years. Symptoms: dyspnoea, emaciation, and a profuse watery nasal discharge which may contain hyperplastic adenomatous epithelial cells; fever and inflammation are absent. Death occurs within ca. 4 months. [Book ref. 33, pp. 807–808.]

**Jaccard coefficient** See entry S<sub>J</sub>.

**jack bean lectin** CONCANAVALIN A.

**jack-in-the-box ascus** *Syn.* BITUNICATE ASCUS.

**Jacquard coefficient** See entry S<sub>J</sub>.

**JAK** See CYTOKINES.

**janimycin** A polypeptide ANTIBIOTIC which inhibits transglycosylation in PEPTIDOGLYCAN synthesis.

**Janthinobacterium** A genus of Gram-negative, strictly aerobic, catalase-positive, chemoorganotrophic bacteria which occur e.g. in soil and water; the organisms are motile (flagellated) rods, 0.8–1.2 × 2.5–6.0 μm. Metabolism is respiratory (oxidative); acid (no gas) is formed from e.g. glucose. Growth occurs in/on simple media (e.g. peptone water); violet, often gelatinous, colonies are formed on nutrient agar. Optimum growth temperature: 25°C, maximum 32°C. MR –ve; VP –ve; usually oxidase +ve. GC%: ca. 61–67. Type species: *J. lividum* (formerly *Chromobacterium lividum*). [Book ref. 22, pp. 376–377.]

**Janus green** A blue basic DYE which has both azine and azo chromophores; it is used e.g. in VITAL STAINING.

**Janus kinase** See CYTOKINES.

**Japanese B encephalitis** (Japanese encephalitis; Russian autumn encephalitis) A viral ENCEPHALITIS which affects man, pigs and horses; it occurs in epidemics in e.g. Japan, China, Korea and parts of India. The disease is usually acute, but may run a protracted course with acute exacerbations. The causal agent is a flavivirus (see FLAVIVIRIDAE) which occurs e.g. in wild birds and is transmitted by mosquitoes (usually *Culex* sp). An inactivated vaccine has been used in Japan. [Review: ARM (1986) 40 395–414.]

**Japanese river fever** *Syn.* SCRUB TYPHUS.

**Japonochytrium** See THRAUSTOCHYTRIDS.

**Jarisch–Herxheimer reaction** (Herxheimer reaction) A potentially fatal reaction which may follow the first effective chemotherapy against e.g. brucellosis or syphilis – or, in general, diseases caused by certain bacteria (particularly spirochaetes) and protozoa. Symptoms (e.g. an initial rise in temperature) are associated with a cascade of CYTOKINES which seem to be responsible for at least some of the pathophysiology. [Review: BCID (1994) 1 65–74.] The reaction has been prevented by treatment with antibodies against tumour necrosis factor (TNF) [NEJM (1996) 335 311–315].

**jarrah dieback** A disease of the jarrah (*Eucalyptus marginata*) – an important timber tree e.g. in Western Australia; the causal agent is generally believed to be *Phytophthora cinnamomi*, but

waterlogging of the soil may be an important contributory factor [New Phyt. (1985) 101 743–753]. (See also TREE DISEASES.)

**javanicin** See NAPHTHAZARINS.

**JC virus** See POLYOMAVIRUS.

**JCM** Japanese Collection of Microorganisms, Riken, Wako-shi, Saitama 351, Japan.

**jelly fungi** Those fungi of the TREMELLALES (e.g. *Exidia glandulosa*, *Tremella mesenterica*) which form gelatinous fruiting bodies – or all fungi (including e.g. *Auricularia* spp) which do so.

**jelly lichens** Gelatinous lichens e.g. of the genera COLLEMA, LEMPHOLEMMA, LEPTOGIUM.

**Jembrana disease** A CATTLE DISEASE, involving e.g. fever, generalized lymphadenopathy, nasal discharge, haemorrhage and splenomegaly; it was formerly assumed to be a tick-borne rickettsial disease but is now known to be caused by the bovine immunodeficiency virus.

**jet loop fermenter** A LOOP FERMENTER in which culture is continually withdrawn from the column and pumped back (together with air/gas) via a nozzle at the base of the DRAFT TUBE; this promotes liquid circulation and dispersion of the injected gas. In the *plunging jet* design of the Vogelbusch IZ fermenter, re-cycled culture (and air) is introduced under pressure at the top of the column (which lacks a draft tube); this design achieves a high level of dissolved oxygen.

**Jew's ear fungus** See AURICULARIA.

**Jeyes fluid** A household and horticultural DISINFECTANT consisting of coal tar acids solubilized with a soap prepared from pine resin and alkali.

**Jirovecella** See ASTOMATIDA.

**JK coryneforms** Coryneform bacteria which are resistant to (usually many) antibiotics; they are being increasingly reported as causes of serious nosocomial infections in immunosuppressed patients and patients with implants (pacemakers, prosthetic heart valves, etc). [Biochemical and cultural characteristics: JCP (1986) 39 654–660.]

**Johne's bacillus** *Mycobacterium paratuberculosis*.

**Johne's disease** (chronic bacillary diarrhoea; paratuberculosis) A chronic intestinal CATTLE DISEASE which may also affect other ruminants (e.g. sheep, goats, deer); it occurs worldwide and is caused by *Mycobacterium paratuberculosis*. Infection occurs on ingestion of contaminated water, grass etc. In cattle, the incubation period is long (usually more than 12 months); symptoms are uncommon in animals under 2 years old. The pathogen multiplies in the intestinal wall which becomes thickened and poorly absorptive; scouring is at first intermittent but becomes persistent and severe. The animal becomes emaciated and anaemic. There is no effective treatment. In goats, the mesenteric lymph nodes become oedematous and there is emaciation, but scouring is not a feature [VR (1983) 113 464–466]. In sheep, the disease involves emaciation but not scouring.

**joint-breaker fever** *Syn.* O'NYONG-NYONG FEVER.

**joint-ill** (*vet.*) In e.g. calves, foals and lambs: lameness involving inflammation of the articular surfaces of the joints, caused by any of a variety of organisms – e.g. *Actinobacillus equuli*, *Actinomyces pyogenes*, *Erysipelothrix rhusiopathiae* (particularly in piglets), salmonellae, *Staphylococcus aureus*.

**joint molecule** (*mol. biol.*) A term sometimes used to refer to a structure composed of two dsDNA molecules held together only

## Jones–Mote sensitivity

by hydrogen bonding – as e.g. in early intermediates formed during homologous RECOMBINATION.

**Jones–Mote sensitivity** (cutaneous basophil hypersensitivity) A form of hypersensitivity which may develop e.g. when a human subject is primed with a soluble protein antigen, or a guinea pig is primed with a protein in incomplete Freund's adjuvant; subsequent challenge with the relevant allergen (within a few days of priming) leads to a weak, non-indurated, erythematous skin reaction in which the lesion contains a high proportion of BASOPHILS. (These responses do not occur in mice.) Jones–Mote sensitivity can be transferred to a non-primed animal by serum (cf. DELAYED HYPERSENSITIVITY).

**Jonesia** A genus which contains the former species *Listeria denitrificans* [IJSB (1987) 37 266–270].

**Jopling reactions** See LEPROSY.

**JPC** See JUNCTIONAL PORE COMPLEX.

**Jud. Comm.** JUDICIAL COMMISSION.

**Judicial Commission** A taxonomic body concerned with the interpretation and/or amendment of the rules of microbial nomenclature.

**juglone** (5-hydroxy-1,4-naphthoquinone) A compound produced in the leaves and roots of walnut trees (*Juglans* spp); it has antifungal and antibacterial activity, and its presence in the tree may play a role in resistance to disease.

[Juglone as a transcription-blocking agent: NAR (2001) 29 767–773.]

**jumping gene** *Syn.* TRANSPOSABLE ELEMENT.

**juncopox virus** See AVIPOXVIRUS.

**junctional pore complex (JPC)** A carbohydrate-export apparatus, reported to occur in certain motile cyanobacteria, which (in at least some cases) includes a tubular structure (minimum diameter 13 nm) that is capable of spanning the cell envelope. It has been suggested that JPCs form the mechanistic basis of GLIDING MOTILITY in cyanobacteria [JB (2000) 182 1191–1199].

**jungle yellow fever** See YELLOW FEVER.

**Junin virus** See ARENAVIRIDAE and ARGENTINIAN HAEMORRHAGIC FEVER.

**junior synonym** See SYNONYM.

**jute retting** See RETTING.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# K

**K** Lysine (see AMINO ACIDS).

**K antigens** Capsular antigens – usually capsular polysaccharides (see CAPSULE). Examples include the capsular antigens of *Streptococcus pneumoniae*, COLOMINIC ACID, and VI ANTIGENS. In Gram-negative bacteria, K antigens can mask O ANTIGENS; in some bacteria the K antigens can be removed by heating (see e.g. VI ANTIGEN), but in others (e.g. *Klebsiella* spp) they are heat-stable. In *Escherichia coli*, several surface antigens originally designated K – e.g. K88, K99 – are actually (proteinaceous) fimbrial antigens, and it has been proposed that they be renamed F antigens (K88 = F4, K99 = F5) [Book ref. 68, pp. 61–64]; polysaccharide K antigens may occur together with fimbrial antigens in certain strains of *E. coli*. (See also ETEC and TEICHOIC ACIDS.)

**K<sup>+</sup>-ATPase** See ION TRANSPORT.

**K cells** Killer cells: lymphoid cells which have cytotoxic/cytolytic activity against target cells; *syn.* NK CELLS.

**K<sup>+</sup> pump** See ION TRANSPORT.

**K<sup>+</sup> transport** See ION TRANSPORT.

**K virus** See POLYOMAVIRUS.

**K vitamins** See QUINONES.

**K1 killer strain** (of *Saccharomyces cerevisiae*) See KILLER FACTOR.

**K1 RNA, K2 RNA** See RNASE P.

**K88, K99** In *Escherichia coli*: fimbrial antigens of certain strains pathogenic in animals – see ETEC, FIMBRIAE and K ANTIGENS.

**Kabackosome** A type of vesicle formed by the hypotonic lysis of a SPHAEROPLAST. A Kabackosome (which contains little or no cytoplasm) is composed of CYTOPLASMIC MEMBRANE; the inner and outer faces of the membrane correspond to those in the original cell. (cf. ETP.)

**KAF** *Syn.* FACTOR I.

**Kaffir pox** See SMALLPOX.

**Kagami fever** See EHRlichia.

**Kahn test** A STANDARD TEST FOR SYPHILIS.

**kala-azar** See VISCERAL LEISHMANIASIS.

**Kanagawa phenomenon** The phenomenon in which those strains of *Vibrio parahaemolyticus* isolated from human patients exhibit clear ( $\beta$ ) haemolysis when grown on WAGATSUMA AGAR containing human RBCs but not on that containing horse RBCs (a Kanagawa +ve reaction), while almost all strains isolated from other sources, including food suspected of causing *V. parahaemolyticus* food poisoning, do not (i.e. are Kanagawa –ve). (Discoloration ( $\alpha$ -haemolysis) and clear haemolysis on both human and horse RBC-containing media are both regarded as Kanagawa –ve results.) The Kanagawa haemolysin is heat-stable, extracellular, cytotoxic and cardiotoxic, and is haemolytic for human, dog and rat RBCs, weakly so for rabbit and sheep RBCs, and inactive against horse RBCs. In feeding experiments (in man), only Kanagawa +ve strains were capable of causing gastroenteritis, but the role of the haemolysin in pathogenesis is unknown; Kanagawa +ve strains appear to be better able to multiply in the intestine than are Kanagawa –ve strains. (See also FOOD POISONING (h).)

**kanamycin** Any of several related AMINOGLYCOSIDE ANTIBIOTICS (kanamycins A, B, C) produced by *Streptomyces kanamyceticus*; the drug used clinically is composed mainly of kanamycin A.

**kanchanomycin** (albofungin) A complex polycyclic ANTIBIOTIC, produced by *Streptomyces* sp, which has both antibacterial

and antitumour activity. In the presence of divalent cations, kanchanomycin binds to DNA and inhibits DNA and RNA synthesis.

**Kaposi's sarcoma** (KS) A rare multifocal neoplastic disease which occurs in two forms: (i) slow and indolent (limited mainly to the skin), and (ii) rapid and fulminant (involving skin and gastrointestinal tract). The milder form occurs in certain ethnic groups (e.g. Ashkenazi Jews). The aggressive form occurs in children in tropical Africa and is also a common feature in HIV-infected patients. (Note that Kaposi's sarcoma occurs also in some immunosuppressed transplant patients.)

Kaposi's sarcoma appears to be associated with human (gamma) herpesvirus 8 (HHV8) [see e.g. Lancet (1997) 349 558–563] in conjunction with the immunosuppressive effects of HIV. [PCR-based investigation of HHV8 in KS biopsies: Am. J. Path. (1997) 150 147–153.] Activation of latent HHV8 in vitro has been achieved by demethylation of the promoter of a transactivator region by means of the reagent tetradecanoylphorbol acetate (TPA), and studies on the level of methylation of the transactivator region in biopsies have suggested a relationship between methylation status and the development of HHV8-associated disease [PNAS (2001) 98 4119–4124].

**Kaposi's varicelliform eruption** May refer either to eczema herpeticum or eczema vaccinatum (see ECZEMA).

**kappa chain** See LIGHT CHAIN.

**kappa particles** See CAEDIBACTER.

**Karatomorpha** See PROTEROMONADIDA.

**Kärber method** See END-POINT DILUTION ASSAY.

**Karelian fever** See SINDBIS VIRUS.

**Karnal bunt** (partial bunt; new bunt) A wheat disease caused by *Neovossia indica* (formerly e.g. *Tilletia indica*); originally a minor disease confined to NW India, it has recently spread through northern India and has become established in Afghanistan, Iraq, Pakistan, and Mexico, apparently transmitted on and in wheat seed. Usually only some of the grains in an ear are attacked; infected parts of the grain are initially grey but gradually turn black and emit a foul odour (trimethylamine). [Bot. Rev. (1983) 49 309–330.] (See also COMMON BUNT.)

**karyogamy** The coalescence of nuclei (cf. PLASMOGAMY).

**karyogram** See KARYOTYPE.

**karyokinesis** *Syn.* MITOSIS.

**karyological relict** (*ciliate protozool.*) Any present-day ciliate whose characteristics (particularly nuclear constitution) resemble those of (presumably) phylogenetically ancient ciliates. (See also KARYORELICTID GYMNOSTOMES and PRIMOCILIATID GYMNOSTOMES.)

**karyolysis** (*histopathol.*) The dissolution of a cell's nucleus with consequent loss of affinity for basic dyes. (cf. KARYORRHESIS.)

**karyomastigont** A nucleus together with its associated flagellum (or flagella) and, when present, axostyle. (See also DIPLOMONADIDA.)

**karyomere** See MACRONUCLEUS.

**karyonide** (caryonide) (*ciliate protozool.*) A clone of cells in which all the macronuclei have been derived from the same macronucleus.

**karyoplast** A nucleus which has been isolated from a (eukaryotic) cell and which is enclosed within a sac of cytoplasmic membrane containing a small amount of cytoplasm. (cf. CYTOPLAST.)

## karyorelictid gymnostomes

**karyorelictid gymnostomes** Presumptively primitive ciliates (subclass GYMNSTOMATIA, order Karyorelictida) which contain diploid, non-dividing macronuclei; genera include e.g. *Geleia*, *KENTROPHOROS*, *LOXODES*, *Remanella* and *Tracheloraphis*.

**karyorrhexis** (*histopathol.*) The fragmentation of a cell's nucleus (cf. KARYOLYSIS; PYKNOSIS).

**karyoskeleton** *Syn.* NUCLEOSKELETON.

**karyosome** A NUCLEOLUS or nucleolus-like body.

**karyotic** (of cells) Nucleated.

**karyotype** The chromosomal constitution of a (eukaryotic) cell in terms of the number, size and morphology of the chromosomes at metaphase. A systematized diagrammatic representation of a karyotype is called an *idiogram*; a systematized photographic representation may be referred to as an *idiogram* or as a *karyogram*.

**kasugamycin** An atypical AMINOGLYCOSIDE ANTIBIOTIC whose molecule contains neither streptidine nor deoxystreptamine. Kasugamycin is bacteriostatic and is also active against certain fungi (e.g. *Pyricularia oryzae* and *Rhizoctonia solani*).

**kat** See KATAL.

**Kata virus** See PESTE DES PETITS RUMINANTS.

**Katadyn silver** Metallic SILVER – containing traces of impurities (gold, palladium etc) – deposited on sand (or other filtering medium) used for the filtration and disinfection of water; the impurities facilitate ionization of the silver.

**katal** (*abbrv.* kat) A unit of enzyme activity: that which increases the rate of conversion of a given chemical reaction by one mole per second under defined conditions.

**katG gene** See ISONIAZID.

**Katodinium** See DINOFLAGELLATES.

**Kauffmann–White classification** A scheme for the classification and identification of the numerous serotypes of SALMONELLA (e.g. for epidemiological purposes). Each serotype is defined by its O ANTIGENS and, where applicable, its H ANTIGENS and VI ANTIGENS, and is given a specific ANTIGENIC FORMULA which indicates the nature of these antigens in the order O, Vi (if present) : H phase 1 : H phase 2. For example, *S. typhi* is designated by the formula 9, 12, [Vi]:d:–. This means that the organism has O antigens 9 and 12, may have Vi antigen (variable presence indicated by [ ]), and has phase 1 flagellar antigen d and no phase 2 flagellar antigen (indicated by a dash) – i.e. PHASE VARIATION does not occur in this serotype. The antigenic formula for *S. panama* is  $\underline{1}$ , 9, 12:1, v:1, 5 where  $\underline{1}$ , 9 and 12 are O antigens, and either phase 1 flagellar antigens 1 and v or phase 2 flagellar antigens 1 and 5 may be present; this serotype has no Vi antigen. Underlining (as in O antigen  $\underline{1}$  in *S. panama*) indicates that the antigen is present as a result of BACTERIOPHAGE CONVERSION. (Phage conversion may lead to a change in serotype: thus, e.g., *S. anatum*, 3, 10:e, h:1, 6, may be converted to *S. newington*, 3,  $\underline{15}$ :e, h:1, 6. Similar effects can occur in bacteria of other genera, including e.g. *Shigella* [serotype-converting bacteriophages and O-antigen modification in *Shigella flexneri*: TIM (2000) 8 17–23].) For further examples of antigenic formulae see SALMONELLA. (See also SMOOTH–ROUGH VARIATION.)

Serotypes thus identified are placed into groups (O groups), the serotypes in each group having in common at least one major O antigen (the *group antigen*) which is not found in members of any other group. For example, the group antigen of group A is O antigen 2; that of group B is O antigen 4; group C, O antigen 6; group D, O antigen 9; group E, O antigen 3. Thus, both *S. typhi* and *S. panama* are group D strains. (Minor O antigens may occur in more than one group: e.g., O antigen 12 occurs in strains from groups A, B and D.)

**Kawasaki disease** An acute, occasionally fatal, febrile disease of unknown cause which affects infants and young children. Kawasaki disease may be a manifestation of an immune-complex-mediated systemic vasculitis [ADC (1984) 59 405–409]; more recently it has been suggested that at least some of the symptoms may be due to a SUPERANTIGEN.

**kb** (kilobase) Of a DNA or RNA strand: a unit of length equal to  $10^3$  bases; the unit may also be used for  $10^3$  base pairs (bp) in dsDNA or dsRNA – although kbp (kilobase-pairs) is also used in this context.

**kbp** See previous entry.

**Kcat mechanism** See PHASEOLOTOXIN.

**KCN broth** (cyanide broth; Møller's [= Moeller's] cyanide medium; potassium cyanide broth) A MEDIUM used in the CYANIDE TEST; it consists of an aqueous solution of peptone (1.0%), NaCl (0.5%),  $\text{KH}_2\text{PO}_4$  (0.0225%),  $\text{Na}_2\text{HPO}_4$  (0.56%), and KCN (0.0075%). The medium may be stored at 4°C for up to ca. 2 weeks.

**KCN test** See CYANIDE TEST.

**kDa** Kilodalton:  $10^3$  DALTONS.

**kDNA** KINETOPLAST DNA.

**KDO** See LIPOPOLYSACCHARIDE.

**Kdp system** See ION TRANSPORT.

**kefir** A fermented milk beverage made in parts of Russia, Bulgaria and the former Yugoslavia. Milk is fermented by a mixed and varied population of organisms which usually include lactobacilli [SAAM (1983) 4 286–294; JAB (1984) 56 503–505], *Lactococcus lactis*, and yeasts (for example, *Saccharomyces* spp); lactic acid, ethanol and carbon dioxide (which causes foaming) are the main products. The organisms become embedded in an extracellular polysaccharide (kefiran) to form whitish, gelatinous granules [scanning electron microscopy: JAB (1980) 48 265–268] which are carried to the surface by bubbles of carbon dioxide. The granules are collected and used as an inoculum for subsequent fermentations; they can be stored for several days in cold milk or water. (See also DAIRY PRODUCTS.)

**kefiran** See KEFIR.

**Kellogg classification** (of *Neisseria gonorrhoeae*) An early classification based on e.g.: (i) appearance of colony; (ii) auto-agglutinability; and (iii) virulence. Types T1 and T2 correspond to fimbriate, virulent strains, while types T3 and T4 correspond to afimbriate, non-virulent strains.

**keloidal blastomycosis** *Syn.* LOBOMYCOSIS.

**kelp** (1) Any of various seaweeds that are used to obtain kelp (sense 2). (2) The ashes obtained by burning various large brown seaweeds such as *Ascophyllum*, *Fucus*, *Laminaria*, *Macrocystis*; such ashes have been used as an agricultural fertilizer and as a source of iodine, potash and soda (sodium carbonate).

**Kelsey–Sykes test** A CAPACITY TEST used to determine the efficacy of each of several dilutions of a given disinfectant under simulated practical conditions. (cf. USE-DILUTION TEST.) To 3 ml of a given dilution of disinfectant is added a 1-ml aliquot of bacterial suspension at times 0, 10 and 20 min; at 8, 18 and 28 min the disinfectant is subcultured to each of five tubes of nutrient broth which are then incubated to detect the presence or absence of viable bacteria. A given dilution passes the test if no growth is obtained in at least two of the five tubes inoculated from it at 8 and 18 min. The test organism used is *Pseudomonas aeruginosa* NCTC 6749, *Proteus vulgaris* NCTC 4635, *Escherichia coli* NCTC 8196 or *Staphylococcus aureus* NCTC 4163; in a given test the organism used is that which is the most resistant to the test disinfectant. To examine the efficacy of the disinfectant under 'dirty' conditions a yeast

suspension is incorporated in each dilution of the disinfectant. The test conditions are standardized – e.g. the bacteria, yeast and disinfectant are each diluted in standard hard water. [PJ (1974) 213 528–530.]

**Kemerovo subgroup** See ORBIVIRUS.

**kennel cough** See MASTADENOVIRUS.

**Kentrophoros** A genus of marine ciliates (subclass GYMNOSTOMATIA) related to LOXODES. Cells: very elongated and flattened (ribbon-like), ciliated only on one side, and associated with ectosymbiotic bacteria; there is no cytostome.

**keratin** A highly insoluble protein found e.g. in hair, wool, horn, skin, feathers. Keratin is degraded by relatively few organisms – e.g. *Candida albicans*, DERMATOPHYTES. (See also PILIMELIA and THERMOMONOSPORA.)

**keratitis** Inflammation of the cornea. (cf. KERATOCONJUNCTIVITIS; see also INFECTIOUS KERATITIS.)

**keratoconjunctivitis** Inflammation of the cornea and conjunctiva. It may be caused e.g. by *Chlamydia trachomatis* (see e.g. TRACHOMA), *Staphylococcus aureus*, HERPES SIMPLEX VIRUS, or adenoviruses (see e.g. EPIDEMIC KERATOCONJUNCTIVITIS).

**keratomycosis** KERATITIS due to a fungus; it is usually due to an opportunist pathogen (e.g. *Aspergillus* spp, *Candida* spp).

**kerion** (exudative ringworm; tinea kerion) A severe form of RINGWORM (usually tinea capitis) in which the dry, scaling skin lesions become inflamed and suppurative.

**kerogen** Solvent-insoluble, condensed (i.e., covalently cross-linked and/or aromatized) organic matter which forms the major part of OIL SHALE; it is formed by the gradual transformation of sedimented biomolecules in the absence of high temperatures and pressures. (*Protokerogen* is a less mature form of kerogen from more recent sediments.) Kerogen is believed to be the precursor material of PETROLEUM and natural gas; on heating it yields HYDROCARBONS. (See also MICROBIAL MAT.)

**kerosene** See PETROLEUM.

**kerosene fungus** See HORMOCONIS.

**kethoxal** (2-keto-3-ethoxyl-*n*-butyraldehyde) A reagent which reacts with and modifies only unpaired guanine residues in DNA or RNA.

**ketoconazole** (1,3-dioxolanyl-methylimidazole) An AZOLE ANTI-FUNGAL AGENT which is effective against various mucocutaneous and cutaneous mycoses (including those caused by fungi resistant to GRISOFULVIN) as well as systemic mycoses such as aspergillosis, blastomycosis, coccidioidomycosis, histoplasmosis, etc; unlike most of the imidazole antifungal agents, ketoconazole can be administered orally.

**ketogenic fermentations** Commercial fermentation processes in which polyhydric alcohols are converted to ketoses: see e.g. DIHYDROXYACETONE FERMENTATION and SORBOSE FERMENTATION.

**$\alpha$ -ketoglutarate dehydrogenase** See TCA CYCLE.

**ketopentose** See PENTOSES.

**kGy** See GRAY.

**Khawkinaea** See EUGLENOID FLAGELLATES.

**KIA** KLIGLER'S IRON AGAR.

**Kickxellales** An order of fungi (class ZYGOMYCETES) which are typically saprotrophic in soil and dung; all species form one-spored sporangia – numbers of which are borne on a short hyphal branch (*sporocladium*). Genera: e.g. *Coemansia*, *Linderina*, *Martensella* (species can be parasitic on other fungi), and *Spiromyces*.

**kidney disease** (Dee disease) A systemic, usually chronic FISH DISEASE affecting salmonids. The kidneys become pale and swollen with characteristic greyish necrotic lesions; mortality may be high. Pathogen: *Renibacterium salmoninarum*.

**kidney stones** (in humans) See UROLITHIASIS

**kieselguhr** Syn. DIATOMACEOUS EARTH.

**kievitone** An isoflavonoid PHYTOALEXIN produced by the French bean (*Phaseolus vulgaris*). Cell-free extracts of *Rhizoctonia solani* elicit high levels of kievitone from excised bean hypocotyls, but those of *Fusarium solani* elicit only trace amounts. Kievitone can be converted to the less fungitoxic kievitone hydrate by an extracellular enzyme produced by *Fusarium solani* f.sp *solani*.

**Kilham rat virus** See PARVOVIRUS.

**killed vaccine** Syn. INACTIVATED VACCINE.

**killer cells** (immunol.) Commonly refers to NK CELLS (q.v.) but may also refer e.g. to cytotoxic T cells.

**killer factor** Any of several protein toxins secreted by 'killer' strains of *Saccharomyces cerevisiae* and encoded by one of two cytoplasmically co-inherited dsRNA elements; the K1 toxin (formed by K1 or type 1 killer strains) binds initially to a cell wall  $\beta$ -glucan of a sensitive cell and then transfers to the cytoplasmic membrane where it disrupts the membrane potential. One of the dsRNA elements (designated M) encodes both the toxin and an 'immunity protein' which confers on the producing cell immunity to the toxin; the toxin contains two subunits,  $\alpha$  and  $\beta$ , both derived by proteolytic processing of a precursor polypeptide during toxin secretion. The precursor polypeptide apparently functions as the immunity protein – possibly by competing with the mature toxin for binding sites on the membrane [Cell (1986) 46 105–113]. The other dsRNA element (designated L) encodes a protein required for the (separate) encapsidation of M and L. The encapsidated particles (termed VLPs: virus-like particles) are variously regarded as plasmids or as viruses (*Saccharomyces cerevisiae* viruses, SeVs – see MYCOVIRUS). [Review: MR (1984) 48 125–156.] (cf. KILLER PLASMIDS; see also BACTERIOICIN.)

**killer helper factor** Syn. INTERLEUKIN-2.

**killer paramecia** Strains of *Paramecium* which are able to kill other ('sensitive') paramecia. See: CAEDIBACTER, LYTICUM, MATE KILLER, PSEUDOCAEDIBACTER, R BODY, SPIN KILLING. (cf. TECTIBACTER.)

**killer plasmids** (in yeasts) In some strains of *Kluyveromyces marxianus* var. *lactis* the cells contain multiple copies of each of two linear, cytoplasmically inherited dsDNA plasmids, pG1 and pG12; cells containing these plasmids secrete a glycoprotein toxin capable of killing other (sensitive) strains of e.g. *Candida*, *Kluyveromyces* and *Saccharomyces* by inhibiting adenylate cyclase activity. These plasmids can be transferred to *Saccharomyces cerevisiae* (e.g. by protoplast fusion) on which they confer the killer phenotype. [ARM (1983) 37 253–276.] (cf. KILLER FACTOR.)

**killer yeasts** See KILLER FACTOR and KILLER PLASMIDS.

**kilobase** See entry kb.

**kimchi** A Chinese and Korean food made by the lactic acid fermentation of vegetables (usually cabbage or radishes). Preparation resembles that of SAUERKRAUT.

**KinA, KinB** See ENDOSPORE (sense 1).

**kinase** An ENZYME which catalyses the transfer of a phosphate group from one substrate (commonly ATP) to another; examples include hexokinase and pyruvate kinase (both involved in the Embden–Meyerhof–Parnas pathway: see Appendix I(a)), ADENYLATE KINASE, and PPI:phosphofructose dikinase (see PYROPHOSPHATE).

**Kineosporia** A genus of bacteria (order ACTINOMYCETALES, wall type I). The organisms form a substrate mycelium but no aerial hyphae; sporangia, each containing one zoospore, develop on

## kinesis

the hyphae. Growth occurs at/below 30°C, but not at 37°C. Type species: *K. aurantiaca*.

**kinesis** (1) A behavioural response in which the speed (but not the direction) of locomotion of a motile organism depends on the intensity of an external stimulus; e.g., when light intensity increases, an organism may swim faster (positive photokinesis) or slower (negative photokinesis). (See also PHOTOTAXIS.) Kinesis, unlike TAXIS, is a continuous response and is not cancelled by ADAPTATION.

(2) A behavioural response in which the rate of activity of an organism depends on the intensity of an external stimulus. When the activity concerned is speed of swimming, the phenomenon is known as *orthokinesis* (*syn.* kinesis sense 1). When the activity concerned is frequency of directional change, the phenomenon is termed *klinokinesis*. [Photochem. Photobiol. (1977) 26 559–560.]

**kinete** A motile zygote, or a motile form derived from a zygote. **kinetic response** *Syn.* KINESIS.

**kinetid** (ciliary corpuscle; kinetosomal territory) In ciliates: a unit of the KINETY; it typically includes a CILIUM with its associated kinetosome, KINETODESMA, cytoplasmic membrane and alveolus (see PELLICLE), and may also include e.g. a MUCOCYST, PARASOMAL SAC and TRICHOCYST together with various microfibres and/or microtubules (e.g. nematodesmata).

**kinetin** 6-Furfurylaminopurine, a compound formed during the hydrolysis of DNA; it has CYTOKININ activity but it apparently does not occur in plants.

**kinetochore** An electron-dense MICROTUBULE-ORGANIZING CENTRE, one of which develops on each side of the CENTROMERE during MITOSIS.

**kinetochore fibre** See MITOSIS.

**kinetocyst** See AXOPODIUM.

**kinetodesma** (kinetodesmos) In some ciliates: one of a series of overlapping endoplasmic fibrils which, by light microscopy, may appear as a single fibre running parallel with, and to the right of, a row of basal bodies in a somatic KINETY; each kinetodesma arises from a kinetosome (near triplets 5–8, GRAIN CONVENTION), passes a little to the right, and then runs anteriorly to terminate in a position where it may overlap the kinetodesma(ta) of the more anterior kinetosome(s). Kinetodesmata have cross-striations of periodicity ca. 30 nm. The role of the kinetodesmata is unknown; they are commonly believed *not* to be involved in ciliary coordination. (See also RULE OF DESMODEXY; SILVER LINE SYSTEM.)

**kinetofragments** In many members of the KINETOFRAGMINOPHOREA: patches or short rows of kinetids (sometimes with non-ciliferous kinetosomes) in the vicinity of the oral area; their evolutionary origin is presumed to have been the anterior ends of somatic kineties.

**Kinetofragminophora** A class of protozoa (phylum CLIOPHORA) which characteristically have an apical or subapical cytostome and a CYTOPHARYNGEAL APPARATUS which is usually conspicuous; COMPOUND CILIATURE is typically absent, and ciliature in the oral region is not obviously differentiated from that in other region(s) of the body. STOMATOGENESIS is typically telokinetal (apparently apokinetal in the ENTODINIOMORPHIDA). This class includes many of the ciliates previously referred to as the 'lower holotrichs' (e.g. the apostomes, chonotrichs, gymnostomes and trichostomes) together with e.g. the suctorians. Subclasses: GYMNOSTOMATIA, HYPOSTOMATIA, SUCTORIA, VESTIBULIFERIA.

**kinetoplast** In protozoa of the KINETOPLASTIDA: a unique structure which forms a distinct region of the mitochondrion; it

comprises a complex network of numerous catenated circular DNA molecules (kDNA), including several thousand small circles (*minicircles*) and fewer (ca. 20–50) identical larger circles (*maxicircles*). The maxicircles are the functional counterpart of the mitochondrial DNA of other eukaryotes, encoding e.g. rRNA and proteins. Minicircles encode most of the gRNAs for RNA EDITING (their only known function). [kDNA: Eukaryotic Cell (2002) 1 495–502].

During cell division, the kinetoplast (and mitochondrion) divides before nuclear division. Kinetoplast division is inhibited by certain drugs, including e.g. ACRIDINES, DIAMIDINES and PHENANTHRIDINE derivatives. (See also DYSKINETOPLASTY.) The kinetoplast stains red with ROMANOWSKY STAINS.

**Kinetoplastida** An order of protozoa (class ZOOASTIGOPHOREA); each organism has a single nucleus, one or two flagella (which arise from flagellar pockets and which often contain a PARAXIAL ROD) and a single, simple or branched, typically elongated mitochondrion which usually contains a KINETOPLAST located close to the flagellar basal body. (See also GLYCOSOME.) Two suborders: BODONINA and TRYPANOSOMATINA.

**kinetosomal territory** *Syn.* KINETID.

**kinetosome** (*protozool.*) *Syn.* BASAL BODY (b).

**kinety** In ciliates: typically, a longitudinal ('meridianal') row of somatic KINETIDS; a kinety corresponds to the 'primary meridian' in the SILVER LINE SYSTEM.

**kingdom** A major taxonomic category (see TAXONOMY) ranking above phylum. Organisms are grouped into kingdoms in various ways according to different schemes; e.g., according to the 'five-kingdoms' classification scheme the kingdoms are Animalia, FUNGI, MONERA, Plantae, and PROTISTA (sense 2).

**Kingella** A genus of catalase-negative, oxidase-positive bacteria (family NEISSERIACEAE) which occur e.g. in the upper respiratory tract. (See also HACEK.) Cells: rods, 1 × 2–3 µm, in pairs or chains. Growth occurs aerobically, and has been reported to occur anaerobically on blood agar with a gaseous phase of 95% hydrogen and 5% carbon dioxide. The organisms are nutritionally fastidious. Optimal growth temperature: 33–37°C. GC%: ~47–55. Type species: *K. kingae*.

**kinins** See CYTOKININS.

**Kinyoun stain** An ACID-FAST STAIN which resembles ZIEHL-NEELSEN'S STAIN but differs in that the stain contains higher concentrations of phenol and basic fuchsin and is used cold; methylene blue may be used as counterstain. [Methods: Book ref. 53, pp. 1381, 1384–1385.]

**Kirby–Bauer technique** See DISC DIFFUSION TEST.

**kirromycin** See POLYENE ANTIBIOTICS (b).

**kirrothricin** See POLYENE ANTIBIOTICS (b).

**Kirsten murine sarcoma virus** (Ki-MSV) A replication-defective MURINE SARCOMA VIRUS isolated from rats inoculated neonatally with a cell-free extract from thymic lymphomas of C3H mice. Ki-MSV resembles HARVEY MURINE SARCOMA VIRUS in carrying the oncogene *v-ras* (*v-Ki-ras*: see RAS) and in causing erythroleukaemia as well as sarcomas in newborn mice.

**kissing disease** See INFECTIOUS MONONUCLEOSIS.

**Kitasatoa** A genus of bacteria which resemble *Streptomyces* spp in e.g. wall type and phage sensitivity; species have been regarded as members of the genus *Streptomyces* [JGM (1983) 129 1743–1813] and as species *incertae sedis* [Book ref. 73, pp. 97–98].

**kitazin** (*O,O*-diethyl-*S*-benzyl phosphorothioate) An ORGANOPHOSPHORUS COMPOUND used as an antifungal agent against rice blast disease; kitazin and its isopropyl analogue (kitazin P) is readily absorbed by plant roots and is rapidly translocated in the

transpiration stream. It appears to function by inhibiting CHITIN synthesis.

**klebicin** (klebecin, klebocin) See BACTERIOCIN.

**Klebs-Löffler bacillus** *Corynebacterium diphtheriae*.

**Klebsiella** (1) A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: straight rods, ca. 0.3–1.0 × 0.6–6.0 μm, occurring singly, in pairs, or in short chains; non-motile. The cells are capsulated and usually form convex, glistening, viscid (mucoid) colonies on carbohydrate-rich media. Serotyping [Book ref. 68, pp. 143–164] is based on capsular (K) rather than on O antigens. Some strains may possess mannose-sensitive (type 1) and/or mannose-resistant (type 3) FIMBRIAE. Typical reactions: acid (sometimes with gas) from glucose; H<sub>2</sub>S –ve; phenylalanine deaminase –ve; ornithine decarboxylase –ve; myo-inositol +ve; growth in KCN media. Many strains are lactose +ve. GC%: 53–58. Type species: *K. pneumoniae*.

*K. oxytoca*. Indole +ve; MR –ve; VP +ve; no gas from lactose at 44.5°C; growth occurs at 10°C; melezitose sometimes +ve; pectate +ve. Occurs in the intestines of man and animals and in plant and aquatic environments.

*K. planticola* (= *K. trevisanii* [IJSB (1986) 36 486–488]). Indole and MR reactions variable; VP +ve; no gas from lactose at 44.5°C; growth occurs at 10°C; melezitose –ve; pectate –ve. Occurs mainly in plant, soil and aquatic environments.

*K. pneumoniae* (including strains sometimes called *K. aerogenes* and *K. edwardsii* – cf. AEROBACTER). Indole –ve; no growth at 10°C; melezitose –ve; pectate –ve. Some strains carry out NITROGEN FIXATION. Strains occur in the intestines and respiratory tract of man and animals and may be pathogenic, causing e.g. bovine MASTITIS, equine metritis, OZAENA, PNEUMONIA, and nosocomial URINARY TRACT INFECTION. Subspecies *pneumoniae*: gas from lactose at 44.5°C; MR –ve, VP +ve (but see METHYL RED TEST); urease +ve. Subspecies *ozaenae* (formerly *K. ozaenae*): lactose fermentation variable; MR (usually) +ve; VP –ve; urease variable. Subspecies *rhinoscleromatis* (formerly *K. rhinoscleromatis*): lactose –ve; MR +ve; VP –ve; urease –ve.

*K. terrigena*. Indole –ve; no gas from lactose at 44.5°C; growth occurs at 10°C; melezitose +ve; pectate –ve. Occurs mainly in soil and aquatic environments.

*K. trevisanii*. See *K. planticola*.

[Book ref. 22, pp. 461–465.]

(2) A genus of EUGLENOID FLAGELLATES found in marine or brackish waters; each cell is partly enclosed in a yellow to brown LORICA.

**Klebsormidium** (*Hormidium*) A genus of filamentous, unbranched, freshwater or terrestrial green algae (division CHLOROPHYTA). The filaments lack a holdfast and are composed of uninucleate cells each containing a single plate-like chloroplast. Zoospores (rarely formed) are asymmetric, biflagellate and naked, and are released via a pore in the mother cell wall. Sexual reproduction is isogamous; gametes are biflagellate. (cf. STICHOCOCCUS.)

**Kleinschmidt monolayer technique** A method for preparing a nucleic acid for examination by ELECTRON MICROSCOPY. Essentially, a solution of e.g. DNA is mixed with a solution of the globular protein cytochrome *c* (which adheres to DNA), and one drop of this mixture is allowed to run down a sloping surface onto an air–liquid interface. This gives rise to a monolayer of denatured cytochrome *c* containing extended molecules of DNA which are thickened by a coating of cytochrome *c*; dsDNA appears thicker than ssDNA. A small area of the monolayer is transferred to a prepared grid, and the preparation is either shadowed on a rotating platform or stained e.g. with uranyl acetate;

the thread-like molecules of DNA thus become more electron-dense than the background. In a modification of this technique, benzalkonium chloride is used instead of cytochrome *c*; since, in this case, the DNA is not thickened with adherent protein, its relationship to other macromolecules (e.g. polymerases) can be determined more easily.

**Klenow fragment** (Klenow enzyme) The larger of two fragments obtained by proteolytic cleavage (using e.g. subtilisin) of the DNA POLYMERASE I of *Escherichia coli*. The Klenow fragment retains 5′-to-3′ polymerase and 3′-to-5′ exonuclease activities but lacks 5′-to-3′ exonuclease activity; it has various uses in genetic engineering techniques and in DNA sequencing methods.

**Klett–Summerson colorimeter** See TURBIDIMETRY.

**Klett unit** A unit of turbidity as measured with the Klett–Summerson colorimeter using monochromatic light of a specified colour.

**Kligler’s iron agar (KIA)** A double-sugar–iron agar (cf. TSI AGAR) used e.g. for distinguishing between members of the Enterobacteriaceae. It is prepared as a slope with a deep butt, and consists of nutrient agar (pH 7.4) supplemented with glucose (ca. 0.1%), lactose (1%), sodium thiosulphate (0.05%), ferric ammonium citrate (0.05%), and phenol red (ca. 0.0025%). In general, bacterial reactions with KIA are similar to those with TSI agar; however, the absence of sucrose in KIA means that the lactose-negative reaction given by some organisms is not masked by their ability to attack sucrose.

**klinokinesis** See KINESIS (sense 2).

**Kloeckera** A genus of yeasts (class HYPHOMYCETES) which have teleomorphs in the genus HANSENIASPORA. Vegetative cells are more or less lemon-shaped (apiculate) and reproduce by bipolar budding in basipetal succession; pseudomycelium may be formed. All species ferment glucose; some ferment sucrose, none ferments maltose (although some species can assimilate maltose). NO<sub>3</sub><sup>–</sup> is not assimilated. All species require inositol and pantothenate for growth. Species (*K. africana*, *K. apiculata*, *K. apis*, *K. corticis*, *K. japonica*, *K. javanica*) have been isolated from fruit, soil, bark etc.

[Book ref. 100, pp. 873–881.]

**Klonostricha** See HYPOTRICHIDA.

**Klossiella** See ADELEORINA.

**Kluyver effect** The phenomenon in which certain yeasts can utilize particular disaccharides aerobically, but not anaerobically. The mechanism underlying the effect is unknown [JGM (1982) 128 2303–2312].

**Kluyvera** A genus of motile bacteria of the ENTEROBACTERIACEAE. MR +ve; VP –ve; usually indole +ve and citrate +ve. 2-Oxoglutarate is formed from glucose. The organisms occur in food, soil and sewage, and may be opportunist pathogens in man. [Book ref. 22, pp. 511–513.]

**Kluyveromyces** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are spheroidal, ovoid, ellipsoidal, or cylindrical to elongate; vegetative reproduction occurs by multilateral budding. Pseudomycelium may be formed. Asci are evanescent; they contain one to many spores which may be crescent-shaped, reniform, spheroidal etc, and which tend to agglutinate after liberation. Cells contain ubiquinone-6 (Q-6). All species can ferment glucose; *K. marxianus* var. *lactis* and some strains of *K. marxianus* var. *marxianus* can ferment LACTOSE. NO<sub>3</sub><sup>–</sup> is not assimilated. Eleven species have been recognized primarily on the basis of hybridization data; on this basis some former species (e.g. *K. bulgaricus*, *K. fragilis*, *K. lactis*) have been relegated to varieties of *K. marxianus* – e.g., ‘*K. fragilis*’ is *K. marxianus* var. *marxianus* (anamorph: *Candida kefyri*, = ‘*C. pseudotropicalis*’), and

## k-MTs

'*K. lactis*' is *K. marxianus* var. *lactis* (anamorph: *Candida spharica*). Other species include e.g. *K. aestuarii*, *K. africanus*, *K. blattae*, *K. polysporus*, *K. thermotolerans* (anamorph: *Candida dattila*). [Book ref. 100, pp. 224–251.] *Kluyveromyces* spp occur in a wide range of habitats: e.g. sea-water (*K. aestuarii*), soil, insects, fruit and other plant material, foods and beverages, etc. (See also CHEESE-MAKING (C), SINGLE-CELL PROTEIN, YEAST EXTRACT, and KILLER PLASMIDS.)

**k-MTs** MICROTUBULES attached to a KINETOCHORE.

**knallgas bacteria** *Syn.* HYDROGEN-OXIDIZING BACTERIA.

**knallgas reaction** (oxyhydrogen reaction) The oxidation of gaseous hydrogen by oxygen. In the HYDROGEN-OXIDIZING BACTERIA this reaction, which provides energy for growth, involves one or more types of HYDROGENASE and a respiratory chain which may contain e.g. *a*-, *b*-, *c*- and *o*-type cytochromes, iron-sulphur proteins and ubiquinones. [Ubiquinones in hydrogen-oxidizing bacteria: SAAM (1983) 4 181–183.] In e.g. chemolithoautotrophically grown *Paracoccus denitrificans*, electrons from hydrogen appear to be transferred to oxygen via hydrogenase, UQ-10 and cytochromes *b*<sub>562</sub> and *o*. In e.g. '*Alcaligenes eutrophus*' (which has both NAD-independent and NAD-reducing hydrogenases) it has been suggested that electrons from hydrogen may be donated to the respiratory chain and/or to NAD – the NADH being oxidized via the respiratory chain.

**knockout mice** Mice in which specific gene(s) have been disrupted (by genetic manipulation at the embryo stage) such that the corresponding gene product(s) are not synthesized in active form.

**knopvelsiekte** The severe form of LUMPY SKIN DISEASE.

**knot** (in DNA) An entanglement within a single, circularly closed DNA molecule, resolution of which (to form a knot-free cccDNA molecule) requires the activity of a TOPOISOMERASE (q.v.).

**koala** (chlamydiosis in) See CHLAMYDIA.

**Koch–Weeks bacillus** *Haemophilus aegyptius*.

**Koch's blue bodies** See EAST COAST FEVER.

**Koch's phenomenon** The phenomenon in which different responses are given by healthy and tuberculous guinea pigs to a subcutaneous injection of virulent tubercle bacilli; reactions in the *tuberculous* animals are manifestations of DELAYED HYPERSENSITIVITY (q.v.).

**Koch's postulates** According to Robert Koch (1843–1910): a set of conditions which should be fulfilled in order to establish that a given organism is the causal agent of a particular disease. (i) The organism must be present in every case of the disease. (ii) It should be isolable in pure culture. (iii) Inoculation of susceptible animals with the isolated organism must produce the disease. (iv) The organism must be observable in, and/or isolable from, the (experimental) diseased animals.

**Koehler illumination** *Syn.* KÖHLER ILLUMINATION.

**Kofoidinium** A genus of DINOFLAGELLATES.

**Köhler illumination** (Koehler illumination) In MICROSCOPY: illumination in which the entire field is lit with uniform intensity, regardless of any non-uniformity in the light source (cf. CRITICAL ILLUMINATION). To obtain Köhler illumination with an external lamp having a condensing lens with an iris diaphragm (*field diaphragm*) outside it: (i) Close the substage CONDENSER diaphragm (*aperture diaphragm*). (ii) Open the field diaphragm. (iii) Using the microscope's *plane* mirror, image the lamp's filament on the underside of the aperture diaphragm; thereafter, keep lamp and microscope in the same relative positions. (iv) Open the aperture diaphragm and almost close the

field diaphragm. (v) Focus on the specimen with a low-power (e.g. ×10) objective, and adjust the substage condenser *slightly* so that the edge of the field diaphragm is in sharp focus in the plane of the specimen. (vi) Open the field diaphragm until the small disc of light in the centre of the field of view has expanded to cover the entire field. Under these conditions an image of the lamp's filament is formed in the lower focal plane of the substage condenser, and divergent rays from *each* point of the filament's image pass through the condenser and emerge as parallel rays which illuminate the specimen.

**koji** A preparation consisting of mould (usually *Aspergillus oryzae*) growing on cooked cereal and/or soybeans; the mould produces enzymes (including a range of proteases, amylases, pectinases, glutaminase, etc) and is used in the production of e.g. SOY SAUCE and MISO.

The inoculum for making koji is a *koji starter* or *tane koji*: a powder consisting of mould spores. *Tane koji* is typically made by inoculating steamed polished rice with spores of selected fungal strains; the rice is spread in shallow trays, incubated at 30°C for ca. 5 days, and the spores are then harvested and dried.

**kojibiose** A reducing disaccharide: α-D-glucopyranosyl-(1 → 2)-D-glucopyranose. It can occur e.g. as a product of enzymic degradation of certain plant carbohydrates, and is present in glycerol TEICHOIC ACIDS of group D streptococci (in which it is linked to the C-2 position of glycerol and may be esterified with D-alanine).

**kojic acid** (5-hydroxy-2-hydroxymethyl-4-pyrone) A secondary metabolite produced e.g. by *Aspergillus* spp (particularly the *flavus-oryzae* group) when grown on glucose, xylose or certain other sugars. It is a chelating agent which gives a strong blood-red colour with Fe<sup>3+</sup>; it also has weak antibiotic activity (enhanced by certain metal ions), being effective mainly against Gram-negative bacteria.

**Kolmer CFT** See STANDARD TESTS FOR SYPHILIS.

**Kolpoda** *Syn.* COLPODA.

**kombu** See LAMINARIA.

**Konservomat** See BATCH RETORT.

**Kopeloff modification** A modification of the GRAM STAIN used for staining anaerobic bacteria. The technique involves the addition of ca. 5 drops of NaHCO<sub>3</sub> solution (5%) to the smear after the latter has been flooded with crystal violet (1%); the iodine solution (iodine 2%, KI 0.1%) includes NaOH (0.4%), decolorization is carried out with acetone–alcohol, and safranin (2%) is used for counterstaining.

**Koplik's spots** Small, white, necrotic lesions formed in the mouth in the early stage of MEASLES.

**Kordyana** See EXOBASIDIALES.

**Korean haemorrhagic fever** (epidemic haemorrhagic fever) A VIRAL HAEMORRHAGIC FEVER involving renal dysfunction, proteinuria and oliguria; the mortality rate may be up to 30%. The causal agent is the Hantaan virus (see HANTAVIRUS); reservoirs of infection are found in rodent populations. Infection typically occurs by inhalation of aerosols of urine, faeces etc. from infected rodents. The disease occurs in Asia and Europe.

**Korfia** See HELOTIALES.

**Kornberg enzyme** See DNA POLYMERASES.

**Koserella** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE. *K. trabulsii* (formerly known as 'enteric group 45' and originally identified as an atypical strain of *Hafnia alvei*) has been isolated from clinical specimens; it is MR +ve; VP –ve; indole –ve; citrate +ve; H<sub>2</sub>S –ve; urease –ve; LDC

+ve; ODC +ve; and it produces acid from cellobiose and melibiose but not from glycerol, lactose or sucrose. [JCM (1985) 21 39–42.]

**Koser's citrate medium** A medium, used for the CITRATE TEST, containing (per 100 ml of water): NaCl (0.5 g), MgSO<sub>4</sub>·7H<sub>2</sub>O (0.02 g), (NH<sub>4</sub>)H<sub>2</sub>PO<sub>4</sub> (0.1 g), K<sub>2</sub>HPO<sub>4</sub> (0.1 g), citric acid (0.2 g); pH 6.8.

**Koster's stain** A stain for detecting *Brucella* spp in mammalian tissues. The smear or section is stained for 1 min in a solution made by mixing saturated aqueous safranin and normal KOH (2:5 v/v); the slide is then washed in tap water and differentiated in 0.1% sulphuric acid (two changes for a total period of 10–20 sec). The slide is washed in tap water and counterstained with 1% carbol methylene blue. *Brucella* stains orange, tissues blue.

**Kotonkan virus** See LYSSAVIRUS.

**koumiss** (kumiss) An acidic, mildly alcoholic, fermented milk beverage made in the former USSR. Traditionally made from mares' milk, it is now also made from cows' milk. Organisms involved in the fermentation include *Lactobacillus bulgaricus* (the main acid-producer) and lactose-fermenting yeasts; the main products of fermentation are lactic acid, ethanol and CO<sub>2</sub>. (See also DAIRY PRODUCTS.)

**Kovács' indole reagent** An INDOLE TEST reagent: *p*-dimethylaminobenzaldehyde (5 g) is dissolved in 75 ml amyl (or isoamyl) alcohol, and conc. HCl (25 ml) is slowly added; it is stored at 4°C in the dark.

**Kovács' oxidase reagent** A 1% aqueous solution of tetramethyl-*p*-phenylenediamine dihydrochloride. (See also OXIDASE TEST.)

**kPa** 10<sup>3</sup> Pa (see PASCAL).

**KpnI** See RESTRICTION ENDONUCLEASE (table).

**krad** 10<sup>3</sup> rad (see RAD).

**kraft pulps** See PAPER SPOilage.

**Krebs cycle** *Syn.* TCA CYCLE.

**Krebspest** *Syn.* CRAYFISH PLAGUE.

**Kruse's bacillus** Archaic name for *Shigella sonnei* (Kruse's '*Bacillus pseudodysenteriae* type E').

**Kudoo** See MYXOSPOREA.

**kumiss** *Syn.* KOUMISS.

**Kunin antigen** *Syn.* ENTEROBACTERIAL COMMON ANTIGEN.

**Kunjin virus** See FLAVIVIRIDAE.

**Kupffer cells** Actively phagocytic cells which line the liver sinusoids.

**Kurthia** A genus of Gram-positive, asporogenous, catalase-positive, obligately aerobic bacteria which occur e.g. in meat and meat products. In the exponential growth phase the organisms occur in long chains of rods (or of short filaments) but in the stationary phase coccoid forms or short rods predominate; individual rods are peritrichously flagellated. *Kurthia* spp are chemoorganotrophs which can utilize certain alcohols (e.g. ethanol, ethanediol), amino acids (e.g. L-alanine) and fatty acids (e.g. butyric acid). VP –ve. Indole-negative. The type species, *K. zopfii*, grows in the temperature range 5–35°C and is killed by heating to 55°C/20 minutes. *K. gibsonii* grows in the range 5–45°C and survives heating to 55°C/20 minutes [SAAM (1983) 4 253–276]. GC%: ca. 36–38.

**kuru** A human TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHY [early description: NEJM (1957) 257 974–978]. The incubation period may range from a few years to some 30 years or more; characteristically there is ataxia, tremor, dysarthria and sometimes late dementia, and death occurs within a year of the onset of symptoms. Kuru is found in certain regions of Papua New Guinea and is believed to result from the ingestion of prion-containing flesh during ritual cannibalism; as this practice has declined, the incidence of kuru has decreased. Kuru can be transmitted experimentally to chimpanzees and to other primate and non-primate animals; goats (but not sheep) inoculated with tissue from kuru victims develop a disease that closely resembles SCRAPIE. [Review of kuru: Book ref. 159, pp. 483–544 (497–510).]

**Kusnezovia** A genus of poorly-characterized, manganese-depositing bacteria found in mud; the organisms have not been obtained in pure culture, and the validity of the genus (and of an apparently similar genus, *Caulococcus*) has been questioned [Book ref. 45, pp. 529–530].

**Kyasanur Forest disease** An acute, tick-borne human disease (vector: mainly *Haemaphysalis* sp) caused by a flavivirus (see FLAVIVIRIDAE); it occurs in Mysore State, India. Onset is sudden, with e.g. fever, headache, severe myalgia, haemorrhages, etc. Mortality rates are generally low (<5%). Monkeys may act as a reservoir of infection.

**Kyzylgach virus** See ALPHAVIRUS.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# L

**L** Leucine (see AMINO ACIDS).

**L-flagella** Lateral flagella – see VIBRIO.

**L-form** (L-phase variant) A defective bacterial cell of spherical or irregular shape, formed either spontaneously (e.g. by *Streptobacillus moniliformis*) or as a result of various stimuli (e.g. temperature shock, osmotic shock, or antibiotics which inhibit cell wall biosynthesis); in an L-form the cell wall is either partly or totally absent. (cf. PROTOPLAST and SPHAEROPLAST.) On removal of the stimulus, an L-form may resume cell wall synthesis and revert to the condition of the original strain, or it may continue to reproduce as an L-form (*stable L-form*). L-forms have been observed in various bacteria – including species of *Bacillus*, *Proteus*, *Streptococcus* and *Vibrio*. L-form colonies often resemble those of *Mycoplasma* spp. (L-forms were named after the Lister Institute of Preventive Medicine, London.) (See also CHLORAZOL BLACK E.)

**L-phase variant** *Syn.* L-FORM.

**L protein** See LEVIVIRIDAE.

**L ring** See FLAGELLUM (a).

**L-selectin** See SELECTINS.

**l-strand** (in adenoviruses) See ADENOVIRIDAE.

**L strand** See H STRAND.

**L-type starter** See LACTIC ACID STARTERS.

**L1 acholeplasmavirus group** *Syn.* PLECTROVIRUS.

**L1–L34 proteins** See RIBOSOME.

**L2 acholeplasmavirus group** *Syn.* PLASMAVIRIDAE.

**L3 acholeplasmavirus group** *Syn.* MV-L3 PHAGE GROUP.

**L18-MDP(A)** See ADJUVANT.

**L-573,655** See ENDOTOXIC SHOCK.

**L-749,345** ERTAPENEM.

**La Crosse virus** A virus of the genus BUNYAVIRUS; this virus is an occasional causal agent of human meningoencephalitis.

**La France disease** See WATERY STIPE.

**labial herpes** See HERPES SIMPLEX.

**label** (probe) See PROBE.

**Laboulbenia** See LABOULBENIALES.

**Laboulbeniales** An order of fungi (subdivision ASCOMYCOTINA) which include species that are obligately parasitic on insects. The minute, non-mycelial but multicellular thallus attaches to the host via a specialized organelle (see FOOT). Some species are monoecious, others dioecious (see also HETEROTHALLISM). The ascocarp is a perithecium. Conidial stages are apparently unknown. Genera: e.g. *Ceratomyces*, *Herpomyces*, *Laboulbenia*, *Rickia*. (cf. SPATHULOSPORALES.)

**Labyrinthomorpha** A phylum of the PROTOZOA which includes the LABYRINTHULAS and the THRAUSTOCHYTRIDS.

**Labyrinthula** See LABYRINTHULAS.

**labyrinthulas** (labyrinthulids; 'net slime moulds') A group of eukaryotic organisms of uncertain taxonomic position; they are classified together with the THRAUSTOCHYTRIDS, being variously regarded as fungi e.g. of the LABYRINTHULOMYCETES, as protozoa of a distinct phylum, Labyrinthomorpha, or as protists of the subphylum Labyrinthulina, phylum GYMNOMYXA. There is probably only one genus, *Labyrinthula*, species of which generally occur in marine habitats on plants and algae; they appear to be at least partially parasitic, and are believed to play a role in the ecologically important 'wasting disease' of eelgrass (*Zostera marina*). One *Labyrinthula* species occurs in fresh water and is apparently parasitic on *Vaucheria*.

The vegetative stage of the organism consists of spindle-shaped cells which produce a branching, anastomosing network of membrane-enclosed 'slime-ways' (variously called the ectoplasmic net, filoplasmodium, net plasmodium, rhizoplasmodium, etc); the cells move (by gliding) within these slime-ways. The vegetative cells contain a characteristic organelle, the *sagenogenetosome* or *sagenogen* (formerly 'bothrosome'), which is apparently involved in the production of the ectoplasmic net and possibly also in the movement of the cells through the net. The cells feed osmotrophically; enzymes are secreted from the ectoplasmic net, and the soluble products of digestion diffuse back to the cells within the net.

In at least some labyrinthulas biflagellate zoospores are formed, each bearing one anteriorly directed tinsel flagellum and one posteriorly directed whiplash flagellum; an orange eyespot occurs at the base of the flagellar apparatus. The zoospores are haploid, their formation involving meiosis. They apparently develop directly into spindle-shaped cells; copulation is presumed to occur between two of these cells.

**labyrinthulids** See LABYRINTHULAS.

**Labyrinthulina** See GYMNOMYXA.

**Labyrinthuloides** See THRAUSTOCHYTRIDS.

**Labyrinthulomycetes** A class of organisms (division MYXOMYCOTA) which includes the LABYRINTHULAS and the THRAUSTOCHYTRIDS; these organisms are apparently unrelated to other members of the Myxomycota.

**lac operon** (lactose operon) An OPERON containing genes which encode proteins involved in the uptake and utilization of  $\beta$ -galactosides such as LACTOSE. The *lac* operon occurs e.g. in *Escherichia coli* – in which it is located at ca. 8 minutes on the chromosome map. A simplified scheme for the *lac* operon is shown in the figure. The *lacZ* gene encodes  $\beta$ -galactosidase, *lacY* encodes a transport protein, ' $\beta$ -galactoside permease', and *lacA* encodes thiogalactoside transacetylase. (LacA catalyses the transfer of an acetyl group from acetyl-CoA to a  $\beta$ -galactoside. Its function *in vivo* is unknown; it has been suggested that it may be involved in the detoxification of non-metabolizable sugars by bringing about their acetylation and, hence, excretion.)

According to an earlier view, control of the *lac* operon (illustrated in the figure) is as follows. In the absence of an inducer, the regulator protein (repressor), which is active in tetramer form, binds tightly to the OPERATOR. The operator (O) is a region of ca. 16 bp which occurs immediately downstream of the promoter (P); the operator is an imperfect PALINDROMIC SEQUENCE centred at about nucleotide +10 in relation to the transcription start site (see PROMOTER). The binding of repressor to the operator reduces transcription to a minimal level (only a few molecules of product being produced per cell).

If an inducer (ALLOLACTOSE or e.g. IPTG) is present, it binds to the operator-bound repressor and causes the repressor to undergo a conformational change that reduces its affinity for the operator; the repressor then detaches from the operator, and the level of *lacZYA* transcription increases rapidly; up to ca. 10000 molecules of  $\beta$ -galactosidase may appear in the cell within minutes of induction. (The presence of inducer does not necessarily lead to expression of the *lac* operon: see CATABOLITE REPRESSION.)

While the above description gives the essential mode of control of the *lac* operon, the actual process is rather more complex [Mol. Microbiol. (1992) 6 2419–2422]. Thus, in

THE *lac* OPERON in *Escherichia coli* (a simplified scheme). The *lac* operon consists of (i) three regulated genes: *lacZ*, *lacY* and *lacA* (see entry); (ii) a promoter (P); (iii) an operator (O); and (iv) the regulator gene, *lacI*, encoding a repressor. *lacI* is transcribed constitutively, at a low rate, from its own independent promoter.

(a) In the absence of an inducer, the regulator protein (LacI) binds to the operator, O, and minimizes transcription of genes *lacZ*, *lacY* and *lacA* by the RNA polymerase (seen here at the promoter); there is some 'leakage': a few molecules of product are formed under these conditions in each cell.

(b) In the presence of lactose (taken up by proton-lactose symport),  $\beta$ -galactosidase converts some of the lactose to allolactose, the inducer of the *lac* operon. Allolactose binds to, and inactivates, the regulator protein – which dissociates from the operator, thus permitting transcription and translation of the regulated genes. (The single mRNA transcript contains an initiator codon and a stop codon for each of the three genes.)

When all the lactose has been metabolized, transcription of the *lac* operon is no longer needed; the inducer (allolactose) is no longer formed, and the (now active) regulator protein represses the operon.

The *lac* operon is subject to CATABOLITE REPRESSION (q.v.).

See entry for further details.

Reproduced from *Bacteria*, 5th edition, Figure 7.11, page 138, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

In addition to the primary operator (O), two other specific sites have been found to bind repressor (albeit with lower affinity): O-2 (located within the *lacZ* gene) and O-3 (found upstream of the promoter); a tetramer of the repressor protein appears to bind to the primary operator (O) and, simultaneously, to either O-2 or O-3, thus forming a DNA loop that may stabilize repressor-operator binding.

Moreover, in addition to the primary promoter (P1), there are at least five other overlapping promoter-like sequences – two upstream and three downstream of P1 – but their role(s) are unknown; some of these promoter-like sequences can be activated by a single base-pair substitution to give a CRP-independent Lac<sup>+</sup> phenotype (but the significance of this is unknown).

As well as the main CRP-binding site (centred ~62 bp upstream from the start site), there is a secondary CRP-binding site which coincides with the (primary) operator sequence. CRP has less affinity for this site, and its role is unknown.

Isopropyl- $\beta$ -D-thiogalactoside (IPTG) is a gratuitous inducer of the *lac* operon, i.e. it acts as an inducer of the operon but is not metabolized by the cell. IPTG is useful e.g. in recombinant DNA technology.

*Mutants defective in regulation of the operon.* *lacI*<sup>-</sup> mutants either fail to produce a repressor or produce an inactive one; transcription of *lacZYA* in these mutants occurs constitutively, but it can be repressed by supplying a functional repressor, i.e. in this case the *lac*<sup>-</sup> phenotype is recessive. However, in so-called *lac*<sup>-d</sup> mutants the mutant phenotype is dominant over the

## Lac plasmid

wild-type; in these cells, a defective (mutant) repressor subunit can interact with wild-type subunits to form a defective tetramer (an example of *negative complementation*).

Mutants designated *lacI<sup>s</sup>* produce a 'super-repressor' which retains its affinity for the operator but has negligible affinity for the inducer – the repressor remains tightly bound to the operator even in the presence of inducer (i.e. the operon is non-inducible), and the defect cannot be overcome by the presence of normal repressor (i.e. the mutant phenotype is dominant).

A mutation in the operator may reduce the affinity of the operator for the repressor; such mutants (designated *lacO<sup>c</sup>* or *o<sup>c</sup>*) express the *lac* genes constitutively, and the *o<sup>c</sup>* allele exhibits CIS-DOMINANCE.

**Lac plasmid** *Syn.* LACTOSE PLASMID.

**lacA gene** See LAC OPERON.

**laccase** A monophenol oxidase (EC 1.14.18.1). Many basidiomycetes (and some ascomycetes and deuteromycetes) produce extracellular laccase which appears to be involved in the degradation of LIGNIN and e.g. in the induction of basidiocarp development [JGM (1982) 128 2763–2770]. Most or all fungal laccases are copper-containing 'blue proteins' which can oxidize *o*- and *p*-phenols and aromatic amines.

**Lachnospira** A genus of bacteria (family BACTEROIDACEAE) which occur e.g. in the bovine RUMEN. Cells: curved rods, 0.4–0.6 × 2.0–4.0 μm, with one lateral or subpolar flagellum per cell; the cells from young cultures may give a weak Gram-positive reaction, while those from older cultures may stain Gram-negatively. Glucose fermentation yields acetate, ethanol, formate, lactate, CO<sub>2</sub> and H<sub>2</sub>; these products, together with methanol, are also formed from pectin fermentation. Butyrate, propionate and succinate are not formed. Growth is flocculent in glucose–rumen fluid media. Type species: *L. multiparus*. [Book ref. 22, pp. 661–662.]

**lachrymal canaliculitis** Inflammation of the lachrymal ducts and adjacent tissues, together with the formation of yellowish concretions within the ducts; the disease is non-invasive, usually mild, and the causal agent is commonly *Arachnia propionica* or *Actinomyces israelii*.

**laciniate** Lobed or notched.

**lacrimoid** (lacrioid) Shaped like a tear-drop.

**Lacrymaria** See GYMNOSTOMATIA.

**lactacin A** See BACTERIOCINS.

**lactacin B** See BACTERIOCINS.

**lactacin F** See BACTERIOCINS.

**β-lactam antibiotics** A family of ANTIBIOTICS, each of which contains the β-lactam ring (see figure). CEPHALOSPORINS and PENICILLINS are produced by fungi, while the more recently discovered members (see CARBAPENEMS, CLAVAMS, MONOBACTAMS, NOCARDICINS) are produced by bacteria [carbapenems and clavams: TIM (1998) 6 203–208]; synthetic and semi-synthetic members have been manufactured. Most β-lactam antibiotics are antibacterial, but some of the newer ones are antifungal. As well as possessing weak or moderate antibacterial activity, CLAVULANIC ACID and many CARBAPENEMS also inhibit β-LACTAMASES (see also β-LACTAMASE INHIBITOR).

The antibacterial action of penicillins and cephalosporins has been widely studied in *Escherichia coli*. One of the earliest proposals was that penicillin acted as an analogue of D-alanine–D-alanine, thus inhibiting the cross-linking of PEPTIDOGLYCAN with resultant lysis of the structurally weakened cells. The β-lactam antibiotics are now known to have multiple killing sites, and various PENICILLIN-BINDING PROTEINS (PBPs) have been identified as lethal targets. In many cases a given β-lactam antibiotic has a roughly similar degree of affinity for more

than one essential PBP – e.g., amoxycillin (PBPs 1A and 2), ampicillin (2, 3, 1A), benzylpenicillin (2, 3), carbenicillin (1A, 3), cefotaxime (1A, 3), cefuroxime (3, 1A), and cloxacillin (1A, 3). However, some β-lactam antibiotics bind preferentially or exclusively to one particular PBP – e.g., cefsulodin, cephalixin, cephaloridine and cephalothin bind preferentially to PBP-1A, mezlocillin binds preferentially to PBP-3, furazlocillin binds exclusively to PBP-3, and mecillinam binds exclusively to PBP-2 (cf. CEFOXITIN, CLAVULANIC ACID and THIENAMYCIN).

Resistance to β-lactam antibiotics may be intrinsic or acquired. In *Pseudomonas aeruginosa* resistance to many β-lactam antibiotics is due to poor penetration of these antibiotics through the outer membrane. In *Escherichia coli* resistance can be due e.g. to a mutation resulting in the loss of the *ompF* PORIN. (In Gram-positive species the CELL WALL offers little hindrance to penetration by molecules the size of β-lactam antibiotics.) Another form of resistance involves mutation resulting in PBPs with lower affinities for β-lactam antibiotics; such PBPs have been detected in e.g. methicillin-resistant strains of *Staphylococcus aureus*, and in benzylpenicillin-resistant strains of *Streptococcus pneumoniae* [JGM (1983) 129 1247–1260]. Resistance to β-lactam antibiotics may also be due to the action of chromosomal or plasmid-specified β-LACTAMASES.

An important source of resistance to β-lactam antibiotics is the *mecA* gene which encodes a novel PBP that has low affinity for β-lactams; this gene can confer high-level resistance to methicillin (and other β-lactams) e.g. in *Staphylococcus aureus* – see MRSA. [Evidence for *in vivo* transfer of *mecA* between staphylococci: Lancet (2001) 357 1674–1675.]

Cephalosporins and penicillins are decomposed by ions of the transition metals (e.g. copper, zinc).

[Nomenclature: JAC (1982) 10 365–372; data review of clinically useful β-lactam antibiotics and those under evaluation: JAC (1986) 17 5–36. Clinical pharmacology and therapeutic uses of penicillins (review): Drugs (1993) 45 866–894.]

**β-lactamase inhibitor** A compound which inhibits the inactivation of β-LACTAM ANTIBIOTICS by β-LACTAMASES; β-lactamase inhibitors include certain β-lactam compounds (e.g. CLAVULANIC ACID) which themselves have little or no antimicrobial activity but which can be combined with β-lactamase-sensitive antibiotics to form clinically useful drugs: see e.g. AUGMENTIN and TIMENTIN.

**β-lactamases** A class of enzymes (EC 3.5.2.6) which hydrolyse the β-lactam (C–N) bond in susceptible β-LACTAM ANTIBIOTICS, such hydrolysis inactivating the antibiotics. (Certain molecular features of a given β-lactam antibiotic may confer resistance to specific β-lactamases; such features include the 7-α-methoxy group in CEPHAMYCINS and the cysteamine side-chain in THIENAMYCIN.)

Bacteria generally exhibit a substantial level of resistance to a given β-lactam antibiotic if they encode a β-lactamase which is active against that antibiotic (but see β-LACTAMASE INHIBITOR). (See also *Microbial resistance to antibiotics* in the entry ANTIBIOTIC.)

β-Lactamases are produced by many species of bacteria, both Gram-positive and Gram-negative. In some cases the enzymes are inducible and liberated into the medium, while in other cases they are synthesized constitutively and retained within the cell envelope. (Some β-lactam antibiotics – including e.g. ceftiofuran and imipenem – are particularly good inducers of β-lactamases.) Studies on the transmembrane signalling pathway in staphylococci indicate that the induction of β-lactamases may depend on a novel mechanism that involves sequential

$\beta$ -LACTAM ANTIBIOTICS. (a) *Penicillin nucleus*. In 6-aminopenicillanic acid (6-APA): R = H. (b) *Cephalosporin nucleus*. In 7-aminocephalosporanic acid (7-ACA): R' = H, R'' = O.CO.CH<sub>3</sub>; in cephalosporin C: R' = CO.(CH<sub>2</sub>)<sub>3</sub>.CHNH<sub>2</sub>.COOH, R'' = O.CO.CH<sub>3</sub>. (c) *Nocardicin nucleus*. (d) *Monobactam nucleus*. (e) *Carbapenem nucleus*. (f) *Clavulanic acid* (a clavam).

cleavage of regulatory proteins [Science (2001) 291 1962–1965; commentary: Science (2001) 291 1915–1916]. In this scheme, the regulation of  $\beta$ -lactamase genes involves initial binding of a  $\beta$ -lactam antibiotic to a cell-surface sensor–transducer protein, BlaR1; the resulting cleavage of BlaR1 gives rise to a (hypothetical) product BlaR2 which, directly or indirectly, brings about cleavage of the transcriptional repressor of  $\beta$ -lactamase genes, allowing expression of these genes.

$\beta$ -Lactamases may be encoded by chromosomal genes and/or by genes in a PLASMID or transposon (see e.g. entry for Tn3). Genes which encode  $\beta$ -lactamases are designated *bla* genes.

The detection of  $\beta$ -lactamases *in vitro* can be facilitated e.g. by the use of NITROCEFIDIN.

*Classification of  $\beta$ -lactamases*. An early scheme classified the  $\beta$ -lactamases according e.g. to their substrate specificities and the location of genes encoding them. The type I  $\beta$ -lactamases included those chromosome-encoded enzymes of enterobacteria and pseudomonads that are active mainly against cephalosporins (i.e. cephalosporinases); type II  $\beta$ -lactamases included chromosome-encoded enzymes of *Proteus* spp that are

active primarily against penicillins (i.e. penicillinases); type III enzymes included plasmid-encoded  $\beta$ -lactamases active against both cephalosporins and penicillins, but not against oxacillin or carbenicillin; type IV  $\beta$ -lactamases included the chromosome-encoded enzymes of *Klebsiella* spp that are active primarily against penicillins; type V  $\beta$ -lactamases included plasmid-encoded enzymes active against oxacillin and/or carbenicillin.

Subsequently, classification of plasmid-encoded  $\beta$ -lactamases of Gram-negative bacteria was based on ISOELECTRIC FOCUSING, and more than 11 types were distinguished [BMB (1984) 40 18–27]. This classification included  $\beta$ -lactamases designated e.g. TEM-1, TEM-2, SHV-1 and HMS-1; these particular enzymes are active against many of (the early) cephalosporins and penicillins, although poorly active against carbenicillin, cloxacillin, methicillin and oxacillin. The OXA-1, -2 and -3 enzymes are active against oxacillin (and e.g. ampicillin and cloxacillin) but poorly active against carbenicillin. The PSE-1, -2, -3 and -4 enzymes of *Pseudomonas* spp are active against carbenicillin (and e.g. ampicillin), while PSE-2 is also active against e.g. oxacillin, methicillin and moxalactam. Subsequent

## Lactarius

to the designation of these (early)  $\beta$ -lactamases, many new  $\beta$ -lactam antibiotics have been introduced, but  $\beta$ -lactamases have tended to evolve in parallel – see later under *Evolution of  $\beta$ -lactamases*.

The  $\beta$ -lactamases have also been classified into four categories (A–D) on the basis of sequence homology (apparent evolutionary relationships). For example, class A  $\beta$ -lactamases (which include e.g. TEM-1, encoded by gene *bla*<sub>TEM-1</sub>) contain a serine residue at the active site of the enzyme; they are found in both Gram-positive and Gram-negative bacteria and are mainly plasmid-encoded enzymes. The class B  $\beta$ -lactamases include zinc-requiring cephalosporinases from *Bacillus cereus*, while class C enzymes include chromosome-encoded cephalosporinases from Gram-negative bacteria.

*Evolution of  $\beta$ -lactamases; extended-spectrum  $\beta$ -lactamases (ESBLs)*. The use of successive ‘generations’ of  $\beta$ -lactam antibiotics, sometimes with  $\beta$ -lactamase inhibitors, created a selective pressure for the development of new  $\beta$ -lactamases that are able to protect bacteria against some of the most recently introduced drugs. Initially, a new generation of so-called ‘extended-spectrum’  $\beta$ -lactam antibiotics were designed to be effective in the presence of the (then) existing  $\beta$ -lactamases, but, following the use of these newer drugs, new variant (mutant) forms of  $\beta$ -lactamase have evolved; these can hydrolyse at least some of the newer antibiotics and are becoming widely disseminated. These so-called *extended-spectrum  $\beta$ -lactamases (ESBLs)* are able to inactivate oxymino- $\beta$ -lactam antibiotics (such as the third-generation cephalosporin *cefotaxime*) and the monobactam AZTREONAM. The ESBLs appear to have evolved mainly from TEM and SHV  $\beta$ -lactamases (both class A enzymes) [ $\beta$ -lactamases (evolution): TIM (1998) 6 323–327]. (Interestingly, evolutionary relationships may exist between  $\beta$ -lactamases and PENICILLIN-BINDING PROTEINS [ARB (1983) 52 853–856].) ESBLs include e.g. TEM-50 (which incorporates resistance to inhibitors) [AAC (1997) 41 1322–1325] and SHV-18 (a plasmid-encoded enzyme from *Klebsiella pneumoniae* K6) [AAC (2000) 44 2382–2388]. Resistance to the fourth-generation cephalosporin *cefepime* has been associated with hyperproduction of SHV-5 [JCM (1998) 36 266–268].

ESBLs are frequently encoded by plasmids that also carry other antibiotic-resistance genes, so that the choice of drugs for chemotherapy against ESBL-producing strains may be limited. It has been suggested that the choice of  $\beta$ -lactam drugs suitable for treating ESBL-positive infections may (at present) be limited to CARBAPENEMS or CEPHAMYCINS [treatment options for extended-spectrum  $\beta$ -lactamase producers: FEMS (2000) 190 181–184].

Infections with strains of *Acinetobacter* and *Pseudomonas aeruginosa* that encode ESBLs of the PER-1 type have been reported to be associated with an increased level of fatalities [JMM (2001) 50 642–645].

**Lactarius** A genus of fungi (family RUSSULACEAE) which form mushroom-shaped, lamellate fruiting bodies that exude a milk-like fluid (‘latex’) when cut; *Lactarius* spp are sometimes called ‘milk caps’. The lactiferous (latex-containing) hyphae appear to store precursors of the pungent dialdehydes vallerol and isovallerol; these dialdehydes may protect the fungus from mycovores [Mycol. (1984) 76 355–358].

**lactase** *Syn.*  $\beta$ -GALACTOSIDASE.

**lactate dehydrogenase virus (LDV)**; lactate dehydrogenase virus; lactate dehydrogenase-elevating virus; Riley virus) An enveloped, roughly spherical RNA virus which causes a persistent, life-long infection in mice of the species *Mus musculus* and *M. caroli*; apparently, other animals, including other rodents, are not susceptible.

The LDV genome is a single molecule of positive-sense ssRNA, and the virus has been placed in the arterivirus group (see ARTERIVIRUS).

LDV replicates only in a particular subset of MACROPHAGES, the macrophages being destroyed in the process. [Determinants of macrophage susceptibility: JGV (1985) 66 1469–1477.] Infection results in a persistent viraemia (maintained by the ongoing production of new susceptible cells) and gives rise to elevated levels of certain plasma enzymes – particularly certain (positively charged) lactate dehydrogenase isoenzymes. Elevated levels of these enzymes result from their reduced rates of clearance from the plasma; such enzymes may be cleared in the normal mouse by the particular subset of macrophages destroyed by LDV.

Infected mice generally show little sign of disease, but they exhibit slight splenomegaly and disturbances in the immune system (altering the growth of tumours, response to infection etc.). In the acute phase of infection there is transient polyclonal activation of antibody-producing cells – resulting in increased immunoglobulin levels – and transient depression of cell-mediated immunity; in the chronic phase, the humoral response is depressed, while cell-mediated immunity returns to normal. Antibodies to LDV are produced, and virus–antibody complexes circulate in the blood; the immune complexes cause little tissue reaction – possibly because they do not bind complement. LDV can apparently cause age-dependent poli-encephalomyelitis (resulting in paralysis) in certain strains of mouse.

LDV is apparently transmitted by blood-sucking parasites and by fighting; transplacental transmission can occur if the mother becomes infected during pregnancy or lactation, but generally does not occur in chronically infected mothers.

[LDV (review): JGV (1985) 66 2297–2312.]

**lactic acid (CH<sub>3</sub>.CHOH.COOH)** A compound present e.g. in many fermented DAIRY PRODUCTS, and also widely used as a food additive. Only the L(+)-isomer can be readily assimilated by man and animals. L(+)-Lactic acid is obtained commercially by the LACTIC ACID FERMENTATION of sucrose by LACTIC ACID BACTERIA; it is used primarily in the food industry, being added e.g. to confectionary, pickles, beverages, etc [AvL (1983) 49 86].

**lactic acid bacteria** A (non-taxonomic) group of Gram-positive, non-sporing bacteria which carry out a LACTIC ACID FERMENTATION of sugars; it includes species of *Lactobacillus*, *Lactococcus*, *Leuconostoc* and *Pediococcus*. (*Bifidobacterium* is sometimes included.)

Lactic acid bacteria are used extensively in the food industry (e.g. BREAD-MAKING (sourdough), DAIRY PRODUCTS, SALAMI); however, they can also cause food spoilage (see e.g. MEAT SPOILAGE; cf MALOLACTIC FERMENTATION). (See also SILAGE.)

Lactic acid bacteria are nutritionally fastidious and weakly proteolytic [for proteolytic systems see AvL (1983) 49 225–245]. Many activities of the lactic acid bacteria (e.g. LACTOSE metabolism) appear to be plasmid-linked [AvL (1983) 49 259–274].

Although lactic acid bacteria are primarily fermentative, many strains can grow in the presence of air and can carry out certain oxidation reactions using flavin-containing oxidases, peroxidases, or NAD-independent dehydrogenases – oxidizing at least some of the pyruvic and lactic acids (formed by fermentative pathways) to acetic acid and carbon dioxide [AvL (1983) 49 209–224]. (See also LEUCONOSTOC.) The hydrogen peroxide formed during these oxidations has some preservative action in fermented foods (see FOOD PRESERVATION (e)).

[Genetics, metabolism and applications of lactic acid bacteria (symposium); FEMS Reviews (1993) 12 1–272.]

**lactic acid fermentation** A type of FERMENTATION (1), carried out e.g. by LACTIC ACID BACTERIA, in which sugars (e.g. LACTOSE, glucose, PENTOSEs) are converted either entirely (or almost entirely) to lactic acid (HOMOLACTIC FERMENTATION) or to a mixture of lactic acid and other products (HETEROLACTIC FERMENTATION) [AVL (1983) 49 209–224]. Lactic acid bacteria produce either L(+)- or D(-)-lactic acid, or both – the nature of the isomer(s) formed being an important taxonomic characteristic (see e.g. LACTOBACILLUS). Which isomer is produced depends on the specificity of the NAD-dependent lactate dehydrogenase (LDH) present; species which produce racemic mixtures usually possess both D- and L-specific LDHs, but in certain lactobacilli the mixture results from the combined action of L-specific LDH and lactic acid racemase. (See also LACTIC ACID and DAIRY PRODUCTS.)

**lactic acid starters** STARTER cultures used to initiate a LACTIC ACID FERMENTATION in the commercial production of e.g. DAIRY PRODUCTS; they may be supplied in freeze-dried or frozen concentrated form.

The starters used for dairy products usually contain 'homolactic' lactobacilli or lactococci as the main lactic acid producers, with leuconostocs and/or strains of *Lactococcus lactis* as 'aroma bacteria' (see DIACETYL). The lactic acid-producing strains carry out HOMOLACTIC FERMENTATION of the lactose in milk – conditions of lactose excess for these bacteria; cows' milk contains ca. 4–7% w/v lactose, much of which remains in the product after fermentation. Only strains which use the PTS/P-β-gal system of LACTOSE (q.v.) metabolism achieve sufficiently rapid growth and produce enough lactic acid to be useful commercially.

Mesophilic starters (used e.g. for making BUTTER) usually contain strains of *Lactococcus lactis* as the main acid-producers; starters which contain only acid-producers (no aroma bacteria) are called N-type (= O-type) starters. B-type (= L-type) starters contain, in addition to N-type organisms, a *Leuconostoc* aroma species – usually *Leuconostoc cremoris* (= '*Betacoccus cremoris*', hence 'B' starter). D-type starters contain N-type organisms and aroma strains of *Lactococcus lactis*. BD-type (= BL-type) starters contain both B- and D-type organisms.

Thermophilic starters (used e.g. for YOGHURT and some CHEESE-MAKING processes) include e.g. *Lactobacillus bulgaricus*, *L. helveticus* and/or *Streptococcus thermophilus*.

A genetically engineered starter culture has been used to control the (food-borne) pathogen *Listeria monocytogenes* in cheddar cheese [AEM (1998) 64 4842–4845]. For cottage cheese, use has been made of a starter containing organisms that produce lactacin 3147 [JAM (1999) 86 251–256].

Starter strains are susceptible to infection by certain phages, and this can lead to problems such as slow (or absent) fermentation associated with economic losses. Efforts have therefore been made to produce 'engineered' starter strains that incorporate resistance to specific phages. For example, some engineered strains exhibit the Per (phage-encoded resistance) phenotype which is conferred by the presence of a high-copy-number plasmid that contains a sequence equivalent to the origin of replication of a particular infecting phage; it appears that the plasmid-borne phage origin (in multiple copies) inhibits phage replication by competing with replication function(s) of the infecting phage. In a different approach, transcription of a plasmid-borne sequence (within the engineered bacterium) gives rise to an anti-sense RNA molecule that can bind to a specific phage mRNA

and prevent its translation. [Improvement and optimization of two engineered phage-resistance mechanisms in *Lactococcus lactis*: AEM (2001) 67 608–616.]

**lactic acidosis (vet.)** See ACIDOSIS (1).

**lactic dehydrogenase virus** Syn. LACTATE DEHYDROGENASE VIRUS.

**lacticin 3147** A pore-forming LANTIBIOTIC produced by *Lactobacillus lactis* subsp. *lactis*. It consists of two peptide components, both of which are needed for activity; each component requires modification by a separate enzyme [Microbiology (2000) 146 2147–2154]. In sensitive cells, the lesions formed by lacticin 3147 are ion-specific pores.

A lacticin 3147-producing starter culture has been tested for its ability to inhibit *Listeria monocytogenes* in the manufacture of cottage cheese [JAM (1999) 86 251–256].

**lactiferous hyphae** See LACTARIUS.

**Lactobacillaceae** A family of bacteria (sole genus: LACTOBACILLUS). [Book ref. 21, p. 576.]

**Lactobacillus** A genus of Gram-positive, asporogenous bacteria which are anaerobic, microaerophilic, or facultatively aerobic. Cells are rods or coccobacilli, occurring singly or in chains. Most strains are non-motile. Catalase –ve, but may be catalase +ve in haem-containing media. Metabolism is predominantly fermentative, lactic acid being formed from glucose either homofermentatively or heterofermentatively. (See LACTIC ACID BACTERIA.) Species are commonly aciduric or acidophilic. Nutritional requirements are complex, generally including carbohydrates, peptones, vitamins etc. Lactobacilli may be grown e.g. on APT agar; growth is stimulated by Tween 80.

The genus (GC%: ca. 32–53) is divided into three subgenera: *Betabacterium*, *Streptobacterium* and *Thermobacterium*. Betabacteria carry out HETEROLACTIC FERMENTATION of glucose (and hence require thiamine and produce CO<sub>2</sub> from glucose); fructose is fermented and can be reduced to mannitol (see e.g. SILAGE), and PENTOSEs may be fermented. Streptobacteria and thermobacteria carry out HOMOLACTIC FERMENTATION of glucose (CO<sub>2</sub> not produced, thiamine not required); fructose is usually fermented but it cannot be reduced to mannitol. Streptobacteria can grow at 15°C (and may or may not grow at 45°C), can ferment pentoses, and produce CO<sub>2</sub> from gluconate. Thermobacteria can generally grow at or above 45°C but not at 15°C, and cannot ferment pentoses or produce CO<sub>2</sub> from gluconate. Species are distinguished by biochemical tests. The nature of the lactic acid produced can be a useful criterion: betabacteria produce DL-lactic acid, streptobacteria and thermobacteria produce (mainly) L(+)-, D(-)- or DL-lactic acid, according to species. Betabacteria include e.g. *L. brevis*, *L. buchneri* (possibly a subspecies of *L. brevis*), *L. cellobiosus*, *L. confusus*, *L. desidiosus*, *L. fermentum*, *L. hilgardii*, *L. viridescens*; streptobacteria include e.g. *L. alimentarius*, *L. casei*, *L. coryniformis*, *L. curvatus*, *L. farciminis*, *L. plantarum*, *L. xylosum* (cf. LACTOCOCCUS); thermobacteria include e.g. *L. acidophilus*, *L. bulgaricus*, *L. delbrueckii* (type species of the genus), *L. helveticus*, *L. lactis*, *L. leichmannii*, *L. ruminis*, *L. salivarius*. [Book ref. 46, pp. 1653–1679.] (*L. bifidus*: see BIFIDOBACTERIUM.) [Classification of *L. bulgaricus*, *L. lactis* and *L. leichmannii* as subspecies of *L. delbrueckii*: SAAM (1983) 4 552–557.]

Lactobacilli are found e.g. in man and animals (see e.g. DENTAL CRIES, GASTROINTESTINAL TRACT FLORA, VAGINA MICROFLORA), in MILK, DAIRY PRODUCTS and other fermented foods and beverages (see e.g. sourdough BREAD-MAKING, PULQUE, SOY SAUCE), and – usually in very small numbers – on plant material (see e.g. SILAGE, PICKLING). (See also BEER SPOILAGE, MALOLACTIC FERMENTATION, MEAT SPOILAGE, MILK SPOILAGE, WINE

## **lactocin 27**

SPOILAGE.) Lactobacilli are generally non-pathogenic, although some strains (particularly of *L. casei* subsp. *rhamnosus*) have been associated with endocarditis, septicaemia and abscesses, and another species (proposed name: *L. piscicola* [IJSB (1984) 34 393–400]) is apparently an opportunist pathogen in salmonid fish.

[*Lactobacillus casei* strain Shirota has been reported to have potent PROBIOTIC activity when administered intraurethrally in an *Escherichia coli* urinary tract infection in mice: AAC (2001) 45 1751–1760.]

**lactocin 27** See BACTERIOCINS.

**lactococcin G** See BACTERIOCINS.

**Lactococcus** A genus of LACTIC ACID BACTERIA which occur e.g. in DAIRY PRODUCTS; the organisms were previously classified in the genus *Streptococcus* (most strains react positively with streptococcal Lancefield group N antiserum). Cells: non-motile cocci, or coccoid forms, which occur singly or in pairs or chains. Metabolism: fermentative, L(+)-lactic acid being the main product of glucose fermentation. Growth can occur at 10°C but not at 45°C. GC% 34–43. Type species: *L. lactis*.

*L. lactis* includes organisms previously known as *Streptococcus lactis*, including the subspecies *lactis* and *diacetylactis* (= *diacetylactis*), *Streptococcus cremoris* (including *S. lactis* subspecies *cremoris*), and *Lactobacillus xylosus*. It was suggested that *Lactococcus* should also include the species *L. plantarum* (= *Streptococcus plantarum*) and *L. raffinolactis* (= *Streptococcus raffinolactis*). [Validation of the names *Lactococcus*, *L. lactis*, *L. lactis* subspecies *cremoris* and *lactis*, and *L. plantarum*: IJSB (1986) 36 354–356.]

**lactoferrin** A SIDEROPHILIN (MWt ca. 90000) which has two iron-binding sites per molecule; it occurs e.g. in milk and tears, and in granules within NEUTROPHILS. Lactoferrin in milk may serve an antimicrobial function by sequestering iron (IRON being an essential requirement for most microorganisms). The lactoferrin in neutrophils may serve an antimicrobial function (during PHAGOCYTOSIS and INFLAMMATION) by catalysing the formation of HYDROXYL RADICAL; levels of lactoferrin in plasma are known to rise during inflammatory processes. Lactoferrin released by neutrophils may enhance the adhesion of neutrophils to tissue cells, and to each other, and may promote chemotaxis in other neutrophils.

**lactoflavin** *Syn.* RIBOFLAVIN.

**lactoperoxidase–thiocyanate–hydrogen peroxide system** (LP system; LPS) An antimicrobial system, present in various body fluids, in which lactoperoxidase (an enzyme present e.g. in saliva, milk etc) catalyses the oxidation, by hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), of thiocyanate (SCN<sup>-</sup>). SCN<sup>-</sup> is a product of the metabolism of e.g. sulphur-containing amino acids and certain glycosides; it is present at relatively high concentrations e.g. in milk from cattle fed on clover or cruciferous plants such as kale or rape. The H<sub>2</sub>O<sub>2</sub> may be derived from indigenous microorganisms (as a metabolic by-product – see HYDROGEN PEROXIDE (b)) or from PMNs. Although the final products of the oxidation (SO<sub>4</sub><sup>2-</sup>, CO<sub>2</sub> and NH<sub>3</sub>) are much less toxic than H<sub>2</sub>O<sub>2</sub>, various short-lived antibacterial intermediates – including e.g. hypothiocyanite, OSCN<sup>-</sup> – are generated during the reaction. The LP system inhibits various bacterial enzymes (including e.g. the EMP enzyme glyceraldehyde 3-phosphate dehydrogenase) and damages the bacterial cytoplasmic membrane, increasing the permeability of the membrane to ions and small molecules. The system can be bactericidal for Gram-negative, catalase-positive bacteria (e.g. enterobacteria, pseudomonads), but is usually

bacteriostatic against Gram-positive, catalase-negative bacteria (e.g. streptococci and lactobacilli).

The LP system has a potential application in the preservation of (refrigerated or uncooled) milk; for this purpose, levels of H<sub>2</sub>O<sub>2</sub> in the milk could be boosted e.g. by the addition of a glucose/glucose oxidase H<sub>2</sub>O<sub>2</sub>-generating system and (if necessary) SCN<sup>-</sup>. Components which activate the LP system have been incorporated into an 'anti-plaque' toothpaste to inhibit oral streptococci (see DENTAL CARIES).

[Review: J. Food Protect. (1984) 47 724–732.]

**lactophenol cotton blue** A general mycological MOUNTANT and DYE. Phenol (20 g), water (20 ml), lactic acid (20 ml), and glycerol (30 ml) are warmed together, and cotton blue (0.05 g) is added.

**lactose** A disaccharide (β-D-galactopyranosyl-(1 → 4)-D-glucopyranose) present in MILK. Lactose is the major source of carbon and energy for LACTIC ACID BACTERIA growing in milk (see also LACTIC ACID FERMENTATION). The ability to metabolize lactose is an important characteristic in the identification of members of the family Enterobacteriaceae.

In *Escherichia coli* and other enterobacteria, and in most lactobacilli (though not *Lactobacillus casei*), lactose is generally taken up by a lactose-specific proton symport TRANSPORT SYSTEM; the lactose is then split into glucose and galactose by β-galactosidase (see also LAC OPERON), the glucose and galactose being metabolized via the EMP and Leloir pathways, respectively: see Appendix III(a).

In e.g. *Lactobacillus casei*, *Lactococcus lactis* and *Staphylococcus aureus*, lactose is taken up by a PEP-dependent phosphotransferase system (see PTS) – entering the cell as lactose phosphate (apparently as lactose bisphosphate in *L. lactis* [Book ref. 11, pp 196–203]) which is then hydrolysed by phospho-β-D-galactosidase (P-β-gal); the glucose (glucose 6-phosphate in *L. lactis*) and galactose 6-phosphate moieties are metabolized via the EMP and D-tagatose 6-phosphate pathways, respectively – see Appendix III(a). In at least some strains of *L. lactis*, all the enzymes for lactose metabolism – from transport to the formation of triose phosphates via the D-tagatose 6-phosphate pathway – appear to be plasmid-encoded [JB (1983) 153 76–83]; strains lacking the lactose plasmid can metabolize lactose via the permease/β-galactosidase mechanism and Leloir pathway, but their rates of lactose metabolism and growth are much reduced (cf. LACTIC ACID STARTERS).

In yeasts, *Kluyveromyces marxianus* var. *lactis* and var. *marxianus* (some strains) are among the few capable of fermenting lactose (see SINGLE-CELL PROTEIN); however, other yeasts may be able to metabolize lactose oxidatively (cf. KLUYVER EFFECT).

**lactose killing** Lactose-mediated SUBSTRATE-ACCELERATED DEATH.

**lactose operon** *Syn.* LAC OPERON.

**lactose plasmid** (Lac plasmid) A PLASMID which specifies the uptake and metabolism of LACTOSE. Conjugative lactose plasmids occur e.g. in some lactococci.

**lacunose** Covered with pits or indentations.

**lacY gene** See LAC OPERON.

**lacZ gene** See LAC OPERON.

**LAD** LEUKOCYTE ADHESION DEFICIENCY.

**Laemmli electrophoresis** *Syn.* SDS-PAGE.

**laeoplectic metachrony** See METACHRONAL WAVES.

**Laetiporus** See APHYLLOPHORALES (Polyporaceae).

**laevulose** D-Fructose.

**LAF** See INTERLEUKIN-1.

**lag phase** (of growth) See BATCH CULTURE.

**Lagarde retort** An air–steam BATCH RETORT.

**Lagenidiales** An order of aquatic fungi (class OOMYCETES) which are parasitic on e.g. other fungi, oyster larvae and crabs' eggs. The thallus is either a single cell or a short filament, according to organism. Genera include *Lagenidium*, *Olpidiopsis*, *Petersenia* (see also ALGAL DISEASES) and *Sirolopidium*.

**Lagenidium** See LAGENIDIALES.

**Lagenophrys** See PERITRICHIA.

**lager-making** See BREWING.

**lagging-strand** See DNA REPLICATION.

**Lagos bat virus** See LYSSAVIRUS.

**Laguna Negra virus** See HANTAVIRUS.

**laking** (of erythrocytes) Lysis, with release of haemoglobin.

**LAL test** LIMULUS AMOEBOCYTE LYSATE TEST.

**lamb dysentery** An acute, fatal disease of young lambs (<10 days old) involving diarrhoea, dysentery and toxæmia; the causal agent is *Clostridium perfringens* type B. Overcrowding is a predisposing factor.

**LamB protein** ('maltoporin') In *Escherichia coli*: an OUTER MEMBRANE protein encoded by the *lamB* gene; it acts as a receptor for bacteriophage lambda, and as a channel-forming protein involved in the uptake of maltose and maltodextrins – and certain other solutes (e.g. some unrelated sugars, and amino acids). (cf. PORIN.) LamB-deficient mutants exhibit impaired active transport of maltose when the external maltose concentration is <10 µM. The channel-forming role of LamB in the uptake of maltodextrins (and possibly also maltose) may depend on its interaction with the periplasmic maltose-binding protein (see BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM). Synthesis of the LamB protein is inducible by maltose and is subject to CATABOLITE REPRESSION.

**lambda chain** See LIGHT CHAIN.

**lambda particles** See LYTICUM.

**lambdoid phages** A group of temperate phages whose genomes can undergo recombination with each other; the group includes e.g. phages λ, 21, 82, 434, φ80, and P22 (see BACTERIOPHAGE λ and BACTERIOPHAGE P22). The genomes of these phages have a more or less common gene sequence, but many of the gene products are genome-specific: e.g., the gpN antiterminators of phages λ, 21 and P22 show little homology and interact only with their own genomes. Phages λ, φ80, 21 and 434 each has a unique immunity region (genes *cI*, *cro*, *o<sub>L</sub>* and *o<sub>R</sub>*) and hence a lysogen containing one of these phages does not show SUPERINFECTION IMMUNITY to the others.

**Lambliia intestinalis** See GIARDIA.

**lambliaiasis** Syn. GIARDIASIS.

**Lambornella** A genus of ciliates of the HYMENOSTOMATIDA; *L. clarki* is endoparasitic in certain mosquitoes.

**lamella** (gill) (*mycol.*) Blade-like sheets of tissue which hang vertically from the underside of the pileus in fruiting bodies of fungi of the AGARICALES and of e.g. PLEUROTUS spp; each lamella consists of a TRAMA (see also SPHAEROCYST) bearing a HYMENIUM which gives rise to basidiospores. In some species (e.g. *Agaricus*) the lamellae are arranged radially around a central stipe; in others (e.g. *Pleurotus*) they radiate fan-wise from a lateral stipe. Lamellae may branch and/or anastomose; their colour at maturity usually reflects the colour of the basidiospores. (See also SPORE PRINT.) The shape of lamellae can be taxonomically important.

In most agarics (including *Agaricus*) the lamellae are *aequihyeniiferous*, i.e., they are wedge-shaped in transverse cross-section (tapering from the attached to the free end), and they form basidia which mature at approximately the same time at all regions in the hymenium. *Inaequihyeniiferous* lamellae occur

e.g. in *Coprinus* spp; they are rectangular in transverse cross-section (opposite faces of the lamella being parallel), and the basidia at the lower (free) end reach maturity before those higher up the lamella. (See also BASIDIOSPORES.)

**lamellate** (*mycol.*) Having lamellae (see LAMELLA).

**lamina** (*algol.*) Syn. BLADE.

**laminaran** Syn. LAMINARIN.

**Laminaria** A genus of large marine algae (division PHAEOPHYTA) which exhibit a heteromorphic ALTERNATION OF GENERATIONS. The sporophyte is a large blade with a stipe and holdfast; growth occurs at the region between stipe and blade, and at the MERISTODERM. The gametophyte is a microscopic filamentous structure. *L. japonica* is used as a food in China (where it is called 'haidai') and e.g. in Japan ('kombu') [Book ref. 130, pp. 688–690]. (See also ALGINATE.)

**laminaribiose** A reducing disaccharide: β-D-glucopyranosyl-(1 → 3)-D-glucopyranose.

**laminarin** (laminaran) The storage polysaccharide characteristic of members of the Phaeophyta. Laminarins are essentially linear (1 → 3)-β-D-glucans in which the chains may terminate with D-mannitol (M-chains, non-reducing) or with D-glucose (G-chains, reducing); low levels of branching via (1 → 6)-β-glucosidic linkages may occur. Laminarins from different sources vary in their mannitol content (usually ca. 2–4%), degree of branching, and average chain length. [Book ref. 37, pp. 481–486.] Laminarins may be attacked e.g. by certain fungi and by *Nocardia* spp. (cf. CHRYSOLAMINARIN.)

**lamivudine** (–)2'-deoxy-3'-thiacytidine: an ANTIVIRAL AGENT with activity against the hepatitis B virus; this nucleoside analogue inhibits the viral DNA polymerase, thus inhibiting viral replication. As a candidate therapeutic agent, lamivudine was able significantly to reduce serum levels of viral DNA in phase III clinical trials. However, resistance to the drug may appear during long-term treatment programmes; such resistance has been found to be associated with mutant forms of the polymerase. [PCR-based detection of mutant strains of HBV with reduced susceptibility to lamivudine: JCM (1999) 37 3338–3347.]

Lamivudine is also an ANTIRETROVIRAL AGENT which acts as a NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR; it is one of the drugs used against AIDS.

**Lampit** See CHAGAS' DISEASE.

**Lamprene** CLOFAZIMINE.

**Lamprocystis** A genus of photosynthetic bacteria (family CHROMATIACEAE). Cells of the sole species, *L. roseopersicina*, are motile cocci, 3–3.5 µm, which contain Bchl *a*, various carotenoids (cell suspensions are typically purple), and gas vacuoles. *L. roseopersicina* is a strict anaerobe which requires sulphide and vitamin B<sub>12</sub>.

**Lamproderma** See MYXOMYCETES.

**Lampropedia** A genus (*incertae sedis*) of aerobic, oxidase-positive, catalase-positive, chemoorganotrophic, Gram-negative bacteria which have been isolated e.g. from stagnant and polluted waters. Cells: non-flagellated, non-pigmented, rounded to cuboid, ca. 1.0–1.5 × 1.0–2.5 µm, which occur in thin, hydrophobic sheets (on liquid and solid media) – each sheet consisting of a number of roughly square 'tablets' of 16–64 cells arranged, with sides adjacent, in the same plane; cell division occurs synchronously. Metabolism: respiratory (oxidative). Carbon and energy sources include TCA cycle intermediates; carbohydrates are not used. Optimum growth temperature: 30°C. GC%: ca. 61. Type species: *L. hyalina*.

[Book ref. 22, pp. 402–406.]

## LAMPs

**LAMPs** See PHAGOCYTOSIS (a).

**lamziekte** A form of BOTULISM in cattle. It occurs in S. Africa and is contracted by the ingestion of carrion contaminated with *C. botulinum* (usually) type D.

**Lancefield's streptococcal grouping test** A procedure for identifying and classifying streptococci; it involves the extraction and identification, by serology, of cell components known as C SUBSTANCES. On the basis of their particular C substances, most strains of STREPTOCOCCUS can be placed into one or other of a number of *Lancefield groups* which are designated A, B, C. . . etc; all the strains in a particular Lancefield group possess a C substance which is serologically distinct from those C substances which characterize the other Lancefield groups. (Some streptococci have more than one type of C substance; thus, e.g., some strains of enterococci contain the C substances of Lancefield groups D and Q.)

The test is often carried out as a RING TEST in a capillary tube: an extract of the strain under test is layered onto an antiserum to a given C substance, and the test is repeated with antisera to different C substances until a positive result (a precipitate at the extract–antiserum interface) is obtained.

**Langerhans' cells** Non-phagocytic cells, derived from bone marrow, found in the skin. Morphologically they resemble DENDRITIC CELLS but, in addition to class II MHC antigens, they bear cell-surface receptors for complement components and for IgG Fc portions; they also contain racket-shaped cytoplasmic organelles (*Birbeck granules*). Langerhans' cells are involved in CONTACT SENSITIVITY.

**Langhans giant cell** See GIANT CELL.

**lankamycin** See MACROLIDE ANTIBIOTICS.

**Lankesterella** A genus of coccidian protozoa (suborder EIMERIORINA) parasitic in amphibia and transmitted by invertebrate vectors. Asexual and sexual development occur in the vertebrate host, sporozoites occurring in red and/or white blood cells.

**lantibiotics** Polycyclic peptide BACTERIOCINS whose molecules include some uncommon residues – e.g. the sulphur-containing amino acid lanthionine (hence *lantibiotic*) and D-amino acids. Lantibiotics are produced by strains of e.g. *Bacillus* and *Lactococcus*, and are typically active against Gram-positive bacteria; they form pores in the cytoplasmic membrane of a target cell, thereby causing ionic leakage and loss of pmf. Examples include NISIN and SUBTILIN.

The presence of lanthionine (and of e.g. D-amino acids) in these peptides results from post-translational modification [TIBS (1992) 17 481–485].

[Biosynthesis and biological activities of lantibiotics: ARM (1998) 52 41–79.]

[Lantibiotics: structure, biosynthesis and mode of action: FEMS Reviews (2001) 25 285–308.]

**LAO binding protein** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**LAP** See ENDOTOXIN.

**lapinized vaccine** A VACCINE containing live organisms whose virulence for a given host species has been attenuated by SERIAL PASSAGE through rabbits.

**Laredo-type strains** See ENTAMOEBIA (*E. histolytica*).

**large granular lymphocytes** See NK CELLS.

**large iridescent insect viruses** See CHLORIRIDOVIRUS.

**large T antigen** See POLYOMAVIRUS.

**lariat** (lariat RNA) See SPLIT GENE (a) and (c).

**las genes** See QUORUM SENSING.

**Lasallia** A genus of LICHENS (order LECANORALES). The thallus resembles that of UMBILICARIA spp but is pustulate in appearance

(convexities in the upper surface corresponding to hollows in the lower surface); asci contain one or two large spores (those of *Umbilicaria* contain 8 smaller spores). (*L. pustulata*: formerly *U. pustulata*.)

**lasalocid** A MACROTETRALIDE antibiotic which is used as an anti-coccidial agent in poultry, and which has been used as a FEED ADDITIVE for ruminants (its mode of action apparently being similar to that of MONENSIN).

**Lassa fever** A VIRAL HAEMORRHAGIC FEVER caused by the Lassa virus (see ARENAVIRIDAE); it occurs in Africa, especially Nigeria, Liberia and Sierra Leone. Early symptoms resemble those of other VHF; petechiae may be present, and there is marked pharyngitis with white patchy exudate adhering to the soft palate and pharyngeal region. In fatal cases death usually occurs during the second week of infection; mortality rates may be 30–66% among hospital cases, but subclinical infections may occur. The natural reservoir of the virus is the multimammate rat *Mastomys natalensis*. Human infection may occur e.g. by contamination of wounds with urine from infected rats; person-to-person transmission also occurs.

**Lassa virus** See ARENAVIRIDAE and LASSA FEVER.

**latamoxef** *Syn.* MOXALACTAM.

**late blight** (of potato) A POTATO DISEASE caused by *Phytophthora infestans* (see PHYTOPHTHORA). Dark patches appear on the upper surfaces of leaves (and sometimes on stems), and patches of white 'mildew' (sporangium-bearing sporangiophores) develop on corresponding regions on the undersides of leaves. Disease may spread rapidly from plant to plant. Tubers develop dark surface patches and succumb to a dry brown rot – and sometimes to a secondary soft rot. Protectants used against late blight include e.g. MANEB and ZINEB. Late blight was responsible for the Irish potato famine in the 1840s.

[Review: Book ref. 58, pp. 3–17.]

**late genes** See VIRUS.

**latent infection** (1) (*animal virol.*) An asymptomatic infection in which infectious virions are not produced. (See PERSISTENCE.)

(2) (*plant virol.*) Any viral infection in which symptoms do not occur – whether or not virus replication occurs.

**latent period** See ONE-STEP GROWTH EXPERIMENT.

**latent virus** A virus which can establish a LATENT INFECTION (sense 1 or 2).

**lateral body** (*virol.*) See POXVIRIDAE.

**lateral transmission** See HORIZONTAL TRANSMISSION.

**laterosporolysin** See THIOL-ACTIVATED CYTOLYSINS.

**latex** (1) A product of the rubber tree, *Hevea brasiliensis*. Natural latex is a colloidal suspension of polyisoprenoid particles in an aqueous phase containing e.g. carbohydrates and proteins; it is readily attacked by a variety of microorganisms. (See also RUBBER SPOILAGE.)

(2) See LATEX PARTICLE TEST.

(3) See LACTARIUS.

**latex particle test** (latex test) (*serol.*) A PASSIVE AGGLUTINATION test in which antibody or soluble antigen is adsorbed to particles of a synthetic latex: e.g. a suspension of particles of polystyrene (commonly ca. 0.81 µm diam.), a substance to which proteins tend to adsorb.

For example, to detect antibodies to a given antigen, antigen-coated particles of latex are exposed to the patient's serum; the presence of homologous antibodies in the serum is indicated by agglutination of the latex particles (which are bound together by antigen–antibody bridges). Uncoated particles of latex, and known negative serum, are used for controls.

Latex particle tests have a wide range of uses, being able not only to detect serum antibodies and soluble antigens but also to

distinguish between different strains of a given pathogen [e.g. rapid detection of *mecA*-positive and *mecA*-negative strains of coagulase-negative staphylococci by an anti-PBP 2a slide latex agglutination test: JCM (2000) 38 2051–2054.]

When specific *antibodies* are bound to the latex particles, the test is often described as a *reverse* (or *reversed*) *passive latex agglutination test*. Thus, e.g. staphylococcal enterotoxins can be tested for (in e.g. food samples) by using a reverse passive latex agglutination test in which the particles are coated with antibodies to the various enterotoxins; agglutination of such particles may occur in the presence of very low concentrations of enterotoxins in the samples.

[Reversed passive latex agglutination test for detecting 'free' verocytotoxin produced by strains of *Escherichia coli* O157 (EHEC): LAM (2001) 32 370–374.]

**Latin binomial** See BINOMIAL.

**Latino virus** See ARENAVIRIDAE.

**lattice hypothesis** (*serol.*) A hypothesis advanced by Marrack in 1934 to account for the observation that antibody and antigen can combine in varying proportions; it postulates that each molecule of antibody has a valency of at least two, and that antigens are multivalent. Thus, when antigens and antibodies combine in suitable proportions (see OPTIMAL PROPORTIONS) large insoluble aggregates (lattices) are formed; under ANTIGEN EXCESS conditions small, soluble complexes are formed. The precipitability of a complex may depend e.g. on its hydrophobicity as well as on its size.

**Laurell's rocket immunoelectrophoresis** *Syn.* ROCKET IMMUNOELECTROPHORESIS.

**lauryl tryptose lactose broth** A medium, containing sodium lauryl sulphate (sodium dodecyl sulphate), used e.g. in the EIJKMAN TEST.

**Lauth's violet** *Syn.* THIONIN.

**LAV** (1) See HIV. (2) LEAFHOPPER A VIRUS.

**laver** (laver bread) Edible algae, particularly certain species of *Porphyra* (known as 'zicai' in China, 'nori' in Japan, and 'purple laver' in some other countries). (See also ULVA.)

**Laverania** A subgenus of PLASMODIUM.

**law of recapitulation** See ONTOGENY.

**lawn plate** A PLATE whose entire surface bears confluent growth of microorganisms of one species or strain; it may be prepared e.g. by incubating a FLOOD PLATE.

**Lb** LEGHAEMOGLOBIN.

**LB broth** See LURIA–BERTANI BROTH.

**LBP** See CD14.

**Lc protein** A PORIN of *Escherichia coli*.

**LCM virus** (lymphocytic choriomeningitis virus, LCMV) The type species of the genus *Arenavirus* (see ARENAVIRIDAE). The main natural host is the house mouse (*Mus musculus*), but the syrian or golden hamster (*Mesocricetus auratus*) can also be an epidemiologically important host. LCMV virus can replicate in a wide range of cultured cells in which infection is usually persistent and without CPE. Embryo or neonatal (immunologically immature) mice inoculated with LCMV survive the infection to become persistent carriers, shedding virus in their urine, faeces, saliva etc throughout their lives (see PERSISTENCE). However, adult mice inoculated intracerebrally with LCMV rapidly succumb to the infection by a mechanism which seems to involve interferon: a 'docile' strain of LCMV which does not induce interferon does not cause a lethal infection [JGV (1983) 64 1827–1830]. (See also GLOMERULONEPHRITIS.) In man, LCMV is a rare cause of disease – which may be an influenza-like illness, an acute, benign aseptic MENINGITIS, or a severe meningoencephalomyelitis.

**LCR** Ligase chain reaction: a PROBE-based method for copying ('amplifying') a given sequence of nucleotides in DNA; like PCR (but unlike NASBA or SDA), LCR involves thermal cycling. Essentially, sample DNA is heat-denatured in order to expose the target sequence (*amplicon*) in one strand – and its complementary sequence in the other strand; on lowering the temperature, two oligonucleotide probes bind (*anneal*) in *adjacent* positions to cover the entire amplicon – while another two probes bind to the amplicon's complementary sequence. If a given pair of probes binds correctly to the target, the 5' terminus of one probe will abut the 3' terminus of the other; when this occurs, a covalent link can be made between the 5' and 3' termini by a heat-stable DNA LIGASE. A pair of ligated probes will thus form a copy of the target sequence and can be used as a target (by other probes) in the subsequent rounds of amplification. Ligation and amplification of the sequence-specific probes argues for the presence of the given target sequence in the sample DNA.

Note that, for ligation to occur, both juxtaposed bases in a given pair of probes must base-pair correctly with the corresponding nucleotides in the template strand (even if mismatches occur elsewhere in the probe–target duplex); moreover, the 5' end of one probe must be phosphorylated in order for ligation to occur.

Commercial LCR-based assays (LCX<sup>®</sup> assays; Abbott Diagnostics) are used to detect specific sequences of DNA from certain pathogens in clinical specimens; such assays include tests for *Chlamydia trachomatis*, *Neisseria gonorrhoeae* and *Mycobacterium tuberculosis*. These assays differ from the (basic) format described above. Thus, the two probes in a bound pair are separated by a gap of one to several nucleotides. Consequently, part of each cycle includes a period of extension, from the 3' end of one probe, by a DNA polymerase present in the reaction mixture; closure of the gap is followed by ligation. Cycling thus involves three phases of temperature; in the Abbott LCX assay for *Chlamydia trachomatis*, these phases are: (i) 93°C for denaturing the dsDNA sample, (ii) 59°C for annealing, and (iii) 62°C for extension/ligation. Corresponding values in the LCX assay for *M. tuberculosis* are (i) 94°C, (ii) 64°C and (iii) 69°C.

An amplification of at least 10 million-fold is commonly achieved in an assay of 30–40 cycles.

Products of the LCX<sup>®</sup> assays are detected by a system called *microparticle enzyme immunoassay* (MEIA). Each of a pair of probes carries – at its *non-ligating* end – a molecule (*hapten*) that is able to bind a specific antibody; the two probes carry different haptens – i.e. they bind different types of antibody. Hence, after cycling, each ligated probe pair consists of a copy of the target sequence flanked by two different haptens (haptens 1 and 2). Microparticles (<1 µm diam.), coated with hapten 1-specific antibodies, are added to the system; the microparticles bind hapten 1 on both ligated and non-ligated probes. The microparticles are then immobilized on a matrix. The *non-ligated* probes bearing hapten 2 are removed by washing. A conjugate, consisting of alkaline phosphatase covalently linked to a hapten 2-specific antibody, is then added to the bound microparticles; the conjugate binds to hapten 2 (via the antibody), thus labelling ligated probe pairs (on the microparticle) with alkaline phosphatase. A substrate for the enzyme, 4-methylumbelliferyl phosphate, is then added and is cleaved to the fluorescent product 4-methylumbelliferone; under ultraviolet radiation, the rate at which fluorescence is generated is proportional to the number of (enzyme-labelled) ligated probe pairs. Readings above a certain cut-off value indicate a positive result, i.e. evidence of a given sequence in the sample; readings

in an 'equivocal zone' (defined in terms of the ratio: sample reading/cut-off value) indicate repeat testing.

Examples of assays with LCx<sup>®</sup> systems include studies on *Chlamydia trachomatis* [JCM (1998) 36 94–99], *Neisseria gonorrhoeae* [JCM (1997) 35 239–242], and *Mycobacterium tuberculosis* [JCM (2002) 40 2305–2307].

Improved reproducibility with LCx<sup>®</sup> assays for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* has been reported following modification of the recommended equivocal zones: from 0.8–0.99 to 0.8–1.5 for *C. trachomatis*, and from 0.8–1.2 to 0.8–2.0 for *N. gonorrhoeae* [JCM (2000) 38 2416–2418].

[LCR in clinical microbiology: Book ref. 221, pp 152–167.]

**LD<sub>50</sub>** Lethal dose (50%): that dose of a given lethal agent which, when given to each of a number of test animals, kills 50% of those animals under given conditions.

**LDC** Lysine decarboxylase: see DECARBOXYLASE TESTS.

**LE markers** See TRANSFORMATION (1).

**leaching** (of ores) Bacteria can promote the leaching (solubilization) of certain metals from their ores. Bacterial leaching (*biomining*) is carried out e.g. for the commercial recovery of copper from low-grade ores containing chalcopyrite (CuFeS<sub>2</sub>) and for the recovery of gold from recalcitrant arsenopyrite ores.

In one process for recovering copper, a liquid containing sulphuric acid and chemolithotrophic bacteria is continually recycled through a mound of crushed ore; in *dump leaching* the mound consists of rough, ungraded ores and waste, while in *heap leaching* it consists of more concentrated, finer ore. Ferrous ions, which leach spontaneously, are oxidized by the bacteria to ferric ions – resulting in ongoing solubilization of iron; the solubilization of iron releases sulphur, which is oxidized to sulphate. These processes may be carried out by e.g. '*Leptospirillum ferrooxidans*' (an iron oxidizer), *Thiobacillus ferrooxidans* (an iron and sulphur oxidizer) and *Thiobacillus thiooxidans* (a sulphur oxidizer). The bacteria obtain nutrients from the percolating liquor and from the ore itself – for example, carbon dioxide may be derived from acidification of carbonates within the ore. Copper in the leachate (up to 5 grams per litre) is periodically removed (e.g. by electrophoresis); the liquor is recycled for months, being supplemented with water to replace losses due to evaporation. Heat generated by bacterial metabolism maintains a temperature of about 40–50°C in the leachate, and the convective upflow of air helps to provide an aerobic environment.

The development of an efficient leaching flora may arise via a succession of species, each being particularly suited e.g. to a given pH. Very low pH is advantageous for leaching copper ores because it inhibits the precipitation of ferric ions; leaching under these conditions has been achieved with strains identified as *Thiobacillus thiooxidans* and '*Leptospirillum ferrooxidans*' – the organisms being identified by characterization of their rRNA genes in DNA extracted from the leachate [AEM (1997) 63 332–334].

Studies on the sulphur chemistry of bacterial leaching suggest that the leaching of pyrite may involve a cyclical degradative process in which thiosulphate and polythionates are among the intermediate products; ferric ions, produced by the ongoing bacterial oxidation of ferrous ions, may have an active role in the oxidation of both pyrite and thiosulphate [AEM (1996) 62 3424–3431].

Biorecovery is also used in e.g. South Africa, Australia and Brazil as a preliminary process in the extraction of gold from certain recalcitrant (arsenopyrite) ores. In these ores, the gold is embedded in a matrix of arsenopyrite so that it cannot

be extracted by cyanidation in the usual way. The ore is crushed and subjected to bacterial action in highly aerated bio-oxidation tanks; arsenopyrite (FeAsS) is solubilized by oxidation (to FeAsO<sub>4</sub> and sulphuric acid), thus exposing the gold for cyanidation. After cyanidation, gold is separated from the gold–cyanide complex e.g. by adsorption to charcoal, and the spent, cyanide-containing liquor is detoxified by bacteria; detoxification involves the oxidation of cyanide to carbon dioxide and urea, and the oxidation of urea to nitrate.

In addition to their use in leaching, bacteria have also been used as 'bioadsorbents' for the recovery of low levels of uranium in certain liquid wastes.

(See also THIOBACILLUS.)

[Microbiology of metal leaching (symposium report): FEMS Reviews (1993) 11 1–267. Mining with microbes (review): Biotechnology (1995) 13 773–778. Predominant types of bacteria used in commercial bioleaching processes: Microbiology (1999) 145 5–13.]

**leader** (leader sequence) A region of an RNA molecule (e.g. certain mRNA molecules, pre-rRNA) between the 5' (promoter) end and the sequence corresponding to the first (or only) structural gene. The leader sequence is commonly non-coding, but may encode a small regulatory peptide (a *leader peptide*): see OPERON (attenuator control) and TNA OPERON.

**leader peptidase** See SIGNAL HYPOTHESIS.

**leader peptide** (1) See LEADER. (2) See SIGNAL HYPOTHESIS.

**leading strand** See DNA REPLICATION.

**leaf blotch** (scald) A CEREAL DISEASE, caused by *Rhynchosporium secalis*, which can affect e.g. barley and rye; large, pale brown lesions with dark brown or purple margins appear mainly on leaves, and crop losses may be severe. (See also FLUTRIAFOL and PROPICONAZOLE.)

**leaf curl** (of peach) See TAPHRINA.

**leaf nodules** See PHYLLLOBACTERIUM.

**leafhopper A virus** (LAV) An unclassified reovirus-like virus which was isolated from the leafhopper *Cicadulina bimaiculata* during the search for the causal agent of MAIZE WALLABY EAR DISEASE; attempts to infect maize plants with LAV have been unsuccessful, and any connection between LAV and MWED has yet to be proved. Although LAV resembles viruses of the genus FIJIVIRUS, it cannot be included in the genus since it is not known to infect any plant species.

**leaky mutation** A MUTATION which results in only partial inactivation of the sequence in which it occurs. (cf. NULL MUTATION.)

**leather spoilage** Leather has a relatively low pH (usually ca. 3–4) and even at high humidities is fairly resistant to bacterial attack; however, at relative humidities of >80% leather is highly susceptible to attack by moulds which may cause significant loss of tensile strength. *Aspergillus* spp are commonly implicated, but other moulds (e.g. species of *Mucor*, *Paecilomyces* and *Rhizopus*) may also be involved. Heavy fungal contamination may raise the pH sufficiently to allow some bacterial growth; e.g. *Bacillus sphaericus* has been isolated from mouldy leather. Preservatives which have been used for treating leather include phenylmercuric salts of fatty acids, *p*-nitrophenol, and β-naphthol. (For the bating of hides by microbial enzymes see PROTEASES.)

**leben** A type of concentrated YOGHURT consumed in e.g. Egypt. Milk is fermented with organisms which include *Lactococcus lactis*, *Streptococcus thermophilus*, *Lactobacillus bulgaricus* and certain lactose-fermenting yeasts. The curd is concentrated by draining off the whey and may then be dried. (See also DAIRY PRODUCTS.)

**LECAM-1** See SELECTINS.

**Lecanactis** See OPEGRAPHALES.

**Lecanidiales** An order of fungi of the ASCOMYCOTINA; members include crustose LICHENS (photobiont commonly green), and saprotrophic and lichenicolous fungi. Ascocarp: APOTHECIOID, sometimes lirelliform. Asci: bitunicate. Genera: e.g. RHIZOCARPON.

**Lecanora** A large genus of LICHENS (order LECANORALES); photobiont: a green alga. Thallus: crustose; apothecia: lecanorine, sessile; spores: aseptate. The genus includes several species which are highly tolerant of air pollution. *L. conizaeoides* is common (on trees, non-basic rocks, brick etc) in industrial and densely populated regions of Europe, but is rare elsewhere; it forms a grey-green, granular-sorediate, sometimes areolate thallus, and apothecia with yellowish- or greenish-brown discs are usually present. *L. dispersa* may occur on concrete, asbestos etc; the thallus may be superficial and whitish, or may grow endolithically, appearing only as a dark stain on rocks, walls etc. The apothecia have yellowish- to dark-brown discs which are often pruinose when young. *L. muralis* has become increasingly common on pavements, walls etc in towns; it forms a more or less circular thallus with radiating lobes and apothecia crowded in the centre.

**lecanoralean ascus** See BITUNICATE ASCUS.

**Lecanorales** An order of fungi of the ASCOMYCOTINA; members include many LICHENS (photobiont usually green), and saprotrophic and lichenicolous fungi. Ascocarp: APOTHECIOID, typically discoid (sometimes stipitate), but podetia (see PODETIUM) are formed by *Cladonia* spp; paraphyses are present. Asci: bitunicate (see BITUNICATE ASCUS), commonly elongated with a thickened apex. Genera: e.g. ACAROSPORA, ALECTORIA, ANAPTYCHIA, BAEOMYCES, BRYORIA, BUELLIA, CANDELARIELLA, CETRARIA, CLADONIA, COLLEMA, DIPLOICIA, EVERNIA, HYPOGYMNIA, LASALIA, LECANORA, LECIDEA, LEMPHOLEMMA, LEPTOGIUM, LICHINA, PANNARIA, PARMELIA, PHYSCIA, PILOPHORUS, RAMALINA, STEREOCAULON, UMBILICARIA, USNEA.

**lecanorine apothecium (lichenol.)** An APOTHECIUM which has a THALLINE MARGIN; such apothecia occur e.g. in lichens of the genera *Lecanora* and *Xanthoria*. (cf. LECIDEINE APOTHECIUM.)

**Lecidea** A genus of crustose LICHENS (order LECANORALES); photobiont: a green alga (e.g. *Trebouxia*). Apothecia: lecideine. Many species of the (originally very large) genus have been transferred to other genera, including e.g. *Fuscidea*, *Huilia*, *Hypocenomyce*, *Lecidella*, *Psilolechia*, *Psora*, *Trapelia*. Thus, e.g., *L. limitata* (thallus: crustose, greenish- to yellowish-grey, sometimes with a dark hypothallus; apothecia: grey or black) is now *Lecidella elaeochroma*; *L. lucida* (thallus: leprose, yellow to yellow-green; apothecia: yellow to pale-brown) is now *Psilolechia lucida*; *L. macrocarpa* (thallus: crustose, grey, with a black hypothallus; apothecia: black) is now *Huilia macrocarpa*; *L. scalaris* (thallus: squamulose, with imbricated squamules) is now *Hypocenomyce scalaris*.

**lecideine apothecium (lichenol.)** An APOTHECIUM which lacks a THALLINE MARGIN, i.e., it has only a PROPER MARGIN. Such apothecia occur e.g. in lichens of the genera *Buellia*, *Lecidea* and *Rhizocarpon*. (cf. LECANORINE APOTHECIUM.)

**Lecidella** See LECIDEA.

**lecithin** Phosphatidylcholine, a type of phospholipid found e.g. in egg-yolk and in the CYTOPLASMIC MEMBRANES of mammalian cells and of some Gram-negative bacteria. Lecithins are derivatives of *phosphatidic acid* (itself a derivative of glycerol 3-phosphate in which the hydroxyl groups at positions 1 and 2 are each esterified with a long-chain fatty acid); in a lecithin, the

phosphate group of phosphatidic acid is esterified with choline:  $(\text{CH}_3)_3\text{N}^+(\text{CH}_2)_2\text{OH}$ .

**lecithinase** A PHOSPHOLIPASE (q.v.) which cleaves LECITHIN. Extracellular lecithinases are formed e.g. by *Bacillus cereus*, *Clostridium bifermentans*, *C. novyi* ( $\gamma$ -toxin), *C. perfringens* ( $\alpha$ -toxin), and strains of *Staphylococcus aureus*; the lecithinase of *C. perfringens* apparently requires  $\text{Zn}^{2+}$  for activity. Those organisms (e.g. *C. novyi*, *C. perfringens*) which form lecithinases that are C-type phospholipases produce zones of opacity around colonies when grown on e.g. EGG-YOLK AGAR due to the formation of insoluble, phosphate-free diacylglycerides ('diglycerides'). (See also MILK SPOILAGE.)

**lecithovitellin agar** *Syn.* EGG-YOLK AGAR.

**lectin pathway** See COMPLEMENT FIXATION (c).

**lectins** Various non-enzymic proteins (usually glycoproteins) which are not products of the immune system (thus excluding antibodies) and which can each bind to specific carbohydrate group(s) and can agglutinate (or precipitate) cells or other entities having these particular (and accessible) group(s). The term 'lectin' originally referred to certain plant products which bind to and agglutinate particular types of erythrocyte (cf. PHYTOHAEMAGGLUTININ sense 2); it is now used for materials of plant, animal or microbial origin which have specific carbohydrate-binding ability – though not necessarily in relation to erythrocytes. Lectins have been obtained e.g. from plants [Book ref. 37, pp. 537–547; ARPphys. (1985) 36 209–234], lichens [Lichenol. (1983) 15 303–305], the snail (*Helix pomatia*), the horseshoe crab (*Limulus polyphemus*), slime moulds (e.g. discoidins from *Dictyostelium discoideum*, pallidins from *Polysphondylium pallidum*), fungi and bacteria (e.g. mannose-sensitive FIMBRIAE).

Lectins have been used e.g. for haemagglutination in blood grouping studies. Many lectins behave as MITOGENS and are used e.g. for lymphocyte activation in immunological studies. In nature, lectins may be involved in plant–microbe symbioses [Book ref. 38, pp. 658–677]; they may play a role in the pathogenesis of some plant diseases [ARPpath. (1983) 21 300–302] and possibly in certain animal diseases (e.g. lectins in raw beans may promote disease in pigs by enhancing attachment of ETEC to the ileal epithelium [CRM (1981) 8 303–338 (324)]). (See also GIARDIASIS.) [Interaction of bacteria and fungi with lectins: ARM (1981) 35 85–112.] (See also CONCAVALIN A; LIMULIN; PHYTOHAEMAGGLUTININ; POKEWEE MITOGEN; TRIFOLIIN A; WHEAT GERM AGGLUTININ.)

**lectotype** A specimen, chosen to serve as NOMENCLATURE TYPE, derived from the original material studied by an author who did not specify a HOLOTYPE; it has nomenclatural precedence over a NEOTYPE.

**LEE** See PATHOGENICITY ISLAND.

**leek yellow stripe virus** See POTYVIRUSES.

**left-handed DNA** See e.g. Z-DNA.

**left splice site** See SPLIT GENE.

**leghaemoglobin (leghemoglobin)** A red haem-containing pigment present (in multiple forms) in the host cell cytoplasm in the ROOT NODULES of leguminous plants. The protein and haem moieties are specified by plant genes and bacteroid genes, respectively. Leghaemoglobins are structurally and functionally similar to animal myoglobins and haemoglobins but have a much higher affinity for oxygen; they release bound oxygen only at low levels of oxygen and thus permit aerobic respiration in the bacteroids while protecting NITROGENASE from oxygen inactivation. [Book ref. 55, pp. 73–79; ARPphys. (1984) 35 443–478.]

**Legionella** See LEGIONELLACEAE.

**Legionellaceae** A family of Gram-negative, asporogenous bacteria. Cells: rod-shaped or filamentous, 2.0 to >20.0 ×

## legionellosis

0.3–0.9 µm; motile, with one, two or more polar or lateral flagella. Cellular fatty acids are predominantly branched. Aerobic; oxidase –ve or weakly +ve. Chemoorganotrophic, using amino acids (non-fermentatively) as carbon and energy sources; carbohydrates are generally not metabolized. Growth requires L-cysteine and iron (Fe<sup>3+</sup>) salts, and can occur e.g. on blood agar supplemented with L-cysteine and iron, on Mueller–Hinton agar supplemented with haemoglobin and IsoVital X, or on buffered charcoal–yeast extract agar (BCYE), but not e.g. on unsupplemented blood agar or nutrient agar. Optimum growth temperature: 35–37°C. Gelatinase +ve; catalase +ve; urease –ve; NO<sub>3</sub><sup>–</sup> not reduced. Several species exhibit a bluish-white autofluorescence under WOOD'S LAMP, and most species produce a diffusible brown pigment on tyrosine-containing media. Species occur in various aquatic habitats: e.g. surface waters, moist soils, thermally polluted streams, domestic water systems, etc; most or all species can be pathogenic for man (see LEGIONELLOSIS). GC%: ca. 39–43; type genus: *Legionella*.

According to some authors [Book ref. 22, pp. 279–288], *Legionella* (type species *L. pneumophila*) is the sole genus of the Legionellaceae, but other authors have divided the family into three genera: *Fluoribacter*, *Legionella* and *Tatlockia* [IJSB (1980) 30 609–614; IJSB (1981) 31 111–115]. Species include e.g. *L. bozemanii* (*Fluoribacter bozemanii*; 'WIGA bacterium'), *L. dumoffii* (*F. dumoffii*; 'Tex-KL bacterium'), *L. feeleii* [AIM (1984) 100 333–338], *L. gormanii* (*F. gormanii*), *L. jordanis*, *L. longbeachae*, *L. micdadei* (*Tatlockia micdadei*; 'TATLOCK agent'; 'guinea-pig agent'; Pittsburg pneumonia agent), *L. oakridgensis*, *L. pneumophila*, *L. sainthelensi* (AEM (1984) 47 369–373), *L. wadsworthii*.

[Taxonomy and typing of legionellae: RMM (1994) 5 79–90.]

Sequencing of the *mip* gene has been reported to provide a basis for unambiguous identification of 39 species of the genus *Legionella* [Mol. Microbiol. (1997) 25 1149–1158; JCM (1998) 36 1560–1567.]

**legionellosis** Any (human) disease caused by a species of *Legionella* (see LEGIONELLACEAE). Most species appear to be capable of causing PNEUMONIA in man. *Legionnaires' disease* is a pneumonia caused by *L. pneumophila*. Infection is believed to occur by inhalation of contaminated aerosols (common sources of infection are air-conditioning cooling towers, showers, nebulizers, etc). [Survival of *L. pneumophila* in a model hot water distribution system: JGM (1984) 130 1751–1756; distribution and persistence of *Legionella* in water systems: MS (1985) 2 40–43.] Incubation period: 2–10 days. Symptoms: malaise, myalgia, headache, followed by fever, chills, and a consolidating pneumonia which primarily involves the alveoli and terminal bronchioles; an intra-alveolar exudate is characteristic of the disease. Other common symptoms include chest and abdominal pains, vomiting, diarrhoea, and mental confusion. Mortality rates may be high, particularly in compromised individuals. [Review: Chest (1984) 85 114–120.] An important feature of pathogenesis is the ability of *L. pneumophila* to invade alveolar macrophages, to inhibit phagosome–lysosome fusion, and to multiply within these cells; such activity may be facilitated by expression of the pathogen's *icm* (= *dot*) genes (see PHAGOCYTOSIS (a)) because mutations in these genes can give rise to modified virulence [TIM (1998) 6 253–255]. Moreover, the results of in vitro studies have suggested that the pathogen's zinc metalloprotease (a 38 kDa secreted protein; = *tissue-destructive protease*) may promote pathogenesis by inhibiting both the oxidative burst and chemotaxis in phagocytic cells [JMM (2001) 50 517–525].

*Pontiac fever* is an acute, febrile, non-pneumonic, self-limiting illness caused by *L. pneumophila* (and by *L. feeleii* [AIM (1984) 100 333–338]). Incubation period: ca. 36 hours. Symptoms: fever, chills, headache, myalgia, arthralgia, diarrhoea, and sometimes neurological symptoms. *Pittsburg pneumonia* is a pneumonia caused by *L. micdadei*.

*Lab. diagnosis*: direct or indirect immunofluorescence tests on e.g. sputum samples; microscopic examination of specimens stained with e.g. DIETERLE SILVER STAIN; analysis of the fatty acids of the isolated organism by GLC.

[Treatment: JAC (1999) 43 747–752.]

**Legionnaires' disease** See LEGIONELLOSIS.

**legume bloat** See BLOAT.

**legume yellows virus** See LUTEOVIRUSES.

**leguminous root nodules** See ROOT NODULES.

**Leidenfrost phenomenon** The formation of a heat-insulating layer of gaseous nitrogen around a specimen when it is plunged into liquid nitrogen. (See also FREEZING.)

**Leifson's flagella stain** (for bacterial flagella) Mix equal volumes of 1.5% w/v aqueous NaCl and 3% w/v aqueous tannic acid; to this mixture add half its volume of a solution of pararosanilin acetate (0.9% w/v) and pararosanilin hydrochloride (0.3% w/v) in 95% ethanol. Prepare a medium-free, slightly cloudy suspension of bacteria in distilled water. Using a wax pencil, draw a ring on a chemically clean glass slide enclosing ca. 2 cm<sup>2</sup>. Spread one loopful of the bacterial suspension within the ringed area; dry at room temperature. Do not fix. Add 1 ml stain; allow to act for ca. 10 min and rinse off gently under the tap. Flagella appear to be coated with a colloidal tannic acid–dye complex, rendering them visible by light microscopy.

**Leighton tube** A test-tube in which part of the wall (near the closed end) forms a flat, rectangular region which can accommodate a cover-glass on which a cell monolayer can be formed.

**Leiotrocha** See PERITRICHIA.

**Leishman–Donovan bodies** Amastigote forms of *Leishmania* in the vertebrate host.

**Leishmania** A genus of parasitic protozoa (family TRYPANOSOMATIDAE) which resemble TRYPANOSOMA species in their ultrastructure. The organisms are the causal agents of LEISHMANIASIS in mammals, and are transmitted by sandflies of several genera (e.g. *Lutzomyia*, *Phlebotomus*, *Sergentomyia*); species of *Leishmania* which are normally dermatotropic sometimes give rise to visceral leishmaniasis, while typically visceralizing strains sometimes cause cutaneous infections. Most leishmaniasis are zoonotic.

In the vertebrate host *Leishmania* grows in the intracellular, amastigote form (ca. 2–10 µm in diam.) – primarily in mononuclear phagocytes (e.g. macrophages). (*Leishmania* species can grow within phagolysosomes: see PHAGOCYTOSIS; amastigote forms of *L. donovani* have been found to contain CATALASE and glutathione peroxidase in amounts greater than those found in the promastigote stage. The ability of *Leishmania* spp to undergo ANTIGENIC VARIATION may contribute to their pathogenicity.) In the sandfly the pathogen occurs in the paramastigote and promastigote forms, the latter being the form infective for man. In cell-free media (e.g. in NNN MEDIUM), and in tissue culture, the organisms grow in the promastigote form.

*Leishmania* spp include *L. aethiopica*, *L. braziliensis*, *L. donovani*, *L. major*, *L. mexicana* and *L. tropica*. Some species are divided into subspecies; e.g., *L. braziliensis* includes e.g. *L. braziliensis braziliensis* (= *L. b. braziliensis*), *L. b. guyanensis* and *L. b. peruviana*. Organisms which cause visceral leishmaniasis have been given separate names in particular geographical

regions: e.g. *L. infantum* (Mediterranean), *L. chagasi* (S. America), and *L. archibaldi* (Sudan); some authors regard all of these as one species, *L. donovani* [Book ref. 72, p. 215].

*Leishmania* spp have been divided into groups ('sections') on the basis of their location within the arthropod vector: see HYPOPYLARIA, PERIPYLARIA, SUPRAPYLARIA; at least some of the reptile-infecting species in the Hypopylaria and Peripylaria appear to be trypanosomes ('*L. tarentolae*' has been renamed *Trypanosoma platydyctyli*).

**leishmanial form** Obsolete *Syn.* AMASTIGOTE.

**leishmaniasis** Any disease caused by a species of LEISHMANIA; see CUTANEOUS LEISHMANIASIS, MUCOCUTANEOUS LEISHMANIASIS, POST-KALA-AZAR DERMAL LEISHMANIASIS and VISCERAL LEISHMANIASIS. [Book ref. 72, pp. 183–249.]

**leishmaniasis recidivans** An intractable form of CUTANEOUS LEISHMANIASIS which may develop after an apparent cure of a previous episode of cutaneous leishmaniasis; lesions, typically non-ulcerating, form around the rim of scar tissue.

**leishmanin test** *Syn.* MONTENEGRO TEST.

**Leishman's stain** See ROMANOWSKY STAINS.

**Leloir pathway** See LACTOSE and Appendix III(a).

**Lelystad virus** See BLUE-EARED PIG DISEASE.

**Lemanea** See RHODOPHYTA.

**Leminorella** A new genus of non-motile Gram-negative bacteria of the ENTEROBACTERIACEAE; two species have been described: *L. grimontii* (the proposed type species) and *L. richardii* [JCM (1985) 21 234–239]. Reactions: e.g. VP –ve; indole –ve; H<sub>2</sub>S +ve; LDC –ve; ODC –ve; ADH –ve; no growth with KCN. Species are relatively inactive biochemically; acid is produced from L-arabinose and D-xylose, but not from a wide range of other sugars (including lactose). Strains have been isolated from human faeces and urine.

**Lempholemma** A genus of gelatinous LICHENS (order LECANORALES); photobiont: *Nostoc*. Thallus: homoiomerous, lacking a cortex. HORMOCYSTS are formed in specialized swollen regions of the thallus (termed *hormocystangia*), and hyphae of the mycobiont are – or may be – associated with the gelatinous sheath of the hormocyst.

**lens-shaped** A phrase sometimes used to describe the shape of a structure or colony etc; as a descriptive phrase it is of doubtful value since a lens may be double-convex, plano-convex, meniscus etc. (cf. LENTICULAR.)

**lentic** Pertaining to aquatic habitats with standing (still) water (e.g. ponds, swamps). (cf. LOTIC.)

**lenticular** (lentiform) Shaped like a lentil or a double-convex lens.

**lentiform** *Syn.* LENTICULAR.

**Lentinula** A genus of fungi of the family Tricholomataceae (order AGARICALES). *L. edodes* (formerly *Lentinus edodes*) forms edible fruiting bodies: see SHII-TAKE. [Chemically defined medium for the fruiting of *L. edodes*: Mycol. (1983) 75 905–908; note on the reclassification of *Lentinus edodes* to *Lentinula edodes*: MS (1986) 3 171; effect of light and aeration on fruiting of *L. edodes*: TBMS (1987) 88 9–20.] (See also MYCOVIRUS.)

**Lentinus** A genus of lignicolous fungi of the APHYLLOPHORALES (family Polyporaceae) which form tough but pliant basidiocarps in which the hymenium is borne on lamellae (see LAMELLA). *L. lepideus* forms a mushroom-shaped basidiocarp in which the fawn-coloured pileus bears dark scales and is supported by a central or eccentric stipe; the lamellae are whitish and decurrent, and the basidiospores are ellipsoidal, hyaline, and ca. 10 × 5 μm. *L. lepideus* causes TIMBER SPOILAGE (see also

STAG'S HORN FUNGUS); it can tolerate quite high concentrations of CREOSOTE. (For *L. edodes* see LENTINULA.)

**Lentivirinae** A subfamily of viruses of the RETROVIRIDAE which includes HIV and the FELINE IMMUNODEFICIENCY VIRUS; other viruses which have been classified in this subfamily (on the basis of e.g. nucleotide sequences) include a number of viruses isolated from diseased sheep and goats – e.g. CAPRINE ARTHRITIS-ENCEPHALITIS VIRUS, VISNA VIRUS and ZWOEGERZIEKTE VIRUS – and the causal agent of SWAMP FEVER (equine infectious anaemia virus).

At least some lentiviruses (including HIV and visna virus) can be cultured; the high rate of transcription of the visna virus in infected cells has been attributed to the presence of both *cis*-acting enhancer sequences and *trans*-acting transcriptional activating factors [Science (1985) 229 482–485].

As well as replicating within (and killing) host cells, at least some lentiviruses (HIV and feline immunodeficiency virus) have been associated with instances of neoplastic disease (e.g. lymphomas); however, in these cases the mechanism of pathogenesis is unclear, and it may be that lentivirus infection permits neoplastic development by (e.g.) undermining immune surveillance.

**Lenzites** See APHYLLOPHORALES (Polyporaceae).

**LEP** Low egg passage: refers to the number of times that a given strain of virus has undergone SERIAL PASSAGE in eggs. (See e.g. FLURY VIRUS; cf. HEP.)

**Lepiota** A genus of fungi (AGARICALES, Agaricaceae) which typically form colourless spores. *L. procera* (the edible 'parasol mushroom') forms a flattened, umbonate, brownish pileus whose upper surface bears loose, darker brown scales. (See also FUNGUS GARDENS.)

**Lepista** A genus of fungi (AGARICALES, Tricholomataceae) which form pink basidiospores. Some species are edible: see BLEWIT.

**leporid herpesvirus 1** See GAMMAHERPESVIRINAE.

**Leporipoxvirus** (myxoma subgroup) A genus of viruses of the CHORDOPOXVIRINAE which infect leporids (hares and rabbits) and squirrels. The viruses commonly cause tumours (fibromas, myxomas) in their hosts, and are commonly transmitted (mechanically) by arthropod vectors. Haemagglutinin is not formed; infectivity of the virion is destroyed e.g. by ether. Type species: myxoma virus (see MYXOMATOSIS); other members: hare fibroma virus, rabbit (Shope) fibroma virus, and squirrel fibroma virus. (See also NON-GENETIC REACTIVATION.)

**lepra cells** See LEPROSY.

**lepra reaction** See LEPROSY.

**Leparia** A genus of LICHENS (of the AGONOMYCETALES) in which the (leprose) thallus forms a soft, powdery crust consisting of loosely associated fungal hyphae and green algal cells; fruiting bodies are unknown. In e.g. *L. incana* the thallus is thick, whitish to greenish grey, and parts may consist only of the (white) mycobiont; *L. incana* is fairly tolerant of air pollution and occurs e.g. on walls, bark etc in damp situations.

**leproma** See LEPROSY.

**lepromin** A preparation obtained by grinding, autoclaving and filtering lepromatous tissue (see LEPROSY); it thus contains heat-stable fractions and includes human antigens unrelated to leprosy.

**lepromin test** A SKIN TEST involving the intra-dermal administration of LEPRONIN. There are three types of reaction: an immediate (*Medina*) reaction; the *Fernandez reaction*, an inflammatory response 24–48 hours after the injection; and the *Mitsuda reaction* which occurs after ca. 3–4 weeks.

In a positive Mitsuda reaction a hard granulomatous nodule occurs at the site of injection. Since normal adults can give a

## leprose

positive Mitsuda reaction it is not diagnostic for leprosy, but a negative Mitsuda reaction is considered to indicate susceptibility to leprosy. The lepromin test can help to classify leprosy: the Mitsuda reaction is negative in lepromatous cases, positive in tuberculoid cases.

**leprose** (*lichenol.*) Refers to a thallus which lacks a cortex and is covered with or consists entirely of soredia (see e.g. LEPRARIA).

**leprosin** Ultrasonicates of tissue-free cells of *Mycobacterium leprae* (derived from lesions).

**leprosy** (Hansen's disease) A chronic human disease, caused by *Mycobacterium leprae*, which is currently found mainly in the tropics and subtropics. It is not readily transmissible. Infection may occur by direct contact, by droplet infection, and/or by contact with fomites. Incubation period: ca. 1–10 years.

*M. leprae* has a predilection for the peripheral nervous system; the CNS is apparently not affected. The disease characteristically involves destruction of nerves – leading to loss of sensitivity (allowing damage to fingers etc. by trauma) as well as weakness/paralysis of muscles.

Leprosy occurs in different forms; the specific type of T cell response to *M. leprae* in a given host correlates with the form of disease.

In *lepromatous* leprosy the CD4<sup>+</sup>:CD8<sup>+</sup> T cell ratio in lesions is ca. 1:2; major T-cell-derived cytokines include interleukins 4 and 10. Bacilli are abundant (e.g. 10<sup>10</sup> bacilli/gram tissue). The multiple skin lesions enlarge/coalesce to form nodules (*lepromas*) – commonly on ear lobes, nose, brows and forehead (but possible elsewhere). Affected skin is typically dry and hairless. Lepromas develop through infiltration of the dermis by *lepra cells* (= *Virchow cells*): histiocytes (macrophages) containing large numbers of bacilli; the infiltrate also contains compact masses of (intra- and extracellular) bacilli associated with cellular debris – ‘globi’ or ‘brown bodies’ – which may reach 200 µm in diameter. Nerve damage is associated with an inflammatory process. Various organs may become involved – e.g. eyes (sometimes leading to blindness), oesophagus, lymphatic system, liver.

In a diffuse form of lepromatous leprosy the infiltrate occurs as a continuous thin sheet in the dermis; an associated necrotizing vasculitis leads to ulceration (the *Lucio phenomenon*).

In *tuberculoid* leprosy the CD4<sup>+</sup>:CD8<sup>+</sup> T cell ratio in lesions is ca. 2:1; major T-cell-derived cytokines include INF-γ and interleukin 2. Skin lesions (epithelioid-cell granulomas infiltrated with lymphocytes) are few, dry, anaesthetic, hypo- or hyperpigmented (or erythematous); Virchow cells are absent, and bacilli are rare/absent. The granulomas, which apparently result from delayed-type hypersensitivity, often damage nerve trunks.

*Borderline* (= *dimorphous*) leprosy is characterized by histopathological features of both lepromatous and tuberculoid forms; the features of one form may predominate. Most cases of leprosy are borderline.

Some patients treated for leprosy may develop one of two types of *reaction state* (acute, immunologically-based episodes). The *lepra reaction* (= Jopling type 1 reaction; reversal reaction) occurs in some borderline cases and may involve e.g. necrosis/ulceration of bacilli-containing tissues and the formation of abscesses in nerve trunks. *Erythema nodosum leprosum* (ENL; Jopling type 2 reaction) occurs in some lepromatous and borderline cases (not in tuberculoid cases); it may result from vasculitis caused by antibody–antigen complexes, and inflammation may affect e.g. eyes, joints, nose and peripheral nerves. ENL may recur repeatedly.

*Laboratory diagnosis.* Biopsies from skin lesions, or e.g. nasal secretions, are stained by acid-fast stains; in lepromatous leprosy the foamy Virchow cells, packed with acid-fast bacilli, are diagnostic. Tuberculoid leprosy may be difficult to differentiate from sarcoidosis or non-leprosy mycobacterial granulomas. (See also LEPROMIN TEST.) The carbohydrate moiety of PGL-I (an *M. leprae* cell-surface glycolipid) may be useful in a serodiagnostic test.

*Chemotherapy.* Currently, antimicrobial treatment involves a combination of drugs: DAPSONE and rifampicin with or without CLOFAZIMINE. Other drugs (e.g. ofloxacin, minocycline) are also effective for treating leprosy. Thalidomide is useful in some cases of ENL.

[Various aspects: TRSTMH (1993) 87 499–517; epidemiology: FEMS (1996) 136 221–230; review: RMM (1998) 9 39–48.]

**lepto-** Prefix meaning fine, narrow, thin.

**Leptogium** A genus of gelatinous LICHENS (order LECANORALES); photobiont: *Nostoc*. The thallus has a cortex, but otherwise resembles that of COLLEMA spp (although generally less gelatinous and often felt-like or tomentose). [Studies on some species: Lichenol. (1983) 15 109–125.]

**Leptolegnia** See SAPROLEGNIALES.

**Leptomitales** An order of aquatic fungi (class OOMYCETES) which are typically saprotrophic – though one species, *Leptomitius lacteus*, may be an opportunist invader of epidermal lesions in fish. The thallus consists of hyphae which bear characteristic constrictions along their lengths, the constrictions often being plugged with CELLULIN GRANULES; in some genera (*Apodachlya*, *Leptomitius*) there is evidence that the cell wall contains both CHITIN and CELLULOSE [Book ref. 174, pp. 62–63]. Other genera include *Aqualinderella* (an anaerobe found in polluted waters) and *Rhipidium*.

**Leptomitius** See LEPTOMITALES.

**leptomonad form** Obsolete *syn.* PROMASTIGOTE.

**Leptomonas** A genus of homoxenous parasitic protozoa (family TRYPANOSOMATIDAE) which typically occur in the gut (sometimes in the haemocoel or in the salivary glands) of insects. The organisms occur in amastigote and promastigote forms, the latter usually being 10–40 µm in length (excluding flagellum), or about twice as long including the flagellum; in some species the cell may be helical, up to 200 µm in length.

**leptomycin B** A product of SECONDARY METABOLISM (in *Streptomyces* spp) which blocks progression through the cell cycle in eukaryotic cells.

**Leptomyxa** See ACARPOMYXEA.

**Leptonema** A genus of bacteria of the order SPIROCHAETALES. [Motility in *L. illini*: see e.g. JB (1996) 178 6539–6545.]

**Leptosphaeria** A genus of fungi (order DOTHEIDIALES) which include saprotrophs and plant parasites (see e.g. BLACKLEG (sense 2), CANE BLIGHT and GLUME BLOTCH); anamorphs occur in e.g. *Camarosporium* and *Septoria*.

**Leptospira** A genus of obligately aerobic bacteria (family LEPTOSPIRACEAE) which occur as free-living organisms in soil and aquatic (freshwater and marine) habitats, and as parasites or pathogens in man and other animals (see LEPTOSPIROSIS). The cells are motile, helical (≥18 coils/cell), 0.1 µm in diameter and from 6 to over 12 µm in length; a single periplasmic flagellum arises at each end of the cell. In liquid media, one or both ends of the cell are typically bent or hooked. Growth occurs on e.g. serum-containing media; optimum growth temperature: 28–30°C. Metabolism is respiratory (oxidative); fatty acids are metabolized by β-oxidation to acetate and CO<sub>2</sub>. Catalase and/or

peroxidase +ve; oxidase +ve. GC%: 35–41, but one strain 53. Type species: *L. interrogans*.

Two species are recognized [Book ref. 22, pp. 62–67]: *L. biflexa* (free living, capable of growth at 13°C, usually resistant to 225 µg/ml 8-azaguanine) and *L. interrogans* (parasitic/pathogenic, usually sensitive to 225 µg/ml 8-azaguanine, and growth inhibited at 13°C). Each species consists of a large number of named serotypes (= serovars) which are classified into named serogroups; thus, e.g. the Icterohaemorrhagiae serogroup of *L. interrogans* contains nearly twenty serotypes, including e.g. *dakota* and *icterohaemorrhagiae*.

**Leptospiraceae** A family of aerobic bacteria of the order SPIROCHAETALES; the cells typically have hooked ends, their cell wall PEPTIDOGLYCAN contains the diamino acid diaminopimelic acid, and their carbon and energy sources are long-chain fatty acids or long-chain fatty alcohols (cf. SPIROCHAETACEAE). One genus: LEPTOSPIRA.

**Leptospirillum ferrooxidans** See LEACHING.

**leptospirosis** A disease of man and animals, caused by any of various serotypes of *Leptospira interrogans*. A wide range of animals can act as carriers, the leptospire normally occurring in the kidney tubules; e.g., serotypes *icterohaemorrhagiae* and *australis* A are carried by rats and other rodents, *canicola* by dogs and pigs, *pomona* by cattle and pigs, *hardjo* and *grippotyphosa* by cattle. In domestic animals the disease ranges from mild to fatal, depending on the animal and serotype involved; symptoms commonly include fever, jaundice, haematuria (cf. RED WATER), and abortion. (Rodents appear not to be significantly affected by leptospire infection.) Animals may continue to excrete leptospire in their urine for several months after recovery.

Man acquires infection either by direct contact with animals or animal carcasses (cf. ZONOSIS) or via water contaminated with urine from infected animals. Infection occurs via wounds or mucous membranes. Incubation period averages ca. 10 days. In the mild form of leptospirosis, onset is abrupt with shivering, fever, prostration, headache, anorexia and myalgia; nausea and vomiting may occur. Renal function is typically impaired, with proteinuria, haematuria etc. Uveitis is a late complication. A severe form of leptospirosis (*Weil's disease*, *infectious jaundice*) is caused by serotype *icterohaemorrhagiae*; symptoms are more intense, with e.g. marked prostration, severe nausea, vomiting and diarrhoea, enlargement of the liver, jaundice, renal dysfunction, haemorrhages, MENINGITIS. Mortality rates: ca. 15–40%. *Lab. diagnosis*: demonstration of rising titres of antibodies (which appear 7–10 days after onset); identification/culture of the pathogen from blood during the first week, later from urine. [ELISA for detection of specific IgM and IgG in human leptospirosis: JGM (1985) 131 377–385.]

**leptotene stage** See MEIOSIS.

**Leptotheca** See MYXOSPORA.

**Leptothrix** A genus of Gram-negative IRON BACTERIA. Cells: polarly flagellated single rods, or chains of rods within a sheath. Type species: *L. ochracea*.

**Leptotrichia** A genus of Gram type-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the human mouth. Cells: non-motile, straight or slightly curved rods, 0.8–1.5 × 5.0–15.0 µm, often occurring in pairs, chains or septate filaments; the cells of young cultures may stain Gram-positively, but the cell wall resembles those of Gram-negative bacteria. Acid (no gas) is formed from carbohydrates; glucose fermentation yields lactic acid with small amounts of acetic and succinic acids. GC%: ca. 25. Type species: *L. buccalis*.

**lesion** A localized region of tissue which has been damaged physically or altered by any pathological process.

**letA gene** See F PLASMID.

**letD gene** See F PLASMID.

**lethal mutation** A mutation which kills the organism in which it occurs (cf. CONDITIONAL LETHAL MUTANT).

**lethal yellowing disease** (of coconut) See COCONUT LETHAL YELLOWING.

**lethal zygotis** During CONJUGATION (sense 1b) between HFR DONORS and F<sup>-</sup> recipients: the phenomenon in which recipients are killed if the ratio of donor cells to recipient cells is high (e.g. ca. 10:1) and the culture is aerated during mating. The effect is not exhibited in F<sup>+</sup> × F<sup>-</sup> crosses.

**lettuce big vein agent** A virus-like agent which causes big vein disease in lettuces (*Lactuca sativa*) and is pathogenic in other plants of the Compositae. In lettuces, symptoms include vein-clearing and vein-banding, and significant economic losses may result – particularly in hydroponically cultured plants. The agent is transmitted by *Olpidium brassicae*.

**lettuce downy mildew** See BREMIA.

**lettuce mosaic virus** See POTYVIRUSES.

**lettuce necrotic yellows virus** See RHABDOVIRIDAE.

**L-leucine biosynthesis** See Appendix IV(b).

**leucine-responsive regulator protein** See LRP.

**leuco compound** A colourless derivative of a dye. (See e.g. leuco METHYLENE BLUE.)

**leucocidin** Any microbial toxin which can damage or kill one or more types of LEUCOCYTE. Leucocidal activity may be shown by e.g. certain staphylococcal HAEMOLYSINS and STREPTOLYSIN S; the PANTON-VALENTINE LEUCOCIDIN has *specific* leucocidal activity.

**leucocyte** (leukocyte) Any white cell of the blood and lymphoid system, including granulocytes (= PMNS), MACROPHAGES, LYMPHOCYTES, and the precursor cells of each of these types. (The term 'leucocyte' is often used to refer solely to the PMNs.) (See also LEUCOCIDIN.)

**leucocytosis** An increase in the number of leucocytes in the blood.

**leucocytosis-promoting factor** *Syn.* PERTUSSIS TOXIN.

**Leucocytozoon** A genus of protozoa of the HAEMOSPORORINA. Species are parasitic in birds; the vectors are commonly blood-sucking flies of the Simuliidae.

**leucolysin** A toxin which lyses leucocytes.

**leucomycin** See MACROLIDE ANTIBIOTICS.

**leuconocin S** See BACTERIOCINS.

**Leuconostoc** A genus of Gram-positive bacteria of the family Streptococcaceae; the organisms occur e.g. in various dairy products and in fermented beverages and fermenting vegetables (see e.g. BUTTERMILK, CHEESE-MAKING, IDLI, LACTIC ACID STARTERS, PULQUE, ROPINESS, SAUERKRAUT and WINE SPOILAGE). Cells: non-motile, spherical or lenticular (maximum dimension ca. 1 µm), typically in pairs or chains. Growth requirements include a suitable carbohydrate and a range of amino acids and vitamins, e.g. BIOTIN, NICOTINIC ACID and THIAMINE. Glucose is metabolized anaerobically by a HETEROLACTIC FERMENTATION in which D(-)-lactic acid, CO<sub>2</sub> and ethanol are the main products; in the presence of O<sub>2</sub>, glucose is used more efficiently than it is under anaerobic conditions, and the end-products include acetic acid rather than ethanol – NADH being reoxidized by NAD(P)H oxidase activity [JGM (1986) 132 1789–1796]. (See also LACTIC ACID BACTERIA.) Optimum growth temperature: 20–30°C. GC%: ca. 38–44. Type species: *L. mesenteroides*.

*L. cremoris* (formerly *L. citrovorum*) can ferment very few carbohydrates (e.g. glucose, galactose and lactose). In the presence of a suitable carbohydrate (as energy source), *L. cremoris* can break down citrate in a non-energy-yielding manner with

## *Leucopaxillus*

the formation of acetoin, DIACETYL, acetate and CO<sub>2</sub>. Dextran are not formed.

*L. dextranicum*. Many carbohydrates (although not e.g. arabinose) are fermented. DEXTRANS are formed.

*L. lactis*. Many carbohydrates (though not e.g. dextrin) are fermented. Dextran are not formed.

*L. mesenteroides*. Many carbohydrates (including e.g. arabinose) are fermented. DEXTRANS are formed.

*L. oenos*. Occurs in wine (see also MALOLACTIC FERMENTATION). Fermentable carbohydrates include e.g. fructose and trehalose. Dextran are not formed. Growth can occur in the presence of 10% ethanol, and can occur at pH 3.7.

*L. paramesenteroides*. Many carbohydrates (including dextrin) are fermented. Dextran are not formed.

It has been proposed that *L. cremoris* and *L. dextranicum* be re-classified as subspecies of *L. mesenteroides* [IJSB (1983) 33 118–119].

[Characterization of *Leuconostoc* spp: Book ref. 143, pp. 147–178.]

***Leucopaxillus*** A genus of fungi of the Tricholomataceae (AGARICALES).

**leucopenia** The presence of reduced numbers of leucocytes in the blood.

**leucoplast** Any colourless PLASTID.

**leucosin** *Syn.* CHRYSOLAMINARIN.

**leucosis** *Syn.* LEUKOSIS.

***Leucosporidium*** See SPORIDIALES and CANDIDA.

***Leucothrix*** A genus of GLIDING BACTERIA (see CYTOPHAGALES) which occur e.g. as epiphytes on marine algae. The organisms are non-sheathed, sessile (attached), colourless filaments whose constituent cells (including non-terminal cells) can round up and become individual gliding gonidia; sulphur is not deposited intracellularly. Metabolism appears to be chemoorganotrophic. GC%: ca. 46–51.

**Leucotrichaceae** See CYTOPHAGALES.

**leucovorin** See FOLIC ACID.

**leukaemia** Any of various progressive, malignant diseases in which increased numbers of (usually abnormal or immature) leucocytes occur in the blood; numbers of circulating erythrocytes and platelets are reduced. Symptoms characteristic of leukaemia include anaemia, a tendency to haemorrhage, and increased susceptibility to infection. Leukaemias are classified on the basis of the time course of the disease (acute or chronic) and the types of cell involved (e.g., granular PMNs and their precursors, B or T lymphocytes or lymphoblasts, or monocytes). Certain retroviruses can cause leukaemias in man, animals or birds: see e.g. ADULT T-CELL LEUKAEMIA; AVIAN ACUTE LEUKAEMIA VIRUSES; BOVINE VIRAL LEUKOSIS; FELINE LEUKAEMIA VIRUS; MURINE LEUKAEMIA VIRUSES.

**leukocyte** See LEUCOCYTE.

**leukocyte adhesion deficiency (LAD)** A genetic disorder (autosomal, recessive) characterized by the failure of leukocytes adequately to express  $\beta_2$  integrin adhesion molecules (see INTEGRINS); such cells are unable to give a normal response during INFLAMMATION, and individuals with LAD have correspondingly lower resistance to infection. [See also Lancet (1999) 353 341–343.]

**leukocyte function-associated antigen** See INTEGRINS.

**leukosis** (leucosis) The (abnormal) proliferation of leukocyte-forming tissue. (See e.g. BOVINE VIRAL LEUKOSIS; LYMPHOID LEUKOSIS.)

**leukotrienes** Derivatives of ARACHIDONIC ACID, and of certain other fatty acids, formed e.g. by leukocytes and macrophages

as a result of immunological or non-immunological stimuli; leukotrienes can e.g. cause contraction of smooth muscle, stimulate vascular permeability, and act as attractants for leucocytes. [Review: ARB (1983) 52 355–377.]

**leukoviruses** Former name for retroviruses of the ONCOVIRINAE, particularly the TYPE C ONCOVIRUS GROUP.

**levamisole** A drug used to stimulate the immune response; inhibit tumour formation; stimulate the phagocytic activity of macrophages; inhibit alkaline phosphatases; treat intestinal disease caused by certain helminths – e.g. that caused by *Ascaris lumbricoides*.

**levan** A linear FRUCTAN consisting mainly of (2 → 6)- $\beta$ -linked fructofuranose residues. Levans are widespread as storage polysaccharides in higher plants (especially grasses), and are produced as extracellular slime by certain bacteria (e.g. species of *Bacillus* and *Streptococcus*). (See also ROPINESS and DENTAL PLAQUE.)

***Leveillula*** See ERYSIPIHALES.

***Levinea*** See CITROBACTER.

**Levinthal's medium** A medium used for the isolation of *Haemophilus* spp; it contains both V FACTOR and X FACTOR. Levinthal stock is made by adding defibrinated horse blood (10%) to a boiling brain–heart infusion broth and filtering through e.g. glass wool and then through a membrane filter. Autoclaved peptone broth is then added, and the whole may be mixed with sterile molten agar and dispensed into Petri dishes. [Recipe: Book ref. 46, pp. 1375–1376.]

**Leviviridae** A family of BACTERIOPHAGES [Book ref. 23, p. 136]; the genome is linear, positive-sense ssRNA (MWt ca. 1.0–1.3 × 10<sup>6</sup>), and the virion is icosahedral (ca. 22–26 nm diam.). One genus: *Levivirus*.

Leviviruses occur e.g. in enterobacteria (e.g. phages  $\alpha 15$ ,  $\beta$ , f2, fr, M12, MS2,  $\mu 2$ , Q $\beta$ , R17 and R23), in *Pseudomonas* (e.g. PP7, 7S) and in *Caulobacter*.

Enterobacterial leviviruses (common in sewage) have been classified into four groups (I–IV) on the basis of serological and physiological properties. Phages of group I (e.g. f2, fr, MS2, R17) and group III (e.g. Q $\beta$ ) have been the most intensively studied. (MS2, f2 and R17 apparently differ only in a number of point mutations.)

The group I virion consists of (i) 180 copies of a single type of coat protein, (ii) one molecule of A protein (= 'maturation protein' – necessary for infectivity and phage maturation), (iii) the RNA genome, and (iv) at least in MS2, spermidine (presumably to neutralize the negative charge on RNA). (The Q $\beta$  virion is similar but contains one molecule of an A2 protein (equivalent to A protein in group I phages) and about three molecules of an A1 protein (= IIB protein); the A1 protein is formed by READTHROUGH of the coat protein gene.) [Capsomeric structure of Q $\beta$ : Nature (1982) 298 819–824.]

The group I phage genome encodes: (i) the A protein; (ii) the coat protein; (iii) a replicase subunit; and (iv) a 'lysis protein' (the gene for which overlaps the coat and replicase genes in the +1 reading frame [Nature (1982) 295 35–41]). The lysis protein (L protein) of MS2 forms specific adhesion sites (junctions of the cytoplasmic and outer membranes); these sites may facilitate lysis of the cell envelope [JB (1989) 171 3331–3336].

In Q $\beta$  and other leviviruses the replicase subunit combines with three host proteins – the S1 protein of the 30S ribosomal subunit, and the elongation factors EF-Tu and EF-Ts (see PROTEIN SYNTHESIS) – to form the active *replicase* (i.e. RNA-dependent RNA polymerase) necessary for phage genome replication. Expression of viral genes is controlled in both quantity

and time; thus, e.g. coat protein is synthesized greatly in excess of A protein, and it acts as a repressor which, later in infection, terminates translation of the replicase subunit gene. Regulation of gene expression may involve changes in the secondary structure of the RNA which alter the availability of ribosome binding sites [e.g. Nature (1982) 295 35–41]. Virion assembly apparently occurs largely or exclusively by spontaneous aggregation.

Most or all enterobacterial leviviruses are 'male-specific' (ANDROPHAGES); f2, MS2, R17, fr, M12 and Q $\beta$  all adsorb specifically to the sides of F pili (cf. INOVIRUS). The *Pseudomonas* phages PP7 and 7S adsorb to the chromosomally specified polar (PSA) fimbriae. *Caulobacter* phages also adsorb to polar fimbriae; only the pre-divisional and swarmer stages are susceptible to infection. Infection of the host cell may, at least in some cases, involve pilus (or fimbria) retraction. The genome enters the host cell together with – and probably mediated by – the A/A2 protein (which is cleaved during penetration).

**Levivirus** See LEVIVIRIDAE.

**levofloxacin** A QUINOLONE ANTIBIOTIC (q.v.).

**levulose** D-Fructose.

**lexA gene** See SOS SYSTEM.

**LFA-1** See INTEGRINS.

**LFA-2** See IMMUNOGLOBULIN SUPERFAMILY.

**LFA-3** See IMMUNOGLOBULIN SUPERFAMILY.

**LFT** (of plasmids) See EPIDEMIC SPREAD.

**LFT lysate** See TRANSDUCTION.

**LGLs** Large granular lymphocytes: see NK CELLS.

**LHC** LIGHT-HARVESTING COMPLEX.

**LHC complex** See CELLULOSE.

**library** (gene bank; gene library) (*mol. biol.*) A collection of recombinant DNA molecules which, together, commonly represents the entire genome of an organism (a *genomic library*) (see figure).

Another type of library consists of a collection of cDNA molecules derived from a mixture of polyadenylated mRNAs isolated from a population of cells of a given strain; this kind of library does not represent the entire genome of the strain.

**Licea** See MYXOMYCETES.

**Liceales** See MYXOMYCETES.

**lichen** A 'composite organism' consisting of a fungus (the mycobiont) and an alga or cyanobacterium (the photobiont – cf. PHYCOBIONT) in symbiotic association; a lichen thallus is morphologically and physiologically quite unlike that of either symbiont growing separately. Lichens are widely distributed, being found from tropical to polar regions in a very wide range of habitats, both terrestrial (e.g. on trees, rocks and soil) and aquatic (freshwater and marine).

Taxonomically, lichens are generally regarded as 'lichenized fungi', classification being based mainly on the nature and origin of their fruiting structures. Most mycobionts appear not to occur in free-living form (but cf. XANTHORIA). The majority are ascomycetes ('ascolichens') belonging mainly to the orders ARTHONIALES, CALICIALES, DOTHIDEALES, GRAPHIDALES, GYALECTALES, LECANIDIALES, LECANORALES, OPEGRAPHALES, PELTIGERALES, PERTUSARIALES, PYRENULALES, TELOSCHISTALES, and VERUCARIALES. Some lichens belong to the Deuteromycotina, and a few to the Hymenomycetes ('basidiolichens').

The photobiont is usually either a green alga (e.g. *Coccomyxa*, *Myrmecia*, *Phycopeltis*, *Pseudotrebouxia*, *Trebouxia* or *Trentepohlia*) or a cyanobacterium (usually *Nostoc* or *Calothrix*). Some lichens may have more than one photobiont: see e.g. SOLORINA and CEPHALODIUM. Free-living counterparts of lichen photobionts occur in nature, but in the lichen the cells

**LIBRARY:** making a (bacterial) genomic library (diagrammatic). Initially, chromosomes are isolated from a population of bacteria of a given strain. The chromosomes are exposed to a RESTRICTION ENDONUCLEASE which cuts at specific sites in each chromosome (*top, left*), forming many fragments of different sizes (*centre, left*).

As in CLONING (q.v.), copies of a given plasmid (*top, right*) provide vector molecules. The plasmid is one which can be cut by the same enzyme as that used to cut the chromosomes; note, however, that the plasmid has only *one* cutting site for the given enzyme – so that cutting simply linearizes the plasmid molecule (*centre, right*).

Chromosomal fragments and linearized plasmids are then mixed in the presence of ATP and DNA ligase, an enzyme that catalyses the formation of phosphodiester bonds. Fragments and plasmids join together, randomly, via their sticky ends to form a large number of recombinant molecules, many consisting of a plasmid circularized with chromosomal DNA. (Plasmid–fragment binding may be promoted by the phosphatase approach described in CLONING.) Because the fragments are of different sizes, the recombinant plasmids will also be of different sizes (*bottom of diagram*). As many millions of fragments and plasmids are used, the recombinant plasmids will, collectively, carry all the DNA of the chromosome, and this collection of recombinant molecules is therefore called a *genomic library*.

By using TRANSFORMATION OR ELECTROPORATION, the library can be inserted into a population of bacteria – different cells receiving different fragments of the chromosome; these cells can then be allowed to form individual colonies, and colonies containing a particular fragment of the chromosome can be detected by various screening processes (see e.g. CLONING).

Reproduced from *Bacteria* 5th edition, Figure 8.7, page 184, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

## lichen

may be modified (e.g., they may be smaller, may lack motile stages, and filamentous forms may become unicellular).

The bionts of a lichen can be separated (e.g. by micromanipulation) and can be maintained in culture, but it is notoriously difficult to induce them to re-synthesize a lichen thallus; re-synthesis has been achieved e.g. for *Endocarpon pusillum*. Culture of the photobiont may be necessary for its identification.

**Morphology and anatomy.** The lichen thallus may be e.g. CRUSTOSE, FOLIOSE, FRUTICOSE, LEPROSE or SQUAMULOSE, or it may have a composite form, with e.g. a squamulose *primary thallus* from which arises a fruticose *secondary thallus* (see PSEUDOPODETIUM; cf. PODETIUM). The simplest type of thallus consists of a loose association of fungal hyphae and photobiont cells, with little or no differentiation (see e.g. LEPRARIA). In gelatinous lichens such as COLLEMA and LEMPHOLEMMA, both bionts are more or less evenly distributed throughout the thallus (i.e. the thallus is *homoiomerous*), with little differentiation into tissues (cf. LEPTOGIUM). In most crustose, foliose and fruticose lichens the thallus is *heteromerous* (stratified): the mycobiont is differentiated to form a surface layer, the *cortex* (a layer of compressed, conglutinated cells or hyphae), which covers the *medulla* (a fibrous tissue of loosely interwoven hyphae), and the photobiont occurs in a layer between the upper cortex and the medulla. One or more differentiated somatic structures may also be present, depending on species: see e.g. CEPHALODIUM; CILIUM (sense 2); CYPHELLA; ISIDIUM; PSEUDOCYPHELLA; RHIZINE; TOMENTUM. (See also PORED EPICORTEX.)

Within the thallus, the hyphae of the mycobiont may be closely appressed to the cells of the photobiont, the walls of both bionts being thinner at the point of contact, or the mycobiont may penetrate the photobiont cells by means of haustoria; the haustoria do not penetrate the plasma membrane in living cells, but may do so in dead cells. [Cytology of mycobiont-photobiont interaction: Lichenol. (1984) 16 111-127.]

**Physiology.** Although traditionally regarded as a mutualistic association, a lichen is now thought to be more a case of 'controlled parasitization' of the photobiont by the mycobiont. It has long been assumed that all the carbon requirements of the mycobiont are fulfilled by photosynthate released by the photobiont; cyanobionts release glucose, while phycobionts release a sugar alcohol (*Trebouxia*, *Myrmecia* and *Coccomyxa* release ribitol, *Trentepohlia* releases erythritol, *Stichococcus* releases sorbitol), and these compounds are converted by the mycobiont to e.g. mannitol and/or arabitol. However, the carbon requirement for lichen growth is small, and could – at least theoretically – be fulfilled e.g. by absorption of organic carbon from the environment; it has also been shown that, in the dark, the mycobiont in *Peltigera* sp can fix substantial amounts of CO<sub>2</sub> mainly via PEP carboxylase activity [Physiol. Plant. (1983) 57 285-290]. The photosynthate received by the mycobiont from the photobiont may thus be necessary not so much for growth as for the maintenance of high levels of soluble carbohydrate (particularly polyols) which appear to function as a reserve of respirable carbon (necessary e.g. when the thallus is hydrated, and hence metabolically active, during periods of darkness) and to protect cell components during periods of desiccation.

Nitrogen requirements may be fulfilled by absorption of e.g. nitrate from the environment. Some lichens contain nitrogen-fixing cyanobacteria – either as the primary photobiont or as an additional biont in specialized cephalodia (see CEPHALODIUM); nitrogen fixed by the cyanobacteria is transferred to the mycobiont.

Vitamins found to be necessary for the growth of the mycobiont in culture are assumed to be supplied by the photobiont in nature.

Lichens accumulate high concentrations of certain metal ions (including heavy metals), but lichen mineral metabolism is not well understood.

Water (in liquid or vapour form) is readily absorbed by lichen thalli; the absorbed water occurs intercellularly and is readily lost by evaporation. The ability to absorb and retain water may be influenced by thallus morphology – e.g., surface area and hence absorptive capacity will be greater in a thallus which is extensively lobed or perforated than in one which is not. (See also RHIZINE.)

'*Lichen substances*' ('lichen acids'). Lichen mycobionts produce a range of water-insoluble secondary metabolites (e.g. higher aliphatic acids and esters, depsides, depsidones, dibenzofurans, anthraquinones) which may be deposited on the medullary hyphae, on the surface of the cortex (often giving a pruinose appearance), in the hymenial discs (see e.g. RHODOCLADONIC ACID), etc. Many of these substances are unique to lichens; they are generally not formed by the isolated mycobionts. Their functions are largely unknown, but may include e.g. protection of the photobiont from high light intensities (see e.g. PARIETIN); inhibition of potentially competing plants (particularly bryophytes) and/or soil microflora in the vicinity of the thallus (e.g. EVERNIC ACID and USNIC ACIDS have antibiotic activity); prevention of grazing of the thallus by invertebrates; etc.

The content of lichen substances in a given lichen is a useful feature in taxonomy and identification. The compounds may be identified e.g. by chromatography, mass spectrometry, microcrystallography etc. Some lichen substances give characteristic colour reactions with certain reagents, and this forms the basis of simple colour tests widely used for identification of lichens in the field. The reagents used are: saturated aqueous calcium hypochlorite ('C'), 10-25% aqueous KOH ('K'), and 1-5% ethanolic *p*-phenylenediamine ('P' or 'PD'). For example, parietin and other anthraquinones give a purple colour with K.

**Growth** of a lichen thallus generally appears to occur at or near the periphery (or apex in fruticose thalli). [Growth in circular thalli: Lichenol. (1981) 13 265-287.] Lichen growth is characteristically slow; the radius of a circular thallus may increase by (e.g.) 0.01-2.50 mm per year, depending on species, rainfall, light intensity, temperature, etc. (See also LICHENOMETRY.) In certain crustose and squamulose lichens (e.g. *Pannaria*, *Pertusaria*, *Rhizocarpon*) a photobiont-free margin (the hypothallus) may be formed around the thallus as the hyphae of the mycobiont grow outwards; the photobiont reproduces by cell division or e.g. by autospore formation, and the daughter cells spread into the region of new fungal growth.

**Reproduction.** Asexual (vegetative) reproduction in lichens may be achieved e.g. by SOREDIUM, ISIDIUM or HORMOCYST formation, or by fragmentation of the thallus. Some lichens may be able to generate new thalli from conidia (which may or may not be produced in pycnidia, according to species).

Sexual reproduction commonly involves ascocarp formation. Lichen ascocarps tend to be longer-lived than those of non-lichenized ascomycetes, and may continue to produce ascospores for a period of years. Since ascospores do not contain the photobiont, the germinating ascospores must acquire the photobiont from the environment. In a few cases (e.g. *Endocarpon* sp, *Pertusaria pertusa*) cells of the photobiont may adhere to the ascospores as they are released, thereby allowing their dissemination with the ascospores. In most cases, however, the fungus

must incorporate free-living cells, or may acquire the appropriate photobiont from propagules (e.g., soredia: probably an important source for TREBOUXIA-containing lichens) present on the substratum. In some lichen species the ascospores may germinate only in the presence of cells of the photobiont; in others, germination gives rise to a mat of hyphae which subsequently incorporates algal or cyanobacterial cells in its immediate vicinity. The mechanism by which the 'correct' photobiont is selected is unknown; some evidence implies a role for LECTINS in the initial recognition step [Lichenol. (1984) 16 103–110]. However, in at least some cases the initial incorporation of algal or cyanobacterial cells seems to be non-selective, all cells except those of the prospective photobiont being killed by the fungus [Nature (1981) 289 169–172].

**Habitat.** Lichens occur in a wide range of habitats – usually attached to substrata such as rocks, soil, bark, leaves, mosses etc, but sometimes unattached. Saxicolous species may be ENDOLITHIC (q.v.) or EPLITHIC, and are often specific for particular types of rock (e.g. acidic or basic); they may facilitate the weathering of rocks both by physical mechanisms (e.g. rhizine penetration, thallus expansion and contraction on wetting and drying) and by chemical mechanisms (e.g. metal chelation by lichen substances, corrosion by CO<sub>2</sub> and/or oxalic acid). Some species can grow on and etch the surface of glass, marble etc, and have caused significant deterioration of stone monuments, stained glass windows etc.

Many lichens can grow in situations where they are exposed to extremes of temperature and desiccation which can be tolerated by few other forms of life – e.g. in hot arid deserts, in polar regions, and at high altitudes. In some harsh environments lichens are important primary producers, and terricolous species may play an important role in stabilization of the soil in such environments.

A few lichens (e.g. *Dermatocarpon weberi*, *Verrucaria aquatilis*) are aquatic, occurring e.g. on rocks submerged in streams. Some lichens occur on rocks by the sea – at or above the intertidal zone, depending on species (see e.g. LICHINA, VER-RUCARIA).

Lichens have been found in some unusual locations: e.g. on the carapaces of giant tortoises, and on the backs of (living) flightless weevils of the genus *Gymnopholus*.

**Lichens and pollution.** Many lichens are highly sensitive to air pollution, probably as a result of their ability to accumulate high concentrations of pollutants. They are killed by low concentrations of e.g. SO<sub>2</sub>, fluoride, fertilizer dust etc; the pollutant primarily responsible for lichen death in industrial regions is generally SO<sub>2</sub>, one effect of which is to degrade chlorophyll to phaeophytin. The various sensitivities of different lichen species to pollution makes them useful biological indicators of pollution levels in a given area (see also INDICATOR ORGANISM); however, sensitivities may be influenced by moisture, temperature and substratum (e.g. corticolous lichens are more sensitive than saxicolous ones). Some lichens are inherently resistant to pollution (see e.g. LECANORA).

Lichen thalli can accumulate high concentrations of heavy metal ions [Lichenol. (1984) 16 173–188] – apparently with little adverse effect on themselves; lichens have thus been used to monitor environmental levels of heavy metals. (See also ACAROSPORA.)

Since lichens are used as food (by man and animals) in some regions, their ability to accumulate toxic substances can be a potential health hazard. For example, lichens accumulated radioactive isotopes (e.g. strontium-90, caesium-137) in arctic

regions which were subjected to fall-out from atmospheric nuclear weapons tests in the 1950s/1960s; lichens in this region form the basis of the food chain: lichen → reindeer (caribou) → man, and correspondingly high levels of e.g. <sup>137</sup>Cs were recorded in Lapps who consumed reindeer meat at that time (although the levels were not considered to be dangerous).

[Lists of references on lichens and air pollution are published regularly in *The Lichenologist*.]

**Uses of lichens.** Some lichens are used as food by people in certain countries: e.g. *Cetraria islandica* ('Iceland moss') is consumed e.g. in Iceland, *Umbilicaria esculenta* ('iwatake') in Japan. Species of *Cladonia* and *Cetraria* form a major part of the winter diet of reindeer (caribou) and other deer in arctic regions. Various lichens have been used since ancient times as sources of dyes: e.g. *Ochrolechia tartarea* yields the purple dye cudbear, *Parmelia* spp a brown dye, and *Roccella* spp LITMUS and the purple dye orchil. Certain lichens – particularly *Evernia prunastri* ('oakmoss') – are used in the manufacture of perfumes, both for their own scent and for their ability to stabilize (fix) other scents. Lichens were formerly widely used in folk medicine; currently, USNIC ACIDS have some medical uses. In Scandinavian countries, *Cladonia stellaris* is harvested on a commercial scale for ornamental uses in wreaths, floral decorations etc [Lichenol. (1979) 11 85–89].

**lichen starch** Syn. LICHENIN.

**lichenan** Syn. LICHENIN.

**lichenicolous** Growing on lichens.

**lichenin** (lichenan; lichen starch; 'moss starch') A linear β-D-glucan consisting mainly of (1 → 3)-β-linked cellobiose units (i.e. units of three (1 → 4)-β-linked glucose residues); it occurs in certain lichens (e.g. *Cetraria islandica*). (cf. ISOLICHENIN.)

**lichenometry** A method for dating glacial deposits, stone monuments etc, based on a knowledge of the growth rates of particular (usually crustose) lichens. The assumption is made that the largest crustose thalli present on a given exposed surface started to grow when the surface first became exposed; the thalli are measured, and their ages estimated from a standard growth curve for the species – thus giving an approximate age for the substratum. Certain thalli of *Rhizocarpon geographicum* have been estimated to be ca. 1000–4500 years old. [Lichenometry with *R. geographicum*: Lichenol. (1983) 15 249–261.]

**Lichina** A genus of small, fruticose LICHENS (order LECANORALES); photobiont: a cyanobacterium. The thallus is more or less gelatinous, brown to black, erect, branching, terete (*L. confinis*) or flattened (*L. pygmaea*), forming tufts or mats on rocks on the seashore at or just above the high-tide level. Apothecia occur immersed in the swollen ends of the branches.

**Lieberkuehnia** See GRANULORETICULOSEA.

**Lieberkühn's organelle** (watchglass organelle) A refractive, lenticular body which occurs, subpericellularly, in or near the buccal cavity in certain hymenostomes.

**lif gene** See LYSOSTAPHIN.

**lig gene** Gene for DNA LIGASE.

**ligase chain reaction** See LCR.

**ligases** (synthetases) ENZYMES (EC class 6) which catalyse covalent bond formation using energy obtained from the cleavage of a pyrophosphate bond (e.g. in ATP); C–O, C–S, C–N and C–C bonds are formed by different subclasses of ligases. (See e.g. DNA LIGASE; cf. SYNTHASE.)

**ligative hyphae** See HYPHA.

**light chain** (*immunol.*) The smaller (MWt ca. 23000) of the two types of polypeptide chain in an IMMUNOGLOBULIN monomer. About half the (ca. 215) amino acid residues in a light chain

## light green

constitute the variable, N-terminal region ( $V_L$ ), while the remainder form the constant, C-terminal region ( $C_L$ ). There are two structurally distinct types of light chain: *kappa* and *lambda*; both types occur in all classes of immunoglobulin, but a given Ig molecule contains only *kappa* or only *lambda* chains. In human Igs, the ratio *kappa*:*lambda* is ca. 70:30, while in mouse Igs it is ca. 95:5.

**light green** A green acid TRIPHENYLMETHANE DYE.

**light-harvesting complex (LHC)** In or on membranes involved in PHOTOSYNTHESIS: a pigment-containing complex which receives radiant energy and transfers energy to REACTION CENTRES; an *antenna* is an array of LHCs. Protein-pigment complexes in LHCs are sometimes indicated by the letter 'B' followed by the absorption maximum or maxima – e.g. B800 indicates absorption at 800 nm.

*LHCs in oxygenic organisms.* In e.g. green algae (CHLOROPHYTA), DIATOMS and DINOFAGELLATES, LHCs occur within the photosynthetic membranes; in addition to CHLOROPHYLL *a*, LHCs in these organisms include Chl *b* (green algae) or Chls  $c_2$  and/or  $c_1$  (diatoms, dinoflagellates). In CRYPTOPHYTES, RHODOPHYTA and CYANOBACTERIA the LHCs include PHYCOBILIPROTEINS which, in cyanobacteria and Rhodophyta, occur in PHYCOBILISOMES attached to thylakoid membranes.

Factors such as light quality and the availability of nitrogen and sulphur can influence the composition of LHCs. [Environmental effects on the LHC of cyanobacteria: JB (1993) 175 575–582.]

*LHCs in anoxygenic organisms.* In bacteria of the RHODOSPIRILLALES the LHCs include bacteriochlorophylls and CAROTENOIDS. In the 'purple' photosynthetic bacteria (RHODOSPIRILLINEAE) LHCs occur in 'intracytoplasmic membranes' (CHROMATOPHORE sense 2) and include bacteriochlorophyll *a* or *b* as well as various carotenoids. In the 'green' photosynthetic bacteria (CHLOROBINEAE) the LHCs characteristically occur in CHLOROSOMES; in green-coloured species of the Chlorobiaceae, the LHCs include Bchls *c* or *d* and the carotenoid chlorobactene, while those of brown-coloured species include Bchl *e* and isorenieratene. In members of the Chloroflexaceae the LHCs include Bchl *c* and  $\beta$ -carotene.

**light reaction** See PHOTOSYNTHESIS.

**light strand** (*mol. biol.*) See H STRAND.

**light trap** (1) A zone of focused light in a liquid medium. Organisms capable of behavioural responses to light may accumulate in, or be excluded from, such a zone of light. Accumulation may occur e.g. when the light-dark boundary offers an intensity gradient sufficient to trigger a PHOBIC RESPONSE such that any attempt by the organisms to leave the light zone incites a change in direction.

(2) The reaction centre in a photosynthetic pigment system.

**LightCycler**<sup>®</sup> See PCR.

**LightCycler Red 640** See PCR.

**LightCycler Red 705** See PCR.

**lignans** A class of dibenzylbutane derivatives which occur in higher plants and in fluids (bile, serum, urine etc) in man and other animals. Mammalian lignans include *enterodiols* (2,3-bis(3-hydroxybenzyl)butane-1,4-diol), and *enterolactone* (*trans*-2,3-bis(3-hydroxybenzyl)- $\gamma$ -butyrolactone); these compounds, which have a potential anti-cancer role, can be synthesized in vitro by human faecal flora [JAB (1985) 58 37–43].

**lignicolous** Living or growing in or on wood.

**Ligniera** See PLASMODIOPHOROMYCETES.

**lignin** A complex, variable, hydrophobic, cross-linked, three-dimensional aromatic polymer of *p*-hydroxyphenylpropanoid

units connected by C–C and C–O–C links; it is formed by the peroxidase-initiated dehydrogenative polymerization of substituted *p*-hydroxycinnamyl alcohols (*p*-coumaryl, coniferyl and sinapyl alcohols). Lignin is a major component in the vascular tissues of terrestrial plants, and constitutes ca. 20–35% of the weight of wood; it occurs with hemicelluloses in the matrix of the cell walls, 'waterproofing' the xylem vessels and providing mechanical strength and protection from enzymic attack. [Lignification in disease resistance in plants: ARPPath. (1980) 18 259–288.] Lignin is tightly bonded to CELLULOSE and HEMICELLULOSES – mainly by hydrogen bonds but also by some covalent bonds.

Lignins are extremely resistant to chemical and enzymic degradation; biological degradation is achieved mainly by fungi – most efficiently by white-rot basidiomycetes (see WHITE ROT) – but also by certain actinomycetes. In the white-rot fungi *Phanerochaete chrysosporium* and *Coriolus versicolor*, lignin degradation is a secondary metabolic process, occurring under low levels of nutrient nitrogen and requiring the presence of a carbon source such as glucose or cellulose [Book ref. 39, pp. 67–90]; it appears not to yield significant carbon or energy, but allows access to the polysaccharide components of the cell walls (see CELLULASES). *P. chrysosporium* produces an extracellular haemoprotein 'ligninase' which, in the presence of H<sub>2</sub>O<sub>2</sub>, can degrade lignin by bringing about oxidative cleavage of the backbone between C $\alpha$  and C $\beta$ , oxidation and hydroxylation of benzylic methylene groups, oxidation of phenols and benzyl alcohols, etc. The haemoprotein functions as a peroxidase. Reaction of the enzyme with H<sub>2</sub>O<sub>2</sub> generates a high-redox-potential porphyrin cation radical (oxy-ferryl complex) which can extract a single electron from an aromatic ring in the lignin substrate to generate an aromatic cationic radical; this is followed by a variety of spontaneous degradative reactions via radical and cation intermediates [FEBS (1985) 183 7–12, 13–16]. *P. chrysosporium* produces multiple forms of the haemoprotein lignin peroxidase [homology among multiple extracellular peroxidases from *P. chrysosporium*: JBC (1987) 262 419–424]. Other enzymes implicated in aerobic lignin degradation include phenol oxidases (e.g. LACCASE) and alcohol oxidase. Quinones, which can be toxic to organisms, are common products of phenol oxidase action; several white-rot fungi produce a cellobiose:quinone oxidoreductase which couples the oxidation of cellobiose with the reduction of quinones [Book ref. 26, pp. 25–26], thus linking cellulose and lignin degradation. [Anaerobic lignin degradation: AEM (1984) 47 998–1004.]

**ligninolytic** Capable of degrading LIGNIN. (cf. LIGNOLYTIC.)

**lignite biodegradation** See COAL BIODEGRADATION.

**lignocellulose** A complex containing LIGNIN, CELLULOSE, and (usually) HEMICELLULOSES.

**lignolytic** Capable of degrading wood. (cf. LIGNINOLYTIC.)

**Limacella** See AGARICALES (Amanitaceae).

**limax amoebae** 'Slug-like' amoebae, i.e., cylindrical (not flattened) MONOPODIAL AMOEBAE, or cylindrical amoebae which 'flow' along without forming obvious pseudopodia.

**limberneck** A form of BOTULISM in birds, especially poultry, caused by *C. botulinum* type A. (cf. WESTERN DUCK DISEASE.)

**Limburger cheese** See CHEESE-MAKING.

**lime sulphur** See SULPHUR.

**limit dextrin** See AMYLASES.

**limit dextrinase** See DEBRANCHING ENZYMES.

**limited resolution** See RESOLVING POWER.

**limited enrichment method** See AUXOTROPH.

**limulin** A LECTIN from the horseshoe crab, *Limulus polyphemus*; it is presumed to bind at sites in LIPOPOLYSACCHARIDES and

can agglutinate *Escherichia coli* and many other Gram-negative bacteria.

**Limulus amoebocyte lysate test (LAL test)** A test used for the detection or quantification of LIPOPOLYSACCHARIDE. The test depends on the ability of LPS to cause gelation of a lysate of the blood cells (amoebocytes) of the horseshoe crab, *Limulus polyphemus*. Quantities of LPS of the order of  $10^{-9}$  g/ml can be detected; different types of LPS differ in their ability to cause gelation. Substances other than LPS (e.g. lipoteichoic acids, polynucleotides) can also cause gelation [FEMS (1983) 20 343–346].

**lincomycin** See LINCOSAMIDES.

**lincosamides** A group of MLS ANTIBIOTICS which contain lincosamine (6-amino-6,8-dideoxyoctose); the group includes e.g. lincomycin (consisting of a substituted pyrrolidine linked to methyl- $\alpha$ -thiolincosamine, produced by *Streptomyces lincolnensis*), clindamycin (7-chloro-7-deoxylincomycin, a semisynthetic derivative of lincomycin), and celesticetin. Lincomycin is active mainly against Gram-positive bacteria (e.g. staphylococci, streptococci, clostridia, *Corynebacterium diphtheriae*) and may be useful e.g. against penicillin-resistant strains. Clindamycin is more active than lincomycin against Gram-negative bacteria, and is effective e.g. against most Gram-positive and Gram-negative anaerobic pathogens (including *Bacteroides fragilis*); it is also active against *Plasmodium* spp. and has been used (with QUININE) in the treatment of malaria. Lincosamides inhibit PROTEIN SYNTHESIS; they bind to the 50S subunit of 70S ribosomes and appear to block the peptidyltransferase reaction. Antiplasmodial action is presumably due to inhibition of mitochondrial protein synthesis.

**lincosamine** See LINCOSAMIDES.

**Linderina** See KICKXELLALES.

**line probe assay** See PROBE.

**linezolid** See OXAZOLIDINONES.

**linkage** (genetics) The degree to which the alleles of two or more given genes are inherited together. Alleles of *unlinked* genes exhibit independent assortment and occur e.g. on different chromosomes. *Linked* genes occur on the same chromosome (or other genetic molecule) and are said to constitute a *linkage group*; the closer together two genes are on a chromosome, the more tightly linked they are – i.e., the lower is their RECOMBINATION FREQUENCY. (Genes far apart on a chromosome may behave as unlinked genes; in bacteriology, genes on the chromosome are sometimes said to be unlinked if they are merely non-contiguous, regardless of the distance between them.)

**linked recognition** (*immunol.*) *Syn.* COGNATE HELP.

**linker DNA** (1) See CHROMATIN. (2) A synthetic oligodeoxyribonucleotide which contains the cleavage site of a particular restriction endonuclease, and which can be ligated to a vector or exogenous DNA fragment prior to CLONING; a linker may serve e.g. to facilitate retrieval of the cloned fragment. (See also POLYLINKER.)

**linker polypeptide** See PHYCOBILISOMES.

**linking number** ( $\alpha$ ) See DNA.

**linseed rust** *Syn.* FLAX RUST.

**lipase** (triacylglycerol acylhydrolase; EC 3.1.1.3) A type of enzyme (see ENZYMES) which hydrolyses glycerides to free fatty acids and (ultimately) glycerol. Non-specific lipases release fatty acids from all three positions of the glycerol moiety of a triglyceride – 1,2(2,3)-diglycerides, 1,3-diglycerides and monoglycerides being formed as intermediates. Other lipases release fatty acids only from the outer (1 and 3) positions of the

glycerol moiety. Lipases function well at the interface between their hydrophobic substrates and the aqueous phase, and can act on triglycerides in micelles or emulsions.

Microbial lipases have some commercial applications. They are used e.g. in digestive aids, in the manufacture of certain cheeses (to improve or accelerate the development of flavour and aroma) and in INTERESTERIFICATION.

*Tests* for bacterial lipase production: (a) growth on EGG-YOLK AGAR; (b) TWEEN HYDROLYSIS; (c) inoculation onto a nutrient agar medium containing a fat (or e.g. corn oil) and NILE BLUE (lipase-producing colonies have a blue halo). A given lipase may not react positively in all tests. (See also FILM AND SPOTS.)

**lipid A** See LIPOPOLYSACCHARIDE.

**lipid A-associated protein** See ENDOTOXIN.

**lipid cyst** See METHYLOCOCCACEAE.

**lipid stain** See e.g. BURDON'S STAIN.

**lipid X** See LIPOPOLYSACCHARIDE.

**lipoproteins** See BACTERIAL CYTOPLASMIC MEMBRANE.

**lipofection** Lipid-aided insertion of nucleic acid into mammalian (and other) cells; uptake is promoted when (e.g.) DNA forms LIPOSOMES with mixed cationic and neutral lipids.

**lipid acid** ( $\alpha$ -lipoic acid; thioctic acid) A coenzyme which is involved in the oxidative decarboxylation of keto-acids: e.g. pyruvate and 2-oxoglutarate are decarboxylated to acetyl-CoA and succinyl-CoA, respectively [see Appendix II(a)]. (See also THIAMINE.) The oxidized form of the coenzyme contains a disulphide bond (–S–S–) which can be reduced to form two –SH groups, the reduced coenzyme (dihydrolipoic acid) being 6,8-dithiooctanoic acid:  $\text{CH}_2\text{SH}.\text{CH}_2.\text{CHSH}.\text{(CH}_2\text{)}_4.\text{COOH}$ .

Lipoic acid is required as a growth factor e.g. by *Tetrahymena* spp; it can replace acetate as a growth factor for e.g. *Lactobacillus casei*.

(See also ARSENIC.)

**Lipomyces** A genus of yeasts (family SACCHAROMYCETACEAE). Cells are spherical or ovoid; vegetative reproduction occurs by multilateral budding or by bud-fission. In most species the cells are each surrounded by a thick mucoid capsule which often contains a starch-like polysaccharide. Cells accumulate lipid, and those from older cultures usually contain one or more lipid globules. Asci typically develop from 'active buds'; an active bud resembles a vegetative bud but develops into an ascus – either following conjugation between the active bud and a protuberance on another cell (or the same cell), or in the absence of conjugation. The mother cell of the active bud may also become an ascus. Ascospores are ellipsoidal or oblong-ellipsoidal, light amber to brown, smooth, or e.g. rough with longitudinal ridges, 2–20 or more per ascus (depending on species). [Ascospore morphology and ultrastructure: IJSB (1984) 34 80–86.] The organisms are non-fermentative and do not assimilate  $\text{NO}_3^-$ . Species (*L. anomalus*, *L. kononenkoae*, *L. lipofer*, *L. starkeyi*, *L. tetrasporus*) have been isolated from soil. [Book ref. 100, pp. 252–262.]

**lipio-oligosaccharide (LOS)** In certain Gram-negative bacteria (e.g. *Neisseria meningitidis*): a (normal) component of the OUTER MEMBRANE which is anatomically equivalent to LIPOPOLYSACCHARIDE (q.v.) but in which the O-specific chains are shorter than those (for example) in the enterobacteria [CRM (1998) 24 281–334].

**lipopolysaccharide (LPS)** Strictly: any lipid-containing polysaccharide; however, the term 'lipopolysaccharide' is commonly used to refer specifically to the endotoxic component of the OUTER MEMBRANE in Gram-negative bacteria. Outer membrane LPS is a complex molecule consisting of three covalently linked

## lipopolysaccharide-binding protein

LIPOLYOSACCHARIDE. General structure of the core oligosaccharide in *Salmonella typhimurium*; the structure is somewhat variable, and possible sites of variation are indicated by parenthesis. Glc = D-glucose; Gal = D-galactose; Hep = 'heptose' (L-glycero-D-mannoheptose); KDO = 3-deoxy-D-manno-octulosonate; GlcNAc = N-acetyl-D-glucosamine; PEtN = phosphorylethanolamine; PPEtN = pyrophosphorylethanolamine; P = phosphate. [Data from e.g. Book ref. 138, pp. 157–207.]

regions: lipid A–core oligosaccharide–O-specific chain. (cf. SMOOTH–ROUGH VARIATION.)

*Lipid A* is a glycolipid which is largely responsible for the endotoxic activity of LPS (see ENDOTOXIN sense 1) and for the ability of LPS to act as a POLYCLONAL ACTIVATOR. In enterobacteria, it consists of a substituted  $\beta$ -linked glucosamine disaccharide – usually (1  $\rightarrow$  6)-linked, but apparently (1  $\rightarrow$  4)-linked e.g. in strains of *Escherichia coli*; the disaccharide is fully substituted with a number of long-chain (e.g. C<sub>12–16</sub>) saturated fatty acids (including 3-hydroxyacids, usually 3-hydroxymyristic acid), phosphate, and the core oligosaccharide (linked to the C-6 position of the non-reducing glucosamine residue). In many enterobacteria the hydroxy fatty acids are 3-O-acylated to form characteristic 3-myristoxymyristic acid residues. Variations in the structure of lipid A occur in other bacteria: e.g., in certain photosynthetic bacteria the glucosamine disaccharide is replaced by a diaminohexose monomer (e.g. 2,3-diamino-2,3-dideoxyglucose in *Rhodospseudomonas viridis*) [LPS in photosynthetic bacteria: ARM (1979) 33 215–239]; 3-hydroxymyristic acid is absent e.g. in *Brucella* strains; 2-hydroxy fatty acids are present e.g. in *Pseudomonas aeruginosa* strains.

*Core oligosaccharide* is a complex oligosaccharide usually linked to lipid A via '2-keto-3-deoxyoctonate', KDO (= 3-deoxy-D-manno-octulosonate). In enterobacteria (e.g. *S. typhimurium* – see figure) cores appear to contain a KDO dimer. *E. coli* K12 strains appear to have cores similar to that of *S. typhimurium*, while B strains have cores containing only glucose, heptose, and KDO. In *P. aeruginosa* the core contains glucose, heptose, KDO, rhamnose, galactosamine and alanine. Certain bacteria (e.g. strains of *Bacteroides*) appear to lack both KDO and heptose.

*O-specific chain* (O side chain) is the immunodominant part of the LPS molecule in the intact bacterial cell. It consists of a variable-length chain of identical (linear or branched) oligosaccharide subunits; the number of subunits may vary even in the same cell. In *Salmonella* serotypes each oligosaccharide subunit typically contains 3, 4 or 5 monosaccharide residues (including hexoses, pentoses, 6-deoxyhexoses, and 2,6-dideoxyhexoses). The O-specific chains determine the specificity of the O ANTIGENS of a given serotype, antigenic specificity being determined by the presence of a particular sugar (see e.g. ABEQUOSE, COLITOSE, PARATOSE, or TYVELOSE), by the positions of glycosidic bonds (e.g. 1  $\rightarrow$  4 or 1  $\rightarrow$  6 linkages), by the anomeric configuration ( $\alpha$  or  $\beta$ ) of the glycosidic linkages, by substituents (e.g. acetyl groups) on sugar residues, etc.

LPS appears to be bound in the outer membrane by hydrophobic bonds and by divalent cations. (Early reports of pyrophosphate bridges between lipid A moieties appear to have received

little experimental support.) A proportion of the LPS can be released from enterobacteria by treatment of cells with EDTA. LPS can be extracted from cells with a phenol–water mixture (ca. 45% w/v phenol in water); an LPS–protein complex (the Boivin antigen) can be extracted by treatment of cells with trichloroacetic acid (TCA). (See also LIMULUS AMOEBOCYTE LYSATE TEST.)

*Biosynthesis of LPS.* (Most of the studies on LPS biosynthesis have been carried out with *S. typhimurium*.) LPS is assembled at the cytoplasmic membrane, and completed LPS molecules are subsequently transferred to the outer membrane – apparently at a limited number of sites which may correspond to ADHESION SITES. Lipid A is built up from glucose 1-phosphate via monosaccharide intermediates such as 2,3-diacetylglucosamine 1-phosphate ('lipid X') [JBC (1985) 260 15536–15541] and variously substituted glucosamine disaccharide derivatives. [For lipid A biosynthesis see e.g. TIM (1998) 6 154–159.] In *S. typhimurium*, the core oligosaccharide is synthesized on the lipid A precursor by the sequential addition of KDO (from a CMP precursor) and other sugars (mostly from UDP precursors, although the nature of the heptose precursor is unknown). The oligosaccharide subunits of the O-specific chains are synthesized on BACTOPRENOL carrier molecules by the sequential addition of sugars from nucleotide precursors (presumably) at the inner face of the cytoplasmic membrane; the bactoprenol–oligosaccharide complex is presumed to be translocated across the cytoplasmic membrane, where the subunits are polymerized on the core oligosaccharide of an incomplete LPS molecule. (Bactoprenol pyrophosphate is released and is dephosphorylated by a specific phosphatase, the monophosphate derivative returning to the inner face of the cytoplasmic membrane for another round of synthesis.) Branches on the O-specific chains may be added before or after polymerization: e.g., in *S. typhimurium* the abequose residue is added to the bactoprenol-linked oligosaccharide, whereas in *S. minneapolis* and other serogroup E<sub>3</sub> (O<sub>3</sub>, 15, 34) salmonellae various residues in the O-specific chains are glucosylated after polymerization.

Inhibition of lipid A biosynthesis is a property of the compound L-573,655; this agent inhibits the enzyme deacetylase (product of the *lpxC* gene) that plays an essential role in the biosynthesis of lipid A [see e.g. Science (1996) 274 980–982].

The antibiotic BACITRACIN inhibits polymerization of the O-specific chain.

[Reviews: CTMT (1982) 17 79–151; Book ref. 92; LPS nomenclature: JB (1986) 166 699–705.]

**lipopolysaccharide-binding protein** See CD14.

**lipoprotein signal peptidase** See SIGNAL HYPOTHESIS.

**liposan** A bioemulsifier (see BIOSURFACTANTS) produced by *Candida lipolytica* when growing e.g. on hexadecane [AEM (1985) 50 965–970].

**liposarcoma** See SARCOMA.

**liposome** An artificial phospholipid vesicle. Liposomes have many uses in biology. For example, various components of biological membranes (e.g. PORINS, viral ENVELOPE proteins) can be incorporated into liposomes, allowing investigation of their properties under controlled conditions. Enzymes can be immobilized (see IMMOBILIZATION) by encapsulation within liposomes. Certain drugs may be encapsulated within liposomes e.g. to protect them from metabolic degradation and/or to prevent them from exerting general toxicity when delivered into the bloodstream; the liposomes fuse with or are endocytosed by cells of the reticuloendothelial system, where they release their contents. [Potential of liposome-mediated antiviral therapy: Antiviral Res. (1985) 5 179–190.] Drug-loaded liposomes can be ‘targeted’ to specific cells by the incorporation of antibodies to antigens in the target cell surface; thus, e.g., ‘immunoliposomes’ incorporating a monoclonal antibody to herpes simplex virus glycoprotein D were found to bind specifically to HSV-infected rabbit corneal cells in vitro [J. Imm. (1986) 136 681–685].

**liposome swelling assay** A method for determining the rate of diffusion of ions or molecules through PORIN channels; purified porins are incorporated into LIPOSOMES, and the rate of influx of specified ions or molecules is estimated from the effects of the (osmotically-induced) influx of water. [Method: JB (1983) 153 241–252.]

**lipoteichoic acid** See TEICHOIC ACIDS.

**Lipschütz body** An intranuclear inclusion body formed (late in infection) in cells infected with e.g. herpes simplex virus type 1 or 2.

**lirella** (lirelliform apothecium) (*lichenol.*) A slit-like (long, narrow) apothecium; lirellae may appear as black branched or unbranched lines with (in *Graphis* spp) or without (in *Opegrapha* spp) raised margins.

**lirelliform apothecium** *Syn.* LIRELLA.

**lissamine rhodamine** (acid rhodamine B; also: sulphorhodamine B) A red FLUOROCHROME (fluorescence: orange-red) used for labelling proteins; it is initially treated with phosphorus pentachloride and acetone to form the highly reactive sulphonyl chloride derivative, and protein–dye conjugation is then effected by a sulphamido condensation.

**Listeria** A genus of Gram-positive, asporogenous, aerobic/facultatively anaerobic bacteria. Cells: rods or coccobacilli (ca.  $0.5 \times 0.5$ – $2 \mu\text{m}$ ), occurring singly or in small groups (‘Chinese letter’ arrangements), palisades or filaments. Optimum temperature range: 25–37°C; growth occurs slowly at 4°C. Most strains catalase +ve. Oxidase –ve. Indole –ve. Aesculin is hydrolysed. Sugars are fermented to acid (no gas). Generally motile. Colonies of *L. monocytogenes*: grey, translucent, about 1 mm in diameter after 24–48 hours; a characteristic bluish colour in obliquely transmitted light. *L. monocytogenes* may give clear haemolysis on e.g. horse- and/or sheep-blood agar.

*Listeria* spp occur (apparently as saprotrophs) e.g. in soil, decaying plant matter, silage, etc., and have been isolated from e.g. faeces of healthy humans and animals; some haemolytic strains of *Listeria* can be pathogenic in man and also in animals (see LISTERIOSIS and MENINGITIS). [Wild birds and silage as reservoirs of *Listeria* in the agricultural environment: JAB (1985) 59 537–543.] [The pathogenicity of *L. monocytogenes* (a public health perspective): RMM (1997) 8 1–14.]

Some (human) infections with *L. monocytogenes* have been linked to the ingestion of certain types of cheese. One approach to the control of *L. monocytogenes* in cheese (during manufacture) involves the use of specific types of starter culture [see e.g. AEM (1998) 64 4842–4845; JAM (1999) 86 251–256].

Studies of e.g. DNA relatedness among strains of *L. monocytogenes* sensu lato have established five distinct ‘genomic groups’, each of which has been given a species designation. Group 1 contains the type strain of *L. monocytogenes* and related strains, and corresponds to *L. monocytogenes* sensu stricto. Group 2 (*L. monocytogenes* serovar 5) has been named *L. ivanovii* [IJSB (1984) 34 336–337]. Group 3 (now *L. innocua*) includes non-haemolytic, non-pathogenic strains. Groups 4 and 5 (now *L. welshimeri* and *L. seeligeri*, respectively [IJSB (1983) 33 866–869]) also include strains which are (apparently) non-pathogenic.

*L. grayi* and *L. murrayi* have been retained in the genus [IJSB (1987) 37 298–300]; *L. denitrificans* is now in *Jonesia* [IJSB (1987) 37 266–270]. [Taxonomy of *Listeria*: IJSB (1991) 41 59–64, (1993) 43 26–31.]

[Typing of *L. monocytogenes* by repetitive element sequence-based PCR: JCM (1999) 37 103–109.]

[Culture etc: Book ref. 46, pp. 1680–1687.]

**listeriolysin** See THIOL-ACTIVATED CYTOLYSINS.

**listeriosis** Any disease of man or animals caused by *Listeria monocytogenes*.

In man, the groups commonly affected are pregnant women (particularly during the third trimester), infants, immunosuppressed adults and the elderly. In pregnant women, the disease may involve e.g. fever, chills, backache and flu-like symptoms; while the mother herself is usually not severely affected, intrauterine infection may lead to premature birth, stillbirth or abortion. (Note that *L. monocytogenes* is one of the few bacterial pathogens which can cross the blood–brain barrier and the placenta.) Early-onset neonatal disease (i.e. within ~2 days) may be largely ‘septicaemic’, with disseminated infection, cardiopulmonary and CNS problems; mortality may be ~50–60%. Late-onset neonatal disease (starting after ~5–6 days) typically involves meningitis; compared with early-onset disease, mortality is somewhat lower. In adults, the common manifestations are CNS involvement, septicaemia and endocarditis.

*L. monocytogenes* can invade intestinal epithelium, invasion being promoted by the bacterial cell-surface INVASIN *internalin A* (encoded by gene *inlA*); the eukaryotic cell-surface receptor for internalin A is a CADHERIN (E-cadherin) which occurs on basolateral surfaces of epithelial cells. Interaction between internalin A and E-cadherin apparently initiates uptake of the bacterium by the host cell. (Interestingly, even latex beads coated with internalin A are internalized by some types of mammalian cell [Inf. Immun. (1997) 65 5309–5319].) Invasion (uptake of the pathogen) resembles the ‘zipper’ mechanism involved in the uptake of *Yersinia enterocolitica* (see *Y. enterocolitica* under FOOD POISONING). *L. monocytogenes* escapes from the phagosome by secreting a pore-forming toxin, *listeriolysin O* (a THIOL-ACTIVATED CYTOLYSIN). Once free in the host cell’s cytoplasm, the pathogen grows and spreads to adjacent cells by *actin-based motility* (as described for *Shigella dysenteriae* in DYSENTERY); in *L. monocytogenes*, the ActA protein plays the same role as IcsA in *Shigella*. When propelled into an adjacent cell, the pathogen becomes enclosed by a double membrane (one membrane from each cell); escape (into the cytoplasm of the adjacent cell) involves secretion of the enzyme *lecithinase* (encoded by gene *plcB*) – which hydrolyses the lecithin content of the double membrane. [Invasion and actin-based motility: EMBO (1998) 17 3797–3806. Internalin–E-cadherin complex (structure): Cell (2002) 111 825–836. Pathogenicity of *L. monocytogenes* (review): RMM (1997) 8 1–14.]

Infection appears to occur primarily via food; foods which have been implicated include e.g. Mexican-style cheese, certain

## Listonella

other cheeses, coleslaw and milk. However, risk assessment is problematic as isolates of *L. monocytogenes* vary widely in their pathogenic potential, and there is no simple test for pathogenicity. A DNA-based method has been used to type 64 isolates of *L. monocytogenes* from human, animal and food sources; the strains clustered primarily according to origin, and, on the basis of the results, it was suggested that only a small proportion of food-borne strains may be pathogenic for humans [JCM (1999) 37 103–109].

In animals, outbreaks may be associated with the consumption of incompletely fermented SILAGE (pH > 5.5); *L. monocytogenes* cannot multiply in properly made silage (pH 4–4.5). The disease may affect e.g. cattle, sheep and goats, and may lead to manifestations such as abortion. The disease is more common in temperate regions.

**Listonella** A genus of Gram-negative bacteria that includes the species *L. anguillarum*, *L. damsela* and *L. pelagia* (formerly *Vibrio anguillarum*, *V. damsela* and *V. pelagia*, respectively) [SAAM (1985) 6 171–182; validation of names: IJSB (1986) 36 354–356]. (See also PHOTOBACTERIUM.)

*L. anguillarum* is an important pathogen of freshwater and marine fish (causing e.g. disease in salmonids, and RED PEST in eels); it is also pathogenic for oyster larvae.

The organism is facultatively halophilic, capable of growing on nutrient agar with 0.5–6.0% NaCl, but not with 8% NaCl. Oxidase +ve. Sucrose (usually) +ve. [Agglutination typing of *Vibrio (Listonella) anguillarum*: AEM (1984) 47 1261–1265.]

**lithobiont** A SAXICOLOUS organism.

**lithocholic acid** See BILE ACIDS.

**Lithophyllum** See RHODOPHYTA.

**lithophyte** Refers to a SAXICOLOUS plant.

**lithotroph** An organism which uses an inorganic substance as substrate in energy metabolism. (cf. ORGANOTROPH; AUTOTROPH.) Among *chemolithotrophs* (see CHEMOTROPH) energy may be obtained by the oxidation of e.g. NH<sub>3</sub> (see NITRIFICATION), H<sub>2</sub> (see e.g. HYDROGEN-OXIDIZING BACTERIA, DISSIMILATORY SULPHATE REDUCTION), sulphur, sulphide and/or thiosulphate (see e.g. THIOBACILLUS), or Fe<sup>2+</sup> (e.g. in *Thiobacillus ferrooxidans*). *Photolithotrophs* use inorganic substrates (e.g. water, sulphur, sulphide, H<sub>2</sub>, or thiosulphate) as electron donors in PHOTOSYNTHESIS.

**litmus** A PH INDICATOR: pH 4.5–8.3 (red to blue); it is obtained from lichens (*Rocella* spp) and is a complex mixture of compounds.

**litmus milk** A bacteriological medium which consists of skim milk (whole MILK without cream) containing sufficient litmus solution to impart a blue-purple colour. Prior to use, the medium is either steamed (20/30 min on each of 3 successive days) or autoclaved (115°C/10 min), and the pH is adjusted to 7.

A given bacterial strain growing in litmus milk may give one of the following reactions. (a) No visible change in the medium. (b) Acid production from lactose (indicated by the LITMUS). (c) Alkali production – commonly due to hydrolysis of casein. (d) Reduction (decolorization) of the litmus. (e) The production of an *acid clot*; the clot, which is soluble in alkali, forms at about pH5 (at or near the IEPs of the various types of CASEIN). The production of acid and gas may give rise to a STORMY CLOT. (f) The formation of a clot at or near pH7. Such clots are formed by certain bacteria (e.g. *Bacillus* spp) which produce rennin-like proteases; the litmus may be reduced before or during clot formation, and peptonization (digestion of the clot) may subsequently occur. (See also MILK SPOILAGE.)

**little t antigen** (small t antigen) See POLYOMAVIRUS.

**littoral** A term used with different meanings by different authors; thus, the littoral region of the *marine* benthic zone is variously regarded as e.g. (a) the 'intertidal region', i.e., the zone which is uncovered at low tide and under water at high tide; (b) a zone below the average low-tide mark which is uncovered only occasionally; (c) that region between the high-tide mark and a depth of 200 metres. In *freshwater* environments the littoral region may refer to those parts of the benthic zone which occur in shallower waters of unspecified depth.

**LIV-I binding protein** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**live vaccine** Any VACCINE containing viable, usually attenuated, microorganisms (see e.g. BCG and STERNE STRAIN).

**liver of sulphur** See SULPHUR.

**liver-stage-antigen 1** See MALARIA.

**liverwort symbioses** See e.g. NOSTOC and MYCORRHIZA.

**lividomycin** Either of two AMINOGLYCOSIDE ANTIBIOTICS (lividomycins A, B), both of which may be regarded as derivatives of NEOMYCIN B.

**Lk** Linking number: see DNA.

**LkA** (of *Pasteurella haemolytica*) See RTX TOXINS.

**LMD** Culture Collection, Laboratory of Microbiology, Julianalaan 67A, 2628 BC Delft, The Netherlands.

**Imp genes** (EBV) See EPSTEIN-BARR VIRUS.

**LmrA** (*Lactococcus lactis*) See ABC TRANSPORTER.

**lobar pneumonia** See PNEUMONIA.

**Lobaria** A genus of foliose LICHENS (order PELTIGERALES). Photobiont: *Myrmecia* (in e.g. *L. pulmonaria*) or *Nostoc* (in e.g. *L. scrobiculata*); *Myrmecia*-containing species may have *Nostoc*-containing cephalodia – cephalodia being fruticose in *L. amplissima* (see CEPHALODIUM). Thallus: large (e.g. up to ca. 20 cm across), lobed, both surfaces corticate; the underside is usually more or less tomentose, often with glabrous patches, and in *L. linita* and *L. pulmonaria* the upper surface is coarsely reticulate. Soredia may be present in e.g. *L. pulmonaria* and *L. scrobiculata*. Apothecia: lecanorine, usually with reddish or brown discs, abundant (in e.g. *L. laetevirens*) or scarce. Found on rocks, bark etc, and generally very sensitive to air pollution.

**Loboa** A genus of fungi (? ENTOMOPHTHORALES). *L. lobo*i causes LOBOMYCOSIS and has not been cultured in vitro. In tissues, it occurs as spherical, thick-walled, hyaline, yeast-like cells (ca. 5–12 µm diam.) which reproduce by budding; sequential budding may lead to the formation of chains of cells.

**lobomycosis** (keloidal blastomycosis) A MYCOSIS, which apparently affects only man and dolphins, caused by *Loboa lobo*i; it occurs in Central and South America. Infection is presumed to occur via wounds; chronic, nodular, keloidal (elevated and scar-like) skin lesions develop chiefly (in man) on exposed areas of the body.

**lobopodium** See PSEUDOPODIUM.

**lobose pseudopodium** See PSEUDOPODIUM.

**Lobosea** A class of naked and testate amoebae (superclass RHIZOPODA) which form either lobopodia or filiform sub-pseudopodia from a broader hyaline lobe. The cells are typically uninucleate; the few multinucleate members do not form plasmodia. Fruiting structures do not occur, but many members can form resistant cysts. Orders: AMOEBIDA, ARCELLINIDA, PELOBIONTIDA, SCHIZOPYRENIDA, TRICHOSIDA.

**lobster diseases** See e.g. BURNED SPOT DISEASE and GAFFKAEMIA.

**local lesion** (*plant virol.*) A discrete lesion (e.g. a patch of chlorosis or necrosis, or a RINGSPOT) which develops as a result of localized viral infection in a leaf, stem etc. A plant which readily develops local lesions when infected with a given virus

may be used for assaying that virus, and is termed a *local lesion host* (= *assay host*); the number of infective virus particles present in a preparation can be assessed from the number of lesions produced when the leaves of a suitable local lesion host are inoculated with a known volume of the preparation. (See also PLANT VIRUSES.)

**Locke's solution** A solution of inorganic salts used e.g. as a liquid overlay for certain solid media. [Recipe: Book ref. 53, p. 2175.]

**lockjaw** *Syn.* TETANUS.

**locomotor fringe** *Syn.* TROCHAL BAND.

**locule** (loculus) A small chamber or cavity: see e.g. ASCOSTROMA and FORAMINIFERIDA.

**Loculoascmycetes** A class of ascomycetes characterized by the formation of bitunicate asci in ascostromata; the genera include e.g. *Elsinoë*, *Mycosphaerella*, *Myriangium* and *Venturia*. The class is not recognized in most modern taxonomic schemes.

**locus** (*genetics*) The position of a given gene, operon, mutation etc on a chromosome, plasmid, or other genetic molecule.

**locus of enterocyte effacement** See PATHOGENICITY ISLAND.

**Lodderomyces** A genus of yeasts (family SACCHAROMYCETACEAE). Cells are spheroidal, ellipsoidal, or cylindrical, and reproduce by multilateral budding; pseudomycelium may be formed. Asci are persistent. Ascospores: smooth, oblong to fusiform, 1 or 2 per ascus. One species, *L. elongisporus*, isolated e.g. from fruit juice and soil. [Book ref. 100, pp. 263–265.]

**lodging** (*plant pathol.*) The collapse of cereal plants due to bending or breaking of the stems; lodging may occur in certain diseases.

**Loeffler's methylene blue** See METHYLENE BLUE.

**Loeffler's serum** A solid medium, usually prepared as a slope, used e.g. for the culture of *Corynebacterium diphtheriae*. The medium contains sterile serum and nutrient broth (3:1 by volume) and glucose (ca. 0.25–0.5% w/v); this mixture may be coagulated by TYNDALLIZATION or, if precautions are taken to prevent foaming, by autoclaving.

**log dilutions** See SERIAL DILUTIONS.

**log phase** (of growth) See BATCH CULTURE.

**logarithmic phase** (of growth) See BATCH CULTURE.

**Lolium enation virus** See FIJIVIRUS.

**lomasomes** Membranous tubular, vesicular or sac-like structures which occur, generally between the cell wall and cytoplasmic membrane, in many fungi; they may be formed by invagination of the cytoplasmic membrane, and often contain particulate matter. The function of lomasomes is unknown; they have been implicated e.g. in cell wall synthesis.

**lon gene** In *Escherichia coli*, a gene which encodes an ATP-dependent protease that e.g. inactivates the SulA (= SfiA) protein (see SOS SYSTEM); the Lon protein is a HEAT-SHOCK PROTEIN.

**long-incubation hepatitis** *Syn.* HEPATITIS B.

**longitudinal binary fission** See BINARY FISSION.

**longus** A large plasmid-encoded fimbria\* (up to 20 µm in length) formed by strains of ETEC. The appendage consists of a repeated 22 kDa subunit, the N-terminal sequence of which shows some homology with that of the subunits of various type IV FIMBRIAE (including the TCP of *Vibrio cholerae* and 'bundle-forming pili' of EPEC). [Mol. Microbiol. (1994) 12 71–82. \*In this paper the appendage is referred to as a 'pilus'.]

**lonomycin** See MACROTETRALIDES.

**loop** An instrument widely used in bacteriology and mycology for the manipulation of small quantities of solid or liquid material – e.g. during INOCULATION; the rod-shaped metal handle holds a piece of platinum or nickel–steel wire (3–10 cm long)

formed into a closed loop at the free end. Before *and* after *each* use the loop and adjacent wire are sterilized by FLAMING and allowed to cool. In use, the sterile loop is brought into contact with e.g. a colony so that a small quantity of material adheres to it; this can then be used as an INOCULUM. If a sterile loop is dipped into e.g. a broth CULTURE and withdrawn, the loop retains a circular film of liquid (containing microorganisms) which can be used as an inoculum; the volume of liquid may be varied by using loops of different sizes. In use, no part of the loop *handle* should enter the culture vessel; loops with longer wires may be used e.g. for inoculating media in bottles. (See also STRAIGHT WIRE; STREAKING.)

**loop fermenter** A FERMENTER in which the culture is continually and efficiently circulated from the bottom of the column to the top – 'loop' referring to the circulatory nature of the flow. Most loop fermenters consist of a vertical cylindrical column containing a coaxial DRAFT TUBE (see e.g. AIRLIFT FERMENTER; JET LOOP FERMENTER; PROPELLER FERMENTER).

**loop model** (of proton translocation) A model, based on the concept of VECTORIAL GROUP TRANSLOCATION, which proposes that electrons travel in a loop within an energy-transducing membrane, starting and finishing at the same surface of the membrane, while protons pass to the opposite side of the membrane. In this model, the binding and release of protons at certain sites in an ELECTRON TRANSPORT CHAIN is seen as a direct consequence of the variation in pK of those sites due to their reduction or oxidation during electron flow.

**looping** (DNA) (transcriptional control) See OPERATOR.

**loose smut** See SMUTS (sense 2).

**LOPAT** Levan formation, oxidase reaction, potato rotting capacity, arginine dihydrolase production, and tobacco sensitivity: criteria which have been used for classifying plant-pathogenic fluorescent pseudomonads.

**lophine** See CHEMILUMINESCENCE.

**Lophomonas** See HYPERMASTIGIDA.

**lophotrichous** Of e.g. flagella: arranged as a tuft at one or both poles of a cell.

**Lordsdale virus** A SMALL ROUND STRUCTURED VIRUS.

**lorica** In certain eukaryotic microorganisms – including certain ciliates (e.g. TINTINNINA), choanoflagellates (see CHOANOFAGELLIDA), CHRYSTOPHYTES, and EUGLENOID FLAGELLATES: a vase-like or bottle-like, commonly mineralized, loose-fitting shell which partially or completely surrounds the cell. (cf. TEST.) Loricated organisms may be free-swimming (e.g. TRACHELOMONAS) or sedentary (e.g. DINOBRYON).

**loricate** Possessing a LORICA.

**LOS** LIPO-OLIGOSACCHARIDE.

**loss mutant** (loss variant) A variety of an organism which has lost one or more phenotypic traits as a result of mutation(s).

**lotic** Pertaining to aquatic habitats with running water (e.g. streams, rivers). (cf. LENTIC.)

**louping-ill** (ovine encephalomyelitis) An acute, sometimes fatal, usually tick-borne encephalomyelitis which affects mainly sheep; the causal agent is a flavivirus (see FLAVIVIRIDAE), and the tick vector is probably always *Ixodes ricinus*. Incubation period: ca. 1–2 weeks; viraemia and fever are followed by e.g. leaping ('louping') movements and paralysis. Death may occur in ca. 1 week. The louping-ill virus can also cause a fatal infection in Red grouse (*Lagopus lagopus scoticus*). Infection of cattle may result in a disease similar to that in sheep. In man, the virus can cause a mild, febrile, influenza-like illness.

**low temperature disease** See COLD WATER DISEASE.

**low-temperature steam disinfection** A process in which e.g. blankets, endoscopes and other types of hospital equipment can

## low-temperature steam–formaldehyde sterilization

be disinfected by exposure to saturated steam below 100°C at subatmospheric pressure in an apparatus resembling a vacuum AUTOCLAVE. Essentially, the chamber – containing the load – is first evacuated to an absolute pressure of ca. 2 kPa or less; steam is then admitted to the chamber and held at a temperature of ca. 73–80°C for 10–15 min – the absolute pressure in the chamber being ca. 39–47 kPa; saturated steam at these temperatures disinfects more efficiently than does water at corresponding temperatures. The load is then dried under vacuum.

**low-temperature steam–formaldehyde sterilization (LTSFS)** A process which resembles the LOW-TEMPERATURE STEAM DISINFECTION process but which incorporates the use of FORMALDEHYDE. One of several possible schedules is as follows. The chamber is evacuated and formaldehyde is admitted; this step is carried out three times. Subsequently, formaldehyde, and then steam, are admitted to the chamber, and a temperature of ca. 73°C is maintained for two hours. The chamber is then evacuated, steam is admitted, and the chamber is again evacuated; this last evacuation removes traces of formaldehyde and steam and gives rise to a dry, odourless load. [Biological indicators for LTSFS: JAB (1985) 58 207–214.]

**low zone tolerance** See IMMUNOLOGICAL TOLERANCE.

**Löwenstein–Jensen medium** A complex solid medium used for isolating *Mycobacterium* spp from e.g. sputum. The medium is prepared by the INSPISSATION of a mixture of homogenized whole hens' eggs and a solution containing asparagine,  $\text{KH}_2\text{PO}_4$ ,  $\text{MgSO}_4$ , citrate, glycerol, potato starch, and malachite green; the pH is ca. 7.0. The medium is prepared (as slopes) in screw-cap bijoux or universal bottles. [Recipe: Book ref. 53, p. 1415.]

**lower fungi** Fungi of the MASTIGOMYCOTINA and the ZYGOMYCOTINA (collectively: the phycmycetes). For some authors 'lower fungi' includes the MYXOMYCOTA as well as the phycmycetes.

**lox site** See BACTERIOPHAGE P1.

**Loxocephalus** See SCUTICOCILIATIDA and PARATENY.

**Loxodes** A genus of freshwater ciliates (subclass GYMNOSTOMATIA) related to KENTROPHOROS. Cells: somewhat flattened, elliptical in outline, with a slit-like cytostome located in a subapical concavity (giving the anterior end of the cell a hook-like appearance). The cytoplasm contains MÜLLER'S VESICLES. [Photobehaviour of *Loxodes*: JP (1986) 33 139–145.]

**Loxophyllum** See GYMNOSTOMATIA.

**LP system** LACTOPEROXIDASE–THIOCYANATE–HYDROGEN PEROXIDE SYSTEM.

**lpp gene** In *Escherichia coli*: the gene which encodes the BRAUN LIPOPROTEIN. (See also MRNA (a).)

**LPP group** A category of filamentous CYANOBACTERIA (section III) which includes the poorly defined genera LYNGBYA, PHORMIDIUM and PLECTONEMA, as well as MICROCOLEUS and *Schizothrix*. In LPP group A the trichomes are straight, sheathed and non-motile, and are composed of disc-shaped cells; motile hormogonia are produced. In LPP group B the trichomes are straight, sheathed or non-sheathed, motile or non-motile, and are composed of isodiametric or cylindrical cells. GC% for the group: 42–67. Species occur in freshwater and marine habitats. (See also STROMATOLITE and EMULCYAN.)

**LPS** (1) LIPOPOLYSACCHARIDE. (2) LACTOPEROXIDASE–THIOCYANATE–HYDROGEN PEROXIDE SYSTEM.

**lpxC gene** See ZINC and LIPOPOLYSACCHARIDE.

**Lrp** In *Escherichia coli*: leucine-responsive regulator protein, a homodimeric protein involved in the regulation of a range of genes/operons – apparently by acting as an activator or (in some cases) repressor of transcription; the activity of Lrp is inhibited

by exogenous leucine. Lrp is reported to be one of several factors which regulate expression of  $E\sigma^{70}$  (see SIGMA FACTOR).

[Lrp: JBC (2002) 277 40309–40323.]

**LS binding protein** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**LSD** See ERGOT ALKALOIDS.

**LT** See ETEC.

**LTA** LipOTEICHOIC ACID.

**LTH** See PASTEURIZATION.

**LTLT** See PASTEURIZATION.

**LTR** Long terminal repeat: see RETROVIRIDAE.

**LuIII virus** See PARVOVIRUS.

**lubimin** A sesquiterpenoid PHYTOALEXIN produced by the potato plant (*Solanum tuberosum*).

**lucerne enation virus** See RHABDOVIRIDAE.

**lucerne transient streak virus (LTSV)** See VELVET TOBACCO MOTTLE VIRUS and VIRUSOID.

**Lucibacterium** An obsolete bacterial genus; *L. harveyi* is now *Vibrio harveyi* (see VIBRIO).

**luciferase** See BIOLUMINESCENCE.

**luciferin** See BIOLUMINESCENCE.

**lucigenin** See CHEMILUMINESCENCE.

**Lucio phenomenon** See LEPROSY.

**Lucké virus** See HERPESVIRIDAE.

**Ludwig's angina** An inflammatory, purulent condition of tissues around the submaxillary gland due to infection by oral bacteria – usually streptococci.

**luer fitting** A type of joint between tubular parts of two items of apparatus: one part is tapered and fits coaxially into the other (correspondingly flared) part, forming a rigid, airtight joint.

**Lugol's iodine** Iodine (5% w/v) and potassium iodide (10% w/v) in distilled water. Diluted Lugol's iodine is used e.g. in the GRAM STAIN, and as a stain for starch granules, cysts of *Entamoeba histolytica*, etc.

**lumber spoilage** See TIMBER SPOILAGE.

**lumicolchicine** See COLCHICINE.

**luminescence** See CHEMILUMINESCENCE and BIOLUMINESCENCE.

**luminol** The compound 5-amino-2,3-dihydro-1,4-phthalazinedione which emits light when exposed to unstable oxygen species (e.g.  $\text{O}_2^-$ ,  $\text{H}_2\text{O}_2$ ,  $\text{OH}\cdot$ ); it is used e.g. as a probe ('chemiluminescent probe') in studies on CHEMILUMINESCENCE – luminol either acting as the sole light emitter or supplementing natural light emitter(s).

**Lumi-Phos 530** A dioxetane substrate (Lumigen, Detroit, USA) which yields chemiluminescence when cleaved by alkaline phosphatase.

**lumper** See TAXONOMY.

**lumpy jaw** See ACTINOMYCOSIS (1).

**lumpy skin disease** Either of two infectious diseases of cattle characterized by the sudden development of flattened, firm, intradermal nodules (up to ca. 4 cm in diameter), regional or generalized lymphadenitis, oedema and dysgalactia; lesions may also occur on the nasal and buccal mucosae. The more severe of the two diseases (*knopvelsiekte*, found in various parts of Africa) is caused by the 'Neethling virus' – a *Capripoxvirus* [genome: JV (2001) 75 7122–7130], while the milder disease (*pseudolumpy skin disease*) is caused by a member of the Alphaherpesvirinae apparently identical to bovine mammillitis virus; these diseases may be transmitted by insect vectors. (cf. ALLERTON DISEASE.)

**lumpy wool** ('mycotic dermatitis') A SHEEP DISEASE, caused by *Dermatophilus congolensis*, characterized by skin lesions and matting of the wool. Infection appears to occur via minor

abrasions or other lesions – particularly when the skin is wet or damp. (cf. DERMATOPHILOSIS.)

**lunar caustic** See SILVER.

**lunate** Crescent-shaped.

**Lundegårdh-type respiration** A type of respiration in which electrons, derived from the substrate, are translocated across a membrane [Arkiv för Botanik (Stockholm) (1945) 32A (No. 12) 1–139 (23–49)]. (cf. EXTRACITOPLASMIC OXIDATION.)

**lung oedema factor** (*vet.*) See 4-IPOMEANOL.

**lupinosis** (*vet.*) A MYCOTOXICOSIS, involving liver damage with jaundice, caused by ingestion of lupin plants (*Lupinus* spp) infected with (or supporting the saprotrophic growth of) *Phomopsis leptostromiformis*. The disease occurs mainly in sheep; other animals (e.g. cattle) may be affected but are less commonly fed lupins. Lupinosis may follow consumption of living plants or lupin hay, and either sweet or bitter lupin cultivars may be involved; the condition is distinct from 'lupin poisoning' caused by alkaloids present in bitter cultivars. In lupins (especially *L. luteus*), *P. leptostromiformis* causes 'stem blight' ('stem spot'), a disease characterized by brownish, sunken, linear lesions on the stem, circular lesions on the pods, and brownish discolorations on the seeds. The fungus can grow saprotrophically on dead lupin plant material and on mature living plants.

**Luria–Bertani broth** A medium containing (per litre): 10 g tryptone, 5 g yeast extract and 10 g (or 5 g) of sodium chloride (NaCl); the pH is adjusted to 7.5 (or 7) with sodium hydroxide (NaOH). (The alternative values indicate variation in different sources of information.)

**Luria–Delbrück fluctuation test** See FLUCTUATION TEST.

**luteic acid** A water-soluble, acidic, extracellular, (1 → 6)-β-linked glucan containing malonic acid residues; it is produced by '*Penicillium luteum*'.

**lutein** See CAROTENOIDS.

**luteose** A β-(1 → 6)-linked glucan produced by '*Penicillium luteum*'.

**luteoskyrin** See YELLOW RICE.

**luteoviruses** (barley yellow dwarf virus group) A group of PLANT VIRUSES in which the virions are icosahedral (ca. 25–30 nm diam.), each containing a single molecule of linear, positive-sense ssRNA (MWt. ca.  $2 \times 10^6$ ). Luteoviruses can infect various monocotyledonous and/or dicotyledonous plants, and many can cause important economic losses in crop plants; transmission occurs persistently (circulatively) via aphids, and weeds may provide important reservoirs of infection. Virus replication is confined to the phloem tissues of the host plant. Symptoms of infection typically include severe stunting with yellowing or reddening of the leaves (which may also become brittle); the severity of the symptoms depends on the virus, species and cultivar of host plant, and environmental conditions. Type member: barley yellow dwarf virus (BYDV), MAV isolate. Other members include e.g. beet mild yellowing virus, beet western yellows virus (BWYV), carrot red leaf virus, legume yellows virus, pea leaf roll virus, potato leaf roll virus, soybean dwarf virus, subterranean clover red leaf virus, tobacco necrotic dwarf virus, turnip yellows virus. Probable members: milk-vetch dwarf virus, subterranean clover stunt virus, and tomato yellow top virus. Possible members include e.g. banana bunchy top virus, beet yellow net virus, celery yellow spot virus, cotton anthocyanosis virus, millet red leaf virus, raspberry leaf curl virus, tobacco vein distorting virus, tobacco yellow net virus, tomato yellow net virus.

**lux operon** See BIOLUMINESCENCE.

**luxS gene** See QUORUM SENSING.

**LV agar** See EGG-YOLK AGAR.

**lyases** ENZYMES (EC class 4) which catalyse either the non-hydrolytic removal of a group from a substrate with the resulting (sometimes transient) formation of a double bond, or the reverse reaction; when the reverse reaction is the more significant (physiologically) the enzyme is often called a SYNTHASE. Subclasses are recognized on the basis of the nature of the bond split: e.g., C–C, C–O or C–N. Lyases include e.g. decarboxylases, aldolases and dehydratases. (See e.g. HYALURONATE LYASE and PECTIC ENZYMES.)

**Lyb antigens** In mice: antigens which occur on certain mature B lymphocytes. Lyb 5<sup>+</sup> cells can respond to polyclonal B cell activators (e.g. LPS) and also to soluble polysaccharide antigens (e.g. certain bacterial capsular antigens); Lyb 5<sup>-</sup> cells can respond to polyclonal B cell activators but not to soluble polysaccharides.

**Lycogala** A genus of slime moulds (class MYXOMYCETES) in which the fruiting bodies are aethalia. *L. epidendrum* – a common species on rotting logs – forms clusters of hemispherical, puff-ball-like, pink to yellowish-brown aethalia, each ca. 0.3–1.5 cm diam.

**lycomarasmin** A TOXIN produced by certain strains of *Fusarium oxysporum* (e.g. some strains of *F. oxysporum* f. sp. *lycopersici*, the causal agent of FUSARIUM WILT in tomatoes). It chelates metal ions, and at high concentrations can cause wilting in plants; however, its role in pathogenesis – if any – is unknown.

**lycopenene** See CAROTENOIDS.

**Lycoperdales** An order of fungi (class GASTEROMYCETES) in which the basidiocarp consists of highly convoluted, hymenium-bearing fertile tissue enclosed by a peridium composed of two or more layers; the organisms are characteristically humicolous or lignicolous saprotrophs.

The so-called 'earth stars' (e.g. *Geastrum*) form globose or onion-shaped basidiocarps ca. 2–10 cm in diameter. When the basidiocarp is mature, the *exoperidium* (the outer layer(s) of the peridium) ruptures and peels back to form a stellate fringe; in *Geastrum*, an apical pore develops in the remaining peridium (*endoperidium*) to permit spore release. (In *Myriostoma coliformis* many pores develop in the endoperidium.)

The (non-stipitate) 'puffballs' include species of *Bovista*, *Calvatia* and *Lycoperdon*. In *Calvatia* spore release depends on peridial rupture and disintegration; *C. gigantea* (the giant puffball) may reach ca. 1 metre across. In *Lycoperdon* the spores are released via a pore which develops in the peridium.

**Lycoperdon** See LYCOPERDALES.

**lycoperdon nut** A hypogean fruiting body of a member of the Elaphomycetales.

**Lyell's syndrome** *Syn.* SCALDED SKIN SYNDROME.

**Lyme disease** (Lyme borreliosis) A disease of humans (and e.g. canines [VR (1995) 136 244–247]) caused by *Borrelia burgdorferi* (see BORRELIA) and transmitted by the bite of (mainly ixodid) ticks.

*Symptoms* (in humans): typically, an initial rash (*erythema migrans*, EM) spreading from the tick bite, followed (after days/weeks) by neurological/musculoskeletal/cardiac signs and, later, joint/neurological/skin symptoms; symptoms vary in both nature and timing.

*Diagnosis*: mainly serological (ELISA) (seroconversion after ~4 weeks); detection of spirochaetes e.g. by culture or PCR examination of blood.

*Chemotherapy*: e.g. ampicillin (during EM), ceftriaxone (for arthritis, cardiac infection). Failure of chemotherapy may be due to inaccessibility to antibiotics of intracellular spirochaetes [see e.g. AAC (1996) 40 1552–1554].

## lymphadenitis

[Review: RMM (1998) 9 99–107; quantitative assay of *B. burgdorferi* in tissues: JCM (1999) 37 1958–1963; treatment of early Lyme disease (review): Drugs (1999) 57 157–173.]

**lymphadenitis** Inflammation of lymph node(s).

**lymphadenopathy** A pathological condition of lymph node(s).

**lymphadenopathy-associated virus** See AIDS.

**lymphadenopathy syndrome** See AIDS.

**lymphangitis** Inflammation of lymph vessel(s).

**lymphatic leukosis viruses** See AVIAN LEUKOSIS VIRUSES.

**Lymphocryptovirus** See GAMMAHERPESVIRINAE.

**lymphocystitis** A FISH DISEASE affecting higher freshwater and marine teleosts. Small, benign, whitish, tumour-like nodules or clusters of nodules develop on skin and fins; the nodules contain greatly hypertrophied cells (to 1 mm diam.) rich in DNA. The fish seems to be little harmed. The causal agent is a virus of the genus *Lymphocystivirus* (family IRIDOVIRIDAE).

**Lymphocystivirus** A genus of viruses (family IRIDOVIRIDAE) which infect fish; the genus includes the causal agent of LYMPHOCYSTIS.

**lymphocyte** A type of LEUCOCYTE found e.g. in blood, lymph and lymph nodes; lymphocytes are essential for humoral immunity (see ANTIBODY FORMATION) and for CELL-MEDIATED IMMUNITY. (See B LYMPHOCYTE and T LYMPHOCYTE.) Lymphocytes are roughly spherical (ca. 8–15 µm in diameter) with non-granular cytoplasm and a large, non-lobed, rounded nucleus which occupies much or most of the cell. Morphologically, B and T lymphocytes are identical; they can be distinguished e.g. by their cell-surface antigens (e.g. using immunofluorescence techniques). B and T lymphocytes can be separated e.g. by passing a mixed suspension through a column of glass beads coated with antiglobulin; the B cells are retained. B cells are less numerous than T cells in the bloodstream. (See also NK CELLS and NULL CELLS.)

**lymphocyte activating factor** See INTERLEUKIN-1.

**lymphocyte homing** See CD44 and CD102.

**lymphocytic choriomeningitis virus** See LCM VIRUS.

**lymphocytosis** The condition in which increased numbers of lymphocytes are present in the blood.

**lymphogranuloma venereum** A VENEREAL DISEASE caused by strains of *Chlamydia trachomatis*; symptoms typically include a lesion on the genitals, followed by inflammation and swelling of lymph nodes in the groin. *Chemotherapy*: e.g. tetracyclines or sulphonamides. (See also FREI TEST.)

**lymphoid leukosis** A POULTRY DISEASE caused by an avian type C oncovirus (see AVIAN LEUKOSIS VIRUSES); B cell lymphomas originate in the bursa of Fabricius and metastasize to other organs, including the liver ('big liver disease'), spleen, kidney, etc. Transmission occurs chiefly via the egg, although horizontal transmission can occur. Only a small proportion of the birds infected actually develop the disease. (cf. MAREK'S DISEASE.)

**lymphokines** The former name for a wide range of biologically active glyco(proteins), produced and secreted by lymphocytes and certain other cells, which are now called CYTOKINES. Among the agents regarded as lymphokines were: (i) B cell growth factors (BCGFs), a term which may refer e.g. to the cytokine now known as interleukin-14; (ii) B cell differentiation factors (BCDFs), which may have included e.g. interleukin-6; (iii) INTERFERONS; (iv) chemotactic factors (see also CHEMOKINES and MIF); (v) various factors that regulate haemopoiesis. [Early account of B cell growth and differentiation factors: Imm. Rev. (1984) 78.]

**lymphoma** Any tumour of lymphoid tissues, or one derived from lymphoid cells. Lymphomas may be classified e.g. on the

basis of the predominant cell type involved and on the degree of differentiation of the neoplastic tissue. (See also BURKITT'S LYMPHOMA, BOVINE VIRAL LEUKOSIS, MAREK'S DISEASE.)

**lymphomatosis** A condition in which multiple lymphomas are formed.

**lymphon** An individual's entire immune system, including e.g. lymphoid tissues, LYMPHOCYTES, MACROPHAGES, and the COMPLEMENT system.

**lymphopoiesis** The development of LYMPHOCYTES.

**lymphoproliferative virus group** See GAMMAHERPESVIRINAE.

**lymphosarcoma** See SARCOMA.

**lymphotactin** (chemokine) See CHEMOKINES.

**lymphotoxin α** *Syn.* Tumour necrosis factor-β (TNF-β).

**lymphotoxin β** A membrane-anchored glycoprotein related to, but distinct from, TNF-α and TNF-β.

**lymphotropic virus group** See GAMMAHERPESVIRINAE.

**lymphotropism** See TROPISM (sense 2).

**Lyngbya** A genus of freshwater and marine cyanobacteria of the LPP GROUP. *L. majuscula* is responsible for causing dermatitis in swimmers (*swimmers' itch*) e.g. in waters off the coasts of Hawaii and Japan; this species can produce several toxins, including the brominated phenolic *aplysiatoxin*, various derivatives of aplysiatoxin (e.g. *debromo-*, *bromo* and *dibromoaplysiatoxin* [structures: PAC (1986) 58 339–350 (345)]), the indole alkaloid *lyngbyatoxin A*, etc. (See also GEOSMIN and PHORMIDIUM.)

**lyngbyatoxin** See LYNGBYA.

**lyophilization** *Syn.* FREEZE-DRYING.

**lysate** The product of cell lysis.

**lysergic acid diethylamide** See ERGOT ALKALOIDS.

**lysigenous** (lysigenic) *Syn.* LYSOGENOUS.

**lysin** An antibody or other entity which, under appropriate conditions, can cause the lysis (rupture) of cells. See e.g. HAEMOLYSIN.

**lysine biosynthesis** See AMINOADIPIC ACID PATHWAY and DIAMINOPIMELIC ACID PATHWAY.

**lysine decarboxylase test** See DECARBOXYLASE TESTS.

**lysis from without** Lysis of a host cell when large numbers of virions adsorb to the host cell surface. (See e.g. T-EVEN PHAGES.)

**lysis inhibition** In certain bacteriophages (e.g. T-even phages, RNA phages): a delay in the lysis of an infected host cell on superinfection of the cell with another phage of the same strain. Mechanism: unknown. Lysis inhibition results in the formation of plaques which each have a turbid halo. (cf. RAPID LYSIS MUTANT.)

**lysis protein** (1) (*syn.* holin) A bacteriophage-encoded protein that forms a pore in the cytoplasmic membrane of an infected bacterium, thus enabling an ENDOLYSIN to gain access to the peptidoglycan. In bacteriophage λ, for example, a holin is encoded by gene *S*; this protein oligomerizes in the cytoplasmic membrane, forming lesions which apparently allow the *R* gene product to reach peptidoglycan [JB (1990) 172 912–921]. The requirement for the *S* gene product in bacteriophage λ apparently reflects the absence of a signal sequence (see SIGNAL HYPOTHESIS) on the peptidoglycan-degrading *R* gene product, i.e. the latter, by itself, could not cross the cytoplasmic membrane and therefore could not effect lysis. In phage T4 the product of the *t* gene appears to have the same role. In BACTERIOPHAGE φ29 (which infects Gram-positive bacteria), an analogous product is encoded by gene *I4* [JB (1993) 175 1038–1042].

In a phage-infected cell, a holin must be active only after normal phage assembly has been completed; if lysis occurred too early then fewer (or no) mature phages would be released

when the cell burst (i.e. the BURST SIZE would be affected). Such early lysis was reported with a strain of phage  $\lambda$  containing a mutant *S* gene [Mol. Microbiol. (1994) 13 495–504].

In some holin-encoding genes there are two start codons (separated by one or two codons), i.e. the gene encodes two polypeptides of slightly different length. The shorter product is the holin, while the longer polypeptide seems to be an inhibitor of holin activity; this arrangement may be a mechanism for controlling the timing of cell lysis [Mol. Microbiol. (1996) 21 675–682].

(2) The product of the 'lysis gene' in a colicin plasmid (see COLICINS).

(3) (*syn.* holin) A protein, product of the *tcdE* gene in *Clostridium difficile*, which appears to promote the release (across the cytoplasmic membrane) of toxin molecules (encoded by genes *tcdA* and *tcdB*) that lack a signal sequence [JMM (2001) 50 613–619].

**Lyso bacter** A genus of unicellular GLIDING BACTERIA; GC%: 65–68. [IJSB (1978) 28 367–393.]

**lysochrome** Any non-ionic coloured substance which *dissolves in* and thus imparts colour to the lipids of cells or tissues. (See e.g. SUDAN BLACK B and NILE BLUE A; cf. DYE.)

**lysogen** A lysogenic cell, or a population of lysogenic cells: see LYSOGENY.

**lysogenic** (1) See LYSOGENY. (2) *Syn.* LYSOGENOUS.

**lysogenic conversion** See BACTERIOPHAGE CONVERSION.

**lysogenic immunity** See SUPERINFECTION IMMUNITY.

**lysogenous** (lysogenic; lysigenous; lysigenic) Refers to a structure, cavity or aperture (e.g. in a fungal fruiting body) which is formed as a result of the breakdown of cells.

**lysogeny** The phenomenon in which the genome of a (temperate) BACTERIOPHAGE establishes a stable, non-lytic presence in its living host without producing progeny virions; the host cell (which is said to be *lysogenic*) can continue to grow and divide, and replication of the phage genome (the *prophage*) is coordinated with that of the host chromosome such that, at each cell division, the prophage is inherited by both daughter cells. The prophage is maintained either by integration into the host chromosome (as in the majority of temperate phages: see e.g. BACTERIOPHAGE  $\lambda$ , BACTERIOPHAGE MU and BACTERIOPHAGE  $\phi$ 105) or as an extrachromosomal plasmid (see e.g. BACTERIOPHAGE P1 and BACTERIOPHAGE F116). (cf. PROVIRUS.) The host cell may or may not exhibit an altered phenotype (see BACTERIOPHAGE CONVERSION).

A prophage normally retains the potential to initiate a lytic cycle in which progeny virions are produced and released by cell lysis; maintenance of the lysogenic state necessitates the repression of lytic functions in the prophage by means of phage-directed synthesis of a repressor protein (see e.g. BACTERIOPHAGE  $\lambda$ ). (See also SUPERINFECTION IMMUNITY.) Derepression – e.g. by inactivation of the repressor protein – results in *induction* of the lytic cycle; induction may occur spontaneously in a small proportion of cells in a lysogenic population. (See also ZYGOTIC INDUCTION.)

(See also PSEUDOLYSOGENY and TRANSDUCTION.)

**Lysol** See PHENOLS.

**lysopeptide** *Syn.* signal peptide: see SIGNAL HYPOTHESIS.

**lyso phagosome** See PHAGOCYTOSIS.

**lysopine** See CROWN GALL.

**lysosome** In eukaryotic cells (only): a closed, intracellular membranous sac (often ca. 0.5  $\mu$ m) containing a wide range of enzymes which, collectively, can degrade various classes of biological macromolecules; the enzymes typically have a pH

optimum of ca. 5.0. (The acidity within a lysosome is maintained by a PROTON ATPASE in the lysosome membrane.) [The lysosome membrane: TIBS (1986) 11 365–368.] Lysosomes develop from the distal end of the GOLGI APPARATUS; they are involved primarily in intracellular digestion: see AUTOLYSIN, FOOD VACUOLE, PHAGOCYTOSIS. A *primary* lysosome is one which has not yet coalesced with an autophagic or food vacuole or a phagosome; following such coalescence the whole is termed a *secondary* lysosome. When digestion is complete the entity remaining is termed a *residual body*.

Certain viruses (e.g. *Reovirus*) depend on lysosomal enzymes for uncoating.

Lysosomes may be damaged or disrupted e.g. by streptolysin O or phalloidin.

**lysostaphin** A 22-kDa BACTERIOCIN produced by *Staphylococcus simulans* (bv *staphylolyticus*) which is active against strains of *Staphylococcus aureus*. Lysostaphin is an endopeptidase which cleaves the glycyl–glycyl peptide bridges in staphylococcal PEPTIDOGLYCAN, causing lysis. Immunity to lysostaphin in the secreting organism is apparently due to modification of its own peptidoglycan by an enzyme encoded by the *lif* gene. Lysostaphin has been investigated for use in reducing numbers of staphylococci in the nose and throat of carriers and for the treatment of staphylococcal infections resistant to  $\beta$ -lactam antibiotics.

**lysozyme** (*N*-acetylmuramidase; endolysin; endo- $\beta$ -*N*-acetyluramide glycanhydrolase; EC 3.2.1.17) An enzyme which hydrolyses the *N*-acetylmuramyl-(1  $\rightarrow$  4)- $\beta$ -linkages in PEPTIDOGLYCAN; it can thus cause BACTERIOLYSIS in species whose peptidoglycan is accessible to enzyme action. (*Micrococcus luteus* – formerly *M. lysodeikticus* – is particularly susceptible and is used in lysozyme assays.) Lysozyme is widely distributed in nature. Animal lysozyme (MWt ca. 14500; IEP ca. 11) occurs e.g. in egg-white, milk, saliva, tears, mucosal secretions, macrophages etc (cf. NON-SPECIFIC IMMUNITY). Structurally distinct enzymes are produced by some bacteria and are coded for by certain bacteriophages (e.g. T2, T4,  $\lambda$ ). An extracellular lysozyme-like enzyme (endo- $\beta$ -*N*-acetylglucosaminidase, EC 3.4.99.17, which cleaves the glucosaminidyl-(1  $\rightarrow$  4)- $\beta$ -linkages in peptidoglycan) is produced by most coagulase-positive and some coagulase-negative staphylococci [Book ref. 44, pp. 746–748].

**lyssa** *Syn.* RABIES.

**Lyssavirus** (rabies virus group) A genus of viruses within the RHABDOVIRIDAE; type species: RABIES VIRUS. The rabies virus is neurotropic; the amino acid sequence of the virion glycoprotein has been shown to resemble that of certain snake venom curaremimetic neurotoxins which bind to acetylcholine receptors on nerve cells [Science (1984) 226 847–848]. The rabies virus can multiply in nearly all types of mammalian and avian cells in culture; it apparently replicates in the host cell cytoplasm, budding predominantly from intracytoplasmic membranes. Unlike VSV (see VESICULOVIRUS), it does not inhibit cellular macromolecule synthesis. (See also FIXED VIRUS; FLURY VIRUS; STREET VIRUS.)

The genus currently contains seven genotypes – all of which, except Lagos bat virus, are able to cause death in humans and/or animals in nature; the genotypes are:

1. Rabies virus
2. Lagos bat virus
3. Mokola virus
4. Duvenhage virus
5. European bat lyssavirus type 1

**lysU gene**

6. European bat lyssavirus type 2
7. Australian bat lyssavirus

The first four genotypes correspond to the four earlier serotypes. Lagos bat virus was isolated from a fruit bat. Duvenhage virus can cause a rabies-like disease in man. Mokola virus (isolated e.g. from shrews and cats) can cause CNS disease in man. Australian bat lyssavirus (reported in 1997) is infective for humans.

Kotonkan virus, isolated from *Culicoides* sp. may cause ephemeral febrile disease in animals and man. This virus, and the Obodhiang virus, isolated from *Mansonia uniformis*, have been associated with the genus *Lyssavirus* but have not been assigned to a genotype.

Phylogenetic analysis of the genus *Lyssavirus* has been able to distinguish two phylogroups: phylogroup I (rabies virus, European bat lyssavirus types 1 and 2, Duvenhage virus and the Australian bat lyssavirus), and phylogroup II (Lagos bat virus and Mokola virus); it is believed that this classification reflects more closely the biological characteristics of lyssaviruses than do the serotypes and genotypes [JV (2001) 75 3268–3276].

**lysU gene** See HEAT-SHOCK PROTEINS.

**Lyt antigens** Cell-surface antigens of murine T cells.

**lytic bacteriophage** *Syn.* VIRULENT BACTERIOPHAGE.

**lytic cycle** (*virol.*) The sequence of events which begins with adsorption of a virus to a susceptible cell and terminates with cell lysis and release of progeny virions.

**lytic infection** (*virol.*) The infection and subsequent lysis of susceptible cells by a VIRUS. (cf. e.g. LYSOGENY.)

**Lyticum** A genus of Gram-negative bacteria which occur as endosymbionts in the cytoplasm of certain strains of *Paramecium aurelia*. Cells: peritrichously flagellated rods, ca. 0.6–0.9 × 2.0–10 μm, which stain well with toluidine blue; in vitro cultivation has been reported. *Lyticum* spp do not contain R bodies (cf. CAEDIBACTER) but they produce labile toxin(s) which lyse sensitive paramecia. Type species: *L. flagellatum*.

*L. flagellatum* (earlier name: lambda particles) includes typically straight rods, while *L. sinuosum* (earlier name: sigma particles) includes curved and spiral rods.

[Book ref. 22, pp. 808–811.]

**lyxose** An aldopentose. (cf. STREPTOSE.)

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# M

**m** Maintenance coefficient: see YIELD COEFFICIENT.

**M** Methionine (see AMINO ACIDS).

**M antigen** (1) Streptococcal M PROTEIN. (2) A protein–LPS surface antigen in *Brucella* spp. (3) The COLANIC ACID capsular antigen in certain enterobacteria.

**M-associated protein** See MAP.

**M bands** (of *Stentor*) See MYONEME.

**M cells** See DYSENTERY.

**M fibres** (of *Stentor*) See MYONEME.

**M fimbriae** FIMBRIAE which occur on some pyelonephritic strains of *Escherichia coli*; they bind to the amino-terminal part of glycophorin A<sup>M</sup>.

**M phase** (of cell cycle) See CELL CYCLE.

**M phenotype** In strains of *Streptococcus pyogenes* and *S. pneumoniae*: an efflux-based resistance to MACROLIDE ANTIBIOTICS (q.v.).

**M plasmid** See MICROCINS.

**M protein** (1) (M antigen) (of streptococci) A heat-stable, trypsin-sensitive protein antigen associated with virulence in certain (M<sup>+</sup>) strains of group A streptococci. The M protein occurs as a fibrillar ‘fuzz’ covering the entire cell surface: the protein molecules apparently occur in extended form as double-stranded,  $\alpha$ -helical coiled coils (ca. 50 nm long) anchored in the cell wall by their C-terminal ends [PNAS (1981) 78 4689–4693]. The M protein protects the cell from phagocytosis, and may play a role in adhesion. M<sup>+</sup> strains often form matt or mucoid colonies on solid media, and may under certain cultural conditions produce an extracellular protease which degrades the M protein. M protein occurs in different antigenic forms, providing a basis for the serological typing of M<sup>+</sup> strains. (See also MAP; R PROTEIN; T PROTEIN.)

(2) (in e.g. *Escherichia coli*) The product of the *lacY* gene of the LAC OPERON.

**M ring** See FLAGELLUM (a).

**M1 RNA** See RNASE P.

**mAb** Monoclonal antibody.

**MAC** (1) (*immunol.*) Membrane attack complex: see COMPLEMENT FIXATION.

(2) (*bacteriol.*) (*syn.* MAIS complex) *Mycobacterium avium* complex: a category of slow-growing mycobacteria which include *M. avium*, *M. intracellulare* and *M. scrofulaceum*. These organisms are causal agents in three main types of infection: (i) cervical adenitis in children, (ii) pulmonary disease in adults, and (iii) disseminated disease in patients with advanced AIDS; treatment for cervical adenitis involves resection of affected node(s), while treatment for pulmonary and disseminated infections involves extended chemotherapy with a multiple drug regimen that includes clarithromycin or azithromycin. [Infections due to MAC and their treatment: BCID (1997) 4 25–61. PCR-based detection of MAC bacteraemia in AIDS patients: JCM (1999) 37 90–94. Cross-reactivity between *M. avium* (and *M. kansasii*) and *M. tuberculosis* in AMTDT: JCM (1999) 37 175–178.]

**Mac-1** See INTEGRINS.

**MacConkey’s agar** An agar-based medium used e.g. for the primary isolation of *Salmonella* and *Shigella* from faeces, for the differentiation of lactose-fermenting enterobacteria from NLFs, etc. The medium contains (w/v): peptone (2%); lactose (1%); sodium taurocholate or glycocholate (0.5%); NaCl (0.5%);

NEUTRAL RED (0.003%); agar (ca. 1.5%). Final pH: ca. 7.4. Colonies of lactose fermenters (e.g. *Escherichia coli*) are pink or red, those of NLFs (e.g. most strains of *Proteus*, *Salmonella* and *Shigella*) are colourless. Most non-enteric bacteria are inhibited by the bile salts. Some commercial preparations also contain crystal violet (1 mg/l) to inhibit Gram-positive bacteria.

**MacConkey’s broth** A broth with the same formulation as MACCONKEY’S AGAR but without the agar. Bromocresol purple may be used instead of neutral red as pH indicator.

**Machupo virus** See ARENAVIRIDAE and BOLIVIAN HAEMORRHAGIC FEVER.

**macrocapsule** See CAPSULE.

**macroconidium** The larger of two types of CONIDIUM formed by certain fungi (see e.g. FUSARIUM).

**macroconjugant** See CONJUGATION (1) (c).

**macrocytic rusts** (eu-form rusts) (1) Those rust fungi (e.g. *Puccinia graminis*) which form five clearly distinct types of spore: pycniospores, aeciospores, uredospores, teliospores and basidiospores (see UREDINIOMYCETES).

(2) Those rust fungi which form more than one type of *binucleate* spore – i.e., aeciospores and/or uredospores in addition to teliospores. (cf. DEMICYCLIC RUSTS.)

**macrocyt** A type of resting stage formed under certain conditions by (at least) some dictyostelid slime moulds (e.g. strains of *Dictyostelium discoideum*, *D. mucoroides*, *Polysphondylium violaceum*). It is formed when myxamoebae aggregate, and the aggregate becomes enclosed in a fibrillar sheath; one of the cells (the ‘phagocytic’ or ‘cytphagic’ cell) enlarges and begins to engulf neighbouring amoebae. When all the peripheral amoebae have been ingested, the remaining giant cell develops a cellulose wall, its single large nucleus divides to form numerous smaller nuclei, and the resulting multinucleate macrocyt enters a period of dormancy. On germination, the macrocyt protoplast divides into large, uninucleate ‘proamoebae’ which in turn divide to form normal-sized vegetative myxamoebae; these are released when the macrocyt wall breaks down.

Macrocyts apparently represent a sexual stage in the dictyostelid life cycle. The large nucleus of the cytophagic cell is believed to be that of a zygote; meiosis is presumed to occur when this nucleus divides to form the multinucleate cyst.

[Review: Book ref. 144, pp. 178–221.]

**Macrocystis** See PHAEOPHYTA.

**macrodilution broth test** See DILUTION TEST.

**macrofibre** In a culture of *Bacillus subtilis* grown under certain conditions: a bundle of aligned chains of cells which can exhibit a right-handed or left-handed helical conformation; the cell wall in the cells of a helically twisted macrofibre is believed to be under torsional stress. The helical conformation appears to depend on the presence of intact glycan backbone chains (rather than intact cross-links) in the cell wall PEPTIDOLYCAN [JGM (1986) 132 2377–2385].

**macrogamete** See ANISOGAMY.

**macroglobulin** (1) *Syn.* IgM (q.v.). (2)  $\alpha_2$ -Macroglobulin is a fibrinolysin inhibitor secreted by macrophages.

**macrolide antibiotics** A large group of MLS ANTIBIOTICS which includes e.g. angolamycin, carbomycin, chalcocomycin, cirramycin, erythromycin, lankamycin, leucomycin (= turimycin),

## macronucleus

megalomycin, methymycin, narbomycin, niddamycin, oleandomycin, relomycin, roxithromycin, spiramycins, troleandomycin and tylosin; they are produced e.g. by species of *Streptomyces*.

The molecule of a macrolide antibiotic contains a large lactone ring (12–14 carbon atoms) substituted with various functional groups and linked glycosidically to one or more sugars (including an aminosugar and, frequently, an unusual deoxysugar); thus, e.g. *erythromycin* (see also POLYKETIDE) consists of a 14-member ring linked to the aminosugar desosamine and the deoxysugar cladinose. (Macrolides which contain a conjugated polyene system form a separate group: see POLYENE ANTIBIOTICS (a).)

The macrolides are typically bacteriostatic and are active mainly against Gram-positive bacteria (including *Streptococcus* spp and *Clostridium* spp), although certain Gram-negative bacteria (e.g. *Haemophilus* spp, *Neisseria* spp, some species of *Bacteroides*) may be susceptible.

Macrolides inhibit PROTEIN SYNTHESIS by binding to the 50S subunit of 70S ribosomes, apparently inhibiting the peptidyl-transferase reaction and/or affecting translocation. The macrolide AZITHROMYCIN inhibits the ability of *Pseudomonas aeruginosa* strain PAO1 to produce virulence factors by inhibiting the pathogen's QUORUM SENSING circuitry [AAC (2001) 45 1930–1933].

In e.g. *Escherichia coli*, resistance to macrolides may be due to a mutation which results in the modification of a protein (L4, or possibly L22) in the 50S ribosomal subunit.

In staphylococci, streptococci and streptomycetes resistance to macrolides (and other MLS antibiotics) may be due to methylation of the ribosomal 23S rRNA (see STREPTOGRAMINS).

In *Streptococcus pyogenes* and *S. pneumoniae*, strains exhibiting the 'M phenotype' contain an efflux-based mechanism which confers resistance specifically to macrolides – i.e. the mechanism does not affect susceptibility to lincosamides or B streptogramins. The efflux mechanism is encoded by a sequence (*mefA*) within a 7244-bp chromosomal element designated Tn1207.1 [AAC (2000) 44 2585–2587].

**macronucleus** (*ciliate protozool.*) The larger of the two types of nucleus characteristically present in ciliates. (cf. MICRONUCLEUS.) Many ciliates contain a single macronucleus, but some contain more than one; according to species, the macronucleus may be e.g. ovoid, elongated, moniliform, C-shaped etc. Macronuclei contain nucleoli and are typically polyploid (they are typically diploid in the karyorelictid gymnostomes – e.g. *Kentrophoros*, *Loxodes*); macronuclear DNA, which is actively transcribed, directs the 'somatic' activities of the cell. During CONJUGATION the macronucleus usually disintegrates – a new one subsequently developing from a micronucleus. In *Oxytricha nova* macronuclear DNA is in the form of small, gene-sized molecules; during its development (from micronuclear DNA) the DNA undergoes a complex series of changes which include polytenization (with the loss of certain sequences), fragmentation, modification (the addition of inverted terminal repeats), and encapsulation within vesicles followed by release and replication [PNAS (1982) 79 3255–3259].

A *heteromerous macronucleus* is one which is subdivided into two parts (*karyomeres*) – the *orthomere* and *paramere* – which differ in their content of DNA and RNA; such nuclei occur in many hypostomes. (See also ENDOSOME (2).) A *homoimerous* (= 'homomerous') macronucleus is one which is not subdivided; such nuclei occur in the majority of ciliates.

**macrophage** A large (10–20 µm), relatively long-lived, amoeboid, phagocytic and pinocytotic LEUCOCYTE present in blood, lymph and other tissues; macrophages develop via the myeloid

pathway from haemopoietic stem cells in the bone marrow, early stages including the monoblast and MONOCYTE. [Macrophages: JCS (1986) supplement 4, 267–286.] Macrophages have important roles in host resistance to pathogenic microorganisms (see PHAGOCYTOSIS, INFLAMMATION, ANTIBODY FORMATION and DELAYED HYPERSENSITIVITY). (See also GIANT CELLS, HISTIOCYTE, KUPFFER CELLS and PMN.)

Macrophages can express a wide range of cell-surface receptors, some of which are expressed constitutively while others can be induced by appropriate stimuli. They include: (i) receptors for the FC PORTION of IgG antibodies; (ii) receptors for various components of COMPLEMENT (e.g. CD46 and CD11c/CD18); (iii) binding sites for lipopolysaccharides (see CD14); (iv) binding sites for type I FIMBRIAE (see CD48); and (v) receptors for various CYTOKINES.

Macrophages also display MHC class II molecules and function as ANTIGEN-PRESENTING CELLS.

Under appropriate conditions (and with suitable stimulation), macrophages secrete a wide range of products, including: (i) certain components of COMPLEMENT (e.g. FACTOR B, PROPERDIN, C1–C5); (ii) FIBRONECTIN; (iii) certain PROSTAGLANDINS; and (iv) various CYTOKINES (e.g. INTERLEUKIN-1, INTERLEUKIN-6, INTERLEUKIN-8, INTERLEUKIN-12, INTERLEUKIN-18, TNF).

*Activation of macrophages.* On activation, a macrophage e.g. (i) becomes more aggressive towards pathogens which have been engulfed by phagocytosis, and (ii) secretes various cytokines. Thus, an activated macrophage is associated with a strong *respiratory burst* (see NEUTROPHIL) in which it produces significant amounts of e.g. SUPEROXIDE, hydrogen peroxide and NITRIC OXIDE; in the activated state a macrophage is able to kill certain ingested pathogens which may not be killed in non-activated macrophages.

Activation may occur e.g. when a macrophage presents antigen to an antigen-specific T LYMPHOCYTE of the Th1 subset (this is an MHC class II-restricted interaction – see HISTOCOMPATIBILITY RESTRICTION). Following such interaction with the macrophage, the T cell secretes an important macrophage-activating factor: interferon-gamma (IFN-γ) (see INTERFERONS). IFN-γ causes the macrophage to mount a respiratory burst (see above) and to secrete cytokines such as IL-1, IL-6, IL-12, IL-18 (see individual entries) and TNF-α (see TNF). Apparently, IFN-γ and lipopolysaccharides (LPS) can act synergistically to enhance the respiratory burst [JBC (1990) 265 20241–20246] and to stimulate the synthesis of cytokines by macrophages. (The ability of IFN-γ and LPS to stimulate cytokine production in macrophages may be inhibited by glucocorticoids.)

Cytokines secreted by a T cell may provide BYSTANDER HELP (q.v.).

Following uptake, some pathogenic bacteria can kill macrophages [see e.g. EMBO (1996) 15 3853–3860; TIM (1998) 6 253–255]; *Yersinia* down-regulates production of the pro-inflammatory cytokine TNF-α in macrophages [Mol. Microbiol. (1998) 27 953–965]. [Interactions between *Mycobacterium tuberculosis* and phagocytes: TIM (1998) 6 328–335.]

Macrophages may be maintained for some time in culture. Viable macrophages adhere to glass and plastics and accumulate dyes such as TRYPAN BLUE.

**macrophage-activating factor** See MAF.

**macropinocytosis** See DYSENTERY.

**macroscopic** Visible to the unaided eye.

**macrostromale** See TETRAHYMENA.

**macrotetalides** A group of ANTIBIOTICS which function as IONOPHORES; they inhibit Gram-positive bacteria. The *cyclic*

macrotetralides (called 'actins' or 'nactins') each contain four similar tetrahydrofuran rings linked via ester bonds; *nonactin* is substituted with four methyl groups, *monactin* with three methyl and one ethyl, *dinactin* with two methyl and two ethyl, and *trinactin* with one methyl and three ethyl groups. *Open-chain* macrotetralides (polyether antibiotics) include alborixin, dianemycin, LASALOCID, lonomycin, MONENSIN, NIGERICIN and tetroneomycin. [Structure and biosynthesis of polyether antibiotics: *J. Nat. Prod.* (1986) 49 35–47.]

**macule** (macula) On e.g. skin: an unelevated spot of discoloration. (cf. PAPULE.)

**maculopapular** Refers to a rash in which both MACULES and PAPULES occur.

**mad cow disease** (BSE) See BOVINE SPONGIFORM ENCEPHALOPATHY.

**mad itch** *Syn.* AUJESZKY'S DISEASE.

**Madin–Darby canine kidney cells** See MDCK CELLS.

**Madura foot** *Syn.* MADUROMYCOSIS.

**Madurella** See HYPHOMYCETES and MADUROMYCOSIS.

**maduromycetes** Certain sporoactinomycetes which have a type III cell wall (see ACTINOMYCETALES) and which typically contain madurose; the group includes *Actinomadura*, *Excelsospora*, *Microbispora*, *Microtetraspora*, *Planobispora*, *Planomonospora*, *Spirillospora* and *Streptosporangium*, but excludes the (morphologically distinguishable) genera *Dermatophilus* and *Frankia* (both wall type III, and both containing madurose) [Book ref. 73, pp. 105–115].

**maduromycosis** (Madura foot) A non-infectious human disease characterized by the formation – usually on feet or hands – of granulomatous, suppurative tumours (mycetomas) of the subcutaneous tissues; eventually the bone may be affected. The causal agent may be any of various fungi (e.g. *Acremonium* spp, *Aspergillus nidulans*, *Madurella* spp, *Pseudallescheria boydii*) or actinomycetes (e.g. *Actinomadura* spp, *Nocardia* spp, *Streptomyces somaliensis*) – the tumours being termed, respectively, eumycetomas (= eumycotic mycetomas) and actinomycetomas (= actinomycotic mycetomas). Infection occurs via wounds. Within the tissues, the pathogen forms characteristic aggregates (called granules or grains); depending on pathogen, the granules may be white, red, yellow, brown or black, soft or hard, and range in size from <15 µm (*Nocardia* spp) to >4 mm (e.g. *Actinomadura madurae*). (cf. ACTINOMYCOSIS.) Treatment of eumycetomas is usually surgical; some actinomycetomas can be controlled with antibiotics (e.g. sulphamethoxazole-trimethoprim + streptomycin).

**madurose** A sugar (3-*O*-methyl-D-galactose) which occurs e.g. in MADUROMYCETES.

**MAECT** Miniature anion exchange centrifugation technique: a method for detecting the presence of e.g. trypanosomes in the blood of patients suspected of suffering from SLEEPING SICKNESS. Blood, diluted with buffer, is passed through a DEAE (ion-exchange) column; erythrocytes are retained in the column, but any trypanosomes which may be present pass through the column and can be concentrated by centrifugation and examined by dark-field MICROSCOPY.

**maedi** (maedi-visna; ovine progressive interstitial pneumonia; Graff–Reinet disease) A chronic, progressive, fatal pneumonia which occurs mainly in sheep (also in goats); the causal agent, a virus of the LENTIVIRINAE, is apparently identical to the VISNA virus, but maedi and visna rarely occur together in one animal. Incubation period: at least two years. Symptoms: progressive emaciation and dyspnoea, with or without coughing and nasal discharge, typically lasting up to six months. (cf. JAAGSIEKTE.) [Book ref. 33, pp. 805–807.]

**maedi-visna** See MAEDI.

**MAF** Macrophage-activating factor: a former name for the CYTOKINE interferon-γ (IFN-γ).

**magenta** *Syn.* basic FUCHSIN.

**Magnaporthe** See POLYSTIGMATALES and AVIRULENCE GENE.

**magnetic separation** See DYNABEADS.

**magnetosome** See MAGNETOTACTIC BACTERIA.

**magnetotactic bacteria** A non-taxonomic grouping of aquatic, microaerophilic, flagellate, Gram-negative bacteria, each of which forms intracellular, enveloped magnetic bodies (*magnetosomes*); the presence of magnetosomes causes the cells to align with lines of magnetic force so that cell motility is given direction (but not assistance) by a magnetic field (*magnetotaxis*).

These bacteria are widespread geographically, occurring in sediments in freshwater and marine habitats. *Aquaspirillum magnetotacticum* has been obtained in pure culture; each cell contains a chain of ca. 20 cuboidal or polyhedral magnetosomes (of side ca. 40 nm) which contain magnetite (Fe<sub>3</sub>O<sub>4</sub>).

[Precipitation of magnetite in magnetotactic bacteria: PTRSLB (1984) 304 529–536. Magnetosomes (review): JGM (1993) 139 1663–1670.]

**magnetotaxis** See MAGNETOTACTIC BACTERIA.

**magnification** The extent to which the image of an object is larger than the object itself. With a compound (light) microscope the total magnification is the magnification of the objective lens multiplied by that of the eyepiece lens; it is determined by the focal lengths of the objective and eyepiece lenses. RESOLVING POWER involves other factors and is distinct from magnification. Different objective lenses having the same magnification may have different resolving powers; resolving power (but not magnification) may be affected by sub-optimal illumination of the specimen. Any increase in magnification which is not accompanied by an increase in resolution is said to be *empty magnification*. The maximum *useful* magnification obtainable with a given objective lens is approximately 1000 times its numerical aperture. Good-quality light microscopes can give a maximum magnification of about 1200×. Higher magnifications are obtainable by ultraviolet microscopy (see MICROSCOPY (f)). In ELECTRON MICROSCOPY magnification can be e.g. 1000000×.

**Maillard reaction** A reaction between a reducing sugar (e.g. lactose) and the free amino groups in proteins, the product being a brown-coloured compound; the extent of the reaction depends on the concentrations of the sugar and protein and on temperature. (See also MILK (treatment processes).)

**maintenance coefficient** (*m*) See YIELD COEFFICIENT.

**maintenance energy** The energy used by a cell for purposes other than growth; maintenance energy is used e.g. for motility, for the maintenance of osmotic pressure in the cell, for maintaining the energized state of the cytoplasmic membrane etc. At high rates of growth the maintenance energy requirement is generally relatively minimal, but at low rates of growth maintenance energy may account for an appreciable proportion of the overall energy requirement. (See also YIELD COEFFICIENT.)

**maintenance medium** See MEDIUM and TISSUE CULTURE.

**MAIS complex** *Mycobacterium avium*–*intracellulare*–*scrofulaceum* complex: a non-taxonomic grouping of species which is convenient for laboratory diagnostic purposes. (See MAC.)

**maize chlorotic dwarf virus** (MCDV; Ohio corn stunt agent) A PLANT VIRUS in which the virions are polyhedral (ca. 30 nm diam.) and contain one molecule of positive-sense ssRNA (MWt ca. 3.2 × 10<sup>6</sup>). Host range is limited to members of the Gramineae; symptoms (in maize) include stunting and chlorotic striping of tertiary leaf veins (cf. CORN STUNT DISEASE). Transmission occurs via leaf-hoppers (e.g. *Graminella nigrifrons*)

## maize diseases

and is semipersistent. The virus overwinters in 'Johnson grass' (*Sorghum halepense*) and other weed grasses. (cf. RICE TUNGRO VIRUS.)

**maize diseases** See CEREAL DISEASES.

**maize dwarf mosaic virus** See POTYVIRUSES.

**maize mosaic virus** See RHABDOVIRIDAE.

**maize rayado fino virus group** A group of isometric ssRNA-containing PLANT VIRUSES which are obligately transmitted by leafhoppers.

**maize rough dwarf virus** See FIJIVIRUS.

**maize streak virus (MSV)** The type member of the GEMINI-VIRUSES. MSV is an important cause of disease in maize (*Zea mays*) in many parts of Africa; leaves of infected plants show e.g. broken, narrow streaks of chlorosis along the veins. MSV is transmitted by leafhoppers of the genus *Cicadulina* [epidemiology: ARE (1978) 23 259–282].

**maize stripe virus** See RICE STRIPE VIRUS GROUP.

**maize wallaby ear disease (MWED)** A disease of maize (*Zea mays*) first described in Australia; symptoms include small swellings on secondary veins on the lower surfaces of leaves, stunting etc. MWED is associated with infestation by leafhoppers (*Cicadulina*, *Nesoclytha*); the causal agent was thought to be a virus (cf. LEAFHOPPER A VIRUS), but there is evidence to suggest that the disease is due to an insect toxin [Ann. Appl. Biol. (1983) 103 185–189].

**major facilitator superfamily (MFS)** See MFS.

**major groove (in DNA)** See DNA.

**major histocompatibility complex (MHC)** In all mammalian species studied: linked genetic loci that dominate the immune response; these genes, and their products, are designated by the prefixes HLA (*human leukocyte antigens*) in man, H-2 in mice, RT1 in rats, ChLA in chimpanzees etc.; the human (HLA) genes occur on chromosome 6.

MHC gene products occur on cell surfaces and serve as markers which e.g. distinguish 'self' (or syngeneic) tissue from 'non-self' (foreign) tissue; thus, MHC gene products determine the outcome of tissue transplants (see also MLR), and they are also involved e.g. in ANTIBODY FORMATION.

Genes in the MHC complex occur in three main groups (classes I, II and III). Most of the genes belong to classes I and II, and the products of these genes are designated *class I* and *class II* antigens, respectively. (Class III genes encode the COMPLEMENT components C2, C4 and factor B.)

Class I and class II antigens are distinguishable on a structural and functional basis.

Class I antigens (encoded by HLA-A, HLA-B and HLA-C genes) each consist of a single transmembrane polypeptide. These antigens are expressed on most nucleated cells in the body, and they are involved e.g. in the recognition of target cells by cytotoxic CD8<sup>+</sup> T cells.

Class II antigens (encoded by the HLA-DP, HLA-DQ and HLA-DR genes) each consist of a two-polypeptide transmembrane structure. These antigens have a limited distribution, being found e.g. on B cells and other ANTIGEN-PRESENTING CELLS; they are involved e.g. in the recognition of APCs by CD4<sup>+</sup> T cells.

For some cells the expression of MHC antigens may be induced, or upregulated, by certain CYTOKINES. For example (at least in vitro), IFN- $\gamma$  (see INTERFERONS) can induce expression/upregulation of class II antigens on e.g. endothelial cells and macrophages (and can also stimulate expression of class I antigens).

**mal de caderas** In South America: (1) *Syn.* SURRA. (2) A fatal paralytic disease of cattle caused by the rabies virus and transmitted by blood-sucking vampire bats.

**mal del pinto** *Syn.* PINTA.

**mal du coit** *Syn.* DOURINE.

**malachite green** A green basic TRIPHENYLMETHANE DYE used e.g. as an ENDOSPORE STAIN.

**malaria** An acute or chronic, sometimes recurrent, infectious disease caused by species of PLASMODIUM and responsible, each year, for some 1–2 million deaths (including many children); the disease is prevalent in tropical and subtropical regions. Malaria may be caused by *Plasmodium falciparum*, *P. malariae*, *P. ovale* or *P. vivax*. (Mixed plasmodial infections can also occur; moreover, *P. knowlesi* and *P. simium*, normally parasites of non-human primates, can infect man under natural conditions, causing 'simian malaria'.)

Natural transmission of the malaria parasite – from an infected to an uninfected individual – occurs via an insect vector: a female mosquito of the genus *Anopheles*. [Systematics of malaria vectors (in particular, the *Anopheles punctulatus* group): IJP (2000) 30 1–17.] If, during a blood meal, the mosquito ingests viable plasmodial gametocytes, male and female gametes can develop and fertilization can take place in the insect's gut; eventually, *sporozoites* – forms of the parasite infective for a human host – appear in the salivary glands of the mosquito, and these can be passed to an uninfected individual during the insect's next blood meal (see figure). [The malaria parasite in the mosquito: PT (2000) 16 196–201.]

Transmission may also occur e.g. by transfusion of infected blood [NEJM (2001) 344 1973–1978].

Incubation period: ca. 7–28 days, or longer. The typical illness is characterized by a series of paroxysms, each involving an attack of rigors followed by high fever and then profuse sweating. These paroxysms occur every ~36–48 hours in falciparum malaria ('malignant tertian malaria'), ~42–48 hours in vivax malaria ('benign tertian malaria'), ~50 hours in ovale malaria ('tertian malaria'), and ~72 hours in malariae malaria ('quartan malaria'). Other symptoms include e.g. headache, malaise, nausea and vomiting, anaemia, and pains in the muscles, joints and abdomen; enlargement of the liver and/or spleen may occur.

Falciparum malaria exhibits the most severe symptoms, and causes the majority of deaths from malaria. In certain blood vessels (the post-capillary venules), parasitized erythrocytes adhere to endothelial cells – although the significance of this in pathogenesis is not fully understood. Such adherence may lead to mechanical obstruction of the vessels; it may, perhaps additionally, activate or damage endothelial cells and/or e.g. stimulate the release of cytokines. Some authors indicate that disease manifestations result almost entirely from cytoadherence (adherence of red blood cells to the endothelium) together with the induction of certain cytokines (TNF- $\alpha$ , IL-1 and IL-6) [BCID (1995) 2 227–247]. In some cases, severe disease has been correlated with a variant form of the TNF- $\alpha$  gene promoter [Nature (1994) 371 508–510]. Another factor in falciparum malaria is 'rosetting': the phenomenon in which uninfected erythrocytes bind to infected red cells; again, the significance of this in pathogenesis is not clear, although some studies suggest an association between rosetting and cerebral malaria. Cytoadherence, rosetting and impaired erythrocyte deformability have been discussed in the context of abnormal microcirculatory blood flow [PT (2000) 16 228–232]. Complications that may be associated with severe malaria include anaemia, DISSEMINATED INTRAVASCULAR COAGULATION, hypoglycaemia and renal failure. (See also BLACKWATER FEVER.) [Pathogenesis of severe falciparum malaria: BCID (1995) 2 249–270.]

MALARIA. The life cycle of the malaria parasite (*Plasmodium*) (diagrammatic) showing the stages which are targets for antimalarial drugs (see table).

Sporozoites, injected into the bloodstream via mosquito bite, penetrate liver cells. A sporozoite grows and develops into a *tissue schizont* which undergoes asexual reproduction (*schizogony*) to produce a number of cells called *merozoites*. On rupture of the liver cell, merozoites enter the bloodstream and infect erythrocytes (red blood cells). Within an erythrocyte, a merozoite develops as a *trophozoite* (growing stage); the young trophozoite is known as the *ring stage* owing to its appearance in stained preparations under the microscope.

The mature trophozoite (*blood schizont*) undergoes schizogony, and many merozoites are released [in a two-step process: PNAS (2001) 98 271–276] when the erythrocyte ruptures. These merozoites infect fresh erythrocytes. Some merozoites become *gametocytes* (i.e. cells with the potential to develop into male and female gametes). If ingested by a mosquito, gametocytes give rise to gametes – and the sexual phase of the life cycle follows.

In two species of *Plasmodium* the sporozoite can form a dormant stage (*hypnozoite*) in liver cells; hypnozoites may remain dormant for months/years. For this form of malaria a 'radical cure' involves treatment with an agent that kills hypnozoites (e.g. primaquine) as well as other drug(s) to deal with the intra-erythrocytic parasites.

Reproduced from *Antimicrobial Drug Action*, Figure 7.1, pages 120–121, R. A. D. Williams, P. A. Lambert & P. Singleton (1996) copyright Bios Scientific Publishers Ltd, UK (ISBN 1-872748-81-3) with permission from the publisher.

## malaria

Natural resistance to falciparum malaria occurs in people heterozygous for the sickle-cell anaemia gene. Resistance to falciparum malaria may also be associated with an absence of the SI<sup>1</sup> antigen, or low levels of CR1 (CD35), on erythrocytes, as SI<sup>1</sup> is involved as a binding site in the rosetting phenomenon [Nature (1997) 388 292–295].

Vivax, ovale and malariae malarias may be self-limiting, even without treatment; however, in subsequent years, species which form *hypnozoites* can give rise to relapses – at increasing intervals of time – as merozoites periodically emerge from the liver.

The receptor for *P. vivax* merozoites on the red blood cell is the Duffy glycoprotein (a marker in the Duffy blood group system), and this glycoprotein is essential for infection [see e.g. Blood (1997) 89 3077–3091]. Many black Africans lack this receptor [a mutation inhibits expression of the Duffy gene: Nature Genetics (1995) 10 224–228] and are accordingly resistant to vivax malaria.

*The immune response to plasmodial infection.* Interactions between plasmodia and the immune system are complex. Immunity develops slowly and tends to be transient; the majority of antigens do not induce immunological memory. Nevertheless, there is an antibody response to sporozoites, asexual blood-stage parasites and gametocytes, and a cell-mediated response which involves e.g. cytotoxic T cells and NK (natural killer) cells. [Clinical immunology of malaria: BCID (1995) 2 227–247.]

*Vaccines against malaria.* Recognition of the need to stimulate immunity by using an ‘antigenic cocktail’ lead to the development of the Colombian synthetic subunit vaccine (SPf66). The future development of vaccines is aimed at improving the protective immune response. [Strategies towards the design of a synthetic subunit malaria vaccine: BCID (1995) 2 389–403.]

The plasmodial antigen PfEMP1 (*Plasmodium falciparum* erythrocyte membrane protein 1) is displayed at the surface of those red blood cells (RBCs; erythrocytes) which are parasitized by *P. falciparum*. PfEMP1 promotes cytoadherence, i.e. the adherence of parasitized RBCs to sites such as the CD36 receptor on endothelial cells; PfEMP1 is therefore a potential target for candidate antimalarial vaccines. In the context of vaccines, however, one problem is that PfEMP1 occurs in variant forms in different strains of the pathogen, and an immune response to a given variant is predominantly variant-specific; nevertheless, studies using monoclonal antibodies have detected cross-reacting epitopes on a number of strains of *P. falciparum*, suggesting the possibility of developing an effective vaccine directed against PfEMP1 [PNAS (2001) 98 2664–2669].

The case has been argued for developing a vaccine against the liver (pre-erythrocytic) stage of the pathogen, thus attacking the disease in the initial stage of infection; a candidate antigen for such a vaccine is liver-stage-antigen-1 (LSA-1), a 200 kDa protein that is expressed specifically by the parasite within liver cells and that appears to have a generally conserved sequence among different isolates. [Pre-erythrocytic immunity: the case for an LSA-1 vaccine: TIP (2001) 17 219–223.]

*Lab. diagnosis.* (i) Detection of parasitaemia by staining blood films (Giemsa). (ii) Detection of *P. falciparum* protein-2 (HRP-2) in haemolysed blood by means of anti-HRP-2 MONOCLONAL ANTIBODIES [PT (1994) 10 494–495]. This principle is used e.g. in the ParaSight-F<sup>TM</sup> test (Becton Dickinson, Maryland, USA). (iii) PCR-based testing with species-specific primers [TRSTMH (1993) 87 649–653]. (iv) A genus-specific and (multiplex) species-specific approach by PCR [JCM (1999) 37 1269–1273]. [Rapid diagnostic techniques: TIP (2001) 17 307–309.]

*Chemotherapy.* Most antimalarials kill intraerythrocytic stages of the parasite. The choice of drug(s) depends e.g. on the local prevalence of parasites resistant to given antimalarials. (See QUININE for the formulae of some antimalarials.)

*Fansidar* (= PYRIMETHAMINE + sulphadoxine) is an oral treatment for uncomplicated falciparum malaria.

Quinoline-type antimalarials include QUININE, quinidine (used e.g. in the USA), chloroquine and mefloquine (see AMINOQUINOLINES). *Parenteral* quinine is considered to be the drug of choice for severe falciparum malaria because few strains of the parasite are resistant to this form of treatment.

*Chloroquine* is used orally for uncomplicated falciparum malaria and for most cases of vivax and ovale malaria.

*Mefloquine* is used orally for uncomplicated malaria and, via nasogastric tube, for severe malaria; neuro-psychiatric side-effects of this drug may be important [BMJ (1995) 310 709–714].

*Halofantrine* is used orally for uncomplicated malaria. This drug (9-phenanthrene methanol), unlike e.g. quinine, seems to be active against the ring-stage trophozoite. The mechanism of action is unknown. Halofantrine is not used for prophylaxis owing e.g. to variable absorption. High levels of the drug have been (rarely) linked with cardiac arrhythmias [Lancet (1993) 341 1054–1056].

*Atovaquone* (hydroxynaphthoquinone) is a candidate oral antimalarial. It appears to inhibit electron transport in the parasite.

*Primaquine* (an 8-aminoquinoline) is active against hypnozoites (but not against blood forms) and is used to prevent relapse in vivax and ovale malaria; for a ‘radical cure’, primaquine is used in conjunction with e.g. chloroquine.

WR238605 (a primaquine analogue) is being developed by the US army (Walter Reed Army Institute of Research). It has shown success in animal systems.

### ANTIMALARIAL DRUGS<sup>a</sup>

Drug	Chemical description	Active against <sup>b</sup>
Artemisinin	Sesquiterpene lactone endoperoxide	BS
Atovaquone <sup>c</sup>	Hydroxynaphthoquinone	BS
Chloroquine	4-Aminoquinoline	BS
Halofantrine	9-Phenanthrene methanol	RS?
Mefloquine	4-Aminoquinoline	BS
Primaquine	8-Aminoquinoline	TS, HYP
Proguanil	Diguanide	TS, BS
Pyrimethamine	Diaminopyrimidine	BS
Quinidine	Quinoline-type (alkaloid)	BS
Quinine	Quinoline-type (alkaloid)	BS
Sulphadoxine	Sulphonamide	BS
WR238605 <sup>c</sup>	8-Aminoquinoline	HYP, GAM

<sup>a</sup> See entry QUININE for the formulae of some antimalarials.

<sup>b</sup> See the figure for stages in the plasmodial life cycle. BS = blood schizont; TS = tissue schizont; HYP = hypnozoite; GAM = gametocyte; RS = ring stage.

<sup>c</sup> Candidate antimalarial.

Reproduced from *Antimicrobial Drug Action*, Table 7.1, page 121, R. A. D. Williams, P. A. Lambert & P. Singleton (1996) copyright Bios Scientific Publishers Ltd, UK (ISBN 1-872748-81-3) with permission from the publisher.

*Proguanil* (= Paludrine, CHLORGUANIDE) is a FOLIC ACID ANTAGONIST; with e.g. chloroquine it is used for prophylaxis. Of alternative prophylactic agents, mefloquine is absolutely contraindicated in early pregnancy.

See also QINGHAOSU.

In general, while antimalarials are used prophylactically by travellers, such use is considered undesirable for residents in endemic areas because it lowers the level of acquired resistance, resulting in high mortality when the drug is withdrawn.

[Chemotherapy: Book ref. 213, pp 119–128.]

[Malaria feature (vaccines, drugs, mosquito engineering etc.): Science (2000) 290 428–441.]

**malarial pigment** *Syn.* HAEMOZOIN.

**Malassezia** (*syn.* *Pityrosporum*) A genus of non-fermentative imperfect yeasts (class HYPHOMYCETES) which occur on the skin in man and animals. The cells are spherical, oblong-ellipsoidal, or cylindrical, and reproduce by monopolar bud-fission. True hyphae are formed infrequently in culture, but are common in skin scales. Growth is commonly stimulated by certain oils (e.g. olive oil); optimum growth temperature: 35–37°C. The organisms can grow on glucose-peptone-yeast extract agar (overlaid with olive oil for *M. furfur*); they do not grow in the liquid media used in standard physiological tests for yeasts. Two species are recognized [Book ref. 100, pp. 882–885]: *M. furfur* (including '*Pityrosporum ovale*' and '*P. orbiculare*', which are currently considered to be variant cultural forms of *M. furfur*), and *M. pachydermatis* (= *P. pachydermatis*, *P. canis*). *M. furfur* occurs e.g. on human skin (see also PITYRIASIS VERSICOLOR); *M. pachydermatis* has been isolated from the ears of dogs (in which it may be associated with otitis externa) and from human skin.

**malate synthase** See TCA CYCLE.

**male-specific phage** *Syn.* ANDROPHAGE.

**malic enzyme** (1) See TCA CYCLE. (2) *Syn.* malolactic enzyme (see MALOLACTIC FERMENTATION).

**malignant** (*med.*) (1) (of disease) Becoming progressively worse (when untreated), usually resulting in death. (2) (of tumours) Refers to a neoplasm which invades adjacent tissues and which may metastasize (see METASTASIS). (cf. CANCER.)

**malignant catarrhal fever** (gangrenous coryza) An acute CATTLE DISEASE caused by a cytomegalovirus-like herpesvirus (see BETAHERPESVIRINAE). The disease is characterized by high fever with severe inflammatory and degenerative lesions in the mucous membranes of the upper respiratory tract and intestinal tract; the eyes may be affected, and blindness may result. Mortality rates are generally high (usually >95%). The disease may also affect certain other ungulates (e.g. sheep, wildebeest, deer). [Review of the disease: VR (1984) 114 581–583.]

**malignant oedema** (*vet.*) Tissue oedema and necrosis, often involving frank GAS GANGRENE, due to wound infection by one or more species of *Clostridium* – e.g. *C. chauvoei*, *C. novyi*, *C. septicum*, *C. sordellii*. Symptoms: fever, with a soft, red, local swelling which becomes dark; in some cases gas production gives rise to a frothy exudate from the wound. Death usually occurs within 1–2 days. *Treatment*: parenteral administration of antibiotics, antitoxin therapy (appropriate only in early stages of the disease), irrigation of the wound with hydrogen peroxide. (See also SWELLED HEAD.)

**malignant pustule** Cutaneous ANTHRAX.

**malignant tertian malaria** See MALARIA.

**mallein test** (*vet.*) A test for GLANDERS (sense 1) involving the intradermal injection of mallein (containing antigens of the pathogen) e.g. into the lower eyelid; a positive reaction is

indicated, after 48 hours, by local oedema and a severe purulent conjunctivitis.

**Mallomonas** A genus of unicellular CHRYSPHYTES which resemble *Chromulina* spp but have a coating of silicified scales; in some species the scales bear long siliceous spines.

**malolactic fermentation** A type of FERMENTATION (sense 2), carried out e.g. by species of *Lactobacillus*, *Leuconostoc* and *Pediococcus*, in which L-malic acid is converted to L-lactic acid and CO<sub>2</sub>. The reaction is apparently catalysed by a single enzyme (the *malolactic enzyme*) which has no L-lactate dehydrogenase activity; the malolactic enzyme from e.g. *Lactobacillus plantarum* has an absolute requirement for Mn(II) and NAD<sup>+</sup>, but the NAD<sup>+</sup> is not reduced. There is no evidence that the reaction yields ATP.

In certain fermented products (e.g. wines, pickled cucumbers, soy sauce, silage) the malolactic fermentation has the effect of reducing the acidity of the product (lactic acid being a weaker acid than malic acid); this may or may not be desirable, depending on the degree and nature of acidity required in the product (see e.g. WINE-MAKING). Malolactic fermentation in wine tends to be slow and may be unpredictable; where required, it may be speeded up by the addition of a pure culture of suitable bacteria (commonly *Leuconostoc oenos*). The gene for malolactic fermentation has been transferred from *Lactobacillus delbrueckii* to a wine yeast in an attempt to produce a yeast capable of simultaneous malolactic and alcoholic fermentations [AEM (1984) 47 288–293]; however, the resulting yeast exhibited only low levels of malolactic fermentation.

**Malpighamoeba** A genus of amoebae (order AMOEBIDA). *M. mellificae* is parasitic in bees (see BEE DISEASES), *M. locustae* is parasitic in locusts [Parasitol. (1976) 72 127–135].

**malt agar** (malt extract agar) A medium made by diluting MALT EXTRACT to a specific gravity of 10° Balling and solidifying it with 2% agar.

**malt extract** An extract of malt, used e.g. as a medium for the culture of a wide range of yeasts and moulds. Malt (1 kg) is mixed with water (2.6 litres). The mixture is held at 45°C for 3 h (with stirring), and then at 63°C for 1 h; it is then filtered and autoclaved. The specific gravity of the filtrate is adjusted to 15° Balling using a Balling saccharometer. Malt extract is available commercially in dehydrated form. (See also BREWING.)

**Malta fever** See BRUCELLOSIS.

**Maltaner antigen** A cardiolipin–lecithin antigen used in certain STANDARD TESTS FOR SYPHILIS.

**maltase** An  $\alpha$ -glucosidase (EC 3.2.1.20) which hydrolyses (1 → 4)- $\alpha$ -D-glucosidic bonds; thus, e.g. maltose is converted to free glucose.

**maltobiose** *Syn.* MALTOSE.

**maltoporin** See LAMB PROTEIN.

**maltose** (maltobiose) A reducing disaccharide:  $\alpha$ -D-glucopyranosyl-(1 → 4)-D-glucopyranose. Maltose is an intermediate in the metabolic mobilization of STARCH in plants (e.g. during the germination of cereal grains – see e.g. BREWING); it also occurs e.g. as a major product of photosynthesis in *Chlorella* symbionts of *Hydra viridis* and of *Paramecium bursaria* (although it is not produced by the non-symbiotic alga). Maltose can be metabolized by a wide range of microorganisms. (For maltose transport in e.g. *Escherichia coli* see BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.) (cf. ISOMALTOSE; see also AMYLASES and MALTAZE.)

**maltotriose** A trisaccharide:  $\alpha$ -D-glucopyranosyl-(1 → 4)- $\alpha$ -D-glucopyranosyl-(1 → 4)-D-glucopyranose. (See also AMYLASES.)

**Mamiella** See MICROMONADOPHYCEAE.

## Mancini test

**Mancini test** See SINGLE DIFFUSION.

**mancozeb** An agricultural antifungal agent consisting of a complex of zinc and MANEB; it is used, for example, against late blight of potato.

**Mandelamine** See HEXAMINE.

**mandelic acid** Hydroxyphenylacetic acid:  $C_6H_5.CHOH.COOH$ . Mandelic acid has bacteriostatic properties and is used as a urinary antiseptic – being excreted unchanged if the urine is sufficiently acidic; it may be used in combination with HEXAMINE.

**Mandler filter** See FILTRATION.

**maneb** (dithane M-22) Manganese ethylene-BISDITHIOCARBAMATE, an agricultural antifungal agent with a spectrum of activity similar to that of ZINEB; it is used e.g. to control diseases caused by *Alternaria solani* and *Phytophthora infestans*.

**manganese** (in microbiology) See e.g. IRON BACTERIA, PSEUDOCATALASE and SUPEROXIDE DISMUTASE.

**mango black spot** See BLACK SPOT (3).

**mannans** Polysaccharides composed of manosyl residues. Linear (1 → 4)- $\beta$ -linked mannans occur in some algae of the Chlorophyta (e.g. *Acetabularia*, *Codium*) – in which they may replace cellulose as the main structural component of the CELL WALL – and in certain plants (e.g. in many palm seeds); in many yeasts the CELL WALL has a high mannan content. Heteroglycans consisting of (1 → 4)- $\beta$ -linked D-glucosyl and D-mannosyl residues (*glucomannans*) are major HEMICELLULOSES in gymnosperms.

**mannitol** The POLYOL corresponding to mannose; it occurs e.g. in many plants, algae, fungi and lichens, and is formed by the reduction of fructose by certain bacteria (see e.g. SILAGE). Mannitol is a major carbohydrate in members of the Phaeophyta and in chrysophytes (in which it is the primary photosynthetic carbohydrate) and in ascomycetous and basidiomycetous fungi; earlier reports that it occurs in the Rhodophyta appear to be incorrect [Book ref. 37, pp. 162–165]. Mannitol can have an osmoregulatory role in certain algae and fungi exposed to fluctuating salinities.

**mannopine** An opine of the agropine type: see e.g. HAIRY ROOT.

**mannose** An aldohexose found e.g. in MANNANS and in animal mucolipids and mucoproteins. (See also NEURAMINIC ACIDS; cf. MANNITOL.)

**mannose-binding lectin** See COMPLEMENT FIXATION (C).

**mannose-resistant haemagglutination** See FIMBRIAE.

**mannose-sensitive haemagglutination** See FIMBRIAE.

**mantle** (*mycol.*) See MYCORRHIZA.

**Mantonella** See EIMERIORINA.

**Mantoniella** See MICROMONADOPHYCEAE.

**Mantoux test** See TUBERCULIN TEST.

**manure gas poisoning** Poisoning of man or animals by gases (e.g.  $H_2S$ ,  $NH_3$ ,  $CO_2$ ) produced by anaerobic bacteria in manure stored in large slurry pits; exposure to high concentrations of these gases – e.g. during mixing of slurries prior to emptying pits – can be rapidly fatal.

**MAP** (1) (M-associated protein) A protein often associated with the streptococcal M PROTEIN; it also occurs in streptococci of groups C and G that have M-like antigens.

(2) MICROTUBULE-ASSOCIATED PROTEIN.

(3) METHIONINE AMINOPEPTIDASE.

**MAP kinase** See ANTHRAX TOXIN.

**map lichens** *Rhizocarpon* spp, particularly *R. geographicum*.

**map unit** (map distance) (1) *Syn.* CENTIMORGAN. (2) Any unit used for indicating the position of markers in a genome: e.g. the chromosome of *Escherichia coli* is divided into 100 minutes (see INTERRUPTED MATING).

**maple bark strippers' disease** An EXTRINSIC ALLERGIC ALVEOLITIS associated with inhalation of the spores of *Cryptostroma corticale*.

**Maranil** Dodecylbenzolsulphonate: an agent used e.g. in BTB AGAR (0.005%) to inhibit swarming by *Proteus* spp.

**Marasmius** See AGARICALES (Tricholomataceae); see also MYCORRHIZA.

**marble bone** *Syn.* OSTEOPETROSIS.

**marble spleen disease** A disease of pheasants caused by an adenovirus very similar to the causal agent of HAEMORRHAGIC ENTERITIS OF TURKEYS. The disease is acute and rapidly fatal, and involves severe pulmonary oedema with enlargement and mottling of the spleen. [Book ref. 116, pp. 537–539.]

**Marburg fever** (green monkey fever) A VIRAL HAEMORRHAGIC FEVER, caused by the Marburg virus (see FILOVIRIDAE), first reported in 1967 when an outbreak occurred in Marburg (W. Germany) among laboratory personnel working with infected tissues of the African green monkey (*Cercopithecus aethiops*). Incubation period: ca. 6–10 days. Onset is sudden, with e.g. fever, mental confusion, diarrhoea, haemorrhages from mucous membranes, and often a maculopapular rash. The disease is often fatal. (Ebola virus causes a similar disease.)

**Marburg virus** See FILOVIRIDAE.

**Marek's disease** (fowl paralysis) A POULTRY DISEASE caused by gallid herpesvirus 1 (see GAMMAHERPESVIRINAE); chickens, turkeys, pheasants, ducks, pigeons and other birds are susceptible, but the principal natural hosts appear to be domestic chickens and their close relatives (*Gallus* spp). Infection seems to occur primarily by inhalation of 'feather dust' released from the feather follicles of infected birds. The classical (chronic) form of the disease involves the development of T-cell lymphomas in the peripheral nerves, causing progressive paralysis. A visceral (acute) form also occurs in which lymphomas develop in internal organs; mortality rates for the acute disease are commonly high. Infected birds remain carriers – probably for life. Live vaccines are available: e.g., vaccination with gallid herpesvirus 2 ('turkey herpesvirus') protects chickens and turkeys against Marek's disease. [Review of Marek's disease and its virus: Book ref. 105, pp. 155–183.]

Marek's disease virus can also cause chronic atherosclerosis in SPF chickens [AJP (1986) 122 62–70]; MDV infection apparently prevents activation of cytoplasmic cholesteryl esterase in arterial smooth muscle cells [JBC (1986) 261 7611–7614]. These observations lend support to the hypothesis that herpesvirus infection may play a role in the pathogenesis of atherosclerosis ('hardening of the arteries') in man [review: MS (1986) 3 50–52].

**Marfanil** (sulphamylon; *p*-aminomethylbenzenesulphonamide:  $NH_2CH_2.C_6H_4.SO_2.NH_2$ ) A drug which has been used e.g. in the topical treatment of wounds, burns, etc. It differs from other SULPHONAMIDES in that it is not a sulphanilamide derivative, the *p*-aminomethyl group replacing the *p*-amino group of sulphanilamide.

**marginal zone B cells** (MZ B cells) A subset of B LYMPHOCYTES found within the marginal zone of the spleen (i.e. the junction of red and white pulp) – together with DENDRITIC CELLS and macrophages; cells in the marginal zone are considered to represent an early form of defence against blood-borne pathogens. MZ B cells are important in responses to T-independent antigens, and they are particularly sensitive to lipopolysaccharides. [See e.g. Science (2000) 290 89–92.]

**Marinomonas** See ALTEROMONAS.

**marker (genetics)** A genetic locus which is associated with a particular (usually readily detectable) phenotypic characteristic: e.g., an antibiotic resistance gene.

**marker rescue** Conferment on a gene, or genes, of the ability to replicate as a result of the integration of the gene(s) with a replication. (See also REACTIVATION *sense* 1.)

**Marseilles fever** *Syn.* BOUTONNEUSE.

**marsh gas** See ANAEROBIC DIGESTION.

**Marssonina** See MELANCONIALES.

**marsupium** *Syn.* BROOD POUCH.

**Marteilia** See STELLATOSPOREA.

**Martensella** See KICKXELLALES.

**marticin** See NAPHTHAZARINS.

**Mason–Pfizer monkey virus (MPMV)** An exogenous, xenotropic retrovirus of the TYPE D RETROVIRUS GROUP. MPMV was isolated from a carcinoma of a rhesus monkey; it has not been shown to be oncogenic either in its natural host or in other primates. (*cf.* SIMIAN AIDS.)

**MASP** MBL-associated serine protease: see COMPLEMENT FIXATION (c).

**mast cell** A cell which can respond to certain stimuli by rapidly secreting e.g. vasoactive products; it is important e.g. in immediate-type hypersensitivity reactions and in acute INFLAMMATION. Unlike the BASOPHIL, the mast cell is primarily a non-circulating cell, occurring e.g. in blood vessels and in the lymphatic system. The (basophilic) cytoplasmic granules in the mast cell contain a variety of biologically active products – e.g. HISTAMINE, HEPARIN, SEROTONIN (significant amounts in some species), and proteases – which are released, within 15–20 sec, on activation and degranulation of the cell. Mast cells can be activated and degranulated e.g. by certain CYTOKINES, ANAPHYLATOXINS, IgE (and certain IgG) antibodies together with their homologous antigens, IgE aggregates (not monomeric IgE), bivalent anti-IgE receptor antibodies, and some LECTINS (e.g. PHA). The mast cell surface contains many high-affinity receptor sites for the Fc portion of IgE, and the cross-linking of surface-bound IgE antibodies by antigen (allergen) appears to be a trigger for degranulation (see also TYPE I REACTION). (Degranulated mast cells gradually replace their histamine.) Activated mast cells also produce e.g. SUPEROXIDE, H<sub>2</sub>O<sub>2</sub>, and factors which are chemotactic for NEUTROPHILS and EOSINOPHILS.

**Mastadenovirus** (mammalian adenoviruses) A genus of adenoviruses (family ADENOVIRIDAE) which infect mammals (including man); type species: human adenovirus type 2 (= h2, = Ad2). Almost all mammalian adenoviruses share a common (group-specific) antigen (a hexon surface antigen); subgenus-specific and species-specific antigens can also be detected.

*Human adenovirus* species are designated by the prefix Ad (or h) followed by the species (serotype) number: Ad1, Ad2, etc (or h1, h2, etc). Human adenoviruses can cause a wide range of diseases (as well as subclinical infections) in humans. Several can induce tumours (mainly sarcomas) when injected into newborn rodents, but none is known to cause tumours in man under natural conditions; however, most human adenoviruses can cause morphological transformation in certain types of cell cultures, causing the formation of characteristic foci of small, often polygonal cells containing scanty cytoplasm and capable of dividing indefinitely. Transformation of cells by adenoviruses involves the integration of viral DNA sequences into host chromosomal DNA. Depending on the host cell, the whole viral genome or (more commonly) a fragment of it may be integrated; integration apparently occurs at random sites in the host DNA, and the viral DNA – together with flanking

host sequences – often undergoes amplification. Transformation requires the integration of at least the E1a region, but the mechanism of transformation is unknown. [Adenoviral genes and transformation: Book ref. 110, pp. 125–172.]

Human adenoviruses have been classified into subgenera (subgroups) on the basis of e.g. DNA characteristics, oncogenicity, subgenus-specific antigens, morphology, haemagglutinating properties, etc:

Subgenus A (Ad12, 18 and 31): GC% of the DNA: 47–49; length of virion fibres: 28–31 nm. Viruses in this subgenus are highly oncogenic when injected into newborn hamsters or rats, causing tumours after ca. 2–4 months; in man, they are associated with upper respiratory tract infections and diarrhoea, or infection may be subclinical.

Subgenus B (Ad3, 7, 11, 14, 16, 21, 34 and 35): GC% of the DNA: 49–52; length of the virion fibres: 9–11 nm. Viruses in this subgenus are weakly oncogenic when injected into newborn hamsters, causing tumours at low incidence after ca. one year; in man, they cause e.g. ARD (Ad3, 7, 14, 21), acute haemorrhagic CYSTITIS (Ad11), PHARYNGOCONJUNCTIVAL FEVER, pneumonia, etc.

Subgenus C (Ad1, 2, 5 and 6): GC% of the DNA: 57–59; length of the virion fibres: 23–31 nm. These viruses are non-oncogenic in newborn rodents, but can cause transformation of rodent cells *in vitro*; they can cause mild to severe upper respiratory tract disease in young children.

Subgenus D (Ad8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36, 37–39): GC% of the DNA: 57–60; length of the virion fibres: 12–13 nm. The viruses are non-oncogenic in newborn hamsters, but may cause mammary adenomas in newborn female rats and can transform rodent cells *in vitro*. Ad8 and Ad19 are causal agents of EPIDEMIC KERATOCONJUNCTIVITIS.

Subgenus E (Ad4): GC% of the DNA: 57; length of virion fibres: 17 nm. Non-oncogenic in newborn hamsters. Ad4 can cause EPIDEMIC KERATOCONJUNCTIVITIS, acute respiratory disease (see ARD), and PHARYNGOCONJUNCTIVAL FEVER.

Two further subgenera, F (Ad40) and G (Ad41), have been recognized but are not yet well characterized; these include the ‘enteric’ or ‘fastidious’ adenoviruses [review: Arch. Virol. (1986) 88 1–17] which cause diarrhoea in infants and young children, and which cannot be propagated in conventional cell cultures. They can be grown in an Ad5-transformed human embryonic kidney cell line.

Most human adenoviruses will not replicate readily in simian cell lines, but may do so in the presence of simian virus 40 (SV40); SV40 can interact extensively with human adenoviruses, e.g. forming SV40–adenovirus hybrids [Book ref. 116, pp. 399–449].

*Animal adenovirus* nomenclature follows at least two different conventions; a species may be designated by a three-letter prefix derived either from the name of the animal plus ‘AV’ (e.g. BAV for bovine adenovirus, SAV for simian adenovirus [Book ref. 116, p. 500]) or from the genus name of the host animal (e.g. bos for cattle, sus for pigs, equ for horses, mus for mice [Book ref. 23, p. 60]), followed in either case by the serotype (species) number – e.g. BAV-3 or bos-3, MAV-1 or mus-1, etc. Infection of animals by adenoviruses may result in (usually mild) respiratory or diarrhoeal illnesses, conjunctivitis, etc. Canine adenovirus type 1 (CAV-1, can-1) can cause encephalitis in foxes and e.g. hepatitis in dogs; CAV-2 is thought to be a causal agent of laryngotracheitis (‘kennel cough’) in dogs. Several animal adenoviruses (11 simian, 2 bovine and 2 canine species) can induce tumours when injected into newborn hamsters. [Animal adenoviruses: Book ref. 116, pp. 497–562.]

## **Mastigocladus**

**Mastigocladus** See FISCHERELLA and CHLOROGLOEOPSIS.

**Mastigomycota** In some taxonomic schemes: a division equivalent to the subdivision MASTIGOMYCOTINA.

**Mastigomycotina** A subdivision of unicellular and (more commonly) mycelial fungi (division EUMYCOTA); most species (though not e.g. *Peronospora* spp) form flagellated spores or gametes. Classes: CHYTRIDIOMYCETES, HYPHOCHYTRIOMYCETES, OOMYCETES.

**mastigoneme** See FLAGELLUM (b).

**Mastigophora** A subphylum of protozoa (phylum SARCOMASTIGOPHORA) which have one or more flagella; cell division is typically symmetrogenic. Classes: PHYTOMASTIGOPHOREA and ZOOMASTIGOPHOREA.

**mastigosome** *Syn.* BASAL BODY (b).

**mastitis** Inflammation of the mammary gland; it may or may not be of microbial causation.

(a) (*med.*) *Puerperal mastitis* may occur in lactating women, commonly ca. 1 month after childbirth, and may be caused by staphylococci or streptococci.

(b) (*vet.*) Mastitis is quite common among farm animals, but is uncommon in mares. In cows, common causal agents include e.g. *Actinomyces pyogenes* ('summer mastitis' in dry cows and pre-calving heifers), *Escherichia coli* ('coliform mastitis' is caused by *E. coli* or other coliforms), *Staphylococcus aureus* (see also BLACK POX), and *Streptococcus agalactiae*, but any of a wide range of organisms may be involved, including various other bacteria (e.g. species of *Pasteurella*, *Pseudomonas*), fungi (e.g. *Aspergillus*, *Candida*) and algae (*Prototheca* spp). In ewes, mastitis is commonly caused by *E. coli*, *S. aureus* or *S. agalactiae* but may be due e.g. to *Mycoplasma agalactiae*, while in mares the causal agent may be e.g. *Streptococcus equi*. In cows, predisposing factors include age and the stage of lactation; thus, e.g. cows which have had ca. four or more lactations, and those within the first two months of lactation, are more susceptible than others. Symptoms may range from mild to an acute inflammatory condition with fever and other systemic effects; the milk contains an increased number of white blood cells, and may contain a significant number of pathogenic microorganisms. (See also CALIFORNIA MASTITIS TEST and CAMP TEST.) *Treatment*: e.g. parenteral administration or intramammary infusion of antibiotics [Book ref. 33, pp. 451–500]. [Chemoprophylaxis in bovine mastitis: Book ref. 121, pp. 193–204.]

[DNA fingerprinting and ribotyping in epidemiological investigations of outbreaks of *Pseudomonas aeruginosa* mastitis among Irish dairy herds: AEM (1999) 65 2723–2729.]

**mat** (microbial) See MICROBIAL MAT.

**MAT locus** See MATING TYPE.

**matching** (in taxometrics) See entry S<sub>SM</sub>.

**MATE** Multidrug and toxic compound extrusion: an EFFLUX MECHANISM which e.g. mediates resistance to antibiotic(s) in certain bacteria (including e.g. *Escherichia coli* and *Vibrio parahaemolyticus*). [Mol. Microbiol. (1999) 31 393–395.]

**mate killer** The term for certain (endosymbiont-containing) strains of ciliate protozoa which, on conjugation (mating), cause the death of the conjugal partner; mate killers include strains of *Paramecium aurelia* (endosymbiont: *Caedibacter paraconjugatus* or *Pseudocaedibacter conjugatus*) and of *Euplotes crassus* and *E. patella* (endosymbionts unnamed). In each case mating is essential for killing; thus, e.g. the ingestion of *C. paraconjugatus* by sensitive paramecia does not cause harmful effects.

**maternal immunity** PASSIVE IMMUNITY acquired by a fetus or neonate from its mother either via the placenta or from COLOSTRUM.

**maternal inheritance** A form of CYTOPLASMIC INHERITANCE in which certain characteristics are transmitted to sexually derived progeny only from the female parent cell. Various hypotheses have been proposed to account for maternal inheritance, and different mechanisms may be applicable in different cases. Thus, in certain cases where maternally inherited genes occur in mitochondria, mitochondria from the male parent are presumed to be excluded from the zygote (see e.g. POKY MUTANT). To account for the maternal inheritance of genes in chloroplast DNA (a phenomenon recorded in some isogamous green algae) it has been proposed that chloroplast DNA from the male parent is preferentially digested [MS (1985) 2 267–270].

**mating** *Syn.* CONJUGATION (sense 1).

**mating type** A strain of an organism which can interact sexually only with other, genetically distinct, strains of the same species. (See also HETEROBALLISM and SYNGEN.)

In *Saccharomyces cerevisiae* mating type is determined at a single genetic locus, designated *MAT*, on chromosome III. In haploid cells, *MAT* is occupied by either the *MATa* allele or the *MAT $\alpha$*  allele – which occur in **a** and  $\alpha$  mating types respectively. According to the widely-accepted ' $\alpha$ 1- $\alpha$ 2 hypothesis', *MATa* and *MAT $\alpha$*  regulate the same groups of structural genes, but their different modes of regulation result in the development of phenotypically different mating types; thus, groups of genes known as '**a**-specific genes' and ' $\alpha$ -specific genes' (which specify the **a** and  $\alpha$  phenotypes, respectively) occur in the cells of both **a** and  $\alpha$  mating types, and the way in which these genes are controlled by the *MAT* locus determines the cell's mating type.

*MAT $\alpha$*  is transcribed in two parts from a central promoter region, the two RNA transcripts being copied from different DNA strands; the parts are called *MAT $\alpha$ 1* and *MAT $\alpha$ 2*. *MAT $\alpha$ 1* expression is necessary for the transcription of the  $\alpha$ -specific genes – whose products include the  $\alpha$ -factor (a PHEROMONE).

*MAT $\alpha$ 2* is a negative regulator of **a**-specific genes.

The (single) *MATa* product has no effect in the **a**-type haploid vegetative cell; by default, **a**-type genes (including that encoding the **a**-type pheromone **a**-factor) are expressed in cells of this mating type.

In most natural isolates of *S. cerevisiae*, spontaneous conversion of the *MATa* allele to the *MAT $\alpha$*  allele, and vice versa, occurs quite frequently – with concomitant switching of mating type; a given population will therefore consist of a mixture of compatible mating types (**a** and  $\alpha$ ) and will give the appearance of being homothallic. (Stability at the *MAT* locus involves another locus, designated *HO* for homothallism, located on chromosome IV.) Switching involves a cassette mechanism, *unexpressed* copies of *MATa* and *MAT $\alpha$*  being stored on chromosome III at sites designated, respectively, *HMR* and *HML*; these genes are silenced by the transcription-resistant form of their chromatin. Switching requires a double-stranded cut at the *MAT* locus, made by the HO ('YZ') endonuclease, followed by excision of the resident *MAT* allele and its replacement with a copy of the allele of the other mating-type (*gene conversion*).

When **a**-type and  $\alpha$ -type cells are mixed, the pheromone from a given mating type causes cells of the other type to stop in the G<sub>1</sub> phase of the CELL CYCLE, and to exhibit a mating type-specific glycoprotein component of the cell wall which promotes fusion between cells of opposite mating types. The zygote, which lacks mating potential and mating type characteristics, is designated **a**/ $\alpha$ .

In the **a**/ $\alpha$  zygote, the  $\alpha$ 2 and **a**1 proteins jointly switch off various genes, including **a**-specific and  $\alpha$ -specific genes and the 'haploid-specific' genes active in both mating types.

**matrix protein** (*bacteriol.*) A former term for PORIN.

**maturase** See SPLIT GENE (b) and (c).

**Maurer's clefts** (Maurer's dots) Large dots, streaks, or 'comas' sometimes observed, on suitable staining, in erythrocytes infected with certain stages of *Plasmodium falciparum*.

**Maus Elberfeld virus** See CARDIOVIRUS.

**maxicell** A bacterial 'cell' obtained by UV irradiation of *recA*, *uvrA* mutant strains of e.g. *Escherichia coli*. Irradiation of such mutants results in damage to and degradation of chromosomal DNA (cf. RECKLESS DNA DEGRADATION); however, if small, multicopy plasmids are present in such cells, some of the plasmids may be undamaged by the UV radiation and can subsequently replicate. These cells therefore synthesize plasmid-encoded proteins almost exclusively; the proteins can be labelled by adding e.g. [<sup>35</sup>S]methionine to the medium. [JB (1979) 137 692–693.] (cf. MINICELL.)

**maxicircle DNA** See KINETOPLAST.

**maximum specific growth rate** ( $\mu_{\max}$ ) See SPECIFIC GROWTH RATE.

**Mayaro fever** An epidemic febrile human disease caused by an ALPHAVIRUS and transmitted by mosquitoes (e.g. *Haemagogus janthinomys*); it occurs in the Caribbean and parts of S. America. Symptoms: e.g. headache, myalgia, arthralgia, and a maculopapular rash. Monkeys are probably the main natural hosts.

**Mayorella** A large genus of amoebae (order AMOEBIDA) which characteristically form several bluntly conical, hyaline pseudopodia of similar lengths. (See also UROID.) Some species have a surface covering of complex scales (not discernible by light microscopy). Species occur in freshwater habitats and e.g. sewage treatment plants. *M. viridans* contains ZOOCHLORELLAE.

**maytansine** See MICROTUBULES.

**mazaedium** A type of ascocarp in which the asci disintegrate to release a powdery mass of ascospores (with sterile elements); mazaedia are formed in members of the Caliciales and in *Onygena*. (The term 'mazaedium' may also refer to the spore mass per se.)

**MBC fungicides** See BENZIMIDAZOLES (a).

**MBL** Mannose-binding lectin: see COMPLEMENT FIXATION (c).

**Mbl protein** See CELL CYCLE (b) (determination of shape).

**MBP** Mannose-binding protein, referred to more commonly as MBL (mannose-binding lectin) – see COMPLEMENT FIXATION (c).

**MBSA** Methylated bovine serum albumin.

**MC29** See AVIAN ACUTE LEUKAEMIA VIRUSES.

**Mcc plasmid** See MICROCINS.

**McCartney bottle** A bottle similar to a UNIVERSAL BOTTLE but which has a narrower neck.

**McClung Toabe egg-yolk agar** (modified) A medium used for the isolation and identification of clostridia and other anaerobes; it permits detection of lecithinase, lipase and proteolytic activity. The medium contains tryptone, yeast extract, glucose, egg yolk, Na<sub>2</sub>HPO<sub>4</sub>, NaCl, MgSO<sub>4</sub> and agar.

**McDonough feline sarcoma virus** See FMS.

**MCF viruses** Mink cell focus-forming viruses: variant MURINE LEUKAEMIA VIRUSES (MuLVs) which can be detected and assayed by their ability to induce foci of transformed cells in monolayer cultures of a mink lung cell line. MCF viruses were originally isolated from mouse strains (e.g. AKR) which show a very high incidence of spontaneous leukaemia. The *env* gene of an MCF virus resembles a mixture of those of murine ecotropic and xenotropic viruses, and confers on it a DUALTROPIC host range. MCF viruses are believed to have arisen by recombination

between an ecotropic MuLV and an endogenous xenotropic retrovirus. Since many MCF viruses have a leukaemogenic potential greater than that of the parent MuLV, it has been suggested that an MCF component may be responsible for 'MuLV-induced' leukaemogenesis. (See also AKV; cf. FRIEND VIRUS.)

**McFadyean's test** A confirmatory test for ANTHRAX carried out, post-mortem, on an infected guinea pig. Blood (from the heart), or a spleen imprint, is stained with polychrome methylene blue; in a positive test, the stained smear reveals large, blue, square-ended bacilli surrounded by a reddish granular capsule.

**McIntosh and Fildes' anaerobic jar** (modified) An ANAEROBIC JAR which consists of a strong cylindrical metal chamber with a flat, circular, gas-tight lid; such jars are referred to by various trade names (e.g. Torbal jar). Media etc are placed in the jar, and the lid is secured by means of a screw clamp. The jar is then evacuated, by a suction pump, via one of two screw-controlled needle valves in the lid; this valve is then closed. (To prevent the vacuum sucking the agar from Petri dishes, plates are incubated lid-side up – cf. GASPAC.) The jar is filled, via the other valve, with gas(es) – e.g. H<sub>2</sub>, or CO<sub>2</sub> and H<sub>2</sub> – from a compressed-gas cylinder or from a gas-filled rubber bladder; this valve is closed, and the cycle of evacuation and re-filling is carried out several times. Attached to the inside of the lid is a gauze envelope containing a catalyst (e.g. palladium-coated pellets of alumina) which promotes chemical combination between hydrogen and the last traces of oxygen in the jar; such catalysts work at room temperatures and are called 'cold' catalysts. The jar also has a side-arm to which is attached a small, thick-walled, closed glass vessel which communicates with the interior of the jar and which contains an indicator of anaerobiosis (e.g. METHYLENE BLUE solution).

**MCP** (1) Methyl-accepting chemotaxis protein (see CHEMOTAXIS).

(2) Membrane co-factor protein (see COMPLEMENT FIXATION (b).)

**MCS** (multiple cloning site) See POLYLINKER.

**M-CSF** See COLONY-STIMULATING FACTORS.

**MDa** Megadalton: 10<sup>6</sup> DALTONS.

**MDCK cells** Madin–Darby canine kidney cells: a heteroploid cell line derived from the kidney of an apparently normal dog. MDCK cell cultures have been used e.g. for the primary isolation and passage of influenza virus type A [PNAS (2000) 97 9654–9658].

**MDP** Muramyl dipeptide: *N*-acetylmuramyl-L-alanyl-D-isoglutamine; a water-soluble component of a modified form of complete FREUND'S ADJUVANT.

**mean doubling time** See GROWTH (a).

**mean generation time** See GROWTH (a).

**measles** (morbilli; cf. RUBELLA) An acute and highly infectious human disease which affects mainly children. (Other primates can be affected.) The causal agent is a MORBILLIVIRUS. Transmission occurs by droplet infection or via fomites; the conjunctivae may be important sites of infection. Incubation period: 8–12 days. In the prodromal stage (2–4 days) there is coryza, cough, fever, and the appearance of KOPLIK'S SPOTS. Subsequently, a maculopapular rash develops on the head, then on the limbs and trunk. The spots are initially bright pink but become deeper red and then brownish – a phenomenon known as 'staining'. Viruses are present in the urine, nasopharyngeal secretions etc during the prodromal period and for several days after the appearance of the rash. Complications may include ENCEPHALITIS [NEJM (1984) 310 137–141]; secondary bacterial infection may result in e.g.

## meat spoilage

OTITIS MEDIA or PNEUMONIA. Measles is usually self-limiting, but may be fatal in young infants or in malnourished children; death is usually due to respiratory complications. Life-long immunity usually follows recovery (cf. SUBACUTE SCLEROSING PANENCEPHALITIS). *Lab. diagnosis*: microscopic examination of smears of the nasal mucosa for epithelial GIANT CELLS; detection of the measles virus in blood, urine or nasal secretions. *Chemotherapy*: none. Measles immune globulin may be used prophylactically in high-risk patients exposed to measles. Live attenuated vaccines (cf. MR and MMR) may be given to infants and young children.

**meat spoilage** The occurrence, nature and extent of meat spoilage depends on e.g. the initial numbers and types of contaminating microorganisms, the conditions of storage (particularly temperature and oxygen tension), the length of storage, and the nature of the meat itself (e.g. its WATER ACTIVITY, glucose content [see e.g. AEM (1982) 44 521–524], pH). Spoilage may involve slime formation, discoloration, souring, and off-odours (due e.g. to the volatile products of microbial amino acid metabolism).

(a) *Carcasses*. Carcass meat is normally surface-contaminated with bacteria and fungi derived from the animal's skin, intestine, faeces etc., from soil, and e.g. from the hands and tools of workers. Even under good hygienic conditions, carcasses are likely to carry  $10^2$ – $10^5$  bacteria/cm<sup>2</sup>, but spoilage commonly becomes apparent only after bacterial numbers reach ca.  $10^7$ – $10^9$  per cm<sup>2</sup>. After slaughter, the pH of meat gradually falls as the muscle glycogen is converted to lactic acid – the final pH depending on the amount of glycogen present at the time of death. The final pH of red meats is commonly 5.4–5.8; chicken leg meat normally has a pH of ca. 6.5, although the breast meat usually has a pH of ca. 5.7. Meat from stressed animals has a higher pH and is more susceptible to spoilage – see DFD MEAT.

For *short-term storage*, carcasses may be chilled to e.g. 0–10°C. Below ca. 10°C psychrotrophic spoilage organisms increase greatly in numbers; by contrast, *pathogenic* organisms (cf. FOOD POISONING) grow very slowly, and their presence is usually not obvious. In most meats, including uncured pig meat and poultry, the commonest spoilage bacteria under aerobic conditions are strains of *Pseudomonas* [JAB (1982) 52 219–228 (taxonomic study)], often occurring together with smaller numbers of bacteria such as *Acinetobacter*, *Alteromonas*, *Brochothrix* and *Lactobacillus* spp. Of the spoilage organisms, *Pseudomonas* spp have the highest growth rate at low temperatures, and this advantage tends to become more marked with decreasing temperature. (In poultry, *Acinetobacter* replaces *Pseudomonas* as the commonest spoilage organism at temperatures above ca. 10°C.) However, *Brochothrix thermosphacta* and *Lactobacillus* spp, for example, are more tolerant than pseudomonads of low  $a_w$ , and these may become dominant on drying carcasses. On *cured* meats (see CURING, e.g. bacon, the commonest spoilage bacteria under aerobic conditions are halophilic, psychrophilic vibrios (e.g. *Vibrio costicola*) and species of *Acinetobacter* and *Micrococcus*; the micrococci are lipolytic and proteolytic, and some strains can reduce nitrite. Fungi found on chilled carcasses include *Cladosporium*, *Penicillium*, *Mucor*, *Rhizopus* and *Thamnidium*, and the yeasts *Candida*, *Cryptococcus* and *Rhodotorula*; these may cause e.g. surface discolorations.

For *long-term storage*, temperatures of ca. –12°C to –18°C are often used; the process of freezing kills or damages a proportion of contaminants, although lower temperatures (e.g. –30°C) are less lethal (see FREEZING). At temperatures between ca. –5°C and –10°C fungal contaminants may become important spoilage agents (see e.g. BLACK SPOT sense 1).

(b) *Packaged meats*. As well as the factors cited above, the nature of spoilage of packaged meats depends on the type of packaging – particularly on the permeability of the packing material to air. Spoilage of chilled red meats typically occurs more rapidly in the presence of oxygen than under vacuum. Under aerobic conditions (e.g. with oxygen-permeable packing film) *Pseudomonas* spp are the commonest spoilage organisms; *Acinetobacter* may be present in significant numbers if the pH is above ca. 6.0. Under anaerobic conditions (e.g. in oxygen-impermeable vacuum packs) these organisms are inhibited, permitting the growth of e.g. *Lactobacillus* spp and *Brochothrix thermosphacta*; CARBON DIOXIDE per se (ca. 10–20% v/v) inhibits the growth of e.g. *Pseudomonas* spp, *Alteromonas putrefaciens*, *Acinetobacter* sp, and *Yersinia enterocolitica*, but not of e.g. *B. thermosphacta* or lactobacilli. (cf. DFD MEAT.)

At low temperatures (e.g. 5°C) vacuum-packed cured meats (e.g. bacon) are susceptible to spoilage by e.g. *Lactobacillus* spp (which may cause e.g. souring) [AvL (1983) 49 327–336]; lactobacilli are resistant to nitrite, smoke (see SMOKING), and low concentrations of salt. At higher salt concentrations, *Micrococcus* spp may become dominant. Cooked hams and cooked sausage (in which CATALASE has been destroyed) may undergo a type of *greening* caused by e.g. lactobacilli (especially *L. viridescens*); these organisms produce H<sub>2</sub>O<sub>2</sub> which oxidizes the porphyrin ring in meat haem pigments to form a green compound (cf. DFD MEAT). (Higher concentrations of H<sub>2</sub>O<sub>2</sub> can produce yellow or colourless compounds.)

[Book ref. 30.]

(See also CANNING; FOOD SPOILAGE; SALAMI; SOFT CORE HAM.)

**mecA gene** See MRSA.

**MECAM** A (synthetic) functional analogue of enterobactin used e.g. in studies on IRON uptake [see e.g. JB (1986) 167 666–680].

**mechanical transmission** Transmission of a parasite by passive transfer from one host to another, e.g. via a mechanical VECTOR, via contaminated tools or instruments etc.

**mechanical vector** See VECTOR (1).

**mechanosensitive channel** (stretch-activated channel) A channel through the CYTOPLASMIC MEMBRANE which responds to increases in the cell's turgor pressure by increasing in pore size, thus facilitating efflux of water and certain solutes [JBC (1997) 272 32150–32157]; one example is the MscL channel in *Escherichia coli* [mechanosensitive channels in *E. coli*: ARP (1997) 59 633–657]. Such channels occur in many types of bacteria and appear to have an important role in OSMOREGULATION; they open when the cell's turgor pressure is just below the level at which fatal disruption would occur [EMBO (1999) 18 1730–1737].

[The gating mechanism of the large mechanosensitive channel in *Mycobacterium tuberculosis*: Nature (2001) 409 720–724.]

**mecI, mecRI genes** See MRSA.

**mecillinam** (Coactin; aminocillin) A derivative of 6-β-amidopenicillanic acid (cf. PENICILLINS) which, in e.g. *Escherichia coli*, binds exclusively to PBP-2 (see PENICILLIN-BINDING PROTEINS).

**medallion clamp** See CLAMP CONNECTION.

**median lethal dose** *Syn.* LD<sub>50</sub> (q.v.).

**medical flat** A flat-sided glass screw-cap bottle obtainable in various sizes.

**medicarpin** An isoflavonoid PHYTOALEXIN produced e.g. by the broad bean (*Vicia faba*). (cf. WYERONE.)

**Medina reaction** See LEPROMIN TEST.

**medium** In microbiology: any liquid or solid preparation made specifically for the growth, storage or transport of microorganisms or other types of cell. Growth media for microorganisms may be used e.g. for the initiation of a CULTURE (or a SUBCULTURE), for ENRICHMENT, or for diagnostic (identification) tests – i.e. tests in which the identity of a given organism may be deduced from the characteristics of its growth in or on particular media. (See also TRANSPORT MEDIUM.) Specialized media are used for the growth/maintenance of mammalian (and other) cells in TISSUE CULTURE (q.v.). Before use, a medium is normally STERILE (sense 1).

Many chemolithoautotrophic bacteria can be cultured in simple aqueous media containing mainly, or only, mixtures of inorganic salts. Nutritionally undemanding heterotrophs can be grown on/in a range of culture media (see e.g. NUTRIENT BROTH and PETONE WATER). Nutritionally 'fastidious' heterotrophs may be grown on an ENRICHED MEDIUM. Strict anaerobes are often cultured on 'pre-reduced' media (see ANAEROBE).

Solid media usually consist of liquid media which have been solidified ('gelled') with an agent such as AGAR or GELATIN; other gelling agents include e.g. ALGINATE, Gelrite (see GELLAN GUM), and PLURONIC POLYOL F127. (See also SILICA GEL.) Solid media (such as e.g. NUTRIENT AGAR) may be used in order to obtain colonies (see COLONY) of a given organism; colonies may be required for identification purposes or e.g. for the determination of viable cell counts (see COUNTING METHODS). Media containing an unusually high concentration of solidifying agent (e.g. *stiff* AGAR) are used e.g. to inhibit SWARMING; those containing less than normal concentrations of solidifying agent (e.g. *semi-solid* or 'sloppy' agar) may be used e.g. for CRAIGIE'S TUBE METHOD.

**Basal medium.** One which, without supplement, can support the growth of various nutritionally undemanding species; see e.g. NUTRIENT BROTH.

**Defined medium.** One in which all the constituents (including trace substances) are quantitatively known.

**Differential medium.** A solid medium on/in which different types of organism may be distinguished by their different forms of growth; see e.g. MACCONKEY'S AGAR; SS AGAR.

**Diphasic medium.** See DIPHASIC MEDIUM.

**Enriched medium.** See ENRICHED MEDIUM.

**Enrichment medium.** See ENRICHMENT MEDIUM.

**Inhibitory medium.** One containing certain constituent(s) which suppress the growth of certain type(s) of microorganism.

**Maintenance medium.** One used for the initial growth and subsequent storage (under conditions of minimal growth) of microorganisms or other cells. For microorganisms, a maintenance medium is used to prepare a CULTURE of the given organism which is then stored either at room temperature or under refrigeration; subculture is required at intervals ranging from 1 to 12 months. Ideally, the constituents of a maintenance medium are the minimum consistent with the need to maintain viability of the organisms. Examples: COOKED MEAT MEDIUM and DORSET'S EGG. (See also TISSUE CULTURE.)

**Pre-reduced medium.** See ANAEROBE.

**Selective medium.** One which allows or encourages the growth of some type(s) of organism in preference to others. The term usually refers to media such as DCA, MacConkey's agar (which generally supports the growth of enteric – but not non-enteric – bacteria), and all the various types of enrichment media; however, all media are selective to some extent.

**Test medium.** One used for diagnostic (identification) tests. Test media are often made by incorporating additional substance(s) into standard or modified liquid or solid media; often a

PH INDICATOR is included to monitor certain aspects of metabolic activity. Examples: KCN BROTH, LITMUS MILK, TSI AGAR.

**Transport medium.** See TRANSPORT MEDIUM.

**MEE** MULTILOCUS ENZYME ELECTROPHORESIS.

**mefA gene** See MACROLIDE ANTIBIOTICS.

**mefloquine** See AMINOQUINOLINES and MALARIA.

**megacins** See BACTERIOCIN.

**megacolon** See CHAGAS' DISEASE.

**megalomycin** See MACROLIDE ANTIBIOTICS.

**Megasphaera** A genus of Gram-negative bacteria (family VEILLONELLACEAE) which occur e.g. in the RUMEN and in the human intestine. Cells: cocci, ca. 2.0–2.5 µm diam., commonly occurring in pairs. The fermentation of glucose yields mainly caproate, while that of lactate yields acetate, propionate, valerate, C<sub>4</sub> fatty acids, much CO<sub>2</sub> and a little H<sub>2</sub> – but little or no caproate. GC%: ca. 54. Type species: *M. elsdenii* (formerly *Peptostreptococcus elsdenii*).

**Megastrypanum** A subgenus of TRYPANOSOMA within the STERCORARIA; species are parasitic in e.g. cattle and sheep. The organisms are large, sometimes greater than 100 µm in length; the kinetoplast is situated approximately mid-way between the nucleus and the posterior end of the cell, and there is a free flagellum. *T. (M.) theileri* occurs in cattle, and is probably transmitted by contaminative infection of mucous membranes etc with metacyclic forms via tabanid vectors; it is generally non-pathogenic. *T. (M.) melophagium* occurs in sheep, and *T. (M.) theodori* occurs in goats.

**megrims** *Syn.* STAGGERS.

**MEIA** (microparticle enzyme immunoassay) See LCR.

**meiocyte** A cell whose nucleus undergoes MEIOSIS.

**meiosis** (reduction division) The process in which a eukaryotic nucleus divides into nuclei whose ploidy is lower than that of the parent nucleus (typically, haploid nuclei being formed from diploid nuclei) and in which RECOMBINATION usually occurs. (cf. MITOSIS.) Meiosis occurs e.g. during the formation of gametes from diploid cells, and at the inception of haplophase in those organisms which exhibit an ALTERNATION OF GENERATIONS. (See also GAMETIC MEIOSIS; SPORIC MEIOSIS; ZYGOTIC MEIOSIS.)

The best-known form of meiosis is that which occurs in higher animals; other forms of meiosis (which differ in one or more aspects) occur in various microorganisms. Meiosis in higher animals involves two distinct nuclear divisions: the first meiotic division (meiosis I) and the second meiotic division (meiosis II) – each division exhibiting a prophase, metaphase, anaphase and telophase. (cf. MITOSIS.)

**Prophase I.** Individual chromosomes, each having previously replicated to form two chromatids, become visible as long, single threads (*leptotene* stage). In the *zygotene* stage each chromosome pairs, lengthwise, with its HOMOLOGUE, the pair of closely adjacent chromosomes being called a *bivalent*; the pairing of chromosomes (*synapsis*) involves the SYNAPTONEMAL COMPLEX. In this stage and/or the next (*pachytene*) stage CROSSING OVER occurs between pairs of non-sister chromatids. In the *diplotene* stage each chromosome begins to separate from its homologue – but the chromosomes of each homologous pair remain in contact at sites of crossing over (see CHIASMA). In the final stage of prophase I (*diakinesis*) the chromosomes condense, and each homologous pair is seen to consist of four chromatids (i.e., a *tetrad*). By the end of diakinesis the nucleolus and nuclear membrane have disintegrated.

**Metaphase I.** Homologous pairs of chromosomes form a layer at the equator of a microtubular *spindle* (as in MITOSIS).

**Anaphase I.** The two chromosomes in each homologous pair move to opposite poles of the spindle.

## meiosporangium

*Telophase I.* Each of the two groups of chromosomes becomes enclosed by a nuclear membrane.

The interval between the first and second meiotic divisions is called *interkinesis* or *interphase II*.

The second meiotic division is analogous to mitosis, and consists of prophase II, metaphase II, anaphase II and telophase II. [Control of meiosis: SEBS (1984) 38.]

**meiosporangium** A SPORANGIUM within which MEIOSIS occurs (see e.g. ALLOMYCES).

**meiospore** A haploid spore formed by meiotic cell division. (See also ALTERNATION OF GENERATIONS.)

**meiotic** Of or pertaining to MEIOSIS.

**Mel B** *Syn.* melarsoprol (see ARSENIC).

**Mel T** See ARSENIC (a).

**Melampsora** A genus of homoxenous and heteroxenous rust fungi (class UREDINIOMYCETES) which typically form caeomatoid aecia, peridiate uredia, and sessile teliospores. (See also FLAX RUST.)

**Melanconiales** An order of fungi (class COELOMYCETES) in which the vegetative mycelium occurs *within* the substrate or host, and the conidiomata are formed in the superficial layers of the host, becoming erumpent at maturity; mature conidiomata are either acervuli or sporodochia. Some species are important plant pathogens (see e.g. ANTHRACNOSE). Genera include COLLETOTRICHUM, *Cylindrosporium*, *Entomosporium*, *Marssonina* and *Pestalotia*. (See also DIPLOCARPON.)

**melanin** A high-MWt, amorphous polymer of indole quinone; melanins are pigments found in plants, animals (including the skin and hair in man), insects etc, and also in certain microorganisms (e.g. in actinomycetes, in hyphal walls of dematiaceous fungi, in the spore walls of e.g. *Mucor* spp). Melanins are relatively non-specific enzyme inhibitors; they may e.g. protect fungal cell walls from enzymic attack [Book ref. 38, pp. 373–374] and prevent cell lysis in old cultures. Melanins in plants may play a role in resistance to fungal infection.

The first step in melanin biosynthesis involves the *o*-hydroxylation of L-tyrosine (by tyrosinase) to form L-3,4-dihydroxyphenylalanine (L-dopa); L-dopa is used e.g. in the treatment of Parkinson's disease, and attempts have been made to adapt melanin-producing microorganisms for the commercial production of L-dopa [Book ref. 31, p. 567].

**Melanogaster** See GASTEROMYCETES (Melanogastrales).

**Melanogastrales** See GASTEROMYCETES.

**Melanoplus sanguinipes** EPV See ENTOMOPOXVIRINAE.

**Melanospora** See SORDARIALES.

**Melanotaenium** A genus of smut fungi (order USTILAGINALES) which are parasitic on the pteridophyte *Selaginella*.

**melarsoprol** See ARSENIC.

**Melasmia** A genus of fungi of the COELOMYCETES. (See also RHYTISMA.)

**melezitose** A trisaccharide –  $\alpha$ -D-glucopyranosyl-(1  $\rightarrow$  3)- $\beta$ -D-fructofuranosyl-(2  $\leftrightarrow$  1)- $\alpha$ -D-glucopyranoside – found in nature e.g. in certain HONEYDEWS. It can be metabolized e.g. by certain *Lactobacillus* spp. Hydrolysis of melezitose by  $\alpha$ -glucosidase yields glucose and turanose ( $\alpha$ -D-glucopyranosyl-(1  $\rightarrow$  3)-D-fructose).

**melibiose** A reducing disaccharide:  $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  6)-D-glucopyranose, formed from RAFFINOSE by the action of  $\beta$ -fructosidase (invertase). In *Escherichia coli* melibiose uptake occurs by Na<sup>+</sup>/melibiose symport (see ION TRANSPORT).

**melioidosis** A disease of man and animals (particularly rodents) caused by *Burkholderia (Pseudomonas) pseudomallei* – commonly by strains of the biotype that are unable to assimilate

L-arabinose. The disease occurs primarily in tropical regions, particularly in S. E. Asia. Infection usually occurs via wounds or (infrequently) by inhalation of contaminated dust or by ingestion.

The causal organism occurs as a free-living bacterium in both soil and water; infection by *B. (P.) pseudomallei* (through cuts, abrasions) has been reported to occur more often during the wet season.

Person-to-person transmission of the disease has been reported [Lancet (1991) 337 1290–1291].

In man, the disease is very variable, ranging from a local suppurative lesion at the site of infection to an acute, fulminating septicaemia. The disease may flare up after long periods of time (as found e.g. in American veterans of the Vietnam war).

In a recent study of melioidosis in Taiwan, all the isolates of *B. (P.) pseudomallei* were reported to be susceptible to the following antibiotics: amoxycillin-clavulanate, piperacillin-tazobactam (tazobactam is a  $\beta$ -lactamase inhibitor), imipenem and meropenem [EID (2001) 7 428–433].

**Meliola** See BLACK MILDEWS.

**Melissococcus** See EUROPEAN FOULBROOD.

**Melittangium** See MYXOBACTERIALES.

**Melksham virus** See SMALL ROUND STRUCTURED VIRUSES.

**Melolontha melolontha** EPV See ENTOMOPOXVIRINAE.

**Melosira** A genus of freshwater and marine centric DIATOMS in which the cylindrical cells (diam. ca. 5–100  $\mu$ m) are typically joined valve-to-valve to form long chains. In many species the valves are highly pleomorphic; in e.g. *M. islandica* valve morphology apparently depends on nutrient (phosphorus and silicon) levels [Limn. Ocean. (1985) 30 414–418]. Sexual reproduction is oogamous.

**melting** (of DNA) See HELIX–COIL TRANSITION.

**Meltzer's reagent** A mycological stain used e.g. for studying spore septation and ascus structure; it consists of iodine (0.5 g), potassium iodide (1–1.5 g), and chloral hydrate (20 g) in distilled water (20 ml).

**membrane anchor sequence** See SIGNAL HYPOTHESIS.

**membrane attack complex** See COMPLEMENT FIXATION (a).

**membrane co-factor protein** See COMPLEMENT FIXATION (b).

**membrane filter** See FILTRATION.

**membrane fusion protein** (MFP) In certain transport systems of Gram-negative bacteria: a protein which appears to act as a link between inner and outer membranes (see e.g. ABC EXPORTER and RND).

**membrane-inlet mass spectrometry** A method used for the direct and continuous monitoring of gas(es) dissolved in a liquid medium, e.g. a bacterial culture. Essentially, a hydrophobic membrane (e.g. PTFE – see FILTRATION) separates the liquid from a vacuum; dissolved gas(es) pass through the membrane into the vacuum and thence into the mass spectrometer. [MS (1984) 1 200–203; Book ref. 132, pp. 239–262; some applications: Book ref. 132, pp. 271–294.]

**membrane potential** See CHEMIOSMOSIS.

**membrane trigger hypothesis** See SIGNAL HYPOTHESIS.

**membranelle** (*protozool.*) A discrete tuft or band of closely packed, apparently coherent cilia which behave as a unified organelle. (cf. SYNCILIUM.) The term is sometimes used to refer specifically to any one of the serially arranged membranelles of the AZM (q.v.). (See also COMPOUND CILIATURE.)

**membranous croup** *Syn.* DIPHTHERIA.

**memory cells** (*immunol.*) Lymphocytes which have had initial contact with specific antigen and which, on subsequent challenge with antigen, can give a rapid and heightened response (compared with the response that followed initial challenge).

Unlike other lymphocytes in the circulation, memory cells persist for long periods of time; they are also distinguishable by certain cell-surface antigens, e.g. CD44.

(See also ANTIBODY FORMATION.)

**menadione** See QUINONES.

**menaquinones** See QUINONES.

**Mendosicutes** A proposed division of the PROCARYOTAE comprising the single class ARCHAEOBACTERIA.

**mengovirus** See CARDIOVIRUS.

**meningitis** Inflammation of the meninges (membranes covering the brain and spinal cord). Meningitis may be of non-microbial causation, or it may result from primary or secondary infection by any of a range of microorganisms which gain access to the meninges via the blood or lymph systems, head wounds, or paranasal sinuses.

(a) *Bacterial meningitis*. Symptoms typically include a severe, throbbing headache, stiff neck, fever, delirium and coma; bacterial meningitis may be rapidly fatal. *Lab. diagnosis*: the pathogen can often be detected by microscopic examination of a Gram-stained smear of CSF sediment.

*Meningococcal meningitis* ('epidemic meningitis') – caused by *Neisseria meningitidis* (the meningococcus) – occurs sporadically or in epidemics. Transmission occurs by direct contact or by droplet infection; asymptomatic carriers harbour meningococci in the nasopharynx. Incubation period: ca. 2–10 days. Onset is usually abrupt, with rapid progression to confusion and coma; meningitic symptoms are often accompanied by petechial or purpuric skin lesions which may become gangrenous. Mortality rates: ca. 25–75% in untreated cases, ca. 7–10% in treated cases. A severe, fulminating form involving cyanosis, coma, and skin and adrenal haemorrhages (*Waterhouse–Friderichsen syndrome*) may be fatal within a few hours. *Chemotherapy*: benzylpenicillin, chloramphenicol. Rifampicin can eliminate meningococci from carriers. [A meningococcal C vaccine in teenagers: *Lancet* (2003) 361 675–676.]

*Haemophilus influenzae* type b is a common cause of bacterial meningitis in infants and young children, often secondary to otitis media, pneumonia or viral respiratory disease. Mortality rates (treated cases): ca. 3–10%. *Chemotherapy*: e.g. chloramphenicol.

*Pneumococcal meningitis* (caused by *Streptococcus pneumoniae*) occurs mostly in infants and the elderly or debilitated. It is commonly associated with pneumococcal pneumonia, but may follow otitis media, head wounds etc. Mortality rates: ca. 20–70%. *Chemotherapy*: e.g. benzylpenicillin, chloramphenicol.

Various other bacteria can cause meningitis in adults – e.g. other streptococci, staphylococci, *Acinetobacter calcoaceticus*, *Listeria monocytogenes*, enterobacteria. *Neonates* are particularly vulnerable to meningitis caused by *Escherichia coli* and other enterobacteria, group B streptococci, *Staphylococcus aureus*, *L. monocytogenes*, *Flavobacterium meningosepticum* etc; mortality rates may be high, and motor or intellectual impairment often persists in survivors.

(b) *Aseptic meningitis* is generally a benign, self-limiting condition characterized by a lymphocytic infiltration of the meninges and raised protein levels in the CSF. It is usually caused by a virus – commonly mumps virus or enteroviruses (e.g. echoviruses or coxsackieviruses), also e.g. ENCEPHALITIS viruses, herpes simplex virus and LCM VIRUS. A lymphocytic meningitis may also occur in e.g. CRYPTOCOCCOSIS, LEPTOSPIROSIS, SYPHILIS and TUBERCULOSIS; following administration of

nerve-tissue rabies vaccines (e.g. Semple vaccine); and in certain non-microbial diseases (e.g. cerebral tumours). (See also MENINGOENCEPHALITIS.)

**meningococcus** *Neisseria meningitidis*.

**meningoencephalitis** Inflammation of the brain and its meninges (cf. ENCEPHALITIS and MENINGITIS). *Primary amoebic meningoencephalitis* is a human disease which affects mainly children and young adults and is usually fatal. It is usually caused by *Naegleria fowleri*. Infection occurs via the nasal mucosa and is usually associated with swimming in e.g. freshwater lakes rich in organic matter. Symptoms may include headache, fever, vomiting, disturbances to taste, smell and vision, and coma; death may occur within ca. 72 h. Amoebae of the *Acanthamoeba-Hartmannella* group may cause a subacute or chronic granulomatous meningoencephalitis. *Lab. diagnosis*: identification of amoebae in the CSF. *Chemotherapy*: e.g. amphotericin B (see also MICONAZOLE).

**meningoencephalomyelitis** See ENCEPHALITIS.

**meningomyelitis** Inflammation of the spinal cord and its meninges (cf. MENINGITIS).

**Meniscus** A genus of Gram-negative, anaerobic (but aerotolerant) bacteria which occur e.g. in anaerobic digester sludge. The cells are capsulated, straight or curved, non-motile rods, 0.7–1.0 × 2.0–3.0 μm, which contain gas vacuoles. The organisms are chemoorganotrophs with a strictly anaerogenic fermentative metabolism; growth requirements include vitamin B<sub>12</sub>, thiamine, and a raised partial pressure of CO<sub>2</sub>. Optimum growth temperature: ca. 30°C. GC%: ca. 45. Type species: *M. glaucopsis*. [Book ref. 22, pp. 135–137.]

**Menoidium** See EUGLENOID FLAGELLATES.

**menthol** See PHENOLS.

**mepacrine** *Syn.* QUINACRINE.

**merbromin** See MERCURY.

**2-mercaptoethanesulphonic acid** Coenzyme M: see METHANOGENESIS.

**mercaptoethanol** (HSCH<sub>2</sub>CH<sub>2</sub>OH) A reagent used e.g. to reduce disulphide bonds in proteins (e.g. immunoglobulins – see FAB PORTION).

**Mercurochrome** See MERCURY.

**mercury** (as an antimicrobial agent) Mercury is a HEAVY METAL whose compounds include many effective antimicrobial agents; such agents are typically reversibly microbistatic, and they have little or no effect on the viability of bacterial endospores – though they can delay germination. The functional part of an antimicrobial mercurial is the mercury cation or the mercury-containing moiety; antimicrobial activity may involve the binding of these entities to certain groups (particularly thiols – but also e.g. amides and amines, purines and pyrimidines) in e.g. enzymes, cell walls, cytoplasmic membranes and nucleic acids. Microbistatic activity can be reversed with e.g. thiols – which probably compete with the mercury-binding sites of the organisms. In bacteria, resistance to mercurials can be plasmid-mediated.

Inorganic mercurials are toxic and irritant to tissues; their activity is readily inhibited or reversed by organic matter (e.g. blood or serum). *Mercuric chloride* (corrosive sublimate) has been used for the disinfection of inanimate objects when other methods are unsuitable, and as a preservative for e.g. paper and timber. *Mercurous chloride* (calomel) has restricted use as a fungicide in horticulture – e.g. as a control against clubroot. *Yellow mercuric oxide* has been used in ointments for the treatment of conjunctivitis and blepharitis. *Ammoniated mercury* (aminomercuric chloride; white precipitate; HgNH<sub>2</sub>Cl) has been used in ophthalmic preparations and for the treatment of superficial mycoses.

## meri-

Organic mercurials are generally less toxic (to man), are less irritant, and are typically more effective antimicrobial agents. *Mercurochrome* (merbromin; disodium 2',7'-dibromo-4'-hydroxymercurifluorescein) was one of the first organic mercurial antiseptics, but it is among the least effective and is no longer widely used. *Nitromersol* (Metaphen; 4-nitro-3-hydroxymercurio-cresol anhydride) is used e.g. in antimicrobial solutions and ointments for the treatment of e.g. conjunctivitis and superficial mycoses. (See also THIOMERSAL.) *Phenylmercuric borate, nitrate* and *acetate* (the most soluble) all have similar antimicrobial properties; they have been used as antiseptics, as preservatives for pharmaceutical preparations, paper, wood etc, and as seed dressings.

Microbial resistance to mercury and organomercurials: see HEAVY METALS.

**meri-** Combining form signifying 'part'.

**Meria** See HYPHOMYCETES and NEMATOPHAGOUS FUNGI.

**Merismopedia** A phycological genus of unicellular 'blue-green algae' (Chroococcales) in which the cells occur (in nature) in rectangular 'plates'. See SYNECHOCYSTIS.

**meristem** A region of an organism at which new, permanent tissue is formed, i.e., a 'growth region' of a plant or multicellular microorganism.

**meristematic nodules** See ROOT NODULES.

**meristoderm** In certain algae (e.g. *Laminaria*): a surface layer of cells which, on division, gives rise to an increase in the thickness of the thallus.

**meristogenous development** (*mycol.*) The development of certain fungal structures (e.g. pycnidia, stromata) by the proliferation and differentiation of a small number of adjacent cells in a single hypha. (cf. SYMPHOGENOUS DEVELOPMENT.)

**mermaid's wine-glass** See ACETABULARIA.

**mero-** Combining form signifying 'part'.

**Merocystis** See EIMERIORINA.

**merodiploid** See DIPLOID.

**merogony** *Syn.* SCHIZOGONY.

**meromictic lake** A permanently stratified lake in which only the upper layers undergo turnover, the lower layer (*hypolimnion*) being typically stagnant, anaerobic, and rich in sulphide. (cf. HOLOMICTIC LAKE.)

**meropenem** A broad-spectrum 1- $\beta$ -methylCARBAPENEM antibiotic. (See also ERTAPENEM.)

**merosporangium** An elongated ('cylindrical') SPORANGIUM containing either a single spore or a small number of spores in a row; merosporangia are formed e.g. by *Piptocephalis* and *Syncephalastrum*.

**merozoite** See SCHIZOGONY.

**merozygote** A bacterium which is part DIPLOID, part haploid; it may be formed in certain processes in which chromosomal genes pass from one bacterium (the donor) to another (the recipient) – see CONJUGATION, TRANSDUCTION and TRANSFORMATION. The genetic complement of a merozygote comprises the *endogenote* (the recipient's own chromosome) and the fragment of genetic material (the *exogenote*) received from the donor. If corresponding ALLELES in the endogenote and exogenote are identical the merozygote is said to be a *homogenote*; if not, it is said to be a *heterogenote*.

**merthiolate** *Syn.* THIOMERSAL.

**Merulius** See APHYLLOPHORALES (Corticaceae). (cf. SERPULA.)

**MES** A pH buffer based on 2-(*N*-morpholino)-ethanesulphonic acid.

**Meselson-Radding model** See RECOMBINATION (Figure 2).

**mesocyst** See CYST (b).

**Mesodinium** See GYMNOSTOMATIA.

**meso-inositol** See INOSITOL.

**mesokaryotic** See DINOFAGELLATES.

**mesophile** An organism whose optimum growth temperature lies within a range generally accepted as ca. 20–45°C; bearing in mind the definition of PSYCHROPHILE, it would be reasonable to extend this range to 15–45°C.

**mesoplankton** See PLANKTON.

**mesoporphyrins** See PORPHYRINS.

**mesosaprobic zone** See SAPROBITY SYSTEM.

**mesosomes** (chondrioids) Intracellular membranous structures, apparently continuous with the CYTOPLASMIC MEMBRANE, which have been observed in electron micrographs of many bacteria. In Gram-positive species they may appear e.g. as parallel or concentric lamellae or as vesicles (perhaps tubules) which may be interconnected; in Gram-negative bacteria mesosomes appear to be smaller and less intricate, and are often seen as simple invaginations of the cytoplasmic membrane. Mesosomes are commonly associated with the developing septum in a dividing cell, but their function – if any – is unknown; they are widely believed to be artefacts derived from the cytoplasmic membrane during preparation of specimens for electron microscopy [see e.g. AvL (1984) 50 433–460 (439–443)]. (cf. INTRACYTOPLASMIC MEMBRANES.)

**Mesostigma** See MICROMONADOPHYCEAE.

**Mesotaenium** A genus of saccoderm DESMIDS.

**messenger RNA** See MRNA.

**messenger RNA-interfering complementary RNA** See ANTI-SENSE RNA.

**metabasidium** A developing BASIDIUM at the stage at which MEIOSIS occurs, or that part of a developing basidium in which meiosis occurs. According to species, the metabasidium may be a later stage of (but morphologically identical to) the PROBASIDIUM, or it may arise – as a separate structure – from the probasidium. According to species, a metabasidium gives rise to sterigmata (each STERIGMA bearing one terminal basidiospore) or to basidiospores borne directly on its surface (i.e., without sterigmata). A metabasidium may be septate (as e.g. in *Tremella*) or aseptate (as e.g. in *Agaricus*). In e.g. rust fungi the metabasidium is a septate structure (= 'promycelium') which grows out from the teliospore.

**metabiosis** The phenomenon in which one organism alters environmental conditions in such a way as to allow the growth of another or others; e.g., utilization of oxygen by aerobic organisms may create anaerobic microenvironments in which strict anaerobes can grow.

**metabisulphites** See SULPHUR DIOXIDE.

**metabolic inhibition test** Any test in which an agent is detected or quantified by its ability to inhibit metabolic activity. For example, a toxin, virus, or other cytotoxic agent can be assayed by determining its ability to inhibit the normal metabolic processes in a tissue culture; normally, the medium in a tissue culture becomes acidic with time, and the titre of the cytotoxic agent can be estimated by determining the highest dilution of the agent which delays or inhibits acidification of the medium.

**metaboly** See EUGLENA.

**metachromasy** The phenomenon in which certain substances (termed *chromotropes*) develop a colour different to that of the dye used to stain them. See e.g. METACHROMATIC GRANULES.

**metachromatic dye** Any DYE which gives rise to METACHROMASY when used to stain *chromotropic* substances.

**metachromatic granules** Intracellular POLYPHOSPHATE-containing granules which, on staining with certain basic dyes (e.g. polychrome methylene blue or toluidine blue – see ALBERT'S STAIN),

exhibit METACHROMASY. [Composition of metachromatic granules: JB (1984) 158 441–446.]

**metachronal waves** (*protozoal*.) Waves which may be seen on the surface of a ciliate due to the beating of its cilia – an effect similar to that produced by an intermittent breeze on a field of barley or tall grass. While the cilia of a given ciliate beat with similar or identical frequencies, they do not, in general, beat synchronously – i.e., all the cilia do not pass simultaneously through the same phase of the beat cycle (see CILIUM). Instead, ciliary beating is usually *metachronous*: adjacent cilia pass through slightly different phases of the beat cycle at any given instant – the phase difference between a given cilium and other cilia in a KINETY increasing and decreasing cyclically with distance from the given cilium. (This results in the smooth motion characteristic of ciliates.) In one type of metachrony (*symplectic* metachrony) a sequence of cilia which, at a given instant, are all passing through (different stages of) the effective stroke of the beat cycle, tend to bunch together to form the crest of a metachronal wave; the crests of such waves move in the direction of the effective stroke. In *antiplectic* metachrony, cilia passing through the effective stroke do not bunch together, and the metachronal crests move in a direction opposite to that of the effective stroke. In both *symplectic* and *antiplectic* metachrony the effective and recovery strokes occur in the plane of the kinety; these types of metachrony are termed *orthoplectic* metachrony. In *diaplectic* metachrony the effective and recovery strokes occur in a plane perpendicular to the kinety; the effective stroke may be to the right (*dexioplectic* metachrony) or to the left (*laeoplectic* metachrony) when looking in the direction of the metachronal wave.

*Symplectic* metachrony is quite rare in ciliates, but *antiplectic* and *diaplectic* (*dexioplectic*) types of metachrony are quite common.

**metacyclic forms** (metatrypanosomes) Trypanosomes, infective for the vertebrate host, which develop at the end of the period of cyclical development in the invertebrate vector; they are trypanostigote in form, with or without a short free flagellum. In *Trypanosoma vivax* a 'surface coat' (see VSG) has been reported to occur on metacyclic forms prior to contact with the mammalian host [Parasitol. (1986) 92 75–82].

**Metacystis** See GYMNOSTOMATA.

**Metadinium** See ENTODINIOMORPHIDA.

**metal leaching** See LEACHING.

**metalaxyl** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**metalimnion** (thermocline) In a lake: the layer of water between the EPILIMNION and the HYPOLIMNION; this layer is characterized by the maximum rate of decrease in temperature with depth.

**Metallogenium** A genus of IRON BACTERIA. The organisms have been reported to be capable of passing through a filter of pore size 0.2 µm and of inhibiting various prokaryotic and eukaryotic microorganisms when cultured with them [Curr. Micro. (1984) 11 349–356].

**metalloporphyrins** See PORPHYRINS.

**metallothionein** A cysteine-rich, low-MWt, inducible protein which binds (and may detoxify) HEAVY METAL ions; metallothioneins from a range of organisms (e.g. *Synechococcus*, *Neurospora*, *Saccharomyces*, crab, horse, man) are structurally similar.

**metaphase** See MITOSIS and MEIOSIS.

**metaphase plate** See MITOSIS.

**Metaphen** See MERCURY.

**Metarhizium** A genus of entomopathogenic fungi (class HYPHOMYCETES). *M. anisopliae* can infect a wide variety of insects; it

produces decapeptide entomotoxins (*destruxins*) which apparently play an important role in pathogenesis. *M. anisopliae* has been used for the BIOLOGICAL CONTROL of e.g. froghoppers (*Mahanarva posticata*) in Brazilian sugar-cane plantations.

**metastasis** (*med.*) The dissemination of disease from a localized site in the body, with the formation of new foci at distant sites. (Usually used in the context of CANCER, but also of certain infectious diseases – e.g. TUBERCULOSIS.) (Hence *verb* metastasize, *adj.* metastatic.)

**metatrypanosomes** *Syn.* METACYCLIC FORMS.

**Metchnikovella** See RUDIMICROSPOREA.

**methacycline** See TETRACYCLINES.

**metham sodium** (vapam) Sodium *N*-methyl-DITHIOCARBAMATE (CH<sub>3</sub>.NH.CS.SNa), a soil fumigant which, in soil, breaks down to form the volatile methyl-isothiocyanate. (cf. DAZOMET, QUINTOZENE.)

**methanal** *Syn.* FORMALDEHYDE.

**methane monoxygenase** (MMO) A MONOOXYGENASE which occurs in methanotrophs (see METHYLOCOCCACEAE) and which catalyses the oxidation of methane to methanol by molecular oxygen; MMO can also catalyse the oxidation of substrates such as *n*-alkanes and *n*-alkenes: e.g., propene (propylene) is oxidized to 1,2-epoxypropane. (See also CO-METABOLISM.)

MMO may be 'particulate' (i.e., membrane bound) or soluble, depending on growth conditions. Thus, e.g., in cells of *Methylococcus capsulatus* and '*Methylosinus trichosporium*' grown on methane, the MMO is soluble or particulate according to whether the culture medium contains low (e.g. 1 µM) or high (e.g. 5 µM) levels of Cu<sup>2+</sup> respectively. However, in *M. capsulatus* only particulate MMO is formed when growth occurs on methanol – in this case an increase in the level of Cu<sup>2+</sup> enhancing MMO activity [JGM (1985) 131 155–163]. The soluble MMO of *M. capsulatus* is a three-component enzyme comprising proteins A (believed to be the oxygenase [JBC (1984) 259 53–59]), B and C, and that of '*Methylosinus trichosporium*' is apparently similar.

The substrate specificities of particulate and soluble MMOs may differ appreciably. Thus, e.g. the soluble MMO of '*M. trichosporium*' can oxidize *n*-alkanes, *n*-alkenes, aromatic and alicyclic compounds, while the particulate MMO of the same organism cannot oxidize aromatic or alicyclic substrates [JGM (1984) 130 3327–3333].

In various types of methanotroph the reducing power requirement for MMO activity *in vitro* (i.e. in cell extracts) appears to be satisfied by NADH for both the soluble and particulate forms of the enzyme. However, it has been proposed that the reducing power needed for *in vivo* particulate MMO activity in '*M. trichosporium*' may be derived from a reduced *c*-type cytochrome. It has been suggested that reducing power for *in vivo* particulate MMO activity in *M. capsulatus* may be supplied by an electron transfer protein (e.g. an Fe–S protein) the reduction of which depends on reversed electron transport [JGM (1983) 129 3487–3497].

**methane production** See METHANOGENESIS.

**methane utilization** See METHANOTROPHY.

**Methanobacillus omelianskii** A syntrophic association of two species of prokaryote: *Methanobacterium bryantii* and an obligate proton reducer (the 'S' organism) which oxidizes ethanol to acetate and hydrogen gas.

**Methanobacteriaceae** A family of METHANOGENS (order METHANOBACTERIALES); two genera: METHANOBACTERIUM and METHANOBREVIBACTER. (This family formerly included *all* the methane-producing species.)

## Methanobacteriales

**Methanobacteriales** An order of METHANOGENS comprising those species whose cell wall contains PSEUDOMUREIN. Two families: METHANOBACTERIACEAE, METHANOTHERMACEAE.

**Methanobacterium** A genus of facultatively autotrophic archaeans (family METHANOBACTERIACEAE). Cells: non-motile rods. Methane may be produced from carbon dioxide and hydrogen and/or from formate. GC% ca. 33–50.

*M. bryantii*. Mesophilic. Cells: morphologically indistinguishable from *M. formicicum* (see below), but the organisms cannot use formate. Growth is stimulated by acetate and B vitamins. (See also METHANOBACILLUS OMELIANSKII.)

*M. formicicum*. Cells: round-ended rods, ca.  $0.6 \times 2\text{--}15 \mu\text{m}$ , often in chains. Formate can be used as an electron donor, and acetate stimulates growth.

*M. thermoautotrophicum*. Thermophilic (opt. temperature:  $65\text{--}70^\circ\text{C}$ ). Formate is not metabolized.

**Methanobrevibacter** A genus of archaeans of the family METHANOBACTERIACEAE. Cells: cocci or short rods, often in pairs or chains. Mesophilic. Methane may be produced from carbon dioxide and hydrogen and/or from formate. GC% ca. 27–32.

*M. arboriphilus*. A facultative autotroph which occurs e.g. in soil (see also WETWOOD). Formate is not used.

*M. ruminantium*. Cells: rods, ca.  $0.7 \times 2.0 \mu\text{m}$ , often in chains. Habitat: the RUMEN. Methane can be formed from carbon dioxide and hydrogen or from formate. Strain M-1 has been used for the BIOASSAY of coenzyme M.

*M. smithii*. Morphologically similar to *M. ruminantium*. Coenzyme M is not required for growth.

**methanochondrion** A term proposed for the apparent organelle formed (in a number of methane-producing archaeans) from invaginated cytoplasmic membrane and assumed to be the site of methanogenesis. (Such a structure is not invariably present in methanogenic species [CJM (1984) 30 594–604].)

**Methanococcaeae** See METHANOCOCCALES.

**Methanococcales** An order of METHANOGENS comprising one family (Methanococcaeae) and one genus, METHANOCOCCUS.

**Methanococcoidea** A genus of METHANOGENS (see METHANOSARCINACEAE). The cells of *M. methylutens* are non-flagellated cocci (ca.  $1 \mu\text{m}$  diam.); the cell wall consists of an S LAYER only. Methanol and methylamine are methanogenic substrates. GC%: ca. 42.

**Methanococcus** A genus of mesophilic and thermophilic archaeans (order METHANOCOCCALES) which occur e.g. in salt-marsh sediments and marine muds. Cells: motile cocci in which the cell wall consists solely of an S LAYER; the GRAM REACTION is negative. Methane is typically produced from carbon dioxide and hydrogen and/or from formate. Most species (but not *M. voltae*) can grow autotrophically. (The original type species, *M. mazei*, differs markedly from the other species, and has been transferred to METHANOSARCINA (*Methanosarcina mazei*), *Methanococcus vannielii* being designated the new type species of the (conserved) genus *Methanococcus* [JUSB (1986) 36 491].) GC%: ca. 30–33.

*M. jannaschii*. Thermophilic (optimum:  $86^\circ\text{C}$ ). Methane is produced from carbon dioxide and hydrogen, but not from formate. The growth rate is the highest of all known methanogens (doubling time: 30 min). Isolated from a HYDROTHERMAL VENT.

*M. maripaludis*. Cells  $1.2\text{--}1.6 \mu\text{m}$  diam. Mesophilic.

*M. mazei*. See METHANOSARCINA.

*M. thermolithotrophicus*. Cells ca.  $1.5 \mu\text{m}$  diam. Thermophilic (optimum:  $65^\circ\text{C}$ ).

*M. vannielii*. Cells ca.  $3\text{--}4 \mu\text{m}$  diam. Mesophilic. Methane is produced from carbon dioxide and hydrogen and from formate.

*M. voltae*. Cells ca.  $0.5\text{--}3.0 \mu\text{m}$  diam. Mesophilic. Growth is optimal in  $0.4 \text{ M NaCl}$ . Methane is produced from carbon dioxide and hydrogen and from formate.

**methanofuran** See METHANOGENESIS.

**methanogen** Any member of the domain ARCHAEA which can carry out METHANOGENESIS; all known methanogens are obligate anaerobes which occur e.g. in muds and in the RUMEN (some forming close physical associations with protozoa [MS (1986) 3 100–105]). (See also ANAEROBIC DIGESTION and WETWOOD.)

Methanogens have been classified in three orders (METHANOBACTERIALES, METHANOCOCCALES, METHANOMICROBIALES) on the basis of 16S rRNA sequence analysis.

Many methanogens can grow chemolithoautotrophically in mineral salts solution with carbon dioxide and hydrogen (although some need e.g. acetate and amino acids). Methanogens are not necessarily confined to simple substrates such as acetate, methanol and methylamines; thus, pure cultures of e.g. *Methanospirillum* can be grown on 2-propanol and certain other alcohols [AEM (1986) 51 1056–1062].

The methanogens have been divided into two groups: group I (carbon dioxide and hydrogen, or formate, typically used), and group II (carbon dioxide and hydrogen, or formate, typically not used); group II includes the family METHANOSARCINACEAE [AVL (1984) 50 557–567].

Autotrophic carbon dioxide fixation apparently occurs via a pathway resembling that used for the synthesis of acetyl-CoA from carbon dioxide in ACETOGENESIS, although formyl tetrahydrofolate synthase does not seem to be involved. Acetyl-CoA appears to be reductively carboxylated to pyruvate – which is converted to phosphoenolpyruvate (PEP); carboxylation of PEP gives rise to oxaloacetate. Oxaloacetate appears to be metabolized to 2-oxoglutarate as in the TCA cycle [see Appendix II(a)] – via citrate in *Methanosarcina barkeri*, via malate in *Methanobacterium thermoautotrophicum*.

Some species (e.g. *Methanococcus thermolithotrophicus*, *Methanosarcina barkeri*) can carry out NITROGEN FIXATION [Nature (1984) 312 284–288; FEMS Ecol. (1985) 31 47–55].

**methanogenesis** The biosynthesis of methane ( $\text{CH}_4$ ): an energy-yielding process carried out by certain members of the domain Archaea (METHANOGENS) in anaerobic environments that are characterized by an  $E_h$  below about  $-330 \text{ mV}$  (see e.g. ANAEROBIC DIGESTION, RUMEN and WETWOOD). Methane can be formed from several substrates: carbon dioxide and hydrogen (or carbon dioxide and formate), acetate, methanol, or methylamines. Methanogenesis involves a number of novel enzymes and coenzymes/cofactors [FEMS Reviews (1999) 23 13–38].

*Methane from carbon dioxide and hydrogen*. Essentially, the carbon atom of carbon dioxide is bound, sequentially, to each of several  $\text{C}_1$ -carrier molecules and undergoes progressive reduction (via formyl and methyl stages) to methane (see figure). The final stage (reduction of  $\text{CoM-S-CH}_3$ ) is thermodynamically favourable ( $\Delta G^0$  greater than  $-100 \text{ kJ}$ ).

*Methane from acetate*. Growth on acetate is slower than that on carbon dioxide and hydrogen; the free energy of the reaction

is about  $-37 \text{ kJ}$ . Note that this pathway differs from the carbon dioxide/hydrogen pathway e.g. in the requirement for an initial stage of ATP-dependent activation.

Methanogenesis from acetate is inhibited by cyanide (which inhibits CO dehydrogenase).

*Methane from methanol*. In this pathway, the methyl group from one molecule of methanol is oxidized to provide electrons

METHANOGENESIS. Two major pathways in the biosynthesis of methane: (i) synthesis from carbon dioxide, and (ii) synthesis from acetate. (Methanol and methylamines are alternative substrates.) The final stage of biosynthesis, i.e. reduction of methyl-coenzyme M (see later), is common to all the methane-forming pathways.

(i) *Methane from carbon dioxide*. In this pathway, the reduction of carbon dioxide can be linked to the oxidation of either hydrogen or formate; the reactions shown occur in both hydrogen- and formate-oxidizing pathways.

Initially, carbon dioxide is reduced to a formyl residue on the coenzyme *methanofuran* (MFR; earlier name: carbon dioxide reduction factor, CDR factor). Methanofuran is a long-chain molecule containing an aromatic ring and a terminal furan ring. This initial reduction is catalysed by formylmethanofuran dehydrogenase. The formyl group is then transferred to *tetrahydromethanopterin* (THMP). Part of the THMP molecule resembles FOLIC ACID, but the molecule is much larger than that of folic acid and it includes a sugar residue. The conversion of 5-formyl-THMP to 5,10-methenyl-THMP<sup>+</sup> is catalysed by the enzyme *N*<sup>5</sup>, *N*<sup>10</sup>-methenyltetrahydromethanopterin cyclohydrolase.

Subsequent reductions in some methanogens (e.g. strains of *Methanosarcina barker*) involve an enzyme acting in association with *coenzyme F*<sub>420</sub> (factor 420), a 5-deazaflavin derivative that serves as an electron carrier. Strains of e.g. *Methanococcus thermolithotrophicus* use an *F*<sub>420</sub>-independent dehydrogenase to convert 5,10-methenyl-THMP<sup>+</sup> to 5,10-methylene-THMP.

Finally, the methyl group is transferred from THMP to *coenzyme M* (CoM-SH; 2-mercaptoethanesulphonic acid; HS(CH<sub>2</sub>)<sub>2</sub>SO<sub>3</sub><sup>-</sup>) in preparation for its reduction to methane by the enzyme *methyl-coenzyme M reductase*; in all cases, the electron donor for this reduction is *coenzyme B* (CoB; 7-mercaptoheptanoylthreonine phosphate). In the reductases from *Methanobacterium thermoautotrophicum* the active site of the enzyme contains two molecules of *coenzyme F*<sub>430</sub> (factor 430), a nickel-containing porphinoid.

Reduction of CoM-S-S-CoB regenerates the two coenzymes.

(ii) *Methane from acetate*. The sequence of reactions shown are those for *Methanosarcina thermophila*; the pathway differs slightly in some methanogens. (Continued on page 470.)

## **Methanogenium**

for the reduction of methyl groups from (three) other molecules of methanol, the products being methane, carbon dioxide and water. For methane synthesis, methyl groups must be bound to coenzyme M in preparation for methanogenic reduction involving CoB-SH (see figure). Contributing to this pathway in *Methanosarcina barkeri* is an enzyme system that includes methanol:corrinoid methyltransferase which catalyses the initial transfer of methyl groups to the corrinoid moiety; further enzymic activity transfers the methyl groups to CoM-SH.

In nature, methanogens are believed to produce most of the methane from acetate; in vitro studies on the degradation of rice straw in anoxic paddy soil have indeed shown that a high proportion of methane is synthesized from acetate under those conditions [FEMS Ecol. (2000) 31 153–161]. Earlier work had suggested that acetate may be the preferred substrate at 10°C, with hydrogen being used at higher temperatures [FEMS Ecol. (1997) 22 145–153]. However, despite the overall picture, in certain locations the contribution of hydrogen to methanogenesis may be ~70–100% [FEMS Ecol. (1999) 28 193–202].

The production of methane in anoxic soils can be suppressed e.g. by nitrate; such inhibition appears to be due to the effects of intermediates of the denitrification process [FEMS Ecol. (1999) 28 49–61].

**Methanogenium** A genus of archaeans of the family METHANOMICROBIAEAE. Cells: cocci in which the cell wall consists of an S LAYER only; the GRAM REACTION is negative. Species include *M. cariaci* and *M. marisnigri*, both peritrichously flagellated organisms with an optimum growth temperature of ca. 20°C.

**methanol utilization** See METHYLOTROPHY.

**Methanobolus** A genus of METHANOGENS (see METHANOSARCINACEAE). The cells of *M. tindarius* are monoflagellated cocci (ca. 1 µm diam.); the cell wall consists of an S LAYER only. Methanol and methylamine are methanogenic substrates. GC%: ca. 46.

**Methanomicrobiaceae** A family of METHANOGENS (order METHANOMICROBIALES); genera: METHANOGENIUM, METHANOMICROBIUM, METHANOSPIRILLUM.

**Methanomicrobiales** An order of METHANOGENS comprising the families METHANOMICROBIAEAE, METHANOPLANACEAE and METHANOSARCINACEAE.

**Methanomicrobium** A genus of archaeans of the family METHANOMICROBIAEAE. Cells: typically short rods in which the cell wall consists of an S LAYER only; the GRAM REACTION is negative.

*M. mobile*. Polarly flagellated rods which need e.g. acetate, THIAMINE, PYRIDOXINE and PABA for growth. Habitat: RUMEN.

*M. paynteri*. Non-motile coccobacilli which occur in marine sediments.

**Methanoplanaceae** A family of METHANOGENS (order METHANOMICROBIALES) [validation: IJSB (1984) 34 270]. One genus: METHANOPLANUS.

### METHANOGENESIS (continued)

Initially, acetate undergoes ATP-dependent activation to acetyl-CoA – catalysed by the two enzymes *acetate kinase* and *phosphotransacetylase*. (In *Methanosaeta*, this section of the pathway differs in that the formation of acetyl-CoA is catalysed by *acetate thiokinase*.) The methyl group is then transferred to *tetrahydrosarcinapterin* (THSP; analogous to THMP, above) by an enzyme complex that includes *CO dehydrogenase* and *CoA synthase*; the activity of these enzymes results in the cleavage of carbon-carbon and carbon-sulphur bonds – and also oxidation of the carbonyl group (from acetyl-CoA) to carbon dioxide. Electrons derived from oxidation of the carbonyl group are involved in the final methanogenic reduction of the methyl group after the latter has been transferred to coenzyme M.

In *Methanosarcina thermophila* the *cam* gene encodes a CARBONIC ANHYDRASE which apparently includes a signal peptide (see SIGNAL HYPOTHESIS); it has been suggested that, by hydrating carbon dioxide in the periplasm, this enzyme may facilitate removal of carbon dioxide from the cytoplasm – and may thus promote conditions thermodynamically more favourable for methanogenesis.

**Methanoplanus** A genus of archaeans of the family METHANOPLANACEAE. The cells of *M. limicola*, the sole species, are plate-like and are bounded by an S LAYER; this organism has strong affinities with *Methanogenium* spp [Book ref. 157, p 17].

**Methanosaeta** A genus of obligately acetotrophic METHANOGENS (methanogens which synthesize methane only from acetate). The organisms, which include *M. concilii* and *M. thermoacetophila*, are found e.g. in rice fields.

**Methanosarcina** A genus of archaeans of the family METHANOSARCINACEAE. Cells: non-motile, coccoid to irregularly shaped forms, ca. 1–3 µm; the heteropolysaccharide-containing cell wall is a thick (up to ca. 200 nm) layer which may be laminated at the periphery. GAS VACUOLES are found in some strains. The original type species, *M. methanica*, has been rejected and replaced by *M. barkeri* [IJSB (1986) 36 492].

*M. acetivorans*. An acetotrophic marine species [AEM (1984) 47 971–978].

*M. barkeri*. Cells grow as aggregates. Most strains can produce methane from carbon dioxide and hydrogen, acetate, methanol or methylamine. Strain FR-19 lyses spontaneously in substrate-depleted media [JGM (1985) 131 1481–1486].

*M. mazei* (cf. METHANOCOCCUS) is similar to *M. barkeri* but differs e.g. in that *M. mazei* metabolizes acetate and methanol readily but carbon dioxide and hydrogen poorly or not at all.

**Methanosarcinaceae** A family of METHANOGENS (order METHANOMICROBIALES). Depending on species or strain, some or all of the following substrates are used for METHANOGENESIS: acetate, CO<sub>2</sub> + H<sub>2</sub>, methanol, methylamines. Genera: METHANOSARCINA, METHANOTHRIX; it has been proposed that the genera METHANOCOCCOIDES and METHANOLOBUS be incorporated in the family [IJSB (1984) 34 444–450].

**Methanospirillum** A genus of archaeans of the family METHANOMICROBIAEAE. *M. hungatei* is a facultative autotroph which occurs in sewage sludge; the cells are curved, sheathed rods or filaments that are lophotrichously flagellated.

**Methanothermaceae** A family of archaeans of the order METHANOBACTERIALES. One genus: METHANOTHERMUS.

**Methanothermus** A genus of archaeans (family METHANOTHERMACEAE) in which the cell wall consists of two layers: a PSEUDOMUREIN-containing layer and an (outermost) S LAYER. Thermophilic (optimum: 83°C).

*M. fervidus*. Cells: non-motile rods, ca. 0.4 × 1–3 µm; the GRAM REACTION is positive. Methane is formed from carbon dioxide and hydrogen but not from formate; yeast extract is needed for growth. GC%: ca. 33.

**Methanotrix** A genus of archaeans of the family METHANOSARCINACEAE. *M. soehngenii* is common in anaerobic digestors; cells: rods, ca. 0.8 × 2 µm, or long, sheathed filaments – each filament often consisting of several hundred rods. The GRAM REACTION is negative. Methane is formed from acetate but not from carbon dioxide and hydrogen or from formate, methanol or methylamine.

*M. concilii* is an acetotrophic species isolated from sewage sludge [CJM (1984) 30 1383–1396]. [Acetate and carbon dioxide assimilation by *M. concilii*: JB (1985) 162 905–908.]

**methanotroph** Any organism capable of METHANOTROPHY.

**methanotrophy** The use of methane as the sole source of carbon and energy; a mode of metabolism which occurs under aerobic and microaerobic conditions in certain bacteria (see e.g. METHYLOCOCCACEAE). (cf. METHYL TROPHY.) Most methanotrophic bacteria are obligately methanotrophic; these organisms include species of *Methylococcus* and *Methylomonas*.

The methanotrophic bacteria occur e.g. in soil, water and sediments. The oxidation of methane by methanotrophs significantly affects the global methane budget in that much less methane reaches the atmosphere; this reduces the contribution of methane to global warming.

In members of the Methylococcaceae, methane is initially oxidized to methanol by METHANE MONOOXYGENASE (q.v.); the subsequent oxidations are: methanol → formaldehyde → formate → carbon dioxide. When methane is used as the sole source of carbon and energy, some formaldehyde is assimilated into cell biomass while the remainder is oxidized to yield energy.

[Methane oxidation in natural waters: AEM (1982) 44 435–446. Methane oxidation by microorganisms: Book ref. 132, pp 173–200. Methanotrophic bacteria (review): MR (1996) 60 439–471. Ecology of methanotrophic species studied by molecular methods: FEMS Ecol. (1998) 27 103–114. Detection and classification of atmospheric methane-oxidizing bacteria in soil: Nature (2000) 405 175–178.]

**methazotrophic** Refers to any organism capable of using methylamines as the sole source of nitrogen (but not as sole source of carbon and energy); methazotrophs include various yeasts, e.g. *Candida utilis*. [Oxidation of methylamines by yeasts: Book ref. 169, pp. 155–164.]

**methenamine** See HEXAMINE.

**methenamine–silver stain** (Grocott–Gomori stain; Gomori stain) A stain used e.g. for detecting actinomycetes or fungi in tissue sections. The section is oxidized in 5% chromic acid for 1 h, washed in tap water, washed for 1 min in 1% sodium bisulphite to eliminate chromic acid, and washed for 10 min in tap water. After 3–4 changes of distilled water the section is immersed in a solution made by adding 0.4% aqueous borax (108 ml) to a mixture of 10% silver nitrate (7 ml) and 3% methenamine (100 ml); the temperature is kept at 58–60°C until the section becomes yellow-brown (30–60 min). The slide is rinsed repeatedly in distilled water, washed for 2–5 min in 2% sodium thiosulphate to remove unreduced silver, washed in tap water, and counterstained for ca. 1 min in a solution of light green (0.04% w/v) containing 0.04% v/v glacial acetic acid. Mycelium stains brown-black, tissues green.

**methicillin** See PENICILLINS.

**methicillin-resistant *Staphylococcus aureus*** See MRSA.

**methicillinase** See MRSA.

**methionine aminopeptidase** (MAP) In bacteria: an enzyme required for excision of the N-terminal methionine of a newly synthesized protein. In e.g. *Escherichia coli*, the N-terminal methionine is cleaved from about 50% of proteins. Whether or not such cleavage occurs in a given protein is influenced by the identity of the *penultimate* N-terminal amino acid; cleavage, or otherwise, of the N-terminal methionine thus determines the identity of the N-terminal amino acid in the *mature* protein, and, in this way, influences the protein's half-life (according to the N-END RULE).

MAP belongs to a diverse family of physiologically important aminopeptidases [bacterial aminopeptidases: FEMS Reviews (1996) 18 319–344].

**L-methionine biosynthesis** See Appendix IV(d). (See also MICRO-CINS.)

**methionine deformylase** In bacteria: an enzyme which cleaves the formyl group from methionine at the N-terminal of a newly synthesized protein.

**L-methionine-DL-sulphoximine** See MSX.

**methisazone** See ISATIN-β-THIOSEMICARBAZONE.

**Methocel** See METHYLCELLULOSE.

**methotrexate** See FOLIC ACID ANTAGONIST.

**methoxatin** See QUINOPROTEIN.

**methoxsalen** 8-MethylPSORALEN.

**methoxyamine** (as a mutagen) See HYDROXYLAMINE.

**6-methoxymellein** A PHYTOALEXIN elicited from the carrot plant e.g. by cupric or mercuric chloride.

**methil-accepting chemotaxis protein** See CHEMOTAXIS.

**methyl blue** (cotton blue) A blue acid TRIPHENYLMETHANE DYE; cf. LACTOPHENOL COTTON BLUE.

**methyl bromide** (CH<sub>3</sub>Br) Methyl bromide vapour is fungicidal, insecticidal and herbicidal; it has good powers of penetration and is used as a fumigant.

**methyl green** A green basic TRIPHENYLMETHANE DYE. (See also METHYL GREEN–PYRONIN STAIN.)

**methyl green–pyronin stain** (Unna–Pappenheim stain) A stain which can distinguish DNA (which stains green) from RNA (which stains red); it can be used e.g. to distinguish lymphocytes from (ribosome-rich) plasma cells.

**methyl orange** A PH INDICATOR: pH 3.0–4.4 (red to orange-yellow); pK<sub>a</sub> 3.6.

**methyl red** A PH INDICATOR: pH 4.4–6.2 (red to yellow); pK<sub>a</sub> 5.1.

**methyl red test** (MR test) An IMVIC TEST which determines the ability of an organism to acidify a phosphate-buffered glucose–peptone medium to pH 4.4 or below. The medium is inoculated and incubated for 48 h at 37°C or 5 days at 30°C. Two drops of METHYL RED solution (0.02% w/v in ca. 50% ethanol) are added to the culture; a red coloration indicates a positive reaction. (N.B. Too short an incubation time may give a false-positive reaction: some organisms (e.g. *Klebsiella pneumoniae* subsp. *pneumoniae*) initially form acidic metabolic products which are later metabolized further.) The VOGES–PROSKAUER TEST can be performed after the MR test using the same culture.

**methyl violet** A composite TRIPHENYLMETHANE DYE which includes crystal violet and 4,4'-bis(dimethylamino)-4''-(methylamino) triphenylmethyl chloride.

**methyl viologen** (Paraquat) 1,1'-Dimethyl-4,4'-dipyridinium, a widely used herbicide. (See also PHOTOSYNTHESIS.) The reduced form of methyl viologen is used e.g. as a reducing agent in laboratory studies.

**3-methyladenine-DNA glycosylase I** See EXCISION REPAIR.

**3-methyladenine-DNA glycosylase II** See ADAPTIVE RESPONSE.

**methylation** (of DNA) See DNA METHYLATION.

**methylcellulose** (Methocel) An unbranched polymer (MWt ca. 143000) used e.g. to increase the viscosity of a medium in order to slow down rapidly motile organisms – see COUNTING METHODS. (cf. FICOLL.)

**methylcobalamin** See VITAMIN B<sub>12</sub>.

**methylene blue** A blue basic thiazine DYE used e.g. in STAINING and VITAL STAINING and as a redox indicator (E<sub>0</sub> = +11 mV at pH 7). (See also e.g. METHYLENE BLUE TEST; TOXOPLASMA DYE TEST.) *Leuco methylene blue* is the reduced (colourless) form of methylene blue. *Loeffler's methylene blue* is

## methylene blue test

prepared by adding 0.01% KOH (100 ml) to 1% methylene blue in 95% ethanol (30 ml). If allowed to 'ripen' (i.e. oxidize slowly) over several months this stain becomes *polychrome methylene blue*: a mixture of methylene blue and certain products of its spontaneous oxidation (e.g. the metachromatic dyes azure A and azure B).

## METHYLENE BLUE

As a redox indicator (see e.g. GASPAC and REDOX POTENTIAL), methylene blue is often used in a TRIS- or phosphate-buffered solution at pH 9; at pH 9 the dye becomes colourless at a lower  $E_h$  than it does at pH 7.

**methylene blue test** (for milk) A test used to assess the numbers of (certain types of) microorganisms in untreated or pasteurized MILK. To a standard volume of milk is added a fixed volume of a solution of METHYLENE BLUE (or methylene blue thiocyanate); the whole is incubated at 37°C and examined periodically. If the milk contains large numbers of organisms that are metabolically active at 37°C, the dye will be quickly reduced to the colourless leuco form; decolorization is delayed if the milk contains relatively few organisms. The time taken for dye decolorization is thus a *guide* to the microbial load. (cf. RESAZURIN TEST.)

**methylglyoxal bypass** A sequence of reactions which can bypass reactions of the EMBDEN-MEYERHOF-PARNAS PATHWAY between triose phosphates and pyruvate. Methylglyoxal synthase converts dihydroxyacetone phosphate to methylglyoxal (2-oxopropanal:  $\text{CH}_3\text{CO}\cdot\text{CHO}$ ) and inorganic phosphate; methylglyoxal can then be converted to D-lactate (by two glutathione-dependent enzymes, glyoxalase I and glyoxalase II), or to pyruvate (by methylglyoxal dehydrogenase). Although these enzymes have been identified in various bacteria and yeasts, their significance *in vivo* remains unclear; they could allow the formation of pyruvate (and hence acetyl-CoA) under conditions of phosphate deficiency which would otherwise limit the formation of 1,3-bisphosphoglycerate from glyceraldehyde 3-phosphate.

Methylglyoxal is cytotoxic, apparently reacting with 7-methylguanosine in rRNA and thereby inhibiting ribosomal function; the glyoxalase system probably plays an important role in detoxifying methylglyoxal formed from dihydroxyacetone phosphate or during other metabolic processes (e.g. the catabolism of certain amino acids).

[Methylglyoxal metabolism: ARM (1984) 38 49–68.]

**2-methylisoborneol** A substance which is produced by certain aquatic actinomycetes and cyanobacteria (e.g. *Lyngbya*); in concentrated form, 2-methylisoborneol has a camphor-like smell, but when diluted it has a 'musty' or 'earthy' odour which can taint WATER SUPPLIES and fish living in the water. (cf. GEOSMIN.)

**methylmethane sulphonate** See ALKYLATING AGENTS.

**N-methyl-N'-nitro-N-nitrosoguanidine** See MNNG.

**N-methyl-N-nitrosourea** See ALKYLATING AGENTS.

**Methylbacterium** A genus of facultatively methylotrophic and methanotrophic, rod-shaped bacteria which can alternatively use glucose and other complex substrates as sole sources of carbon and energy. Type species: *M. organophilum*. (See also METHYLOCOCCACEAE and PROTOMONAS.)

**Methylocaldum** A genus of methylotrophic bacteria classified within the (gamma) PROTEOBACTERIA.

**Methylococcaceae** A family of Gram-negative, obligately methylotrophic bacteria characterized by the ability to use methane as the sole source of carbon and energy under aerobic or microaerobic conditions (see METHANOTROPHY); bacteria which can use other  $\text{C}_1$  compounds, but not methane, are excluded. Two genera: METHYLOCOCCUS and METHYLOMONAS. [Book ref. 22, pp. 256–261.] (cf. METHYLOMONADACEAE.)

Members of the Methylococcaceae occur e.g. in soil and in water overlaying anaerobic mud. The cells range from cocci to rods, and all contain a complex arrangement of intracytoplasmic membranes when grown on methane; some strains are motile (polarly flagellated). Pigments, some water-soluble, are formed by some strains and may be e.g. blue, brown, red or yellow. Certain strains form desiccation-resistant resting stages; these stages may be cysts (similar to those of *Azotobacter* spp), 'lipid cysts' (which contain PHB inclusions, lack intracellular membranes, and have a thick pericellular coating), or 'exospores' (which develop by polar budding, and which are resistant to 85°C/15 min). Metabolism is respiratory (oxidative) with oxygen as the terminal electron acceptor; cytochromes of the *a*, *b*, *c* and *o* types occur in those strains examined. According to strain, the TCA CYCLE may be complete or e.g. may lack 2-oxoglutarate dehydrogenase (in which case the pathway is primarily biosynthetic). All strains can use methanol as a sole source of carbon and energy, and many or all can use formaldehyde. Methane oxidizers can use other carbon compounds, simultaneously with methane, as co-oxidizable substrates to provide carbon and energy; such supplementary carbon and energy sources include e.g. acetate, alkanes, formate, primary alcohols, and various alicyclic, aromatic and heterocyclic compounds. At least one species, *Methylococcus capsulatus*, can fix  $\text{CO}_2$  via the Calvin cycle, and some methanotrophs can carry out NITROGEN FIXATION [JGM (1983) 129 3481–3486]. All strains which have been examined are catalase +ve and oxidase +ve. Aerobic methane-oxidizing bacteria were divided into two major physiological groups; these groups included species which were not formally included in the Methylococcaceae. Type I organisms (e.g. *Methylococcus capsulatus*, *Methylomonas methanica*) form intracytoplasmic membranes comprising bundles of vesicular discs, may form cysts, have an incomplete TCA cycle, and assimilate carbon by the RMP PATHWAY. Type II organisms (e.g. METHYLOBACTERIUM, METHYLOSINUS TRICHOSPORIUM) form paired intracytoplasmic membranes aligned with the cell periphery, may form 'lipid cysts' or 'exospores', have a complete TCA cycle, and assimilate carbon by the SERINE PATHWAY.

[Ecology, isolation and culture: Book ref. 45, pp. 894–902.]

**Methylococcus** A genus of Gram-negative bacteria (family METHYLOCOCCACEAE) which occur e.g. in mud, soil and water. Cells: non-pigmented, non-motile cocci, ca. 1  $\mu\text{m}$  in diameter. The organisms may be cultured on e.g. nitrate-mineral salts media with a gaseous phase consisting of a 30:70 mixture of methane and air; growth occurs between 30 and 50°C (optimally at 37°C), enrichment and primary isolation being carried out at 45°C. GC%: ca. 62.5. Type species: *M. capsulatus*.

**Methylomonadaceae** An obsolete bacterial family which consisted of methylotrophic organisms – the use of methane not being an obligatory requirement. (cf. METHYLOCOCCACEAE.)

**Methylomonas** A genus of Gram-negative bacteria within the family METHYLOCOCCACEAE. Cells: straight or curved, sometimes branched, motile (polarly flagellated) rods, 0.5–1.0  $\times$  1.0–4.0  $\mu\text{m}$ . Growth occurs optimally at 30°C, no growth

occurring at 37°C; enrichment and primary isolation are otherwise as described under METHYLOCOCCUS. A pink pellicle is formed at 30°C; colonies are pink or yellow, consistently pink on subculture. A blue diffusible pigment may be formed in iron-deficient media. GC%: ca. 52. Type species: *M. methanica*. ('*M. methanitrificans*' and '*M. methanooxidans*' may be synonyms of *Methylosinus trichosporium*.)

**Methylophaga** A proposed genus of marine methylotrophic bacteria. The organisms are Gram-negative, strictly aerobic rods which grow on methanol, methylamine(s) or fructose (but not methane) and which require vitamin B<sub>12</sub>; those strains tested use the RMP pathway for carbon assimilation. Two species: *M. marina*, *M. thalassia*. [IJSB (1985) 35 131–139.]

**Methylophilus methylotrophus** A species of obligately methylotrophic, non-methanotrophic bacteria (see METHYLOTROPHY) which assimilate carbon via the RMP pathway and which have been used in the production of SINGLE-CELL PROTEIN.

**Methylosinus trichosporium** A species of methanotrophic, obligately methylotrophic, typically rod-shaped or vibrioid bacteria (see METHANOTROPHY, METHANE MONOOXYGENASE, METHYLOCOCCACEAE). [Effect of growth conditions on intracytoplasmic membranes and MMO activity: JGM (1981) 125 63–84.]

**methylotroph** Any organism capable of METHYLOTROPHY.

**methylotrophy** Oxidative metabolism characterized by (i) obligate or facultative use of C<sub>1</sub> COMPOUNDS as the sole source of carbon and energy, and (ii) assimilation of formaldehyde (produced during methylotrophic metabolism) as a major source of carbon. Methylotrophy includes METHANOTROPHY.

Methylotrophic organisms include certain bacteria (e.g. *Hypomicrobium*, *Methylobacterium* spp, members of the family METHYLOCOCCACEAE, *Methylophaga* spp, *Methylophilus methylotrophus*, *Microcycilus* and *Paracoccus denitrificans*) and some fungi (e.g. species of *Candida*, *Hansenula* and *Pichia*). (cf. CARBOXYDOBACTERIA.)

(a) *Methylotrophy in bacteria*. Most of the C<sub>1</sub> compounds can be oxidized via a sequence of reactions which end in HCHO → HCOOH → CO<sub>2</sub>. Formaldehyde may be assimilated by either the RMP PATHWAY or the SERINE PATHWAY, according to species. (The serine pathway also assimilates some carbon dioxide.) Energy may be derived from direct (non-cyclical) oxidative pathways (e.g. methanol → formaldehyde → formate → carbon dioxide) or from the (cyclical) RMP PATHWAY operating in a dissimilatory mode. The TCA cycle appears to play little or no part in the generation of energy from C<sub>1</sub> substrates.

Methanol is used by most methylotrophs. It is oxidized to formaldehyde by a QUINOPROTEIN: *methanol dehydrogenase* (MDH; EC 1.1.99.8), whose electron acceptor is a soluble form of cytochrome c<sub>L</sub>. [Roles for c cytochromes in methylotrophs: JGM (1984) 130 3319–3325.]

Methane is oxidized to formaldehyde via methanol (see METHANOTROPHY).

Methylamines are oxidized directly to formaldehyde in reactions that usually involve dehydrogenases or monooxygenases; electrons from these substrates may be transferred to cyt *b* (via a flavoprotein), or may be passed to cyt *c* via the 'blue protein' *amicyanin*.

The oxidation of formaldehyde to formate may be catalysed by various enzymes – e.g. (i) MDH; (ii) NAD- and reduced-glutathione-dependent formaldehyde dehydrogenase (EC 1.2.1.1); or (iii) NAD(P)-independent non-specific aldehyde dehydrogenase.

Formate is oxidized by NAD-dependent formate dehydrogenase (EC 1.2.1.2). (Some methylotrophs can use exogenous formate as a source of energy and carbon.)

[Formaldehyde metabolism: Book ref. 169, pp 315–323. Physiology and biochemistry of methylotrophic bacteria: AvL (1987) 53 23–28. Energetics of bacterial metabolism of C<sub>1</sub> compounds: AvL (1987) 53 37–45.]

(b) *Methylotrophy in fungi*. Of C<sub>1</sub> compounds, only methanol has been studied extensively (as a substrate for certain yeasts); however, other C<sub>1</sub> compounds have been reported to be used as substrates by fungi.

The assimilatory and energy-yielding pathways of methanol metabolism in yeasts differ from those in bacteria.

Methanol can be oxidized via the sequence: methanol → formaldehyde → formate → carbon dioxide. The oxidation of methanol to formaldehyde takes place within PEROXISOMES and is catalysed by 'methanol oxidase' (EC 1.1.3.13), a non-specific alcohol oxidase which can oxidize e.g. several alkanols and alkenols, and which consists of eight FAD-containing subunits. The oxidation of methanol yields hydrogen peroxide as well as formaldehyde; CATALASE, within the peroxisome, eliminates the peroxide (as water and oxygen).

Formaldehyde may be assimilated, via the XMP PATHWAY, or may be oxidized to yield energy. The oxidation of formaldehyde occurs within the cytoplasm. In *Candida boidinii* this reaction appears to occur in three stages, the first stage involving NAD<sup>+</sup>- and GSH-linked (reduced-glutathione-linked) formaldehyde dehydrogenase (EC 1.2.1.1):

HCO-SG (*S*-formylglutathione) is hydrolysed by *S*-formylglutathione hydrolase (EC 3.1.2.12):

Finally, HCOOH may be oxidized to carbon dioxide by NAD-linked formate dehydrogenase – although the low substrate affinity of this enzyme in cell-free systems has raised doubts as to its function *in vivo*.

Methylotrophy has also been recorded in the yeast *Hansenula polymorpha*.

NADH generated in methanol-grown yeasts is oxidized in a (ROTENONE-insensitive but cyanide-sensitive) reaction involving an NADH dehydrogenase located at the outer surface of the inner mitochondrial membrane – the maximum energy yield being 2 ATP/NADPH. (In e.g. glucose-grown cells, most NADH is generated intra-mitochondrially and is oxidized by an NADH dehydrogenase located at the inner surface of the inner mitochondrial membrane, the maximum yield of energy being 3 ATP/NADH.)

[Methylotrophic yeasts: AvL (1987) 53 29–36.]

**methymycin** See MACROLIDE ANTIBIOTICS.

**metiram** An agricultural antifungal agent used e.g. for the control of late blight of potato; it is a complex of ZINEB and polyethylene THIURAM DISULPHIDE.

**Metopus** See HETEROTRICHIDA.

**metritis** Inflammation of the uterus. (cf. ENDOMETRITIS; see also CONTAGIOUS EQUINE METRITIS.)

**Metrizamide** See IODINATED DENSITY-GRADIENT MEDIA.

**metrocyste** See SARCOCYSTIS.

**metronidazole** (Flagyl) 1-(2-Hydroxyethyl)-2-methyl-5-nitroimidazole: a NITROIMIDAZOLE antimicrobial agent used to treat e.g. amoebic and balantidial DYSENTERY, GIARDIASIS, genitourinary TRICHOMONIASIS and infections caused by anaerobic bacteria, e.g. PSEUDOMEMBRANOUS COLITIS and VINCENT'S ANGINA. The bactericidal effect of metronidazole on *Helicobacter pylori* appears to depend on the reduced (active)

## **Metschnikowia**

form of the drug rather than on toxic oxygen radicals formed during its reduction [JAC (1998) 41 67–75].

**Metschnikowia** A genus of unicellular and pseudomycelial fungi (family METSCHNIKOWIACEAE) in which multilateral budding occurs. Ascospores: acicular, 1–2 per ascus. Six species are recognized; they occur in aquatic and terrestrial habitats and as parasites in invertebrates. *M. pulcherrima* and *M. reukaufii* are teleomorphs of *Candida pulcherrima* and *Candida reukaufii*, respectively. [Book ref. 100, pp. 266–278.]

**Metschnikowiaceae** (Nematosporaceae; Spermophthoraceae) A family of fungi (order ENDOMYCETALES) which includes unicellular, pseudomycelial and mycelial forms. Ascospores: fusiform to acicular (cf. SACCHAROMYCETACEAE). Genera include e.g. *Ashbya*, *COCCIDIASCUS*, *Eremothecium*, METSCHNIKOWIA, NEMATOSPORA, *Spermophthora*. Members are generally parasitic in plants and/or invertebrates (see e.g. STIGMATOMYCOSIS). Species of *Ashbya* and *Eremothecium* are important commercial sources of riboflavin.

**metula** In the conidiophores of certain fungi: a cell, or a short extension or branch (or part of a branch), which bears one or more *phialides* (see CONIDIUM) at its apex – see e.g. ASPERGILLUS and PENICILLIUM.

**Mexico virus** A SMALL ROUND STRUCTURED VIRUS.

**mezlocillin** See PENICILLINS.

**MF<sub>0</sub>F<sub>1</sub> H<sup>+</sup>-ATPase** See PROTON ATPASE.

**MFP** See MEMBRANE FUSION PROTEIN.

**MFS** Major facilitator superfamily: a category of TRANSPORT SYSTEMS which occur in prokaryotes and eukaryotes; they include pmf-dependent efflux pumps which mediate extrusion of antibiotics – and which therefore confer resistance to particular antibiotic(s). Examples of MFS systems are the various efflux pumps in Gram-negative bacteria which confer resistance to tetracyclines. Each pump encoded by a *tetA* gene is an integral inner membrane protein containing multiple transmembrane helices; *tetA* genes have been found on transposons and plasmids.

**MG fungus** See APHANOMYCES.

**MGIT™ 960** A fully automated BACTEC system (Becton Dickinson) (MGIT = mycobacteria growth indicator tube) used e.g. for detecting *Mycobacterium tuberculosis* [evaluation: JCM (1999) 37 748–752].

**MHA (immunol.)** Major histocompatibility antigen.

**MHA-TP test** Microhaemagglutination assay for *Treponema pallidum* antibodies, a miniaturized form of the TPHA TEST.

**MHC (immunol.)** MAJOR HISTOCOMPATIBILITY COMPLEX.

**MHC restriction** *Syn.* HISTOCOMPATIBILITY RESTRICTION.

**MHD** (1) (*serol.*) Minimum haemolytic dose. (a) The smallest quantity of COMPLEMENT needed to lyse completely a fixed quantity of a standardized suspension of *sensitized* erythrocytes. (See also HAEMOLYTIC SYSTEM.) (b) The smallest quantity of a complement-dependent haemolysin needed to lyse completely a fixed quantity of erythrocytes in the presence of excess complement. (c) The smallest quantity of streptolysin O needed to lyse completely a fixed quantity of erythrocytes in the ANTISTREPTOLYSIN O TEST. (The MHD may be referred to as '1 unit'). (See also HD<sub>50</sub>.)

(2) (*virol.*) Minimum haemagglutinating dose: the smallest quantity of a haemagglutinating virus capable of bringing about maximum agglutination of the erythrocytes in a given volume of a standardized suspension.

**mi-1 gene** See POKY MUTANT.

**MIC** (of an antibiotic) Minimum inhibitory concentration: the lowest concentration of a given antibiotic which inhibits a given type of microorganism under given conditions. (See also E TEST.)

**Mickle shaker** An apparatus used e.g. for the ballistic disintegration of tissue or cells; in principle it resembles the BRAUN MSK TISSUE DISINTEGRATOR. (See also BALLOTINI, CELL DISRUPTION and ULTRASONICATION.)

**miconazole** (1-[2,4-dichloro-β-(2,4-dichlorobenzoyloxy)phenylimidazole]) An AZOLE ANTIFUNGAL AGENT with a broad spectrum of antifungal activity; it also has activity against certain bacteria (particularly Gram-positive species) and e.g. against *Naegleria fowleri*. Miconazole is used mainly in the treatment of superficial mycoses; it is usually administered topically, but can be given intravenously (in cases of invasive or systemic mycosis) or orally (e.g. to reduce intestinal populations of *Candida* spp.).

**Micrasterias** A genus of placoderm DESMIDS.

**microaerobic** Refers to an environment in which oxygen is present (cf. ANAEROBIC) but at a partial pressure which is (usually significantly) lower than that in air.

**microaerophilic** Refers to any organism which grows optimally in a MICROAEROBIC environment. (Frequently the term is also used as a synonym of microaerobic.)

**microalgae** Microscopic algae – particularly unicellular algae such as CHLAMYDOMONAS, CHLORELLA, DIATOMS, etc.

**microarray (DNA)** See DNA CHIP.

**Microascales** An order of fungi of the ASCOMYCOTINA; the organisms are primarily saprotrophs in soil and dung, but some can be pathogenic in man and other animals. Ascocarp: perithecioid or cleistothecioïd, dark and solitary, sometimes setose; hamathecium: absent. Asci: rounded, thin-walled, evanescent. Ascospores: aseptate, pigmented. Genera: e.g. *Microascus*, PSEUDALLESCHERIA.

**Microascus** See MICROASCALAS.

**Microbacterium** A genus of catalase-positive, asporogenous bacteria (order ACTINOMYCETALES, wall type VI – see also PEPTIDOGLYCAN) which frequently occur in dairy products (e.g. spray-dried milk, some cheeses) – presumably as a result of improper cleansing of dairy equipment. In culture the organisms are slender, pleomorphic, non-motile rods. Growth occurs optimally at ca. 30°C on e.g. media containing yeast extract, peptone and milk; L-(+)-lactic acid is formed from glucose. Some strains produce a yellowish pigment. All strains grow aerobically. The organisms are typically thermotolerant, surviving e.g. 63°C/30 min and 72°C/15 min. GC%: ca. 69–70. Type species: *M. lacticum*. (For *M. thermosphactum* see BROCHOTHRIX.)

**microbe** *Syn.* MICROORGANISM.

**microbial insecticides** See BIOLOGICAL CONTROL.

**microbial leaching** (of ores) See LEACHING.

**microbial mat** A complex, benthic microbial community which forms a cohesive layer and which is typically dominated by CYANOBACTERIA or other photosynthetic prokaryotes – and occasionally e.g. by microalgae; microbial mats occur in those regions where environmental stress tends to exclude, or reduce the numbers of, metazoans – e.g. in intertidal and hypersaline regions, in hot springs, and around HYDROTHERMAL VENTS. Microorganisms which occur in microbial mats include e.g. species of *Lynghya* and *Microcoleus*, various purple photosynthetic bacteria, *Chloroflexus*, and certain aerobic and anaerobic chemotrophs, including SULPHATE-REDUCING BACTERIA.

Microbial mats are believed to have given rise to STROMATOLITES, and, under certain conditions, may have been precursor material for KEROGEN and hydrocarbon deposits; in the latter context it has been suggested that oil is more likely to have been derived from marine organic deposits than from terrestrial plant material which, under appropriate conditions, gives rise to coal. [Book ref. 154.]

**microbicidal** Able to kill at least some types of microorganism. (cf. MICROBISTATIC.)

**microbiocoenosis** A natural community of microorganisms (including algae, bacteria and protozoa) characterized by phases of short-lived stability.

**microbiological safety cabinet** *Syn.* SAFETY CABINET.

**microbiology** The study of MICROORGANISMS and their interactions with other organisms and the environment (cf. CELLULAR MICROBIOLOGY). There is considerable overlap between microbiology and certain other disciplines: e.g. biochemistry, immunology, molecular biology and PARASITOLOGY. Microbiology is also directly relevant to certain aspects of medicine, veterinary science, agriculture, the food industry (see FOOD MICROBIOLOGY) and various commercial processes (see INDUSTRIAL MICROBIOLOGY) as well as ecology and pollution studies (see e.g. CARBON CYCLE, NITROGEN CYCLE, SULPHUR CYCLE, SEWAGE TREATMENT and WATER SUPPLIES).

**microbiota** Microscopic organisms, particularly those in soil.

**Microbispora** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur e.g. in soil. The organisms form branched aerial and substrate mycelium, the former (commonly pink) giving rise to pairs of elongated spores; when grown on certain solid media some species (e.g. *M. parva*) deposit crystals of IODININ in the medium. The GC% of the type species (*M. rosea*) has been reported to be ca. 74. [Ecology, isolation and cultivation: Book ref. 46, pp. 2103–2117.]

**microbistatic** Able to inhibit the growth and reproduction of at least some types of microorganism. (cf. MICROBICIDAL.)

**microbody** A particle, typically less than 1 µm diam., consisting of a collection of functionally related enzymes enclosed in a membranous sac; microbodies occur in eukaryotic cells: see e.g. GLYCOSOME, GLYOXYSOME, PEROXISOME. [Microbodies in urate-utilizing yeasts: AvL (1985) 51 33–43. 'How proteins get into microbodies' (review): BBA (1986) 866 179–203.] (cf. HYDROGENOSOME; LYSOSOME.)

**microcapsule** See CAPSULE.

**microcarrier cell culture** A system for culturing eukaryotic cells in which the cells grow to form a confluent layer on the surface of small solid particles suspended in a slowly agitated medium. [Review: AAM (1986) 31 139–179.] (See also TISSUE CULTURE.)

**microcins** A category of low-MWt BACTERIOCINS produced by members of the Enterobacteriaceae and effective e.g. against bacteria of the same family. The microcins differ from COLICINS in their size, and also differ in that their synthesis is not induced by conditions which trigger the SOS SYSTEM. Typically, microcins are synthesized in the stationary phase, and synthesis tends to be repressed in rich media.

The typical microcin ranges in size from a single modified amino acid (microcin A15 appears to be a derivative of methionine) to short or medium-sized peptides (up to ~50 amino acid residues in length). Microcins are characteristically thermostable (e.g. 100°C/30 min), soluble in methanol–water (5:1), and resistant to extremes of pH and to certain proteases.

The microcins can be grouped according to their modes of action: type A microcins inhibit certain metabolic pathways, type B microcins inhibit DNA replication etc. For example, the bacteriostatic microcin A15 inhibits homoserine succinyltransferase in the methionine biosynthetic pathway (see Appendix IV(d)). The bactericidal microcin B17 inhibits DNA gyrase and induces the SOS SYSTEM in *Escherichia coli* K12 [JGM (1986) 132 393–402]. Microcin C7 is a heptapeptide which blocks protein synthesis. (See also COLICIN v.)

Plasmids which specify microcins (M plasmids or, preferably, Mcc plasmids) appear not to encode resistance to conventional

antibiotics. Some of these plasmids are conjugative – e.g. that encoding B17 (pMccB17, an IncFII plasmid) and that encoding C7 (pMccC7, an IncX plasmid).

**Micrococcaceae** A family of asporogenous, Gram-positive cocci which includes the genera MICROCOCCUS (the type genus), STAPHYLOCOCCUS and STOMATOCOCCUS.

**Micrococcus** A genus of Gram-positive, aerobic, chemoorganotrophic, asporogenous, catalase-positive, generally non-motile bacteria which have a GC value (see GC%) of ca. 65–75 and which are typically resistant to lysostaphin; the micrococcal cell wall typically contains little or no teichoic acid (cf. TEICHURONIC ACIDS), and the ratio of glycine to lysine in the PEPTIDOGLYCAN is characteristically <2. (cf. STAPHYLOCOCCUS.) *Micrococcus* spp typically do not utilize glucose anaerobically, and typically do not form acid, aerobically, in a glycerol–erythromycin medium. Metabolism is respiratory (see RESPIRATION). The organisms occur e.g. on mammalian skin and in raw MILK. They can be isolated e.g. on FTO AGAR. Cells: cocci (ca. 1–2 µm diam.) which occur in tetrads and clusters. Most species form a water-insoluble pigment. Type species: *M. luteus*.

*M. agilis*. A red-pigmented, flagellated, psychrophilic species which does not form acid from glucose or mannose, is resistant to lysozyme, and is VP –ve.

*M. denitrificans*. See PARACOCCUS.

*M. kristinae*. An orange-pigmented species which forms acid from glucose and mannose, is resistant to lysozyme, and is VP +ve.

*M. luteus* (formerly *M. lysodeikticus*, *Sarcina pelagia*). A yellow-pigmented species. Acid is generally not formed from glucose or mannose. Most strains are sensitive to LYSOZYME. VP –ve.

*M. radiodurans*. See DEINOCOCCUS.

*M. roseus* (formerly *M. tetragenus*, *M. roseofulvus*). A red- or pink-pigmented species which often forms acid from glucose (but not from mannose), which may be weakly or strongly resistant to lysozyme, and which can hydrolyse gelatin.

Other species: *M. halobius*, *M. lylae*, *M. nishinomiyaensis*, *M. sedentarius*, *M. varians*.

[Book ref. 46, pp. 1539–1547.]

**Microcoleus** A phycological genus of filamentous 'blue-green algae' (Nostocales) which has been included in the LPP GROUP [JGM (1979) 111 1–61 (p. 23)]. The organisms may form extensive mats on sedimented silt in shallow water [JGM (1984) 130 983–990], in salt-marshes, on mudflats etc, and may also grow on damp soil.

**microcolony** (1) A small clone of bacteria in which the cells may be e.g. in direct physical contact or embedded in a common polysaccharide matrix; such colonies occur e.g. in aquatic habitats. (cf. COENOBIMUM, CONSORTIUM.) [Microcolony formation and consortia: Book ref. 108, pp. 373–393.] (2) See CHLAMYDIA. (3) Any very small colony.

**microcomplement fixation** A method for comparing the amino acid sequence in a given reference protein (e.g. an enzyme) with that in the same protein derived from a different strain or organism; the method is used e.g. in microbial TAXONOMY. Essentially, the protein under test is examined for its ability to fix COMPLEMENT when mixed with an antiserum raised against the purified reference protein; the (quantitative) difference in the complement-fixing ability of the test and reference proteins is taken as a measure of the difference between the amino acid sequences of the two proteins. The results are usually given in *ImD units*; 5 *ImD* units represent ca. 1% difference between the amino acid sequences.

## microconidium

**microconidium** (1) A SPERMATIUM. (2) A small CONIDIUM (cf. MACROCONIDIUM).

**microconjugant** See CONJUGATION (1)(c).

**microcycle sporulation** Sporulation immediately following outgrowth of a spore. [Microcycle sporulation in *Bacillus subtilis*: Book ref. 164, pp. 163–167.]

**microcyclic rusts** Those rust fungi (see UREDINIOMYCETES) which form only one type of *binucleate* spore, the teliospore – i.e., aeciospores and uredospores are not formed; they include e.g. some species of *Puccinia*.

**Microcyclus** (1) A genus of fungi of the Dothideales. (2) A genus of Gram-negative, obligately aerobic bacteria which occur e.g. in soil and freshwater habitats. The cells are capsulated curved rods,  $0.3\text{--}1.0 \times 1.0\text{--}3.0 \mu\text{m}$ ; one strain has a single polar flagellum, but most strains are non-motile. The cells of some strains contain GAS VACUOLES. The organisms grow chemoorganotrophically, but chemolithoautotrophic growth, with  $\text{H}_2$  as electron donor, has been reported for some strains; all strains tested are facultative methylotrophs (see METHYLOTROPHY) which can utilize e.g. formate and methanol. Catalase and oxidase +ve. GC%: 66–69. Type species: *M. aquaticus*. (Since the fungal genus *Microcyclus* (Saccardo 1904) takes precedence, a new name has been proposed for the bacterial genus: *Ancylobacter* [JJSB (1983) 33: 397–398].) [Book ref. 22, pp. 133–135.]

**microcyst** (1) (*bacteriol.*) A type of resting cell – which may or may not be resistant to heat, desiccation etc – formed by certain bacteria: e.g. *Sporocytophaga* and certain *Nocardia* spp. (2) (*bacteriol.*) In the MYXOBACTERIALES: *syn.* myxospore. (3) (*bacteriol.*) *Syn.* coccoid body (see COCCOID BODIES). (4) In some SLIME MOULDS: a resting structure formed by the rounding up and encystment of an individual myxamoeba (cf. MACROCYST).

**microcystin** See MICROCYSTIS.

**Microcystis** A phycological genus of unicellular ‘blue-green algae’ (CYANOBACTERIA) which may be referable to SYNECHOCYSTIS. The cells are spherical, occur in mucilaginous colonies, and contain GAS VACUOLES. Species are traditionally distinguished on the basis of cell size and colony form: *M. aeruginosa* and *M. flos-aquae* form colonies in which numerous cells are embedded in a diffuent mucilage, while colonies of *M. marginata* are surrounded by a distinct envelope. (Colony form may be lost in culture.) The organisms do not fix nitrogen.

*Microcystis* spp are planktonic in fresh water, often forming BLOOMS e.g. in reservoirs. Some strains of *M. aeruginosa* produce a cyclic peptide toxin, microcystin, which has hepatotoxic effects in animals drinking the contaminated water; the toxin appears to associate with cytoskeletal actin in a manner similar to phalloidin (see PHALLOTOXINS). Another (peptide?) toxin (‘fast death factor’, microcystin-*c*) is a potent neurotoxin responsible for convulsions, respiratory failure, and rapid death in animals.

**microdilution broth test** See DILUTION TEST.

**Microellobosporia** See STREPTOMYCES.

**microfauna** See MICROFLORA (2).

**microfilament** Any very thin filament – particularly one of polymerized ACTIN.

**microflora** (1) In a microbiological context: the totality of microorganisms normally associated with a given environment or location (see e.g. BODY MICROFLORA); the term ‘flora’ is often used as an abbreviation in this context. (2) In a broader biological context: the microscopic plants and ‘plant-like’ organisms (e.g. bacteria, fungi, algae etc) normally present in a given environment or location, the term *microfauna* being used to refer to the microscopic animals and ‘animal-like’ organisms (e.g. protozoa, nematodes) of that environment/location.

**microforge** See MICROMANIPULATION.

**microfungi** Those fungi in which the individual fructifications are too small to be seen in detail with the unaided eye.

**microgamete** See ANISOGAMY.

**microgamont** A cell which gives rise to microgametes (i.e., male gametes).

**Microglossum** See HELOTIALES.

**Microjoenia** See HYPERMASTIGIDA.

**micromanipulation** (micrurgy) Any procedure involving the physical manipulation of individual cells (or spores etc) or their components. Examples include: the isolation and culture of single cells for genetic studies; dissection of the ciliate infraciliature in cytophysiological studies; intercellular transplantation of nuclei, mitochondria etc. Dissection and transplantation procedures are sometimes referred to as *microsurgery*.

Micromanipulation may be carried out with any conventional microscope that is fitted with a good-quality mechanical stage and a high-power dry (i.e. non-immersion) objective lens; phase contrast microscopy is preferable for certain types of operation. A vibration-free workplace is essential. The material under study may be arranged e.g. on the surface of an agar block, or as a hanging drop preparation, and is commonly contained within a partially enclosed moist chamber on the microscope stage. (The use of a heated objective lens mounting prevents condensation of water vapour on the lower lens.)

The actual manipulation is carried out with glass *microtools* which are prepared in a *microforge*: essentially, an apparatus used to control the movement of a thin glass tube or rod relative to an electrically heated filament – the operation being observed under the low power of a microscope. *Needles* are fine glass filaments which, in the region of the point, may be ca.  $0.2 \mu\text{m}$  in diameter. *Loops* are made in various sizes. *Pipettes*, which may be  $<1 \mu\text{m}$  diameter, are made by drawing out glass tubing which has been heated to plasticity; they have been used e.g. for holding cells during microsurgery: the (heat-polished) tip of the pipette is held against a cell and a gentle suction is applied. Each microtool is fixed in a metal holder which is clamped to a *micropositioner*: essentially, a means whereby the coarse movements of the hand are scaled down to give the finer movements necessary for the control of the microtools. By such means, microtools can make controlled movements, with speed and precision, along all three axes in space. In a simpler method (used for uncomplicated operations) the microtool holder is clamped to the nosepiece of a second microscope; rotation of the fine focusing control of this microscope moves the microtool in a vertical plane, while movements of the microtool relative to the specimen in a horizontal plane can be made by moving the *specimen* with the mechanical stage of the first microscope.

**micrometer** In light MICROSCOPY: a device used for the measurement of a specimen or parts of a specimen. The simplest micrometer is the *ocular micrometer* (= *eyepiece micrometer*, *graticule*, *reticle*, *reticule*): a glass or plastic disc, marked with a series of regular (though arbitrary) graduations, which is placed in the front focal plane of the eyepiece lens, i.e., resting on the FIELD DIAPHRAGM (sense 2); when the micrometer is in place its graduations can be seen superimposed on the image of the specimen. Calibration of the micrometer may be carried out by focusing the microscope on a *slide micrometer*: a glass slide etched with graduations precisely  $5$  or  $10 \mu\text{m}$  apart; if, say,  $10$  graduations of the ocular micrometer correspond to  $5 \mu\text{m}$  on the slide, then  $1$  graduation will measure  $0.5 \mu\text{m}$  in a specimen.

The *filar micrometer* consists of a thin moveable wire in the front focal plane of the eyepiece, the wire being moveable by

means of a knob that controls a fine-threaded screw; calibration is carried out e.g. with a slide micrometer, the distance (in  $\mu\text{m}$ ) travelled by the wire being read off on a scale around the control knob.

**micromethods** (miniaturized methods) In clinical microbiology: various procedures used for routine testing of specimens or microbial isolates in a manner economical of time and/or space and material. Micromethods are commonly used e.g. to carry out, simultaneously, a range of biochemical identification tests on a given (usually bacterial) isolate; these procedures generally make use of commercially available kits, some of which are briefly described below.

The *API* system consists of a plastic strip holding a number of microtubes, each containing a different dehydrated medium; each microtube is inoculated with a suspension of the test organism, mineral oil is added to certain microtubes (to exclude air), and the strip is incubated. Subsequently, reagents are added to detect particular metabolic products, and the results are read and analysed.

The *Enterotube II* system consists of a tube divided into a sequence of 12 compartments, each compartment containing a different agar-based medium; the media are inoculated by passing an inoculum-bearing needle axially through the tube.

The *Minitek* system consists of a plastic plate containing a number of wells, each well containing a paper disc impregnated with a dehydrated medium; each disc is inoculated with a suspension of the test organism, some are then overlaid with mineral oil, and the plate is incubated. Reagents are then added (to certain wells) and the results are read and analysed.

The *PathoTec* system consists of a number of test strips, each impregnated with the dehydrated medium appropriate to a given test; each strip is incubated in a suspension of the test organism (or inoculated directly from a colony) and the test is read after a specified time.

Some systems are designed for anaerobic incubation. The *AN-IDENT* system permits the testing of anaerobes in a strip incubated aerobically.

[Descriptions of some identification kits: Book ref. 120, pp. 52–65.]

(See also BACTEC.)

**micrometre** ( $\mu\text{m}$ )  $10^{-6}$  m, i.e., 1/1000th mm.

**Micromonadophyceae** A proposed class of unicellular, scaly or naked, flagellated green algae (division CHLOROPHYTA) in which the interzonal mitotic spindle persists during cytokinesis [Book ref. 123, pp. 29–72]. Examples of constituent genera are *Cymbomonas*, *Dolichomastix*, *Mamiella* (scaly), *Mantoniella* (scaly), *Mesostigma*, *Micromonas* (naked), *Monomastix*, *Nephroselmis* (= *Heteromastix*) (scaly), *Pedinomonas* (naked), *Pterosperma*, *Pyramimonas* (scaly), *Scourfieldia* (naked), *Trichloris*; many of these genera were formerly included in the PRASINOPHYCEAE. (cf. TETRASELMIS.)

**Micromonas** See MICROMONADOPHYCEAE.

**Micromonospora** A genus of bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in soil, decaying vegetation and aquatic habitats. The organisms form a non-fragmenting, branching substrate mycelium, but usually do not form an aerial mycelium; most species form a pigment (e.g. yellow, blue, purple). Non-motile, darkly-pigmented spores are borne singly at the tips of sporophores which arise from the mycelium; the spores have some resistance to heat (e.g.  $70^\circ\text{C}/30$  min) and to desiccation. Most species are aerobic; some obligately anaerobic species are currently included in the genus, but the GC% of one (*M. ruminantium*) has been reported to be much lower

(ca. 53–56) than that characteristic of the genus (71–73). Many species are cellulolytic. Some species produce useful antibiotics (see e.g. GENTAMICIN). Type species: *M. chalcea*. [Book ref. 73, pp. 67–69.]

**micron** ( $\mu$ )  $10^{-6}$  m (= MICROMETRE).

**micronemes** Small, convoluted, thread-like structures, oval or circular in cross-section, which occur in members of the APICOMPLEXA; function unknown.

**micronucleus** (*ciliate protozool.*) The smaller (commonly  $<5$   $\mu\text{m}$ ) of the two types of nucleus characteristically present in ciliates (cf. MACRONUCLEUS); according to species a cell may contain one, several or many micronuclei, although micronuclei are absent in some viable strains of species which are normally micronucleate. Micronuclei lack nucleoli, are characteristically diploid, and their DNA (which occurs in chromosome form) is transcriptionally inactive; they are involved in genetic recombination (see AUTOGAMY and CONJUGATION) and in the regeneration of macronuclei.

**microorganisms** According to common usage: microscopic organisms (and taxonomically related macroscopic organisms) within the categories ALGAE, ARCHAEA, BACTERIA, FUNGI (including LICHENS), PROTOZOA, VIRUSES and SUBVIRAL AGENTS.

Some authors do not regard viruses and subviral agents as microorganisms – reserving the term ‘organism’ for an entity which consists of one or more cells [Book ref. 159, pp. 11–13]; other authors include PLASMIDS (as well as viruses) within the category ‘organisms’ [Book ref. 161, pp. 3–16].

**micropalaeontology** The study of microscopic fossils. (See also FOSSIL MICROORGANISMS.)

**microparticle enzyme immunoassay** See LCR.

**microperoxidase** Part of a cytochrome *c* molecule (the haem moiety together with part of the protein) which has peroxidase activity and which is used e.g. in CHEMILUMINESCENCE studies.

**microphotography** Photography in which very small photographs are made of macroscopic or large objects. (cf. PHOTOMICROGRAPHY.)

**microplasmodesmata** Minute pores which occur in the septa in certain filamentous prokaryotes: e.g. in hyphae of certain actinomycetes (see ACTINOMYCETALES) and in cyanobacterial TRICHOMES (see also HETEROCYST).

**Micropolyspora** A (proposed) genus of bacteria (order ACTINOMYCETALES, wall type IV) which are found e.g. in mouldy hay, compost and soil. The organisms form substrate and aerial mycelium, both of which give rise to chains of spores; they do not form mycolic acids. *M. brevicatena*, the former type species of *Micropolyspora*, forms mycolic acids and has been transferred to the genus *Nocardia* [JGM (1982) 128 503–527], leaving *Micropolyspora* a proposed genus *nomen conservandum* [Book ref. 73, pp. 123–124]. [Proposal to conserve the name *Micropolyspora* (with *M. faeni* as type species) and new genus description: IJSB (1984) 34 505–507.] *M. faeni*, a common causal agent of FARMERS’ LUNG, forms substrate mycelium of some shade of yellow, orange or brown, and a white aerial mycelium. (*M. faeni* and *M. rectivirgula* appear to be synonyms [JGM (1979) 115 343–354].) *M. viridinigra* and *M. rubrobrunea* have been transferred to the genus *Excelsopora*.

Some authors use the name *Faenia rectivirgula* as a synonym of *M. faeni*.

**micropore** (1) (formerly: micropyle, ultracytostome) In members of the APICOMPLEXA: a small invagination of the pellicle (usually) coincident with a discontinuity of the inner layer of the pellicle. One or more micropores may be present in a given cell; they may function as sites for the ingestion of food. (2) See GEOTRICHUM.

## micropositioner

**micropositioner** See MICROMANIPULATION.

**micropyle** (1) In some species of coccidia (e.g. *Eimeria stiedae*): a thin, polar region in the oocyst wall. (2) See MICROPORE (1).

**microRNA** (miRNA) See ANTISENSE RNA.

**Microscilla** See BACTERIA (taxonomy).

**microscope slide** *Syn.* SLIDE.

**microscopy** The use of an instrument (*microscope*) for examining objects or details which are too small to be seen (or seen clearly)

by the unaided eye; the microscope forms an enlarged *image* of the specimen. In *light microscopy* images are formed by light or ultraviolet radiation (cf. ELECTRON MICROSCOPY).

(a) *Bright-field microscopy* is the commonest form of light microscopy: the form usually meant by the term 'microscopy'. Essentially, light from a lamp is concentrated by the CONDENSER and directed onto the specimen (Fig. 1). The objective lens ('objective') forms a magnified image of the specimen, and this

MICROSCOPY. Figure 1. A research microscope (Leitz Orthoplan) set up for Köhler illumination. Reproduced by permission of Leitz (Instruments) Ltd, Luton, United Kingdom.

MICROSCOPY. Figure 2. Image formation in bright-field microscopy, using a diffraction grating as a specimen. Light entering one slit of the grating gives rise to zero-order rays (single arrowhead), first-order rays (double arrowhead) and second-order rays (terminally dashed lines). An image is formed as a result of interference between diffracted and non-diffracted rays.

MICROSCOPY. Figure 3. Amplitude and phase relationships in phase-contrast microscopy. (See text for explanation.)

MICROSCOPY. Figure 4. Image formation in phase-contrast microscopy: simplified diagrammatic scheme showing spatial relationships between zero-order rays (solid lines from specimen to image plane) and first-order diffracted rays (dashed lines). (See text for explanation.)

image is further magnified by the eyepiece lens (see MAGNIFICATION). The specimen is usually examined on a SLIDE which rests on the stage. (See also HANGING DROP; MICROTOME; SMEAR; WET MOUNT.)

For an image to be formed, light which has passed through the specimen must differ from the background light in amplitude (intensity) and/or in composition (e.g. colour); thus, an image of the specimen is usually seen against a lighter (bright-field) background. Some specimens are translucent and are therefore poorly visible; such specimens can be made light-absorbing by suitable STAINING.

Image formation is often depicted by ray diagrams. However, for objects below a certain size, image formation can be described satisfactorily only in terms of wave optics; this is because such objects cause significant diffraction of light, and the formation of an image depends on interference between diffracted and non-diffracted light waves. Image formation is shown in Fig. 2; the

object shown is a diffraction grating, but biological specimens form images in a similar way. Fig. 2 shows that, for image formation, the objective must collect at least the undeviated (zero-order) light waves *and* the diffracted (first-order) light waves. For a perfect image all the diffracted light should be collected, but this is impracticable. To collect the maximum amount of diffracted light an objective should have a high *numerical aperture*: see RESOLVING POWER. The specimen should be uniformly illuminated, and the (divergent) beam of light from the specimen should fill the entire aperture of the objective (see CRITICAL ILLUMINATION; KÖHLER ILLUMINATION). When using a HIGH-DRY OBJECTIVE, good image formation also requires the use of a COVER-GLASS of the correct thickness. (See also *oil immersion objective* under RESOLVING POWER; cf. CONFOCAL SCANNING LIGHT MICROSCOPY.)

(b) *Dark-field microscopy* (dark-ground microscopy) is used e.g. for examining objects too small to be seen by bright-field microscopy. For low- or medium-power work, the underside of

## microsome

the substage condenser is fitted with a central opaque disc (the *stop* or *patch stop*) which allows only the peripheral rays to pass through the condenser – thus forming a hollow cone of light whose apex is focused in the plane of the specimen; in the absence of a specimen these rays diverge at such an angle that none enters the objective so that the field of view appears dark or black. (The NA of the condenser must be greater than that of the objective.) A specimen scatters the rays, some of which enter the objective and form a bright image of the specimen against a dark background. For high-power work use is made of a special oil-immersion condenser (e.g. a *cardioid condenser*) within which the incident rays are twice reflected so that the emergent rays form a hollow cone of large apical angle. (See also RHEINBERG ILLUMINATION.)

(c) *Phase-contrast microscopy*. A colourless specimen which absorbs little light (e.g. a non-pigmented living cell) is not clearly visible by bright-field microscopy but may be seen by phase-contrast microscopy. When such a specimen diffracts light, the first-order waves are retarded by approximately  $1/4$ -wavelength ( $1/4\lambda$ ) and are of amplitude smaller than that of the zero-order waves (Fig. 3(i)). If these zero-order and first-order waves are allowed to interfere they will produce resultant waves of amplitude (intensity) similar to that of the background waves but differing from them in phase (Fig. 3(ii)); the phase difference cannot be detected by the eye so that no image is seen. (Background waves are waves which do not pass through the specimen before entering the objective lens of the microscope.) If, however, the zero-order and background waves are first retarded by  $1/4\lambda$  (to eliminate the phase difference between the first-order waves and the zero-order and background waves), interference between zero-order and first-order waves will produce a resultant wave (the image-forming wave) of amplitude greater than that of the background wave (Fig. 3(iii)), i.e., a visible image will be formed.

In a phase-contrast microscope the condenser has a ring-shaped aperture in its front focal plane so that a *hollow* cone of light can be focused (as a small bright ring) onto a *phase plate* located in the back focal plane of the objective (Fig. 4). The phase plate is a glass disc on which has been deposited a ring of material (e.g. magnesium fluoride) of such thickness that it retards by  $1/4\lambda$  the light it transmits. In the absence of a specimen all the incident light is focused on and transmitted via the ring. When a specimen is examined, the zero-order and background light is transmitted via the ring, but the first- and higher-order beams pass through the phase plate via regions *not* located in the ring (Fig. 4). In the image plane, interference occurs between zero-order and diffracted light; the resultant waves form a visible image because their amplitude is greater than that of the background waves (Fig. 3(iii)). To increase image contrast further the phase plate ring has deposited on it a thin layer of light-absorbing material which decreases the amplitude of background and zero-order waves; thus the amplitude of the image-forming wave becomes greater *relative to* that of the background wave (Fig. 3(iv)). (The clarity of the image can be improved by using a green filter in the microscope condenser.)

In the above scheme (*negative* or 'bright' phase-contrast microscopy) the zero-order beam is *retarded* by  $1/4\lambda$ , and the specimen appears lighter than the background. In *positive* or 'dark' phase-contrast microscopy the zero-order beam is *advanced*  $1/4\lambda$ ; the specimen appears darker than the background because destructive interference occurs between the zero-order and first-order beams.

[Some improvements in phase-contrast microscopy: JM (1983) 129 49–62.]

(d) *Interference-contrast microscopy* (differential interference-contrast microscopy). This form of microscopy avoids the 'haloes' which surround images formed by phase-contrast microscopy, and gives clearer images of fine detail. It can detect minute differences in specimen thickness and/or refractivity – such differences being indicated by colour differences in the image. In microscopes based on the *shear* system (e.g. the Nomarski microscope) light from the source is initially split into two parallel beams. The *object beam* passes through the specimen, while the *reference beam* passes through a clear or relatively clear area of the slide; subsequently the beams interfere to form an image. In the *double-focus* system both beams are co-axial – the object beam being focused in the plane of the specimen, and the reference beam being focused either above or below this plane; subsequently, the beams interfere to form an image.

(e) *Fluorescence microscopy*. In fluorescence microscopy a (usually) FLUOROCHROME-treated specimen is irradiated with ultraviolet radiation (or, in some cases, blue light) and the light emitted (see FLUORESCENCE) forms the image of the specimen in a manner similar in principle to that in bright-field microscopy. (Some types of specimen exhibit AUTOFLUORESCENCE.) In a fluorescence microscope, the beam from a mercury-arc lamp, or a tungsten lamp, is initially passed through an *exciter filter* which transmits only the exciting radiation. The exciting radiation is then focused onto the specimen either from below (*transmitted-light fluorescence microscopy*) or from above (*incident-light fluorescence microscopy*, or *epifluorescence microscopy*). In epifluorescence microscopy exciting radiation enters the microscope tube from the side and is reflected downwards, by a dichroic mirror, through the objective onto the specimen; the image-forming light emitted from the specimen passes through the objective, through the dichroic mirror (which does not reflect light of visible wavelength), and through the eyepiece. In both transmitted-light and epifluorescence microscopes, a *barrier filter* (= *stopping filter*) is placed below the eyepiece lens; this transmits emitted light of longer wavelength but stops the short wavelength exciting radiation – thus protecting the eyes and, in photomicrography, protecting the film against fogging. One advantage of epifluorescence microscopy, compared with transmitted-light fluorescence microscopy, is that the emitted light is not partially absorbed within the thickness of the specimen; thus a brighter image can be obtained. (See also CITIFLUOR.) (N.B. In all types of fluorescence microscopy it is necessary to use non-fluorescent lenses, slides, cover-glasses, immersion oil, etc.) (See also IMMUNOFLUORESCENCE; ACRIDINE ORANGE; AURAMINE-RHODAMINE STAIN; CALCOFLUOR WHITE.)

(f) *Ultraviolet microscopy* is a form of microscopy in which ultraviolet radiation is used both for illumination of the specimen and for image formation; the image is recorded on a fluorescent screen or on a photographic plate. Ultraviolet microscopy can resolve finer detail than can bright-field microscopy because the wavelength of the image-forming radiation is shorter than that of visible light (see RESOLVING POWER).

(g) *Epimicroscopy* is any form of microscopy in which the illuminating beam is focused on the specimen by the objective; in this type of illumination (= *vertical* or *incident-light* illumination) the objective acts simultaneously as the condenser and objective lens. An example is epifluorescence microscopy: see (e) above.

**microsome** One of many small heterogeneous membranous vesicles obtained e.g. when eukaryotic cells are homogenized and centrifuged; microsomes include e.g. vesicles formed from the rough and smooth ENDOPLASMIC RETICULUM and from the CYTOPLASMIC MEMBRANE.

**microsource** See BIOLUMINESCENCE.

**Microsphaera** See ERYSPHALES.

**Microspora** A genus of filamentous, unbranched green algae (division CHLOROPHYTA).

**Microspora** A phylum of PROTOZOA [JP (1980) 27 37–58] which are obligate intracellular parasites in a wide range of animals, including vertebrates and invertebrates. Mitochondria are absent. The organisms form spores which are small (commonly <10 µm diam.), unicellular in origin, and have walls which lack pores and are not composed of valves (cf. MYXOZOA); each spore contains a single uninucleate or binucleate *sporoplasm* (an amoeboid infective cell which is released on germination of the spore), and a single tubular, coiled, extrusile *polar filament* which is not enclosed within a polar capsule. A *polar cap* covers the attached end of the tubular filament. In many species there is a membranous (vacuolar) region beneath the polar cap (the *polaroplast* or polar sac). Classes: MICROSPOREA; RUDIMICROSPOREA. (See also ENTEROCYTOZOOM; cf. ASCETOSPORIA.)

**Microsporea** A class of protozoa (phylum MICROSPORA) which are parasitic in insects and other invertebrates, in poikilothermic vertebrates, and (rarely) in mammals. The microsporean spore has (typically) a three-layered, dense, refractile wall, and contains a single sporoplasm and a complex extrusion apparatus comprising the polar filament (which extends back from the polar cap and coils around the inside of the spore wall) and (typically) a polaroplast. When a spore is ingested by a host animal, the polar filament is discharged explosively, evert-ing to form a long tube; the explosive force is such that the filament penetrates any host cell in its path, and the infective sporoplasm can then pass through the filament and into the host cell. [Role of pH-triggered Ca<sup>2+</sup> influx in the discharge mechanism: JCB (1985) 100 1834–1838.] The class contains two orders: Minisporida (e.g. *Burkea*, *Chytridiopsis*, *Hessea*) and Microsporida (e.g. *Amblyospora*, ENCEPHALITOOZON, GLUGEA, NOSEMA, *Pleistophora*, THELOHANIA).

**Microsporida** See MICROSPOREA.

**microsporidean** (Pertaining to) a protozoon of the MICROSPORA (formerly of the class Microsporidea, subphylum Cnidospora).

**microsporidiosis** Any disease caused by protozoa of the phylum MICROSPORA. In man, infections occur in both immunocompetent and immunocompromised individuals, although most isolations appear to come from the latter group (particularly AIDS patients).

Infections may occur in any of various sites. For example, travellers' diarrhoea in immunocompetent hosts can be due to intestinal infection by e.g. *Encephalitozoon intestinalis* or *Enterocytozoon bieneusi*, while *Encephalitozoon hellem*, *Nosema ocularum* and *Vittaforma corneae* have been isolated from the eye. Species of *Pleistophora* infect skeletal muscle, while *Trachipleistophora hominis* infects skeletal muscle, eye, kidney and nasopharynx. [Lab identification: JCM (2002) 40 1892–1901.] In immunocompromised individuals, infection by microsporidia is reported to be more common in patients with CD4<sup>+</sup> counts below 100/µl.

[Microsporidiosis: JMM (2000) 49 947–967 (948–952).]

**Microsporium** See DERMATOPHYTES.

**microstome** See TETRAHYMENA.

**microstrainer** See SEWAGE TREATMENT.

**microsurgery** See MICROMANIPULATION.

**Microtetrastpora** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur e.g. in soil. The organisms form a substrate mycelium (usually colourless, grey, or yellowish) and aerial hyphae which give rise to spores (typically) in chains of four. Type species: *M. glauca*. [Ecology, isolation, cultivation: Book ref. 46, pp. 2103–2117.]

**Microthamnion** A genus of filamentous green algae related to TREBOUXIA; the filaments are branched and possess holdfasts.

**Microthorax** See HYPOSTOMATIA.

**Microthrix parvicella** A species of filamentous bacteria isolated from activated sludge [see e.g. JGM (1984) 130 2035–2042].

**microtome** An instrument for cutting thin sheets (*sections*) of tissue (or of individual cells) for examination by MICROSCOPY. Essentially, the instrument consists of a fixed knife and a mechanism which moves the specimen relative to the knife; after each section is cut the specimen is moved towards the knife by a distance equal to the thickness of the section. Sections for ELECTRON MICROSCOPY are cut with an *ultramicrotome*: a more sophisticated instrument having a glass or diamond knife. To ensure rigidity during cutting, the fixed, dehydrated specimen is embedded in paraffin wax (for light microscopy) or e.g. in an epoxy resin (for electron microscopy). Sections for light microscopy are usually about 5–10 µm thick. Sections for electron microscopy are 100 nm or less; these are cut and selected with the aid of a dissecting microscope.

**microtubule-associated proteins (MAPs)** Proteins associated stoichiometrically with the surfaces of MICROTUBULES; certain MAPs are present in only some types of cell. MAPs include e.g. Mg<sup>2+</sup>-activated GTPase; the ATPase dynein; the various *tau* proteins (apparently involved in the assembly and/or stability of MTs); the 'high-MWt MAPs' designated MAP1 and MAP2 (which occur mainly in the cells of higher animals); and the cold stability factor (CSF) which occurs e.g. in mammalian brain cells and which increases the resistance of MTs to cold. (CSF–MT binding is Ca<sup>2+</sup>-sensitive in brain cells.) [Review: ARCB (1986) 2 421–457.]

**microtubule-organizing centre (MTOC)** In eukaryotic cells: any intracellular body or region involved in the initiation and/or assembly of MICROTUBULES: see e.g. BASAL BODY (b), *centrosome* in CENTRIOLE, DEUTEROSOME, KINETOCHORE and SPINDLE POLE BODY.

**microtubules (MTs)** Non-contractile protein tubules, each having a mean external diameter of ca. 24 nm, which occur singly, in pairs or triplets, or in bundles, in most types of *eukaryotic* cell – including the cells of microorganisms, higher plants and animals. (MTs do not occur in *disc*-shaped mammalian erythrocytes, although they are present in the elliptical erythrocytes of the Camelidae, and even in blood platelets.) MTs are involved e.g. in the maintenance of cell shape and structure (see e.g. CYTOSKELETON), in some types of MOTILITY (see e.g. CILIUM and FLAGELLUM (b)), in spindle formation during MITOSIS, and (apparently) in the intracellular translocation of vesicles, LYSOSOMES and other organelles.

The wall of each MT consists of several (typically 13) longitudinally adjacent rows of TUBULIN molecules, each row being called a *protofilament*; MTs can change their length (and, apparently, their intracellular location) by the assembly/disassembly of tubulin units at one or both ends of the tubule. The outer surface of the MT wall bears a number of MICROTUBULE-ASSOCIATED PROTEINS (MAPs). Even when MTs occur in bundles there is seldom direct contact between one MT and another; they are usually separated from one another by an 'exclusion zone' of ca. 10 nm width – a zone into which the MAPs project.

The assembly of tubulin into MTs is apparently associated with the binding of guanine nucleotides to the tubulin molecule: GTP binds at the 'E' site and (more firmly) at the 'N' site; at some stage (during or after incorporation of the tubulin molecule) GTP at the E site is hydrolysed by an Mg<sup>2+</sup>-activated GTPase (an MAP) and inorganic phosphate is released (GDP

## Microviridae

remaining bound to the tubulin). However, the in vitro assembly of MTs can occur (albeit more slowly) with GDP-tubulin (or with non-hydrolysable GTP analogues) – suggesting that energy is not required for MT assembly. In contrast, MT disassembly seems to need GTP and to be energy-dependent. Although assembly and disassembly can occur at both ends of an MT, there is evidence that, at least under certain in vitro conditions, ‘treadmilling’ can occur; treadmilling means the incorporation of tubulin at one end of a microtubule with concomitant disassembly at the other end.

The initiation of MT assembly in vivo occurs usually, but apparently not always, at a MICROTUBULE-ORGANIZING CENTRE.

Various factors and agents can promote or inhibit MT assembly or disassembly. Thus, e.g. the in vitro assembly of tubulin into MTs occurs only above a certain minimal temperature, and is promoted by GTP,  $Mg^{2+}$ , and a low concentration of  $Ca^{2+}$ . Disassembly is promoted e.g. by cold, by high hydrostatic pressures, and by dilution (MTs disassemble below a certain critical concentration); in some cases MT disassembly can be brought about by  $Ca^{2+}$  (above a certain concentration), while in other cases  $Ca^{2+}$  is effective only in combination with CALMODULIN. Other agents which can inhibit the assembly of MTs include e.g. BENZIMIDAZOLES, COLCHICINE, GRISEOFULVIN, the macrolide *maytansine*, PODOPHYLLOTOXIN, *steganacin* (a polycyclic lactone with a trimethoxy-substituted aromatic ring), and certain VINCA ALKALOIDS. MT assembly is promoted e.g. by TAXOL; high concentrations of glycerol stabilize MTs by lowering the rates of assembly and disassembly.

[Reviews: Book ref. 165; MT structure studied by cryoelectron microscopy: JM (1986) 141 361–373.]

**Microviridae** ( $\phi$ X phage group; isometric ssDNA phages) A large, diverse family of icosahedral, lytic, ssDNA-containing BACTERIOPHAGES; hosts: enterobacteria. Members are abundant e.g. in sewage. One genus: *Microvirus*; type species:  $\phi$ X174. Microviruses  $\phi$ X174, S13, G4, G6, G13, G14,  $\alpha$ 3,  $\phi$ A,  $\phi$ B,  $\phi$ C, and  $\phi$ R infect *C* strains of *Escherichia coli*; St-1,  $\phi$ K,  $\phi$ XtB, and U3 infect *E. coli* K12. Growth temperature range, antiserum cross-reactions, host receptor site, and host *dna* function requirements suggest close relationships between  $\phi$ X174, S13, G6,  $\phi$ A and  $\phi$ B, probably between St-1 and  $\phi$ K, and possibly between G4 and  $\phi$ C; G14 and U3 differ from one another and from other microviruses.

The microvirus has an icosahedral capsid (28–32 nm diam.) whose vertices each bear a spike; spikes seem to function in adsorption of phage to host LIPOPOLYSACCHARIDE. The ss cccDNA genome (MWt ca.  $1.7 \times 10^6$ ) comprises 11 genes (*A–H*, *J*, *K* and *A\**), four of which are OVERLAPPING GENES: gene *B* occurs within *A*, *E* within *D*, *K* overlaps *A* and *C*; *B*, *E* and *K* are translated in different reading frames from *A*, *D* and *C*. gpA\* is the C-terminal portion of gpA. Gene products from different microviruses differ slightly in composition. gpF (60 molecules per virion) is the major component of the capsid; each spike comprises gpG (5 molecules) and gpH (1 molecule at the tip). Several copies of gpJ and possibly one of gpA\* are associated with the capsid. gpA functions in genome replication; gpB, gpC, gpD, and possibly gpJ function in phage morphogenesis. gpE is necessary for host cell lysis; it may interfere with the cell membrane and/or may activate host autolytic enzymes. (For microvirus replicative cycles see SSDNA PHAGE, BACTERIOPHAGE  $\phi$ X174 and BACTERIOPHAGE G4.)

**Microvirus** See MICROVIRIDAE.

**microwave radiation** (in sterilization) Microwaves (2.45 GHz) have been used e.g. for the STERILIZATION of plastic tissue-culture vessels [AEM (1982) 44 960–964].

**micrurgy** Syn. MICROMANIPULATION.

**Middelburg virus** See ALPHAVIRUS.

**middle T antigen** See POLYOMAVIRUS.

**Middlebrook 7H-9 broth** A growth medium used for *Mycobacterium* spp; it contains mineral salts, pyridoxine hydrochloride, biotin, sodium glutamate, sodium citrate, and either Tween 80 or glycerol. [Recipe: Book ref. 53, p. 1415.]

**midland cattle disease** A form of BOTULISM in cattle; the disease is due to ingestion of forage or carrion contaminated with *C. botulinum* type C $\beta$  (cf. FORAGE POISONING).

**mid-point potential** See REDOX POTENTIAL.

**Miescher’s tubes** Sarcocysts in tissues (see SARCOCYSTIS).

**MIF** Migration inhibition factor: a CYTOKINE originally obtained from specifically reactive T lymphocytes exposed to the relevant antigen; in vitro, this factor is characterized by its ability to inhibit the movement of macrophages away from the source of MIF. (Other in vitro activities include the activation of NO synthase (see NITRIC OXIDE) in macrophages.) MIF is associated with DELAYED HYPERSENSITIVITY reactions and may account for the accumulation and activity of macrophages in DH lesions.

The human MIF is a 12 kDa protein; its sources include the pituitary gland. The precise in vivo role of MIF has not been established; it may e.g. exert pro-inflammatory activity as a counter-balance to raised levels of (anti-inflammatory) glucocorticoids resulting from stimulation of the hypothalamic–pituitary–adrenal axis.

**migration inhibition factor** See MIF.

**mikamycins** See STREPTOGRAMINS.

**mildews** (*plant pathol.*) See e.g. DOWNY MILDEWS and POWDERY MILDEWS.

**Miles and Misra’s method** (drop method; drop plate method) A COUNTING METHOD for determining the viable cell count of a bacterial suspension. Serial dilutions (often log dilutions) of the suspension are prepared. One drop (of known volume) from each dilution is placed at a separate, recorded position on the surface of a pre-dried agar PLATE; the drops are allowed to dry. The plate is then incubated until visible colonies develop in the small, circular areas corresponding to the drops. If a sufficient number of dilutions has been prepared, a drop from one of the dilutions will give rise to a countable number of discrete colonies. Assuming that each viable cell in the drop gave rise to a separate colony (and knowing the volume of the drop) the viable count can be calculated. In practice, a count is calculated from each of several drops on the plate, and the average is taken.

**milfuram** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**Milgo** See ETHIRIMOL.

**miliary** Resembling millet seed. Miliary TUBERCULOSIS: a form in which numerous small tubercles develop.

**Miliolina** See FORAMINIFERIDA.

**milk** (microbiological aspects) Milk consists primarily of water containing proteins, soluble carbohydrates, electrolytes, lipids and vitamins.

The major protein constituents of milk are CASEINS (which occur in the form of complex micelles); there are also the so-called WHEY PROTEINS such as lactalbumin and lactoglobulin. IMMUNOGLOBULINS occur in high concentrations in COLOSTRUM and in relatively lower concentrations in milk. Various enzymes, e.g., alkaline phosphatase (see PHOSPHATASE TEST), are normally present in raw (i.e., untreated) milk. (See also LACTOFERRIN and LACTOPEROXIDASE–THIOCYANATE–HYDROGEN PEROXIDE SYSTEM.)

The major carbohydrate, LACTOSE (ca. 50 g/l in cow’s milk), contributes ca. 50% of the osmotic pressure of milk (which is isotonic with blood plasma); small amounts of e.g. glucose and galactose are also present.

Electrolytes include  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Na}^+$  and  $\text{K}^+$  together with phosphate, chloride and citrate ions.

Milk lipids are mainly triacylglycerides ('triglycerides') containing the residues of various saturated and unsaturated, branched and unbranched fatty acids; there are also some free fatty acids and phospholipids. Lipids occur as globules (up to ca. 6  $\mu\text{m}$  diam. in freshly secreted milk), each globule being surrounded by a phospholipid-rich 'milk fat globule membrane' derived from the cytoplasmic membrane of the secretory cell. (*Homogenization*, which involves pumping milk under high pressure, reduces the size of the globules (which then do not rise to the surface as 'cream'); the resulting partial loss of phospholipid membrane, and the increased total surface area of the globules, renders the lipid more susceptible to enzymic lipolysis.)

*The microflora of raw (untreated) milk.* Milk drawn aseptically from a healthy animal usually contains few, if any, microorganisms. However, milk may contain large numbers of bacteria if e.g. it is drawn from an animal suffering from asymptomatic or clinical MASTITIS. Freshly drawn milk may be subsequently contaminated e.g. by microorganisms on the exterior of the udder, on milking equipment, or in manure or SILAGE; the temporary storage of raw milk in refrigerated vessels provides an opportunity for the growth of PSYCHROTROPHIC contaminants (e.g. some species of *Pseudomonas*). Organisms frequently found in raw milk include certain species of e.g. ESCHERICHIA (and other enterobacteria), LACTOBACILLUS, LEUCONOSTOC, MICROBACTERIUM, MICROCOCCUS, PSEUDOMONAS, STAPHYLOCOCCUS and *Streptococcus* (see also LACTOCOCCUS), as well as certain yeasts and moulds; various actinomycetes, other organisms, and endospores of e.g. *Bacillus* spp may also be present. The nature and extent of the microbial contamination of raw milk can affect the keeping qualities of the milk following processing; thus, e.g., certain contaminating organisms form heat-stable extracellular enzymes (including lipases) that remain active after the cells that produced them have been killed during processing.

*Microbiological examination of milk.* An assessment of microbial contamination may be made by a total bacterial count (= standard plate count); this can be carried out e.g. by plating an aliquot of milk on yeast extract–milk agar (or similar medium) and incubating aerobically at ca. 30–32°C for several days; low-temperature incubation (for a longer period) may be used to detect psychrotrophs. Colony counts may range from <1000 to  $>10^6$  colonies  $\text{ml}^{-1}$  milk according to the sample's history. (See also DEFT, METHYLENE BLUE TEST and SPIRAL PLATE COUNT METHOD.) [Assessing the bacterial content of milk (review): JAB (1983) 55 187–201.]

*Milk treatment processes.* See e.g. PASTEURIZATION and APPERTIZATION (for UHT treatment). (Certain processes involving heat treatment are carefully designed to avoid or minimize the occurrence of the MAILLARD REACTION.) When milk is derived from animals that have been treated with penicillin, the milk may contain sufficient penicillin to inhibit STARTER strains; in e.g. some CHEESE-MAKING plants such milk is routinely treated with PENICILLINASE.

*Pathogenic microorganisms in milk* can be derived from a site of infection within the milk-producing animal itself; the consumption of such contaminated milk can give rise to disease such as e.g. BRUCELLOSIS, Q FEVER (caused by the ENDOSPORE-forming bacterium *Coxiella burnetii*) and TUBERCULOSIS. (See also LISTERIOSIS and ZOONOSIS.) Any of a variety of pathogenic

microorganisms may contaminate (and survive within) milk following collection.

(See also DAIRY PRODUCTS and MILK SPOILAGE.)

**milk caps** See LACTARIUS.

**milk ring test** (abortus Bang reaction/ringprobe; ABR) A test for detecting BRUCELLOSIS in e.g. cattle. Milk from cows infected with *Brucella abortus* contains antibodies to *B. abortus* adsorbed to the fat globules. In the test, a small sample of milk is mixed with a suspension of killed, stained cells of *B. abortus*, shaken, and incubated for up to one hour. In a *positive* test (antibodies present) the stained cells react with the antibodies and are carried to the surface with the fat globules to form a coloured layer ('ring') of cream. In a *negative* test the cells remain dispersed in the milk.

**milk spoilage** Souring (acidification) of milk (which often results in clotting – see CASEIN) can be caused e.g. by the growth of *Lactococcus lactis* or other LACTIC ACID BACTERIA.

ROPINESS can be caused by slime-forming strains of *Lactobacillus* spp (e.g. *L. brevis*, *L. casei*).

'Broken cream' ('bitty cream'), usually due to *Bacillus cereus* or *B. mycoides*, is characterized by the development (in the cream layer) of small particles which fail to emulsify on shaking; it is thought to involve the activity of microbial LECITHINASES on the milk fat globule membrane (see MILK) with consequent coalescence of globules. Usually, the milk beneath a layer of broken cream subsequently exhibits a non-acid clot ('sweet curdling') due to the effects of extracellular rennin-like microbial enzymes on the milk CASEIN.

Malty off-flavours can be due e.g. to certain strains of *Lactococcus lactis* which convert amino acids to aldehydes (particularly leucine to 3-methylbutanal).

(See also LITMUS MILK and FOOD SPOILAGE.)

**milk-vetch dwarf virus** See LUTEOVIRUSES.

**milkers' nodule** (milkers' node) In man: non-ulcerating, red, nodular (papular) lesions on the hands of milkers caused by localized infection (via abrasions, cuts etc) with the PSEUDOCOW-POX virus.

**milky disease** An INSECT DISEASE affecting larvae of beetles of the family Scarabaeidae. Originally, two forms of the disease were recognized: type A, caused by *Bacillus popilliae*, and type B, caused by *B. lentimorbus* (= *B. popilliae* var. *lentimorbus*); other species associated with milky disease – e.g. *B. fribourgensis* and *B. euloamarahae* – may be varieties of *B. popilliae*. Beetle larvae become infected when they ingest spores of the pathogen; the spores germinate in the gut, and the vegetative cells proliferate, subsequently invading the haemolymph. Sporulation then occurs, resulting in ca.  $5 \times 10^9$  spores/ml and giving the haemolymph the characteristic milky appearance. *B. popilliae*, but not *B. lentimorbus*, forms a parasporal crystal similar to that of *B. thuringiensis* (see DELTA-ENDOTOXIN), but this apparently plays no role in milky disease.

The milky disease pathogens have been used successfully in the USA for the BIOLOGICAL CONTROL of the soil-dwelling larvae of the Japanese beetle (*Popillia japonica*); the spores are produced commercially by the artificial inoculation of living insect larvae. The pathogen may persist in suitable environments, precluding the need for repeated application. *B. popilliae* cannot grow at 37°C and is therefore unlikely to infect mammals.

**millet red leaf virus** See LUTEOVIRUSES.

**millimicron** (m $\mu$ )  $10^{-3}$   $\mu$  (= NANOMETRE).

**Millipore filter** See FILTRATION.

**Milstem** See ETHIRIMOL.

**Milton** See HYPOCHLORITES.

## **min genes**

**min genes** See CELL CYCLE (b).

**MinCDE** See CELL CYCLE (b).

**Minchinia** A genus of protozoa (class STELLATOSPOREA) which are parasitic in aquatic invertebrates, including oysters; *M. costalis* and *M. nelsoni* are economically important pathogens of the American oyster *Crassostrea virginica*, sometimes causing massive mortalities in oyster-beds. *Minchinia* spp have a plasmodial vegetative phase.

**mineralization** In nature: the process in which organic materials are broken down into inorganic materials; mineralization is effected mainly by saprotrophic bacteria and fungi. (cf. BIOMINERALIZATION.) Mineralization in organically polluted rivers and lakes may lead to SELF PURIFICATION (cf. EUTROPHICATION). Mineralization plays an essential part in the cycles of matter: see e.g. CARBON CYCLE, NITROGEN CYCLE, SULPHUR CYCLE.

**miniature anion exchange centrifugation technique** See MAECT.

**miniaturized methods** See MICROMETHODS.

**minicell** In bacteria: an abnormal, small product of cell division which lacks a chromosome and which is formed from a mutant parent cell by septation at a polar (rather than mid-cell) location; although lacking genomic DNA, a minicell may contain one or more plasmids derived from the parent cell. Minicells do not grow, but they contain the components necessary for transcription and translation; they can be useful in genetic studies in that, following infection or transfection with e.g. phage DNA, they will synthesize only phage-encoded proteins.

Minicells can be formed in e.g. *Escherichia coli* and *Bacillus subtilis* by mutation in the *minCD* genes (see prokaryotic CELL CYCLE); MinCD are septation-inhibitory proteins, and their absence permits septation at polar sites as well as at the mid-cell site. Minicells can also be formed from cells in which the FtsZ protein (see CELL CYCLE) is overproduced, i.e. raised levels of FtsZ can override the septation-inhibitory activity of the *min* proteins at polar sites.

(See also MAXICELL.)

**minichromosome** (1) A form in which the genome of certain DNA viruses occurs in the host (animal or plant) cell; the circular viral DNA complexes with histones to form a structure similar or identical to that of the host's CHROMATIN. Minichromosomes are formed e.g. by CAULIFLOWER MOSAIC VIRUS, EPSTEIN-BARR VIRUS, and viruses of the PAPOVAVIRIDAE. Those of SV40 are widely used in studies on chromatin structure; a mature SV40 minichromosome contains ca. 27 nucleosomes, or ca. 25 nucleosomes with a 'nucleosome-free gap'. [Structure of replicating SV40 minichromosomes: JMB (1986) 189–204.]

(2) A plasmid which contains a chromosomal replication origin (usually the *oriC* of *Escherichia coli*) as sole origin of replication.

**minicircle DNA** See KINETOPLAST.

**mini-F plasmid** Any small, self-replicating plasmid constructed from a fragment of the F PLASMID – see e.g. PML31.

**minimal medium** (MM) A type of culture medium which lacks certain growth factors – i.e., it does not support the growth of some or all auxotrophic strains of a given organism, but permits the growth of prototrophic strains. (cf. COMPLETE MEDIUM.)

**mini-Mu** A defective form of BACTERIOPHAGE MU in which the genome lacks certain sequences but has intact ends; owing to the 'headful' mechanism by which Mu DNA is packaged into virions, the shortened genome of a mini-Mu phage is associated with a long sequence of bacterial DNA at the S end. Although mini-Mu phages are defective, they can be replicated and matured in the presence of helper Mu.

A mixture of mini-Mu and helper Mu phages can function more effectively in generalized TRANSDUCTION to *rec*<sup>+</sup> recipients than can Mu alone (which transduces only at very low frequencies); this is probably due to the higher proportion of phage particles containing significant amounts of bacterial DNA which can undergo *rec*-dependent recombination with homologous regions of the recipient's chromosome. However, if the mini-Mu DNA has an intact *A* gene, *recA*<sup>−</sup> recipients can be used; in this type of transduction (termed *mini-muduction*) the transduced DNA is integrated at random locations in the recipient's chromosome, the inserted DNA being flanked by two mini-Mu genomes in the same orientation.

(See also MUDLAC SYSTEM.)

**mini-muduction** See MINI-MU.

**minimum haemagglutinating dose** See MHD.

**minimum haemolytic dose** See MHD.

**minimum inhibitory concentration** (of an antibiotic) See MIC.

**minimum lethal dose** (MLD) (1) The minimum dose of a given lethal agent sufficient to cause 100% mortality in a population of test animals under given conditions.

(2) The minimum dose of a given lethal agent sufficient to kill an individual of a given species of specified body weight under given conditions.

**Minisporida** See MICROSPOREA.

**Minitek system** See MICROMETHODS.

**mink Aleutian disease** See ALEUTIAN DISEASE OF MINK.

**mink cell focus-forming viruses** See MCF VIRUSES.

**mink enteritis virus** See PARVOVIRUS.

**mink leukaemia virus** (MiLV) An endogenous type C retrovirus (subfamily ONCOVIRINAE) isolated from the MV-1-Lu mink lung cell line. It is highly infectious for dog and donkey cells, weakly infectious for mink cells, and non-infectious for murine, goat, human and monkey cells. [Book ref. 114, pp. 118–120.]

**minocycline** See TETRACYCLINES.

**minor groove** (in DNA) See DNA.

**minus-progamone** See PHEROMONE.

**minus strand** (of a gene) (*mol. biol.*) See CODING STRAND.

**minus strand** (*virol.*) See VIRUS.

**minus 10 sequence** See PROMOTER.

**minus 35 sequence** See PROMOTER.

**minute virus of canines** See CANINE PARVOVIRUS.

**minute virus of mice** See PARVOVIRUS.

**minutes** (in relation to genetic loci) See INTERRUPTED MATING and MAP UNIT.

**MIP channel** A molecular pathway, consisting of a single protein in the cytoplasmic membrane (CM), which permits transmembrane movement of water and/or certain other uncharged molecules. Such a channel (designated Aqp1) was first described in the erythrocyte (red blood cell) membrane; it was later shown to be analogous to the major intrinsic protein (MIP) in mammalian lens fibre, to the tonoplast intrinsic proteins in plants, and to the GlpF protein in *Escherichia coli*. MIP proteins (found in all classes of living organisms) share highly conserved regions.

A MIP channel consists of a single polypeptide which apparently passes through the CM a number of times in a series of loops; this structure is believed to form a pathway for either water (channel = *aquaporin*) or glycerol (and/or other uncharged molecules) (channel = *glycerol facilitator*). (In *Lactococcus lactis* the MIP channel transports both water and glycerol.)

The aquaporin in *E. coli* (AqpZ) is encoded by gene *aqpZ*, and the glycerol facilitator (GlpF) is encoded by gene *glpF*. Mutants in *aqpZ* appear to grow poorly under low osmotic

pressure – conditions which, in wild-type strains, appear to stimulate expression of *aqpZ*; this suggests that AqpZ has an important physiological role.

MIP channels occur in some members of the Archaea (e.g. *Archaeoglobus fulgidus*, *Methanobacterium thermoautotrophicum*) but apparently not in others (e.g. *Methanococcus jannaschii*). They also seem to be absent in e.g. *Chlamydia trachomatis*, *Helicobacter pylori*, *Mycobacterium tuberculosis* and *Trponema pallidum*.

[The importance of aquaporin water channel protein structures: EMBO (2000) 19 800–806. Microbial MIP channels: TIM (2000) 8 33–38.]

**Mirabilis mosaic virus** See CAULIMOVIRUSES.

**mirror yeasts** (shadow yeasts) BALLISTOSPORE-forming yeasts (see SPOROBOLOMYCETACEAE); when these yeasts are grown in a Petri dish, the pattern of discharged ballistospores adhering to the lid is a mirror image (or shadow) of the pattern of growth beneath.

**Mischococcus** A genus of freshwater epiphytic algae (class XANTHOPHYCEAE) in which the coccoid, non-motile vegetative cells occur in colonies composed of dichotomously branching gelatinous tubes.

**mismatch repair** A DNA REPAIR system which can correct mismatched (i.e. non-Watson–Crick) base pairs – e.g. those formed during DNA replication when misincorporated nucleotides have escaped proof-reading. Mismatch repair effectively enhances the accuracy of replication. (cf. MUTATOR GENE.)

In *Escherichia coli*, mismatch repair (Dam-directed mismatch repair; DDMR) in the newly replicated daughter strand occurs soon after the failure of proof-reading and before Dam methylation (see DAM GENE) has occurred, i.e. while the new daughter strand is still (transiently) undermethylated. The mismatched base-pair is detected by MutS (*mutS* gene product), and this activates an endonuclease, MutH. [Mutational analysis of the MutH protein from *Escherichia coli*: JBC (2001) 276 12113–12119.] (MutH exhibits sequence homology with a restriction endonuclease, *Sau3AI* [EMBO (1998) 17 1526–1534].) MutH cleaves the new strand at a site 5' to an *unmethylated* GATC (Dam) sequence – which may be up to ~1000 nucleotides from the actual site of mismatch; co-ordination between the mismatch location and the GATC cleavage site may be mediated by the MutL protein. When nicked by MutH, the sequence of daughter strand between the nick site and a site on the other side of the mismatch is removed. It has been assumed that removal of this sequence depends on helicase II (= MutU; = UvrD) and a DNA exonuclease; however, mutants lacking the 3'-to-5' exonuclease ExoI and the 5'-to-3' exonucleases ExoVII and RecJ appear to be capable of normal mismatch repair [JB (1998) 180 989–993]. On removal of the sequence, the single-stranded gap is filled by a DNA polymerase and sealed by a ligase.

The mismatch repair system in *E. coli* is apparently not equally effective against all possible mismatched base pairs [PNAS (1985) 82 503–505].

Mismatched nucleotides can arise not only by misincorporation of bases during replication but also by the formation of heteroduplex DNA during RECOMBINATION. In *E. coli*, if one strand of a heteroduplex is unmethylated, DDMR can apparently correct that strand; if both strands are fully methylated, *either* strand can apparently be corrected by a mismatch repair system involving MutS and UvrD [JMB (1986) 188 147–157]. (See also TRANSFORMATION.)

Strains of *E. coli* lacking *mut* products have defective DNA repair systems, and they exhibit a mutator phenotype. (In

humans, some types of cancer have been linked to mutations in genes homologous to *mutS* and *mutL*.)

Recent work suggests that asymmetry of ATPases on the MutS dimer is crucial for mismatch repair and controls timing of the repair cascade [EMBO (2003) 22 746–756].

**miso** (soy paste; bean paste) A condiment made by fermenting soybeans, usually mixed with cereal. A *KOJI* is prepared by inoculating steamed rice with *Aspergillus oryzae*. Salt and steamed soybeans are added, and the mixture is inoculated with a starter culture of yeasts and bacteria (e.g. *Zygosaccharomyces rouxii*, *Pediococcus halophilus*, *Enterococcus faecalis*), blended, packed tightly into vats, and fermented at 25–30°C for ca. 2–3 months. After ageing for ca. 2 weeks, the product is blended, pasteurized and packaged, or freeze-dried and sold as a powder. [Book ref. 5, pp. 39–86.]

**mis-sense mutation** A MUTATION in which a codon specifying one amino acid is altered so as to specify a different amino acid. The effects of such a mutation range from none (a SILENT MUTATION) to total inactivation of the gene product, depending e.g. on the location of the amino acid in the product and on the nature of the substituted amino acid relative to that of the original. (cf. NONSENSE MUTATION; see also POINT MUTATION.)

**MISTRESS** Milk into steam treatment research equipment small scale: equipment used for research into high-temperature (e.g. UHT) methods of preservation in the food industry. Essentially, milk is sprayed into a steam-containing vessel and, at the end of the holding time, it is drawn through a hole into a vacuum chamber where it cools by expansion.

**mithramycin** See CHROMOMYCIN.

**mitochondrion** A semi-autonomous intracellular organelle, one or more (usually many) of which occur in most types of eukaryotic cell (being absent e.g. in protozoa of the orders Diplomonadida and Pelobiontida); RESPIRATION and the reactions of the TCA CYCLE occur within the mitochondrion. Mitochondria differ in size (<1 µm to >10 µm), shape, and number, according to the type of cell in which they occur and to the physiological state of that cell; a mitochondrion may be spherical, ovoid, elongated, calyciform or irregularly shaped, and some are branched.

*Structure and composition.* A mitochondrion consists of two closed membranous sacs, one fitting closely within the other, and an amorphous *matrix* (enclosed by the inner membrane) which contains the mitochondrial DNA and enzymes of the TCA cycle. The mitochondrial inner membrane is extensively corrugated and forms plate-like, tubular, or finger-like structures (*cristae*) which project into the matrix – often more or less perpendicular to the longitudinal axis of the mitochondrion; the inner membrane contains components of the ELECTRON TRANSPORT CHAIN, PROTON ATPASES and TRANSPORT SYSTEMS for e.g. nucleotides, inorganic phosphate, and Ca<sup>2+</sup>. (See also ION TRANSPORT.) The mitochondrial outer membrane contains PORINS (see also VDAC).

Mitochondrial DNA (mtDNA) is typically in the form of covalently closed circular, double-stranded molecules (differing from the nuclear DNA e.g. in base composition and buoyant density); mtDNA is linear in e.g. certain ciliates (including *Paramecium*), *Physarum polycephalum*, and *Hansenula mrakii*. Mitochondrial genes employ a GENETIC CODE (q.v.) which differs in some respects from the 'universal' code, and some fungal mitochondrial genes contain introns (see SPLIT GENE). Genetic recombination can occur between mtDNAs. (See also PETITE MUTANT.)

## mitogen

*Origin and semi-autonomy of mitochondria.* It is generally believed that mitochondria are formed by the division or fragmentation of pre-existing mitochondria – or (see later) by the development of promitochondria – and that these organelles incorporate new material (i.e., grow) during interdivision periods. The components of mitochondria are encoded partly by the cell's nuclear DNA and partly by the mtDNA. [Nuclear genes encoding mitochondrial proteins in yeast: TIBS (1985) 10 192–194.] Thus, in *Saccharomyces cerevisiae*, mtDNA encodes e.g. tRNAs, two types of rRNA, one ribosomal protein, the apoprotein of cytochrome *b* in Complex III, and a protein designated 'var1'. Certain mitochondrial components are synthesized in the mitochondrion itself. However, while a mitochondrion can synthesize DNA and RNA, and can carry out protein synthesis, many of the proteins needed for these processes are encoded by nuclear genes, synthesized on cytoplasmic ribosomes, and incorporated into the mitochondrion; control of the synthesis of these proteins may be largely at the transcriptional level.

Mitochondrial protein synthesis differs from cytoplasmic protein synthesis e.g. in that it is sensitive to those agents (e.g. CHLORAMPHENICOL, ERYTHROMYCIN) which inhibit bacterial PROTEIN SYNTHESIS; it is not sensitive to CYCLOHEXIMIDE; and it is characterized by the incorporation of *N*-formylmethionine as the first amino acid in a polypeptide chain. These features have lent support to a popular hypothesis which supposes that mitochondria have their evolutionary origins in endosymbiotic prokaryotes. [Mitochondrial origins: PNAS (1985) 82 4443–4447.] (An alternative hypothesis supposes that mitochondria evolved from plasmids.)

In at least some facultatively fermentative organisms (including e.g. *Saccharomyces cerevisiae*) cells growing under anaerobic conditions do not contain functional mitochondria; such cells contain *promitochondria*: organelles which resemble mitochondria but which lack components of the electron transport chain. On exposure to aerobic conditions promitochondria apparently develop into functional mitochondria; reversion to promitochondria occurs if anaerobic growth is resumed.

In e.g. certain fungi mitochondrial defects can alter the nature of the cell's metabolism (see e.g. PETITE MUTANT and POKY MUTANT), and can affect the expression of nuclear genes which are involved e.g. in determining the nature of cell-surface antigens [TIBS (1982) 7 147–151]; inhibition of mitochondrial protein synthesis can affect both meiotic and apomictic sporulation in *Saccharomyces cerevisiae* [Yeast (1985) 1 39–47].

**mitogen** Any agent which, under appropriate conditions, can promote MITOSIS, non-specifically, and can bring about BLAST TRANSFORMATION. (cf. POLYCLONAL ACTIVATORS.) Mitogens include e.g. certain LECTINS (such as PHYTOHAEMAGGLUTININ). (Substances which can promote early events in the activation process – including DNA synthesis – but which cannot promote mitosis are not, strictly speaking, mitogens.)

**mitogen-activated protein kinase** See ANTHRAX TOXIN.

**mitomycin C** ('mitomycin') An ANTIBIOTIC (from *Streptomyces* spp) with general cytotoxic activity; it contains a quinone group and an aziridine (ethyleneimine) ring. It binds to DNA and causes inhibition of DNA replication followed by degradation of DNA; synthesis of proteins and RNA may continue for a time. Mitomycin activity depends on its reduction in vivo (by NADPH-dependent enzymes) to the highly reactive hydroquinone derivative which behaves as a bifunctional ALKYLATING AGENT and forms e.g. covalent cross-links between complementary strands of dsDNA; the semiquinone seems to be formed as

an intermediate and may bind DNA non-covalently and intercalatively (see INTERCALATING AGENT). Preferred sites for alkylation are the O-6 groups of guanine residues. (Reduced mitomycin will also react with RNA and, to a lesser extent, protein.) Alkylation of B-DNA by mitomycin can cause conformational changes that may involve the transition to Z-DNA. Mitomycin is a potent inducer of lysogenic bacteriophages; viral DNA synthesis is relatively resistant to mitomycin.

**mitoplast** The inner membrane of a MITOCHONDRION together with the mitochondrial matrix.

**mitosis** (karyokinesis) A sequence of events which culminates in the division of a eukaryotic nucleus into two genetically similar or identical nuclei whose ploidy is the same as that of the parent nucleus; mitosis occurs during asexual (vegetative) cell division. (cf. MEIOSIS.)

Different types of mitosis occur among the various types of eukaryotic cell. The best-known ('typical') form of mitosis is that which occurs in the cells of higher animals and e.g. in some protozoa; it involves the following stages (in chronological order).

*Prophase.* Individual CHROMOSOMES, each having previously divided into two chromatids, condense and become visible by light microscopy. The NUCLEOLUS becomes indistinct and then invisible. MICROTUBULES of the CYTOSKELETON disassemble, forming a pool of tubulin subunits. From each of two pairs of CENTRIOLES (lying close to each other in the cytoplasm) arises a radial array of microtubules (referred to as an *aster*). Those microtubules which extend from each centriole pair towards the other elongate – the centriole pairs concomitantly moving apart until each eventually forms one pole of a bipolar microtubular *mitotic spindle*; microtubules from each of the centriole pairs (= *polar microtubules* or *polar fibres*) overlap in the mid-region of the spindle.

*Prometaphase.* The nuclear membrane breaks into pieces. KINETOCHORES develop on the chromosome centromeres, and from each kinetochore *kinetochore microtubules* (= k-MTs; *kinetochore fibres*) grow out more or less perpendicularly to the long axis of the chromosome. The k-MTs apparently begin to interact with the spindle (in some as yet unknown way) causing the chromosomes to execute rapid movements.

*Metaphase.* The chromosomes become arranged in a layer (the *metaphase plate*) midway between the poles of the spindle and perpendicular to its axis. The metaphase plate may be maintained for some time, each chromosome possibly being held in dynamic equilibrium by equal and opposite forces generated within the spindle.

*Anaphase.* The two chromatids of each chromosome appear to move along stationary k-MTs to opposite poles of the spindle; de-polymerization of the k-MTs apparently occurs at the kinetochores – the kinetochores possibly being involved in generating the force needed to propel the chromatids towards their respective poles [JCB (1987) 104 9–18]. As the k-MTs shorten, the polar microtubules elongate and the spindle poles move further apart.

*Telophase.* The chromatids become less clearly visible, and a nuclear membrane assembles around each group of chromatids to form two new nuclei – in each of which a new nucleolus appears. [Cell-free system for studying reassembly of the nuclear envelope: Cell (1986) 44 639–652.]

Telophase is followed by CYTOKINESIS. The non-dividing nucleus is called the *interphase* nucleus; DNA replication occurs during interphase.

In many microorganisms mitosis differs significantly from that described above; thus, e.g. there are at least four distinct types of

mitosis–cytokinesis even within the green algae [Book ref. 130, pp. 95–99]. In many algae (e.g. *Dunaliella*, DINOFLAGELLATES) and fungi (e.g. *Albugo* spp, *Mucor hiemalis*, *Saprolegnia ferax*, many yeasts) the nuclear envelope persists throughout mitosis ('closed mitosis') – although in some of these organisms the nuclear envelope develops a number of holes (*fenestrae*). In some organisms the spindle may be wholly intranuclear; this occurs e.g. in many yeasts, including *Saccharomyces*, in which the spindle microtubules arise, at each pole, from a SPINDLE POLE BODY. In EUGLENOID FLAGELLATES the nuclear envelope remains intact, the nucleolus is persistent, and microtubules develop within the nucleus; however, the microtubules apparently do not function as a conventional spindle. In some algae part of the spindle is used as a section of the newly forming cell wall (see PHRAGMOPLAST). (cf. AMITOSIS; see also CELL CYCLE and PARASEXUAL PROCESSES.)

[Mitosis in fungi: Book ref. 168, pp. 12–26, 85–112; sites of microtubule assembly and disassembly in the spindle: Cell (1986) 45 515–527.]

**mitosporangium** A SPORANGIUM within which MITOSIS occurs (see e.g. ALLOMYCES).

**mitotic crossing over** See PARASEXUAL PROCESSES.

**mitotic spindle** See MITOSIS.

**Mitrula** See HELOTIALES.

**Mitsuda reaction** See LEPROMIN TEST.

**mixed acid fermentation** A FERMENTATION (sense 1) carried out e.g. by certain enterobacteria, including *Escherichia coli* and species of *Proteus*, *Salmonella* and *Shigella*. In *E. coli* the products of glucose fermentation may include e.g. acetic and lactic acids, smaller amounts of formic acid (or CO<sub>2</sub> + H<sub>2</sub>) and succinic acid, and ethanol [see Appendix III(e)]; products are formed in relative proportions which depend on organism and growth conditions. Those organisms (e.g. *E. coli*) which have a FORMATE HYDROGEN LYASE system split formic acid (under acid conditions) to CO<sub>2</sub> and H<sub>2</sub>; some of the CO<sub>2</sub> may be assimilated during the formation of succinate. In *E. coli* formate accumulates under alkaline conditions. Species of e.g. *Shigella*, which lack the formate hydrogen lyase system, carry out the fermentation anaerogenically. Enterobacteria which carry out the mixed acid fermentation give a positive METHYL RED TEST. (See also PHOSPHOROCLASTIC SPLIT.)

**mixed bed exchangers** Ion-exchange material containing both cation and anion exchangers.

**mixed culture** See CULTURE.

**mixed-function oxidase** *Syn.* MONOOXYGENASE.

**mixed infection** The concurrent infection of a given individual with more than one pathogen.

**mixed leucocyte reaction** See MLR.

**mixed lymphocyte reaction** See MLR.

**mixed vaccine** A single VACCINE designed to give protection against more than one pathogen; such a vaccine contains PROTECTIVE ANTIGENS and/or TOXOIDS from each of the pathogens. (See e.g. TRIPLE VACCINE; cf. POLYVALENT VACCINE.)

**mixis** The fusion of gametes (fertilization).

**mixoploid** Refers to a population of cells in which the chromosome complement per cell varies among the cells of the population.

**mixotrophy** A mode of metabolism in which energy is obtained by the oxidation of an inorganic substrate, and carbon is obtained from an organic substrate (and sometimes also from the fixation of CO<sub>2</sub> via an autotrophic pathway). In some cases of mixotrophy, energy appears to be derived from the metabolism of an organic substrate as well as an inorganic substrate; this has

been reported e.g. for an iron-oxidizing bacterium [JGM (1984) 130 1337–1349] and for '*Alcaligenes eutrophus*' [JGM (1984) 130 1987–1994]. (See also CHEMOLITHOHETEROTROPH.)

**Miyagawanella** See CHLAMYDIA.

**MK** Menaquinone: see QUINONES.

**MK broth** MÜLLER–KAUFFMANN BROTH.

**MK-0787** See THIENAMYCIN.

**MLD** MINIMUM LETHAL DOSE.

**MLEE** MULTILOCUS ENZYME ELECTROPHORESIS.

**MLOs** *Mycoplasma*-like organisms: wall-less, non-helical, prokaryotic organisms which are associated with invertebrates and plants and which are the causal agents of a number of plant YELLOWS diseases. MLOs have not been cultured in vitro and have not been formally classified, although they are usually associated, taxonomically, with the MOLLICUTES. Various MLOs have been shown to lack a *Spiroplasma*-specific antigen [JGM (1983) 129 1959–1964]. [Book ref. 22, pp. 792–793; wall-less prokaryotes and plants: ARPPATH. (1984) 22 361–396.]

From the mid-1990s, MLOs were referred to by the trivial name *phytoplasma*. Individual MLOs are now being called by names such as *Candidatus Phytoplasma australiense*.

[Phytoplasma: ARM (2000) 54 221–255.]

**MLR (immunol.)** Mixed lymphocyte reaction (= mixed leucocyte reaction or mixed leukocyte reaction): mutual interaction, with blast transformation and proliferation of T cells, which occurs when leukocytes from two allogeneic individuals are mixed and cultured; the greater the disparity between antigens (e.g. MHC class II antigens) on donor and recipient cells the greater the degree of proliferation. (The degree of proliferation may be assessed e.g. by measuring the amount of radioactive thymidine (a DNA precursor) taken up by the cells.)

MLR (which takes several days to perform) is used e.g. to assess the compatibility of transplant donors and recipients. A negative reaction (no proliferation of T cells) is given when cells are derived from identical twins.

**MLS antibiotics** Macrolide, lincosamide and streptogramin B-type antibiotics: a group of structurally distinct antibiotics all of which act on the 50S subunit of 70S ribosomes (see MACROLIDE ANTIBIOTICS, LINCOSAMIDES and STREPTOGRAMINS). [Symposium on MLS antibiotics: JAC (1985) 16 (supplement A).]

Co-resistance to MLS antibiotics in staphylococci, streptococci and streptomycetes can be due to N<sup>6</sup>-methylation of adenine residues in 23S rRNA (see STREPTOGRAMINS).

Strains of *Streptococcus pyogenes* and *S. pneumoniae* that express the 'M phenotype' contain a macrolide-efflux mechanism which confers resistance to macrolides concomitant with sensitivity to lincosamides and B streptogramins (see MACROLIDE ANTIBIOTICS).

**MLS<sub>B/c</sub> strains** See STREPTOGRAMINS.

**MLST** (multilocus sequence typing) A method for TYPING pathogenic bacteria which permits long-term, global-scale tracking of virulent and antibiotic-resistant strains, with information made available on the Internet. In MLST, strains are characterized and classified on the basis of nucleotide sequences in *specific* alleles, this approach giving rise to categorization which is apparently stable over long periods of time.

[MLST (review): TIM (1999) 12 482–487. MLST of methicillin-resistant and methicillin-sensitive clones of *Staphylococcus aureus*: JCM (2000) 38 1008–1015.]

**MluI** See RESTRICTION ENDONUCLEASE (table).

**MLV** MURINE LEUKAEMIA VIRUS.

**MM** MINIMAL MEDIUM.

**MM virus** See CARDIOVIRUS.

## MMLV reverse transcriptase

**MMLV reverse transcriptase** See REVERSE TRANSCRIPTASE.

**MMO** METHANE MONOOXYGENASE.

**MMR** Measles–mumps–rubella vaccine.

**MMS** Methylmethane sulphonate: see ALKYLATING AGENTS.

**MMTV** MOUSE MAMMARY TUMOUR VIRUS.

**MNNG** (*N*-methyl-*N'*-nitro-*N*-nitrosoguanidine; also: 'nitrosoguanidine', NTG) A mutagenic *N*-NITROSO COMPOUND, the mutagenic activity of which appears to depend primarily on methylation of the O-6 position of guanine (see ALKYLATING AGENTS). MNNG acts preferentially at the replication fork in replicating DNA, producing clusters of closely linked mutations (*co-mutagenesis*); it also methylates proteins.

**MNPV** See NUCLEAR POLYHEDROSIS VIRUSES.

**MNU** *N*-Methyl-*N*-nitrosourea: see ALKYLATING AGENTS.

**mobile genetic element** See TRANSPOSABLE ELEMENT.

**Mobilina** See PERITRICHIA.

**mobilization** (*mol. biol.*) See CONJUGATION (1b) (i).

**Mobiluncus** A genus of anaerobic, asporogenous bacteria which occur in the human vagina and which are associated with BACTERIAL VAGINOSIS. Cells: Gram-negative and Gram-variable curved rods (ca. 1.5–3.0 µm in length) which are motile by multiple subpolar flagella; the CELL WALL is of the Gram-positive type [IJSB (1986) 36 288–296]. Metabolic products include acetate and succinate. GC%: 49–52 (T<sub>m</sub>). Type species: *M. curtisii*; other species: *M. mulieris*. [IJSB (1984) 34 177–184.]

**mocimycin** See POLYENE ANTIBIOTICS (b).

**modification** (of DNA) See DNA MODIFICATION.

**modulator protein** See Tn21.

**modulin** Any virulence factor which causes damage by inducing inappropriate activity of CYTOKINES. The modulins include e.g. endotoxins, exotoxins and SUPERANTIGENS. [MR (1996) 60 316–341.]

**Moellerella** A genus of bacteria of the ENTEROBACTERIACEAE. *M. wisconsinensis* (formerly 'enteric group 46') has been isolated from human faeces and is apparently associated with diarrhoea in humans. It is non-motile; MR +ve; citrate +ve (Simmons); VP –ve; indole –ve; LDC, ODC, ADH and phenylalanine deaminase –ve; anaerogenic. On MacConkey's agar colonies are bright red and surrounded by precipitated bile. [JCM (1984) 19 460–463.]

**Moeller's cyanide medium** See KCN BROTH.

**Moeller's decarboxylase broth** See MØLLER'S DECARBOXYLASE BROTH.

**moenomycin** (Flavomycin) A phosphorus-containing glycolipid ANTIBIOTIC in which the lipid moiety (moenocinol) is a C-25 compound structurally analogous to undecaprenylphosphate; it inhibits transglycosylation in PEPTIDOGLYCAN synthesis in Gram-positive bacteria and, at higher concentrations, in Gram-negative bacteria.

**MoFe protein** See NITROGENASE.

**moi** MULTIPLICITY OF INFECTION.

**moiré image** In microscopy: a misleading image due to overlap among multiple structures.

**moist heat** Refers to the use of steam for STERILIZATION. (See also AUTOCLAVE.)

**Mokola virus** See LYSSAVIRUS.

**mol% G + C** See GC%.

**molar growth yield** See YIELD COEFFICIENT.

**molasses** A by-product of the sugar industry: the syrupy liquid which remains after the crystallization of sucrose from sugarcane or sugar-beet syrup. Molasses contains ca. 50–60% sucrose (which cannot be removed by crystallization), 16–20% water, and various non-sugar and inorganic ('ash') components; it is

widely used as a relatively cheap substrate for the commercial production of various microorganisms and microbial products (see e.g. BAKERS' YEAST; CITRIC ACID; INDUSTRIAL ALCOHOL; SINGLE-CELL PROTEIN).

**mold** See MOULD.

**molecular beacon probes** Oligonucleotide probes used for (i) monitoring progress in a nucleic-acid-amplification procedure, and (ii) (in PCR), estimating the initial (pre-amplification) number of target sequences in the sample. The general structure and mode of action of a molecular beacon probe are described in the figure.

Like TAQMAN PROBES (q.v.), molecular beacon probes are added (in large numbers) to the reaction mixture prior to amplification.

In NASBA, molecular beacon probes can be used for real-time monitoring of amplification [NAR (1998) 26 2150–2155].

In PCR, the probes are useful for estimating the initial number of target sequences in a sample (see TAQMAN PROBES for rationale).

Because these probes can be labelled with different kinds of fluorophore (having different emission characteristics), it is possible to carry out a multiplex PCR in which the amplification of each type of target can be followed separately by monitoring the distinct emission from target-specific probes. [Multiplex detection of four pathogenic retroviruses using molecular beacons: PNAS (1999) 96 6394–6399.]

Compared with linear probes (such as TaqMan), molecular beacon probes exhibit greater specificity in binding; for example, a beacon probe of equivalent length can more readily distinguish a one-nucleotide difference between two sequences. [Thermodynamic basis of the enhanced specificity of structured DNA probes: PNAS (1999) 96 6171–6176.]

**molecular chaperone** See FIMBRIAE.

**molecular cloning** See CLONING.

**molecular sieving** *Syn.* GEL FILTRATION.

**Møller's cyanide medium** See KCN BROTH.

**Møller's decarboxylase broth** A medium used for DECARBOXYLASE TESTS. It contains (g/l): peptic digest of animal tissue (5.0), beef extract (5.0), glucose (0.5), BROMCRESOL PURPLE (0.1), cresol red (0.005), pyridoxal (0.005) and L-arginine or L-lysine or L-ornithine (1% final concentration). The pH of the broth is adjusted to 6.0.

**mollucite** A proposed trivial name for any member of the class MOLLICUTES; use of this name could permit 'mycoplasmas' to be used specifically for members of the genus *Mycoplasma*.

**Mollicutes** A class of small, cell-wall-less bacteria which are typically parasitic (sometimes pathogenic) in animals or plants. (cf. TENERICUTES; see also MOLLICUTE.) The class comprises a single order, MYCOPLASMATALES, and two genera *incertae sedis* (ANAEROPLASMA and THERMOPLASMA) [Book ref. 22, pp. 740–793]. (See also MLO.)

**molluscum contagiosum** A human skin disease caused by a virus of the POXVIRIDAE; the virus is apparently unrelated to other poxviruses, and has not been grown in cell cultures or in the CAM. Molluscum contagiosum is characterized by the formation of multiple firm, rounded, whitish, translucent nodules which become crater-like, revealing a white core; the lesions may persist for months or even years. The virus is spread by body contact (e.g. sexual contact) or via fomites.

**Moloney murine leukaemia virus** (Mo-MuLV) A replication-competent *v-onc*<sup>+</sup> MURINE LEUKAEMIA VIRUS originally isolated following passage of a cell-free extract of a transplantable tumour ('Sarcoma 37') in neonatal mice. Mo-MuLV can induce

MOLECULAR BEACON PROBES: structure and mode of action (diagrammatic).

A molecular beacon probe is an oligonucleotide probe sequence flanked by two, short mutually complementary oligonucleotides (side-arms), the molecule being capable of adopting a stem-and-loop conformation (*top*); the terminals of the beacon probe are labelled with a fluorophore (●) and a quencher (■) such that fluorescence is quenched (by juxtaposition of fluorophore and quencher) when the molecule adopts the stem-and-loop conformation.

When a probe (the loop region) binds to the target sequence in an amplicon, the probe–target duplex is both longer and more stable than the stem duplex; hence, on probe binding, the two side-arms of the stem dissociate – thus separating the fluorophore from the quencher and giving rise to a functionally fluorescent probe.

Like TAQMAN PROBES, molecular beacon probes are added to the reaction mixture prior to amplification; they are added in large numbers so that a probe will be available for each amplicon at the end of amplification.

In NASBA, an isothermal process, fluorescence from the bound probes is monitored continually. In PCR, fluorescence is monitored during the primer annealing stage (because only at this stage are fluorescent probe–amplicon duplexes formed).

Reproduced from Figure 4.13, page 102, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission from Kluwer Academic Publishers, Dordrecht, The Netherlands.

thymic leukaemia, disseminated lymphosarcoma, or lymphatic leukaemia in mice after a latent period of ca. 2–3 months. (See also MOLONEY MURINE SARCOMA VIRUS.)

**Moloney murine leukaemia virus reverse transcriptase** See REVERSE TRANSCRIPTASE.

**Moloney murine sarcoma virus** (Mo-MSV) A replication-defective *v-onc*<sup>+</sup> MURINE SARCOMA VIRUS isolated from a BALB/c mouse infected with MOLONEY MURINE LEUKAEMIA VIRUS (Mo-MuLV) and suffering from a rhabdosarcoma; several variants are known, each containing Mo-MuLV-derived sequences and the oncogene *v-mos* (see MOS). Infection of newborn mice with Mo-MSV can result in the appearance of sarcomas within a few days; sarcomas induced in older mice commonly undergo spontaneous regression and recurrence. (cf. GAZDAR MURINE SARCOMA VIRUS.)

**molybdoenzymes** The molybdenum-containing enzymes; they include e.g. aldehyde oxidase, CO OXIDASE, dissimilatory nitrate reductase, NITROGENASE, sulphite oxidase and xanthine oxidase.

**molybdoferredoxin** See NITROGENASE.

**mom gene** See BACTERIOPHAGE MU.

**momilactone** Either of two diterpene PHYTOALEXINS (momilactones A and B) formed by the rice plant (*Oryza sativa*). (See also WL 28325.)

**Monacrosporium** See HYPHOMYCETES and NEMATOPHAGOUS FUNGI.

**monactin** See MACROTETRALIDES.

**-monas** A suffix signifying ‘a unit’.

**monascoflavin** See ANG-KAK.

**monascorubrin** See ANG-KAK.

**Monascus** See PEZIZALES.

**monensin** (monensin sodium; *syn.* rumensin) A MACROTETRALIDE antibiotic synthesized by *Streptomyces cinnamonensis*; it is used e.g. as an anti-coccidial agent in poultry, and as a FEED ADDITIVE for ruminants (e.g. cattle, sheep). (See also FOG FEVER.)

As a feed additive, monensin appears to act by inhibiting those RUMEN microorganisms which produce acetic acid and hydrogen, thereby favouring those which produce propionic acid; thus, it appears that energetically wasteful methanogenesis is suppressed (by as much as 30–40%) as a result of the lack of hydrogen (rather than by direct inhibition of methanogens), and that it is the corresponding increase in propionic acid which leads to increased feed conversion efficiency.

In pure cultures of methanogens both monensin and LASALOCID directly affect membrane function and proton motive force, and in fermenting organic wastes monensin inhibits methanogens and causes an accumulation of acetate. The different susceptibilities of rumen and sewage methanogens may be due to the high Na<sup>+</sup> concentration in rumen fluid; the inhibition of methanogenesis by monensin is known to be prevented by high concentrations of Na<sup>+</sup> [Book ref. 157, pp. 530–531].

Monensin can inhibit the replication of certain viruses whose maturation involves the PALADE PATHWAY.

**Monera** The *prokaryotic* protists – see PROTISTA.

**Monilia** *Syn.* CANDIDA.

## Moniliales

**Moniliales** An order of fungi; depending on taxonomic scheme, the Moniliales includes either most or all of the organisms which constitute the class HYPHOMYCETES.

**moniliasis** *Syn.* CANDIDIASIS.

**monilicolin A** See PHASEOLLIN.

**moniliform** Resembling a string of beads.

**Monilia** See HELOTIALES.

**Moniliophthora** A genus of fungi of the APHYLLOPHORALES; *M. roleri* (anamorph: '*Monilia roleri*') causes POD ROT of cacao.

**monkey-bite encephalomyelitis** See B VIRUS.

**monkeypox** A rare disease of man and other primates; it is caused by the monkeypox virus (see ORTHOMYXOVIRUS). In man, the disease involves generalized exanthema and closely resembles SMALLPOX; it is not readily transmissible from person to person. Monkeypox generally affects people who have not been vaccinated against smallpox and who live in villages in the tropical rain forests of West and Central Africa; the natural reservoir of the virus is unknown. Monkeypox also occurs e.g. in captive monkeys; the symptoms are similar to those in man.

The monkeypox virus is highly lethal in mice and typically forms small, opaque, haemorrhagic pocks on CAM; only B-type inclusion bodies are seen in infected cells. Genome MWt: ca.  $128 \times 10^6$ .

**monoazide ethidium** See ANISOTROPIC INHIBITOR.

**monobactams** A class of monocyclic  $\beta$ -LACTAM ANTIBIOTICS (q.v. for formula). Natural monobactams include e.g. *sulfazecin* (= 'monobactam I',  $R' = D\text{-glu-D-ala}$ ,  $R'' = OCH_3$ ,  $R''' = H$ ,  $R'''' = SO_3H$ ), produced e.g. by *Gluconobacter* and *Acetobacter* spp. and *isosulfazecin*, produced by *Agrobacterium radiobacter* and *Pseudomonas* sp. Synthetic derivatives include e.g. AZTREONAM and the *monophosphams* (2-oxoazetidone-1-phosphonates, where  $R'''' = PO_3X$ ), *monocarbams* ( $R'''' = CONHSO_2X$ ), and *monosulfactams* ( $R'''' = OSO_3^-$ ).

[Review: AAM (1986) 31 181–205.]

**Monoblepharella** See MONOBLEPHARIDALES.

**Monoblepharidales** An order of typically aquatic, saprotrophic fungi (class CHYTRIDIOMYCETES) in which sexual reproduction is *oogamous*, involving a small, motile male gamete and a large non-motile female gamete (a type of sexual reproduction not found in other fungi) (cf. OOMYCETES). The thallus is a well-developed branching mycelium in which the cytoplasm is highly vacuolated ('foamy'); in at least some species the cell wall contains CHITIN. Asexual reproduction involves the formation of elongated, typically cylindrical sporangia containing large numbers of zoospores; each zoospore can give rise to a new thallus. In sexual reproduction, distinct male and female gametangia (antheridia and oogonia, respectively) are formed; the male gametes ('antherozoids') swim to the non-motile oospheres. (In some species the oogonium forms more than one oosphere, and oospheres may be fertilized within or outside the oogonium, according e.g. to species.) After fertilization, the oosphere develops into a thick-walled resting *oospore* which later germinates to form a new thallus. Genera include *Gonapodya*, *Monoblepharella* and *Monoblepharis*.

**Monoblepharis** See MONOBLEPHARIDALES.

**monocarbams** See MONOBACTAMS.

**monocentric** (1) Refers to a thallus in which only one region has a reproductive function. (cf. POLYCENTRIC.)

(2) Refers to a chromosome which has a single, discrete CENTROMERE. (cf. HOLOCENTRIC.)

**Monocercomonas** See TRICHOMONADIDA.

**Monocercomonoides** See OXYMONADIDA.

**monochloramine** See CHLORINE.

**monocins** See BACTERIOCIN.

**monocistronic mRNA** See MRNA.

**monoclonal antibodies** A population of identical antibodies (see ANTIBODY), all of which recognize the same specific DETERMINANT on a simple or complex antigen or hapten. (cf. POLYCLONAL ANTISERUM.) A given population of monoclonal antibodies may be able to react with each of two apparently unrelated antigens if, by chance, those antigens happen to share a common determinant; thus, e.g., monoclonal antibodies which combine with a particular mouse myeloma protein can combine with human C-reactive protein. (cf. CROSS-REACTING ANTIBODY.) Monoclonal antibodies are obtained from B-cell HYBRIDOMAS.

Monoclonal antibodies have an enormous range of actual or potential uses. These include e.g. characterization and detection of viruses [e.g. plant viruses: MS (1984) 1 73–78] and other microorganisms; tissue typing; the study of changes in cell-surface antigens on lymphoid cells during maturation; and the preparation of IMMUNOTOXINS.

**monocystid gregarine** *Syn.* acephaline gregarine.

**Monocystis** A genus of protozoa (subclass GREGARINASINA) many species of which are parasitic in the earthworm (*Lumbricus* spp). Sporozoites enter the seminal vesicles. The developing parasites (*trophozoites*) occur intracellularly in the sperm morulae; the fully-grown, extracellular acephaline trophozoites (*gametocytes*) associate in pairs (*syzygy*) and each pair forms a *gametocyst* within which many gametes develop. The gametes fuse in pairs, and each zygote forms a cyst (*sporocyst*, *pseudonavicella*) within which 8 sporozoites develop.

**monocyte** A large (diam. 10–20  $\mu$ m) phagocytic LEUCOCYTE which contains a single, large, spherical or indented nucleus, and azurophilic peroxidase-containing granules; ca. 200–800 monocytes/ml occur in normal adult human blood. Monocytes differentiate to become MACROPHAGES. Suspensions of monocytes may be prepared e.g. by density flotation [JIM (1984) 69 71–77] or by the use of Sephadex [JIM (1984) 71 25–36].

**monocytosis** *Syn.* MONONUCLEOSIS.

**Monod equation** See SPECIFIC GROWTH RATE.

**Monodictys** See HYPHOMYCETES; see also SOFT ROT (sense 1).

**monoecious** Refers to an organism in which the male and female reproductive structures occur in the same individual. (cf. DIOECIOUS.)

**monogeneric** Refers to a taxon which has only one genus.

**monogenic mRNA** See MRNA.

**monokaryotic** Having one nucleus per cell.

**monokines** Certain soluble, biologically active products of MACROPHAGES – e.g. INTERLEUKIN-1.

**monolayer culture** See TISSUE CULTURE.

**Monomastix** See MICROMONADOPHYCEAE.

**monomitic** See HYPHA.

**monomorphic** Refers to an organism which occurs in only one form or MORPHOTYPE. (cf. POLYMORPHISM.)

**Mononegavirales** A taxon containing viruses which have non-segmented, negative-sense ssRNA genomes, including members of the FILOVIRIDAE, PARAMYXOVIRIDAE and RHABDOVIRIDAE – and (probably) the BORNA DISEASE VIRUS.

**mononuclear leucocyte** (mononuclear phagocyte) (1) *Syn.* MACROPHAGE. (2) *Syn.* MONOCYTE. (3) A macrophage or monocyte.

**mononuclear phagocyte** See MONONUCLEAR LEUCOCYTE.

**mononucleosis** (monocytosis) The condition in which increased numbers of monocytes are present in the blood. (cf. INFECTIOUS MONONUCLEOSIS.)

**monooxygenase** (hydroxylase; mixed-function oxidase; mixed-function oxygenase) An OXYGENASE (EC 1.13.12) which catalyses the incorporation of one atom of molecular oxygen into

a substrate molecule, the other oxygen atom being reduced to water; the reducing power needed for monooxygenase activity may be supplied e.g. by NADH. (See also METHANE MONOOXYGENASE.)

**monophasic serotypes** (in *Salmonella*) See H ANTIGEN.

**monophosphams** See MONOBACTAMS.

**monophyletic** Refers to taxa which have arisen from a common evolutionary line. (cf. POLYPHYLETIC.)

**monoplanetism** In certain OOMYCETES: the phenomenon in which only one type of zoospore is formed and only one swarm period occurs. (cf. DIPLANETISM.)

**monopodial** (*adj.*) Refers to a 'tree-like' form or mode of development of a branching structure – i.e., one with a main, central stem from which lateral branches arise. (cf. SYMPODIAL.)

**monopodial amoebae** Amoebae which normally produce only one lobose PSEUDOPODIUM at a time (although a second, lateral pseudopodium may be produced when the organism changes direction). (See also LIMAX AMOEBAE; cf. POLYPODIAL AMOEBAE.)

**Monosiga** See CHOANOFAGELLIDA.

**monosodium glutamate** See GLUTAMIC ACID.

**monosome** See PROTEIN SYNTHESIS.

**monosomic** See CHROMOSOME ABERRATION.

**monospecific** Refers to a genus which has only one species.

**monospecific antiserum** An antiserum (e.g. a GROUPING ANTISERUM) which is capable of reacting specifically with one particular antigen or antigenic determinant – rather than with several (or many) of the antigens present on cells etc in a given suspension. (cf. POLYVALENT ANTISERUM.)

**monostichomonad membrane** See PARORAL MEMBRANE.

**Monostroma** A genus of green seaweeds (division CHLOROPHYTA) which show a heteromorphic alternation of generations; the gametophyte is a monostromatic sheet or blade (cf. ULVA), the sporophyte is unicellular.

**monostromatic** Refers to a structure which is only one cell thick (see e.g. MONOSTROMA). (cf. DISTROMATIC.)

**monosulfactams** See MONOBACTAMS.

**Monothalamida** See GRANULORETICULOSEA.

**monothetic classification** Any form of classification based on a small number of carefully selected criteria – which are usually interpreted unequivocally (e.g. 'present' or 'absent'); such classification is necessarily biased by the choice of criteria. (cf. POLYTHETIC CLASSIFICATION.)

**monotrichous** Refers to the presence of only one flagellum (or e.g. pilus) per cell.

**monotype** (1) The sole species of a newly proposed genus. (2) Any taxon based on a single TYPE (sense 1).

**monoxenous** *Syn.* HOMOXENOUS.

**Monsur medium** (Monsur's tellurite–bile salt medium) A medium for the primary isolation of *Vibrio cholerae*. It contains e.g. peptone, NaCl (1%), Na<sub>2</sub>CO<sub>3</sub>, sodium tauricholate, and (added after autoclaving) potassium tellurite; pH 9.0–9.2. The liquid medium may be used as a TRANSPORT MEDIUM for specimens containing *V. cholerae*, or may be solidified with agar. [Recipe: Book ref. 46, pp. 1276–1277.] (See also TELLURITE MEDIA.)

**Montenegro test** A SKIN TEST sometimes used in the diagnosis of cutaneous leishmaniasis; the antigen is a suspension of dead *Leishmania promastigotes*.

**Moore swab** (sewer swab) A SWAB used for detecting certain types of pathogen (e.g. species of *Salmonella* and *Vibrio*) in a sewer; it consists of a pad of cotton gauze, or of a length of such gauze wrapped around a wire. The swab, attached by a cord, is suspended in flowing sewage for several days; when retrieved, the swab (or liquid expressed from it) is transferred to

an appropriate liquid medium and incubated. The Moore-swab technique appears to be more effective in small sewers [AEM (1986) 51 425–426].

**Moorella** See CLOSTRIDIUM.

**Mopeia virus** See ARENAVIRIDAE.

**Morax–Axenfeld bacillus** See MORAXELLA.

**Moraxella** A genus of oxidase +ve, typically catalase +ve Gram type-negative bacteria of the family MORAXELLACEAE which occur on mucous membranes (e.g. respiratory tract) in man and other mammals; strains of *Moraxella* can act as opportunist pathogens.

Cells: short rods/cocci which may occur singly or in pairs; non-motile, but may exhibit TWITCHING MOTILITY. Non-pigmented.

Some moraxellae are nutritionally fastidious; all strains can grow on blood agar (some better on chocolate agar); many strains are able to grow on rich, non-blood-containing media or even nutrient agar. Acid is not produced from carbohydrates. Nitrate is reduced by some strains. Optimum growth temperature: 33–36°C. Unlike species of *Neisseria*, no strain produces CARBONIC ANHYDRASE. GC%: ~40–47.5. Type species: *M. lacunata*.

Species include:

*M. atlantae*. Non-haemolytic. Serum is needed for growth; coagulated serum is not liquefied. Growth is stimulated by bile salts. Nitrate is not reduced.

*M. bovis*. A causal agent of e.g. INFECTIOUS KERATITIS. Some strains are catalase –ve. Usually haemolytic (on human blood). Coagulated serum is usually liquefied. Nitrate is usually not reduced. Acetate, butyrate, ethanol and lactate can be metabolized in complex media.

*M. lacunata* (the Morax–Axenfeld bacillus). A causal agent of CONJUNCTIVITIS. Non-haemolytic on human blood. Serum is required for growth; coagulated serum is liquefied. Nitrate is reduced. Phenylalanine deaminase and urease are not formed. Acetate, butyrate and lactate can be metabolized in complex media.

*M. catarrhalis* (formerly *Branhamella catarrhalis*). A causal agent of e.g. respiratory tract infections, acute OTITIS MEDIA and SINUSITIS. Non-haemolytic. Many strains can grow on nutrient agar. On blood agar, the colonies are whitish, convex, and 1–2 mm in diam. after 24 hours. Most strains reduce nitrate and nitrite, and most or all strains are reported to produce a DNase. [Review: Drugs (1986) 31 (supplement 3) 1–142.]

*M. caviae*, *M. cuniculi* and *M. ovis* have been regarded as members of a subgenus, *Branhamella*, within the genus *Moraxella* or as species *incertae sedis* within the genus *Neisseria* (so-called 'false neisseriae') [Book ref. 22, pp 290–296].

**Moraxellaceae** A family of Gram type-negative bacteria comprising the genera ACINETOBACTER, MORAXELLA and PSYCHROBACTER [IJSB (1991) 41 310–319].

**morbidity** (1) The state or condition of being diseased. (2) (morbidity rate) The number of cases of a given disease in relation to the overall population (quoted e.g. as cases per 100000 or per million per annum). (cf. MORTALITY RATE.)

**morbilli** *Syn.* MEASLES.

**morbilloform** Resembling measles.

**Morbillivirus** (measles–rinderpest–distemper (MRD) virus group) A genus of viruses of the PARAMYXOVIRIDAE in which the virions have haemagglutinin but no neuraminidase activity. Virions contain proteins N (nucleocapsid), P (nucleocapsid-associated phosphorylated), H (haemagglutinin), F (fusion) and M (membrane or matrix). (cf. PARAMYXOVIRUS.) All members share a

## **Morchella**

common antigen. Type species: MEASLES virus (MV); other members: CANINE DISTEMPER virus (CDV), PESTE DES PETITS RUMINANTS virus (= Kata virus), and RINDERPEST virus (RV). [Antigenic relationship between MV, CDV and RV: JGV (1986) 67 1381–1392.]

In addition to causing acute disease in their respective hosts, MV and CDV are also associated with persistent infection which may lead to progressive, degenerative neurological disease (see CANINE DISTEMPER and SUBACUTE SCLEROSING PANENCEPHALITIS). It has also been suggested that MV may play a role in the pathogenesis of MULTIPLE SCLEROSIS – possibly by triggering the formation of autoantibodies to neural antigens in certain genetically predisposed individuals [Book ref. 88, pp. 155–165].

**Morchella** A genus of fungi of the order PEZIZALES. The fruiting body, a yellowish to brown APOTHECIUM, consists of a hollow, ovoid or elongated, waxy to brittle sponge-like pileus borne on a stout, hollow stipe – the whole being ca. 5–12 cm in height and ca. 5 cm at the broadest part; the outer surface of the pileus is conspicuously ridged and pitted, the hymenium-lined pits being separated by sterile ridges. Asci: cylindrical, operculate. *M. esculenta* and *M. vulgaris* form edible fruiting bodies ('morels').

**mordant** See STAINING.

**Moredu medium** See WHOOPING COUGH.

**morel** See MORCHELLA.

**Morganella** A genus of Gram-negative bacteria of the tribe PROTEAE. Cells: ca. 0.6–0.7 × 1.0–1.7 µm. Swarming does not occur. Reactions: urease +ve; lipase –ve; gelatin not liquefied at 22°C; H<sub>2</sub>S –ve; citrate –ve; acid from glucose and mannose. Both nicotinic and pantothenic acids are required for growth. Species: *M. morganii* (formerly *Proteus morganii*), found (rarely) in the intestines of animals; in man, it can be an opportunist pathogen and may cause diarrhoea. GC%: 50. [Book ref. 22, pp. 497–498.]

**morganocin** Any BACTERIOCIN from *Morganella*.

**Moro test** See TUBERCULIN TEST.

**moromi** See SOY SAUCE.

**morph (mycol.)** Any (sexual or asexual) stage or state of a given fungus. (See e.g. ANAMORPH; TELEOMORPH; and DIMORPHIC FUNGI (sense 1).)

**morphogene** See CELL CYCLE.

**morphological antifungal agents** A group of agricultural systemic ANTIFUNGAL AGENTS which have eradicator properties. They function by inhibiting ergosterol biosynthesis, thereby disrupting the CYTOPLASMIC MEMBRANE in susceptible fungi; the mode of action differs from that of e.g. PROPICONAZOLE. Morpholines include e.g. FENPROPIMORPH and TRIDEMORPH.

**morphological heterothallism** See HETEROTHALLISM.

**morphological unit (virol.)** See ICOSAHEDRAL SYMMETRY.

**morphology agar** A complex agar-based medium used for determining morphological characteristics of yeasts; it contains amino acids, D-glucose, vitamins, salts and trace elements [composition: Book ref. 100, pp. 100–101]. It is available commercially in dehydrated form.

**morphotype** Any distinct, more or less stable morphological form of a given organism. (See also VARIETY and POLYMORPHISM sense 1.)

**morphovar** See VARIETY.

**mortality rate** Of a given disease: the number of deaths expressed as a proportion of the number of individuals who have contracted the disease in a particular outbreak, or over a specified period of time. (cf. MORBIDITY.)

**Mortierella** See MUCORALES.

**Mortierellaceae** See MUCORALES.

**mos** An ONCOGENE first identified as the transforming determinant of MOLONEY MURINE SARCOMA VIRUS (Mo-MSV). The *c-mos* sequences are hypermethylated, apparently transcriptionally silent (or expressed at very low levels) in normal and transformed murine cells, and lack introns. Wild-type Mo-MSV expresses *v-mos* only at very low levels in cell culture, but a temperature-sensitive mutant (*ts110*) produces higher levels of an unstable *gag-mos* fusion protein (MWt ca. 85000) which has serine or threonine protein kinase activity [review: JGV (1985) 66 1845–1853]. [Properties of mouse and human *c-mos* loci: Book ref. 113, pp. 281–289.]

**mosaic (plant pathol.)** A form of leaf VARIATION in which two or more colours, or shades of colour, develop – the differently coloured areas being somewhat angular with relatively sharp, clear-cut boundaries between them. (cf. MOTTLE.) Mosaics occur in plants infected systemically with certain PLANT VIRUSES; however, similar leaf patterns may be an inherited characteristic or may result from the effects of toxins produced by leaf-feeding arthropods.

**mosquito iridescent virus** See CHLORIRIDOVIRUS.

**moSS starch** *Syn.* LICHENIN.

**most probable number method** See MULTIPLE-TUBE METHOD.

**motB gene** See FLAGELLUM (a).

**motile (microbiol.)** Capable of MOTILITY.

**motile colonies** (1) (*bacteriol.*) The colonies of certain bacteria, e.g. *Bacillus circulans*, can migrate across the surface of a culture plate; the track of such movement is often marked by lines of bacterial growth which arise from cells left behind by the migrating colony.

(2) (*algol.*) See e.g. SYNURA and VOLVOX.

**motility (microbiol.)** Locomotion, i.e. an active process in which a cell or organism moves from place to place by expending energy to exert force(s) against the surrounding medium or the contiguous substratum; passive movements due to changes in buoyancy (see e.g. GAS VACUOLE) are not regarded as true motility (see also TWITCHING MOTILITY).

Not all microorganisms are *motile*, i.e. capable of exhibiting motility; however, those which are motile occur among the algae, archaeans, bacteria, fungi and protozoa. Some non-motile organisms have motile stages in their life cycles – e.g. propagules, gametes.

Motility is an advantage because it enables an organism to respond e.g. to certain environmental stimuli. (See also CHEMOTAXIS.)

Locomotion may be achieved in various ways, depending on organism.

(a) *Amoeboid movement* is characteristic e.g. of some sarcodines (see PSEUDOPODIUM).

(b) CILIUM-mediated locomotion occurs in members of the CILIOPHORA (see also METACHRONAL WAVES).

(c) *Euglenoid movement*: see EUGLENA.

(d) FLAGELLAR MOTILITY involves the activity of one or more flagella (or periplasmic flagella in the SPIROCHAETALES) and is found in many bacteria, protozoa (see MASTIGOPHORA) and algae, and in some fungi (limited to certain lower fungi – e.g. the zoospores of chytrids).

(e) GLIDING MOTILITY occurs in some prokaryotes (e.g. *Beggiatoa*, *Oscillatoria*), and e.g. in some diatoms and desmids. [The motility apparatus in shock-frozen gliding cells of *Myxococcus xanthus* (electron micrographs): Microbiology (2001) 147 939–947.]

(f) *Gregarine movement*, which occurs in some gregarines, is apparently similar or identical to GLIDING MOTILITY (q.v.).

(g) Motility (mechanism unknown) reported in certain strains of *SYNECHOCOCCUS* (q.v.) [see also JB (1997) 179 2524–2528].

(h) In *Serratia marcescens*: flagellum-independent *spreading* (which may involve surface tension) [JB (1995) 177 987–991].

(i) *Actin-based motility*: motility exhibited by certain pathogenic bacteria *within* eukaryotic cells – see DYSENTERY (1a) and LISTERIOSIS.

Direct (microscopical) determination of motility can usually be achieved easily. However, in some organisms – particularly archaeans and bacteria – BROWNIAN MOVEMENT may be mistaken for motility. (See also HANGING DROP and COUNTING METHODS.) Motility in certain organisms may be determined macroscopically: see e.g. SWARMING.

Motile and non-motile bacteria may be separated e.g. by CRAIGIE'S TUBE METHOD.

**MOTT** Mycobacteria other than tuberculosis: refers to certain species of *Mycobacterium* (excluding *M. leprae*) which may be associated with human disease but which are not members of the *Mycobacterium tuberculosis* complex [Book ref. 219, p 329]. The phrase *non-tuberculous mycobacteria* (NTM) is synonymous, and is preferred by some authors [e.g. RMM (1997) 8 125–135].

**mottle** (*plant pathol.*) A form of leaf VARIATION in which two or more colours, or shades of colour, develop – the differently coloured areas being somewhat ill-defined with indistinct boundaries between them. (cf. MOSAIC.) Mottling occurs in plants infected systemically with certain PLANT VIRUSES.

**Mougeotia** A genus of filamentous green algae related to SPIROGYRA. Each cell contains a single plate-like chloroplast in the centre of the cell; the chloroplast can rotate within the cell in response to changes in light intensity.

**mould** (mold) A general, imprecise term for any fungus which forms a visible layer of mycelium and/or spores on the surface of foods, walls etc, but which does not form macroscopic fruiting bodies. (See e.g. BREAD SPOILAGE.)

**mountant** (mounting medium) Any substance used to immerse or impregnate a specimen or smear for microscopical examination. For temporary preparations (see e.g. WET MOUNT) the mountant may be e.g. water, saline, or glycerol. Mountants for permanent preparations include e.g. DPX and CANADA BALSAM; before being mounted in these substances, specimens must be fixed (see FIXATION), dehydrated, and cleared (see CLEARING). For fungal material LACTOPHENOL COTTON BLUE is a useful mountant (and stain) for temporary or permanent preparations.

**mouse Elberfeld virus** See CARDIOVIRUS.

**mouse mammary tumour virus** (MMTV; Bittner virus) A type B retrovirus (see TYPE B ONCOVIRUS GROUP) which induces carcinomas in the mammary glands of several inbred strains of mice. The virus replicates in the alveolar cells of the mammary gland in lactating mice, and is transmitted to the suckling offspring via the milk. MMTV also occurs as an ENDOGENOUS RETROVIRUS in most inbred mouse strains, the provirus (usually present in multiple copies) being transmitted genetically (see RETROVIRIDAE).

MMTV is replication-competent, *v-onc<sup>-</sup>*, does not transform cells in culture, and induces carcinomas after a long latent period. The MMTV genome contains – in addition to *gag*, *pol* and *env* sequences – a potential coding sequence, designated *orf* (for open reading frame), near the 3' end distal to and partly overlapping *env*; the function of this sequence, if any, in carcinogenesis is unknown. Tumours induced by MMTV are clonal (arising mainly from a single infected cell); several factors may influence the development of tumours: e.g. genetic

predisposition, hormonal status, number of pregnancies, etc. A critical factor in tumorigenesis is believed to involve the insertion of the provirus at particular sites in the mouse genome; two such sites have been implicated (*int-1* and *int-2*), neither of which shows homology with any known cellular or viral ONCOGENE. Integration of an MMTV provirus near one of these loci appears to activate the expression of a host gene which is normally silent, possibly by exerting an enhancer function. [Reviews of oncogenesis by MMTV: Book ref. 110, pp. 175–195; JGV (1985) 66 931–943.]

**mouse poliomyelitis** See THEILER'S MURINE ENCEPHALOMYELITIS VIRUS.

**mousepox** See ECTROMELIA VIRUS.

**mouth fungus** (in fish) See COLUMNARIS DISEASE.

**mouth microflora** The microflora of the human mouth may include e.g. species of ACTINOMYCES, BACTEROIDES, CAMPYLOBACTER, CAPNOCYTOPHAGA, EIKENELLA, FUSOBACTERIUM, LEPOTRICHIA, ROTHIA, SELENOMONAS, STAPHYLOCOCCUS, STREPTOCOCCUS, TREPONEMA, WOLINELLA, VEILLONELLA, and various yeasts (e.g. *Candida albicans*) and protozoa (e.g. *Entamoeba gingivalis* and *Trichomonas tenax*). Some of these organisms occur primarily in microaerobic or anaerobic microenvironments such as the gingival sulcus. (See also BODY MICROFLORA; DENTAL PLAQUE; GASTROINTESTINAL TRACT FLORA; RESPIRATORY TRACT MICROFLORA; STOMATITIS.)

**moving-boundary electrophoresis** See ELECTROPHORESIS.

**moxalactam** (latamoxef) An OXACEPHEM antibiotic which is active against a wide range of Gram-negative bacteria.

**moxifloxacin** A QUINOLONE ANTIBIOTIC (q.v.).

**Mozambique virus** See ARENAVIRIDAE.

**mozzarella cheese** See CHEESE-MAKING.

**MPa** 10<sup>6</sup> PASCAL.

**MPED<sub>n</sub>** In a heat STERILIZATION process: the most probable effective dose of thermal energy required to achieve an n-log<sub>10</sub> reduction in the numbers of a given microbial contaminant.

**mpl gene** See PEPTIDOGLYCAN.

**MPN method** See MULTIPLE-TUBE METHOD.

**MppA** See PEPTIDOGLYCAN.

**MPT64** See ESAT-6.

**M<sub>r</sub>** RELATIVE MOLECULAR MASS.

**MR test** See METHYL RED TEST.

**MR vaccine** Measles–rubella vaccine.

**Mrad** 10<sup>6</sup> rad (see RAD).

**mrcA gene** See PENICILLIN-BINDING PROTEINS.

**mrcB gene** See PENICILLIN-BINDING PROTEINS.

**MRD virus group** See MORBILLIVIRUS.

**MreB protein** See CELL CYCLE (b) (determination of shape).

**MRHA** Mannose-resistant haemagglutination (see FIMBRIAE).

**mRNA** Messenger RNA: any RNA molecule which functions as a template for the assembly of amino acids during PROTEIN SYNTHESIS (see GENETIC CODE). In all cells, and in DNA viruses, the mRNA is transcribed from DNA (see TRANSCRIPTION); in RNA viruses, the genome may or may not be able to function directly as mRNA (see VIRUS).

(a) *Prokaryotic mRNAs*. Many bacterial mRNAs are functional as primary transcripts, i.e. they do not require post-transcriptional maturation. An mRNA molecule may contain the transcript of a single gene (*monocistronic* or *monogenic* mRNA) or, more commonly, transcripts of two or more genes (*polycistronic* or *polygenic* mRNA). (See also OPERON.)

A polycistronic mRNA contains several distinct regions: a 5' LEADER; *coding regions* (structural gene transcripts), each beginning with a translation initiation codon and consisting of a

## mRNA

linear sequence of codons; and sometimes a 3'-terminal *trailer*. The coding regions may or may not be separated by non-coding *intercistronic regions* (see also OVERLAPPING GENES).

The synthesis, translation and degradation of bacterial mRNA are closely linked phenomena; *typically*, bacterial mRNAs have a very short half-life, and in some cases degradation may begin even before transcription has been completed. mRNA is particularly prone to degradation in the absence of translation: see POLAR MUTATION. (cf. RRNA.) (See also S LAYER.)

The secondary structure of bacterial mRNA may be important in determining its stability. Stable mRNAs typically contain multiple secondary structures, particularly in the 3'-terminal region, and these may serve to protect the molecule from 3'-to-5' processive exonucleases present in the cell. (One function of the GC-rich stem-and-loop structure in a rho-independent terminator – see TRANSCRIPTION – may be to protect the 3' end of the transcript from degradation by exonucleases.) (See also RETROREGULATION.)

Some bacterial mRNAs – e.g. that transcribed from the *Escherichia coli* gene *lpp* (which encodes an outer membrane lipoprotein) – have atypically long half-lives. Moreover, the rate of degradation of mRNAs can be affected by growth conditions. For example, in *E. coli* the half-life of at least some mRNAs is greatly extended during slow anaerobic growth (doubling time: 700 minutes); in these conditions the rate of *synthesis* of mRNA is much lower, so that extended half-life may be a mechanism for maintaining the expression of such genes during anaerobiosis [Mol. Microbiol. (1993) 9 375–381].

In *Escherichia coli*, no known exonuclease can degrade RNA in the 5'-to-3' direction (i.e. in the direction of transcription and translation). mRNA degradation appears to involve the activity of endonuclease(s) and (3'-to-5') exonuclease(s) (e.g. RNASE II); small pieces of RNA (~10 nucleotides in length) are apparently degraded to single nucleotides by an enzyme designated RNase\* [JB (1991) 173 4653–4659].

**Polyadenylation.** Many prokaryotic mRNAs have a short (e.g. 10–50 nt) polyadenylate 'tail' at the 3' end. This poly(A) (A-A-A...) tail, whose synthesis involves a *poly(A)polymerase*, may influence the half-life (stability) of those mRNAs whose 3' terminus contains a stem-loop structure encoded by a rho-independent transcription terminator; such 3' stem-loop structures tend to resist enzymic degradation, and polyadenylation may facilitate degradation by providing a suitable binding site for enzymes such as 3'-exonuclease polynucleotide phosphorylase.

Interestingly, mutations in gene *pcnB* – which encodes the *Escherichia coli* poly(A)polymerase I (PAP I) – can reduce the copy number of plasmid ColE1. Apparently, the plasmid-encoded antisense molecule RNA I (which inhibits RNA II) is normally polyadenylated, polyadenylation assisting degradation of the molecule; the absence of polyadenylation in *pcnB* mutants tends to stabilize RNA I, i.e. to enhance its inhibitory action on RNA II – causing inhibition of plasmid replication and, hence, a reduction in copy number.

A poly(A) tail of 10 nucleotides was reported earlier in the archaean *Methanococcus vannielii* [JB (1985) 162 909–917.]

The poly(A) tail facilitates isolation of mRNAs by affinity chromatography; thus, mRNAs can be isolated by exploiting base-pairing specificity between the A-A-A... of mRNAs and the T-T-T... of oligo(dT)-cellulose in the matrix. Isolation of mRNAs can also be achieved e.g. by the use of DYNABEADS coated with oligo-dT.

[Polyadenylation of mRNA in bacteria (review): Microbiology (1996) 142 3125–3133. Characterization of *Escherichia coli*

poly(A)polymerase: NAR (2000) 28 1139–1144. Polyadenylation in mycobacteria: Microbiology (2000) 146 633–638.]

**Introns.** As in typical eukaryotic genes, some bacterial, archaean and phage genes include introns (see SPLIT GENE). In the transcripts of such genes any part corresponding to an intron must be removed in order to produce a 'mature' mRNA that correctly encodes the gene product. Bacterial introns are *autocatalytic*, i.e. enzymic activity that develops within a correctly folded mRNA molecule automatically 'splices out' the relevant sequence of nucleotides. In at least some cases, splicing may occur even while the nascent transcript is bound to the ribosome, the ribosome pausing during excision of the intron sequence. [Splicing and translation in bacteria: GD (1998) 12 1243–1247.]

(b) **Eukaryotic mRNAs.** In eukaryotes mRNA is synthesized (by RNA POLYMERASE II) in the nucleus and must be exported to the cytoplasm for translation; typically, mRNA is synthesized as a large precursor molecule (pre-mRNA) which undergoes an extensive maturation process involving *capping* at the 5' end (see below), polyadenylation of the 3' end, and (commonly) splicing out of introns (see SPLIT GENE). The mature mRNA molecule is typically functionally monocistronic. (cf. POLYPROTEIN; see also SUBGENOMIC MRNA.)

Some eukaryotic genes are atypical in that they do not contain introns – thus obviating the need for splicing of mRNA; such genes include most or all of those encoding histones as well as e.g. the gene encoding interferon- $\beta$ .

In the cytoplasm, mRNAs are relatively stable, and they occur complexed with proteins to form *messenger ribonucleoproteins*, mRNPs (= 'informosomes'). [Review: TIBS (1985) 10 162–165.]

**Polyadenylation.** Most eukaryotic mRNAs have a poly(A) (polyadenylate) sequence – about 200 adenylate residues – at the 3' end. This poly(A) tail is not added to the *complete* transcript: at the end of transcription an endonuclease cuts the transcript at a specific site ~10–30 nucleotides downstream of an AAUAAA (or similar) sequence – thus creating an appropriate 3' terminus from which another enzyme, poly(A)polymerase, can synthesize the polyadenylate tail. The function of the poly(A) tail is unknown.

Some eukaryotic mRNAs do not have a poly(A) tail; for example most or all mRNAs that encode histones are apparently poly(A)<sup>-</sup>.

**Capping.** Almost all eukaryotic mRNAs are modified (*capped*) at the 5' end. Capping occurs shortly after the beginning of transcription: an enzyme (*guanylyl transferase*) adds to the newly formed 5' end of the molecule an 'inverted' guanosine residue, i.e. a guanosine residue linked 5'-to-5' to the 5'-triphosphate end of the growing pre-mRNA molecule. A methyl group is then transferred (by a specific 7-methyltransferase) to the N<sup>7</sup> position of the G cap to form the characteristic cap structure:

A cap methylated only at this position is said to be of *type 0*. *Type 1* caps have an additional methyl group at the O<sup>2'</sup>-position of the next (2nd) nucleotide, and sometimes also at the N<sup>6</sup>-position of a penultimate adenine residue; *type 2* caps contain, in addition to the type 1 methyl group(s), a methyl group at the O<sup>2'</sup>-position of the 3rd nucleotide. Apparently, unicellular eukaryotes contain only type 0 caps; type 1 caps predominate in other eukaryotes.

The 5' cap enhances translation by promoting the formation of the translation initiation complex; the recognition of the cap by

specific *cap-binding protein(s)* (CBP) is an important factor in the regulation of gene expression. (The cap may also be involved e.g. in pre-mRNA processing.)

[Cap-binding proteins: Cell (1985) 40 223–224. Cap structure and interaction with CBP: Prog. Mol. Subcell. Biol. (1985) 9 104–155.]

(See also SNRNA.)

Among plant and animal viruses, viral RNA may be capped but not polyadenylated (e.g. TOBACCO MOSAIC VIRUS), polyadenylated but not capped (e.g. poliovirus), or polyadenylated and capped (e.g. ADENOVIRIDAE, POXVIRIDAE). Poliovirus apparently bring about the switch from translation of host (capped) mRNA to translation of viral (uncapped) mRNA at least partly by inactivating the host CBP. (See also e.g. REOVIRUS.)

**mRNP** See MRNA (b).

**MRSA** Methicillin-resistant *Staphylococcus aureus*. Resistance to methicillin is generally accompanied by resistance to other  $\beta$ -lactam antibiotics, and is often accompanied by resistance to e.g. aminoglycosides and macrolides. MRSA has been commonly susceptible to VANCOMYCIN and/or TEICOPLANIN (see also QUINUPRISTIN/DALFOPRISTIN) [but see e.g. Lancet (1999) 353 1587–1588; JCM (2001) 39 591–595]. High-level resistance seems to have been acquired from *Enterococcus faecalis* via transposon Tn1546 [Science (2003) 302 1569–1571].

One report has suggested that strains of MRSA may arise, *in vivo*, through transfer of the *mecA* gene (see below) between strains of staphylococci [Lancet (2001) 357 1674–1675].

High-level ('intrinsic') resistance to methicillin is (chromosomally) encoded by the *mecA* gene whose product is a novel 78 kDa PENICILLIN-BINDING PROTEIN, PBP 2a (= 2'), with a low affinity for  $\beta$ -LACTAM ANTIBIOTICS.

Expression of *mecA* is controlled by various regulatory genes. For example, some strains of MRSA contain a *mecI* gene which encodes a strong repressor; thus, resistance to methicillin may arise e.g. through mutation which inactivates the MecI product or which affects transcription from *mecI*. MecR1 is a sensor–transducer protein in the cell envelope. The binding of a  $\beta$ -lactam antibiotic to MecR1 brings about, indirectly, transcription of the *mecA* gene; transcription involves prior cleavage (i.e. inactivation) of MecI, the repressor of the *mecA* gene. Such induction of *mecA*-based resistance may parallel the induction of  $\beta$ -LACTAMASES (q.v.) [see e.g. Science (2001) 291 1962–1965; commentary: Science 291 1915–1916]. [PCR-based detection of *mecA*, *mecR1* and *mecI* genes in clinical isolates: JAC (2001) 47 297–304.]

(See also 'Induction of resistance to antibiotics' within the entry ANTIBIOTIC.)

*mecA*-mediated resistance can be lost e.g. by mutations in the *fem* genes (*fem* = factor essential for methicillin resistance). The *femAB* operon encodes factors needed for synthesis of normal PEPTIDOGLYCAN cross-links, and in some *femAB* mutants the (abnormal) cross-links are poor substrates for the (transpeptidase) activity of PBP 2a; as the 'routine' (methicillin-sensitive) PBPs are enzymically more effective than PBP 2a on the abnormal cross-links, the (mutant) cell is susceptible to methicillin.

Non-*mecA*-based methicillin resistance can be due to overproduction of  $\beta$ -lactamases (in which case it may be overcome by inhibitors such as CLAVULANIC ACID), to mutant PBPs which have lower affinity for  $\beta$ -lactam antibiotics, or to a reported methicillinase.

[Genetics of MRSA (review): RMM (1998) 9 153–162.]

The phenotypic expression of methicillin resistance is governed by factors that include temperature and salt concentration;

culture media typically contain 4% NaCl and they are incubated at e.g. 30–35°C. MRSA grows in 24–48 hours when inoculated ( $10^4$  cfu) onto Mueller–Hinton agar containing NaCl (4%) and oxacillin (6  $\mu$ g/ml) or methicillin (10  $\mu$ g/ml) [Book ref. 120, p. 151].

*Heteroresistance* refers to the expression of resistance in only a minority of cells in a genetically resistant population; most strains of MRSA are heteroresistant. [Mechanisms of heteroresistance: AAC (1994) 38 724–728.]

Nasal MRSA in carriers may be eliminated by MUPIROCIN; hair and skin may be disinfected by povidone–iodine (see IODINE) or by 4% CHLORHEXIDINE. Some strains of MRSA exhibit plasmid-encoded resistance to mupirocin and/or to chlorhexidine.

MRSA is a serious problem in many areas. Levels of MRSA are low e.g. in Holland – where control includes strict isolation of infected/colonized patients [e.g. RMM (1998) 9 109–116].

[Rapid discrimination between methicillin-sensitive and methicillin-resistant *S. aureus* by intact cell mass spectroscopy: JMM (2000) 49 295–300.]

[Rapid detection of *mecA*-positive and *mecA*-negative coagulase-negative staphylococci by an anti-PBP 2a slide latex agglutination test: JCM (2000) 38 2051–2054.]

[Genotyping of European isolates of MRSA by fluorescent amplified fragment length polymorphism analysis and PFGE: JMM (2001) 50 588–593.]

**MS ring** See FLAGELLUM (a).

**MscL channel** See MECHANOSENSITIVE CHANNEL.

**msDNA** See RETRON.

**MseI** A RESTRICTION ENDONUCLEASE; T/TAA.

**MSHA** Mannose-sensitive haemagglutination (see FIMBRIAE).

**MspI** See RESTRICTION ENDONUCLEASE (table).

**MSU** Mid-stream urine (see URINARY TRACT INFECTION).

**MSV** MAIZE STREAK VIRUS.

**MSX** L-Methionine-DL-sulphoximine: an inhibitor of glutamine synthetase – and hence of AMMONIA ASSIMILATION via the GS/GOGAT pathway.

**MT** Microtubule (see MICROTUBULES).

**mtDNA** Mitochondrial DNA (see MITOCHONDRION).

**MTOC** MICROTUBULE-ORGANIZING CENTRE.

**$\mu$  (mu)** (1) An abbreviation for 'micro-' (i.e. one-millionth).

(2) MICRON. (3) SPECIFIC GROWTH RATE. (4) One of the symbols used to designate the exponential growth rate constant – see GROWTH (a). (cf. BACTERIOPHAGE MU.)

**Mu** See BACTERIOPHAGE MU.

**mu chain** (*immunol.*) See HEAVY CHAIN.

**2 $\mu$  circle** *Syn.* TWO-MICRON DNA PLASMID.

**mu particle** The trivial name for certain bacteria (see CAEDIBACTER and PSEUDOCAEDIBACTER) which are endosymbionts in strains of *Paramecium* and which confer the MATE KILLER characteristic.

**2 $\mu$  plasmid** See TWO-MICRON DNA PLASMID.

**3 $\mu$  plasmid** See THREE-MICRON DNA PLASMID.

***mucA* gene** (1) See SOS SYSTEM. (2) See ALGINATE.

**Mucambo virus** See ALPHAVIRUS.

**mucate** A salt of MUCIC ACID.

***mucB* gene** See SOS SYSTEM.

**mucic acid** HOOC(CHOH)<sub>4</sub>COOH. It is obtained e.g. by the oxidation of galactose.

**muciferous body** See MUCOCYST.

## mucigel

**mucigel** A mucilaginous layer covering the root tips and root hairs of plants; it is composed mainly of pectin-like polysaccharides and is produced by the epidermal cells of the root tips. The mucigel may protect against desiccation, aid in the uptake of plant nutrients, and help to bind soil particles; it often contains large numbers of bacteria. [Book ref. 38, pp. 565–568.]

**mucigenic body** See MUCOCYST.

**mucocutaneous leishmaniasis** LEISHMANIASIS in man and other animals in which the pathogen gives rise (in man) to invasive granulomatous lesions primarily in the oral/nasal mucous membranes; in man the disease may follow an earlier, apparently cured, episode of CUTANEOUS LEISHMANIASIS with a latent period of up to many years. The disease occurs mainly in South America where it is called *espundia*, the causal agent being *Leishmania braziliensis*; a mucocutaneous leishmaniasis caused by *L. donovani* occurs in parts of Africa.

Diagnosis may involve e.g. the MONTENEGRO TEST; pentavalent ANTIMONY compounds and/or antibiotics (e.g. amphotericin B) may be used for treatment.

**mucocyst** (muciferous body; mucigenic body) In many ciliates and some flagellates: a small, sac-like organelle which, when appropriately stimulated, discharges a mucoid material through a pore at the cell surface. In ciliates the mucocyst is an invagination of the outermost membrane, the closed, inner part of the sac being located in the cytoplasm; mucocysts often occur in longitudinal rows parallel to the rows of kinetosomes. In some species mucocysts may be involved e.g. in cyst formation.

**mucoid** Viscous; slimy; mucus-like. The term is often applied to the colonies of certain capsulated bacteria (see CAPSULE; see also CYSTIC FIBROSIS).

**mucolytic agent** A chemical agent used e.g. on a sample of sputum prior to use of the sample as an inoculum on a culture plate; the purpose of the agent is to liquefy the sputum so that (i) the sputum can be manipulated, and (ii) any target cells within the sputum will be exposed to reagents.

Mucolytic agents include dithiothreitol [example of use: JCM (1997) 35 193–196] and *N*-acetyl-L-cysteine [examples of use: JCM (1999) 37 175–178; JCM (1999) 37 137–140].

**mucopeptide** (glycosaminopeptide) (1) *Syn.* PEPTIDOGLYCAN. (2) Any peptide-containing mucopolysaccharide.

**mucopolysaccharide** (glycosaminoglycan) A polysaccharide that contains a high proportion of amino sugars and (commonly) uronic acids; e.g. HYALURONIC ACID.

**mucoprotein** A protein covalently linked to amino sugars.

**mucopurulent** Containing mucus and pus.

**Mucor** A genus of fungi (order MUCORALES) which typically occur as saprotrophs on soil, vegetable matter and dung. The vegetative thallus is usually a branched, aseptate mycelium, though some species are dimorphic. The organisms form ZYGOSPORES (see also SPOROPOLLENIN); many species exhibit HETEROTHALLISM (see also COMPATIBILITY sense 2 and PHEROMONE). (For *M. miehei* and *M. pusillus* see RHIZOMUCOR.)

**Mucoraceae** See MUCORALES.

**Mucorales** An order of fungi (class ZYGOMYCETES) which occur as saprotrophs on decaying vegetable matter, soil or dung, or as parasites or pathogens of plants or animals (see e.g. ZYGOMYCOSIS). The vegetative thallus is typically a well-developed aseptate mycelium; some species (e.g. *Mucor rouxii*, other species of *Mucor*, *Mycotypha* spp) are DIMORPHIC FUNGI (sense 1). The organisms commonly form asexually derived spores in sporangia and/or sporangia. Most species form ZYGOSPORES (q.v.) – cf. Saksenaeaceae (below).

Nine families are recognized [Book ref. 64, pp. 247–248] on the basis of reproductive structures:

Choanephoraceae. Sporangia and sporangia are borne on different types of sporangiophore. Genera: *Blakeslea* (see also PHEROMONE), *Choanephora*. [The family has been redefined to contain *Blakeslea* (sporangia dehiscent), *Choanephora* (sporangia non-dehiscent), and *Poitrasia* (sporangia not formed; sporangia distinctive): Mycol. Pap. (1984) Nr 152.]

Cunninghamellaceae. Sporangia: one-spored; sporangia absent. Genera: e.g. *Cunninghamella* (see also ZYGOMYCOSIS), *Thamocephalis*.

Mortierellaceae. Columellae vestigial or absent. Genera: e.g. *Mortierella* (see also COMPOSTING and ZYGOMYCOSIS).

Mucoraceae. Sporangia are columellate. Genera: e.g. *Absidia* (see also ZYGOMYCOSIS), *Actinomuor*, *Gilbertella*, MUCOR, *Phycomyces* (see also THIAMINE), RHIZOMUCOR, RHIZOPUS and *Zygorhynchus*.

Pilobolaceae. Sporangia are columellate; in *some* species the sporangia are forcibly discharged. Genera: e.g. PILAIRA, PILOBOLUS.

Radiomycetaceae. Sporangia are absent; sporangia are often formed on stoloniferous sporangiophores. Genera: e.g. *Hes-seltinella*.

Saksenaeaceae. Zygospores are apparently not formed. Sporangia are columellate or acolumellate. Genera: *Echinosporangium*, *Saksenaea* (see also ZYGOMYCOSIS).

Syncephalastraceae. Merosporangia are formed. Genera: *Syncephalastrum*.

Thamnidaceae. Sporangia (each containing one to several spores) are formed – sometimes with columellate sporangia on the same or on separate (morphologically similar) sporangiophores. Genera: e.g. *Chaetocladium*, *Mycotypha*, *Thamnidium*.

**mucoran** A water-soluble, alkali-soluble heteroglucan (containing fucose, mannose and glucuronic acid) present e.g. in the cell walls of *Mucor rouxii*; it appears to be maintained in an insoluble form in the cell wall as a result of binding to insoluble glucosamine-containing polymers.

**mucormycosis** See ZYGOMYCOSIS.

**mucosal disease (MD)** A severe CATTLE DISEASE caused by the BVD-MD virus (see PESTIVIRUS). It apparently results from persistent BVD-MD virus infection acquired congenitally (with the consequent development of specific immune tolerance to the virus). MD is characterized by fever, anorexia, nasal discharge, profuse watery diarrhoea, buccal ulceration, etc; dehydration and emaciation are usually followed by death. [VR (1985) 117 240–245.] (cf. BOVINE VIRUS DIARRHOEA.)

**mucron** In acephaline gregarines: a differentiated region of the anterior end of the cell by means of which the developing parasite remains attached to the host cell (cf. EPIMERITE).

**Mudlac system** A system for bringing about GENE FUSIONS or OPERON FUSIONS using a defective form of BACTERIOPHAGE MU ('Mud phage') which carries the *lacZ* gene of *Escherichia coli* (and e.g. an antibiotic resistance marker); when the genome of such a phage transposes in the chromosome of a host cell, *lacZ* is inserted at more or less random sites and hence can be fused to almost any gene or operon in the chromosome. Two basic types of Mud phage can be used. Mud I phages contain an intact *lacZ* gene which can be expressed only if it can be transcribed from the promoter of the gene into which it has inserted; *lacZ* expression can be detected e.g. by plating the cells on Xgal plates (see XGAL). Mud II phages contain *lacZ* minus its translation initiation signals; in this case *lacZ* expression depends on both the promoter and the translation initiation signals of the gene into which it has inserted, the product being a FUSION PROTEIN. (See also MINI-MU.)

**muDUCTION** See MINI-MU.

**Mueller–Hinton medium** A general-purpose medium containing beef infusion, casamino acids (or peptone), and starch. It can be used as a broth or gelled with agar, and may be used e.g. as a base for blood-containing media. [Recipe: Book ref. 53, p. 1403.]

**MUG test** A test which helps to detect *Escherichia coli* in a mixed microflora. An agar-based medium which includes the reagent 4-methylumbelliferyl- $\beta$ -D-glucuronide (MUG) is inoculated with the sample; after incubation, colonies are examined under ultraviolet radiation (wavelength 366 nm). Most strains of *E. coli* form  $\beta$ -glucuronidase – an enzyme which cleaves MUG to a compound that fluoresces greenish-blue under radiation of 366 nm; the presence of fluorescent colonies allows a presumptive identification of *E. coli*. (N.B. Other sources of  $\beta$ -glucuronidase – found e.g. in shellfish samples – can give rise to a false-positive indication.)

In an alternative approach, a colony is smeared on filter paper which has been impregnated with MUG; the filter paper is then examined under ultraviolet radiation.

**mukB gene** See CELL CYCLE (b).

**Müller–Kauffmann broth** A tetrathionate-containing ENRICHMENT MEDIUM used e.g. in the isolation of salmonellas from pre-enrichment cultures of meat products in buffered peptone media.

**Müller's vesicle** In certain gymnostome ciliates (e.g. *Loxodes*): a composite organelle consisting of a membrane-enclosed mineral body (the *statolith*), a vacuole, and structures derived from the overlying kinety; it appears to act as a gravity sensor. [JP (1986) 33 69–76.]

**multi-L-arginyl-poly(L-aspartic acid)** *Syn.* CYANOPHYCIN.

**multicellular** Consisting of more than one (usually many) cells.

**multicistronic mRNA** *Syn.* polycistronic mRNA (see MRNA).

**multicomponent virus** (multipartite virus; multiparticle virus; covirus) A virus which exists as two or more separate particles, each containing only part of the genome; all the particles must be present in a given host cell for the complete replication cycle to occur. (cf. SATELLITE VIRUS.) Many PLANT VIRUSES are multicomponent viruses.

**multicopy inhibition** The phenomenon in which transposition of a single-copy *Tn10* element, resident in a bacterial chromosome, is inhibited 3- to 10-fold in the presence of a multicopy plasmid carrying *IS10-R* (see *Tn10*). The phenomenon is due to inhibition of translation (not transcription) of the transposase gene – apparently as a result of pairing between the start region of the transposase gene transcript and a short complementary RNA molecule (see ANTISENSE RNA) transcribed from the opposite *IS10* strand. [Book ref. 20, pp. 275–277.] (cf. TRANSPOSITION IMMUNITY.)

**multicopy plasmid** A PLASMID whose COPY NUMBER (in a given cell) is high, e.g., 10–30. Multicopy plasmids include e.g. the COLE1 PLASMID and plasmids pBR322, pMB1 and R6K. In a cell containing a multicopy plasmid, the replication of individual plasmids occurs randomly (as indicated by Meselson–Stahl density-shift experiments), and there is no active mechanism for PARTITION.

**multicopy single-stranded DNA** See RETRON.

**multidrug and toxic compound extrusion (MATE)** See MATE.

**multifidene** See PHEROMONE.

**multiline cultivar** (*plant pathol.*) A plant cultivar which is genetically non-uniform, comprising a mixture of plant lines which exhibit different degrees of resistance to a given pathogen or to particular race(s) of a given pathogen. The spread of a particular pathogen through such a cultivar is inhibited, and total crop

loss during an epiphytotic is less likely than it would be for a genetically uniform susceptible cultivar. [Review: ARPPATH. (1985) 23 251–273.]

**multiloculate** (multilocular) Consisting of or having many LO-CULES; see e.g. FORAMINIFERIDA.

**multilocus enzyme electrophoresis (MEE)** A method in which the electrophoretic mobilities of a range of enzymes from one organism are compared with those of equivalent enzymes from one or more closely related organisms; MEE is used e.g. for TYPING microorganisms. In this method, enzymes are isolated and tested under conditions in which enzymic activity is retained; enzymes can be identified in gels by specific colour-generating substrates.

Variation in the electrophoretic mobility of a given enzyme can arise e.g. when a variant form of the enzyme is specified by a different allele of the enzyme-encoding gene; such an enzyme – which may exhibit a different mobility when only a single amino acid differs – is called an *alloenzyme*.

**multilocus sequence typing** See MLST.

**multipartite virus** *Syn.* MULTICOMPONENT VIRUS.

**multiple cloning site** *Syn.* POLYLINKER.

**multiple drug resistance** See ANTIBIOTIC.

**multiple fission** A type of fission in which one cell gives rise to many cells. Multiple fission may involve repeated BINARY FISSION within a common envelope (as e.g. in CYANOBACTERIA of section II), or it may involve a series of nuclear divisions followed by the incorporation of each nucleus in a separate daughter cell (see e.g. SCHIZOGONY).

**multiple sclerosis** A chronic demyelinating disease of the CNS in humans. It is generally believed to be an autoimmune disease, possibly triggered by viral infection; it has been suggested that any of various enveloped viruses may be able to trigger the autoimmune response – which could be mounted against host lipids incorporated (with viral proteins) in the viral envelope [Nature (1986) 321 386]. (See also HTLV; INOUE–MELNICK VIRUS; MORBILLIVIRUS; cf. THEILER'S MURINE ENCEPHALOMYELITIS VIRUS.)

**multiple-tube method** (most probable number (MPN) method) A method for estimating the number of viable organisms (usually bacteria) suspended in a liquid. The method is used e.g. for the bacteriological examination of natural and treated waters; for this purpose, one of several possible procedures is as follows. Five tubes, each containing a suitable liquid growth medium, are each inoculated with a fixed volume of the sample water (or a dilution of it). Another five tubes, containing the same medium, are each inoculated with a smaller fixed volume of the sample, and further sets of tubes are similarly inoculated with progressively smaller volumes. Following incubation, each tube is examined for the presence or absence of growth. (It is assumed that growth will occur in any tube which receives at least one viable organism.) Growth usually occurs in those tubes inoculated with the larger volumes of the sample since these tubes are more likely to have received at least one viable organism in the inoculum. The number of cells in the original sample can be calculated from the pattern of positive (growth) and negative (no growth) tubes by the use of statistical (probability) tables; if a diluted sample were used, the count indicated by the tables is multiplied by the dilution factor. By using a selective medium in the tubes it is possible to estimate the numbers of a particular type of organism in the sample. The multiple-tube method is characterized by a large sampling error. (See also COUNTING METHODS.) [Improved method of computing MPNs: AEM (1983) 45 1646–1650.]

**multiplex PCR** A form of PCR in which two\* or more different targets are amplified, simultaneously, in a single assay. The reaction mixture usually contains two types of primer for each target;

## multiplicity of infection

in some cases, however, one primer can be shared by two targets – e.g. 16S rRNA sequences from two species, *Bacteroides forsythus* and *Prevotella intermedia*, were simultaneously amplified with one forward primer (a BROAD-RANGE PRIMER common to both species) and two species-specific reverse primers [JCM (1999) 37 1621–1624].

Owing to the use of multiple primers, it is particularly important to ensure the absence of complementarity between the 3' ends of the primers in order to avoid the formation of PRIMER-DIMERS.

The possibility of competition between different targets in a multiplex PCR may be investigated by adding a few copies of another target which is amplifiable but distinct from the other targets. Failure of *this* target to amplify (when other(s) are positive) would suggest that competition/inhibition has affected the efficiency of amplification; in these circumstances, the failure of amplification of other target(s) in the same assay would not be considered meaningful [JCM (1998) 36 191–197].

Examples of the use of multiplex PCR include: detection of chlamydiae [JCM (1999) 37 575–580]; detection of vancomycin-resistance genes in enterococci [JCM (1999) 37 2090–2092]; detection of *mecA* and *coa* genes in *Staphylococcus aureus* [JMM (1997) 46 773–778]; detection of different types of virus in cerebrospinal fluid (CSF) [JCM (1997) 35 691–696]; and detection of HIV-1, HIV-2, HTLV-I and HTLV-II [PNAS (1999) 96 6394–6399].

\*The amplification of *two* targets is also referred to as *duplex* PCR.

**multiplicity of infection (moi)** The ratio of virions to susceptible cells in a given system; e.g., a high moi means a large number of virions per cell.

**multiplicity reactivation** See REACTIVATION.

**multiseriate** Arranged in or forming several rows; more than one cell wide.

**multisite mutation** A MUTATION which involves the alteration of two or more contiguous nucleotides. (cf. POINT MUTATION.)

**multivalent vaccine** *Syn.* POLYVALENT VACCINE.

**Multivalvulida** See MYXOSPOREA.

**MuLV** MURINE LEUKAEMIA VIRUS.

**µm** MICROMETRE.

**2µm circle** (2µm plasmid) *Syn.* TWO-MICRON DNA PLASMID.

**mumps** (contagious, infectious or epidemic parotitis) An acute infectious human disease which affects mainly children; it is caused by a PARAMYXOVIRUS. Transmission occurs by droplet infection. Incubation period: 2–3 weeks. The disease ranges from subclinical to severe. Typical symptoms include fever with pain and swelling of one or more salivary glands (usually the parotid). Common complications include MENINGITIS, often with mild encephalitis, and orchitis; oophoritis, mastitis, pancreatitis etc may also occur. Infection seems to confer life-long immunity. *Lab. diagnosis:* serological tests (CFT, HAI test) for mumps virus antibodies; isolation of mumps virus e.g. from pharynx or urine.

**mundticin** A 43-amino-acid class IIa BACTERIOCIN produced by *Enterococcus mundtii*.

**mungbean yellow mosaic virus** See GEMINIVIRUSES.

**mupirocin** (pseudomonic acid A) An antibiotic produced by strains of *Pseudomonas fluorescens*. It is active against staphylococci and streptococci associated with skin infections, and the topically-applied antibiotic has been shown to be effective against experimental infection of surgical wounds by *Staphylococcus aureus* [JAC (1985) 16 519–526]. Mupirocin appears to act by inhibiting isoleucyl-tRNA synthetase. [Review: JAC (1987) 19 1–5.]

**muramic acid** 3-*O*-Lactylglucosamine: see PEPTIDOGLYCAN.

**muramidase** An enzyme which cleaves glycosidic bonds in PEPTIDOGLYCAN: see e.g. LYSOZYME. A muramidase obtained from the bacteriolytic hyphomycete *Chalara* (= '*Chalaropsis*') sp is commonly used in studies on peptidoglycan; this enzyme hydrolyses the same glycosidic bond as lysozyme but differs e.g. in substrate specificity [JBC (1967) 242 5586–5590].

**muramyl dipeptide** See MDP.

**urein** *Syn.* PEPTIDOGLYCAN.

**urein lipoprotein** *Syn.* BRAUN LIPOPROTEIN.

**ureinoplast** Any Gram-negative bacterial cell from which the outer membrane, but not the peptidoglycan, has been removed.

**murid (beta) herpesvirus 1** See BETAHERPESVIRINAE.

**murid herpesvirus 2** See BETAHERPESVIRINAE.

**muriform** Refers to a spore which has both transverse and longitudinal septa.

**murine** Of or pertaining to rats or mice (Muridae).

**murine cytomegalovirus group** See BETAHERPESVIRINAE.

**murine encephalomyocarditis virus** See CARDIOVIRUS.

**murine hepatitis virus** See CORONAVIRIDAE.

**murine leukaemia viruses (MLVs; MuLVs)** A group of type C retroviruses (subfamily ONCOVIRINAE), nearly all of which are replication-competent and *v-onc*<sup>-</sup> (but cf. ABELSON MURINE LEUKAEMIA VIRUS), and some of which can induce e.g. lymphatic leukaemia in mice after a long latent period (see e.g. MOLONEY MURINE LEUKAEMIA VIRUS). (All replication-competent murine type C retroviruses are termed 'murine leukaemia viruses', although most are usually non-leukaemogenic [Book ref. 114, p. 70].)

MuLV-induced leukaemogenesis requires viraemia (i.e., it requires expression and replication of the virus) and an active cellular immune response to the MuLV *env* gene product; it has been suggested that chronic immune stimulation may be a factor in leukaemogenesis. Although the *env* gene product is thought to play a direct role in leukaemogenesis, it has been shown that the primary oncogenic determinant in one MuLV lies outside the *env* region – possibly in the LTR [JV (1983) 47 317–328]. (See also MCF VIRUSES.)

MuLVs have given rise to a range of defective, often acutely oncogenic variants: see e.g. FRIEND VIRUS, HARVEY MURINE SARCOMA VIRUS, MOLONEY MURINE SARCOMA VIRUS, RAUSCHER VIRUS.

**murine poliovirus** *Syn.* THEILER'S MURINE ENCEPHALOMYELITIS VIRUS.

**murine sarcoma viruses (MSV)** A group of highly oncogenic, replication-defective, C-type retroviruses (subfamily ONCOVIRINAE): see e.g. FBS OSTEOSARCOMA VIRUS, GAZDAR MURINE SARCOMA VIRUS, HARVEY MURINE SARCOMA VIRUS, KIRSTEN MURINE SARCOMA VIRUS, and MOLONEY MURINE SARCOMA VIRUS. MSV replication requires the presence of e.g. a MURINE LEUKAEMIA VIRUS as helper.

**murine typhus** See TYPHUS FEVERS.

**MurNAc** *N*-Acetylmuramic acid: see PEPTIDOGLYCAN.

**muropeptides** Products of muramidase (e.g. LYSOZYME) digestion of PEPTIDOGLYCAN. In *Escherichia coli* they are designated C1–C8, according to their migration rates during chromatography; e.g., C3 is a dimeric subunit consisting of two GlcNAc–MurNAc disaccharides bound by a cross-link; C4 consists of a tetrasaccharide – (GlcNAc–MurNAc)<sub>2</sub> – in which there is a cross-link between the two MurNAc residues; C5 and C6 are monomeric subunits (GlcNAc–MurNAc) linked to short peptides. [Book ref. 122, pp. 79–81.]

**murray** *Syn.* REDWATER FEVER.

**Murray Valley fever** (Australia X disease) An acute human disease caused by a flavivirus (see FLAVIVIRIDAE) and transmitted by mosquitoes (e.g. *Culex annulirostris*); it occurs in parts of Australasia. The disease is usually a mild, febrile condition, but encephalitis may occur and may be fatal in young children. Birds may act as a reservoir of infection.

**Murraya** See LISTERIA.

**muscarine** (muscarin) A quaternary ammonium derivative of tetrahydrofuran produced e.g. by *Amanita muscaria* (the fly agaric) and *Inocybe* spp; it is toxic to flies, and infrequently causes a fatal intoxication in humans. (See also MYCETISM.)

**muscolous** Growing on mosses.

**mushroom** (1) Loosely: any umbrella-shaped fungal fruiting body; such a fruiting body consists of a horizontally orientated, circular PILEUS supported, at its centre, by a vertical, columnar STIPE. 'Mushroom' is often reserved for those fruiting bodies in which the pileus has radially arranged lamellae (see LAMELLA) or lamella-like structures on its underside.

(2) Any AGARIC.

(3) The (edible) fruiting body of *Agaricus brunnescens*, the common cultivated mushroom (see AGARICUS and MUSHROOM CULTIVATION). (See also MUSHROOM DISEASES.)

(4) Any edible mushroom – including e.g. ENOKITAKE, OYSTER FUNGUS and SHII-TAKE. (cf. TOADSTOOL.)

**mushroom cultivation** The mycelium of the edible mushroom *Agaricus brunnescens* (= *A. bisporus*) is cultivated on composted material – traditionally a mixture of straw and horse manure (see COMPOSTING; [SEM of flora: JAB (1983) 55 293–304]). After an initial composting period, the compost undergoes 'peak-heating' ('pasteurization') to ca. 50–60°C; during this stage thermophilic actinomycetes and fungi continue to grow, but the number of mesophiles – including many mushroom parasites and pathogens – is reduced. (See also OLIVE-GREEN MOULD.) The compost is then allowed to cool to ca. 25°C and inoculated with SPAWN of a selected strain of *A. brunnescens*. After ca. 14 days, during which the mycelium of *A. brunnescens* grows through the compost, a 'casing layer' of soil or a mixture of peat and chalk or limestone is spread over the compost. The temperature is maintained at ca. 25°C (RH >90%) for ca. 1 week. When the mycelium reaches the surface of the casing layer, the temperature and RH are allowed to fall (e.g. to ca. 16–18°C or less, RH 80–90%) to induce initiation of fruiting. Mature fruiting bodies begin to appear ca. 3 weeks after casing, and then appear in flushes at intervals of ca. 7–10 days. During the growth of *A. brunnescens* the previous (thermophilic) flora declines, and progressive colonization by mesophilic fungi (e.g. species of *Aspergillus* and *Trichoderma*) occurs [TBMS (1980) 74 465–470].

The composting and pasteurization processes appear to be necessary to provide low C:N ratios with high levels of organic nitrogen (ammonia being inhibitory to *A. brunnescens*). The microbial population established during these stages may act as a direct source of nutrients for *A. brunnescens*, which produces a variety of extracellular enzymes (including a  $\beta$ -N-acetylmuramidase) that can lyse and degrade bacteria [JGM (1984) 130 761–769] and fungal mycelium [JGM (1985) 131 1735–1744]. The casing is necessary to switch growth of *A. brunnescens* from vegetative to reproductive. This switch appears to be associated with the activities of bacteria (especially pseudomonads) in the casing layer, possibly involving the removal by the bacteria of certain 'self-inhibitory' fungal metabolites; the casing may also serve to trap some volatile product(s) of *A. brunnescens* or other fungi in the compost [Book ref. 39, p. 291].

Certain other edible agarics are cultivated in some countries; some (e.g. PADI-STRAW MUSHROOM) are grown on waste plant materials, others (e.g. ENOKITAKE, OYSTER FUNGUS, SHII-TAKE) are grown on wood, sawdust, woodchips etc.

(See also MUSHROOM DISEASES.)

**mushroom diseases** Diseases of the cultivated mushroom *Agaricus brunnescens* (= *A. bisporus*) can be caused by bacteria (see e.g. BROWN BLOTCH, GINGER BLOTCH), fungi (see e.g. BUBBLE DISEASES, COBWEB DISEASE, OLIVE-GREEN MOULD) or viruses (see e.g. WATERY STIPE). (See also FUNGUS GNATS.)

**mushroom virus 3** See MYCOVIRUS.

**mussel poisoning** See SHELLFISH POISONING.

**must** See WINE-MAKING.

**mustard gas** See SULPHUR MUSTARDS.

**mut genes** See MUTATOR GENE.

**mutagen** An agent (chemical or physical) which promotes MUTAGENESIS. Most mutagens interact directly with (and damage) DNA, but mutagenesis commonly requires the active participation of the cell itself; e.g., a mutagen may alter a base in DNA such that, although not itself a mutation, it may pair with the wrong base during a subsequent round of DNA replication, resulting in a mutation. The damaging effects of some potential mutagens can be counteracted, to varying extents, by particular DNA REPAIR systems, one of which (error-prone repair: see SOS SYSTEM) plays an important role in mutagenesis induced by certain mutagens.

A given mutagen may be mutagenic in one organism but not in another, or may act differently in different organisms. Physical agents which promote mutagenesis in at least some organisms include e.g. IONIZING RADIATION, ULTRAVIOLET RADIATION and heat (heat apparently increases the rates of spontaneous reactions in DNA, thus increasing the SPONTANEOUS MUTATION rate). Chemical mutagens include e.g. ALKYLATING AGENTS, BASE ANALOGUES, BISULPHITE, HYDROXYLAMINE, certain INTERCALATING AGENTS, and NITROUS ACID; many of these are more reactive with ssDNA than with dsDNA and thus probably act preferentially in single-stranded regions generated e.g. during replication. [Chemical mutagenesis: ARB (1982) 52 655–693.]

**mutagenesis** The generation of one or more MUTATIONS. Mutagenesis may involve SPONTANEOUS MUTATION (see also MUTATOR GENE) or it can be induced in vitro by the use of a MUTAGEN or by recombinant nucleic acid technology (see SITE-SPECIFIC MUTAGENESIS, TRANSPOSON MUTAGENESIS and SIGNATURE-TAGGED MUTAGENESIS).

**mutagenic** Capable of causing MUTAGENESIS.

**mutagenic repair** See SOS SYSTEM.

**mutagenicity test** A test used to detect the mutagenic potential of a particular (usually chemical) agent. Mutagenicity tests are widely used for screening chemicals for potential carcinogenic activity since most direct CARCINOGENS are mutagenic (although not all mutagens are carcinogenic). See e.g. AMES TEST and SOS CHROMOTEST.

**mutan** A water-insoluble glucan, containing mostly (1 → 3)- $\alpha$ - (with some (1 → 6)- $\alpha$ -) glycosidic bonds, produced by certain strains of *Streptococcus mutans*; mutan is a component of DENTAL PLAQUE. [Mutan synthesis and cariogenicity in *S. mutans*: JGM (1981) 127 407–415.]

**mutanolysin** Endo-N-acetylmuramidase.

**mutant** (*adj.* or *noun*) (Refers to) an organism, population, gene, chromosome etc which differs from the corresponding WILD TYPE by one or more MUTATIONS.

**mutasynthesis** The synthesis of novel end-products by a mutant organism which is blocked in the given biosynthetic pathway

## Mutatest

and which is provided with unnatural substrates with which to complete that pathway. Mutasynthesis has been used e.g. to synthesize new antibiotics.

**Mutatest** *Syn.* AMES TEST.

**mutation** A stable, heritable change in the nucleotide sequence of a genetic nucleic acid (DNA or – in RNA viruses, viroids etc – RNA) which typically results in the generation of a new allele and a new phenotype (cf. SILENT MUTATION and CONDITIONAL LETHAL MUTANT). (In a diploid cell, a mutant allele may be recessive to the corresponding WILD TYPE allele present in the same cell, in which case it will not affect the phenotype of the cell.) The generation of a mutation (*mutagenesis*) may occur spontaneously (see SPONTANEOUS MUTATION) or may result from the activity of a MUTAGEN. See also e.g. BACK MUTATION; DELETION MUTATION; FORWARD MUTATION; FRAMESHIFT MUTATION; INSERTION MUTATION; LEAKY MUTATION, MIS-SENSE MUTATION; MULTISITE MUTATION; NONSENSE MUTATION; NULL MUTATION; PLEIOTROPIC MUTATION; POINT MUTATION; POLAR MUTATION; SAME-SENSE MUTATION; SUPPRESSOR MUTATION.

**mutation rate** (*bacteriol.*) The probability that any given cell in a growing population will undergo, spontaneously, a specific MUTATION during its division cycle. The concept of mutation rate can be expressed:

$$a = \frac{m}{d}$$

where  $a$  = mutation rate,  $m$  = the number of specific mutations which have occurred within the population, and  $d$  = the number of individual division cycles within the population. In a SYNCHRONOUS CULTURE,  $d$  may be regarded as  $(n - n_0)$  where  $n$  is the final number of cells, and  $n_0$  is the initial number; thus  $(n - n_0)$  indicates the number of newly formed chromosomes (assuming one per cell) – i.e., the number of genomes in which a mutation could occur. However, in a normal, non-synchronous culture  $(n - n_0)$  will not indicate the number of newly formed chromosomes because chromosome replication will have occurred in some cells which have not divided at the time of counting;  $(n - n_0)$  therefore gives an underestimate of the new genomes, and a statistical correction is applied to the expression for mutation rate, which becomes:

$$a = \frac{m \times 0.69}{n - n_0}$$

Examples of some measured mutation rates: resistance to phage T1 in *Escherichia coli*  $3 \times 10^{-8}$ ; loss of ability to ferment galactose (*E. coli*)  $10^{-10}$ . (A value such as  $5 \times 10^{-8}$  means that, on average, one mutant is formed for every  $2 \times 10^7$  division cycles within the population.) For two independent mutations having rates of, say,  $10^{-6}$  and  $10^{-8}$ , the mutation rate for a double mutant (i.e., a cell having both mutations) would be  $10^{-14}$ .

The actual (observed) mutation rate in respect of a given phenotypic characteristic may be influenced e.g. by the presence of a TRANSPOSABLE ELEMENT. (See also MUTATOR GENE.)

**mutator gene** (mutator) Any gene (designated *mut*) within which certain mutations cause an increase in the rate of SPONTANEOUS MUTATION in other genes. For example, in *Escherichia coli*, mutations in the gene encoding the  $\epsilon$  subunit of DNA POLYMERASE III (*dnaQ* and *mutD* alleles) can result in extremely high levels of spontaneous mutation; mutant alleles may differ from the wild-type allele e.g. by only one or two single base substitutions, leading to one or two amino acid changes in the  $\epsilon$  subunit [MGG (1986) 205 9–13]. The mutation(s) may lead to reduced

accuracy in the polymerizing (nucleotide selection) activity and/or in the proof-reading activity of the enzyme.

Other mutator genes in *E. coli* include genes involved in the MISMATCH REPAIR system.

Another mutator, designated *mutT*, specifically increases the level of  $A \cdot T \rightarrow C \cdot G$  transversions.

[*Escherichia coli* mutator genes: TIM (1999) 7 29–36.]

Some DNA polymerase mutants of *E. coli* exhibit mutation rates which are lower than those in wild-type cells; the corresponding gene is then called an *antimutator gene*. An antimutator gene product presumably permits fewer errors than occur normally during replication – possibly by increasing the efficiency of the proof-reading/editing function of the enzyme.

(See also BACTERIOPHAGE MU.)

**mutator phage** Any phage which, on infection of a host bacterium, causes an increase in the rate of mutation in the host cell (see BACTERIOPHAGE MU and BACTERIOPHAGE D108).

**mutD gene** See DNA POLYMERASE.

**mutH gene** See MISMATCH REPAIR.

**Mutinus** See PHALLALES.

**mutL gene** See MISMATCH REPAIR.

**mutS gene** See MISMATCH REPAIR.

**mutualism** SYMBIOSIS (sense 1) in which both symbionts derive benefit from the association. (cf. COMMENSALISM.) Some authors reserve the term for an obligatory association, i.e., an association of organisms which, in nature, cannot live independently. Optional ('facultative') mutualism is sometimes called PROTOCOOPERATION.

**MV-L3 phage group** (L3 acholeplasmavirus group) A group of MYCOPLASMAVIRUSES probably belonging to the PODOVIRIDAE. Type member: bacteriophage MV-L3 (= MVL3; = L3 strain L3). The MV-L3 virion has a polyhedral head (diam. ca. 60 nm) with a short tail (ca.  $20 \times 9$  nm) attached at one vertex via a collar; it includes five or more proteins and ca. 2% by weight of fucose. Genome: linear dsDNA (MWt  $2.6 \times 10^7$ ). Host: *Acholeplasma laidlawii*; plaques clear, minute. Infected cells are killed but not lysed; progeny virions seem to be released in membrane vesicles which subsequently rupture.

**Mx protein** See INTERFERONS.

**mxi-spa genes** See DYSENTERY.

**myalgia** Muscle pain.

**Myambutol** *Syn.* ETHAMBUTOL.

**myb** An ONCOGENE originally identified as the transforming determinant in avian myeloblastosis virus (AMV; see AVIAN ACUTE LEUKAEMIA VIRUSES); *v-myb* is an altered form of a cellular sequence *amv*, differing from *amv* in gene structure, transcript structure, gene product structure, and in the intracellular location (nucleus) of its product [Book ref. 113, pp. 143–151]. *v-myb*<sup>+</sup> AMV can transform chicken haematopoietic cells in culture, but differs from other acutely transforming retroviruses in that it does not transform fibroblasts in culture; it causes a rapidly fatal leukaemia only in chickens.

**myc** An ONCOGENE originally identified as the transforming determinant of avian myelocytomatosis virus (MC29; see AVIAN ACUTE LEUKAEMIA VIRUSES). The MC29 *v-myc* product is a *gag-myc* fusion protein (P110<sup>gag-myc</sup>) which has no protein kinase activity; it binds to dsDNA and occurs – possibly as a chromatin component – in the nucleus. In humans, *c-myc* is located on chromosome 8 and is involved in the pathogenesis of BURKITT'S LYMPHOMA. In chickens, *c-myc* activation by AVIAN LEUKOSIS VIRUSES appears to result in the development of lymphoid leukaemia.

**mycangium** *Syn.* MYCETANGIUM.

**Mycelia Sterilia** See AGONOMYCETALES.

**mycelium** A group or mass of discrete hyphae (see HYPHA): the form of the vegetative thallus in many types of fungi and in certain bacteria (see ACTINOMYCETALES). (See also AERIAL MYCELIUM, SPROUT MYCELIUM; SUBSTRATE MYCELIUM; cf. PLECTENCHYMA.)

**Mycena** See AGARICALES (Tricholomataceae) and BIOLUMINESCENCE.

**mycetangium** (mycangium) In certain insects: a specialized region within which symbiotic fungi are carried; see e.g. AMBROSIA FUNGI and WOODWASP FUNGI.

**mycetism** (mycetismus) Poisoning due to the ingestion of certain mushrooms (MUSHROOM sense 1) – e.g. the poisonous species of *Amanita* or *Cortinarius*. (cf. MYCOSIS, MYCOTOXICOSIS; see also e.g. AMATOXINS, MUSCARINE and PHALLOTOXINS.) Mycetism can occur in e.g. sheep and cattle as well as in humans; thus, e.g. the toxins in *Cortinarius speciosissimus* are known to cause renal failure in both humans and sheep. (See also ORELLANIN POISONING.)

**mycetismus** *Syn.* MYCETISM.

**mycetocyte** In certain invertebrates, particularly insects: a specialized cell which contains intracellular bacterial or fungal symbionts; if the endosymbiont is a bacterium the term BACTERIOCYTE may be used – although ‘mycetocyte’ is often used regardless of the nature of the endosymbiont. Mycetocytes may be irregularly distributed in certain tissues (e.g. the gut lining) or they may be aggregated into specialized organelles (*mycetomes*) which are usually associated with the gut. In at least some cases the microflora of the mycetome supplies essential nutrients to the insect host. (See also MYCETANGIUM and TROPHOSOME.) [Molecular biology of symbiotic bacteria in aphid mycetocytes: MS (1986) 3 117–120.]

**mycetoma** (1) *Syn.* MADUROMYCOSIS. (2) (fungus ball) A tumour-like mycelial mass formed in the tissues in certain mycoses (see e.g. ASPERGILLOSIS and COCCIDIOIDOMYCOSIS).

**mycetome** See MYCETOCYTE.

**mycetophagous** *Syn.* MYCOPHAGOUS.

**Mycetozoa** A subphylum (phylum GYMNOMYXA) comprising two classes: Eumycetozoa (see EUMYCETOZOEAE) and Acrasea (see ACRASIIOMYCETES).

**Mycocacia** See APHYLLOPHORALES (Corticaceae).

**mycobacteriophage** Any BACTERIOPHAGE which can infect one or more *Mycobacterium* spp. Most mycobacteriophages have a hexagonal head and a non-contractile tail (contractile in I3), and many are readily inactivated by organic solvents. Mycobacteriophages include both temperate and virulent types; in certain cases phage progeny may be released from the living host cell. [Book ref. 54, pp. 326–342.]

**Mycobacterium** A genus of Gram-positive, aerobic to microaerophilic, non-motile, asporogenous bacteria (order ACTINOMYCETALES, wall type IV) that are acid-fast during at least some stage of growth.

Cells: typically straight or curved rods, ca. 0.2–0.8 × 1–10 µm, but may occur as coccoid forms, branched rods or fragile filaments; some strains are capsulated (see also MYCOSIDE C). Individual cells may stain uniformly or may exhibit banding or beading. The CELL WALL contains MYCOLIC ACIDS (see also CORD FACTOR, WAX D and PEPTIDOGLYCAN).

Some strains form CAROTENOID pigments: see PHOTOCROMOGEN and SCOTOCROMOGEN.

Species of *Mycobacterium* occur in soil as free-living saprotrophs, in water [review: JAB (1984) 57 193–211], on plants,

and as parasites and pathogens of man and other animals (including fish) (see e.g. BURULI ULCER, JOHNE'S DISEASE, LEPROSY, SCROFULA and TUBERCULOSIS).

Metabolism is respiratory and, typically, chemoorganotrophic – although chemolithotrophic strains of e.g. *M. marinum* and *M. smegmatis* have been reported. Nutritionally, mycobacteria are generally not fastidious; sources of carbon and nitrogen include e.g. sugars, hydrocarbons and amino acids. In a number of species glycerol and asparagine are preferred sources of C and N, respectively. Growth may be stimulated e.g. by serum or egg-yolk (see also LÖWENSTEIN–JENSEN MEDIUM) or by an increase in the partial pressure of carbon dioxide; in members of the *Mycobacterium tuberculosis* complex growth is enhanced by pyruvate or (in some species) by glycerol. [Nutrition/metabolism in mycobacteria: Book ref. 54, pp 185–271.]

In ‘slow-growing’ (SG) strains, visible growth on solid media may not appear for ~4–6 weeks (up to ~12 weeks in *M. malmoense*). In ‘rapidly growing’ (RG) strains, visible growth on solid media appears within 1 week, often 4–6 days. Note that in BACTEC (liquid) media growth can be detected more rapidly than it can on solid media.

Tests used in the identification of mycobacteria include e.g. the ARYLSULPHATASE TEST, catalase test (that is, persistence of CATALASE activity after incubation at 68°C/20 minutes in neutral phosphate buffer [Book ref. 53, p 1707]), NIACIN TEST, NITRATE REDUCTION TEST, T2H TEST and TWEEN HYDROLYSIS. There are also various molecular methods that are used for detecting, identifying, characterizing and typing certain species: see e.g. PROBE, SPOLIGOTYPING and TMA.

The genus comprises ~50 species. Medically important species are found in the following groups: (i) the *M. tuberculosis* complex (*M. tuberculosis*, *M. bovis*, BCG, *M. africanum* and *M. microti*) – all species associated with tuberculosis; (ii) the *M. avium* complex (*M. avium*, *M. intracellulare* and *M. scrofulaceum*) – see MAC; (iii) *M. leprae*; (iv) ‘non-tuberculous mycobacteria’, or ‘mycobacteria other than tuberculosis’: see MOTT. There is a growing number of infrequently isolated mycobacteria – some with actual or potential ability to cause human disease [RMM (1997) 8 125–135].

GC%: ca. 62–70. Type species: *M. tuberculosis*.

The genus *Mycobacterium* includes the following species:

*M. africanum*. SG; microaerophilic. Similar to *M. bovis*, but results are variable in the niacin and nitrate reduction tests. Sensitive to PYRAZINAMIDE. Can cause human tuberculosis; found primarily in Africa.

*M. avium*. SG; non-pigmented. Typical tests: arylsulphatase –ve; catalase (68°C) variable; growth at 25–42°C +ve; niacin –ve; nitrate reduction –ve; T2H test +ve; Tween hydrolysis –ve. Pathogenic for birds. *M. avium*, *M. intracellulare* and *M. scrofulaceum* form the ‘*M. avium* complex’; these species are associated with various human disease syndromes: see MAC.

*M. bovis* (‘*M. tuberculosis* var. *bovis*’). SG; microaerophilic. Non-pigmented. Typical reactions: catalase (68°C) –ve; growth at 42°C –ve; growth enhancement by pyruvate +ve; niacin –ve; reduction of nitrate –ve; T2H test –ve; Tween hydrolysis variable. Resistant to pyrazinamide. Most strains of *M. bovis* are reported to contain only a single copy of the insertion sequence IS6110.

*M. bovis* is a causal agent of TUBERCULOSIS in both animals and man. Differentiation between *M. bovis* and *M. tuberculosis* may be facilitated by SPOLIGOTYPING.

*M. bovis* BCG is a strain of *M. bovis* which differs e.g. in that growth occurs aerobically. (See also BCG.)

## Mycobacterium

*M. branderi*. SG; non-pigmented/scotochromogenic. Typical tests: arylsulphatase +ve; niacin -ve; reduction of nitrate weak; Tween hydrolysis -ve; growth 25–45°C +ve. [Original description of species: IJSB (1995) 45 549–553.] *M. branderi* has been isolated from the respiratory tract on a number of occasions and may be a causal agent of disease.

*M. celatum*. SG; non-pigmented. Typical tests: catalase (68°C) +ve; arylsulphatase variable; niacin -ve; reduction of nitrate -ve; Tween hydrolysis -ve; T2H test +ve. [Original description of species: IJSB (1993) 43 539–548.]

Strains of *M. celatum* have been classified into three types (I–III) on the basis of RFLP analysis. Type I strains may give false-positive results with a commercial probe for *M. tuberculosis* [JCM (1994) 32 536–538].

*M. celatum* has been isolated from a range of infections, some in patients with AIDS [e.g. Lancet (1994) 344 332; Lancet (1994) 344 1020–1021].

*M. chelonae* (= *M. chelonae*). RG; non-pigmented. Similar to *M. fortuitum* but e.g. does not grow at 42°C (optimum growth temperature ~25°C) and does not reduce nitrate. *M. chelonae* has been isolated e.g. from infected wounds.

*M. farcinogenes*. RG. Resembles *M. fortuitum* (on the basis of DNA homology studies). A causal agent of bovine FARCY.

*M. flavum*. See XANTHOBACTER.

*M. fortuitum*. RG; non-pigmented. Typical tests: arylsulphatase +ve; growth at 42°C +ve; Tween hydrolysis variable; reduction of nitrate +ve. An opportunist pathogen. [DNA relatedness study of the *M. fortuitum*–*M. chelonae* complex: IJSB (1986) 36 458–460.]

*M. gordonae* (previously called *M. aquae*). SG; scotochromogen. The organism occurs in water, and is an occasional cause of pulmonary disease; it is not susceptible to isoniazid or pyrazinamide but is sensitive to some other antimycobacterial drugs. A DNA probe (for identifying isolates) is available commercially.

*M. haemophilum*. SG; non-pigmented. Requires haemin for growth. Growth occurs at 30°C, not at 37°C. Causes disease in the immunosuppressed and in healthy children. [Clinical and laboratory aspects of *M. haemophilum* infections: RMM (1998) 9 49–54.]

*M. interjectum*. SG; scotochromogen. Typical tests: catalase (68°C) +ve; arylsulphatase variable; niacin -ve; reduction of nitrate -ve; Tween hydrolysis variable; growth at 31–37°C +ve; T2H test +ve. [Original description of species: JCM (1993) 31 3083–3089.]

*M. interjectum* was first isolated from a child with chronic submandibular lymphadenitis (and a positive TUBERCULIN TEST). Partial resection of the lymph node and treatment with anti-tuberculosis drugs failed to resolve the infection; subsequent total resection of the node and treatment with isoniazid, clarithromycin and protonamide was successful. *M. interjectum* has been associated with cervical lymphadenitis in a child [JCM (2001) 39 725–727].

*M. intracellulare*. SG; non-pigmented. Similar to *M. avium* but typically arylsulphatase +ve, catalase (68°C) +ve. Tween hydrolysis -ve. Growth occurs at 25–40°C (some strains grow at 40–45°C). (See also MAC.)

*M. kansasii*. SG; usually photochromogenic. Typical tests: arylsulphatase +ve; catalase (68°C) +ve; growth at 25–40°C +ve (some strains grow at 42°C); niacin -ve; reduction of nitrate +ve; T2H test +ve; Tween hydrolysis +ve.

*M. kansasii* can cause human disease similar to pulmonary tuberculosis; moreover, *M. kansasii* can cross-react with *M. tuberculosis* in the AMTDT [JCM (1999) 37 175–178].

However, chemotherapy against *M. kansasii* differs from that used against *M. tuberculosis* (e.g. *M. kansasii* is not susceptible to pyrazinamide); consequently, early identification of the pathogen is essential to ensure correct treatment. [Identification of *M. kansasii* isolates with a DNA probe: JCM (1999) 37 964–970.]

*M. leprae*. SG. The causal agent of LEPROSY. This species can be cultured in the footpads of mice but has not been cultured in cell-free laboratory media. [Review: Book ref. 54, pp 273–307. Various aspects: Ann. Mic. (1982) 133B 5–171. Carbon metabolism in *M. leprae*: JGM (1983) 129 1481–1495.] An examination of the genome sequence of *M. leprae* has revealed massive gene decay, with less than 50% of the genome containing protein-encoding genes [Nature (2001) 409 1007–1011].

*M. lepraemurium*. SG; non-pigmented. The causal agent of murine leprosy. Limited growth has been reported to occur on egg-yolk media when very large inocula are used.

*M. malmoeense*. SG; growth on egg media at 37°C may take up to 12 weeks. This organism can cause disease similar to that associated with members of the *M. avium* complex (see MAC). To facilitate detection/identification of *M. malmoeense* a PCR-based method has been devised and tested successfully [JCM (1999) 37 1454–1458].

*M. marinum*. SG; photochromogenic. Typical tests: arylsulphatase +ve; catalase (68°C) +ve; growth at 30°C +ve; growth at 37°C -ve on primary isolation but +ve after serial subculture; niacin -ve; reduction of nitrate -ve; Tween hydrolysis +ve. This species causes disease in fish and skin granulomas/ulcers in humans [Arch. Derm. (1986) 122 698–703]; it is more common in temperate regions than in tropical regions (cf. *M. ulcerans*).

*M. microti*. SG; aerobic. Non-pigmented. Similar to *M. tuberculosis* but typically gives a variable nitrate reduction test and a negative T2H test. Causal agent of tuberculosis in voles.

*M. paratuberculosis* (*'M. johnei'*). SG; non-pigmented. Typically (results from few strains): catalase (68°C) +ve; niacin -ve; reduction of nitrate -ve; T2H test +ve; Tween hydrolysis variable. (See also IS900 and MYCOBACTINS.)

*M. paratuberculosis* is the causal agent of JOHNE'S DISEASE. (See also CROHN'S DISEASE.) (See also PULSED ELECTRIC FIELD.)

*M. phlei*. RG; scotochromogenic. Typical tests: arylsulphatase -ve (at 3 days) or variable (at 1 week); growth at 52°C +ve; Tween hydrolysis +ve. *M. phlei* is found in soil and on vegetation; it has also been isolated from (i) synovial fluid in a case of Reiter's syndrome, and (ii) a foot wound, and is regarded as an opportunist pathogen.

*M. scrofulaceum*. SG; scotochromogenic. Typical test results: arylsulphatase -ve; catalase (68°C) +ve; growth at 25–42°C +ve; niacin -ve; reduction of nitrate -ve; T2H test +ve; Tween hydrolysis -ve. A causal agent of SCROFULA. (See also MAC.)

*M. senegalense*. RG; scotochromogen. A causal agent of bovine FARCY.

*M. simiae*. SG; some strains photochromogenic, others non-chromogenic. Generally similar to *M. scrofulaceum* but the niacin test is +ve in some strains.

*M. smegmatis*. RG; non-pigmented. Typical test results: arylsulphatase +ve (at 1 week); growth at 45°C +ve; Tween hydrolysis +ve. Found in smegma; believed to be non-pathogenic.

*M. terrae*. SG; non-chromogenic. With *M. nonchromogenicum* and *M. triviale*, forms the 'Terrae group' or *M. terrae* complex - species which are pathogenic but apparently rare.

*M. thermoresistibile*. RG; scotochromogen. Typical test results: arylsulphatase -ve; niacin -ve; reduction of nitrate

–ve; growth at 52°C +ve; Tween hydrolysis +ve; T2H test +ve. Found e.g. in soil. Reported to be pathogenic in lung (several cases); skin and lymph nodes; and breast tissue [JCM (1992) 30 1036–1038].

*M. triplex*. SG; non-pigmented. Isolated from various clinical specimens. [Description of species: JCM (1996) 34 2963–2967.] [*M. triplex* associated with infection in a liver transplant patient: JCM (2001) 39 2033–2034.]

*M. tuberculosis*. SG; aerobic. Non-pigmented. Typical test results: catalase (68°C) –ve; growth at 42°C –ve; growth at 37°C +ve; growth enhanced by glycerol and by pyruvate; niacin +ve; reduction of nitrate +ve; Tween hydrolysis variable; sensitive to pyrazinamide. Usually forms rough, raised, whitish/pale buff colonies ('eugonic' growth).

A casual agent of TUBERCULOSIS.

[Genome sequence of *M. tuberculosis*, strain H37rv: Nature (1998) 393 537–544.] The insertion sequence IS6110 (q.v.) is frequently used for TYPING isolates of *M. tuberculosis*.

*M. ulcerans*. SG; pigmentation variable. Typical test results: catalase (68°C) +ve; growth at 30°C +ve; growth at 37°C –ve; niacin variable; reduction of nitrate –ve; Tween hydrolysis –ve. This species is found in tropical regions e.g. on vegetation; it causes BURULI ULCER.

*M. xenopi*. SG; pigmentation variable. Found in water, and able to cause lesions in the (human) lung. Does not grow at 25°C, grows poorly at 37°C, and has an optimum growth temperature of ca. 42–45°C.

**mycobactins** A family of complex, lipophilic compounds which occur in the cell envelope in most species of *Mycobacterium* (not in *M. paratuberculosis* or in some strains of *M. avium*); they chelate trivalent metal ions, particularly solubilized ferric ions, and are believed to function in iron transport – iron being released after enzymic reduction to the ferrous form. For in vitro growth *M. paratuberculosis* needs mycobactin or e.g. ferric ammonium citrate. [Structure of mycobactins: Book ref. 54, pp. 242–245.] (See also EXOCHELINS and SIDEROPHORES.)

Related compounds occur in *Nocardia*.

**mycobiont** A fungal symbiont – e.g. in a LICHEN or MYCORRHIZA.

**Mycobionta** *Syn.* EUMYCOTA.

**Mycocalia** See NIDULARIALES.

**Mycocaliciaceae** See CALICIALES.

**mycocecidia** GALLS induced by fungi.

**Mycocentrospora** See HYPHOMYCETES; see also CROWN ROT.

**mycochrome** See PHOTOINDUCTION and PHOTOINHIBITION.

**mycodextran** *Syn.* NIGERAN.

**Mycogone** See HYPHOMYCETES; see also BUBBLE DISEASES.

**mycoherbicide** See BIOLOGICAL CONTROL.

**mycolic acids**  $\alpha$ -Substituted,  $\beta$ -hydroxylated fatty acids (having the general formula R'CHOH.CHR''COOH), esters of which are found in the cell walls of e.g. species of *Corynebacterium*, *Mycobacterium*, *Nocardia*, and *Rhodococcus*; in *Mycobacterium* spp the mycolic acids fall within the approximate range C<sub>60</sub>–C<sub>90</sub>, in *Nocardia* C<sub>40</sub>–C<sub>60</sub>, and in *Corynebacterium* C<sub>20</sub>–C<sub>40</sub>.

In mycobacterial mycolic acids R' is usually a C<sub>50</sub>–C<sub>60</sub> chain which often includes double bonds, cyclopropane rings etc, while R'' is a C<sub>22</sub>–C<sub>24</sub> chain. [Structure and biosynthesis: Book ref. 54, pp. 113–128. Mycolic acid patterns in various strains of *Mycobacterium*: JGM (1983) 129 889–891; (1984) 130 363–367, 2733–2736.] (See also WAX D.)

[Mycolic acids in *Corynebacterium* spp: JGM (1984) 130 513–519.]

**mycology** The study of FUNGI.

**mycoparasite** A fungus which is parasitic on other fungi. Mycoparasites include e.g. *Christiansenia pallida* [life history: Mycol. (1984) 76 9–22]; PIPTOCEPHALIS; and *Rozella* spp: endobiotic and holocarpic organisms which parasitize e.g. *Polyphagus euglenae* (itself a parasite of *Euglena* spp) [Mycol. (1984) 76 1039–1048] and other fungi and algae. Certain mycoparasites can apparently exert some control on pathogens of higher plants – e.g., in cases of CLOVER ROT, *Trichoderma viride* (or e.g. *Mitruula sclerotiorum*) can bring about a reduction of the numbers of sclerotia in the soil [Bot. Rev. (1984) 50 491–504]. [Susceptibility of e.g. *Pythium* spp to the mycoparasite *Pythium oligandrum*: SBB (1986) 18 91–96.] (See also CONTACT BIOTROPHIC MYCOPARASITE.)

**mycophagous** (mycetophagous) Fungus-eating.

**mycophenolic acid** An ANTIBIOTIC produced e.g. by *Penicillium brevicompactum* in aerial hyphae formed on solid media [AEM (1981) 41 729–736]. It has antimicrobial and antitumour activity, blocking GMP synthesis by inhibiting the formation of XMP from IMP (see Appendix V(a)).

**Mycoplana** A genus of Gram-negative, aerobic bacteria of uncertain taxonomic affinity; species occur e.g. in soil. The organisms form branching filaments which fragment into irregular, flagellated rods. Some strains can fix nitrogen under microaerobic conditions [JGM (1982) 128 2073–2080]. GC%: ca. 64–69. [Book ref. 46, pp. 2118–2119.]

**mycoplasma** (1) A member of the class MOLLICUTES. (cf. MOLLICUTE.) (2) A member of the genus MYCOPLASMA.

**Mycoplasma** A genus of cell wall-less, sterol-requiring, catalase-negative bacteria (family MYCOPLASMATACEAE) which occur as parasites and pathogens e.g. in the respiratory and urogenital tracts in man and other animals; diseases caused by, or associated with, *Mycoplasma* spp include e.g. AIR SACCULITIS, BRONCHITIS, CONTAGIOUS BOVINE PLEURO-PNEUMONIA, GLASSER'S DISEASE, NON-GONOCOCCAL URETHRITIS, ovine MASTITIS, and PRIMARY ATYPICAL PNEUMONIA (sense 2). (*Mycoplasma* spp are also common contaminants in TISSUE CULTURES.) Cells: typically non-motile (but see below) and pleomorphic, ranging from spherical, ovoid or pear-shaped (ca. 0.3–0.8  $\mu$ m diam.) to branched filamentous forms of near-uniform diameter, several  $\mu$ m to ca. 150  $\mu$ m in length; filaments, the typical forms in young cultures under optimum conditions, subsequently transform into chains of coccoid cells which later break up into individual cells that are capable of passing through membrane filters of pore size 0.22  $\mu$ m or 0.45  $\mu$ m. The cells of some species have a 'tip' structure (possibly part of a microfibrillar 'cytoskeleton') which has been thought to be involved in attachment to host cells, and which (in motile species) appears to have a role in GLIDING MOTILITY – the tip always pointing in the direction of motion.

The attachment organelle and cytoadherence proteins of *M. pneumoniae* have been detected by immunofluorescence microscopy [JB (2001) 183 1621–1630].

The trilaminar cytoplasmic membrane contains sterols (in addition to e.g. phospholipids and proteins) – thus rendering the cells susceptible to POLYENE ANTIBIOTICS and to lysis by e.g. digitonin (which complexes sterols). Some species bear a capsule or slime layer – that in *M. mycoides* subsp *mycoides* being a galactan.

Replication of the genome may precede cytoplasmic division; hence, 'multinucleate' filaments may exist for a time before individual cells are delimited by constriction. Budding can also occur.

Most *Mycoplasma* spp are facultatively anaerobic, some apparently being obligately anaerobic on primary isolation. All species are chemoorganotrophic. 'Fermentative' species can use

## mycoplasma virus type 1 phages

such as glucose (metabolized to e.g. lactic acid via the EMP pathway), while 'non-fermentative' species can use e.g. arginine. All species need cholesterol or related sterols (e.g. cholestanol or stigmaterol). The organisms have a flavin-terminated electron transport chain which lacks both quinones and cytochromes. NADH oxidase occurs in the cytoplasm (cf. *ACHOLEPLASMA*). Growth occurs on complex media (e.g. HAYFLICK MEDIUM); fastidious mycoplasmas may be grown on diphasic SP-4 medium [recipe: Book ref. 22, p. 746]. Colonies (usually <1 mm diam.) are typically of the 'fried egg' type: an opaque, granular central region, embedded in the agar, surrounded by non-granular surface growth. Optimum growth temperature of mammalian strains: 36–37°C. Many species produce weak or clear haemolysis; haemolysis appears to be due to the secretion of H<sub>2</sub>O<sub>2</sub> (a product which is believed to account for some aspects of pathogenicity). Mycoplasmas are commonly sensitive to chloramphenicol and to tetracyclines; most species can tolerate 1:2000/4000 thallos acetate. Broth cultures of *Mycoplasma* spp (supplemented with DMSO or glycerol) can be stored at –70°C; alternatively, broth cultures may be lyophilized. GC%: ca. 23–40. Type species: *M. mycoides*.

The genus currently contains over 60 species which are differentiated on the basis of certain tests: e.g., utilization of glucose and mannose, arginine hydrolysis, phosphatase production, the FILM AND SPOTS reaction, and haemadsorption.

*M. glycyphilum*. An avian species [JGM (1984) 130 597–603].

*M. laidlawii*. Re-classified as *Acholeplasma laidlawii*.

*M. mycoides*. Non-motile cells which often form repeatedly branching filaments. Under certain conditions a culture may contain cells called *rho*-forms; a *rho*-form contains an intracellular organelle (function unknown) which consists essentially of an axial fibre (ca. 40–120 nm diam.) extending the length of the cell and occupying a major part of the cell's volume. *M. mycoides* subsp *mycoides* causes contagious bovine pleuropneumonia.

*M. pneumoniae* (Eaton's agent). A slowly-growing species which causes a primary atypical pneumonia in man. On primary isolation, the colonies (after 5–10 days' incubation) are ca. 50–100 µm in diameter and are entirely granular, i.e., they are not typical 'fried egg' colonies; fried egg colonies generally develop on subculture. The organisms are generally highly sensitive to erythromycin.

*M. pneumoniae* respiratory tract infection is commonly investigated serologically by: (i) a complement-fixation test (CFT) that measures titres of anti-*Mycoplasma* antibodies, or (ii) a more rapid (and more sensitive) immunofluorescence assay for specific IgM antibodies. Following comparison of serology, culture and a PCR-based assay in the diagnosis of *M. pneumoniae* respiratory tract infection in children, it was considered appropriate to use PCR for rapid diagnosis and to confirm/reject any PCR-negative specimens on the basis of CFT examination of paired sera [JCM (1999) 37 14–17].

T-strain mycoplasmas. See UREAPLASMA.

[Book ref. 22, pp. 742–770. *Mycoplasma* characterization: Book ref. 98. *Mycoplasma* evolutionary tree from 5S rRNA sequencing data: PNAS (1985) 82 1160–1164.]

(See also MYCOPLASMAVIRUSES.)

**mycoplasma virus type 1 phages** *Syn.* PLECTROVIRUS.

**mycoplasma virus type 2 phages** *Syn.* PLASMAVIRIDAE.

**Mycoplasmataceae** A family of non-helical, sterol-requiring, cell wall-less bacteria of the order MYCOPLASMATALES. Two genera: MYCOPLASMA (urease-negative) and UREAPLASMA (urease-positive).

**Mycoplasmatales** An order of cell wall-less bacteria of the class MOLLICUTES; it comprises three families: MYCOPLASMATACEAE (non-helical cells which require sterols for growth), ACHOLEPLASMATACEAE (non-helical cells which do not require sterols), and SPIROPLASMATACEAE (cells often helical; sterols required for growth). [Book ref. 22, pp. 741–787.]

**mycoplasma viruses** BACTERIOPHAGES which infect members of the MYCOPLASMATALES: see MV-L3 PHAGE GROUP, PLASMAVIRIDAE, PLECTROVIRUS, SPIROPLASMAVIRUSES. [Review: Intervirology (1982) 18 177–188.]

**mycoplasmosis** Any disease caused by a species of MYCOPLASMA (q.v.)

**mycorrhiza** A stable, usually mutualistic association between a fungus and the root (or rhizoid) of a plant. Mycorrhizas occur in the majority of plants, including vascular and some non-vascular species (e.g. liverworts). The fungi involved (e.g. basidiomycetes, ascomycetes, deuteromycetes) are always associated with the primary cortex of the root, and many appear never to occur as free-living saprotrophs. The formation of mycorrhizas leads to improved uptake of nutrients by the host plant; nutrients are apparently absorbed by hyphae (which may extend some distance from the root) and are transported back to the root to be released into the host tissue. Mycorrhiza formation and efficacy is greatest in nutrient-poor soils, and may be reduced or eliminated by application of soil fertilizers. Three major types of mycorrhiza are recognized.

*Ectomycorrhizas* ('ectotrophic mycorrhizas') occur mainly in temperate forest trees; the fungi involved include basidiomycetes (e.g. agarics, boletes), ascomycetes (e.g. *Tuber* spp) and zygomycetes (*Endogone*). A given tree may associate with more than one species of fungus. In an ectomycorrhiza the fungal hyphae occur on the root surface and may penetrate between the cortical cells of the root, but the cortical cells themselves are not penetrated. Typically, the host root becomes completely enclosed by a sheath of pseudoparenchymal fungal tissue (the *mantle*); hyphae from the mantle may penetrate the soil surrounding the root and also penetrate between the cortical cells of the root to enmesh individual cortical cells in a network of hyphae (the *Hartig net*). The root is morphologically distinct from an uninfected root: e.g., it lacks root hairs and a root cap; it is thicker than an uninfected root and may be a different colour; it may branch extensively and characteristically – e.g. pinnately (in *Fagus* spp) or dichotomously (in *Pinus* spp) – or not at all (e.g. in *Quercus* spp). In certain cases an ectomycorrhiza may develop in the form of nodules (= tubercles), each consisting of a rounded, dense mass of mycorrhizal roots.

Ectomycorrhizal fungi appear to have only limited (or no) ability to use complex carbohydrates (e.g. cellulose); they obtain simple sugars (e.g. glucose, fructose, sucrose) from the plant and store them (e.g. as mannitol, trehalose or glycogen) in the mantle. Benefits to the plant, in addition to improved uptake of nutrients (particularly phosphate), include increased protection from certain pathogens – e.g., the fungus may produce antibiotic(s), or the mantle may function as a mechanical barrier to infection. Many ectomycorrhizal fungi produce PHYTOHORMONES, but the significance of this to the plant is unknown. In certain cases a mycorrhizal association appears to be essential for the normal development of the plant (e.g. in certain *Pinus* spp).

*Endomycorrhizas* ('endotrophic mycorrhizas') involve the development of the fungus *within* the cells of the root cortex; there is usually little or no change in root morphology, and an external fungal sheath is usually not formed. Typically, the fungal hyphae penetrate the cortical cells of the root and develop

intracellularly; subsequently, the hyphae are digested by the root cell, leaving a knot of undigested hyphal wall material in the cell. As the root grows, the fungus invades new cells behind the root meristem; thus, a balance is set up between fungal invasion of the plant and plant digestion of the fungus. There are three main types of endomycorrhiza. (a) The *vesicular-arbuscular* (VA) type, found in a very wide range of plants, in which the (aseptate) fungal hyphae spread through the primary cortex of unsubserved roots and penetrate the cortical cells. A characteristic, much-divided haustorium (the *arbuscule*) is formed, and both intracellular and extracellular hyphae usually develop spherical, lipid-rich, intercalary or terminal swellings (*vesicles*). VA mycorrhizal fungi belong to the genera *Acaulospora*, *Gigaspora*, *Glomus* and *Sclerocystis* (all formerly *Endogone* spp); they have not yet been grown in pure culture. VA mycorrhizas improve uptake of nutrients (particularly phosphate) by the host plant. (b) The *ericoid* type, found in members of the Ericaceae, in which the fungi colonize the fine terminal roots of the host plant and form coils or loops within the host cells. The fungi involved all belong to, or are closely related to, the species *Pezizella ericae*. (c) The *orchid* type, found in embryos and roots in members of the Orchidaceae, in which the fungi penetrate the host cells and form intracellular hyphal coils. All known orchid mycorrhizal fungi are also normal soil saprotrophs or parasites of other plants; they are usually basidiomycetes (e.g. *Armillaria*, *Ceratobasidium*, *Marasmius*, *Thanatephorus*, *Tulasnella*). Mycorrhizal associations appear to be essential to the orchid – at least for germination and seedling growth; orchid seeds are very small and have little or no food reserve, so that (under natural conditions) nutrients must be supplied by an invading fungus for successful germination to occur. Saprotrophic orchids may depend on mycorrhizal fungi throughout their lives, associating with fungi (e.g. *Armillaria mellea*) which can degrade substrates such as cellulose and pectin to simple compounds which the orchid can assimilate. Green orchids generally associate with *Rhizoctonia* (*Thanatephorus*) spp, but may lose their mycorrhizal fungi when mature.

*Ectendomycorrhizas* ('ectendotrophic mycorrhizas') are intermediate in form between ecto- and endomycorrhizas; an organized fungal sheath is formed, and inter- and intracellular penetration of the root cortex occurs. This type of mycorrhiza is formed by only a limited number of plants, including certain members of the Ericaceae – e.g. *Monotropa* (a genus of achlorophyllous herbaceous plants) and *Arbutus* – and the seedlings of certain conifers. The fungi involved are apparently basidiomycetes; some fungi which form ectendomycorrhizas in plants of the Arbutae and Monotropaceae may form ectomycorrhizas in other plants.

[Host–fungus interactions: Book ref. 55, pp. 225–253. General: Book ref. 56. A check list of British mycorrhizas: New Phyt. (1987) 105 (Supplement, 1–102).]

**mycosamine** An aminosugar (3-amino-3,6-dideoxy-D-mannose) found e.g. in NYSTATIN and AMPHOTERICIN B.

**mycoside C** A peptidoglycolipid, distinct from WAX D, formed by some species of *Mycobacterium* (e.g. *M. avium*); in *M. leprae* mycoside C occurs as a fibrillar or crystalline capsule. [Book ref. 54, pp. 28–30.]

**mycosin** *Syn.* CHITOSAN.

**mycosis** Any human or animal disease resulting from infection with a fungus (cf. MYCOTOXICOSIS and MYCETISM). See e.g. ADIASPIROMYCOSIS; ASPERGILLOSIS, BLACK PIEDRA; BLASTOMYCOSIS, CANDIDIASIS; CHROMOBLASTOMYCOSIS; COCCIDIOIDOMYCOSIS;

HISTOPLASMOSIS; LOBOMYCOSIS; MADUROMYCOSIS; ONYCHOMYCOSIS; PARACOCIDIOIDOMYCOSIS; PHAEOPHYCOMYCOSIS; PITYRIASIS NIGRA; PITYRIASIS VERSICOLOR; RHINOSPORIDIOSIS; RINGWORM; SPOROTRICHOSIS; WHITE PIEDRA; ZYGOMYCOSIS.

**mycosis fungoides** A chronic human cutaneous T-cell lymphoma. HTLV-I provirus has been detected in a very small proportion of cases, but HTLV-I is not thought to be an aetiological agent. (cf. ADULT T-CELL LEUKAEMIA.)

**Mycosphaerella** A genus of fungi (order DOTHIDEALES) which include saprotrophs and plant parasites (see e.g. BANANA LEAF SPOT). (See also CLADOSPORIUM.)

**mycotête** See TERMITE–MICROBE ASSOCIATIONS.

**mycotic dermatitis** *Syn.* LUMPY WOOL.

**mycototoxicosis** Any disease of man or animals resulting from the ingestion of MYCOTOXINS (cf. MYCETISM; MYCOSIS). See e.g. ALIMENTARY TOXIC ALEUKIA; DENDRODOCHIOXICOSIS; ERGOTISM; LUPINOSIS, PASPALUM STAGGERS; STACHYBOTRYOTOXICOSIS; YELLOW RICE.

**mycotoxin** A TOXIN produced by a fungus. The term is usually reserved for fungal metabolites that are toxic to man and/or animals and are produced by moulds growing on foodstuffs (cf. MYCETISM). See e.g. AFLATOXINS; ASTELTOXIN; AUROVERTINS; CHLOROPEPTIDE; CITREOVIRIDIN; CITRININ; CYCLOPIAZONIC ACID; ERGOCHROMES; ERGOT ALKALOIDS; OCHRATOXINS; PATULIN; PENITREMS; RUBRATOXINS; SLAFRAMINE; SPORIDEMINS; STERIGMATOCYSTIN; TRICHOHECENES; XANTHOMEGNIN; ZEARALENONE. (cf. IPOMEAMARONE and 4-IPOMEANOL.)

**mycotrophin** See CONTACT BIOTROPHIC MYCOPARASITE.

**mycotrophic** (1) (*of plants*) Refers to the plant partner in a MYCORRHIZA. (2) (*of animals*) Refers to an animal (e.g. an invertebrate) that feeds on fungi.

**Mycotypha** See MUCORALES.

**mycovirus** Any VIRUS which can infect one or more fungi. Mycoviruses have been observed in a wide range of fungi; the majority are isometric (diam. ca. 25–50 nm) dsRNA viruses either with monopartite genomes or with segmented genomes, each segment being encapsidated in a separate particle. Many of the dsRNA virions have been shown to contain an RNA-DEPENDENT RNA POLYMERASE. Six groups of isometric dsRNA mycoviruses have been defined [Interviol. (1984) 22 17–23]. *Group A*: genome monopartite (4.8–6.1 kbp), virion diam. ca. 35–43 nm; members: *Saccharomyces cerevisiae* viruses ScV-L1 (= ScV-LA) and ScV-L2; probable members: *Ustilago maydis* viruses UmV-P1-H1, UmV-P4-H1 and UmV-P6-H1. *Group B*: genome monopartite (8.3 kbp), virion diam. ca. 48 nm; member: *Drechslera* (formerly *Helminthosporium*) *maydis* virus (HmV). *Group C*: genome bipartite (1.6 and 1.4 kbp), virion diam. ca. 30–35 nm; member: *Penicillium stoloniferum* virus S (PsV-S); probable member: *Diplocarpon rosae* virus (DrV). *Group D* (*Gaeumannomyces graminis* virus group 1): genome bipartite (1.8–1.9 and 1.7–1.8 kbp), virion diam. ca. 35 nm; members: *G. graminis* viruses GgV-019/6-A, GgV-OgA-B and GgV-F6-C. *Group E* (*Gaeumannomyces graminis* virus group 2): genome bipartite (2.2–2.3 and 2.0–2.1 kbp), virion diam. ca. 35 nm; members: *G. graminis* viruses GgV-F6-B, GgV-T1-A and GgV-OgA-A. *Group F*: genome tripartite (ca. 3.2, 3.0 and 2.9 kbp), virion diam. ca. 35–40 nm; members: *Penicillium chrysogenum* virus (PcV), *P. brevicompactum* virus (PbV) and '*P. cyaneofulvum*' (= *P. chrysogenum*) virus (Pc-FV). (Pc-FV actually has four dsRNA segments, the 4th probably being a variant, satellite or defective dsRNA.) Two families, Totiviridae and Partitiviridae, have been created to accommodate isometric dsRNA viruses with, respectively, monopartite and bipartite genomes [Interviol. (1986) 25 141–143].

## mycovore

Most dsRNA mycoviruses appear to have a single-layered capsid composed of a single polypeptide species. However, a dsRNA virus from *Lentinula edodes* appears to have a double-shelled capsid [Virology (1982) 123 93–101] and to resemble a PHYTOREOVIRUS. Other mycoviruses include e.g. 'Boletus virus' (a possible member of the POTEXVIRUSES) and mushroom virus 3 (virions bacilliform, ca. 50 × 19 nm); DNA-containing lytic viruses have been observed in certain lower fungi (e.g. *Rhizidiomyces* [Virology (1983) 130 10–20, 21–28]).

Mycoviruses are apparently transmissible only by intracellular routes (e.g. during mating, via spores, or by hyphal anastomosis). In many cases the host fungus shows little evidence of infection (cf. MUSHROOM DISEASES); in certain cases virus infection may affect the virulence of a pathogenic fungus: e.g. an isometric dsRNA virus appears to be associated with virulence in strains of *Rhizoctonia solani* [JGV (1985) 66 1221–1232] – cf. CHESTNUT BLIGHT and DUTCH ELM DISEASE. (See also KILLER FACTOR.)

**mycovore** A fungus-eating animal.

**myelitis** Inflammation of the spinal cord.

**myeloblastosis-associated viruses** See AVIAN LEUKOSIS VIRUSES.

**myeloma** A tumour consisting of a single clone of B LYMPHOCYTES; myelomas can occur spontaneously or they can be induced. A given myeloma secretes Ig ('paraprotein') molecules, all of which are structurally and electrophoretically homogeneous (monoclonal); some myeloma Igs react with environmental antigens. Myeloma cells are used e.g. for HYBRIDOMA formation. (See also BALB/C MICE.)

**myeloperoxidase (MPO)** A haemoprotein (MWt ca. 150000) found e.g. in MACROPHAGES and in the azurophilic granules of NEUTROPHILS; MPO catalyses the oxidation of halide ions to hypohalite. [Role of MPO in oxygen-dependent microbicidal activity of human neutrophils: Blood (1983) 61 483–492.]

**myo-inositol** See INOSITOL.

**myonecrosis** (clostridial) See GAS GANGRENE.

**myoneme** (ciliate protozoal.) A bundle, ribbon or sheet of intracellular protein microfibrils, numbers of which occur in certain ciliates; myonemes are apparently contractile and may thus account for the observed contractility in those organisms which contain them. Myonemes occur below the infraciliature in e.g. *Stentor* and *Spirostomum*; in *Stentor* they are also known as *M bands* or *M fibres*. (See also SPASMONEME.) Myoneme contraction appears to be related to environmental and/or intracellular levels of calcium ions.

**myosin** A rod-shaped protein which occurs in most types of eukaryotic cell; the molecule consists of six polypeptides: two 'heavy chains' and four 'light chains', the light chains occurring at one end of the molecule and contributing to its bulbous 'head'. Myosin molecules can aggregate into bundles, each bundle consisting of a number of longitudinally adjacent molecules arranged so that head regions occur at each end. When contact occurs between a myosin head and an ACTIN microfilament, the head apparently undergoes a conformational change which causes the myosin molecule (or bundle) to move relative to the microfilament; moreover, when interposed between suitably aligned microfilaments, a myosin bundle can apparently cause one microfilament to move relative to the other. Continuing movement of a microfilament relative to a myosin head seems to involve a continual sequence of reversible changes in the conformation of the myosin head – the head repeatedly making and breaking contact with the microfilament, and repeatedly binding and hydrolysing ATP.

**Myoviridae** A family of BACTERIOPHAGES which are characterized by the possession of a long, complex, contractile tail consisting of a central tube surrounded by a coaxial contractile sheath;

the phage head may be isometric or elongated. Type species: T2. Other members include e.g. the T-EVEN PHAGES, BACTERIOPHAGE P1, BACTERIOPHAGE P2, and many other enterobacterial phages; *Bacillus* phages PBS1 (q.v.), SP3, SP8 and SP50; *Clostridium* phage HM3; *Pseudomonas* phage φW-14 (q.v.); etc.

**Myriangium** See DOTHIDEALES.

**Myrica root nodule** See ACTINORRHIZA.

**Myriodesma** See PHAEOPHYTA.

**Myriostoma** See LYCOPERDALES.

**Myrmecia** A genus of unicellular green algae (division CHLOROPHYTA) which may occur as photobionts in certain lichens (see e.g. BAEOMYCES and LOBARIA) or as free-living organisms. The cells are spherical, and each contains a single cup-shaped chloroplast with no pyrenoid; autospores and zoospores may be formed.

**myrotheciotoxicosis** Syn. DENDRODOCHIOTOXICOSIS.

**Myrothecium** See HYPHOMYCETES; see also DENDRODOCHIOTOXICOSIS and TRICHOETHECENES.

**myxamoeba** A non-flagellated amoeboid cell which occurs in the life cycles of the CELLULAR SLIME MOULDS and MYXOMYCETES.

**Myxidium** A genus of protozoa (class MYXOSPORA) which are coelozoic parasites of e.g. sticklebacks (*M. gasterostei*), salamanders (*M. serotinum*) etc. The mature spore contains two polar capsules, one at each end of the spore.

**myxin** An antibiotic produced by *Lysobacter* sp.

**myxo-** A prefix derived from the Greek word for *mucus* or *slime*.

**myxobacter** Any member of the MYXOBACTERIALES.

**Myxobacterales** An order of GLIDING BACTERIA which form *fruiting bodies* (see below) and which have GC values of ca. 68–72%; all species are Gram-negative. (cf. CYTOPHAGALES.) Myxobacteria occur e.g. in soil, on decaying vegetation, and on dung. Vegetative cells, generally 0.4–1.4 × 2–15 μm according to species and growth conditions, may be blunt-ended rods (*Chondromyces*, *Nannocystis*, *Polyangium*) or tapered rods (*Archangium*, *Cystobacter*, *Melittangium*, *Myxococcus*, *Stigmatella*); they bear extracellular slime. The cell wall resembles that of other Gram-negative bacteria (see CELL WALL), although in at least one species (*Myxococcus xanthus*) the peptidoglycan occurs in patches rather than in a continuous layer; the myxobacteria are generally much more sensitive than enteric bacteria to hydrophobic antibiotics such as actinomycin D and novobiocin – suggesting structural differences in the outer membrane. The cells generally contain non-carotenoid pigments and membrane-bound, photoinducible CAROTENOID glycosides (e.g. *myxobacton*: 1',2'-dihydro-1'-glucosyl-4-oxotrolene, and *myxobactin*: 1',2'-dihydro-1'-glucosyl-3,4-dehydrotrolene).

Studies on the motility apparatus of *Myxococcus xanthus* have been carried out with shock-frozen gliding cells [Microbiology (2001) 147 939–947].

Myxobacteria are obligate aerobic chemoorganotrophs. Most species release enzymes which lyse bacteria, yeasts and moulds – organisms which form the primary food source; *Polyangium cellulorum* is atypical in being strongly cellulolytic. Myxobacteria generally grow on solid media containing live or dead microorganisms; the colony or aggregate of cells ('swarm' or 'pseudoplasmodium') is typically thin, flat and wrinkled. Reproduction occurs by transverse binary fission.

Fruiting in myxobacteria may be induced by starvation (or e.g. by the addition of cAMP); the vegetative cells aggregate, and about 80% of them lyse – possibly to provide nutrients for the remainder which become the resting cells (*myxospores*) from which the fruiting body is formed. [Development in *Myxococcus xanthus*: QRB (1984) 59 119–138.] In some genera (e.g. *Chondromyces*, *Nannocystis*, *Polyangium*) the myxospores resemble

vegetative cells, while in others (e.g. *Myxococcus*, *Stigmatella*) they are shorter, or spherical, and refractile; in at least some genera (e.g. *Myxococcus*) the myxospores are more resistant than vegetative cells to e.g. heat and desiccation. (In e.g. *Myxococcus xanthus* myxospore formation – without fruiting – can be induced in broth cultures e.g. by high concentrations of glycerol.) Myxospores can, under suitable conditions, germinate to form vegetative cells – thus completing the life cycle. The myxobacterial fruiting bodies vary in size (from microscopic to ca. 1 mm), shape and composition, according to species; they are often brightly coloured. In some myxobacteria (e.g. *Archangium*, *Myxococcus xanthus*) the fruiting body is merely a small, sessile (non-stalked), rounded or irregularly shaped mound of myxospores set in slime; in *M. stipitatus* it consists of a spherical mass of myxospores raised on a stalk of hardened slime. In many genera the myxospores are enclosed within one or more hard, sac-like structures termed *cysts* or *sporangia*. In *Nannocystis* individual sporangia are embedded in the substrate, while in *Cystobacter* and *Polyangium* the fruiting body consists of a single sessile sporangium or a group of sessile sporangia; in *Chondromyces*, *Melittangium* and *Stigmatella* one or more sporangia occur on simple or branched stalks.

Other myxobacterial genera include e.g. *Angiococcus*, *Coralloccoccus*, *Haploangium* and *Sorangium*.

**myxobactin** See MYXOBACTERALES.

**myxobacton** See MYXOBACTERALES.

**Myxobionta** *Syn.* MYXOMYCOTA.

**Myxobolus** A genus of protozoa (class MYXOSPOREA) which are histozoic parasites in fish. *M. pfeifferi* causes ‘boil disease’ in cyprinid fish, in which the sporonts develop in large (up to 7 cm) tumour-like cysts. *M. cyprini* is a common parasite of the common carp (*Cyprinus carpio*); it develops primarily in the muscle fibres of skeletal muscle, the mature spores subsequently being liberated into the bloodstream where they are retained in the capillaries [Parasitol. (1985) 90 549–555].

**Myxococcus** See MYXOBACTERALES.

**myxoflagellate** A flagellated amoeboid cell formed by members of the MYXOMYCETES.

**Myxogastria** See EUMYCETAZOEA.

**myxoma subgroup** See LEPORIPOXVIRUS.

**myxoma virus** See LEPORIPOXVIRUS and MYXOMATOSIS.

**myxomatosis** An acute infectious disease which primarily affects the European rabbit *Oryctolagus cuniculus*; it is caused by the myxoma virus (see LEPORIPOXVIRUS). In *O. cuniculus* the disease, which is usually rapidly fatal, is characterized by the development of gelatinous tumours (myxomas) in the skin – particularly at mucocutaneous junctions (around the nose, mouth, ears and genitals); the tumours result from accumulation of mucinous material together with cellular proliferation. Transmission occurs (mechanically) via arthropod vectors (rabbit fleas, mosquitoes etc), and by direct contact etc. In its natural host, *Sylvilagus brasiliensis* (a forest rabbit native to Brazil and Uruguay), the myxoma virus usually causes only a localized lesion. Hares and jackrabbits (*Lepus* spp) are generally resistant.

The myxoma virus has been used for the BIOLOGICAL CONTROL of rabbit populations – first in Australia in the early 1950s, later in France and the UK; initially, mortality rates in *O. cuniculus* were very high (up to 99%) but have subsequently declined owing to attenuation of the virus and natural selection of resistant rabbits.

**Myxomycetes** (acellular slime moulds, or ‘true’ slime moulds) A class of SLIME MOULDS of the MYXOMYCOTA (cf. EUMYCETAZOEA). The major vegetative stage is a multinucleate, diploid, migratory

PLASMIDIUM which typically exhibits shuttle streaming (rhythmic reversible flow) of its protoplasm. Multispored, usually macroscopic fruiting bodies develop from the plasmodium. Sexual reproduction occurs in most (if not all) species, and the life cycle typically exhibits alternate haploid and diploid phases. Myxomycetes occur in various habitats, e.g., soil, humus, rotting wood, treebark, dung, decaying vegetation, etc. [Ecologically significant features of myxomycetes: TBMS (1984) 83 1–19.]

*Life cycle.* A haploid spore germinates to release one or more uninucleate myxamoebae or flagellated amoeboid cells (which are typically biflagellated and heterokont); the two types of cell are interconvertible – e.g. myxamoebae may become flagellated in the presence of water. The cells feed phagocytically and osmotrophically, and divide mitotically (flagellated cells first withdrawing their flagella); under unfavourable conditions they may form MICROCYSTS. The amoeboid/flagellated cells function as gametes: cells of compatible mating type fuse, and the zygote develops into the main vegetative stage of the organism, the *plasmodium*. Three main types of plasmodium are distinguished. A *protoplasmodium* is microscopic, resembling a multinucleate amoeba, and lacks reticulations or ‘veins’. Protoplasmodia occur e.g. in ECHINOSTELIUM and many *Licea* spp; each gives rise to a single fruiting body. An *aphanoplasmodium* (formed e.g. by *Stemonitis* spp) is thin, delicate, and inconspicuous, with a reticulum of ‘veins’ leading into a broad, fan-shaped, advancing front; aphanoplasmodia lack a slime sheath, and their protoplasm is relatively non-granular. A *phaneroplasmodium* (formed e.g. in PHYSARUM) resembles an aphanoplasmodium but is much thicker and more robust, and is often conspicuous; its protoplasm is very granular, and it is surrounded by a gelatinous slime sheath – traces of which are left behind on the substratum over which the plasmodium migrates. Shuttle streaming (a rapid, rhythmic, back-and-forth flow) of the protoplasm occurs in aphanoplasmodia and phaneroplasmodia; in protoplasmodia streaming is very slow and irregular. Plasmodia are commonly yellow or white, but they may be e.g. orange, brown, red, violet or black; the larger plasmodia may measure several centimetres to a metre or more across. As it migrates over a substratum, the plasmodium feeds by ingesting bacteria, microalgae, protozoa, yeasts, particles of organic detritus etc, as well as myxamoebae and flagellated cells of its own species (‘cannibalism’); as it grows, its nuclei divide synchronously. Coalescence of two or more plasmodia may occur.

Eventually, the plasmodium gives rise to fruiting bodies (or, in some species, to a SCLEROTIUM). Prior to fruiting, the plasmodium generally flows out onto an exposed surface; in some species light is apparently necessary to initiate fruiting. Three major types of fruiting body are formed, in each of which the spores develop in masses within a persistent or evanescent peridium. A *sporangium* is a relatively small, sessile or stalked structure which is more or less uniform in size and shape for a given species; many sporangia usually develop from a single plasmodium. (See e.g. ARCYRIA and STEMONITIS.) An *aethalium* is typically sessile, relatively large, hemispherical or pulvinate, derived from an entire plasmodium or from a major part of one; aethalia may vary in size and shape even within a single species. (See e.g. LYCOGALA.) (*Pseudoaethalia*, consisting of numerous compacted sporangia, occur in some species.) A *plasmodiocarp* is sessile, irregularly shaped and often branched or reticulate; it is derived from the major veins of an aphanoplasmodium or phaneroplasmodium. (See e.g. HEMITRICHIA.) Depending on species, fruiting bodies may contain e.g. a CAPILLITIUM, COLUMELLA, PSEUDOCAPILLITIUM and/or PSEUDOCOLUMELLA. In some species certain parts of the

## Myxomycota

fruiting body (e.g. peridium, capillitium) bear deposits of lime. Meiosis is believed to occur in the maturing spores; three of the four resulting nuclei apparently degenerate.

Several hundred species of myxomycetes are recognized [descriptions and illustrations: Book ref. 145]. Orders: Echinosteliales (e.g. ECHINOSTELIUM); Echinosteliopsidales (*Bursulla*, *Echinosteliopsis*); Liceales (e.g. *Cribraria*, *Enteridium*, LYCOGALA, *Licea*, *Tubifera*); Physarales (e.g. *Badhamia*, *Didymium*, FULIGO, PHYSARUM); Stemonitales (e.g. *Comatricha*, *Lamproderma*, STEMONITIS); Trichiales (e.g. ARCYRIA, HEMITRICHIA, *Perichaena*, *Trichia*).

**Myxomycota** (Myxobionta) In some mycological classification schemes [e.g. Book ref. 64]: a division which includes the SLIME MOULDS and organisms which resemble slime moulds in certain respects. Classes: ACRASIOMYCETES, Ceratiomyxomycetes (see CERATIOMYXA), DICTYOSTELIOMYCETES, LABYRINTHULOMYCETES, MYXOMYCETES, PLASMODIOPHOROMYCETES, PROTOSTELIOMYCETES. (cf. EUMYCOTA.)

**myxophage** Any bacteriophage whose host is a member of the MYXOBACTERALES. Currently, only DNA myxophages are known; these are designated Mx1, Mx4 etc.

**Myxophyceae** Obsolete class for the CYANOBACTERIA.

**Myxosarcina** A genus of unicellular CYANOBACTERIA (section II) in which growth and binary fission result in cubical aggregates of cells; baecytes initially lack a fibrous outer cell wall layer and are motile (by gliding). GC%: 43–44.

**Myxosoma** A genus of protozoa (class MYXOSPOREA) which are histozoic parasites in fish (see WHIRLING DISEASE).

**myxospore** See MYXOBACTERALES.

**Myxosporaea** A class of protozoa (phylum MYXOZOA) which are parasitic (coelozoic or histozoic) in poikilothermic ('cold-blooded') vertebrates, particularly fish; many members are economically important fish pathogens. The myxosporae spore contains between one and six (typically two) polar capsules (each containing a coiled filament), and one or two sporoplasms; the spore wall consists of two valves (order Bivalvulida: e.g. *Ceratomyxa*, *Chloromyxum*, HENNEGUYA, MYXOBOLUS, MYXOSOMA, MYXIDIUM, *Sinuolinea*, *Sphaeromyxa*, *Sphaerospora*, *Thelohanellus*) or of three or more valves (order Multivalvulida: e.g. *Hexacapsula*, *Kudoa*, *Trilospora*).

*Generalized life cycle.* When ingested by a host animal, the spore explosively discharges its coiled filament(s), the discharged filament apparently serving to attach the organism to the gut epithelium. The amoeboid sporoplasm(s) emerges and passes through the gut wall, subsequently localizing in a

particular tissue (in histozoic species: e.g. species of *Heneguya*, *Kudoa*, *Myxobolus*, *Myxosoma*) or body fluid (in coelozoic species: e.g. *Chloromyxum* spp, *Leptotheca* spp, *Myxidium* spp, *Zschokkella floridanae*). The sporoplasm grows and its nucleus divides many times, resulting in the formation of a multinucleate plasmodium – the main vegetative stage of the organism. Eventually, many of the nuclei in the plasmodium each become segregated into cells (*sporonts*) destined to become spores; depending on species, a sporont may develop into a single spore (monosporous sporont) or into two or more spores within a common envelope (the whole being termed a *pansporoblast*). A sequence of nuclear divisions then ensues, each division apparently giving rise to a 'somatic' nucleus and a 'generative' nucleus. Cells containing somatic nuclei are involved in the formation of the spore wall, polar filament(s) and polar capsule(s), while generative nuclei are incorporated in the sporoplasm(s) (commonly two nuclei per sporoplasm). The mature spores may be released into the bloodstream or may remain in situ until the host is eaten e.g. by another fish or by a bird; in the latter case, the spores may be passed unharmed with the bird's faeces, thus possibly being transported to fresh aquatic habitats. (cf. WHIRLING DISEASE.)

**myxosporidean** (Pertaining to) a protozoon of the MYXOZOA (formerly of the class Myxosporidea, subphylum Cnidospora).

**Myxotheca** See FORAMINIFERIDA.

**Myxotrichum** See GYMNOASCALES.

**myxoviruses** A (non-taxonomic) group of viruses: the ORTHO-MYXOVIRIDAE and PARAMYXOVIRIDAE.

**myxoxanthophyll** See CAROTENOIDS.

**Myxozoa** A phylum of PROTOZOA [JP (1980) 27 37–58] which are mainly intracellular parasites of invertebrates and poikilothermic vertebrates. The organisms form spores of multicellular origin; a spore contains one or more extrusile *polar filaments*, each coiled within a separate sac (the *polar capsule*), and one or more sporoplasms (amoeboid cells which are the infective forms of the organism). The spore wall consists of one, two or three (rarely more) *valves*. Two classes are recognized: ACTINOSPOREA and MYXOSPOREA; however, since two apparently distinct organisms – one from each class – have been found to be different stages in the life cycle of the same organism (see WHIRLING DISEASE), a reappraisal of myxozoan taxonomy may be necessary [discussion: JP (1985) 32 589–591]. (See also MICROSPORA and ASCETOSPOREA.)

**MZ B cells** MARGINAL ZONE B CELLS (q.v.).

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# N

**N** Asparagine (see AMINO ACIDS).

**N-end rule** The observed relationship between the N-terminal amino acid of a protein and the half-life of that protein *in vivo*. In *Escherichia coli*, for example, proteins whose N-terminal amino acid is either arginine or lysine are characterized by a short half-life; early degradation of such proteins may be avoided in strains mutant in the AAT GENE.

**n. gen.** See GENUS NOVUM.

**N-Serve** See NITRAPYRIN.

**n. sp.** See SPECIES NOVA.

**N-type starter** See LACTIC ACID STARTERS.

**NA** Numerical aperture: see RESOLVING POWER.

**Na<sup>+</sup>-ATPase** See ION TRANSPORT and SODIUM MOTIVE FORCE.

**Na<sup>+</sup>-motive force** See SODIUM MOTIVE FORCE.

**Na<sup>+</sup> pump** See ION TRANSPORT.

**nabam** (dithane D-14) Disodium ethyleneBISDITHIOCARBAMATE, an agricultural antifungal agent sometimes used in conjunction with zinc sulphate and lime – when ZINEB is formed.

**nactins** See MACROTETRALIDES.

**NAD** (coenzyme I; cozymase) Nicotinamide adenine dinucleotide (formerly known as diphosphopyridine nucleotide, DPN). NAD is an important coenzyme, functioning as a hydrogen carrier in a wide range of redox reactions; the H is carried on the nicotinamide residue (see figure). The oxidized form of the coenzyme is written NAD<sup>+</sup>, the reduced form as NADH (or NADH + H<sup>+</sup>); hence:

The  $E'_0$  of the NAD<sup>+</sup>/NADH couple is –320 mV.

**NAD phosphate** (NADP: formerly triphosphopyridine nucleotide, TPN, or coenzyme II) functions in the same way as NAD; the  $E'_0$  of the NADP<sup>+</sup>/NADPH couple is –317 mV. Many oxidoreductases are specific for either NAD or NADP, although some can function with either. (When either coenzyme can be used in a given reaction – or e.g. when different coenzymes serve the same function in different organisms – the designation NAD(P) is generally used.) As a broad generalization, NADP is more commonly associated with biosynthetic reactions, NAD with catabolic and energy-yielding reactions. Reduced NADP necessary for biosynthetic reactions may be generated e.g. by

the HEXOSE MONOPHOSPHATE PATHWAY, by the isocitrate dehydrogenase reaction of the TCA CYCLE, and by PHOTOSYNTHESIS in photosynthetic eukaryotes. (See also TRANSHYDROGENASE.) [NADPH production and consumption in yeasts: JGM (1983) 129 953–964.]

In addition to its role as a hydrogen carrier, NAD<sup>+</sup> also functions as an ADP-ribosyl donor in ADP-RIBOSYLATION reactions.

**Biosynthesis of NAD and NADP.** NAD may be synthesized de novo from aspartate and dihydroxyacetone phosphate or from tryptophan (see NICOTINIC ACID; cf. V FACTOR). Nicotinamide released during the degradation of NAD<sup>+</sup> (by NAD<sup>+</sup> nucleosidase) may be re-cycled (i.e., incorporated into new NAD molecules) via the 'pyridine nucleotide salvage cycle'; such a cycle may also be operative in certain organisms which cannot synthesize nicotinic acid/nicotinamide de novo (e.g. *Bordetella pertussis* [AvL (1984) 50 33–37]). NADP is synthesized by the ATP-dependent phosphorylation of NAD by NAD<sup>+</sup> kinase.

**NAD<sup>+</sup> kinase** See NAD.

**NADH–UQ oxidoreductase** Complex I of the mitochondrial ELECTRON TRANSPORT CHAIN.

**NADP** See NAD.

**Nadsonia** A genus of yeasts (family SACCHAROMYCETACEAE) in which the cells are usually lemon-shaped; vegetative reproduction occurs by bipolar bud-fission. Pseudomycelium is not formed. Ascus formation follows conjugation between a bud and its mother cell; ascospores contain a prominent lipid globule and are spherical, brownish, warty or spiny, 1 or 2 per ascus. Glucose is fermented by *N. elongata* and *N. fulvescens*, but not by *N. commutata*. Nitrate is not assimilated. Maximum growth temperature: ca. 24–26°C. Species have been isolated from soil and from the slime flux of trees. [Book ref. 100, pp. 279–284.]

**Naegleria** A genus of amoeboflagellates (order SCHIZOPYRENIDA). Some species (e.g. *N. gruberi*) are entirely free-living. *N. fowleri* (= *N. aerobia*, *N. invades*) is an opportunist pathogen (see MENINGOENCEPHALITIS); it is ca. 10 μm in diameter when rounded, and its single nucleus contains a large central nucleolus. (See also AMOEBOSTOME.) In *N. fowleri* interconversion can occur between the amoebic form and a transient, non-dividing biflagellate form [JB (1981) 147 217–226]. Amoebae can encyst. [ARM (1982) 36 101–123.]

NAD (nicotinamide adenine dinucleotide). NADP = NAD 2'-phosphate.

## nafcillin

**nafcillin** See PENICILLINS.

**naftifine** See ALLYLAMINES.

**NAG vibrios** Non-agglutinable vibrios – see NON-CHOLERA VIBRIOS.

**nagana** Any of a range of trypanosomiasis which affect domestic animals (e.g. cattle) in various parts of Africa and in which the vector is a biting fly, often a species of *Glossina*; the pathogens include *Trypanosoma brucei*, *T. congolense*, *T. suis* and *T. vivax*. Symptoms typically include anaemia, cachexia, and damage to e.g. heart, kidneys and liver; affected cattle typically exhibit a generalized immunosuppression. Abortion and infertility are common in certain areas.

**Nagler's reaction** A test used to detect strains of *Clostridium perfringens* which produce a diffusible LECITHINASE (the  $\alpha$ -toxin). (An antigenically similar phospholipase C, which also cleaves lecithin, is produced by *C. bifermentans*.) When grown on EGG-YOLK AGAR such strains give rise to colonies each of which is surrounded by a zone of opacity. In the Nagler reaction, one half of a plate of egg-yolk agar is spread with anti- $\alpha$ -toxin, and the plate is inoculated with the unknown strain – the inoculum forming a line which extends into both halves of the plate; following incubation, strains which produce  $\alpha$ -toxin produce zones of opacity only in that half of the plate which does not contain antitoxin – although growth occurs in both halves of the plate.

**Nairobi sheep disease** A disease of sheep and goats caused by a virus of the genus **NAIROVIRUS**. It occurs mainly in East Africa. Symptoms include haemorrhagic gastroenteritis, splenomegaly, nephritis, and myocardial degeneration; mortality rates are high. The virus is transmitted by the tick *Rhipicephalus appendiculatus*.

**Nairovirus** A genus of viruses of the **BUNYAVIRIDAE**. Host range: various vertebrates; vectors: primarily ticks. MWts of L, M and S RNAs: ca. 4.1–4.9, 1.5–1.9, and 0.6–0.7  $\times 10^6$ , respectively. MWts of proteins L, G1, G2 and N: ca. 145–200, 72–84, 30–40 and 48–54  $\times 10^3$ , respectively. The genus comprises ca. 6 serogroups, including e.g. the Crimean–Congo haemorrhagic fever group, **NAIROBI SHEEP DISEASE** group, and the Qalyub group.

**naive (immunol.)** Unprimed (cf. **PRIMED**).

**naked** (1) (of viruses) Not enveloped. (2) (of nucleic acids, VIROIDS etc) Not associated with protein.

**nalA gene** See **GYRASE**.

**nalidixic acid** A **QUINOLONE** ANTIBIOTIC. Nalidixic acid inhibits bacterial DNA replication (and, to a lesser extent, RNA and protein synthesis) and causes degradation of DNA in the cell. It acts as a specific inhibitor of **GYRASE**, interfering with the function of the A subunits (cf. **NOVOBIOCIN**) and preventing the breakage-and-reunion activity – and hence the supercoiling and relaxing activities – of the enzyme. The drug apparently causes the formation of a very stable gyrase–DNA complex. In vitro, treatment of the complex with e.g. SDS triggers the cleavage of DNA strands with consequent covalent binding of the 5' ends to the A subunits; in vivo, the complex may block the movement of replication forks [ARB (1981) 50 901–902]. A related quinolone, norfloxacin, has been shown to inhibit gyrase by binding not to the enzyme itself but to regions of ssDNA, suggesting that gyrase is actually inhibited by a DNA–quinolone complex [PNAS (1985) 82 307–311].

[Gyrase-targeted antibiotics: TIM (1998) 6 269–275.]

**name bearer** *Syn.* **NOMENCLATUREL TYPE**.

**naming of microorganisms** See **NOMENCLATURE**.

**NANA** *N*-AcetylNEURAMINIC ACID.

**NANB hepatitis** NON-A–NON-B HEPATITIS.

**Nannizzia** A genus of heterothallic fungi (order **GYMNOASCALLES**) which occur e.g. in soil; anamorphs occur in the genus *Microsporium* (see **DERMATOPHYTES**).

**Nannoceratopsis** A fossil **DINOFLAGELLATE** (lower Jurassic).

**Nannochloris** A genus of green algae. *N. bacillaris* can tolerate a wide range of salinities [stepwise adaptation to salinity: CJB (1985) 63 327–332].

**Nannocystis** See **MYXOBACTERIALES**.

**Nannomonas** A subgenus of **TRYPANOSOMA** within the **SALIVARIA**; species occur, in parts of Africa, as parasites and pathogens in a wide range of wild and domestic animals including cattle, equines and suids (see also **NAGANA**). In the vertebrate host, bloodstream forms are trypomastigotes, <20  $\mu\text{m}$  in length, in which the kinetoplast is subterminal (and typically close to the pellicle) and in which there is no free flagellum. In the vector (*Glossina* spp), trypomastigotes and epimastigotes – which also lack a free flagellum – may reach ca. 40  $\mu\text{m}$  in length. Species include *T. (N.) congolense* and *T. (N.) simiae* (an important pathogen of the pig).

**Nannophrya** See **GYMNOSTOMATIA**.

**nannoplankton** See **PLANKTON**.

**nano bacteria** Minute bacteria, detected e.g. in humans and bovines, which have been classified in the  $\alpha$ -2 subgroup of **Proteobacteria**; the cells are generally about 0.2–0.5  $\mu\text{m}$ , but smaller cells may be seen under the electron microscope (accounting for the ability of these organisms to pass through membrane filters of pore size 0.1  $\mu\text{m}$ ). The cells can form a carbonate apatite deposit on their envelope at near-neutral pH, and it has been suggested that they may contribute e.g. to the development of kidney stones [PNAS (1998) 95 8274–8279] (see also **UROLITHIASIS**).

**Nanochlorum** A genus of very small, unicellular, possibly primitive, eukaryotic green algae (division **CHLOROPHYTA**).

**nanometre (nm)**  $10^9$  m, or  $10^{-3}$   $\mu\text{m}$ .

**nanoplankton** See **PLANKTON**.

**NANP** See **PLASMODIUM**.

**naphthazarins** (naphthazarines) A class of red pigments (5,8-dihydroxynaphthoquinones substituted at position C-2 and sometimes at C-3) produced by **FUSARIUM** spp; they readily chelate multivalent metal ions, and are toxic to plants and insects. Naphthazarins include e.g. fusarubin, isomarticin, javanicin and marticin.

**naphthoquinones** See **QUINONES**.

**naracyclin B** See **CYCLOHEXIMIDE**.

**narasin** An ionophore antibiotic, produced by *Streptomyces aureofaciens*, which is used as an anti-coccidial agent in poultry and as a **FEED ADDITIVE** for ruminants.

**narbomycin** See **MACROLIDE** ANTIBIOTICS.

**NarI** See **RESTRICTION ENDONUCLEASE** (table).

**narrow groove** *Syn.* minor groove (see **DNA**).

**NARTC** Nalidixic acid-resistant thermophilic campylobacters: **CAMPYLOBACTER** strains which are related to but distinct from *C. jejuni* and *C. coli*.

**NASBA** (nucleic acid sequence-based amplification) A method used for the isothermal amplification of RNA target sequences; **NASBA**, which is based on the replication strategy of retroviruses, involves several enzymes (including **REVERSE TRANSCRIPTASE**) and is typically run at  $\sim 41^\circ\text{C}$  for e.g.  $\sim 90$  min. The products include ssRNA amplicons (which are complementary to the target RNA) and double-stranded cDNA.

An outline of **NASBA** is given in the figure.

(*Transcription-mediated amplification* is a very similar process – see **TMA**.)

NASBA (nucleic acid sequence-based amplification): isothermal amplification of an RNA target; amplification is carried out at  $\sim 41^{\circ}\text{C}$ .

The dashed lines are strands of RNA, the solid lines strands of DNA. For each strand the polarity is indicated by a 3' and/or 5' label.

With clinical specimens, amplification of targets is preceded by treatment of the sample to ensure that target sequences, if present, are made accessible. Such pre-treatment necessarily includes release of nucleic acid from organisms and heating to denature target RNA; although RNA is generally single-stranded, intra-strand base-pairing can occur in mRNA and occurs extensively in rRNA. Pre-treatment may also involve inactivation of inhibitory substances. The following stages are involved in amplification:

1. A strand of RNA showing the target sequence (amplicon) delimited by two, short vertical bars. A primer (primer 1) has bound to the 3' end of the amplicon. The 5' end of this primer is tagged with a short sequence (□) containing the *promoter* of an RNA polymerase.
2. The enzyme reverse transcriptase has extended the primer to form a strand of cDNA, thus giving rise to a hybrid RNA:DNA duplex intermediate.
3. The enzyme RNase H has degraded (removed) the RNA strand. Another primer, primer 2, has bound to the 3' end of the cDNA.
4. Reverse transcriptase (which can also synthesize DNA on a DNA template) has extended primer 2 to form double-stranded cDNA; notice that the promoter sequence in primer 1 has also become double stranded as primer 2 has been fully extended on the template to form the complementary strand (■) of the promoter. Now double-stranded, the promoter is functional; an RNA polymerase (○) has bound to the promoter and will synthesize an RNA strand in the direction of the arrow, i.e. in a 5'-to-3' direction.
5. The newly synthesized strand of RNA. Note the strand's polarity: it is *complementary* to the amplicon in the sample RNA (compare 5 with 1).
6. The RNA strand has bound primer 2.
7. Reverse transcriptase has synthesized cDNA on the RNA strand.
8. RNA has been removed by RNase H. Primer 1 has bound to the cDNA.
9. Reverse transcriptase has synthesized a complementary strand of cDNA; note that the 3' end of the template cDNA has also been extended to form a functional (double-stranded) promoter for the RNA polymerase. RNA polymerase has bound to the promoter and will (repeatedly) synthesize RNA strands identical to the one shown at stage 5. These strands can participate in the cyclic phase, leading to high-level amplification of the target. (Continued on page 512.)

## nasopharyngeal carcinoma

As in other nucleic-acid-amplification methods, products can be detected by gel electrophoresis and staining. Alternatively, the amplicons can be monitored by means of MOLECULAR BEACON PROBES [see e.g. NAR (1998) 26 2150–2155].

In clinical microbiology, NASBA is useful e.g. for monitoring the development of transcriptional activity in latent DNA viruses. For example, by monitoring transcripts of the late genes of cytomegalovirus (CMV) it is possible to identify patients at risk for CMV-related disease [JCM (1998) 36 1341–1346]; a commercial assay kit for this purpose has been marketed.

[NASBA in diagnostic microbiology, research and other non-commercial applications: RMM (1999) 10 185–196.]

[Isothermal nucleic-acid-amplification methods (NASBA, TMA, SDA): Book ref. 221, pp 126–151.]

**nasopharyngeal carcinoma (NPC)** A carcinoma arising from the epithelial lining of the post-nasal space. Undifferentiated NPC is associated with EPSTEIN–BARR VIRUS (EBV) infection; the epithelial tumour cells contain multiple copies of EBV DNA, but chromosomal abnormalities have not been detected (cf. BURKITT'S LYMPHOMA). NPC is generally rare, but occurs with high incidence among certain ethnic groups, particularly Cantonese Chinese and Eskimos. Since EBV is ubiquitous, genetic and/or environmental factors are believed to play a role in pathogenesis; nitrosamines (present in salted and dried fish eaten by Cantonese people) and certain components (e.g. phorbol esters) of Chinese herbal medicines have been implicated as potentiating factors.

**nasopharynx microflora** See RESPIRATORY TRACT MICROFLORA.

**nasse** (*protozool.*) *Syn.* CYRTOS.

**Nassellarida** See RADIOLARIA.

**Nassula** A genus of freshwater protozoa (subclass HYPOSTOMATIA). Cells: ovoid to elongate, ca. 150–200 µm in length, completely covered with cilia. Food: e.g. cyanobacteria.

**Nassulida** See HYPOSTOMATIA.

**natamycin** *Syn.* PIMARICIN.

**Natronobacterium** A genus of halophilic, alkalophilic archaeans [FEMS Reviews (1986) 39 9–15].

**Natronococcus** A genus of halophilic and alkalophilic archaeans [FEMS Reviews (1986) 39 9–15].

**natto** A Japanese food made by fermenting soybeans. Soybeans are soaked, steam-cooked, wrapped in rice straw, and incubated at e.g. ca. 40°C for 1–2 days. '*Bacillus natto*' (a strain of *B. subtilis*), supplied by the straw or added as a pure-culture starter, develops and coats the beans with a viscous, sticky polymer; the product develops a strong persistent flavour. [Book ref. 8, pp. 520–521.]

**natural antibodies** Immunoglobulins, present in plasma, which act as antibodies towards antigens with which the body has apparently not been in immunological contact; they may derive e.g. from previous or ongoing subclinical infections or from immunological contact with CROSS-REACTING ANTIGENS.

**natural antigen** *Syn.* ANTIGEN (= IMMUNOGEN sense 1).

**natural immunological tolerance** *Syn.* SELF TOLERANCE.

**natural killer cells** See NK CELLS.

**Naumannella** A genus of bacteria found e.g. in soil and well-waters [see e.g. Book ref. 45, pp. 1049–1059].

**Navicula** A genus of pennate DIATOMS in which the cells are characteristically spindle- or boat-shaped and show gliding motility. Species occur on mud or other substrates in freshwater, marine and terrestrial habitats.

**NBT** Nitroblue TETRAZOLIUM.

**NCAM** See IMMUNOGLOBULIN SUPERFAMILY.

**NCCLS** National Committee for Clinical Laboratory Standards (USA).

**Ncd cells** See PROTOPLAST FUSION.

**NCDO** National Collection of Dairy Organisms, Food Research Institute (Reading), Shinfield, Reading, Berkshire RG2 9AT, UK.

**NCIB** National Collection of Industrial Bacteria, Torry Research Station, P.O. Box 31, 135 Abbey Road, Aberdeen AB9 8DG, Scotland, UK.

**NCMB** National Collection of Marine Bacteria, Torry Research Station, P.O. Box 31, 135 Abbey Road, Aberdeen AB9 8DG, UK.

**NcoI** See RESTRICTION ENDONUCLEASE (table).

**NCPPB** National Collection of Plant Pathogenic Bacteria, Plant Pathology Laboratory, Hatching Green, Harpenden, UK.

**NCS** NEOCARZINOSTATIN (q.v.).

**NCTC** National Collection of Type Cultures, Central Public Health Laboratory, Colindale Avenue, London NW9 5HT, UK.

**NCV** NON-CHOLERA VIBRIO.

**NCVP** Non-O1 *Vibrio cholerae* pilus (non-cholera-vibrio pilus): a filamentous cell-surface appendage found in non-O1 strains of *Vibrio cholerae*, including many strains of the O139 Bengal serogroup. (See also CHOLERA.)

**NDC** Nuclear dehydrogenating clostridia: see GASTROINTESTINAL TRACT FLORA.

**2'-NDG** 2'-Nor-2'-deoxyguanosine: see DHPG.

**Ndumu virus** See ALPHAVIRUS.

**NDV** NEWCASTLE DISEASE VIRUS.

**neamine** (neomycin A) An AMINOGLYCOSIDE ANTIBIOTIC whose molecule contains an aminosugar linked to DEOXYSTREPTAMINE.

**Nebraska calf diarrhoea** See ROTAVIRUS.

**necriidium** (sacrificial cell) In certain filamentous bacteria (e.g. certain cyanobacteria, *Beggiatoa*): a specialized intercalary cell which, by death and lysis, allows fragmentation of the trichome and liberation of hormogonia.

**necrobacillosis** Any of various diseases of man or animals caused by *Fusobacterium necrophorum*.

In humans, *F. necrophorum* can cause e.g. an acute systemic disease characterized by sore throat, submandibular lymphadenopathy, fever with rigors, and subsequently formation of lung abscesses with consequent pleuritic pain and haemoptysis.

In animals, *F. necrophorum* may invade the skin or mucous membranes, usually via damaged tissues, causing necrosis and sometimes abscess formation. In cattle and lambs the pathogen may infect via the navel or rumen and then localize e.g. in the liver. Infections localized to the mouth and larynx ('calf diphtheria') or to the mouth only ('necrotic stomatitis') may also occur. (See also FOOT-ROT.)

NASBA (*continued*)

The double-stranded cDNA templates in stage 9 are permanent products and are continually transcribed by the RNA polymerase. Operation of the cyclic phase produces many copies of the amplicon in the form of (i) complementary RNA (the major product), and (ii) cDNA.

In NASBA, amplification involves three enzymes: reverse transcriptase, RNA polymerase and RNase H; in a similar process, TMA, the role of RNase H is carried out by the reverse transcriptase, so that only two enzymes are used.

Reproduced from *Bacteria*, 5th edition, Figure 8.25, pages 226–227, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

**necrosis** Localized death and degeneration of tissues in a living organism – due e.g. to infection or injury. (See also CASEATION.)

**necrotic stomatitis (vet.)** See NECROBACILLOSIS.

**necrotizing enteritis** *Syn.* ENTERITIS NECROTICANS.

**necrotizing enterocolitis (NEC)** A severe disease of newborn infants; it is characterized by vomiting, abdominal distension, bloody stools, pneumatosis intestinalis, ischaemic necrosis of the intestinal wall and sloughing of the mucosa. The aetiology of NEC is unknown; microorganisms – particularly *Clostridium perfringens* – are believed to play a role in at least some cases. [Book ref. 107, pp. 15–26.]

**necrotizing fasciitis** A condition characterized by soft-tissue oedema and necrosis, with histology-based evidence of necrosis of the superficial fascia, fascial oedema, and an infiltrate of PMNs. A range of bacteria have been isolated from such tissues – including *Staphylococcus aureus*, enterobacteria, and group A streptococci; streptococci have been causally connected with the disease in about 10% of cases.

Identification of the causal agent in a given case facilitates the choice of appropriate chemotherapy; moreover, necrotizing fasciitis may be associated with a risk of familial transmission – a possible indication for chemoprophylaxis of close contacts.

Tissue samples/blood may be culture-negative owing to prior chemotherapy. A small PCR-based study, designed to detect streptococci, found that all 10 cases of confirmed streptococcal aetiology could be identified by testing for the *speB* gene (which encodes exotoxin B in almost all group A streptococci) [JCM (1998) 36 1769–1771].

**necrotizing toxin** A TOXIN which can cause NECROSIS.

**necrotroph** (1) An organism which kills part or all of another organism before deriving nutrients from it; the term is usually applied to an association between a plant and a microorganism.

(2) An organism which derives nutrients from dead plant or animal tissues, whether or not it is responsible for the death of those tissues.

(*cf.* BIOTROPH; PERTHOTROPH.)

**nectin** Protein which forms the 'stalk' region of mitochondrial PROTON ATPASE.

**Nectria** A genus of fungi (order HYPOCREALES) which include plant-pathogenic species (see e.g. APPLE CANKER and BEECH BARK DISEASE; see also PISATIN); anamorphs occur in the genera ACROMONIUM, CYLINDROCARPON and FUSARIUM.

*N. cinnabarina* occurs mainly on the dead branches of woody plants; however, it can cause dieback (particularly in e.g. *Acer* spp), gaining access e.g. via wounds or via dead tissues. Unicellular conidia are formed on simple or sparsely branched conidiophores which develop on orange-pink sporodochia (ca. 1–5 mm diam.) – hence the popular name 'coral spot'. Dark red perithecia (the overwintering stage) subsequently develop on the same sporodochium; each ascus contains eight two-celled ascospores.

*N. galligena* differs from *N. cinnabarina* e.g. in that the conidia are multiseptate and the perithecia are formed singly, without the development of a stroma.

**needle (bacteriol.)** *Syn.* STRAIGHT WIRE.

**needle complex** Part of a type III PROTEIN SECRETION system: a multi-protein structure consisting of a base, which spans the cell envelope, and a needle-like extension from the surface of the bacterium; in overall structure, this complex resembles the hook–basal body portion of a bacterial FLAGELLUM. Studies on the type III protein secretion system of *Salmonella typhimurium* have found that the *prgI* gene product is the main component

of the needle, and that the length of the needle is regulated by the *invJ* gene product [PNAS (2000) 97 10225–10230].

[Structure and composition of the *Shigella flexneri* needle complex: Mol. Microbiol. (2001) 39 652–663.]

Studies on *Yersinia enterocolitica* suggest that the needle is formed by polymerization of a 6 kDa protein, and that polymerization of this protein provides the force necessary for puncturing the cytoplasmic membrane of a eukaryotic cell [PNAS (2001) 98 4669–4674].

**Neethling virus** See LUMPY SKIN DISEASE.

**negative complementation** See COMPLEMENTATION TEST.

**negative contrast** See ELECTRON MICROSCOPY (a).

**negative control** (of an operon) See OPERON.

**negative interference (genetics)** See INTERFERENCE (2).

**negative Pasteur effect** *Syn.* CUSTERS EFFECT.

**negative phase (immunol.)** The phase in which the *in vivo* titre of a given antibody is reduced following administration of the homologous antigen – due to combination of the antigen with circulating antibody.

**negative-sense genome** See VIRUS.

**negative staining** See STAINING and ELECTRON MICROSCOPY (a).

**negative-strand virus** A VIRUS (q.v.) with a negative-sense genome.

**Negishi virus** See FLAVIVIRIDAE.

**Negri bodies** Acidophilic, intracytoplasmic INCLUSION BODIES which develop in cells of the CNS in most cases of human or animal RABIES. They may occur only in the late stage of the disease, and are not formed in FIXED VIRUS infections.

**negro coffee mosaic virus** See POTEXVIRUSES.

**neighbour exclusion principle** See INTERCALATING AGENT.

**Neisser–Wechsberg leucocidin** See *staphylococcal*  $\alpha$ -HAEMOLYSIN.

**Neisseria** A genus of aerobic, oxidase-positive, Gram type-negative bacteria (family NEISSERIACEAE) which occur as parasites or as primary or opportunist pathogens on the mucous membranes of mammals. Cells: typically cocci, 0.6–1.0  $\mu$ m in diameter (which often occur singly, or in pairs with adjacent sides flattened or concave), but in one species (*N. elongata*) the cells are rod-shaped, ca. 0.5  $\mu$ m in width, and often occur as diplobacilli; the cells tend to resist decolorization in the Gram stain. Cells may exhibit TWITCHING MOTILITY, and in some species the FIMBRIAE are associated with pathogenicity. (See also ANTIGENIC VARIATION and IGA1 PROTEASES.) *N. gonorrhoeae* and *N. meningitidis* are nutritionally fastidious (isolation and general culture media including e.g. THAYER–MARTIN AGAR, MUELLER–HINTON MEDIUM and CHOCOLATE AGAR); the other species of *Neisseria* are able to grow on unenriched nutrient agar. The growth of all species is improved by a high relative humidity (ca. 50%). Optimum growth temperature: ca. 35–37°C. All strains form CARBONIC ANHYDRASE (*cf.* MORAXELLA). Most strains form catalase – some strains of *N. elongata* are catalase-negative. (See also SUPEROXOL TEST.) *Neisseria* spp are highly susceptible to desiccation and to exposure to direct sunlight. GC%: ca. 46.5–53.5. Type species: *N. gonorrhoeae*.

*N. canis*. Some strains are haemolytic on rabbit blood; no acid from glucose or other sugars; nitrate is usually reduced; a yellow pigment is formed. Strains have been isolated e.g. from the throats of cats.

*N. caviae*. See FALSE NEISSERIAE.

*N. cinerea*. Non-haemolytic; no acid from glucose or other sugars.

*N. cuniculi*. See FALSE NEISSERIAE.

## Neisseriaceae

*N. denitrificans*. Non-haemolytic; acid is usually formed from glucose, fructose, mannose and sucrose, but not from maltose.

*N. elongata*. Cells rod-shaped; non-haemolytic; can grow in unenriched peptone media; some strains (subsp. *glycolytica*) cause weak acidification of glucose media and are catalase-positive, while others (subsp. *elongata*) do not acidify glucose media and are catalase-negative.

*N. flavescens*. Non-haemolytic; no acid is produced from glucose or other sugars; yellow pigment is formed on Loeffler's serum medium.

*N. gonorrhoeae* (the gonococcus). The causal agent of GONORRHOEA (and a common cause of ophthalmia neonatorum) in man, but apparently not pathogenic in other animals. Culture is carried out under 3–10% CO<sub>2</sub>. Colonies (48-hour): typically round, smooth, convex, greyish-white, opaque, 0.6 mm to >1 mm in diameter, usually becoming mucoid on further incubation. Non-haemolytic. Acid (no gas) is usually formed from glucose but not from other sugars. (See also FIMBRIAE; PEPTIDOGLYCAN; TRANSFORMATION.)

Certain Opa<sup>+</sup> strains of *N. gonorrhoeae* (see OPA PROTEINS) are capable of TRANSCYTOSIS [see e.g. TIM (1998) 6 489–495].

*N. gonorrhoeae* can be detected in clinical specimens by culture and e.g. by a PROBE-based test [PACE 2C test: JCM (1995) 33 2587–2591] and by the ligase chain reaction [Abbott LCx assay (target: *opa* gene): JCM (1998) 36 1630–1633].

[*N. gonorrhoeae* (various molecular TYPING methods): RMM (1998) 9 1–8.]

*N. lactamica*. Some strains are haemolytic (horse blood); acid is usually formed from glucose and maltose, and (unlike other neisseriae) from lactose.

*N. meningitidis* (the meningococcus). A causal agent of MENINGITIS. Culture is carried out under 5–10% CO<sub>2</sub> (which enhances growth). Colonies (24-hour) on Mueller–Hinton agar are typically round, smooth, translucent and butyrous, 1 mm or more in diameter, becoming viscid on further incubation. Non-haemolytic. Acid (no gas) is usually formed from glucose and maltose but not from fructose, lactose, mannose or sucrose. Nitrate is not reduced.

Serogroups A, B, C, D, H–L, X, Y, Z, Z' (= 29E) and W-135 have been distinguished on the basis of polysaccharide capsular antigens. Strains of serogroups A and C (sometimes B) are commonly associated with epidemics. Strains of serogroups H–L are apparently not pathogenic. Strains of serogroups Z and Z' are reported to be killed by normal human serum, and to give rise to disease only in those with underlying health problems.

PCR-based typing of *N. meningitidis* (culture-independent typing, i.e. typing direct from the clinical specimen) may be achieved with specimens that have become culture-negative owing to pre-admission chemotherapy [JCM (1997) 35 1809–1812].

For multilocus sequence typing (see MLST) of *N. meningitidis*, a database of allelic profiles may be found at the website:

<http://mlst.zoo.ox.ac.uk>

[MLST: TIM (1999) 12 482–487.]

*N. mucosa*. Non-haemolytic; acid is usually formed from glucose, maltose, fructose and sucrose; colonies are typically mucoid; unlike most other neisseriae *N. mucosa* reduces nitrate.

*N. ovis*. See FALSE NEISSERIAE.

*N. sicca*. Haemolysis may be exhibited on horse, human, rabbit and/or sheep blood agar; acid is usually formed from glucose, fructose, maltose and sucrose; colonies are dry and wrinkled, and the growth agglutinates spontaneously in saline.

*N. subflava*. Non-haemolytic; acid is usually formed from glucose and maltose, and sometimes from fructose and sucrose. Some strains are saline-agglutinable.

**Neisseriaceae** A family of aerobic, chemoorganotrophic, non-motile, asporogenous Gram type-negative bacteria which are typically parasitic and/or pathogenic in warm-blooded hosts. Most or all strains are oxidase +ve.

The family Neisseriaceae formerly included the genera ACINETOBACTER, KINGELLA, MORAXELLA and NEISSERIA [Book ref. 22, pp 288–309]. The genera *Acinetobacter* and *Moraxella* have been transferred to the family MORAXELLACEAE.

**nekton** Collectively, the actively motile organisms in a body of water (e.g. lake, sea). (cf. PLANKTON; see also NEUSTON.)

**nelfinavir** See ANTIRETROVIRAL AGENTS.

**Nelsonian illumination** *Syn.* CRITICAL ILLUMINATION.

**nematode-trapping fungi** See NEMATOPHAGOUS FUNGI.

**nematodesma** One of a number of bundles of microtubules which reinforce the walls of the ciliate CYTOPHARYNX. (cf. TRICHITE.)

**nematophagous fungi** A heterogeneous group of fungi which derive nutrients from nematode worms. Many are predatory, trapping and killing their prey before invading its tissues, while others infect and apparently parasitize nematodes; most can also grow saprotrophically. Nematophagous fungi occur e.g. in soil and decaying organic matter.

(a) *Nematode-trapping fungi*. Most fungi in this category produce various types of specialized 'trap', generally in response to the presence of nematodes or of compounds such as certain peptides or amino acids (collectively termed 'nemin'). These traps may be simple adhesive knobs (e.g. in *Acaulopage pectospora* [CJB (1985) 63 1386–1390], *Dactylaria candida* [CJB (1977) 55 2956–2970] and *Monacrosporium drechsleri*), relatively undifferentiated adhesive lateral hyphal branches (e.g. in *Tripodsporina aphanopaga*) or adhesive hyphal branches which branch and anastomose to form two- or three-dimensional networks (e.g. in *Arthrobotrys oligospora*, *Dactylella cionopaga* [CJB (1984) 62 674–679], and some *Monacrosporium* spp.) [*A. oligospora*: AvL (1985) 51 385–398 (EM study), 399–407 (microbodies in trap cells); FEMS Ecol. (1985) 31 17–21 (trap formation in liquid culture).] Non-adhesive hyphal rings are formed by some species, and these rings may be constricting (e.g. in *Arthrobotrys dactyloides*, *Dactylaria brochopaga* [CJB (1977) 55 2945–2955], *Dactylella* spp) or non-constricting (e.g. *Dactylaria candida* – which also forms adhesive knobs). When a nematode enters a ring of the constricting type, the ring constricts abruptly, trapping and killing the animal; the mechanism of constriction is unknown, but apparently involves the rapid swelling of cells of the ring in response to contact between the *inner* surface of the ring and the nematode. In the case of a non-constricting ring, a nematode of appropriate size may be trapped when it begins to move through the ring but is too wide to pass right through; in *D. candida* the rings are apparently not effective traps [CJB (1977) 55 2956–2970].

Some fungi (e.g. *Stylopaga*) can trap nematodes without the formation of specialized structures; when a nematode contacts a hypha, the hypha secretes at the point of contact an adhesive which traps the animal.

(b) *Fungi endoparasitic in nematodes*. Some species (e.g. *Meria coniospora*) produce adhesive conidia which adhere to a nematode and germinate, the hyphae then invading the animal; after the death of the host, conidiophores emerge from the body. *Harposporium* spp produce non-adhesive conidia, and a nematode becomes infected by ingestion of these conidia. Certain

chytridiomycetes (e.g. *Catenaria*), oomycetes (e.g. *Nematophthora gynophila*) and zygomycetes (e.g. *Gonimochaete pyriforme* [EM study: CJB (1985) 63 2326–2331]) can infect and parasitize nematodes; *N. gynophila* can apparently play a role in the control of the cereal cyst nematode, *Heterodera avenae* [Nematol. (1980) 26 57–68].

**Nematophthora** See NEMATOPHAGOUS FUNGI.

**Nematospora** A genus of fungi (family METSCHNIKOWIACEAE) in which multilateral budding occurs; a well-developed pseudomycelium is usually formed, and true mycelium may be formed. Ascospores: fusiform with a whip-like appendage at one end, usually 8 per ascus. Species occur mainly as parasites and pathogens of plants (see e.g. STIGMATOMYCOSIS). [Book ref. 100, pp. 285–288.]

**Nematosporaceae** *Syn.* METSCHNIKOWIACEAE.

**Nematostelium** See PROTOSTELIOMYCETES.

**nemin** See NEMATOPHAGOUS FUNGI.

**neantigen** An antigen formed in vivo by the combination of a protein with an exogenous substance. (See also CONTACT SENSITIVITY.)

**Neocallimastix** A genus of anaerobic fungi found in the RUMEN; species include *N. patriciarum* [TBMS (1986) 86 178–181, 103–109] and *N. frontalis*. *N. frontalis* forms multiflagellate zoospores [ultrastructure: CJB (1983) 61 295–307] and produces an extracellular cellulase which is more effective than any other known cellulases in solubilizing the extensively hydrogen-bonded cellulose in cotton fibres [FEMS (1986) 34 37–40]. It has been proposed that *Neocallimastix* be placed in an amended class CHYTRIDIOMYCETES. [Mitosis in and phylogeny of the genus *Neocallimastix*: CJB (1985) 63 1595–1604.]

**neocarzinostatin (NCS)** An antitumour agent, produced by *Streptomyces carzinostaticus*, which consists of an acidic 109-amino-acid protein (containing two disulphide bonds) linked non-covalently to a complex, highly labile, non-protein chromophore which is responsible for the activity of the drug. In vitro, NCS interacts with DNA (its chromophore behaving as an INTERCALATING AGENT), causing single-stranded breaks in which the 3' and 5' ends generally bear 3'-phosphate and 5'-aldehyde groups, respectively; strand breakage occurs mainly at thymidine and deoxyadenosine residues and requires the presence of a thiol and O<sub>2</sub> as cofactors. NCS-induced strand breakage in intact cells appears to occur by a reaction similar to that in vitro [Biochem. (1987) 26 384–390]. NCS can also cause e.g. release of free bases (particularly thymine and adenine) from the DNA.

**Neodiprion sertifer NPV** See BACULOVIRIDAE.

**neogregarines** See GREGARINASINA.

**neomycin** Either of two related AMINOGLYCOSIDE ANTIBIOTICS (neomycins B, C) produced by *Streptomyces fradiae*; the drug used clinically consists mainly of neomycin B with some neomycin C. (cf. NEAMINE.)

**neonatal calf diarrhoea coronavirus** See CORONAVIRIDAE.

**neonatal herpes** See HERPES SIMPLEX.

**neoplasia** Progressive, uncontrolled cell division which, if the progeny cells remain localized (at least initially), results in the formation of an abnormal growth (tumour, neoplasm). (cf. HYPERPLASIA.) In man or animals, a neoplasm may be BENIGN or MALIGNANT (sense 2). (See also CANCER; cf. LEUKAEMIA.)

**neoplasm** See NEOPLASIA.

**Neorickettsia** A genus of Gram-negative bacteria of the tribe EHRLICHIEAE. Cells: coccoid, often pleomorphic, non-motile, maximum dimension ca. 0.5 µm. Growth occurs intracytoplasmically in lymphoid cells of canine animals. Growth does not occur in cell-free media. Type species: *N. helminthoeca*.

*N. helminthoeca*, the sole species, is the causal agent of 'salmon poisoning' in dogs: a disease (usually fatal in untreated cases) which is transmitted by trematodes (flukes) and in which the pathogen occurs singly or in colonies in the cytoplasm of reticuloendothelial cells in lymphoid tissue; the pathogen has not been detected microscopically in circulating lymphocytes, but the blood of a diseased animal is infectious. The fluke-borne disease of dogs known as Elokomin fluke fever appears to be a different disease since immunity to this disease does not confer immunity to salmon poisoning. [Book ref. 22, pp. 710–711.]

**neosaxitoxin** See SAXITOXIN.

**Neo-Sensitabs®** Antibiotic-containing tablets which are used (in place of antibiotic-impregnated paper discs) in antibiotic-sensitivity tests; they are used e.g. in Denmark, Holland, Belgium, Norway, Finland and other countries. Neo-Sensitabs® (produced by A/S ROSCO, Taastrup, Denmark) are colour-coded for identification, and most are stable at room temperature for a minimum of 4 years.

**neosolaniol** See TRICHOHECENES.

**neostibosan** See ANTIMONY.

**neoteny** The persistence, in a mature organism, of features which are characteristic of the immature organism.

**neotype** Any strain which has been described and published in accordance with the relevant nomenclatural code in order to serve as a NOMENCLATORIAL TYPE in place of e.g. a nomenclatorial type which is no longer extant.

**Neovossia** See USTILAGINALES and KARNAL BUNT.

**neoxanthin** See CAROTENOIDS.

**nephelometry** Any procedure in which the concentration of cells (or particles) in a suspension is estimated by passing a beam of (monochromatic) light through the suspension and measuring the intensity of the scattered light – commonly at 90° to the incident light (cf. TURBIDIMETRY). Light scattering is due to intracellular refraction, diffraction, and reflection from the cell surface; the amount of light scattered becomes greater with increases in cell concentration, cell size, and length of light path through the suspension, and with decreases in the wavelength of the incident light. The intensity of the scattered light varies with its angular displacement from the axis of the incident light – exhibiting several peaks of intensity; these peaks are due to interference phenomena. The relationship between the intensities of the incident and scattered light and the concentration of cells is given by:

$$\log_{10}(I_0/I_{\text{scat}}) \propto 1/(\text{cell concentration})$$

where  $I_0$  is the intensity of incident light, and  $I_{\text{scat}}$  is the intensity of scattered light. The sensitivity of a nephelometer is lower when cell concentrations are high owing to the effects of secondary scattering, i.e., redirection of a deflected ray by other cell(s). (See also COUNTING METHODS.)

**nephridial network** See CONTRACTILE VACUOLE.

**nephritic** (1) Pertaining to, or affected with, nephritis. (2) Of or pertaining to the kidneys.

**nephritis** Inflammation of the kidney. (See PYELONEPHRITIS.)

**nephritogenic** Causing nephritis.

**Nephroma** A genus of foliose LICHENS (order PELTIGERALES); photobiont: *Coccomyxa* or *Nostoc*, according to species. Thallus: lobed, corticate on both surfaces, grey, green or brown; apothecia (rare e.g. in *N. expallidum*, common e.g. in *N. laevigatum*) are formed on the lower surface of the thallus near the margins; fertile lobes are usually held erect. Other structures which may be present include *Nostoc*-containing cephalodia (in *Coccomyxa*-containing species – e.g. *N. arcticum*), tubercles on

## *Nephroselmis*

the lower surface (*N. resupinatum*), soredia on the upper surface (*N. parile*) and tomentum on the lower surface (many species). *Nephroma* spp occur mainly on mossy trees and rocks e.g. in boreal regions.

***Nephroselmis*** See MICROMONADOPHYCEAE.

**nephrotoxic** Toxic to the kidneys.

**nepoviruses** ('nematode-transmitted polyhedral viruses'; tobacco ringspot virus group) A group of ssRNA-containing PLANT VIRUSES which have a wide host range. Infected plants may be symptomless, or the leaves may initially develop ringspots, spots, mottling, curling etc; leaves produced subsequently may be symptomless. Vesicular inclusion bodies occur in the cytoplasm of infected cells, usually near the nucleus. Transmission occurs via seeds, via soil nematodes (e.g. *Longidorus* spp), and (experimentally) mechanically; replication does not occur in the nematode vector. Type member: tobacco ringspot virus (TobRV); other members include e.g. cherry leaf roll virus, chicory yellow mottle virus, cocoa necrosis virus, peach rosette mosaic virus, potato black ringspot virus, raspberry ringspot virus, tomato black ring virus, tomato ringspot virus. Possible members: cherry rasp leaf virus, satsuma dwarf virus, strawberry latent ringspot virus, tomato top necrosis virus.

Virion: icosahedral, ca. 28 nm diam.; genome: two linear, positive-sense ssRNA species, RNA1 (MWt ca.  $2.8 \times 10^6$ ) and RNA2 (MWt ca.  $1.3\text{--}2.4 \times 10^6$ ). Virus particles may contain either RNA1 (B particles) or RNA2 (M particles), M and B particles being distinguished by their sedimentation coefficients; T particles contain no RNA, while some (B-like) particles may contain two molecules of RNA2. Both M and B particles are necessary for infectivity. Particles of some nepovirus isolates may also contain a SATELLITE RNA.

RNA1 and RNA2 show little sequence homology; they are polyadenylated at the 3' end and each is covalently linked to a small polypeptide (MWt ca. 3000–6000) which is necessary for infectivity. RNA1 encodes the genome-linked polypeptide and (possibly) the virus-specific replicase; RNA2 encodes the coat protein.

**neritic** Of or pertaining to coastal waters.

**Nernst equation** See e.g. ION TRANSPORT.

**nested PCR** (nPCR) A variant form of PCR carried out in two phases. In the initial phase, a standard form of PCR is run for e.g. ~25 cycles; in the second phase, an aliquot of product from the first phase is used as template for another phase of amplification using a (different) pair of primers that are complementary to subterminal (internal) sequences within the first-phase amplicon. Primers used in the first and second phases have been referred to as 'outer' and 'inner' primers, respectively.

The object of nPCR is to improve sensitivity and specificity in a PCR assay; such improvements may reflect e.g. the extra stage of amplification and the competitive advantage of a shorter amplicon during the second phase. nPCR has been particularly useful for amplifying samples of DNA which are in poor condition or which are of limited quantity.

nPCR assays may suffer from susceptibility to contamination during preparation of the second stage of amplification. However, the problem of contamination can be minimized by using so-called 'one-tube' protocols.

One-tube nPCR has been used e.g. for detecting *Trichomonas vaginalis* in vaginal discharge [JCM (1997) 35 132–138]. Both sets of primers were included in a single reaction mixture (which used the *hot-start* approach). In the first phase of amplification (30 cycles) the annealing temperature was 62°C; at this temperature only the outer primers were able to bind. In the second phase

of amplification (20 cycles) the annealing temperature was lowered to 45°C – permitting binding of the inner primers and leading to the formation of second-phase amplicons. Detection of the second-phase amplicons involved pre-labelling of inner primers. One type of primer was 5'-biotinylated while the other was 5'-labelled with DIGOXIGENIN – so that the double-stranded amplicon was labelled with both compounds. By means of the biotin tag, amplicons were captured on an AVIDIN-coated microtitre plate; an antidigoxigenin–alkaline phosphatase conjugate was used to label the amplicon (by digoxigenin–antidigoxigenin binding), and the label (enzyme) was detected by addition of a reagent (*p*-nitrophenylphosphate) and monitoring colorimetrically at 405 nm for the enzymic cleavage products.

Other examples of nPCR include detection of *Mycobacterium malmoense* [JCM (1999) 37 1454–1458], and nested duplex PCR for the detection of *Bordetella pertussis* and *B. parapertussis* [JCM (1999) 37 606–610].

**net blotch** A CEREAL DISEASE, caused by *Pyrenophora teres*, which affects mainly winter barley. Pale, yellowish blotches, later turning brown, appear on leaves in the autumn; the brown lesions, which have a net-like appearance, may coalesce to form longitudinal stripes. (See also FLUTRIAFOL, GUAZATINE, PROCHLORAZ, PROPICONAZOLE.)

**net plasmodium** See LABYRINTHULAS.

**net slime moulds** See LABYRINTHULAS.

**netilmicin** An AMINOGLYCOSIDE ANTIBIOTIC.

**netropsin** A basic oligopeptide ANTIBIOTIC (isolated from '*Streptomyces netropsis*') containing two *N*-methylpyrrole rings; the functionally similar *distamycin A* contains three such rings. Both netropsin and distamycin bind specifically and avidly to B-DNA, with a strong preference for AT-rich regions [DNA–drug specificity: PNAS (1985) 82 1376–1380]; the drug appears to bind (non-intercalatively) in the minor groove (see DNA). Both drugs show antimicrobial and antitumour activity (apparently by inhibiting synthesis of RNA and DNA) and inhibit the development of DNA viruses, but they are too toxic for clinical use. Low concentrations of netropsin have been reported to inhibit sporulation without affecting growth in *Bacillus subtilis* [CJM (1980) 26 420–426].

**Neuberg's fermentations** Neuberg's '1st form of fermentation' is the ALCOHOLIC FERMENTATION as normally carried out by yeasts such as *Saccharomyces*. Neuberg's '2nd form of fermentation' (= 'glycerol fermentation', 'sulphite fermentation') refers to the alcoholic fermentation perturbed by the presence of sodium bisulphite (NaHSO<sub>3</sub>). Bisulphite forms an addition compound with acetaldehyde, preventing its reduction (by NADH) to ethanol; NADH (from the EMP pathway) instead reduces dihydroxyacetone phosphate to glycerol-3-phosphate – which is dephosphorylated to GLYCEROL. Neuberg's '3rd form of fermentation' refers to the alcoholic fermentation perturbed by imposed alkalinity; the end products are glycerol, ethanol and acetic acid.

**Neufchatel cheese** See CHEESE-MAKING.

**Neufeld quellung phenomenon** See QUELLUNG PHENOMENON.

**neuraminic acid** A C<sub>9</sub>-compound (5-amino-3,5-dideoxy-D-glycero-D-galactonolulosonic acid) derived from mannosamine and pyruvate; *N*-acetyl and *O*-acetyl derivatives (e.g. *N*-acetylneuraminic acid, NANA) are called *sialic acids*. Sialic acids occur widely in animal tissues and fluids – e.g. in glycolipids, mucopolysaccharides and mucoproteins in mucous secretions, serum, brain glycolipids (gangliosides), milk (*N*-acetylneuraminylactose), etc. Terminal sialic acid residues in glycoprotein or glycolipid cell membrane components serve as

receptor sites for the adsorption of certain viruses (see e.g. INFLUENZAVIRUS). (See also COLOMINIC ACID; NEURAMINIDASE; COMPLEMENT FIXATION (b).)

**neuraminidase** (acylneuraminyl hydrolase, EC 3.2.1.18; sialidase) An enzyme which hydrolyses  $\alpha$ -ketosidic linkages between terminal *N*-acetylneuraminic acids and sugar residues in polysaccharides, glycoproteins, etc. Extracellular neuraminidases are produced by certain bacteria (e.g. *Streptococcus pneumoniae*, *Vibrio cholerae*) and occur in certain viruses – e.g. members of the Orthomyxoviridae (see INFLUENZAVIRUS) and Paramyxoviridae (genus PARAMYXOVIRUS). The viral neuraminidase (a RECEPTOR-DESTROYING ENZYME, RDE) lowers the viscosity of mucous secretions, exposing the cell surface receptor sites; it also assists the release of progeny virions by eluting them from their receptors. (See also HAEMAGGLUTINATION.)

Neuraminidases from different sources may have different specificities, but most cannot hydrolyse COLOMINIC ACID (q.v. for exceptions); they are generally inhibited by EDTA.

**neuroexocytosis** See TETANOSPASMIN.

**Neurospora** A genus of fungi (order SORDARIALES) which occur e.g. on burnt or decomposing vegetation; the organisms form longitudinally-ribbed ascospores in asci borne in perithecia. *N. crassa* and *N. sitophila* are both hermaphroditic and heterothallic; other species (e.g. *N. tetrasperma*) are homothallic or secondarily homothallic (see HOMOTHALLISM and HETEROTHALLISM). *N. sitophila* forms a TRICHOGYNE-bearing ascogonium but no antheridium, plasmogamy occurring by spermatization or conidiation; eight-spored asci are formed in dark, pyriform perithecia. Conidial stages occur in *N. crassa* and *N. sitophila*. (See also BREAD SPOILAGE, ONCOM, POKY MUTANT, RAGI, TEMPEH.)

[Control of growth and nuclear division cycle in *N. crassa*: MR (1981) 45 99–122; *Neurospora* plasmids: Book ref. 179, pp. 245–258.]

**neurotoxin** A TOXIN which acts on nerve cells or tissues, or at neuromuscular junctions. See e.g. BOTULINUM TOXIN, SAXITOXIN, TETANOSPASMIN.

**neurotransmitter** See BOTULINUM TOXIN and TETANOSPASMIN.

**neurotropism** See TROPISM (sense 2).

**neuston** The community of organisms which live in the surface film of a body of water (e.g. lake, sea); some members of the community (the *epineuston*) are associated with the upper surface and project into the air, while others (the *hyponeuston*) are associated with the underside of the film and project into the water below. (cf. NEKTON, PLANKTON.)

**neutral dye** See DYE.

**neutral petite** See PETITE MUTANT.

**neutral red** A red, basic azine DYE used e.g. in VITAL STAINING and as a PH INDICATOR: pH 6.8–8.0 (red to yellow). (See also BIOFUEL CELL.)

**neutralism** (1) The coexistence of two different organisms in an association in which neither is affected by the presence of the other.

(2) SYMBIOSIS (sense 1) in which one symbiont is (permanently or temporarily) dependent on the association, and the other derives neither benefit nor harm from the association.

(cf. COMMENSALISM.)

**neutralization test** Any test in which antibody prevents or inhibits the expression of a biological function by a microorganism or toxin. Thus, e.g., a microorganism may be identified by its failure to exhibit certain features (e.g. growth, ability to infect cells or organisms) in the presence of known, specific antiserum; a toxin may be identified or quantified by its failure to produce toxic effects (in vitro or in vivo) following admixture with specific antitoxin. (See also DANYSZ' PHENOMENON.)

**neutropenic enterocolitis** (ileocaecal syndrome) (*med.*) A syndrome characterized by neutropenia (a diminished number of circulating neutrophils) and ulceration, haemorrhage and necrosis of the distal ileum or caecum; *Clostridium septicum* may play a major causative role in the symptoms.

**neutrophil** An amoeboid, phagocytic PMN (q.v.) responsive to chemotactic stimuli – often the major type of cell involved early in acute INFLAMMATION. Neutrophils contain many enzymes (e.g. LYSOZYME, MYELOPEROXIDASE) (see also BPI PROTEIN, LACTOFERRIN). Stimulation (e.g. by opsonized bacteria or concanavalin A) leads to a 'respiratory burst' (metabolic burst) of increased oxygen consumption (over several minutes) starting within seconds of stimulation; much of the oxygen may be used to form SUPER-OXIDE radicals (see PHAGOCYTOSIS). (cf. MACROPHAGE.) (See also CALPROTECTIN.)

**neutrophile** An organism which has an optimum growth pH within the pH range 6–8. (cf. ACIDOPHILE and ALKALOPHILE.)

**nevirapine** See ANTIRETROVIRAL AGENTS and AIDS.

**Nevskia** A poorly characterized genus of aquatic bacteria [see e.g. Book ref. 45, pp. 520–523].

**new combination** In NOMENCLATURE: *syn. COMB. NOV.* (q.v.).

**new variant CJD** See CREUTZFELDT–JAKOB DISEASE.

**New World arenaviruses** See ARENAVIRIDAE.

**Newcastle disease** (avian pneumoencephalitis; Ranikhet disease)

A highly infectious POULTRY DISEASE caused by a PARAMYXOVIRUS. Chickens, turkeys and pheasants may be affected, and mild infections have been reported in ducks, geese and pigeons. Transmission may occur by droplet inhalation or by ingestion of contaminated water or food (e.g. food contaminated with infected pigeon droppings [VR (1984) 115 601–602]). Incubation period: ca. 4–12 days. Symptoms: variable, but commonly include e.g. loss of appetite, diarrhoea, laboured breathing, discharge from eyes, nostrils and mouth, often followed by neurological signs (drowsiness, weakness, paralysis). Mortality rates vary from 0 to ca. 100%. *Lab. diagnosis*: identification of the virus; an HAI test. *Control*: slaughter of infected flocks; vaccination using either live or inactivated vaccines.

The Newcastle disease virus has been reported to cause conjunctivitis in man.

**Newcombe experiment** An experiment by which Newcombe (in 1949) demonstrated that the apparent adaptation of a bacterial population to an altered environment involves the selection of pre-existing mutants.

Nutrient agar plates are each spread with the same quantity of inoculum from a single culture of phage-sensitive bacteria. The plates are incubated for a few hours, during which time each viable cell gives rise to a clone. The plates are then divided into two groups. In group A, the bacterial growth on each plate is redistributed (with a sterile glass spreader) so that the cells of each clone are dispersed over the agar surface. Group B plates are left undisturbed. All plates are then sprayed with a suspension of virulent phage and re-incubated. All the sensitive bacteria lyse; thus, colonies which subsequently develop on any plate must have arisen from cells which were, or had become, resistant to phage.

If phage-resistant bacteria developed adaptively, resistant cells would be formed only *after* exposure of phage; the redistribution of growth in group A plates would therefore not influence the subsequent development of resistant cells, and similar numbers of resistant cells – and hence colonies – should appear on all the plates. If, however, phage-resistant cells arose spontaneously *before* exposure to phage, each resistant (mutant) cell would form a discrete clone of resistant cells; subsequent redistribution

## nexin

of growth on the group A plates would disperse the resistant cells over the agar surface, so that each resistant cell on a group A plate would subsequently form a single colony. On the group B plates, however, each undisturbed clone of resistant cells would form only one colony. Hence, far more colonies would be formed on the group A plates than on the group B plates – as is found in practice. (cf. FLUCTUATION TEST.)

**nexin** See FLAGELLUM (b).

**NF- $\kappa$ B** See CYTOKINES.

**ngaione** See IPOMEAMARONE.

**NGU** NON-GONOCOCCAL URETHRITIS.

**NHI protein** NON-HAEM IRON PROTEIN.

**N<sub>i</sub> protein** See ADENYLATE CYCLASE.

**Nia** A genus of marine fungi (GASTEROMYCETES, Melanogasterales). *N. vibrissa* occurs on submerged wood; it forms globose basidiocarps (2–4 mm diam.) and five-limbed basidiospores.

**niacin** NICOTINIC ACID.

**niacin test** A test used to determine whether or not a detectable amount of niacin is liberated into a solid medium when a given strain of *Mycobacterium* is grown on that medium. Water or saline (ca. 1 ml) is allowed to stand in contact with the medium for 15 min to extract any niacin present. To ca. 0.5 ml extract is added 0.5 ml aniline (4% in ethanol) followed by 0.5 ml cyanogen bromide (CNBr; 10% aqueous); an immediate yellow coloration indicates the presence of niacin (a positive test). (To avoid the formation of free HCN from CNBr, used materials should be treated with NaOH prior to disposal.) In an alternative method the extract is tested with commercial niacin-test strips instead of with aniline and CNBr. [Book ref. 53, p. 1708.]

**niacinamide** Nicotinamide.

**NIAMD** National Institute of Allergy and Infectious Diseases (USA).

**nica** See CONJUGATION (b)(i).

**NICED** National Institute of Cholera and Enteric Diseases, Beliaghata, Calcutta 700010, India.

**Nichols' treponeme** (1) A virulent strain of *Treponema pallidum* subsp. *pallidum*. The organism has been reported to grow and divide on the surface of a tissue culture of cotton-tail rabbit epithelium cells (SfIEP) under 1.5% oxygen [Inf. Immun. (1981) 32 908–915]. (2) Strains of *Treponema refringens*.

**nick** A break in one strand of a dsDNA molecule due to the loss (or absence) of a phosphodiester linkage in an otherwise intact strand, as opposed to the loss (or absence) of one or more nucleotides from the strand, which is termed a *gap*. A nick can be repaired by a DNA LIGASE, a gap cannot.

**nick-closing enzyme** A type I TOPOISOMERASE.

**nick translation technique** A technique used e.g. for preparing a radioactively labelled DNA strand. A dsDNA molecule is nicked, using an appropriate endonuclease, and treated with DNA POLYMERASE I; this enzyme, using the nicks as starting points, can degrade the nicked strand using its 5' → 3' exonucleolytic activity, replacing it with a new strand using its polymerase activity. The presence of plenty of radiolabelled dNTPs in the medium ensures that the new strand will be extensively labelled.

**nickase** An ENDONUCLEASE which makes a single-strand nick in dsDNA (e.g., gpA of BACTERIOPHAGE  $\phi$ X174).

**nicking enzyme** An enzyme that nicks one strand of dsDNA: see NICKASE and RESTRICTION ENDONUCLEASE.

**Nicollia** See BABESIA.

**nicotinamide** See NICOTINIC ACID.

**nicotinamide adenine dinucleotide** See NAD.

**nicotinamide nucleotide transhydrogenase** See TRANSHYDROGENASE.

**nicotinic acid** (niacin) Pyridine 3-carboxylic acid; the corresponding amide, *nicotinamide*, is a component of the important coenzymes NAD (q.v.) and NADP. Niacin may be biosynthesized (via quinolinic acid) from aspartate and dihydroxyacetone phosphate (e.g. in many bacteria, and in *Saccharomyces cerevisiae* growing under anaerobic conditions), or from tryptophan (e.g. in *Xanthomonas* spp and in most fungi – including *S. cerevisiae* growing under aerobic conditions). Organisms auxotrophic for niacin or nicotinamide include e.g. *Lactobacillus* spp (used in the BIOASSAY of niacin), *Morganella* and *Proteus* spp (but not *Providencia*), *Bordetella pertussis*, some yeasts and fungi (e.g. *Mucor rouxii* requires niacin under anaerobic conditions but not under aerobic conditions), and certain protozoa (e.g. *Tetrahymena pyriformis*, coccidia). (See also NIACIN TEST; V FACTOR; VITAMIN.)

**niddamycin** See MACROLIDE ANTIBIOTICS.

**Nidula** See NIDULARIALES.

**Nidulariales** An order of humicolous, lignicolous or coprophilous fungi (class GASTEROMYCETES) characterized by a type of basidiocarp in which the GLEBA occurs in several parts, each part contained within a closed chamber (*peridiole*) which is physically separate from the other chambers; in some species each peridiole is attached to the inside of the (typically cup-shaped or funnel-shaped) peridium by a complex, extensible structure. The appearance of peridioles at the bottom of the peridium (which is open at maturity) has earned these fungi the name 'bird's nest fungi'. Genera include *Crucibulum*, CYATHUS, *Mycocalia* and *Nidula*.

**nif genes** Genes whose expression is necessary for NITROGEN FIXATION. In *Klebsiella pneumoniae* there are at least 17 *nif* genes clustered (close to the *his* operon) in 8 contiguous transcriptional units (*nifJ*, *nifHDK*, *nifY*, *nifENX*, *nifUSVM*, *nifF*, *nifLA*, and *nifBQ*) spanning ca. 23 kb on the chromosome. Genes *nifHDK* are structural genes for NITROGENASE: *nifD* and *nifK* specify the two subunits of the MoFe protein ('Kp1'), *nifH* specifies the subunit of the Fe protein ('Kp2'). The *nifJ* product is the pyruvate:flavodoxin oxidoreductase which transfers electrons from pyruvate to the flavodoxin (*nifF* product) that reduces the Fe protein of nitrogenase. The *nifB*, *nifE*, *nifN* and *nifV* genes all appear to be involved in the synthesis of the FeMo cofactor; *nifQ* appears to be involved in molybdate uptake; *nifM*, *nifS* and *nifU* may be involved in the processing of nitrogenase components; *nifL* and *nifA* are concerned with *nif* gene expression.

Expression of *nif* genes in *K. pneumoniae* is regulated at the transcriptional level and is repressed e.g. by alternative sources of nitrogen, by high oxygen levels, etc. The *nifA* gene specifies an activator of transcription which is necessary for the expression of most *nif* genes. The *nifL* gene specifies a negative regulator which represses transcription in the presence of e.g. amino acids, low levels of NH<sub>4</sub><sup>+</sup>, and oxygen; it appears not to interact directly with DNA but may complex with and inactivate the NifA protein. Transcription of *nif* genes is regulated by the availability of combined nitrogen and is subject to control by the NTR GENES.

The *nif* genes of other bacteria are generally less well characterized: *Azotobacter* appears to have additional copies of *nifH*; in *Bradyrhizobium* strains *nifH* is separated from *nifDK*; *Rhodospseudomonas capsulata* has multiple copies of *nifHDK*, while its other *nif* genes are apparently more widely dispersed on the chromosome than are those of *K. pneumoniae*. In *Rhizobium* spp *nif* genes are located on the Sym plasmid (see entry ROOT NODULES).

In most nitrogen-fixing CYANOBACTERIA, *nif* genes are expressed only in HETEROCYSTs. In vegetative cells of e.g.

*Anabaena*, the *nifH* and *nifD* genes are contiguous, but *nifK* is separated from *nifD* by ca. 11 kb. It has been shown that, late in heterocyst differentiation, the DNA undergoes certain rearrangements, including the excision and circularization of the 11-kb segment between *nifD* and *nifK*; this results in the fusion of *nifK* with *nifHD* and allows coordination of transcription of the *nifHDK* genes.

[*nif* and associated genes in *Acetobacter diazotrophicus*: JB (2000) 182 7088–7091.]

**nifuratel** See NITROFURANS.

**nifuroxime** See NITROFURANS.

**nifurprazine** See NITROFURANS.

**nigeran** (mycodextran) A linear  $\alpha$ -D-glucan in which glucopyranose residues are linked by alternating (1  $\rightarrow$  3)- $\alpha$ - and (1  $\rightarrow$  4)- $\alpha$ -glycosidic linkages; it is soluble in hot water. Nigeran occurs in the hyphal walls of *Aspergillus* spp (but not in *A. nidulans*, which contains PSEUDONIGERAN) and *Penicillium* spp. [Nigeran as a phylogenetic marker: Mycol. (1978) 70 1201–1211.]

**nigericin** A linear MACROTETRALIDE antibiotic which can act as a mobile carrier IONOPHORE for the transport of monovalent cations – K<sup>+</sup> or Rb<sup>+</sup> (or, to a lesser extent, e.g. Na<sup>+</sup>). In order to transport an ion the nigericin molecule loses a proton and binds the ion, and the (electrically neutral) nigericin–ion complex diffuses across the membrane; since nigericin can also cross the membrane in a protonated state, it can bring about the exchange of H<sup>+</sup> for K<sup>+</sup> (see ELECTRONEUTRAL TRANSPORT). Nigericin is used e.g. to alter a membrane pH gradient (see CHEMIOSMOSIS).

**nigerose**  $\alpha$ -D-Glucopyranosyl-(1  $\rightarrow$  3)-D-glucopyranose.

**nigrosin** A black composite indulin-based DYE used e.g. for negative STAINING.

**nika gene** See CONJUGATION (1b)(i).

**nikkomycins** A group of antibiotics which closely resemble POLYOXINS both in structure and in mode of action; nikkomycins have a wider spectrum of activity than polyoxins, being more active e.g. against the yeast forms of *Mucor rouxii* and *Candida albicans*.

**Nikolsky sign** Wrinkling of the skin (evident on gentle stroking) due to separation of the outer epidermis from the basal layer. (See also EPIDERMOLYTIC TOXIN.)

**Nile blue A** (Nile blue sulphate) A blue basic oxazine DYE used e.g. in VITAL STAINING and as a lipid stain. In aqueous solution some of the dye is spontaneously oxidized to the phenoxazone LYSOCHROME Nile red (soluble in aqueous Nile blue A); this allochromatic mixture stains fatty acids and phospholipids blue, and neutral lipids red. Nile blue A can be used as a fluorescent stain for poly- $\beta$ -hydroxybutyrate [AEM (1982) 44 238–241]; Nile red is useful as a vital stain for intracellular lipid droplets, being strongly fluorescent only in a hydrophobic environment [JBC (1985) 100 965–973].

**Nile red** See NILE BLUE A.

**nisin** A low-MWt LANTIBIOTIC produced by strains of *Lactococcus*; genes for nisin synthesis appear to be plasmid-borne. [Nisin (review): AAM (1981) 27 85–123.] Nisin is bactericidal against Gram-positive bacteria, and has some sporicidal activity; it is both heat-stable and acid-stable, but stability and solubility decrease with increasing pH, and nisin is inactivated by certain proteases (e.g. chymotrypsin). Nisin is not used clinically; it is employed as a food PRESERVATIVE, generally in conjunction with heat treatment, in e.g. milk and DAIRY PRODUCTS (in which it occurs naturally) and certain canned vegetables. Canned, low-acid foods in which nisin is used must still receive adequate heat treatment because *Clostridium botulinum* is relatively resistant to nisin. (cf. DIPLOCOCCIN and SUBTILIN.)

[Synergistic action of nisin and CO<sub>2</sub> against *Listeria monocytogenes*: AEM (2000) 66 769–774. Bioassay for nisin in food: AEM (2003) 69 4214–4218.]

**Nitella** See CHAROPHYTES.

**nitrapyrin** (N-Serve) 2-Chloro-6-(trichloromethyl)pyridine, a NITRIFICATION INHIBITOR.

**nitratase** *Syn.* nitrate reductase.

**nitrate broth** Nutrient broth (or peptone water) containing KNO<sub>3</sub> (0.1–0.2% w/v).

**nitrate reductase** See ASSIMILATORY NITRATE REDUCTION; DENITRIFICATION; NITRATE RESPIRATION.

**nitrate reduction** See ASSIMILATORY NITRATE REDUCTION and DISSIMILATORY NITRATE REDUCTION.

**nitrate reduction test** (nitrate test) A test used to indicate whether or not a given bacterial strain can reduce nitrate; the medium and test conditions used depend on the particular organism being examined. For many bacteria (including enterobacteria and pseudomonads, but excluding e.g. *Mycobacterium* spp) the organism is cultured for 2–5 days in NITRATE BROTH. The culture is then tested for the presence of nitrite by adding 0.5 ml 'reagent A' (0.8% w/v sulphanilic acid in 5 N acetic acid) followed by 0.5 ml 'reagent B' (0.6% w/v *N,N*-dimethyl- $\alpha$ -naphthylamine in 5 N acetic acid); if present, nitrite reacts with sulphanilic acid to form a diazonium salt which, with the naphthylamine, forms a soluble red azo dye. The absence of coloration could mean that either (a) nitrate has not been reduced, or (b) the nitrite has itself been reduced. To resolve this question a trace of zinc dust is added; if nitrate is present it is reduced (by the zinc dust) to nitrite (which gives a red coloration) – the absence of coloration indicating possibility (b).

For *Mycobacterium* spp, a small loopful of growth is dispersed in 0.02 M phosphate buffer (pH 7.0) containing 0.01 M NaNO<sub>3</sub>, and the suspension is incubated (37°C/2hours). To the suspension is then added 1 drop of HCl (concentrated HCl:water mixed 1:1 v/v) followed by 2 drops of sulphanilamide solution (0.2% aqueous) and 2 drops of *N*-naphthylethylenediamine dihydrochloride (0.1% aqueous); pink or red coloration indicates reduction of nitrate to nitrite. If no colour develops, the addition of zinc dust causes a red coloration if the medium still contains nitrate – and fails to do so if the nitrate had been reduced beyond nitrite.

**nitrate respiration** ANAEROBIC RESPIRATION in which, typically, nitrate (as terminal electron acceptor) is reduced to nitrite in a reaction catalysed by an enzyme (*dissimilatory nitrate reductase*) located at the end of an ELECTRON TRANSPORT CHAIN; this reaction, which is equivalent to the first stage of DENITRIFICATION, generates proton motive force (pmf: see CHEMIOSMOSIS) which can be used e.g. for ATP synthesis. (cf. DISSIMILATORY NITRATE REDUCTION.) In some organisms the nitrite is excreted, but in others it can be reduced to ammonia. In nitrate respiration the energy yield is less than that obtainable with oxygen as electron acceptor.

In some bacteria (including e.g. *Escherichia coli*) nitrate can be used for the anaerobic oxidation of e.g. NADH, succinate and/or formate – pmf being generated in each case; the resulting nitrite inhibits aconitase and fumarase, thus inhibiting the TCA cycle [Appendix II(a)].

In e.g. *Escherichia coli* a soluble ('assimilatory') nitrite reductase can catalyse the anaerobic reduction of nitrite to ammonia in a reaction coupled to the oxidation of NADH. This reaction does not, in itself, yield energy; however, by regenerating NAD<sup>+</sup> from NADH (produced during the metabolism of e.g. glucose) it tends to prevent the (energetically wasteful) synthesis of ethanol – see

## nitrate test

Appendix III(e) – thereby increasing the yield of acetic acid and, hence, conserving energy via acetyl phosphate. Since the oxidation of NADH by nitrite (i) depends on an exogenous electron acceptor, (ii) results in an overall energy yield greater than that obtainable by the mixed acid fermentation, and (iii) results in a net oxidation of the substrate, it conforms to the definition of RESPIRATION and may be described as ‘nitrite respiration’. In *Desulfovibrio gigas* the coupling of nitrite reduction to the oxidation of hydrogen appears to generate pmf; accordingly, this process, too, may be referred to as nitrite respiration.

Some anaerobic bacteria (e.g. *Clostridium perfringens*) can carry out dissimilatory nitrate reduction [JGM (1975) 87 120–128]. This process, in which nitrate is reduced to ammonia, apparently does not generate pmf; however, it is coupled to the regeneration of NAD<sup>+</sup> from NADH, and brings about an increase in the proportion of those intermediate metabolites which can participate in substrate-level phosphorylation. This process, which is sometimes referred to as ‘fermentative nitrate reduction’, may be regarded as another example of nitrate respiration.

So-called *dissimilatory reduction of nitrate to ammonia* (DRNA) is a respiratory process reported to take place e.g. in marine sediments, particularly where nitrate concentrations are low [see FEMS Ecol. (1996) 19 27–38].

**nitrate test** See NITRATE REDUCTION TEST.

**nitric oxide (NO)** On suitable activation, various types of cell (including macrophages) synthesize an inducible form of the enzyme *nitric oxide synthase* (iNOS); synthesis of iNOS is positively regulated at the level of transcription by certain cytokines (e.g. TNF- $\alpha$ , IFN- $\gamma$ ). iNOS catalyses the NADPH-dependent oxidative deamination of L-arginine to L-citrulline and nitric oxide.

Nitric oxide gives rise to a range of reactive species by interaction with oxygen, water and/or other reactive intermediates; they include *peroxynitrite* (ONOO<sup>-</sup>) (formed by the reaction between superoxide and nitric oxide), nitrogen dioxide and nitrogen trioxide. Peroxynitrite forms an adduct with carbon dioxide that is potentially toxic. In e.g. a target bacterium, nitric oxide and the various reactive species inhibit oxygen-binding haem-containing enzymes (such as terminal oxidases) and certain other iron-containing enzymes (e.g. the TCA cycle enzyme *aconitase*). Damage to an infecting bacterium may include failure of DNA replication and/or the loss of important metabolic processes, leading to death of the cell. The production of large amounts of nitric oxide by iNOS therefore serves a protective role. However, ongoing production of high levels of nitric oxide in a persistent, unresolved infection can suppress the host’s immune system and bring about various forms of disease.

Inhibitors of iNOS inhibit the killing of *Mycobacterium tuberculosis* by IFN- $\gamma$ -activated murine macrophages; moreover, studies in mice indicate that deletion of IFN- $\gamma$  genes increases the susceptibility of the mice to *M. tuberculosis* – this being associated with a deficiency of iNOS.

Bacterial reaction to nitric oxide includes e.g. increased activity of enzymes involved in the antioxidant response to oxidative stress.

[Effects of nitric oxide on pathogens and host: RMM (1998) 9 179–189. Nitric oxide in sepsis and endotoxaemia: JAC (1998) 41 (supplement A) 31–39. Bacterial responses to nitric oxide and nitrosative stress: Mol. Microbiol. (2000) 36 775–783.]

**nitric oxide synthase** See NITRIC OXIDE.

**nitrification** The oxidation of ammonia to nitrite, and nitrite to nitrate: a process which occurs e.g. in aerobic soils, in

aquatic environments, and in the upper (aerobic) region of some sediments. (See also SEWAGE TREATMENT.) Nitrification is carried out by autotrophic bacteria of the family NITROBACTERACEAE and by many heterotrophic organisms, including some fungi. It has been generally supposed that only the autotrophic nitrifying bacteria carry out nitrification to an ecologically significant extent; however, while this appears to be the case e.g. in the sediments of a Scottish estuary [JGM (1984) 130 2301–2308], the potential for heterotrophic nitrification was found to be greater than that for autotrophic nitrification in a Californian forest soil [AEM (1984) 48 802–806].

Autotrophic nitrification occurs in two stages, each stage being carried out by one of the two categories of nitrifying bacteria. (a) *Ammonia to nitrite* (‘nitrosification’). Ammonia is initially oxidized to hydroxylamine (NH<sub>2</sub>OH) in a MONOOXYGENASE-dependent, non-energy-yielding reaction; NH<sub>2</sub>OH is then oxidized to nitrite by an enzyme complex, electrons being transferred to molecular oxygen with concomitant oxidative phosphorylation. (b) *Nitrite to nitrate*. The oxidation of nitrite to nitrate provides energy by oxidative phosphorylation: in at least some nitrite-oxidizing bacteria NO<sub>2</sub><sup>-</sup> is oxidized in the reaction: NO<sub>2</sub><sup>-</sup> + H<sub>2</sub>O → NO<sub>3</sub><sup>-</sup> + 2H<sup>+</sup> + 2e<sup>-</sup>; the electrons are believed to be transferred to cytochrome (cyt) *a*<sub>1</sub> which in turn transfers them via cyt *aa*<sub>3</sub> to molecular oxygen, 1 ATP being formed for each pair of electrons transferred.

In the nitrite-oxidizing bacteria (and probably also in NH<sub>4</sub><sup>+</sup> oxidizers) pyridine nucleotide coenzymes are reduced by reversed electron transport. In at least some nitrite oxidizers, electrons appear to pass from cyt *a*<sub>1</sub>, via cyts *c* and *b*, to a flavoprotein and thence to the pyridine nucleotides; this process is highly energy-dependent, so that nitrifying bacteria need large quantities of NO<sub>2</sub><sup>-</sup> to sustain their relatively slow rates of growth.

Agriculturally, nitrification can be disadvantageous under certain conditions: NO<sub>3</sub><sup>-</sup> is readily leached from the topsoil by rain – thereby becoming unavailable as a source of crop nitrogen. (By contrast, owing to its charge, NH<sub>4</sub><sup>+</sup> is more strongly adsorbed to soil particles and is relatively immobile in top-soils.) Nevertheless, when e.g. the crop’s nitrogen demand is high and the rainfall (and hence risk of leaching) is likely to be low, rapid nitrification may actually be desirable since (a) optimal growth in many or most plants appears to occur only when both NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> are available, and (b) NH<sub>4</sub><sup>+</sup> may be assimilated (in preference to NO<sub>3</sub><sup>-</sup>) by soil microorganisms so that, in the absence of nitrification, much of the available soil nitrogen may be lost to crops as a consequence of being immobilized in microbial biomass. However, when e.g. the risk of leaching is high, the use of NITRIFICATION INHIBITORS can be advantageous; these agents have a temporary effect (they are gradually lost by evaporation and/or decomposition), and they not only benefit soil fertility but also reduce the pollution of groundwater by nitrate. (See also NITROGEN CYCLE.)

**nitrification inhibitors** Agents which retard or block NITRIFICATION; nitrification inhibitors appear to be typically bacteriostatic under field conditions. The agriculturally important agents inhibit microbial oxidation of ammonia and may also inhibit the oxidation of nitrite – though nitrite oxidation is generally much less sensitive to these agents; agents which block only nitrite oxidation cannot be used since they could cause accumulation of (phytotoxic) nitrite ions. Commercial nitrification inhibitors – some of which also have useful antifungal properties – include e.g. DICYANDIAMIDE, ETRIDIAZOLE and NITRAPYRIN. (See also BARBAN and CARBON DISULPHIDE.) [Review: Book ref. 121, pp. 33–43.]

In laboratory studies, acetylene has been used to block ammonia oxidation, and chlorate to block nitrite oxidation, in autotrophic nitrifiers [AEM (1984) 48 802–806].

**nitri-fying bacteria** See NITROBACTERACEAE.

**nitri-loacetic acid** See NTA.

**nitrite** (a) (as a food additive and preservative) See e.g. CURING (sense 1).

(b) (in the environment) See NITROGEN CYCLE.

**nitrite reductase** See ASSIMILATORY NITRATE REDUCTION; DENITRIFICATION; NITRATE RESPIRATION.

**nitrite respiration** See NITRATE RESPIRATION.

**Nitrobacter** A genus of Gram-negative bacteria of the NITROBACTERACEAE; strains occur in soils and in freshwater and marine habitats. Cells of the type species, *N. winogradskyi*, are rods ca. 0.6–0.8 × 1.0–2.0 µm; they are commonly non-motile but may have a single polar flagellum. Peripherally arranged cytomembranes form a cap at one pole of the cell. The cells reproduce by budding. Some strains are obligate chemolithoautotrophs which obtain energy by oxidizing nitrite to nitrate; other strains are facultatively chemoorganoheterotrophic. Storage compounds include PHB. Growth occurs optimally at ca. 25–30° C and at a pH of ca. 7.5–8.0. GC%: ca. 61. (See also CARBOXYSUMES.)

**Nitrobacteraceae** (nitri-fying bacteria) A family of Gram-negative, asporogenous, obligately aerobic bacteria which occur e.g. in soil and in freshwater and marine habitats; the organisms obtain energy by the oxidation of ammonia or nitrite (see NITRIFICATION), and all except some strains of *Nitrobacter winogradskyi* are obligate chemolithoautotrophs. The family includes coccoid, rod-shaped, spiral and lobate bacteria. Cells may be non-motile or may have polar, subpolar or peritrichous flagella. The cells of many species contain characteristic cytomembranes. Most species divide by binary fission; budding occurs in *Nitrobacter winogradskyi*. Species which oxidize ammonia to nitrite are placed in the following genera: NITROSOCOCCUS, NITROSOLOBUS, NITROSOMONAS, NITROSOSPIRA and NITROSOVIBRIO; nitrite-oxidizing species are placed in the genera NITROBACTER, NITROCOCCUS and NITROSPINA.

**nitroble tetrazolium** See TETRAZOLIUM.

**nitroclfin** A chromogenic cephalosporin used to test for β-LACTAMASES; when cleaved by a β-lactamase it changes from yellow to red. (See also PADAC.)

**Nitrococcus** A genus of Gram-negative marine bacteria of the NITROBACTERACEAE. Cells of the type species, *N. mobilis*, are coccoid, ca. 1.5–1.8 µm diameter, each having one or two subpolar flagella; the cells contain tubular cytomembranes arranged randomly in the cytoplasm. The cells reproduce by binary fission. GC%: ca. 61.

**nitrofurans** A family of synthetic ANTIBIOTICS which are derivatives of 2-substituted 5-nitrofurans; they are active against many Gram-positive and Gram-negative bacteria, certain fungi, and some protozoa. Some nitrofurans are used as chemotherapeutic agents, but many are known to be mutagenic/oncogenic. The antibacterial activity of a nitrofuran depends on the (step-wise) intracellular reduction of the nitro group, the intermediate(s) formed being able to cause strand breakage in DNA. (cf. NITROIMIDAZOLES.) In e.g. *Escherichia coli*, the reduction of a nitrofuran involves NADH-linked 'nitrofuran reductase 1' (NR1) and NADPH-linked 'nitrofuran reductase 2' (NR2); mutants lacking NR1 exhibit high-level resistance to nitrofurans. (Little is known about plasmid-encoded resistance to nitrofurans; if it exists, the incidence appears to be negligible.) [Resistance to nitrofurans: Book ref. 160, pp. 317–344.] Examples of nitrofurans:

*Furaladone* is used e.g. against colibacillosis and salmonellosis in pigs and cattle. (See also PULLORUM DISEASE.)

*Furazolidone* (*furoxone*) has been used e.g. against bacillary dysentery and *Salmonella* infections in man, and is used e.g. in the treatment of human GIARDIASIS and certain diseases of animals (e.g. BLACKHEAD).

*Furylfulamide* (AF-2) is an oncogenic nitrofuran once used as a food preservative in Japan.

*Nifuratel* has been used e.g. against vaginal trichomoniasis.

*Nifuroxime* has been used, topically, as an antifungal agent, being active against e.g. *Candida albicans*; it has also been used (in conjunction with furazolidone) against vaginal trichomoniasis.

*Nifurprazine* is used as a topical, broad-spectrum antibacterial agent.

*Nitrofurantoin* (*furadantin*) is the most widely-used nitrofuran. It is used as a broad-spectrum antibacterial agent against infections of the (human) urinary tract; many strains of *Pseudomonas aeruginosa* are resistant, and resistant strains of e.g. *Proteus* also occur.

*Nitrofurazone* (*furacin*) is used, rarely, for the topical treatment of e.g. infected wounds.

**nitrofurantoin** See NITROFURANS.

**nitrofurazone** See NITROFURANS.

**nitrogen cycle** In nature: the cyclical interconversion of nitrogen and its compounds by living organisms and non-biological processes. The major microbial conversions are shown on page 522. (See also AMMONIA ASSIMILATION, AMMONIFICATION, ASSIMILATORY NITRATE REDUCTION, DENITRIFICATION, DISSIMILATORY NITRATE REDUCTION, DISSIMILATORY REDUCTION OF NITRATE TO AMMONIA, NITRATE RESPIRATION, NITRIFICATION, NITROGEN FIXATION.) (cf. CARBON CYCLE and SULPHUR CYCLE.)

**nitrogen fixation** (dinitrogen fixation) The reduction of gaseous nitrogen (dinitrogen, N<sub>2</sub>) to ammonia. (See also NITROGEN CYCLE.)

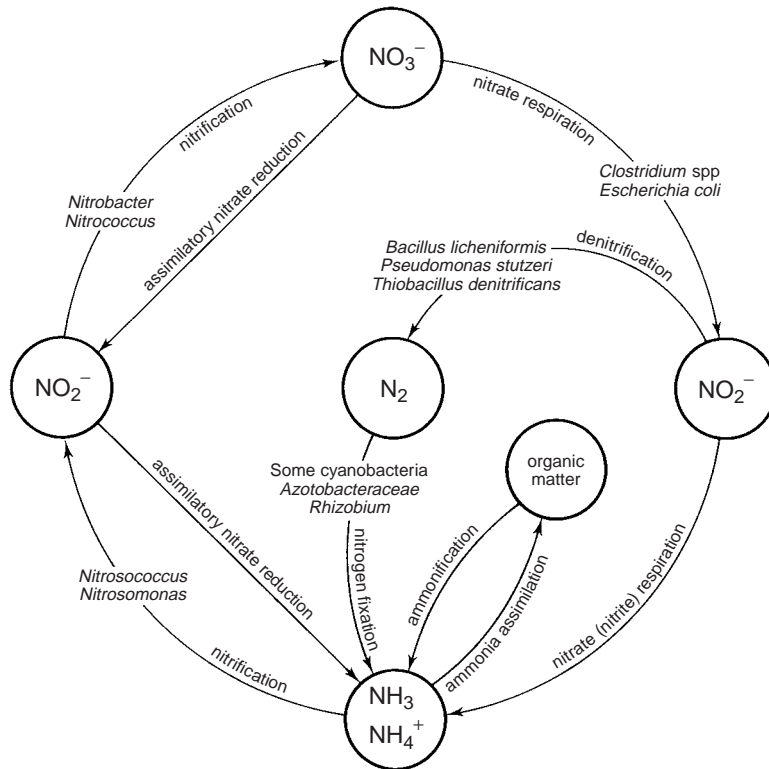

Biological nitrogen fixation is carried out only by certain prokaryotes; these nitrogen-fixing organisms are called *diazotrophs*. The diazotrophs include various cyanobacteria (e.g. *Anabaena*, *Nostoc*, *Plectonema*, *Trichodesmium*); certain species of *Bacillus* and *Clostridium*; *Azospirillum*; *Klebsiella pneumoniae* (some strains); members of the Azotobacteriaceae, Methylococcaceae, Rhizobiaceae and Rhodospirillales; and certain species of the Archaea.

That plants are unable to fix nitrogen is interesting in that, during evolution, plants are believed to have incorporated prokaryotes as organelles (e.g. mitochondria). However, during that period of evolution, prokaryotes may not have yet developed nitrogen-fixing ability and, moreover, plants may not have been subjected to sufficient selection pressure [PTRSLB (1992) 338 409–416].

The free-living diazotrophs occur e.g. in soil and water, while a number of diazotrophs form symbiotic associations with other organisms (which benefit from a supply of fixed nitrogen). AZOSPIRILLUM fixes nitrogen in the RHIZOSPHERE of various plants, including some important crop plants. Certain species of AZOTOBACTER fix nitrogen in association with the roots of a grass, *Paspalum notatum*, and the surface of the green seaweed *Codium*. *Clostridium* spp are found in waterlogged (anaerobic) soils, and may also fix nitrogen in the intestines of man and other animals.

*Frankia* spp form symbiotic associations with certain non-leguminous plants (see ACTINORRHIZA), while *Rhizobium/Bradyrhizobium* spp are found in leguminous ROOT NODULES and STEM NODULES.

## nitrogen fixation

NITROGEN CYCLE – microbial aspects, with examples of organisms. (For cross-references see entry NITROGEN CYCLE.) Not shown is the activity of ANAMMOX BACTERIA (q.v.).

Reproduced from *Bacteria* 5th edition, Figure 10.2, page 258, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

Nitrogen-fixing cyanobacteria are an important source of nitrogen e.g. in rice paddies; for example, *Anabaena azollae* forms a symbiotic association with a small, floating fresh-water fern, *Azolla*, that is used as 'green manure' in rice-growing regions of the Far East. (See also NOSTOC.) Cyanobacteria can also form associations with certain LICHENS (see e.g. CEPHALODIUM).

Both free-living and symbiotic nitrogen-fixers occur in the open ocean, and such organisms may contribute significantly to the nitrogen budget of these waters. [Nitrogen-fixing microorganisms in tropical and subtropical oceans: TIM (2000) 8 68–73.]

The benefits enjoyed by those plants that have nitrogen-fixing symbiotic partners have suggested that the growth of certain crop plants, such as cereals, may be improved by infecting them experimentally with nitrogen-fixing organisms. Experiments have been carried out to determine whether *wheat* can be infected with the nitrogen-fixing bacterium *Azorhizobium caulinodans* (which nodulates a tropical legume, *Sesbania rostrata*); *A. caulinodans* became established endophytically (in the xylem and root meristem), and the wheat showed significantly increased dry weight and nitrogen content compared with uninoculated control plants [Proc. RSLB (1997) 264 341–346].

Nitrogen fixation is catalysed by the enzyme complex NITROGENASE. The reaction requires a strong reducing agent (source of electrons) and consumes ~12–16 molecules of ATP per molecule of nitrogen fixed; electrons from a source such as hydrogen or NADPH are transferred e.g. to a FERREDOXIN or FLAVODOXIN and thence to nitrogenase. (For in vitro work, the artificial reductant dithionite can be used.)

In some diazotrophs (e.g. *Bacillus polymyxa*, *Clostridium pasteurianum*, *Klebsiella pneumoniae*, some cyanobacteria) reducing power and ATP can both be obtained from pyruvate. Reducing power is provided by the oxidative decarboxylation of pyruvate to acetyl-CoA (catalysed by the enzyme pyruvate:flavodoxin oxidoreductase); the acetyl-CoA is converted to acetyl phosphate – from which phosphate can be transferred to ADP in a substrate-level phosphorylation.

The ammonia produced by nitrogen fixation may be assimilated e.g. via the GOGAT pathway (see AMMONIA ASSIMILATION).

Nitrogenase is highly sensitive to oxygen, and many diazotrophs (e.g. clostridia) fix nitrogen anaerobically or microaerobically. In some cyanobacteria the process is carried out within specialized cells (see HETEROCYST). Certain diazotrophs have specific mechanisms for protecting nitrogenase during aerobic nitrogen fixation; for example, rhizobium bacteroids in ROOT

NODULES are protected by LEGHAEMOGLOBIN. (See also TRICHODESMIUM.) Strains of *Azotobacter* and possibly *Gloeotheca* [JGM (1984) 130 495–503] exhibit oxygen-scavenging 'respiratory protection': they show high rates of respiration in the presence of high levels of oxygen, their branched respiratory chains being poorly coupled to ATP synthesis; respiration thus serves primarily to consume oxygen. In those organisms which have an 'uptake hydrogenase' (see NITROGENASE), the transfer of electrons from hydrogen – via an electron transport chain to oxygen (as terminal electron acceptor) – may also help to protect nitrogenase from oxygen. In unicellular, aerobic, nitrogen-fixing cyanobacteria of the genus *Cyanothece*, nitrogen fixation was found to occur only in the dark period during alternating 12-hour light/dark cycles, but was continuous during 24-hour illumination; nitrogen fixation during the dark period would avoid exposure to the oxygen evolved by photosynthesis, but continuous fixation during continual illumination requires additional explanation – and may involve the 'inclusion granules' that develop under nitrogen-fixing conditions [JB (1993) 175 1284–1292].

[Cyanobacterial nitrogen fixation (oxygen relationships): MR (1992) 56 340–373. Nitrogen fixation by non-heterocystous cyanobacteria: FEMS Reviews (1997) 19 139–185.]

**nitrogen mustards** Highly reactive bifunctional ALKYLATING AGENTS, most of which correspond to the general formula  $\text{Cl}(\text{CH}_2)_2\text{NR}(\text{CH}_2)_2\text{Cl}$ . They are toxic (e.g. causing blisters on contact with the skin), mutagenic and carcinogenic, and promote IMMUNOSUPPRESSION. Nitrogen mustards (and the SULPHUR MUSTARDS) react with DNA e.g. at the N-7 position of guanine residues, forming mono-adducts as well as inter- and intra-strand cross-links.

**nitrogen-regulated genes** See NTR GENES.

**nitrogenase** (dinitrogenase) An enzyme complex (EC 1.18.2.1) which catalyses biological NITROGEN FIXATION: it combines with  $\text{N}_2$  and reduces it to  $\text{NH}_3$ . Nitrogenase can also reduce other substrates – e.g., acetylene, azide, cyanide, nitrous oxide; the reduction of acetylene to ethylene (detectable by gas chromatography) is the basis of an assay for nitrogenase. The nitrogenase complex typically comprises two components: the MoFe (or FeMo) protein (also called e.g. component I, molybdoferredoxin, azofermo, or dinitrogenase), and the Fe protein (= e.g. component II, azoferredoxin, azofer, dinitrogenase reductase). The MoFe protein (MWt ca. 220000–250000) is an  $\alpha_2\beta_2$  tetramer containing ca. 50 iron atoms, 2 molybdenum atoms, and ca. 30 acid-labile sulphide groups; the molybdenum occurs in an FeMo cofactor (FeMoco) containing at least 1Mo per 6Fe [ARB (1984) 53 231–257]. (An alternative nitrogenase has been found in a strain of *Azotobacter chroococcum* in which the MoFe protein is replaced by a vanadium-containing protein [Nature (1986) 322 388–390].) The Fe protein (MWt ca. 55000–60000) contains two identical protein subunits, 4 iron atoms and 4 acid-labile sulphide groups. The substrate (e.g.  $\text{N}_2$ ) is bound by the MoFe protein and, in the presence of Mg-ATP, electrons are transferred from reduced ferredoxin or flavodoxin to the Fe protein which, in turn, reduces the MoFe protein with concomitant ATP hydrolysis. (At least 2ATP are hydrolysed for each electron transferred.)

In an apparently inevitable side-reaction of nitrogenase, electrons are transferred to protons, resulting in the ATP-dependent evolution of  $\text{H}_2$ ;  $\text{H}_2$  evolution thus competes with nitrogen fixation for energy and reducing power. Some organisms (e.g. some *Rhizobium* bacteroids [Book ref. 55, pp. 179–203], *Azotobacter* spp. and some cyanobacteria) possess an oxygen-dependent enzyme system termed 'uptake hydrogenase' which oxidizes the  $\text{H}_2$  to yield ATP; this enzyme system also serves to remove  $\text{H}_2$

(a competitive inhibitor of nitrogenase) from the active centre of nitrogenase.

Nitrogenase action is slow, and large amounts of the enzyme are necessary for effective nitrogen fixation; the enzyme complex may comprise up to 10% of the cellular protein in an actively diazotrophic cell.

Control of nitrogenase may occur at the transcriptional level (see NIF GENES) or at the level of the enzyme itself. Nitrogenase is inhibited e.g. by  $\text{H}_2$ ,  $\text{NH}_3$  (indirectly), and  $\text{NO}_3^-$  (probably via nitrite); addition of  $\text{NH}_3$  to cultures of nitrogen-fixing photosynthetic bacteria or *Azospirillum* results in inactivation of the Fe protein by covalent modification. Nitrogenase is highly oxygen-labile (see NITROGEN FIXATION).

**nitroimidazoles** A group of synthetic antimicrobial agents which are maximally effective against anaerobes. Their activity appears to depend on at least partial reduction of the nitro group by metabolic pathways linked to low-redox-potential electron transport components (such as ferredoxin) in the susceptible organism; reduction results in the formation of short-lived cytotoxic intermediate(s) – see HYDROGENOSOME. (cf. NITROFURANS.) Nitroimidazoles include e.g. azomycin (2-nitroimidazole), carnidazole [1-(2-ethylcarbamothioic acid *O*-methyl ester)-2-methyl-5-nitroimidazole], DIMETRIDAZOLE, flunidazole [1-(2-hydroxyethyl)-2-(*p*-fluorophenyl)-5-nitroimidazole], METRONIDAZOLE, ornidazole [1-(3-chloro-2-hydroxypropyl)-2-methyl-5-nitroimidazole], panidazole [1-(2-(4-pyridyl)-ethyl)-2-methyl-5-nitroimidazole], secnidazole [1-(2-hydroxypropyl)-2-methyl-5-nitroimidazole], and tinidazole [1-(2-(ethylsulphonyl)-ethyl)-2-methyl-5-nitroimidazole]. [Comparative evaluation of the 2-methyl-5-nitroimidazoles against *Bacteroides fragilis*: AAC (1985) 28 561–564.]

**nitromersol** See MERCURY.

**nitrophenols** (as disinfectants) See PHENOLS.

**N-nitroso compounds** Compounds which contain the group  $-\text{N}=\text{N}=\text{O}$ . Many nitroso compounds are effective MUTAGENS: e.g., dialkylnitrosamines ( $\text{R}_2\text{N}=\text{N}=\text{O}$ ), *N*-alkylnitrosoureas ( $\text{NH}_2\text{CO.NR.N}=\text{O}$ ), and *N*-alkyl-*N'*-nitro-*N*-nitrosoguanidines ( $\text{NO}_2\text{.NH.C}=\text{NH.NR.N}=\text{O}$ ; see e.g. MNNG) act as ALKYLATING AGENTS (after metabolic activation in the case of dialkylnitrosamines). *Halonitrosoureas* – e.g. 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU), bis-(2-fluoroethyl)-nitrosourea (BFNU), and 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) – apparently transfer haloethyl, hydroxyethyl and aminoethyl groups to various positions in bases in DNA.

**Nitrosococcus** A genus of Gram-negative bacteria of the NITROBACTERACEAE; the organisms occur in soil and in freshwater and marine habitats. Cells: cocci, diameter 1.5  $\mu\text{m}$  or greater, which divide by binary fission. *N. mobilis* and *N. oceanus* are motile with one or more flagella; they differ in the arrangement of their cytomembranes. (See also CARBOXYSOMES.) *N. nitrosus* is non-motile. GC% (*N. oceanus*): ca. 51.

**nitrosification** See NITRIFICATION.

**nitrosoguanidine** See MNNG.

**Nitrosolobus** A genus of Gram-negative bacteria of the NITROBACTERACEAE; the organisms occur in soil. Cells: irregularly rounded ('lobular'), ca. 1.0–1.5  $\mu\text{m}$  in diameter, with 1–20 flagella; the cells divide by binary fission. Cytomembranes compartmentalize the cell into several central regions and a larger number of peripheral regions. GC%: ca. 53–55.

**Nitrosomonas** A genus of Gram-negative bacteria of the NITROBACTERACEAE; strains occur e.g. in soils and in freshwater and marine habitats. Cells of the type species, *N. europaea*, are typically rod-shaped, ca. 0.8–1.0  $\times$  1.0–2.0  $\mu\text{m}$ , and either

## Nitrospira

non-motile or motile with 1–2 subpolar flagella. The cells contain lamellar cytomembranes in a mainly peripheral arrangement. Marine strains (and some other strains) have an S LAYER. (See also CARBOXYSOMES.) GC%: ca. 47–51.

**Nitrospira** A genus of Gram-negative bacteria of the NITROBACTERACEAE; the organisms occur in soil. Under the light microscope the cells appear as rods, ca. 0.3–0.4 × 0.8–1.0 μm, but they appear as tightly coiled spirals under the electron microscope; the cells may be non-motile, or motile with 1–6 flagella, and they divide by binary fission. Cytomembranes are absent. Type species: *N. briensis*. GC%: ca. 54.

**nitrosoureas** See N-NITROSO COMPOUNDS.

**Nitrosovibrio** A genus of Gram-negative bacteria of the NITROBACTERACEAE. The type species, *N. tenuis*, is represented by a single isolate from soil in the Hawaiian Islands; cells: straight to curved rods, ca. 0.3–0.4 × 1.1–3.0 μm (coccioid in stationary-phase cultures), with 1–4 lateral or subpolar flagella. Extensive cytomembranes are lacking. Cells divide by binary fission.

**Nitrospina** A genus of Gram-negative marine bacteria of the NITROBACTERACEAE. Cells of the type species, *N. gracilis*, are non-motile rods, ca. 0.3–0.4 × 2.6–6.5 μm, which divide by binary fission; the cells may contain numerous deposits of glycogen. GC%: ca. 58. (See also CARBOXYSOMES.)

**nitrous acid** (as a MUTAGEN) Nitrous acid (HNO<sub>2</sub>) can cause the oxidative deamination of guanine (G), cytosine (C) and adenine (A) to form xanthine (X), uracil (U) and hypoxanthine (HX), respectively. When DNA treated with nitrous acid undergoes replication, X pairs with C which, on subsequent replication, pairs with G: i.e., no mutation results from G deamination. U pairs with A, and HX pairs with C: thus deamination of C and A leads to G-C-to-A-T and A-T-to-G-C transitions, respectively. (HNO<sub>2</sub> can also cause e.g. cross-linking between bases.)

In e.g. *Escherichia coli* the abnormal bases HX and U can be removed from DNA by specific hypoxanthine- and URACIL-DNA GLYCOSYLASES.

**Nitschkea** See SORDARIALES.

**Nitzschia** See DIATOMS.

**nivalenol** See TRICHOTHECENES.

**NK cells** Natural killer cells: lymphoid cells, derived from bone marrow stem cells, which are related to, but antigenically distinct from, T LYMPHOCYTES; NK cells do not express the T cell receptor (TCR), and do not express CD3, CD4 or CD8 antigens but they do express the CD16 antigen. NK cells are classified as *large granular lymphocytes* (LGLs).

NK cells have little phagocytic activity, but they can exert cytotoxic/cytolytic activity against various pathogens, against host cells infected with certain bacteria (e.g. *Listeria monocytogenes*) or viruses, and against certain tumours; moreover, NK cells can be stimulated to release CYTOKINES, including IFN-γ (see INTERFERONS).

NK cells may bind to target cells (e.g. virus-infected cells) via the CD16 receptor – i.e. CD16 binding to the Fc portion of antibodies that have bound to the target cell (see ADCC). Alternatively, binding to target cells may occur in an antibody-independent way – receptors on NK cells binding directly to ligands on the target cell.

The killing activity of NK cells appears to involve the release of perforins and granzymes which induce APOPTOSIS in target cells.

NK cells can attack virus-infected host cells which do not express viral antigen, linked to MHC class I molecules, at the cell surface; such cells would not normally be targeted by CD8<sup>+</sup>

cytotoxic T cells – which are MHC class I-restricted. (NK cells are not MHC class I-restricted; in fact, class I molecules inhibit the killing activity of NK cells.) This role of NK cells appears to be particularly valuable in that many viruses are able to inhibit the display of MHC class I-linked viral antigens at the cell surface.

The killing activity of NK cells is stimulated by certain cytokines, including INTERLEUKIN 12.

**NLF** A non-lactose-fermenting bacterium.

**nm** (nanometre) 10<sup>-9</sup> m, or 10<sup>-3</sup> μm.

**NMR** NUCLEAR MAGNETIC RESONANCE.

**NNN medium** (Novy, Nicolle and MacNeal's medium) A DIPHASIC MEDIUM used e.g. for the culture of certain *Leishmania* spp and sterocarian trypanosomes. It is a blood agar SLOPE (containing defibrinated mammalian blood) to which has been added a small volume of e.g. Locke's solution containing antibiotics to inhibit bacterial growth. The inoculated slope is incubated (e.g. 25–28°C) for days or weeks; a loopful of fluid can be removed at intervals for examination.

In culture, pathogenic flagellates may form only certain morphological types; *Leishmania donovani* grows in the promastigote form, although *Trypanosoma cruzi* cultures contain e.g. epimastigotes and metacyclic forms.

**NNRTI** NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR.

**Noble agar** A purified (washed) form of AGAR.

**noble rot** (*pourriture noble*; *Edelfäule*) A rot of grapes caused by *Botrytis cinerea*. On ripe or over-ripe white grapes the mould penetrates the grape skins and leads to loss of water; must from such grapes is thus more concentrated than normal and is used for making high-quality sweet wines (see WINE-MAKING). (The same mould on unripe or black grapes renders them useless for wine-making.)

**nocardamine** A colourless, trihydroxamate SIDEROPHORE produced e.g. by certain actinomycetes and by *Pseudomonas stutzeri* under iron-deficient conditions. [JGM (1980) 118 125–129.]

**Nocardia** A genus of Gram-positive, aerobic, chemoorganotrophic, non-motile bacteria (order ACTINOMYCETALES, wall type IV) which occur e.g. in soil and as pathogens of man and other animals (see e.g. MADUROMYCOSIS, NOCARDIOSIS; see also NOCARDICINS); the degree of acid-fastness appears to be variable even within a given isolate. The organisms typically form a branched (substrate and aerial) mycelium (hyphae 1 μm or less in diam.) which, according to species, tends to fragment more or less readily into rods and coccioid forms, some of the latter being heat- and/or desiccation-resistant (see MICROCYST (1)). Cell walls contain MYCOLIC ACIDS. Growth occurs readily at 30°C and 37°C on enriched media; colonies are often wrinkled or ridged, and may be any of a variety of colours. Glucose is metabolized oxidatively. GC%: 64–72. Type species: *N. asteroides*.

The genus includes e.g. *N. amarae* (isolated e.g. from the foam on an activated-sludge sewage treatment plant) and also *N. asteroides*, *N. brasiliensis* and *N. farcinica* (Kyoto-1 group), *N. otitidis-caviarum*, and *N. vaccinii* (a species reported to produce galls in the blueberry plant). '*N. autotrophica*', '*N. mediterranea*' and '*N. rugosa*' each have type IV actinomycete walls but they do not contain mycolic acids and have been removed from the genus [Book ref. 73, pp. 89–91, 129].

(See also e.g. HYDROCARBONS and RUBBER SPOILAGE.)

**nocardicins** A class of monocyclic β-LACTAM ANTIBIOTICS (q.v. for structure) produced by a species of *Nocardia*.

**nocardioform actinomycetes** A category within the order ACTINOMYCETALES which includes *Caseobacter*, *Corynebacterium*,

*Mycobacterium*, *Nocardia* and *Rhodococcus* – organisms which form either non-mycelial growth or a fragmenting mycelium and which have a cell wall of chemotype IV. (cf. SPOROACTINOMYCETES.)

**Nocardioideae** A genus of aerobic soil bacteria (order ACTINOMYCETALES, wall type I) which form branching substrate and aerial mycelia that fragment into coccoid and rod-shaped pieces. GC%: ca. 66–67. Type species: *N. albus*. [Book ref. 73, pp. 100–101.]

**Nocardiosis** A genus of bacteria (order ACTINOMYCETALES, wall type III) which occur e.g. in soil. The organisms form branching, fragmenting substrate mycelium, and an aerial mycelium which gives rise to long chains of spores – each spore tending to form at an angle to its neighbours, thus giving the chain an undulating appearance. GC%: ca. 70–76. Type species: *N. dassonvillei* (formerly *Actinomadura dassonvillei*). [Book ref. 73, pp. 117–118.]

**nocardiosis** An acute or chronic disease of man and animals, caused by a species of *Nocardia* (commonly *N. asteroides*). The disease may be systemic: suppurative lesions are formed mainly in the lungs, but the infection may disseminate to other organs (brain, kidney etc). Nodular, often suppurating, subcutaneous lesions may result from disseminated infection or from primary infection via a wound. (See also MADUROMYCOSIS.)

**nocardomycolic acids** MYCOLIC ACIDS of *Nocardia* spp.

**Noctiluca** A genus of marine, bioluminescent, heterotrophic (holozoic) DINOFLAGELLATES. The vegetative cells are large (e.g. 200–2000 µm diam.), roughly spherical (with no girdle), and have highly vacuolated cytoplasm; the flagella are very short, the transverse flagellum being reduced to a small projection. There is a deep sulcus from the region of which arises a retractable *tentacle*; the tentacle is apparently sticky and aids in the capture of prey. A cytostome is present near the base of the tentacle. Some strains of *Noctiluca* contain endosymbiotic unicellular green flagellates in vacuoles within the cell. (See also BIOLUMINESCENCE.)

**Nodamura virus** See NODAVIRIDAE.

**Nodaviridae** (Nodamura virus group) A family of ssRNA viruses which infect insects of the Diptera, Coleoptera and Lepidoptera. The virions are roughly spherical, naked, 29 nm diam., and each contains one major polypeptide species and two molecules of non-polyadenylated ssRNA (MWts ca. 1.15 and 0.46 × 10<sup>6</sup>), both of which are necessary for infection. The type species, Nodamura virus, was isolated from mosquitoes (*Culex tritaeniorhynchus*) in Japan; it can replicate in various insects, can cause a lethal infection in suckling mice, and can replicate in various vertebrate and invertebrate cell cultures (including e.g. BHK cells). Other member: Black beetle virus, isolated from the New Zealand Black beetle, *Heteronychus arator*. Possible members include e.g. Arkansas bee virus.

**Nodosaria** See FORAMINIFERIDA.

**Nodularia** A genus of filamentous freshwater and marine (littoral) CYANOBACTERIA (section IV) in which the trichomes are made up of disc-shaped vegetative cells. Heterocysts may be intercalary or terminal. GC%: ca. 41. *N. spumigena* is a gas-vacuolate, primarily freshwater, bloom-forming species which may form toxin(s) responsible for severe vomiting and bloody diarrhoea, or chronic liver and kidney damage, in animals which drink the water.

**nodules** (*plant microbiol.*) See ACTINORRHIZAE; PHYLLOBACTERIUM; ROOT NODULES; STEM NODULES.

**nodulins** ROOT NODULE-specific proteins specified by host plant genes; they appear to be involved in symbiotic nitrogen fixation and nitrogen metabolism. *C-nodulins* ('common nodulins')

occur in all (leguminous) root nodules; *S-nodulins* are specific to the nodules of certain plant species. [Book ref. 55, pp. 79–83; review of nodulins and nodulin genes in *Glycine max* (soybean): PMB (1986) 7 51–61.]

**nogalamycin** See ANTHRACYCLINE ANTIBIOTICS.

**nom. cons.** *Nomen conservandum*: a CONSERVED NAME.

**nom. dub.** NOMEN DUBIUM (q.v.).

**nom. nud.** NOMEN NUDUM (q.v.).

**nom. rejic.** NOMEN REJICIENDUM (q.v.).

**nom. rev.** NOMEN REVICTUM.

**Nomarski interference-contrast microscopy** See MICROSCOPY (d).

**nomen conservandum** (nom. cons.) A CONSERVED NAME.

**nomen dubium** (nom. dub.) A name which cannot, with certainty, be applied to a specific organism; the uncertainty may be due e.g. to an incomplete description of an organism in the original publication.

**nomen nudum** (nom. nud.) In NOMENCLATURE: a name which, when proposed, was not supported by an adequate description of the relevant taxon.

**nomen rejiciendum** (nom. rej.; nom. rejic.) Any name which has been rejected by a recognized taxonomic authority.

**nomen revictum** (nom. rev.) A revived name.

**nomenclatural type** (name bearer, nominifer, or 'type') Commonly, a viable specimen of a given organism to which a name has been attached and which is regarded as the permanent representative, or reference specimen, of a given taxon; otherwise, e.g., a preserved specimen or a photographic (or other) representation – sometimes simply a description – of an organism to which is permanently attached the name of a given taxon. (See also TYPE SPECIES and TYPE STRAIN.) [Bacterial types: Book ref. 22, p. 21.]

**nomenclature** (*microbiol.*) The naming of organisms: one of the functions of TAXONOMY. Nomenclature is formally governed by an array of rules and priorities promulgated by various ad hoc bodies – each concerned with a particular type of organism; thus, e.g. bacterial names are regulated by the International Committee on Systematic Bacteriology which promulgates the International Code of Nomenclature of Bacteria [Book ref. 71 and subsequent revisions]. (Nevertheless, such rules and regulations are not always universally adhered to – due e.g. to a lack of awareness or to disagreement with published opinions.)

With some exceptions (see later) each species of microorganism is referred to by a unique BINOMIAL. (The names of species and genera are usually printed in italics; in typewritten and handwritten manuscripts such names are usually underlined.) Where ambiguity cannot arise the generic name may be abbreviated; thus, e.g. *Staphylococcus aureus* may be written *Staph. aureus* or *S. aureus*. The name of a species is sometimes followed by an authority citation; this gives the name(s) of the author(s) who first proposed the name in a 'valid publication' and may also give the date of that publication – e.g. *Bacillus cereus* Frankland and Frankland 1887. (A *valid publication* is one which contains an adequate description of a newly proposed taxon and a correctly formulated Latin or Latinized name; it must be in printed form and must be available to the public or to the scientific community. A publication which lacks an adequate description but which fulfils the other requirements is called an *effective publication*.) Sometimes a double citation is used – e.g. *Escherichia coli* (Migula 1895) Castellani and Chalmers 1919; here, Migula is the author who described the organism under the name *Bacillus coli*, and Castellani and Chalmers are the authors who first described

## nomenspecies

NOMENCLATURE: some suffixes used in microbial nomenclature

	Algae	Bacteria	Fungi	Protozoa	Viruses
Division (phylum)	-phyta		-mycota	-a	
Subdivision (subphylum)	-phytina		-mycotina	-a	
Superclass				-a	
Class	-phyceae		-mycetes	-ea	
Subclass	-phycidae		-mycetidae	-ia	
Superorder				-idea	
Order	-ales	-ales	-ales	-ida	
Suborder	-ineae	-ineae	-ineae	-ina	
Superfamily				-oidea	
Family	-aceae	-aceae	-aceae	-idae	-viridae
Subfamily	-oideae	-oideae	-oideae	-inae	-virinae
Tribe	-eae	-eae	-eae	-ini	
Subtribe	-inae	-inae	-inae		
Genus					-virus

the organism as *Escherichia coli*. (Sometimes an organism is known by one or more trivial names, as well as by its scientific name; these may be descriptive – e.g. ‘orange-peel fungus’ – or may have historical or other interest.)

Taxa below the rank of species may be referred to by the binomial of the given species followed by a further designation(s): e.g., *Campylobacter sputorum* subsp *bubulus*, *Fusarium solani* f. sp. *pisi*, *Pseudomonas syringae* pv. *savastanoi*, *Puccinia graminis* var. *phlei-pratensis* Race 1. (See also TERNARY COMBINATION.)

A taxon of the rank genus or above is referred to by a unique uninomial (one-name designation); the rank of a particular named taxon is often indicated by a standardized suffix (see table above).

While an organism may bear only one valid taxonomic name, certain fungi may be referred to by a second binomial (see e.g. FORM GENUS); in deuteromycetes the name of the TELEOMORPH (where known) is the valid taxonomic name – that of the anamorph sometimes being written, in parenthesis, afterwards: e.g. *Ajellomyces dermatitidis* (*Blastomyces dermatitidis*).

**nomenspecies** (1) One or more strains designated by a given binomial, i.e., a strain or group of strains treated as a species but not necessarily recognized as such taxonomically. (2) A type species.

**nomifer** *Syn.* NOMENCLATRURAL TYPE.

**Nomuraea** A genus of fungi of the HYPHOMYCETES. *N. rileyi* has been evaluated for the BIOLOGICAL CONTROL of caterpillars of noctuid moths; it can be grown on artificial media [inexpensive media and methods: *J. Inv. Path.* (1986) 48 246–248], and its conidia can remain infective when sprayed onto crops. Conidia germinate on the surface of a caterpillar, and hyphae penetrate the insect, subsequently growing in the haemocoel; the caterpillar usually dies within 1–2 days and becomes covered with a dense mycelial mat from which conidia are eventually produced.

**non-A–non-B hepatitis** (NANB hepatitis) See HEPATITIS C.

**nonactin** See MACROTETRALIDES.

**non-agglutinable vibrios** *Syn.* NON-CHOLERA VIBRIOS.

**non-agglutinating antibodies** BLOCKING ANTIBODIES (sense 1).

**non-brewed condiment** See VINEGAR.

**non-cellular** *Syn.* ACELLULAR.

**non-cholera vibrios** (NCVs; non-agglutinable vibrios) Those strains of *Vibrio cholerae* which are not agglutinated by O1 (or

O139) antiserum; strains of *V. cholerae* which cause CHOLERA (q.v.) are characteristically agglutinated by O1 (or O139) antiserum. NCVs are classified serologically into serogroups O2 to O138; they are generally regarded as less pathogenic than O1 (or O139) strains, although they may cause mild to severe, cholera-like disease.

(See also NCVp.)

**non-circulative transmission** (of viruses) (*plant pathol.*) (1) A mode of transmission in which viruses are temporarily associated with surface region(s) of an insect VECTOR; non-circulatively transmitted viruses can be acquired from an infected plant and transmitted to a healthy plant within seconds or minutes, i.e., there is no latent period (cf. CIRCULATIVE TRANSMISSION). A distinction is sometimes made between those cases in which virus is retained by the vector for minutes or hours (*non-persistent transmission*) and those cases in which virus is retained for up to several days (*semi-persistent transmission*).

In non-circulative transmission the insect’s ability to transmit a previously acquired virus is lost during moulting. When an insect moults it replaces its external body covering, parts of the pharynx, and the anterior and posterior regions of the gut lining; hence, any virus carried superficially is shed, and the loss of infectivity during moulting is regarded as a diagnostic feature of non-circulative transmission.

In many cases, non-circulative transmission involves more than the simple mechanical contamination of the surface of an insect vector. For example, aphid-borne transmission of *purified* POTYVIRUSES occurs only if the aphid vector acquires a ‘helper component’ (HC) before or simultaneously with – but not subsequent to – acquiring the virus; HC is a virus-encoded protein (serologically distinct from either virus structural protein or ‘pinwheel’ protein) which occurs in potyvirus-infected leaves, and which can be obtained in the laboratory by cell-free translation of viral RNA. The *uptake* of virus by the aphid vector is apparently not influenced by the presence or absence of HC [MS (1984) 1 191–193]. Interestingly, the HC of a given potyvirus can also promote the aphid-borne transmission of certain other potyviruses – and even some unrelated viruses (e.g. potato aucuba mosaic virus) – which are not aphid-transmissible in the absence of HC. (HC is not necessary for mechanical, i.e., manual, infection of plants by potyviruses.) In certain CAULIMOVIRUSES, aphid-borne transmission is – as in potyviruses – dependent on helper factors (termed ‘transmission

factors' in this virus group), and the aphid-borne transmission of certain caulimoviruses which are not normally aphid-transmissible can be promoted by transmission factor from other caulimoviruses [JGV (1985) 66 921–923].

(2) The term 'non-circulative transmission' (or 'non-persistent transmission') is sometimes used to refer to the transmission of viruses by vectors other than insects; examples include transmission of SOIL-BORNE WHEAT MOSAIC VIRUS and TOBACCO NECROSIS VIRUS by species of *Polymyxa* and *Olpidium*, respectively, and the transmission of NEPOVIRUSES by nematodes of the genera *Longidorus* and *Xiphinema*.

**non-coding strand** (of dsDNA) See CODING STRAND.

**non-cognate interaction** (*immunol.*) Interaction between a B cell and a T cell in which each cell recognizes, and binds to, a separate (physically distinct) molecule (cf. COGNATE HELP); the T cell may influence the B cell via soluble factors (i.e. CYTOKINES).

**non-complementing diploid** See PROTOPLAST FUSION.

**non-conjugative plasmid** (1) As commonly used: a PLASMID which does not encode one or more of the functions needed for its own intercellular transmission by CONJUGATION (sense 1b). (cf. CONJUGATIVE PLASMID.)

(2) According to some authors [ARG (1979) 13 99–125 (105–106)]: a plasmid which does not encode one or more of the functions (e.g. pilus formation) needed for specific cell–cell contact, and which may or may not be capable of being mobilized.

**non-disjunction** Atypical distribution of chromosomes or chromatids (or parts thereof) to the poles of the spindle during MEIOSIS or MITOSIS. (See e.g. PARASEXUAL PROCESSES.)

**non-genetic reactivation** (*virol.*) A phenomenon in which an inactivated virus (which cannot complete its replication cycle when infecting cells on its own) can produce viable progeny virions in the presence of a second, closely related virus as a result of COMPLEMENTATION between viral proteins. An example is the 'Berry–Dedrick phenomenon' in which rabbits infected with a mixture of heat-inactivated myxoma virus and infectious (non-damaged) rabbit fibroma virus may develop myxomatosis. (cf. REACTIVATION.)

**non-gonococcal urethritis** (NGU; non-specific urethritis, NSU) Sexually transmitted URETHRITIS caused by any organism other than *Neisseria gonorrhoeae* (cf. GONORRHOEA and URINARY TRACT INFECTION). The causal agent is commonly *Chlamydia trachomatis* which infects the epithelium of the urinary tract. Symptoms of chlamydial infection may be mild, or there may be severe urethritis with a profuse purulent discharge (usually in males); the infection may spread to the genital tract epithelium, causing e.g. epididymitis in males, salpingitis in females [BMB (1983) 39 133–150]. Other causal agents of NGU include e.g. *Candida albicans*, *Trichomonas vaginalis*, *Mycoplasma hominis*, and (possibly) *Ureaplasma urealyticum*. *Chemotherapy*: tetracyclines.

**non-haem iron protein** A category of iron-containing proteins in which the iron is not present as part of a HAEM (sense 1) moiety; they were once believed to include all IRON-SULPHUR PROTEINS but some of the latter are now known to contain e.g. SIROHAEM.

**non-histone proteins** A range of different proteins, other than HISTONES, associated with CHROMATIN; many occur in relatively small amounts. Examples include those proteins involved in transcription (e.g. RNA polymerases) and so-called HMG proteins (high-mobility group proteins) – the latter being characterized by their DNA-binding domains (see HMG BOX).

The HMG1 protein is a small (25 kDa), highly charged protein which contains two similar HMG boxes (designated A

and B). It occur in large numbers (e.g.  $10^6$  copies per nucleus) and binds to dsDNA in an apparently non-sequence-specific manner – although it binds strongly to specific DNA structures such as angular or kinked DNA or four-way junctions. HMG1 can also interact with certain other DNA-binding proteins and, in this way, can cause sharp bends to develop in dsDNA; this ability can enhance the activity of certain transcription factors, and HMG1 apparently affects the expression of particular genes.

HMG1 also has extra-nuclear activity. In vitro, it can be secreted by macrophages on stimulation by CYTOKINES or ENDO-TOXIN, and it may have a role e.g. in inflammation. More recently it has been reported that HMG1 is released by certain damaged or necrotic cells, including endothelial cells, and that it can act as a chemoattractant, induce cell migration and bring about reorganization in the cytoskeleton in certain cells [JCB (2001) 152 1197–1206].

**Nonidet P-40** A non-ionic detergent of the polyoxyethylene *p*-*t*-octyl phenol series.

**Nonion** See FORAMINIFERA.

**non-Mendelian inheritance** *Syn.* CYTOPLASMIC INHERITANCE.

**non-nucleoside reverse transcriptase inhibitors** (NNRTIs) A category of ANTIRETROVIRAL AGENTS (q.v.) that includes delavirdine, efavirenz and nevirapine. The NNRTIs are structurally diverse compounds; they bind to reverse transcriptase and inhibit enzyme activity. The clinically used NNRTIs are reported to be effective against the reverse transcriptase of HIV-1 but not against that of HIV-2. (See also NU-1320.)

[NNRTIs and other antiretroviral agents in the treatment of AIDS: BMJ (2001) 322 1410–1412.]

**non-O1 *Vibrio cholerae* pilus** See NCVP.

**non-permissive conditions** See CONDITIONAL LETHAL MUTANT.

**non-persistent transmission** See NON-CIRCULATIVE TRANSMISSION.

**non-photochromogen** A term used (very loosely) to refer e.g. to any strain of *Mycobacterium* which (i) forms little or no pigment, (ii) does not form pigment during early growth, and/or (iii) does not need to grow in the light in order to produce pigment (cf. SCOTOCROMOGEN).

**non-propagative viruses** See CIRCULATIVE TRANSMISSION.

**non-reciprocal recombination** See RECOMBINATION.

**nonsense codon** See GENETIC CODE.

**nonsense mutation** A MUTATION in which a codon specifying an amino acid is altered to a nonsense (chain-terminating) codon: e.g. an amber codon (*amber mutation*) or an ochre codon (*ochre mutation*). (cf. MIS-SENSE MUTATION.)

**nonsense suppressor** See SUPPRESSOR MUTATION.

**non-specific immunity** The constitutive (or, in certain cases, acquired) resistance of the body to foreign materials in general – including those (living and non-living) materials with which it has had no previous contact. Non-specific immunity involves e.g. PHAGOCYTOSIS and the activities of INTERFERONS, LYSOZYME and PROPERDIN. (cf. SPECIFIC IMMUNITY.)

**non-specific immunization** The administration of certain immunostimulants (e.g. BCG) in order to elicit a heightened immune response to antigen(s) unrelated to the immunostimulant.

**non-specific immunotherapy** The therapeutic use of NON-SPECIFIC IMMUNIZATION.

**non-specific urethritis** *Syn.* NON-GONOCOCCAL URETHRITIS.

**non-specific vaginitis** *Syn.* BACTERIAL VAGINOSIS.

**non-sterilizing immunity** *Syn.* PREMUNITION.

**non-steroidal anti-inflammatory drugs** (NSAIDs) See PROSTAGLANDINS.

**non-sulphur purple bacteria** See RHODOSPIRILLACEAE.

## non-treponemal tests

**non-treponemal tests** *Syn.* STANDARD TESTS FOR SYPHILIS.

**non-vibrio cholera** Any CHOLERA-like disease caused by organisms other than *Vibrio cholerae* – e.g. enterotoxigenic strains of *Escherichia coli* (see ETEC).

**nopaline** An opine:  $N^2$ -(1,3-dicarboxypropyl)-L-arginine – see CROWN GALL.

**nopalinic acid** See CROWN GALL.

**2'-nor-2'-deoxyguanosine** See DHPG.

**norfloxacin** See QUINOLONE ANTIBIOTICS.

**nori** See LAVER.

**Normandina** A genus (*incertae sedis*) of LICHENS; photobiont: *Trebouxia*. The thallus is squamulose, the squamules being shell-shaped, 1–2 mm across, bluish-green, with raised, often sorediate margins. Fruiting structures are unknown; however, ascocarps of a (probably parasitic) fungus (*Sphaerulina chlorococca*) may be visible as dark dots on the surface of the thallus. The sole species, *N. pulchella*, occurs as an epiphyte on bryophytes.

**North American blastomycosis** *Syn.* BLASTOMYCOSIS.

**Northern blot** See BLOTTING.

**Norwalk virus** (Norwalk agent) A small (27 nm) non-enveloped virus categorized as a SMALL ROUND STRUCTURED VIRUS (q.v.); it was first described in Norwalk, Ohio, in 1972. Norwalk virus can cause outbreaks of diarrhoeal disease/gastroenteritis, and is transmitted by the faecal–oral route. (cf. SNOW MOUNTAIN AGENT; see also WATER SUPPLIES and FOOD POISONING (i).)

**nose microflora** See RESPIRATORY TRACT MICROFLORA.

**Nosema** A genus of protozoa (class MICROSPOREA) which are parasitic mainly in insects.

*N. apis* is parasitic in epithelial cells of the midgut in the honeybee (*Apis mellifera*); spores liberated by disruption of the epithelial cells are voided in the faeces. Infection occurs by ingestion; transovarial transmission apparently does not occur. (See also BEE DISEASES.)

*N. bombycis* causes *pébrine* – a commonly fatal disease of silkworms (larvae of the silk-moth, *Bombyx mori*). Infection may occur by ingestion of mulberry leaves contaminated with spore-containing faeces from an infected silkworm. The spores germinate in the gut; reproduction occurs first in gut epithelium—but later in various tissues. Infected silkworms have characteristic dark spots. Transmission can occur transovarially.

*N. cuniculi*: see ENCEPHALITIZOON.

Other species may parasitize mosquitoes, moths, fish, etc; *N. algerae* and *N. locustae* have been tested for use in the BIOLOGICAL CONTROL of mosquitoes and grasshoppers, respectively.

**nosocomial disease** A disease acquired in hospital. Infection rates of about 30% have been reported for patients in adult intensive-care units [review: Lancet (2003) 361 2068–2077].

**Nostoc** A genus of filamentous CYANOBACTERIA (section IV) in which the vegetative cells are spherical, ovoid or cylindrical; young trichomes formed from hormogonia have terminal heterocysts, but in longer trichomes heterocysts may also occur in intercalary positions. Akinetes, if formed, often occur in chains and develop half-way between two heterocysts. In *N. muscorum*, at least, gas vacuoles occur only in hormogonia (see HORMOGONIUM). GC%: 39–46.

In nature, free-living *Nostoc* spp occur in various habitats (e.g. river-beds, wet rocks, damp soil), typically forming green to blackish gelatinous colonies up to several centimetres across; the colony form is rarely retained in culture.

*Nostoc* spp form symbiotic associations with a wide range of eukaryotes, the latter deriving benefit from the ability of the cyanobiont to fix nitrogen. In LICHENS, *Nostoc* may be the main photobiont (e.g. in *Collema*, some *Peltigera* spp) or may occur

in discrete cephalodia (see CEPHALODIUM). In liverworts (e.g. *Blasia*, *Cavicularia*) and hornworts (*Anthoceros*), *Nostoc* occurs in cavities in the underside of the thallus. Among angiosperms, *Gunnera* (a genus of rhubarb-like marsh plants) contains '*Nostoc punctiforme*' in mucilage-filled glands in the plant stem at the bases of petioles; the cyanobiont penetrates between the cortical cells and enters meristematic cells, thus becoming an intracellular symbiont. [Development of *Nostoc* in *Gunnera* mucilage glands: Bot. Gaz. (1985) 146 56–62.] Cycads are the only gymnosperms known to be capable – via symbionts – of nitrogen fixation; they develop coralloid root nodules which contain symbiotic nitrogen-fixing cyanobacteria (*Nostoc*) in mucilage-filled spaces in the root cortex [ultrastructural studies of *Nostoc*–*Zamia* association: New Phyt. (1985) 101 707–716].

**Nostocales** See CYANOBACTERIA.

**notatin** A flavoprotein GLUCOSE OXIDASE produced intracellularly e.g. by '*Penicillium notatum*' (= *P. chrysogenum*). It can show antimicrobial activity due to the production of HYDROGEN PEROXIDE.

**NotI** See RESTRICTION ENDONUCLEASE (table).

**notifiable diseases** Those diseases (of man, animals or plants) the occurrence (or suspected occurrence) of which must, by law, be notified to the appropriate authorities.

**novel antigen** Any weakly immunogenic or non-immunogenic molecule which can be made (more) immunogenic by CONJUGATION (sense 2) with an immunogenic molecule. (cf. HAPTEN; NEOANTIGEN.)

**novobiocin** (albamycin) An ANTIBIOTIC (produced e.g. by *Streptomyces spheroides* and *S. niveus*): 4,7-dihydroxy-3-amino-8-methylcoumarin linked via the 3-amino group to a substituted *p*-hydroxybenzoic acid and via the 7-hydroxy group to a substituted hexose (*noviose*). Novobiocin is more active against Gram-positive than Gram-negative bacteria; resistance develops readily. It primarily inhibits synthesis of DNA and, to a lesser extent, RNA. It selectively and competitively inhibits the binding of ATP to GYRASE B subunits; thus DNA supercoiling by gyrase is inhibited, but the (ATP-independent) DNA-relaxing gyrase activity is not. (See also CURING.) Secondary effects of novobiocin include inhibition of protein and cell wall synthesis. (See also COUMERMYCINS; cf. NALIDIXIC ACID.)

**Novyella** A subgenus of PLASMODIUM.

**Nowakowskiella** A genus of eucarpic, polycentric fungi (order CHYTRIDIALES) which are typically aquatic saprotrophs. The vegetative thallus includes a RHIZOMYCELIUM whose branching rhizoids penetrate the substratum. Operculate zoosporangia are formed, and each liberated zoospore germinates to form a rhizomycelium. Thick-walled resting spores are formed on pseudoparenchymatous structures, but whether or not these are sexual structures is unknown.

**noxythiolin** (*N*-methyl-*N'*-hydroxymethylthiourea) A broad-spectrum antimicrobial agent which has been used e.g. for the treatment of bacterial peritonitis; its activity appears to depend on the release of FORMALDEHYDE. Noxythiolin can kill blastospores of *Candida albicans* in vitro [JAB (1986) 60 319–325].

**nPCR** See NESTED PCR.

**NPV** NUCLEAR POLYHEDROSIS VIRUS.

**NR1 plasmid** See R100 PLASMID.

**nrda gene** (*dnaF* gene) A gene which codes for ribonucleotide reductase.

**nrdb gene** See SPLIT GENE (e).

**nrdd gene** See SPLIT GENE (e).

**NRRL** Culture collection of the Northern Regional Research Laboratories, US Dept. Agriculture, 1815 North University St, Peoria, Illinois 61604, USA.

**NRTIs** NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS.

***NruI*** See RESTRICTION ENDONUCLEASE (table).

**N<sub>s</sub> protein** See ADENYLATE CYCLASE.

**NSAIDs** Non-steroidal anti-inflammatory drugs. (See also PROSTAGLANDINS.)

**NSU** See NON-GONOCOCCAL URETHRITIS.

**nt** Abbreviation for nucleotide(s).

**NTA** Nitriloacetic acid, N(CH<sub>2</sub>COOH)<sub>3</sub> (= triglycollamic acid), a chelating agent which complexes a range of cations (e.g. Ca<sup>2+</sup>, Zn<sup>2+</sup>) – though less efficiently than does EDTA. It may be carcinogenic.

**NTG** Nitrosoguanidine: see MNNG.

**NTM** Non-tuberculous mycobacteria (see MOTT).

**NTP** NUCLEOSIDE-5'-triphosphate.

***ntr* genes** In enterobacteria, *rpoN* (= *ntrA*, *glnF*), *ntrB* (= *glnL*) and *ntrC* (= *glnG*): genes whose products control the expression of *nitrogen-regulated genes* – the latter including e.g. *glnA* (encoding glutamine synthetase, GS), NIF GENES, and genes concerned with transport and degradation of amino acids; transcription of nitrogen-regulated genes is typically repressed in the presence of high concentrations of ammonia and induced when ammonia becomes limiting. (See also AMMONIA ASSIMILATION.)

*rpoN* (*ntrA*) encodes an enhancer-dependent SIGMA FACTOR,  $\sigma^{54}$ , involved in the control of initiation of transcription of nitrogen-regulated genes. [ $\sigma^{54}$  (minireview): JB (2000) 182 4129–4136.] NtrC is an *activator* protein that permits transcription from  $E\sigma^{54}$  (see SIGMA FACTOR). NtrB appears to be involved in the activation of NtrC.

The *glnA* operon in *Salmonella typhimurium* contains at least two promoters. P2, nearest the structural genes, is the major nitrogen-regulated promoter; transcription from P2 requires the *rpoN* and *ntrC* gene products. ( $E\sigma^{70}$  apparently cannot initiate transcription from P2.) P1 is a secondary promoter, upstream from P2, which is activated by the cAMP–CRP complex (see

CATABOLITE REPRESSION); it is not dependent on the *rpoN* and *ntrC* gene products.

In *Klebsiella pneumoniae*, transcription of all the NIF GENES is dependent on the sigma factor  $\sigma^{54}$  (*rpoN* gene product). Transcription of the *first* operon, *nifLA*, requires the NtrC activator; after transcription of this operation, the NifA product functions as an activator for  $\sigma^{54}$  in all subsequent *nif* genes/operons (see figure). However, while NtrC and NifA are functionally related, NtrC – but not NifA – is activated by phosphorylation.

**nu particle** See PSEUDOCAEDIBACTER.

**NU-1320** (*syn.* NU1320) A candidate anti-AIDS drug within the category NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS. It is reported to be several million times more potent than AZT but to have a very low level of toxicity. The drug was discovered by Tronchet's team in Geneva and is being developed by the French company Mayoly Spindler.

**nuclear area** (nuclear body) (*bacteriol.*) See CHROMOSOME.

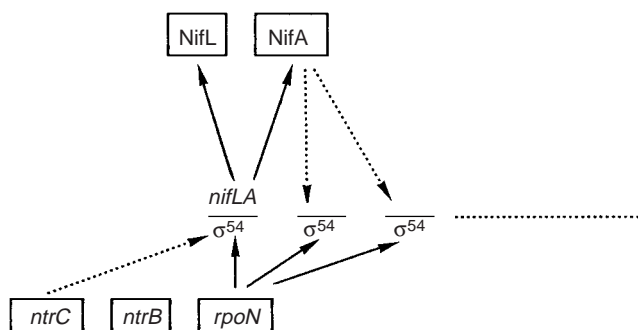

**nuclear dehydrogenating clostridia** See GASTROINTESTINAL TRACT FLORA.

**nuclear factor- $\kappa$ B** See CYTOKINES.

**nuclear localization signal** See CROWN GALL.

**nuclear magnetic resonance** (NMR) The absorption and consequent emission of electromagnetic radiation by the nuclei of certain types of atom in the presence of a strong magnetic field. This phenomenon is the basis of a non-destructive, non-invasive method used (e.g. in biochemistry, medicine and microbiology) for elucidating the structures, conformations and interactions of molecules in both in vitro and in vivo systems; NMR is used primarily for investigating small molecules (MWt <2000) in solution.

*Principle.* The types of nuclei particularly suitable for NMR studies occur in those atoms which have an *odd* mass number. In such atoms (e.g. <sup>1</sup>H, <sup>13</sup>C, <sup>31</sup>P) the nucleus has a magnetic moment, and in the presence of a strong external magnetic field the nuclear magnetic axis 'wobbles' about the field's axis with a characteristic *precession* frequency; exposure to a pulse of radiation at the precession frequency will increase the amplitude of the wobble (= nuclear magnetic resonance). When the resonance decays it generates electromagnetic radiation which

*ntr* GENES: control of the *nif* genes by the *ntr* genes in *Klebsiella pneumoniae* (diagrammatic) (see entry). Transcription of all the *nif* genes/operons requires the enhancer-dependent sigma factor  $\sigma^{54}$  (*rpoN* gene product); additionally, transcription *initially* requires an activated (phosphorylated) NtrC protein – which is present when combined nitrogen is limiting. NtrB is apparently involved in regulating the activity of NtrC.

The first *nif* genes to be transcribed are those in the *nifLA* operon. NifA, which is functionally related to NtrC, takes over the role of activator of  $E\sigma^{54}$  for all subsequent *nif* genes/operons. NifL can inhibit NifA in the presence of combined nitrogen; moreover, NifA is inactivated by oxygen. Nitrogen fixation is blocked completely by null mutations in *rpoN*, *ntrC* or *nifA*.

## nuclear petite

can be detected by its ability to induce a signal (a radiofrequency alternating voltage) in a coil tuned to the particular resonance frequency. Usually, a single excitatory pulse produces only a weak resonance signal, so that several hundred or several thousand intermittent pulses are commonly used, the resulting resonance signals being added together in a computer.

The resonance frequency of a given nucleus is influenced by the precise location of the atom within a molecule: if atoms of a given type (e.g.  $^1\text{H}$ ) are located in different molecular environments (e.g.  $\text{CH}_2$ ,  $\text{CH}_3$ ,  $\text{OH}$ ) their nuclei will have slightly different resonance frequencies. When, due to a chemical reaction, an atom moves to a different molecular environment, the resonance frequency of its nucleus will change to that specified by the new location. A given type of nucleus within a particular molecular environment may be identified by its *chemical shift* ( $\delta$ ): the relative amount by which its resonance frequency is shifted from that of a given reference standard – which, for  $^1\text{H}$ , is the agent tetramethylsilane (TMS),  $(\text{CH}_3)_4\text{Si}$ ; chemical shift is expressed in the dimensionless unit ‘parts per million’ (ppm).

If, for a given type of nucleus (e.g.  $^1\text{H}$ ), the nuclear resonance frequency is determined (under standard conditions) for each type of molecular environment, it is possible e.g. to follow the progress of a chemical reaction by monitoring changes in signal strength at the various resonance frequencies; this is possible because the signal strength at a given resonance frequency is proportional to the number of nuclei occupying a given type of molecular environment.

An NMR signal is a composite radio-frequency trace which incorporates simultaneous signals at various resonance frequencies; it is called a *free induction decay* (FID) since signal intensity decreases to zero as all the nuclei relax into their former (pre-excited) state of thermal equilibrium. The various resonance signals are separated out from the FID by mathematical manipulation involving the *Fourier transform*: a function which relates a complex waveform to its component spectrum of frequencies.

The apparatus used for NMR includes an electromagnet or a superconducting magnet in order to obtain a strong magnetic field. Field strength directly influences the absolute resonance frequencies of nuclei; thus, e.g., resonance frequencies of  $^1\text{H}$  nuclei are centred around ca. 42.6 megacycles (= megahertz, MHz) when the magnetic field is 1 tesla (= 10000 gauss), while at 4.7 tesla the  $^1\text{H}$  nucleus resonates at ca. 200 MHz. Other resonance frequencies include e.g. (MHz per tesla): 10.7 ( $^{13}\text{C}$ ), 4.31 ( $^{15}\text{N}$ ) and 17.24 ( $^{31}\text{P}$ ).

[Book ref. 151; NMR and its clinical applications: BMB (1984) 40 113–201; NMR in biochemistry: Book ref. 152, pp. 1–67; NMR and drug design: Book ref. 153, pp. 267–281; microbiological applications of NMR: MS (1985) 2 203–211, 340–345.]

**nuclear petite** See PETITE MUTANT.

**nuclear polyhedrosis viruses** (NPVs) Viruses belonging to subgroup A of the BACULOVIRIDAE (q.v.). Virus replication and occlusion body formation occur exclusively in the host cell nucleus (cf. CYTOPLASMIC POLYHEDROSIS VIRUS GROUP). The NPV virion may contain a single nucleocapsid (SNPV) or many nucleocapsids (MNPV). Type species: *Autographa californica* NPV (AcMNPV); other members include e.g. *Bombyx mori* (silkworm) NPV (BmSNPV), *Orygia pseudotsugata* (Douglas Fir tussock moth) NPVs (OpSNPV and OpMNPV), and viruses from many other insects and from certain crustacea.

**Nuclearia** A genus of amoebae (class FILOSEA). *N. delicatula* feeds by ingesting filamentous cyanobacteria [feeding behaviour and structure: JP (1986) 33 369–374].

**nuclease** Any enzyme which can cleave the sugar–phosphate backbone of a NUCLEIC ACID. (See also EXONUCLEASE and ENDONUCLEASE.)

**nuclease S<sub>1</sub>** *Syn.* ENDONUCLEASE S<sub>1</sub>.

**nucleation site** See CELL CYCLE (b).

**nucleic acid** A polymer of NUCLEOTIDES in which the 3′ position of one nucleotide sugar is linked to the 5′ position of the next by a phosphodiester bridge. In a linear nucleic acid strand, one end typically has a free 5′-phosphate group, the other a free 3′-hydroxyl group. (See DNA and RNA.)

**nucleic acid sequence-based amplification** See NASBA.

**nucleocapsid** A structure containing nucleic acid and protein which forms part (or all) of a virion. Depending on virus, ‘nucleocapsid’ may refer e.g. to the CORE plus the CAPSID (see e.g. HERPESVIRIDAE, TOGAVIRIDAE) or to a helical nucleoprotein structure (see e.g. ARENAVIRIDAE, PARAMYXOVIRIDAE, TOBACCO MOSAIC VIRUS); it corresponds to the ‘core’ in the REOVIRIDAE.

**nucleoid** (1) (*bacteriol.*) The bacterial CHROMOSOME [review: MR (1994) 58 211–232]. During cell division, the mechanism by which nucleoids are partitioned to daughter cells is unknown [partitioning in *Escherichia coli*: JB (1992) 174 7883–7889; in *Bacillus*: JB (1998) 180 547–555].

(2) (*virol.*) The ribonucleoprotein structure within the core, or the core itself, in the virion of a retrovirus (see RETROVIRIDAE).

(3) Mitochondrial or chloroplast DNA.

(4) The electron-dense central core in a PEROXISOME.

**nucleolar organizer** See NUCLEOLUS.

**nucleolus** Within most types of eukaryotic NUCLEUS: a distinct region, not delimited by a membrane, in which at least some species of rRNA are synthesized and assembled into ribonucleoprotein subunits of RIBOSOMES. In the nucleolus rRNA is transcribed from a *nucleolar organizer*, i.e., a group of tandemly repeated chromosomal genes which encode rRNA and which are transcribed by RNA polymerase I. (See also RRNA.) [Nucleolar structure and ribosome biogenesis: TIBS (1986) 11 438–442.] In most cases nucleoli do not persist during MITOSIS (cf. ENDOSOME sense 3). Nucleoli do not occur e.g. in the ciliate MICRONUCLEUS.

**nucleoside** A compound consisting of a purine or pyrimidine base covalently linked to a pentose – usually ribose (in *ribonucleosides*) or 2-deoxyribose (in *deoxyribonucleosides*); the figure shows some of the bases commonly found in nucleosides.

Ribonucleosides containing the bases adenine, guanine, cytosine, uracil, thymine and hypoxanthine are called (respectively) adenosine, guanosine, cytidine, uridine, thymidine and inosine. The corresponding deoxyribonucleosides are called deoxyadenosine, deoxyguanosine etc. (Note that ‘thymidine’ usually refers to *deoxythymidine* as thymine is associated primarily with DNA.) (cf. NUCLEOTIDE; see also Appendix V.)

**nucleoside antibiotic** A NUCLEOSIDE-containing ANTIBIOTIC: see e.g. POLYOXINS, PSICOFURANINE, PUROMYCIN, SHOWDOMYCIN.

**nucleoside reverse transcriptase inhibitors** (NRTIs) A category of deoxyribonucleoside analogues which are used e.g. as ANTIRETROVIRAL AGENTS (q.v.); all NRTIs have a similar mode of action – see AZT for details. These agents are involved in chemotherapy against AIDS [BMJ (2001) 322 1410–1412].

Examples of NRTIs: AZT (zidovudine); didanosine (2′,3′-dideoxyinosine); LAMIVUDINE; stavudine (2′,3′-dideoxythymidine); and zalcitabine (2′,3′-dideoxycytidine).

NRTIs can be mutually antagonistic: see e.g. AZT.

The anti-HIV activity of an NRTI may be raised by increasing the ratio of NRTIs to the cell’s own dNTPs; this can be done e.g. by using hydroxyurea to inhibit the enzyme ribonucleotide

NUCLEOSIDE: some of the bases commonly found in nucleosides. Reproduced from *Bacteria* 5th edition, Figure 7.3, page 112, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

reductase (this causing a decrease in endogenous dNTPs). This approach was found to give clinical benefit when hydroxyurea was combined with didanosine in the Swiss HIV Cohort Study (1998).

At least some NRTIs have been used against DNA viruses, i.e. they also inhibit DNA-dependent DNA polymerases (see e.g. LAMIVUDINE).

**nucleoskeleton** In a eukaryotic cell: an intranuclear framework, analogous to the CYTOSKELETON, which is believed to include e.g. points of anchorage for complexes involved in the replication and transcription of DNA; the concept of a nucleoskeleton is supported e.g. by demonstrations of intranuclear actin and myosin, and by the demonstration that DNA polymerases are retained within nuclei, under isotonic conditions, following treatment of the encapsulated nuclei with restriction endonucleases [EMBO (1986) 5 1403–1410]. There is also evidence that the cytoskeleton and nucleoskeleton are connected at the nuclear periphery. Transport between nucleus and cytoplasm may involve an ATP- and actomyosin-dependent control of the nuclear pore complex [JCB (1986) 102 859–862].

[Organization beyond the gene: TIBS (1986) 11 249–252.]

**nucleosome** See CHROMATIN.

**nucleotide** A NUCLEOSIDE in which the sugar carries one or more phosphate groups (see figure); nucleotides are the subunits of NUCLEIC ACIDS. (See also ATP.)

Pathways for the de novo biosynthesis of the main nucleotides are shown in Appendix V. Deoxyribonucleotides are synthesized by the reduction of ribonucleotides catalysed by the enzyme *ribonucleotide reductase*. In *Escherichia coli*, deoxyribonucleotides are synthesized mainly by a THIOREDOXIN-dependent reduction of ribonucleoside 5'-di phosphates, while in e.g. *Lactobacillus leichmannii* ribonucleoside 5'-tri phosphates are reduced in a VITAMIN B12-dependent reaction.

In addition to de novo synthesis, nucleotides can be synthesized using purine and pyrimidine bases derived from pre-formed nucleotides in a so-called 'salvage cycle'. (See also NAD and THYMIDINE KINASE.)

Antibiotics which affect nucleotide biosynthesis include AZASERINE; DON; HADACIDIN; MYCOPHENOLIC ACID and PSICOFURANINE.

**nucleotide excision repair** See EXCISION REPAIR.

**nucleotropism** See TROPISM (sense 2).

**Nucleopore filter** See FILTRATION.

**nucleus** Within a eukaryotic cell: a membrane-limited body which contains e.g. CHROMOSOMES and one or more nucleoli (see NUCLEOLUS). (See also NUCLEOSKELETON.) The number of chromosomes per nucleus depends e.g. on species. (See also PLOIDY.) The nuclear membrane consists of a double unit-type membrane which is perforated by a number of pores; the outermost membrane is continuous with the ENDOPLASMIC RETICULUM, and the space between the two membranes is called the *perinuclear space*.

A cell may contain more than one nucleus (see e.g. COENOCYTE and SYNCYTIUM), and ciliate protozoa typically have two *types* of nuclei (see MACRONUCLEUS and MICRONUCLEUS). The *fungus* nucleus is characteristically much smaller than the nuclei of most other eukaryotes, and in many cases fungal chromosomes cannot be seen by light microscopy [the fungal nucleus: Book ref. 168].

***Nudaurelia*  $\beta$  virus group** A family of non-enveloped, icosahedral (ca. 35 nm diam.), ssRNA-containing viruses which infect lepidopteran insects; the genome is a single molecule of positive-sense ssRNA (MWt ca.  $1.8-1.9 \times 10^6$ ).

NUCLEOTIDE. The figure shows a *ribonucleotide*; ribonucleotides are the subunits in RNA. In a *deoxyribonucleotide* the 2' position of ribose carries -H rather than -OH; deoxyribonucleotides are the subunits in DNA. The ribonucleotide in the figure is a *ribonucleoside monophosphate*; a *ribonucleoside triphosphate* (such as ATP) carries a chain of three phosphate groups -  $\alpha$ ,  $\beta$  and (terminal)  $\gamma$  - at the 5' position of the ribose.

In a *dideoxyribonucleotide* (used e.g. in DNA SEQUENCING), the 2' and 3' positions in the ribose carry -H (instead of -OH).

## null cells

Type species: *Nudaurelia*  $\beta$  virus (N $\beta$ V), isolated from the pine emperor moth – *Nudaurelia cytherea capensis* (= *Imbrasia cytherea*) – whose larvae cause extensive defoliation of pine trees in South Africa. Other members of the family have been isolated from various lepidopteran hosts – e.g. *Darna trima* (a pest of coconut and oil palms in SE Asia), *Thosea asigna* (a pest of oil palms in Malaysia), *Trichoplusia ni* (cabbage looper). The viruses have not been propagated in cell culture, and must be cultivated by inoculation into suitable host larvae; virus replication occurs in the cytoplasm of gut cells. Infected larvae become flaccid. [Review in JGV (1985) 66 647–659.]

**null cells** (*immunol.*) Lymphoid cells which lack characteristic B cell and T cell antigens; some are non-cytolytic, others are cytolytic – the latter including NK CELLS.

**null mutation** A MUTATION which results in complete loss of function of the sequence in which it occurs. (cf. LEAKY MUTATION.)

**numerical aperture** See RESOLVING POWER.

**numerical taxonomy** (taxometrics) A computer-assisted form of TAXONOMY in which the organisms in a given study are sorted into groups of mutually similar organisms on the basis of a large number (ideally >50) of observable properties (*characters*); typically, every character is regarded as having the same degree of importance, i.e. equal 'weighting', in the computation of similarities (cf. ADANSONIAN TAXONOMY; see also POLYTHETIC CLASSIFICATION). (The use of a computer is not strictly essential, but the calculations involved would otherwise take an inordinate length of time.) Numerical taxonomy is primarily a form of PHENETIC CLASSIFICATION in which the aim is to define TAXOSPECIES (see also PHENON); however, the availability of certain fundamental data (derived e.g. from DNA homology studies) has permitted the method to be modified for use in PHYLOGENETIC CLASSIFICATION.

In numerical taxonomy each strain – or OTU (q.v.) – among those to be classified is initially examined or tested in respect of each of the biochemical, morphological or other characters used as criteria in the study. The nature or value of a given test result is then expressed in a form such as + or – (or e.g. as 0 or 1); for example, 'growth at 45°C' could be written as '+', while '-' could be used for 'no growth at 45°C'. Each OTU in the study may thus be defined by a series of simple symbols; this is the form in which the data are fed into the computer.

In the computer the first step in classification is the comparison of each OTU with every other OTU – likenesses being expressed as percentage similarities; for example, two given OTUs which match in any 60 out of 80 characters would have a percentage similarity of 75%. (There are actually several different ways in which a given pair of OTUs can be compared: see entry  $S_{SM}$  and compare it with  $S_G$ ,  $S_J$  and  $S_P$ ; cf. entry  $D_P$ .) The result of these initial comparisons is a list of percentage similarities – each having been derived from the comparison of one given OTU with another given OTU; these data are usually printed out as an S MATRIX. The computer may be programmed to search the percentage similarities for pairs or groups of 'identical organisms', i.e., pairs or groups which exhibit a mutual similarity of 100%; such pairs or groups are called '100% clusters'. On the computer printout such clusters, if present, may appear thus:

```
100%   5–10–11–19–
        43–47–
        29–31–33–
```

in which each number (5, 10 etc) is the designation of one of the OTUs in the study; in this example three clusters are

formed at the 100% level of similarity. Although strains within a given cluster are mutually 100% similar, no information is given here on the degree of similarity which exists between the OTUs of one cluster and those of another. The remaining OTUs are progressively added at successive, lower levels of similarity (e.g. 97%, 95%, 80%, 75%, 50%) to one or other of the initially formed clusters. Additionally, two or more clusters may unite at a given level of similarity; thus, e.g. in the above example the clusters 43–47 – and 29–31–33 – may form a single cluster at, say, 75% – meaning that one or more OTUs in a given cluster has a mutual similarity of at least 75% with one or more OTUs in the other cluster. The mode in which OTUs are added to a cluster, and in which clusters unite, may be varied according to the purpose of the taxonomist: see e.g. SINGLE LINKAGE and UPGMA. At the end of the study the result of clustering may be shown e.g. in a PHENOGRAM or in a SHADED MATRIX. The processed data can then be examined to determine whether or not a given phenon can be regarded as a TAXON.

**Nummilites** See FORAMINIFERIDA.

**nummilitids** See FORAMINIFERIDA.

**nungham** The freshwater red alga *Lemanea mamillosa* (division RHODOPHYTA) used as a food in India.

**nu/nu mice** A strain of congenitally athymic mice.

**nusa gene** See TRANSCRIPTION and BACTERIOPHAGE LAMBDA.

**nutrient agar** NUTRIENT BROTH gelled with 1.5–2.0% AGAR: a general-purpose solid basal MEDIUM.

**nutrient broth** A liquid basal MEDIUM; the name may refer to either extract broth or infusion broth. *Extract broth* (the type most commonly used) may be prepared as an aqueous solution of beef extract and peptone (each ca. 0.5–1.0% w/v) and sodium chloride (ca. 0.5% w/v); it is sterilized by autoclaving, and the final pH is ca. 7.2–7.4. Powdered (dehydrated) extract broth is available commercially; it is reconstituted with distilled (or tap) water, dispensed into tubes, and autoclaved. *Infusion broth* is prepared by infusing overnight, at 4°C, 50 g of minced lean beef in 100 ml distilled water; peptone (ca. 1% w/v) and sodium chloride (ca. 0.5% w/v) are added, and the mixture is boiled, filtered, and sterilized by autoclaving. Final pH: ca. 7.3–7.5.

**nutritionally variant streptococci** (NVS) Strains of *Streptococcus*, present e.g. in the normal human throat and urogenital tract, which are characterized by a requirement for cysteine, or for pyridoxal hydrochloride or pyridoxamine hydrochloride, when grown on complex media; the organisms were originally detected as satellite colonies (see SATELLITE PHENOMENON) of viridans streptococci associated with colonies of *Staphylococcus*. Two species are distinguished: *S. adjacens* and *S. defectivus*, the latter species differing from *S. adjacens* e.g. in fermenting trehalose and forming  $\beta$ -galactosidase. The organisms may form a red pigment. NVS may be responsible for ~5% of those cases of endocarditis which involve oral streptococci.

**Nuttallia** See BABESIA.

**nvCJD** New variant CREUTZFELDT–JAKOB DISEASE.

**NVDP** See PLASMIDIUM.

**NVL** No visible lesion.

**NVS** NUTRITIONALLY VARIANT STREPTOCOCCI.

**Nycodenz** See IODINATED DENSITY-GRADIENT MEDIA.

**nystatin** (fungicidin) An antifungal POLYENE ANTIBIOTIC, produced by *Streptomyces noursei* and named after the New York State Health Department (where it was discovered). It contains MYCOSAMINE and is usually classed as a tetraene, although it contains six double bonds (four conjugated double bonds separated from two others by two methylene groups). Nystatin is used primarily for the topical treatment of superficial mycoses (e.g. mucosal *Candida* infections); it is not absorbed when taken orally.

# O

**O antigens** (Boivin antigens) The heat-stable, alcohol-resistant LIPOPOLYSACCHARIDE–protein somatic antigens of Gram-negative bacteria (particularly members of the Enterobacteriaceae); O antigens are important in the serological characterization of enterobacteria (see e.g. KAUFFMANN–WHITE CLASSIFICATION). Antigenic specificity is determined by the polysaccharide O-specific chains (see LIPOPOLYSACCHARIDE). O antigens may be modified e.g. by BACTERIOPHAGE CONVERSION or by mutation (e.g. in salmonellae a mutation may give rise to T1 side-chains, consisting of ribose and galactose residues, instead of normal O-specific chains – see also SMOOTH–ROUGH VARIATION). (See also VI ANTIGENS.)

**O side chain** See LIPOPOLYSACCHARIDE.

**O-specific chain** See LIPOPOLYSACCHARIDE.

**O-type starter** See LACTIC ACID STARTERS.

**O1 strains** (of *Vibrio cholerae*) See VIBRIO.

**O/129** 2,4-Diamino-6,7-diisopropylpteridine: a water-soluble agent bacteriostatic for e.g. many members of the Vibrionaceae (e.g. most *Vibrio* strains). Sensitivity to O/129 may be determined using O/129-impregnated discs on nutrient agar containing 0.5% w/v NaCl.

Some strains of *Vibrio cholerae* produce a trimethoprim-resistant dihydrofolate reductase (DHFR) and are resistant to both trimethoprim and O/129; the gene encoding the DHFR may be borne on a plasmid or on a transposon [Ann. Mic. (1985) 136B 265–273].

**O139 Bengal** (*Vibrio cholerae*) See CHOLERA.

**O157:H7 *E. coli*** See EHEC.

**oak butt rot** See BUTT ROT.

**oak-moss** *Evernia prunastri*.

**oak wilt** A disease of oak trees (*Quercus* spp) caused by *Ceratocystis fagacearum*. Infection occurs via wounds (made e.g. by man or woodpeckers). The fungus forms pressure cushions (sclerotia) between the infected xylem and phloem, bursting open the overlying bark and allowing entry of insects, particularly sap-feeding beetles of the Nitidulidae, which act as vectors of the disease.

**Oakley–Fulthorpe test** See DOUBLE DIFFUSION.

**oar weed** Any species of *Laminaria* which has an oar-shaped thallus, e.g. *L. digitata* and *L. hyperborea*.

**oat diseases** See CEREAL DISEASES.

**oat mosaic virus** See POTYVIRUSES.

**oat necrotic mottle virus** See POTYVIRUSES.

**oat sterile dwarf virus** See FIJIVIRUS.

**oat striate virus** See RHABDOVIRIDAE.

**Obesumbacterium** A genus of non-motile, slow-growing bacteria of the ENTEROBACTERIACEAE (apparently related to *Hafnia alvei*), found as contaminants in fermenting beer wort. Cells: pleomorphic rods, 0.8–2.0 × 1.5–100 μm (short, fat rods predominate in wort). [Book ref. 22, pp. 506–509.]

**objective** (objective lens) See MICROSCOPY (a).

**obligate** Refers to an essential attribute of a given organism. For example, an obligate aerobe is an organism which grows only under aerobic conditions, and an obligate parasite is an organism which, in nature, can grow only as a parasite. (cf. FACULTATIVE.)

**obligate proton reducers** See ANAEROBIC DIGESTION.

**Obodhiang virus** See LYSSAVIRUS.

**occlusion bodies** See BACULOVIRIDAE.

**Occlusosporida** See STELLATOSPOREA.

**Oceanospirillum** A genus of marine (coastal), Gram-negative, asporogenous bacteria formerly included in the genus SPIRILLUM. Cells: rigid, helical, 0.3–1.4 × ca. 5–20 μm. POLAR MEMBRANES and intracellular PHB granules are present. COCCOID BODIES predominate in old cultures in all species except *O. japonicum*. Motile, with bipolar tufts of flagella (or, in *O. pusillum*, a single flagellum at each pole). Aerobic; metabolism is strictly respiratory. Nitrate respiration does not occur, but some species can reduce NO<sub>3</sub><sup>-</sup>. Oxidase +ve; catalase and phosphatase variable; indole –ve; arylsulphatase –ve. Optimum growth temperature: 25–32°C. Seawater is required for growth. Carbon sources: amino acids or salts of organic acids, but not carbohydrates. GC%: 42–51. Type species: *O. linum*. Nine species are recognized [Book ref. 22, pp. 104–110].

**ocellus** See EYESPOT (sense 1).

**Ochotereniaia** See TRICHOSTOMATIDA.

**ochratoxins** A group of MYCOTOXINS produced by species of *Penicillium* and *Aspergillus*. Ochratoxin A is a dihydrocoumarin derivative linked to L-phenylalanine via an amide bond; it inhibits phosphoenolpyruvate carboxykinase. Ingestion of ochratoxin A in contaminated food causes nephropathy in e.g. cattle, pigs and man.

**ochre codon** See GENETIC CODE.

**ochre mutation** See NONSENSE MUTATION.

**ochre suppressor** See SUPPRESSOR MUTATION.

**Ochrobium** A genus of IRON BACTERIA. Cells: ellipsoidal to rod-shaped. Type species: *O. tectum*. [Population ecology of *Ochrobium*: JGM (1981) 125 85–93.]

**Ochrolechia** A genus of crustose LICHENS (order PERTUSARIALES). Photobiont: a green alga. Thallus: often thick, warty, irregular in shape. Apothecia: lecanorine, with characteristically thick thalline margins and yellowish or pinkish discs. Species generally occur on rocks, sometimes also on bark; *O. frigida* occurs on the ground on mosses etc. *O. tartarea* has been harvested on a commercial scale for the production of CUBBEAR.

**Ochromonas** A genus of unicellular CHRYSOPHYTES. The cell is usually ovoid, contains (typically) two parietal chloroplasts, and has two flagella of unequal length. (See also FLAGELLAR MOTILITY (b).) The organisms are both photosynthetic and phagotrophic, apparently requiring organic nutrients (e.g. VITAMIN B<sub>12</sub>) or prey for survival. Some forms have a delicate, cup-shaped LORICA composed of microfibrils of CHITIN; typically, the lorica adheres via a stalk to the substratum or to other cells. (Loricated forms of *O. malhamensis* are sometimes known as *Poterioochromonas stipitata*.)

**Ockelbo disease** See SINDBIS VIRUS.

**OCT plasmid** An IncP-2 *Pseudomonas* PLASMID (ca. 500 kb) which encodes the capacity to metabolize octane and decane. (cf. TOL PLASMID.) [Characterization of the OCT plasmid: JB (1986) 165 650–653.]

**octapeptins** A group of ANTIBIOTICS closely related to the POLYMYXINS; they differ e.g. in having a shorter side-chain and a longer β-hydroxy fatty acid residue. A mixture of octapeptins A and B is up to ten times more effective than polymyxin B against certain Gram-positive bacteria.

**Octomyxa** See PLASMODIOPHOROMYCETES.

**octopine** N<sup>2</sup>-(D-1-carboxyethyl)-L-arginine – see CROWN GALL.

Other, related opines include histopine and lysopine.

**octopinic acid** See CROWN GALL.

## ***Octopus vulgaris* disease virus**

***Octopus vulgaris* disease virus** See IRIDOVIRUS.

***Octosporella*** See EIMERIORINA.

**ocular** *Syn.* eyepiece (see MICROSCOPY).

**ocular herpes** See HERPES SIMPLEX.

**ocular micrometer** See MICROMETER.

**OD** Optical density (see TURBIDIMETRY).

**ODC** Ornithine decarboxylase: see DECARBOXYLASE TESTS.

**Odontostomatida** An order of typically freshwater, 'polysaprobic' ciliate protozoa (class POLYHYMENOPHOREA) in which the cells are laterally compressed, have reduced somatic ciliature, and often have posterior spines or cirri. Genera include e.g. *Epalxella* (formerly *Epalxis*), *Pelodinium*, SAPRODINIUM.

**oedema** (edema; 'dropsy') The abnormal accumulation of fluid in body tissues. (cf. ASCITES.)

**oedema disease** (bowel oedema) A PIG DISEASE which typically attacks young animals subjected to stress (e.g. change of diet at weaning). It is apparently caused by toxigenic strains of *Escherichia coli*. Infection may result in sudden death, or there may be oedema of certain tissues (especially the stomach wall and mesentery) with signs of nervous disturbance (incoordination, loss of balance) usually followed by coma and death.

**oedematolysin** See THIOL-ACTIVATED CYTOLYSINS.

**Oedogonium** A genus of freshwater (commonly epiphytic), unbranched filamentous green algae (division CHLOROPHYTA). Each filament is composed of uninucleate cells and is usually attached to the substratum by a differentiated basal cell. The individual cells each contain a single parietal reticulate chloroplast with several pyrenoids. In some cells of the filament the cell wall has a characteristic series of ridges (the 'cap') at one end; these ridges result from an unusual mode of cell division: shortly after mitosis, the cell wall ruptures and the cell increases rapidly in size before the cross-wall is formed. Asexual reproduction occurs by the formation of multiflagellate, naked zoospores; sexual reproduction is oogamous. (See also BULBOCHAETE.)

**Oerskovia** A genus of asporogenous bacteria (order ACTINOMYCETALES, wall type VI) which occur e.g. in soil. In culture the organisms form a primary mycelium which fragments into small, monotrichously flagellated rods (ca.  $0.4 \times 1.1 \mu\text{m}$ ) that develop into larger, peritrichously flagellated rods, the latter giving rise to a branched mycelium in which the hyphal diameter is ca.  $0.5 \mu\text{m}$ . Growth occurs aerobically (organisms catalase-positive) or anaerobically (organisms catalase-negative) on rich media (e.g. trypticase-soy agar) with the formation of yellowish colonies; glucose can be metabolized either oxidatively or fermentatively. GC%: ca. 70–75. Type species: *O. turbata*. [Book ref. 73, pp. 52–53.]

**O–F test** OXIDATION–FERMENTATION TEST.

**OFAGE** Orthogonal-field-alternation gel electrophoresis: a form of PFGE (q.v.) used e.g. for separating chromosomes by size. OFAGE has been used e.g. to obtain a karyotype of the yeast *Saccharomyces cerevisiae* [PNAS (1985) 82 3756–3760].

**ofloxacin** See QUINOLONE ANTIBIOTICS.

**Ogawa variant** See VIBRIO (*V. cholerae*).

**ogi** A Nigerian food: a type of sour porridge made by the natural fermentation of ground maize, sorghum or millet. A range of organisms is present, including e.g. *Lactobacillus plantarum* and various yeasts.

**O'Hara's disease** See TULARAEMIA.

**Ohio corn stunt agent** *Syn.* MAIZE CHLOROTIC DWARF VIRUS.

**Oidiopsis** See HYPHOMYCETES and ERYSIPTHALES.

**oidium** (*mycol.*) A thin-walled THALLOSPORE; oidia may function as disseminative spores or as male gametes.

**Oidium** See HYPHOMYCETES and ERYSIPTHALES.

**Oikomonas** A genus of colourless, unicellular CHRYSOPHYTES which resemble *Chromulina* spp; the organisms occur in organically polluted waters, activated sludge, etc.

**oil biodeterioration** See PETROLEUM.

**oil-immersion condenser** See RESOLVING POWER and MICROSCOPY (b).

**oil-immersion objective** See RESOLVING POWER.

**oil shale** A grey or black ancient sedimentary rock which consists primarily of KEROGEN with a small proportion of solvent-soluble organic matter.

**O<sub>1</sub> locus** See FINOP SYSTEM.

**Okazaki fragments** See DNA REPLICATION.

**OKT antigens** The former name for surface antigens on human T LYMPHOCYTES. The designation 'OKT' was replaced by 'CD' – for example, OKT4 is now CD4.

**old dog encephalitis** See CANINE DISTEMPER.

**old tuberculin** See TUBERCULIN.

**oleandomycin** A MACROLIDE ANTIBIOTIC (from *Streptomyces antibioticus*) closely related to erythromycin. (cf. SIGMAMYCIN.)

**olefin metabolism** See HYDROCARBONS.

**oligo(dT)-cellulose** See MRNA (a).

**oligodynamic effect** The antibacterial (or antimicrobial) action exerted by low concentrations of certain metals in elemental form (see HEAVY METALS); the effect may be observed by placing small metal discs on a flood plate and measuring the zone of no growth surrounding each disc following appropriate incubation.

**Oligohymenophorea** A class of protozoa (phylum CILIOPHORA) in which, typically, the cytostome occurs at the base of a BUCCAL CAVITY, and the oral ciliature is obviously differentiated from the somatic ciliature; the PARORAL MEMBRANE is characteristically of the stichodyad type; and STOMATOGENESIS is buccokinetal or parakinetal. This class includes ciliates previously referred to as 'higher holotrichs' (e.g. the hymenostomes) together with e.g. the astomes. Subclasses: HYMENOSTOMATIA, PERITRICHIA.

**oligomycin** An antibiotic, produced by *Streptomyces* spp, which binds non-covalently to mitochondrial ( $F_0F_1$ )-type PROTON ATPASES, inhibiting the transfer of protons through the  $F_0$  site and, hence, inhibiting both ATP hydrolysis and OXIDATIVE PHOSPHORYLATION. Oligomycin does not collapse pmf (cf. UNCOUPLING AGENTS).

**oligonucleotide cataloguing** See RRNA OLIGONUCLEOTIDE CATALOGUING.

**oligonucleotide-directed mutagenesis** See SITE-SPECIFIC MUTAGENESIS.

**oligonucleotide fingerprinting** Any FINGERPRINTING technique in which the fingerprint consists of a strain-specific pattern of oligonucleotides. For example, to differentiate strains of an RNA virus, the genome is digested with a sequence-specific enzyme (such as RNASE T1) and the resulting oligonucleotide fragments are subjected to gel ELECTROPHORESIS; the pattern (bands) of fragments in the gel constitute the characteristic fingerprint of the given strain of virus.

**oligosaccharide** A carbohydrate consisting of 2 to ca. 10 monosaccharides joined by glycosidic linkages.

**oligosaprobic zone** See SAPROBITY SYSTEM.

**Oligotrichida** An order of ciliate protozoa (class POLYHYMENOPHOREA) which are typically free-living, marine, pelagic organisms, but which include some freshwater and edaphic species. Cells: rounded to elongate with a thickened pellicle and (in many species) a perilemma; somatic ciliature is typically reduced, and in some species the oral ciliature is divided into two parts: one part within the buccal cavity, the other encircling the anterior end of the cell. Some species are loricate.

Members of the suborder Oligotrichina are typically small and rounded organisms whose somatic ciliature may consist of only a few short rows of 'bristles', but which may have groups of 'cirri' or 'bristles' forming an equatorially encircling band; genera include e.g. HALTERIA, *Strombidium*, *Strombilidium*, and *Tontonia*.

The other suborder, TINTINNINA (q.v.), comprises a distinctive group of organisms.

**Oligotrichina** See OLIGOTRICHIDA.

**oligotroph** Any organism which can grow in relatively nutrient-poor environments (cf. COPIOTROPH).

**oligotrophic** (1) Of or pertaining to an OLIGOTROPH. (2) Of lakes, rivers etc: containing low levels of nutrients, particularly of those nutrients which support the growth of aerobic photosynthetic organisms. (cf. EUTROPHIC.)

**olivanic acids** An ill-defined group of CARBAPENEM antibiotics derived from *Streptomyces olivaceus* and other *Streptomyces* spp.

**olive-green mould** *Chaetomium olivaceum*: a mould which frequently grows on mushroom compost after pasteurization (see MUSHROOM CULTIVATION) and which inhibits mycelial development in *Agaricus brunnescens* by competition for nutrients. [Biological control by a thermophilic *Bacillus* sp: AEM (1983) 45 511–515.]

**olive knot** A disease of the olive, oleander and privet, in which small galls develop on young twigs and leaves. The causal agent is *Pseudomonas syringae* pv. *savastanoi*; the pathogen produces IAA and cytokinin which may be responsible for the formation of the galls. In at least some strains IAA production appears to be plasmid-mediated. Infection occurs via wounds. Transmission may occur via the olive fly (*Dacus oleae*).

**olives** (pickled) See PICKLING.

**olivomycin** See CHROMOMYCIN.

**Olpidiopsis** See LAGENIDIALES.

**Olpidium** A genus of unicellular, endobiotic, holocarpic fungi (order CHYTRIDIALES) which are parasitic on algae and other aquatic organisms and on some terrestrial plants; *Olpidium* spp are also involved in the transmission of the LETTUCE BIG VEIN AGENT and the TOBACCO NECROSIS VIRUS. In the asexual cycle of *O. viciae* a zoospore settles on a susceptible host (*Vicia*), encysts, and the cyst's contents enter a host cell; after intracellular growth and a number of nuclear divisions, the fungus eventually forms an inoperculate zoosporangium – the numerous zoospores subsequently escaping via one or more pores. In the sexual cycle, two morphologically indistinguishable zoospores fuse and then encyst on a susceptible host; the cyst's contents enter a host cell and develop into thick-walled resting sporangia. Karyogamy (and probably meiosis) occur before the germination of resting sporangia – each of which produces a number of zoospores.

**OM** OUTER MEMBRANE.

**omasum** See RUMEN.

**O'Meara's method** See VOGES–PROSKAUER TEST.

**ω-oxidation** See HYDROCARBONS.

**ω (omega) protein** See TOPOISOMERASE.

**omicron** An endosymbiotic, Gram-negative, rod-shaped bacterium which occurs in the cytoplasm of *Euplotes* spp; it does not confer a killer characteristic, and it appears to be essential for the viability of its protozoan host. [Book ref. 22, p. 798.]

**omnivorous** Refers to protozoa which feed on microscopic 'animals' (e.g. other protozoa) and 'plants' (e.g. algae, bacteria). (cf. CARNIVOROUS; HERBIVOROUS.)

**Omp** The designation of certain major OUTER MEMBRANE PROTEINS, each type of protein being distinguished as OmpA, OmpC

etc. Some of these proteins are PORINS – for example OmpC and OmpF (see OSMOREGULATION). In *Escherichia coli*, OmpA (also called e.g. 3A, d and II\*) is a product of the *ompA* gene (also called e.g. *con*, *tolG* and *tut*); it apparently spans the thickness of the outer membrane but does not seem to function as a porin. OmpA-deficient mutants have an unstable outer membrane and are deficient in conjugation and in sensitivity to colicin L and phages K3 and TuII. In *E. coli*, OmpT is a protease involved in type IV (autotransporter) protein secretion.

**OMP** Orotidine 5'-monophosphate [see Appendix V(b)].

**OmpA** See OMP.

**Omphalotus** See AGARICALES (Tricholomataceae).

**OMP** See OSMOREGULATION.

**OmpT protein** See PROTEIN SECRETION (type IV systems).

**Omsk haemorrhagic fever** See VIRAL HAEMORRHAGIC FEVERS and FLAVIVIRIDAE.

**onc** See ONCOGENE.

**Oncobasidium** See TULASNELLALES and VASCULAR-STREAK DIE-BACK.

**oncogen** See ONCOGENIC.

**oncogene** A gene which can (potentially) induce neoplastic transformation in the cell in which it occurs or into which it is introduced. Oncogenes occur e.g. in certain viruses, particularly members of the RETROVIRIDAE. Viral oncogenes (*v-onc*), originally identified as the transforming determinants of acutely oncogenic retroviruses, were subsequently found to have closely related cellular homologues (designated *c-onc* or *proto-onc*) in the chromosomes of eukaryotes; *c-onc* sequences have been highly conserved through evolution, and homologous genes have been found in all vertebrates examined, as well as in lower eukaryotes such as *Drosophila* and *Saccharomyces*. In the normal cell, at least some oncogenes are known to have one or more major roles in cell growth/development. Retroviral *v-onc* sequences may have arisen from *c-onc* genes by recombination (see RETROVIRIDAE) and may differ from them e.g. in lacking introns; they are often expressed with adjacent viral sequences as fusion proteins.

Retroviral and cellular oncogenes are usually referred to by three-letter designations based on the retrovirus in which they were first identified: e.g. *myc* from myelocytomatosis virus, *fes* from feline sarcoma virus, etc; viral genes are prefixed by *v-* (e.g. *v-myc*), their cellular homologues by *c-* or *proto-* (e.g. *c-myc* or *proto-myc*).

A *v-onc* gene introduced into a cell by an infecting retrovirus may induce the neoplastic transformation of that cell in various ways. The products of many retroviral oncogenes (e.g. *v-abl*, *v-fes*, *v-fps*, *v-ros*, *v-src*, *v-yes*) have tyrosine-specific protein kinase activity, transferring  $\gamma$ -phosphate from ATP (or GTP) to tyrosine residues in proteins. (See ABL, FES and SRC; cf. ERB and MOS.) In normal (non-neoplastic) cells, tyrosine kinase activity is associated with the receptors for certain growth-promoting peptides: e.g. epidermal growth factor (EGF), platelet-derived growth factor (PDGF) and insulin. Oncogenic tyrosine kinase activity has been targeted by selective inhibitors of proteins encoded by e.g. *bcr-abl* and *v-abl*; some inhibitors can be effective against a range of oncogenic kinases [e.g. Pharmacology and Experimental Therapeutics (2000) 295 139–145], and this has encouraged the screening of existing clinically useful drugs for activity against the emergent drug-resistant mutant kinases [PNAS (2005) 102 11011–11016].

*v-myc* and *v-myb* products lack tyrosine kinase activity (see MYC and MYB). *v-sis* encodes a protein almost identical to the B chain of human PDGF.

## oncogenesis

Modification or activation of a *c-onc* sequence is apparently involved in certain cases of oncogenesis, and may even prove to be a common mechanism of oncogenesis in general. Oncogenesis could result from alterations in the properties of a *c-onc* gene product (e.g. as a result of mutation – see RAS), or from abnormal regulation of a *c-onc* gene; for example, a *c-onc* gene which is normally silent or expressed at very low levels in a particular cell may be activated by the insertion of a retroviral provirus adjacent to and upstream of the *c-onc* sequence, the sequence thus coming under the control of the viral transcriptional regulation signals (see e.g. AVIAN LEUKOSIS VIRUSES). The regulation of a *c-onc* gene may also be disturbed as a result of its translocation to a novel context by chromosomal rearrangements (see e.g. ABL and BURKITT'S LYMPHOMA).

Viral genes involved in oncogenesis induced by certain DNA viruses are sometimes referred to as oncogenes, although they differ in several respects from the oncogenes of retroviruses; they are viral genes which apparently have no cellular homologues and which encode proteins essential for virus replication. (See e.g. MASTADENOVIRUS and POLYOMAVIRUS; cf. EPSTEIN-BARR VIRUS.)

**oncogenesis** The development of a (benign or malignant) tumour (or other neoplastic condition: e.g. LEUKAEMIA).

A tumour may develop e.g. as a result of the effect on an ONCOGENE of a rearrangement of chromosomes or of mutation (see e.g. ABL, BURKETT'S LYMPHOMA, RAS).

**oncogenic** Strictly: refers to any agent which can induce the formation of a tumour; more generally, the term is often applied to any agent which can bring about the neoplastic transformation of cells – either *in vivo* (resulting in the formation of a tumour or e.g. LEUKAEMIA) or in TISSUE CULTURE. Such agents may be termed *oncogens* (cf. CARCINOGEN).

**oncom** (ontjom) An Indonesian food made by the fermentation of (usually) peanut press-cake from which at least some of the oil has been extracted. The presscake is broken into fragments, soaked, steamed and cooled, placed in shallow trays, inoculated with a starter (RAGI) of *Neurospora intermedia* or *Rhizopus oligosporus*, and incubated at ca. 30°C; the mould binds the fragments into a cake which becomes coated with pink-orange, powdery conidia (*Neurospora*) or black sporangia (*Rhizopus*). [Book ref. 8, pp. 513–515.] (cf. TEMPEH.)

**oncoviruses** Former name for viruses of the ONCOVIRINAE.

**Oncovirinae** A subfamily of viruses of the RETROVIRIDAE; the subfamily includes all of the oncogenic retroviruses as well as many closely related but non-oncogenic retroviruses. On the basis of e.g. morphology and mode of development, the subfamily has been divided into the type B viruses (genus TYPE B ONCOVIRUS GROUP), type C viruses (genus TYPE C ONCOVIRUS GROUP), and type D viruses (proposed genus TYPE D RETROVIRUS GROUP) [Book ref. 23, p. 125]. (See also HTLV.)

**one-carbon compounds** See C<sub>1</sub> COMPOUNDS.

**one-step growth experiment** A procedure devised by Ellis and Delbrück [JGP (1939) 22 365–384] for the quantitative study of lytic bacteriophage multiplication; it has since been modified for the study of other lytic viruses.

A suspension of susceptible cells is inoculated with enough viruses to infect every cell. After allowing time for virus adsorption, unadsorbed viruses are removed. The cell suspension is then incubated at a suitable temperature, and aliquots are periodically withdrawn and subjected to e.g. PLAQUE ASSAY. During the initial period (*latent period*) the number of plaques per aliquot typically remains fairly constant; in this period each virus-infected cell behaves as a single 'infectious centre' capable

of giving rise to a single plaque – regardless of the number of virions it may contain. (The latent period lasts ca. 20–25 min in phage T2/*Escherichia coli* B systems, but may be of the order of hours in virus-infected animal cells.) Aliquots taken sequentially after the latent period give progressively increasing numbers of plaques; during this period the infected cells begin to lyse, releasing large numbers of infectious virions each capable of giving rise to a plaque. The number of plaques per aliquot reaches a plateau when all the cells have lysed. (See also BURST SIZE.) If the virions are labile the plateau is followed by a *decay period* characterized by a fall in plaque titres.

If, during the latent period, the cells in each aliquot are lysed artificially – e.g. by the addition of SDS (for animal cells) or chloroform (for Gram-negative bacteria) – a so-called *eclipse period* can be distinguished. In this period, which begins at the same time as the latent period, infectious virions cannot usually be detected owing to the 'uncoating' of the virus following infection; the eclipse period ends when the first progeny virions are assembled. (The latent period normally continues until the host cell lyses naturally, i.e., after the assembly of many progeny virions.)

**one-tube nPCR** See NESTED PCR.

**one-way incompatibility** INCOMPATIBILITY exhibited by two given plasmids only when one particular plasmid is introduced into a cell containing the other; if the second plasmid is introduced into a cell containing the first, incompatibility is not exhibited. [One-way incompatibility between IncH1 plasmids and the F plasmid: JGM (1985) 131 1523–1530.]

**onion rot** *White rot* (which can also affect e.g. leeks) is caused by *Sclerotium cepivorum*; leaves become yellow and die, and the rotting roots and scale bases become covered with white, fluffy mycelium. Black sclerotia develop in or on necrotic tissue. *Neck rot*, caused by *Botrytis aclada* (= *B. allii*), is more common in stored onions. A *soft rot* can be caused by *Burkholderia cepacia* (formerly *Pseudomonas cepacia*). (See also SMUDGE.)

**onion yellow dwarf virus** See POTYVIRUSES.

**onium compounds** *Syn.* QUATERNARY AMMONIUM COMPOUNDS.

**ONPG test** A test used to detect β-D-galactosidase activity in bacteria. A loopful of growth of the test organism (grown on e.g. TSI agar) is introduced into phosphate-buffered peptone water (pH 7.0) containing ONPG (*o*-nitrophenyl-β-D-galactopyranoside); the medium is then incubated at 37°C. β-GALACTOSIDASE hydrolyses ONPG to galactose and *o*-nitrophenol – the latter (being yellow) acting as a test indicator. Organisms which give a positive ONPG test do not necessarily metabolize lactose since they may not synthesize a lactose permease. (ONPG can enter cells without a specific permease.)

**ontjom** *Syn.* ONCOM.

**ontogeny** The range of stages which occur during the development of an individual organism to the mature or adult stage. The supposition that ontogeny recapitulates PHYLOGENY (the 'law of recapitulation' or the 'recapitulation theory') was made by the 19th-Century biologist Haeckel.

**onychomycosis** MYCOSIS of nails (cf. PARONYCHIA). [Review: Clinical Microbiology Reviews (1998) 11 415–429.]

**Onygena** See GYMNOASCALES.

**o'nyong-nyong fever** (joint-breaker fever) A human disease caused by an ALPHAVIRUS and transmitted by anopheline mosquitoes; it occurs e.g. in Africa. Symptoms: fever, headache, myalgia, maculopapular rash, and severe arthralgia. Wild primates may act as a reservoir of the virus.

**oocyst** (1) (*mycol.*) *Syn.* OOGONIUM. (2) (*protozool.*) A structure in which sporozoites are formed. (3) An encysted fertilized female gamete.

**Oocystis** A genus of unicellular, non-motile, ellipsoidal or lemon-shaped, freshwater green algae (division CHLOROPHYTA); asexual reproduction occurs by autospore formation.

**Oodinium** See DINOFLAGELLATES and VELVET DISEASE.

**oogamy** Fertilization involving morphologically distinguishable male and female elements – typically a large non-motile female gamete and a small motile male gamete (see e.g. MONOBLEPHARIDALES; cf. OOMYCETES). (See also ANISOGAMY.)

**oogonium** A female structure in which one or more gametes (*oospores*) develop; a fertilized oosphere is called an *oospore*.

**ookinete** A motile zygote.

**Oomycetes** A class of aquatic and terrestrial fungi (subdivision MASTIGOMYCOTINA) which typically give rise to zoospores having one anteriorly-directed tinsel flagellum and one posteriorly-directed whiplash flagellum (cf. PERONOSPORA). The organisms include saprotrophs and parasites – the latter including some important pathogens of cultivated crops. According to species, the thallus ranges from a simple, unicellular, holocarpic structure to a well-developed mycelium; in at least some species the thallus is diploid. The CELL WALL is generally believed to lack chitin and to contain CELLULOSE; however, there is evidence that CHITIN and cellulose both occur in the wall in e.g. certain members of the LEPTOMITALEA and Saprolegniales. Some oomycetes exhibit DIPLANETISM, others MONOPLANETISM. Sexual reproduction is *oogamous*, involving the fusion of non-motile male and female elements within gametangia (cf. MONOBLEPHARIDALES). Orders: LAGENIDIALES, LEPTOMITALEA, PERONOSPORALES, SAPROLEGNIALES.

Some authors include this class of fungi in the subdivision Diplomastigomycotina of the division Mastigomycota.

**oophoritis** Inflammation of the ovaries.

**oosphere** See OOGONIUM.

**oospore** See OOGONIUM.

**Oosporidium** A genus of non-fermentative imperfect yeasts (class HYPHOMYCETES). The cells are variously shaped, reproduce by multilateral bud-fission, and usually remain attached to each other to form long chains. Asexual endospores are formed, arthrospores are not. Pink or orange-yellow non-carotenoid pigments are synthesized. One species: *O. margaritifera*, isolated from the slime flux of trees. [Book ref. 100, pp. 886–889.]

**Opa proteins** (of *Neisseria*) In pathogenic strains of *Neisseria*: OUTER MEMBRANE adhesins, encoded by *opa* genes, whose presence affects the opacity (hence Opa) and colour of the colonies (owing to increased bacterial aggregation); the Opa proteins mediate adhesion to (and uptake by) epithelial cells or opsonin-independent phagocytosis by PMNs. (Non-pathogenic strains of *Neisseria* contain genes with sequences homologous to those of the *opa* genes; it is possible that the products of these genes may mediate mucosal colonization by commensal strains.) (See also CD66.)

Some Opa<sup>+</sup> strains exhibit TRANSCYTOSIS.

Within a given cell, the chromosome contains several allelic (variant) forms of *opa* gene, and the organisms exhibit phase variation, i.e. a given cell may change (e.g.) from expressing a single type of *opa* gene to expressing more than one type (or no type) of *opa* gene. Phase variation is regulated by certain DNA re-arrangements in the 5' leader sequence of the *opa* genes. The 5' region of these genes contains multiple copies of a pentameric sequence (CTCTT), and the number of copies of this 'coding repeat' can vary; thus, while all the *opa* genes are transcribed constitutively, translation of a transcript will give rise to a functional Opa protein only if the number of (pentameric) coding repeats is such that the coding sequence of the gene is in the correct reading frame.

[Role of Opa proteins in interactions with host (eukaryotic) cells: TIM (1998) 6 489–495.]

**opacity-associated proteins** (of *Neisseria*) See OPA PROTEINS.

**opal codon** See GENETIC CODE.

**Opalina** See OPALINATA.

**Opalinata** A subphylum of protozoa (phylum SARCOMASTIGOPHORA); the organisms are typically parasitic in amphibians. Individual cells are often oval or elongated, ca. 60–600 µm in length (according to species), and are generally flattened and leaf-like; each contains two or more (typically many) identical nuclei, and none has a cytostome. Each cell bears many short flagella (which are described as 'cilia' by some authors). Asexual reproduction typically occurs by longitudinal (INTERKINETAL) binary fission. In *Opalina* spp (rectal parasites of the frog) a phase of rapid asexual multiplication and encystment coincides with the breeding season of its amphibian host; it is believed that this phase is triggered by the host's hormonal activity. Cysts, the infective stages, are voided by the frog and ingested by tadpoles – in which encystment is followed by repeated longitudinal fission and the production of flagellated gametes. After syngamy, the encysted zygote is voided and ingested by another tadpole in which the zygote may undergo fission and gamete formation, or develop to form the mature, multinucleate trophic stage. (See also ENTAMOEBIA (*E. paulista*).) Other genera include *Cepedea* and *Zelleriella*.

**Opegrapha** A genus of crustose LICHENS (order OPEGRAPHALES). Photobiont: *Trentepohlia*. Fruiting structures may be lirelliform (see LIRELLA) or rounded. Species occur on rocks, bark etc.

**Opegraphales** An order of fungi of the ASCOMYCOTINA; members include crustose to fruticose LICHENS (photobiont commonly trentepohlioid) and lichenicolous fungi. Ascocarp: APOTHECIOID, with a typically thick, carbonaceous excipulum. Asci: bitunicate, elongated to clavate. Genera: e.g. *Lecanactis*, OPEGRAPHA, ROCCELLA.

**open complex** See TRANSCRIPTION.

**open culture** *Syn.* CONTINUOUS CULTURE.

**open reading frame** (ORF) A sequence of codons (see GENETIC CODE), starting with an initiator codon and ending with a stop codon, which encodes a known or (as yet) unidentified polypeptide—or (see later) part of a polypeptide; the existence of an ORF is revealed by sequencing studies (see DNA SEQUENCING). A reading frame is said to be 'blocked' if a stop codon is located close to the initiator codon.

In some cases, two adjacent ORFs *jointly* encode a single polypeptide; translation of such a polypeptide requires some kind of mechanism (see e.g. READTHROUGH) that permits such coupling. In one case, the mechanism of translational bypassing of a 50-nucleotide gap between two ORFs appears to involve (i) a stem-loop structure between the first ORF and the coding gap, and (ii) a sequence of amino acid residues within the nascent peptide translated from the first ORF [EMBO (2000) 19 2671–2680].

**open-system culture** *Syn.* CONTINUOUS CULTURE.

**operational taxonomic unit** See OTU.

**operator** (*mol. biol.*) Any specific nucleotide sequence to which a regulatory element can bind in order to control the expression (transcription) of a given gene or operon. An operator commonly consists of, or contains, a PALINDROMIC SEQUENCE, and it may lie e.g. between the PROMOTER and the coding sequence of a gene, or between the promoter and first structural gene in an operon – or (as in the TRP OPERON) it may occur entirely within the promoter region.

## Opercularia

In operons under negative promoter control, the binding of repressor to operator sequence(s) inhibits initiation of transcription. The *gal* operon (encoding utilization of galactose, and biosynthesis of UDP-galactose) contains *two* operators (located on either side of the promoter region); it appears that, in the repressed state, these two sequences may be physically linked by an oligomer of the repressor protein (GalR) to form a *DNA loop* that (by sequestering the promoter region) inhibits initiation of transcription. (See also LAC OPERON.) Such DNA looping is also used for transcriptional control in the *araBAD* operon (see ARA OPERON). This operon contains four operator sequences, and the way in which the regulatory protein (AraC) binds to particular sequences (influenced by the presence/absence of arabinose) controls the activity of the *araBAD* operon. When arabinose is absent, AraC binds to the I<sub>1</sub> and O<sub>2</sub> operators, forming a loop that represses transcription. In the presence of arabinose, the arabinose–AraC complex binds to the I<sub>1</sub> and I<sub>2</sub> operators (which are close together and also referred to, jointly, as the initiator, *araI*); this promotes transcription of *araBAD*.

In *Pseudomonas aeruginosa*, synthesis of the siderophore PYOVERDIN is apparently controlled by a transcriptional regulator, the FUR PROTEIN, via an operator designated the ‘Fur box’ or ‘iron box’; with adequate iron, Fur binds to the operator, blocking transcription of *pvdS* – a gene encoding a SIGMA FACTOR necessary for the synthesis of pyoverdinin [see JB (1996) 178 2299–2313].

Iron-regulated transcriptional control occurs at the operator of the *tox* gene encoding diphtheria toxin. Repression of *tox* by transitional metal ions apparently involves a helix-to-coil change in the repressor protein (DtxR); in this (iron-modified) state, dimers of DtxR inhibit transcription by binding on either side of the operator region [Nature (1998) 394 502–506].

**Opercularia** A genus of sedentary ciliate protozoa (subclass PERITRICHIA) which occur in various freshwater habitats; some species (e.g. *O. coarctata*) are common in SEWAGE TREATMENT plants. *Opercularia* resembles CARCHESIUM, but the zooid lacks a flared rim, and the stalks are non-contractile.

**operculate ascus** An ASCUS whose wall has a large, annular, apical thickening that encloses a circular region of thinner wall tissue; the circular region of tissue ruptures prior to ascospore discharge.

**operculum (mycol.)** A hinged lid or an easily detachable portion of the wall in a sac-like spore-bearing structure (see e.g. OPERCULATE ASCUS).

**operon** In prokaryotes: two or more genes whose expression can be co-ordinated from (i) a common PROMOTER, the *contiguous* genes being transcribed as a single polycistronic mRNA (see e.g. LAC OPERON) or (ii) a common regulatory region – mRNAs being formed by DIVERGENT TRANSCRIPTION from different promoters.

The genes in an operon are often – though not necessarily – functionally related: e.g. they may encode enzymes of a particular metabolic pathway. The organization of genes into an operon may allow their expression to be co-ordinately ‘turned on’ (*induced*) or ‘turned off’ (*repressed*) according to the cell’s needs. For example, enzymes of a catabolic pathway may be induced in the presence of the substrate of that pathway, and repressed again when the substrate has been used up; enzymes of an anabolic pathway must be induced when the end-product of the pathway becomes limiting and repressed when adequate levels of the product have been synthesized. Regulation of structural gene expression may occur at the level of transcription

initiation (*promoter control*), transcription termination (*attenuator control*), or a combination of both; exceptionally, regulation occurs at the level of translation.

**Promoter control.** An operon under promoter control is commonly regulated by the product of a specific *regulator gene* which may or may not be contiguous with the structural genes. (Opinions differ as to whether or not the regulator gene should be regarded as part of the operon.) The regulator gene generally has its own promoter and may be expressed constitutively or may be subject e.g. to AUTOGENOUS REGULATION. The operon is said to be under *negative control* if the structural genes are expressed until ‘turned off’ by the regulator protein, and under *positive control* if they are not expressed until ‘turned on’ by the regulator protein. (The regulator protein may require a low-MWT *effector molecule* for activity.)

In a negatively controlled operon the regulator gene encodes a *repressor protein* which binds to a specific region of the DNA (the OPERATOR) upstream of the structural genes, thereby preventing the initiation of transcription. If the structural genes encode enzymes of a catabolic pathway, the presence of the substrate brings about the induction of gene expression. The molecule effecting induction is called an *inducer*; it is not necessarily the substrate of the pathway itself, but may be e.g. a derivative of it. (Certain analogues of the natural inducer may also act as inducers; an analogue which can act as an inducer but which cannot be metabolized by the cell is called a *gratuitous inducer*.) The inducer inactivates the repressor, causing it to release the operator and allow transcription to proceed. When the substrate is removed (e.g. when all of the substrate has been metabolized) the repressor again binds to the operator and transcription ceases; since mRNA is generally short-lived in bacteria (see MRNA), enzyme synthesis also rapidly ceases. (See e.g. LAC OPERON.)

Structural genes encoding enzymes involved in an anabolic pathway may also be subject to negative control. In this case, the regulator gene encodes an *aporepressor* which cannot itself bind to the operator of the operon, but which can do so when it interacts with the end-product of the pathway (or a derivative or analogue of it), the *corepressor*.

In a positively-controlled operon the regulator protein may be an *activator* (= *inducer protein*) which binds to a region of the operon (the *initiator*), thereby turning on (activating) transcription initiation. In the case of a catabolic operon the regulator gene may encode an *apo-activator* which must interact with the substrate (or a derivative of it), the *co-activator*, to form a functional activator. (See e.g. ARA OPERON.)

**Attenuator control.** Attenuation is a regulatory mechanism in which gene expression is prevented by the termination of transcription at a rho-independent terminator (see TRANSCRIPTION), the *attenuator*, in the LEADER region of the mRNA; thus, transcription is terminated before the RNA polymerase reaches the first structural gene of the operon. Whether or not transcription terminates at the attenuator depends on the secondary structure adopted by the leader region of the mRNA: in one conformation the stem-and-loop structure of the rho-independent terminator is formed and transcription is terminated, while in the alternative conformation the terminator structure is not formed and transcription continues into the structural genes.

Attenuation is involved e.g. in the regulation of various operons concerned with amino acid biosynthesis. In these operons the leader encodes a small peptide which contains a relatively high proportion of the amino acid whose biosynthesis is encoded by the operon. If the amino acid is present at levels

adequate to meet the cell's requirements, the leader peptide is synthesized and the mRNA adopts the conformation which terminates transcription at the attenuator. However, when levels of the amino acid fall, the corresponding aa-tRNA becomes limiting and the ribosome translating the leader peptide stalls when it reaches the codon(s) for that amino acid; the presence of a stalled ribosome in this position causes the mRNA to adopt the alternative conformation (sometimes called the 'antiterminator'), and transcription continues through the attenuator and into the structural genes of the operon.

Operons subject to attenuator control include e.g. the HIS OPERON and the TRP OPERON. Attenuation is also involved in the regulation of e.g. genes involved in pyrimidine nucleotide biosynthesis [Appendix V(b)]; *pyrBI* (encoding subunits of aspartate carbamoyltransferase) and *pyrE* (encoding orotate phosphoribosyl transferase) are regulated in response to the level of cellular UTP [review: TIBS (1986) 11 362–365]. (cf. TNA OPERON.)

**Translational control.** Translational control is exemplified by the IF3-L35-L20 operon (containing genes *infC-rpmI-rplT* respectively) in *Escherichia coli*; this operon (transcribed as a polycistronic mRNA) encodes two ribosomal proteins (L35, L20) and a protein factor involved in protein synthesis (IF3: translation initiation factor 3). Translation of L35 and L20 is repressed by L20, i.e. the concentration of L20 in the cell regulates gene expression – high levels of L20 repressing translation. Repression by L20 appears to involve the binding of L20 to mRNA at a site upstream of *rpmI*. The mechanism of repression by L20 is unknown – L20 could simply block mRNA–ribosome binding, or it could bind the ribosome to form an inactive complex. However, in vitro studies suggest the possibility that regulation may involve an RNA 'pseudoknot' formed by base-pairing between mRNA sites upstream of *rpmI*; it has been suggested that L20 may stabilize the pseudoknot (which includes the Shine–Dalgarno sequence and initiator codon of *rpmI*) so as to inhibit ribosome binding and, hence, prevent translation of both *rpmI* and *rplT* [EMBO (1996) 15 4402–4413]. (See also RIBOSOME.)

**operon fusion** In genetic engineering: the fusion of two operons (which are transcribed in the same direction) e.g. by the deletion of a region of DNA between them; the structural genes of the second operon thus come under the control of the regulatory sequences (promoter, operator etc) of the first. (cf. GENE FUSION; see also MUDLAC SYSTEM.)

**Ophiobolus** See DOTHIDEALES. (For *O. graminis* see GAEUMANNOMYCES.)

**ophiobolus patch disease** See TAKE-ALL.

**Ophiocytium** A genus of unicellular algae (class XANTHOPHYCEAE) in which the vegetative cell is rod-shaped to filamentous and is either free-floating or attached to the substratum by a stalk; the cell is usually multinucleate and reproduces by zoospore or aplanospore formation.

**Ophiostoma** See OPHIOSTOMATALES.

**Ophiostomatales** An order of saprotrophic and plant-parasitic fungi of the subdivision ASCOMYCOTINA. Ascocarp: a black, long-necked, superficial or partly immersed perithecium; hamathecium: absent. Asci: unitunicate and thin-walled, rounded to ellipsoidal, evanescent. Genera: e.g. CERATOCYSTIS. (The genus *Ophiostoma* is distinguished by some authors.)

**Ophioglena** See HYMENOSTOMATIDA.

**ophthalmia** Inflammation of any part of the eye, especially the conjunctiva. (See also CONJUNCTIVITIS.)

**ophthalmia neonatorum** Ophthalmia affecting newborn babies, usually contracted from the birth canal; it is commonly caused

by *Neisseria gonorrhoeae* (see GONORRHOEA) or *Chlamydia trachomatis*. (The disease caused by *C. trachomatis* is also called *inclusion blennorrhoea* or *inclusion conjunctivitis*.) [Chlamydial ophthalmia neonatorum (aetiology, epidemiology, diagnosis, prophylaxis and treatment): Book ref. 193, pp. 297–304.]

**opine** See CROWN GALL.

**opisthe** (*ciliate protozool.*) The posterior of the two cells formed during HOMOTHETOGENIC cell division. (cf. PROTER.)

**opisthomastigote** See HERPETOMONAS and TRYPANOSOMATIDAE.

**oppBCDF genes** See PEPTIDOGLYCAN.

**opportunistic pathogens** Organisms which are normally free-living, or which occur as part of the normal body flora, but which may adopt a pathogenic role under certain conditions – e.g. when the normal antimicrobial defence mechanisms of the host have become impaired; thus, e.g. *Bacteroides* spp (common inhabitants of the human gut) may give rise to peritonitis following bowel surgery. (See also ENDOGENOUS INFECTION.)

**opsin** The apoprotein of e.g. BACTERIORHODOPSIN (bacteriorhodopsin), HALORHODOPSIN (halo-opsin) or SLOW-CYCLING RHODOPSIN (slow-opsin).

**opsonic index** The ratio of phagocytic activity of a patient's blood to that of a normal (non-immune) subject in respect of a specific opsonin. To determine the opsonic index: both (citratd) blood samples are incubated for 15 min with a standard number of the relevant antigenic particles (usually microbial cells); the average number of particles engulfed by the phagocytes is then determined by microscopy of smears from each sample – the ratio of the two averages being the opsonic index.

**opsonin** Any molecule which, when combined with a particulate antigen, increases the susceptibility of that antigen to PHAGOCYTOSIS. Opsonins include: (i) certain types of antibody (e.g. most types of IgG) – receptors for the FC PORTION of an antibody occurring e.g. on the macrophage surface; (ii) the C3b and C4b components of COMPLEMENT; (iii) certain ACUTE-PHASE PROTEINS.

**opsonization** The process in which a particulate antigen (e.g. a microbial cell) becomes more susceptible to PHAGOCYTOSIS as a result of combination with an OPSONIN. The term may refer to either a complement-dependent or complement-independent increase in susceptibility.

**optical bleach** *Syn.* FLUORESCENT BRIGHTENER.

**optical brightener** *Syn.* FLUORESCENT BRIGHTENER.

**optical density** See TURBIDIMETRY.

**optical staining** *Syn.* RHEINBERG ILLUMINATION.

**optimal proportions** (optimal ratio; equivalence) (*serol.*) In a PRECIPITIN TEST: the proportions in which antigen and antibody must be mixed in order to obtain the maximum amount of precipitate; for a given antigen–antibody system different optimal proportions are observed in the DEAN AND WEBB TITRATION and the RAMON TITRATION. (See also ANTIGEN EXCESS and LATTICE HYPOTHESIS.)

**optochin** Ethylhydrocupreine hydrochloride (EHC): a reagent which strongly inhibits the growth of *Streptococcus pneumoniae*; other streptococci which form colonies similar to those of *S. pneumoniae* are commonly resistant to ten or more times the concentration of optochin that inhibits *S. pneumoniae*. Optochin is used to detect the presence of *S. pneumoniae* in a mixed flora; the sample is streaked onto the surface of a solid medium, and an optochin-impregnated paper disc is placed on the medium prior to incubation. A significant decrease in the number of colonies in the vicinity of the disc may indicate the presence of *S. pneumoniae*.

**oral hairy leukoplakia** See HAIRY LEUKOPLAKIA.

## oral herpes

**oral herpes** See HERPES SIMPLEX.

**oral microbiology** Microbiology of the mouth: see e.g. MOUTH MICROFLORA. (See also DENTAL CARIES, DENTAL PLAQUE and PERIODONTITIS.)

**oral rehydration solution** A solution of salts and glucose recommended by the WHO (World Health Organization) for use as an oral treatment in cases of severe diarrhoeal disease and dysentery. One litre contains: sodium chloride (3.5 g), sodium citrate (2.9 g), potassium chloride (1.5 g) and anhydrous glucose (20.0 g).

**orange peel fungus** See ALEURIA.

**Orbivirus** A genus of viruses of the REOVIRIDAE. The capsid contains at least seven polypeptide species, of which four are major structural components. Genome: 10 molecules of dsRNA. Type species: bluetongue virus. Orbiviruses infect a wide range of arthropods (mainly insects) and vertebrates, and some can cause disease in man or animals (see e.g. AFRICAN HORSE SICKNESS, BLUETONGUE; cf. COLORADO TICK FEVER); transmission is by vectors such as midges, mosquitoes, sandflies and ticks. The genus comprises many named viruses which are classified in the following serological subgroups (main vertebrate and invertebrate hosts in parentheses): African horse sickness (equines; *Culicoides*); bluetongue (ruminants; *Culicoides*); Changuinola (rodents; *Phlebotomus*); Colorado tick fever (man and rodents; ticks) – but see COLORADO TICK FEVER; Corripata (birds, mosquitoes); epizootic haemorrhagic disease (deer; ?*Culicoides*); equine encephalosis (equines; unknown); Eubenangee (kangaroos, wallabies; mosquitoes); Kemerovo (various; ticks); Palyam (unknown; *Culicoides*, mosquitoes); Wallal (kangaroos, etc; *Culicoides*); Warrego (cattle, kangaroos, wallabies; *Culicoides*). [Review: Book ref. 83, pp. 287–357; biochemistry: Arch. Virol. (1984) 82 1–18.]

**orchid fleck virus** See RHABDOVIRIDAE.

**orchid mycorrhiza** See MYCORRHIZA.

**orchil** (orseille) A purple dye obtained from species of the lichen ROCCELLA.

**orchinol** 2,4-Dimethoxy-6-hydroxy-9,10-dihydrophenanthrene: a wide-spectrum antifungal PHYTOALEXIN produced by the tubers (and, to a lesser degree, by the roots and stems) of certain orchids (e.g. *Orchis militaris*) in response to infection with parasitic or mycorrhizal fungi (e.g. *Rhizoctonia repens*) or with certain soil bacteria.

**orchitis** Inflammation of the testes.

**orcinol** 3,5-Dihydroxytoluene – a compound obtained from various lichen species.

**order** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**orellanin poisoning** MYCETISM, involving renal dysfunction, due to the ingestion of *Cortinarius orellanus*.

**ores** (microbial leaching) See LEACHING.

**orf** *Syn.* CONTAGIOUS PUSTULAR DERMATITIS (1).

**ORF** OPEN READING FRAME.

**orf subgroup** See PARAPOXVIRUS.

**orf18 gene** See CONJUGATIVE TRANSPOSITION.

**organelle** Any structure which forms part of a cell and which performs a specialized function: e.g. a FLAGELLUM, a MITOCHONDRION, or the PARORAL MEMBRANES of a ciliate.

**organic acids** (as antimicrobial agents) Certain organic acids and their salts or esters are used as PRESERVATIVES and e.g. as antifungal agents for the treatment of skin diseases (see e.g. BENZOIC ACID, PARABENZOATES, SALICYLIC ACID, SORBIC ACID and UNDECYLENIC ACID). Typically, their antimicrobial activity is maximum in the lower pH range; this is commonly taken as evidence that activity depends on the unionized molecule,

although changes in pH may also affect e.g. transport systems and/or surface properties in the target cells. In membrane vesicles of *Escherichia coli*, parabens and sorbic acid were found to eliminate  $\Delta\text{pH}$  – leaving  $\Delta\psi$  much less disturbed [JGM (1985) 131 73–76].

**organism** See MICROORGANISM.

**organoleptic** Affecting the organs of sense – particularly those of taste and smell.

**organophosphorus compounds** Phosphorus-containing organic compounds are widely used as insecticides and acaricides, and some are also effective agricultural ANTIFUNGAL AGENTS; the latter include e.g. ditalimfos (used against barley powdery mildew), HINOZAN, KITAZIN, and PYRAZOPHOS. [Accumulation, metabolism and effects of organophosphorus insecticides on microorganisms: AAM (1982) 28 149–200.]

**organotin** See TIN.

**organotroph** An organism which obtains energy by the metabolism of an organic substrate (i.e., a *chemoorganotroph*) or which uses an organic substrate as an electron donor in phototrophic metabolism (i.e. a *photoorganotroph*). (cf. LITHOTROPH; HETEROTROPH.) Chemoorganotrophs may obtain energy from organic substrates e.g. by FERMENTATION (sense 1) and/or by RESPIRATION; substrates may include any of a wide range of compounds, e.g. (depending on species) various sugars, amino acids, fatty acids, cyclic compounds, etc. Photoorganotrophs include e.g. certain photosynthetic bacteria which use relatively simple substrates (e.g. acetate, caproate, lactate) as electron donors in PHOTOSYNTHESIS.

**orgmet** See BIOMIMETIC TECHNOLOGY.

**ori** A designation which usually indicates an origin of DNA REPLICATION (see e.g. *oriC*); *oriT* is an origin of transfer (see CONJUGATION sense 1b).

**ori1** See F PLASMID.

**ori2** See F PLASMID.

**oriC** An origin of chromosome replication. In *Escherichia coli* the *oriC* region is ca. 245 bp long and contains sequences for recognition by and interaction with initiation factors; these sequences are precisely separated by ‘spacer’ sequences [Book ref. 69, pp. 257–273; interaction of *oriC* with proteins: pp. 289–301]. (See also DNA REPLICATION.)

**oriental sore** See CUTANEOUS LEISHMANIASIS.

**origin** (*mol. biol.*) See DNA REPLICATION.

**oriS** See F PLASMID.

**orisome** See DNA REPLICATION.

**oriT** See CONJUGATION (1b) (i).

**oriV** The/an origin of vegetative replication in a PLASMID. (cf. *oriT* in CONJUGATION (1b) (i).)

**Orleans process** See VINEGAR.

**ornidazole** See NITROIMIDAZOLES.

**L-ornithine** See e.g. Appendix IV(a).

**ornithine carbamoyltransferase** See ARGININE DIHYDROLASE and Appendix IV(a).

**ornithine decarboxylase test** See DECARBOXYLASE TESTS.

**Ornithocercus** A genus of tropical marine DINOFLAGELLATES in which the cells have elaborate thecal extensions (‘wings’).

**ornithocoprophilous** Preferring a habitat rich in bird faeces.

**ornithosis** See PSITTACOSIS.

**orotate** Uracil 4-carboxylate: see Appendix V(b).

**orotidine monophosphate** See Appendix V(b).

**Oroya fever** See BARTONELLOSIS.

**orphan virus** A virus which is not known to cause any disease.

**orseille** *Syn.* ORCHIL.

**Orthocerina** See FORAMINIFERIDA.

**orthochromatic dye** A dye which does *not* give metachromatic effects (see METACHROMASY).

**Orthodonella** See HYPOSTOMATIA.

**orthokinesis** See KINESIS (sense 2).

**orthomere** See MACRONUCLEUS.

**Orthomyxoviridae** A family of pleomorphic, enveloped VIRUSES which have a segmented, negative-sense ssRNA genome (cf. PARAMYXOVIRIDAE). Virus replication in host cells is inhibited by actinomycin D and by  $\alpha$ -amanitin. Orthomyxoviruses are mainly pathogens of the upper respiratory tract in man, animals and birds; they include influenza viruses A, B and C, distinguished on the basis of their ribonucleoprotein antigens. Influenza viruses A and B constitute one genus: INFLUENZAVIRUS; INFLUENZA VIRUS C probably constitutes a separate genus.

Two other viruses (DHORI VIRUS and THOGOTO VIRUS), previously considered to have affinities with the Bunyaviridae, have been shown to resemble orthomyxoviruses in structure; both viruses have a segmented genome of seven ssRNA molecules. [Virol. (1983) 127 205–219.]

**orthoplectic metachrony** See METACHRONAL WAVES.

**Orthopoxvirus** (vaccinia subgroup) A genus of viruses of the CHORDOPOXVIRINAE. The orthopoxviruses are morphologically indistinguishable from each other and are very closely related serologically; they are distinguished chiefly on the basis of their biological properties. Orthopoxviruses grow on the CAM, producing 'pocks' characteristic for each virus; they can also replicate in certain cells in culture (e.g. chick embryo fibroblasts, Vero cells, HeLa cells, etc.). All members produce a lipoprotein haemagglutinin in infected cells; this haemagglutinin apparently becomes incorporated in the host cell membrane, and may be present on the surface of (extracellular) virions. Recombination between different orthopoxviruses occurs readily: e.g. a recombinant has been derived from vaccinia and ectromelia viruses which exhibits specific pathogenicity markers of both parents [JGV (1985) 66 621–626]. (See POXVIRIDAE for replication cycle etc.)

Type species: VACCINIA VIRUS; other members: buffalopox virus, camelpox virus, cowpox virus, ECTROMELIA VIRUS, MONKEYPOX virus, rabbitpox virus, VARIOLA VIRUS.

**Orthoreovirus** *Syn.* REOVIRUS.

**Oryctes rhinoceros virus** See BACULOVIRIDAE.

**Orygia pseudotsugata NPV** See NUCLEAR POLYHEDROSIS VIRUSES.

**Oscillatoria** A genus of filamentous CYANOBACTERIA (section III) in which the trichomes are straight, motile (see GLIDING MOTILITY), and composed of disc-shaped cells with little or no constriction between them; sheath formation is never pronounced. GAS VACUOLES may be present, and hormogonia are formed by fragmentation of whole trichomes. GC%: 40–50. Species include e.g. *O. agardhii*, *O. limnetica*, *O. princeps*, and *O. rubescens*; *O. redekei* strains may belong to the genus *Pseudanabaena*. (See also TRICHODESMIUM.) The organisms occur in a wide range of habitats, including aquatic (freshwater, brackish and marine) and damp terrestrial environments, often forming dense conspicuous mats. (See also GEOSMIN and PAINT SPOILAGE.) *O. limnetica* has a high sulphide tolerance and characteristically occurs, together with purple and green photosynthetic bacteria, in sulphide-rich anaerobic habitats, where it can carry out facultative anoxygenic phototrophy using H<sub>2</sub>S as an electron donor for CO<sub>2</sub> assimilation (see CYANOBACTERIA).

**Oscillochloris** See CHLOROFLEXACEAE.

**OSCP** Oligomycin-sensitivity-conferring protein: see PROTON ATPASE.

**Osler's nodes** See ENDOCARDITIS.

**osmic acid** See OSMIUM TETROXIDE.

**osmiophilic** Having an affinity for OSMIUM TETROXIDE.

**osmium tetroxide** ('osmic acid'; OsO<sub>4</sub>) A volatile compound used e.g. for post-FIXATION (1–2% w/v in phosphate or cacodylate buffer); the specimen is immersed in (or exposed to the vapour of) the solution. OsO<sub>4</sub> may cross-link and stabilize e.g. lipids by reacting with their double bonds. Longer exposure to OsO<sub>4</sub> may be used for positive staining in ELECTRON MICROSCOPY.

**osmolyte** *Syn.* OSMOTICUM.

**osmophilic** Refers to an organism which grows optimally in or on media of high osmotic pressure.

**osmoregulation** A form of ADAPTATION in which a cell increases or decreases its intracellular osmotic pressure in response to an increase or decrease, respectively, in extracellular osmotic pressure. Maintenance of internal osmotic pressure, within certain limits, is necessary for growth/viability; for example, osmotic withdrawal of water from a cell – without adaptive response – would tend to raise the concentrations of some solutes to levels that may be inhibitory or lethal.

In microorganisms osmoregulation involves the regulation of intracellular concentrations of certain types of solute and/or (in some eukaryotes) the action of CONTRACTILE VACUOLES.

Solutes used in osmoregulation include certain ions (e.g. K<sup>+</sup>) and a number of low-MWt organic compounds such as glutamate and glycine betaine ((CH<sub>3</sub>)<sub>3</sub>.N<sup>+</sup>.CH<sub>2</sub>COO<sup>-</sup>), a substance common in nature. (See also COMPATIBLE SOLUTE.)

Solutes (*osmotica*) may be taken up from the environment and/or synthesized in situ. Uptake or pumping out of ions through the cytoplasmic membrane involves e.g. the activity of particular types of ATPase; this form of osmoregulation is common in bacteria: see e.g. the *Escherichia coli* Kdp-based system in TWO-COMPONENT REGULATORY SYSTEMS. Another form of osmoregulation in *E. coli* is controlled by a different two-component system. In this system, increased osmolarity in the environment stimulates the kinase activity of a cell-envelope sensor, EnvZ, which transfers phosphate to the regulator protein, OmpR; activated OmpR (i) enhances transcription from *ompC* (the gene encoding OmpC PORIN) and (ii) inhibits transcription from the OmpF porin gene. Hence, increased osmolarity results in a modified outer membrane containing a higher proportion of OmpC (which forms a pore smaller than that of OmpF).

Following osmotic up-shift, uptake of glycine betaine is common in both Gram-positive and Gram-negative bacteria. In *E. coli* this compatible solute is taken up very efficiently by a binding-protein-dependent transport system (a so-called ABC importer) designated ProU [FEMS Reviews (1994) 14 3–20].

The bacterium *Sinorhizobium meliloti* actually metabolizes most of the known osmoprotectants, including glycine betaine; in *S. meliloti*, osmotic up-shift triggers the accumulation of *endogenous* solutes (e.g. glutamate and *N*-acetylglutaminylglutamine amide) – accumulation being stimulated e.g. by exogenous sucrose [JB (1998) 180 5044–5051].

[Regulation of compatible solute accumulation in bacteria: Mol. Microbiol. (1998) 29 397–407.]

Osmotic down-shift triggers efflux systems. For example, K<sup>+</sup> ions and glutamate are released rapidly by *E. coli* (efflux apparently being energy-independent); much of the K<sup>+</sup> released is believed to pass through *mechanosensitive channels* in the CYTOPLASMIC MEMBRANE: stretch-activated channels which respond to increases in the cell's turgor pressure by increasing their pore size [JBC (1997) 272 32150–32157]. In some bacteria (including *E. coli*) the membrane contains structures called *aquaporins* that may contribute to osmoregulation.

## osmotic shock

In the alga *DUNALIELLA*, glycerol appears to play a major role in osmoregulation. In this organism, the GLYCEROL cycle (glycerol → dihydroxyacetone (DHA) → DHA-phosphate (DHAP) → glycerol phosphate → glycerol) can be used to accumulate glycerol when external osmotic pressure is high – DHAP being derived from the Calvin cycle or from starch. In *Poterochromonas malhamensis*, ISOFLORIDOSIDE is used as an osmoregulatory agent.

**osmotic shock** ('cold shock') In cells or subcellular organelles etc.: sudden change(s) in osmotic pressure sufficient to cause physical disruption. Osmotic shock has been used e.g. to release periplasmic enzymes from Gram-negative bacteria. The cells are pre-incubated in 20% sucrose containing EDTA and TRIS buffer, and then rapidly diluted in cold (e.g. 4°C), dilute MgCl<sub>2</sub> solution (e.g. 0.005 M); on centrifugation the liberated enzymes remain in the supernatant. During pre-incubation sucrose enters the periplasmic space, causing plasmolysis; on dilution, water enters the periplasmic space at a rate much greater than that of sucrose efflux via the porin channels – resulting in the rupture of the OUTER MEMBRANE.

**osmotic shock-sensitive permease** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**osmotica** See OSMOTICUM.

**osmoticum** (*pl.* osmotica) A substance which contributes significantly to intracellular osmotic pressure. (See also OSMOREGULATION.)

**osmotrophy** A mode of nutrition in which soluble nutrients are absorbed through the cell surface – as occurs e.g. in bacteria and fungi. (cf. PHAGOTROPHY.)

**osteomyelitis** Inflammation of bone. *Acute osteomyelitis* is caused by bacterial infection via wounds or via the blood from another site of infection (e.g. skin, throat); it may occur as a complication of septicaemia. The commonest causal agent is *Staphylococcus aureus*. Acute osteomyelitis occurs most commonly in children and affects mainly the long bones of the arms and legs. Symptoms: e.g. fever and bone pain, with inflammation of the overlying skin; subsequent bone growth may be prevented. *Chronic osteomyelitis* may be due e.g. to tubercle bacilli, the vertebrae being most commonly involved (*Pott's disease*); spinal deformity may result. Chronic osteomyelitis may also occur as a complication of *Salmonella* infection (see e.g. FOOD POISONING (e)) – especially in patients with sickle-cell disease, bone defects, or prostheses; other causal agents include e.g. *Pseudomonas aeruginosa* (especially in drug addicts and open-heart surgery patients) and *Escherichia coli*.

**osteopetrosis** ('marble bone') A disease characterized by the formation of abnormally dense bone. In chickens, osteopetrosis ('big bone disease') may result from infection with an AVIAN LEUKOSIS VIRUS (ALV), and involves the abnormal thickening of bones – particularly the long bones of the legs – as a result of abnormal growth and differentiation of ALV-infected osteoblasts. Most exogenous ALVs appear to have the potential for inducing osteopetrosis, although strains differ in the time of onset of disease after infection, and in the severity of the disease induced. The time of onset and severity of disease seem to correlate with the amount of viral DNA in osteoblasts; affected cells each contain several to many copies of unintegrated viral DNA as well as integrated (proviral) DNA [Virology (1985) 141 130–143]. It has been reported that sequences near the 5'-LTR of the ALV genome are responsible for osteopetrosis induction [JV (1986) 59 45–49], while 3'-*env*-LTR sequences influence the time of onset and severity of the disease [Virology (1985) 145 94–104].

**osteosarcoma** See SARCOMA.

**ostiole** (*mycol.*) A tubular or pore-like opening to the exterior in e.g. a perithecium, pseudoperithecium or pycnidium.

**Ostracoblabe implexa** A coenocytic, mycelial fungus (taxonomic position uncertain) which occurs on the shells of marine molluscs, obtaining nutrients from the organic matrix of the shell. In the European flat oyster (*Ostrea edulis*) the fungus causes *shell disease*: it penetrates between the shell and mantle of the oyster, causing severe irritation; the oyster responds by producing a highly proteinaceous shell which further encourages growth of the fungus. Shell disease occurs mainly in shallow waters where temperatures commonly exceed 18°C. [Book ref. 1, pp. 216–218.] (See also OYSTER DISEASES.)

**Ostreobium** A genus of siphonaceous green algae (division CHLOROPHYTA) which grow endolithically in shells and corals (and beneath the layer of zooxanthellae in corals) in tropical and temperate oceans; the cells contain siphonoin and siphonoxanthin, and their photosynthetic pigments have absorption maxima in the far-red.

**ostreogrycins** See STREPTOGRAMINS.

**ostropalean ascus** An ASCUS whose wall contains a substantial, non-refractive apical thickening (apical cap); at maturity, the ascospores are discharged via a narrow channel in the cap. Such asci characteristically contain filiform ascospores.

**Ostropales** An order of saprotrophic, plant-parasitic and lichenized fungi of the ASCOMYCOTINA. Ascocarp: apothecium or perithecioid. Asci: unitunicate, inoperculate, cylindrical. Ascospores: commonly filiform.

**OT** Old TUBERCULIN.

**Oth-25/89/J virus** A SMALL ROUND STRUCTURED VIRUS.

**otitis media** Inflammation of the middle ear. The condition is commonly suppurative; pyogenic bacteria from the throat infect the middle ear via the eustachian tube – often following an upper respiratory tract infection or tonsillitis. The eustachian tube becomes blocked, and pus formation causes bulging and sometimes rupture of the eardrum. Causal agents include e.g. *Haemophilus influenzae*, *Moraxella (Branhamella) catarrhalis*, *Streptococcus pneumoniae* and *S. pyogenes*.

**otomycosis** A MYCOSIS affecting the ears (see e.g. ASPERGILLOSIS).

**Ottens' antigens** Polysaccharide antigens which occur in many strains of *Streptococcus milleri* but which seldom occur in other streptococci.

**OTU** Operational taxonomic unit: a designation applied to each individual strain, species, genus etc used in classification carried out by NUMERICAL TAXONOMY; in bacteriology OTU commonly refers to a given strain.

**ouabain** ( $\gamma$ -strophanthin) A polycyclic, L-rhamnose-containing glycoside which inhibits Na<sup>+</sup>/K<sup>+</sup>-ATPase (see ION TRANSPORT).

**Ouchterlony test** A GEL DIFFUSION test of the DOUBLE DIFFUSION, double DIMENSION type. A pattern of holes ('wells') is cut into a sheet of agar (or similar material) contained (e.g.) in a Petri dish. The number and arrangement of wells depend on the number and nature of the samples to be tested, and on the purpose of the test. Each well is filled with an antigen, antibody (usually antiserum), or control preparation; the whole is covered (to prevent drying) and incubated (usually at room temperature) for hours or (more usually) days. The diagram shows the arrangement of wells, and some possible results, for the serological comparison of two samples of antiserum.

**Oudemansiella** See AGARICALES (Tricholomataceae).

**Oudin test** See SINGLE DIFFUSION.

**out genes** See PROTEIN SECRETION (type II systems).

**outer envelope** See SPIROCHAETALES.

OUCHTERLONY TEST. (a) *Reaction of identity*. With wells located symmetrically, the lines of precipitate are symmetrical and do not overlap. Since the antigens (Ag) in the top two wells react identically with the antibody (Ab) they are taken to be serologically identical. (b) *Reaction of partial identity*. X is a line of precipitate formed where antibody and its homologous antigen ( $Ag_a$ ) meet in optimal proportions. At Y, antibody and a *cross-reactive* antigen ( $Ag_b$ ) meet in optimal proportions. In this instance,  $Ag_b$  has less affinity than  $Ag_a$  for the antibody, and antibody which has diffused beyond Y forms a precipitate with  $Ag_a$  at Z; Z, which is called a *spur*, points towards the cross-reactive antigen. (c) *Reaction of non-identity*. Two independent precipitating systems are present: each antibody reacts only with its homologous antigen.

**outer membrane (OM)** The outer layer of the CELL WALL in Gram-negative bacteria: a composite layer external to the PEPTIDOGLYCAN sacculus. The OM is an important permeability barrier (see later) which helps to control the cell's internal environment and give protection against certain antibiotics and other harmful agents. In pathogenic Gram-negative bacteria the hydrophilicity of the OM may help the cells to evade phagocytosis.

*Composition of the OM.* Most studies on the OM have been carried out on *Escherichia coli* and *Salmonella typhimurium*, and the following refers primarily to these and related enterobacteria. In electronmicrographs, the OM is seen as a trilaminar structure. Much of it consists of an asymmetrical lipid bilayer: a monolayer of phospholipid molecules forming the inner layer, and LIPOPOLYSACCHARIDE (LPS) molecules forming the outer (external) layer; the LPS molecules are so arranged that lipid A contributes to the hydrophobic interior of the membrane, and the (hydrophilic) O-specific chains are directed outwards.

Almost half the mass of the OM consists of proteins, and the various species of protein are distributed throughout the membrane – either embedded or partly embedded in the lipid bilayer. The quantitatively dominant ‘major proteins’ include the specialized channel-forming (‘pore-forming’) transmembrane proteins (see PORIN), the BRAUN LIPOPROTEIN, and (in *E. coli*) the OmpA protein (see OMP). Other proteins include those involved in the uptake of specific substance(s) (see e.g. BTUB PROTEIN, FEPA PROTEIN, LAMB PROTEIN, TONA PROTEIN, TSX PROTEIN), and enzymes such as proteases (see e.g. OmpT protein in type IV PROTEIN SECRETION) and phospholipases.

In members of the Enterobacteriaceae the outer surface of the OM carries a significant amount of ENTEROBACTERIAL COMMON ANTIGEN.

A stable and functional OM depends on ionic and other interactions between the various components. The core oligosaccharides of adjacent LPS molecules appear to be linked by divalent cations, particularly magnesium and calcium ions; in this context the phosphate group(s) of the heptose residue(s) may be important because their loss has been correlated with increased leakiness of the OM to hydrophobic molecules. Each LPS molecule is also hydrophobically bound (via lipid A) to the fatty acid chains of phospholipids. Some of the proteins appear to be linked to heptose residue(s) – or to the adjacent glucose residue – of the core oligosaccharide; thus, rough mutants which lack distal residues of the core oligosaccharide retain normal amounts of OM protein, while deep rough mutants which lack

the heptose residue(s) have significantly lower amounts of OM protein. Porins (and e.g. OmpA protein) are bound to the underlying layer of peptidoglycan by ionic links; OmpA is readily released by treatment with SDS at temperatures below 56°C, but porins remain bound even after treatment with 2% SDS at 60°C – their removal requiring drastic treatment with SDS or e.g. with 0.5 M NaCl.

At a number of locations the OM is linked covalently to peptidoglycan via the Braun lipoprotein (see CELL WALL), the lipid portion of the Braun lipoprotein apparently being anchored in the hydrophobic interior of the OM.

At various localized regions there are apparent fusions between the OM and the cytoplasmic membrane (see ADHESION SITE); these sites are believed to be involved e.g. in the export of LPS and porin proteins from the cytoplasmic membrane to the OM. (Although widely accepted, a few authors question the existence of adhesion sites.)

*Permeability of the OM.* In wild-type (smooth) enteric bacteria the OM is permeable to small ions and small hydrophilic molecules; these entities can thus be taken up across the outer membrane in an energy-independent manner. The OM is generally much less permeable (or impermeable) to hydrophobic molecules – and to amphipathic molecules such as bile salts and SDS; such molecules do not pass easily through the porin channels, and their inability to penetrate the OM reflects the low permeability of the asymmetric lipid bilayer. In many cases, therefore, uptake across the outer membrane is energy-dependent (see e.g. TONB PROTEIN).

In deep rough mutants (e.g. the Rd and Re mutants of *Salmonella typhimurium*) the permeability of the OM to e.g. crystal violet, nafcillin, phenol and other hydrophobic molecules – and to anionic and cationic detergents – is much higher. This increased permeability may be due e.g. to the loss of some LPS molecules and their replacement by phospholipid molecules, resulting in the formation of phospholipid bilayers which are presumed to be more permeable to lipophilic substances. Alternatively, or perhaps additionally, rough mutants may be defective in LPS–LPS cross-linking; thus, the absence of phosphate group(s) in the core oligosaccharide may permit hydrophobic molecules to pass through gaps between the LPS molecules. [Review: CRM (1986) 13 1–62.]

*Experimental disruption of the OM.* Some of the LPS molecules (up to ca. 50% of the total) can be removed from the OM by the action of metal ion chelators, such as EDTA (q.v.), in the presence of TRIS buffer – or by high concentrations of TRIS

## outer membrane protein

(e.g. 0.1 M, pH 7.2) without EDTA; by sequestering divalent cations, chelators increase the electrostatic repulsion between LPS molecules (and between LPS and acidic protein molecules), while TRIS may further destabilize the membrane by replacing LPS-bound cations. Cells thus treated become permeable to various hydrophobic molecules (e.g. actinomycin D, novobiocin). (See also OSMOTIC SHOCK.)

An EDTA–TRIS–LYSOZYME mixture can be used for the gentle lysis of Gram-negative bacteria, while the same procedure carried out in hypertonic sucrose solution can be used for SPHAEROPLAST formation.

POLYMYXINS, polylysines and polyornithines are examples of other agents which disrupt the OM and which increase its permeability. [Agents that increase the permeability of the OM: MR (1992) 56 395–411.] (See also BPI PROTEIN.)

Low concentrations of magnesium ions (e.g. 0.1–5.0 mM) can help to stabilize the OM in deep rough mutants, but high concentrations of divalent cations (particularly calcium, but also magnesium) can destabilize/disrupt the wild-type OM; thus, e.g. 100 mM magnesium ions in the cold (0–4°C) causes the release of periplasmic  $\beta$ -lactamases in *Salmonella typhimurium*. High concentrations of cations may cause these effects by raising the melting point of the membrane lipids: at low temperatures the fluidity of the membrane may be decreased to such an extent that it readily ruptures; this effect is used to promote TRANSFORMATION and TRANSFECTION in enterobacteria.

**outer membrane protein** In Gram-negative bacteria: any of a range of proteins in the OUTER MEMBRANE – see e.g. OMP, FEPA PROTEIN, LAMB PROTEIN, TONA PROTEIN and PORIN. (cf. TONB PROTEIN.)

**outer primers** See NESTED PCR.

**outer sheath** See SPIROCHAETALES.

**outer veil** (*mycol.*) *Syn.* UNIVERSAL VEIL.

**outgrowth** (of bacterial endospores) See ENDOSPORE (sense 1(a)).

**overgrowth syndrome** See GASTROINTESTINAL TRACT FLORA.

**overlapping genes** Two (or more) GENES in which part or all of one gene is coextensive with part of another. The genes may be translated in different reading frames (see GENETIC CODE) or in the same reading frame with different start and/or stop points (see e.g. LEVIVIRIDAE and MICROVIRIDAE) or different splicing patterns. The phenomenon of overlapping genes maximizes the coding capacity of a genome, and can also provide a means for the regulation of expression of the genes.

**overoxidation** See ACETOBACTER.

**overpressure retort** See BATCH RETORT.

**overproduction** Synthesis of high concentrations of a given protein, usually a heterologous (i.e. 'foreign') protein, in a genetically modified organism. This procedure has been used e.g. for the synthesis of STREPTOKINASE and other therapeutic agents in *Escherichia coli*.

*E. coli* is commonly used for overproduction, but it cannot express certain genes – for example, eukaryotic genes whose products require specific post-translational modification in a eukaryotic cell. Moreover, genes containing introns would not be expressed (although this problem can be circumvented by using cDNA).

Efficient, high-level expression of heterologous genes in *E. coli* requires careful attention to specific aspects of the procedure; some of the relevant factors are considered below.

Transcription of the heterologous gene should be optimized by using a strong, tightly regulated promoter in the expression vector. The use of a tightly regulated promoter is necessary because gene expression should not occur until the population

of *E. coli* has reached a high density; this avoids an early depression of growth rate and maximizes the yield of the required protein. Such tight regulation is clearly essential if the gene product is frankly toxic for *E. coli*. Moreover, the choice of transcription regulator should be appropriate; thus, e.g. a toxic inducer such as IPTG (isopropyl- $\beta$ -D-thiogalactoside) would not be optimal for the overproduction of therapeutic proteins.

The efficiency of translation depends on factors such as the precise Shine–Dalgarno (SD) sequence and the number of nucleotides between the SD sequence and the start codon; these aspects of translational efficiency must be considered when constructing the expression vector. Additionally, some genes contain a DOWNSTREAM BOX whose precise sequence may be an important factor in efficient translation in *E. coli*. A further consideration is CODON BIAS.

One poorly understood problem is the appearance of 'inclusion bodies' – aggregates of unfolded or incorrectly folded proteins which form insoluble masses in the cytoplasm; this may result in little or no biologically active product. Approaches to this problem include (i) the use of a lower growth temperature, (ii) co-expression of so-called 'chaperone' proteins to promote correct folding, and (iii) use of gene fusion techniques; the latter method may involve fusion of the heterologous gene with another gene whose product promotes solubility of the fusion protein. (If, however, the inclusion body proteins can be correctly folded *in vitro*, the development of such bodies can be advantageous in that they may facilitate purification of the protein product and help to prevent degradation of the product by intracellular proteases.)

A further problem to consider is the risk of proteolysis by *E. coli* proteases. This risk may be avoided or minimized by targeting the protein product to the bacterial periplasm (in which there are fewer proteases). Another approach involves elimination of particular proteolytic site(s) in the product by re-coding the gene in a way which does not alter the product's biological activity. A further possibility is to fuse the heterologous gene with another gene whose product is secreted. Re-coding a gene may also help to increase the stability of certain proteins which are (inherently) unstable owing to the presence of particular amino acids (e.g. arginine, leucine, lysine, tryptophan) at the N-terminal. (In re-coding, it should be noted that the *penultimate* N-terminal amino acid in a bacterial protein is also important in that it may potentiate removal of the terminal N-formylmethionine (by methionine aminopeptidase) and thus itself become the terminal amino acid.)

A different approach to proteolysis involves the use of cells mutant in the *rpoH* gene (see HEAT-SHOCK PROTEINS); because RpoH promotes expression of the Lon protease these mutants are deficient in Lon, and such mutants have been found to give greatly increased yields of heterologous proteins.

[Achieving high-level expression of genes in *E. coli*: MR (1996) 60 512–538.]

**overwound DNA** See DNA.

**ovine diseases** See SHEEP DISEASES.

**ovine encephalomyelitis** *Syn.* LOUPING-ILL.

**ovine foot-rot** See FOOT-ROT.

**ovine progressive interstitial pneumonia** See MAEDI.

**Ovivor** See EIMERIORINA.

**Ovulariopsis** See HYPHOMYCETES and ERSIPHALES.

**OXA-type  $\beta$ -lactamase** See  $\beta$ -LACTAMASES.

**oxacephems** Compounds (e.g. MOXALACTAM) structurally resembling cephalosporins but having oxygen instead of sulphur at position 1 (see  $\beta$ -LACTAM ANTIBIOTICS, Figure (b)).

**oxacillin** See PENICILLINS.

**oxadixyl** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**Oxalobacter formigenes** See UROLITHIASIS.

**Oxalophagus** A proposed genus of bacteria containing organisms which have been included in the genus *Clostridium* [IJSB (1994) 44 812–826].

**oxathiin antifungal agents** See e.g. CARBOXIN.

**oxazolidinones** Synthetic antibiotics which inhibit PROTEIN SYNTHESIS in (mainly) Gram-positive bacteria; they include *linezolid* and *eperezolid*. Oxazolidinones bind to the 50S ribosomal subunit in the central region of domain V of 23S rRNA – a site similar to that targeted by chloramphenicol and lincomycin; this site is within the peptidyltransferase region of the ribosome, and it is thought that these drugs may affect function(s) associated with this location of the ribosome [JB (2000) 182 5325–5331].

Linezolid (administered orally or intravenously) is a bacteriostatic agent which is effective (MIC 1–4 mg/l) against e.g. *S. pneumoniae*, staphylococci and enterococci; it can be useful against MRSA and other multidrug-resistant pathogens. [Review: TIM (1997) 5 196–200.] Linezolid has been licenced for use in the USA.

[Linezolid (when to use?): JAC (2000) 46 347–350.]

[Linezolid: review of use in the management of serious Gram-positive infections: Drugs (2001) 61 525–551.] Clinical resistance to linezolid has been reported in vancomycin-resistant enterococci (VRE) [Lancet (2001) 357 1179].

**Oxford strain** A strain of *Staphylococcus aureus* (NCTC strain 6571) which is sensitive to a wide range of antibiotics; it may be used as a control in antibiotic sensitivity tests.

**oxic** Refers to an environment in which oxygen is present.

**oxiconazole** See AZOLE ANTIFUNGAL AGENTS.

**oxidase** An OXIDOREDUCTASE which catalyses a reaction in which electrons removed from a substrate are donated *directly* to O<sub>2</sub>.

**oxidase reagent** See OXIDASE TEST.

**oxidase test** A test used to detect the presence, in bacteria, of cytochrome *c* and its associated oxidase. In one form of the test, filter paper is moistened with a few drops of KOVÁCS' OXIDASE REAGENT, and a small amount of bacterial growth is smeared onto the moist filter paper with a glass spatula or a platinum loop. (Nichrome or iron-containing loops may give a false-positive reaction.) In a positive test (cyt *c* and cyt *c* oxidase present) a purple coloration (due to oxidation of the reagent) develops immediately or within 10 sec; electrons are transferred from the reagent to cyt *c* and thence, via cyt *c* oxidase, to molecular oxygen. In the so-called *cytochrome oxidase test* (= *indophenol oxidase test*) the reagent used is a mixture of equal volumes of 1%  $\alpha$ -naphthol in 95% ethanol and 1% aqueous *p*-aminodimethylaniline oxalate; when the reagent is poured over bacterial growth, a positive result is indicated by a strong blue coloration (due to indophenol blue formation) within ca. 30 sec. (cf. BENZIDINE TEST.)

**oxidation–fermentation test** (Hugh and Leifson's test; O–F test) A test used to indicate whether a given carbohydrate (usually glucose) is attacked oxidatively or fermentatively (or not at all) by a given strain of bacterium. The peptone–agar medium includes NaCl, K<sub>2</sub>HPO<sub>4</sub>, the carbohydrate, and a pH indicator (usually BROMTHYMOL BLUE); the unused medium is green (if bromthymol blue is used) and has a pH of 7.1. In the test, each of two tubes of the (oxygen-free) medium is stab-inoculated with the test organism, and the medium in one of the tubes is immediately covered with a layer of sterile liquid paraffin ca. 1 cm in depth. Both tubes are then incubated and subsequently examined for evidence of carbohydrate utilization (acidification: yellowing

of the medium). Acidification in only the uncovered medium indicates oxidative attack on the carbohydrate, while acidification in the covered tube indicates that the carbohydrate can be attacked fermentatively; no reaction in either tube usually indicates that the particular carbohydrate is not utilized by the test organism. [Modified medium for marine bacteria: AEM (1985) 49 1541–1543.]

**oxidation–reduction potential** REDOX POTENTIAL.

**oxidative metabolism** See RESPIRATION.

**oxidative pentose phosphate pathway** *Syn.* HEXOSE MONOPHOSPHATE PATHWAY.

**oxidative phosphorylation** As commonly used: the phosphorylation of ADP to ATP, or the formation of PYROPHOSPHATE from inorganic phosphate, in a reaction which is driven by energy derived from proton motive force (see CHEMIOSMOSIS) generated by means of a *respiratory* chain; electron transport may be driven by aerobic RESPIRATION or by ANAEROBIC RESPIRATION. Oxidative phosphorylation may be catalysed by a PROTON ATPASE or a PROTON PPASE. (cf. ELECTRON TRANSPORT PHOSPHORYLATION and SUBSTRATE-LEVEL PHOSPHORYLATION.)

**oxidative rancidity** RANCIDITY due to AUTOXIDATION of a food's unsaturated fatty acids; such oxidation is encouraged e.g. by metal ions and by light. The occurrence of oxidative rancidity can be inhibited or delayed e.g. by refrigeration, by removing oxygen (e.g. by vacuum packing), or by the use of ANTIOXIDANTS.

**oxidizing agents** (as antimicrobial agents) Strong or moderately strong oxidizing agents can behave as effective antimicrobial agents when they are present in adequate concentrations under suitable conditions. However, their use as DISINFECTANTS is often limited by their high reactivity – which renders them liable to inactivation in the presence of excess organic matter. Inactivation by inert organic matter can be compensated for by using a concentration of the oxidizing agent sufficient to oxidize the inert matter and to leave a residual concentration which can act against viable microorganisms – see e.g. *chlorine demand* in WATER SUPPLIES. (For 'adaptation' of bacteria to oxidizing agents see HYDROGEN PEROXIDE.)

Antimicrobial oxidizing agents include e.g. CHLORINE, HYDROGEN PEROXIDE, HYPOCHLORITES, OZONE and POTASSIUM PERMANGANATE.

**oxidoreductases** ENZYMES (EC class 1) which catalyse oxidation–reduction reactions. (See also DEHYDROGENASE; OXIDASE; OXYGENASE; PEROXIDASE.)

**oxine** *Syn.* 8-HYDROXYQUINOLINE.

**Oxobacter** See CLOSTRIDIUM.

**2-oxoglutarate dehydrogenase** See TCA CYCLE.

**oxolinic acid** An analogue of NALIDIXIC ACID; it resembles nalidixic acid in its mode of action but is much more potent.

**6-oxo-PGF<sub>1 $\alpha$</sub>**  See PROSTACYCLIN.

**oxycarboxin** See CARBOXIN.

**Oxyfume Sterilants** A range of STERILANTS containing ETHYLENE OXIDE.

**oxygenase** An OXIDOREDUCTASE which catalyses the incorporation of one or both atoms of a molecule of oxygen into a molecule of substrate. A MONOOXYGENASE catalyses the incorporation of one atom of oxygen, the other being reduced to water; a dioxygenase (EC 1.13.11) catalyses the incorporation of both atoms of oxygen. Oxygenases are frequently involved e.g. in the first step of the bacterial degradation of HYDROCARBONS.

**oxygenic photosynthesis** See PHOTOSYNTHESIS.

**oxyhydrogen reaction** KNALLGAS REACTION.

**Oxymonadida** An order of protozoa (class ZOOMASTIGOPHOREA) which are parasitic in insects (e.g. termites). Cells have one

## ***Oxymonas***

to many axostyles (which, in some genera, are contractile) and one or more karyomastigonts, each containing four flagella arranged typically in two pairs; the kinetosomes of each flagellar pair are connected by a 'preaxostyle': a paracrystalline structure into which are inserted the anterior ends of the axostylar microtubules. Mitochondria and Golgi apparatus are absent. Genera: e.g. *Monocercomonoides*, *Oxymonas*, *Pyronympha*.

***Oxymonas*** See OXYMONADIDA.

**Oxyphotobacteria** A proposed class of oxygenic, photosynthetic prokaryotes (division GRACILICUTES) comprising the CYANOBACTERIA and the PROCHLOROPHYTES.

**oxyR locus** See HYDROGEN PEROXIDE.

**Oxyrrhis** See DINOFLAGELLATES.

**oxysome** *Syn.* FERNÁNDEZ-MORÁN PARTICLE.

**oxysporum wilt** See FUSARIUM WILT.

**oxytetracycline** See TETRACYCLINES.

**Oxytricha** See HYPOTRICHIDA.

**oyster cap** *Syn.* OYSTER FUNGUS.

**oyster diseases** For pathogens of oysters (e.g., *Ostrea* and *Crassostrea* spp) see e.g. LAGENIDIALES; MINCHINIA; OSTRACOBLABE IMPLEXA; PERKINSUS; VAHLKAMPFIA; VIBRIO (e.g. *V. anguillarum*). (See also INVERTEBRATE DISEASES.)

**oyster fungus** (oyster mushroom or oyster cap) Any species of *Pleurotus*, but especially *P. ostreatus*. A number of *Pleurotus* spp are edible and can easily be cultivated by inoculating logs

(cf. SHII-TAKE); oyster fungi have also been grown on a number of waste materials such as sawdust, cereal straws, cotton waste, waste paper etc. [Mycol. (1983) 75 351–360.]

**ozaena** (ozena) Rhinitis, caused by *Klebsiella pneumoniae* subsp *ozaenae*, characterized by a profuse, mucopurulent, fetid nasal discharge with crusting of the nasal mucosa.

**ozena** *Syn.* OZAENA.

**ozone** (as an antimicrobial agent) Ozone (O<sub>3</sub>) is an OXIDIZING AGENT which reacts readily with most types of organic matter and which is active against a wide range of microorganisms; it is more efficient at lower temperatures, and requires a minimum relative humidity of ca. 60% for the disinfection of surfaces. Ozone has been used for the preservation of certain foods, but it is active against only surface contaminants, and it is not suitable for use with fats, meat etc which are likely to be oxidized. Ozone is sometimes used for the disinfection of potable WATER SUPPLIES; for this purpose it is superior to chlorine in that it is a stronger oxidizing agent, it is less affected by pH, and it does not impart a taste or odour. The treatment of wastewater (processed sewage) with ozone, rather than with chlorine, is advantageous e.g. in that it avoids the production of possibly toxic chlorinated organic compounds. The disinfection of water by ozone has been studied by monitoring the consumption of ozone-generated hydroxyl free radicals [Wat. Res. (1984) 18 473–478]. (See also INFLUENZA.)

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# P

**p** (1) Prefix denoting the polypeptide product of a gene (see e.g. RETROVIRIDAE). (2) Designation for a precursor molecule (as e.g. in pTP in ADENOVIRIDAE). (3) Prefix denoting a PLASMID, usually a recombinant plasmid.

**P** Proline (see AMINO ACIDS).

**P agar** An agar medium containing peptone (1%), yeast extract (0.5%), NaCl (0.5%), glucose (0.1%) and agar (1.5%).

**P antigen** (parvovirus receptor) See ERYTHROVIRUS.

**P fimbriae** Chromosome-encoded FIMBRIAE found e.g. on many strains of *Escherichia coli* associated with human PYELONEPHRITIS or CYSTITIS. P fimbriae mediate mannose-resistant adhesion; they bind to  $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  4)- $\beta$ -D-galactopyranoside receptors on ceramide-linked glycosphingolipids in human uroepithelium.

Adhesion of *E. coli* to urinary tract epithelium elicits the release of various CYTOKINES, including IL-6 and the chemokine IL-8. P fimbriae are reported to be more potent than other bacterial adhesins as an elicitor of IL-6; this cytokine can e.g. stimulate the synthesis of immunoglobulins and promote the release of ACUTE-PHASE PROTEINS.

The expression of P fimbriae is regulated by temperature, and is believed to involve the H-NS PROTEIN (q.v.).

P fimbriae are encoded by genes of the *pap* operon. These genes include *papA* (encoding the major fimbrial subunit), *papCD* (encoding, respectively, 'usher' and 'chaperone' proteins – see FIMBRIAE), and *papB* (encoding a regulatory protein). [P fimbriae: structure, genetics, assembly: FEMS Reviews (2000) 24 21–44 (27–31).]

Interestingly, the PapB protein is involved in regulatory cross-talk between the *fim* and *pap* adhesin operons in *E. coli* – PapB being able to inhibit expression of type I fimbriae (see FIMBRIAE) [EMBO (2000) 19 1450–1457].

P fimbriae are also called 'Pap pili' (Pap = pili associated with pyelonephritis).

**987P fimbriae** See F6 FIMBRIAE.

**P ring** See FLAGELLUM (a).

**P segment** See RECOMBINATIONAL REGULATION.

**P-selectin** See SELECTINS.

**P site** (of a ribosome) See PROTEIN SYNTHESIS.

**P1 plasmid** See BACTERIOPHAGE P1.

**p15A** See COLEI PLASMID.

**p21 family** (Ras superfamily) See G PROTEINS.

**P48** See PROTEIN SECRETION.

**p55** (CD 120a) See TNF.

**p75** (CD 120b) See TNF.

**P-450** See CYTOCHROMES.

**P582** A sirohaem-containing sulphite reductase which occurs in *Desulfotomaculum nigrificans*. (cf. DESULFOVIRIDIN.)

**Pa** See PASCAL.

**PABA** (PAB) *p*-AMINOBENZOIC ACID.

**pac site** A packaging initiation site in the DNA of certain bacteriophages: see e.g. BACTERIOPHAGE P22 and BACTERIOPHAGE P1. (See also TRANSDUCTION.)

**PA-CBT** See IMMUNOSORBENT ELECTRON MICROSCOPY.

**PACE 2C test** See PROBE.

**PA-CGT** See IMMUNOSORBENT ELECTRON MICROSCOPY.

**pachyman** A water- and alkali-insoluble (1  $\rightarrow$  3)- $\beta$ -glucan comprising ca. 250–700 glucose residues with several (1  $\rightarrow$  6)

$\beta$ -linked branch points per molecule; it occurs in the sclerotia of *Poria cocos*.

**Pachysolen** A genus of yeasts (family SACCHAROMYCETACEAE). Cells are spheroidal to ellipsoidal and reproduce by multilateral budding; pseudomycelium is poorly developed or absent. Ascus formation is characteristic: an ascus develops at the tip of a tube which grows from a vegetative cell; the walls of the cell and tube become thickened and refractile except at the ascospore-bearing end – where the wall is thin and splits to release bowler-hat-shaped ascospores. Glucose is fermented; NO<sub>3</sub><sup>–</sup> is assimilated. One species: *P. tannophilus*, isolated from concentrated tanning liquors. [Book ref. 100, pp. 289–291.]

**pachytene stage** See MEIOSIS.

**Pachytichospora** A genus of yeasts (family SACCHAROMYCETACEAE). [Book ref. 100, pp. 292–294.]

**packet** (of cells) A more or less regular arrangement of cells formed as a result of successive cell divisions along three mutually perpendicular axes, the progeny cells failing to separate. Packets are formed e.g. by *Sarcina* and *Sarcinosporon*. (cf. SARCINIFORM.)

**pactamycin** An antibiotic which specifically inhibits the initiation of translation during PROTEIN SYNTHESIS – apparently by inhibiting binding of the initiator tRNA to the initiation complex. Pactamycin has been used for genome mapping e.g. in picornaviruses which synthesize a POLYPROTEIN from a single initiation site (see PICORNAVIRIDAE). The antibiotic is added, together with radioactively-labelled amino acids, to virus-infected cells. Label is incorporated only into those polypeptides which were initiated before addition of pactamycin. A polyprotein molecule subsequently completed will contain an amount of label which depends on the stage of elongation reached when the drug and label were added; different polyprotein molecules will therefore contain different amounts of label – a minority bearing label near the N-terminus and a majority bearing label near the C-terminus (corresponding to the 5' and 3' ends of the mRNA, respectively). Thus, the amount of label present in the polypeptides derived from the polyprotein indicates the relative positions of their structural genes in the genome.

**PADAC** A violet-coloured pyridine-2-azo-*p*-dimethylanilide cephalosporin derivative which turns yellow on hydrolysis (e.g. by  $\beta$ -LACTAMASES); it is used in assays for  $\beta$ -lactamase levels. (See also PENICILLINASE.)

**paddy-straw mushroom** *Syn.* PADI-STRAW MUSHROOM.

**PADGEM** See SELECTINS.

**paddy-straw mushroom** (paddy-straw, rice-straw or straw mushroom) Either of the tropical edible mushrooms *Volvariella volvacea* and *V. diplasia*, widely cultivated in S. E. Asia and the Far East. The mushrooms are traditionally grown on soaked (uncomposted) rice-straw, but the modern method – using e.g. composted rice-straw and cotton waste – resembles that for cultivating *Agaricus brunnescens* (see MUSHROOM CULTIVATION).

**Paeclomyces** A genus of fungi of the class HYPHOMYCETES; teleomorphs occur in e.g. BYSSOCHLAMYS. (See also COAL BIODEGRADATION; INDUSTRIAL ALCOHOL; LEATHER SPOILAGE; PAPER SPOILAGE; SINGLE-CELL PROTEIN.)

**PAGE** POLYACRYLAMIDE GEL ELECTROPHORESIS.

**PAI** See PATHOGENICITY ISLAND.

**paint spoilage** The susceptibility of liquid paints to microbial attack depends mainly on the nature of the solid phase and

## paired organelles

its solvent. Liquid emulsion paints may contain a variety of organic substances (e.g. as stabilizers, thickeners), inorganic constituents, and a high content of water, and may be susceptible to attack by bacteria (e.g. *Pseudomonas* spp) and fungi (e.g. *Fusarium* spp); biocides incorporated in such paints (to extend shelf-life) include e.g. organo-tins (such as tributyl tin oxide), certain QUATERNARY AMMONIUM COMPOUNDS, and mercurials such as phenylmercuric acetate. Oil-based liquid paints are less susceptible to spoilage, but the hardened films of both oil-based and emulsion paints are susceptible to attack – particularly under humid conditions and when surfaces are soiled; spoilage organisms may obtain nutrients from the film itself, from surface contamination, or from the substrate (wood etc) beneath the film. Spoilage organisms include species of the fungi *Aspergillus*, *Aureobasidium*, *Cladosporium* and *Penicillium*; cyanobacteria (e.g. *Nostoc*, *Oscillatoria*) and algae (e.g. *Trentepohlia*) may grow given adequate moisture and light. Biocides are incorporated in paints to help paint films resist microbial attack; these include e.g. organo-mercury compounds, SALICYLANILIDES, halogenated phenolics, and a variety of copper and zinc compounds.

Antifouling paints are used e.g. on ships' hulls to inhibit both spoilage and colonization by microorganisms and other organisms. In soluble-matrix paints the binder constituent is (slowly) soluble in seawater, low levels of biocide continually becoming available at the surface. In other paints, biocide diffuses slowly to the surface of an insoluble matrix. Biocides used include e.g. copper and zinc compounds, phenols and dithiocarbamates; some (e.g. tributyl tin oxide) inhibit algae as well as fungi.

**paired organelles** *Syn.* RHOPTRIES.

**paired sera** Two samples of serum from a given patient – the second sample taken e.g. days or weeks after the first. Paired sera are used e.g. to monitor changes in antibody titres.

**Palade pathway** In a eukaryotic cell: the path followed by many types of protein from their site of synthesis to their final cellular or extracellular location. Thus, e.g., a protein destined for secretion is synthesized on a ribosome bound to the cytoplasmic face of the rough ENDOPLASMIC RETICULUM (RER); it is translocated to the luminal face of the RER (see SIGNAL HYPOTHESIS) and is then enclosed within a vesicle (*cisterna*) which buds from the smooth endoplasmic reticulum and subsequently coalesces with a vesicle in the GOLGI APPARATUS. Finally, a secretory vesicle (containing the protein) buds from the Golgi apparatus and subsequently fuses with the cytoplasmic membrane to release the protein at the cell surface. Other types of protein – e.g. those destined for the cytoplasmic membrane itself, or for the lumen of a LYSOSOME – follow an analogous pathway; additionally, in cells infected with certain enveloped viruses the viral ENVELOPE proteins are transported to their appropriate membrane via this pathway. The production of secretory vesicles at the Golgi apparatus, and the subsequent fusion of these vesicles with the cytoplasmic membrane, can be inhibited e.g. by MONENSIN – which can therefore inhibit the replication of certain viruses.

Characteristically, proteins become progressively more glycosylated during their passage along the Palade pathway, and their intracellular location may even be determined by their degree of glycosylation. The glycosylation of newly synthesized (cell or viral) proteins may be inhibited e.g. by TUNICAMYCIN.

Proteins that are not transported via the Palade pathway include e.g. the small subunit of ribulose-1,5-bisphosphate carboxylase-oxygenase. This protein is synthesized (with an N-terminal signal peptide) on a cytoplasmic (i.e., not membrane-bound) ribosome and is taken up, post-translationally, by chloroplasts – being proteolytically processed during or after uptake.

**Pali** See RESTRICTION ENDONUCLEASE (table).

**palindromic sequence** A region of a nucleic acid which contains a pair of INVERTED REPEAT sequences. In a double-stranded molecule, such a region shows two-fold rotational (dyad) symmetry – or hyphenated dyad symmetry if the two IR sequences are separated by another sequence. A double-stranded palindromic sequence can adopt either of two possible conformations: a linear structure with interstrand hydrogen-bonding – e.g.

– or a cruciform structure in which the two strands each form HAIRPINS by intrastrand hydrogen-bonding. For steric reasons, non-paired bases occur at the proximal and distal ends of the hairpins in a cruciform, and the linear form is normally the more stable form. However, the formation of a cruciform tends to relieve the torsional strain of supercoiling in negatively supercoiled DNA, and purified negatively supercoiled DNA containing palindromic sequences tends to adopt a cruciform structure in vitro [JBC (1982) 257 6292–6295]; nevertheless, cruciforms appear not to be formed in vivo [Book ref. 69, pp. 19–28].

Palindromic sequences occur e.g. in many operators, DNA replication origins, transcription terminators, etc, and are apparently important e.g. in protein–DNA recognition. (See also e.g. DEPENDOVIRUS.)

[Properties of palindromic sequences: JB (1985) 161 1103–1111.]

**palindromic unit** *Syn.* REP SEQUENCE.

**palisade** A number of elongated cells (or other structures) arranged side by side in a row, adjacent cells being in contact.

**palisade plectenchyma** See PLECTENCHYMA.

**pallidins** See LECTINS.

**Palmaria** A genus of algae of the RHODOPHYTA. *P. palmata* (formerly *Rhodymenia palmata*) is used as food ('dulce') in various countries.

**Palmella** A genus of freshwater green algae (division CHLOROPHYTA). (See also PALMELLOID PHASE.)

**palmella phase** *Syn.* PALMELLOID PHASE.

**palmelloid phase** (palmella phase) A vegetative phase formed under certain environmental conditions (e.g. on damp soil, agar media etc) by some unicellular green algae which are usually flagellated and motile (e.g. CHLAMYDOMONAS); the flagellated cells lose or withdraw their flagella and form a type of colony in which an indefinite number of cells is embedded in a gelatinous or mucilaginous matrix. The cells continue to divide within the matrix, and under suitable conditions (e.g. when the colony is flooded with water) they can develop flagella and escape from the colony.

A 'palmelloid' type of colony is the usual vegetative form in some *Chlamydomonas*-like algae (e.g. *Palmella*, TETRASPORA); in these algae motile cells are generally released from the colonies only as gametes or zoospores.

**Paludrine** See CHLORGUANIDE.

**Palyam subgroup** See ORBIVIRUS.

**palynology** The study of (fossil and living) pollen and spores.

**pAMβ<sub>1</sub>** See CONJUGATION (1b) (ii).

**Panacide** Dichlorophane (see BISPHENOLS).

**Panaeolus** See AGARICALES (Strophariaceae).

**Panama disease** See FUSARIUM WILT.

**panemic** An EPIDEMIC affecting (simultaneously) large numbers of people in a major geographical area, or worldwide.

**Pandorina** A genus of freshwater flagellate green algae (division CHLOROPHYTA) which form motile, ball-like coenobia consisting of clusters of 4–32 cells with no central space. (cf. VOLVOX.)

**panelling** Refers to the condition of a can (see CANNING) in which, due to atmospheric pressure, part of the wall of the can has collapsed inwards. Panelling occurs e.g. in large high-vacuum cans, in cans cooled under excessive pressure, or in cans whose walls are made of thin tinplate.

**pangola stunt virus** See FIJIVIRUS.

**panidazole** See NITROIMIDAZOLES.

**panleukopenia** A significant reduction in the numbers of both lymphocytes and neutrophils – a condition brought about e.g. by the FELINE PANLEUKOPENIA VIRUS.

**panmictic** Of, or pertaining to, PANMIXIS.

**panmixis** (panmixia) Unrestricted interbreeding.

**Pannaria** A genus of LICHENS (order LECANORALES). Photobiont: *Nostoc*. Thallus: mainly squamulose, bluish-grey, with a dark hypothallus. Apothecia: lecanorine with reddish-brown discs. Species occur among mosses on bark, rocks etc.

**panose**  $\alpha$ -Glucosyl-(1  $\rightarrow$  6)-*D*-maltose.

**Pansoil** See ETRIDIAZOLE.

**pansporoblast** See MYXOSPOREA.

**pantheine** See PANTOTHENIC ACID.

**pantoic acid** See PANTOTHENIC ACID.

**Panton–Valentine leucocidin** (PVL) A staphylococcal LEUCOCIDIN which specifically lyses human or rabbit PMNs and macrophages; no other type of cell appears to be affected. PVL consists of two synergistically acting components, designated ‘fast’ (F) and ‘slow’ (S) (indicating their migration rates on CMC columns). According to a recent model, the S component binds to GM<sub>1</sub> receptors on sensitive cells, causing activation of an endogenous (membrane-bound) phospholipase A<sub>2</sub> and stimulating uptake of Ca<sup>2+</sup>; F then binds to products of phospholipase action and rapidly induces the formation of K<sup>+</sup>-specific ion channels in the membrane. The resulting secondary effects lead to lysis. [Book ref. 44, pp. 732–737.] Insensitive cells may bind S but do not bind F – possibly because activation of phospholipase does not occur. The role of PVL in pathogenesis is unclear; in e.g. staphylococcal abscesses it may kill phagocytes and thus facilitate the survival and spread of the pathogen.

**pantotheine** See PANTOTHENIC ACID.

**pantothenic acid** A water-soluble VITAMIN which consists of *pantoic acid* (2,4-dihydroxy-3,3-dimethylbutyric acid) linked by an amide bond to  $\beta$ -alanine. Pantothenic acid is linked to 2-mercaptoethylamine (= cysteamine) to form *pantheine* (= pantotheine); *pantheine* 4'-phosphate is a component of COENZYME A (q.v. for formula) and is also the prosthetic group of acyl-carrier proteins (ACPs) involved e.g. in fatty acid biosynthesis.

Pantothenic acid is required as a growth factor e.g. by many yeasts (e.g. *Candida* spp, *Saccharomyces* spp), the filamentous fungus *Polyporus texanus*, certain bacteria (e.g. *Acetobacter* spp, *Lactobacillus* spp, *Morganella* spp), and certain protozoa (e.g. *Crithidia* spp, *Leishmania* spp, *Tetrahymena* spp). The requirement for pantothenic acid may be satisfied by its precursor(s) – e.g.,  $\beta$ -alanine, pantoic acid.

**panotropic** (*virolog.*) Refers to a virus which can infect many types of cell. (See also TROPISM sense 2.)

**PAP** (1) 3'-Phosphoadenosine-5'-phosphate ('adenosine-3',5'-diphosphate'): see ASSIMILATORY SULPHATE REDUCTION.

(2) Poly(A)polymerase: see MRNA.

**pap operon** See FIMBRIAE.

**Pap pili** See P FIMBRIAE.

**PAP technique** (peroxidase–antiperoxidase technique) An IMMUNOPEROXIDASE METHOD which involves three antibody-mediated stages. Initially, separate antisera are raised (e.g. in rats) against (i) the specific antigen and (ii) a peroxidase; if these antisera are rat-derived, anti-rat Ig antiserum is raised e.g. in a rabbit. To locate specific antigen in a section, the section is first treated with rat antiserum homologous to the antigen ('primary' antiserum) and then washed free of uncombined antibody. The section is then treated with *excess* rabbit anti-rat Ig antiserum; under such antiserum-excess conditions, rabbit anti-rat Ig antibodies tend to bind to rat antibodies with only one of their combining sites. The section is washed and then treated with rat anti-peroxidase antiserum – these antibodies being bound by the free combining sites of the rabbit anti-rat Ig antibodies. (The rabbit anti-rat Ig antibodies are called 'bridging' or 'linking' antibodies.) Peroxidase is then added and combines with rat anti-peroxidase. Peroxidase (and hence antigen) is detected by incubating the section with reagents as in the ABC IMMUNOPEROXIDASE METHOD.

**papain** A heat-stable, basic thiol PROTEASE (EC 3.4.22.2) obtained from the latex and unripe fruit of the pawpaw (*Carica papaya*). (See also IMMUNOGLOBULINS.)

**Papaya mosaic virus** See POTEXVIRUSES.

**Papaya ringspot virus** See POTYVIRUSES.

**PapB** See P FIMBRIAE.

**paper partition chromatography** See CHROMATOGRAPHY.

**paper spoilage** Pulpwood (timber selected for pulping) may be attacked e.g. by cellulolytic fungi such as *Poria* and *Stereum* (see also TIMBER SPOILAGE). Wood *pulp* (produced from pulpwood by mechanical or chemical methods) is a watery suspension containing e.g. cellulose, hemicelluloses, sugars and proteins; it is susceptible to attack by a range of cellulolytic fungi (e.g. species of *Aspergillus*, *Cladosporium*, *Fusarium*, *Phoma* and *Stereum*) and fungi which cause darkening or staining (e.g. species of *Aureobasidium*, *Caecilomyces* and *Penicillium*). Chemically prepared pulps – e.g. those containing acidified Ca(HSO<sub>3</sub>)<sub>2</sub> (*acid sulphite pulps*) or NaOH and Na<sub>2</sub>SO<sub>3</sub> (*kraft pulps*) – are generally less susceptible to spoilage than are mechanically prepared pulps. Cellulolytic attack on either pulpwood or pulp shortens the cellulose fibres, resulting in inferior (weaker) paper. Slime formation in pulps is due e.g. to species of *Alcaligenes*, coliforms and other bacteria (*Serratia* forms red slime), and to fungi such as *Fusarium* and *Geotrichum*; slime may cause weaknesses, holes and/or discoloration in the paper. PRESERVATIVES used in pulps include e.g. dichlorophane, pentachlorophenol, and salicylanilides; slime formation has been controlled e.g. by chlorine and mercurials. Finished paper and board products have a low moisture content and are subject to fungal spoilage (particularly under high humidity) by e.g. *Chaetomium globosum*, *Stachybotrys atra* and other cellulolytic species; *Aspergillus* and *Penicillium* spp are common causes of discoloration. Paper and board preservatives include e.g. copper and zinc compounds, dichlorophane, and dithiocarbamates.

**papilla** A microcolony, within and visibly distinct from, a larger colony. For example, a colony of Lac<sup>-</sup> mutant cells of *Escherichia coli* may contain a papilla that consists of a subpopulation of Lac<sup>+</sup> revertants; on MacConkey's agar, such a papilla would be pink/red in a colourless colony.

**papilloma** (*pl.* papillomas or papillomata) A small tumour of epithelial tissue (skin, mucous membranes, or glandular ducts), caused by a PAPILLOMAVIRUS; papillomas affecting the skin are commonly known as *warts* or *verrucae*. Papillomaviruses are largely host-specific, and different types of papillomavirus may cause morphologically distinct types of papilloma in a given

## Papillomavirus

host. In man, papillomas are caused by human papilloma viruses (HPVs): e.g. *plantar warts*, caused by HPV-1, occur on the soles of the feet and are flat, being pressed into the dermis by the weight of the body; *genital warts* (venereal warts, papillomata acuminata, condylomata acuminata), caused by HPV-6, occur in the anogenital region and are transmitted by sexual contact (cf. BUSCHKE-LÖWENSTEIN TUMOUR and MOLLUSCUM CONTAGIOSUM).

Papillomas are usually benign, but those caused by certain viruses can become malignant in the presence of certain 'cofactors' – e.g., certain animal papillomas can become malignant on exposure to sunlight. (cf. EPIDERMODYSPLASIA VERRUCIFORMIS.) In cattle, papillomas (caused by bovine papilloma virus 4) in the oesophagus and forestomachs can become malignant if the cattle eat bracken (*Pteridium aquilinum*). In humans, HPVs associated with genital warts are believed to play a role in the development of cancer of the genital tract (particularly of the cervix) [BMJ (1984) 288 735–737; Lancet (1986) i 573–575].

**Papillomavirus** A genus of viruses of the PAPOVAVIRIDAE. Type species: cottontail rabbit (Shope) papilloma virus (CRPV) [genomic structure: PNAS (1985) 82 1580–1584]; other members include human papilloma viruses (many types, designated HPV-1, HPV-2 etc), bovine papilloma viruses (BPV-1, BPV-2 etc), and papilloma viruses infecting deer, dogs, goats, horses, rats and sheep. Papilloma viruses can induce benign squamous epithelial tumours of the cutaneous and mucosal epithelium of their hosts (see PAPILOMA). The virus can infect – but not replicate in – the basal cells of the epidermis or mucosa, establishing a persistent infection in which multiple copies of the viral DNA occur in the nucleus in the form of circular extrachromosomal molecules; however, production of virions can occur only in the non-dividing, differentiated squamous epithelial cells of the stratum spinosum and stratum corneum. (Since these cells cannot be grown in culture, papilloma viruses cannot be propagated in vitro, and molecular biological studies have depended largely on the use of cloned viral DNA.)

Although the papillomas induced by papilloma viruses are usually benign, certain human and animal papilloma viruses may be involved in the development of malignant tumours; in most of these systems infection with the papilloma virus is by itself insufficient for malignant transformation, and additional physical, chemical and/or biological factors are necessary for carcinogenesis (see PAPILOMA and EPIDERMODYSPLASIA VERRUCIFORMIS). In experimental systems, several papilloma viruses can induce fibroblastic tumours in hamsters and can transform rodent cells in vitro (although such cells do not produce virions). The mechanism of transformation is unknown. In BPV-1, the presence of only a portion (69%) of the viral genome is necessary for transformation, and the expression of viral genes is apparently necessary; BPV-1 appears to carry multiple transforming genes [PNAS (1985) 82 1030–1034]. There is evidence that viral DNA may integrate into the host chromosome in at least some cases of malignancy – e.g. integrated HPV-16 DNA has been detected in malignant tumours of the human genital tract [JGV (1985) 66 1515–1522; see also *Gynecologic Oncology* (1992) 47 263–266].

**Papovaviridae** (papovavirus group) A family of non-enveloped, small, icosahedral DNA viruses, most of which infect mammals (cf. BUDGERIGAR FLEDGLING DISEASE VIRUS); most or all members can induce tumours in certain host animals. Viral DNA replication and assembly occur in the host cell nucleus. The family contains two genera: PAPILOMAVIRUS and POLYOMAVIRUS, distinguished on the basis of size, genome characteristics, a genus-specific antigen (detected in disrupted virions), and biological properties.

The papovavirus virion consists of an icosahedral capsid, diam. ca 45 nm (*Polyomavirus*) or 55 nm (*Papillomavirus*), which comprises 72 capsomers and which contains a supercoiled, covalently closed circular dsDNA genome; the DNA – MWt ca.  $3 \times 10^6$  (ca. 5 kb) in *Polyomavirus*, ca.  $5 \times 10^6$  (ca. 8 kb) in *Papillomavirus* – is associated with host-derived histones. (In the host cell, the viral DNA occurs in the nucleus – usually as a MINICHROMOSOME.) Papovavirus virions do not contain lipid or carbohydrates and are resistant to lipid solvents, low pH, heat treatment, etc.

**papovaviruses** Viruses of the PAPOVAVIRIDAE.

**PAPS** 3'-Phosphoadenosine-5'-phosphosulphate (also called adenosine-3'-phosphate-5'-sulphatophosphate or 3'-phosphoadenylsulphate). See ASSIMILATORY SULPHATE REDUCTION. (cf. APS.)

**papulacandin B** An antibiotic which is effective against yeasts but apparently not against other fungi, bacteria or protozoa; it inhibits the formation of CELL WALL  $\beta$ -D-glucan in whole cells and sphaeroplasts of e.g. *Saccharomyces cerevisiae* and *Candida albicans*. (cf. ACULEACIN A.)

**papule** On skin: a small, discrete, raised, solid lesion. (cf. MACULE, VESICLE.)

**par locus** See PARTITION.

**para-aminobenzoic acid** See *p*-AMINOBENZOIC ACID.

**parabactin** See SIDEROPHORES.

**Parabasalidea** A superorder of protozoa (class ZOOMASTIGOPHOREA) which consists of the two orders HYPERMASTIGIDA and TRICHOMONADIDA.

**parabens** PARABENZOATES.

**parabenzoates** (parabens) Antifungal and antibacterial esters of *p*-hydroxybenzoic acid used e.g. as PRESERVATIVES in various foods, cosmetics and pharmaceuticals; they are more effective against fungi and Gram-positive bacteria than Gram-negative bacteria. Antimicrobial activity and insolubility in water both increase with increases in the chain length of the substituent group. Parabens are active at neutral as well as at acidic values of pH. (cf. BENZOIC ACID.)

**paracentric** (of a chromosome) To one side of the CENTROMERE; e.g., a paracentric inversion is a CHROMOSOME ABERRATION in which the inverted segment does not contain the centromere. (cf. PERICENTRIC.)

**paracoagulation** Clumping of cells (rather than clotting of plasma) which occurs e.g. when plasma (containing an anticoagulant) is mixed with a suspension of cells whose surface components include either staphylococcal clumping factor (see COAGULASE) or protamine sulphate.

**Paracoccidioides** A genus of fungi of the class HYPHOMYCETES. *P. brasiliensis*, the causal agent of PARACOCCTIDIOIDOMYCOSIS, is a dimorphic fungus which occurs within tissues in a yeast-like form; the spherical, yeast-like cells (ca. 5–60  $\mu$ m) can form several large buds (each bud attached to the parent cell by a narrow neck) or many small buds (forming the so-called ship's wheel form). When cultured at 37°C on blood-agar, *P. brasiliensis* grows in the yeast-like form; when cultured at room temperature or at 25°C on Sabouraud's dextrose agar (see SABOURAUD'S MEDIUM) it gives rise to a colourless, septate mycelium and to 'chlamydo-spores' and cells which resemble conidia. (See also CELL WALL (c) and PSEUDONIGERAN.)

**paracoccidioidomycosis** (South American blastomycosis) A chronic granulomatous human disease caused by *Paracoccidioides brasiliensis*; it occurs mainly in Central and South America. Infection may result in a benign or progressive lung disease, in a mucocutaneous disease (with formation of granulomatous ulcers chiefly on the mucous membranes of the mouth, nose and

eyes, accompanied by regional lymphadenopathy), or in a systemic disease involving various internal organs. *Lab. diagnosis*: microscopy of infected tissues; serological tests (e.g. an EIA [SAB (1984) 22 73–78]). (cf. BLASTOMYCOSIS.)

**Paracoccus** A genus (*incertae sedis*) of aerobic, oxidase-positive, catalase-positive, Gram-negative bacteria which occur e.g. in soil and in meat-curing brines. Cells: non-motile cocci or rods which typically contain granules of PHB. Metabolism: respiratory (oxidative), the terminal electron acceptor being O<sub>2</sub> or (in anaerobic respiration) nitrate, nitrite or nitrous oxide. One species (*P. halodenitrificans*) is chemoorganotrophic and halophilic, the other (*P. denitrificans*) is facultatively chemolithotrophic and methylotrophic (see METHYLOTROPHY) and is non-halophilic. Carbon sources include a wide range of organic compounds. Optimum growth temperature: 25–30°C. GC%: ca. 64–67. Type species: *P. denitrificans*.

*P. denitrificans* (formerly *Micrococcus denitrificans*). Cells (on e.g. nutrient agar): cocci, ca. 0.5–0.9 µm diam., or rods, ca. 0.9–1.2 µm in length. (See also PORINS.)

*P. halodenitrificans*. Cells (on e.g. nutrient agar containing 1.0 M (5.8% NaCl): cocci, ca. 0.5–0.9 µm diam.; cells grown in lower concentrations of electrolyte (e.g. 0.6 M NaCl) are usually distorted, and no growth occurs below ca. 0.5 M NaCl. Isolated from meat-curing brines.

[Book ref. 22, pp. 399–402.]

**paracolon** An outdated term for those enterobacteria which do not metabolize lactose within 24/48 hours at 37°C.

**paracytosis** Invasive behaviour by certain pathogenic bacteria in which the pathogen crosses a layer of (eukaryotic) cells by passing between the cells; thus, e.g. *Haemophilus influenzae* can pass between the cells of lung epithelium [paracytosis by *H. influenzae* in tissue cultures of lung epithelial cells: Inf. Immun. (1995) 63 4729–4737]. (See also TRANSCYTOSIS.)

**paraffin metabolism** See HYDROCARBONS.

**paraflagellar rod** *Syn.* PARAXIAL ROD.

**paraformaldehyde** (HO(CH<sub>2</sub>O)<sub>n</sub>H) A solid, white, polymeric form of FORMALDEHYDE which, when heated, yields gaseous formaldehyde.

**parainfluenza viruses** See PARAMYXOVIRUS.

**parakinetal stomatogenesis** See STOMATOGENESIS.

**paralytic shellfish poisoning** See SHELLFISH POISONING.

**paramastigote** A form assumed by the cells of species of *Herpetomonas* and *Leishmania* during certain stages in their life cycles: see TRYPANOSOMATIDAE.

**Paramecium** ('slipper animalcule') A genus of (typically) freshwater protozoa (order HYMENOSTOMATIDA). Cells: ovoid or elongate with uniform somatic ciliature; length varies with species: *P. aurelia* is ca. 120–200 µm, *P. bursaria* ca. 90–150 µm, *P. caudatum* ca. 180–300 µm, *P. multimicronucleatum* ca. 200–300 µm, and *P. trichum* ca. 50–120 µm. The buccal cavity is ventral and contains a single PARORAL MEMBRANE (= endoral membrane), two peniculi (see PENICULUS) and a QUADRULUS. STOMATOGENESIS is buccokinetal. Many species have one micronucleus and one macronucleus; *P. aurelia* has an additional micronucleus, and *P. multimicronucleatum* has three or four micronuclei. The presence of two CONTRACTILE VACUOLES is typical, and most species have large numbers of TRICHOCYSTS. Cysts are not formed. Paramecia are said to be negatively galvanotactic. Many strains of *Paramecium* contain endosymbionts: see CAEDIBACTER, HOLOSPORA, LYTICUM, PSEUDOCAEDIBACTER, TECTIBACTER; see also KILLER PARAMECIA, MU PARTICLE, ZOOCHLORELLAE. [Endonucleobiosis in ciliates: Int. Rev. Cytol. (1986) 102 169–213.]

Asexual reproduction occurs by binary fission. AUTOGAMY and CONJUGATION occur in at least some species; mating types are divided into SYNGENS.

Paramecia consume bacteria and e.g. small flagellates. Certain species of *Paramecium* are a major food source for DIDINIUM.

**paramere** See MACRONUCLEUS.

**Paramoeba** A genus of marine amoebae (order AMOEBIDA). Species are generally free-living. However, *P. perniciosa* is apparently an obligate parasite of the blue crab (*Callinectes sapidus*) in which it can cause high mortality rates during moulting; another *Paramoeba* sp has been implicated as the cause of mass mortalities among sea urchins in Nova Scotia [J. Parasitol. (1985) 71 559–565].

**paramylon** (*syn.* paramylum) A storage polysaccharide, a (1 → 3)-β-D-glucan, characteristic of the EUGLENOID FLAGELLATES. Paramylon occurs in refractile granules of various forms – discs, rings, rods etc – depending on species. Paramylon granules give no colour reaction with iodine. In *Euglena gracilis* paramylon is synthesized on a protein primer [Bioch. J. (1978) 174 283–290].

**paramylum** *Syn.* PARAMYLON.

**Paramyxa** See PARAMYXEA.

**Paramyxea** A class of protozoa (phylum ASCETOSPORA) in which the spores are bicellular, consisting of a parietal cell and a sporoplasm. The spore wall has no orifice. One order: Paramyxida; genera include *Paramyxa*.

**Paramyxoviridae** A family of enveloped VIRUSES which have a non-segmented, negative-sense ssRNA genome. The family includes some important pathogens of humans, animals and birds – e.g. the causal agents of CANINE DISTEMPER, MEASLES, MUMPS, NEWCASTLE DISEASE, RINDERPEST, and various respiratory diseases. The viruses are transmitted mainly via the air (aerosols etc); vectors are unknown.

Virion: pleomorphic (usually roughly spherical), ca. 150–200 nm or more in diameter, containing 5–7 polypeptide species, one molecule of negative-sense linear ssRNA (MWt ca. 5–7 × 10<sup>6</sup>) (some particles may contain positive-sense RNA strands), and 20–25% by weight of lipid. The envelope, which encloses a helical nucleocapsid, is derived from the host cell plasma membrane and contains virus glycoproteins (which form surface projections ca. 8 nm long) and a non-glycosylated virus protein (M). The virions contain various enzymes, including e.g. transcriptase, polyadenylate transferase, mRNA methyltransferase. The virions are inactivated by lipid solvents, non-ionic detergents, formaldehyde, oxidizing agents, etc.

Members of the Paramyxoviridae can be propagated in various types of cell culture. Infection occurs by fusion of the virus envelope with the plasma membrane of the host cell. Transcription and replication occur in the cytoplasm, the nucleocapsid functioning as template. Virions mature by budding through the host cell plasma membrane at sites containing the virus envelope proteins. Infected host cells commonly lyse, but temperate and persistent infections also occur, commonly resulting in cell fusion and syncytium formation, inclusions, haemadsorption, etc.

The family is divided into three genera – MORBILLIVIRUS, PARAMYXOVIRUS and PNEUMOVIRUS – on the basis of e.g. neuraminidase activity, virion structure, etc.

**Paramyxovirus** A genus of viruses of the PARAMYXOVIRIDAE in which the virions have both haemagglutinin and NEURAMINIDASE activities. The genus includes e.g. NEWCASTLE DISEASE VIRUS (NDV) (type species), MUMPS VIRUS, and parainfluenza viruses type 1 human, type 1 murine (= Sendai virus), type 2 (human), type 3 (human, bovine and ovine), type 4 (human), and type 5

## paramyxoviruses

(avian, canine and simian). (See also CALF PNEUMONIA, COMMON COLD, PNEUMONIA (g).)

The paramyxovirus virion consists of a helical nucleocapsid, composed of the genomic ssRNA and proteins NP, P and L, surrounded by an envelope containing a non-glycosylated protein (M) in the inner layer, and two glycoproteins which extend across the width of the envelope and beyond the outer surface to form spikes. Proteins P and/or L may have transcriptase activity. Protein M plays an important role in virus assembly. The larger of the envelope glycoproteins (designated HN) has cell-binding, haemagglutinating and neuraminidase activities, while the smaller (F) has haemolytic activity and promotes fusion between the virus envelope and the host plasma membrane. The F protein can also promote cell–cell fusion, a property exploited e.g. in the use of UV-inactivated Sendai virus in the production of hybrid cells (see e.g. HYBRIDOMA). In the Sendai and mumps viruses the F protein is synthesized as an inactive precursor, F<sub>0</sub>, which is activated by proteolytic cleavage. [Sequence of the F protein gene in Sendai virus: JGV (1985) 66 317–331.]

Host cell infection occurs by adsorption, via HN, to the cell surface, followed by F protein-mediated fusion between the virus envelope and the host plasma membrane; antibodies to HN and F proteins appear to be important in limiting or preventing infection in vivo. Within the host cell, virus RNA is transcribed into six (mostly monocistronic) mRNAs. In addition to the six structural proteins, two non-structural proteins (C and C') are synthesized from a reading frame overlapping that of the P gene. HN and F proteins are synthesized on membrane-bound polysomes, glycosylated, and inserted into the host plasma membrane; during maturation, the virions bud through the region of the membrane containing these proteins.

**paramyxoviruses** (1) Viruses of the PARAMYXOVIRIDAE. (2) Viruses of the genus PARAMYXOVIRUS.

**Parana virus** See ARENAVIRIDAE.

**Paranaplasma** A genus of bacteria of the family Anaplasmataceae [Book ref. 21, pp. 908–909]; *P. caudatum* is now *Anaplasma caudatum* [Book ref. 22, p. 722].

**parapertussis** See WHOOPING COUGH.

**paraphysis** (1) A type of sterile, basally-attached, branched or unbranched filament (of unknown function), many of which occur among the hymenial asci in the ascocarps of certain ascomycetes; paraphyses may or may not project above the level of the asci. (cf. EPITHECIUM and HAMATHECIUM.) *Apical paraphyses* are sterile filaments which originate in the upper wall of a pseudothecial locule and grow downwards into the centrum, their tips remaining unattached. (cf. PSEUDOPARAPHYSIS.)

(2) *Syn.* BASIDIOLE (sense 3).

**paraphysoid** (1) In some (particularly lichenized) ascomycetes: a structure which resembles a PSEUDOPARAPHYSIS but which generally has few septa, and which may be formed before or after the asci have developed.

(2) In basidiomycetes: a sterile hymenial structure, e.g. a BASIDIOLE (sense 3).

**Paraphysomonas** A (probably heterogeneous) genus of freshwater and marine, non-pigmented CHRYSOPHYTES (q.v.) which bear various types (according to species) of silicified scales.

**paraplectenchyma** See PLECTENCHYMA.

**Parapoxvirus** (orf subgroup) A genus of viruses of the CHORDOXVIRINAE which infect ungulates and may infect man. Type species: orf virus (see CONTAGIOUS PUSTULAR DERMATITIS sense 1); other members: bovine pustular stomatitis virus, chamois contagious ecthyma virus, PSEUDOCOWPOX virus (= MILKERS' NODULE virus, paravaccinia virus).

Parapoxvirus virions are ovoid, ca. 250 × 160 nm (for orf virus) to 300 × 190 nm (for pseudocowpox virus); the outer surface of the virion exhibits a characteristic criss-cross pattern in negatively stained preparations. DNA MWt: ca. 85 × 10<sup>6</sup>. Haemagglutinin is not formed. Infected cells contain only B-type inclusion bodies. Infectivity of virions can be destroyed e.g. by heating at 58–60°C for 30 min. Parapoxviruses do not produce pocks in CAM. They can bring about NON-GENETIC REACTIVATION of inactivated orthopoxviruses.

**paraprotein** Immunoglobulin produced by a neoplastic clone of B cells. (See also MYELOMA.)

**parapyle** See RADIOLARIA.

**Paraquat** *Syn.* METHYL VIOLOGEN.

**pararosanolin** A reddish TRIPHENYLMETHANE DYE.

**pararotaviruses** (group B rotaviruses) Viruses which are morphologically indistinguishable from ROTAVIRUSES but which lack the group-specific antigen common to all other known (avian and mammalian) rotaviruses; the 11 dsRNA segments also have a unique and characteristic electrophoretic migration pattern. Pararotaviruses have been isolated from human stool specimens, but their clinical significance – if any – is unknown.

**parasexual processes** (*mycol.*) Non-sexual processes which can result in the formation of recombinant nuclei. The process first reported in *Aspergillus nidulans* (and later found in many ascomycetes and in some deuteromycetes and basidiomycetes) has been called the standard parasexual process. This process starts with the formation of a heterokaryotic cell or mycelium (see HETEROKARYOSIS) and involves the fusion of two genetically dissimilar haploid nuclei (in the heterokaryon) to form a single diploid nucleus. Recombination can then occur through mitotic crossing over – i.e., the (infrequent) reciprocal exchange of chromatid segments between homologous chromosomes during mitotic propagation of the diploid nucleus – or (e.g. in *Saccharomyces cerevisiae*) predominantly by gene conversion [MR (1985) 49 33–58 (43–47)]. Haploidization (the formation of haploid progeny nuclei) involves NON-DISJUNCTION in which there is a stepwise loss of one member of each pair of homologous chromosomes during successive mitoses.

For the imperfect fungi parasexuality brings the advantage of genetic recombination. The importance of parasexual processes in nature is uncertain.

[Review: Book ref. 168, pp. 191–214.]

**ParaSight-F™ test** See MALARIA.

**parasitaemia** (parasitemia) The presence of parasites in the bloodstream.

**parasite** See PARASITISM. A parasite may be obligatorily or facultatively parasitic; it may be host- or strain-specific or able to parasitize a range of hosts. Parasites which remain external to the host's cells or tissues are called *ectoparasites*, while those that live intracellularly or within tissues are called *endoparasites*. If the host suffers significant harm, or is killed, through the activity of a microbial parasite, the parasite is referred to as a PATHOGEN.

Compared to its free-living (non-parasitic) relatives, a parasite often exhibits certain aspects of degeneracy – e.g. a reduction in, or loss of, structures, organelles, or metabolic mechanisms involving the ingestion and digestion of food, respiration, osmoregulation or excretion. Adaptation to the parasitic mode of life may be regarded as a form of specialization; some parasites are so well integrated into the economy of their hosts that they can be cultivated in vitro only with difficulty, or not at all.

**parasitism** SYMBIOSIS (sense 1) in which one organism (the PARASITE) benefits at the expense of the other (the *host*); typically, the parasite obtains its nutrients from the host, and the association is detrimental to the host. (cf. COMMENSALISM.)

**parasitology** The study of certain PARASITES: their life cycles, ecology, transmission, etc; those parasites studied in parasitology include some which are classified as microorganisms (e.g. amoebae, trypanosomes, malarial parasites) as well as various arthropods, helminths, etc. Pathogenic bacteria, fungi and viruses are traditionally not included within the scope of parasitology – even though they can live parasitically.

**parasol ants** See FUNGUS GARDENS.

**parasol mushroom** See LEPIOTA.

**parasomal sac** In many ciliates (e.g. *Paramecium*): a small flask-like invagination of the surface membrane near the ciliary bases, possibly involved in pinocytosis.

**Parasponia** See BRADYRHIZOBIUM.

**parasporal crystal** See DELTA-ENDOTOXIN and MILKY DISEASE.

**paratenic** Refers to an alternative host (of a parasite) which is incidental to the normal life cycle of the parasite: i.e. the paratenic host is neither essential for nor interferes with the completion of the parasite's life cycle.

**parateny** (*ciliate protozool.*) The condition in which part(s) of a cell have lines of kinetids arranged perpendicularly to the longitudinal axis of the cell; parateny is characteristic of some scuticociliates (e.g. *Loxoccephalus*).

**paratope** (1) The COMBINING SITE of an antibody. (2) The site at which a cell-surface receptor combines with an exogenous molecule.

**paratose** (3,6-dideoxy-D-glucose) A sugar, first isolated from *Salmonella paratyphi*, which occurs in the O-specific chains of the LIPOPOLYSACCHARIDE in certain *Salmonella* serotypes and which contributes to the specificity of O antigen 2 in group A salmonellae (see KAUFFMANN-WHITE CLASSIFICATION).

**paratrachoma** See INCLUSION CONJUNCTIVITIS.

**paratuberculosis** *Syn.* JOHNE'S DISEASE.

**paratyphoid fever** (paratyphoid) (1) (*med.*) An acute infectious disease caused by *Salmonella paratyphi* A, B or C. It resembles TYPHOID FEVER in modes of transmission and infection, but symptoms are milder and are often accompanied by gastroenteritis.

(2) (*vet.*) Any disease (paratyphoid, salmonellosis) caused by a serotype of *Salmonella* and characterized by septicaemia (particularly in young animals) and/or enteritis. In cattle, paratyphoid is often caused by *S. dublin*, and sometimes e.g. by *S. typhimurium*; in the acute enteric form symptoms include fever and diarrhoea, while chronic enteritis may cause general unthriftiness. In pigs, the causal agents include *S. choleraesuis* and *S. typhimurium*; the acute enteric form, involving fever and diarrhoea, is often complicated by pulmonary involvement, while in the (usually fatal) septicaemic form there may be nervous involvement, red-purple skin discoloration (e.g. on the ears and abdomen), and subcutaneous petechial haemorrhages. In horses, *S. typhimurium* can cause e.g. an acute febrile condition with diarrhoea and dehydration, while in very young foals it can cause a fatal septicaemia. An asymptomatic carrier state can occur in cattle, pigs and (to a limited extent) horses.

**Parauronema** See SCUTICOCILIATIDA.

**paravaccinia virus** See PARAPOXVIRUS.

**paraxial rod** (paraxial rod) In the FLAGELLUM of many members of the KINETOPLASTIDA, DINOFLAGELLATES and EUGLENOID FLAGELLATES: a filament or rod which runs, within the flagellar membrane, parallel to the axoneme or (in the helical transverse flagellum of a dinoflagellate) parallel to the axis of the axoneme. [Paraxial rod in trypanosomatids: JP (1986) 33 552–557.]

**paracentric objectives** In a given microscope: a set of objective lenses each of which gives a field of view whose centre is identical to that of the others. (cf. PARFOCAL OBJECTIVES.)

**parC gene** See CELL CYCLE (b).

**parE gene** See QUINOLONE ANTIBIOTICS.

**parenteral** Administered by any route *except* the alimentary canal.

**parenthesome** See DOLIPORE SEPTUM.

**parfocal objectives** In MICROSCOPY: a set of objective lenses which, in a given microscope, can be interchanged (by rotating the nosepiece) without the need to re-adjust the focusing controls. (cf. PARCENTRIC OBJECTIVES.)

**parietal** Lying near to, or attached to, the inner face of the wall of a structure; may refer e.g. to algal chloroplasts which lie close to the cell wall.

**parietin** An orange anthraquinone pigment found in lichens of the Teloschistaceae, in certain free-living fungi (e.g. *Aspergillus* and *Penicillium* spp), and in a few higher plants; it gives a purple colour with KOH. Parietin is present at higher concentrations in *Xanthoria parietina* thalli growing in bright light than in those growing in shade, and probably serves to protect the photobiont from high-intensity light.

**pariobasidium** In certain basidiomycetes: the distal, functional part of a mature METABASIDIUM whose proximal region consists of remnants of the probasidium [TBMS (1973) 61 497–512].

**Park nucleotide** UDP-*N*-acetylmuramyl pentapeptide: an intermediate in the biosynthesis of PEPTIDOGLYCAN.

**Parmelia** A large genus of LICHENS (order LECANORALES); photobiont: a green alga. The thallus is foliose, usually with rhizines on the underside; according to species, the upper surface may be yellowish, grey, greyish-green, brown etc, and soredia, isidia, or pseudocyphellae may be formed. Apothecia are lecanorine. Species occur on rocks, bark, wood etc.

**Parmesan cheese** See CHEESE-MAKING.

**PARNA** See CUCUMOVIRUSES.

**paromomycin** Either of two related AMINOGLYCOSIDE ANTIBIOTICS, produced by *Streptomyces rimosus*, which may be regarded as derivatives of neomycins B and C.

**paronychia** Inflammation of the folds of tissue surrounding a fingernail or toenail. It may be caused e.g. by *Candida* spp (see CANDIDIASIS), by certain bacteria, or by HERPES SIMPLEX VIRUS ('herpetic paronychia'). (cf. ONYCHOMYCOSIS; WHITLOW.)

**paroral membrane** In many ciliates: a membrane, composed of multiple cilia, which occurs on the right-hand side or border of the buccal cavity; such membranes are often undulatory and are sometimes called 'undulating membranes'. In ciliates of the OLIGOHYMENOPHOREA (e.g. hymenostomes) the paroral membrane is characteristically of the *stichodyad* type: a double row of kinetosomes arranged in a zigzag pattern, only the outermost kinetosomes commonly bearing cilia (see also HAPLOKINETY); in *Paramecium* the paroral membrane is also called the *endoral membrane*. In many or most ciliates of the POLYHYMENOPHOREA the paroral membrane is of the *stichomonad* (= *monostichomonad*) type in which the infraciliature consists of a single row of kinetosomes; other polyhymenophoreans have *diplostichomonad* membranes (the kinetosomes forming two parallel rows) or – in some hypotrichs – *polystichomonad* membranes (the kinetosomes forming more than two parallel rows). In some ciliates of the SCUTICOCILIATIDA the paroral membrane is clearly divided into two or three parts. (cf. AZM.)

**parotitis** Inflammation of the parotid gland. (cf. MUMPS.)

**parrot fever** *Syn.* PSITTACOSIS.

**parsnip mosaic virus** See POTYVIRUSES.

**parthenogenesis** The development of progeny from a female reproductive structure without the involvement of a male gamete. The term is sometimes used to include cases of AMIXIS and APOMIXIS.

## partial veil

**partial veil** (inner veil) (*mycol.*) In the immature fruiting bodies of certain agarics (e.g. *Agaricus* spp): a membranous tissue which extends from the margin of the pileus to the stipe; when intact, the partial veil seals off the gill cavity. As the fruiting body grows, the partial veil tears – leaving a ring of tissue (the *annulus*) around the stipe, and (often) a ragged ring of tissue (the *cortina*) attached to the periphery of the pileus. (cf. UNIVERSAL VEIL.)

**partition** (of plasmids) Segregation to daughter cells during cell division.

In high-COPY-NUMBER plasmids (e.g. COLE1 PLASMID) partition appears to depend on random segregation to daughter cells: there appear to be no special mechanisms for active partition.

In low-copy-number plasmids (e.g. the F plasmid, IncFII plasmids) active mechanisms are essential for accurate partition; such mechanisms prevent the segregation of plasmid-free daughter cells at cell division and help to maintain a stable copy number. These plasmids contain specific loci (designated e.g. *par*, *sop* or *sta*) associated with partition. The ParM protein of plasmid R1 polymerizes at a *parC*-ParR complex, the resulting filaments apparently forcing the plasmids to segregate [EMBO (2002) 21 3119–3127]. Plasmids with similar/identical partition sites would, if present in the same cell, exhibit instability in partition and (hence) copy number, i.e. INCOMPATIBILITY.

Some plasmids which form multimers have efficient mechanisms for monomerization; thus, e.g. BACTERIOPHAGE P1 encodes a SITE-SPECIFIC RECOMBINATION system. Plasmid R46 encodes a recombinase at the *per* locus.

Partition in R1 appears to involve a mitosis-like process mediated by actin-like filaments. The *par* (partitioning) locus includes: *parC*, a centromere-like region, and the genes *parM* and *parR*. Partitioning seems to occur as follows. A pair of plasmids (formed at the cell's mid-cell replication machinery) become linked by the binding of ParR to the *parC* region of each plasmid; *parC*-ParR-*parC* is the *partitioning complex* that acts as a nucleation site on which ATP-ParM molecules polymerize to form actin-like filaments. Continued polymerization lengthens the filaments, forcing the plasmids to opposite poles [EMBO (2002) 21 3119–3127].

**partition chromatography** See CHROMATOGRAPHY.

**Partitiviridae** See MYCOVIRUS.

**partner gene** See FUSION PROTEIN.

**partridge wood** Wood which has undergone a pocket rot caused e.g. by *Stereum frustulatum*.

**parvaquone** A naphthoquinone drug used e.g. in the treatment of EAST COAST FEVER.

**parvo-like viruses** See SMALL ROUND STRUCTURED VIRUSES.

**parvobacteria** A term sometimes used to refer to some or all of the small Gram-negative bacilli, e.g. species of *Brucella* and *Pasteurella*.

**Parvoviridae** A family of non-enveloped, isometric ssDNA viruses which infect invertebrates or vertebrates; virus replication occurs in the host cell nucleus. Virion: ~15–28 nm diameter, typically with icosahedral symmetry and usually containing three or four types of polypeptide; genome: one molecule of linear ssDNA. In some members of the family each virion contains negative-sense DNA; in other members, some of the virions in a population contain negative-sense DNA while others contain positive-sense DNA.

The virions are typically highly resistant to adverse conditions, surviving e.g. 56°C/>60 min, pH 3–9, lipid solvents, and many types of protease; they can generally be inactivated by formaldehyde, hydroxylamine, β-propiolactone, oxidizing agents or ultraviolet radiation.

Genera: DENSOVIRUS, DEPENDOVIRUS, ERYTHROVIRUS, PARVOVIRUS. [Cell infection: JV (2004) 78 6709–6714.]

**Parvovirus** (parvovirus group) A genus of autonomous, helper-independent viruses (family PARVOVIRIDAE) which infect vertebrates, causing important diseases in domestic and other animals; parvoviruses responsible for human diseases are classified in the genus ERYTHROVIRUS. (So-called ‘parvovirus-like agents’ – associated with human food poisoning – are unrelated (ssRNA) viruses currently referred to as SMALL ROUND STRUCTURED VIRUSES.)

The type species is *r-1* (= Kilham rat virus or ‘rat virus’). Other members include e.g. Aleutian mink disease virus (see ALEUTIAN DISEASE OF MINK), bovine parvovirus, feline parvovirus (including the subspecies FELINE PANLEUKOPENIA VIRUS, CANINE PARVOVIRUS, mink enteritis virus), goose parvovirus (causal agent of a fatal hepatitis in goslings aged 8–30 days), H-1 virus, LuIII virus, porcine parvovirus (an important cause of infertility, abortion and stillbirth), and minute virus of mice (MVM). Several parvoviruses (e.g. H-1, LuIII) were originally isolated from cell cultures.

Most parvoviruses can agglutinate the erythrocytes (red blood cells) of at least one species of animal. [Differences in haemagglutinating activity among strains of canine parvovirus: JGV (1988) 69 349–354.]

The autonomous parvoviruses are characterized by their need to replicate in dividing cells, and in at least some cases (see ERYTHROVIRUS) a virus may be highly tropic for cells in a particular phase of the cell cycle. (The frequent association of parvoviruses with tumours may be due to their preference for dividing cells – rather than to an oncogenic potential; in fact, parvoviruses are reported to have anti-neoplastic potential [Book ref. 97, pp 344–345].)

In some parvoviruses the virions contain only negative-strand DNA; in others, the virions in a given population may contain *either* negative-strand *or* positive-strand DNA.

In autonomous parvoviruses, replication of the DNA is believed to follow a ‘rolling hairpin’ model [modified rolling hairpin model: JV (1985) 54 171–177], which is outlined below.

Replication of the single-stranded DNA genome is facilitated by the presence of a PALINDROMIC SEQUENCE at both ends of the strand; in B19 parvovirus (see ERYTHROVIRUS) the two terminal palindromes are identical. Replication begins at the 3′ end, where the palindromic sequence folds back on itself to form a T-shaped double-stranded structure; strand synthesis from the 3′ terminus gives rise to a double-stranded replicative form which extends to the 5′ terminus of the genome. (During strand synthesis, the T-shaped structure at the 5′ end is apparently ‘opened up’ by strand displacement.) The original 5′ end of the genome thus becomes paired with a newly synthesized strand that includes a (complementary) copy of the palindrome. The palindrome in each strand spontaneously forms a double-stranded T-shaped structure – so that the 3′ end is now positioned to use the newly synthesized strand as a template for ongoing synthesis. Strand synthesis along this (newly synthesized) template continues with synthesis along the original genome strand, resulting in a double-stranded genomic dimer. Nicking at specific sites leads to regeneration and recycling of intermediates and the formation of progeny genomes (see reference for further details).

**parvoviruses** (1) Viruses of the PARVOVIRIDAE. (2) Viruses of the genus PARVOVIRUS.

**PAS** (*p*-aminosalicylic acid) A chemotherapeutic agent which is bacteriostatic for some *Mycobacterium* spp, e.g., *M. tuberculosis*; it is used, together with e.g. ISONIAZID, in the treatment

of TUBERCULOSIS. PAS is incorporated in FOLIC ACID (in place of PABA), giving rise to an analogue with impaired activity.

**PAS reaction** (periodic acid–Schiff reaction) A procedure for demonstrating the presence of certain carbohydrates – e.g. CELLULOSE, GLYCOGEN, STARCH. Adjacent hydroxyl groups in the carbohydrate are oxidized to aldehyde groups by periodic acid (HIO<sub>4</sub>); the aldehyde groups react with SCHIFF'S REAGENT to give a purple coloration. (Tetraacetic acid or chromic acid may be used in place of periodic acid.) A positive PAS reaction is also given by sugars containing an unsubstituted amino group adjacent to a hydroxyl group (as in CHITOSAN). The PAS reaction has been used e.g. to detect certain pathogenic fungi (e.g. *Blastomyces dermatitidis*, *Histoplasma capsulatum*) in tissue sections.

**pascal (Pa)** The SI unit of pressure; 1 pascal is equal to 1 newton/metre<sup>2</sup>. 1 mmHg = 1 torr = 133.3 Pa = 0.133 kPa. (1 atmosphere = 14.7 lb/inch<sup>2</sup> = 101.325 kPa.) (cf. BAR.)

**paspalinines** See PASPALUM STAGGERS.

**paspalum staggers** A MYCOTOXICOSIS which affects mainly cattle but also sheep and horses; it is caused by the ingestion of tremorgenic toxins (paspalinines) when grazing *Paspalum* grasses ergotized by *Claviceps paspali*. Symptoms: hypersensitivity to noise and movement, followed by muscle tremors and incoordination. Recovery is usually rapid following removal from affected pastures.

**Paspalum striate mosaic virus** See GEMINIVIRUSES.

**passage** See SERIAL PASSAGE.

**passive agglutination** (*serol.*) Any form of AGGLUTINATION in which the combination of antibodies with antigens is made readily detectable by the prior adsorption of the antigen or antibody to an unrelated particulate entity – e.g. a cell or a colloidal particle. Thus, e.g., a soluble antibody or antigen may be adsorbed to bentonite or latex (see LATEX PARTICLE TEST) or to erythrocytes (see BOYDEN PROCEDURE); antibodies may be adsorbed e.g. to staphylococci (see SENSITIZATION (sense 5) and PROTEIN A). (If erythrocytes are used, the procedure is referred to as *passive haemagglutination*.)

**passive agglutination test** Any test, involving PASSIVE AGGLUTINATION, used for detecting or quantifying specific antibodies or antigens – e.g., antibodies homologous to soluble antigens, or particulate antigens homologous to particle-bound antibodies; in such tests the combination of particle-bound antigen (or antibody) with homologous antibody (or antigen) causes AGGLUTINATION of the particles. Passive agglutination tests are appreciably more sensitive than PRECIPITIN TESTS.

**passive haemagglutination** See PASSIVE AGGLUTINATION.

**passive haemolysis** See HAEMOLYSIS.

**passive immunity** (adoptive immunity) Temporary immunity brought about by the transfer of pre-formed antibody, or specifically sensitized lymphocytes, from an immune individual to a non-immune individual – the latter thus becoming immune without necessarily having had contact with the corresponding antigen(s). Passive immunity can be acquired e.g. by transfer of antibody via the placenta, in COLOSTRUM, or by passive IMMUNIZATION.

**passive immunization** See IMMUNIZATION.

**Pasteur effect** In organisms capable of both fermentative and respiratory modes of metabolism (e.g. *Saccharomyces cerevisiae*): the inhibition of glycolysis in the presence of O<sub>2</sub>, manifested by the inhibition of ethanol formation and a decrease in the amount of glucose used. This effect reflects the higher energy yield obtained from glucose by RESPIRATION than by FERMENTATION. The Pasteur effect can apparently be explained, at least in part, by the allosteric modulation of phosphofructokinase

activity in response to the ADENYLATE ENERGY CHARGE (see EMBDEN–MEYERHOF–PARNAS PATHWAY). (cf. CUSTERS EFFECT.)

The Pasteur effect is not observed e.g. in yeast cells growing in the presence of high concentrations of glucose: cf. CRABTREE EFFECT.

**Pasteur pipette** An open-ended glass tube (internal diam. ca. 5 mm) with one end drawn out to an internal diam. ca. 1 mm; the wide end is fitted with a rubber bulb. It is used e.g. for non-quantitative transfer of liquids, but may be roughly calibrated: e.g. if 50 drops are delivered per ml, each drop is 0.02 ml. For aseptic work Pasteur pipettes are plugged (see PLUGGING) and sterilized before use.

**Pasteurella** A genus of Gram-negative bacteria of the PASTEURACEAE. (The following account is based on data from Book ref. 22, pp. 552–558, but cf. final paragraphs of entry for proposals for a revised classification.) Cells: usually coccoid, rod-shaped or pleomorphic, ca. 0.3–1.0 × 1–2 μm, occurring singly or sometimes in pairs or short chains. Bipolar staining is common. On primary isolation virulent strains usually have a carbohydrate (e.g. hyaluronic acid) capsule which may be lost on subculture. Optimum growth temperature: 37°C. Only *P. aerogenes* and *P. haemolytica* can grow on MacConkey's agar. Most strains are non-haemolytic (cf. *P. haemolytica*). Glucose is usually fermented anaerogenically – gas being formed only by *P. aerogenes* and *Pasteurella* 'gas' (a urease +ve strain which may be a biotype of *P. pneumotropica*). MR –ve; VP –ve; oxidase +ve (some strains of *P. multocida* are –ve); gelatinase –ve; LDC –ve; ADH –ve; usually lactose –ve. GC%: 40–45. Type species: *P. multocida*.

*P. aerogenes*. Gas from glucose; indole –ve; urease +ve. Commensal in the intestines of pigs.

*P. gallinarum*. Indole –ve; urease –ve. Occurs e.g. in the upper respiratory tract of poultry and may be associated with chronic respiratory disease in poultry.

*P. haemolytica*. Haemolytic (e.g. on bovine blood agar); indole –ve; urease –ve. Can cause primary or secondary pneumonia in e.g. cattle and sheep, and is a major cause of 'shipping fever' (see BOVINE RESPIRATORY DISEASE); it can also cause e.g. mastitis in ewes and septicaemia in lambs. (See also RTX TOXINS.)

*P. multocida* (formerly *P. septica*). Indole +ve; urease –ve. Pathogenic in a range of animals, causing e.g. HAEMORRHAGIC SEPTICAEMIA (in cattle), FOWL CHOLERA, 'shipping fever', and secondary infections (see e.g. SWINE INFLUENZA). Can be an opportunist pathogen in man e.g. following animal bites (see e.g. CAT-BITE FEVER). [Genomic sequence of a common avian strain of *P. multocida*: PNAS (2001) 98 3460–3465.]

*P. pestis*: see YERSINIA.

*P. pneumotropica*. Indole +ve; urease +ve. Occurs in the nasopharynx in rodents and other animals, and can cause e.g. respiratory tract infection in laboratory rodents.

*P. pseudotuberculosis*: see YERSINIA.

*P. tularensis*: see FRANCISELLA.

*P. ureae*. Indole –ve; urease +ve. Occurs occasionally in the upper respiratory tract in humans.

In a proposal for a revised classification [IJSB (1985) 35 309–322] it was suggested that the genus should include the following species: *P. anatis* sp. nov.; *P. avium*; *P. canis* sp. nov. (includes e.g. the former *P. multocida* biotype 6); *P. dagmatis* sp. nov. (includes organisms previously called *P. 'gas'* or *P. pneumotropica* type Henriksen); *P. gallinarum*; *P. langaa* sp. nov.; *P. multocida* (includes three subspecies: *gallicida*, *multocida* and *septica*); *P. stomatis* sp. nov.; *P. volantium* sp.

## Pasteurellaceae

nov. (V-factor-requiring avian and human strains). Organisms referred to as *P. haemolytica*, *P. pneumotropica* biotypes Jawetz and Heyl, *P. testudinis* and *P. ureae* were excluded from the genus, and were said to be more closely related to the *Actinobacillus* group; *P. aerogenes* and *P. multocida* biotype 1 were also excluded.

It was later proposed that *P. ureae* be transferred to the genus *Actinobacillus* (as *A. ureae*) [IJSB (1986) 36 343–344].

**Pasteurellaceae** A family of Gram-negative, asporogenous, facultatively anaerobic bacteria. Cells: coccoid to rod-shaped, sometimes pleomorphic or filamentous; non-motile. Chemoorganotrophic (respiratory and fermentative); demethylmenaquinones (see QUINONES) are involved in aerobic and anaerobic electron transport. Nutritionally fastidious, requiring organic nitrogen and various growth factors. Chocolate or blood agars can be used for primary isolation of most strains. NO<sub>3</sub><sup>-</sup> is reduced to NO<sub>2</sub><sup>-</sup>. Acid (usually without gas) is usually formed from glucose but may be difficult to detect by conventional methods. Typically oxidase +ve; catalase +ve; alkaline phosphatase +ve. Species are parasitic in man, animals and birds; some are pathogenic. Type genus: PASTEURELLA; other genera: ACTINOBACILLUS and HAEMOPHILUS. [Book ref. 22, pp. 550–575.]

**pasteurellosis (vet.)** Any of a range of (primarily) septicaemic or pneumonic diseases caused by species of *Pasteurella*. (See e.g. shipping fever in BOVINE RESPIRATORY DISEASE; HAEMORRHAGIC SEPTICAEMIA (2).)

**Pasteuria** A genus of BUDDING BACTERIA which typically occur attached to particulate matter in aquatic environments; in these organisms the (proteinaceous) cell wall lacks peptidoglycan. *P. ramosa* is a parasite of water-fleas (*Daphnia* spp). [Book ref. 45, pp. 490–492.] A strain formerly designated *P. ramosa* was reclassified in a new genus, *Pirella* [IJSB (1984) 34 492–495].

**pasteurization** A form of heat treatment which kills certain pathogens and/or spoilage organisms in e.g. milk and certain foods; temperatures below 100°C are used. (cf. APPERTIZATION.) For MILK, an early form of pasteurization involved holding the milk at a minimum of 63°C for at least 30 min (low temperature holding, LTH; low temperature long time, LTLT). In a more recent method milk is held at a minimum of 72°C for at least 15 sec (flash pasteurization; high temperature short time, HTST). Pasteurization is lethal for the causal agents of a number of milk-transmissible diseases (e.g. salmonellosis, tuberculosis) as well as for a proportion of the milk microflora. It also inactivates certain bacterial enzymes (e.g. lipases) which would otherwise cause milk spoilage. (Both the LTLT and the HTST methods may be inadequate for the inactivation of *Coxiella burnetii* (see Q FEVER).)

The term 'pasteurization' has also been used for the mild heat disinfection (80°C/5 min) of medical instruments.

**pasture bloat** See BLOAT.

**patch stop** See MICROSCOPY (b).

**patch test** Any form of SKIN TEST in which the antigen is applied to the surface of the skin – see e.g. VOLLMER PATCH TEST.

**patching** See CAPPING (sense 3).

**patent period (med., vet.)** The period during which parasitic organisms can be demonstrated in blood, tissues, faeces etc of the host. (cf. PREPATENT PERIOD.)

**pathogen** Any MICROORGANISM which, by direct interaction with (infection of) another organism (by convention, a multicellular organism), causes DISEASE in that organism. A pathogen is not, therefore, any microorganism which is causally connected with disease: for example, a microbe which produces a TOXIN that

causes disease in the absence of the microbe itself would not be regarded as a pathogen. Thus, a toxinogenic strain of *Gonyaulax* may – indirectly – cause paralytic SHELLFISH POISONING in man, but it is not regarded as a human pathogen since it has never been known to cause disease by infecting man. Similarly, while *Claviceps purpurea* can be regarded as a pathogen of certain cereals, it cannot be called a human pathogen – even though the ergot alkaloids it produces can cause ERGOTISM in man. By analogy, *Clostridium botulinum* (often described as a pathogen in medical circles) is not acting as a pathogen when its toxin, in the absence of the bacterium, causes BOTULISM in an adult human, although it does act as a pathogen *sensu stricto* when it causes infant botulism, wound botulism, or certain (apparently atypical) *C. botulinum* infections in adults. (See also OPPORTUNIST PATHOGEN.)

By custom, disease-causing higher organisms, such as trematode worms, are referred to as parasites rather than pathogens. (See also PARASITOLOGY.)

**pathogenesis** The process or mechanism of disease development.

**pathogenesis-related proteins (plant pathol.)** A group of low-MWt, low-IEP proteins, resistant to proteases, formed de novo in plant tissues in response to infection with a pathogen; of unknown function, they are thought to have a role in resistance to disease. They were first found in tobacco cultivars exhibiting HYPERSENSITIVITY to tobacco mosaic virus infection, but occur in other plants infected with viruses, viroids, fungi or bacteria. (cf. PHYTOALEXINS.)

**pathogenic** Able to behave as a PATHOGEN.

**pathogenicity island (PAI)** In a bacterial pathogen: a cluster or 'cassette' of genes encoding a set of virulence factors; such sequences usually occur in the chromosome but their GC% is typically unlike that of the chromosome – suggesting acquisition by horizontal transfer. Many PAIs (e.g. *cag* in *Helicobacter pylori*) are flanked by direct repeats. (cf. AVIRULENCE GENE.) A PAI is often located at a site adjacent to a tRNA gene.

The LEE (locus of enterocyte effacement) PAI is found in all strains of EPEC and in many strains of EHEC. LEE is a 35.5 kb chromosomal sequence which is not flanked by direct repeats; in EPEC it is located 16 bp downstream of the *selC* gene (which encodes the tRNA for selenocysteine) [PNAS (1995) 92 1664–1668]. The LEE PAI encodes components of a type III secretory system (see PROTEIN SECRETION) as well as various effector molecules. [Type III secretory systems and pathogenicity islands (review): JMM (2001) 50 116–126.] Specific genes (and products) include:

*eae* – an adhesin (*intimin*).

*espA* – a cell–cell linking structure (?)

*espB* – an activator of epithelial cell enzymes (?)

*escN* – an ATPase for the secretory system (?)

*tir* – (*espE* in EHEC) Tir protein (see EPEC).

(The names of genes encoding components of the type III system in EPEC differ from those in the earlier literature; these genes are now designated *esc* – e.g. *escN* was formerly *sepB*.)

At least some genes in LEE (including *eae*, and those of secreted proteins, such as *espB*) are under transcriptional control from a regulatory region (*per*) in a plasmid (EPEC adherence factor plasmid; EAF plasmid) found in all strains of EPEC. This plasmid also encodes the so-called *bundle-forming pili* (BFP) which may be involved in the formation of microcolonies on the intestinal epithelium (see EPEC).

[Model of EPEC pathogenesis: TIM (1998) 6 169–172.]

Other PAIs include *cag* in *Helicobacter pylori* [PNAS (1996) 93 14648–14653; Nature (1997) 388 539–547], and the island

encoding so-called 'toxin co-regulated pili' (TCP) in *Vibrio cholerae*.

*Salmonella* spp contain at least five distinct PAIs. For example, SPI-1 includes the *inv-spa* genes that encode a type III secretory system used in the invasion of epithelial cells. SPI-3 encodes products needed for survival in macrophages; like LEE, this PAI is located downstream of *selC*. SPI-5 apparently contributes specifically to enteropathogenicity [Mol. Microbiol. (1998) 29 883–891].

In *Staphylococcus aureus*, the gene for toxic shock toxin is carried by a mobile pathogenicity island [Mol. Microbiol. (1998) 29 527–543].

**pathognomonic** Of symptoms: characteristic of, or specific to, a given disease.

**PathoTec system** See MICROMETHODS.

**pathotype, pathovar** See VARIETY.

**patricins** See STREPTOGRAMINS.

**patronym** (patronymic) In NOMENCLATURE: any name derived from that of a person.

**Pattern coefficient** See entry  $S_p$ .

**Pattern difference** See entry  $D_p$ .

**patulin** (clavacin, clavatin, claviformin) An antibacterial, anti-fungal, antimetabolic (and possibly carcinogenic) MYCOTOXIN formed by species of *Penicillium*, *Aspergillus* and *Byssoschlamys*. It is a heterocyclic compound which is soluble e.g. in water and alcohol and which reacts with sulphhydryl groups. It occurs e.g. in animal feeds and has been implicated in fatalities in cattle. It is formed by *P. expansum* in apples and has been detected in commercial apple juice; it is destroyed by  $SO_2$  and by alcoholic fermentation. [Mode of action on *Saccharomyces cerevisiae*: AEM (1983) 45 110–115.]

**Paul–Bunnell test** A haemagglutination test used to detect and quantify a HETEROPHIL ANTIBODY (the 'Paul–Bunnell antibody') which usually appears in cases of INFECTIOUS MONONUCLEOSIS. (Heterophil antibodies may not be detectable in very young children (e.g. <4 years of age), so that the test may be unreliable in this group.) The antibody appears 1–3 weeks after the onset of symptoms and may persist for months; it agglutinates the red blood cells of the sheep, horse and ox. The test determines the titre of serum which agglutinates sheep RBCs.

In a modified form of the test, one sample of serum is pre-absorbed with OX RBCs (which bind the Paul–Bunnell antibody); another sample is absorbed with guinea-pig tissue (which binds e.g. Forssman antibodies but not the Paul–Bunnell antibody); as Forssman antibodies can agglutinate sheep RBCs, pre-absorption makes the test more specific for the Paul–Bunnell antibody.

**Paulinella** A genus of testate amoebae similar to EUGLYPHA spp. *P. chromatophora*, a small (20–30  $\mu$ m long), ovoid, freshwater species, contains two CYANELLES (*Synechococcus*); on division, each daughter receives one cyanelle, which subsequently divides.

**Paxillus** See BOLETALES.

**PBP** PENICILLIN-BINDING PROTEIN.

**PBP 2a** (PBP 2') See PENICILLIN-BINDING PROTEINS and MRSA.

**pbpA gene** See PENICILLIN-BINDING PROTEINS.

**pbpB gene** See PENICILLIN-BINDING PROTEINS.

**pBR322** A small, multicopy, non-conjugative PLASMID (4362 bp) which carries genes for resistance to ampicillin and tetracycline; it resembles the COLE1 PLASMID in its mode of replication. pBR322 is widely used as a CLONING VECTOR [review: Gene (1986) 50 3–40]; insertion of DNA at restriction sites in resistance gene(s) is detected by loss of antibiotic resistance.

**PBS** (1) Phosphate-buffered saline. (2) Primer binding sites: see RETROVIRIDAE.

**PCBs** Polychlorinated biphenyls (see BIOREMEDIATION).

**PCC** Pasteur Culture Collection.

**pCF-10** See SURFACE EXCLUSION.

**PCNB** See QUINTOZENE.

**pcnB gene** See MRNA (a) and PLASMID (replication).

**PCP** See BIOREMEDIATION.

**PCR** (polymerase chain reaction) A method for copying ('amplifying') specific sequences of nucleotides (see AMPLICON senses 1 and 2) in DNA; a modified form of the process (REVERSE TRANSCRIPTASE PCR) is used for copying sequences in RNA. PCR depends on the ability of a (thermostable) DNA polymerase to extend a primer on a template containing the amplicon (see figure). (Patents covering PCR are owned by Hoffmann-La Roche.) Other methods for amplifying nucleic acids include LCR, NASBA and SDA; unlike PCR, the latter two methods are conducted isothermally.

Repeated rounds of replication (i.e. ongoing *cycling*) in PCR can yield millions of amplicons within hours; usually, the sequence being copied is less than 2000 base-pairs in length, but longer sequences have been copied.

In the basic form of PCR the reaction mixture includes: (i) the sample (dsDNA); (ii) the *primers*: oligonucleotides (~20–30 base-pairs in length) of two types – one type complementary to the 3' end of the amplicon in one strand, the other type complementary to the 3' end of the amplicon in the other strand; (iii) deoxyribonucleoside triphosphates of all four types; (iv) a thermostable DNA polymerase – e.g. the *Taq* DNA polymerase (see DNA POLYMERASE for examples of polymerases used in PCR).

Temperature cycling (see figure) can be controlled manually; however, it is usually achieved by carrying out the reaction in an instrument (a *thermal cyclor* or *thermocycler*) in which timing is controlled automatically (see THERMOCYCLER). In most cases, each cycle of PCR involves a sequence of three levels of temperature: (i) e.g. 94/95°C for strand separation (denaturation of the sample duplex DNA); (ii) a temperature suitable for the binding of primers (*annealing*); and (iii) a temperature suitable for extension, i.e. ongoing synthesis of a DNA strand, from the primer, on the template strand. In some cases a two-temperature protocol has been used – e.g. a denaturing temperature of 94°C and combined annealing/extension at 68°C; this is possible e.g. with the GeneAmp® 9700 system (Perkin-Elmer) amplifying a 500-nucleotide amplicon of phage  $\lambda$  DNA.

While denaturation and extension temperatures are generally ~94/95°C and 72°C, respectively, the temperature used for annealing varies widely according to the particular assay. One factor which influences annealing temperature is the GC% of the primers – GC%-rich primers requiring a higher annealing temperature to avoid the formation of spurious products through 'mispriming' (binding of primers to inappropriate sequences in the template). (Examples of some primer-binding temperatures: GC% 33: 45°C [JCM (1999) 37 772–774]; GC% 62: 63°C [NAR (1998) 26 3614–3615].) One way of finding an optimal annealing temperature is TOUCHDOWN PCR.

For some purposes (e.g. ARBITRARILY PRIMED PCR) a primer is required to bind to a target sequence to which it is not fully complementary. In such cases, PCR can be run under so-called *low-stringency* conditions, i.e. particular values of temperature, pH and electrolyte concentration which optimize primer–target binding by helping to overcome, or minimize, the effects of mismatches between primer and target. *High-stringency* conditions are those which allow primer–target binding to occur only when the primer and target sequences are exactly complementary, or very nearly so. The greater the

## PCR

PCR (polymerase chain reaction): the basic method (principle, diagrammatic).

(a) Part of a double-stranded molecule of DNA: two antiparallel strands held together by base-pairing. The sequence to be amplified (the *amplicon*) is delimited by short vertical bars.

(b) Initial heating to e.g. 95°C has separated the two strands of DNA. Transient cooling to 45–65°C has permitted the *primers* – shown as short, solid lines – to bind (= *anneal*) to their respective (complementary) sites on the template strands; notice the locations of the bound primers in relation to the site of the amplicon. The temperature is then increased to e.g. 72°C, and DNA synthesis (dashed line) occurs from the 3' end of each primer. Note that each of the newly synthesized strands in this first round of replication is longer than the amplicon.

(c) The second round of replication begins with initial heating (to ~95°C) so that the new daughter strands (synthesized in the first round of replication) are separated from their templates. Each new daughter strand (as well as the two parental strands) can then act as a template. In the diagram, a primer has bound to each new daughter strand and has been extended (dashed line). Note that the strand synthesized on a new daughter strand is the same length as the amplicon; such strands rapidly become numerically dominant in subsequent rounds of replication.

Reproduced from Figure 4.1, page 57, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission of Kluwer Academic Publishers, Dordrecht, The Netherlands.

stringency (e.g. the higher the temperature) the greater will be the degree of matching needed between primer and target for successful binding to occur.

Difficulties in designing a primer – owing e.g. to insufficient data on the target sequence – may be approached by using a ‘universal nucleotide’ in place of one or more of the unknown nucleotides [universal nucleotides: *Nature* (1994) 369 492–493].

Successful PCR requires close attention to detail and also exclusion of contamination by DNA from the environment and/or from the apparatus.

*Contamination by extraneous DNA.* Extraneous DNA may contain (i) sequences that are able to bind the primers being used and/or (ii) sequences able to prime irrelevant sites in the sample DNA; either way, unwanted sequences may be amplified – forming a troublesome mixture of products and reducing the efficiency of amplification of the required sequence.

There are two main approaches to the control of contamination. First, *amplicon containment*; this involves division of

the working space into a number of dedicated areas – each area being used for only certain stage(s) of the procedure. In one common scheme there are five designated areas, two of which are reserved for (i) cycling and (ii) analysis of products.

The second approach, *amplicon inactivation*, can be achieved by either of two methods. In one method, *isopsoralen* (see PSORALENS) is added to the reaction mixture before cycling. After cycling, the reaction mixture is exposed to ultraviolet radiation – e.g. 365 nm/15 minutes/4°C; this results in covalently cross-linked double-stranded amplicons which – as they cannot be denatured into single-stranded templates – cannot jeopardize later assays in the same apparatus/laboratory. (Activation of isopsoralen at low temperature is more efficient than at room temperature [JCM (1999) 37 261–262].)

In the second form of amplicon inactivation, all PCR assays are carried out routinely with deoxyuridine triphosphate (dUTP) instead of the usual deoxythymidine triphosphate (dTTP); as a result, dUMP is incorporated into all amplified products during cycling. (Such products can be detected and analysed

in the usual way.) In each assay, the reaction mixture also includes the enzyme URACIL-DNA GLYCOSYLASE (= uracil-*N*-glycosylase, UNG); consequently, if amplicons from *previous* assay(s) contaminate a given assay, then those contaminating amplicons will be degraded by the dual effects of (i) enzymic removal of uracil by UNG, and then (ii) denaturation and strand breakage caused by the high initial temperature of the first cycle in the new assay. (This high temperature also inactivates UNG; this is necessary in order to avoid degradation of products in the new assay.)

*Inhibitors and facilitators of PCR.* Some (e.g. clinical) specimens may contain substance(s) which inhibit PCR – so that a false-negative result may be obtained even when a given specimen contains the particular amplicon of interest. Inhibitors are found in a wide range of clinical specimens, e.g. bone marrow aspirates, cerebrospinal fluid, faeces and urine. PCR-inhibitory components of blood cells include haemoglobin (in erythrocytes) and lactoferrin (in leukocytes). [Purification and characterization of PCR-inhibitory components in blood cells: JCM (2001) 39 485–493.]

Inhibitors of PCR also include the blood anticoagulants SPS (sodium polyanetholesulphonate) [JCM (1998) 36 2810–2816] and HEPARIN; haemin; and agar (see GELLAN GUM for an alternative to the agar component in transport media).

The problem of inhibitors may be approached in several ways. For example, specimens may be diluted in order to reduce the concentration of the inhibitory substance(s); however, this also lowers the number of copies of the target sequence (if any) in the specimen and may lower the sensitivity of the assay.

Inhibitors in faeces appear to include complex polysaccharides of dietary origin; these inhibitors can be removed (at least partially) by means of a modified form of a commercial process used for preparing purified DNA from tissues and viruses [JCM (1997) 35 995–998]. The removal of some polysaccharide inhibitors of PCR may be achieved by means of agarose–DNA preparations [NAR (1998) 26 3309–3310].

In another form of nucleic-acid amplification, TMA (q.v.), certain inhibitors can be inactivated by treating specimens with the detergent sodium dodecyl sulphate (SDS) [JCM (1997) 35 307–310]. SDS has been used for a similar purpose in tests based on the ligase chain reaction (LCR) [JCM (1998) 36 1324–1329].

A distinct approach to the problem of inhibitors is offered by the use of magnetic separation techniques (see e.g. DYNABEADS); following capture on Dynabeads, specific molecules may be washed free of inhibitory substance(s).

The presence of inhibitors may be detected in several ways. For example, an aliquot of the specimen may be ‘spiked’ with the given target DNA prior to assay; in general, this is not a good idea because it involves extra handling of the specific target sequence and, hence, increases the risk of contamination.

An alternative approach uses an internal control (IC) consisting of molecules of nucleic acid that (i) contain binding sites for the given primers, and (ii) are distinguishable from the actual target by the presence of a unique PROBE-binding region. On efficient amplification of a specimen containing specific target and IC (but lacking inhibitors), two types of product are likely to be obtained: (i) amplicons from the actual target, and (ii) copies of the IC (identifiable by a specific probe). Failure to obtain copies of both target and IC may indicate the presence of inhibitors; amplification of the IC in the absence of target amplification suggests lack of target sequences in the specimen. In one experiment, 20 copies of the IC were added to each test sample, and a positive IC signal was taken to indicate that amplification

was satisfactory when targets were present at the limit of the test’s sensitivity [JCM (1998) 36 191–197].

Even when known inhibitors have been taken into account it is mandatory to include suitable controls to detect the effects of unknown/unexpected inhibitors (which may occur in only certain batches of a given type of specimen).

*Amplification facilitators* are agents which can enhance the efficiency of PCR in the presence of inhibitory substance(s); such agents may also e.g. improve the specificity of PCR and increase the fidelity of DNA synthesis. Amplification facilitators include e.g. bovine serum albumin (BSA) and betaine; some facilitators are effective against a range of inhibitors while others have more selective activity. [Effects of amplification facilitators on diagnostic PCR in the presence of blood, faeces and meat: JCM (2000) 38 4463–4470.]

*Detection of PCR products.* In the ‘standard’ form of PCR the products consist of millions of amplicons whose *precise* length (exact number of base pairs) is determined by the target-binding sites of the primer pair (see figure). Such products, all the same size, can be readily detected/identified by gel electrophoresis as a single band at a precise location in the gel. Typically, electrophoresis is carried out in an agarose gel, and the band of products is detected by staining with ethidium bromide and examining the gel under ultraviolet radiation. To facilitate identification, another lane in the *same* gel is used for electrophoresis of a set of fragments of known size (e.g. 100, 200, 300... base pairs); this gives a scale (‘ladder’) with which the experimental band(s) can be compared.

Gel electrophoresis is also used for detecting the products in MULTIPLEX PCR (in which products of more than one size are formed) and in ARBITRARILY PRIMED PCR (in which there are products of very many sizes – the multiple bands of products forming a *fingerprint* of the sample DNA).

Band(s) of products within a gel strip may be further examined by Southern blotting followed by SOUTHERN HYBRIDIZATION.

The identity of amplicons from a given reaction can also be checked by subjecting them to a particular RESTRICTION ENDONUCLEASE and checking (by electrophoresis) to see whether fragments of *expected* sizes have been formed.

Amplicons can be rapidly detected by a plate-based hybridization assay. First, single-stranded amplicons are prepared by denaturing the products. These amplicons are then exposed to *detector probes* which are complementary to a given sequence in the amplicon; each PROBE is labelled with the enzyme alkaline phosphatase. The whole is then transferred to a microtitre plate whose wells have been coated with *capture probes* – probes complementary to a different sequence in the amplicon. Incubation at 37°C permits amplicons (if present) to bind to the (surface-bound) capture probes. After washing (to remove unbound detector probes), a substrate for alkaline phosphatase is added to detect any bound, enzyme-labelled amplicons; if present, the enzyme will cleave the substrate, and this can be detected by monitoring the optical density of the mixture. This method has been used for detecting *Bordetella pertussis* in clinical specimens (by detecting a sequence of nucleotides specific to the pathogen) [JCM (1997) 35 117–120].

Products can also be detected rapidly by PCR DIG-ELISA. In this method, the PCR reaction mixture includes DIGOXIGENIN-tagged deoxyuridine triphosphate (dUTP) so that dUMP is incorporated into the products. Moreover, the primers are 5'-biotinylated so that, after cycling, products can be captured on the STREPTAVIDIN-coated surface of a well in a microtitre plate. Any products captured on the well’s surface can then

## PCR DIG-ELISA

be detected by exposing the well to a *conjugate* consisting of antidigoxigenin (the antibody to digoxigenin) covalently bound to alkaline phosphatase; any bound, digoxigenin-tagged products will bind the conjugate (via the antibody) and, hence, become labelled with alkaline phosphatase. As in the previous method, the enzymic label is detected by adding an appropriate substrate and monitoring the optical density. This method has been used for screening salmonellae [JCM (1997) 35 714–718]. Note that, unlike the previous method, this method does not confirm the identity of the products by specific hybridization(s).

Real-time detection of products is possible e.g. with TAQMAN PROBES (q.v.) and MOLECULAR BEACON PROBES.

The LightCycler™ (Roche) is a thermocycler in which detection (and/or quantification) of products can be achieved by at least two distinct methods. One method uses SYBR® Green I (Molecular Probes Inc., Eugene, OR, USA) – a dye which fluoresces strongly (530 nm) when it binds to the minor groove of dsDNA. In PCR, this dye can be used to monitor the cycle-by-cycle build-up of products by including it in the reaction mixture and measuring its fluorescence at the end of the *extension* stage in each cycle – that is, when all amplicons are double-stranded, the quantity of dsDNA is at a maximum in that cycle, and the maximum amount of dye has been bound. With ongoing cycling, there is a progressive increase in the amount of dsDNA at the end of extension and, hence, in fluorescence from the bound dye.

Detection of products by the LightCycler can also be achieved by a probe-based format. Two types of probe, included (in large numbers) in the reaction mixture, can bind to *adjacent* sites on an internal (non-terminal) sequence in the amplicon. When bound, the 3' end of probe 1 (labelled with fluorescein) is juxtaposed to the 5' end of probe 2 (labelled with the dye LightCycler Red 640). When probes are bound in this way, fluorescence from probe 1 provides excitation for the dye on probe 2 (by a process called *fluorescence resonance energy transfer*, FRET); when excited in this way, the dye on probe 2 emits radiation of wavelength 640 nm. During cycling, probes 1 and 2 bind to amplicons at the *annealing* stage, and the signal (at 640 nm) is read at this stage. Subsequent primer extension displaces the probes – so that (because the dyes are then no longer juxtaposed) fluorescence from probe 2 ceases. During ongoing cycling, probes bind to increasing numbers of amplicons at the annealing stage in each cycle and give rise to a progressively increasing signal at that stage.

Optionally, the LightCycler can work in duplex mode, i.e. detecting two targets (in the same sample) by using two pairs of primers and two (different) pairs of probes; one probe in one pair is labelled with LightCycler Red 640, and one probe in the other pair is labelled with LightCycler Red 705 – so that two independent signals are obtained from the one sample. [Duplex LightCycler assay for detecting (i) the *mecA* gene and (ii) a *Staphylococcus aureus*-specific marker: JCM (2000) 38 2429–2433.]

*Quantification in PCR.* The number of target sequences in a sample *before* amplification can be estimated by several commercial systems. These include TaqMan® probes (PE Applied Biosystems) and the probe-based and SYBR® Green I formats of the LightCycler™ (Roche); in all cases, quantification in a given reaction requires identification of the *threshold cycle* – see TAQMAN PROBES for rationale. (See also MOLECULAR BEACON PROBES.)

*Uses of PCR.* PCR is an extremely flexible technique which has found use in fields as diverse as palaeobiology and forensic science.

In microbiology, PCR is used e.g. for detecting and identifying specific microorganisms in medical or environmental specimens; this use depends on the amplification and examination of sequences of nucleotides which are *specific* to the organisms of interest. Such an approach is particularly useful for those organisms which cannot be cultured – or which grow very slowly (e.g. *Mycobacterium tuberculosis*). For diagnostic purposes, primers must be specific to sequences found *only* in a given pathogen (for example, a sequence in a gene encoding a unique toxin). Examples of the use of PCR for detecting pathogens include: *Bacteroides forsythus* [JCM (1999) 37 1621–1624], *Bordetella pertussis* [JCM (1999) 37 606–610], chlamydiae [JCM (1999) 37 575–580], *Escherichia coli* O157 [JCM (1998) 36 1801–1804], *Fusarium* spp [JCM (1999) 37 2434–2438], group A streptococci [JCM (1998) 36 1769–1771], HIV-1, HIV-2, HTLV-I, HTLV-II [PNAS (1999) 96 6394–6399], rhinoviruses [JCM (1999) 37 524–530] and *Trichomonas vaginalis* [JCM (1997) 35 132–138].

For PCR in TYPING see: AFLP FINGERPRINTING, ARBITRARILY PRIMED PCR, PCR-RIBOTYPING, REP-PCR, RFLP, SPOLIGOTYPING and SSCP.

PCR is also used e.g. for (i) detecting specific virulence factors – such as toxins (e.g. diphtheria toxin) [JCM (1997) 35 1651–1655]; (ii) detecting genes that confer resistance to antibiotics (e.g. the *mecA* gene in staphylococci [JCM (1999) 37 3029–3030]); (iii) surveying the diversity of species in environmental samples by means of BROAD-RANGE PRIMERS; (iv) DIFFERENTIAL DISPLAY.

(See also ARBITRARILY PRIMED PCR; ASYMMETRIC PCR; HOT-START PCR; MULTIPLEX PCR; NESTED PCR; REP-PCR; REVERSE TRANSCRIPTASE PCR.)

[PCR in clinical microbiology: Book ref. 221, pp 56–125.]

**PCR DIG-ELISA** See PCR.

**PCR-ISH** See IN SITU PCR.

**PCR-RFLP** See RFLP.

**PCR-ribotyping** An alternative to RIBOTYPING (q.v.) in which, initially, PCR is used to amplify a particular sequence in the *rrn* operon (usually the intergenic spacer region between the 16S and 23S genes); in many bacteria the chromosome contains multiple copies of this sequence and, moreover, the length of the sequence may vary even within the same chromosome. The amplicons are examined by gel electrophoresis, giving a fingerprint of the strain under test. Strains are classified into 'PCR ribotypes' on the basis of differences in their fingerprints. PCR-ribotyping has been used e.g. for typing strains of *Burkholderia* [JCM (1992) 30 2084–2087] and *Clostridium difficile* [RMM (1997) 8 (supplement 1) S55–S56], and detecting species of *Rhizobium* [LAM (1999) 28 137–141].

**PCR-SSCP** See SSCP.

**PDGF** Platelet-derived growth factor.

**pea early-browning virus** See TOBRAVIRUSES.

**pea enation mosaic virus (PEMV)** An ssRNA-containing PLANT VIRUS which has a narrow host range; transmission occurs (circulatively) via aphids (e.g. *Acyrtosiphon pisi*). Virion: icosahedral, ca. 28 nm diam.; two types occur, differing in  $S_w^{20}$ . Genome: two molecules of linear positive-sense ssRNA (MWts ca. 1.7 and  $1.3 \times 10^6$ ), sometimes with a third molecule of MWt ca.  $0.3 \times 10^6$ . PEMV replicates in the nucleus; vesicular cytopathological structures arise from the nuclear membrane.

**pea leaf roll virus** See LUTEOVIRUSES.

**pea mosaic virus** See POTYVIRUSES.

**pea streak virus** See CARLAVIRUSES.

**peach leaf curl** See TAPHRINA.

**peach rosette mosaic virus** See NEPOVIRUSES.  
**peanut (toxicity associated with fungal contamination)** See AFLA-TOXINS.

**peanut clamp virus** See TOBRAVIRUSES.

**peanut clump virus** See SOIL-BORNE WHEAT MOSAIC VIRUS and TOBAMOVIRUSES.

**peanut mottle virus** See POTYVIRUSES.

**peanut stunt virus** See CUCUMOVIRUSES.

**peanut yellow mottle virus** See TYMOVIRUSES.

**pear decline disease** A YELLOWS disease of pear trees caused by an MLO; oxytetracycline hydrochloride is used for control.

**peat scours** See SCOURS.

**pébrine** See NOSEMA.

**pectase** See PECTIC ENZYMES.

**pectates** Salts of pectic acid – see PECTINS.

**pectic acid** See PECTINS.

**pectic enzymes** ('pectinases') Enzymes which degrade PECTINS; they are widely distributed among microorganisms. There are two broad categories of pectic enzyme: those which de-esterify pectins (pectinesterases) and those which degrade the galacturonan backbone chain (depolymerases).

*Pectinesterase* (pectin methyl-esterase, pectase, pectin pectyl-hydrolase, EC 3.1.1.11) de-esterifies pectins, producing methanol and pectic acid; pectinesterases occur in higher plants, numerous fungi (including some yeasts) and some bacteria.

*Pectic depolymerases* include both hydrolases, which hydrolyse glycosidic linkages in the galacturonan, and lyases, which cleave a glycosidic bond with the formation of a double bond between C-4 and C-5 in the residue at the newly formed non-reducing end ( $\beta$ -elimination). These enzymes vary in their specificities; most function mainly or only on non-esterified galacturonans (pectic acids). Depolymerases which act as endoenzymes include e.g. *endopolygalacturonase* (poly-(1  $\rightarrow$  4)- $\alpha$ -D galacturonide glycanhydrolase, EC 3.2.1.15), produced by many plant-pathogenic and saprotrophic fungi and bacteria and by some yeasts; *endopectate lyase* (polygalacturonic acid *trans*-eliminase, endopolygalacturonate lyase, EC 4.2.2.2), produced by various bacteria – especially SOFT ROT (2) agents – and some plant-pathogenic fungi; and *endopectin lyase* (pectin lyase, polymethoxylgalacturonide lyase, EC 4.2.2.10 – the only depolymerase specific for highly esterified pectins), produced mainly by fungi. Exoenzymes include *exopolygalacturonase* (poly (1  $\rightarrow$  4)- $\alpha$ -D-galacturonide galacturonohydrolase, EC 3.2.1.67), produced e.g. by plants, fungi and some bacteria; and *exopectate lyase* (EC 4.2.2.9 – an enzyme which liberates unsaturated dimers or, less commonly, trimers [e.g. JGM (1982) 128 2661–2665] from the reducing end of a pectic acid), produced e.g. by certain bacteria.

Pectinolytic organisms can be important plant pathogens and causal agents of spoilage of fresh and preserved fruit and vegetables (see e.g. SOFT ROT (2); PICKLING; CANNING). Many plants have cell wall-associated proteins which act as inhibitors of endopolygalacturonases *in vitro*; these proteins are thought to serve a defensive role against invasion by pectinolytic pathogens, although it has been reported that they may not be effective *in vivo* [PP (1985) 34 54–60]. (See also TANNINS.) Pectinolytic organisms also fulfil useful roles: see e.g. COFFEE; RETTING; RUMEN. Preparations of pectic enzymes, obtained mainly from *Aspergillus niger*, are used e.g. to facilitate pressing in the extraction of fruit juices, to clarify (reduce turbidity and viscosity of) fruit juices, etc. (See also ENZYMES.)

**pectic polysaccharides** (*syn.* pectic substances) Polysaccharides obtained from isolated plant cell walls by extraction with

boiling water (with or without EDTA) or dilute acid (cf. HEMICELLULOSES); they generally include PECTINS, pectic acid and its salts (pectates), and certain neutral polysaccharides (e.g. arabinogalactans) which occur in association with pectins.

**pectic substances** *Syn.* PECTIC POLYSACCHARIDES.

**pectin** See PECTINS.

**pectin methyl-esterase** See PECTIC ENZYMES.

**pectinases** See PECTIC ENZYMES.

**pectinate** (1) (*adj.*) Arranged like the teeth of a comb. (2) (*noun*) A salt of 'PECTINIC ACID'.

**Pectinatus** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which have been isolated from spoiled beers. Cells: round-ended, slightly curved or helical rods or filaments, 0.7–0.8  $\times$  2.0–32.0  $\mu$ m; lateral flagella arise in a line along the concave side of the cell. Acid is formed from the fermentation of e.g. arabinose, fructose, glucose, glycerol, lactate, maltose and mannitol; lactate fermentation yields acetic, propionic and succinic acids, and CO<sub>2</sub>, as major products. GC%: ca. 40. Type species: *P. cerevisiophilus*.

**pectinella** One of the circumferential bands of cilia which encircle some ciliates (e.g. *Didinium*). (cf. TROCHAL BAND.)

**pectinesterases** See PECTIC ENZYMES.

**pectinic acid** An outmoded term for colloidal galacturonans which have a methyl ester content intermediate between that of PECTINS and pectic acids.

**pectinolytic** (pectolytic) Able to degrade PECTINS – see PECTIC ENZYMES.

**pectins** The major component of the PECTIC POLYSACCHARIDES. Pectins consist essentially of (1  $\rightarrow$  4)- $\alpha$ -D-linked galacturonic acid residues (= pectic acid); a variable number of the C-6 carboxyl groups are methyl-esterified, and, commonly,  $\alpha$ -L-rhamnose residues occur at intervals within the chain (forming a rhamnogalacturonan). Other neutral sugars (e.g. L-arabinose, D-galactose) may occur in (usually short) side-chains. Pectins occur in the primary cell walls and intercellular regions of plants (many fruits have a high pectin content); they also occur in the cell walls of certain algae.

Pectins are powerful gelling agents and are widely used in the food industry (e.g. as a setting agent in jams) and in pharmaceuticals and cosmetics. Pectin-degrading enzymes (PECTIC ENZYMES) are produced by a wide range of microorganisms but not by higher animals or by man. (See also RUMEN.)

**Pectobacterium** See ERWINIA (Carotovora group).

**pectolytic** *Syn.* PECTINOLYTIC.

**Pediastrum** A genus of freshwater colonial green algae (division CHLOROPHYTA). Each colony is flat and disc-like (up to ca. 100  $\mu$ m diam.) and is typically made up of a central cell surrounded by concentric rings of cells; the outermost cells each have two lobes projecting radially outwards, so that the colony resembles a miniature gear-wheel.

**pedicel** A small stalk. In the fruiting bodies of some myxobacteria: a branch of the common (main) stalk bearing a single sporangium.

**Pedinomonas** See MICROMONADOPHYCEAE.

**pediocin PA-1** A 44-amino-acid, pore-forming BACTERIOCIN produced by species of *Pediococcus*; it is active against *Listeria* spp.

**Pediococcus** A genus of Gram-positive bacteria of the family Streptococcaceae. Cells: non-motile cocci (ca. 1  $\mu$ m diam.), commonly in pairs and tetrads. Certain vitamins and amino acids are essential for growth. Growth occurs optimally under microaerobic conditions; glucose is fermented homofermentatively and anaerogenically to DL-lactic acid, L(+)-lactic acid generally predominating. (See also LACTIC ACID FERMENTATION.)

## pedology

The nomenclature of the species of *Pediococcus* is confused [for discussion see Book ref. 143, pp. 179–211]. Some authors have recognized the following species as validly published: *P. acidilactici*, *P. damnosus* (formerly *P. cerevisiae*), *P. dextrinicus*, *P. halophilus*, *P. parvulus* and *P. pentosaceus*. (See also BEER SPOILAGE; IDL; LACTIC ACID BACTERIA; MALOLACTIC FERMENTATION; MISO; PICKLING; SOY SAUCE.)

**pedology** Soil science.

**Pedomicrobium** A genus of budding PROSTHECATE BACTERIA found e.g. in soils; the life cycle is similar to that of HYPHOMICROBIUM but differs e.g. in that the mother cell may have many prosthecae and typically bears a coating of iron and/or manganese compounds.

**peduncle disease** See COLD WATER DISEASE.

**PEF** PULSED ELECTRIC FIELD.

**pefloxacacin** See QUINOLONE ANTIBIOTICS.

**PEG** POLYETHYLENE GLYCOL.

**pegylated** Refers to the form of a given molecule, prepared in vitro, which consists of a construct containing a polyethylene glycol moiety.

**peitschengeissel flagellum** See FLAGELLUM (b).

**Pekilo process** See SINGLE-CELL PROTEIN.

**Pekin duck hepatitis B virus** *Syn.* DUCK HEPATITIS B VIRUS.

**pelagic** May refer to that region of an aquatic habitat (e.g. lake, sea) comprising the entire body of water but excluding the BENTHIC zone, or may refer to organisms living in that region. (See also NEKTON; NEUSTON; PLANKTON.)

**Pelagophycus** See PHAEOPHYTA.

**Pelargonium blackleg** See BLACKLEG (2).

**pellet** (1) The packed sedimented material formed by CENTRIFUGATION. (2) A spherical colony formed by the growth of a mycelial fungus within a liquid medium.

**pellicle** (1) (*bacteriol.*, *mycol.*) A continuous or fragmentary film, or a mat of organisms, formed at the surface of a liquid culture by certain bacteria or fungi.

A *bacterial* pellicle may comprise bacterial cells, extracellular products, or both. Strains of *Acetobacter xylinum* (see ACETOBACTER) form a tough pellicle of CELLULOSE; each cell produces a single cellulose ribbon composed of a number of microfibrils which apparently emanate from distinct sites along the outer membrane [Book ref. 38, pp. 526–528]. The cellulose ribbons from many cells aggregate to form a network which floats to the surface of the medium, carrying the cells with it – presumably a mechanism for maintaining the organisms in the upper, oxygenated regions of the medium.

Among *fungi*, pellicles are formed on liquid cultures e.g. by various yeasts (see e.g. ‘flor’ yeasts in WINE-MAKING) and by some mycelial fungi (e.g. *Penicillium* spp).

(2) (*mycol.*) Any superficial membranous structure which can easily be removed from the tissues beneath it.

(3) (*protozool.*) A composite membranous structure which forms the limiting envelope in many protozoa. In some flagellates (e.g. *Trypanosoma*) the pellicle consists essentially of the cytoplasmic membrane (= plasmalemma) supported from beneath by a system of microtubules; some authors do not regard such a simple type of cell envelope as a pellicle. (cf. EUGLENOID FLAGELLATES.) In coccidia (phylum APICOMPLEXA) the pellicle of the sporozoite and merozoite stages consists of three unit-type membranes, the outermost membrane (plasmalemma) enclosing the entire cell; the middle and inner membranes are closely apposed and together form the inner pellicular complex – a structure which underlies the plasmalemma (except at the MICROPORES and at regions delimited by the POLAR RINGS)

and is separated from it by an electron-translucent layer ca. 15–20 nm thick. In the apicomplexan *Gregarina garhami* the three-membrane-thick pellicle forms a series of longitudinal folds, the crests of which are associated with two sets of longitudinal filaments which have been postulated to have a role in gliding motility [JUR (1984) 88 66–76].

The typical ciliate pellicle consists of three layers of unit-type membrane, the outermost of which (the plasmalemma) covers the entire organism, including the cilia. The two inner layers are sometimes called ‘alveolar membranes’; the space between these membranes is partitioned, forming a number of vesicles or alveoli which lie beneath the plasmalemma. Adjacent alveoli may or may not be in communication; in some species (see e.g. COLEPS) the alveoli contain inorganic deposits and constitute a semi-rigid endoskeleton. The alveolar pellicle does not cover the entire organism, and in some ciliates it forms only a relatively small part of the cell envelope. Even when the alveolar pellicle forms the major part of the cell envelope it is absent in the region of the CYTOSTOME, and it is characteristically penetrated by the MUCOCYSTS and by the kinetosomes of the cilia – which penetrate below the level of the innermost membrane. The inner surface of the innermost membrane may be in contact with a dense fibrillar layer of peripheral cytoplasm (the *epiplasm*); the epiplasm may be the site of connection and/or anchorage of subpellicular structures and/or pellicular structures. Some authors consider the epiplasm to be part of the pellicle.

(See also CORTEX; KINETY; SILVER LINE SYSTEM.)

**pellis** (cutis; cuticle) (*mycol.*) Non-velar cortical layers of a basidiocarp.

**pellucid** Transparent or translucent.

**Pelobacter** A genus of Gram-negative, rod-shaped anaerobic bacteria. Metabolism: fermentative; sugars are not utilized. Species include *P. acidigallici*; *P. venetianus* [name validation: IJSB (1984) 34 91–92]; *P. carbinolicus* and *P. propionicus* [name validation: IJSB (1984) 34 355–357].

**Pelobiontida** An order of naked, typically multinucleate amoebae (class LOBOSEA) which, when in motion, are typically cylindrical or elongate-ovoid, and which lack mitochondria but contain endosymbiotic bacteria. Flagellate stages are unknown. The organisms are free-living in freshwater (typically microaerobic) habitats, feeding mostly on non-motile or slow-moving algae (e.g. diatoms). The order includes the genus *Pelomyxa*. (See also PSEUDOPODIUM and UROID.)

**Pelochromatium roseo-viride** See CHLOROCHROMATIUM AGGREGATUM.

**Pelodictyon** A genus of photosynthetic bacteria (family CHLOROBIACEAE). The cells are rod-like or coccoid and contain GAS VACUOLES. Cell division occurs predominantly by binary fission; cells of *P. clathratiforme* form chains which, owing to the occurrence of ternary fission in some cells in the chains, develop into colonial structures consisting of three-dimensional networks.

**Pelodinium** See ODONTOSTOMATIDA.

**Pelomyxa** See PELOBIONTIDA.

**Pelosisigma** A proposed genus of filamentous bacteria which occur, in S-shaped bundles, on mud and in fresh and brackish waters. [Book ref. 22, p. 138.]

**pelotons** Coils or balls of fungal hyphae within root cortical cells in certain endomycorrhizas.

**Peltier system** (thermocyclers) See THERMOCYCLER.

**Peltigera** A genus of foliose LICHENS (order PELTIGERALES). Photobiont: *Coccomyxa* (e.g. in *P. aphthosa*) or *Nostoc* (e.g. in *P. canina*); *Coccomyxa*-containing species commonly have *Nostoc*-containing cephalodia (see CEPHALODIUM). Thallus: typically large and more or less deeply lobed, lobes ca. 1–10 cm or

more in length; only the upper surface has a cortex, the lower surface often being tomentose and marked with 'veins'. Conspicuous rhizines are present on the lower surface in many species. Apothecia are formed on the upper surface – often borne on narrow, erect, stalk-like extensions of the thallus margin. Species occur e.g. on soil, rotting logs etc; many are widely distributed.

**Peltigerales** An order of fungi of the ASCOMYCOTINA; members include foliose LICHENS (photobiont green or cyanobacterial) which often have cephalodia. Ascocarp: APOTHECIOID, with filiform paraphyses not forming a distinct epithecium. Asci: bitunicate, cylindrical. Ascospores are often elongated and multiseptate. Genera: e.g. LOBARIA, NEPHROMA, PELTIGERA, PSEUDOCYPHELLARIA, SOLORINA, STICTA.

**peltigeroside**  $\beta$ -D-Galactofuranosyl-(1  $\rightarrow$  3)-D-mannitol, found in *Peltigera* spp.

**Pelvetia** See PHAEOPHYTA.

**penhigus neonatorum** See SCALDED SKIN SYNDROME.

**penams** Compounds which contain the penicillin nucleus (see  $\beta$ -LACTAM ANTIBIOTICS). (cf. PENEMS.)

**peniclovir** A guanine nucleoside analogue ANTIVIRAL AGENT; it is effective against alphaherpesviruses. Peniclovir is used e.g. as a topical agent (1% in creams) for the treatment of labial and genital herpes simplex infections. (See also FAMCICLOVIR.)

**penems** A class of antibiotics; a penem contains a penicillin-like nucleus in which a double bond occurs between C-2 and C-3 (see  $\beta$ -LACTAM ANTIBIOTICS, Figure (a)).

**penicillic acid** A secondary metabolite of certain *Penicillium* and *Aspergillus* spp; it is carcinogenic in rats when administered by subcutaneous injection.

**penicillin** Any of the PENICILLINS, or (specifically) penicillin G.

**penicillin acylase** *Syn.* PENICILLIN AMIDASE.

**penicillin amidase** (penicillin acylase; penicillin amidohydrolase) An enzyme (EC 3.5.1.11) produced by many Gram-positive and Gram-negative bacteria; it cleaves the side-chain of PENICILLINS to form 6-aminopenicillanic acid.

**penicillin amidohydrolase** *Syn.* PENICILLIN AMIDASE.

**penicillin-binding proteins** (PBPs) Proteins which occur in the cell envelope of Gram-positive and Gram-negative bacteria and which bind covalently to PENICILLINS and to related  $\beta$ -LACTAM ANTIBIOTICS; according to species, there may be up to eight distinct types of PBP in a given cell. Different PBPs vary in their ability to bind particular  $\beta$ -lactam antibiotics.

The PBPs of a given species are numbered in order of decreasing MWt (PBP-1, PBP-2 etc.); similar patterns of PBPs occur in taxonomically related species.

PBPs have enzymic roles in the biosynthesis of PEPTIDOGLYCAN; they are thus involved e.g. in cell elongation and septum formation. (See also CELL CYCLE and THREE-FOR-ONE MODEL.)

Some PBPs are essential for cell viability, and these constitute the killing sites of the  $\beta$ -lactam antibiotics; a  $\beta$ -lactam antibiotic acylates (thus inactivating) a catalytic site on a PBP.

Low-MWt (~40000–50000) PBPs are typically efficient *carboxypeptidases* (see PROTEASES) and/or endopeptidases. In vivo they appear to play a subordinate role, and are apparently non-essential for cell viability.

High-MWt (>60000) PBPs are less abundant in the cell but at least one type appears to be essential for cell viability; they are generally more sensitive than the low-MWt PBPs to penicillins. The enzymic roles of these PBPs include mediation in *transglycosylation* and *transpeptidation*, i.e. the assembly of glycan subunits and the formation of peptide cross-links, respectively.

In *Escherichia coli* the high-MWt PBPs are PBP-1A, PBP-1B, PBP-2 and PBP-3 (see below).

PBP-1A and PBP-1B (encoded by genes *mrcA* and *mrcB*, respectively) are involved in cell elongation; inactivation of both of these PBPs leads to rapid lysis of growing cells.

PBP-2 (encoded by gene *pbpA*) is essential for maintaining the rod shape of the cell during growth; a null mutation in *pbpA* gives rise to spherical cells that eventually lyse. PBP-2 may be capable of substituting for PBP-1B in mutant cells which lack a functional PBP-1B. (See also MECILLINAM.)

PBP-3 (encoded by gene *ftsI*; also called *pbpB*) is required for peptidoglycan synthesis in the SEPTUM. Inactivation of PBP-3 leads to formation of filaments and eventual lysis.

The low-MWt PBPs (PBP-4, PBP-5, PBP-6) are encoded by genes *dacB*, *dacA* and *dacC*, respectively.

PBPs 4 and 5 have carboxypeptidase activity, PBP-5 being responsible e.g. for cleavage of the terminal D-ala from the pentapeptide side chain.

[Location of PBPs in *E. coli*: JB (1986) 165 269–275.]

In *Staphylococcus aureus*, PBP 2a (= PBP2') is associated with high-level resistance to methicillin: see MRSA.

**penicillin G** *Syn.* BENZYL PENICILLIN.

**penicillin N** (*syn.* cephalosporin N; synnematin B) An antibiotic (6-(D- $\alpha$ -aminoadipyl)aminopenicillanic acid) produced by *Acremonium kiliense* (= *Cephalosporium acremonium*) (cf. PENICILLINS). Isopenicillin N has an L- $\alpha$ -aminoadipyl side-chain.

**penicillin V** *Syn.* PHENOXYMETHYL PENICILLIN.

**penicillinase** A  $\beta$ -LACTAMASE active mainly or solely against PENICILLINS, forming PENICILLOIC ACIDS.

Penicillinase production (e.g. by staphylococci) can be demonstrated e.g. with *N*-phenyl-1-naphthylamine-azo-*o*-carboxybenzene, a substance which is yellow and soluble in alkaline form, purple and insoluble in acid form. Agar plates bearing growth of the test organism are flooded with a solution of the alkaline (yellow) form, dried, and then flooded with a solution of penicillin; penicillinase-producing colonies develop a purple colour. Other methods are based on the ability of penicilloic acid to react with iodine and to decolorize a starch-iodine complex; for example, the bacteria are grown on an agar medium containing 1% w/v soluble starch, and the plate is flooded with a solution of benzylpenicillin and 0.1 N iodine in KI; penicillinase-producing colonies are each surrounded by a white halo against a blue-black background. (See also PADAC.)

[Staphylococcal penicillinase: Book ref. 44, pp. 768–775.]

**penicillins** A class of antibiotics, each characterized by a  $\beta$ -lactam ring fused to a thiazolidine ring (see  $\beta$ -LACTAM ANTIBIOTICS for structures and mode of action). The original penicillins (BENZYL PENICILLIN and PHENOXYMETHYL PENICILLIN) are not effective against  $\beta$ -LACTAMASE-producing Gram-positive bacteria, and they are generally rather ineffective against Gram-negative species owing to poor penetration of the outer membrane; they are produced by species of *Penicillium* (cf. PENICILLIN N). Cleavage of benzylpenicillin by PENICILLIN AMIDASE yields 6-aminopenicillanic acid (6-APA), a precursor from which can be prepared many semi-synthetic penicillins with improved antimicrobial properties. Semi-synthetic penicillins which are resistant to many  $\beta$ -lactamases (particularly those of staphylococci) include e.g. *methicillin* (6-(2,6-dimethoxybenzamido)penicillanic acid), *nafcillin* (6-(2-ethoxy-1-naphthamido)penicillanic acid), *cloxacillin*, *dicloxacillin*, *flucloxacillin* and *oxacillin*; typically, these penicillins are poorly effective against Gram-negative bacteria. Improved activity against Gram-negative species (coupled with resistance to some  $\beta$ -lactamases) is given by *ampicillin* (6-( $\alpha$ -aminobenzylamido)penicillanic acid) and its derivatives (e.g.

## penicilliosis

AMOXICYLLIN, APALCILLIN, *azlocillin*, *becampicillin*, *mezlocillin*, *pivampicillin*, and *talampicillin*), and by *carbenicillin* (6-( $\alpha$ -carboxybenzamido)penicillanic acid) and its derivatives (e.g. *carfecillin* and *ticarcillin*); typically, these penicillins are less effective than benzylpenicillin against Gram-positive species.

Penicillins for oral administration (which must be acid-stable) include ampicillin, phenoxymethylpenicillin and phenoxethylpenicillin; benzylpenicillin, carbenicillin and methicillin are administered parenterally. Infrequently, penicillins can act as ALLERGENS, the various penicillins commonly exhibiting cross-allergenicity (cf. CEPHALOSPORINS). (See also MECILLINAM.)

[Clinical pharmacology and therapeutic uses of penicillins (review): *Drugs* (1993) 45 866–894.]

**penicilliosis** A disease of man or animals caused by a species of *Penicillium*. For example, *P. marneffei* can cause a progressive, disseminated, fatal human disease characterized by proliferation of yeast-like fungal cells within histiocytes, followed by the development of foci of necrosis and eventually abscess formation [*AJCP* (1985) 84 323–327].

**Penicillium** A genus of fungi of the class HYPHOMYCETES; teleomorphs occur e.g. in the genus TALAROMYCES. The organisms are widespread in nature and are characteristically saprotrophic; however, *P. marneffei* can cause PENICILLIOSIS (see also SUBEROSIS), and many species form toxins (see e.g. CHLOROPEPTIDE, CITREOVIRIDIN, CYCLOPIAZONIC ACID, ERGOCHROMES, FUMITREMORGIN, GLIOTOXIN, OCHRATOXINS, PATULIN, PENITREMS, RUBRATOXINS, VERRUCOLOGEN). Some species can cause spoilage of various types of material (see e.g. BREAD SPOILAGE, CHEESE SPOILAGE, PAPER SPOILAGE), some are used in manufacturing processes (see e.g. CHEESE MAKING), and some produce useful antibiotics (see e.g. GRISEOFULVIN, MYCOPHENOLIC ACID, PENICILLINS).

*Penicillium* spp form a well-developed septate mycelium; in most species the aerial mycelium is colourless, but mycelium within the substratum may exhibit distinctive colours – the underside ('reverse') of a colony often being some shade of yellow, orange, red or purple; diffusible pigments are formed by some species. The conidiophores each consist essentially of an erect or prostrate hypha (*stipe*), often ca. 100–250  $\mu$ m in length, which may be unbranched or branched. The tip of an unbranched conidiophore may terminate in a cluster of phialides (see CONIDIUM) (as in e.g. *P. frequentans*) or in a cluster of metulae (see METULA) (as in e.g. *P. variabile*). In branched conidiophores, each branch (*ramus*) terminates in one or more metulae. (The term 'ramus' is generally reserved for any cell or hypha which occurs between a metula and its stipe; however, confusingly, the terms 'ramus' and 'metula' are sometimes used as though they were synonymous.) The terminal region of a conidiophore (including phialides, metulae and/or rami) is termed the *penicillus*. In most species the conidiophores occur as discrete structures, but in e.g. *P. claviforme* and *P. concentricum* they form synnemata, and in e.g. *P. expansum* they form coremia. The conidia are spherical to ellipsoidal, aseptate, up to ca. 5  $\mu$ m; in masses, they may be e.g. blue-green, grey-green or yellow, according to species. Colonies may appear e.g. velvety or woolly, and in some species they typically bear surface drops of exudate. Sclerotia are formed e.g. by *P. raistrickii* and *P. thomii*.

Species include e.g. *P. brevicompactum*, *P. charlesii*, *P. chrysogenum*, *P. citreoviride*, *P. digitatum*, *P. frequentans*, *P. griseofulvum*, *P. islandicum*, *P. italicum*, *P. janthinellum*, *P. marneffei*, *P. oxalicum*, *P. roqueforti*, and *P. rubrum*.

[Identification manual and atlas of *Penicillium* spp: Book ref. 185.]

**Penicillium brevicompactum virus** See MYCOVIRUS.

**Penicillium chrysogenum virus** See MYCOVIRUS.

**Penicillium cyaneofulvum virus** See MYCOVIRUS.

**Penicillium stoloniferum virus S** See MYCOVIRUS.

**penicilloic acids** Compounds formed when the  $\beta$ -lactam (C–N) bond in penicillins (see  $\beta$ -LACTAM ANTIBIOTICS) is hydrolysed by a  $\beta$ -LACTAMASE.

**penicillopepsin** An acid aspartyl PROTEASE from *Penicillium janthinellum*; it has two catalytically important aspartyl residues in its active centre.

**penicillus** See PENICILLIUM.

**Penicillus** A genus of siphonaceous, calcified green seaweeds related to HALIMEDA; when mature, the thallus bears an apical tuft of branches and somewhat resembles a shaving brush.

**peniculus** A ribbon-like membranelle consisting of a number of rows of cilia; peniculi occur in the buccal cavity of *Paramecium* and related ciliates.

**Peniophora** See APHYLLOPHORALES (Corticaceae) and HETEROBASIDIUM.

**penitrems** Steroid MYCOTOXINS produced by *Penicillium* spp – e.g. *P. verrucosum* (*P. cyclopium*); ingestion by e.g. sheep, cattle or horses of feed contaminated with penitrems can lead to weakness, tremors, convulsions and death. These toxins (produced by soil penicillia) may play a role in the pathogenesis of *ryegrass staggers*: a condition associated with grazing perennial ryegrass (*Lolium perenne*) pastures. [Book ref. 33, pp. 1161–1162, 1167–1168.]

**Penium** A genus of placoderm DESMIDS. The cells are cylindrical, round-ended, and have a median suture line but no sinus (cf. CLOSTERIUM).

**pennate diatoms** See DIATOMS.

**Pennoxide** A STERILANT containing ETHYLENE OXIDE (12%) and dichlorodifluoromethane (88%).

**penny bun** See BOLETALES.

**pentachlorophenol** See PHENOLS and BIOREMEDIATION.

**pentamer** See ICOSAHEDRAL SYMMETRY.

**pentamidine isethionate** An aromatic DIAMIDINE used e.g. in the treatment of African trypanosomiasis and *Pneumocystis carinii* pneumonia.

**Pentatrichomonas** See TRICHOMONAS.

**Penthesta process** See AIV PROCESS.

**pentitols** Five-carbon POLYOLS (e.g. ARABITOL, RIBITOL, xylitol). Pentitols can be metabolized e.g. by many yeasts and by certain bacteria; e.g., strains of *Lactobacillus casei* metabolize xylitol and ribitol as shown in Appendix III(d), the end-products including acetate, ethanol (cf. PENTOSE), and a mixture of D- and L-lactate (even though L-lactate is the main product of glucose fermentation in this species).

**penton** See ADENOVIRIDAE.

**pentosans** Polysaccharides consisting of PENTOSE residues: see e.g. XYLANS.

**pentose phosphate cycle** *Syn.* HEXOSE MONOPHOSPHATE PATHWAY. (cf. CALVIN CYCLE.)

**pentose phosphate pathway** *Syn.* HEXOSE MONOPHOSPHATE PATHWAY.

**pentoses** Five-carbon sugars. Aldopentoses (general formula CH<sub>2</sub>OH(CHOH)<sub>3</sub>CHO) include e.g. ARABINOSE, RIBOSE and XYLOSE. The corresponding ketopentoses (general formula CH<sub>2</sub>OH.CO.(CHOH)<sub>2</sub>CH<sub>2</sub>OH) are called pentuloses (e.g. RIBULOSE, XYLULOSE). (cf. PENTITOLS and PENTOSANS.)

Pentoses can be used as substrates by many bacteria and fungi, being metabolized via different pathways in different species. Heterofermentative LACTIC ACID BACTERIA and 'homofermentative' streptococci, pediococci and streptobacteria ferment pentoses to equimolar quantities of lactic and acetic

acids via xylulose 5-phosphate and the phosphoketolase reaction (Appendix III (d and b), [AvL (1983) 49 209–224]); the pentoses are taken up either by specific permeases or by PEP-dependent phosphotransferase systems (see PTS). (Thermobacteria are unable to ferment pentoses.) In e.g. *Bacillus* spp, some enterobacteria and certain yeasts pentoses/pentuloses are converted [as in Appendix III(d)] to xylulose 5-phosphate, ribulose 5-phosphate or ribose 5-phosphate which can enter the HEXOSE MONOPHOSPHATE PATHWAY [Appendix I(b)].

(See also ARA OPERON and INDUSTRIAL ALCOHOL.)

**pentostat** See VIDARABINE.

**pentraxin proteins** See ACUTE-PHASE PROTEINS.

**pentulose** See PENTOSES.

**PEP** Phosphoenolpyruvate.

**PEP-dependent phosphotransferase system** See PTS.

**PEP potential** The sum of the intracellular concentrations of phosphoenolpyruvate (PEP) and 2-phosphoglycerate [JB (1977) 130 583–595]. In cells of e.g. streptococci, high intracellular levels of these compounds develop during starvation, ensuring that when sugars become available they can be taken up rapidly by the (PEP-dependent) PTS. (See also FLUORIDES.)

**peplomer** See ENVELOPE (sense 1).

**peplos** *Syn.* ENVELOPE (sense 1).

**pepsin** A PROTEASE (EC 3.4.23.1) which is present in the stomach in most vertebrates and which shows maximum activity at low pH (ca. 1–2); it is denatured at pH >6.

**pepstatin** A peptide inhibitor of aspartyl proteases such as PENICILLOPEPSIN.

**peptidase** *Syn.* PROTEASE.

**peptide antibiotics** See e.g. BACITRACIN, CECROPINS, DEFENSINS, EDEINES, GRAMICIDINS, POLYMYXINS, TYROCIDINS.

**peptide nucleic acid (PNA)** See PNA.

**peptidoglycan** (murein; mucopeptide; glycosaminopeptide) A heteropolymer which is found in the CELL WALL of most bacteria (cf. e.g. PASTEURIA and PLANCTOMYCES), and which is also present in the cortex of bacterial ENDOSPORES, but which is not found in members of the ARCHAEA (cf. PSEUDOMUREIN). Peptidoglycan (PG) is the component which is primarily responsible for the mechanical strength of the cell wall (protecting the cell e.g. against osmotic lysis) and for maintaining the shape of the cell.

*Structure of PG.* PG consists essentially of linear, heteropolysaccharide backbone chains that are cross-linked, via short peptides, to form a net-like molecule (the ‘murein sacculus’ – see (a) in the figure); in almost all cases the sacculus envelops the bacterial protoplast (incomplete, or ‘patchy’, peptidoglycan occurs e.g. in *Myxococcus xanthus*: see MYXOBACTERIALES).

In *Escherichia coli*, the backbone chains consist of alternating (1 → 4)-β-linked residues of *N*-acetyl-D-glucosamine (GlcNAc) and its 3-*O*-D-lactyl ether derivative, *N*-acetylmuramic acid (MurNAc). A MurNAc residue may be linked, via its carboxyl group, to a short peptide (the *stem peptide*) – commonly the tetrapeptide L-alanine–D-glutamic acid–*meso*-diaminopimelic acid–D-alanine. Cross-links between the backbone chains are formed directly between the D-alanine of one stem peptide and the *meso*-diaminopimelic acid (*meso*-DAP) of another on an adjacent chain (see (b) in figure). The backbone chains run *perpendicular* to the long axis of the cell.

Each peptide bridge shown in the figure links a given backbone chain to *one* of the other backbone chains. However, as described in the legend, some peptide bridges link together more than two backbone chains, and such links are essential features in the THREE-FOR-ONE MODEL of peptidoglycan growth.

In many other Gram-negative bacteria the PG is more or less similar to that of *E. coli*, but many variations in PG structure occur among the Gram-positive bacteria; for example, backbone chains in *Mycobacterium* spp contain *N*-glycolylmuramic acid, and in *Staphylococcus aureus* 30–50% of the muramic acid residues are not acetylated. Even in strains of *Neisseria gonorrhoeae*, though, the PG is extensively *O*-acetylated, and it contains 1,6-anhydromuramyl residues [JGM (1985) 131 3397–3400]. The stem peptides may contain e.g. L-lysine in place of *meso*-DAP (in *S. aureus*), and isoglutamine instead of D-glutamic acid (in *S. aureus* and mycobacteria). Cross-links between stem peptides may occur via a short ‘interpeptide bridge’ (e.g. a penta- or hexaglycine bridge in *S. aureus*), and may occur in different positions in different species. The degree of cross-linking also varies with species, being generally more extensive in Gram-positive species. [PG structure in staphylococci and mycobacteria: Book refs 44 and 54, respectively.]

*Classification based on PG structure.* The structure of PG in a given strain tends to be constant and independent of environmental conditions (although, exceptionally, the amino acid content of the interpeptide bridge in staphylococcal PG can be affected to some extent by the availability of amino acids in the growth medium). PG structure may therefore be a useful feature in taxonomy. Depending on the mode of cross-linking, two basic ‘PG types’ can be recognized. In *group A* PGs, cross-links occur between the distal amino group of the diamino acid in position 3 of one stem peptide and the D-alanine in position 4 of another stem peptide; the cross-link may be direct (as in *E. coli*) or may involve an interpeptide bridge (as in *S. aureus*). In *group B* PGs an interpeptide bridge occurs between the carboxyl group of D-glutamic acid in position 2 of one stem peptide and the carboxyl group of D-alanine in position 4 of another. Group B PGs are much less common than group A PGs; they are found in certain coryneforms (e.g. strains of *Agromyces*, *Arthrobacter*, *Brevibacterium*, *Curtobacterium* and *Microbacterium*), in certain anaerobes (e.g. *Acetobacterium woodii*) and in *Erysipelothrix rhusiopathiae*. PG is also classified e.g. on the basis of the nature of the peptide bridge and of the amino acid at position 3. (See also ACTINOMYCETALES.) [Analysis of PG composition and structure: Book ref. 138, pp 123–156.]

*Peptidoglycan in relation to the cell envelope.* In Gram-positive bacteria, PG is the major component of the cell wall and is covalently linked to e.g. TEICHOIC ACIDS. (See also e.g. WAX D.) The PG layer is significantly thicker than that found in most Gram-negative bacteria. Interestingly, the thickness of the PG layer in many cyanobacteria is similar to that typical of Gram-positive species, and in at least some strains of cyanobacteria the degree of cross-linking resembles that found in Gram-positive bacteria [JB (2000) 182 1191–1199].

In Gram-negative bacteria PG occurs as a layer between the cytoplasmic and outer membranes (see CELL WALL), and is linked covalently to the outer membrane by the BRAUN LIPOPROTEIN. (See also ADHESION SITE.) The content of PG may depend on the phase of growth: e.g. in *E. coli* the PG is reported to be 0.7–0.8% or 1.4–1.9% of the dry weight of log-phase or stationary-phase cells, respectively [JB (1985) 163 208–212]. It has been suggested that, in *E. coli*, the PG occurs as a gel which fills the entire space between the inner and outer membranes (‘periplasmic gel’) [JB (1984) 160 143–152]; it was proposed that this gel may be more extensively cross-linked near the outer membrane, becoming progressively less cross-linked towards the cytoplasmic membrane, and that periplasmic

PEPTIDOGLYCAN. The structures shown are typical of those in *Escherichia coli*; similar types of peptidoglycan are found in many other Gram-negative bacteria. (Continued on page 567.)

proteins may diffuse freely in the gel. However, this would imply *multilayered* PG, and measurements of the turnover of PG in *E. coli* have suggested that the lateral wall of the cell may contain a *monolayer* of PG, with multilayered PG probably at the poles of the cell [JB (1993) 175 7–11].

*Biosynthesis of peptidoglycan in E. coli.* The initial step in biosynthesis may be regarded as the formation of the UDP (uridine 5'-diphosphate) derivative of *N*-acetylglucosamine (here designated UDP-GlcNAc); this occurs in the cytoplasm.

Some of the UDP-GlcNAc is converted to UDP-*N*-acetylmuramic acid (UDP-MurNAc). This conversion begins with a reaction between UDP-GlcNAc and phosphoenolpyruvate catalysed by the enzyme phosphoenolpyruvate:UDP-GlcNAc enolpyruvyl transferase; the UDP-GlcNAc-3-enolpyruvyl ether intermediate is reduced to UDP-MurNAc in an NADPH-dependent reaction. (Conversion of UDP-GlcNAc to UDP-MurNAc is blocked by FOSFOMYCIN.)

Still within the cytoplasm, amino acids are added sequentially to UDP-MurNAc – by enzymes that require ATP and magnesium (or manganese) ions – to form UDP-*N*-acetylmuramylpentapeptide (the 'Park nucleotide'), which includes a terminal D-alanyl-D-alanine (added as a dipeptide). (See also CYCLOSERINE.) The Park nucleotide is then transferred, with release of UMP, to BACTOPRENOL monophosphate in the cytoplasmic membrane. UDP-GlcNAc is subsequently incorporated, with release of UDP, to complete the bactoprenol–disaccharide–pentapeptide subunit (a step which is inhibited by NISIN).

Disaccharide–pentapeptide subunits are transferred from the cytoplasmic membrane to the periplasmic region. Such transfer (blocked by VANCOMYCIN) involves release of the bactoprenol–pyrophosphate (bactoprenol–PP) – which thus remains in the cytoplasmic membrane. Bactoprenol–PP must be dephosphorylated (by a membrane-bound pyrophosphatase) to the monophosphate form before it can again act as an acceptor of the P–MurNAc–pentapeptide; dephosphorylation is inhibited by BACITRACIN.

In the periplasm, the disaccharide–pentapeptide subunits are inserted into the growing peptidoglycan sacculus. According to one scheme [Microbiology (1996) 142 1911–1918], the disaccharides are polymerized (forming new backbone chains) by *transglycosylation* reactions that involve the enzymic activities of PENICILLIN-BINDING PROTEINS (see also MOENOMYCIN). (Although *transglycosylation* reactions seem to be catalysed primarily by penicillin-binding proteins, a penicillin-insensitive glycan polymerase, distinct from PBPs, has been reported in

*E. coli* [FEBS (1984) 168 155–160].) These new chains are inserted into pre-existing peptidoglycan by the formation of new peptide cross-links (*transpeptidation* – again, involving penicillin-binding proteins) in a manner described by the THREE-FOR-ONE MODEL (q.v.).

During *transpeptidation* reactions, the terminal D-alanine of a pentapeptide is cleaved, and the transpeptidase binds to the remaining D-alanine residue to form an acyl-enzyme complex; this conserves the energy of the peptide bond and allows the formation of a new peptide bond – in the absence of ATP – between the acyl group and an amino group of a peptide on another glycan chain. The liberated D-alanine re-enters the cytoplasm via a specific transport system (see also CYCLOSERINE). (See also  $\beta$ -LACTAM ANTIBIOTICS; LYSOSTAPHIN; LYSOZYME; MUROPEPTIDES.)

One report has linked peptidoglycan synthesis with the synthesis of membrane phospholipids [Microbiology (1996) 142 2871–2877].

*PG turnover during growth in E. coli.* During growth in *E. coli* the PG is continually degraded (by periplasmic enzymes) and partly re-cycled. In one model, the PG is degraded to disaccharide–tripeptide subunits which complex with a periplasmic binding protein designated MppA; this complex is then taken up across the cytoplasmic membrane by a specific transport system (encoded by genes *oppBCDF*). Within the cytoplasm, the tripeptide (i.e. L-alanyl–D-glutamyl–*meso*-DAP) is cleaved from the subunit by an *amidase* and linked to UDP-MurNAc by a *ligase* [*mpl* gene product: JB (1996) 178 5347–5352] – thus re-entering the pathway of peptidoglycan biosynthesis [JB (1998) 180 1215–1223].

*Biosynthesis of PG in Gram-positive bacteria.* The general scenario is similar to that in Gram-negative species – differences including e.g. the use of other types of derivative in the glycan chains (such as *N*-glycolylmuramic acid in mycobacteria). When the PG contains an interpeptide bridge, this is added during the intra-membrane stage; in *Staphylococcus aureus*, for example, the pentaglycine bridge is incorporated from a specific glycyl-tRNA donor. The addition of new PG to the (thick) Gram-positive cell wall has been described by the INSIDE-TO-OUTSIDE MODEL.

*Transport through the peptidoglycan barrier.* The cell envelope must, on occasion, be permeable to certain large molecules (e.g. a DNA–protein complex during at least some types of conjugation); moreover, discontinuity in the PG is necessary for the assembly of various TRANSPORT SYSTEMS. It follows that the PG

PEPTIDOGLYCAN (*continued*) (a) The three-dimensional net-like peptidoglycan molecule: backbone chains of alternating residues of *N*-acetylglucosamine (G) and *N*-acetylmuramic acid (M) are held together by short peptides which link *N*-acetylmuramic acid residues. Each of the peptide bridges shown in the diagram links a given backbone chain to *one* other backbone chain. However, there are also peptide bridges which link together more than two backbone chains; the different types of peptide bridge in *E. coli* are briefly described in (b), below.

(b) Part of two adjacent backbone chains showing the mode of linkage between them. Each *N*-acetylmuramic acid residue bears a short *stem peptide* – in this example, the tetrapeptide L-alanine–D-glutamic acid–*meso*-diaminopimelic acid (*meso*-DAP)–D-alanine (shown in dotted boxes); in this kind of peptide bridge there is a direct, covalent link between the D-alanine of one stem peptide and the  $\epsilon$ -amino group of *meso*-DAP in the other stem peptide. As this particular type of peptide bridge involves two stem peptides, each consisting of four amino acid residues, it has been referred to as a *tetra-tetra dimer* (or a tetra-tetra). Another type of peptide bridge, the *tetra-tri-dimer* (tetra-tri), is formed from one tetrapeptide and one tripeptide. A *trimer* peptide bridge is one which links together three of the glycan backbone chains; this occurs when a stem peptide on a *third* backbone chain forms a covalent linkage with the free  $\epsilon$ -amino group (see diagram) of a dimer bridge. An appreciation of these different types of peptide bridge is essential for understanding the 3-for-1 model (THREE-FOR-ONE MODEL) of replication of the peptidoglycan sacculus.

The enzyme *lysozyme* hydrolyses the *N*-acetylmuramyl-(1→4) linkages in the backbone chain (see diagram); such activity weakens the cell envelope, and may lead to osmotic lysis.

Reproduced from *Bacteria*, 5th edition, Figure 2.7, pages 20–21, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

## peptidyl transferase

barrier must be able to be breached without sacrificing the cell's structural integrity. The assembly of transport-specific or other structures which cross the cell envelope is therefore likely to require local modification of the PG, and the assembly of some of these structures has indeed been associated with peptidoglycan metabolism [JB (1996) 178 5555–5562].

**peptidyl transferase** See PROTEIN SYNTHESIS.

**Peptococcus** A genus of Gram-positive, asporogenous, anaerobic bacteria which can ferment amino acids or peptones and which may or may not ferment carbohydrates. Cells: cocci (ca. 1 µm diam.) occurring in pairs, tetrads, clumps and short chains. The organisms have been isolated e.g. from lesions (abscesses etc) in man, often as part of a mixed microflora. (See also VAGINA MICROFLORA.) It has been proposed (mainly on the basis of GC values) that the species *P. asaccharolyticus*, *P. indolicus*, *P. magnus* and *P. prevotii* be transferred to the genus PEPTOSTREPTOCOCCUS [IJSB (1983) 33 683–698]; the GC% of the type species, *Peptococcus niger*, is ca. 51. (For *P. saccharolyticus* see STAPHYLOCOCCUS (*S. saccharolyticus*)).

**peptone** A soluble product of protein hydrolysis; peptones are not coagulated by heat, are not precipitated by saturated (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, but are precipitated by phosphotungstic acid.

**peptone water** A MEDIUM containing 1–2% PEPTONE and 0.5% NaCl in water.

**peptone-water sugars** ('sugars') A range of liquid media each of which consists of PEPTONE WATER to which has been added a particular carbohydrate (final concentration often ca. 1% w/v) and a pH indicator (e.g. ANDRADE'S INDICATOR); such media are used to determine which (if any) of a series of carbohydrates are metabolized by a given strain of microorganism. The carbohydrates used include e.g. arabinose, galactose, glucose, lactose, maltose, mannitol, mannose, rhamnose, sucrose, and xylose. Bacterial growth in a given peptone-water sugar may give rise to acid, or acid and gas, as breakdown product(s) of the carbohydrate; acid is detected by the pH indicator, and gas production is detected by a DURHAM TUBE. 'Broth sugars' are used in the same way as peptone-water sugars; in broth sugars the carbohydrate is dissolved in 'broth' (e.g. peptone and meat extract) rather than in peptone water alone. For nutritionally fastidious organisms, peptone-water sugars or broth sugars are supplemented with e.g. serum ('serum sugars' or 'serum water sugars'), or with particular growth requirement(s), in order to permit growth to occur.

Some bacteria (e.g. certain *Bacillus* spp) produce an alkaline reaction in conventional sugars owing to the formation of excess alkaline breakdown products from the peptone; since this would mask acid production from carbohydrates, such organisms are tested in e.g. inorganic salts–carbohydrate media such as AMMONIUM SALT SUGARS.

**peptone–yeast extract–glucose medium** See PYG MEDIUM.

**peptonization** The formation of PEPTONE from protein.

**Peptostreptococcus** A genus of Gram-positive, asporogenous, anaerobic bacteria which can ferment amino acids or peptones and which may or may not ferment carbohydrates. Cells: cocci (ca. 1 µm diam.) which typically occur in chains. The organisms have been isolated e.g. from lesions in man, often as part of a mixed microflora. (See also GASTROINTESTINAL TRACT FLORA.) Species: *P. anaerobius* (the type species; GC%: ca. 33–34), *P. micros* (GC%: ca. 28), *P. parvulus* (GC%: ca. 44–45) and *P. productus* (GC%: ca. 44); it has been suggested that the saccharolytic species (*P. parvulus* and *P. productus*) be omitted from the genus [FEMS (1983) 17 197–200]. It has been proposed that organisms previously referred to as *Gaffky*

*anaerobia* be included within the genus *Peptostreptococcus* as *P. tetradius* [IJSB (1983) 33 683–698]. (For *P. elsdenii* see MEGASPHAERA.) (cf. PEPTOCOCCUS.)

**per locus** See PARTITION.

**Per phenotype** Phage-encoded resistance phenotype (see LACTIC ACID STARTERS).

**PER-1 ESBLs** See β-LACTAMASES.

**peracetic acid** See HYDROGEN PEROXIDE (a).

**peracids** See HYDROGEN PEROXIDE (a).

**Peranema** A genus of colourless, heterotrophic (holozoic) EULENOID FLAGELLATES which ingest prey (unicellular algae and protozoa) by means of a specialized organelle (the *pharyngeal rod organ*) consisting of two parallel tapering rods (pharyngeal rods, trichites); essentially, ingestion of prey involves protrusion of the pharyngeal rods which adhere to the prey and then retract, the prey eventually being engulfed in a food vacuole at a cytostome situated subapically. (The rods can also be used to puncture or cut larger prey, allowing access to the cell contents.) *Peranema* has a characteristic smooth, gliding type of motility. One of the emergent flagella is extended forwards and held straight, movement being limited to a coiling or flickering of the tip, while a second is folded back along the cell and adheres to the pellicle. Genera closely related to *Peranema* include *Entosiphon* and HETERONEMA.

**perborate** See HYDROGEN PEROXIDE (a).

**perchlorate degradation** See BIOREMEDIATION.

**percolating filter** See SEWAGE TREATMENT.

**percurrent proliferation** In conidiogenesis (see CONIDIUM): the development, by the conidiogenous cell, of a new conidium-forming apex which grows through the previous apex; percurrent proliferation occurs e.g. in annellidic development (see CONIDIUM) and in the formation of new conidiogenous ampullae in *Gonatotryum*.

**perfect stage** (*mycol.*) See TELEOMORPH.

**perforins** See APOPTOSIS.

**perfringocins** See BACTERIOCIN.

**perfringolysin** See THIOL-ACTIVATED CYTOLYSINS.

**peribacteroid membrane** See ROOT NODULES.

**pericentric** (of a chromosome) On both sides of, or including, the CENTROMERE; e.g., a pericentric inversion is a CHROMOSOME ABERRATION in which the inverted segment contains the centromere. (cf. PARACENTRIC.)

**pericentriolar structure** See CENTRIOLE.

**Perichaena** See MYXOMYCETES.

**periclinal** Parallel to a given surface. (cf. ANTICLINAL.)

**Periconia** See HYPHOMYCETES.

**peridermioid** Refers to a peridiate, typically tongue-shaped (flattened) acium of the type formed e.g. by species of *Cronartium* and *Pucciniastrum*.

**Peridermium** See UREDINIOMYCETES.

**peridiate** Having a PERIDIUM.

**peridinin** See CAROTENOIDS.

**Peridinium** See DINOFLLAGELLATES.

**peridiole** See NIDULARIALES and PISOLITHUS.

**peridium** The outer enveloping wall which encloses the spores, or the spore-bearing structures, in the fruiting bodies of various fungi (e.g. GASTEROMYCETES) and acellular slime moulds (MYXOMYCETES). (See also e.g. CLEISTOTHECIUM and PERITHECIUM.)

**Périgord truffle** See TRUFFLES.

**perihepatitis** Inflammation of the peritoneal coat of the liver; it can result from localized infection, trauma, or systemic inflammatory disease. [Review of chlamydial perihepatitis: BMB (1983) 39 159–162.] (See also CURTIS–FITZ-HUGH SYNDROME.)

**perilemma** In many oligotrich ciliates: a membrane external to the pellicle.

**perimycin** (*syn.* fungimycin) A PEROSAMINE-containing heptaene POLYENE ANTIBIOTIC produced by a strain of *Streptomyces coelicolor*.

**perinuclear space** See NUCLEUS.

**periodic acid–Schiff reaction** See PAS REACTION.

**periodontitis** An acute or chronic inflammation of tooth-supporting tissues. The periodontium includes the *periodontal ligament*: a cup-like mass of fibrous connective tissue which binds the root of the tooth to the tooth socket in the jaw bone; the term 'periodontium' may also include the *cementum* (a bone-like substance which invests the root of the tooth), the *free gingiva* (see GINGIVITIS), and the *alveolar bone* (i.e. that part of the jaw bone which forms the tooth socket that binds the periodontal ligament).

Periodontitis is promoted by the accumulation of DENTAL PLAQUE in or near the *gingival sulcus*: the shallow groove (1–2 mm deep) at the tooth–gum junction; under these conditions the gum may shrink away from the tooth (the gingival sulcus enlarging to form a *periodontal pocket*) – thus exposing the cementum and the periodontal ligament to microbial attack.

In periodontal disease there is an increased flow of CREVICULAR FLUID.

Various bacterial species have been causally connected with periodontitis, but the aetiology of the disease is not yet fully understood; the human oral microflora has not yet been fully characterized, and it is possible that currently uncultured organisms may contribute to periodontitis. In one study, samples of healthy and periodontic material were examined with the object of investigating (from PCR-determined sequence data) whether any specific types of organism correlate with disease; one organism, whose data suggested a close relationship to asaccharolytic *Eubacterium* spp., was found only in deep pockets in periodontitis patients, possibly indicating an association with advanced periodontitis [JCM (1999) 37 1469–1473].

Bacteria which have been aetiologically linked to periodontitis include species of BACTEROIDES (e.g. *B. gingivalis*) and FUSOBACTERIUM; *Actinobacillus actinomycetemcomitans* and *Capnocytophaga* sp have been implicated in 'juvenile periodontitis'. (See also CENTIPEDA.)

Multiplex PCR has been used for the simultaneous detection of *Bacteroides forsythus* and *Prevotella intermedia* in 152 clinical samples, including 38 specimens of plaque [JCM (1999) 37 1621–1624].

**peripheral membrane cylinder** See ASCUS.

**peripheral membrane protein** See CYTOPLASMIC MEMBRANE.

**periphyses** (*sing.* periphysis) Short, sterile filaments which form a lining in the ostiolar canal in a perithecium or pseudoperithecium.

**periphyton community** *Syn.* AUFWUCHS.

**periplasm** *Syn.* PERIPLASMIC REGION.

**periplasmic binding protein** *Syn.* BINDING PROTEIN (sense 1).

**periplasmic fibrils** See SPIROCHAETALES.

**periplasmic flagella** See SPIROCHAETALES.

**periplasmic gel** See PEPTIDOGLYCAN.

**periplasmic region** (periplasmic space; periplasm) In Gram-positive bacteria and archaeans: the region between the CYTOPLASMIC MEMBRANE and the CELL WALL; in Gram-negative bacteria: the region between the cytoplasmic membrane and the OUTER MEMBRANE – or, according to some authors, between the cytoplasmic membrane and the layer of PEPTIDOGLYCAN.

Certain enzymes and other proteins are located partially or entirely in the periplasmic region and may be released from

the cell e.g. by OSMOTIC SHOCK. (See also BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM and EXTRACRYTOPLASMIC OXIDATION.)

**periplasmic space** *Syn.* PERIPLASMIC REGION.

**periplast** The cell envelope, or particular layer(s) of the cell envelope, in certain algae and protozoa; see e.g. PELLICLE (sense 3) and CHOANOFLAGELLIDA.

**Peripylaria** A category ('section') of LEISHMANIA species which multiply in the anterior part of the hindgut of the arthropod vector, and then migrate to the pharynx, cibarium and proboscis; it includes e.g. *L. braziliensis* and '*L. tarentolae*'. (cf. HYPOPYLARIA, SUPRAPYLARIA.)

**periseptal annulus** In Gram-negative bacteria: a continuous circumferential 'fusion' between the OUTER MEMBRANE and the cytoplasmic membrane, one annulus occurring on each side of the site of cell division – thus delimiting a small periplasmic compartment at the site of future septum formation. [PNAS (1983) 80 1372–1376.] (cf. ADHESION SITE.)

**peristome** (1) The buccal cavity, or the extreme distal part of the buccal cavity, together with the somatic region adjacent to it; the term is used primarily for the appropriate parts in peritrichs and in certain spirotrichs, but it is sometimes used for the convoluted distal region of some chonotrichs. (cf. INFUNDIBULUM.) (2) *Syn.* BUCCAL CAVITY.

**perithecioid** Having the general characteristics of a PERITHECIUM.

**perithecioid pseudothecium** See ASCOSTROMA.

**perithecium** A hollow, spheroidal or flask-shaped ASCOCARP (ca. 100–300 µm) which opens to the exterior via an OSTIOLE; asci develop inside the perithecium, commonly in the form of a hymenial layer or as a basal tuft. According to species, perithecia may develop on the surface of a substratum or fungal STROMA, or embedded within a fungal stroma, and the wall (*peridium*) of a perithecium may be membranous or brittle, brightly coloured or dark. Some perithecia contain (in addition to asci) sterile structures such as paraphyses. (For ascospore discharge see ASCOSPORE.) Perithecia are formed e.g. by members of the SORDARIALES and SPHAERIALES.

(cf. ASCOSTROMA (pseudoperithecium).)

**peritonitis** Localized or generalized inflammation of the peritoneum (the membrane which lines the abdominal cavity and covers the viscera).

**peritrich** A member of the PERITRICHIA.

**Peritrichia** A subclass of freshwater, estuarine and marine ciliate protozoa (class OLIGOHYMENOPHOREA); one order: Peritrichida. In *mature* peritrichs, the somatic ciliature is limited or absent, but the oral ciliature is well developed and includes rows of cilia which – looking *into* the buccal cavity – spiral downwards towards the cytostome in an *anticlockwise* (counterclockwise) direction. According to species, individual cells may be shaped like an egg, bell or bottle etc; in some species the cell (*zooid*) is attached to the substratum either directly or by means of a contractile or non-contractile stalk. Some species are loricate, and some form colonies. STOMATOGENESIS is buccokinetal. Asexual reproduction in sedentary species may occur e.g. by budding with the formation of a motile, ciliated 'larva' (*telotroch*).

Predominantly sedentary peritrichs are placed in the suborder Sessilina (genera: e.g. *Apiosoma*, *Campanella*, CARCHESIUM, *Ellobiophrya*, *Epistylis*, *Lagenophrys*, OPERCULARIA, *Rhabdostyla*, *Scyphidia*, *Vaginicola*, VORTICELLA, *Zoothamnium*). The mobile peritrichs (all ecto- or endoparasitic, occasionally pathogenic, in freshwater or marine vertebrates and invertebrates) are placed in the suborder Mobilina (genera: e.g. *Leiotrocha*, *Trichodina*, *Vauchomia*).

## Peritrichida

**Peritrichida** See PERITRICHIA.

**peritrichous** Refers to flagella (or e.g. fimbriae) which are distributed more or less uniformly over the cell surface.

**perkinetal** (*ciliate protozoal.*) Refers to the plane of cell division: perpendicular to the kineties. (cf. HOMOTHETOGENIC.)

**Perkinsasida** A class of parasitic, homoxenous protozoa (phylum APICOMPLEXA) in which the form of the conoid is atypical; reproduction is asexual. One species: *Perkinsus marinus* (see PERKINSUS).

**Perkinsea** A class of protozoa [JP (1980) 27 37–58] equivalent to the PERKINSASIDA.

**Perkinsus** A genus of protozoa of the PERKINSASIDA [J. Parasitol. (1978) 64 549] formerly regarded as fungi of the genus *Dermocystidium*. *P. marinus* is a pathogen of oysters.

**permeoplast** A cyanobacterial cell which has been treated with lysozyme and EDTA; permeoplasts have been used for the TRANSFORMATION of certain cyanobacteria.

**permease** (porter; transporter) A TRANSPORT SYSTEM or the (non-enzymic) component of a multicomponent transport system that effects transmembrane translocation of the substrate. (See also ION TRANSPORT.)

**permissive cell** (*virol.*) A cell which permits the replication of a given virus, with the consequent production of infectious progeny virions. (cf. ABORTIVE INFECTION.)

**permissive conditions** See CONDITIONAL LETHAL MUTANT.

**Peronophythora** See PERONOSPORALES.

**Peronosclerospora** See PERONOSPORALES.

**Peronospora** A genus of obligately plant parasitic fungi of the order PERONOSPORALES. Within the host plant, the (intercellular) mycelium gives rise to short club-shaped or branching filamentous haustoria. Conidia develop singly on curved, tapering and branching conidiophores which emerge from the stomata. On germination, the conidia form germ tubes – as do the (sexually-produced) oospores. *P. destructor* and *P. parasitica* cause DOWNY MILDEWS on onions and crucifers, respectively. *P. tabacina* causes the TOBACCO DISEASE *blue mould* – a disease which occurs worldwide; blue mould is encouraged by wet weather, and has been controlled e.g. by dithiocarbamates or metalaxyl.

**Peronosporales** An order of aquatic and terrestrial fungi (class OOMYCETES) which include both saprotrophs and parasites – some of the latter being major plant pathogens (see e.g. DOWNY MILDEWS). (See also PHENYLAMIDE ANTIFUNGAL AGENTS.) The thallus is characteristically a well-developed, coenocytic, branching mycelium which, in parasitic species, may give rise to haustoria. Asexually-derived zoospores are formed by most species; they are typically produced in rounded sporangia which are borne either on undifferentiated hyphae or on distinct sporangiophores, according to species. In *Bremia* and *Peronospora* the asexually-derived spores are conidia (see CONIDIUM) rather than sporangiospores. Sexual reproduction is oogamous (see OOMYCETES).

According to species, oogonia and antheridia are borne on the same or on different hyphae, and each may be uninucleate or multinucleate. Fertilization involves gametangial contact, the oosphere subsequently developing into a thick-walled oospore. Genera include ALBUGO, BASIDIOPHORA, BREMIA, *Bremiella*, *Peronophythora*, *Peronosclerospora*, PERONOSPORA, PHYTOPHthora, PLASMOPARA, *Pseudoperonospora*, PYTHIUM, *Sclerophthora*, SCLEROSPORA, and ZOOPHAGUS.

**perosamine** An aminosugar (4-amino-4,6-dideoxy-D-mannose) found e.g. in PERIMYCIN.

**peroxidase** An OXIDOREDUCTASE which catalyses a reaction in which the oxidation of a substrate is coupled with the reduction of hydrogen peroxide. See e.g. LIGNIN; cf. CATALASE.

**peroxidase–antiperoxidase technique** See PAP TECHNIQUE.

**peroxin** See PEX MUTATION.

**peroxynitrite** See NITRIC OXIDE.

**peroxisome** A type of MICROBODY found in many kinds of eukaryotic cell, including certain fungi, protozoa and algae. Peroxisomes contain a range of enzymes – including e.g. peroxidase, CATALASE, D-amino acid oxidase, dehydrogenase and acyl transferase. Each peroxisome is typically rounded, with a granular matrix and commonly an electron-dense core (= *nucleoid*); it is bounded by a single trilaminar membrane ~4.5–8 nm in thickness. Peroxisomes apparently develop by incorporating their component proteins (synthesized on free polysomes) and eventually dividing into daughter peroxisomes; this contrasts with the earlier view of biogenesis which supposed that peroxisomes budded from the endoplasmic reticulum.

In animal-type cells, peroxisomes carry out a range of functions which (depending on type of cell) include respiration, oxidation of alcohol and fatty acids, synthesis of plasmalogens, and purine metabolism; in plant/algal cells, functions include GLUCONEOGENESIS and PHOTORESPIRATION.

In methylotrophic yeasts (see METHYLOTROPHY) the peroxisomes, which contain methanol oxidase, occur in greater number and size when the yeasts are grown on methanol (rather than e.g. glucose). [Peroxisomes in methylotrophic yeasts: AMP (1983) 24 1–82.] (See also HYDROCARBONS.)

[Recent developments in peroxisome biology: Endeavour (1996) (new series) 20 68–73.]

[Peroxisome membrane proteins (role in biogenesis and function of the peroxisome): FEMS Reviews (2000) 24 291–301.]

**persistence** (*virol.*) The phenomenon in which a virus remains within a cell, organism or population [Book ref. 90] for a prolonged period of time, during which it may or may not replicate to produce infectious progeny virions; if the virus persists in cryptic form, without production of infectious virions and without causing symptoms in the host, it is said to be *latent*. (Some authors reserve the term 'persistence' for those cases in which infectious virions are continually produced [Book ref. 148, p. 161].)

In a host organism, persistence (*sensu lato*) may be established directly or may follow an acute phase of disease. Various categories of persistent infection can be distinguished. (a) Infectious virions are not produced and infection is asymptomatic ('latent infection'); in some cases the virus may, under certain conditions, be 'reactivated' to produce infectious virions and cause sporadic recurrences of illness (see e.g. HERPES ZOSTER). (b) Infectious virions are not produced, but disease may nevertheless eventually occur (see e.g. SUBACUTE SCLEROSING PANENCEPHALITIS). (c) Infectious virions are continually produced but no symptoms are apparent – resulting in a CARRIER (sense 1). (See also LCM VIRUS.) (d) Infectious virions are continually produced, and ongoing chronic disease results.

Viral strategies for persistence in cells/hosts include e.g. integration of viral nucleic acid into host chromosomal DNA (as in the RETROVIRIDAE), or maintenance of viral nucleic acid in a stable extrachromosomal form (see e.g. EPSTEIN–BARR VIRUS); in some cases impaired immunological responses or immunological tolerance may be important factors. In cell cultures, persistence may result from the formation of viral mutants or of DEFECTIVE INTERFERING PARTICLES. (See also CARRIER CULTURE.)

**persistent generalized lymphadenopathy** See AIDS.

**persistent virus** (1) See CIRCULATIVE TRANSMISSION. (2) A virus which can establish a persistent infection (see PERSISTENCE).

**peractin** A cell-surface adhesin found in species of *Bordetella*.

**perthophyte** *Syn.* PERTHOTROPH.

**perthotroph** (perthophyte) (1) A parasite which kills tissues within a living host, subsequently deriving nutrients from the dead tissues. (2) An organism which derives nutrients from dead tissues within a living host – whether or not it kills those tissues itself. (The term is usually applied to plant/microorganism interactions.) (cf. BIOTROPH; NECROTROPH.)

**Pertusaria** A genus of crustose LICHENS (order PERTUSARIALES); photobiont: a green alga. Apothecia frequently occur several together in warts on the thallus; they are initially perithecium-like with a pore-like opening, but in some species they subsequently open out to form flat or concave discs. In *P. pertusa*, the periphery of the thallus is surrounded by a white hypothallus; the apothecia do not open out as they mature. In *P. amara*, the thallus bears scattered white soralia (0.5–1.5 mm diam.) which have a bitter taste due to the presence of picrolichenic acid; apothecia are rare, but when present they are solitary and the mature discs are open and sorediate. Species occur e.g. on bark.

**Pertusariales** An order of fungi of the ASCOMYCOTINA; members include crustose LICHENS (photobiont commonly green), and saprotrophic and lichenicolous fungi. Ascocarp: APOTHECIOD, sometimes lirelliform. Asci: bitunicate. Genera: e.g. OCHROLECHIA, PERTUSARIA.

**pertussigen** *Syn.* PERTUSSIS TOXIN.

**pertussis** *Syn.* WHOOPING COUGH.

**pertussis toxin** (pertussigen; islet-activating protein; histamine-sensitizing factor; leucocytosis-promoting factor) An exotoxin, produced by *Bordetella pertussis*, which is one of the virulence factors associated with WHOOPING COUGH (see also CYCLOLYSIN, DERMONECROTIC TOXIN, TRACHEAL CYTOTOXIN).

The structure of pertussis toxin (PT) resembles that of e.g. CHOLERA TOXIN and SHIGA TOXIN: all of these toxins have an AB<sub>5</sub> arrangement of subunits in which five B subunits form a pentameric ring, and the A subunit occupies a central position to one side of the plane of the ring.

The B subunits of PT are not identical; some of them have binding sites for specific receptor molecules on eukaryotic target cells.

The A subunit is a 26 kDa protein with ADP-ribosyl transferase activity. Within the target cell it ADP-ribosylates a particular heterotrimeric G protein, G<sub>i</sub> (= N<sub>i</sub>), which normally inhibits the activity of ADENYLATE CYCLASE; ADP-ribosylation inhibits G<sub>i</sub>, leading to an increase in the intracellular concentration of cyclic AMP (cAMP). (cf. CHOLERA TOXIN.)

*B. paraptussis* apparently contains a silent (i.e. non-expressed) gene for pertussis toxin.

**Pesotum** See CERATOCYSTIS and HYPHOMYCETES.

**Pestalotia** See MELANCONIALES.

**peste des petits ruminants** (*syn.* pseudorinderpest) A disease of sheep and goats which occurs in W. Africa. Symptoms include fever, nasal and ocular discharge, and necrotic stomatitis, followed by severe enteritis and pneumonia; mortality rates may be >90%.

The causal agent is a virus (the 'Kata virus') of the genus MORBILLIVIRUS.

**pesticin I** A BACTERIOCIN produced by strains of *Yersinia pestis*; it is active against *Y. pseudotuberculosis* and strains of *Escherichia coli*. Production of pesticin I correlates with the production of a fibrinolytic factor and a coagulase.

**pestis minor** A mild form of PLAGUE in which buboes are formed without systemic symptoms.

**Pestivirus** A genus of viruses (family TOGAVIRIDAE) which infect pigs (SWINE FEVER virus) and ruminants (BOVINE VIRUS

DIARRHOEA/MUCOSAL DISEASE (BVD-MD) virus, and the closely related BORDER DISEASE virus). The viruses do not replicate in invertebrates and are not vector-borne. Pestiviruses can be transmitted transplacentally, and may cause abortion or malformation of the fetus.

**petal breaking** *Syn.* COLOUR BREAKING.

**petechia** See PURPURA.

**Petersenia** See LAGENIDIALES and ALGAL DISEASES.

**petite mutant** In certain yeasts (including e.g. *Saccharomyces cerevisiae*): a mutant strain characterized by the formation of abnormally small colonies; petite mutants are respiration-deficient owing to functionally defective mitochondria (see MITOCHONDRION), and they exhibit a low growth rate since they are restricted to the less efficient fermentative mode of metabolism.

In *nuclear petite* (= *segregational petite*) mutants the mutant characteristic is due to mutation(s) in the nuclear (chromosomal) DNA which affect mitochondrial function; such mutations arise with frequencies similar to those of other chromosomal mutations, and they can be induced by mutagenic agents such as ultraviolet radiation. Crosses between nuclear petites and wild-type strains yield petite and wild-type progeny in the ratio 1:1.

In *cytoplasmic petite* mutants the mutant characteristic is due to mutation(s) in the mitochondrial DNA. *Neutral petite* (= *rho*<sup>0</sup> *petite*) mutants are completely devoid of mtDNA; they are the main or sole types of petite mutant which arise in the presence of high concentrations of INTERCALATING AGENTS. In crosses between neutral petites and wild-type strains the *rho*<sup>0</sup> genotype is recessive. In *suppressive petite* (= *rho*<sup>-</sup> *petite*) mutants the mtDNA has suffered deletion(s) such that, in general, much less than 50% of the wild-type mtDNA remains. In crosses between *rho*<sup>-</sup> and wild-type strains, some of the progeny have only the petite genotype, the wild-type genotype having been lost – an effect called *suppression*; in highly suppressive petites, loss of wild-type mtDNA is apparently due to the preferential replication of petite mtDNA – possibly owing to higher concentrations of origin-like sequences in the petite mtDNA.

(cf. POKY MUTANT.)

**Petractis** See GYALECTALES.

**Petri dish** A (usually) round, shallow, flat-bottomed, glass or plastic dish (often ca. 10 cm diam.) with a vertical side, together with a similar, slightly larger structure which forms a loosely-fitting lid. Petri dishes are used in microbiology e.g. for the preparation of PLATES. (See also VENT.)

**Petriellidium** See PSEUDALLESCHERIA.

**Petroderma** See PHAEOPHYTA.

**petroleum** Crude oil, i.e., oil in the form obtained from oil deposits within the earth. (See also KEROGEN.) Petroleum is an extremely complex mixture of components, including aliphatic, alicyclic and aromatic hydrocarbons together with e.g. various heterocyclic compounds. It can be converted into various 'refined' products – used e.g. as fuels for internal combustion engines – which are still mostly complex mixtures (e.g. kerosene may contain 5000–10000 different compounds). Many of the components of petroleum and its products can be degraded by microorganisms (see e.g. HYDROCARBONS).

Contamination of petroleum-derived fuels and oils by certain microorganisms can be a serious economic problem, resulting in e.g. corrosion of fuel tanks, blockage of fuel pipes and filters, alteration of chemical and functional properties of lubrication and cutting oils, etc. Microbial growth requires the presence of at least some water (which may result e.g. from condensation),

## **Petunia vein-clearing virus**

growth occurring in the water or at the oil–water or fuel–water interface. Organisms commonly involved include hydrocarbon-utilizing microbes such as *Hormoconis resiniae* (formerly *Cladosporium resiniae*) (particularly in aviation kerosene), strains of *Aspergillus* and *Pseudomonas*, etc. However, not all spoilage organisms are necessarily hydrocarbon utilizers: some may obtain nutrients from solutes in the aqueous phase, from impurities in the fuel, etc. (See also BIOBOR and EGME.)

[Petroleum microbiology: Book ref. 155.]

**Petunia vein-clearing virus** See CAULIMOVIRUSES.

**pex mutation** Any mutation which results in a deficiency in PEROXISOME biogenesis; *pex* genes encode various *peroxins*, i.e. protein constituents of the peroxisome. Most peroxins so far identified are components of the peroxisome membrane.

**pexicyst** An EXTRUSOME which occurs e.g. in *Didinium*; on discharge it adheres to the prey.

**Peziza** A genus of fungi (order PEZIZALES) which form light-brown, sessile, discoid or cup-shaped apothecia, often several centimetres across; the ascospores are typically biguttulate.

**Pezizales** An order of fungi (subdivision ASCOMYCOTINA) which occur e.g. on wood, soil and dung. Ascocarp: typically APOTHECIOID (but closed and hypogean in some species), with paraphyses. Asci: unitunicate, cylindrical to globose, with a non-thickened apex which typically opens, at maturity, by a slit or operculum (see OPERCULATE ASCUS). Genera: e.g. ALEURIA, *Ascobolus*, *Carbomyces*, *Gyromitra*, HELVELLA, *Monascus*, MORCHELLA, PEZIZA, PYRONEMA, *Sarcoscypha*, SCUTELLINIA, TUBER, VERPA.

**Pezizella** See HELOTIALES.

**PF4** (chemokine) See CHEMOKINES.

**PF155** See PLASMODIUM.

**PFA** PHOSPHONOFORMIC ACID.

**Pfeiffer phenomenon** The rapid lysis of *Vibrio cholerae* by specific antibody and COMPLEMENT.

**Pfeifferinella** See EIMERIORINA.

**Pfeiffer's bacillus** *Haemophilus influenzae*.

**Pfeiffer's disease** INFECTIOUS MONONUCLEOSIS.

**PFGE** Pulsed-field gel electrophoresis: any of several forms of gel ELECTROPHORESIS used for separating large molecules of nucleic acid (up to  $\sim 10^6$  base pairs in length). Essentially, electric fields are applied to the gel alternately from different angles so that the net migration of a given molecule depends on the speed with which it can change its direction of movement; this separates the nucleic acid molecules according to size. The range of sizes of molecule which can be separated is determined by the pulse *length*: short pulses are used for separating the (relatively) smaller molecules, while longer pulses are used for separating the larger molecules. (It may also be possible to choose a pulse length which includes plasmids in the assay; such a pulse length may exclude the largest chromosomal fragments.)

Following PFGE, bands of fragments may be detected in the gel e.g. by staining with ethidium bromide.

Various forms of PFGE differ e.g. in the number, type and location of electrodes; in some forms, electrodes can periodically switch polarity.

In contour-clamped homogeneous electric field electrophoresis (CHEF), electrophoresis is carried out in a hexagonal chamber in which electrodes are located on sides 2, 3, 5 and 6; this procedure is reported to be reproducible and highly discriminatory. (See also OFAGE.)

PFGE is used e.g. in TYPING. For example, this approach is used for separating large fragments of DNA produced when bacterial chromosomes are cleaved with so-called 'rare-cutting'

restriction endonucleases (see DNA FINGERPRINTING). According to some authors, PFGE is the 'gold standard' among molecular typing methods. [Guidelines for typing bacterial strains with PFGE: JCM (1995) 33 2233–2239.]

PFGE has been used e.g. for subtyping strains of the Penner HS11 serotype of *Campylobacter jejuni* [JMM (1998) 47 353–357], isolates of *Shigella dysenteriae* type 1 [JMM (1999) 48 781–784], and strains of *Serratia marcescens* [JCM (1997) 35 325–327] and *Vibrio parahaemolyticus* [JCM (1999) 37 2473–2478]. CHEF has been used e.g. for typing strains of *Neisseria gonorrhoea* [JMM (1993) 38 366–370].

[Comparison of PFGE with five other molecular methods for typing methicillin-resistant strains of *Staphylococcus aureus*: JMM (1998) 47 341–351.]

**pFM739** See INCOMPATIBILITY.

**pfmdr1** See AMINOQUINOLINES.

**pfu** PLAQUE-FORMING UNIT.

**Pfu DNA polymerase**<sup>TM</sup> See DNA POLYMERASE.

**PG** (1) PROSTAGLANDIN. (2) PEPTIDOGLYCAN.

**PGD<sub>2</sub>** See PROSTAGLANDINS.

**PGE<sub>2</sub>** See PROSTAGLANDINS.

**PGF<sub>2α</sub>** See PROSTAGLANDINS.

**Pgh1** See AMINOQUINOLINES.

**PGI<sub>2</sub>** See PROSTACYCLIN.

**pGKl** plasmids See KILLER PLASMIDS.

**PGL** (persistent generalized lymphadenopathy) See AIDS.

**pH indicator** A substance which changes colour over a particular pH range(s): see e.g. ANDRADE'S INDICATOR; BROMCRESOL GREEN; BROMCRESOL PURPLE; BROMPHENOL BLUE; BROMTHYMOL BLUE; CHLORPHENOL RED; CONGO RED; CRESOL RED; LITMUS; METHYL ORANGE; METHYL RED; NEUTRAL RED; PHENOL RED; PHENOLPHTHALEIN; THYMOL BLUE; THYMOLPHTHALEIN. (See also e.g. LITMUS MILK; MACCONKEY'S AGAR; METHYL RED TEST.)

**pH-stat** See CONTINUOUS CULTURE.

**PHA** (1) PHYTOHAEMAGGLUTININ. (2) Passive haemagglutination (see PASSIVE AGGLUTINATION). (3) Poly-β-hydroxyalkanoate: see POLY-β-HYDROXYBUTYRATE.

**Phacidium** See HELOTIALES.

**Phacus** A genus of EUGLENOID FLAGELLATES in which the cell has a rigid pellicle and is usually flattened with a posterior point, often appearing somewhat leaf-shaped.

**Phaeodactylum** A genus of pennate DIATOMS. *P. tricornutum* is polymorphic, occurring in three main morphotypes: oval, fusiform, and triradiate (cells with three corners – often extended into arms); the latter two forms may occur in chains, and the fusiform type is the most stable of the three. Daughter cells are (initially) of the same morphotype as the parent cell. The cell wall is almost entirely organic, the only siliceous structures being the griddle bands (up to 10); one valve is partially silicified in the oval morphotype.

**Phaeodarea** See RADIOLARIA.

**phaeodium** See RADIOLARIA.

**Phaeographis** See GRAPHIDALES.

**phaeohyphomycosis** Any of a range of human and animal diseases caused by any of several black moulds (e.g. *Dactylaria gallopava*, *Drechslera* spp, *Exophiala* spp, *Wangiella dermatitidis*, *Xylohypha bantiana* (formerly *Cladosporium bantianum*)) which form dark-walled septate mycelium in the tissues (cf. CHROMOBLASTOMYCOSIS). Such diseases generally affect only debilitated or immunosuppressed individuals; they usually involve the formation of chronic, progressive, subcutaneous abscesses or warty lesions in various parts of the body. The disease may be systemic, particularly when caused by *X. bantiana* (which tends

to localize in the brain, but which may also cause pulmonary infections) or by *W. dermatitidis*.

**Phaeophyceae** The sole class within the PHAEOPHYTA.

**Phaeophyta** (brown algae) A division of predominantly marine ALGAE (freshwater members including species of e.g. *Bodanella* and *Heribaudiella*). The thallus ranges from an adherent disc or crust to hollow bulbous or whip-like forms, branched filaments and giant complex forms – the latter reaching 50 metres or more in length and containing sieve tubes within which photosynthate can be translocated; there are no unicellular species. The CELL WALL contains cellulose and e.g. FUCOIDIN and ALGINATES. Within the CHLOROPLASTS the THYLAKOIDS characteristically occur in groups of three. Brown algae contain CHLOROPHYLLS *a*, *c*<sub>1</sub> and *c*<sub>2</sub>; certain CAROTENOIDS (e.g. fucoxanthin); carbohydrates such as MANNITOL and LAMINARIN; sterols (e.g. fucosterol and cholesterol); and sometimes large amounts of TANNINS ('fucosan') stored in 'fucosan vesicles' (= *physodes*) in the cytoplasm. Sexual processes include isogamy and oogamy, and many species exhibit a heteromorphic or isomorphic ALTERNATION OF GENERATIONS; the biflagellate, pyriform gametes each have one anteriorly-directed tinsel FLAGELLUM, and one posteriorly-directed whiplash flagellum. Some species form PHEROMONES. Life cycles are often complex.

Orders include [Book ref. 130]: Ascoseirales (e.g. *Ascoseira*); Chordariales (e.g. *Chordaria*, *Cladosiphon*, *Halothrix*); Cutleriales (e.g. *Cutleria*); Desmarestiales (e.g. *Desmarestia*); Dictyosiphonales (e.g. *Dictyosiphon*, *Striaria*); Dictyotales (e.g. *Dictyota*, *Zonaria*); Durvillaeales (*Durvillaea*); Ectocarpales (e.g. *Ectocarpus*, *Petroderma*, *Ralfsia*); Fucales (e.g. *Ascophyllum*, *Cystoseira*, FUCUS, *Halidrys*, *Himantalia*, *Myriodesma*, *Pelvetia*, *Sargassum*, *Turbinaria*); Laminariales (e.g. *Alaria*, *Chorda*, *Costaria*, LAMINARIA, *Macrocystis*, *Pelagophycus*, *Thalassiosiphon*, UNDARIA); Scytosiphonales (e.g. *Colpomenia*, *Hydroclathrus*, *Scytosiphon*); Sphacelariales (e.g. *Cladostephus*, *Halopteris*, *Sphacelaria*); Sporochneales (e.g. *Sporochneus*); Tilopteridaceae (e.g. *Haplospora*, *Tilopteris*).

[Evolution of the Phaeophyta (particularly Fucales): Book ref. 167, pp. 11–46.]

**phaeophytin** A derivative of CHLOROPHYLL in which Mg<sup>2+</sup> is replaced by two protons. (cf. BACTERIOPHAEPHYTIN.)

**phaeosporeae** See SACCARDOAN SYSTEM.

**Phaffia** A genus of imperfect yeasts (class HYPHOMYCETES).

The cells are ellipsoidal, occurring singly, in pairs, or occasionally in short chains; they reproduce by budding. Spheroidal chlamydospores containing refractile granules are formed e.g. after several days in malt extract. Colonies on e.g. malt agar are orange-red or salmon-pink due to the synthesis of carotenoid pigments, predominantly astaxanthin (3,3'-dihydroxy-4,4'-diketo-β-carotene, a red pigment common among animals – particularly crustaceans, echinoderms and tunicates – but rare in plants). Glucose and certain other sugars are fermented. Neither inositol nor NO<sub>3</sub><sup>-</sup> is assimilated. One species: *P. rhodozyma*, isolated from tree exudates. [Book ref. 100, pp. 890–892.]

**phage** Abbreviation for BACTERIOPHAGE. (For 'phage G4', 'phage λ' etc see entries BACTERIOPHAGE G4, BACTERIOPHAGE λ etc.)

**phage conversion** *Syn.* BACTERIOPHAGE CONVERSION.

**phage typing** A form of TYPING in which strains of bacteria are distinguished on the basis of differences in their susceptibilities to a range of BACTERIOPHAGES. Initially, a FLOOD PLATE is prepared from a culture of the strain under test; the surface of the plate is then dried (by leaving the plate in a 37°C incubator, with the lid partly off, for 10–20 minutes) and a grid is drawn on the base of the plate. The agar surface corresponding to each square

of the grid is inoculated with one drop of a phage suspension (at ROUTINE TEST DILUTION) – each square being inoculated with a different phage; the plate is then incubated. Each of the phages used for typing is lytic for one strain, or a limited number of strains, of the species under test; a phage which lyses the particular strain being tested will form a clear macroscopic area amid the opaque layer of bacterial growth. The test strain can then be defined in terms of the phages to which it is sensitive. (The results of phage typing may be affected if the bacterium under test carries a PLASMID encoding a RESTRICTION ENDONUCLEASE which destroys phage nucleic acid.) Strains of *Salmonella typhi* which bear the VI ANTIGEN may be typed by a range of phages each of which is specific for one or more of the Vi strains of *S. typhi*; this procedure is often termed Vi phage typing.

**phagemid** A CLONING vector which includes (i) a plasmid's origin of replication; (ii) a multiple cloning site (MCS), i.e. a POLYLINKER; (iii) a marker gene (e.g. a gene encoding resistance to kanamycin); and (iv) the origin of replication of a filamentous phage (e.g. that of the ssDNA phage φ1). The DNA sample (to be cloned) is inserted via the MCS, and the phagemid is then inserted into a bacterium e.g. by transformation.

A phagemid can be used e.g. for making double-stranded copies of the given fragment (i.e. used as a conventional cloning vector). It can also be used for making single-stranded copies if the phagemid-carrying bacteria are infected with a 'helper phage', e.g. phage M13, which promotes replication from the *phage* origin in the phagemid; the single-stranded copies are packaged into phage coat proteins (encoded by the helper phage) and exported to the medium. When freed from phage coat proteins, the single-stranded copies of the insert can be used e.g. for sequence analysis (see DNA SEQUENCING).

A phagemid may contain a promoter on each strand, either side of the MCS, so that, if required, the cloned fragment can be transcribed.

**phagocyte** Any cell which can carry out PHAGOCYTOSIS – particularly a neutrophil or macrophage.

**phagocytosis** The process in which particulate matter is ingested, and usually digested, by certain types of cell or microorganism (cf. PINOCYTOSIS). In mammals, phagocytosis by certain leucocytes is an important aspect of the immune defence system, while in some microorganisms phagocytosis is a mode of feeding.

(a) In mammals, phagocytosis is carried out e.g. by NEUTROPHILS and MACROPHAGES. Essentially, the particle (e.g. an opsonized bacterium) initially binds to the surface of the phagocyte; the phagocyte's cytoplasmic membrane then invaginates to form a pocket which contains the particle. (Different intracellular signals may be generated in the phagocyte according to whether engulfment was triggered from antibody- or complement-binding sites.) Subsequently, the invaginated membrane forms a closed, intracellular sac or vacuole, the *phagosome*. (A phagosome which contains a parasite is called a *parasitophorous vacuole*.) The pH within the phagosome decreases, and the phagosome coalesces with one or more LYOSOMES to form a *phagolysosome* (= *lysophagosome*) within which the bacterium etc. may be killed and degraded.

The maturation of a phagosome into a phagolysosome can be monitored from changes in (i) its internal pH, and (ii) the associated proteins; for example, a phagolysosome is characterized by so-called lysosome-associated membrane proteins (LAMPs).

Antimicrobial activity within phagocytes is promoted by (i) the wide range of lysosomal enzymes, and (ii) the intracellular formation of certain toxic derivatives of oxygen – see

## phagolysosome

e.g. SUPEROXIDE, HYDROGEN PEROXIDE, SINGLET OXYGEN and HYDROXYL RADICAL (species formed during the 'oxidative burst' (= 'respiratory burst') characteristic of some types of phagocyte); such derivatives are formed e.g. by neutrophils and macrophages. In NEUTROPHILS (q.v.), the oxygen derivatives are generated within 30–60 seconds of cell-surface stimulation. Ferric ions bound to lysosomal LACTOFERRIN may serve to promote the formation of hydroxyl radical from hydrogen peroxide and superoxide. During the oxidative burst, the consumption of oxygen by the phagocyte increases sharply. (See also CHEMILUMINESCENCE.) Reactive oxygen derivatives are also released to the extracellular environment.

Some bacteria can resist ingestion by phagocytes as a consequence of their capsular or cell-wall components. For example, the capsule of *Bacillus anthracis* is anti-phagocytic (cf. STERNE STRAIN). Again, the PROTEIN A cell-wall component of *Staphylococcus aureus* may serve to inhibit opsonization by binding the Fc portion of antibodies.

Some pathogens can kill phagocytes: see e.g. APOPTOSIS and LEUCOCIDINS.

Certain pathogens (e.g. *Coxiella*, *Leishmania* spp, *Listeria monocytogenes* and *Mycobacterium lepraemurium*) can survive or grow within phagosomes, or phagolysosomes, avoiding destruction by various mechanisms. For example, in the case of *Chlamydia* spp, *Legionella pneumophila* and *Mycobacterium tuberculosis* the phagosome does not acidify and does not fuse with the lysosome. Under certain circumstances, some pathogens (e.g. *Mycobacterium leprae*, *Rickettsia mooseri*, *Trypanosoma cruzi*) can escape from the phagosome and grow within the cytoplasm of the phagocyte. (See also REOVIRUS.)

Phagosomes containing live *Toxoplasma gondii* resist fusion with lysosomes, and *T. gondii* may also fail to trigger the phagocyte's oxidative mechanism and may inhibit development of the normal acidification of the phagosome. *M. leprae* apparently fails to stimulate the generation of superoxide anion by the phagocyte.

In some cases a pathogen is not taken up and killed because it has actually invaded the phagocyte. Invasion may involve uptake via adhesins and receptors which differ from those involved in routine phagocytosis. The initial contact between pathogen and phagocyte may be important in determining the pathogen's fate; for example, of the various modes of binding, some may favour survival by failing to trigger an oxidative burst within the phagocyte. In the case of *Legionella pneumophila*, the phagosome in a macrophage maintains near-neutral pH, and the pathogen is able to multiply, killing the phagocyte. In this organism the *icm* (intracellular multiplication) genes – also called *dot* (defect in organelle trafficking) genes – are believed to encode a secretory system (and associated effector molecules) involved e.g. in blocking phagosome–lysosome fusion; mutations in these genes have been found to affect the pathogen's ability to multiply within, and kill, macrophages [see e.g. TIM (1998) 6 253–255].

It has been reported that the zinc metalloprotease secreted by *L. pneumophila* inhibits (i) the oxidative burst, and (ii) chemotaxis in phagocytes [JMM (2001) 50 517–525].

In the case of *Mycobacterium tuberculosis*, invasion/survival may be influenced by (i) the cell-surface chemistry of the given strain; (ii) the site of infection (e.g. lung); and (iii) the timing of pathogen–phagocyte contact (e.g. at initial infection, or later). The opsonization of *M. tuberculosis* may occur via any of four pathways of COMPLEMENT FIXATION (q.v.); however, non-opsonic (complement- and antibody-independent) binding of the pathogen to the phagocyte may be important for initial infection

of the normal lung. [*M. tuberculosis*–phagocyte interactions: TIM (1998) 6 328–335.]

[Bacterial invasion of host cells: Book ref. 218, pp. 223–272.] (b) Among microorganisms, particulate food is ingested e.g. by many sarcodines (see also PSEUDOPODIUM), ciliates and flagellates; in (at least) most of the ciliates, the essential features of phagocytosis appear to resemble those described in (a) above: particle(s) are enclosed within an invagination of the cytoplasmic membrane which gives rise to a closed intracellular vesicle (FOOD VACUOLE). In many ciliates there is a single, specialized site for phagocytosis (see CYTOSTOME), while in suctorians ingestion may occur at the tip of each of the tentacles.

**phagolysosome** See PHAGOCYTOSIS.

**Phagomyxa** A genus of endoparasitic, phagocytic, plasmodial organisms. *P. algarum* occurs in the cells of marine algae; it appears to resemble members of the PLASMODIOPHOROMYCETES but apparently does not form cysts.

**phagosome** See PHAGOCYTOSIS.

**phagotrophy** A mode of nutrition in which nutrients are ingested in particulate form, as in some protozoa. (cf. OSMOTROPHY.)

**phagotype** See VARIETY.

**phagovar** See VARIETY.

**Phalacrocleptes** A genus of protozoa (placed tentatively in the subclass SUCTORIA [Book ref. 135, p. 239]) which have short tentacles but which lack both cilia and infraciliature at all stages of the life cycle. The organisms are parasitic on polychaete annelids.

**phallacidin** See PHALLOTOXINS.

**Phallales** An order of humicolous and lignicolous fungi (class GASTEROMYCETES) which include both epigeal and hypogean species. The immature basidiocarp ('egg') is rounded, ca. one to several centimetres in size, and consists essentially of a gleba enveloped in gelatinous material and enclosed within a membranous peridium. In some species the peridium is indehiscent, the basidiospores within being dispersed, when mature, on rupture of the peridium e.g. by burrowing animals. In other species (the 'stinkhorns') the 'egg' contains a mass of spongy tissue (the *receptacle*) which, during maturation of the basidiocarp, expands (rupturing the peridium) to form a typically hollow, columnar structure – also called the receptacle (or *pseudostem*) – which carries the hymenium-bearing gleba at its apex; autolysis of the glebal material gives rise to an often evil-smelling liquid which attracts certain insects, the latter dispersing the basidiospores. The stinkhorns include e.g. species of *Clathrus*, *Mutinus* and *Phallus*.

**phallin B** See PHALLOTOXINS.

**phallisin** See PHALLOTOXINS.

**phalloidin** See PHALLOTOXINS.

**phalloin** See PHALLOTOXINS.

**phallotoxins** A group of cyclic heptapeptide toxins present in *Amanita phalloides* and e.g. in *A. verna*. Phallotoxins include e.g. phallacidin, phallin B, phallisin, phalloidin and phalloin; they generally contain unusual amino acids: e.g. phalloidin, a bicyclic heptapeptide, contains D-threonine, 4(*cis*)-hydroxy-L-proline and  $\gamma$ , $\delta$ -dihydroxy-L-leucine, and is resistant to all proteases which have been tested. Phallotoxins produce clinical symptoms within a few hours of ingestion and are generally less toxic than AMATOXINS; symptoms of phallotoxin poisoning include weakness, severe vomiting and diarrhoea, and sometimes death. Degenerative changes occur in the cells of the liver. Phalloidin binds specifically and strongly to F-actin [binding site: EMBO (1985) 4 2815–2818], effectively accelerating G-to-F-actin polymerization (see ACTIN) and increasing the stability

of actin filaments; consequently, cellular functions associated with the microfilament system (e.g. cytoplasmic streaming, cell motility) are irreversibly blocked. (See also MYCETISM.)

**Phallus** See PHALLALES.

**Phanerochaete** See APHYLLOPHORALES (Corticaceae).

**phaneroplasmidium** See MYXOMYCETES.

**pharyngeal basket** *Syn.* CYRTOS.

**pharyngeal rod organ** See PERANEMA.

**pharyngitis** Inflammation of the pharynx. Acute pharyngitis is often caused by *Streptococcus pyogenes*; symptoms include e.g. sore throat, fever, pharyngeal exudate. Other causes include any of a range of viruses – e.g. adenovirus (see PHARYNGOCONJUNCTIVAL FEVER), COMMON COLD VIRUSES, coxsackieviruses (see also HERPANGINA), EB virus (see INFECTIOUS MONONUCLEOSIS).

**pharyngoconjunctival fever** A (usually mild) disease, affecting mainly children and young adults, caused by certain adenoviruses (see MASTADENOVIRUS). Symptoms: fever, inflammation of conjunctivae and/or pharynx, and enlargement of cervical lymph nodes.

**phase-contrast microscopy** See MICROSCOPY (c).

**phase degradation** Phase variation in BORDETELLA.

**phase-shift mutation** *Syn.* FRAMESHIFT MUTATION.

**phase variation** Spontaneous switching from the synthesis of a given cell-surface component to the synthesis of a different form of that component – or the starting, or stopping, of synthesis of such a component; each form of a given component depends on the expression of a specific allele, so that the number of different forms of that component depends on the allelic complement of the organism (cf. ANTIGENIC VARIATION).

The term 'phase variation' was initially applied to the alternation of flagellar components in *Salmonella*, but is now applied more generally to a range of phenomena involving variation in cell surface components. Many of these phenomena are known to involve re-arrangements of DNA.

Some well-studied examples of phase variation include the prototypical flagellar phase variation in *Salmonella* (see below); the on/off switching of type I FIMBRIAE (q.v.) in *Escherichia coli*;

and the expression of OPA PROTEINS in *Neisseria*. Variation in the Vi antigen of *Citrobacter freundii* may be a further example.

In most strains of *Salmonella* the filament of the FLAGELLUM contains either of two distinct types of FLAGELLIN encoded by genes H1 (= *fliC*) and H2 (= *fliB*); normally, only one of these genes is expressed at any given time, so that the flagellar filament contains either the H1 gene product or the H2 gene product. (Note that there are many different alleles of gene H1; the product of a given H1 allele – i.e. a particular *phase 1 antigen* (formerly called a 'specific-phase antigen') – is found only in certain serotypes of *Salmonella*. Gene H2 also occurs in a number of allelic forms. However, in many cases, a given product of gene H2 – i.e. a particular *phase 2 antigen* (formerly called a 'group-phase antigen') – occurs in a wide range of serotypes of *Salmonella*; for example, the phase 2 antigen '1' occurs in many, if not most, of the serotypes. Some salmonellae, including *S. typhi*, do not have phase 2 antigens. (See also H ANTIGEN, KAUFFMANN-WHITE CLASSIFICATION and CRAIGIE'S TUBE METHOD.)

One of the consequences of phase variation in *Salmonella* is the formation of flagella which may differ e.g. antigenically and/or in susceptibility to FLAGELLOTROPIC PHAGES.

The switch from H1 to H2 gene expression is reversible and occurs at a frequency of about  $10^{-5}$  to  $10^{-3}$  per cell per generation.

Switching involves the inversion of a specific, 995-bp sequence of nucleotides which includes the promoter of the H2 gene. When this sequence is in *one* orientation, the promoter can be used for transcription of the H2 gene – so that, in this case, the H2 gene product is incorporated into the flagellar filament. The H2 gene actually forms part of an operon that includes a gene (*rh1* or *rH1*) whose product represses the H1 gene; thus, with the sequence orientated this way, the H2 product is formed and the H1 product is repressed.

Inversion of the control sequence prevents transcription of H2 – and also prevents formation of the H1 repressor; hence,

PHASE VARIATION: alternation of flagellar proteins in *Salmonella* (principle, diagrammatic; see entry).

In most strains of *Salmonella* the flagellar filament contains either of two distinct types of protein, encoded by genes H1 and H2. Normally, only one of these genes is expressed at any given time, so that the flagellar filament contains either the H1 gene product or the H2 gene product.

The promoter (●) of the H2 operon is flanked by two short inverted repeats (▨) which are recognized by a site-specific recombinase; that is, the sequence containing the promoter can be inverted by site-specific recombination.

*Top.* The position of the H2 promoter is such that the H2 operon can be transcribed. The H2 gene product is incorporated in the flagellar filament, and the H1 repressor protein blocks transcription of the H1 gene.

*Below.* Site-specific recombination has occurred between the two inverted repeats, so that the sequence containing the H2 promoter has been inverted. In this new orientation the H2 promoter is no longer functional. Because the H2 operon is not transcribed, the H1 repressor is not formed, and this permits transcription of the H1 gene – so that the flagellar filament now contains the H1 gene product.

Reproduced from *Bacteria*, 5th edition, Figure 8.3, page 168, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

## phaseollidin

with the sequence in *this* orientation the product of the H1 gene is incorporated into the flagellar filament.

Inversion of the control sequence – in either direction – involves SITE-SPECIFIC RECOMBINATION between two short INVERTED REPEATS, one of which is located at each end of the control sequence. The recombinase which mediates inversion is encoded by gene *hin* (= *vH2* or *vh2*) which, like the H2 promoter, occurs on the control sequence. The scheme for flagellar phase variation in *Salmonella* is shown diagrammatically in the figure.

(See also RECOMBINATIONAL REGULATION.)

**phaseollidin** An isoflavonoid PHYTOALEXIN produced by the French bean (*Phaseolus vulgaris*).

**phaseollin** An isoflavonoid PHYTOALEXIN (7-hydroxy-3',4'-dimethylchromanocoumarin) produced by the French bean (*Phaseolus vulgaris*). It can be elicited e.g. by the polypeptide elicitor *monilicolin A* which can be obtained from culture filtrates of *Monilinia fructicola*.

**phaseolotoxin** A chlorosis-inducing TOXIN produced by *Pseudomonas syringae* pv. *phaseolicola*; it irreversibly inactivates ornithine carbamoyltransferase, an enzyme which catalyses the formation of citrulline from ornithine and carbamoyl phosphate. The toxin–enzyme interaction involves the so-called 'Kcat' mechanism; in this mechanism the target molecule (enzyme in this case) activates the toxin, and the activated toxin then brings about specific alkylation of the enzyme. *P. syringae* pv. *phaseolicola* can produce a form of ornithine carbamoyltransferase which is insensitive to the toxin.

Phaseolotoxin may also inhibit HYPERSENSITIVITY (sense 2) in the host plant.

**phasins** See e.g. POLY- $\beta$ -HYDROXYBUTYRATE.

**phasmid** (1) A construct formed by recombination between e.g. a phage  $\lambda$  genome and a plasmid containing the  $\lambda$  *att* site and *cos* site. Integration of the plasmid into the phage genome is mediated (within a host bacterial cell) by the phage integrase site-specific recombination system (see BACTERIOPHAGE LAMBDA). The resulting genome–plasmid hybrid can be encapsidated during the assembly of phage virions. Phasmids are useful tools in genetic engineering since genes carried by the original plasmid can readily be introduced into other host cells by infection of those cells by phasmid-containing phage virions. (cf. COSMID.)

(2) (*biol.*) A caudal chemoreceptor in nematodes of the class Phasmodia.

**PHB** POLY- $\beta$ -HYDROXYBUTYRATE.

**Phellinus** See APHYLLOPHORALES (Hymenochaetaceae).

**phenanthridine** An INTERCALATING AGENT which has trypanocidal and antitumour activity. Phenanthridine derivatives include e.g. ETHIDIUM BROMIDE.

**phenethicillin** *Syn.* PHENOXYETHYLPENICILLIN.

**phenetic classification** Any form of classification which is based on the observable (phenotypic and genotypic) characteristics of organisms – regardless of their ancestral lineage. (cf. PHYLOGENETIC CLASSIFICATION.) The relationship between two given organisms may be expressed as the proportion or percentage of similarities or differences on the basis of a certain minimum number of specified criteria (see e.g. NUMERICAL TAXONOMY).

**phenocopy** A cell or organism whose phenotype has become modified in a way which mimics a phenotypic modification that is due to genetic change. For example, F<sup>+</sup> donors of *Escherichia coli* (see F PLASMID) may lose their donor characteristics under certain conditions – e.g. when grown to maximum density in aerated broth; such transfer-deficient cells mimic F<sup>-</sup> cells and are therefore called F<sup>-</sup> phenocopies. (See also SURFACE

EXCLUSION.) When cultured in a fresh medium, F<sup>-</sup> phenocopies revert to the donor state.

Studies on F<sup>-</sup> phenocopies reveal e.g. a low level of nicking at *oriT* in the late stationary phase – although the F pilus transfer apparatus appears to be maintained in the cell envelope even after cessation of transcription of the main transfer region [Microbiology (1998) 144 2579–2587].

**phenogram** Any dendrogram which expresses phenetic relationships. (cf. CLADOGRAM.)

**phenol** (as a disinfectant) See PHENOLS.

**phenol coefficient** A number which expresses the antimicrobial activity of a given *phenolic* DISINFECTANT relative to that of phenol under standard conditions; it can be determined by e.g. the RIDEAL–WALKER TEST or the CHICK–MARTIN TEST.

**phenol red** A PH INDICATOR: pH 6.8–8.4 (yellow to red); pK<sub>a</sub> 7.9.

**phenolates** (in iron uptake) See SIDEROPHORES.

**phenolic disinfectants** See PHENOLS.

**phenolphthaleim** A PH INDICATOR: pH 8.3–10.0 (colourless to red); pK<sub>a</sub> 9.6.

**phenols** (as ANTISEPTICS and/or DISINFECTANTS) Phenol and its derivatives ('phenolics' – cresols, xylenols etc) are microbistatic or microbicidal, depending on e.g. concentration and temperature; they may act e.g. by affecting bacterial membrane potentials or membrane permeability, or by coagulating the cytoplasm. The antimicrobial activity of phenolics increases with boiling point, but so too does their insolubility in water and (in general) their susceptibility to inactivation by organic matter; high-boiling-point phenolics tend to be less toxic to tissues. Phenolic disinfectants typically have a high DILUTION COEFFICIENT, and they can be inactivated by non-ionic surfactants; those which are poorly soluble in water may be solubilized by alkali or prepared as suspensions with soaps.

*Phenol* (carbolic acid, C<sub>6</sub>H<sub>5</sub>OH) is soluble in water and (under appropriate conditions) may be bactericidal, fungicidal and virucidal; its activity against bacterial endospores and acid-fast bacteria tends to be very slow. It is toxic to tissues. Phenol (now produced mainly by chemical synthesis) is used e.g. as a preservative in animal glues.

In general, alkyl- and halogen-substituted phenolics exhibit enhanced antimicrobial activity, tend to be less toxic to tissues, and are typically less water-soluble than phenol. In 4-alkylphenols, activity increases with alkyl chain length up to 6 carbon atoms. Among halogenated phenols, 4-halophenols are the most active; in phenolics containing both alkyl and halogen substituents, activity is maximum when these are in the 2 and 4 positions, respectively. Nitrophenols tend to be more toxic than other phenolics to tissues. Polyhydric phenols generally have weak antimicrobial activity. (See also BISPHENOLS.)

*Lysol* consists of 2-, 3- and 4-cresols (methylphenols) solubilized by soap. Aqueous Lysol (0.5%) kills many non-sporing pathogens in 15 min, but endospores may survive in 2% Lysol for several days. *Amyl-3-cresol* is used e.g. in antiseptic lozenges and mouthwashes. *Sudol* consists of xylenols (dimethylphenols) and ethylphenols; it is more active and less corrosive than Lysol and is active against e.g. staphylococci and tubercle bacilli. Aqueous Sudol (2%) can inactivate *Clostridium perfringens* endospores in about 4 hours, but inactivation of *Bacillus subtilis* endospores has been found to require 6 hours in a 66% solution. *Hexylresorcinol* (4-*n*-hexyl-1,3-dihydroxybenzene) has been used as a skin wound cleanser, a urinary antiseptic, and a constituent of throat lozenges. *Menthol* (3-methyl-6-isopropylphenol) and *carvacrol* (2-methyl-5-isopropylphenol)

are both used in antiseptic lozenges and mouthwashes. *Thymol* (5-methyl-2-isopropylphenol) is used as a disinfectant, as an antiseptic (e.g. in mouthwashes), and as a preservative (e.g. in urine samples pending biochemical tests). *2-Phenylphenol* (2-hydroxydiphenyl) is primarily an antifungal agent but also has antibacterial activity; it has been used e.g. as a fungicide in the paper industry, as a preservative in waxed papers, and as a constituent of PINE DISINFECTANTS. *Sodium-o-phenylphenate* is used e.g. for the initial antifungal disinfection of stored fruits. *2-Benzyl-4-chlorophenol* is active against Gram-positive and Gram-negative bacteria, protozoa and fungi; it is used e.g. in antiseptic soaps. *Chlorocresol* (4-chloro-3-methylphenol) is used e.g. as a preservative for pharmaceutical products and e.g. for glues and paints. It is also used as a biocide in a low-temperature (98–100°C) STERILIZATION process. *Chloroxylenols* (e.g. 4-chloro-3,5-dimethylphenol) are used e.g. as topical antiseptics; they are active ingredients in *Dettol*. *Pentachlorophenol* is used e.g. as a fungicide in wood pulp and as a preservative for leather, paper and textiles. *Picric acid* (2,4,6-trinitrophenol), which has antibacterial and antifungal properties, is also used as a chemical FIXATIVE. *4-Nitrophenol* is used as a preservative in the leather industry. (See also DINITROPHENOLS.)

(See also BLACK FLUIDS; CREOSOTE; SALICYLIC ACID; WHITE FLUIDS.)

**phenon** Any group established on the basis of PHENETIC CLASSIFICATION; in some cases a phenon may be considered to be more or less equivalent to a TAXON.

**phenosafranine** A green redox dye – see REDOX POTENTIAL.

**phenotype** The observable characteristics of an organism, either in total or with respect to one or more particular named characteristics. The phenotype of an organism is the manifestation of gene expression in that organism. (cf. GENOTYPE.)

**phenotypic adaptation** See ADAPTATION.

**phenotypic lag** A delay in the phenotypic expression of a new allele – acquired e.g. by mutation or by gene transfer (e.g. transduction) – due e.g. to SEGREGATION LAG.

**phenotypic mixing** In a cell simultaneously infected by genetically different viruses: the formation of progeny virions which either incorporate the genome of one virus within the capsid of another (*transcapsidation* or *genomic masking*) or contain structural components derived from different 'parent' viruses. (See also PSEUDOTYPE.)

**phenotypic suppression** The suppression of a mutant phenotype by non-genetic (environmental) factors. For example, during mRNA synthesis, 5-fluorouracil (5-FU) can be incorporated instead of uracil and can be misread as cytosine during subsequent translation; thus, e.g., the nonsense codon UAG may occasionally be misread as CAG (specifying glutamine), thus simulating a nonsense SUPPRESSOR MUTATION. The accuracy of translation may also be affected by alteration of ribosomes e.g. in the presence of STREPTOMYCIN; the resulting mis-reading of certain codons may lead to the suppression of certain mutations.

**phenoxetol** See ALCOHOLS.

**phenoxyethanol** See ALCOHOLS.

**$\beta$ -phenoxyethyl dimethyldodecyl ammonium bromide** Dimphephen bromide (see QUATERNARY AMMONIUM COMPOUNDS).

**phenoxyethylpenicillin** (pheneticillin) A semisynthetic penicillin; R = C<sub>6</sub>H<sub>5</sub>.O.CH(CH<sub>3</sub>).CO (see  $\beta$ -LACTAM ANTIBIOTICS). Its activity is similar to that of benzylpenicillin, but it can be administered orally.

**phenoxymethylpenicillin** (penicillin V) One of the first natural penicillins to be produced (from *P. chrysogenum*); in phenoxymethylpenicillin R = C<sub>6</sub>H<sub>5</sub>.O.CH<sub>2</sub>.CO (see  $\beta$ -LACTAM

ANTIBIOTICS). Its activity is similar to that of BENZYLPENICILLIN, but it can be administered orally.

**phenylalanine agar** A medium (usually prepared as a slope) containing (g/100 ml water): yeast extract (0.3), L-phenylalanine (0.1), Na<sub>2</sub>HPO<sub>4</sub> (0.1), NaCl (0.5), agar (1.2).

**L-phenylalanine biosynthesis** See AROMATIC AMINO ACID BIOSYNTHESIS.

**phenylalanine deaminase test** A test used to determine the ability of an organism to deaminate phenylalanine to phenylpyruvic acid. In one form of the test, the organism is grown overnight on PHENYLALANINE AGAR, and 0.2 ml of 10% aqueous FeCl<sub>3</sub> is added to the growth; phenylpyruvic acid, if present, gives a green coloration with the FeCl<sub>3</sub>. Bacteria which usually give a positive test include e.g. *Proteus vulgaris* and *Moraxella phenylpyruvica*.

**phenylamide antifungal agents** A group of ANTIFUNGAL AGENTS which includes the acylalanines *benalaxyl*, *furalaxyl* and *metalaxyl*, the butyrolactones *milfuram* and *cyprofuram*, and the oxazolidinone ring-containing *oxadixyl*. The phenylamides show in vitro activity against members of the Peronosporales and certain other fungi [Mycol. (1985) 77 424–432]. Metalaxyl (trade name: e.g. Ridomil) is widely used as an agricultural antifungal agent against a range of peronosporalean plant pathogens; it is a systemic fungicide which is most effective in young, actively growing foliage, and is often mixed with a contact fungicide such as copper, captan or mancozeb for maximum efficacy.

**phenylethanol** See ALCOHOLS.

**phenylmercuric salts** See MERCURY.

**phenylmethanol** See ALCOHOLS.

**phenylpenicillin** A semi-synthetic penicillin; R = C<sub>6</sub>H<sub>5</sub>.CO– (see  $\beta$ -LACTAM ANTIBIOTICS). It is less active than benzylpenicillin.

**2-phenylphenol** See PHENOLS.

**pheromone** A type of molecule, released by an organism, which can cause one or more (non-harmful, non-nutritional) effects in another individual – typically an individual of the same species. (cf. ANTIBIOTIC; HORMONE). For example, a 'sex pheromone' can encourage sexual interaction between individuals e.g. by acting as a chemoattractant (see CHEMOTAXIS), by causing a TROPISM, and/or by promoting cell–cell adhesion (see below).

*Bacterial pheromones.* Pheromones (small linear peptides) are secreted e.g. by those cells of *Enterococcus faecalis* that are potential recipients for certain plasmids; a given pheromone can act on other (potential donor) cells of *E. faecalis* that are carrying a particular CONJUGATIVE PLASMID – causing them to form a cell-surface adhesin called 'aggregation substance' which promotes donor–recipient adhesion. (Because culture filtrates of recipients also cause donor–donor aggregation, these pheromones have been called 'clumping-inducing agents'.) On receipt of a plasmid (by CONJUGATION), a recipient stops secreting the corresponding pheromone (but may continue to secrete the pheromones corresponding to other plasmids). Each type of *E. faecalis* pheromone is designated according to the particular plasmid to which its function was originally linked; thus, e.g. pheromones cAD1 and cAM373 act on (donor) cells carrying the plasmids pAD1 and pAM373 respectively. [Review: CRM (1986) 13 309–334.]

In *Bacillus subtilis*, pheromones are involved in the development of competence for transformation and in the initiation of endospore formation (see QUORUM SENSING).

*Fungal pheromones.* Many fungi form sex pheromones. For example, in *Allomyces* spp, female gametangia and gametes release the pheromone *sirenin* (a sesquiterpene diol); male gametes take up and inactivate *sirenin*, and move chemotactically towards its source.

In dioecious species of *Achlya*, the vegetative female thallus forms a steroid pheromone (*antheridiol*, 'hormone A') which stimulates the male thallus to form antheridial hyphae; the male thallus takes up, and inactivates, the pheromone and forms another steroid pheromone ('hormone B') which stimulates the female thallus to form oogonia.

In some bipolarly heterothallic zygomycetes (e.g. strains of *Blakeslea trispora* and *Mucor mucedo*), development of sexual structures in the 'plus' and 'minus' mating types (see HETEROTHALLISM) is governed by *trisporic acid* derivatives (formerly referred to as GAMONE) – terpene carboxylic acids synthesized from  $\beta$ -carotene. The plus strains synthesize and secrete the pheromone *prohormone P*<sup>+</sup> ('plus-progamone'), a methylidihydrotrisporate; minus strains synthesize and secrete a trisporol pheromone called *prohormone P*<sup>-</sup> (formerly 'minus-progamone'). It appears that when each pheromone is taken up by strains of the opposite mating type it is converted to trisporic acid in situ. The trisporic acid promotes sexual development and increases *prohormone* synthesis.

Pheromones produced by *Saccharomyces cerevisiae* include the  $\alpha$ -factor and the **a**-factor (see MATING TYPE). The  $\alpha$ -factor is a tridecapeptide (13 amino acid residues) synthesized as a high-MWt precursor (which, interestingly, resembles the hormone precursors in higher eukaryotes); the precursor is sequentially cleaved by three proteinases: *yscF*, *yscIV* (formerly dipeptidyl-aminopeptidase A, or X-prolyldipeptidylaminopeptidase), and (apparently) *ysc $\alpha$* . The **a**-factor, an undecapeptide (11 residues), is apparently also synthesized in precursor form. [MS (1986) 3 107–114.]

*Algal pheromones.* Pheromones are produced by various algae. In some cases a given pheromone can act on algae of different genera; for example, among brown algae, the pheromone *ectocarpene* (a cyclic hydrocarbon) can act on *Ectocarpus* and *Sphacelaria*, while *multifidene* is effective in *Chorda* and *Cutleria*. The pheromone *desmarestene* (structurally similar to ectocarpene) acts as an attractant to male gametes in the brown alga *Cladostephus* [Naturwissenschaften (1986) 73 99–100].

ϕ Unwinding angle: see INTERCALATING AGENT.

**ϕ6 phage group** *Syn.* CYSTOVIRIDAE.

**phialide** (phialid) See CONIDIUM.

**phialidic development** See CONIDIUM.

**Phialoascus** See ENDOMYCETALES.

**Phialophora** A genus of fungi (class HYPHOMYCETES) which include plant-pathogenic species – e.g. *P. cinerescens* (causal agent of carnation wilt). (See also CHROMOBLASTOMYCOSIS.) [Species parasitic on bdelloid rotifers: Mycol. (1984) 76 1107–1110.] The mycelium is septate, and the conidia (produced from phialides) are non-septate, colourless or pigmented. (For *P. dermatitidis* see WANGIELLA.)

**phialopore** See VOLVOX.

**Phialospora** See DOTHIDEALES.

**Philadelphia chromosome** An abnormal human chromosome 22 associated with chronic myelogenous leukaemia: see ABL.

**Phialaster** See SCUTICOCILIATIDA.

**Philomiragia bacterium** A non-motile bacterium pathogenic in muskrats. It was formerly called *Yersinia philomiragia*, but has been excluded from *Yersinia* on the basis of DNA homology studies [Book ref. 22, p. 506].

**pHisoHex** See BISPHENOLS.

**ϕX phage group** *Syn.* MICROVIRIDAE.

**Phlebia** See APHYLLOPHORALES (Corticiciaeae).

**Phlebotomus** A genus of blood-sucking sandflies which includes the vectors of certain diseases.

**Phlebovirus** (sandfly fever group) A genus of viruses of the BUNYAVIRIDAE. Host range: various vertebrates; vectors: primarily phlebotomine sandflies. The genus appears to include only one serological group with >30 viruses (including e.g. Punta Toro virus, RIFT VALLEY FEVER virus, Rio Grande virus, Sicilian sandfly fever virus). MWts of L, M and S RNAs: ca. 2.6–2.8, 1.8–2.2, and 0.7–0.8 × 10<sup>6</sup>, respectively; MWts of proteins L, G1, G2 and N: ca. 145–200, 55–70, 50–60, and 20–30 × 10<sup>3</sup>, respectively. The phlebovirus M RNA appears to resemble that of the bunyaviruses (see BUNYAVIRIDAE) in its genetic organization; however, the S RNA of Punta Toro virus appears to be an AMBISENSE RNA, encoding the NS<sub>s</sub> protein on a viral-sense subgenomic mRNA and the N protein on a viral-complementary subgenomic mRNA.

**Phleogena** See AURICULARIALES.

**phlobaphenes** See TANNINS.

**phloem necrosis** (of coffee) A disease of the coffee plant (e.g. *Coffea liberica*, *C. arabica*) caused by *Phytophthora* sp. Symptoms: leaves become yellow and fall prematurely, and CALLOSE is deposited in the sieve tubes. Only plants older than ca. two years are affected. Vectors: unknown, but heteropterans are suspected.

**phloeophagous** 'Bark-eating' (see e.g. AMBROSIA FUNGI).

**Phlogiotis** See TREMELLALES.

**phlogistic** Able to cause inflammation.

**phloretin** See PHLORIDZIN.

**phlorhizin** *Syn.* PHLORIDZIN.

**phloridzin** (phlorhizin) A phenolic glycoside formed in certain tissues in apple trees (*Malus* spp) and in other members of the Rosaceae. The aglycone part of phloridzin, *phloretin* ( $\beta$ -(4-hydroxyphenyl)-propionophlorophenone), can be liberated by  $\beta$ -glycosidases and oxidized by polyphenol oxidase to yield polymers that are toxic to e.g. *Venturia inaequalis*.

**PHLS** Public Health Laboratory Service, 61 Colindale Avenue, London NW9, United Kingdom.

**pho regulon** (phosphate regulon) In *Escherichia coli*: a REGULON comprising the *pho* genes: phosphate-controlled genes whose activity depends on the level of available Pi (inorganic orthophosphate). The cell's response to Pi starvation is complex and not fully understood, but the following model has been suggested for regulation of the *pho* genes.

Regulation is exerted partly through the products of genes *phoR* and *phoB*. PhoR and PhoB are associated in a TWO-COMPONENT REGULATORY SYSTEM in which PhoR is a sensor protein in the cytoplasmic membrane, and PhoB acts as a regulator protein. With low levels of phosphate, PhoR undergoes ATP-dependent autophosphorylation and transfers phosphate to PhoB. PhoB~P behaves as a transcriptional activator by binding to the so-called *phosphate box*: a nucleotide sequence associated with the promoters of e.g. the *phoA*, *phoE* and *phoS* genes; PhoA is a periplasmic alkaline PHOSPHATASE (which releases Pi from organic phosphate esters), PhoE is a PORIN (for phosphate uptake), and PhoS is a Pi-binding protein. If phosphate levels rise, PhoB~P is de-phosphorylated by the joint activity of PhoR and the product of gene *phoU*; this switches off the *pho* regulon.

Regulation of *pho* genes appears also to involve element(s) of the *pst* (phosphate-specific transport) operon because phosphatase (PhoA) is produced constitutively in *pst* mutants.

**phoA gene** See PHO REGULON.

**phoB gene** See PHO REGULON.

**phobic response** (shock movement; shock reaction; avoiding reaction) A transient behavioural response of a motile organism to a noxious stimulus, where the stimulus is an abrupt change in an external parameter (e.g., a light/dark boundary). The nature of

the response depends on the organism, but typically the organism stops and then either reverses or reorientates and proceeds in a new, randomly selected direction. If conditions in the new direction are not significantly better, the phobic response may be repeated until the organism eventually moves into a more favourable region – when smooth swimming tends to supervene; thus, repeated phobic responses may result in a net progress in the more beneficial direction ('phobotaxis').

**phobotaxis** See PHOBIC RESPONSE.

**phoE gene** See PHO REGULON and PORIN.

**Pholiota** See AGARICALES (Strophariaceae).

**Phoma** A genus of fungi (order SPHAEROPSIDALES) which include many plant pathogens (see e.g. BLACKLEG sense 2, and GANGRENE sense 2). Colourless, ovoid conidia develop singly on conidiophores borne in brown, spherical or spheroidal, thin-walled, papillate, uniloculate, ostiolate pycnidia immersed in the substratum.

**Phomopsis** See SPHAEROPSIDALES.

**phoR gene** See PHO REGULON.

**phorbol ester** 12-*O*-tetradecanoylphorbol-13-acetate. (See also ZEBRA.)

**-phore** A suffix which signifies 'carrier of' or 'bearer of' – e.g. SPOROPHORE, IONOPHORE.

**Phormidium** A genus of cyanobacteria of the LPP GROUP. Species occur e.g. with other filamentous cyanobacteria (e.g. *Lyngbya*, *Oscillatoria*) in mats on sediments in marine lagoons, salt-marshes etc. (See also STROMATOLITE and EMULCYAN.)

**phoront** See TOMITE.

**phorophyte** The host plant of an epiphyte.

**phoS gene** See PHO REGULON.

**phosphatase** (orthophosphoric monoester phosphohydrolase) Any enzyme which hydrolyses esters of phosphoric acid; phosphatases are classified (according to their pH optima) as *acid phosphatases* (EC 3.1.3.2) or *alkaline phosphatases* (EC 3.1.3.1). (See also ENZYMES.) They are widely distributed among living organisms, including many bacteria.

*Staphylococcal phosphatases.* An *acid phosphatase* (pH optimum 5.2) is produced by most or all coagulase-positive staphylococci and (generally in smaller amounts) by some coagulase-negative strains. The enzyme may be secreted into the medium or may be loosely or tightly cell-bound – the proportions of each depending on strain and medium composition. An *alkaline phosphatase* (pH optimum 10.8) is apparently cell-bound. Phosphatase production may be demonstrated by growing the test organism on a solid medium containing the sodium salt of phenolphthalein diphosphate. After incubation, the plate is exposed to gaseous ammonia; colonies of phosphatase-producing strains become deep pink owing to the presence of free PHENOLPHTHALEIN. (Coagulase-negative strains which initially appear phosphatase-negative may produce phosphatase on prolonged incubation.) Phosphatase may be assayed e.g. using the artificial substrate *p*-nitrophenyl phosphate; *p*-nitrophenol (yellow at alkaline pH) is released by acid or alkaline phosphatases and can be assayed spectrophotometrically (at 400 nm). (See also XP.)

Staphylococcal phosphatase production appears to have little or no significance in pathogenicity. [Staphylococcal phosphatases: Book ref. 44, pp. 775–780.]

In e.g. *Escherichia coli* a periplasmic alkaline phosphatase is produced in response to inorganic phosphate starvation: see PHO REGULON.

**phosphatase test** (for milk) A test used to detect the presence of alkaline PHOSPHATASE in *pasteurized* MILK; the enzyme, which

is normally present in raw (i.e., untreated) milk, is inactivated by PASTEURIZATION – so that the test determines the efficiency of the pasteurization process. Milk containing alkaline-buffered disodium *p*-nitrophenyl phosphate is incubated at 37°C for 2 hours and then examined (e.g. by colorimetry) for the presence or intensity of yellow coloration due to *p*-nitrophenol. A false-positive result can be obtained if, subsequent to pasteurization, the milk has been contaminated with phosphatase-producing organisms.

Enzymic activity may reappear ('reactivation') in e.g. cream which has been treated by HTST pasteurization; reactivation can be promoted by the addition of MgCl<sub>2</sub>.

**phosphate box** See PHO REGULON.

**phosphate-controlled genes** See PHO REGULON.

**phosphate potential** See CHEMIOSMOSIS.

**phosphate regulon** See PHO REGULON.

**phosphatidases** *Syn.* PHOSPHOLIPASES.

**phosphatidic acid** See LECITHIN.

**phosphatidylcholine** See LECITHIN.

**phosphatidylethanolamine** A product of esterification of ethanolamine (NH<sub>2</sub>(CH<sub>2</sub>)<sub>2</sub>OH) with phosphatidic acid (see LECITHIN); it occurs e.g. in the CYTOPLASMIC MEMBRANE in many bacteria.

**phosphoadenosine phosphosulphate** See PAPS.

**phosphoenolpyruvate carboxykinase** See Appendix II(b).

**phosphoenolpyruvate carboxylase** See Appendix II(b).

**phosphoenolpyruvate carboxytransphosphorylase** See Appendix II(b).

**phosphoenolpyruvate-dependent phosphotransferase system** See PTS.

**phosphoenolpyruvate synthase** See Appendix II(b).

**phosphofructokinase** See EMBDEN–MEYERHOF–PARNAS PATHWAY.

**6-phosphogluconate pathway** May refer to either HETEROLACTIC FERMENTATION or the HEXOSE MONOPHOSPHATE PATHWAY.

**phosphoketolase** See HETEROLACTIC FERMENTATION.

**phospholipases** (phosphatidases) Enzymes that hydrolyse phospholipids, releasing fatty acids or other groups (cf. LIPASES). Phospholipases A<sub>1</sub> and A<sub>2</sub> release fatty acids from, respectively, positions 1 and 2 of a phospholipid; phospholipases C and D release the base – in phosphorylated and unphosphorylated form, respectively – from e.g. phosphatidylcholines (lecithins), sphingomyelins etc. Phospholipases may act specifically (or preferentially) on particular phospholipids – see e.g. LECITHINASE and SPHINGOMYELINASE.

**phosphonoacetic acid** (PAA) An ANTIVIRAL AGENT (used as disodium phosphonoacetate, = Fosfonet sodium) which is similar to, but more toxic than, PHOSPHONOFORMIC ACID.

**phosphonoformic acid** (PFA) An ANTIVIRAL AGENT (used as trisodium phosphonofornate, NaO.CO.PO.(ONa)<sub>2</sub>, = Foscarnet sodium) which acts by selectively inhibiting the DNA polymerases of a number of viruses (and the reverse transcriptase of retroviruses) – apparently by acting as an analogue of pyrophosphate. It is effective e.g. in the topical treatment of herpesvirus infections.

**phosphonomycin** *Syn.* FOSFOMYCIN.

**phosphorelay** See ENDOSPORE (sense 1).

**phosphorescence** (1) The emission of light which occurs when certain substances absorb radiation; emission occurs as electrons excited to the triplet state (T<sub>1</sub>) are returning to the (unexcited) ground state (S<sub>0</sub>). The light emitted is of wavelength longer than that of the exciting radiation; emission typically lasts for 10<sup>-6</sup> sec to 1 sec or longer. (cf. FLUORESCENCE.) (2) The term is sometimes applied, incorrectly, to BIOLUMINESCENCE.

## phosphoribulokinase

**phosphoribulokinase** See CALVIN CYCLE.

**phosphoroclastic split** A reaction, analogous to hydrolysis, in which a molecule is cleaved with the addition of the components of phosphoric acid. The term is usually applied to the 'pyruvic phosphoroclast' – the reaction pyruvate + H<sub>3</sub>PO<sub>4</sub> → acetyl phosphate + formate (or CO<sub>2</sub> and H<sub>2</sub>), a reaction which occurs e.g. in the MIXED ACID FERMENTATION and in the BUTYRIC ACID FERMENTATION, and which is also carried out by many SULPHATE-REDUCING BACTERIA (including species of *Desulfobacter*, *Desulfotomaculum* and *Desulfovibrio*). However, the initial product of pyruvate cleavage is actually acetyl-CoA, acetyl phosphate being formed from acetyl-CoA by the action of phosphotransacetylase; acetyl phosphate is subsequently dephosphorylated in the presence of ADP to yield acetate and ATP (enzyme: acetokinase).

**phosphorylation potential** See CHEMIOSMOSIS.

**phosphotransferase transport system** See PTS.

**photic zone** That zone of an aquatic habitat which is penetrable by sunlight and in which PHOTOSYNTHESIS can occur. In the upper part of the zone (*euphotic zone*) the amount of oxygen produced by photosynthesis exceeds that consumed by respiration (over a 24-hour period); the opposite situation occurs in the lower part of the zone (*dysphotic zone*), while between these zones (at the *compensation level*) photosynthetic oxygen production and respiratory oxygen consumption are balanced. (cf. APHOTIC ZONE.)

**photoautotroph** A phototrophic AUTOTROPH.

**Photobacterium** A genus of Gram-negative bacteria of the family VIBRIONACEAE. Cells: straight rods, 0.8–1.3 × 1.8–2.4 μm. Motile, with one to three unsheathed polar flagella. All species grow at 20°C but not at 40°C; *P. phosphoreum* and some strains of *P. angustum* can grow at 4°C. Growth requires Na<sup>+</sup> (opt. ca. 3% NaCl). Many strains are oxidase –ve. PHB accumulates in cells under certain conditions, but exogenous β-hydroxybutyrate is not utilized. Strains are sensitive to O/129. *P. phosphoreum* and *P. leiognathi* (formerly *P. mandapamensis*) exhibit blue-green BIOLUMINESCENCE and occur in seawater, on and in marine animals (see also FISH SPOILAGE), and in specialized luminous organs in certain marine fish. (See also SUPEROXIDE DISMUTASE.) GC%: 40–44. Type species: *P. phosphoreum*.

It has been suggested that the genus should include *P. leiognathi* and *P. phosphoreum*, and that *Vibrio fischeri* and *V. logei* should be transferred from the genus VIBRIO (q.v.) as *P. fischeri* and *P. logei*, respectively; it was also suggested that *P. angustum* is a biovar of *P. leiognathi* [SAAM (1985) 6 171–182].

**photobiont** A photosynthetic symbiont. (See also PHYCOBIONT.)

**photochromogen** Any strain of MYCOBACTERIUM in which a period of exposure to light is necessary for the development of pigmentation. (cf. SCOTOCHROMOGEN; NON-PHOTOCHROMOGEN.)

**Photocyta** (photocytes) A (suggested) URKINGDOM (sense 2) comprising the halobacteria (e.g. *Halobacterium* spp) and the EUBACTERIA, the proposed relatedness of these organisms being based on three-dimensional RIBOSOME structure [PNAS (1985) 82 3716–3720]; it has been proposed that the photocytes, together with the methanogens, gave rise to the Eocyta (see ARCHAEBACTERIA) and the eukaryotes [Nature (1986) 319 626].

**photocytes** See PHOTOCYTA.

**photodissociation** Light-induced chemical dissociation (see e.g. CARBON MONOXIDE (b)).

**photodynamic effect** Light-induced damage or death which occurs when some microorganisms (particularly bacteria) are stained with certain fluorescent dyes (e.g. ACRIDINE ORANGE, EOSIN, ROSE BENGAL) and subsequently exposed to strong light

under aerobic conditions; this effect appears to be due largely to the formation of SINGLET OXYGEN [JAB (1985) 58 391–400]. ETHIDIUM BROMIDE can cause a light-induced nicking of DNA.

**photoheterotroph** A phototrophic HETEROTROPH.

**photoinduction and photoinhibition** (in fungi) In many fungi, light is needed for, or encourages, the development of fruiting bodies or spores, or the formation of particular compounds (*photoinduction*); in other fungi light inhibits growth and/or sporulation (*photoinhibition*). Commonly, light in the blue-violet region of the spectrum is effective in photoinduction/photoinhibition.

In some cases light may be needed only for the completion of a particular phase of development, e.g., the initiation of fruiting in *Pyronema omphalodes*, or the development of the pileus in *Lentinus lepideus* (cf. STAG'S HORN FUNGUS). Conidium formation is photoinducible in e.g. *Trichoderma viride*, and in *Choanephora cucurbitarum* it is stimulated by darkness preceded by a period of exposure to light. In some species of *Coprinus* fruiting bodies develop more rapidly in the light, i.e., light encourages fruiting but is not essential for it. In *Phycomyces blakesleeanus* carotenoid synthesis is stimulated by light, while some species of *Fusarium* and *Verticillium* which normally form negligible amounts of carotenoids form significant amounts of these compounds in the presence of light.

Photoinhibition of growth and/or sporulation occurs e.g. in at least some species of *Alternaria* and *Penicillium*. In e.g. *Alternaria cichorii*, *A. tomato* and *Botrytis cinerea*, conidium formation is controlled by a photoreceptor system referred to as *mycochrome*. On exposure to blue light mycochrome adopts the M<sub>NUV</sub> form, in the presence of which conidia are not formed and conidiophores may revert to vegetative hyphae; on exposure to near-ultraviolet mycochrome adopts the M<sub>B</sub> form, in the presence of which conidia can be formed. In *A. cichorii* the blue-light inhibition of conidium formation can be reversed by a period of darkness [CJB (1986) 64 1016–1017].

**photoinhibition** See PHOTOINDUCTION AND PHOTONHIBITION.

**photokinesis** A KINESIS (sense 1 or 2) in which the stimulus is light intensity.

**photolithotroph** See LITHOTROPH.

**photolyase** In some bacteria (including *Escherichia coli*): an enzyme which can repair thymine dimers in DNA damaged by ULTRAVIOLET RADIATION; the energy needed for repair is derived from (visible) light. In vitro studies on the repair of thymine dimers may be facilitated by using the reagent potassium permanganate (KMnO<sub>4</sub>) [NAR (1998) 26 3940–3943].

**photomicrograph** A photograph obtained by PHOTOMICROGRAPHY.

**photomicrography** Photography of microscopic objects through a microscope; it may involve the attachment of a camera to a microscope, or the use of a *photomicroscope*: a microscope which incorporates a camera. (cf. MICROPHOTOGRAPHY.)

**photomicroscope** See PHOTOMICROGRAPHY.

**photomorphogenesis** The formation of new cells or tissues under the stimulus of light.

**photoorganotroph** See ORGANOTROPH.

**photophobic response** A light-induced PHOBIC RESPONSE.

**photophosphorylation** See PHOTOSYNTHESIS and PURPLE MEMBRANE.

**photoactivation** (photo restoration) A mechanism of DNA REPAIR in which pyrimidine dimers (formed as a result of exposure to ULTRAVIOLET RADIATION) are cleaved by exposure of the cells to light of wavelength ca. 300–600 nm; in *Escherichia coli* the reaction is mediated by the product of the *phr* gene (*DNA photolyase*) which, when bound to a pyrimidine dimer,

absorbs light energy and cleaves the bonds between the bases ('monomerization'). [Action mechanism of *E. coli* DNA photolyase: JBC (1987) 262 478–485, 486–491, 492–498.] The *phr* gene product may also play a role in UvrABC-dependent repair of UV damage in the dark [JB (1985) 161 602–608]. Photoreactivation does not occur e.g. in *Bacillus subtilis*.

**photoreceptor** An organelle or region specialized for receiving light stimuli: see e.g. EYESPOT (sense 1), STENTORIN and STENTOR.

**photoreduction** In photosynthetic organisms (see PHOTOSYNTHESIS): any light-dependent reduction – e.g., the reduction of  $\text{NAD}^+$ , or of  $\text{CO}_2$  via the Calvin cycle; electron donors used in photoreductions include e.g. water and  $\text{H}_2\text{S}$ .

In certain algae (e.g. *Chlorella*, *Chlamydomonas*, *Scenedesmus*) hydrogen can act as electron donor for the reduction of  $\text{CO}_2$ ; HYDROGENASE is involved, and the process can occur only after the algae have been incubated anaerobically with hydrogen, followed by illumination with low levels of light.

**photorespiration** ( $\text{C}_2$  carbon oxidation cycle) In photosynthetic organisms which fix  $\text{CO}_2$  via the CALVIN CYCLE: a light-dependent process in which oxygen is consumed and  $\text{CO}_2$  is evolved, but which is distinct from true (energy-yielding) RESPIRATION; photorespiration occurs under conditions of relatively high  $\text{O}_2$  and low  $\text{CO}_2$  concentrations and high light intensities, and results from the ability of RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE-OXYGENASE (RuBisCO) to act as an oxygenase under these conditions. RuBisCO catalyses the oxygenation and cleavage of ribulose 1,5-bisphosphate (RuBP) to 3-phosphoglycerate and 2-phosphoglycolate. (The dependence of photorespiration on light is thus explained by the need for photosynthesis to drive the CALVIN CYCLE and hence supply RuBP.) The 2-phosphoglycolate is dephosphorylated to glycolate which may be excreted – e.g. by certain microalgae and cyanobacteria (often resulting in relatively high levels of glycolate in aquatic environments) – and/or may be metabolized further: e.g. glycolate  $\rightarrow$  glyoxylate  $\rightarrow$  glycine  $\rightarrow$  serine  $\rightarrow$  hydroxypyruvate  $\rightarrow$  glycerate  $\rightarrow$  3-phosphoglycerate (the 'glycolate pathway'). The step glycolate  $\rightarrow$  glyoxylate is also an  $\text{O}_2$ -consuming step (catalysed by glycolate oxidase);  $\text{H}_2\text{O}_2$  generated during the reaction is rapidly degraded by catalase. (The glycolate  $\rightarrow$  glyoxylate conversion occurs in PEROXISOMES in photosynthetic eukaryotes.) The 3-phosphoglycerate generated by the glycolate pathway and by the original cleavage of RuBP by RuBisCO may then enter the Calvin cycle. An alternative pathway for glycolate metabolism in some organisms involves the oxidation of glycolate to glyoxylate which is then converted to glycerate via tartronic semialdehyde (TSA). In either pathway,  $\text{CO}_2$  is lost: in the glycolate pathway during the glycine  $\rightarrow$  serine reaction (during which two glycine molecules are converted to one of serine with loss of both  $\text{CO}_2$  and  $\text{NH}_3$ ), and in the TSA pathway during the formation of TSA from glyoxylate ( $2\text{CHO.COOH} \rightarrow \text{CHO.CHOH.COOH} + \text{CO}_2$ ). Photorespiration thus results in a net loss of photosynthetic productivity. Its physiological significance is still not understood. In green algae, photorespiration is suppressed by  $\text{CO}_2$ -concentrating mechanisms which become operative at low  $\text{CO}_2$  levels. [Review of photorespiration: ARPphys (1984) 35 415–442.] (cf. WARBURG EFFECT.)

A process very similar to photorespiration (although independent of light) occurs in some chemolithoautotrophic bacteria (e.g. *Alcaligenes eutrophus*, *Thiobacillus neapolitanus*) which fix  $\text{CO}_2$  via the Calvin cycle; by analogy with photorespiration, this process has been called 'chemorespiration'. [Book ref. 115, pp. 129–173.]

**photorestitution** *Syn.* PHOTOREACTIVATION.

**photosynthate** Any carbohydrate product of photosynthesis.

**photosynthesis** In certain (photosynthetic) organisms: the process in which radiant energy is absorbed by specialized CHLOROPHYLL-containing pigment system(s) and is converted to forms of energy (including chemical energy) which can be used for metabolic and other purposes (cf. PURPLE MEMBRANE); radiation of wavelengths in the visible spectrum is used by plants, ALGAE and photosynthetic bacteria (including CYANOBACTERIA and members of the RHODOSPIRILLALES), while some photosynthetic bacteria can also use infrared radiation. *Light reaction* refers, collectively, to those photochemical events involved in the conversion of radiant energy; *dark reaction* (= *light-independent reaction*) generally refers, collectively, to those reactions in which photosynthetically derived chemical energy is used for the synthesis of carbohydrate(s).

In all cases, the conversion of radiant energy occurs in a specialized ENERGY-TRANSDUCING MEMBRANE containing CHLOROPHYLLS or bacteriochlorophylls, accessory pigments, and components of ELECTRON TRANSPORT CHAIN(S). Within such a photosynthetic membrane there are well defined chlorophyll-containing REACTION CENTRES towards which radiant energy is channelled via LIGHT-HARVESTING COMPLEXES. On excitation of a reaction centre with radiant energy, the mid-point REDOX POTENTIAL of the reaction centre chlorophyll changes from a high positive value to a high negative value, and electrons are consequently ejected ('charge separation') from the chlorophyll (the 'primary electron donor'). The ejected electrons, by virtue of the high negative redox potential of their source, are associated with a certain amount of energy; these electrons can therefore pass down an electron transport chain in the direction of less negative (or more positive) potentials and, in doing so, can provide the energy for (a) the transmembrane pumping of protons (thereby contributing to a *proton motive force* – see CHEMOSMOSIS) or (b) the reduction of pyridine nucleotides. The precise nature of photosynthetic energy conversion differs among the different groups of photosynthetic organisms.

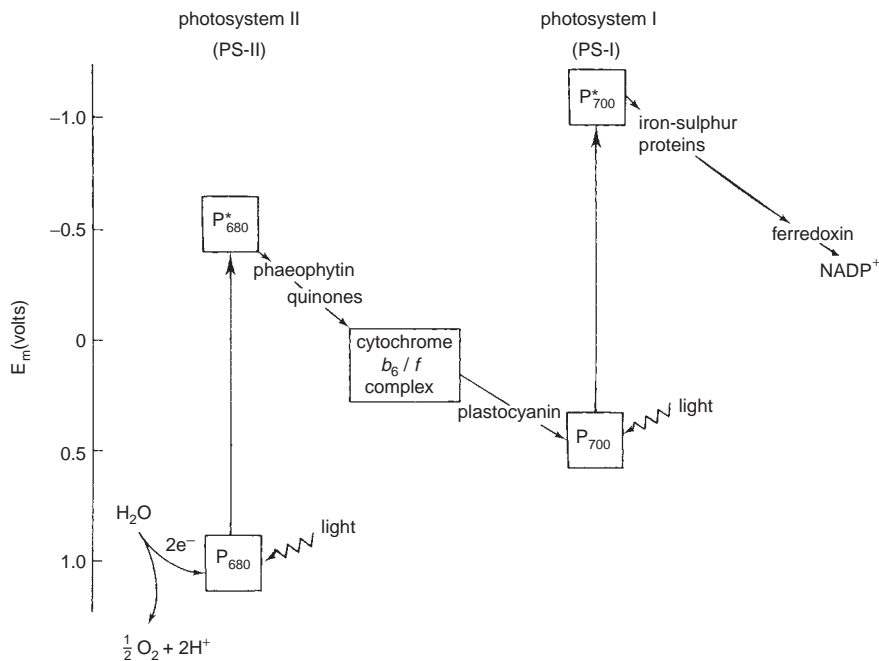

(a) *Photosynthesis in bacteria of the Rhodospirillales* (anoxygenic photosynthesis) occurs only under anaerobic conditions, and only one type of reaction centre appears to occur in a given species.

In the 'purple' photosynthetic bacteria (RHODOSPIRILLINEAE), electrons which have been ejected from the bacteriochlorophyll follow a *cyclic* path: e.g. from the bacteriochlorophyll to BACTERIOPHAEOPHYTIN and thence – probably via QUINONES, *b*- and *c*-type cytochrome(s) – back to the reaction centre; this cyclic electron flow causes the transmembrane pumping of protons, i.e., it generates pmf. The pmf can be used, by means of membrane-bound PROTON ATPASES, for the synthesis of ATP (*photophosphorylation*). At least some of these organisms can obtain reducing power by REVERSE ELECTRON TRANSPORT; in this process, photosynthetically generated pmf is used to reduce  $\text{NAD}^+$  at a membrane-bound NADH dehydrogenase – electrons being obtained from an external electron donor (such as hydrogen or sulphide). NADPH is obtained via a TRANSHYDROGENASE.

In the 'green' photosynthetic bacteria (CHLOROBINEAE), the light-energized reaction centre reaches a much lower (more negative) potential (ca. –550 mV) than is the case in the purple bacteria, and – consequently – the ejected electrons are able to effect the reduction of  $\text{NAD}^+$  (the  $E_{m,7}$  of the  $\text{NAD}^+/\text{NADH}$  redox couple being –320 mV); the reduction of  $\text{NAD}^+$  involves a *non-cyclic* electron transport path which is believed to include iron–sulphur proteins. Electrons which are removed from the

## photosynthesis

PHOTOSYNTHESIS. Simplified 'Z scheme' for non-cyclic, oxygenic photosynthetic electron transport (scale approximate). Each photosystem (PS-I and PS-II) consists of a reaction centre together with its associated accessory pigments.  $P_{680}$  and  $P_{700}$  represent the chlorophylls in the reaction centres of PS-II and PS-I, respectively;  $P_{680}^*$  and  $P_{700}^*$  represent the excited state in  $P_{680}$  and  $P_{700}$ , respectively. The cytochrome  $b_6/f$  complex includes cyts  $b_6$  and  $f$ , quinone, and a Rieske iron-sulphur protein.

reaction centre during non-cyclic electron flow must be replaced if photosynthesis is to continue; these electrons are obtained (via a pathway containing cytochrome  $c_{555}$ ) from certain substrates (e.g. sulphide). Water is never used as an electron donor, so that this type of photosynthesis is always anoxygenic.

The green photosynthetic bacteria appear to be also capable of *cyclic* electron flow – electrons returning to the reaction centre via a menaquinone and cytochrome  $c_{555}$ .

In many photosynthetic bacteria the dark reaction involves the fixation of carbon dioxide via the CALVIN CYCLE; however, at least some of the green photosynthetic bacteria use the REDUCTIVE TRICARBOXYLIC ACID CYCLE for this purpose. Apart from photochemical reactions, most of the reactions which occur in photosynthetic bacteria are known to occur in non-photosynthetic species; thus, e.g. the Calvin cycle occurs in chemolithotrophic bacteria.

(b) *Photosynthesis in algae and cyanobacteria.* Photosynthesis in these organisms differs from that described in (a) in that: (i) it occurs *aerobically*; (ii) it involves a composite photosynthetic system (as shown in the figure); (iii) it involves non-cyclic electron flow in which the terminal electron donor, water, is oxidized to oxygen – such photosynthesis thus being *oxygenic*. [How does PSII split water? (review) TIBS (1996) 21 44–49.] (Some species of cyanobacteria, e.g. *Oscillatoria limnetica*, can also carry out DCMU-insensitive, anaerobic, anoxygenic photosynthesis in which  $H_2S$  is used as external electron donor.) (See also PHOTOREDUCTION.) Oxygenic photosynthesis in algae

and cyanobacteria (and *Prochloron*) closely resembles that in higher green plants.

The characteristic (oxygenic, non-cyclic) mode of photosynthesis in algae and cyanobacteria is generally depicted by the so-called *Z scheme* (see figure). In this scheme, the midpoint redox potential of chlorophyll in the reaction centre of photosystem II (PS-II) changes from ca. +1.0 volt to between ca. –550 and –600 mV when the reaction centre receives a photon of light; electrons which are ejected from PS-II (and which are replaced by the oxidation of water) flow 'downhill' (i.e., towards less negative or more positive potentials) via QUINONES (generally believed to include plastoquinones), the CYTOCHROME  $b_6/f$  complex, and PLASTOCYANIN, to the reaction centre of photosystem I (PS-I). This electron flow is associated with the development of a proton gradient across the thylakoid membrane. In chloroplasts the inner surface of the thylakoid membrane becomes positive with respect to the outer (stromal) surface; the associated pmf can be utilized by membrane-bound PROTON ATPASES for ATP synthesis (photophosphorylation) – the  $CF_1$  part of the ATPase, and (hence) ATP synthesis, occurring at the outer surface of the thylakoid membrane.
