Dictionary of  
**Microbiology**  
and  
**Molecular Biology**  
Third Edition, Revised

*We would like to dedicate this book to the memory of Hubert Sainsbury. His lively and enquiring mind and his passion for knowledge and understanding were always an inspiration, and his enthusiasm for this Dictionary was a strong motivating force during its long gestation. The book owes more to him than he would have believed.*

Typeset in 10/12pt Times by Laserwords Private Limited, Chennai, India

Printed and bound in Great Britain by Antony Rowe Ltd, Chippenham, Wiltshire, UK

This book is printed on acid-free paper responsibly manufactured from sustainable forestry, in which at least two trees are planted for each one used for paper production.

# Preface

This edition follows the style of previous editions. It has similar aims, and was written with the same enthusiasm and care.

It is vital that readers be aware of the type of alphabetization used in the Dictionary. A glance at 'Notes for the User' – particularly the first paragraph – is essential.

September 2001

## Preface to the Second Edition

In writing this new edition of the Dictionary we had several aims in mind. One of these was to provide clear and up-to-date definitions of the numerous terms and phrases which form the currency of communication in modern microbiology and molecular biology. In recent years the rapid advances in these disciplines have thrown up a plethora of new terms and designations which, although widely used in the literature, are seldom defined outside the book or paper in which they first appeared; moreover, ongoing advances in knowledge have frequently demanded changes in the definitions of older terms – a fact which is not always appreciated and which can therefore lead to misunderstanding. Accordingly, we have endeavoured to define all of these terms in a way which reflects their actual usage in current journals and texts, and have also given (where appropriate) former meanings, alternative meanings, and synonyms.

A second – but no less important – aim was to encapsulate and integrate, in a single volume, a body of knowledge covering the many and varied aspects of microbiology. Such a reference work would seem to be particularly useful in these days of increasing specialization in which the reader of a paper or review is often expected to have prior knowledge of both the terminology and the overall biological context of a given topic. It was with this in mind that we aimed to assemble a detailed, comprehensive and interlinked body of information ranging from the classical descriptive aspects of microbiology to current developments in related areas of bioenergetics, biochemistry and molecular biology. By using extensive cross-referencing we have been able to indicate many of the natural links which exist between different aspects of a particular topic, and between the diverse parts of the whole subject area of microbiology and molecular biology; hence the reader can extend his knowledge of a given topic in any of various directions by following up relevant cross-references, and in the same way he can come to see the topic in its broader contexts. The dictionary format is ideal for this purpose, offering a flexible, ‘modular’ approach to building up knowledge and updating specific areas of interest.

There are other more obvious advantages in a reference work with such a wide coverage. Microbiological data are currently disseminated among numerous books and journals, so that it can be difficult for a reader to know where to turn for information on a term or topic which is completely unfamiliar to him. As a simple example, the name of an unfamiliar genus, if mentioned out of context, might refer to a bacterium, a fungus, an alga or a protozoan, and many books on each of these groups of organisms may have to be consulted merely to establish its identity; the problem can be even more acute if the meaning of an unfamiliar term is required. A reader may therefore be saved many hours of frustrating literature-searching by a single volume to which he can turn for information on any aspect of microbiology.

An important new feature of this edition is the inclusion of a large number of references to recent papers, reviews and monographs in microbiology and allied subjects. Some of these references fulfil the conventional role of indicating sources of information, but many of them are intended to permit access to more detailed information on particular or general aspects of a topic – often in mainstream journals, but sometimes in publications to which the average microbiologist may seldom refer. Furthermore, most of the references cited are themselves good sources of references through which the reader can establish the background of, and follow developments in, a given area.

While writing this book we were very fortunate in having exceptional and invaluable cooperation from a number of libraries in South-West England. In particular, we would like to acknowledge the generous help of Mr B. P. Jones, B.A., F.L.A., of the Medical Library, University of Bristol, Mrs Jean Mitchell of the Library at Bickton College of Agriculture, Devon, and Maureen Hammett of Exeter Central Library, Devon. Finally,

**Preface to the Second Edition**

we are grateful to Michael Dixon, Patricia Sharp, and Prue Theaker at John Wiley & Sons, Chichester, for their enthusiastic and efficient cooperation in the production of the book.

Paul Singleton & Diana Sainsbury  
Clyst St Mary, Devon, April 1987

## Notes for the User

1. *Alphabetization*. Alphabetization would need no comment if every term consisted of a single word; in practice, however, many terms consist of two or more words and often contain single letters, numbers, symbols etc. Terms consisting of two or more words can be alphabetized in either of two ways: on the basis of the first word, or on the basis that both or all of the words are run together and treated as one; thus, e.g., according to the ‘first-word’ (‘nothing-before-something’) system, *red tide* comes before *redox potential*, but according to the second system *redox potential* comes before *red tide*. Terms in this Dictionary have been alphabetized by the first-word system; in this system a single letter counts as a word (hence e.g. *R plasmid* comes before *rabies*), as does a group of letters (e.g. an abbreviation, or a gene designation). Examples:

<b>air sacculitis</b>	<b>atoxyl</b>	<b>black stem rust</b>	<b>RecA protein</b>
<b>airlift fermenter</b>	<b>ATP</b>	<b>black wart disease</b>	<b>recapitulation theory</b>
<b>AIV process</b>	<b>ATP synthase</b>	<b>black yeasts</b>	<b>recB gene</b>
<b>Ajellomyces</b>	<b>ATPase</b>	<b>blackeye cowpea mosaic virus</b>	<b>RecBC pathway</b>

When a *hyphen* connects two complete words, or occurs between a letter (or group of letters) and a word, the hyphen is regarded as a space; however, if a hyphen is used to link a *prefix* to a word (i.e., if the letters preceding the hyphen form a part-word which cannot stand alone) the term is alphabetized as though it were a single, non-hyphenated word. (In a few cases an entry heading contains words which can be written as separate, hyphenated or non-hyphenated words, or closed up as a single word: e.g. *red water fever*, *red-water fever*, *redwater fever*; in such cases an entry or cross-reference has been included in both possible positions.)

Examples:

<b>BL-type starter</b>	<b>M</b>	<b>nonsense mutation</b>	<b>preaxostyle</b>
<b>bla gene</b>	<b>M antigen</b>	<b>nonsense suppressor</b>	<b>pre-B cell</b>
<b>black beans</b>	<b>M-associated protein</b>	<b>non-specific immunity</b>	<b>prebuccal area</b>
<b>Black beetle virus</b>	<b>M bands</b>	<b>non-specific immunization</b>	<b>precipitation</b>

When a *Greek letter* forms a significant part of an entry heading it is counted as a word and is alphabetized as spelt (i.e.,  $\alpha$  as alpha,  $\beta$  as beta, etc: see Appendix VI for the Greek alphabet). A Greek letter is ignored for the purposes of alphabetization if it is a relatively minor qualification: e.g., part of a chemical designation (which can usually be replaced by a number, as in  $\beta$ -hydroxybutyrate, = 3-hydroxybutyrate). Examples:

<b>Delhi boil</b>	<b>MTOC</b>	<b>pHisoHex</b>	<b>polyhedrosis</b>
<b><math>\Delta</math></b>	<b><math>\mu</math></b>	<b><math>\phi</math>X phage group</b>	<b>poly-<math>\beta</math>-hydroxyalkanoate</b>
<b>delta agent</b>	<b>Mu</b>	<b>Phlebia</b>	<b>poly-<math>\beta</math>-hydroxybutyrate</b>
<b><math>\delta</math> antigen</b>	<b>mu chain</b>	<b>Phlebotomus</b>	<b>Polyhymenophorea</b>

A *number* which forms part of an entry heading affects the position of that entry only if the number immediately follows a letter or word (but cf. chemical names, below). A number which precedes a letter or word is usually ignored, although in the few cases where a number is the first and *main* part of an entry heading it is alphabetized as spelt. Letter–number combinations come after a letter–space but before letter–letter combinations, as in the illustrative sequence A, A2, A2A, A3, A22, AA, ABA etc. Roman numerals are treated as ordinary numbers (I as 1, II as 2 etc). (The reader should bear in mind that, in an unfamiliar term, ‘I’ could be a letter I or a Roman one, and its location in the Dictionary will be affected accordingly; similarly, ‘V’ could be letter V or Roman five. O and 0 (zero) may also be confused. If in doubt check both possible positions.) Examples:

<b>bacteriophage Pf2</b>	<b>D loop</b>	<b>Fitz-Hugh–Curtis syndrome</b>	<b>T1 side-chains</b>
<b>bacteriophage <math>\phi</math>I</b>	<b>D period</b>	<b>five–five–five test</b>	<b>T-2 toxin</b>
<b>bacteriophage <math>\phi</math>II</b>	<b>12D process</b>	<b>five-kingdom classification</b>	<b>T2H test</b>
<b>bacteriophage <math>\phi</math>6</b>	<b>D-type particles</b>	<b>five–three–two symmetry</b>	<b>T7 phage group</b>

Notes for the User

*Subscript/superscript* numbers and letters are alphabetized as though they were ordinary numbers and letters (except in the case of ion designations: see below). Examples:

avoparcin	B virus	C3 convertase	CO <sub>2</sub>
a <sub>w</sub>	B <sub>12</sub> coenzymes	C <sub>3</sub> cycle	CO <sub>2</sub> -stat
axenic	B663	C3bina	CoA
axial fibrils	Babes–Ernst granules	C5 convertase	coactin

*Primes, apostrophes* and other *non-alphabetizable symbols* (including e.g. plus, minus and % signs) are ignored. Examples:

brown rust	F antigens	Gautieriales	pluronic polyol F127
Browne's tubes	F <sup>+</sup> donor	Gazdar murine sarcoma virus	plus progamone
Brownian movement	F-duction	GC%	plus strand
Brown's tubes	F factor	GC type	Pluteaceae

In *chemical names* qualifications such as D-, L-, N-, o-, p-, numbers and Greek letters, as well as hyphens between parts of chemical names, are all ignored for the purposes of alphabetization. Examples:

acetyl-CoA synthetase	diazomycin A	methylmethane sulphonate
N-acetyl-D-glucosamine	6-diazo-5-oxo-L-norleucine	N-methyl-N'-nitro-N-nitrosoguanidine
acetylmethylcarbinol	diazotroph	N-methyl-N-nitrosourea
N-acetylmuramic acid	dibromoaplysiatoxin	<i>Methylobacterium</i>

In entry headings which include an *ion designation*, the ion is treated as a word, the charge being ignored; thus, H<sup>+</sup> is regarded as H, Ca<sup>2+</sup> as Ca, etc. Examples:

H antigens	H <sup>+</sup> /P ratio	K cells	Na <sup>+</sup> -ATPase
H <sup>+</sup> -ATPase	H <sup>+</sup> -PPase	K <sup>+</sup> pump	Na <sup>+</sup> -motive force
H <sup>+</sup> /2e <sup>-</sup> ratio	H strand	K <sup>+</sup> transport	Na <sup>+</sup> pump
H-lysin	H-1 virus	K virus	nabam

2. *Cross-references.* References from one entry to another within the Dictionary are indicated by SMALL CAPITAL letters. In order to effect maximum economy of space, information given in any particular entry is seldom repeated elsewhere, and cross-referencing has been extensively employed to ensure continuity of information. In some cases a complete understanding of an entry, or an appreciation of context, is dependent on a knowledge of information given in other entries; where it is particularly important to follow up a cross-reference, the cross-reference is followed by 'q.v.'. In other cases a cross-reference may be used to link one topic with another of related interest, or to extend the scope of a given topic in one or more directions; in such cases a cross-reference is usually preceded by 'see also' or 'cf.'. (N.B. For a variety of reasons, not every microbiological term or taxon used in the text is cross-referred – even though most of these terms and taxa are defined in the Dictionary; the reader is therefore urged to use the Dictionary for *any* unfamiliar term or taxon.)

When reading an entry for a genus, family or other taxon, it is especially important to follow up, when indicated, a cross-reference to the higher taxon to which it belongs. An entry for a given higher taxon gives the essential features applicable to all members of that taxon, and such features are usually *not* repeated in the entries for each of the constituent lower-ranked taxa; thus, in failing to follow up such cross-references, the reader will forfeit fundamental information relating to the lower taxon in question.

In some cases an entry heading is followed simply by 'See CROSS-REFERENCE'. This is *not* intended to indicate that the two terms are synonymous (usually they are not); such referral signifies only that the meaning of the term is given under the heading indicated. When the entry heading and cross-reference are synonymous, this is indicated by *Syn.*, thus: **entry heading** *Syn.* CROSS-REFERENCE.

3. *External references.* References to papers, articles etc in books or journals are given in square brackets. In order to save space, books are referred to by a 'Book ref.' number, and journal titles are abbreviated

somewhat more than is usual; keys to book reference numbers and journal title abbreviations can be found at the end of the Dictionary (after the Appendices).

A book reference is usually quoted as a source of general background information for the reader, while papers in journals are usually quoted for specific details of current information (or for reviews) and/or for their references to other literature in the field. We should emphasize that the papers we have cited are not necessarily (and are commonly not) those which were the first to report a particular fact, finding or theory; rather, we have chosen, where possible, to cite the most recent references available to us, so that the reader is referred to *current* information and can, if he wishes, trace the earlier literature via references given in the cited papers. We should also point out that the quoting of a single reference in an entry is not intended to indicate that the entry was written solely from information in that paper or book. In relatively few cases does the information in an entry derive from a single source; in the great majority of entries the information has been derived from, or checked against, a range of sources, but limitations of space have necessarily prevented us from citing all of them.

4. *Numbered definitions*. In some cases a term is used with different meanings by different authors, or it may have different meanings in different contexts; for such a term the various definitions are indicated by (1), (2), (3), etc. The order in which the numbered definitions occur is *not* intended to reflect in any way appropriateness or frequency of usage.

5. *Taxonomy*. See entries ALGAE, BACTERIA, FUNGI, PROTOZOA and VIRUS for some general comments on the taxonomy of each of these groups of microorganisms. Each of these entries (except that on bacteria) provides a starting point from which the reader can, via cross-references, follow through a hierarchical system down to the level of genus and, in many cases, species and below; similarly, the hierarchy can be ascended from genus upwards.

6. *The Greek alphabet*. See Appendix VI.

# A

**A** (1) Adenine (or the corresponding nucleoside or nucleotide) in a nucleic acid. (2) Alanine (see AMINO ACIDS).

**Å** (Ångström unit)  $10^{-10}$  m (=  $10^{-1}$  nm).

**2-5A** See INTERFERONS.

**A-DNA** See DNA.

**a-factor** See MATING TYPE.

**A layer** An S LAYER associated with virulence in strains of *Aeromonas salmonicida*.

**A-protein** In TOBACCO MOSAIC VIRUS: a mixture of small oligomers and monomers of coat protein subunits which occur in equilibrium with the larger 'disc' aggregates under conditions of physiological pH and ionic strength; coat protein occurs mainly as A-protein under conditions of high pH and low ionic strength. (cf. PROTEIN A.)

**A site** (of a ribosome) See PROTEIN SYNTHESIS.

**A-tubule** (A-subfibre) See FLAGELLUM (b).

**A-type inclusion body** See POXVIRIDAE.

**A-type particles** Intracellular, non-infectious, retrovirus-like particles. Many embryonic and transformed mouse cells contain retrovirus-like 'intracisternal A-type particles' (IAPs) which form by budding at the endoplasmic reticulum; these particles have reverse transcriptase activity and an RNA genome coding for the structural protein of the particles. The mouse genome contains ca. 1000 copies (per haploid genome) of DNA sequences homologous to IAP-associated RNA; these sequences appear to be capable of transposition within the mouse genome – probably via an RNA intermediate [Book ref. 113, pp. 273–279], i.e., they may be RETROTRANSPOSONS. Some A-type particles are non-enveloped precursors of B-type particles (see TYPE B ONCOVIRUS GROUP).

**A23187** An IONOPHORE which transports divalent cations, particularly  $\text{Ca}^{2+}$ ; it can effect the transmembrane exchange of  $1\text{Ca}^{2+}$  (or  $1\text{Mg}^{2+}$ ) for  $2\text{H}^{+}$  without causing perturbation in the gradients of other monovalent cations.

**AAA ATPases** 'ATPases associated with diverse cellular activities'. AAA ATPases occur e.g. in PEROXISOMES and as components of eukaryotic PROTEASOMES.

**AAA pathway** AMINOADIPIC ACID PATHWAY.

**AAC** Aminoglycoside acetyltransferase (see AMINOGLYCOSIDE ANTIBIOTICS).

**AAD** Aminoglycoside adenylyltransferase (see AMINOGLYCOSIDE ANTIBIOTICS).

**AAS** Aminoalkylsilane (3-aminopropyltriethoxy-silane, APES; 3(triethoxysilyl)-propylamine, TESPA): a reagent used for binding a tissue section to the surface of a glass slide (e.g. for in situ hybridization); it reacts with silica glass and provides aminoalkyl groups which bind to aldehyde or ketone groups in the tissue section.

**aat gene** In *Escherichia coli*: a gene whose product promotes the early degradation of those proteins whose N-terminal amino acid is either arginine or lysine. *aat* encodes an 'amino acid transferase' which catalyses the addition of a leucine or phenylalanine residue to the N-terminus of the protein; this destabilizes the protein, facilitating its degradation. (See also N-END RULE.)

**AatII** See RESTRICTION ENDONUCLEASE (table).

**Aaterra** See ETRIDIAZOLE.

**AAUAAA locus** See MRNA (b).

**AAV** Adeno-associated virus: see DEPENDOVIRUS.

**ab** (immunol.) ANTIBODY.

**AB-transhydrogenase** See TRANSHYDROGENASE.

**ABA** ABSICISIC ACID.

**abacavir** A NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR.

**abacterial pyuria** See PYURIA.

**Abbe condenser** A simple two- or three-lens substage CONDENSER which is uncorrected for spherical or chromatic aberrations.

**ABC** (1) (immunol.) ANTIGEN-BINDING CELL. (2) See ABC TRANSPORTER.

**ABC excinuclease** See EXCISION REPAIR.

**ABC exporter** An ABC TRANSPORTER concerned with export/secretion. These systems are found in both prokaryotic and eukaryotic microorganisms and in higher animals, including man. (The mammalian transporters include P-glycoprotein ('multidrug-resistance protein') – a molecular pump by which some types of cancer cell can extrude anti-cancer drugs.) In *Saccharomyces cerevisiae*, an ABC exporter mediates secretion of a peptide PHEROMONE (the a-factor) which regulates sexual interaction.

In bacteria, ABC exporters transport various proteins (including enzymes and antibiotics) and, in some species, the polysaccharide components of the capsule; an exporter may be able to transport various related or similar molecules. [Bacterial ABC exporters: MR (1993) 57 995–1017.]

In *Escherichia coli* the  $\alpha$ -haemolysin is secreted via an ABC exporter – a one-step process direct from cytoplasm to environment; this exporter is in the *type I* class of protein secretory systems in Gram-negative bacteria (see PROTEIN SECRETION).

Other proteins secreted by these systems include the cyclolysin of *Bordetella pertussis* and the alkaline protease of *Pseudomonas aeruginosa*. In *Streptomyces antibioticus* an ABC exporter secretes the antibiotic OLEANDOMYCIN.

Bacterial proteins secreted by ABC exporters typically lack an N-terminal signal sequence (see SIGNAL HYPOTHESIS) but they have a C-terminal *secretion sequence* that may interact directly with the ABC protein. Exporters which transport molecules to the periplasm, or outer membrane, as the *final* destination may have fewer protein components than those exporters which *secrete* proteins.

In Gram-negative bacteria, at least some exporters appear to consist of (i) ABC proteins; (ii) a *membrane fusion protein* (MFP) (in the periplasm and cytoplasmic membrane); and (iii) an OUTER MEMBRANE component. Assembly seems to occur in a definite sequence which is promoted and/or initiated by the binding of substrate (i.e. the molecule to be secreted) to the ABC protein; in this scheme, substrate-ABC binding is followed by ABC-MFP interaction – MFP then binding to the outer membrane, presumably to complete the secretory channel [EMBO (1996) 15 5804–5811].

**ABC immunoperoxidase method** An IMMUNOPEROXIDASE METHOD involving the use of a preformed avidin-biotin-peroxidase complex (ABC) which has surplus biotin-binding capacity. Initially, a ('primary') antiserum is raised against the required antigen; if the primary antiserum is derived from e.g. a rat, a 'secondary' anti-rat antiserum is prepared, and the anti-rat Ig antibodies are BIOTINYLATED. To locate a specific antigen, the section is treated with primary antiserum, washed, and then treated with secondary antiserum; the subsequent addition of ABC localizes peroxidase at the site of specific antigen (since the

## ABC protein

ABC adheres non-specifically to biotin). Peroxidase (and hence antigen) is detected by incubating the section with e.g. H<sub>2</sub>O<sub>2</sub> and diaminobenzidine (which results in the antigenic site being stained brown) or H<sub>2</sub>O<sub>2</sub> and 4-chloro-1-naphthol (resulting in a blue stain).

The ABC method can be used for paraffin-embedded sections, frozen sections, and smears. Endogenous (tissue or cell) peroxidase may be quenched e.g. with H<sub>2</sub>O<sub>2</sub> in methanol.

**ABC protein** See ABC TRANSPORTER.

**ABC transporter** (traffic ATPase) A type of TRANSPORT SYSTEM which, in bacteria, consists typically of a multiprotein complex in the cell envelope, two of the proteins having a specific ATP-binding site (termed the *ATP-binding cassette*; ABC) on their cytoplasmic surface; a (bacterial) protein with an ABC site has been called an 'ABC protein' or an 'ABC subunit'. In eukaryotes, an ABC transporter generally consists of a single polypeptide chain – which also has two ATP-binding sites. Transport mediated by an ABC transporter is energized by ATP hydrolysis at the ABC sites. [ATP-hydrolysing regions of ABC transporters: FEMS Reviews (1998) 22 1–20.] (See also PROTEIN SECRETION.)

A given type of ABC transporter imports or exports/secretates certain type(s) of ion or molecule. Collectively, these transporters import or secrete a wide range of substances, including ions, sugars and proteins; for example, some import nutrients, or ions for OSMOREGULATION, while others secrete antibiotics or protein toxins. The LmrA transporter in *Lactococcus lactis* mediates an efflux system that extrudes amphiphilic compounds and appears to be functionally identical to the mammalian P-glycoprotein that mediates multidrug-resistance [Nature (1998) 391 291–295]. The AtrB transporter of *Aspergillus nidulans* mediates energy-dependent efflux of a range of fungicides [Microbiology (2000) 146 1987–1997].

ABC transporters occur e.g. in Gram-positive and Gram-negative bacteria, members of the Archaea, and in higher animals, including man. In man, certain inheritable diseases (e.g. CYSTIC FIBROSIS and adrenoleukodystrophy) result from defective ABC transporters.

The bacterial *ABC importer* is commonly called a BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM (q.v.). (See also ABC EXPORTER.)

**ABE process** An industrial process in which acetone, butanol and ethanol are produced by the fermentation of e.g. molasses by *Clostridium acetobutylicum*. (See also ACETONE–BUTANOL FERMENTATION.)

**Abelson murine leukaemia virus** (Ab-MuLV) A replication-defective, *v-onc*<sup>+</sup> MURINE LEUKAEMIA VIRUS isolated from a prednisolone-treated BALB/c mouse inoculated with Moloney murine leukaemia virus (Mo-MuLV). Ab-MuLV apparently arose by recombination between Mo-MuLV and mouse *c-abl* sequences; the *v-abl* product has tyrosine kinase activity. (See also ABL.) Ab-MuLV induces B-cell lymphoid leukaemia with a short latent period (3–4 weeks). [Abelson virus–cell interactions: Adv. Imm. (1985) 37 73–98.]

**abequose** (3,6-dideoxy-D-galactose) A sugar, first isolated from *Salmonella abortusequi*, which occurs in the O-specific chains of the LIPOPOLYSACCHARIDE in certain *Salmonella* serotypes and which contributes to the specificity of O antigen 4 in group B salmonellae (see KAUFFMANN–WHITE CLASSIFICATION).

**aberration** (chromosomal) See CHROMOSOME ABERRATION.

**abhyemial** Of or pertaining to a region opposite or away from the HYMENIUM.

**abiogenesis** (spontaneous generation) The spontaneous formation of living organisms from non-living material; apart from

its application to the evolutionary origin of life, this doctrine has long been abandoned.

**abiotic** Non-living; of non-biological origin.

**abl** An ONCOGENE originally identified as the transforming determinant of ABELSON MURINE LEUKAEMIA VIRUS (Ab-MuLV). The *v-abl* product has tyrosine kinase activity. In humans, *c-abl* normally occurs on chromosome 9, but is translocated to chromosome 22q- (the Philadelphia chromosome) in cells from patients with chronic myelogenous leukaemia (CML); in chromosome 22 it forms a chimeric fusion gene, *bcg-abl*, encoding a tumour-specific tyrosine kinase designated P210.

**ablastin** Antibody which specifically inhibits reproduction of epimastigote forms of *Trypanosoma lewisi* in the vertebrate host.

**abomasitis** Inflammation of the abomasum. (See also BRAXY; cf. RUMENTITIS.)

**abomasum** See RUMEN.

**aboral** Away from, or opposite to, the mouth.

**abortifacient** Able to cause abortion.

**abortive infection** (*virol.*) A viral infection of (*non-permissive*) cells which does not result in the formation of infectious progeny virions, even though some viral genes (e.g. early genes) may be expressed. (cf. PERMISSIVE CELL.)

**abortive transduction** See TRANSDUCTION.

**abortus Bang reaction** (abortus Bang ring-probe) *Syn.* MILK RING TEST.

**ABR** See MILK RING TEST.

**abrB gene** See ENDOSPORE (figure (a) legend).

**abscess** A localized collection of PUS surrounded by inflamed and necrotic tissue; it may subside spontaneously or may rupture and drain before healing. Abscesses may occur in any tissue and may be caused by any of a variety of organisms. Abscesses in internal organs (e.g. liver, kidney, brain) may follow bacteraemia or septicaemia and may be due to staphylococci, streptococci, coliforms, etc. A *cold* (or *chronic*) abscess is one with little inflammation, often due to tubercle bacilli. (See also DYSENTERY (b) and QUINSY.)

**abscisic acid** (ABA) A terpenoid PHYTOHORMONE which acts e.g. as a growth inhibitor, as an inhibitor of germination, and as an accelerator of e.g. leaf abscission. ABA is also formed (as a secondary metabolite) e.g. by the fungus *Cercospora rosicola*.

**Absidia** See MUCORALES.

**absorption** (*serol.*) The removal or effective removal of particular antibodies, antigens, or other agents from a given sample (e.g. serum) by the addition of particular antigens, antibodies, or agents to that sample; the resulting antigen–antibody (or other) complexes may or may not be physically removed from the sample. Absorption is used e.g. to remove HETEROPHIL ANTIBODIES.

**absorptive pinocytosis** See PINOCYTOSIS.

**7-ACA** 7-Aminocephalosporanic acid (see CEPHALOSPORINS).

**Acanthamoeba** A genus of amoebae (order AMOEBA) in which the pseudopodia each have a broad hyaline zone (see PSEUDOPODIUM) from which arise several to many slender, tapering, flexible, and sometimes forked projections (*acanthopodia*). Polyhedral or roughly circular cysts with cellulose-containing walls are formed. Species are widespread and common in soil and fresh water, where they prey on e.g. bacteria, yeasts etc. [Adhesion of *Acanthamoeba castellanii* to bacterial flagella: JGM (1984) 130 1449–1458; bacterial endosymbionts of *Acanthamoeba*: J. Parasitol. (1985) 71 89–95.] Some strains can cause e.g. eye infections, MENINGOENCEPHALITIS [pathogenicity: RMM (1994) 5 12–20]. (cf. HARTMANNELLA.)

**Acantharea** A class of marine, mostly planktonic protozoa (superclass ACTINOPODA) which have elaborate 'skeletons' composed of strontium sulphate; typically, the skeleton consists of 10 spines arranged diametrically in the (more or less spherical) cell, or 20 spines which radiate from the cell centre (where they may or may not be joined at their bases, according to species). In many species the cell contains a central capsule (cf. RADIIOLARIA); many species contain zooxanthellae. Five orders are recognized; genera include e.g. *Acanthochiasma*, *Acanthometra*, *Astrolophus*, *Gigartacon*.

**Acanthochiasma** See ACANTHAREA.

**Acanthocystis** See CENTROHELIDA.

**Acanthoeca** See CHOANOFAGELLIDA.

**Acanthometra** See ACANTHAREA.

**acanthopodia** See ACANTHAMOEBA.

**acaricide** Any chemical which kills mites and ticks (order Acarina).

**Acarospora** A genus of LICHENS (order LECANORALES). Thallus: crustose, areolate, with prominent areolae. Apothecia are embedded in the areolae; ascospores: very small, many per ascus. All species are saxicolous, some are ENDOLITHIC; *A. smaragdula* occurs on rocks and slag rich in heavy metals.

**Acarpomyxea** A class of protozoa (superclass RHIZOPODA) with characteristics intermediate between those of the naked amoebae and the plasmodial slime moulds: they form small plasmodia (or large uninucleate plasmodium-like forms) which are usually branched and which sometimes anastomose to form a coarse reticulum. Spores, fruiting bodies and tests are absent; cysts are produced by some species. Orders: Leptomyxida (soil and freshwater organisms, e.g. *Leptomyxa* [Book ref. 133, pp. 143–144], *Rhizamoeba*) and Stereomyxida (marine organisms, e.g., *Coralomyxa*, *Stereomyxa*).

**Acaryophrya** See GYMNOSTOMATIA.

**Acaulopage** See e.g. NEMATOPHAGOUS FUNGI.

**Acaulospora** See ENDOGONALES.

**acceptor site** (of a ribosome) See PROTEIN SYNTHESIS.

**acceptor splice site** See SPLIT GENE (a).

**accessory cells** (*immunol.*) Those cells which, together with B LYMPHOCYTES and/or T LYMPHOCYTES, are involved in the expression of humoral and/or cell-mediated immune responses; they include e.g. MACROPHAGES, DENDRITIC CELLS, and LANGERHANS' CELLS.

**accessory pigments** In PHOTOSYNTHESIS: those pigments contained in LIGHT-HARVESTING COMPLEXES.

**AcCoA** Acetyl-COENZYME A.

**Ace toxin** (*Vibrio cholerae*) See BACTERIOPHAGE CTXΦ.

**acellular** (non-cellular) (1) Refers to an organism, usually a protozoan, which consists essentially of a single cell but in which occur functionally specialized regions sometimes regarded as analogous to the organs and tissues of a differentiated multicellular organism. (2) Refers to an organism (e.g. a VIRUS) or structure (e.g. the stalk of ACYTOSTELIUM) which is not CELLULAR in any sense. (3) Not divided into cells (as e.g. in a PLASMODIUM).

**acellular slime moulds** See MYXOMYCETES.

**acentric** (of a chromosome) Having no CENTROMERE.

**acephaline gregarines** See GREGARINASINA.

**acer tar spot** See RHYTISMA.

**acervulus** A flat or saucer-shaped fungal STROMA supporting a mass of typically short and densely-packed conidiophores; acervuli commonly develop subcuticularly or subepidermally in a plant host, becoming erumpent at maturity, i.e., rupturing the overlying plant tissue to allow dispersal of the conidia. Some acervuli bear setae (see SETA).

**Acetabularia** A genus of DASYCLADALEAN ALGAE. The vegetative thallus consists of a single cell in which the CELL WALL contains MANNAN as a major component and is generally more or less heavily calcified; the cell is differentiated into an erect stalk or axis (up to several centimetres tall) anchored to the substratum by a branching rhizoid. The single nucleus is located in one branch of the rhizoid. As the stalk grows, whorls of sterile 'hairs' develop around the tip; these hairs are eventually shed, leaving rings of scars around the stalk. When the thallus is mature, gametangia develop as an apical whorl of elongated sac-like structures which, depending on species, may or may not be joined to form a characteristic *cap* (giving rise to the popular name 'mermaid's wine-glass'). Once the gametangial sacs have developed, the primary nucleus in the rhizoid grows to ca. 20 times its original size; it then undergoes meiosis, and numerous small secondary nuclei are formed. These migrate from the rhizoid to the gametangia by cytoplasmic streaming. Within a gametangial sac, each nucleus becomes surrounded by a resistant wall, resulting in the formation of many resistant cysts; the cyst walls contain cellulose rather than mannan, and are often heavily calcified. The cysts are liberated into the sea and then undergo a period of dormancy before liberating numerous biflagellate isogametes; pairs of gametes fuse to form zygotes which then develop into new vegetative thalli.

**acetate formation** See e.g. ACETIFICATION and ACETOGENESIS.

**acetate thiokinase** See METHANOGENESIS.

**acetate utilization** See e.g. METHANOGENESIS and TCA CYCLE.

**Acetator** See VINEGAR.

**acetic acid bacteria** (1) *Acetobacter* spp. (2) Any bacteria capable of ACETIFICATION, including *Acetobacter* spp and *Glucanobacter* sp.

**acetilastic** Able to catabolize acetate.

**acetification** The aerobic conversion of ethanol to acetic acid by bacteria (usually *Acetobacter* spp). Ethanol is converted to hydrated acetaldehyde (CH<sub>3</sub>CH(OH)<sub>2</sub>) which is then dehydrogenated to give acetic acid. Acetification is an exothermic process. (See also e.g. VINEGAR, BEER SPOILAGE, WINE SPOILAGE.)

**Acetivibrio** A genus of bacteria (family BACTEROIDACEAE) whose natural habitat is unknown. Cells: straight to slightly curved rods, 0.5–0.9 × 1.5–10.0 μm; in motile species the concave side of the cell has either a single flagellum or a number of flagella which arise in a line along the longitudinal axis of the cell. The cells stain Gram-negatively but the cell wall of the type species resembles those of Gram-positive bacteria. The major products of carbohydrate fermentation typically include acetic acid, ethanol, CO<sub>2</sub> and H<sub>2</sub>; butyric, lactic, propionic and succinic acids are not formed. GC%: ca. 37–40. Type species: *A. cellulolyticus*.

*A. cellulolyticus*. Monotrichous. Substrates include cellobiose, cellulose and salicin; aesculin is not hydrolysed. The type strain was isolated from a methanogenic enrichment culture.

*A. cellulosolvans*. A non-motile species (isolated from sewage sludge) which can hydrolyse cellulose, cellobiose, aesculin and salicin; the cells apparently have an outer membrane. [JJSB (1984) 34 419–422.]

*A. ethanolignens*. Multitrichous. Substrates include fructose, galactose, lactose, maltose, mannitol and mannose – but not cellobiose, cellulose or aesculin. *A. ethanolignens* is consistently present in the colons of pigs suffering from SWINE DYSENTERY.

**Acetobacter** A genus of Gram type-negative bacteria of the family ACETOBACTERACEAE; the organisms occur e.g. on certain fruits and flowers, are responsible for some types of BEER SPOILAGE and WINE SPOILAGE, and are used e.g. in the manufacture of VINEGAR.

## Acetobacteraceae

Cells: typically ovoid or rod-shaped, 0.6–0.8 × 1.0–4.0 µm, non-motile or with peritrichous or lateral flagella. Most strains are catalase-positive. Typically, ethanol is oxidized to acetic acid, and acetic acid is oxidized ('overoxidation') to CO<sub>2</sub> (cf. GLUCONOBACTER). Principal substrates include e.g. ethanol, glycerol and lactate; most strains grow well on glucose–yeast extract–CaCO<sub>3</sub> agar (GYC agar), forming round pale colonies. (See also CARR MEDIUM.) Some strains form CELLULOSE (see PELLICLE (1)). Sugars appear to be metabolized primarily via the HEXOSE MONOPHOSPHATE PATHWAY and the TCA CYCLE; phosphofruktokinase seems to be absent (cf. Appendix I(a)). The ENTNER–DOUDOROFF PATHWAY appears to occur only in cellulose-synthesizing strains. Growth on HOYER'S MEDIUM appears to involve enzymes of the glyoxylate shunt. Optimum growth temperature: 25–30°C. GC%: ca. 51–65. Type species: *A. aceti*.

*A. aceti*. Ketogenic with glycerol or sorbitol substrates; 5-ketogluconic acid (but not 2,5-diketogluconic acid) formed from D-glucose. No diffusible brown pigments are formed on GYC agar. Grows on sodium acetate.

*A. hansenii*. Ketogenic with glycerol or sorbitol substrates; 5-ketogluconic acid (but not 2,5-diketogluconic acid) is formed by some strains from D-glucose. No growth on sodium acetate. No diffusible brown pigments are formed on GYC agar. (cf. *A. xylinum*.)

*A. liquefaciens*. Brown diffusible pigments are formed on GYC agar. 2,5-Diketogluconic acid is formed from D-glucose. Ketogenic with glycerol as substrate.

*A. pasteurianus*. Ketogluconic acids are not formed from D-glucose. No brown diffusible pigments are formed on GYC agar. Some strains (formerly called *A. peroxydans*) are catalase-negative. (cf. *A. xylinum*.)

*A. peroxydans*. See *A. pasteurianus*.

*A. suboxydans*. See GLUCONOBACTER.

*A. xylinum*. Cellulose-producing strains formerly classified as a subspecies of *A. aceti*, then distributed between the two species *A. hansenii* and *A. pasteurianus*; *A. xylinum* has now been accepted as a revived name for cellulose-forming and celluloseless, acetate-oxidizing strains [IJSB (1984) 34 270–271].

[Book ref. 22, pp. 268–274.]

**Acetobacteraceae** A family of aerobic, oxidase-negative, chemo-organotrophic, Gram type-negative bacteria which typically oxidize ethanol to acetic acid. Metabolism: strictly respiratory (oxidative), with O<sub>2</sub> as terminal electron acceptor. Growth occurs optimally at ca. pH 5–6. The organisms occur e.g. in acidic, ethanol-containing habitats. GC%: ca. 51–65. Two genera: ACETOBACTER (type genus), GLUCONOBACTER [Book ref. 22, pp. 267–278].

**Acetobacterium** A genus of Gram-negative, obligately anaerobic bacteria which occur in marine and freshwater sediments [IJSB (1977) 27 355–361]. Cells: polarly flagellated ovoid rods, ca. 1.0 × 2.0 µm, often in pairs. The type species, *A. woodii*, can carry out a homoacetate fermentation of e.g. fructose, glucose or lactate, or can grow chemolithoautotrophically (see ACETOGENESIS); it contains group B PEPTIDOGLYCAN. Optimum growth temperature: 30°C. GC%: ca. 39. (See also ANAEROBIC DIGESTION.)

**acetogen** (1) Any bacterium (e.g. *Acetobacterium woodii*, *Clostridium acetium*, *C. thermoacetium*) which produces acetate – as the *main* product – from certain sugars (via homoacetate fermentation and reduction of carbon dioxide) and (in some strains) from carbon dioxide and hydrogen (see ACETOGENESIS).

(2) (hydrogenogen; proton-reducing acetogen) Any bacterium which can use protons as electron acceptors for the

oxidation of certain substrates (e.g. ethanol, lactate, fatty acids) to acetate with concomitant formation of hydrogen. Obligate hydrogenogens include e.g. SYNTROPHOMONAS (see also ANAEROBIC DIGESTION). Some SULPHATE-REDUCING BACTERIA appear to be facultative hydrogenogens. The synthesis of acetate by hydrogenogens is thermodynamically favourable only when the partial pressure of hydrogen is very low – e.g. in the presence of a hydrogen-utilizing methanogen.

**acetogenesis** Acetate formation. A variety of microorganisms can form acetate, as a major or minor product, e.g. via the MIXED ACID FERMENTATION or PROPIONIC ACID FERMENTATION. (cf. ACETIFICATION.)

The term is also used more specifically to refer to the *particular* pathways used by the ACETOGENS (sense 1). These organisms form acetate, as the *main* product, from e.g. certain hexoses in a process (*homoacetate fermentation*) in which the hexose is metabolized to pyruvate (via the EMBDEN–MEYERHOF–PARNAS PATHWAY) and thence to acetate and carbon dioxide.

Additional acetate is formed as follows. Some of the carbon dioxide is reduced to formate; this formate is bound to tetrahydrofolate (THF) and is further reduced (in an ATP-dependent reaction) to yield 5-methyl-THF. The methyl group is then transferred to coenzyme B<sub>12</sub>. The remainder of the carbon dioxide is reduced to carbon monoxide (by CO dehydrogenase). Carbon monoxide reacts with methyl-coenzyme B<sub>12</sub> in the presence of coenzyme A and CO dehydrogenase disulphide reductase to yield acetyl-CoA. Acetyl-CoA is converted to acetate and CoASH with concomitant substrate-level phosphorylation to yield ATP.

Some acetogens (e.g. *A. woodii*, *C. acetium*, some strains of *C. thermoacetium*) can form acetate from carbon dioxide and hydrogen [autotrophic pathways in acetogens: JBC (1986) 261 1609–1615]. This process resembles the latter part of the pathway above: CO is derived from carbon dioxide, 2H<sup>+</sup> and 2e<sup>-</sup>, and 5-methyl-THF from THF, carbon dioxide and hydrogen.

**acetoin** (CH<sub>3</sub>.CHOH.CO.CH<sub>3</sub>; acetylmethylcarbinol) See e.g. Appendix III(c); BUTANEDIOL FERMENTATION; VOGES–PROSKAUER TEST.

**Acetomonas** Former name of GLUCONOBACTER.

**acetone–butanol fermentation** (solvent fermentation) A FERMENTATION (sense 1), carried out by certain saccharolytic species of *Clostridium* (e.g. *C. acetobutylicum*), in which the products include acetone (or isopropanol) and *n*-butanol (collectively referred to as 'solvent'). Glucose is initially metabolized via the BUTYRIC ACID FERMENTATION, but subsequently the pH drops to ca. 4.5–5.0 and acetone and *n*-butanol are formed as major end products [Appendix III (g)]. This fermentation is carried out on an industrial scale to a limited extent. [Review: AAM (1986) 31 24–33, 61–92.]

**acetosyringone** See CROWN GALL.

**3-acetoxindole** See INDOXYL ACETATE.

**acetylcholine** (neurotransmitter) See BOTULINUM TOXIN.

**acetyl-CoA synthetase** See TCA CYCLE.

**N-acetyl-L-cysteine** See MUCOLYTIC AGENT.

**N-acetyl-D-glucosamine** (GlcNAc) *N*-Acetyl-(2-amino-2-deoxy-D-glucose): an amino sugar present in various polysaccharides – see e.g. CHITIN, HYALURONIC ACID, LIPOPOLYSACCHARIDE, PEPTIDOGLYCAN (q.v. for formula), TEIHOIC ACIDS.

**acetylmethylcarbinol** *Syn.* ACETOIN.

**N-acetylmuramic acid** See PEPTIDOGLYCAN.

**N-acetylmuramidase** *Syn.* LYSOZYME.

**N-acetylneuraminic acid** See NEURAMINIC ACID.

**A-CGT** See IMMUNOSORBENT ELECTRON MICROSCOPY.

**achlorophyllous** *Syn.* ACHLOROTIC.

**achlorotic** (achlorophyllous) Lacking chlorophyll. (cf. APOCHLOROTIC.)

**Achlya** A genus of aquatic fungi (order SAPROLEGNIALES) in which the thallus is characteristically a branched, coenocytic mycelium; the width of the hyphae varies with species. Although *Achlya* species are typically saprotrophic some have been reported to parasitize rice plants. (See also DIPLANETISM, HETEROETHALLISM and PHEROMONE.)

**Achnanthes** See DIATOMS.

**Acholeplasma** A genus of facultatively anaerobic, urease-negative bacteria (family ACHOLEPLASMATACEAE) which are associated with various vertebrates (and possibly with invertebrates and plants), and which also occur e.g. in soil and sewage and as contaminants in TISSUE CULTURES. Cells: non-motile cocci (minimum diam. ca. 300 nm) or filaments (typically ca. 2–5 µm in length); carotenoid pigments occur in some species. The organisms resemble *Mycoplasma* spp in their general properties, but differ e.g. in that their growth is sterol-independent, and in that NADH oxidase occurs in the cytoplasmic membrane rather than in the cytoplasm. *Acholeplasma* spp are susceptible to various ACHOLEPLASMAVIRUSES. GC%: ca. 26–36. Type species: *A. laidlawii*; other species: *A. axanthum*, *A. equifetale*, *A. granularum*, *A. hippikon*, *A. modicum*, *A. morum*, *A. oculi*. [Book ref. 22, pp. 775–781.]

**Acholeplasmataceae** A family of bacteria of the order MYCOPLASMATALES; species of the sole genus, ACHOLEPLASMA, differ from the other members of the order e.g. in that their growth is not sterol-dependent. [Proposal for re-classifying Acholeplasmataceae as the order Acholeplasmatales: IJSB (1984) 34 346–349.]

**acholeplasmaviruses** BACTERIOPHAGES which infect *Acholeplasma* species: see PLECTROVIRUS, PLASMAVIRIDAE, MV-L3 PHAGE GROUP.

**achromat** (achromatic objective) An objective lens (see MICROSCOPY) in which chromatic aberration has been corrected for two colours (usually red and blue), and spherical aberration has been corrected for one colour (usually yellow–green). (cf. APOCHROMAT.) A FLAT-FIELD OBJECTIVE LENS of this type is called a *planachromat*.

**Achromobacter** An obsolete bacterial genus.

**achromogenic** Refers to an organism (or e.g. reagent) which does not produce pigment (or colour); used e.g. of non-pigmented strains of normally CHROMOGENIC organisms.

**achromycin** See TETRACYCLINES.

**aciclovir** A spelling used by some authors for the drug ACYCLOVIR.

**acicular** Needle-shaped.

**Aciculoconidium** A genus of fungi (class HYPHOMYCETES) which form budding ovoid or ellipsoidal cells (occurring singly or in short chains or clusters) as well as branched septate hyphae. Conidia are formed terminally and are acicular, rounded at one end and pointed at the other. NO<sub>3</sub><sup>-</sup> is not assimilated. One species: *A. aculeatum* (formerly *Trichosporon aculeatum*), isolated from *Drosophila* spp. [Book ref. 100, pp. 558–561.]

**acid dye** See DYE.

**acid-fast organisms** Organisms (e.g. *Mycobacterium* spp) which, once stained with an ACID-FAST STAIN, cannot be decolorized by mineral acids or by mixtures of acid and ethanol.

**acid-fast stain** Any stain used to detect or demonstrate ACID-FAST ORGANISMS – e.g. ZIEHL–NEELSEN'S STAIN, AURAMINE–RHODAMINE STAIN.

**acid fuchsin** See FUCHSIN.

**acid phosphatase** See PHOSPHATASE.

**Acidaminococcus** A genus of Gram-negative bacteria (family VEILLONELLACEAE) which occur e.g. in the intestine in humans and pigs. Cells: typically kidney-shaped cocci, 0.6–1.0 µm diam, occurring in pairs. Amino acids are the main sources of carbon and energy; all strains need e.g. arginine, glutamate, tryptophan and valine, and most need e.g. cysteine and histidine. In general, the organisms metabolize carbohydrates weakly or not at all. Optimum growth temperature: 30–37°C. Optimum pH: 7.0. GC%: ca. 57. Type species: *A. fermentans*.

**acidophile** An organism which grows optimally under acidic conditions, having an optimum growth pH below 6 (and sometimes as low as 1, or below), and which typically grows poorly, or not at all, at or above pH 7: see e.g. SULFOLOBUS, THERMOPLASMA, THIOBACILLUS. (cf. ALKALOPHILE and NEUTROPHILE; see also LEACHING.)

**acidophilus milk** A sour, medicinal beverage made by fermenting heat-treated, partially skimmed milk with *Lactobacillus acidophilus*. (Viable *L. acidophilus* appears to have a therapeutic effect on some intestinal disorders.) The main fermentation product is lactic acid which reaches a level of ca. 1.0%. A more palatable preparation, 'sweet acidophilus milk', is made by adding *L. acidophilus* to milk at ca. 5°C; under these conditions the cells remain viable but lactic acid is not produced. (See also DAIRY PRODUCTS.)

**acidosis** (1) (lactic acidosis) (*vet.*) A (sometimes fatal) condition which may occur in ruminants fed excessive amounts of readily fermentable carbohydrates (e.g. starch, sugars – found e.g. in grain and beet, respectively) or when the transfer from a roughage to a 'concentrate' diet is made too quickly. Under these conditions the rate of acid production in the RUMEN is very high; the resulting fall in pH in the rumen (due mainly to the accumulation of lactic acid) inhibits cellulolytic bacteria and protozoa, and favours the growth of certain LACTIC ACID BACTERIA – so that the pH falls still further. (See also RUMENITIS.) A gradual transition from roughage to concentrate may permit the somewhat more acid-tolerant bacterium *Megasphaera elsdenii* to metabolize the lactic acid and maintain a normal pH in the rumen. (See also THIOPEPTIN.)

(2) (*med., vet.*) A pathological condition characterized by an abnormally low pH in the blood and tissues.

**Acidothermus** A proposed genus of aerobic, thermophilic (growing at 37–70°C), acidophilic (growing at pH 3.5–7.0), cellulolytic, non-motile, rod-shaped to filamentous bacteria isolated from acidic hot springs; GC%: ca. 60.7. [IJSB (1986) 36 435–443.]

**aciduric** Tolerant of acidic conditions. (cf. ACIDOPHILE.)

**Acinertia** See GYMNOSTOMATIA.

**Acineta** See SUCTORIA.

**Acinetobacter** A genus of strictly aerobic, oxidase –ve, catalase +ve Gram-type-negative bacteria of the family MORAXELLACEAE (within the gamma subdivision of PROTEOBACTERIA); the organisms occur e.g. in soil and water and may act as opportunist pathogens in man. (See also MEAT SPOILAGE and SEWAGE TREATMENT.)

Cells: short rods, 0.9–1.6 × 1.5–2.5 µm, or coccobacilli (coccoid in stationary-phase cultures); cells often in pairs. Non-motile, but may exhibit TWITCHING MOTILITY. Non-pigmented.

Metabolism is respiratory (oxidative), with oxygen as terminal electron acceptor; no growth occurs anaerobically, with or without nitrate.

## AcLVs

Most strains can grow on a mineral salts medium containing an organic carbon source such as acetate, ethanol or lactate as the sole source of carbon and energy; some can use amino acids (e.g. L-leucine, ornithine) and/or pentoses (e.g. L-arabinose, D-xylose), and some are able to degrade e.g. benzoate, *n*-hexadecane and alicyclic compounds (see HYDROCARBONS). Acinetobacters appear to contain all the enzymes of the TCA CYCLE and the glyoxylate cycle. Many carbohydrates can be used. Most strains in the *A. calcoaceticus*–*A. baumannii* complex (and in certain other groups) can form acid from glucose (oxidatively), but many (e.g. most strains designated *A. lwoffii*) cannot. The optimal growth temperature is typically 33–35°C. GC%: ~38–47. Type species: *A. calcoaceticus*.

The taxonomy of *Acinetobacter* is confused and unsatisfactory. Emended descriptions of the two species *A. calcoaceticus* and *A. lwoffii*, and proposals for four new species (*A. baumannii*, *A. haemolyticus*, *A. johnsonii* and *A. junii*), were published in 1986 [JSB (1986) 36 228–240]. Since then, a number of adjustments have been made to the taxonomic structure of the genus. [Taxonomy, and epidemiology of *Acinetobacter* infections: RMM (1995) 6 186–195.]

*Acinetobacter* has been isolated in a number of hospital-associated (and other) outbreaks of disease, often as part of a mixed infection; in most cases such infections involve glucolytic strains of the *A. calcoaceticus*–*A. baumannii* complex – particularly *A. baumannii* (also called group 2, or genospecies 2). The most common manifestations of disease include septicaemia and infections of the urinary tract, lower respiratory tract and central nervous system. Transmission may occur by direct contact or may involve the airborne route. *Acinetobacter* have been reported to survive on dry surfaces for at least as long as e.g. *Staphylococcus aureus*.

One problem associated with the pathogenic role of *Acinetobacter* is that these organisms appear easily to acquire resistance to antibiotics – so that they have the potential to develop as multiresistant pathogens; currently, for example, acinetobacters are reported to be resistant to most  $\beta$ -lactam antibiotics, particularly penicillins and cephalosporins, and to chloramphenicol and trimethoprim–sulphamethoxazole. [Mechanisms of antimicrobial resistance in *A. baumannii*: RMM (1998) 9 87–97.]

## AcLVs AVIAN ACUTE LEUKAEMIA VIRUSES.

**acne** A chronic skin disorder characterized by increased sebum production and the formation of comedones ('blackheads' and 'whiteheads') which plug the hair follicles. *Propionibacterium acnes*, present in the pilosebaceous canal (see SKIN MICROFLORA), may play a causal role; it produces a lipase that hydrolyses sebum triglycerides to free fatty acids, and these can cause inflammation and comedones [JPed (1983) 103 849–854]. *Treatment*: e.g. topical SALICYLIC ACID or benzoyl peroxide; the latter has keratinolytic activity and exerts bactericidal action on *P. acnes* by releasing free-radical oxygen.

**Aconchulinida** See FILOSEA.

**aconitase** See Appendix II(a) and NITRIC OXIDE.

**Aconta** Algae of the RHODOPHYTA. (cf. CONTOPHORA.)

**acquired immune deficiency syndrome** See AIDS.

**acquired immunity** (1) SPECIFIC IMMUNITY acquired through exposure to a given antigen. (2) PASSIVE IMMUNITY. (3) NON-SPECIFIC IMMUNITY acquired through exposure to certain viruses (see e.g. INTERFERONS) or by immunization with BCG.

**Acrasea** See ACASIOMYCETES.

**acrasids** See ACASIOMYCETES.

**acrasin** In cellular slime moulds: a generic term for a chemoattractant substance which is produced by cells and which serves

as a chemoattractant for cell aggregation. Acrasins are a diverse group of substances; they include cAMP in *Dictyostelium discoideum* (q.v.), a pterin in *Dictyostelium lacteum* [PNAS (1982) 79 6270–6274], and a dipeptide, 'glorin', in *Polysphondylium violaceum* (q.v.).

**Acrasiomycetes** (acrasid cellular slime moulds; acrasids) A class of cellular SLIME MOULDS (division MYXOMYCOTA) in which the vegetative phase consists of amoeboid cells that form lobose pseudopodia; the amoebae aggregate (without streaming) to form a pseudoplasmodium which is not slug-like and does not migrate (cf. DICTYOSTELIOMYCETES). The pseudoplasmodium gives rise to multispored fruiting bodies which may have long or short stalks (but no cellulosic stalk tube) bearing e.g. simple globular sori or branched or unbranched chains of spores. Flagellated cells have been observed in only one species (*Pocheina rosea*). Sexual processes are unknown. Acrasids occur in various habitats: e.g. dung, tree-bark, dead plant materials, etc. Genera include *Acrasis*, *Copromyxa*, *Copromyxella*, *Fonticula*, *Gutulinopsis*, *Pocheina* (formerly *Guttulina*).

(Zoological taxonomic equivalents of the Acrasiomycetes include the class Acrasea of the MYCETOZOA, and the class Acrasea of the RHIZOPODA.)

**Acrasis** See ACASIOMYCETES.

**Acremonium** A genus of fungi of the class HYPHOMYCETES; teleomorphs occur in e.g. *Emericellopsis* and *Nectria*. The genus includes organisms formerly classified as species of *Cephalosporium* [for references see MS (1986) 3 169–170]. *Acremonium* spp form septate mycelium; conidia, often in gelatinous masses, are produced from phialides which develop from simple, single branches of the vegetative hyphae. *A. kiliense* (= *Cephalosporium acremonium*) produces cephalosporin C (see CEPHALOSPORINS). (See also MADUROMYCOSIS.)

**acridine orange** (basic orange, or euchrysin; 3,6-bis(dimethyl-amino)-acridinium chloride) A basic dye and FLUOROCHROME used e.g. in fluorescence MICROSCOPY to distinguish between dsDNA (which fluoresces green) and ss nucleic acids (which fluoresce orange-red). Sublethal concentrations of the dye are used for CURING plasmids. (See also ACRIDINES.)

**acridines** Heterocyclic compounds which include acridine and its derivatives. At low concentrations, aminoacridines (e.g. proflavine (3,6-diaminoacridine), QUINACRINE) appear to bind to dsDNA (or to double-stranded regions of ssDNA) primarily as INTERCALATING AGENTS. At higher concentrations there is also a weaker, secondary type of binding in which the acridine binds to the outside of dsDNA or to ssDNA or ssRNA; the two types of binding may account for the differential staining of DNA and RNA by ACRIDINE ORANGE. [Book ref. 14, pp. 274–306.] Acridines inhibit DNA and RNA synthesis and cause e.g. FRAMESHIFT MUTATIONS. They are used e.g. as antimicrobial agents (see e.g. ACRIFLAVINE), as mutagens, and as fluorescent stains for nucleic acids; they also have potential antitumour activity. (See also CURING (2).)

As *antimicrobial agents*, acridines are active against a wide range of bacteria, but they are not sporicidal; some are active against certain parasitic protozoa (see e.g. QUINACRINE and KINETOPLAST) and inhibit the replication of certain viruses. Activity is not significantly affected by proteinaceous matter. [Acridines as antibacterials (review): JAC (2001) 47 1–13.]

As *mutagens*, acridines may be effective in replicating bacteriophages but are generally not effective in bacteria. However, compounds in which an acridine nucleus is linked to an alkylating side-chain – *ICR compounds* (ICR = Institute for Cancer Research) – can induce frameshift and other mutations in bacteria.

ACRIDINE. The numbering system used in this dictionary is indicated by the numbers which are not in parentheses; an alternative numbering system (numbers in parentheses) is used by some authors.

**acriflavine** (acriflavin; *syn.* euflavin) 3,6-Diamino-10-methylacridinium chloride *or* (according to some authors) a mixture of this compound and 3,6-diaminoacridine (proflavine). Acriflavine is soluble in water and in ethanol, and has been used as an ANTISEPTIC. (See also ACRIDINES.)

**acro-** Prefix meaning tip or outermost part.

**Acrocordia** See PYRENULALES.

**acrolein** (CH<sub>2</sub>=CH-CHO) An aldehyde used e.g. for PRE-FIXATION; it penetrates tissues more rapidly than GLUTARALDEHYDE.

**acronematic** Refers to a eukaryotic FLAGELLUM which is smooth and tapers to a fine point.

**acropetal development** Development from the base, or point of attachment, towards the tip; e.g., in a chain of acropetally developing spores the first-formed spores occupy positions in the chain nearest the base of the spore-bearing structure, while spores formed later occupy positions in the distal parts of the chain. (cf. BASIPETAL DEVELOPMENT.)

**acropoleuogenous** Located both at the tip and on the sides of an elongated structure.

**Actiniphonia** A genus of branched, filamentous, siphonocladous green algae (division CHLOROPHYTA).

**Acrospermum** See CLAVICIPITALES.

**acrylate pathway** See PROPIONIC ACID FERMENTATION.

**ActA protein** (*Listeria monocytogenes*) See LISTERIOSIS.

**actaplanin** See VANCOMYCIN.

**Actidione** *Syn.* CYCLOHEXIMIDE.

**actin** (1) A protein, found in most types of eukaryotic cell, which can polymerize (reversibly) to form non-contractile filaments (*microfilaments*) that are involved e.g. in maintaining cell shape and structure (see e.g. CYTOSKELETON) and (together with MYOSIN) in CAPPING (sense 3), amoeboid movement (see PSEUDOPODIUM), CYTOPLASMIC STREAMING, PHAGOCYTOSIS, and (in higher animals) muscle contraction.

Actins from various sources are similar in structure. The monomeric form (*G-actin*) is a globular protein (MWt ca. 42000) consisting of ca. 375 amino acid residues; each molecule can bind one molecule of ATP. In most non-muscle cells, *G-actin* occurs in dynamic equilibrium with the polymerized (filamentous) form, *F-actin*, which consists of a helical, double-stranded chain of monomers ca. 7 nm thick. Although *F-actin* is itself non-contractile, its interaction with myosin can cause microfilaments to slide relative to one another – thereby bringing about movements and contractions in structures bound to the microfilaments. During the polymerization of *G-actin* ATP is hydrolysed; as in the assembly of MICROTUBULES, energy is not essential for – but increases the rate of – polymerization. Polymerization and depolymerization can occur at both ends of a microfilament, but one of the ends may grow (or depolymerize) at a greater rate than the other. (See also CAPPING sense 2.)

The formation and fate of microfilaments are regulated *in vivo* e.g. by various proteins. *Profilin* binds to *G-actin*, inhibiting polymerization. *Gelsolin* (in e.g. macrophages), *severin* (in *Dicystostelium*), *fragmin* (in *Physarum*), and *villin* (in microvilli) can each cleave *F-actin* into fragments in a Ca<sup>2+</sup>-dependent reaction, thereby e.g. effecting a gel-to-sol transition. *Filamin* and *α-actinin* can cross-link microfilaments, promoting gel formation. *β-Actinin* can act as a CAPPING (sense 2) protein. *Vinculin* may help to anchor microfilaments to other cell components. [Binding of microfilaments to the cytoplasmic membrane in *Dicystostelium discoideum*: JCB (1986) 102 2067–2075.] *Fimbrin* binds together longitudinally adjacent microfilaments to form bundles.

Actin polymerization/depolymerization is affected e.g. by agents such as CYTOCHALASINS and by phalloidin (see PHALLOTOXINS).

(2) See MACROTETRALIDES.

**actin-based motility** See DYSENTERY (1a) and LISTERIOSIS.

**Actinichona** See HYPOSTOMATIA.

**α-actinin** See ACTIN.

**β-actinin** See ACTIN.

**actino-** Prefix signifying a ray or rays.

**actinobacillosis** Any animal (or human) disease caused by a species of *Actinobacillus*. *A. lignieresii* causes granulomatous lesions in and around the mouth – particularly the tongue ('wooden tongue') – in cattle; in sheep *A. lignieresii* is associated with suppurative lesions in the skin and internal organs. *A. equuli* is pathogenic for horses (see SLEEPY FOAL DISEASE) and pigs; in pigs symptoms may include fever, haemorrhagic or necrotic skin lesions, arthritis and endocarditis. *A. suis* causes septicaemia and localized lesions in pigs. (See also PERIODONTITIS.)

**Actinobacillus** A genus of Gram-negative bacteria of the PASTURELLACEAE. Cells: mostly rod-shaped (ca. 0.3–0.5 × 0.6–1.4 μm), but a cocal form often occurs at the end of a rod, giving a characteristic 'Morse code' form; filaments may occur in media containing glucose or maltose. Extracellular slime is often produced. Cells stain irregularly. Glucose, fructose, xylose, and (most strains) lactose are fermented (no gas). Growth occurs only on complex media; all species (except *A. actinomycetemcomitans*) can grow on MacConkey's agar. Most species are non-haemolytic, but *A. suis* and some strains of *A. equuli* exhibit clear haemolysis on sheep blood agar; *A. suis* causes partial haemolysis on horse blood agar. GC%: 40–43. Type species: *A. lignieresii*.

Actinobacilli occur as commensals in the alimentary, respiratory and/or genital tracts of animals: *A. lignieresii* in cattle and sheep, *A. equuli* in horses, *A. suis* in pigs(?) and horses, *A. capsulatus* in rabbits(?), *A. actinomycetemcomitans* in man. All can be opportunistic pathogens (see ACTINOBACILLOSIS). (*A. muris* = *Streptobacillus moniliformis*; *A. mallei* = *Pseudomonas mallei*; *A. ureae*: see PASTURELLA.)

[Book ref. 22, pp. 570–575; proposal to re-classify *A. actinomycetemcomitans* as *Haemophilus actinomycetemcomitans*: IJBS (1985) 35 337–341.]

**Actinobifida** An obsolete genus of actinomycetes which included species with dichotomously-branching sporophores; at least some strains were transferred to THERMOMONOSPORA.

**Actinobolina** A genus of carnivorous ciliates (subclass GYMNSTOMATIA). Cells: roughly ovoid, with uniform somatic ciliature, an apical cytostome, TOXICYSTS, and retractable tentacles distributed evenly over the body.

**Actinocephalus** See GREGARINASINA.

**actinoidin** See VANCOMYCIN.

## *Actinomadura*

**Actinomadura** A genus of bacteria (order ACTINOMYCETALES, wall type III; group: maduromycetes) which occur e.g. in soil; some species (*A. madurae*, *A. pelletieri*) can be pathogenic in man (see MADUROMYCOSIS). The organisms form a branching, usually stable, substrate mycelium, but (spore-forming) aerial mycelium may be common or rare according to species; some species contain only trace amounts of madurose, or none at all. GC%: reported to be within the range 65–78. Type species: *A. madurae*. [Taxonomic studies on *Actinomadura* and *Nocardioopsis*: JGM (1983) 129 3433–3446; ecology, isolation and cultivation: Book ref. 46, pp. 2103–2117.]

**Actinomucor** See MUCORALES.

**Actinomyces** A genus of asporogenous bacteria (order ACTINOMYCETALES; wall type varies with species); species occur in warm-blooded animals e.g. as part of the microflora of the mucous membranes (particularly in the mouth) and can act as opportunist pathogens. The organisms occur as rods, branched rods or filaments, or as a rudimentary mycelium. All species can grow anaerobically, or under reduced partial pressure of oxygen; growth *in vitro* occurs readily on rich media at 37°C, and is typically enhanced if the partial pressure of carbon dioxide is increased. Carbohydrates are fermented anaerogenically – acetic, lactic and succinic acids being the main acidic end products of glucose fermentation in PYG MEDIUM. Most species are catalase-negative; *A. viscosus* is catalase-positive. GC%: ca. 57–73. Type species: *A. bovis*.

*A. bovis* (wall type VI) and *A. israelii* (wall type V) can cause chronic disease in animals and man (see ACTINOMYCOSIS); *A. naeslundii* and *A. viscosus* (both wall type V) can cause periodontitis e.g. in rodents. (See also COAGGREGATION.) *A. pyogenes* (formerly *Corynebacterium pyogenes* [JGM (1982) 128 901–903]) is the cause of ‘summer mastitis’ in cattle, and is often isolated from pyogenic lesions in cattle, pigs and other animals; *A. pyogenes* typically occurs as short rods or coryneforms which secrete a soluble haemolysin. *A. hordeovulneris* [IJSB (1984) 34 439–443] is a causal agent of actinomycosis in dogs.

**Actinomycetales** An order of GRAM TYPE-positive, typically aerobic bacteria; species range from those which occur as cocci and/or rods to those which form a well-developed, branching SUBSTRATE MYCELIUM and/or AERIAL MYCELIUM, and which may form sophisticated structures such as sclerotia, sporangia and synnemata. (cf. ACTINOMYCETE.) Most members of the order have a GC% > 55, thus distinguishing them from species of the other major subbranch of Gram-positive bacteria: the *Clostridium–Bacillus–Thermoactinomyces* line (but cf. CORYNEBACTERIUM, RENIBACTERIUM and THERMOACTINOMYCETES). Phylogenetic relationships between actinomycetes are indicated by 16S rRNA oligonucleotide cataloguing and nucleic acid hybridization; within the order, groups of genera can be distinguished on the basis of e.g. the chemical nature of the cell wall and the lipid profiles of the organisms. [The system of classification adopted in the Dictionary is based on the scheme proposed in Book ref. 73, pp. 7–164.]

Actinomycetes are widespread in nature, occurring typically in soil, composts (see COMPOSTING) and aquatic habitats; most species are free-living and saprotrophic, but some form symbiotic associations (see e.g. ACTINORRHIZA) and others are pathogenic in man, other animals, and plants (see e.g. ACTINOMYCOSIS, DERMATOPHILOSIS, JOHN’S DISEASE, POTATO SCAB, and TUBERCULOSIS). The organisms are chemoorganotrophs; collectively they can degrade a wide range of substances which include e.g. agar, cellulose, chitin, keratin, paraffins and rubber. Some species produce important antibiotics (see e.g. STREPTOMYCETES).

**Ultrastructure and staining.** The cell structure is that of a Gram-positive prokaryote; most species give an unequivocally positive reaction in the Gram stain (but see e.g. CELLULOMONAS), and some species are acid-fast (see e.g. MYCOBACTERIUM, NOCARDIA, RHODOCOCCLUS). Cytoplasmic inclusions observed in at least some species include e.g. granules of poly-β-hydroxybutyrate, polyphosphate, and polysaccharide, and globules of lipid. The cell wall commonly appears to be either uniformly electron-dense or three-layered, the electron-density of the middle layer being somewhat less than that of the layer on either side of it. The wall contains PEPTIDOGLYCAN and other polymers, e.g. TEICHOIC ACIDS – although the latter appear not to occur in the NOCARDIOFORM ACTINOMYCETES; the cell wall is commonly surrounded by a layer of diffuse or (in sporoactinomycetes) fibrous material. Depending on the presence of certain amino acids in the peptidoglycan, and the identity of the cell wall sugars, eight wall types (chemotypes I–VIII) of actinomycetes can be distinguished [Book ref. 46, pp. 1915–1922]:

I. LL-DAP (LL-diaminopimelic acid), glycine.

II. *meso*-DAP, glycine.

III. *meso*-DAP.

IV. *meso*-DAP, arabinose, galactose.

V. Lysine, ornithine.

VI. Lysine; aspartic acid and galactose sometimes present.

VII. DAB (2,4-diaminobutyric acid), glycine; lysine sometimes present.

VIII. Ornithine.

A further wall type (IX), characterized by *meso*-DAP and numerous amino acids, was defined for species of MYCOPLANA.

In most species which form non-fragmenting mycelium (e.g. *Streptomyces* spp) the vegetative hyphae are largely aseptate, although septa (cross-walls) can be present – particularly in the older parts of the mycelium. The septa in non-fragmenting mycelium have been designated type 1 septa; each septum consists of a single layer which develops centripetally from the cell wall. Such septa may contain microplasmodesmata, each 4–10 nm in diameter.

In fragmenting mycelium each septum consists of two distinct layers, each layer eventually forming a terminal wall of one of the two neighbouring cells; such septa are designated type 2 septa.

**Spore formation.** Spores are formed by the septation and fragmentation of hyphae, the spore wall being formed, at least in part, from all the wall layers of the sporogenous hypha. Spore-delimiting septa are of various types, and different types may occur even within a given genus; such septa have been designated type I (two layers developing centripetally), type II (two layers which develop centripetally on a single, initially-formed annulus), and type III (a single, thick layer which develops centripetally). Spore chains are reported to develop acropetally (in e.g. *Pseudonocardia*), basipetally (in e.g. *Micropolyspora*), randomly (in e.g. *Nocardioopsis*), or more or less simultaneously (in e.g. *Streptomyces*).

In some actinomycetes the spores are formed within sporangia: see e.g. ACTINOPLANES, AMORPHOSPORANGIUM, AMPULLARIELLA, DACTYLOSPORANGIUM, FRANKIA and PILIMELIA.

**Genetic aspects.** Genetic exchange has been studied in various actinomycetes, particularly *Streptomyces* spp [*Streptomyces* genetics: Book ref. 73, pp. 229–286; genetics of nocardioform actinomycetes: Book ref. 73, pp. 201–228]. Actinomycetes are hosts to a number of ACTINOPHAGES, and generalized transduction with phage φSV1 has been recorded in strains of *Streptomyces* [JGM (1979) 110 479–482]. Actinomycetes can contain various transmissible or non-transmissible plasmids, some of which

are involved in antibiotic production. Genetic analyses have been carried out by methods involving e.g. conjugation and protoplast fusion.

Genera include: ACTINOMADURA, ACTINOMYCES, ACTINOPLANES, ACTINOPOLYSPORA, ACTINOSYNNEMA, AGROMYCES, AMORPHOSPORANGIUM, AMPULLARIELLA, ARACHNIA, ARCANOBACTERIUM, ARTHROBACTER, BREVI BACTERIUM, CASEOBACTER, CELLULOMONAS, CORYNEBACTERIUM, CURTOBACTERIUM, DACTYLOSPORANGIUM, DERMATOPHILUS, EXCELLOSPORA, FRANKIA, GEODERMATOPHILUS, INTRASPORANGIUM, KINEOSPORIA, MICROBACTERIUM, MICROBISPORIA, MICROMONOSPORIA, MICROPOLYSPORA, MICROTETRASPORA, MYCOBACTERIUM, NOCARDIA, NOCARDIOIDES, NOCARDIOPSIS, OERSKOVIA, PILIMELIA, PLANOBISPORIA, PLANOMONOSPORIA, PROMICROMONOSPORIA, PSEUDONOCARDIA, RENIBACTERIUM, RHODOCOCUS, ROTHIA, SACCHAROMONOSPORIA, SACCHAROPOLYSPORA, SPIRILLOSPORA, SPORICHTHYA, STREPTOALLOTEICHUS, STREPTOMYCES, STREPTOSPORANGIUM, STREPTOVERTICILLIUM, THERMOMONOSPORIA.

[Ecology, isolation, cultivation etc: Book ref. 46, pp. 1915–2123.]

**actinomycete** Any member of the order ACTINOMYCETALES; the name is often used to refer specifically to those species which form mycelium, i.e. excluding many members of the NOCARDIOFORM ACTINOMYCETES.

**actinomycetoma** See MADUROMYCOSIS.

**actinomycin D** (actinomycin C<sub>1</sub>) An ANTIBIOTIC from *Streptomyces* sp; it contains a (red) substituted phenoxazone chromophore linked to two identical pentapeptide lactone rings. All cell types are potentially susceptible, any resistance being due to low permeability of cells to the drug. Actinomycin D specifically inhibits DNA-directed RNA synthesis. It binds specifically to B-DNA as an INTERCALATING AGENT ( $\phi$  ca. 26°). The phenoxazone chromophore intercalates primarily between two adjacent (antiparallel) GC pairs, while the lactone rings fit into the minor groove [ARB (1981) 50 171–172]. The drug dissociates from DNA only very slowly; it blocks the movement of RNA polymerase along its DNA template. (Since actinomycin D shows little binding to AT-rich PROMOTERS chain initiation is not inhibited.) DNA replication may be insensitive to actinomycin D because strand separation by the replicative apparatus may facilitate dissociation of the antibiotic.

**actinomycosis** (1) Any human or animal disease caused by a species of ACTINOMYCES: *A. israelii* in man, *A. bovis* in cattle. Infection is probably endogenous. Dense nodular lesions are formed, mainly around the jaw ('lumpy jaw'), developing into pus-discharging abscesses. Abscesses may also occur in the lungs, brain or intestine. *Lab. diagnosis:* the pathogen may be isolated from small yellow granules ('sulphur granules') present in the pus. *Chemotherapy:* e.g. penicillins.

(2) Any human or animal disease caused by an ACTINOMYCETE: e.g. actinomycosis (sense 1); MADUROMYCOSIS. (See also LACHRYMAL CANALICULITIS.)

**actinophage** Any BACTERIOPHAGE whose host(s) are member(s) of the ACTINOMYCETALES. Actinophages, which include both temperate and virulent types, can be isolated from e.g. soils and composts; most have a wide host range, but some (e.g. BACTERIOPHAGE  $\phi$ EC, BACTERIOPHAGE VP5) can infect only one or a few species. (See also STYLOVIRIDAE.) [Soil actinophages which lyse *Streptomyces* spp: JGM (1984) 130 2639–2649.]

**Actinophryida** An order of protozoa (class HELIOZOEIA) in which the cells have no skeleton and no centroplast (cf. CENTROHELIDA). Some members have flagellated stages. Sexual processes have been observed in some species. Genera include e.g. ACTINOPHRYS, ACTINOSPHAERIUM, *Ciliophrys*.

**Actinophrys** A genus of heliozoa (order ACTINOPHRYIDA). *A. sol* is common among vegetation in freshwater ponds and lakes. The cell is ca. 40–50  $\mu$ m diam., with a highly vacuolated cytoplasm; the distinction between ectoplasm and endoplasm is not clear in living cells (cf. ACTINOSPHAERIUM). The axial filaments of the axopodia (see AXOPODIUM) originate close to the single central nucleus. Reproduction occurs asexually by binary fission. Autogamy occurs when environmental conditions are unfavourable: meiosis follows encystment of the uninucleate cell, 2–4 gametes being formed; fusion of gametes results in the formation of zygotes which can remain dormant in the cyst until conditions improve.

**Actinoplanes** A genus of aerobic, sporogenous bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in soil, plant litter and aquatic habitats. The organisms form a branching surface mycelium, hyphal diameter ca. 0.2–1.5  $\mu$ m, which may also ramify into the substratum; the mycelium later forms vertical hyphae, each developing, at its tip, a (commonly spherical) desiccation-resistant sporangium containing a number of spherical or oval spores – each bearing a polar tuft of flagella. Colonies may be e.g. yellow, orange, red, blue, brown or purple. Type species: *A. philippinensis*. [Morphology, ecology, isolation: Book ref. 46, 2004–2010; isolation: JAB (1982) 52 209–218.]

**Actinopoda** A superclass of protozoa (subphylum SARCODINA) which are typically more or less spherical, typically have axopodia (filopodia in some members), and are usually planktonic. Classes: ACANTHAREA, HELIOZOEIA, Phaeodarea and Polycystinea (see RADIOLARIA).

**Actinopolyspora** A genus of bacteria (order ACTINOMYCETALES, wall type IV); the sole species, *A. halophila*, was isolated from a salt-rich bacteriological medium. The organisms form substrate and aerial mycelium, the latter giving rise to chains of spores; at least 10% (w/v) sodium chloride is required for growth, the optimum being ca. 15–20%, and the maximum ca. 30%. GC%: ca. 64. Type species: *A. halophila*. [Book ref. 73, 122–123.]

**Actinopycnidium** See STREPTOMYCES.

**actinorrhiza** A bacterium–plant root association in which nitrogen-fixing root nodules are formed in certain non-leguminous angiosperms infected (through root hairs) by FRANKIA strains; the plants involved are typically woody pioneers of nutrient-poor soils in cold or temperate regions in the northern hemisphere. There are at least two morphological types of actinorrhizal root nodule. In the *Alnus* type, formed in *Alnus* spp (alder) and many other plants, the root nodules are coralloid (i.e., thickened and dichotomously branched). In the *Myrica* type, formed e.g. in species of *Myrica*, *Casuarina* and *Rubus*, the nodule is clothed with upward-growing (negatively geotropic) rootlets which may aid aeration in boggy habitats. In either type, the endophyte occurs within the cortical parenchyma of the nodule and does not invade vascular or meristematic tissues. In the distal part of the nodule the (young) hyphae spread from cell to cell, perforating the host cell walls. In the proximal part the hyphal tips swell to form vesicles which appear to provide a reducing environment within which NITROGEN FIXATION can occur; rates of nitrogen fixation are comparable to those in leguminous ROOT NODULES. [Book ref. 55, pp. 205–223.] (See also MYCORRHIZA.)

**Actinosphaerium** A genus of heliozoa (order ACTINOPHRYIDA) in which the cells are multinucleate and ca. 200  $\mu$ m to 1.0 mm in diameter, according to species; the highly vacuolated ectoplasm is clearly distinct from the granular endoplasm (cf. ACTINOPHRYS). Numerous needle-like axopodia radiate from the

## **Actinosporangium**

cell, their axial filaments arising at the junction between ectoplasm and endoplasm. Asexual reproduction involves plasmotomy. Autogamy occurs when environmental conditions become unfavourable: the cell produces a gelatinous covering, and many of its nuclei degenerate; numerous uninucleate daughter cells are produced, and each encysts. Meiosis within the cyst results in two haploid gametes which fuse, and the resulting zygote remains dormant until conditions improve.

**Actinosporangium** See STREPTOMYCETES.

**Actinosporea** A class of protozoa (phylum MYXOZOA) which are parasitic in invertebrates (particularly annelid worms). The spores contain 3 polar capsules (each enclosing a single polar filament) and several to many sporoplasms. The spore wall consists of 3 valves which may be smooth (e.g. in *Sphaeractinomyxon*) or drawn out into long, horn-like processes (as in *Triactinomyxon*, a parasite of tubificid and sipunculid worms). (cf. WHIRLING DISEASE.)

**Actinosynnema** A genus of bacteria (order ACTINOMYCETALES, wall type III) which occur e.g. on vegetable matter in aquatic habitats. The organisms form a thin, branching, yellow substrate mycelium (hyphae <1 µm diam.) on which develop synnemata (up to ca. 180 µm in height) or 'dome-like bodies'; aerial hyphae may arise from the substrate mycelium, or from the tips of the synnemata, and give rise to chains of spores which become motile (flagellated) in liquid media. GC%: ca. 71. Type species: *A. mirum*. [Book ref. 73, pp 116–117.]

**activated acetic acid pathway** See AUTOTROPH.

**activated sludge** See SEWAGE TREATMENT.

**activation** (*immunol.*) (1) (of lymphocytes) A process which begins with BLAST TRANSFORMATION and continues with proliferation (cell division) and differentiation; some authors use 'activation' to refer specifically to stage(s) preceding proliferation. (2) (of complement) See COMPLEMENT FIXATION. (3) See MACROPHAGE. (4) (of spores) See ENDOSPORE and SPORE.

**activation-induced cytidine deaminase** See RNA EDITING.

**activator** (1) *Syn.* COFACTOR (sense 2). (2) See SPORE. (3) See OPERON and REGULON.

**active bud** See LIPOMYCETES.

**active immunity** Specific IMMUNITY (3) afforded by the body's own immunological defence mechanisms following exposure to antigen. (cf. PASSIVE IMMUNITY.)

**active immunization** See IMMUNIZATION.

**active transport** See TRANSPORT SYSTEMS.

**actomyosin** An actin–myosin complex (see ACTIN and MYOSIN).

**acleacin A** An antibiotic which is active against yeasts, inhibiting the formation of yeast CELL WALL GLUCAN. *Echinocandin B* is a structurally related antibiotic with an apparently similar mode of action. (cf. PAPULACANDIN B.)

**acleate** Slender and sharp-pointed, or bearing narrow spines.

**acute** (*med.*) Refers to any disease which has a rapid onset and which persists for a relatively short period of time (e.g. days) – terminating in recovery or death. The term is also used to refer to an exceptionally severe or painful condition. (cf. CHRONIC.)

**acute cardiac beriberi** See CITREOVIRIDIN.

**acute haemorrhagic conjunctivitis (AHC)** A highly infectious form of CONJUNCTIVITIS, a worldwide pandemic of which occurred during 1969–1971; it is caused by enterovirus 70 (see ENTEROVIRUS) and is characterized by subconjunctival haemorrhages ranging from petechiae to larger areas covering the bulbar conjunctivae. Recovery is usually complete in ca. 10 days.

**acute herpetic gingivostomatitis** See GINGIVITIS.

**acute necrotizing ulcerative gingivitis** See GINGIVITIS.

**acute-phase proteins** Various types of protein, found in plasma, formed as a rapid response to infection; they are synthesized in the liver e.g. under stimulation from cytokines produced in a region of INFLAMMATION. These proteins include C-REACTIVE PROTEIN (CRP) and *serum amyloid A* (SAA), both of which can bind to phospholipids in the microbial cell envelope and act as OPSONINS; additionally, binding by CRP activates COMPLEMENT. CRP and SAA are so-called *pentraxin* proteins in which the molecule consists of five identical subunits.

(See also CD14.)

**acute-phase serum** Serum obtained from a patient during the acute phase of a disease.

**acute respiratory disease** See ARD.

**ACV** ACYCLOVIR.

**ACVs** See VACCINE.

**acycloguanosine** *Syn.* ACYCLOVIR.

**acyclovir** (ACV; acycloguanosine; Zovirax) An ANTIVIRAL AGENT, 9-(2-hydroxyethoxymethyl)guanine, which is active against alphaherpesviruses. It is phosphorylated by the virus-encoded thymidine kinase to the monophosphate; the monophosphate is converted by host-cell enzymes to the active triphosphate form which inhibits DNA polymerase – the viral polymerase being much more sensitive than the cellular  $\alpha$ -polymerase. (cf. BROMOVINYLDEOXYURIDINE.) Uninfected cells do not effectively phosphorylate acyclovir, and the drug is relatively non-toxic to the host.

Acyclovir is used topically, systemically or orally in the treatment of e.g. herpes simplex keratitis, primary genital herpes, mucocutaneous herpes simplex in immunocompromised patients, progressive varicella and HERPES ZOSTER. Acyclovir is not equally active against all alphaherpesviruses – its ability to inhibit the replication of varicella-zoster virus is approximately 10-fold lower than its ability to inhibit replication of herpes simplex virus. [Use of acyclovir in the treatment of herpes zoster: RMM (1995) 6 165–174 (167–170).]

**acylalanine antifungal agents** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**N-acyl-L-homoserine lactone** See QUORUM SENSING.

**Acytostelium** A genus of cellular slime moulds (class DICTYOSTELIOMYCETES) in which the sorocarp stalk is acellular, cellulose, slender, and apparently tubular; no myxamoebae are sacrificed in stalk formation (cf. DICTYOSTELIUM). The stalk bears a single terminal sorus of spores. Four species are recognized [descriptions and key: Book ref. 144, pp. 393–407].

**Ad** Human adenovirus: see MASTADENOVIRUS.

**A–D group** ALKALESCENS–DISPAR GROUP.

**ADA deficiency** See ADENOSINE DEAMINASE DEFICIENCY.

**ada gene** See ADAPTIVE RESPONSE.

**adamantanamine** See AMANTADINE.

**adamantane** See AMANTADINE.

**Adansonian taxonomy** A method of biological classification, proposed in the 18th century by Michel Adanson, in which relationships between organisms are defined by the number of characteristics which the organisms have in common; the same degree of importance ('weighting') is attached to each characteristic. (cf. NUMERICAL TAXONOMY.)

**adaptation** Change(s) in an organism, or population of organisms, by means of which the organism(s) become more suited to prevailing environmental conditions. *Genetic* adaptation involves e.g. mutation and selection: those (mutant) organisms in a given population which are genetically more suited to the existing environment thrive and become numerically dominant. (See also FLUCTUATION TEST.) *Non-genetic* (*phenotypic*) adaptation

may involve a change in metabolic activity – e.g., by enzyme induction or repression (see OPERON). (See also CHROMATIC ADAPTATION.) Behavioural adaptation may involve changes in tactic responses (see TAXIS); thus, e.g., if a phototactic organism is subjected to a sudden increase in light intensity followed by steady illumination at the new intensity, the organism initially responds phototactically, but after a period of time it adapts to the new light intensity and resumes its normal pattern of motility. (See also CHEMOTAXIS.)

**adaptive response** A DNA REPAIR system which is induced in cells of *Escherichia coli* in response to exposure to low concentrations of certain ALKYLATING AGENTS (e.g. MNGG, MNU); the response is independent of the SOS system.

Genes involved in the adaptive response include *ada*, *aidB*, *alkA* and *alkB*.

The *alkA* gene encodes 3-methyladenine-DNA glycosylase II, an enzyme which (despite its name) cleaves various methylated bases (e.g.  $N^3$ - or  $N^7$ -methylpurines and  $O^2$ -methylpyrimidines) from alkylated DNA; studies on the crystal structure of AlkA complexed with DNA indicate that the enzyme distorts DNA considerably as it 'flips out' (i.e. exposes) the target site [EMBO (2000) 19 758–766]. (Another enzyme of *E. coli*, DNA glycosylase I (the Tag protein; *tag* gene product), is synthesized *constitutively*; the Tag protein cleaves 3-methyladenine from DNA.)

DNA is susceptible to chemical change owing to the reactivity of its bases [Nature (1993) 362 709–715]. As well as methylation *in vitro*, DNA is also subject to aberrant, non-enzymatic methylation *in vivo* via *S*-adenosylmethionine (normally a legitimate methyl donor) which can give rise to 3-methyladenine and/or 7-methylguanine; these aberrant methylated bases are also cleaved by the glycosylases mentioned above.

Cleavage of a chemically aberrant base, to form an AP SITE, is the first stage in the repair process; repair continues via BASE EXCISION REPAIR.

A different aspect of the adaptive response involves the *ada* gene product: a bifunctional methyltransferase which directly reverses the effects of the methylating agent. One function of Ada transfers a methyl group from a major-groove adduct –  $O^6$ -methylguanine (a potentially highly mutagenic lesion) or  $O^4$ -methylthymine – to a cysteine residue near the C-terminus of the Ada protein itself. The second function of the Ada protein transfers a methyl group from a methyl phosphotriester (formed by methylation of a phosphodiester bond in the DNA) to a cysteine residue in the N-terminal portion of the protein. Once methylated at both sites, the Ada protein is inactivated.

The Ada protein acts as a positive regulator of its own expression as well as that of *aidB*, *alkA* and *alkB*; alkylation of the Ada protein from a methyl phosphotriester is apparently the intracellular signal for induction of the adaptive response [Cell (1986) 45 315–324].

**adaptor** (*mol. biol.*) A synthetic oligodeoxyribonucleotide which is similar to a *linker* (see LINKER DNA) but which contains more than one type of restriction site and may also have pre-existing STICKY ENDS.

**ADCC** Antibody-dependent CELL-MEDIATED CYTOTOXICITY: the killing of antibody-coated target cells by a non-phagocytic mechanism in which the effector cell (see e.g. NK CELLS) initially binds to the Fc portion of the (bound) antibodies via specific receptors. (See also CD16.)

**addition mutation** *Syn.* INSERTION MUTATION.

**Adelea** See ADELEORINA.

**Adeleina** A suborder of protozoa (order Eucoccida [JP (1964) 11 7–20] or Eucoccidiida [JP (1980) 27 37–58]) equivalent to the ADELEORINA.

**Adeleorina** A suborder of protozoa (order EUCCOCCIDIORIDA) in which syzygy characteristically occurs (cf. EIMERIORINA, HAEMOSPORORINA). Genera include *Adelea*, *Haemogregarina*, *Klossiella*.

**adenine arabinoside** *Syn.* VIDARABINE.

**adenitis** Inflammation of gland(s).

**adeno-associated viruses** See DEPENDOVIRUS.

**adeno-satellite viruses** See DEPENDOVIRUS.

**adenosine** See NUCLEOSIDE and Appendix V(a).

**adenosine 3',5'-cyclic monophosphate** See CYCLIC AMP.

**adenosine deaminase deficiency** A congenital lack of the enzyme adenosine deaminase (EC 3.5.4.4), the effects of which include a marked reduction in the numbers of functional B and T lymphocytes. (See SEVERE COMBINED IMMUNODEFICIENCY.)

The disease has been treated by GENE THERAPY.

**adenosine triphosphatase** See ATPASE.

**adenosine 5'-triphosphate** See ATP.

**Adenoviridae** (adenovirus family) A family of non-enveloped, icosahedral, linear dsDNA-containing viruses which infect mammals (genus *Mastadenovirus*) or birds (genus *Aviadenovirus*).

Adenoviruses are generally specific for one or a few closely related host species; infection may be asymptomatic or may result in various diseases (see AVIADENOVIRUS and MASTADENOVIRUS). Many adenoviruses can induce tumours when injected into newborn rodents, but none is known to cause tumours in natural circumstances. In cell cultures, adenoviruses cause characteristic CPE, including the rounding of cells and the formation of grape-like clusters of cells; adenovirus replication and assembly occur in the nucleus, resulting in the formation of intranuclear inclusion bodies. Virions sometimes form paracrystalline arrays. Many adenoviruses can haemagglutinate RBCs from various species.

The adenovirus virion consists of an icosahedral CAPSID (ca. 70–90 nm diam.) enclosing a core in which the DNA genome is closely associated with a basic (arginine-rich) viral polypeptide (VP), VII. The capsid is composed of 252 capsomers: 240 hexons (capsomers each surrounded by 6 other capsomers) and 12 pentons (one at each vertex, each surrounded by 5 'peripentonal' hexons). Each penton consists of a penton base (composed of viral polypeptide III) associated – apparently by hydrophobic interactions – with one (in mammalian adenoviruses) or two (in most avian adenoviruses) glycoprotein fibres (viral polypeptide IV); each fibre carries a terminal 'knob' ca. 4 nm in diam. The fibres can act as haemagglutinins and are the sites of attachment of the virion to a host cell-surface receptor. The hexons each consist of three molecules of viral polypeptide II; they make up the bulk of the icosahedron. Various other minor viral polypeptides occur in the virion.

The adenovirus dsDNA genome (MWt ca. 20–25 × 10<sup>6</sup> for mammalian strains, ca. 30 × 10<sup>6</sup> for avian strains) is covalently linked at the 5' end of each strand to a hydrophobic 'terminal protein', TP (MWt ca. 55000); the DNA has an inverted terminal repeat (ITR) of different length in different adenoviruses. In most adenoviruses examined, the 5'-terminal residue is dCMP (dGMP in CELO virus).

Adenovirus virions are stable and are not inactivated by e.g. lipid solvents or by pancreatic proteases, low pH, or bile salts.

**Replication cycle.** The virion attaches via its fibres to a specific cell-surface receptor, and enters the cell by endocytosis or by direct penetration of the plasma membrane. Most of

## adenoviruses

the capsid proteins are removed in the cytoplasm; the virion core enters the nucleus, where the uncoating is completed to release viral DNA almost free of virion polypeptides. Virus gene expression then begins. The viral dsDNA contains genetic information on both strands. [By convention, the AT-rich half of the DNA molecule is designated the right-hand end, and the strand transcribed from left to right is called the r-strand, the leftward-transcribed strand being called the l-strand; the DNA is divided into 100 'map units' (m.u.): Book ref. 116, pp. 40–42.] *Early genes* (regions E1a, E1b, E2a, E3, E4) are expressed before the onset of viral DNA replication. *Late genes* (regions L1, L2, L3, L4 and L5) are expressed only after the initiation of DNA synthesis. *Intermediate genes* (regions E2b and IVa<sub>2</sub>) are expressed in the presence or absence of DNA synthesis. Region E1a encodes proteins involved in the regulation of expression of other early genes, and is also involved in transformation (see MASTADENOVIRUS). The RNA transcripts are capped (with m<sup>7</sup>G<sup>5</sup>ppp<sup>5</sup>N) and polyadenylated (see MRNA) in the nucleus before being transferred to the cytoplasm for translation.

Viral DNA replication requires the terminal protein, TP, as well as virus-encoded DNA polymerase and other viral and host proteins. TP is synthesized as an 80K (MWt 80000) precursor, pTP, which binds covalently to nascent replicating DNA strands. pTP is cleaved to the mature 55K TP late in virion assembly; possibly at this stage, pTP reacts with a dCTP molecule and becomes covalently bound to a dCMP residue, the 3'-OH of which is believed to act as a primer for the initiation of DNA synthesis (cf. BACTERIOPHAGE φ29). Late gene expression, resulting in the synthesis of viral structural proteins, is accompanied by the cessation of cellular protein synthesis, and virus assembly may result in the production of up to 10<sup>5</sup> virions per cell.

[Book ref. 116.]

**adenoviruses** Viruses of the ADENOVIRIDAE.

**adenylate cyclase** An enzyme (EC 4.6.1.1) which catalyses the synthesis of CYCLIC AMP (cAMP) from ATP. (cAMP is degraded to AMP by the enzyme cAMP phosphodiesterase.)

In *Escherichia coli* and other enterobacteria, adenylylate cyclase is a single protein (product of the *cya* gene) whose activity is modified e.g. by the PTS system (see CATABOLITE REPRESSION); it may also be regulated directly by pmf, and its synthesis may be repressed by cAMP-CRP.

The EF component of ANTHRAX TOXIN and the CYCLOLYSIN of *Bordetella pertussis* both have CALMODULIN-stimulated adenylylate cyclase activity; the pore-forming activity of the cyclolysin may serve to internalize its adenylylate cyclase activity, resulting e.g. in raised levels of cAMP in cells of the immune system.

In higher eukaryotes, adenylylate cyclase occurs as part of a plasma membrane complex which includes e.g. hormone receptors and GTP-binding regulatory components (so-called *G proteins*; = *N proteins*); G<sub>s</sub> (= N<sub>s</sub>) stimulates adenylylate cyclase, G<sub>i</sub> (= N<sub>i</sub>) inhibits it. This system is the target for certain bacterial toxins: see e.g. CHOLERA TOXIN and PERTUSSIS TOXIN.

**adenylate energy charge** (energy charge, EC) A unitless parameter which gives a measure of the total energy associated with the adenylylate system, at a given time, within a cell. It is defined as:

$$EC = \frac{[ATP] + 1/2 [ADP]}{[ATP] + [ADP] + [AMP]}$$

Cells growing under ideal conditions have an energy charge of ca. 0.8–0.95, while senescent cells may have an EC of ca. 0.6 or less. Changes in the relative proportions of adenine nucleotides in a cell (i.e., changes in EC) have regulatory

effects on various metabolic processes – the activity of certain enzymes being regulated by the actual concentration of a given adenine nucleotide or by the ratio of particular nucleotides (e.g. ATP:ADP). Thus, e.g., in certain yeasts the enzyme phosphofructokinase is inhibited by ATP (an effect which is reversed by AMP), while in *Escherichia coli* the same enzyme is stimulated by ADP; hence, glycolysis tends to be stimulated when the EC is depressed.

Energy charge is also a regulatory factor for the degree of supercoiling (superhelical density) in a cell's DNA; changes in superhelical density can, in turn, influence the activity of various gene promoters. Thus, via energy charge and superhelicity, the environment can modulate the expression of particular genes. (Interestingly, the expression of genes or operons may also be regulated by *local* changes in superhelicity due to divergent transcription from closely spaced gene promoters [Mol. Microbiol. (2001) 39 1109–1115].)

Estimations of EC involve both rapid sampling and precautions to prevent hydrolysis or interconversion of adenine nucleotides. ATP is often measured by techniques which involve CHEMILUMINESCENCE.

**adenylate kinase** An enzyme (EC 2.7.4.3) which catalyses the reversible conversion of two molecules of adenosine 5'-diphosphate (ADP) to one molecule each of ATP and AMP. [Structural and catalytic properties of adenylylate kinase from *Escherichia coli*: JBC (1987) 262 622–629.]

**adenylylsulphate** See APS.

**ADH** ARGININE DIHYDROLASE.

**adherent cells** (*immunol.*) Cells which adhere to e.g. glass and plastics; they include e.g. MACROPHAGES and DENDRITIC CELLS.

**adhesin** A cell-surface component, or appendage, which mediates ADHESION to other cells or to inanimate surfaces or interfaces; there are many different types of adhesin, and a given organism may have more than one type. (The term *adhesin* is also used to include certain secreted substances which behave as adhesins – e.g. MUTAN.)

*Bacterial adhesins.* Many bacterial adhesins are FIMBRIAE, and in some pathogenic species fimbrial adhesins are important virulence factors which mediate the initial stage of pathogenesis (adhesion to specific site(s) in the host organism). For example, fimbria-mediated adhesion is important for virulence in ETEC – strains of *Escherichia coli* whose capacity to cause disease depends on their ability to bind to the intestinal mucosa; among strains of ETEC there are more than 10 different types of fimbrial adhesin (as well as non-fimbrial adhesins) [RMM (1996) 7 165–177]. [Expression of fimbriae by enteric pathogens (review): TIM (1998) 6 282–287.] Fimbrial adhesins are also important in *Haemophilus influenzae* type b for the initial binding to respiratory tract epithelium [adhesins in *Haemophilus*, *Actinobacillus* and *Pasteurella*: FEMS Reviews (1998) 22 45–59]. (See also UPEC and P FIMBRIAE.)

Some fimbrial adhesins additionally function as an INVASIN (see e.g. UPEC) or as a phage receptor (see e.g. BACTERIOPHAGE CTXφ).

The dimensions and charge characteristics of fimbriae are such that they experience minimal repulsion from a surface bearing charge of the same polarity; thus, fimbrial adhesins can help to bridge the gap between the charged bacterial surface (see ZETA POTENTIAL) and the surface of another cell or substratum which bears a charge similar (in polarity) to that on the bacterium.

Non-fimbrial adhesins include the filamentous haemagglutinin (FHA) of *Bordetella pertussis*, the high-molecular-weight adhesion proteins (HMW1, HMW2) of 'non-typable' strains of

*Haemophilus influenzae*, and the M PROTEIN of streptococci. (See also DR ADHESINS and OPA PROTEINS.)

Proteinaceous ‘capsular’ adhesins include K88 in certain strains of *Escherichia coli*.

Non-proteinaceous adhesins include the capsular carbohydrates of *Rhizobium trifolii* which bind to TRIFOLIIN A on the root hairs of the clover plant. (See also streptococcal lipOTEICHOIC ACIDS.)

*Receptors for bacterial adhesins.* Binding sites for bacterial adhesins on mammalian tissues include various cell-surface molecules, but a given adhesin typically binds only to a specific site. For example, the type I FIMBRIAE of *E. coli* bind to mannose residues, while the P fimbriae of uropathogenic *E. coli* bind to  $\alpha$ -D-galactopyranosyl-(1-4)- $\beta$ -D-galactopyranoside receptors of glycolipids on urinary tract epithelium. Some pathogens (e.g. *Bordetella pertussis*, *Borrelia burgdorferi*, *Yersinia enterocolitica*) bind to specific INTEGRINS. Protein adhesins of *Staphylococcus aureus* bind to components such as collagen and fibronectin in the mammalian extracellular matrix [TIM (1998) 6 484–488]. Certain LECTINS (q.v.) may promote disease by enhancing attachment of ETEC to the porcine ileum.

**adhesion** Microorganisms often bind specifically or non-specifically to a substratum or to other cells – adhesion being mediated by specialized microbial components or structures: see e.g. ADHESIN and PROSTHECA.

For some *pathogens*, adhesion to specific host cells or tissues is a prerequisite for disease, so that, in these organisms, adhesins are important virulence factors (see ADHESIN).

The adherence of a pathogen to a host cell may be necessary simply promote the host’s uptake of a secreted toxin. However, in some cases, adhesion triggers a more interactive sequence of events. For example, when the FHA adhesin of *Bordetella pertussis* binds to an INTEGRIN receptor on a monocyte, it generates signals within the monocyte that upregulate the expression of a second type of integrin – one which binds to a different site on the adhesin. Thus, this pathogen ‘manipulates’ the host cell’s internal signalling system in order to secure for itself additional binding sites. In another example, the binding of UPEC (q.v.) to uroepithelium via type I FIMBRIAE promotes uptake (internalization) of the pathogen. In enteropathogenic *E. coli*, initial adhesion to gut epithelium is followed by complex prokaryote–eukaryote interactions that result in a unique form of colonization by the pathogen (see EPEC).

The adhesion of bacteria to inanimate surfaces can be problematical in the context of prosthetic devices. Infection associated with these devices is a serious complication which is often difficult to treat (not least because adherent bacteria are typically less susceptible to antibiotics) [prosthetic device infections: RMM (1998) 9 163–170].

Free-living microorganisms in aquatic habitats often adhere to submerged surfaces on stones, particles of debris, other organisms or man-made structures – sometimes forming BIOFILMS. (See also EPILITHON.) Adhesion may affect the activity of such organisms because the conditions at a submerged surface differ from those in the bulk aqueous phase; for example, surfaces can adsorb nutrients and/or stimulatory or inhibitory ions, so that solid–liquid interfaces may be significantly more advantageous or disadvantageous compared with the liquid phase. Cell–cell interactions may or may not be facilitated in biofilms.

The interaction between microorganisms and a surface is governed by various physicochemical forces that may include electrostatic attraction or repulsion, hydrophobic interaction (i.e. mutual attraction between hydrophobic molecules), hydrogen

bonding, and van der Waals’ forces. Because some types of cell resemble colloids in their dimensions and electrical characteristics (see ZETA POTENTIAL), the interaction between a cell and a substratum (or between two cells) in an aqueous medium is sometimes considered in the context of classical colloid theory – in particular the theory of Derjaguin, Landau, Verwey and Overbeek (the ‘DLVO’ theory). The DLVO theory supposes that a particle which bears a distributed surface charge of given polarity is surrounded by a layer of ions of opposite charge – forming a so-called ‘double layer’ extending some distance from the surface of the particle; two similarly charged particles will therefore be mutually repulsive through the interaction of their double layers. An increase in the ionic concentration in the medium effectively compresses each double layer – so that the particles can then approach each other more closely; in a number of cases, cell–substratum or cell–cell contact has been shown to be facilitated by raising the concentration of electrolyte. However, a rigid application of the DLVO theory (or any other mathematically based theory) to biological systems is made difficult by a number of factors which include the susceptibility of the cell to physical deformation, the chemical complexity and non-uniformity of the cell surface, and the possibility of ionic flux across juxtaposed surfaces.

Microorganisms which are normally attached to a substratum may be dispersed by means of either non-adherent progeny or propagules – or they may be able to detach, temporarily, in order to colonize fresh surfaces. The hydrophobic, benthic cyanobacterium *Phormidium* J-1 appears to achieve dispersal by forming an emulsifying agent (EMULCYAN) which masks cell-surface hydrophobicity – permitting detachment; the emulcyan is presumed to be washed off the cells at some stage so that attachment is again possible [FEMS Ecol. (1985) 31 3–9].

**adhesion site** (Bayer’s junction; Bayer’s patch) In Gram-negative bacteria: a localized ‘fusion’ between the OUTER MEMBRANE and CYTOPLASMIC MEMBRANE [Book ref. 101, pp. 167–202]. In electronmicrographs, a plasmolysed cell may show adhesion sites under some experimental conditions but not under others [JB (1984) 160 143–152]. [Cell envelope fraction with apparent adhesion sites: JBC (1986) 261 428–443.]

Adhesion sites appear to be osmotically sensitive, physiologically important regions of the cell envelope which serve e.g. as sites for the export of proteins (such as porins), LPS molecules [JB (1982) 149 758–767] and filamentous phages, as sites of infection for certain phages, and as the anchorage sites of e.g. F pili. Certain proteins (e.g. penicillin binding protein 3, THIOREDOXIN [JB (1987) 169 2659–2666]) have been associated with adhesion sites.

[Mol. Microbiol. (1994) 14 597–607.]

(See also PERISEPTAL ANNULUS, and ‘lysis protein’ in LEVIVIRIDAE.)

**adiaspiromycosis** (adiaspirosis; haplomycosis) A non-infectious MYCOSIS which primarily affects animals, rarely affecting man. It is caused by *Chrysosporium parvum* var. *parvum* (formerly *Emmonsia parva* or *Haplosporangium parvum*) or by *C. parvum* var. *crecscens* (formerly *E. crecscens*). Infection occurs by inhalation of conidia (formed e.g. in soil); the conidia enlarge within the lungs to reach diameters of ca. 40  $\mu$ m (var. *parvum*) or 400  $\mu$ m (var. *crecscens*). Granulomas may develop around the adiaspores.

**adiaspirosis** *Syn.* ADIASPIROMYCOSIS.

**adiaspore** A spore (conidium) which grows in size without dividing – see e.g. ADIASPIROMYCOSIS and CHRYSOSPORIUM.

## adjuvant

**adjuvant** (1) (*immunol.*) Any substance which, when administered with or before an antigen, heightens and/or affects qualitatively the immune response in terms of antibody formation and/or the cell-mediated response. (The adjuvant L18-MDP(A) has also been reported to enhance non-specific phagocytosis by polymorphonuclear leucocytes [JGM (1982) 128 2361–2370].) Adjuvants include e.g. BCG, aluminium hydroxide, and water-in-oil emulsions (e.g. FREUND'S ADJUVANT). (2) Any substance which is added to a drug or other chemical (e.g. a disinfectant) to enhance its activity.

**Adjuvant 65** A water-in-oil emulsion ADJUVANT made by emulsifying peanut oil with mannide monooleate and stabilizing with aluminium monostearate.

**adk gene** (*dnaW* gene) In *Escherichia coli*: the gene for adenylate kinase.

**Adler test** A test used for the identification of *Leishmania* spp. The organisms are cultured in an immune serum; in the presence of homologous antibodies, promastigotes develop in clusters or syncytia.

**adnate** (1) Of the region of lamella–stipe attachment in an agaric: extending for a length equal to much or most of the depth of the lamella.

(2) Of flagellar spines: flattened against the flagellum from which they arise.

**adnexed** (*mycol.*) Of the region of lamella–stipe attachment in an agaric: extending for a length equal to only a small fraction of the depth of the lamella.

**adonitol** *Syn.* RIBITOL.

**adoptive immunity** *Syn.* PASSIVE IMMUNITY.

**adoral ciliary spiral** See AZM.

**adoral zone of membranelles** See AZM.

**ADP** Adenosine 5'-diphosphate. (See also ATP and ADENYLATE KINASE.)

**ADP-ribosylation** The transfer of an ADP-ribosyl group from NAD<sup>+</sup> to a protein, catalysed by an ADP-ribosyl transferase. In eukaryotic cells, various proteins may be ADP-ribosylated – apparently as a normal regulatory mechanism; certain bacterial toxins act by exerting an ADP-ribosyl transferase function: see e.g. BOTULINUM C2 TOXIN, CHOLERA TOXIN, DIPHTHERIA TOXIN, EXOTOXIN A and PERTUSSIS TOXIN. ADP-ribosylation also occurs e.g. in cells of *Escherichia coli* infected with BACTERIOPHAGE T4, the host RNA polymerase undergoing phage-induced ADP-ribosylation. [Review: TIBS (1986) 11 171–175.]

**adrenalin** (epinephrine) A multifunctional hormone, secreted by the adrenal gland, which affects e.g. carbohydrate metabolism and the activity of smooth muscle, particularly that of the cardiovascular and bronchial systems. Adrenalin is used e.g. for the treatment of ANAPHYLACTIC SHOCK – in which it counteracts the effects of histamine, relaxing smooth muscle and reducing vascular permeability.

**adriamycin** See ANTHRACYCLINE ANTIBIOTICS.

**ADRY reagents** Certain substituted thiophenes which can e.g. stimulate the photooxidation of cytochrome *b*<sub>559</sub> in photosystem II (see PHOTOSYNTHESIS).

**adsorption** (*serol.*) Non-specific adherence of substances (in solution or in suspension) to cells or to other forms of particulate matter. (See e.g. BOYDEN PROCEDURE; cf. ABSORPTION.)

**adsorption chromatography** See CHROMATOGRAPHY.

**adult T-cell leukaemia** (ATL; adult T-cell leukaemia/lymphoma, ATLL) A T-cell LEUKAEMIA (q.v.) which affects adults; the causal agent is an exogenous retrovirus, HTLV-I (see HTLV). ATL is endemic in certain regions of Japan, the Caribbean, Africa and the Americas.

In the carrier state the incidence of ATL is low; latency can last for many decades.

The disease has been categorized into four clinical subtypes: acute, chronic, smouldering and lymphoma. Acute cases comprise the majority. Chronic and smouldering forms often progress to the acute form. In some cases disease is nodal rather than leukaemic.

Various manifestations of ATL may be seen. In many cases there are lesions in liver, spleen and/or lymph nodes, though other sites (including the central nervous system) may be affected; skin lesions may include nodules, ulcers or rashes. Hypercalcaemia may be present, and the undermined immune system may permit infection by opportunist pathogens (e.g. *Pneumocystis carinii*, cytomegalovirus).

Leukaemic cells are monoclonal, originating from a single cell infected with HTLV-I; the cells are larger than normal and may have multilobed or convoluted nuclei.

The median survival time for the acute form of ATL is reported to be ~6 months (~2 years for the chronic form).

*Lab. diagnosis.* Diagnosis involves e.g. clinical observation, serology (for anti-HTLV-I antibody) and detection of abnormal T cells by microscopy.

*Chemotherapy.* Given the absence of standard therapy, it has been recommended that treatment be limited to acute and lymphoma-type cases; for these patients combination chemotherapy may be successful, but relapses (often involving the CNS) are common.

[ATL (epidemiology, leukaemogenesis, clinical features, laboratory findings, diagnosis, treatment, prognosis and prevention): BCH (2000) 13 231–243.]

(cf. MYCOSIS FUNGOIDES and SÉZARY SYNDROME.)

**adventitious septum** See SEPTUM (b).

**aecial cup** See UREDINIOMYCETES stage I.

**aecidioid** (cupulate) Refers to a peridiate, cup-shaped to cylindrical aecium of the type formed e.g. by species of *Puccinia* and *Uromyces*.

**aecidiospore** See UREDINIOMYCETES stage I.

**aecidium** See UREDINIOMYCETES stage I.

**aeciospore** See UREDINIOMYCETES stage I.

**aecium** See UREDINIOMYCETES stage I.

**Aedes** A genus of mosquitoes (order Diptera, family Culicidae); *Aedes* spp are vectors of certain diseases: see e.g. CHIKUNGUNYA FEVER, YELLOW FEVER.

**Aedes aegypti** EPV See ENTOMOPOXVIRINAE.

**Aedes albopictus cell-fusing agent** See FLAVIVIRIDAE.

**Aegyptianella** A genus of Gram-negative bacteria of the family ANAPLASMATACEAE. Cells: pleomorphic cocci (diam. ca. 0.3–0.8 µm) which form membrane-limited inclusion bodies (each containing up to 30 cells) within the erythrocytes of the infected host (cf. ANAPLASMA). The sole species, *A. pullorum*, is parasitic in a range of birds and can cause disease e.g. in chickens; transmission occurs mainly or exclusively via ticks. *A. pullorum* occurs in southern Europe and the Mediterranean area, in Africa south of the Sahara, and in Asia.

**aequihyeniiferous** See LAMELLA.

**Aer** See AEROTAXIS.

**aerial mycelium** In many actinomycetes: mycelium which projects above the level of the medium; no aerial mycelium is formed e.g. by *Arachnia* or *Intrasporangium*, while *Sporichthya* forms only aerial mycelium. Aerial mycelium and SUBSTRATE MYCELIUM differ e.g. morphologically, structurally and physiologically [Book ref. 73, pp. 169–170]; aerial mycelium is typically less branched and, in at least some species, its surface is

hydrophobic. In some genera the aerial mycelium is the main, or only, part of the organism which bears spores or sporophores.

**Aerobacter** An obsolete bacterial genus (*nom. rejic.*). Most strains formerly regarded as '*Aerobacter aerogenes*' are referable (e.g. on the basis of motility) to *Klebsiella pneumoniae* or to *Enterobacter aerogenes*. [Book ref. 21, pp. 322, 324, 339–340.]

**aerobactin** See **SIDEROPHORES**.

**aerobe** An organism which has the ability to grow in the presence of oxygen, i.e., in or on media or substrates which are in contact with air – the term commonly being reserved for those organisms which, in nature, normally grow in aerobic habitats; some aerobes can also grow under anaerobic conditions, i.e., they are **FACULTATIVE anaerobes**. (cf. **ANAEROBE**; see also **MICROAEROPHILIC** and **ANAEROBIC RESPIRATION**.)

**aerobic** (1) Refers to an environment in which oxygen is present at a partial pressure similar to that in air. (cf. **ANAEROBIC**, **MICROAEROBIC**.) (2) Having the characteristic(s) of **AEROBE(s)**.

**aerobiosis** (1) The state or condition in which oxygen is present. (2) Life in the presence of air.

**Aerococcus** A genus of Gram-positive bacteria of the family Streptococcaceae. Cells: non-motile cocci, commonly in pairs and tetrads. Growth occurs optimally under microaerobic conditions; glucose is fermented homofermentatively to L(+)-lactic acid. Some strains form a pseudocatalase. *A. viridans* (formerly *Gaffkya homari* and *Pediococcus homari*) is the causal agent of GAFFKAEMIA.

**aerogenic** Gas-producing.

**aeromonad** A species or strain of *Aeromonas*.

**Aeromonadaceae** See **AEROMONAS**.

**Aeromonas** A genus of Gram-negative bacteria of the VIBRIONACEAE. [Proposal to move *Aeromonas* from the Vibrionaceae to a new family, Aeromonadaceae: SAAM (1985) 6 171–182; IJSB (1986) 36 473–477.] Cells variable: straight, rounded rods or coccobacilli (0.3–1.0 × 1.0–3.5 µm) – occurring singly, in pairs, or in short chains – or short filaments. The genus is divided into two groups: non-motile psychrotrophs (*A. salmonicida*) and motile mesophiles (*A. hydrophila* group). Motile cells usually have a single, polar, unsheathed flagellum (wavelength ca. 1.7 µm); some cells in young cultures on solid media may be peritrichously flagellate. *Aeromonas* spp are oxidase +ve; a range of sugars and organic acids can be used as carbon sources; acid (± gas) is formed from glucose but not e.g. from inositol; gelatinase, DNase, RNase and Tween 80 esterase (lipase) are formed; NO<sub>3</sub><sup>-</sup> is reduced to NO<sub>2</sub><sup>-</sup>. NaCl is not required for growth. Strains are resistant to O/129. Most strains can grow on e.g. nutrient agar or trypticase-soy agar but usually not e.g. on TCBS agar. [Media, identification etc: Book ref. 46, pp. 1288–1294.] GC%: 57–63. Type species: *A. hydrophila*.

The taxonomy of the motile strains remains unsettled. Three species have been recognized: *A. hydrophila*, *A. caviae* and *A. sobria* [Book ref. 22, pp. 545–548]. ('*A. punctata*' is regarded as a later synonym of *A. hydrophila*, with VP –ve, anaerogenic strains now included in *A. caviae*; '*A. proteolytica*' = *Vibrio proteolyticus*.) Motile strains can grow on many media used for enterobacteria (e.g. DCA, MacConkey's agar), usually forming colourless (lactose –ve) colonies. Optimum growth temperature: ca. 28°C, maximum usually 38–41°C; some strains can grow at 5°C. Species occur in fresh water, sewage, and associated with aquatic animals; strains can cause disease in fish (see e.g. **RED PEST** and **RED MOUTH**), amphibians (e.g. **RED LEG**), reptiles, and cattle, and in man – causing e.g. septicaemia, meningitis, gastroenteritis (enterotoxigenic strains), etc.

*A. salmonicida* has an optimum growth temperature of 22–25°C, maximum usually ca. 35°C; most strains can grow

at 5°C. Three subspecies are recognized. Subsp. *salmonicida* is indole –ve, aesculin +ve, and produces a water-soluble brown pigment when grown aerobically on media containing 0.1% tyrosine or phenylalanine. Subsp. *achromogenes* is indole +ve/–ve, aesculin –ve, and does not produce brown pigment. Subsp. *masoucida* is indole +ve, aesculin +ve, and does not produce brown pigment. *A. salmonicida* is haemolytic on blood agar. The species is strictly parasitic and often pathogenic in fish, causing e.g. **FURUNCULOSIS** and secondary infections in various other diseases.

[*Aeromonas* bacteriophages: Ann. Vir. (1985) 136E 175–199.]

**aerosol** Minute (colloidal) particles of liquid and/or solid dispersed in a gas (e.g. air), formed e.g. by sneezing, coughing, liquids splashing, bubbles bursting, etc. An aerosol may contain viable microorganisms.

**aerotaxis** A **TAXIS** in which a (motile) cell migrates along an oxygen concentration gradient to a location where the concentration of oxygen is optimal for that cell.

In bacteria, aerotaxis appears to be exhibited by all aerobic and facultatively aerobic motile species. Interestingly, though, organisms which use oxygen as terminal electron acceptor in energy metabolism do not necessarily migrate to positions where oxygen is at atmospheric levels; for example, the respiratory-type bacterium *Azospirillum brasiliense* is microaerophilic, and this organism migrates towards regions where the oxygen concentration is only 3–5 µM. (This species may have a highly efficient oxidase which enables it to carry out oxygen-based respiratory metabolism in microaerobic conditions.)

For some time it has been thought that aerotaxis may be linked to changes in proton motive force (pmf). In support of this idea, it was found that different types of change in pmf (i.e. increases or decreases) are associated with different effects on motility; thus, for example, if the partial pressure of oxygen is kept constant, then an artificially induced increase in pmf encourages smooth, continual swimming, while a decrease in pmf promotes tumbling in peritrichously flagellated cells. More recently it has been shown that, in *A. brasiliense*, pmf increases when the cell swims towards the preferred concentration of oxygen and decreases when the cell swims in the opposite direction; this has suggested that the change in level of pmf acts as a signal which regulates aerotactic movements [JB (1996) 178 5199–5204]. Aerotaxis apparently cannot occur in a bacterium in which the pmf is at a maximum; under such conditions certain other (pmf-independent) taxes – e.g. **CHEMOTAXIS** – may occur.

In *Escherichia coli* a sensor protein, Aer, may mediate aerotaxis by responding to redox changes in component(s) of the electron transport chain; the Tsr protein (an MCP in chemotaxis) appears to be another, independent sensor for aerotaxis and may respond to changes in pmf [PNAS (1997) 94 10541–10546].

**aerotolerant** Refers to an **ANAEROBE** which, in the presence of air, can either survive (but not grow) or grow at sub-optimal rates.

**aeruginocin** *Syn.* PYOCIN.

**aesculin** (esculin) The 6-β-D-glucosyl derivative of 6,7-dihydroxycoumarin. Certain bacteria (e.g. most strains of the former group D streptococci, many *Bacteroides* spp – including *B. fragilis*) can hydrolyse aesculin to yield 6,7-dihydroxycoumarin which gives a brown coloration with soluble ferric salts. (Hydrolysis may also be detected by the disappearance of aesculin fluorescence under Wood's lamp.)

Various media are used for aesculin hydrolysis tests. *Aesculin broth* may contain e.g. aesculin (0.1%) and FeCl<sub>3</sub> (0.05%) in heart infusion broth. *Aesculin agar* is aesculin broth gelled with

## aethalium

agar. *Bile-aesculin agar* contains e.g. oxgall (4%), aesculin (0.1%) and ferric citrate (0.05%) in nutrient agar. *Bacteroides bile-aesculin agar* is bile-aesculin agar with the addition of e.g. haemin and gentamicin.

The former group D streptococci can be identified by their ability to cause blackening on bile-aesculin agar slants – usually within 48 h; most non-group D streptococci do not cause blackening, although some viridans streptococci may do so.

**aethalium** See MYXOMYCETES.

**aetiology** (etiology) The study of *causation*. The aetiological agent of an infectious disease is the organism which initiates/causes the disease.

**aetioporphyrim** See PORPHYRINS.

**AEV** Avian erythroblastosis virus: see AVIAN ACUTE LEUKAEMIA VIRUSES.

**AF-2** (furylfuramide) See NITROFURANS.

**AFC** (*immunol.*) Antibody-forming cell.

**AFDW** Ash-free dry weight.

**affinity** (*immunol.*) The strength of binding between a given antibody and a single antigenic determinant or monovalent hapten. Factors which affect affinity include the area of contact between the antibody combining site and the antigenic determinant, the closeness of fit, and the nature of the intermolecular forces involved. (cf. AVIDITY.)

**affinity chromatography** See CHROMATOGRAPHY.

**affinity labelling** A technique used to identify the COMBINING SITE of an antibody. In one method, the antibody is allowed to combine with a homologous HAPTEN (the 'affinity label') that carries an azide side-chain; on subsequent irradiation with ultraviolet light the azide forms a highly reactive nitrene group that combines with any of a range of organic groups in the combining site. The nature of the combining site may subsequently be determined e.g. by chemical analysis.

**affinity maturation** See ANTIBODY FORMATION.

**affinity tail** See FUSION PROTEIN.

**aflatoxicosis** A MYCOTOXICOSIS caused by ingestion of AFLATOXINS.

**aflatoxins** A group of MYCOTOXINS, produced by strains of *Aspergillus flavus* and *A. parasiticus*, which contain a bifuran moiety fused at the 4,5 ring positions to a substituted coumarin. (cf. STERIGMATOCYSTIN.) Aflatoxins are soluble in organic solvents, and some exhibit fluorescence on UV irradiation; they are extremely heat-stable. Aflatoxins are toxic to a wide range of eukaryotes; they can retard germination and growth in plants, inhibit the germination of several moulds (e.g. *Mucor*, *Neurospora*, *Penicillium*), and are hepatotoxic and hepatocarcinogenic in animals. Severe outbreaks of disease have occurred in domestic animals and poultry fed with aflatoxin-contaminated feedstuffs – particularly groundnut and cereal feeds. (See also HEPATITIS X; TURKEY X DISEASE; cf. RUBRATOXINS.) Aflatoxins can affect the immune system, reducing resistance to infection, and may increase the risk of hepatocellular carcinoma due to HEPATITIS B VIRUS infection. The toxins can inhibit mitosis in tissue cultures. Aflatoxins may e.g. cause errors in DNA replication by reacting with guanine bases; toxic effects may differ in different species. [Aflatoxin biosynthesis genes: AEM (2004) 70 1253–1262; (2005) 71 3192–3198.]

**AFLP fingerprinting** A PCR-based TYPING method [original description: NAR (1995) 23 4407–4414] which requires only a small amount of purified genomic DNA. The principle of the method is outlined in the figure. (In the standard protocol, primers are end-labelled; a simplified procedure avoids the need for end-labelling of primers by using  $\alpha$ -labelled

nucleotides ( $\alpha$ - $^{33}\text{P}$ -dATP) that are incorporated into products during amplification [BioTechniques (2000) 28 622–623].)

[Taxonomic evaluation of *Bacillus anthracis* and related species by AFLP fingerprinting: JB (1997) 179 818–824. AFLP fingerprinting used for detecting genetic variation in *Xanthomonas*: Microbiology (1999) 145 107–114. AFLP-based study of *Escherichia coli*: JCM (1999) 37 1274–1279. Review of AFLP fingerprinting: JCM (1999) 37 3083–3091.]

**African farcy** *Syn.* EPIZOOTIC LYMPHANGITIS.

**African horse sickness** An infectious HORSE DISEASE caused by an *Orbivirus* and transmitted by insects (e.g. *Culicoides* spp); it occurs in Africa, parts of the Middle East, and the Mediterranean region. The disease may be acute, with an incubation period of ca. 5–7 days, followed by fever, laboured breathing, severe paroxysms of coughing, and a profuse nasal discharge of yellowish, frothy serous fluid; death usually occurs within 4–5 days of onset. Subacute forms of the disease may occur in enzootic areas: an incubation period of up to 3 weeks is followed by oedema of the head region, spreading to the chest; cardiac and pulmonary symptoms and paralysis of the oesophagus may occur, but mortality rates are generally lower than in the acute form. A mild form involving fever and moderate dyspnoea ('horse sickness fever') may occur e.g. in partially immune animals. African horse sickness may also cause severe debility in mules and donkeys, but mortality rates are lower than in horses. Control: e.g. vaccination; control of vectors.

**African swine fever** A highly infectious PIG DISEASE which clinically resembles European SWINE FEVER (q.v.); it occurs e.g. in Africa, Spain and Portugal. The causal agent is a virus previously classified in the IRIDOVIRIDAE but currently considered to belong to a separate family. The virion is icosahedral, enveloped, and contains a DNA-dependent RNA polymerase and RNA-modifying enzymes; the genome is dsDNA (MWt ca.  $100 \times 10^6$ ) in which the strands are covalently joined at each end (cf. POXVIRIDAE), and which contains terminal inverted repeats.

**African trypanosomiasis** See TRYPANOSOMIASIS.

**ag** (*immunol.*) ANTIGEN.

**Agamococcidiorida** An order in the COCCIDIASINA.

**agamont** See ALTERNATION OF GENERATIONS.

**agar** A complex galactan which is widely used (in gel form) as a base for many kinds of solid and semi-solid microbiological MEDIUM; agar (or agarose – see below) is also used e.g. in techniques such as GEL DIFFUSION, GEL FILTRATION and ELECTROPHORESIS, and in industry as a gelling agent in foods, pharmaceuticals etc. Agar is produced by many marine rhodophycan algae and is obtained commercially from e.g. *Gelidium* and *Gracilaria* spp; in the alga it is associated with the CELL WALL and intercellular matrix. (The term 'agar' derives from the Malay *agar-agar* which refers to certain edible seaweeds.)

Agar consists of two main components: *agarose* (ca. 70%) and *agaropectin* (ca. 30%). Agarose is a non-sulphated linear polymer consisting of alternating residues of D-galactose and 3,6-anhydro-L-galactose: [-3,6-anhydro- $\alpha$ -L-galactopyranosyl-(1  $\rightarrow$  3)- $\beta$ -D-galactopyranosyl-(1  $\rightarrow$  4)-] $_n$ ; in agarose from some species, a proportion of the D-galactose residues have 6-O-methyl substituents. Agaropectin is a mixture of sulphated galactans which may also contain e.g. glucuronic acid or pyruvic acid, depending on source. (Agar-like substances from non-commercial seaweeds show various structural differences from commercial agar [Book ref. 38, pp. 291–292].)

An agar gel is a translucent or transparent jelly-like substance formed when a mixture of agar and water is heated to  $>100^\circ\text{C}$  and then cooled; gelling occurs at ca.  $40$ – $45^\circ\text{C}$ .

**AFLP FINGERPRINTING (principle, diagrammatic).**

Chromosomes of the test strain are initially digested with *two* types of RESTRICTION ENDONUCLEASE, commonly *EcoRI* (recognition site: G/AATTC) and *MseI* (recognition site: T/TAA). As a result, the two sticky ends of each fragment may be created either by the same enzyme or by different enzymes.

The chromosomal fragments are then mixed with 'adaptor' molecules of two types, here designated A and B. Each type of adaptor molecule is a short DNA sequence which has *one* sticky end that corresponds to the recognition sequence of *one* of the two restriction enzymes. The reaction mixture contains a ligase, so that covalent binding between fragments and adaptor molecules gives rise to the following sequences: A-fragment-A, A-fragment-B, B-fragment-A and B-fragment-B. *Note.* In each adaptor molecule a 'mutant' nucleotide is incorporated immediately adjacent to the sticky end so that, after ligation to a fragment, the cutting site of the enzyme is *not* restored; thus, following ligation, the sequence is not susceptible to restriction.

The fragments, flanked on each side by (ligated) adaptor molecules, are now subjected to PCR under high-stringency conditions.

Each PCR primer is designed to be complementary to one or other of the adaptor molecules, including the restriction site; however, an important feature of each primer is that its 3' end extends for one or a few nucleotides *beyond* the restriction site – i.e. into the 'unknown' fragment. The one (or few) 3' nucleotide(s) of the primer are *selective* nucleotides, i.e. the primer will be extended only if these nucleotides are paired with *complementary* nucleotides in the fragment. Hence, while primers may bind to all fragments in the mixture, only a subset of fragments will be amplified, i.e. those fragments containing nucleotides that are complementary to the selective 3' nucleotide(s) of the primer. A primer with one selective nucleotide has a 1-in-4 chance of binding to a complementary nucleotide in the fragment; this type of primer will amplify only about one in four of the fragments to which it binds.

The primers of one type are labelled so that, following PCR and gel electrophoresis of the products, a fingerprint of (e.g. ~50–200) detectable bands is obtained.

(a) Each restriction fragment is flanked by (ligated) adaptor molecules.

(b) *Left.* A fragment's sticky end produced by *EcoRI* (N = nucleotide). *Right.* An adaptor molecule with the complementary 5'-AATT overhang; note that, in the overhang strand, the 5'-AATT is followed by G, rather than C.

(c) Following base-pairing of the sticky ends in (b), and ligation, the resulting sequence

differs from the cutting site of *EcoRI* and is not susceptible to cleavage by *EcoRI*.

(d) During cycling, a primer binds to one strand of the fragment–adaptor junction region. As this primer's 3'-terminal (selective) nucleotide is T, the primer will be extended only if the complementary nucleotide (A) occurs at this location in the fragment; extension will not occur on this fragment if T is mis-matched.

Reproduced from Figure 7.6, page 193, in *DNA Methods in Clinical Microbiology* (ISBN 07923-6307-8), Paul Singleton (2000), with kind permission from Kluwer Academic Publishers, Dordrecht, The Netherlands.

## agar diffusion test

Media made from Japanese agars usually contain 1.5–2.0% w/v agar; however, *semi-solid* agars contain 0.5% or less, and *stiff* agars contain e.g. 8% w/v. (If New Zealand agars are used, these concentrations should be halved to give gels of similar strengths.) Sterile gels are prepared by autoclaving a suspension of agar in water (see AUTOCLAVE). Growth media are prepared by adding nutrients, selective agents etc to the agar – usually before autoclaving but sometimes after (see e.g. BLOOD AGAR). If the medium is to have a pH of 6.0 or less, the pH must be adjusted after autoclaving, since agar is hydrolysed during heating at low pH. Various refined forms of agar may be used for specific purposes: e.g. *ion-free* agar may be used in immunoelectrophoresis. (See also ELECTROENDOSMOSIS.)

Agar is a useful base for microbiological media in that it gels at moderate temperatures and, once set, the gels are stable at temperatures up to ca. 65°C or higher (although syneresis tends to occur at these temperatures); furthermore, the ability to degrade agar is confined to only a few organisms (including e.g. strains of *Streptomyces coelicolor*, certain marine pseudomonads, marine species of *Cytophaga*). (cf. GELATIN.) However, agar shortages, product variability, and rising prices have led to a search for suitable substitutes for agar; substitutes which have found some applications include CARRAGEENAN, Gelrite (see GELLAN GUM), low-methoxy PECTINS, and SILICA GELS.

**agar diffusion test** A DIFFUSION TEST which differs from the DISC DIFFUSION TEST in that, instead of employing antibiotic-impregnated discs, a *solution* of each antibiotic is allowed to diffuse from a separate ‘well’ cut into the agar.

**agar dilution test** See DILUTION TEST.

**agar disc diffusion test** *Syn.* DISC DIFFUSION TEST.

**agar gel diffusion** See GEL DIFFUSION.

**agar plate** See PLATE.

**agar-slide method** *Syn.* DIP-SLIDE METHOD.

**agaric** (1) Any fungus of the Agaricaceae. (2) Any fungus of the AGARICALES. (3) Any fungus whose hymenium is borne on lamellae (see LAMELLA).

**Agaricaceae** See AGARICALES.

**Agaricales** An order of terrestrial (typically humicolous or lignicolous), mainly saprotrophic fungi (subclass HOLOBASIDIOMYCETIDAE) most of which form mushroom-shaped, gymnocarpic or semiangiocarpic, fleshy fruiting bodies in which the hymenium is borne on radially arranged ‘gills’ (= lamellae, see LAMELLA) on the underside of the pileus; the pileus and (when present) stipe do not contain sphaerocysts (cf. RUSSULALES). (See also SECOTIOID FUNGI.) The order may be divided into families on the basis of e.g. basidiospore colour, the structure of the trama, and the nature of the cortical layers of the pileus [Book ref. 64, pp. 7–8]; these families include:

Agaricaceae. Basidiocarp: stipitate, typically with an annulus when mature; basidiospores: typically dark brown or colourless, but not rust- or cinnamon-coloured. Genera include AGARICUS and LEPIOTA.

Amanitaceae. Basidiocarp: stipitate, the lamellae each having a divergent BILATERAL TRAMA; basidiospores: white or pale. Some species form both a PARTIAL VEIL and a UNIVERSAL VEIL. Genera include AMANITA (volva formed), *Limacella* (volva not formed), and TERMITOMYCES.

Bolbitiaceae. Basidiocarp: stipitate; basidiospores: ochre or cinnamon to rust-brown. Genera include *Agrocybe* and *Conocybe*.

Coprinaceae. Basidiocarp: stipitate, a palisade-like layer of cells occurring in the pellis; basidiospores: dark or black, each usually containing a germ pore. Genera include COPRINUS and *Psathyrella*.

Cortinariaceae. Basidiocarp: stipitate, characteristically with a fine, cobweb-like cortina; basidiospores: rust-coloured or some shade of brown, smooth to rough. Genera include *Cortinarius*, *Galerina*, *Inocybe* (see also MUSCARINE).

Crepidotaceae. Basidiocarp: non-stipitate, or with a rudimentary lateral stipe; basidiospores: cinnamon-coloured. Genera include CREPIDOTUS.

Hygrophoraceae (‘wax caps’). Basidiocarp: stipitate, often brightly coloured, the lamellae being waxy, and the basidia typically elongated; basidiospores: colourless. Genera include *Hygrocybe* and *Hygrophorus*.

Pluteaceae. Basidiocarp: stipitate with a volva, the lamellae each having a convergent BILATERAL TRAMA; basidiospores: pink. Genera include *Volvariella* (see also PADL-STRAW MUSHROOM).

Strophariaceae. Basidiocarp: stipitate (stipe often elongated), pileus e.g. buff, yellow, ochre, or (in *Stropharia aeruginosa*) greenish; basidiospores: typically brown to purplish-brown. Genera include *Hypholoma*, *Panaeolus*, *Pholiota*, *Psilocybe*, *Stropharia*. (See also HALLUCINOGENIC MUSHROOMS.)

Tricholomataceae. Basidiocarp: stipitate, lamellae with non-bilateral trama; basidiospores: white or pink, without a germ pore. Genera include ARMILLARIA, *Clitocybe*, *Collybia*, *Crinipellis* (see also WITCHES’ BROOM), *Flammulina* (see also ENOKITAKE), LENTINULA, LEPISTA, *Marasmius* (see also MYCORRHIZA), *Mycena* (see also BIOLUMINESCENCE), *Omphalotus*, *Oudemansiella*, *Tricholoma*.

**agaricoid** Refers to the type of fruiting body which is characteristic of fungi of the AGARICALES: gymnocarpic, with the hymenium forming a layer on lamellae and giving rise to ballistospores. (cf. GASTEROID.)

**Agaricus** (formerly *Psalliota*) A genus of fungi (AGARICALES, Agaricaceae), most (not all) species of which are edible. Except in *A. brunnescens*, the basidia each form four basidiospores; basidiospores are dark brown and commonly ovoid. *A. arvensis* is the horse mushroom, *A. campestris* the common or field mushroom, and *A. silvicola* the wood mushroom (all edible species). *A. brunnescens* (= *A. bisporus*), a species which forms two-spored basidia, is the cultivated mushroom (see MUSHROOM CULTIVATION). (See also FUNGUS GARDENS.)

**agarobiose** A disaccharide: 3,6-anhydro-4-*O*-(β-D-galactopyranosyl)-L-galactose, a degradation product of AGAR.

**agaroplectin** See AGAR.

**agarophyte** (agarphyte) Any AGAR-producing seaweed.

**agarose** See AGAR.

**agar-dependent polyencephalomyelitis** (in mice) See LACTATE DEHYDROGENASE VIRUS.

**agglutinated test** (*protozool.*) See e.g. FORAMINIFERIDA.

**agglutination** The formation of insoluble aggregates following the combination of antibodies with cells or other particulate antigens (see e.g. WEIL-FELIX TEST) or with soluble antigens bound to cells or other particles (see e.g. LATEX PARTICLE TEST), or following the combination of soluble (or particulate) antigens with cell-bound or particle-bound antibodies (see e.g. PROTEIN A); agglutination may also be mediated by e.g. LECTINS or by fibrinogen (see clumping factor in COAGULASE). Agglutination may be detected macroscopically as suspended aggregates or (subsequently) as sedimented aggregates. (See also PASSIVE AGGLUTINATION and HAEMAGGLUTINATION; cf. PRECIPITATION and FLOCCULATION sense 1.)

On sedimentation, agglutinated particles may form a mat over a relatively large area of the bottom of the test-tube; by contrast, non-agglutinated particles generally sediment to form a smaller, dense button in the control tube.

**agglutination factor** (*algot.*) See CHLAMYDOMONAS.

**agglutination test** Any test in which reactions between particulate and/or soluble entities (particularly free or particle-bound antibodies and antigens) is detected by AGGLUTINATION.

**agglutinin** (1) Any ANTIBODY involved in an AGGLUTINATION reaction. (2) Any substance which can agglutinate cells or inanimate particles by binding to their surface components.

**agglutininogen** The antigen homologous to an agglutinin.

**Aggregata** See EIMERIORINA.

**aggregate gold standard** See GOLD STANDARD.

**aggregation substance** See PHEROMONE.

**aggresin** Any product or component of a pathogenic microorganism which promotes the invasiveness of that organism – see e.g. HYALURONATE LYASE. (cf. STREPTOKINASE; see also ADHESION and IGA1 PROTEASES.)

**aglycon** The non-sugar portion of a glycoside.

**agmatine** See e.g. DECARBOXYLASE TESTS.

**Agmenellum** A phycological genus of ‘blue-green algae’ currently included in the SYNECHOCOCCUS complex.

**agnogene** See AGNOPROTEIN.

**agnoprotein** A 61-amino acid, highly basic polypeptide encoded by a gene (the ‘agnogene’) in the late leader region of SIMIAN VIRUS 40; it appears to play a role in viral assembly.

**Agonomycetales** (Mycelia Sterilia) An order of fungi (class HYPHOMYCETES) which include species that form neither conidia nor sexual structures, though some species have been found to have teleomorphs in the Ascomycotina or the Basidiomycotina. The order includes lichenized fungi (e.g. LEPRARIA) and plant pathogens (see e.g. RHIZOCTONIA and SCLEROTIUM).

**agr locus** (in *Staphylococcus aureus*) Accessory gene regulator locus: a chromosomal sequence which encodes, *inter alia*, (i) the sensor and response regulator of a TWO-COMPONENT REGULATORY SYSTEM (AgrA–AgrC), and (ii) an octapeptide ‘pheromone’ which is secreted by the cell and which, at appropriate concentrations (see QUORUM SENSING), activates the two-component system. When activated, the AgrA–AgrC system upregulates expression of the (*agr*-encoded) transcript RNA III which, in turn, regulates the expression of genes for exotoxins and certain cell-surface-associated virulence factors.

Another two-component system, encoded by the *srrAB* genes (staphylococcal respiratory response genes), appears to regulate the expression of exotoxins and certain cell-surface virulence factors in accordance with the levels of environmental oxygen, such regulation being exerted, in part, via the *agr* system [JB (2001) 183 1113–1123].

**agranulocyte** Any white blood cell which has non-granular cytoplasm, e.g., a LYMPHOCYTE.

**Agrobacterium** A genus of Gram-negative bacteria of the RHIZOBIACEAE. Cells: rods (0.6–1.0 × 1.5–3.0 μm), capsulated. Motile, with between one (often non-polar) and six peritrichous flagella. Optimum growth temperature: 25–28°C. Species can metabolize a wide range of mono- and disaccharides and salts of organic acids; acid (no gas) is formed from glucose (which is metabolized mainly via the ENTNER–DOUDOROFF PATHWAY and the HEXOSE MONOPHOSPHATE PATHWAY). Colonies on carbohydrate-containing media are typically mucilaginous, abundant extracellular slime (including a neutral (1 → 2)-β-glucan) being produced. (See also CURDLAN.) Some strains can use NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> as nitrogen sources, while others require amino acids; some strains can carry out NITRATE RESPIRATION. Nitrogen fixation does not occur. GC%: 57–63. Type species: *A. tumefaciens*.

*Agrobacterium* spp occur in soil, mainly in the rhizosphere. All (except *A. radiobacter*) can infect a wide range of dicotyledonous plants (and some gymnosperms) and induce the formation of self-proliferating galls or adventitious roots. The species are defined primarily or solely on the basis of their pathogenic characteristics: *A. radiobacter* is non-pathogenic, *A. rhizogenes* causes HAIRY ROOT, *A. rubi* causes CANE GALL, and *A. tumefaciens* causes CROWN GALL. However, pathogenicity depends on the presence of a plasmid(s) and can readily be altered or lost; hence the currently recognized species do not reflect true taxonomic relationships among the agrobacteria. [Book ref. 22, pp. 244–254.]

[Media and culture: Book ref. 45, 842–855.]

**agrocin 84** See AGROCINS.

**agrocinopines** A class of (sugar phosphodiester) opines found in CROWN GALL. (See also AGROCINS.)

**agrocins** Antibiotics which are produced by certain strains of *Agrobacterium* and which are active against other strains of the same genus; being non-protein in structure, agrocins are not strictly BACTERIOCINS. Agrocin 84 is produced by a non-pathogenic, nopaline-catabolizing strain of *A. radiobacter* (strain 84, NCPPB 2407) and is selectively active against agrobacteria which harbour a nopaline Ti plasmid. Strain 84 is used in the BIOLOGICAL CONTROL OF CROWN GALL; a cell suspension is used to treat seeds, roots or wounded plant surfaces (e.g. graft wounds), and almost 100% control of nopaline pathogens (responsible for most of the economic damage due to crown gall) can be achieved. Agrocin 84 is an adenine nucleotide derivative containing an N<sup>6</sup>-phosphoramidate substituent (necessary for uptake by sensitive cells) and a 5′-phosphoramidate substituent (necessary for toxicity). Agrocin 84 is taken up by sensitive strains via a high-affinity ‘agrocin permease’, apparently an agrocinopine transport system normally inducible by agrocinopines (sugar phosphodiesters) present in galls caused by nopaline strains. Strain 84 contains at least three plasmids: one (pAgK84, 47.7 kb) coding for agrocin 84 production, another (pAt84b, ca. 200 kb) coding for nopaline catabolism. pAgK84 is self-transmissible only at very low frequencies, but can be mobilized by the conjugative plasmid pAt84b. As transfer of pAgK84 to a crown gall pathogen could threaten the continued use of agrocin 84 in biocontrol, a transfer-deficient mutant strain was prepared. However, strain K84 apparently exerts some activity against agrocin 84-resistant pathogens independently of pAgK84 [AEM (1999) 65 1936–1940].

**Agrocybe** See AGARICALES (Bolbitiaceae).

**agroinfection** A method for introducing viral DNA (or cDNA) into a plant. Viral DNA is initially incorporated into the T-DNA part of a Ti plasmid. The plasmid is then introduced into the bacterium *Agrobacterium tumefaciens*–which is used to infect the plant; during infection the viral DNA is transferred to plant cells within the T-DNA (see CROWN GALL). [Example of use: JV (2003) 77 3247–3256.]

**Agromyces** A genus of microaerophilic to anaerobic, catalase-negative, asporogenous bacteria (order ACTINOMYCETALES, wall type VII – see also PEPTIDOGLYCAN). The organisms grow as a branched mycelium which subsequently fragments into coccoid and diphtheroid forms; metabolism: oxidative. *A. ramosus*, the type species, occurs in large numbers in certain soils; it appears to attack and destroy other species of bacteria [AEM (1983) 46 881–888].

**agropine** See CROWN GALL and HAIRY ROOT.

**Agropyron mosaic virus** See POTYVIRUSES.

**AHG** (*serol.*) Anti-human globulin: ANTIGLOBULIN homologous to human globulins.

## AHL

**AHL** See QUORUM SENSING.

**ahpC gene** See ISONIAZID.

**AID** (activation-induced cytidine deaminase) See RNA EDITING.

**AIDA-I** In *Escherichia coli*: an adhesin that mediates diffuse adherence (to e.g. HeLa cells) – hence the designation adhesin involuned in diffuse adherence. AIDA-I is the  $\alpha$  domain of an autotransporter (see type IV systems in PROTEIN SECRETION); in wild-type cells the  $\alpha$  domain is apparently cleaved (autocatalytically?), but it remains attached (non-covalently) to the cell surface.

(See also AUTODISPLAY.)

**aidB gene** See ADAPTIVE RESPONSE.

**AIDS** (acquired immune deficiency syndrome) In an HIV<sup>+</sup> individual (see HIV): the stage of disease characterized by (i) counts of CD4<sup>+</sup> T LYMPHOCYTES commonly within or below the range 200–500/ $\mu$ l (in adults and adolescents) and (ii) the presence of one or more category C diseases (AIDS-defining diseases specified in the clinical staging system of the Centers for Disease Control (CDC), Atlanta, Georgia, USA); category C diseases include e.g. CANDIDIASIS of the lower respiratory tract; disseminated COCCIDIOIDOMYCOSIS; extrapulmonary CRYPTOCOCCOSIS; retinitis due to cytomegalovirus (BETAHERPESVIRINAE); herpes simplex oesophagitis; HIV-related encephalopathy; extrapulmonary HISTOPLASMOVIS; chronic infection with ISOSPORA; KAPOSI'S SARCOMA; primary lymphoma of the brain; extrapulmonary infection with *Mycobacterium tuberculosis* (see also MAC); pneumonia caused by PNEUMOCYSTIS CARINII; TOXOPLASMOVIS of the brain. [Infections in AIDS (MICROSPORIDIOSIS, invasive pneumococcal disease, non-typhoid salmonellae): JMM (2000) 49 947–957.]

The normal CD4 count in adults/adolescents is  $\sim$ 1000/ $\mu$ l; in neonates it is much higher ( $\geq$ 2000), so that the adult-based relationship between CD4 counts and susceptibility to opportunist pathogens is not appropriate for very young children.

[AIDS Insight (various aspects): Nature (2001) 410 961–1007.]

*Transmission/containment of HIV.*

HIV can be transmitted: (i) by sexual contact (male  $\leftrightarrow$  female, as well as homosexual); (ii) via transfusion of (infected) blood or blood products (e.g. contaminated Factor VIII formerly given to haemophiliacs); (iii) via the placenta; (iv) by breast-feeding; and (v) through use of contaminated needles by intravenous drug abusers.

The highest concentration of virus (free and intracellular) is found in blood; HIV also occurs e.g. in semen, milk and cerebrospinal fluid.

Efforts to prevent/limit the spread of HIV have included: (i) education (making clear the basic facts of the disease, including routes of transmission); (ii) discouraging promiscuity; (iii) encouraging the use of condoms; (iv) discouraging needle-sharing by drug addicts; (v) screening of blood donors; (vi) treatment of blood products.

*Clinical manifestations of HIV infection.*

Infection is commonly followed, in  $\sim$ 2–6 weeks, by an early 'acute' phase which is characterized by high-level viraemia; p24 antigen (the major core protein: see HIV) can often be demonstrated in serum during the viraemic phase. Levels of virus remain high for some weeks – after which there is a sharp decline (and a loss of detectable p24 antigen); this decline in viraemia appears to reflect the activity of antigen-specific CD8<sup>+</sup> cytotoxic T cells (see T LYMPHOCYTE) and may also involve non-specific killing of virus-infected cells by NK CELLS.

Antibodies (e.g. anti-gp120, anti-p24) are first detectable  $\sim$ 6–12 weeks after infection; their appearance may follow, or coincide with, the rapid decline in viraemia.

During seroconversion some patients experience a *seroconversion illness* which may include e.g. fever, sore throat, skin rash, generalized lymphadenopathy, pneumonitis, gastrointestinal and/or CNS involvement.

A subsequent phase of infection is characterized by *persistent generalized lymphadenopathy* (PGL) (also called *lymphadenopathy syndrome*) – swollen lymph nodes reflecting an active immune response to HIV. (In some cases, PGL is the first manifestation of disease following infection, i.e. in patients who do not exhibit an acute phase.) Infection may then become asymptomatic ('clinically latent'), and this state may continue for months or years (during which time viral replication continues).

Patients with clinically latent infection, as well as those with PGL, may pass directly to AIDS. Alternatively, both types of patient may progress to AIDS via a further stage commonly referred to as the *AIDS-related complex* (ARC) (= category B of the CDC clinical staging system). Category B diseases include bacillary angiomatosis (see BARTONELLA), oropharyngeal candidiasis, HAIRY LEUKOPLAKIA, LISTERIOSIS, PID (pelvic inflammatory disease), herpes zoster (involving at least two distinct episodes, or more than one dermatome), and peripheral neuropathy.

In AIDS, the final stage, the CD4<sup>+</sup> count is often  $<$ 200 cells/ $\mu$ l; there is high-level viraemia, and the p24 antigen is again detectable. Note that the AIDS-defining diseases (see above) include those that result from infection by 'low-grade' pathogens, i.e. organisms which generally cause disease only in those patients who are severely immunodeficient (including HIV<sup>-</sup> individuals who may be immunodeficient for other reasons). Conversely, the 'high-grade' pathogens (which can cause disease even in the immunocompetent) may cause disease in HIV<sup>+</sup> patients whose immune system is only marginally impaired.

*Immunopathogenesis.*

In HIV<sup>+</sup> individuals, the reduction in numbers of CD4<sup>+</sup> T cells may arise in various ways – e.g. (i) productive infection by HIV and subsequent lysis; (ii) killing of HIV-infected cells by HIV-specific CD8<sup>+</sup> cytotoxic T cells (see T LYMPHOCYTE) or by NK CELLS; (iii) ADCC (of virus-infected cells). It also appears that non-infected CD4<sup>+</sup> T cells may be susceptible to attack e.g. by HIV-specific cytotoxic T cells or by NK CELLS; this may occur when free (isolated) gp120 protein (see HIV) binds to CD4 on virus-free ('bystander') cells – such cells then becoming vulnerable to the antiviral immune response. CD4<sup>+</sup> cells may also be vulnerable to APOPTOSIS if viral gp120 cross-links CD4 molecules on the cell surface, such cross-linking resulting in an upregulation of the FAS antigen.

Following depletion of CD4<sup>+</sup> T cells, the virus may persist within tissue macrophages (see under *Chemotherapy*, below).

HIV infection produces (i) a direct effect (death of infected cells), and (ii) an indirect effect (weakening of the overall immune system). The direct effect may include neurological deficits (e.g. encephalopathy) as well as immunological damage; the indirect effect is manifested in the range of ARC and AIDS-defining diseases (including both neoplastic and opportunistic diseases).

Depletion of CD4<sup>+</sup> T cells is only one of many abnormalities in the immune system of HIV<sup>+</sup>/AIDS patients. Other types of cell (including B cells) are reported to display abnormalities, and DELAYED HYPERSENSITIVITY reactions may be either absent or of reduced intensity.

The role of CYTOKINES in HIV infection has yet to be clarified, but it seems that, at some stage, the cytokine milieu becomes aberrant, and that increased amounts of e.g. TNF- $\alpha$  and several interleukins (including INTERLEUKIN-4) are formed. It has been suggested that TNF- $\alpha$  may promote viral transcription through activation of the host cell's nuclear transcription factor, NF- $\kappa$ B (see HIV), and that increased levels of IL-4 may bring about a (deleterious) switch to the Th2 subset of T cells (see T LYMPHOCYTE).

#### *Diagnosis of HIV infection.*

In adults and adolescents, laboratory diagnosis of HIV infection is serologically based.

The viral antigen p24 (major core protein) is commonly detectable (transiently) in blood during the initial viraemic (acute) phase of infection, i.e. before any antibodies are detectable. However, not all patients exhibit an acute phase of infection; while a positive test for p24 is useful, a negative test is not a reliable indication of the absence of HIV infection.

Tests for anti-HIV antibodies (e.g. anti-gp120) may be carried out e.g. by ELISA. A positive result may be confirmed by Western blot analysis of viral proteins. Antibodies are commonly present by ~6 weeks post-infection, although positive serology is sometimes delayed. (In some cases, patients who are serologically negative have been implicated, epidemiologically, in the transmission of AIDS.)

Serology is inappropriate for neonates and very young children: if the mother is HIV<sup>+</sup> then, owing to passive transfer of maternal antibodies, the neonate will also contain anti-HIV antibodies, whether infected or not. Culture is a useful approach for diagnosis in this context.

The pre-seroconversion 'window' (the period, post-infection, before development of antibodies) presents a problem in blood transfusion because donor samples taken in this period are likely to contain virus. To minimize this risk, samples can be subjected to PCR-based tests designed to detect viral nucleic acid. Such tests may involve initial concentration of virions from plasma [Lancet (1999) 353 359–363]. Alternatively, the procedure may test for the integrated (i.e. provirus) form of HIV; in this case, PCR is carried out on DNA extracted from blood leukocytes [PNAS (1999) 96 6394–6399]. (See also BLOOD DNA ISOLATION KITS.)

#### *Chemotherapy for HIV infection.*

The drug zidovudine (see AZT) was the first agent used for the treatment of HIV infection. Although initially successful, the use of AZT was found to be limited by the development of drug-resistant strains of HIV. In recent years, combinations of ANTIRETROVIRAL AGENTS have been used in so-called 'highly active antiretroviral therapy' (see HAART). Attempts are being made to extend the range of antiretroviral agents by developing inhibitors of the viral integrase (in order to inhibit integration of HIV provirus into the host cell's genome). (See also NU-1320.)

Even with HAART, however, HIV commonly (or always) emerges after cessation of therapy, and it is generally believed that, during therapy, HIV persists in CD4<sup>+</sup> memory T cells. However, using a chimeric virus (simian immunodeficiency virus/HIV-1), it has been shown that tissue macrophages (in lymph nodes, liver, spleen etc.) form the principal reservoir of virus following depletion of CD4<sup>+</sup> T cells in rhesus macaques; this has suggested that macrophages may be a major source of HIV in the symptomatic phase of human infection [PNAS (2001) 98 658–663].

The drug nevirapine is reported to inhibit intrauterine transmission of HIV to the fetus in a proportion of cases.

One problem associated with chemotherapy is that the combination of drugs used in HAART is often augmented by other

drugs (e.g. antibiotics) used for the treatment of opportunistic infections; this provides potential for adverse drug–drug interactions. [Drug interactions in AIDS: JMM (2000) 49 947–967 (957–962).]

One suggested approach is to combine chemotherapy (using a range of drugs to discourage the emergence of resistant strains of virus) with a programme of vaccination aimed at maintaining or increasing the population of specific cytotoxic T lymphocytes (CTLs); an appropriate level of CTLs would serve to augment the effects of chemotherapy by helping to prevent the growth of mutant strains of virus [PNAS (2000) 97 8193–8195].

*Gene therapy.* See GENE THERAPY.

#### *Anti-AIDS vaccines.*

The production of an anti-AIDS vaccine is fraught with difficulties. One of the major problems is the extensive variability of the envelope protein gp120 (see HIV); a vaccine which is active against one isolate of HIV may be less active, or non-active, against many other isolates.

Early attempts at a vaccine included the use of a recombinant VACCINIA VIRUS containing the *env* sequence of HIV [Nature (1987) 326 249–250].

More recently it has been found that a particular, hyper-variable part of the gp120 glycoprotein, the V3 loop, is an immunodominant area which influences certain phenotypic features of the virus, including infectivity; within this region is a tetrapeptide subregion, GPGR (see AMINO ACID), which seems to be conserved in a large number of field isolates.

Recent studies have examined the effect of variation in the V3 loop on the immunogenic potential of gp120, and it appears that certain changes in composition have considerable influence on the immune response to this glycoprotein [Arch. Virol. (2000) 145 2087–2103].

Considerable efforts are currently being made to find a useful anti-AIDS vaccine, emphasis often being placed on the need for combined antibody- and cell-mediated responses. In one approach, a DNA VACCINE – HIV-derived DNA linked to polylactide co-glycolide – was found significantly to improve both cell-mediated and humoral immunity in monkeys. Use is being made of various vectors in candidate vaccines – including e.g. *Salmonella*, canarypoxvirus and Semliki Forest virus. [AIDS vaccines (news focus): Science (2001) 291 1686–1688.]

AIDS-like diseases have been recognized in certain animals – e.g. cats (see FELINE LEUKAEMIA VIRUS) and monkeys (see SIMIAN AIDS).

**AIDS-related complex (ARC)** See AIDS.

**AIDS virus** See AIDS.

**Aino virus** See AKABANE VIRUS DISEASE and BUNYAVIRUS.

**air** (microbiological aspects) Air normally contains various microorganisms (particularly spores), pollen, and other particulate matter (see also AEROSOL); the microflora varies e.g. with location, general weather conditions, and with particular factors (such as relative humidity), while the viability of the microflora depends e.g. on the extent to which the air has been exposed to ultraviolet radiation. The airborne microflora is sampled e.g. in studies on pneumonitis-type allergies [Book ref. 51, pp. 27–65], environmental microflora [AEM (1983) 45 919–934], the stability of aerosols [AEM (1982) 44 903–908], and organisms of potential meteorological interest [AEM (1982) 44 1059–1063]. Instruments used to sample the airborne microflora include those of the simple gravity-type (e.g. the DURHAM SHELTER, TAUBER TRAP), and e.g. the ALL-GLASS IMPINGER, ANDERSEN SAMPLER, HIRST SPORE TRAP and ROTOROD (see also SLIT SAMPLER). (In the context of air samplers the terms 'impactor' and 'impinger' are sometimes used indiscriminately; thus, e.g. the Andersen sampler has

## air bladder

been described as a 'sieve impinger' [Book ref. 51, pp. 59–61] and as a 'cascade impactor' [Book ref. 57, p. 163].) Individual types of sampler have particular limitations; for example, gravity-type instruments tend to collect the larger particles in preference to smaller ones, the Rotorod can be used only for short periods of time in air containing high concentrations of particulate matter, while some samplers tend to dehydrate the collecting medium and the deposited microorganisms.

The air in confined spaces can be disinfected e.g. by ULTRAVIOLET RADIATION, by sprays of e.g. propylene glycol, or by the use of hydrophobic membrane filters (see FILTRATION).

**air bladder** (*algol.*) *Syn.* PNEUMATOCYST.

**air sacculitis** A POULTRY DISEASE which affects mainly chickens and turkey poults, particularly birds reared in broiler houses. It is caused by *Mycoplasma gallisepticum*, *M. synoviae* or (in turkeys only) *M. meleagridis* – often in association with *Escherichia coli* or respiratory virus infection. Symptoms: coughing, nasal discharge, conjunctivitis etc; sinuses below the eyes are characteristically swollen. The air sacs become filled with a thick white or yellowish caseous material. Transmission may occur from parent to offspring via the egg and from bird to bird.

**airlift fermenter** A LOOP FERMENTER in which the circulation of the culture is typically achieved by pumping air in at the bottom of a DRAFT TUBE (or at the base of the annulus) – the air being voided via an opening in the top of the column; the air bubbles lower the hydrostatic pressure of culture in the draft tube so that culture continually flows down the annulus and up into the draft tube. (Reversed flow occurs if air is bubbled into the annulus.) The ICI *pressure-cycle fermenter* (used for Pruteen production – see SINGLE-CELL PROTEIN) is an example of a *tubular loop* airlift fermenter. It consists essentially of two tall vertical columns (of different diameters) which communicate at top and bottom, and there is no draft tube; air is pumped into the bottom of the wider column (the 'riser') and promotes circulation on the airlift principle. This fermenter achieves a high level of dissolved oxygen since oxygen solubility is increased by the increased hydrostatic pressure at the base of the (tall) riser; additionally, the physical separation of riser and downcomer facilitates the removal of heat by allowing the inclusion of a heat-exchanger in the downcomer. [Construction, behaviour and uses of airlift fermenters: Book ref. 3, pp. 67–95.]

**AIV process** A process for preparing SILAGE by direct acidification of vegetable matter (to ca. pH 3.5) with a mixture of dilute HCl and H<sub>2</sub>SO<sub>4</sub>. In the *Penthesta process* HCl and H<sub>3</sub>PO<sub>4</sub> are used.

**Ajellomyces** A genus of fungi of the GYMNOASCALAE. *A. dermatitidis* = teleomorph of *Blastomyces dermatitidis* (q.v.); it is heterothallic and produces spherical, 8-spored asci. *A. capsulatus* = teleomorph of *Histoplasma capsulatum* (q.v.).

**Akabane virus disease** A CATTLE DISEASE (which can also affect sheep and goats) caused by the Akabane virus (genus BUNYAVIRUS, serogroup Simbu) and transmitted by midges (*Culicoides* spp) and mosquitoes; it occurs e.g. in Africa, Australia and Japan. Infection of cows early in pregnancy causes malformation of the fetus; deformities depend on the stage of development at the time of infection, but may involve absence of cerebral hemispheres (hydranencephaly) and/or fixation of joints leading to deformities of limbs and spine (arthrogryposis). Abortion or stillbirth may occur. The cow shows no other clinical symptoms.

A similar condition is caused by the Aino virus (*Bunyavirus*, serogroup Simbu).

**akinetete** (1) In certain CYANOBACTERIA: a specialized cell which shows some resistance to desiccation and cold and which

apparently functions as an overwintering propagule. Akinetes are formed under various growth-limiting environmental conditions (e.g., nutrient limitation); in e.g. *Anabaena* spp, akinetes develop adjacent to HETEROCYSTs, while in e.g. *Nostoc* spp they develop in positions midway between two heterocysts. An akinete is typically larger than a vegetative cell; it has a thickened wall and granular cytoplasm rich in storage materials (cyanophycin, glycogen etc). Rates of photosynthesis, respiration etc are usually much lower in akinetes than in vegetative cells; in e.g. *Anabaena doliolum*, akinetes appear to be deficient in both photosynthesis and inorganic nitrogen metabolism [JGM (1984) 130 1299–1302]. On germination of an akinete, a single cell or short filament may be released via a pore in – or by rupture of – the akinete wall, depending on species.

(2) (*algol.*) A thick-walled non-motile resting cell produced by certain algae of the CHLOROPHYTA and XANTHOPHYCEAE.

(3) (*mycol.*) A non-motile spore.

**akinetoplasty** Obsolete *syn.* DYSKINETOPLASTY.

**AkTA** (of *Actinobacillus actinomycetemcomitans*) See RTX TOXINS.

**AKV** A replication-competent MURINE LEUKAEMIA VIRUS which occurs endogenously in various strains of mice (e.g. AKR, BALB/c). It appears to have given rise to the transforming virus 'AKR mink cell focus-forming virus' (AKR-MCF) by recombination with one or more endogenous xenotropic viruses. (See also MCF VIRUSES.)

**alafosfalin** (alaphosphin; L-alanyl-L-1-aminoethylphosphonic acid) A synthetic ANTIBIOTIC which is taken up by the LL-dipeptide transport system of a sensitive cell; it is subsequently hydrolysed intracellularly to release the inhibitory component, 1-aminoethylphosphonic acid (ala-P), which itself cannot cross the cytoplasmic membrane. (cf. WARHEAD DELIVERY.) Ala-P acts by competitively inhibiting alanine racemase and – at higher concentrations – by inhibiting the addition of L-alanine to UDP-MurNAc during PEPTIDOGLYCAN synthesis. Alafosfalin has a broad spectrum of activity, but is generally more effective against Gram-negative than Gram-positive bacteria.

**alamethicin** A water-soluble peptide antibiotic (MWt ca. 2100) which is produced – often together with a related antibiotic, *suzukacillin* – by strains of *Trichoderma viride*. It can act as an IONOPHORE [Book ref. 14, pp. 219–224].

**L-alanine biosynthesis** See Appendix IV(b) and AMMONIA ASSIMILATION.

**ala-P (AlaP)** See ALAFOSFALIN.

**alaphosphin** *Syn.* ALAFOSFALIN.

**Alaria** See PHAEOPHYTA.

**alarmone** A low-MWt molecule, synthesis of which serves as a trigger or signal for the redirection of cellular metabolism in response to a particular type of stress; an example is ppGpp in STRINGENT CONTROL (sense 1).

**alastrim** See SMALLPOX.

**alazopeptin** See DON.

**albamycin** *Syn.* NOVOBIOCIN.

**Albert's stain** A stain used to demonstrate METACHROMATIC GRANULES. To prepare Albert's stain: TOLUIDINE BLUE (0.15 g) and MALACHITE GREEN (0.2 g) are dissolved in 95% ethanol (2 ml) and added to 1% acetic acid (100 ml); the whole is filtered after standing for 24 h. A heat-fixed smear is stained with Albert's stain (3–5 min), washed in tap water, and blotted dry; LUGOL'S IODINE is applied for 1 min and the smear washed and blotted dry. Granules stain black, cytoplasm pale green.

**albicidin** An antibiotic, produced by *Xanthomonas albilineans*, which inhibits DNA synthesis in *Escherichia coli* [JGM (1985) 131 1069–1075].

**albofungin** *Syn.* KANCHANOMYCIN.

**albomycin** See SIDEROMYCINS.

**alborixin** See MACROTETRALIDES.

**Albugo** A genus of obligately plant-parasitic fungi (order PERONOSPORALES) which are distinguished by their production of basipetally formed chains of zoosporangia. *A. candida* (economically the most important species) is the causal agent of 'white rust' of crucifers (= 'crucifer white blister' or 'white blister disease'). Within the tissues of the host plant, this fungus forms a branching, aseptate, intercellular mycelium which produces rounded haustoria. The chains of zoosporangia develop on short, club-shaped sporangiophores beneath the host's epidermis, giving rise to smooth, white, blister-like lesions within which the zoosporangia are compacted; subsequently, the epidermis ruptures, and the powdery mass of zoosporangia is dispersed by wind and rain. During sexual reproduction, oogonia and antheridia are produced within the host, and a fertilization tube is formed between them; following fertilization and meiosis, the oosphere gives rise to a thick-walled, warty oospore which later germinates to form zoospores.

**albumen** The white of an egg. (cf. ALBUMINS.)

**albumins** A class of low-MWt proteins which are soluble in dilute salt solutions and (unlike globulins) readily soluble in water.

**Alcaligenes** A genus (*incertae sedis*) of catalase-positive, oxidase-positive, Gram-negative bacteria which occur e.g. in soil, water, the alimentary tract in vertebrates, and in clinical specimens. Cells: non-pigmented rods (up to ca. 3.0 µm in length), coccobacilli, or cocci (ca. 0.5–1.0 µm diam.), with 1–12 flagella per cell. Metabolism is respiratory (oxidative); all strains can use O<sub>2</sub> as terminal electron acceptor, and some can use nitrate (anaerobic respiration). All strains can grow chemoorganotrophically on e.g. amino acids, acetate, fumarate, lactate, malate or succinate – carbohydrates being little used, although some strains can use (and form acid from) glucose and/or xylose; some (H<sub>2</sub>-oxidizing) strains can grow chemolithotrophically. The organisms usually grow well on e.g. peptone-containing media and blood agar. Alkali is formed from the salts of certain organic acids and from some amides. GC%: ca. 56–70. Type species: *A. faecalis*.

*A. denitrificans*. Most strains can reduce both nitrate and nitrite to N<sub>2</sub>. Strains of subsp. *xylosoxydans* are typically able to use glucose and xylose, those of subsp. *denitrificans* are not. The species includes strains previously named *A. ruhlandii* (H<sub>2</sub>-oxidizing organisms which have sheathed, peritrichous flagella), and '*Achromobacter xylosoxidans*'.

*A. faecalis*. Most strains (including those previously named *A. odorans*) can reduce nitrite but not nitrate. No chemolithotrophic strains have been reported.

*A. odorans*. See *A. faecalis*.

*A. ruhlandii*. See *A. denitrificans*.

Species *incertae sedis* [according to Book ref. 22, pp. 370–373] include the peritrichously flagellated, aerobic, H<sub>2</sub>-oxidizing bacteria known as *A. eutrophus*, *A. lactus* and *A. paradoxus*, and the non-fermentative, peritrichously flagellated marine bacteria known as *A. aestus*, *A. aquamarinus*, *A. cupidus*, *A. pacificus* and *A. venustus* (see DELEYA); these organisms are considered not to belong to the genus *Alcaligenes*.

[Book ref. 22, pp. 361–373.]

**alcian blue** A basic dye used e.g. for staining glycoproteins and polysaccharides.

**alcohol oxidase** (alcohol:oxygennitrate oxidoreductase; EC 1.1.3.13)

An enzyme (see ENZYMES) which oxidizes alcohols, giving the

corresponding aldehydes and H<sub>2</sub>O<sub>2</sub>. It is obtained e.g. from *Pichia pastoris*. (See also LIGNIN.)

**alcoholic beverages** See e.g. BREWING, CIDER, KEFIR, KOUMISS, PULQUE, SAKE, SPIRITS, WINE-MAKING.

**alcoholic fermentation** (ethanol fermentation) A type of FERMENTATION (sense 1), carried out by various yeasts and other fungi (e.g. species of *Saccharomyces*, *Pichia*, *Aspergillus*, *Fusarium*, *Mucor*) and by certain bacteria (e.g. *Zymomonas*), in which ethanol is formed from D-glucose (or certain other sugars, depending e.g. on organism). In e.g. *Saccharomyces*, glucose is converted to pyruvate via the EMBDEN-MEYERHOF-PARNAS PATHWAY; pyruvate is decarboxylated to acetaldehyde by pyruvate decarboxylase and thiamine pyrophosphate, and acetaldehyde is then reduced to ethanol by NAD-dependent alcohol dehydrogenase – thus allowing reoxidation of the NAD reduced during the EMP pathway. Small amounts of side-products are usually formed, e.g., GLYCEROL (see also NEUBERG'S FERMENTATIONS), acetaldehyde, lactic acid, 2,3-butanediol, succinic and acetic acids, and FUSEL OIL; these occur in proportions which depend on organism and conditions. Alcoholic fermentation by *Saccharomyces* spp is widely exploited commercially: see e.g. BREWING, CIDER, INDUSTRIAL ALCOHOL, SPIRITS, WINE-MAKING. (cf. ZYMONOMAS.)

[Physiological function of alcohol dehydrogenases and long-chain (C<sub>30</sub>) fatty acids in the alcohol tolerance (~8% ethanol) of a mutant strain of *Thermoanaerobacter ethanolicus*: AEM (2002) 68 1914–1918.]

**alcohols** (as antimicrobial agents) Under appropriate conditions certain alcohols can be rapidly lethal to a range of bacteria, fungi and viruses; they have little or no effect on endospores. The mechanism of antimicrobial activity may involve the denaturation of structural proteins or enzymes and/or the solubilization of lipids (e.g. those in the bacterial cytoplasmic membrane, or in the envelope of certain viruses); methanol and ethanol can cause translational errors in protein synthesis. The antimicrobial activity of alcohols increases with molecular weight and with chain length up to ca. C<sub>10</sub>; above this, insolubility becomes important. Activity decreases in the order primary, *iso*-primary, secondary, tertiary.

*Methanol* (methyl alcohol, CH<sub>3</sub>OH) has poor antimicrobial activity. *Ethanol* (ethyl alcohol, C<sub>2</sub>H<sub>5</sub>OH) exerts maximum activity as ca. 60–90% (v/v) ethanol/water mixtures. *Isopropanol* (isopropyl alcohol, (CH<sub>3</sub>)<sub>2</sub>CHOH) is less volatile and more effective than ethanol, and is used e.g. as a skin antiseptic. *Phenylethanol* (phenylethyl alcohol, C<sub>6</sub>H<sub>5</sub>(CH<sub>2</sub>)<sub>2</sub>OH) is more active against Gram-negative than Gram-positive bacteria, and has been used e.g. as a selective agent in bacteriological media. *Phenoxyethanol* (phenoxetol, C<sub>6</sub>H<sub>5</sub>O(CH<sub>2</sub>)<sub>2</sub>OH) and *benzyl alcohol* (phenylmethanol, C<sub>6</sub>H<sub>5</sub>CH<sub>2</sub>OH) are used e.g. as preservatives in pharmaceutical preparations; the activity of benzyl alcohol is improved by halogenation: 2,4-dichlorobenzyl alcohol is used e.g. as a skin antiseptic. *Ethylene glycol*, *propylene glycol* and *trimethylene glycol* (dihydric alcohols) have been used, in aerosol form, for the disinfection of air; a relative humidity of ca. 60% is required. *Bronopol* (2-bromo-2-nitropropan-1,3-diol) is an antibacterial and antifungal compound used e.g. as a preservative in pharmaceutical preparations. The trihydric alcohol *glycerol* is bacteriostatic at concentrations above 50%; it has been used e.g. as a preservative in vaccines. (See also DISINFECTANTS and STERILIZATION.)

**aldopentose** See PENTOSEs.

**Alectoria** A genus of LICHENS (order LECANORALES); photobiont: a green alga. The thallus is fruticose, greenish-grey or fuscous

## Aleppo boil

black, and lacks a whitish central strand (cf. USNEA); ascospores are large, brown when mature, 2–4 per ascus (cf. BRYORIA). Species occur e.g. on trees, rocks etc.

**Aleppo boil** See CUTANEOUS LEISHMANIASIS.

**aleukia** Absence or reduced numbers of leucocytes in the blood.

**Aleuria** A genus of fungi (order PEZIZALES) which form sessile or stipitate, discoid or cup-shaped, minute or conspicuous apothecia in which the hymenium may be red, orange (as in *A. aurantia*, the 'orange peel fungus'), or yellow.

**aleuriospore** (*mycol.*) A term which has been used to refer to various types of spore – including e.g. thick-walled and thin-walled, pigmented and non-pigmented blastoconidia – and which has become meaningless owing to indiscriminate use.

**Aleutian disease of mink** A progressive disease of mink caused by an autonomous PARVOVIRUS; it is a virus-induced immune complex-mediated disease and is characterized by glomerulonephritis, arteritis, plasmacytosis and hypergammaglobulinaemia. Death may occur 2–24 months after infection. Virus strain and host genotype are major determinants of disease development. Mink homozygous for the (recessive) Aleutian coat colour gene are most susceptible; infected non-Aleutian mink may have a slow progressive disease, may not have disease, or may later shed the virus. [3D structure of ADM virus and implications for pathogenicity: JV (1999) 73 6882–6891.]

**Alexandrium tamarense** *Syn. Gonyaulax tamarensis.*

**alexin** (1) (*immunol.*) Archaic *syn.* COMPLEMENT. (2) (*plant pathol.*) *Syn.* PHYTOALEXIN.

**alfalfa mosaic virus (AMV)** A multicomponent ssRNA-containing PLANT VIRUS which has a wide host range and is transmitted via seeds (in some plants), by aphids (non-persistently), and mechanically (under experimental conditions). The genome consists of three linear positive-sense ssRNA molecules: RNA1 (MWt ca.  $1.1 \times 10^6$ ), RNA2 (MWt ca.  $0.8 \times 10^6$ ) and RNA3 (MWt  $0.7 \times 10^6$ ); coat protein mRNA ('RNA4', MWt ca.  $0.3 \times 10^6$ ) is also encapsidated. The four RNAs are capped at the 5' end and occur in at least four different types of virus particle, three bacilliform (B particles:  $58 \times 18$  nm; M particles:  $48 \times 18$  nm; T particles:  $36 \times 18$  nm) and one ellipsoidal (Ta particles: ca.  $28 \times 18$  nm). B, M and T particles contain one molecule of RNA1, RNA2 and RNA3, respectively; Ta particles contain two molecules of RNA4. RNAs 1, 2 and 3, together with coat protein or RNA4, are necessary for infectivity; coat protein from most ILARVIRUSES can also activate the AMV genome. AMV particles accumulate mainly in the host cell cytoplasm and may form whorled aggregates.

**Alferon N<sup>TM</sup>** See INTERFERONS.

**ALG** (*serol.*) See ANTILYMPHOCYTE SERUM.

**algae** A heterogeneous group of unicellular and multicellular *eukaryotic* photosynthetic organisms. (cf. CYANOBACTERIA, PROCHLOROPHYTES, RHODOSPIRILLALES; see also MICROORGANISMS.) Algae resemble higher plants in that they evolve oxygen during PHOTOSYNTHESIS, and in that their photosynthetic pigments include CHLOROPHYLL *a*; they differ from vascular plants e.g. in that they typically lack vascular conducting systems – although sieve tubes occur in some of the large brown SEAWEEDES. Algae differ from bryophytes (mosses etc) in that, in most cases, algal reproductive structures (when formed) lack a peripheral envelope of sterile cells (cf. CHAROPHYTES). Some organisms are classified in both algal and protozoal classification schemes: see PHYTOMASTIGOPHOREA.

Aquatic algae occur in fresh, brackish and marine waters (according to species) where they are often important in PRIMARY PRODUCTION. (See also PLANKTON.) Terrestrial algae occur

e.g. on damp soil, on ice ('ice algae' – see DIATOMS) and snow ('snow algae' – see RED SNOW), and on tree-trunks etc. Some algae are photobionts in LICHENS or endosymbionts in various organisms (see e.g. ZOOCHLORELLAE and ZOOXANTHELLAE). [Algal symbioses: Book ref. 129.] A few algae are parasitic or pathogenic (see e.g. CHOREOCOLAX, HOLMSELLA, PROTOTHECA, RED RUST). (See also ALGAL DISEASES.)

Certain algae have domestic and/or commercial or industrial uses: see e.g. AGAR, ALGINATE, CARRAGEENAN, DIATOMACEOUS EARTH, FUNORAN, FURCELLARAN, KELP, LAVER, NUNGHAM, SINGLE-CELL PROTEIN, YAKULT.

Algae are classified on the basis of their pigments, types of storage carbohydrate, types and arrangements of flagella, CHLOROPLAST ultrastructure (including arrangement of THYLAKOIDS) and CELL WALL composition. However, there is currently no universally accepted taxonomic scheme which encompasses all the algae; moreover alternative taxonomic schemes coexist even within particular subgroups of algae: see CHLOROMONADS, CHLOROPHYTA, CHRYSOPHYTES, CRYPTOPHYTES, DIATOMS, DINOFLAGELLATES, EULENOID FLAGELLATES, PHAEOPHYTA, PRYMNESIOPHYCEAE, RHODOPHYTA, SILICOFAGELLATES and XANTHOPHYCEAE.

According to species, algae range from unicellular organisms of a few micrometres to seaweeds of 50 metres or more in length. (Unicellular organisms occur in most of the main groups of algae – cf. PHAEOPHYTA.) A CELL WALL is present in most algae but is absent in a few unicellular algae (e.g. PORPHYRIDIUM). The multicellular algae exhibit a great diversity of forms which include branched and unbranched filaments or ribbons, sheets of cells etc; in the thalli of some species there is considerable differentiation – e.g. in *Laminaria* spp the thallus includes structures analogous to root, stem and leaf (*holdfast*, *stipe* and *blade*, respectively) and a system of photosynthate-conducting sieve tubes. (See also PNEUMATOCYST.) (Differentiation occurs also e.g. in the unicellular alga ACETABULARIA.) Meristematic tissue may occur in apical, intercalary and/or diffuse regions depending e.g. on species. Some unicellular algae are motile (see also MOTILITY). Colonial organization is exhibited by certain microalgae (see e.g. COENOBIVM (sense 2) and PALMELLOID PHASE).

Although normally photosynthetic, some algae (e.g. species of CHLAMYDOMONAS, CHLORELLA and SCENEDESMUS) can grow chemoorganotrophically, in the dark, on substrates such as glucose or acetate; some algae (e.g. OCHROMONAS) can ingest particulate food by phagocytosis.

Sexual reproduction (often oogamous) occurs in many algae, and a number of algae exhibit an ALTERNATION OF GENERATIONS which may be isomorphic (e.g. in *Ectocarpus*, *Ulva*) or heteromorphic (e.g. in *Laminaria*).

**algal diseases** ALGAE are subject to various diseases of microbial aetiology, some of which are of economic importance in seaweeds cultivated for food etc. Thus, e.g., diseases of *Laminaria japonica* ('haidai') include 'frond twist disease' caused by a mycoplasma-like organism, and various rots caused by alginatodegrading bacteria; sporelings in culture may be killed by H<sub>2</sub>S produced e.g. by sulphate-reducing bacteria [Book ref. 130, pp. 706–708]. *Porphyra* spp are subject to 'red wasting disease' (= red rot disease, *Pythium* red rot) caused by *Pythium* spp [Experientia (1979) 35 443–444], and to 'green spot disease' caused by localized infection with species of *Pseudomonas* or *Vibrio*. Various red algae may be attacked by *Petersenia* spp: e.g. *Petersenia palmariae* infects *Palmaria mollis* [CJB (1985) 63 404–408, 409–418]. Other microorganisms which

can infect algae, but whose pathogenicity is uncertain, include e.g. LABYRINTHULAS, PHAGOMYXA, and members of the PLASMODIOPHOROMYCETES. (See also CHOREOCOLAX, HOLMSELLA and PHYCOVIRUS.)

**algal rust** *Syn.* RED RUST.

**algicides** Chemical agents which kill algae. Algicides include e.g. copper sulphate (see also BLOOM) and TBTO. Some herbicides (e.g. Diquat, Paraquat, TERBUTRYNE) are also effective against at least some algae, as are various general disinfectants (e.g. chlorine in WATER SUPPLIES).

**algin** *Syn.* ALGINATE.

**alginate** *Syn.* ALGINATE LYASE.

**alginate** A salt of alginic acid: a linear polymer consisting of (1 → 4)-β-linked D-mannuronic acid residues and (1 → 4)-α-linked L-guluronic acid residues. (Guluronic acid is the C-5 epimer of mannuronic acid.)

Alginates occur in the CELL WALL and intercellular mucilage in phaeophyceyan algae; a similar polymer (differing in that at least some of the mannuronic acid residues are acetylated) occurs as capsular material in certain ('mucoid') strains of *Pseudomonas* and in the resting stage of *Azotobacter vinelandii*. (See also CAPSULE (bacterial) and CYST (bacterial).)

Algal alginic acid is insoluble in water but sodium alginate is soluble; alginate solutions form gels in the presence of Ca<sup>2+</sup>.

The alginate molecule contains mannuronic acid-rich regions ('M-blocks'), guluronic acid-rich regions ('G-blocks'), and regions containing both types of residue ('MG-blocks'). The binding of calcium ions (and other divalent cations) occurs preferentially at the G-blocks; a calcium alginate gel can therefore be envisaged as a three-dimensional network of long-chain molecules cross-linked (between G-blocks) by calcium ions. In the alga, where alginate is in equilibrium with seawater, alginate is associated mainly with calcium, magnesium and sodium ions. The composition (and hence properties) of the polymer varies with species (e.g. alginate from *Laminaria* spp is rich in guluronic acid, while that from *Ascophyllum* and *Macrocystis* is rich in mannuronic acid) and also varies with environmental conditions; the composition of the polymer may even differ in different parts of the same plant.

[Biosynthesis of alginate: *Microbiology* (1998) 144 1133–1143.]

*Alginate in bacteria.*

Genes for alginate synthesis are common in strains of *Pseudomonas aeruginosa*, but strains isolated from the general environment typically do not express these genes. In patients with CYSTIC FIBROSIS, conditions in the lung seem to select for mucoid (i.e. alginate-producing) strains; in these patients *P. aeruginosa* can form a viscous alginate slime associated with a poor prognosis. In *P. aeruginosa* the conversion of non-mucoid strains to mucoidy may occur if a specific SIGMA FACTOR – AlgU (= σ<sup>E</sup>) – becomes available for transcription of the alginate genes. Constitutive expression of AlgU may occur as a result of mutation in the *muc* genes, the activity of AlgU being inhibited by binding of MucA. [Mucoidy of *P. aeruginosa* in cystic fibrosis: *JB* (1996) 178 4997–5004. Alginate/biofilms/antibiotic resistance in *P. aeruginosa*: *JB* (2001) 183 5395–5401.]

AlgU is also required for alginate production in *Azotobacter vinelandii*, and the activity of the sigma factor is similarly regulated by products of the *muc* genes; the products of both *mucA* and *mucC* have a negative role in alginate production [*JB* (2000) 182 6550–6556]. [Alginate formation in *A. vinelandii* in the stationary phase: *Microbiology* (2001) 147 483–490.] *Commercial applications of alginate.*

Alginates have a wide range of uses. Calcium alginate fibres can be made by passing a solution of sodium alginate through a spinneret immersed in a solution of calcium chloride acidified with hydrochloric acid; calcium alginate is precipitated in the form of continuous threads which may be processed (stabilized) to form *calcium alginate wool*. This material (marketed as e.g. 'Calgitex') is used as a COTTON WOOL substitute for making SWABS or absorbent and absorbable surgical dressings. (Calcium alginate swabs have been reported to be inhibitory when used to prepare cultures of herpes simplex virus.) Calcium alginate wool can be sterilized by autoclaving or by dry heat; it can be dissolved e.g. in a 5% solution of sodium citrate or in quarter-strength Ringer's solution containing 1% sodium hexametaphosphate. Thus, a swab carrying an inoculum can be completely dissolved to release its entire complement of microorganisms.

In industry, alginates are used e.g. as emulsifiers and thickeners in foods (alginates are easily digested), cosmetics, pharmaceuticals etc., and as supports for the IMMOBILIZATION of cells or enzymes (for which purpose alginates rich in guluronic acid are preferred as they form stronger gels).

**alginate lyase** (alginase) Any enzyme within the categories EC 4.2.2.3 and EC 4.2.2.11 which can degrade ALGINATE; such enzymes have been isolated from many types of organism. [Alginate lyase (sources, characteristics, structure–function analysis, roles and applications): *ARM* (2000) 54 289–340.]

**alginic acid** See ALGINATE.

**algorivorous** Feeding on algae.

**algology** The study of ALGAE.

**AlgU** (σ<sup>E</sup>) See ALGINATE.

**alicyclic hydrocarbons** See HYDROCARBONS.

**alimentary toxic aleukia** A severe, usually lethal MYCOTOXICOSIS caused by ingestion of mouldy grain contaminated with certain TRICHOTHECENES – usually T-2 toxin produced by *Fusarium tricinctum*. Symptoms include extreme leucopenia and multiple haemorrhages.

**aliphatic hydrocarbons** See HYDROCARBONS.

**alkA gene** See ADAPTIVE RESPONSE.

**Alkaescens–Dispar group** Non-motile strains of *Escherichia coli* in which glucose is fermented anaerogenically and lactose fermentation is delayed or absent.

**alkaline peptone water** See APW.

**alkaline phosphatase** See PHOSPHATASE.

**alkaline phosphatase test** See e.g. PHOSPHATASE TEST (for milk).

**alkaliphile** *Syn.* ALKALOPHILE.

**alkalophile** (alkaliphile) An organism which grows optimally under alkaline conditions – typically exhibiting one or more growth optima within the pH range 8–11 – and which typically grows slowly, or not at all, at or below pH 7. (cf. ACIDOPHILE.) Alkalophiles include a range of bacteria – e.g. certain *Bacillus* spp (including *B. alcalophilus*, *B. firmus* and *B. pasteurii*), *Ectothiorhodospira abdelmalekii*, *Exiguobacterium aurantiacum*, species of *Natronobacterium* and *Natronococcus*, and *Thermomicrobium roseum* – and certain fungi; the organisms occur e.g. in natural alkaline lakes and in waters made alkaline by the effluents from certain industrial processes (such as rayon manufacture). (Natural alkaline environments are characterized by high concentrations of free or complexed Na<sub>2</sub>CO<sub>3</sub> – and usually by high concentrations of NaCl.) A number of alkalophiles have an obligate requirement for Na<sup>+</sup> – an ion important e.g. in SYMPORT processes; in at least some flagellated alkalophiles flagellar rotation is driven by SODIUM MOTIVE FORCE. However, in some species capable of

## alkane metabolism

growth at neutral pH, Na<sup>+</sup> is required only under non-alkaline conditions. [Book ref. 192; the alkaline saline environment: Book ref. 191, pp. 25–54; genetic engineering of alkaliphiles: Book ref. 191, pp. 297–315.]

**alkane metabolism** See HYDROCARBONS.

**alkB gene** See ADAPTIVE RESPONSE.

**alkene metabolism** See HYDROCARBONS.

**alkylating agents** Agents which react with nucleophilic groups (e.g. amino, carboxyl, hydroxyl, phosphate, and/or sulphhydryl groups) in e.g. proteins and nucleic acids, substituting them with alkyl groups. (As commonly used, the term 'alkylating agent' is also applied to agents which substitute nucleophilic groups with derivatives of alkyl groups: e.g. hydroxyethyl groups in the case of ETHYLENE OXIDE.) *Bifunctional* alkylating agents have two reactive groups and can cause cross-linking between nucleophilic groups in proteins and/or nucleic acids (see e.g. NITROGEN MUSTARDS and MITOMYCIN C). (See also SULPHUR MUSTARDS.)

Depending e.g. on their reactivities, alkylating agents can be effective antimicrobial agents and/or MUTAGENS. Some react directly with cell components, others (e.g. alkyl-*N*-nitrosamines: see *N*-NITROSO COMPOUNDS) require prior metabolic activation (apparently to generate an alkyl carbonium cation). In general, methylating agents are more reactive with DNA than are the corresponding ethylating agents.

Alkylating agents form a range of products with DNA. However, only some of the lesions are directly mutagenic: e.g. *O*<sup>6</sup>-alkylguanine can pair with thymine during subsequent DNA replication, resulting in G·C-to-A·T transitions, and alkylation of the *O*-4 position of thymine can cause A·T-to-G·C transitions. Most other lesions (e.g. *N*<sup>7</sup>-alkylguanine, *N*<sup>3</sup>-alkyladenine) are not directly mutagenic, but they may be lethal unless repaired by the cell (e.g. alkylation of the *N*-3 position of adenine blocks replication forks); various DNA REPAIR systems can recognize and repair alkylated bases (see e.g. ADAPTIVE RESPONSE).

The mutagenic effects of a given alkylating agent depend largely on the nature of the lesions it produces. For example, MNNG (q.v.), EMS (ethylmethane sulphonate) and MNU (*N*-methyl-*N*-nitrosourea: see *N*-NITROSO COMPOUNDS) produce relatively more directly mutagenic lesions (particularly *O*<sup>6</sup>-alkylguanine), while MMS (methylmethane sulphonate) produces higher proportions of e.g. *N*<sup>7</sup>-methylguanine and *N*<sup>3</sup>-methyladenine but relatively little *O*<sup>6</sup>-methylguanine. However, in organisms (such as *Escherichia coli*) which have an inducible error-prone repair system (see SOS SYSTEM), MMS can be mutagenic by causing lesions which induce this system; even in the case of directly mutagenic agents such as MNNG, a proportion of the mutations induced may be due to error-prone repair in *E. coli* [JB (1985) 163 213–220].

**alkyldimethylbenzylammonium chloride** See QUATERNARY AMMONIUM COMPOUNDS.

***N*-alkylnitrosoureas** See *N*-NITROSO COMPOUNDS.

**all-glass impinger** (bubbler) An instrument used e.g. for sampling the airborne microflora. (See also AIR.) Essentially, it consists of a vertical glass cylinder, containing a volume of liquid, and a longer, narrower glass tube fitted coaxially within the cylinder and partly submerged in the liquid; when suction is applied to the annular space, air is drawn in through the narrow tube and bubbles up through the liquid – during which process particles are transferred from the air to the liquid.

**allantoid** Sausage-shaped; elongated and slightly curved with rounded ends.

**allele** (allelomorph) Any of one or more alternative forms of a given GENE; both (or all) alleles of a given gene are concerned with the same trait or characteristic, but the product or function coded for by a particular allele differs, qualitatively and/or quantitatively, from that coded for by other alleles of that gene. Three or more alleles of a given gene constitute an *allelomorphic series*. In a diploid cell or organism the members of an allelic pair (i.e., the two alleles of a given gene) occupy corresponding positions (loci) on a pair of homologous chromosomes; if these alleles are genetically identical the cell or organism is said to be *homozygous* – if genetically different, *heterozygous* – with respect to the particular gene. A *wild-type allele* is one which codes for a particular phenotypic characteristic found in the WILD TYPE strain of a given organism. (See also DOMINANCE.)

**allelomorph** *Syn.* ALLELE.

**allergen** An antigen (or autocoupling HAPTEN – e.g., certain drugs) which can initiate a state of HYPERSENSITIVITY (commonly IMMEDIATE HYPERSENSITIVITY) or which can provoke a hypersensitivity reaction in individuals already sensitized with the allergen.

**allergic alveolitis** See EXTRINSIC ALLERGIC ALVEOLITIS.

**allergy** (1) A condition in which contact with a given allergen provokes a TYPE I REACTION. (See also PRAUSNITZ-KÜSTNER TEST.) (2) A condition in which contact with a given allergen gives rise to any manifestation of HYPERSENSITIVITY (see e.g. EXTRINSIC ALLERGIC ALVEOLITIS). (3) Formerly, the condition of a PRIMED individual.

**allergy of infection** An early name for DELAYED HYPERSENSITIVITY.

**Allerton disease** An African CATTLE DISEASE which involves a mild febrile condition followed by the appearance of skin nodules; it is caused by the bovine mammillitis virus and is apparently similar or identical to pseudo-LUMPY SKIN DISEASE.

***Allescheria boydii*** See PSEUDALLESCHERIA.

**alloantigen** Antigen from a genetically different individual of the same species.

**allochromasy** Gradual, spontaneous chemical modification which occurs in the solutions of certain dyes – a single dye becoming a mixture of dyes. (See e.g. polychrome METHYLENE BLUE and NILE BLUE A.)

**allochthonous** Not indigenous to a given environment. (cf. AUTOCHTHONOUS sense 1.)

**alloenzyme** See MULTILOCUS ENZYME ELECTROPHORESIS.

**alogeneic** Derived from a genetically different individual of the same species. (cf. SYNGENEIC; XENOGENEIC.)

***Allogromia*** See FORAMINIFERIDA.

***Allogromiina*** See FORAMINIFERIDA.

**allolactose** β-D-Galactopyranosyl-(1 → 6)-D-glucopyranose: a minor product of β-galactosidase action on LACTOSE; it is the natural inducer of the LAC OPERON in *Escherichia coli*.

***Allomonas*** A genus of bacteria (family VIBRIONACEAE) which have been isolated from fresh water, sewage and faeces; GC%: ca. 57. Type species: *A. enterica* [IJSB (1984) 34 150–154].

***Allomyces*** A genus of fungi (order BLASTOCLADIALES) which occur in moist soils, muds, and water. The thallus is a branched, coenocytic mycelium which is attached to the substratum by branching rhizoids; in at least some species the cell wall contains CHITIN. (See also CONCENTRIC BODIES.) Some species exhibit an ALTERNATION OF GENERATIONS (q.v.). In e.g. *A. macrogynus*, the sporothallus forms both thick-walled resistant sporangia (*meiosporangia*) and thin-walled sporangia (*mitosporangia*); the meiosporangia give rise to haploid zoospores (which develop into gametothalli), while the mitosporangia form diploid

zoospores (which develop into new sporothalli). Terminal branches of a gametothallus give rise to an orange-coloured distal male gametangium and a colourless subterminal female gametangium; the small male gametes fuse with the larger female gametes, and the zygote germinates to form a sporothallus. (See also PHEROMONE.)

Species which do not exhibit sexual processes are sometimes placed in the subgenus *Brachyallomyces*.

**allopatric** Existing in different environments or geographical regions (cf. SYMPATRIC).

**allophycocyanins** See PHYCOBILIPROTEINS.

**allotype** Any one of a range of serologically distinguishable variant forms of an Ig molecule produced as a consequence of allelic variation in the Ig-specifying genes; a given allotype is thus present only in those individuals who have the relevant allele (cf. ISOTYPE). Different allotypes usually differ in amino acid sequence in the 'constant' region of their heavy or light chains; sometimes the variable region is involved. Allotypes in man include e.g. the Gm (G1m, G2m etc) allotypes of IgG.

**allulose phosphate pathway** *Syn.* RMP PATHWAY.

**allylamines** A group of synthetic ANTIFUNGAL AGENTS which are highly active against dermatophytes and show somewhat variable activity against yeasts (e.g. *Candida* spp), apparently by inhibiting the enzyme squalene epoxidase; they include naftifine and terbinafine. Terbinafine has *in vitro* activity against *Paracoccidioides brasiliensis* [JCM (2002) 40 2828–2831].

**Alnus root nodule** See ACTINORRHIZA.

**alopecia** Loss of hair.

**α** (linking number) See DNA.

**α chain** (*immunol.*) See HEAVY CHAIN.

**α-factor** See MATING TYPE.

**α-granules** CYANOPHYCIN granules.

**α interferon** See INTERFERONS.

**α operon** See RIBOSOME (biogenesis).

**α peptide** ('auto-α') A peptide (185 amino acids long) which is cleaved from the N-terminus of the (*lacZ*-encoded) β-galactosidase of *Escherichia coli* e.g. during autoclaving. The α peptide can restore some β-galactosidase activity to a population of cells which, owing to a deletion mutation in *lacZ*, produce an inactive enzyme lacking the N-terminal portion.

The *lacZ* sequence corresponding to the α peptide can be used as a marker in a CLONING vector. During cloning, use is made of a restriction endonuclease which cleaves at a site within this sequence; thus any insertion of exogenous DNA will usually result in loss of α peptide synthesis. The DNA is introduced into suitable *lacZ* deletion mutants, and the cells are plated on Xgal medium (see XGAL). Cells which receive the intact vector form blue colonies (due to complementation between the α peptide and the defective β-galactosidase), while those receiving recombinant DNA usually form white colonies.

**α1-α2 hypothesis** See MATING TYPE.

**Alphaherpesvirinae** (herpes simplex virus group) A subfamily of viruses of the HERPESVIRIDAE (q.v.). Alphaherpesviruses have a short replication cycle (<24 hours); they spread rapidly in cell cultures, causing mass lysis of susceptible cells.

The natural host range varies from narrow to wide, according to virus. While, in cell cultures, latent infection with (non-defective) viruses does not occur readily, latent infection often occurs in nerve ganglia within the living host.

The subfamily includes at least two genera: *Simplexvirus* (human herpesvirus 1 group) and *Poikilovirus* (proposed name) (suid herpesvirus 1 group) [Intervirol. (1986) 25 141–143].

The type species of the genus *Simplexvirus* is human (alpha) herpesvirus 1 (HERPES SIMPLEX virus type 1, HSV-1). The linear

dsDNA genome of HSV-1 (~152 kbp) contains two regions, designated L ('long') and S ('short'), each region flanked by inverted repeats; the ability of each region (L and S) to invert, independently, means that DNA isolated from virions will include four isomeric forms. The genome also includes several copies of a short sequence (*a*) – a *cis*-acting region involved in circularization of the genome. [Molecular epidemiology of herpes simplex virus type 1: RMM (1998) 9 217–224.]

Other simplexviruses include human (alpha) herpesvirus 2 (HSV-2), bovine – or bovid – (alpha) herpesvirus 2 (bovine mammillitis virus, causal agent of e.g. BOVINE ULCERATIVE MAMMILLITIS), and probably cercopithecine (or cercopithecoid) herpesviruses 1 (B VIRUS) and 2.

The type species of the genus '*Poikilovirus*' is suid (alpha) herpesvirus 1 (AUJESZKY'S DISEASE virus). Other members include human (alpha) herpesvirus 3 (varicella-zoster virus (VZV), causal agent of CHICKENPOX and HERPES ZOSTER [review: AVR (1983) 28 285–356]) and equid (alpha) herpesvirus 1 (equine abortion virus, causal agent of e.g. abortion, respiratory disease and/or neurological disease in horses). (See also DELTA HERPESVIRUS.)

Probable members of the Alphaherpesvirinae include equid herpesvirus 3 (EQUINE COITAL EXANTHEMA virus) and felid herpesvirus 1 (FELINE RHINOTRACHEITIS virus). Possible members of the subfamily include canid herpesvirus 1 (canine herpesvirus).

**Alphavirus** ('arbovirus group A') A genus of viruses of the family TOGAVIRIDAE (q.v. for replication cycle etc); nearly all members are transmitted by mosquitoes, and many can cause disease (commonly encephalitis or fever with rash and arthralgia) in man and/or animals. Some alphaviruses are grouped into three serologically defined complexes – the complex-specific antigen being associated with the E1 protein (see TOGAVIRIDAE), the species-specific antigen with the E2 protein. The *Semliki Forest virus complex* includes Bebaru virus, CHIKUNGUNYA FEVER virus, GETAH VIRUS, MAYARO FEVER virus, O'NYONG-NYONG FEVER virus, ROSS RIVER virus, Sagiyama virus, SEMLIKI FOREST VIRUS, and Una virus. The *Venezuelan equine encephalomyelitis* (= *Venezuelan encephalitis*) virus complex includes Cabassou virus, Everglades virus, Mucambo virus, Pixuna virus, and VENEZUELAN EQUINE ENCEPHALOMYELITIS virus. The *Western equine encephalomyelitis* (= *Western encephalitis*) virus complex includes Aura virus, Fort Morgan virus, Highlands J virus, Kyzylgach virus, SINDBIS VIRUS, WESTERN EQUINE ENCEPHALOMYELITIS virus, and Whataroa virus. Other alphaviruses include Barmah Forest virus [JGV (1986) 67 295–299], originally thought to be a bunyavirus; EASTERN EQUINE ENCEPHALOMYELITIS (= Eastern encephalitis) virus; Middelburg virus; and Ndumu virus.

[Clinical aspects: Book ref. 148, pp. 931–953.]

**ALS** ANTILYMPHOCYTE SERUM.

**Alsever's solution** A solution containing D-glucose (20.5 g), sodium citrate dihydrate (8.0 g) and NaCl (4.2 g) dissolved in distilled water (1.0 litre); the pH is adjusted to 6.1 with citric acid. The solution is sterilized by filtration and used for the preservation of sheep blood; blood is added to Alsever's solution (1:1 by volume) and stored at 4°C.

**Alternaria** A genus of fungi (class HYPHOMYCETES) which include many plant-pathogenic species – e.g. *A. solani* (see e.g. EARLY BLIGHT) and *A. radicina* (causal agent of black rot of carrot seedlings and stored carrots). (See also TIMBER STAINING.) *Alternaria* spp form septate mycelium and pyriform to elongated, dark-coloured conidia which usually have both transverse and longitudinal septa; conidiogenesis is tetric (see CONIDIUM), the conidia developing singly or in chains.

## alternaria rot

**alternaria rot** A firm, dark rot produced in various plant hosts by species of *Alternaria*.

**alternaric acid** A complex compound, produced by *Alternaria solani*, which contains a diketotetrahydropyran group linked to a long-chain fatty acid; it inhibits germination of the spores of certain fungi, and causes wilting and necrosis in the tissues of higher plants.

**alternate host** (of heteroecious rust fungi) (1) The *secondary* host (see UREDINIOMYCETES). (2) Sometimes, loosely: either host of a heteroecious rust.

**alternation of generations** In the life cycles of some organisms: the alternating formation of one or more generations of mature haploid individuals and one or more generations of mature diploid individuals; in this context 'mature' refers to the ability of the organisms to produce reproductive cells (gametes or spores). An alternation of generations occurs e.g. in some fungi (e.g. *Allomyces* spp), in certain protozoa of the FORAMINIFERIDA, and in many algae (e.g. *Laminaria*).

An individual in the diploid phase is known variously as a *sporophyte*, *sporothallus* or *agamont*. When a sporophyte undergoes meiotic division (*sporic meiosis*) it gives rise to haploid *meiospores*. Each meiospore gives rise to a haploid individual known variously as a *gametophyte*, *gametothallus* or *gamont*; individuals in this generation produce gametes. Male and female gametes may be formed on the same gametophyte (as e.g. in *Allomyces macrogynus*) or on separate male and female gametophytes (as e.g. in *Laminaria*). The gametes fuse to form a (diploid) zygote from which a sporophyte develops. An *isomorphic* (= *homologous*) *alternation of generations* is one in which the gametophyte and sporophyte are morphologically similar. A *heteromorphic* (= *heterologous*) *alternation of generations* is one in which the gametophyte and sporophyte differ morphologically – and perhaps also in other ways: see e.g. CELL WALL (algal).

**alternative splicing** See SPLIT GENE.

**Alteromonas** A genus (*incertae sedis*) of aerobic, chemoorganotrophic, Gram-negative bacteria which occur in coastal and marine waters. [Book ref. 22, pp. 343–352.] Cells: straight or curved, round-ended rods, 0.7–1.5 × 1.8–3.0 μm, each having a single, unsheathed polar flagellum. Some species form insoluble pigments: orange and yellow non-carotenoid pigments are formed by *A. aurantia* and *A. citrea*, respectively; *A. luteoviolacea* forms violacein; *A. rubra* forms prodigiosin; some strains of *A. hanedai* form soluble brown pigments. '*A. hanedai*' (see SHEWANELLA) exhibits BIOLUMINESCENCE. Metabolism is exclusively respiratory (oxidative), with O<sub>2</sub> as terminal electron acceptor. All species need Na<sup>+</sup> for growth (optimum: 100 mM Na<sup>+</sup>). Utilizable carbon sources vary with species; they include e.g. acetate, alcohols, amino acids, aromatic compounds and sugars. Some species can attack extracellular alginate and/or chitin; several species – including *A. communis*, *A. espejiana*, *A. haloplanktis*, *A. macleodii*, *A. undina* and *A. vaga* – can metabolize D-glucose via an inducible ENTNER–DOUDOROFF PATHWAY. (It has been proposed that *A. communis* and *A. vaga* be transferred to a new genus, *Marinomonas* [JGM (1983) 129 3057–3074].) No species can accumulate PHB intracellularly. All species grow at 20°C. GC%: ca. 38–50. Type species: *A. macleodii*. (See also BACTERIOPHAGE PM2.)

*A. nigrifaciens* ([IJSB (1984) 34 145–149], formerly '*Pseudomonas nigrifaciens*') and '*A. putrefaciens*' (formerly '*Pseudomonas putrefaciens*', now *Shewanella putrefaciens*: see SHEWANELLA) can be responsible for e.g. FISH SPOILAGE and/OR MEAT SPOILAGE (see also BUTTER and DFD MEAT).

**altro-heptulose** Syn. SEDOHEPTULOSE.

**Alu sequences** In the human genome: a family of closely related, dispersed sequences, each ca. 300 nt long, many of which contain a common cleavage site for the restriction enzyme *AluI*; *Alu*-like sequences occur in the genomes of other mammals and of certain lower eukaryotes. (cf. REP SEQUENCE.)

**AluI** A RESTRICTION ENDONUCLEASE from *Arthrobacter luteus*; AG/CT.

**ALV** AVIAN LEUKOSIS VIRUS.

**alveolar membrane** (*protozool.*) See PELLICLE (sense 3).

**alveolitis** Inflammation of the pulmonary alveoli. (cf. PNEUMONIA; see also EXTRINSIC ALLERGIC ALVEOLITIS.)

**alveolysin** See THIOL-ACTIVATED CYTOLYSINS.

**Alysiella** A genus of GLIDING BACTERIA (see CYTOPHAGALES); *A. filiformis* occurs in the oral cavity in various vertebrates. The organisms occur as flat filaments – each composed of elongated cells (2–3 μm long) arranged side-by-side. Gliding occurs in a direction perpendicular to the long axis of the cells – i.e. along the axis of the filament. Metabolism: chemoorganotrophic.

**Alzheimer's disease** See CREUTZFELDT–JAKOB DISEASE.

**am mutant** An 'amber mutant', i.e., a mutant with an amber NONSENSE MUTATION.

**amaas** See SMALLPOX.

**amanin** See AMATOXINS.

**Amanita** A genus of fungi (AGARICALES, Amanitaceae) which occur in deciduous and/or coniferous woodlands; some species form mycorrhizal associations – e.g. *A. muscaria* with birch (*Betula*). According to species, the colour of the pileus may be e.g. white, yellowish, red or brown. *A. muscaria* (the 'fly agaric') forms a bright red pileus to which often adhere scattered white scales (remnants of the universal veil). Some species are highly poisonous; these include e.g. *A. muscaria* (see also MUSCARINE), *A. pantherina*, *A. phalloides* (the 'death cap fungus'), *A. verna*, and *A. virosa* (the 'destroying angel'). (See also AMATOXINS.)

**Amanitaceae** See AGARICALES.

**α-amanitin** An AMATOXIN which, at low concentrations, specifically inhibits eukaryotic RNA POLYMERASE II; RNA polymerase III is inhibited at high concentrations.

**amantadine** (1-adamantanamine hydrochloride; 1-aminoadamantane hydrochloride) A polycyclic ANTIVIRAL AGENT (adamantane = tricyclodecane, C<sub>10</sub>H<sub>16</sub>) which inhibits the replication of certain viruses in tissue culture. It is used for the prophylaxis and early treatment of INFLUENZA caused by type A influenzaviruses; it can be administered orally or by aerosol.

At high concentrations, the action of amantadine is non-specific: it raises the pH in endosomes and thus inhibits membrane fusion following endocytosis of a virus (see ENVELOPE). At lower concentrations the drug selectively inhibits an early stage in the infection of type A influenza viruses, the primary target apparently being the M2 protein (see INFLUENZAVIRUS); the activity of the drug results in failure of the pH-dependent fusion of viral and vesicle membranes.

*Rimantadine* (α-methyl-1-adamantane methylamine hydrochloride) resembles amantadine in its spectrum of activity but apparently causes fewer side-effects.

**amanullin** See AMATOXINS.

**Amapari virus** See ARENAVIRIDAE.

**amastigote** A form assumed by the cells of many species of the TRYPANOSOMATIDAE (q.v.) during certain stages of their life cycles. (See also LEISHMAN–DONOVAN BODIES.)

**amatoxins** Toxic cyclic peptides which occur in some species of *Amanita*, e.g. *A. phalloides*, *A. verna*. In man, small quantities of toxin (e.g. 5 mg) may be lethal; clinical effects are produced in

ca. 8–24 hours after ingestion. Initial symptoms include severe vomiting and diarrhoea; degenerative changes occur in the liver and kidneys, and death may follow within a few days.

Amatoxins include  $\alpha$ -AMANITIN,  $\beta$ -,  $\gamma$ - and  $\epsilon$ -amanitins, and amanin. A non-toxic compound of similar chemical composition, *amanullin*, also occurs in *A. phalloides*. The amatoxins are more toxic than the PHALLOTOXINS found in *Amanita* spp. (Other *Amanita* toxins include tryptamines such as *bufotenine* (see also HALLUCINOGENIC MUSHROOMS) and isoxazole alkaloids such as *ibotenic acid*.)

**amber codon** See GENETIC CODE.

**amber mutation** See NONSENSE MUTATION.

**amber suppressor** See SUPPRESSOR MUTATION.

**ambisense RNA** A viral ssRNA genome or genome segment which is positive-sense with respect to some genes but negative-sense with respect to others (see VIRUS). Ambisense genome segments have been found in the ARENAVIRIDAE and in the genus PHLEBOVIRUS. In these cases the –ve-sense sequences are transcribed directly into (viral-complementary) subgenomic mRNA; however, +ve-sense sequences are expressed only after genome replication, subgenomic mRNA being transcribed from the RNA strand complementary to the genomic strand. [Review: AVR (1986) 31 1–51.]

**Amblyospora** See MICROSPOREA.

**amboceptor** Current usage: *syn.* HAEMOLYTIC IMMUNE BODY.

**ambrosia fungi** Fungi which grow in the tunnels made by wood-boring ambrosia beetles, e.g. *Xyleborus* spp (Scolytidae). The beetle larvae and adults form tunnels mainly in the sapwood of fallen timber and of dead or weakened standing trees; healthy trees are not normally attacked. The beetles derive nutrients mainly or solely from the fungal growth lining their tunnels (i.e., they are ‘xylomycetophagous’); wood apparently plays little or no direct part in their nutrition. (In some cases the ambrosia fungi also appear to be necessary for reproduction or pupation of the beetles, possibly by supplying an essential sterol.) Each of the many species of ambrosia beetle is associated with one or more particular species of fungus, usually a hyphomycete (e.g. *Ambrosiella* sp, *Fusarium* sp) or an ascomycete (e.g. *Ambrosiozyma* sp, *Dipodascus* sp). The fungus grows in the tunnels as a palisade-like layer or as separate or confluent sporodochia, frequently bearing chains of conidia or terminal chlamydospores; the mycelium may penetrate the wood to a depth of a few millimetres. Ambrosia fungi appear to use only storage sugars, starch etc in the wood cells, and do not cause significant damage to the structural components of the wood. Fungal propagules (spores or yeast-like cells) are carried to new tunnels in specialized pockets (*mycetangia* or *mycangia*) in the exoskeleton of the (usually female) beetle; mycetangia contain an oily secretion and differ in structure and location in different species of beetle.

Bark-boring (‘phloeophagous’) beetles of the Scolytidae are also associated with various fungi, including e.g. sap-stain fungi (mostly *Ceratocystis* spp): see also DUTCH ELM DISEASE. In many cases these associations are fortuitous and non-specific, but some blue-stain fungi may be carried in mycetangium-like structures, such a structure occurring e.g. at the anterior margin of the prothorax in *Dendroctonus frontalis*.

(See also WOODWASP FUNGI.)

**Ambrosiozyma** A genus of fungi (family SACCHAROMYCETACEAE) which form budding yeast cells, pseudomycelium, and true mycelium with dolipore-like septa. Asci are formed on the hyphae; ascospores are bowler-hat-shaped. Species have been isolated e.g. from the tunnels of wood-boring beetles. [Book ref. 100, pp. 106–113.] (cf. AMBROSIA FUNGI.)

**ambruticin** An antifungal antibiotic (a cyclopropylpolyene-pyran acid) obtained from a strain of *Polyangium cellulosum*; it shows in vitro activity against e.g. *Candida* spp, dermatophytes, and other pathogenic fungi.

**amdinocillin** *Syn.* MECILLINAM.

**ameba** *Syn.* AMOEBIA.

**American foulbrood** A BEE DISEASE which affects the larvae of *Apis mellifera* – usually after they have spun their cocoons; the causal agent is *Bacillus larvae*. Infection occurs by ingestion of food contaminated by spores of *B. larvae*. The spores germinate in the gut, and the bacteria penetrate to the haemolymph and multiply; the larvae die, turn brown, and putrefy. (cf. EUROPEAN FOULBROOD.)

**amerosporae** See SACCARDOAN SYSTEM.

**Ames test** (Mutatest; *Salmonella*/microsome assay) A test for detecting whether or not a particular agent is mutagenic (and hence possibly carcinogenic) by determining its ability to cause reversion to prototrophy in certain histidine-requiring mutants of *Salmonella typhimurium*. Various ‘tester strains’ of *S. typhimurium* may be used, each having a different type of MUTATION (frameshift, missense or nonsense) in the histidine operon. Many of the strains used also contain mutations in *uvrB* (preventing EXCISION REPAIR) and in *rfa* (causing LPS deficiency and hence increased permeability to certain chemicals); most contain the plasmid pKM101 which carries genes for error-prone repair (see SOS SYSTEM) and which thus enhances the mutagenic effects of DNA-damaging agents. Since certain chemicals are mutagenic/carcinogenic only after metabolic activation, the test commonly includes a preparation of microsomal enzymes from a liver homogenate (9000 g supernatant, fraction ‘S9’) obtained from rats pre-treated with a carcinogen (to induce the appropriate enzymes).

The test may be carried out e.g. as a ‘plate incorporation test’. A culture of a particular tester strain of *S. typhimurium*, an S9 preparation, and the chemical under test are mixed with soft agar containing a low concentration of histidine, and this is poured onto a minimal agar plate; the whole is then incubated at 37°C for 48 h in the dark. The low level of histidine permits limited growth of the auxotrophic mutant cells, resulting in a background of confluent light growth in the upper layer of agar (‘top agar’); any prototrophic revertants (whose growth is not limited) can be seen as isolated colonies. In scoring revertants, account must be taken of the (known) spontaneous reversion rate for the strain used. (Absence of background growth implies that the agent under test has general antibacterial activity, and any colonies which develop are unlikely to be revertants.) The basic test has been modified in various ways for particular purposes. [Example of use with a carbamic acid derivative: AAC (2005) 49 1160–1168.]

(See also SOS CHROMOTEST.)

**amicyanin** A BLUE PROTEIN (MWt ca. 12000) present in certain methylamine-utilizing bacteria (e.g. ‘*Pseudomonas* AM1’) – see METHYLOTROPHY.

**Amies transport medium** See TRANSPORT MEDIUM.

**amikacin** A semi-synthetic derivative of KANAMYCIN A which contains an  $\alpha$ -aminohydroxybutyric acid residue; it is more active than kanamycin against e.g. *Pseudomonas aeruginosa* and has been used against gentamicin-resistant strains.

**aminacrine** *Syn.* 9-AMINOACRIDINE.

**amino acids** For principal biosynthetic pathways see Appendix IV; see also e.g. AROMATIC AMINO ACID BIOSYNTHESIS, GLUTAMIC ACID, OPERON (attenuator control). For standard abbreviations for amino acids see table.

## 9-aminoacridine

### AMINO ACIDS: standard abbreviations

Amino acid	Three-letter abbreviation	One-letter abbreviation
alanine	Ala	A
arginine	Arg	R
asparagine	Asn	N
aspartic acid	Asp	D
cysteine	Cys	C
glutamic acid	Glu	E
glutamine	Gln	Q
glycine	Gly	G
histidine	His	H
isoleucine	Ile	I
leucine	Leu	L
lysine	Lys	K
methionine	Met	M
phenylalanine	Phe	F
proline	Pro	P
serine	Ser	S
threonine	Thr	T
tryptophan	Trp	W
tyrosine	Tyr	Y
valine	Val	V

**9-aminoacridine** (aminacrine) A substituted acridine (see ACRIDINES) used e.g. as an ANTISEPTIC for the treatment of wounds, and as a laser dye.

**aminoacyl-tRNA synthetase** See PROTEIN SYNTHESIS.

**aminoadipic acid pathway** (AAA pathway) A pathway for lysine biosynthesis [see Appendix IV(e)] which occurs only in certain lower fungi (Blastocladales, Chytridiales, Mucorales), ascomycetes (including e.g. *Saccharomyces*), basidiomycetes, and euglenoid flagellates. [Review: CRM (1985) 12 131–151.] (cf. DIAMINOPIMELIC ACID PATHWAY.)

**p-aminobenzoic acid** (PABA; PAB) A component of FOLIC ACID. PABA is synthesized from chorismate [see Appendix IV(f)]. Certain microorganisms – e.g. *Clostridium* and *Lactobacillus* spp – require PABA as a growth factor. (See also PAS and SULPHONAMIDES.)

**7-aminocephalosporanic acid** See CEPHALOSPORINS.

**aminoglycoside antibiotics** A class of broad-spectrum ANTI-BIOTICS; a typical aminoglycoside antibiotic contains an aminosugar and either STREPTIDINE or (more commonly) 2-DEOXYSTREPTAMINE. [Book ref. 14, pp 418–442, gives detailed chemical structures.]

This group of antibiotics is generally taken to include e.g. AMIKACIN, APRAMYCIN, butirosin, FRAMYCETIN, GENTAMICIN, hygromycin B, KANAMYCIN, KASUGAMYCIN, LIVIDOMYCIN, NEAMINE, NEOMYCIN, netilmicin, PAROMOMYCIN, ribostamycin, SISOMYCIN, SPECTINOMYCIN, STREPTOMYCIN and TOBRAMYCIN.

Many aminoglycoside antibiotics are bactericidal but some (e.g. kasugamycin, spectinomycin) are bacteriostatic. Aminoglycoside antibiotics are active against both Gram-positive and Gram-negative bacteria; at least some (e.g. gentamicin, kanamycin, streptomycin) are inactive, or only weakly active, against certain archaeans (methanogens [SAAM (1985) 6 125–131]), while others (e.g. kasugamycin, neomycin, paromomycin, STREPTOMYCIN) are active against both prokaryotic and eukaryotic microorganisms.

Aminoglycoside antibiotics are less effective under anaerobic conditions and are ineffective against obligate anaerobes.

The aminoglycoside antibiotics are widely used therapeutically, sometimes in combination with other drugs. [Clinical roles of aminoglycosides (symposium): Am. J. Med. (1985) 79 (1A) 1–76.] Side-effects (particularly with neomycin and streptomycin) include dose-dependent damage to the 8th cranial nerve (associated with ototoxicity); kidney damage and hypersensitivity reactions are also possible.

Aminoglycoside antibiotics bind to the 30S ribosomal subunit in bacteria – some (e.g. streptomycin) bind at a single site while others (e.g. gentamicin, kanamycin, neomycin) apparently bind at multiple sites. They inhibit PROTEIN SYNTHESIS. For example, low levels of streptomycin cause misreading of mRNA (i.e. incorporation of incorrect amino acids) while higher levels completely inhibit protein synthesis – apparently by blocking ribosomes specifically at the start of translation. There are other sites of activity (e.g. the outer membrane in Gram-negative bacteria), but the main effect of these antibiotics appears to result from their influence on protein synthesis.

Resistance to aminoglycoside antibiotics can arise by several distinct mechanisms: (i) mutation(s) in ribosomal proteins of the 30S subunit which can affect the binding of these antibiotics (see e.g. STREPTOMYCIN); (ii) modification (inactivation) of the antibiotics by plasmid-encoded or chromosome-encoded bacterial enzymes which carry out *O*-phosphorylation, *N*-acetylation or *O*-adenylation; (iii) reduced uptake. [TIM (1998) 6 323–327.]

Mutations giving one-step high-level resistance to aminoglycoside antibiotics are uncommon, but resistance to some (e.g. spectinomycin, streptomycin) can occur in this way; spectinomycin-resistant mutants do not show cross-resistance to streptomycin, and streptomycin-resistant mutants do not show cross-resistance to those antibiotics (e.g. kanamycin) which appear to bind at multiple sites on the ribosome.

Aminoglycoside antibiotic-inactivating enzymes include acetyltransferases (AACs), adenylyltransferases (AADs) and phosphotransferases (APHs) [for nomenclature and sites of action see: BMB (1984) 40 28–35]. Some of these enzymes can inactivate only a few aminoglycoside antibiotics while others can inactivate many; some are found only in Gram-negative species or in Gram-positive species, and some are found only in e.g. *Pseudomonas* or *Staphylococcus* spp. Some of the enzymes occur in a wide range of species. (See also e.g. Tn5 and Tn21.)

Certain (mutant) bacteria exhibit drug-dependence in respect of certain aminoglycoside antibiotics: see e.g. SPECTINOMYCIN and STREPTOMYCIN.

**6-aminopenicillanic acid** (6-APA) A derivative of natural PENICILLINS (see  $\beta$ -LACTAM ANTIBIOTICS for structure): a precursor of many semi-synthetic penicillins. 6-APA itself has little or no antibacterial activity.

**aminopeptidase** See PROTEASES. (See also METHIONINE AMINOPEPTIDASE.)

**aminopterin** See FOLIC ACID ANTAGONIST.

**2-aminopurine** See BASE ANALOGUES.

**aminoquinolines** A group of ANTIMALARIAL AGENTS that include 4-aminoquinolines (e.g. chloroquine, mefloquine, amodiaquine) and 8-aminoquinolines (e.g. primaquine). The quinoline-type antimalarials (including quinine) apparently kill the parasite by preventing its detoxification of the ferriprotoporphyrin IX by-product of haemoglobin metabolism (see HAEMOZOIN and QUININE).

Chloroquine is an inexpensive synthetic drug which is used orally for treating uncomplicated malaria. It has also been used

## ammonification

parenterally to treat severe malaria; however, as resistant strains of the parasite are common, other drugs may be recommended for the treatment of severe disease.

Chloroquine is generally the drug of choice for non-falciparum malaria, and is also used (with e.g. proguanil) for prophylaxis.

Mefloquine has been used for uncomplicated falciparum malaria and (via nasogastric tube) for the treatment of severe disease. It has also been used prophylactically where, owing to resistance, chloroquine/proguanil may be ineffective. Mefloquine prophylaxis is absolutely contraindicated in the first trimester of pregnancy, and should not be used in the second or third trimesters; its therapeutic use in pregnancy, especially during the first trimester, should take into consideration the potential risk to the fetus. The drug is not recommended e.g. for treating patients with epilepsy or for prophylaxis in those with e.g. severe renal insufficiency or abnormal liver function [mefloquine (evaluation): *Drugs* (1993) 45 430–475].

The mode of resistance to quinoline-type drugs is poorly understood, but a consistent finding is that resistant strains accumulate lower levels of the drug. Most studies have been carried out on chloroquine, and several mechanisms have been suggested. (i) Weakened proton pump activity in the membrane of the parasite's food vacuole may result in a higher pH within the vacuole; this would tend to decrease the level of protonation of chloroquine in the vacuole and, hence, militate against its retention within the vacuole (the non-protonated form of the drug can freely diffuse outward across the vacuolar membrane). However, the mechanism of chloroquine accumulation assumed in this model (i.e. uptake by inward diffusion into the vacuole, and retention following protonation) may not account for the high levels of drug achieved in sensitive strains of the parasite. (ii) The vacuolar membrane in *P. falciparum* includes an ABC TRANSPORTER, designated Pgh1, encoded by gene *pfmdr1*. When *pfmdr1* was expressed in Chinese hamster ovary cells, Pgh1 apparently localized within the membrane of the lysosome and mediated uptake of chloroquine. This may indicate that Pgh1 mediates the uptake of chloroquine into the food vacuole of *P. falciparum*; this is supported by the observation that 'deamplification' of *pfmdr1* occurs in mutants selected for chloroquine resistance [EMBO (1992) 11 3067–3075]. Interestingly, when chloroquine-resistant mutants were selected for mefloquine resistance (by mefloquine-limited growth), the mefloquine-resistant mutants were found to over-express Pgh1 and to be less resistant to chloroquine (but more resistant to e.g. quinine). Hence, resistance to chloroquine and mefloquine seem to be inversely related; this is not understood. Moreover, the apparent cross-resistance between mefloquine and quinine may mean that resistance to mefloquine in geographical areas not previously exposed to mefloquine may have developed as a result of exposure to quinine [PNAS (1994) 91 1143–1147].

[Mode of action and mechanism of resistance to antimalarial drugs: *Acta Tropica* (1994) 56 157–171.]

**p-aminosalicylic acid** See PAS.

**amitosis** In certain eukaryotes: an atypical form of MITOSIS (q.v.) in which the chromosomes do not condense, a spindle is not formed, the nuclear membrane persists throughout division, and the nucleus divides by constriction.

**amixis** In certain haploid organisms: a type of reproduction, considered to be a deviant form of the sexual process, in which karyogamy and meiosis do not occur even though morphologically differentiated structures (e.g. spore-containing asci) are formed; thus, e.g., the eight haploid ascospores formed (per ascus) by *Podospora arizonensis* are said to be derived by

mitotic divisions of each nucleus of the dikaryon in the ascus mother cell. (cf. APOMIXIS.)

**Ammodiscus** See FORAMINIFERIDA.

**Ammonia** See FORAMINIFERIDA.

**ammonia assimilation** Ammonia can be used as the sole source of nitrogen by many types of microorganism; it may be obtained from an external source or produced intracellularly – for example, by deamination reactions or by ASSIMILATORY NITRATE REDUCTION.

Ammonia can be taken up readily through the cytoplasmic membrane; ammonium ions require a TRANSPORT SYSTEM [transport of ammonium ions in bacteria: *FEMS Reviews* (1985) 32 87–100].

Within the cell, ammonia can be assimilated in different ways.

With high concentrations of ammonia, some bacteria (including *Escherichia coli*, *Klebsiella* spp) use ammonia for the reductive amination of 2-oxoglutarate to L-glutamate in a reaction catalysed by NADPH-dependent *glutamate dehydrogenase* (GDH; EC 1.4.1.2). L-Glutamate can act as an N-donor in transamination reactions in which amino acids are synthesized from 2-oxoacids; *E. coli* synthesizes three low-specificity transaminases: transaminase A (which preferentially catalyses the synthesis of e.g. L-alanine and L-aspartate), B (aromatic amino acids) and C (branched-chain amino acids).

With low concentrations of ammonia (e.g. <ca. 1 mM) many bacteria and other organisms assimilate ammonia via a two-step reaction which is catalysed by (i) *glutamine synthetase* (GS; EC 6.3.1.2) and (ii) *glutamine:2-oxoglutarate aminotransferase* (GOGAT; *glutamate synthase*; EC 1.4.1.13). In this pathway, glutamate is initially aminated to glutamine in an ATP-dependent, GS-catalysed reaction which consumes ammonia. Then, in an NADPH-dependent, GOGAT-catalysed amination, one molecule of glutamine and one of 2-oxoglutarate yield two molecules of glutamate (see Appendix IV(a)). Many organisms can use the initial (GS-catalysed) step for glutamine synthesis, glutamine being used as a donor of amino groups in the biosynthesis of e.g. purines, carbamoyl phosphate (a precursor of pyrimidines), histidine and tryptophan.

In *E. coli*, it appears that the GDH-catalysed pathway is used under energy-limiting conditions (the other pathway is ATP-dependent). [Pathway choice in glutamate synthesis in *E. coli*: *JB* (1998) 180 4571–4575.] Mutants of *E. coli* lacking both pathways cannot use exogenous ammonia, but can grow on an external source of glutamate.

In enterobacteria, the GDH and GS/GOGAT systems are regulated at the level of transcription and (in the case of GS) enzyme activity. High concentrations of ammonia repress the synthesis of GS (and other nitrogen-regulated genes: see NTR GENES) and induce the synthesis of GDH; this situation is reversed when ammonia levels become limiting. GS activity is controlled in response to ammonia levels, the enzyme being inactivated by (reversible) adenylylation in the presence of high levels of ammonia.

In e.g. *Streptomyces venezuelae* the anaerobic assimilation of ammonia involves synthesis of alanine by the reductive amination of pyruvate via NADH-dependent *alanine dehydrogenase* (EC 1.4.1.1) [CJM (1985) 31 629–634].

In *Streptomyces clavuligerus* the GS/GOGAT pathway appears to be the only one for ammonia assimilation [JGM (1986) 132 1305–1317].

**ammoniacal silver nitrate** See SILVER.

**ammoniated mercury** See MERCURY.

**ammonification** The formation of free ammonia (or NH<sub>4</sub><sup>+</sup>) during the microbial breakdown of nitrogenous organic matter

## ammonium salt sugars

and/or during DISSIMILATORY NITRATE REDUCTION. Ammonia does not normally accumulate under aerobic conditions (being readily assimilated by a wide range of organisms), but may do so under anaerobic conditions. (See also MINERALIZATION; NITROGEN CYCLE; SAPROBITY SYSTEM.)

**ammonium salt sugars** A range of media used for determining which (if any) of a series of carbohydrates are metabolized by a given organism; these media are used e.g. for those organisms which form excess alkaline products from peptone media and which, therefore, cannot be tested in PEPTONE-WATER SUGARS. The medium contains (g/l): KCl (0.2),  $MgSO_4 \cdot 7H_2O$  (0.2),  $(NH_4)_2HPO_4$  (1.0), yeast extract (0.2), agar (20) and bromocresol purple (4 ml of a 0.2% solution); the carbohydrate is added after autoclaving (to give a final concentration of 1% w/v), and the medium is poured to form slopes.

**amoeba** (ameba) A type of cell or organism characterized by its ability to alter its shape drastically, generally by the extrusion of one or more pseudopodia (see PSEUDOPODIUM). Such amoeboid cells are characteristic of the SARCODINA, but also occur in other groups – for example, in the genus HISTOMONAS (see also MACROPHAGE).

**Amoeba** A genus of free-living amoebae (order AMOEBIDA). The cell is differentiated into an outer hyaline layer (the *ectoplasm*) and an inner granular *endoplasm*. Each cell typically forms several lobopodia, one of which is dominant at a given time, and each of which has a hemispherical tip and (usually) a hyaline cap. Reproduction occurs asexually by binary fission.

*A. proteus* is common in slow-moving or still freshwater habitats – often on the undersides of floating leaves; it feeds mainly on small flagellates, ciliates and bacteria. The cell may reach ca. 600  $\mu m$  diam. (See also x-BACTERIA.)

**amoebiasis** (1) Any disease of man or animals caused by a protozoon of the AMOEBIDA – see e.g. DYSENTERY (b) and MENINGOENCEPHALITIS. (2) *Syn.* amoebic DYSENTERY.

**amoebic dysentery** See DYSENTERY (b).

**amoebicide** Strictly: any chemical agent which kills amoebae; in practice, the term is commonly used for any drug which is active against (particularly) *Entamoeba histolytica*, even when the drug may inhibit, rather than kill, the parasite (i.e., it may act as an *amoebistat*). (See e.g. ARSENIC; DILOXANIDE; EMETINE; FUMAGILLIN; 8-HYDROXYQUINOLINE; METRONIDAZOLE.)

**Amoebida** An order of naked, typically uninucleate (cf. CHAOS) amoebae (class LOBOSEA) in which mitochondria are typically present (cf. PELOBIONTIDA) and flagellate stages do not occur (cf. SCHIZOPYRENIDA). Most species occur in fresh water and/or moist soil (e.g. ACANTHAMOEBA, AMOEBA, *Echinamoeba*, MAYORELLA, *Rosculus*, *Saccamoeba*, *Thecamoeba*, TRICHAMOEBA, *Vannella*, *Vexillifera*); some are marine (e.g. *Flabellula*, PARAMOEBA, most *Platyamoeba* spp), and a few are parasitic (see e.g. ENDAMOEBA, ENDOLIMAX, ENTAMOEBA, IODAMOEBA, MALPIGHAMOEBA, PARAMOEBA). (See also HYDRAMOEBA.) [Descriptions of freshwater and soil species and genera: Book ref. 133.]

**Amoebidiales** See TRICHOMYCETES.

**Amoebidium** See TRICHOMYCETES.

**amoebistat** See AMOEBICIDE.

**Amoebobacter** See CHROMATIACEAE.

**amoeboflagellate** An essentially amoeboid protozoon which can – at least under certain circumstances – form flagella as well as pseudopodia. (See e.g. SCHIZOPYRENIDA; HISTOMONAS.)

**amoeboid** AMOEBA-like.

**amoeboid movement** See PSEUDOPODIUM.

**amoeboma** See DYSENTERY (b).

**amoebostome** A sucker-like structure present on free-living cells of *Naegleria fowleri*; amoebostomes are apparently used to engulf food particles [JP (1985) 32 12–19]. (cf. CYTOSTOME).

**Amorphosporangium** A genus of bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in leaf litter. The organisms resemble *Actinoplanes* spp but differ e.g. in that the sporangium is highly irregular in shape, and the zoospores are rod-shaped. Type species: *A. auranticolor*.

**Amorphotheca resiniae** See HORMOCONIS.

**amoxicillin** A PENICILLIN; 6-( $\alpha$ -amino-4-hydroxybenzylamido) penicillanic acid. (See also AUGMENTIN.)

**AMP** Adenosine 5'-monophosphate [see Appendix V(a)]. (See also ADENYLATE KINASE; cf. CYCLIC AMP.)

**Amphiacantha** See RUDIMICROSPORA.

**amphibiotic** (1) Amphibious. (2) Able to behave either as a commensal or as a parasite in a given host. (See also OPPORTUNIST PATHOGENS.)

**amphibolic pathway** A metabolic pathway which can have both catabolic and anabolic functions: e.g. the TCA CYCLE.

**Amphidinium** See DINOFLAGELLATES.

**amphiesma** The wall – including the vesicles, thecal plates (if present), etc. – of a DINOFLAGELLATE.

**amphigenous** Situated or growing on both sides of, or all over, a given structure.

**amphipathic** Having both hydrophilic and hydrophobic regions.

**amphiphilic** *Syn.* AMPHIPATHIC.

**amphispore** A type of dark, thick-walled uredospore formed e.g. by some species of *Hyalospora* and *Puccinia*.

**Amphistegina** See FORAMINIFERIDA.

**amphithecium** (*lichenol.*) *Syn.* THALLINE MARGIN.

**amphitrichous** Refers to the presence of a single flagellum (or e.g. fimbria) at each pole of a cell.

**amphitrophic** Refers to an organism which can grow photosynthetically in the light and chemotrophically in the dark.

**ampholyte** An electrolyte whose molecule has both acidic and basic groups; the pH of a solution of a given ampholyte depends on the relative strengths of its acidic and basic groups. (See also ISOELECTRIC FOCUSING.)

**Amphora** A genus of pennate DIATOMS in which the cingulum is much wider on one side (the 'dorsal' side) than on the other, resulting in the two valves facing in more or less the same direction; the raphes in both valves can thus both make contact with the substratum. Species are aquatic, benthic organisms capable of GLIDING MOTILITY.

**amphoteric dye** See DYE.

**amphotericin B** A MYCOSAMINE-containing heptaene POLYENE ANTIBIOTIC produced by *Streptomyces nodosus*. It is active against a wide range of fungi and certain pathogenic protozoa; it is administered orally for the treatment of various mycoses, including systemic infections, but its clinical use is limited by its nephrotoxicity. (See also VISCERAL LEISHMANIASIS.)

**amphotropic** Refers to a retrovirus which can replicate both in its host of origin and in 'foreign' host cells (e.g. a murine retrovirus which can replicate in both murine and non-murine mammalian cells). Murine amphotropic viruses do not show cross-interference or cross-neutralization with the ecotropic or xenotropic murine retroviruses, i.e., their *env* glycoproteins are unrelated to those of the ecotropic or xenotropic viruses [Book ref. 114, p. 73]. (cf. DUALTROPIC.)

**ampicillin** See PENICILLINS.

**amplicon** (1) In a target molecule of nucleic acid: the specific sequence of nucleotides which is to be copied (amplified) by a nucleic-acid-amplification technique such as NASBA or PCR.

(2) A copy of the specific nucleotide sequence which has been amplified by a nucleic-acid-amplification technique such as NASBA or PCR.

(3) A defective virus vector [e.g. PNAS (1985) 82 694–698].

**amplicon containment** See PCR.

**amplicon inactivation** See PCR.

**amplification** (*mol. biol.*) See GENE AMPLIFICATION.

**amplification pathway** (*immunol.*) See COMPLEMENT FIXATION (b).

**amplified *Mycobacterium tuberculosis* direct test** See TMA.

**amplimer** An alternative (though infrequently used) name for a primer in a PCR reaction.

**AmpliQ Gold™ DNA polymerase** See HOT-START PCR.

**AmpliWax™** See HOT-START PCR.

**ampoule** *Syn.* VIAL.

**AMPPD®** Trade name (Tropix, Bedford, MA, USA) of a 1,2-dioxetane substrate which gives rise to CHEMILUMINESCENCE when activated by the enzyme alkaline phosphatase.

**amprenavir** See ANTIRETROVIRAL AGENTS.

**amprolium** A coccidiostatic agent which is structurally similar to thiamine.

**ampulla** (1) (*protozool.*) In certain ciliates (e.g. some hymenostomes): a channel, or the wider part of a channel, leading into a contractile vacuole.

(2) (*protozool.*) In certain hypostome ciliates: an adhesive organelle.

(3) (*mycol.*) The expanded, terminal region of some types of conidiogenous cell (see CONIDIUM).

(4) (*mycol.*) The expanded, terminal region of some types of conidiophore (see e.g. ASPERGILLUS).

**Ampullariella** A genus of bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in soil and freshwater habitats. The organisms resemble *Actinoplanes* spp but differ e.g. in that the rod-shaped zoospores are formed in parallel rows within the cylindrical sporangium. Type species: *A. regularis*.

**ampullate development** See CONIDIUM.

**ampulliform** Flask-shaped.

**Amsacta moorei** EPV See ENTOMOPOXVIRINAE.

**AMTDT** See TMA.

**AMU** ATOMIC MASS UNIT.

**amv** See MYB.

**AMV** Avian myeloblastosis virus: see AVIAN ACUTE LEUKAEMIA VIRUSES.

**AMV reverse transcriptase** See REVERSE TRANSCRIPTASE.

**amygdaliform** Shaped like an almond.

**amygdalin** A  $\beta$ -glycoside, present e.g. in bitter almonds, consisting of GENTIOBIOSE linked to mandelonitrile. On  $\beta$ -glucosidase action (or acid hydrolysis), amygdalin yields hydrogen cyanide, glucose and benzaldehyde.

**amylases** Enzymes which cleave glucosidic linkages in e.g. STARCH or GLYCOGEN.

$\alpha$ -Amylases ((1  $\rightarrow$  4)- $\alpha$ -D-glucan 4-glucanhydrolases, EC 3.2.1.1) are endoenzymes which have little action on terminal (1  $\rightarrow$  4)- $\alpha$ -bonds or on bonds adjacent to (1  $\rightarrow$  6)- $\alpha$  branch points. They act on amylopectin and glycogen to form glucose, maltose and branched  $\alpha$ -limit DEXTRINS, and on amylose to form first maltose and maltotriose, then slowly on maltotriose to form maltose and glucose.  $\alpha$ -Amylases are common among microorganisms. They are obtained commercially mainly from *Bacillus* spp (see also IMMOBILIZATION (sense 1)) and are used e.g. for processing starch to form glucose syrups: insoluble starch granules are dispersed in water by heating, and the starch is partially hydrolysed with thermostable  $\alpha$ -amylases from

*B. amyloliquefaciens* and/or *B. licheniformis*. Further hydrolysis is achieved using e.g.  $\gamma$ -amylases (see below).

$\beta$ -Amylases ((1  $\rightarrow$  4)- $\alpha$ -D-glucan maltohydrolases, EC 3.2.1.2) are exoenzymes which cleave alternate bonds from the non-reducing end of a linear (1  $\rightarrow$  4)- $\alpha$ -D-glucan; thus, e.g. amylose is degraded to maltose.  $\beta$ -Amylase action is halted at (1  $\rightarrow$  6)- $\alpha$  branch points; thus maltose and  $\beta$ -limit dextrins are formed from glycogen and amylopectin.  $\beta$ -Amylases are common in plants and are produced e.g. by *Bacillus* and *Streptomyces* spp. They may be used, together with DEBRANCHING ENZYMES, in the manufacture of maltose syrups from starch.  $\beta$ -Amylases are inhibited by SCHARDINGER DEXTRINS.

$\gamma$ -Amylases (amyloglucosidases, glucoamylases, (1  $\rightarrow$  4)- $\alpha$ -D-glucan glucohydrolases, exo-(1  $\rightarrow$  4)- $\alpha$ -glucosidases, EC 3.2.1.3) are exoenzymes which cleave (1  $\rightarrow$  4)- $\alpha$ -bonds consecutively from the non-reducing end of a (1  $\rightarrow$  4)- $\alpha$ -D-glucan to yield  $\beta$ -D-glucose; they can also cleave (1  $\rightarrow$  6)- $\alpha$ - and (1  $\rightarrow$  3)- $\alpha$ -bonds, although at a much lower rate.  $\gamma$ -Amylases are found mainly in fungi and are obtained commercially e.g. from *Aspergillus niger* and *Rhizopus* spp. They are used to convert malto-oligosaccharides (e.g. limit dextrins) to D-glucose (see above).

(See also BREAD-MAKING and ENZYMES.)

**amyl-3-cresol** See PHENOLS.

**amyloglucosidases** See  $\gamma$ -AMYLASES and DEBRANCHING ENZYMES.

**amyloid** (1) Starch-like; staining blue or blue-black with iodine (e.g. MELTZER'S REAGENT). (2) (*med.*) An abnormal protein deposited, intercellularly, in various tissues in certain pathological conditions.

**amyolytic** Capable of hydrolysing STARCH.

**amylopectin** See STARCH.

**amyloplast** A non-pigmented PLASTID which synthesizes and stores STARCH.

**amylose** See STARCH.

**Amylostereum** See APHYLLOPHORALES (Stereaceae).

**amylovorin** An extracellular polysaccharide which is produced by strains of *Erwinia amylovora* and which may be involved in the production of wilt symptoms in FIREBLIGHT; it consists essentially of a (1  $\rightarrow$  3)- and (1  $\rightarrow$  6)- $\beta$ -linked galactan backbone with side-chains containing residues of galactose, glucuronic acid, glucose and pyruvate.

**amyllum stars** Star-shaped aggregates of starch-filled cells which develop from the lower nodes in CHAROPHYTES and function in vegetative propagation.

**amytal** A barbiturate which acts as a mitochondrial RESPIRATORY INHIBITOR: its binding site(s) and mechanism of action appear to be similar to those of ROTENONE. Many bacterial systems are partially or completely insensitive to amytal.

**Anabaena** A genus of filamentous CYANOBACTERIA (section IV) in which the trichomes are made up of spherical, ovoid or cylindrical vegetative cells; heterocysts may be intercalary or terminal. GC%: 38–44. Species include e.g. *A. azollae*, *A. cylindrica*, *A. flos-aquae* and *A. variabilis*, distinguished e.g. on the basis of cell size and shape, filament form, etc; however, some of these characteristics may be variable in culture.

*A. flos-aquae* contains GAS VACUOLES; it can form extensive BLOOMS in (usually) freshwater habitats, and may produce various toxins (*anatoxins*) which may be lethal to animals which drink the water. Anatoxin-*a* is an alkaloid which resembles cocaine; it acts as a potent post-synaptic depolarizing neuromuscular blocking agent, causing stupor, tremors, prostration, convulsions, opisthotonos and death.

## anabolism

*A. azollae* occurs in symbiotic association with species of the small floating freshwater fern *Azolla* (Azollaceae). The nitrogen-fixing *A. azollae* occurs in a specialized cavity at the base of the upper lobe of each leaflet; it has a higher proportion of heterocysts than do free-living *Anabaena* spp. and grows poorly when isolated from the fern. *Azolla* grows e.g. in rice fields in the Far East, where it is an important source of nitrogen. The nitrogen becomes available to the rice plants only when the fern dies, sinks and decomposes; this occurs when the temperature rises and coincides with growth and tillering of the rice plants. *Azolla* has also been used as a forage crop for animals in Asia. [Expression of two kdp operons in *Anabaena* strain L-31 and relevance to desiccation: JV (2005) 71 5297–5302.]

**anabolism** The metabolic reactions by which cell components, extracellular products etc are built up from organic and/or inorganic precursors. Anabolism requires an input of energy which, in organotrophs, may be derived from CATABOLISM of exogenous organic compounds (cf. LITHOTROPH). (See also ANAPLEROTIC SEQUENCES.)

**Anacystis** A genus of cyanobacteria; those strains designated '*A. nidulans*' are apparently strains of *Synechococcus* (restricted sense: see SYNECHOCOCCUS) [Ann. Mic. (1983) 134B 21–36]. [Cell cycle events in '*A. nidulans*': JGM (1984) 130 2535–2542.]

**anaerobe** An organism which has the ability to grow in the absence of oxygen, the term commonly being reserved for those organisms which, in nature, normally grow in – or can grow only in – anaerobic habitats; some anaerobes can also grow under aerobic conditions, i.e., they are FACULTATIVE aerobes. (cf. AEROBE; see also AEROTOLERANT and MICROAEROPHILIC.) Obligately anaerobic organisms occur e.g. in anaerobic river muds and in the RUMEN (see also ANAEROBIC DIGESTION and TERMITE–MICROBE ASSOCIATIONS).

The energy-yielding metabolism of an anaerobe may be primarily or solely fermentative (see FERMENTATION sense 1), respiratory (oxidative) (see ANAEROBIC RESPIRATION), or photosynthetic (see anoxygenic PHOTOSYNTHESIS).

**Culture of obligate anaerobes.** A strict anaerobe requires an oxygen-free gaseous phase above the surface of the medium (see ANAEROBIC JAR) and a medium free from dissolved oxygen; even under these conditions, however, many anaerobes will not grow unless the medium has been pre-reduced, i.e., poised at or below a particular REDOX POTENTIAL. The  $E_h$  of chemically pre-reduced media is usually  $-150$  mV to  $-350$  mV at pH 7; the precise  $E_h$  required by a given anaerobe may depend e.g. on the size of the inoculum – ongoing growth tending to lower the  $E_h$  in the surrounding medium. Apart from incubation per se, the handling of a strict anaerobe (i.e., transfer, inoculation etc) is often carried out in an oxygen-free environment (see ROLL-TUBE TECHNIQUE). However, it has been reported that certain strict anaerobes (e.g. *Fusobacterium* sp) can be handled in air, without significant loss of viability, when use is made of media (containing reducing agents) which have been stored anaerobically prior to inoculation; nevertheless, a significant loss of viability occurs when use is made of cysteine-containing media which have been stored aerobically [CJM (1984) 30 228–235]. Reducing agents containing a sulphhydryl group (e.g.,  $H_2S$ , cysteine, thioglycollate) have been found to increase the oxygen sensitivity of various sulphate-reducing bacteria [FEMS Ecol. (1985) 31 39–45]. (See also BREWER'S THIOGLYCOLLATE MEDIUM; COOKED MEAT MEDIUM; POUR PLATE; SHAKE CULTURE (1).)

**Oxygen sensitivity of anaerobes.** Some anaerobes are killed by exposure to gaseous oxygen, while the growth of others may

be stopped or merely retarded. In some cases oxygen sensitivity is believed to be due to the lack of enzymes such as CATALASE and SUPEROXIDE DISMUTASE – the cells thus lacking protection against the toxic metabolites  $H_2O_2$  and  $O_2^-$ . Another suggestion is that an unacceptably high (positive or low negative)  $E_h$  may lead to a high intracellular  $E_h$  which, in turn, may e.g. prevent reduction in redox couple(s) which are normally freely reversible within the growing organism, and/or cause irreversible oxidation of vital components.

**anaerobic** (1) Refers to an environment in which oxygen is absent. (cf. AEROBIC.) (2) Having the characteristic(s) of ANAEROBE(s).

**anaerobic digestion** The anaerobic breakdown of complex animal and/or plant materials to simple substances which include a high proportion of gaseous and soluble products; it involves a diverse range of organisms whose metabolic pathways are closely interrelated, and occurs e.g. in benthic muds, in the RUMEN and in certain types of SEWAGE TREATMENT plant (see also TERMITE–MICROBE ASSOCIATIONS).

Initially, polysaccharides, lipids and proteins are cleaved, by extracellular enzymes, to (respectively) sugars, (usually) fatty acids and glycerol, and amino acids; most polysaccharides – including cellulose, pectins and starch – are readily cleaved, but LIGNIN is not readily degraded. The sugars and other small molecules are fermented by various organisms (e.g. species of *Bacteroides*, *Clostridium*, *Selenomonas*, *Succinivibrio* and *Veillonella*) to products which include acetate, butyrate, ethanol, lactate, propionate and succinate – together with carbon dioxide and hydrogen. Propionate can be metabolized to acetate and/or carbon dioxide by e.g. *Desulfobulbus*, *Desulfonema* and *Syntrophobacter*. [Propionate and succinate degradation: JGM (1985) 131 643–650.]

Carbon dioxide and hydrogen are metabolized to acetate by some bacteria (e.g. *Acetobacterium woodii*, *Clostridium acetium* – see ACETOGENESIS) and to methane by certain METHANOGENS. The scavenging of hydrogen by these organisms creates conditions suitable for the growth of the so-called *obligate proton reducers* or *obligate hydrogenogens* (see e.g. SYNTROPHOMONAS) – which metabolize ethanol, lactate (and other products of the initial fermentation) to acetate and hydrogen; for these organisms only protons can act as electron acceptors, and the continual scavenging of the resulting hydrogen is essential for their growth.

In some anaerobic ecosystems acetate is metabolized to methane by e.g. *Methanosarcina* and/or oxidized to carbon dioxide by SULPHATE-REDUCING BACTERIA (e.g. *Desulfobacter postgatei*) and sulphur-reducing species (e.g. *Desulfuromonas acetoxidans*); the latter organisms form hydrogen sulphide as a by-product. In the presence of high concentrations of sulphate, the sulphate-reducing bacteria can inhibit METHANOGENESIS by using both acetate and hydrogen. In the rumen, however, much of the acetate is absorbed by the ruminant itself.

The process of anaerobic digestion results in an appreciable reduction in the bulk of biodegradable solids – a particularly useful feature in SEWAGE TREATMENT. The conversion of organic carbon to methane forms an important part of the CARBON CYCLE.

In sewage treatment (and in the treatment of other organic wastes – such as agricultural and food-industry effluents) anaerobic digestion can yield a rich, relatively odourless agricultural fertilizer (rich in microbial biomass) and a useful fuel gas (*biogas*, also called *marsh gas*, *sewer gas*, *sludge gas*) which may contain 50% or more of methane; ca. 30–70% of solids may be converted to gases – the actual proportion depending

e.g. on the substrate(s), the initial percentage of solids and the retention time.

**anaerobic jar** A container used for the incubation of materials (e.g. inoculated media) in the absence of oxygen or, in general, under gaseous conditions other than atmospheric. See e.g. BREWER JAR, GASPAK, MCINTOSH AND FILDES' ANAEROBIC JAR. (See also HOLDING-FLUSH JAR PROCEDURE.)

**anaerobic respiration** RESPIRATION under anaerobic conditions, the terminal electron acceptor being (according to species and/or environmental conditions): fumarate, nitrate, nitrite, nitrous oxide, elemental sulphur, sulphate etc. See e.g. DISSIMILATORY SULPHATE REDUCTION, FUMARATE RESPIRATION, NITRATE RESPIRATION, SULPHUR RESPIRATION and DENITRIFICATION. (See also dissimilatory perchlorate reduction in the entry BIOREMEDIATION.)

**anaerobiosis** (1) The complete absence, or (loosely) the paucity, of gaseous or dissolved elemental oxygen in a given place or environment. In nature, such conditions occur e.g. in the bottom muds of ponds and rivers and in the intestinal tracts of animals (see e.g. RUMEN). (See also ANAEROBIC JAR and ROLL-TUBE TECHNIQUE.) In aerobic habitats, anaerobic microenvironments may be created by the consumption of locally available oxygen e.g. by facultatively anaerobic organisms.

(2) Life in the absence of air.

**Anaerobiospirillum** A genus of Gram-negative bacteria (family BACTEROIDACEAE). Cells: round-ended helical rods, 0.6–0.8 × 3.0–8.0 µm, with bipolar tufts of flagella. Various sugars (e.g. glucose, lactose, sucrose) are fermented, the major products of glucose metabolism being succinate and acetate. GC%: ca. 44. Type species: *A. succiniciproductens*, first isolated from dogs. [In human bacteraemia: JCM (1998) 36 1209–1213. Ileocolitis in cats: JCM (2004) 42 2752–2758.]

**anaerogenic** Refers to an organism which does not produce gas from a given substrate.

**Anaeroplasma** A genus of obligately anaerobic, cell wall-less, sterol-requiring bacteria (class MOLLICUTES) which occur e.g. in the RUMEN. Cells: non-motile, coccoid to pleomorphic; plasmalogens are major components of polar lipids in the cytoplasmic membrane. Some strains are bacteriolytic, causing clearing in agar media containing e.g. *Escherichia coli*. Carbohydrates are fermented to e.g. acetic, formic and lactic acids (together with propionic or succinic acid in some strains), ethanol and CO<sub>2</sub>. GC%: ca. 29–34. Type species: *A. abactoclasticum*; other species: *A. bactoclasticum*. [Nucleic acid relationships among anaerobic mycoplasmas: JGM (1985) 131 1223–1227.]

**Anaerovibrio** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN. Cells: curved rods, ca. 0.5 × 1.2–3.6 µm; monotrichously (polarly) flagellated. Carbon sources include e.g. fructose, lactate and ribose; major fermentation products from these substrates include propionic and acetic acids and CO<sub>2</sub>. Fermentation of glycerol yields mainly propionic acid. Lipolytic, producing clearing on linseed oil agar. Type species: *A. lipolytica*.

**ana-holomorph (mycol.)** A fungus for which no sexual stage or state has been identified. (See also DEUTEROMYCOTINA.)

**anammox bacteria** Bacteria able to oxidize ammonia to dinitrogen, anaerobically, using nitrite as electron acceptor [see e.g. Nature (2003) 422 608–611].

**anamnestic response** In persons or animals: a heightened response to the second or subsequent administration of a particular antigen given some time after the initial administration; thus, e.g., the concentration of specific antibody increases at a rate much greater than that in response to the first dose of the antigen. (See also BOOSTER.)

**anamorph (mycol.)** The asexual (= imperfect) stage or state of a given fungus. (cf. ANA-HOLOMORPH; HOLOMORPH; SYNANAMORPH; TELEOMORPH.)

**anamorph-genus** *Syn.* FORM GENUS.

**anamorph-species** *Syn.* form species.

**anaphase** See MITOSIS and MEIOSIS.

**anaphylactic shock** A manifestation of IMMEDIATE HYPERSENSITIVITY involving a TYPE 1 REACTION. In man, the symptoms of anaphylactic shock include bronchospasm (contraction of bronchial smooth muscle) and cyanosis; in severe cases death may occur, in minutes or hours, from asphyxiation due to bronchiolar contraction and/or laryngeal oedema or from a major fall in blood pressure resulting from vascular permeability. First-line treatment includes administration of ADRENALIN.

**anaphylatoxins** The fragments C3a and C5a formed during COMPLEMENT FIXATION; they induce the release of HISTAMINE from MAST CELLS, and C5a is chemotactic for neutrophils and monocytes.

**anaphylaxis** *Syn.* TYPE 1 REACTION.

**Anaplasma** A genus of Gram-negative bacteria (family ANAPLASMATACEAE) – once thought to be protozoa of the PIROPLASMEA. Cells: cocci, diam. ca. 0.3 µm. They infect erythrocytes, multiplying by binary fission within membrane-limited vacuoles (formed by invagination of the erythrocyte membrane) to form inclusion bodies – each containing up to ca. 10 cells. The inclusion body typically occupies either a central or a marginal position within the erythrocyte. *Anaplasma* spp (*A. caudatum*, *A. centrale*, *A. marginale* and *A. ovis*) occur worldwide; they apparently infect only ruminants (see ANAPLASMOSIS). (cf. PARANAPLASMA.)

**Anaplasmataceae** A family of bacteria (order RICKETTSIALES) that included AEGYPTIANELLA, ANAPLASMA, EPERYTHROZON and HAEMOBARTONELLA. In a proposed reorganization, changes include transfer of species of EHRlichIEAE and WOLBACHIEAE to this family; in this edition of the dictionary the lower taxa of this family reflect earlier classifications. [Proposed reorganization of Anaplasmataceae and Rickettsiaceae: International Journal of Systematic and Evolutionary Microbiology (2001) 51 2145–2165.]

**anaplasmosis** Any disease caused by an *Anaplasma* sp; transmission occurs mainly via ticks. In cattle, *A. marginale* can cause a severe anaemia with debility and wasting; in sheep and goats infection with *A. marginale* or *A. ovis* is usually subclinical. [Book ref. 33, pp. 875–878.]

**anaplerotic sequences** Sequences of reactions which serve to replenish 'pools' of intermediates which have been depleted as a consequence of biosynthesis – see e.g. TCA CYCLE.

**Anaptychia** A genus of foliose or fruticose LICHENS (order LECANORALES). Photobiont: a green alga. Apothecia: lecanorine; ascospores: brown, one-septate. Species may occur on e.g. rocks or bark.

**anatid herpesvirus 1** See DUCK VIRUS ENTERITIS.

**anatoxin** (1) See ANABAENA. (2) *Syn.* TOXOID.

**Ancalochloris** See CHLOROBIACEAE.

**Ancalomicrobium** A genus of chemoorganotrophic, facultatively anaerobic PROSTHECATE BACTERIA found in aquatic habitats. In high nutrient concentrations the cells are non-motile, rounded to rod-shaped; in low nutrient concentrations they first become ovoid, knobbed, subpolarly flagellate cells, subsequently developing into non-motile forms bearing two to eight cylindrical (occasionally bifurcated) prosthecae. Cell division occurs by budding from the cell body. One species: *A. adetum*.

**anchor sequence** See SIGNAL HYPOTHESIS.

## **Ancistrocoma**

**Ancistrocoma** See HYPOSTOMATIA.

**Ancistrum** See SCUTICOCILIATIDA.

**Ancylobacter** See MICROCYCCLUS (2).

**Ancyloinema** A genus of saccoderm DESMIDS.

**Andersen sampler** An instrument used e.g. for sampling the airborne microflora. (See also AIR.) Essentially, the instrument permits air to be drawn, sequentially, over the surface of each of a number of vertically stacked agar plates or adhesive-coated glass or metal discs; a suction pump, connected at the base of the instrument, draws air in through an opening at the top of the stack. Before reaching each plate or disc, the air passes through a radially-arranged pattern of holes in a metal screen – the size of the holes in a given screen being smaller than those in the preceding one; hence, the size range of particles collected by a given plate depends on the position of the plate within the stack.

**Andes virus** See HANTAVIRUS.

**Andrade's indicator** A PH INDICATOR used e.g. in PEPTONE-WATER SUGARS. To 100 ml 0.5% aqueous acid FUCHSIN is added 15 ml 4% NaOH; the solution is allowed to stand at room temperature for a day, or until its colour changes to a very pale yellow. (A further 1–2 ml NaOH may be added if this has not occurred after 24h.) This solution (before or after autoclaving) is added to the medium (1 ml in 90 ml); the indicator becomes red at ca. pH 5.5.

**androphage** (male-specific phage) Any BACTERIOPHAGE which infects only host cells that contain a conjugative plasmid. Androphages include members of the genus INOVIRUS and of the family LEVIVIRIDAE. (cf. FEMALE-SPECIFIC PHAGE.)

**anemochoric** Dispersed by the wind.

**anergy** (*immunol.*) A state of unresponsiveness to antigenic stimulus; the term is used to refer e.g. to a B cell or T cell, or to an individual person or animal. The absence of a DELAYED HYPERSENSITIVITY reaction in a PRIMED subject on exposure to the relevant antigen would be one manifestation of anergy; for example, anergy may be exhibited when tuberculous individuals – particularly those with extensive pulmonary tuberculosis – are given a tuberculin test. 'T cell anergy' can be induced by a SUPERANTIGEN.

**aneuploid** (anorthoploid) Having one or more complete chromosomes in excess of, or less than, the normal haploid, diploid or polyploid number characteristic of the species. (See also HETEROPLD.)

**aneurin** *Syn.* THIAMINE.

**Angiocyctis** See EIMERIORINA.

**angiocarpic development** (angiocarpous development) (*mycol.*)

The mode of development of a fruiting body in which the spores reach maturity within a closed chamber or cavity in the fruiting body. (See e.g. GASTEROMYCETES.) (cf. GYMNOCARPIC DEVELOPMENT.)

**Angiococcus** See MYXOBACTERALES.

**angiomatosis** (bacillary) See BARTONELLA.

**ang-kak** (ang-quac, angkak; red rice) A Chinese product (used mainly as a colouring agent for foods) made by the fermentation of rice by *Monascus purpureus* strains; the fungus produces two pigments: monascorubrin (red) and monascorubrin (yellow).

**angolamycin** See MACROLIDE ANTIBIOTICS.

**Ångström unit** (Å)  $10^{-10}$  m (=  $10^{-1}$  nm).

**anguibactin** See SIDEROPHORES.

**anguidine** Diacetoxyscirpenol: see TRICHOHECENES.

**anicteric** Without jaundice.

**AN-IDENT** See MICROMETHODS.

**aniline dyes** Dyes derived from aniline (aminobenzene, C<sub>6</sub>H<sub>5</sub>NH<sub>2</sub>), e.g., some TRIPHENYLMETHANE DYES.

**animal viruses** Viruses (see VIRUS) which can infect and replicate in the cells of animals – including mammals, birds, poikilothermic vertebrates and/or invertebrates. See table for general features.

The host range for a given animal virus varies from very narrow (e.g. in nature, rubella and variola viruses apparently infect only man) to very wide (e.g. rabies virus can infect most mammals, while ARBOVIRUSES can replicate in both invertebrates and mammals). A virus may be transmitted from host to host directly (by body contact), via aerosols (DROPLET INFECTION), via food or water (see e.g. FOOD POISONING and POLYHEDRA), via a VECTOR, etc; some viruses can be transmitted transovarially or can cross the placenta and infect the fetus.

Probably, many virus infections in animals are asymptomatic, but some can result in diseases ranging from mild and self-limiting (e.g. most cases of the COMMON COLD) to severe or fatal (e.g. AIDS, RABIES, YELLOW FEVER). The virus may remain more or less localized at the site of infection (e.g. in some forms of HERPES SIMPLEX, and in PAPILOMAS), or it may spread systemically via the bloodstream, lymphatic system or nervous system – often replicating preferentially or only in a specific tissue or organ. (See also TROPISM sense 2 and PERSISTENCE.) Disease symptoms may be due e.g. to disturbances in host cell structure and/or metabolism, host cell lysis, immune responses in the host animal, etc. Animal viruses have been implicated in certain cancers (see DNA TUMOUR VIRUS and ONCOVIRINAE) and in other diseases of unknown causation – e.g. atherosclerosis (see MAREK'S DISEASE), MULTIPLE SCLEROSIS, and even psychiatric disorders (see BORNA DISEASE and RETROVIRIDAE).

Identification of animal viruses often cannot be based entirely on clinical manifestations of infection: infection may be asymptomatic, different viruses can sometimes cause similar diseases (see e.g. ENCEPHALITIS), and similar viruses may cause widely differing diseases (see e.g. ENTEROVIRUS). Thus, identification often depends on laboratory procedures: e.g., LIGHT MICROSCOPY (for e.g. CYTOPATHIC EFFECT) or ELECTRON MICROSCOPY of clinical specimens; propagation of the virus in TISSUE CULTURE, EMBRYONATED EGGS or living animals, followed by observation of any virus-induced effects; serological tests (e.g. COMPLEMENT-FIXATION TEST, ELISA, HAEMAGGLUTINATION-INHIBITION TEST, HAEMAGGLUTINATION-INHIBITION TEST, IMMUNOFLOURESCENCE, IMMUNOSORBENT ELECTRON MICROSCOPY, NEUTRALIZATION TEST, etc). TYPING (e.g. for epidemiological purposes) may involve e.g. serological tests and/or nucleic acid HYBRIDIZATION techniques. PCR-based examination may be used e.g. to identify drug-resistance mutations [genotyping of HIV-1: Lancet (1999) 353 2195–2199].

In only a few cases can virus diseases in animals be controlled by chemotherapy (see ANTIVIRAL AGENTS); in most cases prevention is the only means of disease control. In humans, this may involve e.g. vaccination, isolation of infected patients, elimination of vectors, etc; SMALLPOX has been effectively eradicated by such methods. Virus diseases of other animals may be controlled by similar methods, and also e.g. by slaughter of infected animals, quarantine of animals for transportation, etc. Viruses which cause INSECT DISEASES are sometimes used in the BIOLOGICAL CONTROL of insect pests.

(cf. PLANT VIRUSES.)

**animalcules** (Animaliculae) An archaic term for microscopic organisms, particularly protozoa.

**anisogamy** The union of gametes which differ in form and/or physiology. When the gametes differ in size, the larger (*macrogamete*) is regarded as female, the smaller (*microgamete*) as male. (See e.g. OOGAMY; cf. ISOGAMY.)

## ANIMAL VIRUSES: basic characteristics

Genome <sup>a</sup>	Presence of envelope	Nucleocapsid symmetry	Virus family <sup>b</sup> (host type <sup>c</sup> in parentheses)
<i>dsDNA</i>			
monopartite, ccc, sc	+	helical	Baculoviridae (I)
monopartite (partially ds)	+	isometric	Hepadnaviridae (V)
monopartite, linear	+	isometric	Herpesviridae (V)
monopartite, strands covalently joined at each end	+/-	complex	Poxviridae (V;I)
monopartite (possibly sometimes bipartite), linear	+/-	isometric	Iridoviridae (I;V)
monopartite, linear, with 5'-terminal protein	-	isometric	Adenoviridae (V)
monopartite, ccc, sc	-	isometric	Papovaviridae (V)
<i>ssDNA</i>			
monopartite, linear; -ve-sense, or either -ve- or +ve-sense	-	isometric	Parvoviridae (V;I)
ccc	-	isometric	porcine circovirus (V)
<i>dsRNA</i> (linear)			
bipartite, with terminal protein	-	isometric	Birnaviridae (V;I)
multipartite	-	isometric	Reoviridae (V;I;P)
<i>ssRNA</i> (linear)			
+ve-sense, monopartite	+	helical	Toroviridae <sup>d</sup> (V)
+ve-sense, monopartite	+	helical	Coronaviridae (V)
+ve-sense, 'diploid'	+	isometric	Retroviridae (V;I?)
+ve-sense, monopartite	+	isometric	Togaviridae (V;I;P?)
+ve-sense, monopartite	+	isometric	Flaviviridae (V;I)
+ve-sense, monopartite	-	isometric	Caliciviridae (V)
+ve-sense, monopartite	-	isometric	<i>Nudaurelia</i> $\beta$ virus group (I)
+ve-sense, monopartite	-	isometric	Picornaviridae (V;I)
+ve-sense, bipartite	-	isometric	Nodaviridae (I)
-ve-sense? monopartite	+	helical	Filoviridae <sup>d</sup> (V)
-ve-sense, monopartite	+	helical	Paramyxoviridae (V)
-ve-sense, monopartite	+	helical	Rhabdoviridae (V;I;P)
-ve-sense <sup>e</sup> , bipartite	+	helical	Arenaviridae (V)
-ve-sense <sup>e</sup> , tripartite	+	helical	Bunyaviridae (V;I)
-ve-sense, multipartite	+	helical	Orthomyxoviridae (V)
<i>ssRNA</i> (circular)			
?-sense, monopartite	+	isometric	delta virus (V)

<sup>a</sup> See entry VIRUS for generalized account. ccc = covalently closed circular; ds = double-stranded; sc = supercoiled; ss = single-stranded.

<sup>b</sup> See separate entries for details.

<sup>c</sup> I = invertebrate; P = plant; V = vertebrate.

<sup>d</sup> Proposed family.

<sup>e</sup> Some segments are ambisense.

**anisokont** *Syn.* HETEROKONT.

**Anisopodiaceae** See HYPHOCHYTRIOMYCETES.

**anisomycin** (2-[*p*-methoxybenzyl]-3,4-pyrrolidinediol 3-acetate)

An antibiotic which inhibits protein synthesis in eukaryotes, binding to 80S ribosomes and inhibiting the peptidyltransferase reaction. Many members of the ARCHAEA (e.g. species of *Halobacterium*, *Methanobacterium* and *Thermoplasma*) are also sensitive to anisomycin, although *Methanococcus* and *Methanosarcina* spp are relatively resistant [Book ref. 157, p. 538].

**anisotropic inhibitor** A type of compound (e.g. monoazide ethidium) which inhibits energy transduction in OXIDATIVE PHOSPHORYLATION by binding to certain negatively charged sites on the outer surface of the mitochondrial inner membrane; the occurrence of redox reactions within the membrane stimulates the binding of anisotropic inhibitors to these sites, and this has been taken to indicate that redox reactions cause conformational changes in membrane proteins [PNAS (1985) 82 1331-1335]. The binding sites of anisotropic inhibitors (hydrophobic proteins designated *chargerin I* and *chargerin II*) may correspond

## anisotropic medium

to sites in Complexes I, III and IV of the mitochondrial ELECTRON TRANSPORT CHAIN and to the  $F_0$  moiety of the PROTON ATPASE.

**anisotropic medium** (optics) See BIREFRINGENCE.

**Ankistrodesmus** A genus of unicellular, non-motile green algae (division CHLOROPHYTA); the cells are generally long and thin and may be straight, curved, helical etc, sometimes occurring in bundles. (See also TBTO.)

**anlage** (pl. anlagen) (*ciliate protozool.*) Syn. INITIAL(S).

**annealing** (of primers) See PCR.

**annulate ascus** An ASCUS whose wall has a small, annular, apical thickening that is often amyloid or light-refractive; at maturity, the ascospores are released via a pore in the centre of the thickening.

**annellations** See CONIDIUM.

**annellide** See CONIDIUM.

**annellidic development** See CONIDIUM.

**annulus** (*microbiol.*) Any of various structures which are ring-shaped (either actually or in cross-section). Examples include e.g. the outermost layer (= 'sheath') of the contractile stalk in some peritrich ciliates, the PERISEPTAL ANNULUS, and the annular remnant of the PARTIAL VEIL.

**Anodonta** See ZOOCHLORELLAE.

**Anomooneis** See DIATOMS.

**anonymous mycobacteria** Syn. ATYPICAL MYCOBACTERIA.

**Anopheles** A genus of mosquitoes (order Diptera, family Culicidae); *Anopheles* spp are vectors of MALARIA.

**anopheline** Refers to mosquitoes of the genus *Anopheles*.

**Anoplophrya** See ASTOMATIDA.

**anorthoploid** Syn. ANEUPLOID.

**anoxia** A deficiency or lack of oxygen. (Hence *adj.* anoxic.)

**anoxygenic** Not producing oxygen.

**anoxygenic photosynthesis** See PHOTOSYNTHESIS.

**Anoxyphotobacteria** A proposed class of anoxygenic photosynthetic prokaryotes (division GRACILICUTES); see RHODOSPIRILLALES.

**ansamycins** A group of structurally related ANTIBIOTICS consisting of a macrocyclic ring which comprises an aromatic moiety spanned by an aliphatic bridge. Ansamycins (which include e.g. rifamycins, streptovaricins and tolypomycins) are produced by actinomycetes and appear to share a common mode of antibacterial action (see RIFAMYCINS); at high concentrations they also show activity against certain viruses in cell cultures.

**anserid herpesvirus 1** See DUCK VIRUS ENTERITIS.

**antagonism** The inhibition of one entity by another of similar kind. Examples: one antibiotic may reduce or abolish the effects of another (e.g. a bacteriostatic drug will counteract the effects of a drug which acts only on growing cells); acid-producing organisms may inhibit or kill acid-intolerant organisms sharing the same environment. (cf. SYNERGISM.)

**antapical organelle** In the bacterium *Thiovulum majus*: the presumed source of a thin (adhesive?) thread or stalk which projects from the surface of the organism.

**antenna** (in PHOTOSYNTHESIS) See LIGHT-HARVESTING COMPLEX.

**anterior station** (*parasitol.*) The anterior part of the alimentary canal and/or the salivary glands of an arthropod vector; infective forms of parasites in the anterior station can be transmitted to the vertebrate host by the bite of the vector. (cf. INOCULATIVE INFECTION.)

**antheraxanthin** See CAROTENOIDS.

**antheridiol** See PHEROMONE.

**antheridium** A male gametangium.

**anthracnose** Any of various plant diseases – particularly those caused by fungi of the MELANCONIALES – in which discrete, dark-coloured, necrotic lesions develop on the leaves and/or fruits.

For example, anthracnose of beans (*Phaseolus* spp) is caused by *Colletotrichum lindemuthianum* and is characterized by brown or black lesions (sometimes bearing masses of pink conidia) on the leaves, pods and seeds.

**anthracycline antibiotics** ANTIBIOTICS which have a tetrahydro-tetracenequinone chromophore (containing three flat, coplanar, 6-membered rings). They function as INTERCALATING AGENTS, inhibiting DNA and RNA synthesis. *Daunomycin* (= rubidomycin, daunorubin), produced by *Streptomyces* sp, is an anticancer agent which binds to dsDNA ( $\phi$  ca.  $12^\circ$ ) with no apparent base preference; it contains an aminosugar (daunosamine) which projects into the major groove and stabilizes the drug–DNA complex by electrostatic interaction with phosphate in the DNA. *Adriamycin* is very similar to daunomycin in structure and function. Other anthracyclines: *nogalamycin* (antitumour agent,  $\phi$  ca.  $18^\circ$ ), *cinerubin*, *rhodomycin*.

**anthramycin** A member of the pyrrolo-(1,4)-benzodiazepine group of antibiotics; other members include sibiromycin and tomaymycin. Anthramycin (produced by *Streptomyces refuineus*) has antibacterial and antitumour activity; it binds covalently to DNA, causing e.g. inhibition of DNA and RNA synthesis. The modes of action of sibiromycin and tomaymycin are apparently similar.

**anthranilate** An intermediate in tryptophan biosynthesis: see Appendix IV(f).

**anthrax** A disease – primarily of animals, but also of man – caused by strains of *Bacillus anthracis* that are both capsulated and toxinogenic (see ANTHRAX TOXIN, BACILLUS and STERNE STRAIN).

In man the disease is usually localized, resulting from infection of skin lesions (*anthrax boil*, *cutaneous anthrax*, *malignant pustule*); sepsis may develop in untreated cases. Rarely, infection occurs via the lungs (*pulmonary anthrax*, *woolsorters' disease*) or gut (*intestinal anthrax*), leading to sepsis; germination of the endospores of *B. anthracis*, and expression of toxin genes, have been demonstrated within (murine) alveolar macrophages [Mol. Microbiol. (1999) 31 9–17]. If treated promptly (e.g. with benzylpenicillin or other  $\beta$ -lactam antibiotic) mortality is low; if untreated, the septicaemic form is usually fatal.

In herbivores (e.g. cattle, sheep, horses), the ingestion of *B. anthracis* spores during grazing can lead to rapidly fatal sepsis ('splenic fever').

(See also MCFADYVEAN'S TEST.)

[Anthrax (various aspects): JAM (1999) 87 189–321.]

**anthrax toxin** The TOXIN, produced by *Bacillus anthracis*, which is responsible for pathogenesis in ANTHRAX. Anthrax toxin comprises three protein components: *oedema factor* (EF, factor I), '*protective antigen*' (PA, factor II) and *lethal factor* (LF, factor III); independently, each component has no biological activity. All three components are encoded by plasmid pOX1. (The capsule of *B. anthracis*, an essential anti-phagocytic attribute of the pathogen, is encoded by plasmid pOX2.)

*Activity of the toxin.* PA forms a  $\beta$ -barrel structure in the eukaryotic cell membrane; this permits translocation, into the cell, of the two catalytic components of the toxin, LF and EF.

LF is a zinc protease. Within the eukaryotic cell, LF cleaves *mitogen-activated protein* (MAP) *kinase*, inactivating it. MAP kinase is an essential component in eukaryotic signalling; inhibition of the MAP kinase pathway blocks the development of cells at a specific point in the cell cycle. (LF is also a potent inducer of cytokines, and is thought to be active at a concentration of  $10^{-18}$  M.)

EF is an ADENYLATE CYCLASE which, within the eukaryotic cell, is stimulated by CALMODULIN, thus causing an increase in the level of cyclic AMP (cAMP). EF is responsible for the oedematous aspect of anthrax (and may also inactivate phagocytic cells).

**anthroponosis** (1) An infectious disease which can be contracted by humans, the pathogen being normally maintained in a reservoir consisting of human population(s). (cf. ZOONOSIS.) (2) An infectious disease which can be contracted by animals, the pathogen being normally maintained in a reservoir consisting of human population(s) [use of term (sense 2): JMM (1997) 46 372–376].

**anthrophilic** Refers to a parasite or pathogen which preferentially infects man (cf. ZOOPHILIC).

**antibacterial agents** Agents which kill, or inhibit the growth of, bacteria – e.g. certain ANTIBIOTICS, ANTISEPTICS and DISINFECTANTS.

**antibiogram** The pattern of sensitivities of a given microorganism towards a range of antibiotics.

**antibiosis** The antagonism of one organism towards another or others.

**antibiotic** (1) Originally, the term used for any *microbial* product which, in low concentrations, inhibits or kills susceptible microorganisms; with this meaning, the term could distinguish between an agent such as penicillin (produced by a fungus) and synthetic (i.e. man-made) antimicrobials such as sulphonamides. This use of the term became untenable when penicillins and other natural (i.e. microbially synthesized) antimicrobial products were modified, or synthesized *de novo*, in the laboratory.

(2) Currently, the term *antibiotic* is used most commonly to refer to any natural, semi-synthetic or wholly synthetic antimicrobial agent effective at low concentrations – although products which are active against *viruses* are usually referred to as ANTIVIRAL AGENTS rather than antibiotics.

This account refers primarily to antibiotics in a medical/veterinary context, i.e. as agents used for the prevention or treatment of infectious diseases in man and other animals. However, it should be noted that natural antibiotics (e.g. BACTERIOCINS) have ecological roles. Moreover, some antibiotics (e.g. NISIN) are used as food preservatives, while others (e.g. AGROCINS) are used in BIOLOGICAL CONTROL. Certain antibiotics have been used in the control of *plant* diseases (e.g. COCONUT LETHAL YELLOWING).

For therapeutic or prophylactic use, antibiotics should, ideally, be toxic only for (the appropriate) pathogens – i.e. they should be harmless to the patient; in other words, antibiotics should exhibit an appropriate level of *selective toxicity*. Even so, many of the antibiotics currently in use are associated with important side-effects – e.g. streptomycin may cause dose-dependent damage to the 8th cranial nerve, while penicillins may provoke hypersensitivity reactions (ANAPHYLACTIC SHOCK) in certain patients. Some antibiotics are contraindicated for particular categories of patient (e.g. pregnant women). (See also THERAPEUTIC INDEX.) Of the large number of known antibiotics, relatively few are suitable for clinical use; some are too highly toxic for human or animal use, and some would be ineffective as antimicrobial agents at safe doses.

An antibiotic may be MICROBICIDAL or MICROBISTATIC; some can be microbicidal or microbistatic according e.g. to concentration.

Mixtures of antibiotics may exhibit synergism or antagonism. *Synergism* is exhibited when two antibiotics, acting simultaneously on an organism, produce an effect which is greater than

the sum of their individual effects; cotrimoxazole is an example of a synergistic combination of antibiotics (trimethoprim + sulphamethoxazole) – two drugs which block different reactions in the same pathway.

*Antagonism* is the converse of synergism. For example, antibiotics which inhibit growth will antagonize other antibiotics (e.g. penicillins) which are active only on growing cells. In another form of antagonism, the presence of certain types of antibiotic will promote the synthesis of inducible enzymes that inactivate *other* antibiotics; thus, for example, certain  $\beta$ -lactam antibiotics (such as imipenem or ceftoxitin) can induce the synthesis of enzymes called  $\beta$ -lactamases which inactivate other  $\beta$ -lactam antibiotics. (For this reason, those  $\beta$ -lactam antibiotics which are strong inducers of  $\beta$ -lactamases are not used in combination with other  $\beta$ -lactam antibiotics.)

The antimicrobial activity of an antibiotic in the human (or animal) body does not necessarily correspond to its activity in laboratory tests. For example, under *in vivo* conditions an antibiotic may bind to plasma proteins so that only a fraction of the administered dose is available for antimicrobial activity. Moreover, some antibiotics are administered in an inactive form that depends on *in vivo* metabolism for the development of its activity (see e.g. *p*-N-succinylsulphatriazole in SULPHONAMIDES).

The ability of certain antibiotics (e.g. fluoroquinolones, rifampicin) to remain in an active state *within* phagocytes is an important feature because some bacterial pathogens can survive, or even grow, following uptake by phagocytic cells [RMM (1995) 6 228–235].

*Antibiotic action.* To be effective an antibiotic must (at least) enter the cell envelope; commonly, antibiotics must pass through the cell envelope in order to reach their target sites. Entry into a cell often occurs via an energy-dependent transport system (see e.g. entries CYCLOSERINE, POLYOXINS, TETRACYCLINES, WARHEAD DELIVERY).

Within the pathogen, a given antibiotic acts at specific target site(s). Depending on antibiotic, the target site may be e.g.: (i) enzymes that catalyse the synthesis of a structural polymer in the cell envelope; (ii) the cytoplasmic membrane (certain antibiotics cause leakiness incompatible with cell viability); (iii) enzymes required for the synthesis or supercoiling of nucleic acids; (iv) the ribosome (some antibiotics can inhibit protein synthesis by binding to specific sites on the ribosome); (v) enzymes required for biosynthesis of an essential coenzyme – for example, dihydrofolate reductase (required for the synthesis of tetrahydrofolate) is inhibited by trimethoprim.

Antibiotics of the same group have similar or identical target sites, and they all affect cells in the same way. However, antibiotics from different groups may have a similar target site; thus, for example, the target site of oxazolidinones appears to overlap the binding sites of both lincomycin and chloramphenicol [JB (2000) 182 5325–5331].

Some target sites are found in only certain categories of microorganism; for example, the cell wall polymer *peptidoglycan* occurs only in bacteria – so that antibiotics directed specifically against this target are unlikely to be of use against (e.g.) fungi. Clearly, no antibiotic is effective against all pathogens, and in many cases the activity of a given antibiotic is limited to a particular subset of organisms; in the context of bacterial pathogens, a *broad-spectrum* antibiotic is one which can be effective against a wide range of species, including both Gram-positive and Gram-negative bacteria.

Some examples of antibiotics (in various target regions) are listed below; see individual entries for mode of action etc.

## antibiotic

*Bacterial cell wall (peptidoglycan).* CYCLOSERINE;  $\beta$ -LACTAM ANTIBIOTICS; MOENOMYCIN; VANCOMYCIN.

*Bacterial cytoplasmic membrane.* DEPSIPEPTIDE ANTIBIOTICS; GRAMICIDINS; POLYMYXINS; TYROCIDINS.

*DNA intercalating agents.* ACTINOMYCIN D; ANTHRACYCLINE ANTIBIOTICS; QUINOXALINE ANTIBIOTICS.

*Folic acid antagonists.* CHLORGUANIDE; PYRIMETHAMINE; TRIMETHOPRIM. (See also SULPHONAMIDES.)

*Fungal cell wall.* ACULEACIN A; NIKKOMYCINS; PAPULACANDIN B; POLYOXINS.

*Fungal cytoplasmic membrane.* POLYENE ANTIBIOTICS (sense a).

*Gyrase.* COUMERMYCINS; NOVOBIOCIN; QUINOLONE ANTIBIOTICS.

*Ribosome (protein synthesis).* AMINOGLYCOSIDE ANTIBIOTICS; ANISOMYCIN; CHLORAMPHENICOL; CYCLOHEXIMIDE; FLORFENICOL; FUSIDIC ACID; LINCOSAMIDES; MACROLIDE ANTIBIOTICS; OXAZOLIDINONES; POLYENE ANTIBIOTICS (sense b); PUROMYCIN; SPARSOMYCIN; SPECTINOMYCIN; TETRACYCLINES; THIOSTREPTON; TIAMULIN; VIOMYCIN.

*RNA polymerase.* ANSAMYCINS (e.g. RIFAMYCINS) (see also STREPTOLYDIGIN).

*Microbial resistance to antibiotics.* Resistance to a given antibiotic ('drug resistance') is said to be *constitutive* (= *intrinsic*) in cells which (i) lack the specific target of that antibiotic, (ii) have an alternative form of the target that is not affected by the antibiotic, and/or (iii) are inherently impermeable to the antibiotic. For example: (i) species of *Mycoplasma*, which lack cell walls, are intrinsically resistant to penicillins (which inhibit the synthesis of a cell wall polymer); (ii) strains of *Staphylococcus aureus* that exhibit intrinsic resistance to methicillin contain an alternative form of the target (see MRSA); (iii) many Gram-negative bacteria are intrinsically resistant to e.g. benzylpenicillin because their outer membrane is impermeable to the antibiotic.

A cell may *acquire* heritable resistance to one or more antibiotics in several ways. In bacteria, gene(s) specifying resistance to one or more antibiotics may be transferred to an antibiotic-susceptible cell by CONJUGATION, TRANSDUCTION, TRANSFORMATION or CONJUGATIVE TRANSPOSITION; resistance may also develop as a consequence of MUTATION. The way in which resistance is acquired is important in that it may determine the range of antibiotics to which a cell becomes resistant. Thus, a single point mutation commonly confers resistance to only one type of antibiotic (or to those antibiotics which share the same target site). By contrast, receipt of an R PLASMID or TRANSPOSON may confer resistance to either a single antibiotic or to two or more *unrelated* antibiotics (*multiple drug resistance*).

*Mechanisms of resistance to antibiotics.* Six main mechanisms can be distinguished:

(i) *Mutation.* The target site of a given antibiotic may be modified as a result of a MUTATION such that the target (e.g. enzyme, ribosome) functions more or less normally in the presence of otherwise inhibitory concentrations of the antibiotic (see e.g. STREPTOMYCIN). The cell in which such a mutation has occurred can therefore grow and give rise to a population of resistant cells in the presence of the given antibiotic. Examples of mutation-mediated resistance: (i) point mutations affecting 23S rRNA which confer resistance to macrolide antibiotics [AAC (1996) 40 477–480]; (ii) point mutations in the *rpoB* gene of *Mycobacterium tuberculosis* (encoding a subunit of RNA polymerase) conferring resistance to rifampicin. Although resistance-conferring mutations are commonly located within known sequences in the genome, resistance may also arise through mutation at novel sites; for example,

in a strain of *Streptococcus pneumoniae*, mutation outside the recognized 'quinolone resistance-determining region' has been associated with enhanced resistance to certain of the newer fluoroquinolones [AAC (2001) 45 952–995].

(ii) *Inactivation or degradation of antibiotics by enzymes.* Enzymes which inactivate or degrade antibiotics are encoded by genes that occur e.g. in plasmids or chromosomes. Such enzymes include the acetyltransferases, adenyltransferases and phosphotransferases that are active against aminoglycoside antibiotics [TIM (1998) 6 323–327], the enzyme CHLORAMPHENICOL acetyltransferase, and the  $\beta$ -LACTAMASES which inactivate penicillins and related antibiotics.

(iii) *Efflux mechanisms.* See EFFLUX MECHANISM. Some efflux mechanisms involve an ABC TRANSPORTER. [Efflux-mediated resistance to fluoroquinolones in Gram-negative bacteria: AAC (2000) 44 2233–2241.]

(iv) *Diminished permeability.* Any change in the composition of the cell envelope which hinders the uptake of an antibiotic will either increase the MIC of that antibiotic or else give rise to high-level resistance. For example, diminished permeability in *Enterobacter aerogenes*, associated with an alteration in the outer membrane porins, has been reported to affect this organism's susceptibility to various antibiotics, including some of the fourth-generation cephalosporins (e.g. cefepime) [Microbiology (1998) 144 3003–3009].

Interestingly, in *Escherichia coli*, phenotypic (*non-heritable*) resistance to some antibiotics (e.g. ampicillin, chloramphenicol) can be induced by the presence of certain chemorepellents – e.g. acetylsalicylate (aspirin) and benzoate – which are detected by the *tsr* gene product; this phenomenon has been attributed to inhibition of synthesis of the OmpF porin by the chemorepellent [FEMS (1987) 40 233–237].

(v) *Increased synthesis of an affected metabolite.* Increased production of a given metabolite may overcome competitive inhibition by the antibiotic; for example, production of higher levels of PABA is one form of resistance to sulphonamides.

(vi) *Acquisition of an antibiotic-insensitive target.* One example is the acquisition of a methicillin-resistant penicillin-binding protein by strains of *Staphylococcus aureus* (see MRSA).

[Mechanisms of resistance to  $\beta$ -lactam, aminoglycoside, quinolone and other antibiotics in *Acinetobacter baumannii*: RMM (1998) 9 87–97.]

*Induction of resistance to antibiotics.* Resistance to certain antibiotics is inducible – the presence of such antibiotics (over a certain minimum concentration) promoting resistance in the cell. For example, in some Gram-positive bacteria (e.g. staphylococci), the enzyme chloramphenicol acetyltransferase may be induced in the presence of its substrate, CHLORAMPHENICOL (see also TRANSLATIONAL ATTENUATION). Also in staphylococci, several distinct modes of resistance to  $\beta$ -lactam antibiotics may be induced by the presence of these antibiotics; thus, resistance may be due to the induction of  $\beta$ -LACTAMASES (leading to mechanism ii, above) or to induction of the specific PENICILLIN-BINDING PROTEIN (PBP) 2a (see MRSA) (mechanism vi, above). In the case of inducible resistance to  $\beta$ -lactam antibiotics, studies on the transmembrane signalling pathway have indicated that induced resistance – through either  $\beta$ -lactamases or the *mecA* product PBP 2a – may depend on a novel mechanism involving sequential cleavage of several regulatory proteins [Science (2001) 291 1962–1965; commentary: Science (2001) 291 1915–1916]. In this scheme, regulation of *mecA* expression involves initial binding of a  $\beta$ -lactam antibiotic to a cell-surface sensor–transducer: the MecR1 protein; as a consequence, MecR1 undergoes cleavage, and a (hypothetical) product of such cleavage, MecR2,

directly or indirectly brings about cleavage of the transcriptional repressor protein, MecI – thus allowing expression of *mecA*. (See also  $\beta$ -LACTAMASES.)

**Antibiotic-sensitivity (antibiotic-susceptibility) tests.** Laboratory tests are often carried out to determine the susceptibility of a given pathogen to various antibiotics (the pattern of sensitivities being referred to as the pathogen's *antibiogram*); the results of such tests may enable the clinician to select optimal antibiotic(s) for chemotherapy.

A common form of test is the DISC DIFFUSION TEST (q.v.; see also NEO-SENSITABS); this kind of test is intended primarily for those bacteria which produce visible growth after overnight incubation (rather than slow-growing species such as *Mycobacterium tuberculosis*). (See also DILUTION TEST.)

The E TEST is a diffusion test which can indicate an MIC.

Other methods, such as LATEX PARTICLE TESTS, have been assessed for their ability to detect resistance to methicillin in staphylococci [rapid detection of *mecA*-positive and *mecA*-negative coagulase-negative staphylococci by an anti-penicillin binding protein 2a slide latex agglutination test: JCM (2000) 38 2051–2054].

Molecular methods (including PCR-based tests) can also be used in certain cases for detecting antibiotic resistance. [Rapid identification of methicillin-resistant *Staphylococcus aureus* and simultaneous species confirmation using real-time fluorescence PCR: JCM (2000) 38 2429–2433. Multiplex PCR for detection of genes for *Staphylococcus aureus* enterotoxins, exfoliative toxins, toxic shock syndrome toxin 1 and methicillin resistance: JCM (2000) 38 1032–1035. Simultaneous identification and typing of multidrug-resistant *Mycobacterium tuberculosis* isolates by analysis of *pnxA* and *rpoB*: JMM (2000) 49 651–656.] (See also *line probe assay* in the entry PROBE.)

[DNA-based ('genotypic') antibiotic susceptibility testing: Book ref. 221, pp 203–228.]

**Clinical impact of bacterial resistance to antibiotics.** Although large numbers of new antibiotics have been identified in the last few decades, bacterial resistance to existing drugs has continued to emerge so that, in some cases, therapeutic options have become very limited; examples of such resistance include: vancomycin-resistant enterococci [EID (2001) 7 183–187]; tetracycline-resistant gonococci; penicillin-resistant pneumococci [Drugs (1996) 51 (supplement 1) 1–5]; multidrug-resistant *Vibrio cholerae* O1 [Lancet (1997) 349 924]; multidrug-resistant *Mycobacterium bovis* [Lancet (1997) 350 1738–1742]; and low-level resistance to vancomycin in MRSA [JAC (1997) 40 135–136]. [The crisis in antibiotic resistance: Science (1992) 257 1064–1073.] There is thus an ongoing need to develop new antibiotics and to prevent, or delay, the emergence of resistance to those drugs that are currently useful by avoiding inappropriate usage; given the value of antibiotics in medicine (and our current dependence on them) it is essential that new drugs be used carefully and rationally [quinupristin/dalfopristin and linezolid: where, when, which and whether to use?: JAC (2000) 46 347–350]. Already, clinical resistance to linezolid has been reported in vancomycin-resistant strains of *Enterococcus faecium* (vancomycin-resistant enterococci, VRE) [Lancet (2001) 357 1179].

[Controlling antimicrobial resistance in hospitals (infection control and use of antibiotics): EID (2001) 7 188–192.]

Because of ongoing development of resistance in pathogenic bacteria, new targets for antibiotics are being sought within the bacterial cell. One target in *Escherichia coli* is *de-acetylase* (a zinc-requiring enzyme, product of gene *lpxC*) which is

essential for the synthesis of lipid A (an integral part of the outer membrane in Gram-negative bacteria) (see ENDOTOXIC SHOCK). New approaches to antibiotics may also involve agents such as CcdB (see F PLASMID) and certain bacteriocins. By contrast, peptide deformylase (PDF), which cleaves the N-terminal formyl group from nascent bacterial polypeptides (see PROTEIN SYNTHESIS), seems less than optimal as a candidate drug target; certain derivatives of hydroxamic acid are potent inhibitors of PDF, but resistance to these agents develops readily, and the drugs appear to be only bacteriostatic [AAC (2001) 45 1058–1064].

The ongoing problem of antibiotic-resistant pathogens has prompted consideration of other anti-infection modalities, including bacteriophage therapy [AAC (2001) 45 649–659].

**Antibiotics for chemotherapy: factors affecting the choice.** Antibiotics may be wasted if they are used without due regard to specificity and pharmacology; moreover, use of inappropriate drugs may forfeit the chance of helping the patient and may also exacerbate unnecessarily the general problem of antibiotic resistance. The kind of factors which affect the choice of antibiotic include:

- Effectiveness against relevant pathogens. In ideal circumstances the pathogen's identity and its sensitivity to antibiotics are known prior to treatment. However, in certain diseases (e.g. meningitis) therapy is often begun before the aetiology has been confirmed. When this happens the choice of antibiotic is based on the *probable* pathogen; probability reflects factors such as (local) prevalence of particular species/strains of pathogen, reported problems of resistance in the pathogen, and the patient's age/general condition. [Example: management of bacterial meningitis (paediatric patients): RMM (1997) 8 171–178.]
- Prevalence of antibiotic-resistant strains in the locality. Many pathogens are now resistant to antibiotic(s) to which they were once invariably sensitive; moreover, some pathogens are resistant to a *range* of drugs so that, in some cases, therapeutic options are extremely limited.
- Antagonism towards other antibiotics – or even towards other therapeutic agents; for example, rifampicin can potentiate certain mammalian enzymes and, as a consequence, may interfere with oral contraception.
- Possible side-effects (e.g. penicillin allergy).
- In pregnant patients: possible teratogenicity.
- Pharmacokinetics. The physicochemical nature of a drug determines its ability to reach particular sites when administered via a given route. For example, if certain drugs are injected intravenously they do not reach the cerebrospinal fluid (CSF) because they cannot pass the blood–brain barrier; other types of drug can, and some can do so only if the permeability of this barrier has been increased e.g. as a result of inflammation.

(See also ANTIFUNGAL AGENTS, ANTIPROTOZOAL AGENTS, ANTISEPTICS and DISINFECTANTS.)

**antibiotic-associated colitis** See COLITIS.

**antibody** (ab) Any IMMUNOGLOBULIN molecule produced in direct response to an ANTIGEN (or to an autocoupling HAPTEN) and which can combine specifically, non-covalently, and reversibly with the antigen which elicited its formation (see also ANTIBODY FORMATION); specificity is not necessarily absolute: see CROSS-REACTING ANTIBODY. (A MYELOMA can produce Ig with antibody function in the absence of antigenic stimulation. See also PASSIVE IMMUNITY.) The term 'antibody' is also used to refer to a

## antibody absorption

homogeneous or heterogeneous *population* of antibodies (see MONOCLONAL ANTIBODIES and POLYCLONAL ANTISERUM).

Antibody–antigen combination occurs by contact between specific antibody COMBINING SITES and antigenic DETERMINANTS, and may promote COMPLEMENT FIXATION. (See also VALENCY, COMPLEMENT-FIXING ANTIBODIES, and OPTIMAL PROPORTIONS.) In vivo, antibody–antigen combination may be beneficial if the antigenic stimulus derives from an invading pathogen (see e.g. OPSONIN), but can be harmful (see e.g. IMMEDIATE HYPERSENSITIVITY). (See also e.g. AGGLUTININ; BLOCKING ANTIBODIES; CYTOPHILIC ANTIBODIES; NATURAL ANTIBODIES; PRECIPITIN.)

Antibodies may be identified, assayed etc in vitro by a range of techniques – see e.g. GEL DIFFUSION; IMMUNOASSAY; IMMUNOELECTROPHORESIS; IMMUNOFLUORESCENCE; PRECIPITIN TEST. Detection and quantification of specific antibodies in samples of SERUM are important in the diagnosis of many diseases.

**antibody absorption** See ABSORPTION.

**antibody-dependent cell-mediated cytotoxicity** See ADCC.

**antibody excess** The presence of a high antibody-to-antigen ratio. In an agglutination test gross antibody excess may give rise to a PROZONE – possibly due to the saturation of antigenic determinants by antibodies in the absence of free antigen with which to form links.

**antibody formation** An IMMUNE RESPONSE in which B LYMPHOCYTES synthesize and secrete ANTIBODY of a given antigenic specificity after immunological contact with the corresponding ANTIGEN; for so-called THYMUS-DEPENDENT ANTIGENS, B cells require help from antigen-specific CD4<sup>+</sup> T LYMPHOCYTES ('T helper cells') and/or the products of such T cells (cf. THYMUS-INDEPENDENT ANTIGENS).

*The response to thymus-independent antigens.*

Thymus-independent (TI) antigens (such as lipopolysaccharides and bacterial cell wall polysaccharides) induce antibody formation independently of T cells. When activated by TI antigens, certain B cells – CD5<sup>+</sup> ('B1') cells (see B LYMPHOCYTE) and MARGINAL ZONE B CELLS – proliferate and secrete antibodies; however, the expanded clone of B cells does not give rise to memory cells (see later), and the antibodies formed in response to these antigens are almost exclusively of the IgM class. [T-independent immune response (new aspects of B cell biology): Science (2000) 290 89–92.]

*The response to thymus-dependent antigens.*

The process of antibody formation is incompletely understood; the following is a generally accepted scenario.

To elicit antibodies, a thymus-dependent (TD) antigen must initially be taken up and *processed*, intracellularly, by an ANTIGEN-PRESENTING CELL (APC). Processing involves enzymic degradation of the antigen; a particular (peptide) fragment of the antigen is then linked to an MHC class II molecule (synthesized in the APC) and *presented*, at the surface of the APC, to an antigen-specific T cell.

B lymphocytes can act as APCs, so that antigen (plus MHC class II molecule) may be presented at the surface of a B cell to an antigen-specific T cell; T cells of the Th2 subset (see T LYMPHOCYTE) characteristically act as 'helper' cells in this context. The (antigen-specific) T cell binds to the antigen with its T CELL RECEPTOR – thus physically linking B and T cells via the antigen; the MHC class II molecule (on the B cell) binds to the CD4 antigen on the T cell.

Other 'paired interactions' also occur between binding sites on the B and T cells. Thus, certain receptors (B7.1, B7.2) on the B cell bind to antigen CD28 (q.v.) on the T cell; such binding permits the T cell to synthesize INTERLEUKIN-2 – a cytokine

which promotes activation and clonal proliferation of the T cell and induces it to release cytokines, including INTERLEUKIN-4. However, once activated, T cells produce the cell-surface antigen CTLA-4 (= CD152), a molecule (similar to CD28) to which B7.1 and B7.2 can bind; interaction between B7.1/B7.2 and CTLA-4 may initiate a signal which terminates synthesis of IL-2 in the T cell. (Note that, while IL-2 is not a characteristic product of the Th2 subset of T cells, transient synthesis of this cytokine at an early stage would appear to be necessary as it seems to be an essential growth factor for T cells.)

Yet another paired interaction between the B and T cells involves CD40 (q.v.).

The mutual (physical) co-operation between the B cell and T cell (described above) is referred to as *cognate help* or *linked recognition*.

The activated, proliferating B cells form an expanded clone. Some of the cells of this clone become antibody-secreting PLASMA CELLS. Others become MEMORY CELLS; these cells do not secrete antibody but retain the potential to do so, rapidly, if subsequently challenged with the same antigen (giving a heightened *secondary response*). (See also ANAMNESTIC RESPONSE.)

Initially, antibodies secreted by plasma cells are of the IgM class. Subsequently, plasma cells form antibodies of another class – generally IgG – but of the same specificity; such *class switching* (= *isotype switching*) is promoted by several stimuli – including the binding of B cell antigen CD40 to the corresponding T cell ligand, and the activity of the T-cell-derived cytokine INTERLEUKIN-4.

Class switching occurs in so-called *germinal centres* within lymph nodes and spleen. Such sites are also involved in a process known as *affinity maturation*; in this process, mutant cells among the (proliferating) antigen-stimulated B cells are selected for high-affinity binding to the specific antigen – selective pressure presumably being a falling concentration of the given antigen. Within the B cells a process known as *somatic hypermutation* gives rise to mutations that are concentrated in the V regions of antibody genes; as a consequence, different B cells produce antibodies with different levels of affinity for the given antigen – those producing antibody with the highest affinity being selected. [Hypermutation in antibody genes: PTRSLB (2001) 356 1–125.] (See also RNA EDITING.)

In the response to an antigen not previously encountered (a *primary response*) the numbers of specifically reactive B cells (prior to clonal expansion) are likely to be low. Under these conditions it may be that the presentation of antigen to T cells is carried out not by B cells but by other, more numerous, APCs such as macrophages or dendritic cells. In this scenario, interaction between APC and T cell activates the T cell – which then secretes various cytokines; these cytokines may induce differentiation, proliferation and antibody secretion in B cells that have bound the specific antigen and which are close to (though not necessarily in contact with) the activated T cells [Book ref. 227, pp 207–208].

When produced in response to invasion by pathogens (or their products – e.g. toxins), antibodies commonly have a protective role (see e.g. ADCC and OPSONIZATION). However, under certain conditions, antibodies can promote damage to the host's tissues (see IMMEDIATE HYPERSENSITIVITY).

**anticapsin** See BACILYSIN.

**anticiinal** Perpendicular to a given surface. (cf. PERICLINAL.)

**anticoagulant** Any agent which inhibits the coagulation (clotting) of blood – e.g. EDTA, HEPARIN, sodium citrate, sodium oxalate. SPS is used in BLOOD CULTURE.

**anticodon** See GENETIC CODE.

**anticomplementary** (*immunol.*) Refers to any substance (e.g. ZYMOSAN), or to any system (e.g. pre-formed antigen-antibody complexes) *other than* the specific combination of antibody with antigen, which brings about COMPLEMENT FIXATION. If present in a COMPLEMENT-FIXATION TEST, anticomplementary factors can – by fixing complement – simulate the effects of antigen-antibody combination, giving a false-positive reaction.

**anti-downstream box** See DOWNSTREAM BOX.

**antifol** *Syn.* FOLIC ACID ANTAGONIST.

**antifungal agents** Chemical agents (including certain ANTIBIOTICS) which either kill or inhibit the growth of fungi (fungicidal and fungistatic action, respectively). (Antifungal agents are often called 'fungicides' regardless of whether their action is fungicidal or fungistatic.) Antifungal agents are used e.g. for the treatment or prevention of fungal diseases of man, animals and plants, and as PRESERVATIVES for a wide range of materials.

(a) *Medical and veterinary* antifungal agents ('antimycotics') are used for the treatment of local and systemic mycoses (see MYCOSIS); such agents include e.g. ALLYLAMINES, AZOLE ANTIFUNGAL AGENTS, CYCLOHEXIMIDE, FLUCYTOSINE, GRISEOFULVIN, NITROFURANS, POLYENE ANTIBIOTICS, SALICYLIC ACID, TOLNAFTATE. Many general DISINFECTANTS and ANTISEPTICS also have antifungal activity.

(b) *Agricultural* antifungal agents (used against fungal diseases of crop plants) may function as ERADICANTS and/or as PROTECTANTS; they fall into two broad categories: *contact* (*surface* or *non-systemic*) antifungal agents, which adhere to plant surfaces but do not penetrate the plant tissues, and *systemic* antifungal agents, which are taken up by the plant and translocated within its tissues – usually in the transpiration stream (from roots to leaves). In general, a contact agent typically acts as a general enzyme inhibitor, while a systemic agent usually acts at a specific target site (process or structure) in the fungal cell. Fungi may rapidly acquire resistance to an agent which has a single target site, and continued use of such agents has led in many cases to the emergence and spread of resistant strains of fungal pathogens; the risk of emergence of resistant strains can be reduced by using mixtures containing two or more agents which have different modes of action. Agricultural antifungal agents include e.g. BENZIMIDAZOLES (a), BISDITHIOCARBAMATES, CARBOXIN, CHLORONEB, CHLORONITROBENZENES, copper sulphate (see COPPER), DICARBOXIMIDES, DICHLOFLUANID, DICHLONE, DINITROPHENOLS, DITHIOCARBAMATES, DODINE, ETHAZOLE, GLYODIN, HYDROXYPYRIMIDINE ANTIFUNGAL AGENTS, IMAZALIL, MORPHOLINE ANTIFUNGAL AGENTS, certain ORGANOPHOSPHORUS COMPOUNDS, PHENYLAMIDE ANTIFUNGAL AGENTS, PHTHALIMIDE ANTIFUNGAL AGENTS, PROCHLORAZ, PYRACARBOLID, QUINONE ANTIFUNGAL AGENTS, SULPHUR, THIRAM, TRIFORINE. (See also AUREOFUNGIN, GRISEOFULVIN and POLYOXINS.)

**antigen** (ag) Any agent which can elicit an IMMUNE RESPONSE (cf. HAPTEN); 'antigen' may refer to an individual macromolecule or to a homogeneous or heterogeneous population of antigenic macromolecules. A given antigen usually contains more than one DETERMINANT (see also POLYCLONAL ANTISERUM). An antigen may be soluble (e.g. microbial toxins, extracts) or particulate. The most effective antigens are proteins and polysaccharides (see also Z-DNA); in general, large molecules are more antigenic than are smaller ones, and antigenicity is enhanced by the presence of an ADJUVANT. Minute quantities (e.g. a few µg) of antigen may be sufficient to elicit an immune response – the actual amount required depending e.g. on the route of administration.

The surface of a microorganism typically consists of repeating patterns of antigens, and the classification of some groups of microorganisms is based on differences between the antigens of different strains (see e.g. KAUFFMANN-WHITE CLASSIFICATION). (See also e.g. ALLERGEN; ANTIBODY; ANTIGENIC VARIATION; IDIOTYPE; IMMUNIZATION; THYMUS-DEPENDENT ANTIGENS.)

**antigen-binding cell** (ABC) (1) Any cell which can bind only a specific antigen. (2) Any cell (including e.g. macrophages) which can bind various antigens.

**antigen deletion** In a microorganism: the loss of particular antigenic determinant(s) due e.g. to a mutation or to the loss of a plasmid. (cf. ANTIGEN GAIN.)

**antigen excess** The presence of a high antigen-to-antibody ratio. Under conditions of gross antigen excess precipitation does not occur since, according to the LATTICE HYPOTHESIS, all the combining sites of antibodies are bound to otherwise unattached antigens – leaving no combining sites free to form cross-links and hence larger (insoluble) complexes. (See also TYPE III REACTION.)

**antigen gain** In a microorganism: the formation of new antigenic determinant(s). Antigen gain may be due e.g. to a MUTATION, to the acquisition of a PLASMID, or to BACTERIOPHAGE CONVERSION; thus, e.g., the sex factor in a conjugative plasmid specifies certain donor-specific antigens, while certain cell-surface antigens in *Salmonella* strains are present only when the cells are lysogenized by a particular phage. (cf. ANTIGEN DELETION.)

**antigen-presenting cell** (APC) (cf. a range of cells which bind antigen and present it to an antigen-specific T cell. APCs, which bear MHC class II cell-surface molecules (see HISTOCOMPATIBILITY RESTRICTION), include B LYMPHOCYTES, macrophages, dendritic cells, Langerhans' cells and Kupffer cells.

**antigen-specific T helper cell** A T LYMPHOCYTE which is specific for, i.e. activated by, a given, specific antigen; such a T cell may give COGNATE HELP to a B cell which has bound the same antigen (see ANTIBODY FORMATION). (See also CARRIER-SPECIFIC T HELPER CELL.)

**antigenic** (1) *Syn.* immunogenic (see IMMUNOGENICITY). (2) Of or pertaining to an ANTIGEN or antigens.

**antigenic competition** Inhibition of the immune response to a given antigen or DETERMINANT due to exposure to another (different) antigen or determinant; antigenic competition has been regarded as a form of natural immunosuppression.

In *intermolecular* competition, suppression of the response to a given antigen may occur as the result of the previous administration of the other antigen (*sequential competition*) or of the simultaneous administration of the other antigen. By carefully adjusting ('balancing') the relative amounts of the antigens, antigenic competition may be reduced or abolished; this is important e.g. in the preparation of MIXED VACCINES.

In *intramolecular competition* the response to a given determinant is inhibited by the presence of another determinant on the same macromolecule. For example, with IgG as antigen, good titres of anti-Fc may be produced but relatively few anti-Fab antibodies are formed – fewer than would be formed against isolated Fab fragments (i.e., relative to Fab, Fc is *immunodominant*).

**antigenic determinant** See DETERMINANT.

**antigenic drift** (immunological drift) In a given species, strain or type of microorganism: minor changes in antigenic specificity which occur over an extended period of time (e.g. years) – see e.g. INFLUENZAVIRUS. (cf. ANTIGENIC SHIFT; ANTIGENIC VARIATION.)

**antigenic formula** Any symbolic notation which indicates the antigenic nature of an organism – see e.g. KAUFFMANN-WHITE CLASSIFICATION.

## antigenic shift

**antigenic shift** In a given species, strain or type of microorganism: major change(s) in antigenic specificity which apparently occur abruptly. For example, antigenic shifts in strains of INFLUENZAVIRUS have been reported to coincide with pandemics of influenza. (cf. ANTIGENIC DRIFT; ANTIGENIC VARIATION.)

**antigenic variation** Successive changes which occur in the surface antigens of certain microorganisms; in some cases, each alternative antigen results from the expression of a specific allele (see PHASE VARIATION), but in other cases (e.g. the fimbriae of *Neisseria* – see below), successive new antigens are created by repeated recombinational events.

Antigenic variation may help a pathogen to evade the host's immune defence system; thus, e.g. new antigenic forms of the pathogen which arise in the host may not be susceptible to OPSONIZATION by those antibodies which have developed in response to the previous antigenic forms.

Antigenic variation occurs e.g. in *Borrelia* (see RELAPSING FEVER), INFLUENZAVIRUS, visna virus, *Leishmania*, *Plasmodium* and *Trypanosoma* spp (see VSG).

The major structural subunit in the fimbriae of *Neisseria gonorrhoeae* (which are type IV FIMBRIAE) is encoded by the chromosomal gene *pilE*. The chromosome also contains copies of a gene, *pilS*, with which *pilE* can undergo repeated RECOMBINATION; moreover, recombination can also occur between *pilE* and any homologous DNA acquired through transformation. Recombinational events continually create new versions of the subunit gene, so that the fimbriae of this organism can be synthesized from any one of a very large number of variant forms of the subunit, giving rise to extensive antigenic variation [Mol. Microbiol. (1996) 21 433–440]. These fimbriae are also subject to phase variation (on/off switching). (The Opa adhesins of *Neisseria* undergo phase variation by DNA re-arrangements that alter reading frames in *opa* genes [TIM (1998) 6 489–495].)

[An update of antigenic variation in African trypanosomes: TIP (2001) 17 338–343.]

**antigenicity** The capacity to function as an ANTIGEN. (cf. IMMUNOGENICITY.)

**antiglobulin** (Coombs' reagent) Antibody homologous to the antigenic determinants of serum globulins, particularly IMMUNOGLOBULINS; antiglobulin-Ig combination can occur without involvement of the specific COMBINING SITES of the Ig molecule.

**antiglobulin consumption test** (*serol.*) Any CONSUMPTION TEST in which the presence of cell- or particle-bound Ig is detected by the consumption of added ANTIGLOBULIN. For example, the in vitro combination of autoantibodies with homologous cell-surface antigens can be detected by washing the cells free of uncombined antibody and incubating them with antiglobulin; if autoantibody-antigen combination has occurred, antiglobulin will be consumed and may cause agglutination by the formation of cell-autoantibody-antiglobulin complexes. The amount of antiglobulin consumed can be determined e.g. by titrating the unconsumed antiglobulin against Ig-coated erythrocytes.

**antiglobulin test** (*serol.*) Any test in which the presence of Ig (including BLOCKING ANTIBODIES, sense 1) is detected by exploiting the ability of ANTIGLOBULIN to agglutinate Ig-bound antigens.

**anti-idiotypic** Antiserum to the variable-region domains of an Ig molecule (cf. IDIOTYPE); it contains antibodies homologous to each of the individual determinants (IDIOTOPES), though the different types of antibody may differ quantitatively and in their AFFINITY for their respective determinants.

**antilymphocyte serum** (ALS) Antiserum to the cell-surface antigens of LYMPHOCYTES; it is used e.g. for IMMUNOSUPPRESSION. Antilymphocyte globulin (ALG) is the globulin fraction of ALS.

**antimalarial agents** ('antimalarials') Drugs which are effective in the chemotherapy and/or chemoprophylaxis of MALARIA. Most of these drugs are effective against only one stage of the malaria parasite – e.g. chloroquine, mefloquine, quinine and QINGHAOSU are SCHIZONTICIDES. Primaquine and WR238605 are both active against hypnozoites; primaquine is also active against tissue schizonts (i.e. schizonts within liver cells), and WR238605 is also active against gametocytes.

(See AMINOQUINOLINES, QINGHAOSU, QUININE, PYRIMETHAMINE and MALARIA for details of antimalarials.)

Combinations of antimalarials are often used for treatment; this helps e.g. to limit the emergence of resistant strains of the parasite.

**antimetabolite** A substance which competitively inhibits the utilization, by an organism, of an exogenous substrate or endogenous metabolite. (See e.g. SULPHONAMIDES.)

**antimony** (as an antimicrobial agent) Antimony is a HEAVY METAL whose compounds have long been used as therapeutic agents – though their toxic effects were often greater than the benefits they bestowed. Antimonials have found use in the treatment of certain diseases of protozoal aetiology, e.g. leishmaniasis, and other diseases, e.g. schistosomiasis. It is believed that trivalent antimony is necessary for antimicrobial activity, and that pentavalent compounds owe their activity to in vivo conversion to the trivalent state. Antimonials have been shown to combine with essential sulphhydryl groups in trypanosomal enzymes involved in glucose metabolism; such inhibition may be reversed by thiol compounds, e.g. cysteine. Trivalent antimonials include e.g. potassium antimonyl tartrate (*tartar emetic*;  $2[\text{K}(\text{SbO})_2\cdot\text{C}_4\text{H}_4\text{O}_6]\cdot\text{H}_2\text{O}$ ) and *stibophen* (sodium antimony bis[pyrocatechol-3,5-disulphonate]). Pentavalent antimonials include e.g. *stibanilic acid* (*p*-aminobenzenestibonic acid) and its sodium salt (*stibamine*), both of which are constituents of a number of widely-used drugs – e.g. *ethyl stibamine* (*neostibosan*) which is used for the treatment of espundia and kala-azar.

**antimutator gene** See MUTATOR GENE.

**antimycin A** An antibiotic which acts as a RESPIRATORY INHIBITOR in Complex III of the mitochondrial ELECTRON TRANSPORT CHAIN, apparently blocking electron flow between *b*-type cytochromes and *cyt c*<sub>1</sub>; antimycin A and HOQNO appear to act at a common site which may be associated with the *b*-type cytochromes.

**antimycotic** See ANTIFUNGAL AGENTS (a).

**antioxidant** (*food sci.*) A substance added to certain foods to inhibit oxidation of the lipids in those foods – thus enhancing stability and prolonging shelf-life. (See also OXIDATIVE RANCIDITY.) Antioxidants currently used include e.g. ascorbic acid, butylated hydroxyanisole, butylated hydroxytoluene, carotene, propylgallate and tertiary butylhydroquinone. Some antioxidants have antimicrobial properties [CRM (1985) 12 153–183].

**antiparallel** (of DNA strands) See DNA.

**antiplectic metachrony** See METACHRONAL WAVES.

**antiport** (counter transport, exchange diffusion) The transmembrane transport of a solute (e.g. a given ion) coupled, directly, to the transmembrane transport of a different solute in the opposite direction. (cf. SYMPORT, UNIPOINT; see also ION TRANSPORT.)

**antiprotozoal agents** Chemical agents which kill or inhibit protozoa; they include e.g. AMINOQUINOLINES; antimonials (see ANTIMONY); arsenicals (see ARSENIC); certain DIAMIDINES; DILOXANIDE; EMETINE; 8-HYDROXYQUINOLINE; METRONIDAZOLE; MONENSIN; NITROFURANS; PYRIMETHAMINE; SULPHONAMIDES; SURAMIN. (See also antimalarial agents under MALARIA.) [Review: Book ref. 153, pp. 95–132.]

**antiretroviral agents** Any of a range of compounds which can inhibit the replication of retroviruses (i.e. viruses of the

RETROVIRIDAE); these agents are used e.g. in chemotherapy against HIV infection and AIDS. [BMJ (2001) 322 1410–1412.]

The three main groups of antiretroviral agents are: (i) NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (q.v. for examples); (ii) NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (delavirdine, efavirenz and nevirapine) [the emerging role of NNRTIs in antiretroviral therapy: Drugs (2001) 61 19–26]; (iii) PROTEASE INHIBITORS (amprenavir, indinavir, nelfinavir, ritonavir and saquinavir). The target for protease inhibitors is the viral protease (encoded by the *pol* region in HIV). Single-drug chemotherapy is prone to failure owing to the emergence of drug-resistant mutant viruses. (cf. HAART.)

**antisense RNA** Any RNA that can recognize a specific sense sequence in RNA or DNA and affect the activity/expression of that sequence: see e.g. COLE1 PLASMID, FINOP SYSTEM and R1 PLASMID.

MicroRNAs (miRNAs) are ~20–25 nt RNAs that regulate genes post-transcriptionally by binding to, and blocking, mRNAs; they are cut (by an RNase-III-like enzyme: Dicer) from longer transcripts. Human miRNAs appear to bind preferentially to AT-rich 3'-untranslated regions of mRNAs [PNAS (2005) 102 15557–15562].

ssRNA can form triple-strand structures with dsDNA (cf. TRIPLEX DNA) and can also bind to ssDNA during transcription, in each case affecting transcription. Antisense RNA is also involved in RNA INTERFERENCE.

Note that, in contrast to the above, sequence-specific RNAs mediate RdDM (RNA-directed DNA methylation), in plant and human cells, and RNA EDITING.

**antisense strand** The non-CODING STRAND.

**antiseptics** ('degerming') Prophylactic or therapeutic treatment of human or animal tissues with ANTISEPTICS. (cf. SEPSIS.)

**antiseptic paint** ANTIBODY-containing secretions which bathe the mucous surfaces of the body.

**antiseptics** Chemical agents used for treating human and animal tissues (particularly skin) with the object of killing or inhibiting pathogens. Antiseptics are typically non-injurious to living tissues (cf. DISINFECTANTS). For examples of antiseptics see under ACRIFLAVINE; ALCOHOLS; AMINOACRIDINE; BISPHENOLS; CHLORHEXIDINE; CHLORINE; IODINE; PHENOLS; QUATERNARY AMMONIUM COMPOUNDS; SALICYLANILIDES; SALICYLIC ACID; TRICLOSAN.

**antiserum** (immune serum) SERUM containing antibodies to one or more particular antigens.

**anti-sigma factor** (anti- $\sigma$  factor) Any molecule which can inhibit the normal activity of a given SIGMA FACTOR by binding to it.

Examples of anti-sigma factors include e.g. (i) FlgM (see SIGMA FACTOR); (ii) DnaK, which inhibits  $\sigma^{32}$  (see HEAT-SHOCK PROTEINS); and (iii) AsiA, a protein, encoded by bacteriophage T4, which is active during phage development in *Escherichia coli* and which can (*inter alia*) inhibit the *E. coli*  $\sigma^{70}$  sigma factor.

The Rsd protein ('regulator of sigma D'; *rsd* gene product) can inhibit  $\sigma^{70}$  in *E. coli*, and it has been proposed that Rsd is involved in the switching from  $\sigma^{70}$  to  $\sigma^S$  during the transition from exponential growth to the stationary phase in this organism [JB (1999) 181 3768–3776].

[Anti-sigma factors: ARM (1998) 52 231–286.]

**antistreptolysin O test** (ASLT; ASO test; ASOT) A test used for detecting/quantifying serum antibodies to STREPTOLYSIN O; it is of use e.g. in the differential diagnosis of RHEUMATIC FEVER and rheumatoid arthritis. In one method, INACTIVATED SERUM is serially diluted, and to each dilution is added a fixed volume of streptolysin O solution; after incubation at

4°C for several hours (or 37°C for ca. 15 minutes) – to allow antibody–streptolysin O combination – a fixed volume of RBC suspension is added to each dilution, and incubation carried out at 37°C for 30–45 minutes. Complete absence of haemolysis in a given tube indicates that streptolysin O in that tube has been fully neutralized by antibodies. The ASOT titre (often expressed in TODD UNITS) is given by the highest dilution of serum which completely inhibits haemolysis. ASOT can also be carried out as a LATEX PARTICLE TEST using streptolysin O-coated particles.

**antitermination** A process in which, during TRANSCRIPTION, the RNA polymerase fails to recognize a transcription termination signal and therefore continues transcription beyond the terminator. Antitermination may involve various mechanisms and can serve as a means for the regulation of gene expression (see e.g. BACTERIOPHAGE LAMBDA (gpV) and OPERON (attenuator control)) and for the prevention of erroneous transcription termination (see e.g. RRNA).

**antitoxin** (1) An antibody to a toxin. (2) An antiserum which contains antibodies to one or more particular toxins.

**antiviral agents** Agents which inhibit the replication of viruses in cells, tissues or organisms – either directly (e.g. by inhibiting a specific viral enzyme) or by inducing the synthesis of INTERFERON. (See also TILORONE.)

Owing to poor selective toxicity and/or the ready emergence of resistant strains of virus, relatively few compounds which exhibit antiviral activity in cell cultures are suitable for clinical use, and many of these are limited to topical treatment of localized infections.

ANTIRETROVIRAL AGENTS (q.v.) are antiviral agents used e.g. in chemotherapy against AIDS.

Examples of antiviral agents include: ACYCLOVIR, AMANTADINE, ANSAMYCINS, ARABINOSYL NUCLEOSIDES, ARILDONE, BROMOVINYLDIOXYURIDINE, CYCLARIDINE, DHBG, DHPA, DHPG, DIDEMNINS, ENVIROXIME, EPIPOLYTHIAPIPERAZINEDIONES, FAMCICLOVIR, GANCICLOVIR, IDOXURIDINE, LAMIVUDINE, MONENSIN, PENCICLOVIR, PHOSPHONOACETIC ACID, PHOSPHONFORMIC ACID, RIBAVIRIN, SINEFUNGIN, THIOSEMICARBAZONES, TRIFLUOROTHYIMIDINE, TUNICAMYCIN, VALACICLOVIR, ZANAMIVIR. [See also Book ref. 134.]

**AOAC** Association of Official Analytical Chemists (of the USA).

**AOAC use-dilution test** A CARRIER TEST (q.v.), devised by the AOAC, which determines the USE-DILUTION of a given disinfectant. To each of a number of dilutions of the disinfectant is added a (contaminated) small steel carrier; after immersion for 10 min, each carrier is transferred to broth to detect any surviving microorganisms. Sporocidal activity is determined by exposing the endospores of *Bacillus subtilis* ATCC 19659 or *Clostridium sporogenes* ATCC 9081 to the disinfectant and subsequently testing for viability.

**AP endonuclease** See BASE EXCISION REPAIR.

**AP site** An apyrimidinic or apurinic site in DNA (see ADAPTIVE RESPONSE and URACIL-DNA GLYCOSYLASE).

**6-APA** 6-AMINOPENICILLANIC ACID.

**ApaI** See RESTRICTION ENDONUCLEASE (table).

**apalcillin** A penicillin (see PENICILLINS) which is active against both Gram-positive and Gram-negative bacteria (including *Pseudomonas aeruginosa*) [AAC (1982) 21 906–911].

**Apc** APHIDICOLIN.

**aperture diaphragm** See CONDENSER.

**APES** See AAS.

**APH** Aminoglycoside phosphotransferase (see AMINOGLYCOSIDE ANTIBIOTICS).

**Aphanizomenon** A genus of filamentous CYANOBACTERIA; the cells are cylindrical with closely abutting ends, and the filaments

## **Aphanoascus**

aggregate to form raft-like floating colonies. GAS VACUOLES are present, and heterocysts occur but are often sparse. Trichomes commonly terminate in tapering, colourless 'hair cells'.

*A. flos-aquae* is an important freshwater BLOOM-forming species in temperate regions; it may also occur in brackish waters. The filaments of this species typically form wispy, flake-like colonies, the formation of which, in culture at least, appears to depend on the presence of iron. Strains of *A. flos-aquae* produce toxins ('aphantoxin') which may apparently include e.g. SAXITOXIN and neosaxitoxin; 'aphantoxin' acts as a neuromuscular blocking agent, and is toxic for amphibia, fish, etc.

**Aphanoascus** See GYMNOASCALES.

**Aphanocapsa** See SYNECHOCYSTIS.

**Aphanochaete** A genus of filamentous, prostrate, branched green algae (division CHLOROPHYTA) which grow as epiphytes on other freshwater algae. Some of the cells in the filaments bear unicellular 'hairs' with bulbous bases. Quadriflagellate zoospores or aplanospores are formed; sexual reproduction is oogamous.

**Aphanomyces** A genus of predominantly aquatic fungi of the order SAPROLEGNIALES (q.v.). A species known as the 'MG fungus' has been reported to cause a mycotic granuloma of fish [Book ref. 1, pp. 195–197], while *A. astaci* causes CRAYFISH PLAGUE. Plant-pathogenic species include *A. brassicae*, *A. camptostylus*, *A. cochlioides* (on sugar-beet), *A. euteiches* (on peas) and *A. raphani* (on radish).

**aphanoplasmodium** See MYXOMYCETES.

**Aphanothece** A phycological genus of unicellular 'blue-green algae' (Chroococcales) apparently referable to *Cyanothece* (see SYNECHOCOCCUS).

**aphantoxin** See APHANIZOMENON.

**aphid** (bacteriocytes) See BUCHNERA.

**aphidicolin** (Apc) A tetracyclic diterpenoid, isolated from '*Cephalosporium aphidicola*', which – in eukaryotic cells – is a potent and specific inhibitor of DNA POLYMERASE  $\alpha$ . Apc has no effect on bacterial DNA polymerases, but it inhibits growth and DNA synthesis in certain members of the ARCHAEA: e.g. halobacteria [FEMS (1984) 25 187–190] and methanogens [SAAM (1985) 6 111–118]. (cf. DDTPP.)

**aphotic zone** That part of an aquatic habitat below the PHOTIC ZONE.

**aphthous fever** *Syn.* FOOT AND MOUTH DISEASE.

**Aphthovirus** A genus of viruses (family PICORNAVIRIDAE) which infect mainly cloven-hooved animals, causing FOOT AND MOUTH DISEASE; there are 7 serotypes and many antigenically distinct strains. Aphthovirus virions are rapidly inactivated at pH below ca. 6–7, but are appreciably resistant to desiccation; stability of the virions is generally increased by high ionic concentrations and low temperatures.

**Aphylophorales** (Polyporales) An order of terrestrial (typically humicolous or lignicolous), mainly saprotrophic fungi (subclass HOLOBASIDIOMYCETIDAE) which characteristically form tough (rather than fleshy), macroscopic, gymnocarpic fruiting bodies that may be e.g. crust-like, erect and coralloid, bracket-shaped (BRACKET FUNGI) etc; the hymenium may be borne on a smooth, toothed or irregular surface, and it may form the lining of tubular pores (in 'polypores') or the surface layer on clavate or coralloid basidiocarps or on lamellae.

Constituent families [Book ref. 64, p.20] include e.g.:

Clavariaceae. Basidiocarp: erect – simple and clavate ('club fungi'), branched, or coralloid ('coral fungi') – and often brightly coloured (e.g. pink, yellow, violet); basidiospores: white or pale cream, typically non-amyloid. Genera: e.g. *Clavaria* and *Typhula* (see also SNOW MOULD).

Coniophoraceae. Basidiocarp: characteristically resupinate; basidiospores: pigmented, with a cyanophilic spore wall. Genera: e.g. CONIOPHORA, *Gyrodontium*, and SERPULA.

Corticiaceae. Basidiocarp: characteristically resupinate or effused-reflexed, with a hymenium that may be e.g. smooth or wrinkled. Genera: e.g. *Botryobasidium*, *Christiansenia* (see also MYCOPARASITE), *Merulius*, *Mycocacia*, *Peniophora* (see also HETEROBASIDIUM), *Phanerochaete* (see also WHITE ROT and LIGNIN), and *Phlebia*.

Fistulinaceae. Basidiocarp: annual, pileate with a lateral stipe, fleshy and moist; the hymenophore consists of a layer of closely packed parallel tubules. *Fistulina hepatica* (the edible 'beef-steak fungus') causes BROWN OAK. It forms a fan-shaped or tongue-shaped basidiocarp whose upper surface is rusty brown, and whose lower (hymenial) surface is pale yellow when unbroken; the reddish monomitic context of the pileus exudes a red liquid when cut.

Ganodermataceae. Basidiocarp: annual or perennial, typically fan-shaped and horizontal, either non-stipitate or borne on a lateral stipe; the context of the pileus is trimitic, and the underside of the pileus bears a porous hymenophore. Basidiospores: ovoid, typically flattened at one pole; ornamentations on the inner, brown layer of the spore wall penetrate deeply into the outer, hyaline layer of the spore wall. The organisms occur e.g. on felled timber; *Ganoderma applanatum* causes heart rots in various types of tree, infection occurring via wounds.

Hydnaceae. Basidiocarp: typically mushroom-shaped, with a monomitic, non-xanthochroic context; the hymenophore consists of a layer of pendulous tooth-like processes ('spines' or 'teeth') on the underside of the pileus. Basidiospores: non-pigmented, spheroidal. *Hydnum repandum* (the 'hedgehog fungus') is an edible species which forms a thick, commonly cream-coloured pileus and a short, thick stipe which is often eccentrically located on the pileus; the teeth are often decurrent.

Hymenochaetaceae. Basidiocarp: annual or perennial, ranging from resupinate to pileate or clavate according to species; hymenophore: poroid (in e.g. INONOTUS and *Phelellinus*) to smooth (in *Hymenochaete*). Basidiospores: pigmented or colourless. The organisms are commonly lignicolous.

Polyporaceae. Basidiocarp: annual or perennial, ranging (with species) from resupinate to pileate (either stipitate or sessile); the context is non-xanthochroic, and (according to species) may be mono-, di- or trimitic, and e.g. corky, leathery or woody. The hymenophore is typically porous, the hymenium being confined to the walls of the pores. (cf. LENTINUS, PLEUROTUS.) Basidiospores: colourless and usually smooth. The organisms grow on felled timber and on living trees. Genera: e.g. CORIOLUS, DAEDALEA, FOMES, *Grifola*, HETEROBASIDIUM, *Irpex*, *Laetiporus*, LENTINUS, *Lenzites*, PIPTOPORUS, PLEUROTUS, POLYPORUS, PORIA, *Rigidoporus* (see also BUTT ROT), TRAMETES and *Tyromyces*.

Schizophyllaceae. Basidiocarp: fan-shaped or lobed; basidiospores: colourless and smooth. The organisms are characteristically lignicolous. Genera: e.g. SCHIZOPHYLLUM.

Sparassidaceae. Basidiocarp: branching, flattened, monomitic lobes, the hymenium being on both sides of the erect lobes. Genera: e.g. SPARASSIS.

Stereaceae. Basidiocarp: appressed, effused-reflexed or stipitate, typically dimitic; basidiospores: colourless and smooth. The organisms are characteristically lignicolous. Genera: e.g. *Amylostereum* (see also WOODWASP FUNGI), *Chondrostereum* (see also SILVER LEAF), *Podoscypha*, STEREUM.

**API system** See MICROMETHODS.

**apical** Terminal: at the tip or distal part of a structure. *Antonym:* basal.

**apical complex** A collective term for the CONOID, MICRONEMES, POLAR RING and RHOPTRIES – some or all of which are found in members of the APICOMPLEXA, particularly in motile stages. (Some authors include the MICROPORES and/or the subpellicular tubules as part of the apical complex.)

**apical granule** *Syn.* SPITZENKÖRPER.

**apical paraphysis** See PARAPHYSIS.

**Apicomplexa** A phylum of parasitic PROTOZOA with one type of nucleus, no cilia and no flagella (some have flagellated microgametes); components of the APICAL COMPLEX are present at some stage in the life cycle. Classes: PERKINSASIDA, SPOROZOASIDA. [Cytoskeleton: Microbiology and Molecular Biology Reviews (2002) 66 21–38.]

**apiculate** Having a short, pointed projection (*apiculus*) at one end.

**Apliosoma** See PERITRICHIA.

**Aplanochytrium** See THRAUSTOCHYTRIDS.

**aplanogamete** A non-motile GAMETE.

**aplanospore** A non-motile spore.

**aplastic crisis** (in parvovirus B19 infection) See ERYTHROVIRUS.

**aplysiatoxin** See LYNGBYA.

**APO-1** See FAS.

**apo-activator** See OPERON.

**apochlorotic** Having lost chlorophyll – either during evolutionary development or during growth under certain conditions. Apochlorotic organisms may have lost either chloroplasts or chlorophyll; in the latter case a colourless plastid (leucoplast) may be formed. (cf. ACHLOROTIC; see also BLEACHING.)

**apochromat** (apochromatic objective) An objective lens (see MICROSCOPY) in which chromatic aberration has been corrected for three colours (red, green, and blue), and spherical aberration has been corrected for two colours (red and blue). (cf. ACHROMAT.) A FLAT-FIELD OBJECTIVE LENS of this type is called a *planapochromat*.

**Apodachlya** See LEPTOMITALEA.

**apoenzyme** The protein component of a PROSTHETIC GROUP-requiring enzyme. (cf. HOLOENZYME.)

**apokinetal stomatogenesis** See STOMATOGENESIS.

**apomict** See APOMIXIS.

**apomixis** (*microbiol.*) In certain diploid organisms: a type of reproduction, considered to be a deviant form of the sexual process, in which meiosis, gamete formation and fertilization do not occur even though morphologically differentiated structures (e.g. spore-containing asci) are formed; progeny produced apomictically from a given cell (the apomict) are genetically identical to that cell. Thus, e.g., some apomictic strains of *Saccharomyces cerevisiae* form asci each containing two uninucleate diploid spores [Yeast (1985) 1 39–47]. (cf. AMIXIS.)

**apoplastidic** Lacking a PLASTID.

**apoptosis** In eukaryotic cells: cell death which occurs in a regulated ('programmed') manner: i.e. death resulting from an organized process involving an internal mechanism that characteristically includes fragmentation of the genome.

Apoptosis is a natural process. For example, in vertebrates it occurs during embryogenesis, while in invertebrates it occurs during metamorphosis.

Apoptosis can also be induced by physical and chemical factors – e.g. heat, radiation and agents such as glucocorticoids. Moreover, apoptosis can be induced by certain pathogens. Thus, e.g. in HIV-infected individuals (see AIDS), apoptosis may occur in CD4<sup>+</sup> T cells which have bound viral protein. Again, poliovirus 2A protease is reported to induce apoptosis in human embryonic kidney epithelial cells [MCB (2000) 20 1271–1277].

Some bacteria can induce apoptosis in host cells. Thus, for example, on phagocytosis by a macrophage, *Shigella* can escape from the vacuole and then induce apoptosis in the phagocyte by means of a plasmid-encoded protein, IpaB. IpaB, secreted by a type III secretory system (see PROTEIN SECRETION), activates the host cell's IL-1 $\beta$ -converting enzyme (ICE, see INTERLEUKIN-1); activated ICE (i) initiates apoptosis in the macrophage, and (ii) activates the intracellular, inactive form of IL-1 $\beta$ . Activated IL-1 $\beta$ , when extracellular, may initiate an acute inflammatory response (involving TNF- $\alpha$ , IL-1, IL-6 and IL-8). In one model of shigellosis, these events have a positive role in promoting a pro-inflammatory response that helps to control the infection [TIM (1997) 5 201–204].

The *Shigella* example (above) involves an endogenous stimulus (via the IpaB protein). Exogenous stimuli include the binding of certain cytokines, or immune cells, to specific cell-surface receptors on target cells. Thus, apoptosis is one of the possible effects which may follow when tumour necrosis factor binds to its receptor (see TNF). Induction of apoptosis by CD8<sup>+</sup> T cells may be possible in at least two different ways. One way involves interaction between cell-surface molecules on the T cell and target cell (see FAS). Alternatively, following contact between T cell and target cell, the T cell may release pore-forming lethal agents (*perforins*) – and also *granzymes* which are believed to activate *caspases* (see below) in the target cell.

Whatever the stimulus that triggers apoptosis (in different types of cell under differing conditions), it appears that the mechanism of this process is dependent on certain intracellular cysteine proteases (*caspases*) that are synthesized as ZYMOGENS and activated specifically during apoptosis; these enzymes, which have a cysteine residue at the active site, cleave specific protein substrates at a site adjacent to an aspartic acid residue. The activity of a caspase on a substrate molecule may lead to either inactivation or (less commonly) activation of the given protein; for example, caspase-mediated activation of a certain nuclease (*caspase-activated DNase*, CAD) leads to fragmentation of genomic DNA and formation of the characteristic nucleosomal 'ladder'. (CAD occurs in living cells, in inactive form, complexed with an inhibitory entity referred to as ICAD.)

The activation of caspases appears to occur commonly by proteolytic cleavage of the zymogen form, and, in at least some cases, one caspase may be activated by an 'upstream' caspase in a *caspase cascade*. An understanding of the mechanism(s) involved in caspase activation is central to an appreciation of the process of apoptosis, and this area is being actively researched.

[Programmed cell death (concept, mechanism and control): Biol. Rev. (1992) 67 287–319. Apoptosis (reviews on biochemistry and other aspects of the process): Nature (2000) 407 770–816.]

**apopressor** See OPERON.

**Aporpium** See TREMELLALES.

**Apostomatida** See HYPOSTOMATIA.

**aposymbiotic** Refers to an organism (aposymbiont) which has lost symbionts it normally possesses.

**apothecioid** Of an ASCOCARP: having, at maturity, a hymenium more or less open to the environment – as in a typical APOTHECIUM; apothecioid ascocarps may be e.g. cup-shaped, discoid (circular and flat), or lirelliform (see LIRELLA).

**apothecioid pseudothecium** See ASCOSTROMA.

**apothecium** A typically dish- or cup-shaped or discoid, sessile or stipitate ASCOCARP, the inner (or upper) surface of which is lined with a hymenial layer of asci (often interspersed with paraphyses); the main structural tissue of the apothecium is

## AP-PCR

called the *excipulum*, and the thin layer of hyphae between the hymenium and the excipulum is termed the *hypothecium* or *subhymenium*. Some apothecia are not cup-like or discoid: see e.g. MORCHELLA, PODETIUM and VERPA. Apothecia range from minute to 10 cm or more in diameter; those formed by e.g. species of *Aleuria* and *Scutellinia* are brightly coloured. (See also LECANORINE APOTHECIUM.)

**AP-PCR** See ARBITRARILY PRIMED PCR.

**appertization** A method of FOOD PRESERVATION in which certain types of food are exposed to a temperature/time regime which renders them safe for the consumer and microbiologically stable for extended, or indefinite, periods of time on subsequent storage in hermetically sealed containers at temperatures below 40°C; appertized foods are not necessarily sterile, and in certain cases (see CANNING) appertized foods must be kept under refrigeration. For foods which have no intrinsic properties (e.g. acidity) inhibitory to microbial growth and/or toxin production, appertization involves treatment which, at least, destroys the spores of pathogenic bacteria (particularly *Clostridium botulinum*); acidic foods (below ca. pH 4.5), and those containing appropriate concentrations of e.g. sodium nitrite, are appertized at somewhat lower temperatures. High temperature short time (HTST) appertization involves heat processing at high temperatures for periods ranging from ca. 2 sec to several minutes (cf. HTST PASTEURIZATION). In the ultra-high temperature (UHT) appertization of milk the process involves e.g. maintenance of a minimum temperature of ca. 140°C for at least 2 or 3 sec. (cf. RADAPPERTIZATION.)

**apple canker** A CANKER of apple trees caused by *Nectria galligena* f. sp. *mali*; other trees – e.g. pear, poplar, hawthorn – may also be affected. Enlarged, sunken lesions develop on the branches; bark in the centre of a lesion dies and may break away. Infection occurs via wounds or leaf scars, and can be initiated by ascospores and by conidia.

**apple chlorotic leafspot virus** See CLOSTEROVIRUSES.

**apple diseases** See e.g. APPLE CANKER, APPLE SCAB, BROWN ROT (sense 2) and FIREBLIGHT.

**apple mosaic virus** See ILARVIRUSES.

**apple scab** An important disease of apple trees (*Malus*) caused by *Venturia inaequalis* (see VENTURIA). In spring, germinating ascospores infect via wounds or by means of appressoria. Small dark spots appear on leaves; on fruits, small dark velvety lesions enlarge to brown, corky scabs. Conidia, formed during late spring and summer, spread the disease. Control: antifungal sprays (see e.g. BENOMYL, DICHLONE, GLYODIN and TRIFORINE). (See also FIREBLIGHT.)

**apple stem grooving virus** See CLOSTEROVIRUSES.

**App(NH)p** ( $\beta$ , $\gamma$ -imido)ATP: a (biologically) non-hydrolysable analogue of ATP.

**appressed** Lying close to, or flattened against, a surface.

**appressorium** A specialized, flattened region of a hypha or germ tube formed by some plant-pathogenic fungi (e.g. *Puccinia graminis*, *Venturia inaequalis*); it aids infection by adhering closely to the surface of a host cell and producing a small outgrowth of fungal tissue (*infection peg*) which penetrates the host cell wall. A plant may respond to an infection peg by depositing a small region of wall-like material (a *papilla*) near the site of attempted penetration; such a papilla can sometimes prevent infection.

**apramycin** An AMINOGLYCOSIDE ANTIBIOTIC which is resistant to many of the enzymes which inactivate antibiotics of this group; it is inactivated by e.g. chromosome- and plasmid-specified acetyltransferases [JGM (1984) 130 473–482].

**aprotinin** A basic polypeptide which inhibits many serine PROTEASES, including e.g. trypsin, chymotrypsin, and some bacterial proteases.

**APS** Adenosine-5'-phosphosulphate (also called adenosine-5'-sulphatophosphate or adenylylsulphate). See ASSIMILATORY SULPHATE REDUCTION and DISSIMILATORY SULPHATE REDUCTION.

APS (adenosine 5'-phosphosulphate)

**APT agar** An agar-based medium containing tryptone, yeast extract, glucose, Tween 80, citrate, and various inorganic salts. [Recipe: Book ref. 46, p. 1661.] It is used for isolating organisms such as lactobacilli and *Brochothrix* from e.g. meat and meat products.

**APT paper** BLOTTING paper impregnated with 2-aminophenylthioether; before use, APT is chemically modified to its reactive diazo derivative, and is then able to bind (covalently) ssDNA, RNA and/or protein via the diazonium group.

**APW** Alkaline peptone water: 1% peptone and 1% NaCl in distilled water, pH adjusted to 8.6–9.0, used e.g. for isolating *Vibrio cholerae*.

**ApxIA, ApxIIA** (of *Actinobacillus pleuropneumoniae*) See RTX TOXINS.

**AqpZ** See MIP CHANNEL.

**Aqualinderella** See LEPTOMITALES.

**aquaporin** See MIP CHANNEL.

**Aquaspirillum** A phylogenetically heterogeneous genus of Gram-negative, asporogenous bacteria formerly included in the genus SPIRILLUM. Cells: fairly rigid, generally helical (0.2–1.4 × ca. 2 – >30 μm, according to species); *A. delicatum* cells are mainly vibrioid, and those of *A. fasciculus* are straight rods. S LAYERS, intracellular PHB granules, and POLAR MEMBRANES are commonly present; COCCOID BODIES are commonly formed. Motile, typically with bipolar tufts of flagella (*A. polymorphum* has a single flagellum at each pole, *A. delicatum* has one or two flagella at one pole only). Cells swim in a straight line with a characteristic corkscrew-like motion; *A. fasciculus* swims effectively only in media of high viscosity. Metabolism is respiratory; species are usually aerobic or microaerophilic, but some can carry out NITRATE RESPIRATION under anaerobic conditions. Carbon sources: amino acids or salts of organic acids, but usually not carbohydrates; *A. autotrophicum* can grow autolithotrophically with CO<sub>2</sub>, H<sub>2</sub> and O<sub>2</sub>. Nitrogen source: NH<sub>4</sub><sup>+</sup>; *A. peregrinum*, *A. fasciculus* and strains of *A. itersonii* can fix N<sub>2</sub> under anaerobic conditions. Aquaspirilla are typically oxidase +ve; catalase +ve; usually phosphatase +ve; indole –ve; arylsulphatase –ve. No growth with 3% NaCl. Optimum growth temperature: usually ca. 30–32°C (ca. 20°C for *A. psychrophilum*, 41°C for *A. bengal*). GC%: 49–66. Type species: *A. serpens*. About 17

species are recognized on the basis of morphology, nutrition and GC%.

Aquaspirilla occur in a wide range of freshwater habitats – e.g., stagnant waters rich in organic matter; none appears to be pathogenic.

[Book ref. 22, pp. 72–90. Media, culture etc: Book ref. 45, pp. 596–608.]

(See also MAGNETOTACTIC BACTERIA; cf. AZOSPIRILLUM; OCEANOSPIRILLUM; SPIRILLUM; SPOROSPIRILLUM.)

**aquifer** See WATER SUPPLIES.

**ara operon** (arabinose operon) An OPERON concerned with the metabolism of ARABINOSE; when used without qualification, the term 'ara operon' usually refers to the *araBAD* operon, but in e.g. *Escherichia coli* three distinct genetic loci are involved in the uptake and metabolism of L-arabinose: *araBAD* (at ca. 1 min on the chromosome map), *araFG* (at ca. 45 min) and *araE* (at ca. 61 min). The *araBAD* operon encodes enzymes for the conversion of L-arabinose to D-xylulose 5-phosphate; the *araA* gene encodes L-arabinose ketol-isomerase, *araB* encodes L-ribulokinase, *araD* encodes ribulose 5-phosphate 4-epimerase. The *araFG* operon specifies a high-affinity BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM for L-arabinose; *araF* encodes the binding protein, *araG* the membrane component. The *araE* gene specifies a protein involved in an independent low-affinity transport system.

All three operons are controlled by the product of the regulator gene *araC* which is located next to *araBAD* but transcribed in the opposite direction. (See also REGULON.) In the absence of arabinose, the AraC protein behaves as a repressor of the *araBAD* operon, binding to the OPERATOR and preventing transcription (*negative* promoter control: see OPERON). However, when arabinose is present it converts the AraC protein into an activator which binds to an initiator (*araI*) to promote *araBAD* transcription (*positive* promoter control). (The *araC* gene is itself subject to autogenous regulation, i.e., the AraC protein represses its own synthesis.) Thus, expression of the *araBAD* operon depends on the relative amounts of repressor and activator, which in turn depend on the level of arabinose (the co-activator).

The *ara* regulon is also subject to CATABOLITE REPRESSION.

**ara-A** *Syn.* VIDARABINE.

**araBAD operon** See ARA OPERON.

**Arabidopsis thaliana** A flowering brassica widely used as a model plant for research. [Genome sequence and other data: Nature (2000) 408 791–826.] (See also CAMALEXIN.)

**arabinogalactans** See PECTIC POLYSACCHARIDES. (See also WAX D.)

**arabinose** An aldopentose (see PENTOSES) which occurs e.g. as a component of hemicelluloses (see e.g. XYLANS) and PECTIC POLYSACCHARIDES, and in the cell walls of certain bacteria (e.g. *Nocardia* spp). Arabinose can be metabolized by various bacteria, including e.g. *Escherichia coli* and strains of *Salmonella*, *Bacillus*, and lactic acid bacteria [Appendix III(d)]. Arabinose is heat-labile; solutions should be sterilized by filtration. (See also ARA OPERON.)

**arabinose operon** See ARA OPERON.

**arabinosyl nucleosides** A group of compounds which inhibit various enzymes – including DNA polymerases and reverse transcriptase – by acting as analogues of biological nucleosides and nucleotides. Arabinosyl nucleosides inhibit DNA synthesis in a variety of eukaryotic cells, and have been used as anti-tumour and ANTIVIRAL AGENTS; in general, viral replication is more sensitive to these agents than are the host cells. Arabinosyl

nucleosides probably must be converted to the corresponding nucleoside 5'-triphosphate for activity. (See e.g. ARA-T; CYTARABINE; FIAC; FMAU; VIDARABINE.)

**arabinoxylans** Heteroglycans containing both xylose and arabinose (cf. XYLANS).

**arabitol** A PENTITOL formed e.g. by the reduction of ARABINOSE. It occurs, often with MANNITOL, in various basidiomycetes and ascomycetes.

**ara-C** *Syn.* CYTARABINE.

**araC gene** See ARA OPERON.

**arachidonic acid** In mammals: an essential C<sub>20</sub> straight-chain fatty acid – CH<sub>3</sub>(CH<sub>2</sub>)<sub>3</sub>(CH<sub>2</sub>CH=CH)<sub>4</sub>(CH<sub>2</sub>)<sub>3</sub>COOH; it occurs e.g. as a component of cell membrane phospholipids, and (bound to protein) in blood. Free arachidonic acid is formed e.g. during the activation of lymphocytes, and is a precursor of e.g. LEUKOTRIENES, PROSTACYCLIN, PROSTAGLANDINS and thromboxanes.

**Arachnia** A genus of anaerobic (but aerotolerant), catalase-negative, asporogenous bacteria (order ACTINOMYCETALES, wall type I). The organisms grow as a substrate mycelium which fragments into branched filaments and irregularly-shaped rods; aerial hyphae are not formed. Metabolism: fermentative, fermentation of glucose yielding primarily acetic and propionic acids; growth occurs readily in vitro on rich media at 37°C. *A. propionica*, the type species (GC%: 63–65), is pathogenic in man and other animals; it is a common causal agent of LACHRYMAL CANALICULITIS.

**arachnoid** Resembling a spider's web.

**Arachnoidiscus** See DIATOMS.

**Arachnula** See GRANULORETICULOSEA.

**araE gene** See ARA OPERON.

**araFG operon** See ARA OPERON.

**aranotin** See EPIPOLYTHIAPERAZINEDIONES.

**ara-T** (1-β-D-arabinofuranosylthymine) An ARABINOSYL NUCLEOSIDE isolated from a marine sponge (*Cryptoethya crypta*). It has antiviral activity against herpes simplex viruses (HSV-1 and -2), varicella-zoster virus and vaccinia virus, and is relatively non-toxic to animal cells.

**arbitrarily primed PCR** Certain TYPING methods in which PCR is used with primers of arbitrary (i.e. random) sequence to copy discrete sequences of chromosomal DNA. Only one type of primer is used (cf. standard PCR protocol), and during the annealing stage the primers bind to various 'best-fit' sequences on the strands of DNA. As the primer is of arbitrary sequence it is not possible to predict which chromosomal sequences will be copied; however, results are reproducible if the method is carefully standardized – including not only the primer sequence but also e.g. the use of a specific type of DNA polymerase [NAR (1993) 21 4647–4648] and a particular procedure for preparing the sample DNA [NAR (1994) 22 1921–1922]. Various guidelines have been recommended for promoting reliability and reproducibility in arbitrarily primed PCR [JCM (1997) 35 339–346].

The method is outlined in the figure.

Arbitrarily primed PCR (AP-PCR) was first published as a typing procedure in 1990 [NAR (1990) 18 7213–7218; NAR (1990) 18 6531–6535]. Another typing method – RAPD (q.v.) – is based on the same principle; it generally employs shorter primers (~10-mer) compared with those used in AP-PCR (>20-mer), but, even so, some authors regard the two methods as identical.

Typing methods based on this principle have two main advantages. First, the entire chromosome can participate in

## arboricolous

ARBITRARILY PRIMED PCR (principle, diagrammatic). In the diagram, the two strands of chromosomal DNA (which have been separated by heat) are shown as long parallel lines. During the annealing (primer-binding) stage of PCR, copies of the arbitrary primer bind at a number of 'best-fit' sequences, on both strands of DNA, under low-stringency conditions. In some cases (by chance), two primers will bind, on opposite strands, a few hundred bases apart; if strand elongation can occur efficiently from these two primers, and if elongation is time-limited, two short strands of DNA will be produced. In the diagram (*right-hand side*), two primers (short lines) have bound, close together, on opposite strands; two more primers (*left-hand side*) have bound, further apart, on opposite strands. Strand elongation from each primer (*dashed line*) has produced the four fragments shown. (Note that a fragment synthesized on one strand contains a copy of the best-fit sequence of the other strand.) Another cycle of low-stringency PCR produces more copies of the fragments. Subsequently, many cycles of PCR are carried out under higher stringency (using the same primer). Under these conditions, primers bind to best-fit sequences (rather than elsewhere) on the fragments formed by low-stringency PCR – although (due to the higher stringency), primers may not bind to best-fit sequences on *all* of the fragments, so that only a proportion of the fragments formed under low stringency may be amplified under higher stringency. The length of the fragments formed under higher stringency is shown by the distance between each pair of arrowheads.

On electrophoresis, the fragments from a given strain form a characteristic pattern of bands (the *fingerprint*).

Reproduced from *Bacteria* 5th edition, Figure 16.4(c), page 434, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

the comparison of strains. Second, no prior knowledge of the genome's sequence is required, so that, potentially, any isolate may be typed.

**arboricolous** Living/growing on trees.

**arboviruses** 'Arthropod-borne viruses': a non-taxonomic category of viruses which can replicate in both vertebrate hosts and arthropod vectors; arboviruses include e.g. members of the families ARENAVIRIDAE, BUNYAVIRIDAE, Reoviridae (ORBIVIRUS), Togaviridae (ALPHAVIRUS), and FLAVIVIRIDAE. [Vector competence of mosquitoes for arboviruses: ARE (1983) 28 229–262.]

**arbuscule** See MYCORRHIZA.

**ARC** (AIDS-related complex) See AIDS.

**Arcanobacterium** A genus of asporogenous bacteria (order ACTINOMYCETALES, wall type VI). In culture the organisms initially grow as irregular rods which may later become granular and segmented or may give rise to coryneform cells; growth occurs anaerobically or aerobically and is enhanced by blood or serum or by increased partial pressures of carbon dioxide. Growth is poor on tellurite media. Type species: *A. haemolyticum* (formerly *Corynebacterium haemolyticum* [JGM (1982) 128 1279–1281]).

**Arcella** A genus of testate amoebae (order ARCELLINIDA) in which the test is predominantly or entirely organic. In *A. vulgaris* the test is more or less spherical (ca. 30–100 µm diam.) and is typically somewhat translucent in young cells, often becoming

darker with age. The cell contains two nuclei. Slender lobopodia are extended through a ventral aperture and are used chiefly for feeding. A gas-filled vacuole may be formed in the cytoplasm and apparently aids in the orientation of the organism. *A. dentata* has a test bearing lateral spines, giving it a stellate appearance when viewed from above. *Arcella* spp occur among vegetation in ponds, in soil, etc.

**Arcellinida** An order of freshwater and soil amoebae (class LOBOSEA) in which the cell is surrounded by a TEST which may be primarily organic or primarily inorganic in composition, and which is perforated by a single aperture through which pseudopodia can be extended. The cells commonly contain two or more nuclei. Reproduction occurs asexually e.g. by binary fission. Genera include e.g. ARCELLA, *Centropyxis*, COCHLIPODIUM, DIFFLUGIA.

**Archaea** A DOMAIN of prokaryotic organisms which are evolutionarily distinct from members of the domain BACTERIA [see e.g. JB (1994) 176 1–6]. These organisms were formerly classified in the kingdom Archaeobacteria, being distinguished from other prokaryotes (kingdom Eubacteria) on the basis of e.g. nucleotide sequences in 16S rRNA; later, the distinction between these two groups of prokaryotes was deemed to be more fundamental than previously supposed, and each kingdom was elevated to the taxonomic rank of domain.

Many archaeans are associated with environments characterized by e.g. high temperatures or high salinity, and such organisms have been referred to as *extremophiles*. Nevertheless, some archaeans are found in 'moderate' environments such as soil [e.g. PNAS (1997) 94 277–282]. [Archaeal dominance in the mesopelagic zone of the Pacific Ocean: Nature (2001) 409 507–510.]

The domain Archaea has been divided into the kingdoms Euryarchaeota and Crenarchaeota. Euryarchaeota includes halophiles (e.g. HALOBACTERIUM) and METHANOGENS. Crenarchaeota includes 'sulphur-dependent' species such as DESULFUROCOCCUS and SULFOLOBUS.

Archaeans differ from bacteria in many ways. For example, gene expression (transcription and translation) appears to be closer to the eukaryotic pattern than the prokaryotic pattern [TIM (1998) 6 222–228]. The archaeal DNA-dependent RNA POLYMERASE resembles more closely the eukaryotic (nuclear) polymerase than the bacterial enzyme. Elongation factors in protein synthesis are (unlike their bacterial counterparts) sensitive to DIPHTHERIA TOXIN. [Assembly of the archaeal signal recognition particle from recombinant components: NAR (2000) 28 1365–1373.]

[Replication origin of archaeans: TIBS (2000) 25 521–523.]

At least some archaeal enzymes appear to have unique structures [TIM (1998) 6 307–314].

In some archaeans the cell wall may consist mainly or solely of an S LAYER (q.v.) closely associated with the cytoplasmic membrane. The cell wall in some species contains a peptidoglycan-like polymer, PSEUDOMUREIN (which is not cleaved by the enzyme LYSOZYME).

The cytoplasmic membrane contains lipids of a type which do not occur in species of Bacteria. In contrast to the ester-linked bacterial lipids, archaeal lipids are characteristically ether-linked molecules that contain e.g. isoprenoid or hydro-isoprenoid components. Certain archaeal and bacterial lipids are structurally analogous – e.g. the di-ether and di-ester lipids, both types of molecule having a single polar end. However, the archaeal lipids also include other types – such as tetra-*O*-di(biphytanyl) diglycerol – which contain two ether-linked glycerol residues,

one at *each* end of the molecule; such molecules, which have two polar ends, may span the width of the cytoplasmic membrane.

[Protein translocation across the archaeal cytoplasmic membrane: FEMS Reviews (2004) 28 3–24.]

The archaeal flagellum is markedly different in composition, structure and apparent mode of assembly from that found in bacteria. For example, the subunit, flagellin, is typically glycosylated, and it contains a *signal sequence* (see SIGNAL HYPOTHESIS) – suggesting passage into/through the cytoplasmic membrane (cf. bacterial flagellin, which passes through the hollow structures of the developing flagellum); this latter feature (as well as certain similarities between archaeal flagellins and bacterial type 4 fimbriae) suggests that archaeal flagella assemble from the *base* (in contrast to ‘tip growth’ in bacteria) [JB (1996) 178 5057–5065]. The archaeal flagellar filament is typically much thinner than the bacterial filament.

Various similar or analogous proteins have been found in archaeans and bacteria. For example, the archaeal RadA protein is apparently analogous to the RecA protein in bacteria [GD (1998) 12 1248–1253]. Again, an FtsZ protein occurs in members of both domains, suggesting that the cell division apparatus was similar in a common ancestor [Mol. Microbiol. (1996) 21 313–319]. [The CELL CYCLE in archaeans: Mol. Microbiol. (2003) 48 599–604.]

**archaeon** A member of the domain ARCHAEA. The term is also spelt ‘archaeon’.

**Archaeobacteria** A kingdom (now obsolete) which included all those prokaryotes not classified in the kingdom EUBACTERIA. [Phylogeny of the Archaeobacteria: SAAM (1985) 6 251–256.] Some archaeobacteria were placed in a separate taxon, Eocyta, on the basis of ribosomal characteristics [PNAS (1984) 81 3786–3790]. (See also EOCYTES.) Members of the Archaeobacteria are now included in the domain ARCHAEA.

**Archaeobacteria** A proposed class of prokaryotes (see MENDOSCUTES) corresponding to the (later) kingdom ARCHAEABACTERIA (now also obsolete).

**Archangium** See MYXOBACTERIALES.

**archicarp** In ascomycetes: the cell(s) which give rise to a fruiting body or to a part of it.

**archigregarines** See GREGARINASINA.

**Archobacter** A genus of Gram-negative, asporogenous bacteria of the family Campylobacteraceae. Cells: spiral rods with unsheathed flagella. Catalase +ve. Nitrate is reduced. Typically urease –ve. These organisms resemble *Campylobacter* spp but differ e.g. in their ability to grow in air at 15–25°C. *A. butzleri* and *A. cryophilus* have been isolated from patients with diarrhoea, including children in the developing countries; most strains do not hydrolyse hippurate but do hydrolyse indoxyl acetate.

**arcuate** Curved like a bow; arched.

**Arcyria** A genus of slime moulds (class MYXOMYCETES) which form stalked, globose to cylindrical sporangia; the peridium is evanescent, and the spores in masses may be yellow, pinkish, red, etc. *A. cinerea* is common on dead wood and humus.

**ARD** Acute respiratory disease: a general term for any such disease affecting closed populations of people (e.g. military recruits, school children). Major causal agents of ARDs are adenoviruses (usually Ad3, Ad4, Ad7, Ad14, or Ad21 – see MASTADENOVIRUS); an incubation period of ca. 5–7 days is followed by fever, chills, headache, malaise and coryza, but the disease is usually mild and self-limiting. A live vaccine, administered orally in enteric-coated capsules, is widely used for preventing adenoviral ARD in military recruits.

**arenaceous** Resembling or (referring e.g. to the test of DIFFLUGIA) incorporating or bearing grains of sand.

**Arenaviridae** (arenavirus group) A family of enveloped ssRNA viruses. One genus: *Arenavirus*; type species: lymphocytic choriomeningitis virus (LCMV). LCMV has a worldwide distribution; other arenaviruses are restricted to, and named after, particular geographical areas: Lassa virus, Mozambique (= Mopeia) virus (probable member), and the ‘New World’ arenaviruses (the Tacaribe complex) – Amapari (Brazil), Junín (Argentina), Latino and Machupo (Bolivia), Parana (Paraguay), Pichinde (Columbia), Tacaribe (Trinidad), and Tamiami (Florida, USA) viruses. In the natural host (usually a single rodent species) arenavirus infection is persistent and silent (see PERSISTENCE); transmission occurs vertically and horizontally, apparently without involving vectors. Only LCMV, Lassa, Junín and Machupo viruses cause significant human disease (see LASSA FEVER, LCM VIRUS, VIRAL HAEMORRHAGIC FEVERS).

The arenavirus virion is spherical or pleomorphic, diam. ca. 50–300 nm (average: 110–130 nm). It consists of a lipoprotein envelope enclosing a core of viral ribonucleoprotein (RNP) and several host ribosomes (each 20–25 nm diam.). The envelope is derived from the plasma membrane of the host cell and bears club-shaped, apparently hollow surface projections 5–10 nm long [JGV (1983) 64 2157–2167]. There are two types of viral ssRNA, designated L (31–34S, MWt 2.1–3.2 × 10<sup>6</sup>) and S (22–25S, MWt 1.1–1.6 × 10<sup>6</sup>); the viral RNAs are complexed with the major structural protein of the virion (N protein, ‘p63’) to form a filamentous RNP nucleocapsid which has a beaded appearance in the electron microscope and which forms non-covalently closed, supercoiled circles of various sizes [JGV (1983) 64 833–842]. The viral RNA is usually described as negative-sense, but certain viral proteins are apparently encoded by +ve-sense sequences in the genome – see AMBISENSE RNA; thus, e.g., the viral N protein is encoded by a sequence complementary to the 3′-half of the S RNA, while the viral glycoproteins are synthesized from a sequence corresponding to the 5′-half of the S RNA. A non-glycosylated protein with RNA-dependent RNA polymerase activity has been found in virions of Pichinde virus. Arenavirus virions can be inactivated by temperatures > 56°C, by pH < 5.5 or > 8.5, and by organic solvents or detergents.

Arenaviruses can replicate in a wide range of mammalian cell cultures (e.g. BHK-21, Vero and L cells). Virus replication occurs in the cell cytoplasm; the virus matures by budding through the plasma membrane, when ribosomes become incorporated in the virion.

**Arenavirus** See ARENAVIRIDAE.

**areolate** Divided up into small areas (areolae). (Used e.g. of a lichen thallus: see e.g. RHIZOCARPON.)

**arg-poly(asp)** *Syn.* CYANOPHYCIN.

**arg regulon** See ARGININE BIOSYNTHESIS.

**Argentinian haemorrhagic fever** A VIRAL HAEMORRHAGIC FEVER caused by the Junín virus (see ARENAVIRIDAE). Mortality: usually ca. 3–15%.

**argentophilic** Staining well with SILVER STAINS.

**L-arginine biosynthesis** See Appendix IV(a). In *Escherichia coli* the genes encoding enzymes for arginine biosynthesis constitute a REGULON (the *arg* regulon); four of the genes occur in a cluster (*argECBH*), the remainder occur singly at loci scattered around the chromosome. [Biosynthesis and metabolism of arginine in bacteria: MR (1986) 50 314–352.]

**arginine decarboxylase test** See DECARBOXYLASE TESTS.

**arginine deiminase** See ARGININE DIHYDROLASE.

## arginine dihydrolase

**arginine dihydrolase (ADH)** An enzyme system which catalyses the catabolism of arginine, with a concomitant substrate-level phosphorylation; the system occurs in a range of bacteria. (i) *Arginine deiminase* hydrolyses arginine to citrulline and ammonia. (ii) *Ornithine carbamoyltransferase* catalyses a phosphorylytic cleavage of citrulline to form carbamoyl phosphate and ornithine. (iii) *Carbamate kinase* transfers the phosphate group of carbamoyl phosphate to ADP to form ATP and carbamic acid, the latter dissociating spontaneously to CO<sub>2</sub> and NH<sub>3</sub>.

Tests for ADH production are widely used in the identification of certain bacteria (e.g. members of the ENTEROBACTERIACEAE). Typically, the organism is grown in a medium containing L-arginine and a pH indicator; the presence of ADH is indicated by an alkaline reaction after a few days' incubation. [Methods: Book ref. 2, pp. 411–412.]

**arg-poly(asp)** *Syn.* CYANOPHYCIN.

**argT gene** See BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM.

**Argyn** See SILVER.

**Argyrol** See SILVER.

**argyrome** *Syn.* SILVER LINE SYSTEM.

**argyrophilic** *Syn.* ARGENTOPHILIC.

**arildone** (4-[6-(2-chloro-4-methoxyphenoxy)-hexyl]-3,5-heptanedione) An ANTIVIRAL AGENT which is active against various DNA and RNA viruses *in vitro*; it blocks uncoating in polioviruses and apparently also in herpes simplex viruses. Arildone may be useful clinically e.g. in the topical treatment of HERPES SIMPLEX infections.

**Arizona** See SALMONELLA.

**arizonosis** A POULTRY DISEASE, caused by *Salmonella arizonae* (= *Arizona hinshawii*), characterized by malaise, diarrhoea, and often symptoms of CNS involvement.

**Arkansas bee virus** See NODAVIRIDAE.

**ArlS–ArlR** See TWO-COMPONENT REGULATORY SYSTEM.

**Armillaria** ('*Armillariella*') A genus of mainly lignicolous fungi (AGARICALES, Tricholomataceae). *A. mellea* (the 'honey fungus') grows saprotrophically on many types of wood, forms a symbiotic association with certain orchids (see MYCORRHIZA), and is parasitic on a range of deciduous and coniferous trees, on certain shrubs, and on some herbaceous plants. The fruiting body is highly variable in colour and appearance, the pileus being convex to flat (ca. 3–15 cm diam.), ochre to brown, with darker scales particularly near the centre; the upper part of the stipe, which often bears a wide annulus, is initially whitish, later reddish-brown. Basidiospores: ca. 8–9 × 5–6 μm. The fruiting bodies (which exhibit BIOLUMINESCENCE) typically occur in clusters. The organism spreads by means of tough, black RHIZOMORPHS ('boot laces') which may be found e.g. under the bark of infected trees or in soil. (See also CARBON DISULPHIDE and THREITOL.)

**Armillariella** See ARMILLARIA.

**armoured dinoflagellates** See DINOFLAGELLATES.

**aroA gene** See STAPHYLOCOCCUS (*S. aureus*).

**arogenate** See AROMATIC AMINO ACID BIOSYNTHESIS.

**aroH gene** See TRP OPERON.

**aroma bacteria** See DIACETYL.

**aromatic amino acid biosynthesis** Phenylalanine (Phe), tyrosine (Tyr) and tryptophan (Trp) are synthesized via the shikimate pathway: Appendix IV(f). Although most of the steps in this pathway are apparently more or less universal, the control mechanisms and physical organization of the enzymes (e.g. the formation of multienzyme complexes) vary between species and may be useful taxonomic criteria [CRM (1982) 9 227–252]. The reactions by which prephenate is converted to Phe and Tyr

also differ in different species. Thus, e.g., *Escherichia coli* and *Bacillus subtilis* synthesize Tyr via 4-hydroxyphenylpyruvate (HPP), and Phe via phenylpyruvate (PPy) [see Appendix IV(f)]. Certain cyanobacteria and 'coryneforms' (*Corynebacterium glutamicum*, *Brevibacterium* spp) synthesize Phe via PPy but lack prephenate dehydrogenase and synthesize Tyr via arogenate (= 'pretyrosine'). *Pseudomonas diminuta* synthesizes Phe via arogenate but Tyr via HPP, while *P. aeruginosa* can synthesize Phe and Tyr via PPy and HPP, respectively, and also via arogenate. *Euglena gracilis* synthesizes both Phe and Tyr via arogenate only.

(See also TRP OPERON.)

**aromatic hydrocarbons** See HYDROCARBONS.

**array (DNA)** See DNA CHIP.

**Arrhenatherum blue dwarf virus** See FIJIVIRUS.

**Arrhenius effect** See *staphylococcal α*-HAEMOLYSIS.

**Arrhenosphaera** See ASCOSPHAERALES.

**ARS** Autonomously replicating sequence: a DNA sequence (first described from the yeast *Saccharomyces cerevisiae*) which, when linked to a non-replicative DNA fragment, promotes the capacity for autonomous intracellular replication. ARSs occur in the yeast genome with a frequency of about one ARS for every ~40 kilobases. Efficient replication of ARS-containing DNA fragments may require other factors such as the CEN (centromere) element and the minichromosome maintenance protein 1.

Many of the ARSs appear to function as origins of replication, although some are so-called *silent origins*; some of the ARSs (both active and silent) are reported to act as transcription silencers.

Most of the studies on ARSs have been carried out on eukaryotes—particularly on yeasts (e.g. *Saccharomyces*, *Hansenula*). However, ARSs have also been reported in prokaryotes [see e.g. JB (2003) 185 5959–5966].

**arsenate respiration** See SELENATE RESPIRATION.

**arsenic** (a) (as an antimicrobial agent) The aromatic compounds of arsenic include some effective antimicrobial agents, some of which have found use in chemotherapy; however, some of these 'arsenicals' have been discontinued owing to toxicity.

The antimicrobial activity of arsenicals appears to involve their reaction with thiol (–SH) groups within cells—resulting e.g. in the inhibition of many enzymes; LIPOIC ACID is particularly sensitive because arsenic can bridge the two thiol groups in this coenzyme.

Apparently, pentavalent arsenic in an arsenical must be converted, *in vivo*, to the trivalent state before the arsenical can act as an antimicrobial agent.

The selective activity of arsenicals is believed to be due to differences in the permeability of different types of cell. Microorganisms can be protected from arsenicals by e.g. thiols, *p*-aminobenzoic acid or quinoid dyes.

*Atoxyl* (NH<sub>2</sub>.C<sub>6</sub>H<sub>4</sub>.As(OH)<sub>2</sub>O; *p*-aminophenylarsonic acid) was the first arsenical to be used against trypanosomiasis.

*Salvarsan* (3,3'-diamino-4,4'-dihydroxyarsenobenzene) was formerly used e.g. for the treatment of syphilis and trypanosomiasis; it is oxidized *in vivo* to produce the toxic agent: 3-amino-4-hydroxyphenylarsenoxide. This drug has now been superseded.

*Glycobiarsol* (bismuth *N*-glycolyl-*p*-arsanilate) has been used for treating amoebic dysentery.

*Tryparsamide* (*p*-*N*-phenylglycineamidoarsonic acid) has been used for late-stage trypanosomiasis (African trypanosomiasis: sleeping sickness). Note that arsenicals are not active against *Trypanosoma cruzi* (Chagas' disease).

*Melarsoprol* (a derivative of benzene arsenous acid – a trivalent arsenical) is effective against both West and East African strains of the causal agent of sleeping sickness (*Trypanosoma brucei gambiense* and *T. brucei rhodesiense*, respectively). The specific target of the drug is trypanothione ( $N^1, N^8$ -bis[glutathionyl]spermidine) [PNAS (1989) 86 2607–2611]. Melarsoprol reacts with trypanothione to form an adduct (Mel T) which inhibits trypanothione disulphide reductase – an enzyme essential for regulating the parasite's thiol/disulphide balance. Melarsoprol crosses the blood–brain barrier less readily than eflornithine, but it is still regarded as the most effective trypanocidal drug available for treating sleeping sickness [AP (1994) 33 1–47].

Trypanosomes exposed sub-lethally to arsenicals develop resistance quite readily, possibly owing to decreased uptake.

(b)(in energy metabolism) Some bacteria use arsenate (or selenate) as electron acceptor in anaerobic respiration, electron donors including e.g. acetate, lactate and ethanol (according to species); cell-envelope reductases have been found [FEMS Reviews (1999) 23 615–627]. Arsenite is used as electron donor in autotrophic CARBON DIOXIDE fixation and as a respiratory electron acceptor [FEMS Ecol. (2004) 48 15–27; JB (2004) 186 1614–1619].

**ART** Automated reagin test: a qualitative or quantitative STANDARD TEST FOR SYPHILIS similar in principle to the RPR TEST.

**arteannuin** *Syn.* QINGHAOSU.

**artefact** (artifact) Any feature which does not occur in a specimen under natural conditions, but which may be seen in that specimen during experimentation. Artefacts are due to the disturbance introduced by the process of experimentation or observation; they may occur e.g. as a result of FIXATION.

**artemether** See QINGHAOSU.

**artemisinin** *Syn.* QINGHAOSU.

**arteritis** Inflammation of an artery or arteries.

**Arterivirus** A genus of viruses (family TOGAVIRIDAE); the arterivirus group currently includes LACTATE DEHYDROGENASE VIRUS, SIMIAN HAEMORRHAGIC FEVER VIRUS, the 'Lelystad' virus (see BLUE-EARED PIG DISEASE) and *equine arteritis virus*.

In equines, equine arteritis virus causes necrosis of small arteries with various clinical manifestations – for example, rhinitis, oedema, enteritis, bronchopneumonia. Infection of pregnant mares commonly results in abortion. Transmission occurs both horizontally and vertically; vectors are unknown. The virus can infect a range of vertebrate cells *in vitro*.

The viruses in this group are similar in their morphology and genomic organization; moreover, all exhibit a predilection for macrophages, and all tend to cause a lengthy period of viraemia.

**artesanate** See QINGHAOSU.

**Arthonia** See ARTHONIALES.

**Arthoniales** An order of fungi of the ASCOMYCOTINA; members include crustose LICHENS (photobiont green, often trentepohlioid) and lichenicolous and saprotrophic fungi. Ascocarps are APOTHECIOID and may be lirelliform, irregular, etc; they contain paraphysoids. Asci are bitunicate, usually clavate. Genera: e.g. *Arthonia*.

**Arthopyrenia** A genus of crustose LICHENS of the order DOTHIDEALES; ascospores have one to several septa. *A. halodytes* (photobiont '*Hyella*') is a marine species which grows endolithically in calcareous rocks and on the shells of limpets, barnacles etc in the intertidal zone; it occurs in Europe and N. America.

**arthralgia** Joint pain.

**arthric conidium** See CONIDIUM.

**arthritis** Inflammation of one or more joints. It may occur as a symptom or complication of various infectious diseases – e.g.

brucellosis, gonorrhoea, Haverhill fever, Lyme disease, rickettsioses, syphilis, tuberculosis, yaws; it may also be caused by certain viruses – e.g., parvovirus [Lancet (1985) *i* 419–421, 422–425], Ross River virus, rubella virus. *Septic arthritis* is due to infection of the synovial fluid – commonly by staphylococci – e.g. secondarily to OSTEOMYELITIS in an adjacent bone, or as a complication of septicaemia; *S. epidermidis* may cause chronic septic arthritis of the hip following total hip replacement. (See also RHEUMATOID ARTHRITIS and REITER SYNDROME.)

**Arthroascus** A genus of fungi (family SACCHAROMYCETACEAE) which form yeast cells (which bud, often bipolarly, on a wide base) and true mycelium (which tends to break up into arthrospores). Asci are formed directly after conjugation between two cells. Non-fermentative;  $\text{NO}_3^-$  is not assimilated. Species: *A. javanensis*, isolated e.g. from soil, fruit, rotting wood. [Book ref. 100, pp. 114–116.]

**Arthrobacter** A genus of obligately aerobic, catalase-positive, asporogenous bacteria (order ACTINOMYCETALES, wall type VI – see also PEPTIDOGLYCAN) which occur in the soil. In culture the organisms initially grow as irregular, 'lumpy', pleomorphic rods, with or without primary branching, but stationary-phase cultures consist predominantly of spherical or ovoid cells; on subculture rod-shaped forms develop. Optimum growth temperature: ca. 25°C. *Arthrobacter* spp have an oxidative-type metabolism; they are not cellulolytic. GC%: ca. 59–66. Type species: *A. globiformis*.

**Arthrobotrys** A genus of fungi of the HYPHOMYCETES. Species can grow saprotrophically and can trap and digest nematodes (see NEMATOPHAGOUS FUNGI); *A. oligospora* can also attack and kill other fungi [FEMS Ecol. (1985) 31 283–291].

**arthroconidium** *Syn.* ARTHROSPORE.

**Arthrocytistis** See EIMERIORINA.

**Arthroderma** A genus of fungi of the GYMNOASCALES (anamorphs: CHRYSOSPORIUM; *Trichophyton*).

**arthrospore** (arthroconidium) (1) An *arthric* CONIDIUM. (2) Any CONIDIUM formed by *thallic* conidiogenesis.

**Arthuria** See UREDINIOMYCETES.

**Arthus reaction** A severe local inflammatory skin reaction which involves a TYPE III REACTION; the reaction becomes maximal 3–12 hours after the intradermal administration of antigen, and involves erythema, oedema, and local haemorrhage and necrosis.

**Arthus-type reaction** Any disorder, other than the classical ARTHUS REACTION, which involves a TYPE III REACTION – see e.g. FARMERS' LUNG and GLOMERULONEPHRITIS.

**artichoke curly dwarf virus** See POTEXVIRUSES.

**artichoke mottled crinkle virus** See TOMBUSVIRUSES.

**artifact** *Syn.* ARTEFACT.

**Artogeia rapae** GV See BACULOVIRIDAE.

**ARV** See HIV.

**arylsulphatase** An enzyme which can hydrolyse aromatic sulphate esters at the O–S bond; arylsulphatases occur e.g. in some *Aspergillus* and *Mycobacterium* spp.

**arylsulphatase test** A test used in the identification of *Mycobacterium* spp. Essentially, the test strain is grown in a liquid medium containing tripotassium phenolphthalein disulphate (TPD); ARYLSULPHATASE-*positive* strains cleave TPD to PHENOL-PHTHALEIN which is detected by a colour change on addition of alkali after 10 days (for slow-growing strains) or after 3 or 7 days (for rapidly-growing strains).

**ascarylose** 3,6-Dideoxy- $\beta$ -L-mannopyranose: a sugar found e.g. in the LIPOPOLYSACCHARIDE of certain strains of *Yersinia pseudotuberculosis* (and in the eggs of *Ascaris* worms).

**Ascetospora** A phylum of PROTOZOA [JP (1980) 27 37–58] which form spores containing one or more sporoplasms but

## Aschaffenburg–Mullen phosphatase test

no extrusion apparatus (no polar capsules or polar filaments). (cf. MICROSPORA; MYXOZOA.) The organisms are parasitic in invertebrates. Classes: PARAMYXEA and STELLATOSPOREA.

**Aschaffenburg–Mullen phosphatase test** *Syn.* PHOSPHATASE TEST (for milk).

**Aschersonia** A genus of fungi (order SPHAEROPSIDALES) which include parasites of scale insects and whiteflies. Strains of *Aschersonia* have been used e.g. in Florida for the biological control of scale insects.

**asci** See ASCUS.

**ascigerous** Bearing, or giving rise to, asci (see ASCUS).

**ascites** The condition in which fluid (ascitic fluid) accumulates in the peritoneal cavity during certain pathological conditions. (See also INFECTIOUS DROPSY (of carp).)

**Ascobolus** See PEZIZALES.

**ascocarp** (ascoma) A structure at the surface of which, or within which, asci (see ASCUS) develop; the main forms of ascocarp are the APOTHECIUM, ASCOSTROMA, CLEISTOTHECIUM and PERITHECIUM. (Ascocarps are not produced e.g. by *Saccharomyces* spp and related yeasts.)

In *ascohymental* species ascocarp development appears to follow the sexual stimulus, i.e., plasmogamy (fertilization) precedes ascocarp development; in *ascolocular* species the initiation of ascocarp development (i.e., formation of a stroma) occurs before plasmogamy. In general, ascohymental species form unitunicate asci, and ascolocular species form bitunicate asci.

**Ascochyta** A genus of fungi of the order SPHAEROPSIDALES; *A. pisi* is the causal agent of leaf spot disease of the pea plant. Conidiophores are borne in dark, thick-walled, non-setose, unilocular, ostiolate pycnidia that are immersed in the host tissue.

**Ascocoryne** See HELOTIALES.

**ascogenous** ASCUS-forming.

**ascogone** *Syn.* ASCOGONIUM.

**ascogonium** (ascogone) In ascomycetes: the female GAMETANGIUM; it may be unicellular or multicellular, simple or complex in form, and it may or may not bear a TRICHOGYNE (according to species).

**ascohymental** See ASCOCARP.

**Ascoideaceae** See ENDOMYCETALES.

**ascolichen** An ascomycetous LICHEN.

**Ascoli's thermoprecipitin test** A serological PRECIPITIN TEST used to detect antigens of *Bacillus anthracis* (causal agent of ANTHRAX) in various animal products (e.g. hides). The material is extracted with e.g. boiling saline, and the extract is layered over a known positive antiserum in a RING TEST.

**ascolocular** See ASCOCARP.

**ascoma** *Syn.* ASCOCARP.

**ascomycetes** Fungi of the subdivision ASCOMYCOTINA. (In some taxonomic schemes these fungi form the class Ascomycetes.)

**Ascomycotina** (the 'ascomycetes') A subdivision of fungi (division EUMYCOTA) characterized by the formation of sexually derived spores (ASCOSPORES) in *asci* (see ASCUS). The ascomycetes are typically terrestrial saprotrophs or parasites; they include e.g. most YEASTS, the edible morels and TRUFFLES, the cup fungi, the POWDERY MILDEWS, BLACK MILDEWS and SOOTY MOULDS, and organisms which are better known in their asexual ('deuteromycete') states: the common 'blue moulds' and 'green moulds'. Marine ascomycetes include members of the SPATHULOSPORALES.

In most species the thallus is a well-developed, septate, branching mycelium in which the CELL WALL contains CHITIN (see also SEPTUM); however, some ascomycetes are unicellular organisms, and some are DIMORPHIC FUNGI.

In the *typical* life cycle, the germination of an ascospore leads to the development of a septate mycelium consisting of uninucleate, haploid cells. Many (but not all) ascomycetes then exhibit a conidial (= asexual, imperfect or anamorphic) phase in which conidia (see CONIDIUM) are formed; although the anamorph is part of the HOLOMORPH, anamorphs are commonly (for convenience) classified in the DEUTEROMYCOTINA. At some stage the thallus enters DIKARYOPHASE – e.g. by GAMETANGIAL CONTACT, SOMATOGAMY or SPERMATIZATION. Subsequently, karyogamy and MEIOSIS occur in the developing ASCOCARP – which commonly gives rise to asci which each contain 8 (haploid) ascospores. In the typical life cycle diplophase is thus of limited duration; however, in some ascomycetes (e.g. many yeasts) diplophase is dominant – plasmogamy and karyogamy quickly following ascospore formation, so that the vegetative cells are commonly diploid.

In some taxonomic schemes [see e.g. Book ref. 64] classes are not recognized; instead, the ascomycetes are divided into 37 orders: ARTHONIALES; ASCOSPHAERALES; CALICIALES; CLAVICIPITIALES; Coryneliales; Cytariales; DIAPORTHALES; Diatrypales; DOTHIDEALES; ELAPHOMYCETALES; ENDOMYCETALES; ERYSIPIHALES; EUROTIALES; GRAPHIDIALES; GYALECTALES; GYMNOASCALES; HELOTIALES; HYPOCREALES; LABOULBENIALES; LECANIDIALES; LECANORALES; MICROASCALES; OPEGRAPHALES; OPHIOSTOMATALES; OSTROPALES; PELTIGERALES; PERTUSARIALES; PEZIZALES; POLYSTIGMATALES; PYRENULALES; RHYTISMATALES; SORDARIALES; SPATHULOSPORALES; SPHAERIALES; TAPHRINALES; TELOSCHISTALES; VERRUCARIALES.

**Ascophyllum** See PHAEOPHYTA.

**L-ascorbic acid** (vitamin C; L-threo-2,3,4,5,6-pentahydroxy-2-hexenoic acid-4-lactone) A VITAMIN, essential to man but not normally to microorganisms, found e.g. in fresh fruit and vegetables; it can be synthesized e.g. by certain algae and strains of *Aspergillus niger*. It is a strong reducing agent (oxidized form = dehydroascorbic acid) used e.g. as a poisoning agent in media for anaerobes (see REDOX POTENTIAL). Commercial manufacture (the Reichstein process) involves the hydrogenation of glucose to D-sorbitol followed by the SORBOSE FERMENTATION; L-sorbose is converted chemically to ascorbic acid.

**Ascoseira** See PHAEOPHYTA.

**Ascospaera** See ASCOSPHAERALES.

**Ascospaerales** An order of fungi (subdivision ASCOMYCOTINA) which are associated with bees and pollen. Genera: *Ascospaera* (see CHALKBROOD), *Arrhenosphaera* and BETTSIA.

**ascospore** A SPORE formed within an ASCUS. According to species, ascospores may be septate or aseptate, and may be any of a variety of shapes, sizes and colours. On germination, the ascospores of most species form germ tube(s), while those of yeasts characteristically give rise to budding cells.

*Ascospore discharge.* In most ascomycetes the ascospores are forcibly ejected from the ascus; forcible ejection can occur either from a UNITUNICATE ASCUS or from a BITUNICATE ASCUS. The mechanism of ascospore ejection appears to be unknown; however, ejection probably depends on the development of pressure within the ascus by the absorption of water – e.g. as a result of the enzymic breakdown of a polysaccharide with consequent increase in osmotic pressure. Different mechanisms may be involved in different ascomycetes.

In apothecial ascomycetes ('discomycetes') the ascospores are often released simultaneously by a large proportion of the asci; this results in a visible cloud of ascospores and is called *puffing*.

In cleistothecial ascomycetes the mature asci appear to swell up and rupture the cleistothecial wall. In some species the

protruding (or totally freed) asci release their ascospores by violent disintegration.

In perithecial ascomycetes various strategies have evolved to ensure that the ascospores do not remain trapped within the perithecium. Thus, e.g. in *Sordaria fimicola* each of the hymenial asci, in turn, elongates, discharges its ascospores, and collapses. In ascomycetes which form long-necked perithecia the asci may become detached from the hymenium and are subsequently blown through the ostiole as a result of pressure in the perithecial cavity; however, in species of *Ceratocystis* the asci are evanescent, and the mature ascospores are slowly extruded in a slimy mass through the perithecial neck.

In the ascostromal ascomycete *Myriangium*, ascospore discharge is necessarily preceded by disintegration of the stroma – which occurs as a result of weathering. Once exposed to the environment the (bitunicate) asci forcibly eject their ascospores.

In e.g. *Tuber* spp (and other hypogean ascomycetes) the ascospores are not forcibly discharged. In such species ascospore dispersal is mediated e.g. by burrowing animals.

Ascospore discharge can be strongly influenced by environmental conditions (e.g. light, humidity), and a distinct periodicity of spore discharge ('endogenous rhythm') has been detected in a number of species. In ascomycetes which form deeply concave (cupulate) apothecia the asci are commonly positively phototropic; asci which line the near-vertical walls of the apothecium thus direct their spores outwards (into the environment) rather than towards the opposite wall of the apothecium. In some fungi, e.g. *Daldinia concentrica*, ascospore discharge occurs mainly or exclusively in the dark.

**ascostroma** An ASCOCARP consisting of a STROMA (sense 1) containing one or more cavities (*locules*), each locule containing one or more asci (see ASCUS). In each locule the CENTRUM is bounded only by the stromatic tissue; this contrasts with the ascocarp structure of those ascomycetes (e.g. *Xylaria* spp) which form perithecia immersed in a stroma: in such species a distinct perithecial wall occurs within the locule. A uniloculate ascostroma (i.e., one containing a single locule) may contain a hymenial layer of asci, and may thus resemble a perithecium; such a structure is referred to as a *perithecioid pseudothecium* or *pseudoperithecium*. (In e.g. *Rhytidhysterion* the hymenium forms an apothecium-like structure which is called an *apothecioid pseudothecium*.) In some ascomycetes (e.g. *Myriangium*) the asci develop in uniascal locules which are scattered irregularly in the stroma. An ascostroma may develop on the surface of, or within, the substratum.

**Ascotricha** See SPHAERIALES.

**ascus** (*pl.* asci) A microscopic, sac-like structure within which are formed the sexually derived (or, exceptionally, parthenogenically derived) spores (ASCOSPORES) of fungi of the subdivision ASCOMYCOTINA. Asci are commonly cylindrical or clavate, but can be e.g. cup-shaped, globose or dumb-bell-shaped, according to species; a mature ascus typically contains eight ascospores, but in some species it contains e.g. two or four ascospores, or (in e.g. *Kluyveromyces* and *Lipomyces*) more than eight ascospores. Asci may be formed within or at the surface of an ASCOCARP, and may occur singly, in groups, or in a closely packed layer (*hymenium*) which, according to species, may be interspersed with sterile structures (see e.g. PARAPHYSIS). In some species the asci are evanescent (see also PROTUNICATE ASCUS).

Ascus formation is usually preceded by plasmogamy – which, depending on species, may be GAMETANGIAL CONTACT, GAMETANGIAL COPULATION, SOMATOGAMY or SPERMATIZATION. Many ascomycetes exhibit HETEROTHALLISM. (See also MATING TYPE.)

Following plasmogamy, the events leading to ascus formation vary according to species.

*Ascus formation in ascogenous yeasts.* After plasmogamy (which may occur e.g. by the fusion of somatic cells or ascospores), karyogamy commonly follows without delay. The zygote may undergo MEIOSIS immediately (as e.g. in *Schizosaccharomyces octosporus*) so that the ascus develops directly from the zygote; alternatively, meiosis may be delayed for one or more mitotic divisions (e.g. as in the diploid budding phase of *Saccharomyces cerevisiae*) – in which case the ascus develops following meiosis in one of the diploid descendants of the zygote. Following meiosis, the four (haploid) nuclei may develop directly into four ascospores (as in e.g. *S. cerevisiae*) or there may be subsequent mitotic division with the eventual formation of e.g. eight ascospores (as in e.g. *S. octosporus*). The process by which a nucleus gives rise to an ascospore is called *free cell formation* (see below).

*Ascus formation in other ascomycetes.* (The following is necessarily a *generalized* account since details of the process vary from species to species.) After plasmogamy, karyogamy is typically delayed. One or more hyphae (*ascogenous hyphae*) arise from the ASCOGONIUM, and the (haploid) male and female nuclei migrate into these hyphae. The tip of each hypha then curves to form a crook (*crozier*) such that two nuclei (one from each parent) occur in the curved upper portion of the crozier. These nuclei then undergo mitosis, simultaneously, with their mitotic spindles arranged parallel to the long axis of the ascogenous hypha; the subsequent formation of a septum creates an apical cell (the *ascus mother cell*) which contains one daughter nucleus from each of the two original nuclei. Karyogamy now occurs. The zygote undergoes meiosis followed by one or more mitotic divisions to produce the number of haploid nuclei (ascospore initials) characteristic of the species. The ascospores develop by *free cell formation*. In this process, each nucleus (with a portion of cytoplasm) becomes enclosed within an envelope (the spore-delimiting membrane, SDM) composed of two unit-type membranes. In some ascomycetes (e.g. many members of the Endomycetales) the nucleus may be enveloped directly by vesicles (derived from the GOLGI APPARATUS or Golgi-equivalent?) which develop in association with the SPINDLE POLE BODY. In other species, e.g., *Taphrina deformans* and some species of *Tuber*, each nucleus becomes enveloped by membrane derived from invaginations of the ascus plasma membrane. However, in most 'euascomycetes' the SDMs derive from a system of nuclear and/or endoplasmic reticular membranes which, initially, form a discontinuous layer around the periphery of the ascus cytoplasm (the *peripheral membrane cylinder*). That portion of the ascus cytoplasm which is *not* incorporated into ascospores is termed the *epiplasm*. Ascospore wall material is subsequently laid down between the two layers of the SDM. [Ascospore development: Book ref. 175, pp. 107–129.]

*Types of ascus.* There are at least nine morphologically and/or functionally distinct types of ascus [Bot. J. Lin. Soc. (1981) 82 15–34 (29–33)]; see e.g. ANNELATE ASCUS, BITUNICATE ASCUS, OPERCULATE ASCUS, OSTROPALEAN ASCUS and PROTUNICATE ASCUS. (See also UNITUNICATE ASCUS and BILABIATE.)

**ascus mother cell** See ASCUS.

**Asellariales** See TRICHOMYCETES.

**asepsis** (1) The state in which potentially harmful microorganisms (e.g. pathogens in a medical context, spoilage organisms in an industrial context) are absent from particular tissues, materials or environments; in this sense asepsis does not necessarily

## aseptate

involve sterility (cf. STERILE (sense 1)). (2) A state of sterility. (See also ANTISEPSIS and STERILIZATION.)

**aseptate** Lacking septa – see SEPTUM.

**aseptic** (*adj.*) Refers to ASEPSIS (sense 1 or 2).

**aseptic meningitis** See MENINGITIS (b).

**aseptic technique** Precautionary measures taken to prevent the contamination of cultures, sterile media etc and/or the infection of persons, animals or plants by extraneous microorganisms. Thus, e.g. all vessels for media etc must initially be STERILE (pre-sterilized disposable petri dishes, syringes etc are often used). The working surfaces of instruments (forceps, LOOPS etc), and the rims of bottles used for dispensing sterile (non-flammable) materials, are sterilized by FLAMING. Before use, sterile material should not be exposed to non-sterile material or conditions. The risk of contamination is reduced by treating bench surfaces etc with DISINFECTANTS and/or with ultraviolet radiation (see STERILIZATION). Procedures (e.g. INOCULATION) are carried out in such a way that exposure to the atmosphere is reduced to a minimum, or is eliminated (see e.g. SAFETY CABINET).

**Ashbya** See METSCHNIKOWIACEAE and STIGMATOMYCOSIS; see also RIBOFLAVIN.

**AsiA** See ANTI-SIGMA FACTOR.

**Asian flu** See INFLUENZAVIRUS.

**Asiatic cholera** *Syn.* CHOLERA.

**ASLT** ANTISTREPTOLYSIN O TEST.

**ASO test** ANTISTREPTOLYSIN O TEST.

**ASOT** ANTISTREPTOLYSIN O TEST.

**L-asparaginase** (L-asparagine aminohydrolase; EC 3.5.1.1) An enzyme which hydrolyses L-asparagine to L-aspartate and NH<sub>3</sub>. L-Asparaginase (e.g. from *Escherichia coli* or *Citrobacter* sp) is used as an anticancer agent – e.g. for treating acute lymphocytic leukaemia in which the cancer cells require exogenous asparagine. (See also ENZYMES.)

**L-asparagine biosynthesis** See Appendix IV(d).

**asparenomycins** CARBAPENEM antibiotics.

**aspartame** L-Aspartyl-L-phenylalanine methyl ester; it is used as a sweetener in certain foods and beverages.

**aspartase** See ASPARTATE BIOSYNTHESIS.

**aspartate ammonia-lyase** See ASPARTATE BIOSYNTHESIS.

**L-aspartate biosynthesis** For the main pathway of aspartate biosynthesis see Appendix IV(d). In many microorganisms, aspartate can also be produced from fumarate and ammonia by the enzyme *aspartase* (L-aspartate ammonia-lyase, EC 4.3.1.1), but this (reversible) reaction is probably more important in the deamination of aspartate than in its synthesis. (cf. IMMOBILIZATION sense 1.)

**aspartokinase** See Appendix IV(d).

**aspergillic acid** An antibiotic (a pyrazine derivative) formed by *Aspergillus flavus*.

**aspergilloma** See ASPERGILLOSIS.

**aspergilliosis** Any disease of man or animals in which the causal agent is a species of ASPERGILLUS.

In man, the causal agent is usually *A. fumigatus*, although *A. flavus*, *A. niger* or *A. terreus* may be involved. Infection usually occurs by inhalation of air-borne conidia, but may occur via wounds or by ingestion. The disease may be non-invasive, the fungus colonizing a pre-existing lung cavity (e.g. a lung cyst or healed tuberculosis lesion) and forming compact mycelial masses called *aspergillomas* (cf. MYCETOMA sense 2); symptoms may be absent or may include chronic productive cough and haemoptysis. Less commonly, the disease may become invasive, disseminating to other organs (particularly in immunocompromised patients); this form is commonly fatal.

In some (atopic) individuals inhalation of *Aspergillus* conidia can lead to allergic bronchopulmonary aspergillosis ('extrinsic bronchial asthma'); the conidia may germinate in the bronchi and sputum plugs, but the hyphae do not normally invade the tissues. Other forms of aspergillosis include e.g. infections of the ear or paranasal sinuses. *Lab. diagnosis:* cultural or microscopical (or histological) examination of e.g. biopsy material; *repeated* isolation of *Aspergillus* (e.g. from sputum) is presumptive evidence of infection. In some forms of aspergillosis specific antibodies may be demonstrated by gel diffusion techniques.

Aspergillosis can affect a wide range of animals, causing e.g. pneumonia, gastroenteritis (e.g. in calves), or placentitis leading to abortion (e.g. in cattle, sheep and horses). Birds (including poultry) are particularly susceptible; almost any organ can be affected, and the disease may be acute and (usually) fatal (as in 'brooder pneumonia' of baby chicks) or chronic (in adult birds). (See also AFLATOXINS.)

**Aspergillus** A genus of fungi of the class HYPHOMYCETES: some species are known to have ascomycetous teleomorphs (see later). The organisms are widespread in nature, and are characteristically saprotrophic; they can use a wide range of substrates as nutrients. Some species can be pathogenic (see e.g. ASPERGILLOSIS, MADUROMYCOSIS, STONEBROOD), and many produce toxins (see e.g. AFLATOXINS, ASTELTOXIN, CYCLOPIAZONIC ACID, FESCUE FOOT, GLIOTOXIN, OCHRATOXINS, PATULIN, STERIGMATOCYSTIN). Some species can cause deterioration in various types of material (see e.g. BREAD SPOILAGE, CHEESE SPOILAGE, COAL BIODEGRADATION, GLASS, LEATHER SPOILAGE, PAINT SPOILAGE, PAPER SPOILAGE, PETROLEUM), while certain species are used in the manufacture of particular enzymes, foods or other commodities (see e.g. AMYLASES, BRINASE, CATALASE, CITRIC ACID, COFFEE, GLUCOSE OXIDASE, HAMANATTO, KOJI, MISO, PECTIC ENZYMES, SAKE, TAKADIASTASE).

*Aspergillus* spp form a well-developed, septate mycelium. (See also NIGERAN and PSEUDONIGERAN.) Each conidiophore, which develops from a FOOT CELL (sense 2), consists of an erect hypha which has a more or less spherical terminal swelling (the *ampulla* or *vesicle*). In some species the ampulla is partly or completely covered by a layer of *phialides* ('primary sterigmata') – see CONIDIUM; in most species, however, the ampulla is covered by a layer of short, finger-like extensions ('primary sterigmata' or *metulae*) which give rise to the phialides ('secondary sterigmata') at their distal ends. Each phialide produces a basipetally formed chain of spherical, pigmented, aseptate conidia which, according to species, may be e.g. yellow, green or black. (Spore colour can also vary according to available trace elements in the medium; thus, e.g. *A. niger* may form yellow (instead of the normal black) conidia if levels of copper are low.) The ampulla, together with its metulae and/or phialides and associated chains of conidia, is called a *conidial head*. A PARASEXUAL PROCESS occurs e.g. in *A. nidulans*.

Species include e.g. *A. flavus*, *A. fumigatus*, *A. glaucus* (teleomorph: EUROTIIUM), *A. nidulans* (teleomorph: EMERICELLA), *A. niger*, *A. oryzae*, *A. parasiticus*, *A. phialiseptus*, *A. terreus* and *A. versicolor*.

*A. fumigatus* (teleomorph: SARTORYA) is a major cause of aspergillosis in man. In the conidial head, the ampulla may appear domed (rather than spherical) owing to the gradual widening of the distal end of the conidiophore, and it bears a layer of phialides over the distal half to three-quarters of its surface; the proximally situated phialides are longer, and are inclined such that their free ends tend to be parallel with the more distal phialides – the chains of grey-green, spherical conidia thus

forming a parallel-sided columnar spore mass which may reach ca. 1 mm in length. *A. fumigatus* has been reported to grow at 50°C. (See also FUMAGILLIN.)

*A. phialiseptus* is morphologically similar to *A. fumigatus*, but it forms septate phialides which are longer than those of *A. fumigatus*.

**Aspidisca** A genus of ciliate protozoa (order HYPOTRICHIDA) related to *Euplotes* but differing e.g. in typically having a relatively reduced oral ciliature; species occur in freshwater and marine habitats, and e.g. in some SEWAGE TREATMENT plants.

**aspirin** See PROSTAGLANDINS.

**asporogenous** Not capable of forming spores.

**assay host** (*plant virol.*) *Syn.* LOCAL LESION host.

**assimilatory nitrate reduction** The (typically aerobic) reduction of nitrate to ammonia, the ammonia being assimilated as a source of nitrogen (see AMMONIA ASSIMILATION); nitrate can be used as the sole source of nitrogen by many bacteria, various fungi, and most algae and plants. Nitrate is initially reduced to nitrite – typically by a soluble, oxygen-insensitive enzyme (*assimilatory nitrate reductase*) in a reaction in which the electron donor may be a reduced pyridine nucleotide or a reduced ferredoxin; in fungi the electron donor is often (sometimes specifically) NADPH, but in e.g. *Candida nitratophila* it can be either NADH or NADPH [JGM (1986) 132 1997–2003]. The assimilatory reduction of nitrate to nitrite does not generate proton motive force – cf. DISSIMILATORY NITRATE REDUCTION. Nitrite is reduced to ammonia by an *assimilatory nitrite reductase*, reducing power being derived (according to organism) from NADPH, NADH or reduced ferredoxin – commonly the latter in algae and higher plants. The synthesis/activity of enzymes involved in assimilatory nitrate reduction is regulated at least partly by the extracellular concentrations of ammonia and nitrate.

**assimilatory sulphate reduction** Sulphate can be used as the sole source of sulphur by most microorganisms. The major assimilatory pathway in bacteria and fungi is shown in the figure. (cf. DISSIMILATORY SULPHATE REDUCTION; see also SULPHUR CYCLE.)

**Astasia** See EUGLENOID FLAGELLATES.

**astaxanthin** See PHAFFIA.

**asteltoxin** A polyene MYCOTOXIN isolated from toxic maize meal cultures of *Aspergillus stellatus* (= *A. variegator*, *Emericella variegator*). In experimental animals asteltoxin can cause e.g. paralysis of hind-limbs and respiratory impairment.

**aster** (*cell biol.*) See MITOSIS.

**aster yellows** See YELLOWES.

**Asterionella** A genus of freshwater and marine planktonic pennate DIATOMS. *A. formosa* occurs e.g. in lakes and reservoirs, forming blooms in spring and, to a lesser extent, in autumn. In this and other species each individual vegetative cell is long and narrow with slightly flared ends; a variable number of cells (ca. 8 under optimum conditions) form a star-shaped colony in which each corner of one end of a given cell is joined to one corner of a neighbouring cell.

**Asticcacaulis** A genus of chemoorganotrophic, strictly aerobic PROSTHECATE BACTERIA; habitat and life-cycle are similar to those of CAULOBACTER, but one or more prosthecae arise subpolarly and/or laterally and do not have an adhesive role – adhesive material occurring on the cell surface.

**Astomatida** An order of protozoa (subclass HYMENOSTOMATIA) in which the cells are typically large or long, are uniformly ciliated, contain a number of contractile vacuoles, lack a cytoproct, and are invariably mouthless; some species have an elaborate holdfast organelle. Asexual reproduction may involve budding

ASSIMILATORY SULPHATE REDUCTION in bacteria and fungi. APS = adenosine-5'-phosphosulphate (see APS); PAPS = 3'-phosphoadenosine-5'-phosphosulphate; PAP = 3'-phosphoadenosine-5'-phosphate. The pathway for the assimilation of sulphide depends on organism. In e.g. *Escherichia coli* sulphide is incorporated into O-acetylserine to form cysteine [Appendix IV(c)]. In e.g. *Yarrowia* (*Saccharomycopsis*) *lipolytica* sulphide may be incorporated into O-acetylserine (to form cysteine) or into O-acetylhomoserine to form homocysteine; homocysteine may be converted to methionine [Appendix IV(d)] or (via cystathionine) to cysteine [see e.g. MGG (1979) 174 33–38].

and (in e.g. *Intoshellina*) the formation of chain-like colonies. The organisms are endoparasites of e.g. annelids, molluscs and amphibians in freshwater and marine habitats. Genera include e.g. *Anoplophrya*, *Cepedietta*, *Jirovecella*, and *Radiophrya*.

**astomatous** Refers to any structure or cell which does not have a pore, opening, or mouth.

**astome** A member of the ASTOMATIDA.

**Astracantha** See RADIOLARIA.

**Astraeus** See SCLERODERMATALES.

**Astrephomene** A genus of VOLVOX-like green algae which form spherical coenobia of 16–128 cells.

## Astrolophus

**Astrolophus** See ACANTHAREA.

**astropyle** See RADIOLARIA.

**astroviruses** Spherical, ether-resistant viruses, 29–30 nm diam., which have a characteristic five- or six-pointed star-shaped surface pattern. Astroviruses have been observed in normal and diarrhoeic faeces and may cause gastroenteritis in infants, calves, lambs and piglets. Lamb astrovirus apparently contains ssRNA [JGV (1981) 53 47–55].

**ASW** Artificial seawater. [Recipes: Book ref. 2, p. 436.]

**asymmetric PCR** A variant form of PCR in which one of the two types of primer in the reaction mixture is used at a much lower concentration (e.g. 1:50) – so that this primer will be used up quickly when cycling begins; a normal concentration of the other primer ensures that *one* strand of the amplicon will be significantly amplified. Asymmetric PCR can be used for preparing single-stranded DNA products suitable e.g. for DNA SEQUENCING.

An alternative procedure for obtaining ssDNA products from PCR involves tagging *one* of the two types of primer with BIOTIN, both primers being used at normal concentrations [NAR (1996) 24 3645–3646]. After cycling, STREPTAVIDIN is added to the reaction mixture; streptavidin binds to the biotinylated products, i.e. it binds to one of the two types of ssDNA product (but not to the complementary product). Gel electrophoresis in a *denaturing* gel (which inhibits hybridization between the complementary ssDNA products) separates the two types of product because the electrophoretic mobility of the streptavidin-bound product is greatly reduced. If a *particular* product strand is required, the primer which forms the other strand is biotinylated.

**asymmetric unit membrane** See UROPLAKIN.

**asymptomatic** Without symptoms.

**AT type** See BASE RATIO.

**ATCC** American Type Culture Collection, 12301 Parklawn Drive, Rockville, Maryland 20852, USA.

**ateline herpesvirus** See e.g. GAMMAHERPESVIRINAE ('*Herpesvirus ateles*').

**Athalamida** See GRANULORETICULOSEA.

**atherosclerosis** See MAREK'S DISEASE.

**Athiorhodaceae** See RHODOSPIRILLACEAE.

**athlete's foot** (tinea pedis) RINGWORM of the foot, characterized by itching (often with cracking and scaling) of the skin – particularly that between the toes. Causal agents: usually *Epidermophyton floccosum* or *Trichophyton* spp; *Candida albicans* (see CANDIDIASIS) can cause a similar condition.

**athymic** Lacking a thymus.

**Atkinsiella** A genus of fungi (order SAPROLEGNIALES) which include organisms parasitic on e.g. the eggs of marine crustacea. Species include *A. dubia*, *A. entomophaga* and *A. hamanaensis* [Book ref. 1, pp. 201–202].

**ATL** ADULT T-CELL LEUKAEMIA.

**Atmungsferment** Cytochrome *aa*<sub>3</sub>.

**atomic mass unit** (AMU; u) A unit of atomic mass: one-twelfth of the mass of a neutral <sup>12</sup>C atom; it is ca. 1.6605655 × 10<sup>-24</sup> gram. (cf. DALTON; RELATIVE MOLECULAR MASS.)

**Atopobium** A genus of asporogenous, obligately anaerobic, catalase-negative Gram-positive bacteria; cells: short rods or cocci which occur singly, in pairs or short chains. Non-motile. Glucose is metabolized to lactic, acetic and formic acids. *A. parvulus* was formerly classified as *Streptococcus parvulus*.

GC%: 35–46. Type species: *A. minutum*.

[Proposal for the genus *Atopobium*: FEMS (1992) 95 235–240.]

**atopy** An inherited tendency to develop immunological HYPERSENSITIVITY states.

**atovaquone** See MALARIA.

**Atoxoplasma** A genus of protozoa (suborder EIMERIORINA) similar to LANKESTERELLA but parasitic in birds. [Book ref. 18, p.13.]

**atoxyl** See ARSENIC.

**ATP** Adenosine 5'-triphosphate (see figure). (See also NUCLEOTIDE.) In both prokaryotic and eukaryotic cells ATP actively participates in a range of processes and reactions which involve the conversion or expenditure of energy (see also ATPASE); energy derived from chemotrophic or phototrophic metabolism holds the mass-action ratio of the reaction (ATP ↔ ADP + Pi) at values such that ATP hydrolysis is thermodynamically highly favourable, i.e., it can yield free energy which the cell can use for specific purposes. (See also ADENYLATE ENERGY CHARGE.)

ATP (adenosine 5'-triphosphate)

The phosphorylation of ADP to ATP commonly occurs by OXIDATIVE PHOSPHORYLATION, photophosphorylation or SUBSTRATE-LEVEL PHOSPHORYLATION; in some organisms PYROPHOSPHATE hydrolysis by a PROTON PMPASE can be coupled to ADP phosphorylation via proton motive force (see CHEMIOSMOSIS).

In some energy-requiring reactions nucleotides other than ATP may be used; thus, e.g., guanosine 5'-triphosphate (GTP) is involved in certain stages in PROTEIN SYNTHESIS.

Small amounts of ATP can be detected e.g. by techniques which involve CHEMILUMINESCENCE.

**ATP-binding cassette** See ABC TRANSPORTER.

**ATP synthase** See ATPASE.

**ATPase** Adenosine 5'-triphosphatase: any of a wide range of structurally and functionally distinct enzymes and enzyme complexes capable of hydrolysing a phosphate bond in ATP (q.v.) – cf. KINASE; many types of ATPase (sometimes called ATP synthases) can catalyse the synthesis of ATP (see e.g. OXIDATIVE PHOSPHORYLATION) as well as the hydrolysis of ATP. Most ATPases appear to be  $\gamma$ -phosphohydrolases, i.e., they catalyse the dephosphorylation of ATP to adenosine 5'-diphosphate (ADP) and inorganic phosphate (Pi), and/or the converse reaction.

Energy derived from the hydrolysis of ATP by a given ATPase may be used, directly, in one or other of two main types of energy-requiring activity: (a) energy conversion and/or the transmembrane translocation of ions (see e.g. PROTON ATPASE and ION TRANSPORT); (b) mechanical work (see e.g. PRIMOSOME and eukaryotic FLAGELLUM). By generating or augmenting proton motive force (see CHEMIOSMOSIS), ATP hydrolysis can supply energy for some functions (e.g. rotation of the bacterial FLAGELLUM) that cannot use ATP as a direct source of energy.

*Note on nomenclature.* The activity of some *proton*-translocating ATPases is enhanced by specific ions – e.g. the cytoplasmic membrane of *Escherichia coli* contains a 'Ca<sup>2+</sup>,

Mg<sup>2+</sup>-stimulated ATPase'; confusingly, this terminology is also used for some ATPases which translocate ions other than protons: see e.g. ION TRANSPORT.

**ATP-γS** Adenosine-5'-(γ-thio)triphosphate: a (biologically) non-hydrolysable ATP analogue.

**atractyloside** A glucoside, produced by the Mediterranean thistle (*Atractylis gummifera*), which competitively inhibits the ADP/ATP exchange carrier system in the mitochondrial inner membrane. (cf. BONGKREKIC ACID; WEDELOSIDE.)

**AtrB** An ABC TRANSPORTER in *Aspergillus nidulans*.

**atrichous** (1) Hairless. (2) Lacking flagella. (3) Lacking any filamentous appendages (flagella, fimbriae etc).

**atrium** (*ciliate* protozoal.) A shallow concavity in the cytosomal region – particularly in certain hypostomes.

**att site** A DNA sequence at which site-specific recombination occurs during integration of the genome of a temperate bacteriophage into the chromosome of its host; the site on the phage genome is designated *attP*, that on the host chromosome *attB*. (See e.g. BACTERIOPHAGE λ.)

**attaching and effacing lesions** See EPEC.

**attB site** See ATT SITE.

**attenuated** (1) Of e.g. a structure: becoming narrow; tapered. (2) Having a reduced virulence – see ATTENUATION (1) and (2).

**attenuated vaccine** A VACCINE containing live pathogens whose virulence for a given host species has been reduced or abolished by ATTENUATION.

**attenuation** (1) (*immunol.*) Any procedure in which the virulence of a given (live) pathogen for a particular host species is reduced or abolished without altering its immunogenicity; attenuation may be achieved by SERIAL PASSAGE and may be used to prepare VACCINES (e.g., the SABIN VACCINE). (2) A reduction in the virulence of a pathogen under natural conditions. (3) See SPIRITS. (4) (*mol. biol.*) See OPERON.

**attenuator** See OPERON.

**attP site** See ATT SITE.

**atypical interstitial pneumonia** (of cattle) Any of a clinically distinct group of acute or chronic respiratory diseases which typically involve e.g. pulmonary emphysema and oedema, hyperplasia of alveolar epithelium and interstitial cells, and an unresponsiveness to treatment [Book ref. 33, pp. 1255–1261]. (cf. BOVINE RESPIRATORY DISEASE.) In no naturally occurring case has the causal agent been established with certainty; causes may include the effects of noxious gases, metabolic products (see FOG FEVER), dusts (see BOVINE FARMERS' LUNG), a ketone constituent of the weed *Perilla frutescens*, or IPOMEANOL. (See also PNEUMONIA.)

**atypical mycobacteria** (anonymous mycobacteria) Species of MYCOBACTERIUM which can cause disease in man but which (unlike *M. tuberculosis* and *M. bovis*) do not cause fatal, disseminated disease when inoculated into guinea pigs. Atypical mycobacteria often give a negative NIACIN TEST.

**Au antigen** See HEPATITIS B VIRUS.

**Audouinella** See RHODOPHYTA.

**Aufwuchs** (periphyton community) Organisms (including certain algae and sessilidians) which colonize and form a coating on submerged objects (stones, plants, etc) in aquatic habitats.

**Augmentin** A mixture of AMOXICILLIN and CLAVULANIC ACID used e.g. in the treatment of urinary tract infections.

**Augusta disease** (of tulips) See TOBACCO NECROSIS VIRUS.

**Aujeszky's disease** (pseudorabies; mad itch; infectious bulbar paralysis) A PIG DISEASE which may also affect e.g. cattle, dogs, cats and rats; it occurs in North America, Europe, S. E. Asia, and the UK. The causal agent is a herpesvirus (see

ALPHAHERPESVIRINAE). Infection probably occurs mainly via the upper respiratory tract; the virus then invades the nervous system. In piglets, symptoms may include vomiting or diarrhoea, fever, trembling, incoordination, convulsions, and prostration; mortality rates may reach 100% in neonates. In adult pigs infection may be asymptomatic or may result in e.g. fever, respiratory symptoms, anorexia, and abortion; recovery usually occurs in a few days. A carrier state is recognized. In cattle, dogs and cats, the disease may resemble the active form of RABIES, with signs of intense itching, salivation, convulsions, and death. [Book ref. 27.]

**Aulacantha** See RADIOLARIA.

**Aulosira** A phycological genus of filamentous 'blue-green algae' (Nostocales) in which both heterocysts and akinetes are formed (cf. CYANOBACTERIA section IV).

**AUM** See UROPLAKIN.

**Aura virus** See ALPHAVIRUS.

**auramine O** A basic, yellow, substituted diphenylmethane FLUOROCHROME; fluorescence: yellow.

**auramine–rhodamine stain** A fluorescent ACID-FAST STAIN. The stain is made by mixing auramine O (1.5 g) and rhodamine B (0.75 g) with distilled water (25 ml) and melted phenol (10 ml); this mixture is added to distilled water (25 ml) and glycerol (75 ml), well mixed, and filtered through glass wool. A heat-fixed smear is stained for 15–20 min at 37°C and rinsed in distilled water. Decolorization, for 2–3 min, is attempted with 70% ethanol containing 0.5% v/v conc. HCl. The smear is washed in distilled water and then flooded with 'counterstain' (0.5% aqueous potassium permanganate) for ca. 2 min to suppress non-specific fluorescence of tissue debris etc. (Prolonged counterstaining would mask the fluorescence of acid-fast organisms in the smear.) The smear is then washed in distilled water, blotted dry, and examined by fluorescence MICROSCOPY.

**Aureobasidium** (*Pullularia*) See HYPHOMYCETES; see also BLACK YEASTS; PAINT SPOILAGE; PULLULAN; SAP-STAIN.

**aureofungin** An antifungal antibiotic of the heptaene group of POLYENE ANTIBIOTICS produced by *Streptoverticillium cinnamomeum* var. *terrificolum*; it is a golden-yellow powder which is insoluble in water but soluble in dilute alkali or ethanol. Aureofungin is active against a wide range of plant-pathogenic fungi, is translocated within the plant, and has been used e.g. for crop spraying and for the prevention of seed-borne disease. [Book ref. 121, pp. 137–148.]

**aureomycin** See TETRACYCLINES.

**Auricularia** A genus of fungi of the order AURICULARIALES. *A. auricula-judae* (the 'Jew's ear fungus') can be parasitic e.g. on elder (*Sambucus*). An edible species, *A. polytricha*, is cultivated on oak (*Quercus*) in China. (See also FUNGUS GARDENS.)

**Auriculariales** An order of fungi (subclass PHRAGMOBASIDIOMYCETIDAE) which typically form elongated, *transversely* septate basidia in gymnocarpous or semiangiocarpous fruiting bodies which may be e.g. stalked or sessile, and which are characteristically gelatinous or waxy; the basidiocarp may be e.g. cup-shaped or ear-shaped. Some species are saprotrophs; others are parasitic e.g. on mosses and on other fungi. Genera include e.g. AURICULARIA, *Helicobasidium* and *Phleogenia*.

**aurintricarboxylic acid** (ATA) A TRIPHENYLMETHANE DYE which inhibits PROTEIN SYNTHESIS in prokaryote and eukaryote cell-free extracts; it appears to inhibit the binding of mRNA to ribosomes and, at higher concentrations, can inhibit chain elongation. ATA strongly chelates metal ions.

## aurodox

**aurodox** See POLYENE ANTIBIOTICS (b).

**aurovertins** A group of polyene,  $\alpha$ -pyrone-containing MYCOTOXINS isolated from cultures of *Calcarisporium arbuscula*. [Biosynthesis: PAC (1986) 58 239–256.] Aurovertins bind non-covalently to, and inhibit, (F<sub>0</sub>F<sub>1</sub>)-type PROTON ATPASES.

**Australia antigen** HBsAg: see HEPATITIS B VIRUS.

**Australia X disease** Syn. MURRAY VALLEY FEVER.

**Australian bat lyssavirus** See LYSSAVIRUS.

**auto-agglutination** (saline agglutination) Spontaneous agglutination which may occur when bacterial cells (or other particulate materials) are suspended in e.g. saline. (See also VW ANTIGENS.)

**auto- $\alpha$**  Syn. ALPHA PEPTIDE.

**autoantibody** An ANTIBODY produced by an individual against one of its own antigens. (See e.g. TYPE V REACTION.)

**autoantigen** An antigen homologous to an AUTOANTIBODY.

**Autobiocounter M 4000** See HACCP.

**autocatalytic splicing** See SPLIT GENE (b, c and e).

**autochthonous** (1) Indigenous to a given environment. (cf. ALLOCHTHONOUS.) In a given environment the autochthonous microorganisms maintain more or less constant numbers or

biomass – reflecting more or less constant (albeit typically low) levels of nutrients. (cf. ZYMOGENOUS.)

(2) (*immunol.*) Syn. AUTOLOGOUS.

**autoclave** An apparatus within which objects or materials can be heat-sterilized by (air-free) saturated steam, under pressure, at temperatures usually in the range 115–134°C. (The pressure itself plays little or no part in the STERILIZATION process – which depends on the combined effects of heat and water vapour.) The simplest ('bench-type') autoclaves resemble the domestic pressure cooker in both principle and appearance. Material to be autoclaved is placed on a rack in the chamber and the lid clamped securely in position with the valve open; water in the bottom of the chamber is boiled (by means of an internal electric element, or by external heating) and the steam allowed to escape, via a valve in the lid, until all the air has been displaced from the chamber. The valve is then closed; on further heating, water continues to vaporize, and the pressure and temperature of the steam rise to levels determined by the setting of the steam exhaust valve – which then opens to maintain the required pressure and temperature of steam in the chamber. For a given

AUTOCLAVE. Simplified, diagrammatic representation of a Series 225 steam-mains autoclave (courtesy of Baird and Tatlock (London) Ltd).

**A.** Steam inlet valve. The valve is opened/closed electromagnetically – its operation being governed by the pressure controller/indicator. (Control by temperature – via the thermocouple – is an available option.) **B.** Pressure controller/indicator. **C.** Door microswitch – a safety device; electrical power is connected to the autoclave only when the microswitch has been actuated, i.e., when the door has been fully closed. Additionally, this device automatically opens the steam exit valve if any attempt is made to open the door while the chamber is under pressure. **D.** Door closure bolts which operate microswitches. **E.** Safety valve set to open at 275 kPa. **F.** Filters which prevent blockage of steam discharge lines and steam trap. **G.** Thermocouple pocket: temperature control/indicator/recording option. **H.** Manually-operated by-pass valve – can be operated in case of electrical power failure. (Under such conditions valve **J** could not be opened.) The valve contains a built-in bleed which permits a small but continual flow of steam from the chamber to the exterior. **J.** Electrically-operated steam exit valve. **K.** Steam trap.

**Operational sequence.** 1. Insert load. 2. Secure door. 3. Set controls for required pressure/temperature and sterilizing time. 4. Switch on power. Steam enters the chamber through **A**, and the downwardly-displaced air is purged, via filters **F**, through (a) the steam trap **K** and (b) the permanent bleed **H**; **J** is closed, and when steam leaves the chamber, **K** closes. **A** closes when the chamber pressure reaches the selected value. Steam continues to leave the chamber via the permanent bleed **H** – permitting continual temperature monitoring by the thermocouple **G**; since **G** is located at the lowest (and hence coolest) part of the system, it measures the 'worst case' temperature – the chamber temperature always being higher than that registered by **G**. Sterilizing conditions within the chamber are maintained (against heat losses and against the continual steam bleed) by periodically admitting a pulse of steam via **A**. At the end of the sterilization cycle steam is discharged from the chamber via **J**; when atmospheric pressure has been re-established in the chamber the door can be opened and the load withdrawn.

Automatic timing of the sterilization cycle commences when the chamber pressure (or, optionally, temperature – measured by **G**) reaches the desired value.

steam temperature the time required for sterilization depends on the nature of the load – the rate of steam penetration and the heat capacity of the load being important considerations. Sterilizing temperature/time combinations used with bench-type or larger autoclaves are commonly 115°C (10lb/inch<sup>2</sup>; ca. 69 kPa) for 30–35 min; 121°C (15lb/inch<sup>2</sup>; ca. 103 kPa) for 15–20 min; 134°C (30 lb/inch<sup>2</sup>; ca. 207 kPa) for 4 min. These times may be varied according to e.g. the nature of the load and the nature and degree of contamination. Large autoclaves, used e.g. in hospitals and industry, often use steam piped direct from a boiler, and frequently incorporate automatic controls for timing etc (see Figure). (See also STEAM TRAP.)

*Steam quality* is important for effective sterilization. If air is present in an operating autoclave, the temperature corresponding to a given pressure is lower than it would be in the complete absence of air; thus, air must be completely purged from the autoclave chamber, and all free space within the chamber must be filled with *saturated* steam at the required temperature and pressure. Saturated steam is steam which holds the maximum amount of water vapour for its temperature and pressure. (Saturated steam effects optimum heat transfer since it delivers up a large amount of latent heat when condensing on objects in the chamber during the initial (pre-sterilization) heating-up period.) In a bench-type autoclave the steam is necessarily saturated since it remains in contact with water in the chamber. In a larger autoclave, steam entering the chamber from a boiler should, for maximum efficiency, be dry as well as saturated, i.e., it should contain no water in the liquid phase. (Wet saturated steam contains droplets of water.) *Superheated* steam is an unsaturated vapour formed when the pressure of dry saturated steam (at constant temperature) is lowered, or when the temperature of dry saturated steam (at constant pressure) is raised in the absence of free water. Superheated steam tends to behave as a gas, and must be at temperatures higher than those of saturated steam to achieve sterilization; it may be formed e.g. when steam is piped from a boiler to a large autoclave – particularly at a pressure-reduction valve.

In most large autoclaves steam enters near the top of the chamber, and air is purged by downward displacement; this may permit pockets of air to become trapped at the bottom of deep, empty vessels – e.g. bottles with small openings or long, narrow necks – and such regions may not be adequately exposed to sterilizing conditions. (Air may also be trapped in items of apparatus which are totally enclosed in a wrapping of e.g. aluminium foil.) In a *vacuum autoclave* air is purged from the chamber by connecting it briefly to a vacuum line; when steam subsequently enters the chamber it can penetrate more easily into flasks and between the fibres of surgical dressings etc so that the overall sterilizing time is reduced.

At the end of the sterilization cycle in a large autoclave the steam inlet valve is closed (or closes automatically); the autoclave may be left to cool slowly, or steam within the chamber may be allowed to escape via the steam exit valve until pressure in the chamber is equal to that of the atmosphere – when the chamber can be safely opened. When bottles of liquid have been autoclaved the temperature and pressure in the chamber should be allowed to decrease slowly to prevent boiling and the consequent loss of contents and/or damage to bottles. (Screw-caps on bottles should always be loosened *prior* to autoclaving.) Sometimes a partial vacuum is allowed to form in the chamber as the steam condenses; this can be advantageous since it tends to dry materials (e.g. dressings) in the chamber. When ‘breaking the vacuum’, i.e. allowing ingress of air to the chamber,

the entry of contaminated air is prevented by the presence of a filter in the air intake line. In vacuum autoclaves steam can be removed, and materials dried, by connecting a vacuum line to the chamber.

Regular monitoring of an autoclave’s performance is important; monitoring devices should be used to check the temperatures reached at a number of different locations within the chamber. Monitoring devices may be physical (e.g. thermocouples), chemical (e.g. BROWNE’S TUBES), or biological (test envelopes containing the endospores of e.g. *Bacillus stearothermophilus*). In biological monitoring the autoclaved spores are tested for viability by attempting to culture them; although such a process is directly related to the aim of autoclaving, it involves a built-in delay (i.e. the incubation time). (See also AUTOCLAVE TAPE; BOWIE–DICK TEST.)

Some materials (e.g. petroleum jelly, liquid paraffin) cannot be sterilized by autoclaving owing to their impermeability to steam; such materials (and e.g. clean glassware) are usually sterilized in a HOT-AIR OVEN.

(See also CHEMICLAVE; LOW-TEMPERATURE STEAM DISINFECTION; STEAMER; STERILIZER.)

**autoclave tape** Paper tape (usually self-adhesive) which changes colour (or exhibits other visible changes) when exposed to sterilizing conditions in an AUTOCLAVE. (See also BOWIE–DICK TEST.)

**autocolony** A colony (or coenobium) which develops within one cell of a parent colony and which, when released, resembles the parent colony (see e.g. SCENEDESMUS). (cf. AUTOSPORE.)

**autocompartmentalization** See PROTEASOME.

**autocoupling hapten** See HAPTEN.

**autodigestion** (of lamellae) See BASIDIOSPORES.

**autodisplay** (*biotechnol.*) Autotransporter-mediated display of recombinant proteins at the cell surface of *Escherichia coli*. In this method, the  $\alpha$  domain of the AIDA-1 *autotransporter* (see type IV systems in PROTEIN SECRETION) is replaced by a recombinant protein; this is done by preparing a fusion protein consisting of the sequence encoding the  $\beta$  domain and that encoding the (heterologous) recombinant protein. In one study, the  $\alpha$  domain was replaced e.g. by the cholera toxin B subunit; cells with the (normal) outer membrane protease OmpT cleaved the (recombinant)  $\alpha$  domain, which was released from the cell, but in mutant (*ompT*<sup>−</sup>) cells, which lack a functional OmpT protease, the subunit was not cleaved, but displayed at the cell surface. [Autodisplay: JB (1997) 179 794–804.]

**autoecious** *Syn.* HOMOXENOUS.

**autofluorescence** See FLUORESCENCE.

**autogamy** (self fertilization) In certain protozoa: a sequence of events which culminates in the fusion of haploid nuclei or gametes derived from a single cell; autogamy occurs e.g. in certain ciliates (e.g. *Paramecium* – but apparently not in e.g. *Tetrahymena*) and in some sarcodines.

In *Paramecium aurelia* each of the two micronuclei undergoes meiosis; of the eight haploid *pronuclei* produced all except one disintegrate. The surviving pronucleus divides mitotically to form a pair of gametic nuclei; these nuclei subsequently fuse to form the (homozygous) zygotic nucleus (= *synkaryon*). Two mitotic divisions then occur; two of the resulting (diploid) nuclei become new micronuclei, the other two become macronuclei – the original macronucleus having disintegrated during the preceding events. During the next binary fission one macronucleus passes to each daughter cell; both micronuclei divide, mitotically, and a pair of micronuclei passes to each daughter cell – thus re-establishing the normal nuclear constitution.

## autogenous regulation

Since only the original complement of genes is involved, the potential for genetic change in autogamy is less than that in CONJUGATION; nevertheless, new combinations of alleles may be formed during the meiotic divisions. (See also ACTINOPHYRY and ACTINOSPHERIUM.)

In some organisms autogamy occurs spontaneously; in others it may be induced by starvation, ageing, radiation etc.

**autogenous regulation** (*mol. biol.*) The regulation of expression of a gene or operon by its own product(s). (See e.g. RIBOSOME (biogenesis).)

**autogenous vaccine** A VACCINE prepared by the culture and inactivation of pathogen(s) isolated from a patient and subsequently used to inoculate that patient.

**Autographa californica NPV** See NUCLEAR POLYHEDROSIS VIRUSES.

**autoimmune disease** Any disease directly attributable to AUTOIMMUNITY. In some autoimmune diseases (e.g. acquired haemolytic anaemias) antibodies play a significant role, but many autoimmune diseases are cell-mediated. (See also e.g. MULTIPLE SCLEROSIS.)

**autoimmunity** An expression of IMMUNITY (1) in which the body directs immunological mechanism(s) against one or more of its own components. (See also TYPE V REACTION.)

**autoinducer** See AUTOINDUCIBLE ENZYME and QUORUM SENSING.

**autoinducible enzyme** A (repressible) enzyme whose induction in a given organism is brought about by the presence of a specific compound (*autoinducer*) that is produced by the organism itself (cf. enzyme induction in e.g. the LAC OPERON). An example is bacterial luciferase (see BIOLUMINESCENCE). In this system autoinducer is secreted by the bacteria and can accumulate to the critical, effective concentration (sufficient to bring about derepression) only when the organisms are in a confined environment (e.g. in the luminous organs of certain marine fish).

**autoinfection** Infection resulting from the transfer of a pathogen from one site to another in the same individual (cf. RE-INFECTION).

**autologous** (*immunol.*) Present in or derived from an individual's own tissues.

**autologous blood transfusion** See TRANSFUSION-TRANSMITTED INFECTION.

**autolysate** The products of AUTOLYSIS. (See e.g. YEAST EXTRACT.)

**autolysin** (autolytic enzyme) Any of a range of endogenous enzymes which, by degradation of certain structural cell components (e.g. PEPTIDOGLYCAN in bacteria), can bring about AUTOLYSIS or AUTOPHAGY; autolysins are apparently involved in normal processes of growth and development (e.g., spore germination; cell wall polymer extension and cell separation during normal growth). Mutant bacteria defective in autolysin activity may show e.g. abnormal growth forms (e.g. filaments) or resistance to antibiotics active against the wild-type. In prokaryotes, autolysins occur in the cell wall or (in Gram-negative species) in the periplasmic space, often as inactive precursors which are activated e.g. by proteases (see also BILE SOLUBILITY); in eukaryotes autolysins are sequestered in LYSOSOMES.

**autolysis** The lysis of a cell due to the action of its AUTOLYSINS – usually following the death of the cell or tissue.

**autolytic enzyme** *Syn.* AUTOLYSIN.

**automatic volumetric spore trap** *Syn.* HIRST SPORE TRAP.

**autonomously replicating sequence** See ARS.

**autophagy** The digestion, by a eukaryotic cell, of some of its own internal components – e.g., during periods of starvation. (See FOOD VACUOLE.)

**autoplaque** A plaque (in a bacterial lawn plate) which resembles that caused by a lytic bacteriophage, but in which no phage can

be demonstrated. Autoplques occur e.g. in cultures of certain strains of *Rhizobium leguminosarum* biotype *trifolii* and seem to result from autolysis.

**autoplast** A PROTOPLAST or SPHAEROPLAST which results from the action of an organism's own autolytic enzymes.

**autoradiography** (radioautography) The use of a photographic process to locate and/or quantify a radioactively-labelled substance previously incorporated in living cells or tissues; autoradiography can be used e.g. to study sites of biosynthesis, turnover rates, and transport. Initially, a radioactive substrate is taken up by the living cells, and the label becomes incorporated in structures, metabolites etc as would be the non-labelled analogue. (The labelled substrate may be introduced using a PULSE-CHASE TECHNIQUE; since radioactive labels can be injurious to cells, dose and duration of the pulse may have to be limited.) The cells/tissues are then prepared for microscopy (e.g., fixed, dehydrated, embedded, sectioned, stained). For ELECTRON MICROSCOPY the section (e.g. on a formvar-coated grid) is stained with e.g. lead citrate or uranyl acetate, and is coated with a thin (ca. 5 nm) layer of carbon; the carbon layer is then overlaid with a thin layer of photographic emulsion, and the whole preparation is left in the dark at e.g. 4°C for a period of the order of days or weeks. Each point source of radioactivity in the section will affect the overlying area of emulsion, giving rise (on developing and fixing the emulsion) to a local deposit of silver which, under the EM, commonly appears as a tangled filament. Under the light microscope each silver deposit appears as a dot or fleck. Since the silver deposits are superimposed on the tissue section, the cellular location of the radioactive components can be determined.

For optimum resolution, the section, carbon layer, and emulsion layer must each be very thin; given a choice of suitable radioactive sources, it is preferable to use the one with the least emission energy. Low-energy radiators, e.g. <sup>3</sup>H, tend to affect a small area of the emulsion immediately above each point source; with radiators of high emission energy, e.g. <sup>32</sup>P, each point source gives a wide-angled cone of effective radiation which affects a larger area of emulsion. Radioactive precursors used for studying particular cell components include e.g. [<sup>3</sup>H]thymidine (DNA), [<sup>3</sup>H]glucose (polysaccharides), and [<sup>3</sup>H]proline (proteins). [Book ref. 4, pp. 235–277.]

**autosome** Any chromosome other than a sex chromosome.

**autospore** (*algol.*) A type of spore, formed asexually, which is an exact morphological replica of the parent cell. The term is usually reserved for aplanospores produced by *Chlorella* and related algae, but is sometimes extended to include e.g. the planospores of e.g. BRACHIOMONAS.

**autotransporter** See PROTEIN SECRETION (type IV systems).

**autotroph** An organism which uses CARBON DIOXIDE for most or all of its carbon requirements (cf. HETEROTROPH; LITHOTROPH); all obligate autotrophs appear to be either chemolithotrophs or photolithotrophs, and 'autotroph' is often used with the implication of lithoautotrophy (see also CHEMOTROPH). In many autotrophs CO<sub>2</sub> fixation occurs via the CALVIN CYCLE or via the REDUCTIVE TRICARBOXYLIC ACID CYCLE. Some ACETOGENS fix CO<sub>2</sub> via a different pathway (sometimes called the 'activated acetic acid pathway') in which acetyl-CoA can be synthesized by the reduction of two molecules of CO<sub>2</sub> (see ACETOGENESIS); a similar pathway occurs in *Desulfovibrio baarsii* in which the methyl and carboxyl groups of acetyl-CoA are derived from formate and CO<sub>2</sub> respectively [FEMS (1985) 28 311–315]. An analogous pathway occurs in METHANOGENS.

**autoxidation** Spontaneous oxidation by atmospheric oxygen: see e.g. OXIDATIVE RANCIDITY and SULPHUR CYCLE.

**auxanogram** See AUXANOGRAPHIC TECHNIQUE.

**auxanographic technique** A procedure used e.g. for identifying the substances which a given organism can use as carbon sources, or for identifying the growth factor(s) required by an AUXOTROPH.

To identify usable carbon sources, a plate of medium which lacks a carbon source is heavily inoculated with the test organism; a small quantity of one of each of a number of different carbon sources is then placed at a separate location on the plate. Following incubation, usable carbon sources are indicated by growth at their locations on the plate. The pattern of usable carbon sources (or e.g. nitrogen sources) is termed an *auxanogram*; closely related organisms which are characterized by different auxanograms are said to be different *auxotypes* (= *auxanographic types*).

An analogous procedure is used for examining a suspected auxotroph; a solid MINIMAL MEDIUM is inoculated with the test organism, and to the plate are then added small, discrete amounts of (a) a mixture of amino acids, (b) a mixture of vitamins, and (c) one or more possible requirements for nucleic acid synthesis. Following incubation, growth at one or other location on the plate indicates the identity of the growth factor(s) required. If, for example, growth occurs at the location of the mixed amino acids, the analysis is continued by repeating the procedure with separate, discrete inoculations of individual amino acids until the specific requirement(s) is/are known.

**auxanographic type** See AUXANOGRAPHIC TECHNIQUE.

**auxins** PHYTOHORMONES which promote stem elongation and, in conjunction with CYTOKININS and/or GIBBERELLINS, play important roles in many plant processes; auxins, which are derivatives of tryptophan, are produced mainly at stem apices and in young leaves. Similar or identical compounds are also formed by certain microorganisms (including a number of plant pathogens).

In many plants the main auxin appears to be indole 3-acetic acid (IAA, also known as 'auxin' or 'heteroauxin'), a compound synthesized via the precursor indole 3-acetonitrile (IAN). In vivo, IAA can e.g. stimulate ETHYLENE production, but the mechanisms by which IAA functions in the overall regulation of growth are not well understood. Regulation of the in vivo level of IAA appears to involve an enzyme, 'IAA-oxidase', which oxidizes IAA to products which include 3-methylene-oxindole and indolealdehyde; this enzymic oxidation is stimulated e.g. by certain monophenols (e.g. *p*-coumaric acid) and by Mn<sup>2+</sup>, and is inhibited by certain diphenol derivatives (e.g. CAFFEIC ACID, CHLOROGENIC ACID, QUERCETIN and SCOPOLETIN).

Certain plant diseases of microbial causation are characterized by the presence of atypical levels of auxins in the diseased plants. *Hyperauxiny* (abnormally high levels of auxins) occurs in many diseases and can arise in various ways – see e.g. CLUBROOT, CROWN GALL, OLIVE KNOT and SCOPOLETIN. The nature of the relationship between hyperauxiny and disease development is not well understood.

**auxochrome** In a DYE molecule: any ionizable group by means of which the CHROMOPHORE can bind to target molecule(s).

**auxospore** See DIATOMS.

**auxotroph** A strain of microorganism which lacks the ability to synthesize one or more essential growth factors; an auxotroph arises by the occurrence of one or more mutations in a PROTOTROPH. A medium used to culture a given auxotroph must contain any factors which the organism cannot synthesize: see COMPLETE MEDIUM and MINIMAL MEDIUM.

Auxotrophy results from a cell's genetically determined inability to produce (normal amounts of) functional enzyme(s)

which catalyse particular stage(s) in the synthesis of essential growth factor(s); such a block may involve (a) the complete absence of enzyme; (b) the presence of normal enzyme in subnormal amounts; (c) the presence of abnormal enzyme which is devoid of or has lowered enzymic activity. (See also SYNTROPHISM.)

Apparent auxotrophy may result e.g. from a defective TRANSPORT SYSTEM; thus, e.g. an organism may appear to be an auxotroph if it is unable to take up a substrate which is necessary for the synthesis of an essential growth factor. (See also CRYPTIC MUTANT.)

*Isolation of auxotrophic mutants.* Since auxotrophs have nutritional requirements in excess of those of the corresponding (prototrophic) wild-type strains, they cannot be isolated from mixed auxotroph-prototroph populations by common selective culture methods.

In the *limited enrichment* method, a dilute suspension of mutagenized cells is inoculated onto a minimal medium which has been enriched with limiting amounts of nutrients; the dilution is chosen such that isolated colonies are obtained following incubation. Any auxotrophic cells which may be present form colonies which quickly exhaust the nutrient supply at their locations – so that colony size is restricted; a colony of prototrophic cells, which is not restricted by nutrient supply, attains a greater size. Thus, small colonies may be presumed to be those of auxotrophs.

In the *delayed enrichment* method, the mutagenized preparation of cells is first inoculated onto a minimal medium. A small quantity of molten minimal agar is then layered onto the surface of the inoculated medium and allowed to set. The plate is then incubated. Colonies are formed only by prototrophs, and the positions occupied by these colonies are recorded. Finally, complete medium is layered onto the surface of the plate and allowed to set; the plate is then re-incubated. As nutrients diffuse into the minimal agar the auxotrophic cells begin to grow and form colonies.

Auxotrophic mutants may also be isolated by a REPLICA PLATING process.

Another method is based on the differing effects of PENICILLIN on growing and non-growing cells of certain (penicillin-sensitive) organisms. If a well-washed mixture of auxotrophic and prototrophic cells is suspended in a minimal medium with an appropriate concentration of penicillin, the prototrophs are lysed while the auxotrophs, being unable to grow, remain viable. The suspension is then washed and is plated on a complete medium to recover the auxotrophs. In this method it is essential that the mutagenized cells be grown in a complete medium for several cell-division cycles *prior to penicillin treatment*. This is essential because the newly mutated cells contain the full complement of enzymes etc found in the prototroph; only after several rounds of cell division do the progeny cells exhibit a truly auxotrophic phenotype. Only low concentrations of cells should be used in this method since substances from the lysed cells may be used as nutrients by the auxotrophs – thereby rendering the latter susceptible to lysis by penicillin. (cf. STREPTOZOTOCIN.)

**auxotype** See AUXANOGRAPHIC TECHNIQUE.

**avenacin** A fluorescent polycyclic SAPONIN formed in the roots of oat plants (*Avena* spp). Avenacin confers resistance, in *Avena* spp, to many strains of *Gaeumannomyces graminis* (see TAKE-ALL); however, *G. graminis* var. *avenae* forms an extracellular glycosidase which detoxifies the compound.

**avermectins** Macrolide-like antihelmintic agents, obtained from *Streptomyces avermitilis*, which are active against various human and animal parasites [AEM (2003) 69 1263–1269].

## aversion zone

**aversion zone** (*mycol.*) A zone of growth inhibition separating two fungal colonies; such zones are formed e.g. when strains of *Phycomyces blakesleeanae* of similar mating type are cultured on the same plate.

**Aviadenovirus** (avian adenoviruses) A genus of adenoviruses (family ADENOVIRIDAE) which infect birds; type species: fowl adenovirus type 1 (= chick embryo lethal orphan (CELO) virus, = gal-1). Diseases caused by aviadenoviruses include e.g. EGG-DROP SYNDROME 1976, HAEMORRHAGIC ENTERITIS OF TURKEYS, INCLUSION BODY HEPATITIS, and MARBLE SPLEEN DISEASE. Several avian adenoviruses (including CELO virus) can induce tumours in newborn rodents (cf. MASTADENOVIRUS).

**avian acute leukaemia viruses** (AcLVs) A group of replication-defective, *v-onc*<sup>+</sup> type C retroviruses (subfamily ONCOVIRINAE) which cause acute erythroid and myeloid leukaemias in chickens; they may also induce carcinomas, endotheliomas and sarcomas. AcLVs include avian myeloblastosis virus, AMV (which carries *v-myb*); avian erythroblastosis virus, AEV (which carries *v-erb*); and avian myelocytomatosis virus, MC29 (which carries *v-myc*). (See also ERB, MYB and MYC.) AcLV replication requires the presence of a replication-competent helper virus (see e.g. AVIAN LEUKOSIS VIRUSES). [Molecular biology of AcLVs: Book ref. 105, pp. 38–63.]

**avian encephalomyelitis** (epidemic tremor) A POULTRY DISEASE caused by an ENTEROVIRUS; infection in adult birds is usually asymptomatic, but in young chicks symptoms may include ataxia, tremors and somnolence. Infection occurs e.g. by ingestion of food contaminated with faeces from infected birds; transmission can also occur via the egg.

**avian erythroblastosis virus** See AVIAN ACUTE LEUKAEMIA VIRUSES.

**avian infectious bronchitis** An acute, highly infectious POULTRY DISEASE caused by a coronavirus (IBV – see CORONAVIRIDAE). The symptoms include gasping, coughing, nasal discharge, etc; mortality rates may be high. Secondary bacterial infection may be common. [Experimentally-produced disease with mixed IBV/*Escherichia coli* infection: JGV (1985) 66 777–786.] Live vaccines are available. A strain of the avian infectious bronchitis virus (the ‘T’ strain) may cause avian kidney disease (Cummings’ disease).

**avian infectious laryngotracheitis** An acute POULTRY DISEASE, affecting mainly chickens and pheasants, caused by gallid herpesvirus 3. Mortality rates may be high.

**avian leukosis complex** A group of POULTRY DISEASES which includes e.g. LYMPHOID LEUKOSIS and MAREK’S DISEASE.

**avian leukosis viruses** (ALVs; lymphatic leukosis viruses; lymphatic leukaemia viruses) A group of avian type C retroviruses (subfamily ONCOVIRINAE) which usually induce neoplastic disease only after a long latent period (several months or more). The most common neoplasm induced is LYMPHOID LEUKOSIS. (See also OSTEOPETROSIS.) ALVs are replication-competent and *v-onc*<sup>+</sup> (see RETROVIRIDAE). In some cases induction of neoplastic disease may involve the insertion of a viral LTR adjacent to and upstream of a *c-onc* (usually *c-myc*) sequence, the LTR acting as a promoter for *c-onc* expression; alternatively, or perhaps additionally, an LTR may have a promoter-unrelated transcription-enhancing function [Book ref. 105, pp. 64–68]. Neoplastic transformation may require the activation of a second cellular gene, *B-lym*, in addition to *c-myc*.

ALVs often occur in association with replication-defective *v-onc*<sup>+</sup> viruses (e.g. AVIAN ACUTE LEUKAEMIA VIRUSES) as ‘helper’ or ‘associated’ viruses; such ALVs include Rous-associated viruses (RAVs) and myeloblastosis-associated viruses (MAVs).

**avian myeloblastosis virus** See AVIAN ACUTE LEUKAEMIA VIRUSES and MYB.

**avian myeloblastosis virus reverse transcriptase** See REVERSE TRANSCRIPTASE.

**avian myelocytomatosis virus** See AVIAN ACUTE LEUKAEMIA VIRUSES.

**avian pneumoencephalitis** *Syn.* NEWCASTLE DISEASE.

**avian reticuloendotheliosis viruses** (REVs) A group of type C avian retroviruses of the ONCOVIRINAE. The group includes the replication-competent viruses duck infectious anaemia virus, Trager duck spleen necrosis virus and chicken syncytial virus, and the replication-defective, *v-onc*<sup>+</sup> (*v-rel*<sup>+</sup>) strain T virus (REV-T) and its associated helper virus (REAV, = REV-A). REVs are pathogenic in poultry (chickens, ducks, turkeys), causing a range of (usually rapidly lethal) diseases: e.g. anaemia, visceral reticuloendotheliosis, enlargement and necrosis of the spleen, lymphomas, and infiltrative nerve lesions. REV-T and its helper (REV-A) can be lethal in chickens within ca. 7–14 days of infection; the REV-A component has been reported to induce or activate a splenic suppressor cell population which inhibits the proliferation of cytotoxic cells capable of lysing REV-T-induced tumour cells [MS (1984) 1 107–112].

**avian sarcoma viruses** (ASVs) A group of *v-onc*<sup>+</sup> type C retroviruses (subfamily ONCOVIRINAE) which, after a short latent period, cause tumours in fowl and (sometimes) other animals. The group includes ROUS SARCOMA VIRUS, Fujinami sarcoma virus (which carries *v-fps*), and Yamaguichi-73 sarcoma virus (which carries *v-yes*). (cf. FES.)

**avian tubercle bacillus** *Mycobacterium avium*.

**avianized vaccine** Any vaccine containing microorganisms whose virulence for a given host has been attenuated by adaptation in live chicks and/or serial passage through chick embryos (eggs). Attenuated organisms may or may not be inactivated prior to use in a vaccine. The FLURY VIRUS is an avianized strain.

**Avicel** A commercial preparation consisting of ground microcrystalline (insoluble) CELLULOSE (average DP ca. 200); it is used e.g. for determining the ability of an organism or enzyme to degrade microcrystalline cellulose. (cf. CM-CELLULOSE.)

**avidin** A protein (MWt ca. 68000) present e.g. in the white of raw hens’ eggs; the chicken avidin molecule consists of four identical subunits, and it can bind – non-covalently, but very strongly – four molecules of BIOTIN. (See also ABC IMMUNOPEROXIDASE METHOD; cf. STREPTAVIDIN.)

**avidity** (*immunol.*) The stability of the antibody–antigen complex formed when multivalent antigen and homologous anti-serum are mixed. Avidity depends not only on the AFFINITY of the individual determinant-combining site bonds but also on the number of satisfied valencies of the antigens and antibodies since, e.g., a complex in which two antigen molecules are linked by two antibody molecules is disproportionately more stable than a complex in which the two antigen molecules are linked by a single antibody molecule.

**Aviemoore model** See RECOMBINATION (figure 2).

**Avipoxvirus** (fowlpox subgroup) A genus of viruses of the CHORDOPOXVIRINAE which infect birds (see e.g. FOWL POX). Avipoxviruses are commonly transmitted (mechanically) by arthropod vectors. Infected cells form lipid-rich A-type inclusion bodies; haemagglutinin is not formed. Infectivity is ether-resistant. Members are closely related serologically. Type species: fowlpox virus; other members include canarypox, juncopox, pigeonpox, quailpox, sparrowpox, starlingpox and turkeypox viruses. (See also POXVIRIDAE.)

**avirulence gene** (*avr gene*) (*plant pathol.*) In a plant-pathogenic microorganism: a gene which interacts, functionally, with a

specific 'resistance gene' in certain strain(s) of the host species, eliciting a defensive response (HYPERSENSITIVITY) which results in resistance to that particular strain of the pathogen. The products of such genes appear to be delivered to the interior of plant cells via a type III PROTEIN SECRETION system (designated Hrp: hypersensitivity response and pathogenicity) [see e.g. JB (1997) 179 5655–5662]; under in vitro conditions, the Hrp system in *Pseudomonas syringae* pv. *tomato* has been found to include a filamentous pilus, 6–8 nm in diameter, in which HrpA is a major structural protein [PNAS (1997) 94 3459–3464]. (See also HOP PROTEINS.)

Avirulence genes form part of the 'gene-for-gene' concept that relates to interaction between plants and their pathogens [ARPath. (1971) 9 275–296]. [Gene-for-gene complementarity in plant–pathogen interactions: ARG (1990) 24 447–463.] Direct interaction between the products of a resistance gene and an avirulence gene has been reported to occur, for example, when strains of rice expressing the *Pi-ta* resistance gene are challenged with strains of the rice pathogen *Magnaporthe grisea* (= *Pyricularia oryzae*) that express *AVR-Pita*; against this challenge, the plant failed to succumb to rice BLAST DISEASE [EMBO (2000) 19 4004–4014].

Avirulence genes from *Pseudomonas syringae* commonly have a GC% of ~40–50, i.e. markedly below the chromosomal values (59–61) typical of the species; such a difference in GC% – also commonly seen between PATHOGENICITY ISLANDS and their host chromosomes – is consistent with the concept of horizontal transfer of these genes. Also consistent with horizontal transfer is the finding of highly conserved sequences flanking avirulence genes in *P. syringae* pv. *pisi* [Microbiology (2001) 147 1171–1182].

(See also HARPIN.)

**avirulent** Not exhibiting VIRULENCE.

**avocado sunblotch viroid** See VIROID.

**avoiding reaction** *Syn.* PHOBIC RESPONSE.

**avoparcin** A glycopeptide antibiotic, produced by *Streptomyces candidus*, which inhibits Gram-positive bacteria by interfering with peptidoglycan synthesis (see VANCOMYCIN); it is a well-established FEED ADDITIVE for pigs and poultry, and has been found to have growth-promoting properties for ruminants. In sheep, avoparcin appears to shift the balance of cellulolytic bacteria from ruminococci to *Bacteroides succinogenes* [JGM (1985) 131 427–435].

**avr gene** (*plant pathol.*) See AVIRULENCE GENE.

$a_w$  Symbol for WATER ACTIVITY.

**axenic** Of a culture: containing or comprising cells of a single species. Thus, e.g., an axenic bacterial culture is a pure (uncontaminated) culture of a single species or strain, while an axenic tissue culture is one which contains cells (of one or more types) from one species (or individual) with no microbial contaminants, intracellular parasites, viruses etc. Certain microorganisms – e.g. obligately intracellular bacteria, obligately predatory protozoa – cannot be grown axenically.

**axial fibrils** See SPIROCHAETALES.

**axial filament** (1) See ENDOSPORE (bacterial). (2) See SPIROCHAETALES. (3) See AXOPODIUM.

**axile** Situated in the centre or on the axis.

**axoneme** (1) See FLAGELLUM (b). (2) See AXOPODIUM.

**axopodium** A fine, rod-like, often tapering, relatively rigid type of PSEUDOPodium which has an axial core of microtubules (the *axial filament*, *axial rod* or *axoneme*). Axopodia occur e.g. in HELIOZOEAE and RADIOLARIA in which they typically emanate radially from the cell body. They function mainly in feeding

(but see HELIOZOEAE). When an axopodium comes into contact with a prey organism, it adheres to it and may – at least in some cases – immobilize it; the axopodia of some heliozoa have extrusomes (*kinetocysts*) which may function in immobilizing prey. Ingestion may involve the retraction of the axopodium with the prey, and/or a co-operative engulfing action of a number of pseudopodia in the vicinity.

**axostyle** A rod-like endoskeletal structure which occurs in some protozoa (e.g. *Giardia*, *Hexamita*, *Trichomonas*); in *Trichomonas* it extends from the anterior end of the cell and projects a short distance beyond the posterior end. (cf. COSTA; see also OXYMONADIDA.)

**azaserine** ( $\text{CO}_2\text{H.CHNH}_2.\text{CH}_2.\text{O.CO.CH}=\text{NH}^+=\text{N}^-$ ) AN ANTI-BIOTIC and antitumour agent obtained from *Streptomyces* sp. It is an analogue of glutamine and blocks a number of reactions in which glutamine acts as an  $\text{NH}_2$  donor; in particular, it binds to and inactivates phosphoribosylformylglycinamide synthetase, thus preventing purine (and hence nucleotide) synthesis (see Appendix V(a)). (cf. DON; HADACIDIN.)

**azathioprine** See IMMUNOSUPPRESSION.

**azdimecillin** See POLYENE ANTIBIOTICS (b).

**azide** ( $\text{N}_3^-$ ) Azide acts e.g. as a RESPIRATORY INHIBITOR by combining with, and preventing the reduction of, oxidized CYTOCHROME OXIDASES of the *aa\_3*-type.

Sodium azide ( $\text{NaN}_3$ ) is an antimicrobial agent used e.g. as a preservative in some laboratory reagents (0.1% final concentration  $\text{NaN}_3$ ). It is also used e.g. in certain selective media (0.025% w/v  $\text{NaN}_3$ ) for the isolation of enterococci from samples of sewage-polluted water; at this concentration coliforms and many other Gram-negative bacteria are inhibited.

**3'-azido-3'-deoxythymidine** See AZT.

**azithromycin** A MACROLIDE ANTIBIOTIC used e.g. as an alternative to clarithromycin in the prophylaxis and treatment of infections involving members of the *M. avium* complex (see MAC). The drug tends to concentrate in macrophages and tissue cells. Strains resistant to azithromycin are also resistant to clarithromycin. Side-effects are uncommon; they include nausea, diarrhoea, headaches, dizziness, deafness. (See also QUORUM SENSING.)

**azocillin** See PENICILLINS.

**AZM** Adoral zone of membranelles: a number of MEMBRANELLES serially arranged in a definite and taxonomically important pattern along the left-hand side of the oral area in many members of the OLIGOHYMENOPHOREA and POLYHYMENOPHOREA; the corresponding ciliature in peritrichs and spirotrichs is sometimes called the *adoral ciliary spiral*. The AZM is primarily concerned with feeding (i.e., the production of water currents directed towards the cytostome) but is sometimes used also for locomotion. (cf. PARORAL MEMBRANE.)

**Azoarcus** See SPLIT GENE (e).

**azofer** See NITROGENASE.

**azofermo** See NITROGENASE.

**azoferredoxin** See NITROGENASE.

**azole antifungal agents** A group of synthetic, broad-spectrum ANTIFUNGAL AGENTS, many of which are useful in the treatment of mycoses in man and animals while others are effective against many fungal diseases of plants. The group contains two main categories: the *imidazole* derivatives (e.g. the agriculturally useful BENZIMIDAZOLES and the medical and veterinary drugs bifonazole, butoconazole, clotrimazole, econazole, fenticonazole, isoconazole, ketoconazole, miconazole, oxiconazole, sulconazole, tioconazole, and zinconazole) and the *triazole* derivatives (e.g. the agricultural antifungals flutriafol, propiconazole, triadimefon, and triadimenol, and the medical drugs itraconazole, terconazole and vibunazole). Most of the medically

## Azolla

useful azoles are administered topically, being poorly absorbed from the gut and/or too toxic for systemic use; however, a few (e.g. ketoconazole, itraconazole and vibunazole) can be given orally.

With the exception of the BENZIMIDAZOLES, the azoles generally appear to have the same primary mode of action. At minimal fungistatic concentrations they interfere with the permeability and function of the CYTOPLASMIC MEMBRANE by inhibiting the biosynthesis of ergosterol. In the normal biosynthetic pathway ergosterol is synthesized from its precursor lanosterol by a 14 $\alpha$ -demethylation reaction which involves a cytochrome P-450-dependent monooxygenation step; the azole compound binds (in place of oxygen) to the 6th coordination position of the P-450 haem iron, thus preventing the monooxygenation step. As a result, 14 $\alpha$ -methylated sterols accumulate and ergosterol (and cholesterol) levels fall; this not only alters membrane permeability: the altered lipid environment of the membrane also interferes with the activity and/or control of other enzyme systems (e.g. chitin synthase). Miconazole – in addition to its effect on the cytoplasmic membrane – also exerts an apparently direct inhibitory effect on the mitochondrial ATPase in yeasts such as *Candida albicans* and *Saccharomyces cerevisiae* [Eur. J. Bioch. (1984) 143 273–276].

Actively growing fungi exposed to minimal fungistatic concentrations of azoles (e.g. 10<sup>-8</sup>–10<sup>-7</sup> M for miconazole) show characteristic structural changes, including the formation of dense membrane-derived vesicles at the cell periphery. At somewhat higher fungistatic concentrations (e.g. 10<sup>-6</sup> M miconazole) changes in the cell vacuole also occur, the vacuole becoming filled with vesicles and granular material. At still higher concentrations (e.g. 10<sup>-5</sup> M miconazole) the azoles become fungicidal, causing degeneration of organelles (mitochondria and nuclei).

[Review of medically useful azoles: Book ref. 153, pp. 133–153.]

**Azolla** See ANABAENA.

**Azomonas** A genus of Gram-negative or (*A. macrocytogenes*) Gram-variable, motile bacteria (family AZOTOBACTERACEAE) which occur e.g. in soil and water. Cysts are not formed (cf. AZOTOBACTER). Most strains form water-soluble pigments, but none forms insoluble pigments; a fluorescent pigment is formed by some strains in iron-deficient media. Carbon sources used by all species include e.g. fructose, glucose, acetate, fumarate, lactate, and ethanol; all species can fix nitrogen and can use ammonium salts as the sole source of nitrogen. Optimum growth temperature: 30–37°C, according to species. GC%: ca. 52–59. Type species: *A. agilis*.

*A. agilis*. Peritrichously flagellated. Can use e.g. malonate, but not mannitol. Growth can occur at 32°C and 37°C.

*A. insignis*. Lophotrichously flagellated. Can use e.g. malonate, but not mannitol. Growth can occur at 32°C but not at 37°C.

*A. macrocytogenes*. Monotrichously flagellated (rarely biflagellated at one pole). Can use mannitol and maltose, but not malonate.

[Book ref. 22, pp. 230–234.]

**azomycin** See NITROIMIDAZOLES.

**Azorhizobium caulinodans** See NITROGEN FIXATION.

**Azospirillum** A genus of Gram-negative or Gram-variable, asporogenous, nitrogen-fixing bacteria. Cells: curved and straight rods, often with pointed ends, ca. 1.0 × 2.1–3.8  $\mu$ m. Motile by a single polar flagellum; numerous lateral flagella (of shorter

wavelength) are also formed during growth on solid media at 30°C. Enlarged, ovoid or pleomorphic, non-motile, capsulated forms ('C forms') may develop under certain conditions (e.g. in old cultures). Metabolism is mainly respiratory, with either oxygen or NO<sub>3</sub><sup>-</sup> acting as terminal electron acceptor; DENITRIFICATION occurs under microaerobic conditions. Glucose or fructose may be fermented weakly. Disaccharides are not metabolized. Oxidase +ve; catalase variable; phosphatase +ve; indole -ve; weakly pectinolytic. Optimum growth temperature: 35–37°C. Colonies on potato agar are typically pink, often wrinkled, not slimy. NITROGEN FIXATION occurs under microaerobic conditions; an 'uptake hydrogenase' (see NITROGENASE) is present, and *A. lipoferum* (but not *A. brasilense*) can grow as an H<sub>2</sub>-dependent lithoautotroph. Aerobic growth can also occur in the presence of fixed nitrogen (e.g. NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>). GC%: 69–71. Type species: *A. lipoferum* (formerly *Spirillum lipoferum*).

[Book ref. 22, pp. 94–104.]

Azospirilla occur in soil, both free-living and in association with the roots of grasses (including cereals) and tuberous plants; the bacteria occur on the root surface, in the mucigel, and also within the tissues of the root (outer and inner cortex and stele). The plant appears to benefit from the nitrogen fixed by the bacteria; nodule formation does not occur (cf. ROOT NODULES). There is some degree of host specificity: 'C4 plants' (e.g. maize) are infected by *A. lipoferum*, 'C3 plants' (e.g. barley, oats, rice, rye, wheat) by strains of *A. brasilense*.

**Azotobacter** A genus of Gram-negative, CYST-forming bacteria (family AZOTOBACTERACEAE) which occur e.g. in fertile soils of near-neutral pH. The cells are peritrichously flagellated or non-motile, and are commonly short rods or coccobacilli – though *A. paspali* regularly forms both rods and long filaments; the organisms appear to contain many copies of the chromosome per cell [JGM (1984) 130 1603–1612]. Carbon sources used by all species include e.g. glucose, fructose, sucrose, acetate, fumarate, gluconate, and ethanol; most species can use nitrate and/or ammonium salts as a source of nitrogen. In the presence of combined nitrogen growth can occur within the pH range ca. 5–8.5; NITROGEN FIXATION occurs optimally within the pH range 7–7.5. In laboratory cultures nitrogen-fixing ability declines with age, and is very poor immediately prior to encystment. (Cyst-formation occurs maximally in old cultures on nitrogen-free media containing 0.2% butanol.) The optimum growth temperature varies with species, and is ca. 30–37°C. GC%: ca. 63–68. Type species: *A. chroococcum*.

*A. armeniacus*. Peritrichously flagellated. Can use e.g. caprylate and mannitol but not e.g. caproate; some strains can use propionate.

*A. beijerinckii*. Non-motile. Can use e.g. malonate and propionate but not caproate or rhamnose.

*A. chroococcum*. Peritrichously flagellated. Can use e.g. caproate, mannitol and propionate, but not e.g. caprylate.

*A. nigricans*. Non-motile. Cannot use caproate, propionate or rhamnose. Some strains form e.g. a yellow or dark non-diffusible pigment or a dark diffusible pigment.

*A. paspali*. Peritrichously flagellated. Cannot use caproate, caprylate, malonate, mannitol, propionate or rhamnose, but can use oxaloacetate, and some strains can use propan-1-ol. Appears to occur only on (or within?) the root cortex of the grass *Paspalum notatum*.

*A. vinelandii*. Peritrichously flagellated; non-motile strains have been reported. Can use caproate, caprylate, malonate,

mannitol, propionate and rhamnose. A yellowish-green water-soluble fluorescent pigment is formed on iron-deficient media.

[Book ref. 22, pp. 220–229.]

**Azotobacteraceae** A family of Gram-negative (or Gram-variable), aerobic, chemoorganotrophic bacteria which occur in soil, in the rhizosphere, and in aquatic habitats; the organisms are capable of NITROGEN FIXATION – typically under free-living conditions, but sometimes in association with higher plants. Cells: ovoid, or round-ended rods (sometimes filaments), 1.5–2.0  $\mu\text{m}$  or more in width, which may be motile (polarly or peritrichously flagellated) or non-motile; some species form cysts. Pigments, some fluorescent, are formed by some species. PHB can be accumulated. Catalase +ve. Oxidase +ve (most strains of most species). GC%: ca. 52–68. Two genera: AZOMONAS, AZOTOBACTER. [Book ref. 22, pp. 219–234.]

**azotoflavin** See FLAVODOXINS.

**AZT** (3'-azido-3'-deoxythymidine; zidovudine) A thymidine analogue ANTIRETROVIRAL AGENT used in the treatment of AIDS. AZT is converted by cellular enzymes to the triphosphate derivative which is then incorporated – instead of thymidine – into (provirus) DNA by the viral REVERSE TRANSCRIPTASE (see RETROVIRIDAE); the presence of the 3'-azido group inhibits further chain elongation by preventing the formation of a phosphodiester bond at the 3' position. Cellular DNA polymerase  $\alpha$  is much less sensitive than reverse transcriptase to AZT triphosphate.

AZT competes for intracellular phosphorylation with another NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITOR, stavudine.

As high-level resistance develops readily if AZT is used alone, it is used in combination with other drugs.

Unlike other nucleoside reverse transcriptase inhibitors, AZT undergoes significant metabolism (glucuronidation) in the liver;

drugs (e.g. PROBENECID) that inhibit glucuronidation may therefore affect the plasma concentration of AZT.

The use of AZT is associated with megaloblastic changes; the drug may induce a dose-dependent macrocytic anaemia (less often a severe normocytic anaemia) and is also able to induce neutropenia [haematological aspects of HIV infection: BCH (2000) 13 215–230].

The value of AZT in anti-AIDS combination drug therapy (against HIV-1) was indicated by an in vitro study in which those nucleoside reverse transcriptase inhibitors which lacked the 3'-azido moiety were less active against a particular mutant form of the reverse transcriptase [AAC (2005) 49 1139–1144].

**azthreonam** *Syn.* AZTREONAM.

**aztreonam** (azthreonam) A MONOBACTAM derivative in which  $R'$  = an aminothiazoleoxime group,  $R''$  = H,  $R'''$  =  $\text{CH}_3$ ,  $R''''$  =  $\text{SO}_3^- \text{K}^+$  (see  $\beta$ -LACTAM ANTIBIOTICS). It is active only against aerobic Gram-negative bacteria, having a high degree of specificity for PBP3 of Gram-negative bacteria (see PENICILLIN-BINDING PROTEINS); it is resistant to most  $\beta$ -lactamases. [Action, use: Drugs (1986) 31 96–130.]

**Azuki bean mosaic virus** See POTYVIRUSES.

**azure** See *polychrome* METHYLENE BLUE.

**azurin** (1) A BLUE PROTEIN which occurs in certain bacteria (e.g. *Alcaligenes denitrificans*, *Bordetella pertussis*, *Paracoccus denitrificans*, *Pseudomonas aeruginosa*); depending on source, the MWt ranges from ca. 12000 to ca. 15000, and the  $E_m$  appears to be in the approximate range 230–330 mV.

(2) A solution of  $\text{CuSO}_4$  and  $\text{NH}_4\text{OH}$  used as an agricultural antifungal agent.

**azygospore** A parthenogenically derived spore, similar to a ZYGOSPORE, formed e.g. by many species of the Mucorales.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# B

**B cell** (*immunol.*) *Syn.* B LYMPHOCYTE.

**B cell differentiation factor** See LYMPHOKINES.

**B cell growth factor** See LYMPHOKINES.

**B cell superantigen** See SUPERANTIGEN.

**B-DNA** See DNA.

**B lymphocyte** (B cell) A type of LYMPHOCYTE concerned primarily with ANTIBODY FORMATION (cf. T LYMPHOCYTE). In mammals, B cells are formed initially in the fetal liver, but later they develop from haemopoietic stem cells in the bone marrow. (In birds, B cells appear to develop in the BURSA OF FABRICIUS.) B cells occur e.g. in blood, in lymph and in the spleen. In an adult, the B cell population consists of  $>10^6$  clones, the cells of each clone being potential sources of antibodies with a unique and highly specific antigen-binding capacity.

In mammals, B cells mature in a series of stages. Stem cells give rise to *pro-B cells* which, in turn, develop as *pre-B cells*. Pre-B cells differ from mature B cells e.g. in that they express no surface immunoglobulin (Ig), i.e. they are sIg<sup>-</sup>, although they contain *mu* HEAVY CHAINS (associated with so-called *surrogate light chains*) which may be located at the cell surface. The next stage, the *immature B cell*, is characterized by the presence of *monomeric* IgM at the cell surface; interaction with specific antigen at this stage may lead to inactivation of the cell. The *mature B cell* displays IgM and IgD at the cell surface (with antigen-binding sites facing outwards); the IgM and IgD have identical antigenic specificity. The B cell reaches maturity, in an antigen-independent way, within the bone marrow.

In addition to antibodies, the surface of a mature B cell displays various types of molecule involved in the recognition of exogenous factors and the initiation of intracellular signalling. These molecules include: (i) a receptor that mediates *isotype switching* (= *class switching* – e.g. the IgM → IgG switch following antigenic stimulation) (see CD40); (ii) MHC class II molecules (required for presenting antigen to a T cell: see ANTIBODY FORMATION); (iii) co-stimulatory molecules (designated B7.1 and B7.2) which, during B cell–T cell contact, bind to a specific T cell receptor and initiate signals that activate the T cell (see CD28); (iv) CD32: a low-affinity receptor for the Fc portion of IgG (the binding of antigen-bound antibody to CD32 may suppress the ongoing production of specific antibodies); (v) CD21 (involved in B cell activation, and a binding site for certain components of COMPLEMENT); (vi) receptors for CYTOKINES (including INTERLEUKIN-1; INTERLEUKIN-4, which e.g. induces isotype switching and promotes expression of MHC class II molecules on B cells; and INTERLEUKIN-6).

The body's B cell population can be divided into three subsets on the basis of the CD5 and CD23 antigens. B cells in the general circulation are mainly CD5<sup>-</sup>, CD23<sup>+</sup>; they have a relatively short existence and are continually renewed from the bone marrow stem cells. Two other subsets, one CD5<sup>+</sup>, CD23<sup>-</sup>, and the other CD5<sup>-</sup>, CD23<sup>-</sup>, are found mainly in mucosal sites (e.g. the peritoneal cavity) and are self-renewing (albeit with precursor cells in the bone marrow); these cells can rapidly produce IgM antibodies (of a limited range of specificities) in response to bacterial polysaccharides, and can do so without help from T cells. These two populations of B cells are viewed as a first line of defence against bacterial incursion in sites which are particularly vulnerable to infection.

No further development of the B cell occurs unless it encounters specific antigen e.g. within so-called *germinal centres* in the spleen or lymph nodes. In the event of contact with specific antigen, the outcome depends e.g. on the type of antigen involved and the contribution of T cells: see ANTIBODY FORMATION. When a B cell is appropriately stimulated it prepares for the role of antibody formation by initially undergoing BLAST TRANSFORMATION and then proliferating to form a clone of cells of identical antigenic specificity (= *clonal expansion*); some of these cells develop as PLASMA CELLS while others (commonly) become MEMORY CELLS.

B cells which do not bind specific antigen remain viable for a limited period of time and subsequently undergo APOPTOSIS.

**B-tubule** (B-subfibre) See FLAGELLUM (b).

**B-type inclusion body** See POXVIRIDAE.

**B-type particles** See TYPE B ONCOVIRUS GROUP.

**B-type starter** See LACTIC ACID STARTERS.

**B virus** (cercopithecine herpesvirus 1; cercopithecid herpesvirus 1; herpesvirus B; *Herpesvirus simiae*) A herpesvirus (subfamily ALPHAPERESVIRINAE) which naturally infects monkeys of the genus *Macaca*. In rhesus monkeys (*M. mulatta*) infection may be asymptomatic, or vesicular lesions (which may ulcerate) may develop in the mouth and sometimes on the skin and conjunctivae. B virus may be transmitted to humans e.g. by monkey bites or scratches, and can cause in humans a severe (usually fatal) encephalomyelitis ('monkey-bite encephalomyelitis').

**B<sub>12</sub> coenzymes** See VITAMIN B<sub>12</sub>.

**B19 parvovirus** See ERYTHROVIRUS.

**B663** CLOFAZIMINE.

**Babes–Ernst granules** METACHROMATIC GRANULES observed in bacteria.

**Babesia** A genus of protozoa (subclass PIROPLASMASINA) parasitic in invertebrates and in the erythrocytes (RBCs) of vertebrates (cf. THEILERIA); at least some species (including *B. equi* and *B. microti*) develop in the lymphocytes (as well as in the RBCs) of the vertebrate host, and it has been suggested that such species be transferred to other genera (e.g. *Nicolli*, *Nuttallia*). Some species (e.g. *B. bigemina*, *B. bovis*) can cause tick-borne disease in domestic animals (see REDWATER FEVER), and some (e.g. *B. divergens*, *B. microti*) can cause disease in man [ARE (1981) 26 90–92]. The cells of *Babesia* are rounded or pyriform, ca. 1–6 μm. In the typical life cycle, sporozoites of *Babesia* are injected into the vertebrate host by the tick vector, and each sporozoite enters an RBC and undergoes schizogony to form two or four merozoites – which infect fresh RBCs when the host cell ruptures. Following the tick's meal of infected blood, gametes are formed in the tick's gut, and these fuse and give rise to a (motile) kinete which passes, via various tissues, to the salivary glands – there undergoing sporogony and forming many sporozoites. Unlike *Theileria*, *Babesia* can invade the ovary and egg of the tick, and can be transmitted transovarially to the tick's offspring. [Life cycles of *Babesia* and *Theileria*: AP (1984) 23 37–103.]

**babesiosis** Any disease of man or animals caused by a species of BABESIA (e.g. REDWATER FEVER).

**Bacillaria** See DIATOMS.

**Bacillariophyta** See DIATOMS.

**bacillary angiomatosis** See BARTONELLA.

**bacillary dysentery** See DYSENTERY (a).

**bacillary white diarrhoea** *Syn.* PULLORUM DISEASE.

**bacille Calmette–Guérin** See BCG.

**bacillin** *Syn.* BACILYSIN.

**bacillus** (1) A member of the genus *BACILLUS*. (2) Any rod-shaped bacterial cell, i.e., a cell whose length is ca. two or more times greater than its width. (cf. COCCOBACILLUS and FILAMENT.) A bacillus may be straight or curved (cf. *VIBRIO* sense 2), with rounded, truncated or tapered ends (cf. FUSIFORM), and may occur singly, in groups, pairs, chains, etc. (See also PALISADE.)

**Bacillus** A genus of GRAM TYPE-positive, strictly aerobic or facultatively anaerobic, typically catalase-positive, rod-shaped, ENDOSPORE-forming bacteria. The organisms typically occur as saprotrophs in soil and water, but certain species can be pathogenic in man and other mammals (see e.g. *B. anthracis* and *B. cereus*, below) and some species are entomopathogenic (see e.g. *B. moritai*, *B. popilliae* and *B. thuringiensis*). [Insecticidal species: Book ref. 171, pp. 185–209; MR (1986) 50 1–24.] *Bacillus* spp can cause biodeterioration (see e.g. FLAT SOUR, LEATHER SPOILAGE, SWELL), but some species are used commercially as sources of antibiotics (see e.g. BACITRACIN, POLYMYXINS) or other products (e.g. DEBRANCHING ENZYMES, GLUCOSE ISOMERASE, GLYCEROKINASE, SUBTILISINS).

Cells: typically motile rods, commonly ca.  $0.5\text{--}1.5 \times 2\text{--}6 \mu\text{m}$ , often in chains; some strains form a CAPSULE, and some are pigmented. (See also S LAYER and TEICHOIC ACIDS.) Metabolism may be respiratory (see RESPIRATION) – some strains being capable of NITRATE RESPIRATION – or facultatively fermentative (see FERMENTATION); a few species (e.g. *B. macerans*, *B. polymyxa*) can carry out NITROGEN FIXATION. Most species are chemoorganoheterotrophs; *B. schlegelii* can grow chemolithoautotrophically (see CARBOXYDOBACTERIA). Utilizable substrates for organoheterotrophic species range from simple sugars and other carbohydrates to e.g. uric acid (see *B. fastidiosus*) and proteinaceous materials; PENTOSEs are metabolized via the HEXOSE MONOPHOSPHATE PATHWAY. Many species can grow on NUTRIENT AGAR. Storage compounds include e.g. POLY- $\beta$ -HYDROXYBUTYRATE. The genus includes psychrotrophs (e.g. *B. globisporus*), thermophiles (e.g. *B. schlegelii*, *B. stearothermophilus*) and alkalophiles (e.g. *B. alcalophilus*, *B. firmus*). GC%: ca. 30–70. Type species: *B. subtilis*.

*B. alcalophilus*. An ALKALOPHILE (q.v.): optimum growth pH ca. 9–10; no growth below pH 7.

*B. alvei*. See EUROPEAN FOULBROOD.

*B. amyloliquefaciens*. Similar or identical to *B. subtilis*. (See also AMYLASES.)

*B. amylolyticus*. *Nom. rev.* [IJSB (1984) 34 224–226].

*B. aneurinoliticus*. A species, related to *B. brevis*, which produces a thiaminase. (See also BACTERIOPHAGE  $\phi$ BA1.)

*B. anthracis*. The causal agent of ANTHRAX. Cells: non-motile, ca.  $1.5 \times 3\text{--}6 \mu\text{m}$ , typically square-ended and usually in chains. Virulent strains form a PLASMID-encoded toxin (see ANTHRAX TOXIN) and a plasmid-encoded poly-D-glutamic acid CAPSULE. [Capsule-encoding plasmid: see e.g. Inf. Immun. (1985) 49 291–297.] (cf. STERNE STRAIN.) Growth occurs on nutrient agar. In biochemical tests *B. anthracis* gives results very similar to those of *B. cereus*. Lecithinase activity is weak or absent. Haemolysis on sheep-blood agar is weak or absent. *B. anthracis* is susceptible to the ‘ $\gamma$  phage’ (*B. cereus* is not). On agar containing benzylpenicillin (0.05–0.5 unit/ml) *B. anthracis* gives rise to chains of enlarged, spherical cells (‘string of pearls’ effect).

*B. azotofixans*. A proposed (nitrogen-fixing) species from Brazilian soil [IJSB (1984) 34 451–456].

*B.adius*. Similar to *B. brevis*. Growth is not inhibited by 5% NaCl. The (ellipsoidal) spore does not distend the cell.

*B. brevis*. Typically forms no acid or gas from carbohydrates. Growth occurs at 50°C. Spore: ellipsoidal, distending the cell. (See also TYROCIDINS.)

‘*B. caldolyticus* group’. Strains (including *B. caldotenax* and *B. caldovelox*) closely related to *B. stearothermophilus*.

*B. cereus*. A saprotroph or opportunist pathogen which can cause FOOD POISONING (q.v.) or, rarely, e.g. meningitis. [Meningitis due to *B. cereus*, and review of *Bacillus* infections other than anthrax: Israel J. Med. Sci. (1983) 19 546–551.] Cells: typically motile rods (mean width ca.  $1.5 \mu\text{m}$ ), sometimes pigmented. Spore: ellipsoidal, not distending the cell. Acid is formed in anaerobic glucose broth; no acid is formed from arabinose, mannitol or xylose. No gas is formed from carbohydrates. Most strains are VP +ve. Starch and casein are hydrolysed, and lecithinase are produced. Nitrate is reduced by most strains. No growth at 50°C.

*B. circulans*. Similar to *B. polymyxa* but ferments carbohydrates anaerogenically; typically, a range of carbohydrates is fermented. (See also MOTILE COLONIES.)

*B. coagulans*. Forms lactic acid as the major product of glucose fermentation; 2,3-butanediol is also produced. No gas is formed from carbohydrates. VP +ve. (See also GLUCOSE ISOMERASE.)

*B. euloomarae*. See MILKY DISEASE.

*B. fastidiosus*. Obligately aerobic. Uses uric acid as a source of carbon, nitrogen and energy.

*B. firmus*. An ALKALOPHILE. Forms acid from glucose but typically from few other carbohydrates.

*B. fribourgensis*. See MILKY DISEASE.

*B. globisporus*. A PSYCHROTROPH (maximum growth temperature ca. 25–30°C). Urease +ve. Spore: round, distending the cell.

*B. larvae*. See AMERICAN FOULBROOD.

*B. lautus*. *Nom. rev.* [IJSB (1984) 34 224–226].

*B. lentimorbis*. See MILKY DISEASE.

*B. licheniformis*. Morphologically and biochemically similar to *B. subtilis*, but growth readily occurs anaerobically (see also DENITRIFYING BACTERIA).

*B. macerans*. Biochemically very similar to *B. polymyxa*. Forms SCHARDINGER DEXTRINS.

*B. megaterium*. Cell width commonly ca.  $1.5 \mu\text{m}$  but may reach ca.  $3.0 \mu\text{m}$  in carbohydrate-containing media. Spore: ellipsoidal, not distending the cell. Glucose and many other carbohydrates are utilized anaerogenically.

*B. moritai*. A species pathogenic e.g. in house-flies. The addition of *B. moritai* spores to faeces has been found to reduce the emergence of adult house-flies by up to ca. 90%.

*B. mycoides*. Morphologically and biochemically very similar to *B. cereus*. Often regarded as a non-motile variety of *B. cereus*.

*B. pabuli*. *Nom. rev.* [IJSB (1984) 34 224–226].

*B. pasteurii*. An ALKALOPHILE (optimum growth at ca. pH 9). Cells: typically slender (ca.  $0.5\text{--}1.0 \mu\text{m}$  wide). Spore: spherical, typically distending the cell. Carbohydrates are attacked either very weakly or not at all. Urease +ve.  $\text{NH}_3$  is needed for growth.

‘*B. piliformis*’. See TYZZER’S DISEASE.

*B. polymyxa*. Cells: typically slender (ca.  $0.5\text{--}1.0 \mu\text{m}$  wide); usually motile. Spore: ellipsoidal, distending the cell. Grows well anaerobically, and produces acid and gas from carbohydrates; typically, glucose, mannitol, and many other sugars and sugar alcohols are utilized. Glucose is fermented via the BUTANEDIOL FERMENTATION. Most strains attack e.g. casein, gelatin, starch

## **bacillus Calmette–Guérin**

and pectins, and most can carry out NITROGEN FIXATION. (See also POLYMYXINS.)

*B. popilliae*. See MILKY DISEASE.

*B. psychrophilus*. A proposed (psychrophilic) species [IJSB (1984) 34 121–123].

*B. pulvificiens*. Proposed species (isolated from a diseased bee) [IJSB (1984) 34 410–413].

*B. pumilus*. Cells: typically slender (0.5–1.0 µm wide); usually motile. Spore: elongated, not distending the cell. Metabolically similar to *B. subtilis*, but starch is not utilized. Usually VP +ve.

*B. schlegelii*. See CARBOXYDOBACTERIA and HYDROGEN-OXIDIZING BACTERIA.

*B. sphaericus*. Cells: slender (ca. 0.5–1.0 µm wide); usually motile. Spore: spherical, distending the cell. Typically, carbohydrates are not utilized. Can cause LEATHER SPOILAGE, and can be insecticidal to e.g. mosquito larvae – toxicity apparently being due to an uncharacterized toxin and not associated with sporulation. [Field evaluation of a *B. sphaericus* strain as a mosquito ‘biocide’: J. Inv. Path. (1986) 48 133–138.]

*B. stearothermophilus*. Thermophilic; can grow at e.g. 65°C. Cells: ca. 1.0 µm wide; spore: ellipsoidal, often distending the cell. The spores are highly resistant to heat, and are sometimes used to monitor AUTOCLAVE performance. (See also FLAT SOUR.) Typically, a range of carbohydrates can be metabolized anaerobically and anaerogenically; the main product of carbohydrate fermentation commonly appears to be lactic acid. (See also GLYCEROKINASE.)

*B. subtilis*. Cells: slender (typically ca. 0.8 µm wide), usually motile; chains are uncommon. (See also CERULENIN and MACROFIBRE.) Spore: ellipsoidal, usually not distending the cell. Metabolism appears to be primarily respiratory. Growth does not occur in anaerobic glucose broth. Glucose, various other sugars and sugar alcohols, and starch, are metabolized anaerogenically. VP +ve. Nitrate is reduced. Casein and gelatin are hydrolysed. Phages which infect *B. subtilis* include e.g. BACTERIOPHAGE PBS1, BACTERIOPHAGE φ105 and BACTERIOPHAGE SPO1.

*B. thuringiensis*. An entomopathogenic species which is morphologically and biochemically very similar to *B. cereus*, differing primarily in its formation of DELTA ENDOTOXIN (q.v.).

*B. validus*. *Nom. rev.* [IJSB (1984) 34 224–226].

Other species include e.g. *B. insolitus*, *B. laterosporus*, *B. lentus*, and *B. pantothenicus*.

*Note on the identification of species.* Some mutually contradictory tables of biochemical test reactions have been published. For example, the VP test reactions (obtained using traditional methods) given in Book ref. 46, p. 1731 differ significantly, in respect of a number of species, from those (obtained using the API system) given in JGM (1984) 130 1871–1882. (Species designated as ‘VP +ve’ above are confirmed as such in many sources.)

**bacillus Calmette–Guérin** See BCG.

**bacilysin** (‘bacillin’; ‘tetaïne’) A dipeptide ANTIBIOTIC which is active against a wide range of Gram-positive and Gram-negative bacteria and e.g. against *Candida albicans*. It consists of a C-terminal epoxy-L-amino acid (‘anticapsin’) and an N-terminal L-alanine residue; it is taken up by peptide transport systems in sensitive cells, and is subsequently hydrolysed by cellular enzymes to release the anticapsin – an inhibitor of glucosamine (and hence e.g. PEPTIDOGLYCAN) synthesis. (cf. WARHEAD DELIVERY.)

**bacitracin** A cyclic dodecapeptide ANTIBIOTIC produced by strains of *Bacillus* spp. It is active against many Gram-positive and certain Gram-negative bacteria (e.g. *Neisseria* spp.,

*Haemophilus* spp). In the presence of divalent cations (particularly Zn<sup>2+</sup>) bacitracin binds to bactoprenol pyrophosphate, inhibiting the regeneration of bactoprenol monophosphate during e.g. PEPTIDOGLYCAN biosynthesis; it can also inhibit other processes involving bactoprenol pyrophosphate (e.g. O-specific chain formation in LIPOPOLYSACCHARIDE biosynthesis) and can affect membrane permeability. Bacitracin is used clinically e.g. for the topical treatment of local infections, and as a FEED ADDITIVE for ruminants to decrease methane production in the RUMEN.

**back focal plane** Of a convex lens: the focal plane furthest from the light source.

**back mutation** (reverse mutation) (1) A MUTATION which reverses the effects of a FORWARD MUTATION by restoring the original nucleotide sequence. (2) Either a mutation as in sense 1 above, or an *intragenic* SUPPRESSOR MUTATION.

**background mutation** *Syn.* SPONTANEOUS MUTATION.

**bacon spoilage** See MEAT SPOILAGE.

**BACTEC™ culture systems** Liquid media (marketed by Becton Dickinson) which can be used e.g. for the growth of *Mycobacterium tuberculosis* – growth being detectable more rapidly (~1–2 weeks) than is usually possible on solid media (~6 weeks). These media may be used for (i) detecting *M. tuberculosis* in clinical specimens, and (ii) examining an isolate of the pathogen for susceptibility to antibiotics; for the latter purpose an isolate is tested for growth (or lack of growth) in a medium containing a known amount of the given antibiotic.

Earlier BACTEC systems were radiometric, i.e. they detected growth by detecting radioactive carbon dioxide produced from a radioactive substrate in the medium. A more recent system, the BACTEC MGIT™ 960 (MGIT = mycobacteria growth indicator tube), monitors growth by means of a fluorescent sensor system which detects the consumption of oxygen. [Evaluation of BACTEC MGIT 960: JCM (1999) 37 748–752.]

**bacteraemia** (bacteremia) The condition in which viable bacteria are present in the bloodstream. (cf. PYAEMIA; SEPTICAEMIA.)

**bacteremia** *Syn.* BACTERAEMIA.

**bacteria** (*singular:* bacterium) (1) Formerly: a term which referred, collectively, to *all* prokaryotic microorganisms (see PROKARYOTE); the term was also used to refer to a population of specific prokaryote(s) of any given type.

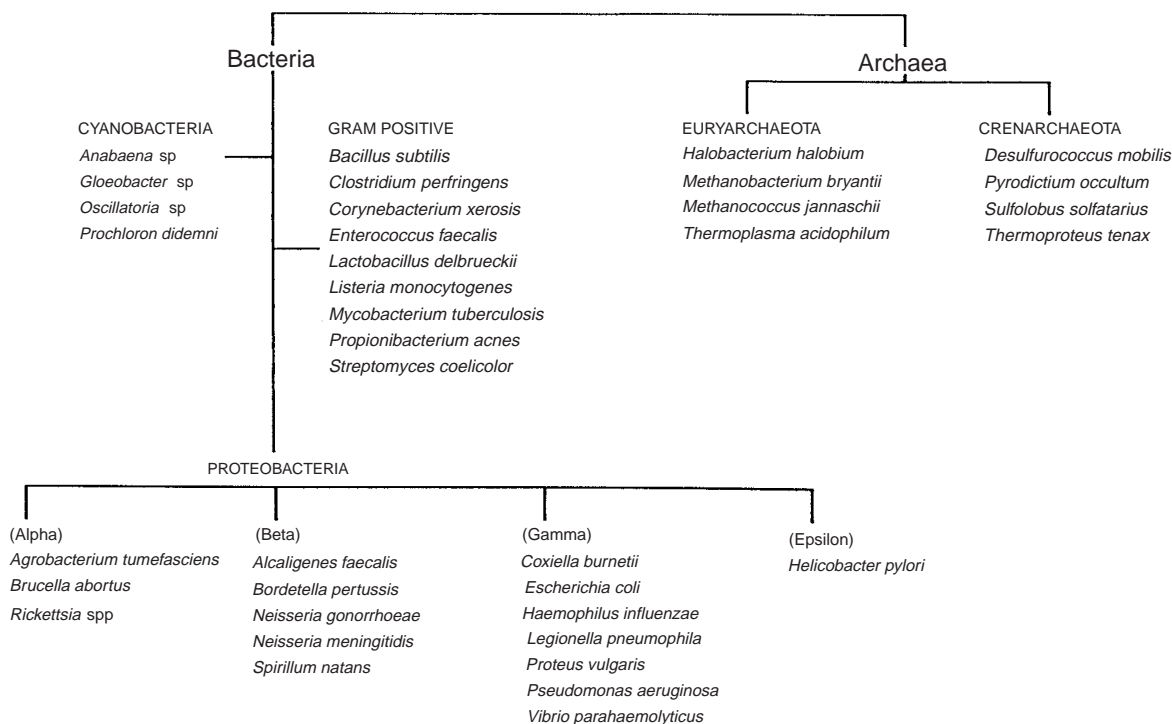

(2) All, or particular, members of the domain Bacteria (see next entry).

*Note.* In literature prior to the 1980s ‘bacteria’ was always used with the meaning given in sense 1. With the establishment of the domain ARCHAEA (q.v.), appropriate usage is that given in sense 2.

**Bacteria** A taxon (DOMAIN) comprising one of the two fundamentally distinct groups of prokaryotic microorganisms (see PROKARYOTE and ARCHAEA). (See also previous entry.)

The bacteria are a diverse group of (usually) single-celled organisms. Most are free-living, occurring e.g. in soil, on plants, in various aquatic habitats, and even in antarctic snow [AEM (2000) 66 4514–4517]; some are important in the cycles of matter (see CARBON CYCLE, NITROGEN CYCLE, SULPHUR CYCLE). Bacteria are also found as symbionts in plants, animals and certain microorganisms (see CAEDIBACTER, MYCETOCYTE, ROOT NODULES, RUMEN).

A minority of bacteria occur as intracellular or extracellular parasites or pathogens in man and/or other animals. In man, bacteria can cause a number of major and minor diseases – which include e.g. ANTHRAX, BOTULISM, BRUCELLOSIS, CHOLERA, DIPHTHERIA, DYSENTERY, ERYSIPELAS, GONORRHOEA, LEGIONNAIRE’S DISEASE, LEPROSY, LYME DISEASE, MENINGITIS, PLAGUE, PSEUDOMEMBRANOUS COLITIS, Q FEVER, SCARLET

**BACTERIA:** examples of species in some of the groups in a current taxonomic scheme for the Bacteria (some species of the domain Archaea are also shown); the lines are not intended to reflect evolutionary distances between the organisms. A number of groups not shown in the figure are outlined in the text; note, for example, that the Gram-positive species are divided into 'high GC%' and 'low GC%'.

Reproduced from *Bacteria*, 5th edition, Figure 16.5, page 436, Paul Singleton (1999) copyright John Wiley & Sons Ltd (UK) (ISBN 0471-98880-4) with permission from the publisher.

FEVER, SYPHILIS, TETANUS, TOXIC SHOCK SYNDROME, TRACHOMA, TUBERCULOSIS, TULARAEMIA, TYPHOID, TYPHUS FEVERS, WHIPPLE'S DISEASE and WHOOPING COUGH.

Bacteria cause economically important diseases in livestock as well as infections in wild animals – see e.g. CATTLE DISEASES, FISH DISEASES, HORSE DISEASES, PIG DISEASES, SHEEP DISEASES. (See also INSECT DISEASES.)

Relatively few bacteria cause disease in plants (but see e.g. ERWINIA, SPIROPLASMA, XANTHOMONAS).

Predatory/bacteriolytic bacteria include species of ANAEROPLASMA, BDELLOVIBRIO, MYXOBACTERIALES and VAMPIROVIBRIO.

Bacteria are used in a number of commercial/manufacturing processes: see e.g. BIOPOL, DAIRY PRODUCTS, GLUTAMIC ACID, LEACHING, PICKLING, RETTING, SAUERKRAUT, SOY SAUCE, SUBTILISINS, VINEGAR, VITAMIN B12. Certain antibiotics (e.g. POLYMYXINS, STREPTOMYCIN and some  $\beta$ -LACTAM ANTIBIOTICS) can be synthesized by bacteria. (See also BIOASSAY, BIOFUEL CELL and BIOLOGICAL CONTROL.)

In size, most bacteria are between 1 and 10  $\mu\text{m}$  (maximum dimension). The smallest range from  $<1 \mu\text{m}$  (e.g. *Chlamydia*, *Francisella*, *Rickettsia*). One of the largest ( $>600 \mu\text{m}$ ) is *Epsilonleishmania fishelsoni* [Nature (1993) 362 239–241].

The basic shapes of bacteria are BACILLUS (sense 2) (also called 'rod'), COCCUS and SPIRILLUM (sense 1); the coccus seems likely to be a degenerate form of the rod [evolution of

bacterial morphology: Microbiology (1998) 144 2803–2808]. (See also e.g. COCCOBACILLUS, FILAMENT, L FORM, MYCELIUM, PLEOMORPHISM (sense 1), SPIROCHAETALES and VIBRIO (sense 2).) In general, the shape of a bacterium is determined primarily by its species. (cf. PROTOPLAST.)

According to species, a bacterial cell may have certain appendages: see e.g. FIMBRIAE, FLAGELLUM, PILI, PROSTHECA AND SPINA. (See also CAPSULE.)

Many types of bacteria are motile (see MOTILITY); motile species commonly exhibit CHEMOTAXIS.

Cells may occur singly or in pairs, chains, clusters, PACKETS, PALISADES etc.; some bacteria of the order ACTINOMYCETALES form a mycelium. (See also COENOCYTE and CONSORTIUM.)

Some species form EXOSPORES; some form ENDOSPORES. Members of the MYXOBACTERIALES form fruiting bodies.

A bacterial cell lacks the sophisticated physical compartmentalization of eukaryotic cells. However, bacteria exhibit a 'functional compartmentalization' [FEMS Reviews (1993) 104 327–346]; this refers to various *molecular* strategies – such as the self-assembly of protein components of composite enzyme systems (see e.g. PROTEASOME). Moreover, the localization of proteins in a bacterium now appears to be much more organized than was previously supposed [Science (1997) 276 712–718]. [Dynamic spatial regulation in the bacterial cell: Cell (2000) 100 89–98.]

## bacterial blotch of mushrooms

In most species there is a characteristic type of CELL WALL in which PEPTIDOGLYCAN is a common constituent (cf. ARCHAEA); the mycoplasmas are atypical in being wall-less.

Ester-linked lipids occur in the bacterial CYTOPLASMIC MEMBRANE (cf. ARCHAEA). In common with e.g. higher animals and plants, the cytoplasmic membrane in many (not all) bacteria (and in some archaeans) contains aquaporins and/or glycerol facilitators: see MIP CHANNELS. (See also OSMOREGULATION.)

Various TRANSPORT SYSTEMS are associated with the cell envelope (see e.g. PROTEIN SECRETION and PTS). TWO-COMPONENT REGULATORY SYSTEMS regulate responses to various environmental stimuli.

Energy may be obtained by FERMENTATION (sense 1), by RESPIRATION, and/or (in e.g. CYANOBACTERIA) by PHOTOSYNTHESIS. (See also PURPLE MEMBRANE.)

According to species, bacteria may be obligate or facultative AEROBES or ANAEROBES. They may be CHEMOTROPHS and/or PHOTOTROPHS, HETEROTROPHS or AUTOTROPHS, and some are CHEMOLITHOAUTOTROPHS.

The bacterial genome commonly consists of covalently-closed circular DNA; however, in some bacteria (e.g. *Borrelia burgdorferi* and species of *Streptomyces*) the DNA is linear. The number of chromosomes per cell depends e.g. on species and on the growth rate. In *Vibrio cholerae* the genome consists of two circular chromosomes (chromosome 1 = ca. 2961 kb; chromosome 2 = ca. 1073 kb) [Nature (2000) 406 477–483]. For some species, the complete sequence of nucleotides in the genome has been determined – e.g. *Borrelia burgdorferi* [Nature (1997) 390 580–586], *Buchnera* [Nature (2000) 407 81–86], *Escherichia coli* [Science (1997) 277 1453–1474], *E. coli* O157:H7 [Nature (2001) 409 529–533; erratum: Nature (2001) 410 240], *Helicobacter pylori* [Nature (1997) 388 539–547], *Mycobacterium tuberculosis* [Nature (1998) 393 537–544] and *Neisseria meningitidis* (serogroup A strain) [Nature (2000) 404 502–506].

In many bacteria the genome is supplemented by one or more plasmids (see PLASMID); bacterial plasmids are commonly circular, but some are linear. Certain bacteria are normally plasmid-free; they include species of *Anaplasma*, *Bartonella*, *Brucella* and *Rickettsia*. (See also BACTERIOPHAGE and LYSOGENY.)

Reproduction occurs asexually, usually by BINARY FISSION but sometimes by BUDDING or TERNARY FISSION. (See also CELL CYCLE.) A developmental cycle occurs e.g. in CAULOBACTER, CHLAMYDIA and RHODOMICROBIUM.

Despite the lack of sexual reproduction, gene transfer between bacteria can occur by CONJUGATION, CONJUGATIVE TRANSPOSITION, TRANSDUCTION or TRANSFORMATION.

*Taxonomy.* Until the 1980s, bacterial TAXONOMY was based primarily on criteria such as staining reaction, morphology and substrate requirements. Although some of the earlier taxa (e.g. ENTEROBACTERIACEAE) are still recognized, the modern approach is based mainly on molecular criteria, i.e. base sequences in nucleic acids. Using molecular criteria, bacteria have been divided into a number of groups which are believed to reflect evolutionary affinities; some of these groups are shown in the figure on page 71. An outline of the scheme is as follows.

- Cyanobacteria (see CYANOBACTERIA).
- *Cytophaga/Flexibacter/Bacteroides* group. As well as the named organisms, the group includes species of e.g. *Flavobacterium*, *Microscilla*, *Saprospira*, *Sphingobacterium*, *Spirisoma* and *Sporocytophaga*.
- Fibrobacteria. *Fibrobacter* spp.
- Fusobacteria. *Fusobacterium*, *Leptotrichia* spp.

- Gram-positive bacteria (high GC%). Species of *Arthrobacter*, *Bifidobacterium*, *Corynebacterium*, *Faenia*, *Frankia*, *Gardnerella*, *Mycobacterium* and *Streptomyces*.
- Gram-positive bacteria (low GC%). Species of e.g. *Bacillus*, *Clostridium*, *Desulfotomaculum*, *Enterococcus*, *Erysipelothrix*, *Gemella*, *Lactobacillus*, *Leuconostoc*, *Listeria* and *Pediococcus*.
- Green non-sulphur bacteria. Species of e.g. *Chloroflexus*.
- *Planctomyces/Chlamydia* group. Species of e.g. *Chlamydia*, *Isosphaera*, *Planctomyces*.
- Proteobacteria (purple bacteria). See PROTEOBACTERIA.
- Spirochaetes. Species of e.g. *Borrelia*, *Leptonema*, *Spirochaeta*, *Treponema*.
- Thermotogales. Species of e.g. *Fervidobacterium*, *Geotoga*, *Thermotoga*.

*Bacteria from ancient sources.* It has been reported that an organism resembling *Bacillus* has been cultured from a brine inclusion located *within* a salt crystal believed to be ~250 million years old [Nature (2000) 407 897–900; discussion 844–845].

[Bacteria (general text): Book ref. 223.]

**bacterial blotch of mushrooms** See BROWN BLOTCH and GINGER BLOTCH.

**bacterial endocarditis** ENDOCARDITIS caused by bacteria.

**bacterial fin rot** A common FISH DISEASE in which infection e.g. by species of *Flexibacter*, *Aeromonas* or *Pseudomonas* leads to progressive necrosis of fins and tail; stress is an important factor in disease development. Secondary SAPROLEGNIASIS is common.

**bacterial gill disease** A FISH DISEASE affecting salmonids. Filamentous bacteria (genus uncertain) cover the gills, and death by asphyxia may result. The *primary* cause is unknown, but overcrowding is a predisposing factor.

**bacterial kidney disease** See KIDNEY DISEASE.

**bacterial leaching** (of ores) See LEACHING.

**bacterial overgrowth syndrome** See GASTROINTESTINAL TRACT FLORA.

**bacterial vaginosis** (non-specific vaginitis) A syndrome characterized by a malodorous vaginal discharge and an increase, in the vagina, in the numbers of certain bacteria – e.g. species of *Bacteroides* and GARDNERELLA (see also MOBILUNCUS); under these conditions the vaginal pH is usually >4.5, the E<sub>h</sub> of the vaginal epithelial surface is ca. +71 mV to –257 mV (normal values ca. +322 mV to +137 mV) [JID (1985) 152 379–382], and ‘clue cells’ (vaginal epithelial cells coated with small Gram-negative rods) can usually be seen in vaginal smears. In cases of bacterial vaginosis, vaginal secretions typically give a fishy, amine-like odour when treated with 10% KOH. [Diagnostic criteria: Am. J. Med. (1983) 74 14–22; JCM (1985) 22 686–687.]

**Bacteriastrium** See DIATOMS.

**bactericidal** (bacteriocidal) Able to kill at least some types of bacteria. (cf. BACTERIOSTATIC.)

**bactericidal/permeability-increasing protein** See BPI PROTEIN.

**bactericidin** (1) An antibody which, under appropriate conditions, can act as a bactericidal agent. (2) A non-specific bactericidal plasma factor (see e.g. COMPLEMENT FIXATION). (3) An antibacterial protein produced by an invertebrate – see e.g. SAR-COTOXINS.

**bacterin** A VACCINE containing killed bacterial cells.

**bacteriochlorophylls** See CHLOROPHYLLS.

**bacteriocidal** *Syn.* BACTERICIDAL.

**bacteriocin** (bacteriocine) Any of a wide variety of (usually) protein or peptide ANTIBIOTICS, produced by certain strains of

Gram-positive and Gram-negative bacteria, which are bacteriostatic or bactericidal – often specifically to organisms that are closely related to the bacteriocin-producing strain. Bacteriocins include e.g. COLICINS, MICROCINS and LANTIBIOTICS.

Agents analogous to bacteriocins are produced by members of the Archaea; these agents (e.g. the *halocins* produced by halobacteria) are apparently not homologous to any bacteriocin in terms of amino acid sequences.

In size and structure, bacteriocins range from a simple modified amino acid (microcin A15), through short peptides and high-MWt colicins, to phage-like PYOCINS. (See also BACTERIOPHAGE  $\Phi$ BA1.) Some bacteriocins (lantibiotics) undergo distinctive post-translational modification which is necessary for their activity. The lantibiotic LACTICIN 3147 (produced by *Lactobacillus lactis* subsp. *lactis*) is a *two-component* bacteriocin – both peptides being necessary for activity; moreover, each of the two peptides needs modification by a separate enzyme [Microbiology (2000) 146 2147–2154].

Evolutionary relationships are evident within some groups of bacteriocins. [Molecular mechanisms of bacteriocin evolution: ARG (1998) 32 255–278.]

Bacteriocins are commonly encoded by PLASMIDS (see e.g. COLICIN PLASMID); bacteriocin-encoding plasmids include both conjugative and non-conjugative types. Examples of *chromosomally* encoded bacteriocins include ‘bacteriocin 28b’ (a colicin encoded by *Serratia marcescens*) and some of the class IIa bacteriocins produced by lactic acid bacteria (see later).

The mode of regulation of bacteriocin synthesis varies among the different groups. For example, synthesis of colicins is promoted by those conditions which trigger the SOS SYSTEM (see COLICIN PLASMID). By contrast, many bacteriocins of the lactic acid bacteria appear to be regulated by a *three-component system* which includes a histidine protein kinase, a response regulator, and an induction factor. (cf. TWO-COMPONENT REGULATORY SYSTEM). Induction factors (IFs) are small heat-stable peptides produced by the bacteriocinogenic cell. The mechanism by which IFs promote synthesis of bacteriocin is unknown, but it has been suggested that they may trigger synthesis as a result of their gradual intracellular accumulation or that their influence may reflect environmental factors. Synthesis of the bacteriocin *sakacin A* (produced by *Lactobacillus sake*) is reported to be regulated by a three-component system (which includes a 23-amino-acid cationic peptide) in a temperature-sensitive way [Microbiology (2000) 146 2155–2160]. The bacteriocin *divergin V41*, produced by *Carnobacterium divergens* strain V41, may be regulated by a two-component system [Microbiology (1998) 144 2837–2844].

The different types of bacteriocin are released in different ways from the cells which synthesize them. For example, release of colicins depends on a *lysis protein* which causes a (non-specific) increase in the permeability of the cell envelope – allowing dispersal of the bacteriocin (but with concomitant adverse effects on the producing cell). By contrast, certain bacteriocins (e.g. ENTEROCIN P) are secreted via a *sec*-dependent pathway, while some class IIa bacteriocins of the lactic acid bacteria are reported to be secreted by ABC TRANSPORTERS.

The import of some types of bacteriocin (e.g. colicins) into sensitive cells depends on the binding of the bacteriocin to a *specific* cell-surface receptor. In most or all cases, uptake of colicins appears to be an energy-dependent process (pmf being needed for transport across the outer membrane, and ATP hydrolysis being involved in transport across the cytoplasmic membrane); the route of translocation through the cell envelope depends on the given colicin (see groups A and B COLICINS). By contrast,

studies on pediocin PA-1 (a class IIa bacteriocin produced by *Pediococcus* spp) reported binding to liposomes in the absence of a protein receptor [AEM (1997) 63 524–531] – suggesting that a protein receptor may not be an absolute requirement for these bacteriocins; it may be that these (cationic) bacteriocins bind to anionic phospholipid groups in the membrane.

A given bacteriocin acts on a susceptible target cell in a characteristic way. Some bacteriocins (e.g. some colicins, lantibiotics) form pores in the cytoplasmic membrane; some (e.g. microcin B17) inhibit DNA gyrase; some (e.g. LYSTOSTAPHIN) disrupt PEPTIDOGLYCAN; and some (e.g. CLOACIN DF13) cleave 16S rRNA. It appears that, in some cases, a single bacteriocin molecule can be lethal for a sensitive cell. (Although bacteriocins are active primarily against bacteria, certain colicins and VIBRIOCINS have been reported to affect some types of eukaryotic cell [JAC (1980) 6 424–427].)

Various mechanisms provide a cell with immunity to the bacteriocin(s) it encodes. For example, while cells actively secreting colicins are damaged by their lysis proteins, neighbouring cells of the *same* strain, repressed for colicin synthesis, are protected by immunity proteins (see COLICINS). Cells producing LYSTOSTAPHIN achieve immunity by modifying their own peptidoglycan. Cells producing the lantibiotic EPIDERMIN achieve immunity by operating an ATP-dependent pump (transport system) which actively secretes any molecules of the agent that are taken up.

*Biotechnological applications of bacteriocins.* The great diversity of bacteriocins, and the ability of many of them to kill/inhibit certain pathogenic bacteria, has prompted much research into the possibility of using particular bacteriocins as antibiotics and/or as food preservatives/additives (see e.g. LACTICIN 3147).

Particularly useful bacteriocins are produced by certain LACTIC ACID BACTERIA (e.g. species of *Carnobacterium*, *Enterococcus*, *Lactobacillus* and *Lactococcus*), some of which are highly active against important food-borne pathogens (such as *Listeria monocytogenes*). According to structural and other characteristics, bacteriocins of the *lactic acid bacteria* have been classified into four classes [FEMS Reviews (1993) 12 39–86]:

*Class I.* LANTIBIOTICS: small, typically pore-forming peptides containing unusual constituents (such as lanthionine) – e.g. EPIDERMIN and NISIN.

*Class II.* Small peptides (<10 kDa) which lack unusual constituents (such as lanthionine) and which have a specific form of processing site in the precursor molecule; they exhibit stability at e.g. 100–120°C. This category is divided into three subgroups. *Class IIa* bacteriocins contain a specific N-terminal sequence, and all are highly active against *Listeria* spp. They include PEDIOCIN PA-1 and SAKACIN A. [Biosynthesis, structure and activity of class IIa bacteriocins: FEMS Reviews (2000) 24 85–106.] *Class IIb* bacteriocins are two-component, pore-forming agents. They include e.g. lactacin F and lactococcin G. *Class IIc* bacteriocins are thiol-activated peptides which require reduced cysteine residues for activity.

*Class III.* Large (>30 kDa) heat-labile proteins; they include helveticin J, lactacin A and lactacin B.

*Class IV.* Bacteriocins which consist of a protein moiety plus at least one non-protein (e.g. lipid) constituent which is necessary for activity. They include lactocin 27, leuconocin S and plantaricin S.

*Other bacteriocins.* See also PESTICIN I, PYOCINS, STAPHYLOCOCCIN and ULCERACIN 378. Bacteriocins are also produced by *Bacillus megaterium* (megacins), *Klebsiella* spp (klebicins), *Listeria monocytogenes* (monocins [Zbl. Bakt. Hyg. A (1986) 261

**bacteriocin 28b**

12–28]) and by *Clostridium botulinum* (boticins), *C. butyricum* (butyricins) and *C. perfringens* (perfringocins). (cf. AGROCINS and KILLER FACTOR.)

**bacteriocin 28b** See COLICINS.

**bacteriocin typing** A form of TYPING in which strains of bacteria are distinguished on the basis of the BACTERIOCIN(s) they produce or the bacteriocin(s) to which they are susceptible.

In one common form of bacteriocin typing (used e.g. for colicins and pyocins) the strain under test is inoculated in a diametrical strip on a blood agar plate which is incubated for ca. 12–24 hours; growth is scraped from the plate and discarded, and any cells remaining on the plate are killed by exposure to chloroform. The chloroform is allowed to evaporate, leaving a band of bacteriocin-impregnated agar. Indicator strains are then inoculated onto the agar in lines perpendicular to, and passing through, the bacteriocin-containing band; on incubation, the growth of sensitive strains is inhibited inside the band. In this procedure the test organism is typed by the range of strains susceptible to its bacteriocin(s). [Revised method for pyocin typing: JCM (1984) 20 47–50.]

**bacteriocinogenic** Able to produce a BACTERIOCIN.

**bacteriocinogenic factor** The earlier name for any PLASMID that encodes a BACTERIOCIN.

**bacteriocuprein** A bacterial CuZnSOD (see SUPEROXIDE DISMUTASE).

**bacteriocyte** In certain invertebrates, particularly insects: a specialized cell which contains intracellular bacterial symbionts. (cf. MYCETOCYTE.) Bacteriocytes occur e.g. in the cockroach (see BLATTABACTERIUM), in some marine sponges (containing ‘*Aphanocapsa*’ endosymbionts) and in aphids (see BUCHNERA).

**bacteriolysis** The lysis (rupture) of bacterial cells. In nature, various microorganisms produce enzymes or antibiotics which lyse bacteria – either to provide nutrients or (presumably) for competitive advantage. (See e.g. ANAEROPLASMA, ENSIFER, LYSOSTAPHIN, MUSHROOM CULTIVATION, MYXOBACTERIALES.) Most BACTERIOPHAGES eventually lyse their host cells to release their progeny. In the laboratory bacteria may be lysed mechanically or enzymically (see CELL DISRUPTION).

**bacterio-opsin** See OPSIN.

**bacteriophageophytin** A PHAEOPHYTIN derivative of a bacteriochlorophyll. Bacteriophageophytins occur e.g. in the REACTION CENTRES in a number of ‘purple’ photosynthetic bacteria and in the cytoplasmic membrane of some ‘green’ photosynthetic bacteria.

**bacteriophage** (phage) Any VIRUS whose host is a bacterium. (Viruses which infect cyanobacteria are conventionally called CYANOPHAGES.) Most – probably all – bacteria can be infected by particular phages; commonly, a given phage can infect only one or a few strains or species of bacteria. The consequences of phage infection depend on phage and host, and to some extent on

BACTERIOPHAGES: some representative examples<sup>a</sup>

Bacteriophage (or phage group)	Virion morphology	Principal host(s)
<i>Genome: linear dsDNA<sup>b</sup></i>		
λ	isometric head + long non-contractile tail	<i>Escherichia coli</i>
Mu	isometric head + long contractile tail	enterobacteria
MV-L3	isometric head + short tail	<i>Acholeplasma laidlawii</i>
N4	isometric head + short non-contractile tail	<i>Escherichia coli</i>
P1	isometric head + long contractile tail	<i>Escherichia coli</i>
P2	isometric head + long contractile tail	<i>Escherichia coli</i>
P22	isometric head + minimal tail	<i>Salmonella</i>
φ29	elongated head + short non-contractile tail	<i>Bacillus subtilis</i>
SPO1	isometric head + long contractile tail	<i>Bacillus subtilis</i>
T4	elongated head + long contractile tail	<i>Escherichia coli</i>
T7	isometric head + short non-contractile tail	enterobacteria
Tectiviridae (e.g. PRD1, AP50)	isometric with internal lipid membrane (no tail)	various
<i>Genome: ccc dsDNA<sup>b</sup></i>		
MV-L2	pleomorphic; envelope enclosing a DNA–protein complex	<i>Acholeplasma laidlawii</i>
PM2	icosahedral with internal lipid membrane	<i>Alteromonas espejiana</i>
<i>Genome: ccc ssDNA<sup>b</sup></i>		
Inoviridae (e.g. f1, MV-L51)	filamentous or rod-shaped	various
Microviridae (e.g. φX174)	icosahedral	enterobacteria
<i>Genome: dsRNA<sup>b</sup></i>		
φ6	enveloped nucleocapsid	<i>Pseudomonas syringae</i> pv. <i>phaseolicola</i>
<i>Genome: ssRNA<sup>b</sup></i>		
Leviviridae (e.g. MS2, Qβ)	icosahedral	various

<sup>a</sup> See separate entries for details.

<sup>b</sup> In the virion.

ccc = covalently closed circular; ds = double-stranded; ss = single-stranded.

conditions. Some (*virulent*) phages always induce a LYTIC CYCLE in the host cell, while other (*temperate*) phages can establish a stable, non-lytic relationship (LYSOGENY) with the host. Some phages can replicate and produce progeny virions within the host cell without killing or lysing it (see INOVIRIDAE and INOVIRUS). Phages of the MV-L3 PHAGE GROUP apparently kill their host cells without actually lysing them.

The antibacterial activity of phages has been exploited (primarily in Eastern Europe and the former Soviet Union) for both therapeutic and prophylactic use against various bacterial pathogens (including strains of *Escherichia*, *Klebsiella*, *Proteus*, *Pseudomonas*, *Salmonella*, *Shigella*, *Staphylococcus* and *Streptococcus*) [AAC (2001) 45 649–659].

Bacteriophages are a highly diverse group of viruses. Of the many hundreds known, relatively few have been thoroughly characterized [guidelines for phage characterization: AVR (1978) 23 1–24]. Some phages have been included in the overall taxonomic scheme for the viruses [Book ref. 23], and these are classified in the families CORTICOVIRIDAE, CYSTOVIRIDAE, INOVIRIDAE, LEVIVIRIDAE, MICROVIRIDAE, MYOVIRIDAE, PLASMAVIRIDAE, PODOVIRIDAE, STYLOVIRIDAE and TECTIVIRIDAE; however, many phages remain unclassified.

Morphologically, phage virions may be small and icosahedral, ca. 23–32 nm diam. (e.g. Q $\beta$  and  $\phi$ X174); filamentous, ca. 760–1950  $\times$  6 nm (INOVIRUS); pleomorphic (e.g. BACTERIOPHAGE MV-L2); or – in many phages – complex in structure with a polyhedral ‘head’ (the CAPSID) linked (often via a more or less complex connecting structure) to a long or short, simple or complex, contractile or non-contractile ‘tail’ (see e.g. PODOVIRIDAE, STYLOVIRIDAE, T-EVEN PHAGES). While in many phages the virions consist only of protein and the nucleic acid genome, some have a significant content of lipid – either as an external ENVELOPE (e.g. in  $\phi$ 6 and MV-L2) or as an internal layer (in BACTERIOPHAGE PM2 and phages of the TECTIVIRIDAE); the T-even phages contain e.g. dihydroperoxy hexaglutamate, phages of the MV-L3 group contain fucose, and MS2 contains spermidine.

The genome of a phage may be linear dsDNA, ccc dsDNA, ccc ssDNA, linear dsRNA or linear ssRNA (see Table). In some of the DNA phages the DNA contains unusual bases: e.g. PBS1 contains deoxyuracil instead of thymine,  $\phi$ W-14 contains  $\alpha$ -putrescinythymine, T-even phages contain hydroxymethylcytosine instead of cytosine, SP8 and SPO1 contain 5-hydroxymethyluracil instead of thymine. (See also BACTERIOPHAGE MU and RESTRICTION-MODIFICATION SYSTEM.)

The phage replication cycle begins when the virion adsorbs to the host at specific cell-surface sites: e.g., particular components of the cell wall (see e.g. BTUB PROTEIN and LAMB PROTEIN), the flagellum (see FLAGELLOTROPIC PHAGE), a sex pilus (see ANDROPHAGES), etc. Some phages adsorb only in the presence of appropriate concentrations of certain ions or of certain organic ‘adsorption cofactors’ (e.g. tryptophan for BACTERIOPHAGE T4). In Gram-negative bacteria penetration is believed to occur – at least in some phages – at ADHESION SITES. Either the entire virion, or the phage genome with or without certain phage proteins, enters the host cell: see e.g. INOVIRUS, LEVIVIRIDAE, and entries for bacteriophages N4,  $\phi$ 6 and T4 for examples. For at least some of the phages with contractile tails (see MYOVIRIDAE) – e.g. BACTERIOPHAGE T4 (q.v.) – the genome is understood to be injected (by a syringe-like action) into the periplasmic region of the bacterium. However, many phages have non-contractile tails, and some are entirely tail-less; hitherto, little information has been available on the way in which the genome of such phages is translocated into the host cell. Studies on phage T7

have indicated that, on attaching to the host cell, the phage ejects proteins that may assemble to form a channel across the bacterial cell envelope through which the genome is translocated; it has been speculated that two of the ejected proteins may form the components of a ‘motor’ that rachets phage DNA into the host cell [Mol. Microbiol. (2001) 40 1–8].

For phage development to proceed, the phage nucleic acid must escape degradation by the host’s RESTRICTION ENDONUCLEASE system. For a general account of viral replication strategies see VIRUS; for detailed accounts of particular phages see following entries. Virion assembly may occur by the spontaneous aggregation of the various phage components, but the more complex virions require the participation of non-structural phage-coded proteins (see SCAFFOLDING PROTEIN). Host cell lysis may be induced by phage-coded enzymes or by activation of host cell autolysins. (See also LYSIS FROM WITHOUT, LYSIS PROTEIN and ONE-STEP GROWTH EXPERIMENT.)

Bacteriophages can cause considerable economic problems in certain biotechnological processes such as the manufacture of dairy products, antibiotics, etc. A few phages are medically important in that they encode certain toxins (see BACTERIOPHAGE CONVERSION). In microbiology, phages are useful e.g. for PHAGE TYPING, for achieving gene transfer between bacteria (see TRANSDUCTION), for probing the molecular biology of bacteria, etc.

Phages may be cultivated and/or assayed e.g. by inoculation at low multiplicity of infection on a LAWN PLATE of susceptible bacteria (see PLAQUE and PLAQUE ASSAY). They may also be cultivated in broth cultures of host bacteria, the activity of virulent phages being indicated by the progressive decrease in turbidity of the culture as the cells lyse; a suspension of phages may be prepared from the lysate e.g. by CENTRIFUGATION or by membrane FILTRATION to remove bacterial debris.

**bacteriophage 7-7-1** See FLAGELLOTROPIC PHAGE.

**bacteriophage 21** See LAMBDOID PHAGES.

**bacteriophage 82** See LAMBDOID PHAGES.

**bacteriophage 434** See LAMBDOID PHAGES.

**bacteriophage 1307** See PLASMAVIRIDAE.

**bacteriophage  $\alpha$ 3** See MICROVIRIDAE and BACTERIOPHAGE G4. (Also: a dsDNA-containing phage of ‘*Achromobacter* sp 2’ [JGV (1981) 53 275–281].)

**bacteriophage  $\alpha$ 15** See LEVIVIRIDAE.

**bacteriophage AP50** See TECTIVIRIDAE.

**bacteriophage Bam35** See TECTIVIRIDAE.

**bacteriophage  $\beta$**  See LEVIVIRIDAE. (cf. Corynepage  $\beta$  – see DIPHTHERIA TOXIN.)

**bacteriophage BF23** A bacteriophage which infects *Escherichia coli* and which resembles phage T5. (See also BTUB PROTEIN.)

**bacteriophage BPB1** See STYLOVIRIDAE.

**bacteriophage Cf** See INOVIRUS.

**bacteriophage  $\chi$**  See STYLOVIRIDAE.

**bacteriophage conversion** (phage conversion) In a bacterium: the acquisition, loss or modification of one or more phenotypic characteristics as a result of infection by a BACTERIOPHAGE – typically a temperate phage (*lysogenic conversion*); it may result e.g. from the expression of phage genes or from inactivation of one or more bacterial genes due to insertion of a prophage into the bacterial chromosome. (Phenotypic alteration in a recipient cell due to TRANSDUCTION of bacterial DNA is not regarded as phage conversion.)

Phage conversion is responsible for toxigenicity in a number of pathogenic bacteria. For example, phages encode CHOLERA TOXIN, DIPHTHERIA TOXIN and the shiga-like toxins of enterohaemorrhagic strains of *Escherichia coli* (including O157:H7)

## bacteriophage CTXΦ

(see SHIGA TOXIN). The enterotoxin A of *Staphylococcus aureus* (see ENTEROTOXIN) is phage-encoded in at least some strains. (See also BETACIN.)

In *Staphylococcus aureus*, lipase activity is lost on infection with phage L54a owing to inactivation of the lipase structural gene (into which the prophage inserts) [JB (1986) 166 385–391].

Lysogenic conversion can also be manifested by a change in cell-surface antigens, i.e. a change in serotype. For example, in group E salmonellae, phage  $\epsilon_{15}$  converts antigens 3,10 to 3,15, and the LPS of the latter serotype can act as a receptor for phage  $\epsilon_{34}$  which, in turn, converts the antigen type to 3,15,34 (for the meaning of underlined numbers see KAUFFMANN–WHITE CLASSIFICATION). Phage-mediated modification of serotype is important e.g. when developing vaccine strains of a pathogen [see e.g. TIM (2000) 8 17–23].

(See also PSEUDOLYSOGENY.)

**bacteriophage CTXΦ** A temperate, filamentous ssDNA BACTERIOPHAGE which infects *Vibrio cholerae* and encodes CHOLERA TOXIN (as well as the Ace and Zot toxins). The double-stranded form of the genome can integrate into the bacterial chromosome in a site-specific, RecA-independent process. Isolates of lysogenic EI Tor and O139 strains of *V. cholerae* typically contain tandem arrays of prophage DNA at a single locus within the large chromosome, and it appears that the presence of multiple copies of the prophage is necessary for the production of virions; it also seems that the genomes of progeny virions are formed by a process in which replicative forms of the phage develop through hybridization between adjacent prophages (or between a prophage and a (phage-related) RS1 element in the chromosome) [PNAS (2000) 97 8572–8577]. The cell-surface receptor for CTXΦ occurs on so-called *toxin co-regulated pili* (TCP) (encoded by a chromosomal PATHOGENICITY ISLAND); genes encoding TCP and the cholera toxin are jointly, and positively, regulated by transcriptional regulator proteins (ToxR, ToxS, ToxT) which apparently become active on receipt of appropriate signals within the gut. Lysogenic conversion of (non-lysogenic) cells of *V. cholerae* can occur in the mammalian gut in the presence of phage-donating strains; this apparently reflects infection by phage following induction of TCP receptors by the gut-derived signals. [Science (1996) 272 1910–1914; Cell (1996) 87 795–798; Mol. Microbiol. (1997) 24 917–926; TIM (1998) 6 295–297.]

Infection of *V. cholerae* by CTXΦ is dependent on the *tolQRA* gene products [JB (2000) 182 1739–1747].

In the classical biotype of *V. cholerae*, the prophages are present either singly or as two fused prophages, and integration occurs at two sites; this biotype produces cholera toxin but, apparently owing to deficiencies in the structure of arrays (and the absence of RS1), does not produce virions [JB (2000) 182 6992–6998].

**bacteriophage D108** A mutator bacteriophage which is very similar to BACTERIOPHAGE MU; the phage D108 genome shows ca. 90% homology with that of phage Mu, differing mainly in the early-gene region at the left end [EMBO (1985) 4 3031–3037].

**bacteriophages  $\epsilon_{15}$ ,  $\epsilon_{34}$**  See BACTERIOPHAGE CONVERSION.

**bacteriophage f1** See INOVIRUS.

**bacteriophage f2** See LEVIVIRIDAE.

**bacteriophage F116** A temperate, transducing phage (family STYLOVIRIDAE) which infects *Pseudomonas aeruginosa*; in lysogenic cells the prophage appears to have an extrachromosomal location [JV (1977) 22 844–847].

**bacteriophage fd** See INOVIRUS.

**bacteriophage fr** See LEVIVIRIDAE.

**bacteriophage G4** An isometric ssDNA PHAGE of the MICROVIRIDAE. On penetrating the host cell, the ss cccDNA genome is coated with host SSB protein; a GC-rich region between genes *F* and *G* probably remains uncoated. Stage I (see ssDNA PHAGE) is independent of host *dnaB* function (as it is in microviruses St-1,  $\alpha 3$ ,  $\phi K$  and  $\phi XtB$  – cf. BACTERIOPHAGE  $\phi X174$ ). The *F–G* intergenic region seems to fold into a secondary structure [JV (1986) 58 450–458] which is capable of direct (*dnaB*-independent) recognition by host PRIMASE (cf. PRIMOSOME and DNAB GENE). Primase synthesizes a short RNA primer at a unique site (*ori*) in the intergenic region. The *c* strand is completed as in other ssDNA PHAGES. Stage II in G4 requires *dnaB* function, presumably for initiation of  $\nu$  strand synthesis. (Phages St-1,  $\phi K$  and  $\alpha 3$  do not require *dnaB* at any stage.) G4  $\nu$  strand synthesis begins at the  $\nu$  strand origin ( $O_{\nu}$ ) in gene A; the *c* strand origin ( $O_c$ ) in the *F–G* intergenic region is on the opposite side of the molecule.  $\nu$  strand synthesis seems to proceed by the displacement of the old  $\nu$  strand as a closed loop (D LOOP) at the  $O_{\nu}$  site, and hence is independent of a gpA-induced nick (cf. BACTERIOPHAGE  $\phi X174$ ). Synthesis of  $\nu$  strand by DNA polymerase III holoenzyme and Rep protein proceeds unidirectionally. When the replication fork passes  $O_c$ , primer synthesis can begin on the displaced loop, and *c* strand synthesis can proceed in the opposite direction. The parental  $\nu$  and *c* circles may separate before replication of either is complete. G4 seems to resemble  $\phi X174$  (q.v.) in stage III and morphogenesis.

**bacteriophage G6** See MICROVIRIDAE and BACTERIOPHAGE  $\phi X174$ .

**bacteriophage G13** See MICROVIRIDAE and BACTERIOPHAGE  $\phi X174$ .

**bacteriophage G14** See MICROVIRIDAE and BACTERIOPHAGE  $\phi X174$ .

**bacteriophage HM3** See MYOVIRIDAE.

**bacteriophage I3** See MYCOBACTERIOPHAGES.

**bacteriophage If1** An INOVIRUS which adsorbs specifically to I-type pili of enterobacterial hosts; phage If2 is very similar.

**bacteriophage If2** See BACTERIOPHAGE IF1.

**bacteriophage IKE** An INOVIRUS specific for enterobacteria which contain an IncN plasmid; the phage can apparently establish a pseudolysogenic infection of its host [CJM (1978) 24 1595–1601]. [Nucleotide sequence and genetic organization of IKE genome: JMB (1985) 181 27–39.]

**bacteriophage L1 group** See PLECTROVIRUS.

**bacteriophage L2 group** See PLASMAVIRIDAE.

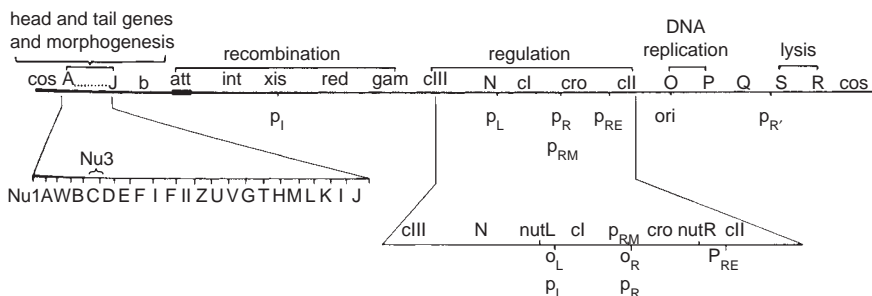

**bacteriophage L3 group** See MV-L3 PHAGE GROUP.

**bacteriophage L4** A BACTERIOPHAGE closely related to BACTERIOPHAGE P22 but defective in maintenance of lysogeny; it is commonly used as a transduction vector in *Salmonella typhimurium*.

**bacteriophage L17** See TECTIVIRIDAE.

**bacteriophage L34a** See BACTERIOPHAGE CONVERSION.

**bacteriophage  $\lambda$**  A temperate BACTERIOPHAGE (family STYLOVIRIDAE) which infects *Escherichia coli*. Head: icosahedral, ca. 55 nm diam., composed of two major structural proteins (gpE and gpD) and several minor proteins (gpB, gpC, gpFII). Tail: long (ca. 150 × 10 nm), flexible, tubular, non-contractile, joined to the head via a 'neck' or 'connector' region, and terminating at the distal end in a small basal structure to which is attached a single fibre (the adsorption organelle). (See also LAMB PROTEIN.) Genome: linear dsDNA (48514 bp long [nucleotide sequence: JMB (1982) 162 729–773]) with single-stranded 12-base 5' STICKY ENDS (designated *cos*). On infection of a host cell, phage DNA is transferred to the host through the tail and is immediately circularized by base-pairing between the sticky ends followed by host DNA ligase action. Subsequent events may eventually lead either to host cell lysis (involving the production and release of

BACTERIOPHAGE  $\lambda$ . Simplified map of the virion genome (*not* drawn to scale). See entry for explanation.

progeny phages) or LYSOGENY (during which  $\lambda$  DNA becomes integrated into the host chromosome); the initial sequence of events is common to both pathways.

**Lytic cycle.** Transcription of  $\lambda$  DNA by the host RNA polymerase proceeds leftwards from promoter  $p_L$  and rightwards from promoter  $p_R$ , stopping at rho-dependent terminators shortly beyond genes  $N$  and  $cro$  ('immediate early' genes), respectively (see figure).  $gpN$  functions as an antiterminator which is specific for transcription initiated at the early promoters  $p_L$  and  $p_R$ ;  $gpN$  recognizes special sites (*nutL* and *nutR*) – regions of hyphenated dyad symmetry – downstream from  $p_L$  and  $p_R$ , and when the host RNA polymerase traverses these sites it is modified by  $gpN$  (in the presence of the host *nusA* gene product) such that it can read through subsequent terminators. As a result, genes to the left of  $N$  (*cIII*...*att*) and to the right of  $cro$  (*cII*...*Q*) – delayed early genes – are expressed. Expression of *cro* is necessary for the continuation of the lytic cycle (see later).  $gpN$  is unstable (half-life ca. 5 min), so that continued  $N$  expression is necessary for ongoing transcription of the delayed early genes.

$\lambda$  DNA REPLICATION is initiated at a site (*ori*) in the *O* gene and requires  $gpO$ ,  $gpP$ , and certain host proteins, including DnaB protein, primase (DnaG protein), RNA polymerase, and components of the DNA polymerase III holoenzyme (but not e.g. *dnaA*, *dnaC* or *dnaI* functions).  $\lambda$   $gpO$  binds both to a 19-bp tandem repeat in the *ori* region and to  $\lambda$   $gpP$ ;  $gpP$  interacts with DnaB protein and appears to act as an analogue of *E. coli* DnaC protein (see PRIMOSOME). Initially, the  $\lambda$  cccDNA is replicated by the CAIRNS MECHANISM, but later replication proceeds by a ROLLING CIRCLE MECHANISM to yield double-stranded concatemers. Phage structural components (and e.g. lysozyme necessary for host cell lysis) are encoded by late phage genes (*S*, *R*, *A*...*J* – juxtaposed by circularization of the genome); transcription of these genes is turned on by the delayed early gene product  $gpQ$ , which functions as an antiterminator of late mRNA initiated at  $p_R$ . Phage morphogenesis is complex, involving host proteins as well as many phage-coded functions. In essence,  $gpB$  and  $gpC$  appear to form a complex with  $gpNu3$ , and  $gpE$  is then incorporated; these components undergo modification (fusion/cleavage reactions), and the scaffolding protein  $gpNu3$  is cleaved during or after its elimination from the head precursor. Concatemeric  $\lambda$  DNA is cut (by a  $gpNu1$ – $gpA$  complex) at a *cos* site; a left *cos* site is inserted into the capsid precursor, and DNA insertion continues until the next *cos* site is reached, when the DNA is cleaved. (cf. COSMID.) The resulting head structure is stabilized by the addition of  $gpD$ ,  $gpW$  and  $gpFII$ . The tail is assembled separately and

interacts spontaneously with the completed head to form the mature infectious virion.

**Lysogeny and the lysis/lysogeny decision.** During the early period of phage transcription, the system is committed neither to lysis nor to lysogeny, expression of immediate early and delayed early genes being necessary for both pathways. Expression of late genes results in lysis, while establishment of lysogeny requires the repression of most of the  $\lambda$  genes by a repressor protein (*gpCI*); *gpCI* prevents both leftward and rightward transcription by binding to operator regions ( $o_L$  and  $o_R$ ) that overlap  $p_L$  and  $p_R$ , respectively. When a host cell is first infected, *cI* cannot be expressed. However, transcription of  $N$  allows transcription of *cII* and *cIII*, and both *gpCII* and *gpCIII* are necessary for repressor synthesis. *gpCII* functions as a positive regulator for the initiation of repressor synthesis from  $p_{RE}$  (=  $p_E$ ), being necessary for recognition of this promoter by RNA polymerase. *gpCII* is unstable in vivo owing to proteolysis by host proteins (products of the *hflA* and *hflB* genes being involved); this proteolysis is apparently inhibited by *gpCIII* and by cAMP–CAP. The establishment of lysogeny is favoured by certain environmental conditions, e.g., by starvation of cells prior to infection, and by a high multiplicity of infection (MOI). It has been suggested that starvation may increase cAMP–CAP levels, while high MOI increases levels of *gpCIII* (a gene dosage effect); in either case the result is stabilization of *gpCII* thus favouring lysogeny.

Once synthesized, the repressor maintains its own synthesis by activating *cI* expression from an alternative promoter,  $p_{RM}$  (=  $p_M$ ); transcription from  $p_{RM}$  can occur only when repressor is bound to  $o_R$ . Translation of the  $p_{RM}$ -initiated mRNA is much less efficient than that of the  $p_{RE}$ -initiated mRNA. Thus, synthesis of repressor occurs at high levels by the  $p_{RE}$ -dependent 'establishment circuit' and at lower levels by the  $p_{RM}$ -dependent 'maintenance circuit'.

The repressor is antagonized by the product of the immediate early gene *cro*: *gpCRO* ('antirepressor') prevents transcription of *cI* from  $p_{RM}$ , and reduces (but does not eliminate) transcription of early genes from  $p_L$  and  $p_R$  [*cro*-operator and repressor–operator interaction: ARB (1984) 53 293–321]; thus *gpCRO* prevents 'maintenance synthesis' of repressor and also (by reducing *gpCII* formation) 'establishment synthesis' from  $p_{RE}$ . Sufficient early gene transcription persists to allow expression of *Q* and hence of the late genes, so that the lytic cycle can be completed. The lysis/lysogeny decision thus depends on whether *gpCI* or *gpCRO* occupies the operators  $o_R$  and  $o_L$ ; this in turn depends largely on the level of *gpCII* (which also affects

## bacteriophage M12

integration – see later) and hence is subject to influence by the host cell e.g. in response to environmental conditions.

In *Escherichia coli* lysogeny involves integration of the phage cccDNA with the host chromosome. This occurs by SITE-SPECIFIC RECOMBINATION, i.e., by reciprocal recombination between specific ‘attachment sites’ – one on the phage genome (*attP*) and one on the host genome (*attB*, also called *att<sup>λ</sup>*, situated between genes *gal* and *bio*); each *att* sequence consists of a central ‘core’ sequence (O) which is common to both *attB* and *attP*, flanked by ‘arm’ sequences designated B and B’ for *attB*, P and P’ for *attP*. Integration requires the *int* gene product (integrase) and certain host proteins, including DNA gyrase and INTEGRATION HOST FACTOR, IHF. (IHF consists of two subunits,  $\alpha$  and  $\beta$ : products of genes *himA* and *himD* (= *hip*), respectively.) Integrase recognizes *attB* and *attP*, while IHF recognizes only *attP*. Interaction between these recombination proteins, bound to their *att* sites, brings about recombination by the formation of a staggered break in the O region followed by strand exchange and ligation. The integrated prophage is thus flanked by hybrid *att* regions, *attL* (BOP’) and *attR* (POB’). The integration reaction is reversible, but while integration involves recognition between *attP* and *attB*, excision – the reverse reaction – requires recognition between *attL* and *attR*; excision requires an additional phage protein, the *xis* gene product (excisionase), which can bind to a specific region in the P arm of *attP* and *attR* [PNAS (1985) 82 997–1001]. The regulation of the reaction such that integration occurs preferentially under conditions which favour lysogeny, while excision occurs only on induction of a lysogen, is achieved by control of the amounts of integrase and excisionase available.

The *int* gene can be transcribed from either of two promoters: *p<sub>L</sub>* and *p<sub>I</sub>*; however, integrase is produced only during establishment of lysogeny and not during the lytic cycle. Under conditions which favour lysogeny, *gpcII* not only activates *cl* expression (hence preventing transcription from *p<sub>L</sub>*), it also activates *int* expression from *p<sub>I</sub>*. (Since *p<sub>I</sub>* overlaps *xis*, transcription from this promoter allows expression of *int* without that of *xis*, thus favouring integration.) However, under lytic conditions – during which transcription proceeds from *p<sub>L</sub>* – *int* gene expression is prevented by RETROREGULATION: *gpN*-modified, *p<sub>L</sub>*-initiated transcription extends beyond *int*, through *att*, and into the *b* region; the *b* region contains a sequence (*sib*) which causes the 3’ end of the corresponding mRNA to adopt a secondary structure which is recognized and cleaved by RNase III (q.v.). This cleavage is followed by degradation of the transcript in the 3’-to-5’ direction, thus preventing *int* expression. (Under conditions which favour lysogeny, the *p<sub>I</sub>*-initiated transcript, which terminates before the *sib* region, is a poor substrate for RNase III, and hence *int* expression can occur.)

Induction of  $\lambda$  may occur spontaneously (ca. 1 per 10<sup>2</sup>–10<sup>5</sup> lysogenic cells per generation); however, high levels of induction may be brought about by agents which damage DNA (e.g., UV irradiation, mitomycin C). Damage to DNA results in the ‘activation’ of the host RecA protein (see RECA PROTEIN), resulting in cleavage and inactivation of the repressor. (Levels of DNA damage necessary for  $\lambda$  induction are higher than those required to induce the SOS SYSTEM; presumably *gpcI* becomes susceptible to RecA-mediated cleavage only when host cell viability is threatened.) Since the repressor functions as a positive regulator for its own synthesis, its inactivation also prevents the synthesis of replacement repressor molecules. Inactivation of the repressor allows transcription from *p<sub>L</sub>* and *p<sub>R</sub>*, followed by excision of the prophage and completion of the

events of the lytic cycle. In contrast to *p<sub>L</sub>*-initiated transcription in the lytic cycle, *p<sub>L</sub>*-initiated transcription in the prophage results in the expression of both *int* and *xis* (necessary for excision). This is possible because, owing to the permuted gene order in the prophage, the *sib*-containing *b* region is no longer immediately downstream from *int*; the *p<sub>L</sub>*-initiated transcript is thus not recognized by RNase III, and both *int* and *xis* can be expressed.

[General review: Book ref. 79;  $\lambda$ -host interactions: MR (1984) 48 299–325.]

**bacteriophage M12** See LEVIVIRIDAE.

**bacteriophage M13** See INOVIRUS.

**bacteriophage MS2** See LEVIVIRIDAE.

**bacteriophage Mu** A temperate bacteriophage which can infect various enterobacteria (e.g. *Escherichia coli*, *Citrobacter freundii*, *Erwinia* spp, and certain mutant strains of *Salmonella typhimurium*). The phage particle has an icosahedral head (ca. 60 nm diam.) and a contractile tail (ca. 100 nm long when extended, 60 nm when contracted) to which is attached a base plate with spikes and tail fibres; the phage tail adsorbs to LPS in the outer membrane of a host cell. Phage particles contain linear dsDNA ca. 39 kb long.

An early event after phage infection – regardless of whether infection will eventually result in a lytic cycle or the lysogenic state – is the integration of Mu DNA into the host chromosome at a more or less randomly selected location. Integration often results in the inactivation of the gene in which it occurs; ca. 2–3% of bacteria in a population acquire a recognizable mutation on lysogenization by Mu, a frequency much greater than the spontaneous mutation rate in the absence of Mu – i.e., Mu acts as a mutator phage (Mu = abbr. for mutator). The initial integration event may be conservative (i.e., both strands of the Mu DNA may be inserted) and appears to be a simple (non-replicative) insertion; it requires the product of Mu gene *A* which can recognize and bind to the ends of Mu DNA [Cell (1984) 39 387–394]. Synthesis of a repressor (the *c* gene product) results in lysogeny and immunity to superinfection by Mu.

During the lytic cycle, Mu DNA replication occurs entirely by repeated replicative transposition of the integrated DNA (which thus functions as a giant TRANSPOSON, causing chromosomal deletions, inversions, duplications etc); Mu DNA insertion results in a 5-bp duplication of the target DNA (cf. Tn3). Transposition occurs at very high frequency (ca. 100 transpositions per cell in ca. 30 min), copies of Mu DNA being inserted at random locations in the chromosome; this results in the death of the host cell, and ca. 100 progeny phages are released ca. 60 min after infection. Transposition is controlled by the products of phage genes *A* and *B* and requires continual synthesis of *gpA* – which apparently acts stoichiometrically; *gpA* functions as a transposase, *gpB* apparently functions in the modification of *gpA* activity. [Role of DNA topology in Mu transposition: Cell (1986) 45 793–800.]

Phage Mu DNA contains three regions, designated  $\alpha$  (ca. 33 kb), *G* (ca. 3 kb) and  $\beta$  (ca. 1.7 kb), flanked by random sequences of bacterial DNA (see below). The  $\alpha$  region contains most of the phage genes, including e.g. the repressor (*c*) gene, all the early functions, all the head functions, and most of the tail functions. The *G* region carries the remainder of the tail functions and specifies the host range of the phage. The *G* segment is flanked by short inverted repeats, and can invert by reciprocal recombination between these sequences; when in one orientation, designated G(+), it specifies a host range which includes *E. coli* K12 strains, but in the alternative

G(-) orientation it specifies different tail fibres specific for a different host range. [Host cell receptors for Mu G(+) and G(-) types: FEMS (1985) 28 307–310.] (See also G LOOP and BACTERIOPHAGE P1.) A gene designated *gin*, in the  $\beta$  region adjacent to the G region, is essential for G inversion; *gin* encodes a site-specific recombination enzyme which is stimulated by a small, heat-stable host protein [BBA (1986) 866 170–177] and which apparently recognizes the inverted repeats flanking the G segment. In the lysogenic state, the G segment undergoes inversion at a slow but steady rate due to a low level of *gin* expression. The level of *gin* expression is thought to be about the same during the lytic cycle, but G inversion rarely has time to occur before the lytic cycle is complete; hence G loops are rarely observed in denatured/renatured Mu DNA in lysates from lytic infections. (See also RECOMBINATIONAL REGULATION.)

In addition to *gin*, the  $\beta$  region also contains a gene (*mom*) which encodes a DNA modification function. The targets for this modification system are adenine residues in pentanucleotide sequences 5'... (C/G)A(C/G)NPy...3'; ca. 15% of the adenine residues in the Mu DNA are modified, the modified bases being N<sup>6</sup>-(1-acetamido)-2-deoxyadenosine. The modified DNA is resistant not only to the host restriction system *in vivo* but also to *in vitro* cleavage by a range of restriction endonucleases. The *mom* gene is apparently repressed in the prophage but is strongly expressed on induction; the host Dam methylase (product of the DAM GENE) is necessary for *mom* gene expression [mechanism: EMBO (1986) 5 2719–2728].

During phage assembly, Mu DNA is packaged by a 'headful' mechanism: packaging begins near the 'left' (*c*) end of the Mu DNA and continues until ca. 39 kb of DNA have been incorporated into the phage head. The Mu DNA itself is ca. 37.5 kb long; thus, the packaging mechanism results in a variable length of bacterial DNA at each end of the phage genome (on average ca. 50–100 bp at the *c* end, ca. 1700 bp at the 'right' or S end). These end sequences are random because of the random insertion of Mu DNA into the host chromosome; they appear as 'split ends' in phage DNA which has been denatured and reannealed. The 'split ends' are lost when the phage DNA integrates into a new host chromosome. (See also MINI-MU.)

Mu can function as a generalized transducing phage, mediating gene transfer at frequencies of ca.  $10^{-7}$ . Transduction by Mu can be detected only in *rec*<sup>+</sup> recipient cells. The transducing particles, which contain only host DNA, probably arise by the rare packaging into Mu heads of host DNA instead of phage DNA.

[Review: Book ref. 20, pp. 105–158; behaviour of Mu in *Salmonella typhi*: JGM (1986) 132 83–89.]

**bacteriophage  $\mu$ 2** See LEVIVIRIDAE.

**bacteriophage MV-L1** See PLECTROVIRUS.

**bacteriophage MV-L2** (MVL2, L2 strain L2) A species of the PLASMAVIRIDAE. Host: *Acholeplasma laidlawii*; plaques small, turbid. Genome: negatively supercoiled ds cccDNA (MWt ca.  $7.8 \times 10^6$ ). Virion: roughly spherical, somewhat pleomorphic, (50–)80(–125) nm in diameter, sensitive to detergents, organic solvents, and heat (e.g. 60°C for 5 min). There is apparently no rigid helical or icosahedral nucleocapsid. The virion seems to consist of DNA condensed with protein and enclosed within a flexible, lipid-containing, 'unit-type' membrane apparently derived from the host cell membrane. Infection leads to lysogeny, the phage DNA becoming integrated with the host's chromosome. Progeny virions are released by budding through the host cell membrane; lysis does not occur, and the host remains viable.

**bacteriophage MV-L3** See MV-L3 PHAGE GROUP.

**bacteriophage MV-L51** See PLECTROVIRUS.

**bacteriophage 06N 58P** See CORTICOVIRIDAE.

**bacteriophage N4** A virulent coliphage of the PODOVIRIDAE.

Genome: linear dsDNA (ca. 71 kb) containing terminal direct repeats 400–450 bp long and a 7-base 3' overhang at one end. The phage particle contains a rifampicin-resistant DNA-dependent RNA polymerase which is injected into the host cell with the DNA and which is necessary for transcription of N4 early genes. Transcription of intermediate (middle) genes requires the synthesis and activity of three N4 early proteins, two of which are components of a second rifampicin-resistant RNA polymerase; transcription of late genes requires *E. coli* RNA polymerase activity. Host DNA replication is blocked by an N4 early gene product, but host RNA and protein synthesis continues (except in the case of cAMP-dependent operons). The N4 genome codes for most functions required for its replication, including a DNA polymerase and DNA-binding protein; the only host functions it appears to require are gyrase, DNA polymerase 5' → 3' exonuclease activity, DNA ligase, and *nrda* gene function [Book ref. 69, pp. 245–254].

**bacteriophage P1** A temperate BACTERIOPHAGE (family MYOVIRIDAE) which infects *Escherichia coli* and *Shigella* spp. Virion: icosahedral head (ca. 90 nm diam.) with a long, complex contractile tail bearing a base-plate and tail fibres. Genome: dsDNA (MWt ca.  $66 \times 10^6$ ), circularly permuted and terminally redundant. On infection of a host cell, the genome circularizes (with loss of redundancy) and may enter a LYTIC CYCLE or establish LYSOGENY. Relatively little is known about the lytic cycle; both  $\theta$ - and  $\sigma$ -type modes of DNA replication occur early in infection, but later only  $\sigma$ -type replication can be observed. DNA packaging occurs by a 'headful' mechanism, starting at a unique site (*pac*); cleavage of DNA at a *pac* site apparently occurs early in infection, before phage heads are formed, and the enzyme responsible may remain bound to the DNA and subsequently interact with a prohead to initiate packaging. (cf. BACTERIOPHAGE P22.)

In the lysogenic state, the P1 prophage does not normally integrate into the host chromosome, but persists as an autonomous, circular PLASMID (P1 plasmid) which is maintained at one or two copies per host chromosome. The replication control system of the P1 plasmid resembles that of the F PLASMID (q.v.) e.g. in that it involves a plasmid-encoded protein (designated RepA in the P1 plasmid) which is essential for replication and which autoregulates its own synthesis. Moreover, the *repA* gene is flanked on each side by multiple 19-bp repeat sequences, and it appears that one of these multiple repeats (*incA*) may be involved in the control of copy number in that it appears to titrate the RepA protein. [P1 replication: JBC (1986) 261 3548–3555.] The P1 plasmids are segregated (see PARTITION) with great accuracy at each host cell division, and spontaneous loss of the plasmid is extremely rare. This high degree of accuracy involves several mechanisms. For example, P1 encodes a SITE-SPECIFIC RECOMBINATION (SSR) system which facilitates accurate partition by efficiently resolving plasmid dimers into monomers. (Dimers are formed by homologous recombination between the two plasmids resulting from replication.) This system involves a site (*loxP*) on the plasmid at which SSR occurs, and a gene (*cre*) encoding the recombinase. (The *lox*-Cre system also catalyses cyclization of the phage genome on infection of the host – at least in RecA<sup>-</sup> hosts; it can also mediate the rare integration of the P1 plasmid into the host chromosome at a site designated *loxB*.) [Regulation of the *cre* gene: JMB (1986) 187 197–212.] Partition per se involves a sequence (*par*) in the plasmid; a gene (*parA*)

## bacteriophage P2

within this sequence encodes a protein which may promote partition by binding to the plasmid at a particular site (*incB*) and to (probably) the host cell envelope [JMB (1985) 185 261–272].

P1 also has a second SSR system which is responsible for the inversion of a 4.2-kb segment (the C segment) of the P1 genome. The C segment was first identified as a 'C loop' analogous to the G LOOP of bacteriophage Mu. The C segment of P1 and the G segment of Mu are homologous (each specifies different host ranges in different orientations), and their controlling elements (encoded by *cin* in P1, *gin* in Mu) can complement each other (see also RECOMBINATIONAL REGULATION). However, the inverted repeats at each end of the C segment are not homologous with those of the G segment. (Efficient inversion of the C segment apparently requires an additional *cis*-acting sequence, distinct from the cross-over sites *cixL* and *cixR* [PNAS (1985) 82 3776–3780].)

[The P1 genome: JB (2004) 186 7032–7068.]

**bacteriophage P2** A temperate BACTERIOPHAGE (family MYOVIRIDAE) which infects *Escherichia coli*. The phage virion consists of an isometric head attached to a contractile tail. Genome: linear dsDNA (MWt ca.  $22 \times 10^6$ ) which has 19-base STICKY ENDS. On infection of a host cell, the DNA forms closed circular molecules which, in lysogenic infections, can integrate into the host chromosome at a preferred site near the *his* operon; the phage 'attachment site' (*attP*) occurs between genes *int* (encoding the P2 integrase) and *ogr* (see below). (cf. BACTERIOPHAGE LAMBDA.)

P2 DNA replication occurs unidirectionally from a single origin near the right-hand end of the genome. Replication requires P2 genes *A* and *B* and (at least) host genes *dnaB*, *polC* and *rep*; P2 gpA is a (preferentially *cis*-acting) DNA-binding protein. The products of DNA replication are cccDNA monomers (i.e., concatemers are not formed). Expression of P2 late genes (which encode phage structural components) depends on the expression of the *ogr* gene, which in turn depends on P2 DNA replication. (cf. BACTERIOPHAGE P4.) During phage assembly, the DNA monomer undergoes staggered cleavage at a unique site (*cos*) to form the linear molecule with sticky ends characteristic of the P2 virion.

**bacteriophage P4** A satellite BACTERIOPHAGE (see SATELLITE VIRUS) which infects *Escherichia coli* and which requires all of the late genes of a helper phage such as BACTERIOPHAGE P2 to complete its replication cycle. The P4 genome is linear dsDNA (ca. 11.4 kb) with 19-nucleotide sticky ends which allow the DNA to circularize in the host cell. P4 DNA replication occurs bidirectionally from a single origin [JMB (1985) 182 519–527]; an early P4 gene product, gp $\alpha$ , is required for P4 DNA replication and is apparently a (rifamycin-resistant) primase [JMB (1985) 182 509–517]. In the absence of a helper phage, P4 can replicate its DNA and can lysogenize its host, but progeny virions can be formed only in the presence of a helper. In cells co-infected with P2 and P4, P4 capsids predominate and are assembled largely from P2 head proteins – although the P4 capsid is smaller than that of P2. P4 alters the regulation of transcription of P2 head proteins; the product of the P4  $\delta$  gene is apparently a *trans*-acting accessory transcription factor which can substitute for P2 gp $\alpha$  and thus circumvent the dependence of late P2 genes on P2 DNA replication [Book ref. 118, pp. 108–110].

**bacteriophage P7** A BACTERIOPHAGE which is closely related to BACTERIOPHAGE P1; however, P1 and P7 are heteroimmune and differ in plasmid maintenance functions.

**bacteriophage P22** A temperate BACTERIOPHAGE (family PODOVIRIDAE) which infects *Salmonella* (smooth strains). The virion

consists of an icosahedral head (ca. 60 nm diam.) attached via a short tubular 'neck' to a 'tail' which is essentially no more than a hexagonal base-plate bearing short spikes. The 'tail' region has endorhamnosidase activity. Genome: dsDNA (MWt ca.  $26 \times 10^6$ ), terminally redundant, and circularly permuted in certain regions of the genome.

On infection of a host cell, the linear DNA is circularized either by the host RecA system or by a general recombinase encoded by the P22 *erf* gene. In the lytic cycle, the DNA may undergo some replication in the circular form; subsequently, concatemers many unit genomes in length are produced. During virion assembly, a prohead consisting mainly of coat protein (gp5) and a SCAFFOLDING PROTEIN (gp8) interacts with a concatemeric DNA molecule; DNA is encapsidated, beginning at a specific site (*pac*) in the concatemer and proceeding sequentially until the head is full, and the scaffolding protein is eliminated intact (and is recycled). It appears that once the first packaging event has been completed, the remaining DNA of the concatemer is encapsidated by other proheads – i.e., the leading end of the DNA which enters the second and subsequent proheads is determined not by the *pac* site but by the length of DNA packaged by previous prohead(s). (The mechanism of this is uncertain; the initial cleavage at the *pac* site can apparently occur in the absence of encapsidation [JMB (1982) 154 565–579].) (cf. BACTERIOPHAGE P1.) Maturation of the virion requires the addition of certain minor phage proteins. (See also TRANSDUCTION.)

The lysogenic pathway in P22 is essentially similar to that in  $\lambda$  (see LAMBDOID PHAGES). The prophage inserts in the *Salmonella* chromosome at a site between *proA* and *proC*; insertion is catalysed by a P22-specified integrase encoded by an *int* gene located close to the *att* site.

**bacteriophage PA2** See STYLOVIRIDAE.

**bacteriophage PBS1** A large, morphologically complex FLAG-ELLOTROPIC PHAGE (family MYOVIRIDAE) which infects *Bacillus subtilis*; its DNA contains deoxyuridine instead of thymidine. PBS1 is a pseudotemperate phage, establishing a carrier state in its host (see PSEUDOLYSOGENY); it can mediate transduction.

**bacteriophage PBSX** A defective bacteriophage, the prophage of which is normally present in the chromosome of its host, *Bacillus subtilis*. When induced by mitomycin C, PBSX packages 13-kb lengths of DNA which may include sequences from any region of the host chromosome, packaging probably occurring by a 'headful' mechanism [JV (1985) 54 773–780].

**bacteriophage Pf1** See INOVIRUS.

**bacteriophage Pf2** See INOVIRUS.

**bacteriophage  $\phi$ I** See T7 PHAGE GROUP.

**bacteriophage  $\phi$ II** See T7 PHAGE GROUP.

**bacteriophage  $\phi$ 6** The sole member of the family Cystoviridae.

Host: *Pseudomonas syringae* pv. *phaseolicola*; plaques clear, diam. 1–3 mm. Some strains of *P. pseudoalcaligenes* can be infected. The virion (diam. ca. 75 nm) has a segmented genome of three pieces of dsRNA designated L, M and S (MWt ca. 5.0, 3.1 and  $2.3 \times 10^6$ , respectively). [Nucleotide sequence of, and translational control in, the S segment: JV (1986) 58 142–151.] The RNA occurs in a polyhedral inner particle (composed of proteins P1, P2, P4 and P7) which is covered with a layer of protein P8 – the whole forming the nucleocapsid (diam. ca. 60 nm). The nucleocapsid is surrounded by a phospholipid- and protein-containing envelope (P3, P5, P6, P9, ?P10) which can be removed (with loss of infectivity) by treatment with detergents. An RNA polymerase (P1, P2) is associated with the capsid. The virion also contains an enzyme (P5, ?P10) active against the host cell wall; this enzyme seems necessary both for penetration of the host and for the release of phage progeny.

The virion adsorbs (P3, P6) to the sides of the subpolar host pili; the  $\phi$ 6 envelope fuses with the host outer membrane, and the nucleocapsid *minus* P8 enters the host cell. Inside the cell the phage RNA polymerase catalyses RNA synthesis; an ss mRNA, designated *l* (MWt ca.  $2.2 \times 10^6$ ), is transcribed early and codes for P1, P2, P4 and P7. These four proteins form a 120S procapsid or *previrion I* which incorporates progeny dsRNA to form *previrion II*. (The synthesis of dsRNA is not understood, but it occurs within a subvirion structure. A model for the initiation of replication and transcription in bacteriophage  $\phi$ 6 has been proposed [Nature (2001) 410 235–240].) *Previrion II* synthesizes ss mRNAs *m* and *s* (MWt ca.  $1.4$  and  $1.1 \times 10^6$ , respectively); *s* codes for P8 and P9, *m* for P3, P6 and P10 (and possibly also P4 and P7). *Previrion II* incorporates P8 to form the complete nucleocapsid. Finally, the lipoprotein envelope is added – apparently mediated by the (non-structural) phage protein P12; although the lipid is apparently derived from host phospholipid, the membrane is formed in the cytoplasm and not in contact with the cell membrane. Phage release occurs by host cell lysis.

(Note: the name bacteriophage  $\phi$ 6 has also been used for a pilus-dependent dsDNA phage of *Caulobacter* [JV (1980) 35 949–954].)

**bacteriophage  $\phi$ 29** A BACTERIOPHAGE (family PODOVIRIDAE) which infects strains of *Bacillus subtilis* and those of certain other species of *Bacillus*. The virion has a complex morphology: an elongated head (ca.  $32 \times 42$  nm), bearing protein fibres at each end, joined via a connector region to a short tail. Genome: linear dsDNA (ca. 18 kb) with 6-bp terminal inverted repeats. The 5' end of each strand in the DNA genome is formed by a dAMP residue; each dAMP residue is linked covalently (via a phosphodiester bond) to a serine residue in a phage-encoded protein (gp3) – a so-called *terminal protein* (TP). The terminal proteins are essential for initiation of replication of the  $\phi$ 29 genome.

Replication of the linear  $\phi$ 29 DNA is initiated at both ends of the molecule (not simultaneously); it involves a phage-encoded DNA polymerase (gp2) which has exonuclease activity [NAR (1985) 12 1239–1249]. The polymerase binds to a *free* molecule of the TP, and this complex localizes at the 3' end of each strand – perhaps by interacting with TP at the adjacent 5' end. The polymerase then mediates a dATP-dependent reaction in which dAMP is covalently linked to the complexed TP; this dAMP residue serves as a 3'-OH primer. The polymerase begins strand synthesis (5'-to-3'), and after insertion of nucleotide 10 the polymerase and TP dissociate from one another – the TP remaining covalently bound at the 5' end of the new strand while the polymerase continues to extend the (DNA) primer. The polymerase is able to displace the (5'-to-3') strand complementary to the template, and to achieve good processivity, without help from a helicase or from other factors [JBC (1996) 271 8509–8512]. Replication of the  $\phi$ 29 genome is an example of so-called *protein priming* – only one example of the strategies used for replicating a linear genome. [Protein priming of DNA replication in phage  $\phi$ 29: EMBO (1997) 16 2519–2527.] (See also ADENOVIRIDAE.)

During phage assembly, the major coat protein (gp8) is assembled with the aid of a (re-cyclable) scaffolding protein (gp7) which is displaced as the DNA is incorporated. [Morphogenesis: JV (1985) 53 856–861.]

The packaging of DNA into the phage head requires energy from ATP hydrolysis. It also requires certain phage-encoded RNA molecules designated pRNA. [DNA packaging: Cell

(1998) 94 147–150.] In a current model, a number of pRNA molecules form a (static) ring-shaped structure around a hole in the phage head through which the genome is inserted; the connector (a dodecamer of gp10, 75 Å in length, with an axial channel) rotates, driven by ATP hydrolysis, and the 'threaded' (i.e. helical) DNA molecule enters the phage head like a bolt drawn through a nut when the nut is rotated [Nature (2000) 408 745–750].

Host cell lysis involves a phage-encoded peptidoglycan-degrading enzyme; however, lysis also requires the product of phage gene *l4* which is apparently a LYSIS PROTEIN [JB (1993) 175 1038–1042].

**bacteriophage  $\phi$ 80** See STYLOVIRIDAE and LAMBDOID PHAGES.

**bacteriophage  $\phi$ 105** A temperate BACTERIOPHAGE which infects *Bacillus subtilis* (see STYLOVIRIDAE). The virion consists of an isometric head (ca. 52 nm diam.) attached to a flexible, non-contractile tail (ca. 220 nm long) which bears a baseplate with six appendages. Genome: dsDNA (MWt ca.  $26 \times 10^6$ ), non-permuted, apparently with sticky ends. During lysogeny, the phage DNA integrates at a specific attachment site in the host chromosome but, unlike e.g. BACTERIOPHAGE  $\lambda$ , it appears not to circularize prior to integration, and the prophage is not circularly permuted with respect to the virion DNA; the mechanism of integration is not understood. On induction,  $\phi$ 105 DNA apparently replicates in situ, together with adjacent regions of host DNA, and the phage DNA is subsequently excised from the newly synthesized molecules. LFT (but not HFT) lysates have been described; transduction appears to require that the recipient be a  $\phi$ 105 lysogen. [Book ref. 170, pp. 251–256, 273–275.]

**bacteriophage  $\phi$ A** See MICROVIRIDAE.

**bacteriophage  $\phi$ B** See MICROVIRIDAE.

**bacteriophage  $\phi$ BA1** A temperate, tailed, dsDNA-containing BACTERIOPHAGE isolated from *Bacillus aneurinolyticus*. The virions apparently have a BACTERIOCIN-like killing activity against some strains of *B. aneurinolyticus*; this activity is independent of phage gene expression (phage DNA is rapidly degraded in the sensitive cells), and may be due to a proteinaceous component of the intact virion [JV (1986) 59 103–111]. (cf. BETACIN.)

**bacteriophage  $\phi$ C** (1) See MICROVIRIDAE. (2) See STYLOVIRIDAE.

**bacteriophage  $\phi$ C31** A temperate bacteriophage originally isolated from *Streptomyces coelicolor*; it can infect a wide range of *Streptomyces* spp. Genome: dsDNA (ca. 41.5 kb) with sticky ends. The prophage integrates in the host chromosome at a specific attachment site.

**bacteriophage  $\phi$ CbK** See STYLOVIRIDAE.

**bacteriophage  $\phi$ D328** See STYLOVIRIDAE.

**bacteriophage  $\phi$ EC** A tailed, temperate ACTINOPHAGE whose hosts are species of *Rhodococcus*; genome: linear dsDNA.  $\phi$ EC is inactivated by various lipid solvents. [Book ref. 73, pp. 216–218.]

**bacteriophage  $\phi$ K** See MICROVIRIDAE and BACTERIOPHAGE G4.

**bacteriophage  $\phi$ NS11** See TECTIVIRIDAE.

**bacteriophage  $\phi$ R** See MICROVIRIDAE.

**bacteriophage  $\phi$ W-14** A bacteriophage (family MYOVIRIDAE) which infects and lyses certain strains of *Pseudomonas acidovorans*. In  $\phi$ W-14 DNA ca. 50% of the thymine residues are hypermodified, occurring as  $\alpha$ -putrescinylythymine; the hypermodified bases are apparently essential for the production of viable progeny phages – probably being required for DNA packaging [Virol. (1983) 124 152–160].

**bacteriophage  $\phi$ X174** The type species of the MICROVIRIDAE (q.v. for morphology etc). After adsorption of  $\phi$ X174 to a host cell, the ss cccDNA phage genome penetrates the cell and is

## bacteriophage $\phi$ Xahb

coated with host SSB protein; a region between genes *F* and *G* (which can form hairpin loops) remains uncoated. Stage I (see SSDNA PHAGES) is dependent on host *dnaB* function (as it is in microviruses S13, G6, G13, G14 and  $\phi$ Xahb – cf. BACTERIOPHAGE G4). A PRIMOSOME assembles at a specific *n'* recognition sequence in the *F–G* intergenic region. The primosome migrates (5' to 3') along the  $\nu$  strand (displacing the SSB protein?), synthesizing primers at several sites. The *c* strand is completed as in other SSDNA PHAGES to form the ds RF (parental RF). It seems that most components of the primosome remain bound to the parental RF throughout this and subsequent stages, and that this obviates the need for supercoiling of the RF by gyrase – a step previously thought to be essential for initiation of stage II [PNAS (1981) 78 1436–1440]. Stage II:  $\phi$ X174 gpA nicks the  $\nu$  strand of the parental RF at a specific site in gene *A* and becomes covalently bound to the 5' end of the nicked strand. The 3' end is elongated by host DNA polymerase III holoenzyme in a ROLLING CIRCLE MECHANISM; ahead of holoenzyme action, the two RF strands are processively unwound by a complex of gpA and Rep protein. (The presence of gpA allows Rep protein to begin unwinding from the *nick* – not normally possible for HELICASES.) As synthesis proceeds, the displaced  $\nu$  strand (attached by its 5' end to gpA at the replication fork) forms a growing loop which can function as template for the discontinuous synthesis of a *c* strand (primed by the conserved parental RF primosome components). When one genome length of  $\nu$  DNA has been displaced, it is excised and circularized by gpA and the *c* strand is completed to form the progeny RF. Progeny RFs are supercoiled by GYRASE and seem at this stage to function primarily as templates for transcription of phage genes. Stage III is closely coupled to phage morphogenesis. RFI (see RF) is cleaved by gpA, as in stage II, to form an RFII–gpA complex which, in the presence of gpC, associates with a procapsid (consisting of gpB, gpD, gpF, gpG and gpH) to form a 50S particle.  $\nu$  strand synthesis and displacement seem to occur by a rolling circle mechanism; as the  $\nu$  strand is displaced, it is packaged within the procapsid. Packaging (but not phage DNA synthesis) requires gpJ, a component of the phage capsid [JV (1985) 54 345–350]. When a complete  $\nu$  strand has been displaced it is cleaved and circularized by gpA, releasing the RFII–gpA complex (for further rounds of  $\nu$  strand synthesis) and an ss cccDNA-containing immature phage particle; gpB and gpD are subsequently lost to form the mature 114S  $\phi$ X174 virion.

**bacteriophage  $\phi$ Xahb** See BACTERIOPHAGE  $\phi$ X174.

**bacteriophage  $\phi$ XtB** See MICROVIRIDAE.

**bacteriophage PM2** The type species of the CORTICOVIRIDAE; host: *Alteromonas espejiana* BAL-31 (= *Pseudomonas* BAL-31). The virion is icosahedral (diam. ca. 60 nm) and is sensitive to organic solvents and detergents; it comprises four major proteins, 12–14% by weight phospholipid, and supercoiled ds cccDNA (MWt ca.  $6 \times 10^6$ ). The outer layer of the capsid is an icosahedral shell of protein PII (= sp27) with spikes of protein PI (= sp43) at the vertices. Within this is a lipid bilayer membrane whose composition reflects that of the host cell membrane at the time of phage assembly. The membrane seems to be associated with one or both of the remaining two proteins; these proteins may also be associated with the DNA, and at least one has transcriptase activity. Virions adsorb to the host cell wall. Maturation occurs at the cell periphery. The progeny are released by cell lysis.

**bacteriophage Q $\beta$**  See LEVIVIRIDAE.

**bacteriophage R1** See STYLOVIRIDAE.

**bacteriophage R2** See STYLOVIRIDAE.

**bacteriophage R17** See LEVIVIRIDAE.

**bacteriophage R23** See LEVIVIRIDAE.

**bacteriophage 7S** See LEVIVIRIDAE.

**bacteriophage S13** See MICROVIRIDAE and BACTERIOPHAGE  $\phi$ X174.

**bacteriophage SP3** See MYOVIRIDAE.

**bacteriophage SP6** A BACTERIOPHAGE which infects *Salmonella typhimurium*; it has a linear dsDNA genome (ca. 43.5 kb) and appears to resemble BACTERIOPHAGE T7 in its morphology and development. SP6 encodes a rifamycin-resistant RNA polymerase which is synthesized shortly after infection of a host cell. [Nucleotide sequence and expression of the cloned SP6 RNA polymerase gene: NAR (1987) 15 2653–2664.]

**bacteriophage SP8** See MYOVIRIDAE.

**bacteriophage SP50** See MYOVIRIDAE.

**bacteriophage SP $\beta$**  See STYLOVIRIDAE and BETACIN.

**bacteriophage SPO1** A virulent BACTERIOPHAGE which infects *Bacillus subtilis*. The virion consists of a large isometric head, containing >7 different polypeptides, joined via a complex connector structure to a contractile tail which terminates in a complex base-plate. The genome is a single molecule of linear dsDNA, MWt ca.  $10^8$ , which contains hydroxymethyluracil. [Review: Book ref. 170, pp. 218–245.]

SPO1 is widely used in studies of transcriptional regulation in Gram-positive bacteria. Phage genes are expressed in three phases: early, middle and late. Early gene promoters are of the same type as those of host genes involved in vegetative functions, allowing transcription of early phage genes by the (unmodified) host RNA POLYMERASE. One early gene, gene 28, encodes a novel SIGMA FACTOR ( $\sigma^{gp28}$ ) which replaces the host  $\sigma^{43}$  (formerly known as  $\sigma^{55}$ ), resulting in a holoenzyme which can recognize only phage middle promoters. Middle genes include genes 33 and 34, the expression of which is necessary for late gene transcription; gp33 and gp34 together replace the  $\sigma^{gp28}$  in the RNA polymerase, resulting in an enzyme which – in the presence of the delta factor (see RNA POLYMERASE) – recognizes only late phage promoters, thus allowing the transcription of late genes (which encode phage structural components). (See also ENDOSPORE sense 1.)

**bacteriophage SPO2** A temperate BACTERIOPHAGE which infects *Bacillus subtilis*. Virion: an isometric head (ca. 50 nm diam.) attached to a tail ca. 180 nm long. Genome: dsDNA, MWt ca.  $26 \times 10^6$ . [Book ref. 170, pp. 247–268 (256–259).]

**bacteriophage St-1** See MICROVIRIDAE and BACTERIOPHAGE G4.

**bacteriophage SV-C1** See SPIROPLASMAVIRUSES.

**bacteriophage SV-C2** See SPIROPLASMAVIRUSES.

**bacteriophage SV-C3** See SPIROPLASMAVIRUSES.

**bacteriophage T1** See STYLOVIRIDAE.

**bacteriophage T2** See T-EVEN PHAGES and MYOVIRIDAE.

**bacteriophage T3** A bacteriophage (family PODOVIRIDAE) which is very closely related to BACTERIOPHAGE T7.

**bacteriophage T4** A virulent enterobacterial (linear dsDNA-containing) BACTERIOPHAGE – the best-known representative of the T-even phages. (See entry T-EVEN PHAGES for phage structure, nature of genome etc; see also MYOVIRIDAE.)

The T4 infection cycle is initiated when the phage attaches, via the distal tips of its long tail fibres, to specific sites on the

host cell surface (see T-EVEN PHAGES). The tail fibres may occur in either of two states: extended or 'retracted' (i.e., folded back along the tail sheath and head); infection can occur only when the fibres are extended. Transition between the two states is affected by conditions: retraction (and hence loss of infectivity) is promoted by e.g. low pH, low temperature, low ionic strength, and in some strains by the absence of the adsorption cofactor tryptophan. Binding is initially reversible, but is followed by irreversible binding during which the base-plate undergoes a conformational change from a hexagonal form to an expanded, star-shaped structure with a central opening. This in turn triggers the contraction (by conformational change) of the tail sheath and the penetration of the host cell envelope by the inner tail tube. (Penetration may occur at ADHESION SITES.) The phage DNA is then transferred through the tail inner tube to the host cell. Since the inner tube tip appears to penetrate only as far as the outer surface of the host cytoplasmic membrane, DNA apparently does not enter the cytoplasm directly; uptake of the DNA by the host cell appears to require a membrane potential and can be inhibited by ionophores.

Infection of the host cell is followed by transcription of the T4 DNA. This occurs in three main phases: early (immediate early and delayed early), middle, and late; each phase occurs at a distinct time after infection, is initiated at a distinct class of promoters, and requires a different transcription apparatus. The host RNA POLYMERASE is apparently used throughout, but undergoes a series of phage-induced alterations (e.g. ADP-ribosylation of first one, then both, of its  $\alpha$  subunits) which affect its activity and affinities (e.g. for sigma factor); T4 gp55 is a SIGMA FACTOR which is necessary for the transcription of T4 late genes. Early effects on the host cell include the cessation of host DNA, RNA and protein synthesis (within 2–5 min of infection), unfolding of the host nucleoid, and degradation of host DNA by phage-coded nucleases specific for cytosine-containing DNA. The nucleotides thus released are used for the synthesis of progeny phage DNA.

Late transcription is coupled to T4 DNA replication, which begins ca. 5 min after infection. Replication can be initiated at multiple origins [locations: JV (1985) 54 271–277] and occurs bidirectionally. It appears to be catalysed by a complex of phage-coded proteins (a 'replisome' – see DNA REPLICATION), including gp43 (DNA polymerase), gp32 (an SSB protein), gp44/45/62 (DNA polymerase accessory proteins which e.g. increase polymerase processivity and affinity for DNA), *gpdda* (a 5'-to-3' helicase), and gp41 and gp61 (involved in the priming of Okazaki fragments). Leading strand synthesis is probably primed initially by host RNA polymerase. Okazaki fragments in lagging strand synthesis are primed by the formation of pentaribonucleotide primers (pppApCpNpNpN, where N = any of the 4 nucleotides) by gp41 and gp61; gp41 may be analogous to the DnaB protein of *Escherichia coli* (see DNAB GENE), while gp61 may be a PRIMASE. When elongation is complete, the 3' end of the template for each lagging strand remains single-stranded; these single-stranded regions can 'invade' homologous regions of other phage DNA molecules, forming recombinational forks (see RECOMBINATION) and resulting in the formation of complex, branching, concatemeric intermediates. Resolution of the branches appears to require gp49 (T4 endonuclease VII). Later rounds of DNA replication may be initiated at recombinational forks, allowing replication to become independent of the (altered) host RNA polymerase. (Alteration of the RNA polymerase may prevent its recognition of origin promoters.) Modification of the DNA (glucosylation and methylation) occurs on the

completed polynucleotide strands; HMC substitution occurs at the level of precursor synthesis, involving hydroxymethylation of dCTP.

Phage components are encoded by late phage genes. Heads, tail fibres and base-plates are each assembled by separate pathways. Head assembly involves at least 20 genes. Initially, a prohead is assembled on the host cytoplasmic membrane; the prohead consists of a shell surrounding a central core, the latter acting as scaffolding and controlling the assembly, size and shape of the prohead. When this structure is complete, nearly all of its constituent proteins undergo proteolytic cleavage, resulting in the removal of the core and the formation of a 'cleaved prohead'. The cleaved prohead detaches from the membrane, and the main shell protein (gp23) undergoes extensive conformational changes which result in expansion of the prohead; this step is probably normally accompanied by DNA packaging. DNA is packaged by the 'headful' mechanism: one end of a linear concatemeric DNA molecule is inserted into the prohead, and the DNA continues to be incorporated until the head is full, when the DNA is cleaved (thus yielding the circularly permuted genome characteristic of T4). Base-plate assembly occurs by separate assembly of the hub and wedges (see T-EVEN PHAGES), followed by binding of the six wedges around the hub. The tail is then polymerized (inner tube first) on the base-plate. The completed tail structure associates spontaneously with the DNA-containing head, and finally the tail fibres and collar 'whiskers' are added.

Progeny phages are released by lysis of the host cell. The mechanism of lysis is still not fully understood, but requires T4-coded LYSOZYME (*gpe*), the function of gene *t* (see LYSIS PROTEIN), and possibly gp5 (the base-plate hub lysozyme – see T-EVEN PHAGES).

[Reviews on all aspects of T4: Book ref. 99.]

**bacteriophage T5** See STYLOVIRIDAE.

**bacteriophage T6** See T-EVEN PHAGES.

**bacteriophage T7** A virulent bacteriophage of the PODOVIRIDAE which infects *Escherichia coli* and other enterobacteria. Head: isometric, ca. 60 nm diam. [capsid architecture: Virology (1983) 124 109–120]. Tail: ca. 17 nm long, with six short fibres; the distal end of the tail adsorbs to LPS in the outer membrane of a host cell. The T7 genome is a linear, non-permuted dsDNA molecule (ca. 40 kb) with terminally redundant ends (160 bp). T7 early genes constitute a single operon near the left end of the genome; these genes are transcribed by the host RNA polymerase and are concerned mainly with switching off host gene transcription and switching on transcription of T7 intermediate and late genes. (The large early-gene transcript is cleaved by host RNase III (q.v.) to give mRNAs.) Early gene products include a protein kinase (gp0.7), which phosphorylates and inactivates the host RNA polymerase (thus preventing further early gene transcription), and an RNA polymerase (gp1) which transcribes the T7 intermediate genes (concerned mainly with T7 DNA replication) and late genes (concerned with phage assembly and release of phage progeny by host cell lysis). Another phage product, gp2, also binds to and inactivates host RNA polymerase. The phage RNA polymerase is highly specific for T7 promoters; thus, by inhibiting host RNA polymerase, all transcriptional activity in the cell is switched to T7 DNA. [Organization and expression of T7 DNA: CSHSQB (1983) 47 999–1007.]

Replication of T7 DNA (which remains linear throughout) is achieved mainly by proteins encoded by T7 DNA; it occurs in three stages: (i) *Initiation* occurs at a single site near the 'left' end of the genome. (Secondary sites can be used,

## bacteriophage T<sub>b</sub>

although less efficiently, if the primary site is deleted.) The T7 gp1 RNA polymerase is necessary for initiation, apparently synthesizing a short primer from promoters in the initiation region. (ii) Bidirectional *elongation* (from the RNA primers) catalysed mainly by two phage-coded enzymes: gp5 and gp4. The protein gp5 combines with host THIOREDOXIN to form a DNA polymerase which synthesizes DNA on the RNA primers in the 5'-to-3' direction, thus forming the leading strands. The protein gp4 is a multifunctional enzyme with primase, helicase and NTPase activity; it binds to unwound ssDNA regions of parental DNA and translocates unidirectionally in the 5'-to-3' direction (driven by NTP hydrolysis), unwinding the parental strands ahead of the replication forks. As it encounters specific primase recognition sites in the DNA, gp4 synthesizes tetranucleotide primers (pppApCpCpC or pppApCpCpA) which provide the 3'-OH ends necessary for initiation of lagging strand synthesis by the T7 DNA polymerase. [Book ref. 69, pp. 135–151.] Nucleotides for T7 DNA synthesis are provided by degradation of host DNA by T7 gp3 (an endonuclease) and gp6 (an exonuclease); gp6 (and/or host DNA polymerase I) may be involved in the removal of RNA primers. (iii) The newly synthesized daughter duplexes undergo recombination, probably mainly end-to-end, to form concatemers several times the length of a T7 genome [Virol. (1982) 123 474–479]; these concatemers undergo further rounds of replication. Each concatemer apparently contains only a single copy of the 160-bp terminal repeat sequence at the junctions between the genomes; the terminal repetition of the mature DNA is generated during maturation and packaging of the DNA into preformed prohead structures, when the concatemers are cleaved (possibly by gp3) into genome lengths. Mature progeny phages are released by host cell lysis (gp3.5 has lysozyme activity).

Studies on the rate of internalization of the phage genome during infection have led to new insight into the mechanism by which the DNA of phage T7 is transferred to the bacterial cell. It appears that, following attachment, the phage ejects certain proteins which may form a channel across the bacterial cell envelope through which DNA is transferred; it has been speculated that two of the ejected proteins may be components of a 'motor' which ratchets DNA into the host cell [Mol. Microbiol. (2001) 40 1–8].

**bacteriophage T<sub>b</sub>** *Syn.* TBILISI PHAGE.

**bacteriophage typing** See PHAGE TYPING.

**bacteriophage U3** See MICROVIRIDAE.

**bacteriophage v1** See PLASMAVIRIDAE.

**bacteriophage v2** See PLASMAVIRIDAE.

**bacteriophage v4** See PLASMAVIRIDAE.

**bacteriophage v5** See PLASMAVIRIDAE.

**bacteriophage v6** See INOVIRUS.

**bacteriophage v7** See PLASMAVIRIDAE.

**bacteriophage VP5** An ACTINOPHAGE of the STYLOVIRIDAE which infects *Streptomyces coelicolor*.

**bacteriophage W31** See T7 PHAGE GROUP.

**bacteriophage Xf** See INOVIRUS.

**bacteriophage Xf2** See INOVIRUS.

**bacteriophage Z** See BETACIN.

**bacteriophage ZJ/2** See INOVIRUS.

**bacteriophages** See BACTERIOPHAGE.

**bacteriophagous** Refers to organisms (e.g. certain protozoa) which consume bacteria.

**bacteriorhodopsin** A hydrophobic, pigment-containing protein (MWt ca. 27000) which is the major protein constituent of the PURPLE MEMBRANE in *Halobacterium salinarium*; it

is involved in the (energy-generating) light-dependent transmembrane translocation of protons. The protein part of the bacteriorhodopsin molecule (apoprotein, bacterio-opsin) consists of seven membrane-spanning regions; the pigment – RETINAL – occurs within the space bounded by these seven regions, being linked to one of them via a lysine residue.

Bacteriorhodopsin occurs in hexagonal arrays in the plane of the membrane.

On illumination, bacteriorhodopsin undergoes a cyclical series of changes with a periodicity of ca. 5–10 msec, and this photocycling is associated with the pumping of protons from the inner (cytoplasmic) to the outer side of the membrane, i.e. generation of proton motive force (pmf). During photocycling at least five photointermediates appear to be formed; these are designated: K<sub>590</sub>, L<sub>550</sub>, M<sub>412</sub>, N<sub>530</sub> and O<sub>640</sub> (the numbers being wavelengths, in nm, of maximum absorption). bR<sub>568</sub> is the light-adapted ground state.

Recent studies have clarified the mechanism, and route, of vectorial energy-dependent transport of protons across the membrane. Light induces the isomerization of (protonated) retinal from all-*trans* to 13-*cis*, isomerization resulting in deprotonation of the retinal – the proton being transferred to the asp-85 residue of the protein. Deprotonation of the retinal causes it to change conformation, and this, in turn, modifies the protein's conformation – opening up a channel which permits entry of a proton from the cytoplasmic side of the membrane; this proton reprotonates residue asp-96 – the proton from asp-96 having been donated to reprotonate retinal. The proton on asp-85 is transferred to the exterior of the membrane; this transfer appears to coincide with the N<sub>530</sub> photointermediate.

When incorporated into LIPOSOMES, bacteriorhodopsin tends (except at low pH) to adopt an orientation opposite to that in the cytoplasmic membrane – and hence to mediate inward pumping of protons.

[Bacteriorhodopsin (overview): Nature (2000) 406 569–570. Structural changes in bacteriorhodopsin coupled to proton transport: Nature (2000) 406 645–648. Structural alterations in the M state: Nature (2000) 406 649–652. Molecular mechanism of vectorial proton translocation: Nature (2000) 406 653–657.]

**bacterioruberins** C<sub>50</sub> CAROTENOID pigments which occur in members of the HALOBACTERIACEAE.

**bacteriostatic** (bacteristatic) Able to inhibit the growth and reproduction of at least some types of bacteria. (cf. BACTERICIDAL.)

**bacteriostatic** *Syn.* BACTERIOSTATIC.

**bacterium** See BACTERIA.

**Bacterium** A bacterial genus which has been obsolete for decades; various bacteria, e.g. *Escherichia coli*, *Clostridium chauvoei* etc., were once referred to as *B. coli*, *B. chauvoei* etc.

**bacterium-associated haemophagocytic syndrome** (BAHS) See HAEMOPHAGOCYTIC SYNDROME.

**bacteriuria** The presence of bacteria in the urine.

**bacterivore** Any organism (e.g. a ciliate or amoeba) which ingests bacteria as its main or sole source of nutrients. (cf. e.g. DETRITIVORE.)

**bacterization** The process of coating seeds, tubers etc. with certain bacteria (e.g. *Azotobacter*), prior to planting, with the object of improving plant growth.

**bacteroid** A bacterium-like cell or a modified bacterial cell – see e.g. ROOT NODULES. (In an ACTINORRHIZA, 'bacteroid' may refer e.g. to a senescent hyphal fragment.)

**Bacteroidaceae** A family of (typically) Gram-negative, anaerobic, chemoorganotrophic, asporogenous, motile and non-motile,

typically rod-shaped or filamentous bacteria, some of which are pathogenic in man and other animals. Genera: ACETIVIBRIO, ANAEROBIOSPIRILLUM, ANAEROVIBRIO, BACTEROIDES, BUTYRIVIBRIO, FUSOBACTERIUM, LACHNOSPIRA, LEPTOTRICHIA, PECTINATUS, SELENOMONAS, SUCCINIMONAS, SUCCINIVIBRIO and WOLINELLA. In some of these organisms (e.g. *Acetivibrio*, *Butyrivibrio*, *Lachnospira*) the CELL WALL appears to resemble the Gram-positive (rather than Gram-negative) type of wall; since these organisms give a negative or variable reaction in the Gram stain (at least under some conditions) they have been grouped with the frankly Gram-negative genera [Book ref. 22, pp. 602–662].

**Bacteroides** A genus of Gram-negative bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN and in the mouth and intestinal tract in man and other animals; some species are opportunist pathogens, being isolated from abscesses and other types of lesion (see e.g. FOOT-ROT; PNEUMONIA (f); SCALD). (See also ANAEROBIC DIGESTION; TERMITE-MICROBE ASSOCIATIONS; WETWOOD.) Cells: typically rods or filaments, non-motile or peritrichously flagellated, sometimes with central or terminal swellings or vacuoles. Some species form a dark or black pigment. [Black-pigmented strains from animals: JAB (1983) 55 247–252.] Metabolism is typically fermentative, though some strains can carry out FUMARATE RESPIRATION in media containing haemin – electron donors including formate and H<sub>2</sub>. Most species ('fermentative', 'saccharoclastic' or 'saccharolytic' species) typically attack a range of sugars, producing a mixture of products which may include acetic, formic, lactic, propionic and succinic acids; such species usually use or need CO<sub>2</sub> – which is assimilated by the reductive carboxylation of succinate to 2-oxoglutarate. Other species attack sugars weakly, or not at all, but utilize peptones with the formation of mixtures of either small amounts of e.g. acetic, formic, lactic and succinic acids, or mixtures of larger amounts of e.g. acetic, butyric, propionic and succinic acids – isobutyric and isovaleric acids being formed whenever butyric acid is formed. Primary isolation may be carried out on media containing e.g. peptone, yeast extract, haemin and menaquinone under at least 5% CO<sub>2</sub>. GC%: ca. 28–61. Type species: *B. fragilis*.

*B. endodontalis*. A non-saccharolytic, black-pigmented species isolated from the dental root canal [IJSB (1984) 34 118–120].

*B. fragilis* (formerly *Fusififormis fragilis*). Cells (in glucose broth): non-motile round-ended rods, 0.8–1.3 × 1.6–8.0 μm. Catalase +ve (most other species are catalase –ve). Saccharolytic; in haemin-containing media some strains form a *b*-type cytochrome and can carry out fumarate respiration. On horse- or rabbit-blood agar colonies are typically smooth, round, entire, low convex, grey and non-haemolytic; some strains produce clear ('β') haemolysis. Optimum growth temperature: 37°C. *B. fragilis* may be sensitive to e.g. CEFOTIXIM and clindamycin (see LINCOSAMIDES). (The '*B. fragilis* group' commonly includes former subspecies of *B. fragilis* which are currently classified as species: *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron* and *B. vulgatus*.)

*B. melaninogenicus*. A saccharolytic species which forms a black pigment (a haem derivative) and which has SOD activity; it occurs e.g. in the human mouth.

*B. nodosus*. A non-motile, non-saccharolytic species which causes foot-rot in sheep. [Surface structure and virulence of *B. nodosus*: JGM (1983) 129 225–234.]

*B. ochraceus*. See CAPNOCYTOPHAGA.

*B. pneumosintes* (formerly *Dialister pneumosintes*). A non-saccharolytic species which occurs e.g. in the human nasopharynx and which may be a secondary invader in upper respiratory tract infections. Cells: typically 0.2–0.4 × 0.3–0.6 μm.

*B. ruminicola*. A saccharolytic species which ferments a wide range of carbohydrates, including e.g. cellobiose and starch; it occurs in the RUMEN.

*B. succinogenes*. A saccharolytic rumen species which attacks relatively few sugars but which can utilize cellobiose and cellulose; unlike *B. ruminicola*, this species does not digest gelatin or hydrolyse aesculin.

*B. termitidis* (formerly *Sphaerophorus siccus* var. *termitidis*). A saccharolytic species which occurs in the intestinal tract in termites.

Other species: *B. amylophilus*, *B. asaccharolyticus*, *B. bivius*, *B. buccae*, *B. capillosus*, *B. coagulans*, *B. corporis*, *B. denticola*, *B. disiens*, *B. distasonis*, *B. eggerthii*, *B. furcosus*, *B. gingivalis*, *B. gracilis*, *B. hypermegas*, *B. intermedius*, *B. levii*, *B. loeschei*, *B. macacae*, *B. microfusis*, *B. multiacidus*, *B. oralis*, *B. oris*, *B. ovatus*, *B. praecolus* (cf. TISSIERELLA), *B. putredinis*, *B. splanchnicus*, *B. thetaiotaomicron*, *B. uniformis*, *B. ureolyticus*, *B. vulgatus* and *B. zoogloeiformans*.

[Book ref. 22, pp. 604–631; *Bacteroides* of the human lower intestinal tract: ARM (1984) 38 293–314.]

**Bacto** The designation of products of Difco Laboratories Inc., Detroit, USA.

**bactoprenol** (undecaprenol) In bacteria: a lipid-soluble, membrane-bound polyprenol consisting of a linear chain of 11 unsaturated isoprene units:

Bactoprenol phosphate acts as a carrier in the synthesis of a number of cell envelope and extracellular polymers: e.g., PEPTIDOGLYCAN, LIPOPOLYSACCHARIDE, TEICHOIC ACIDS and certain CAPSULE polymers; it apparently facilitates the transfer of lipophobic sugar residues across the cytoplasmic membrane. (cf. DOLICHOL; see also TUNICAMYCIN.)

**Baculoviridae** A family of ccc dsDNA-containing VIRUSES which infect arthropods (particularly insects of the Diptera, Hymenoptera and Lepidoptera). Baculovirus virions are structurally complex, consisting of one or more nucleocapsids within an envelope; virions containing one nucleocapsid per envelope are rod-shaped, ca. 200–400 × 40–60 nm. The genome is non-segmented circular supercoiled dsDNA, MWt ca. 58–110 × 10<sup>6</sup>.

The family is divided (on morphological criteria) into three subgroups: *A* (the NUCLEAR POLYHEDROSIS VIRUSES, NPVs), *B* (the GRANULOSIS VIRUSES, GVs), and *C*. (cf. POLYDNAVIRIDAE.) The NPVs and GVs are characterized by the formation of intracellular crystalline protein *occlusion bodies* within which virions are embedded; the NPVs form polyhedral intranuclear occlusion bodies (called POLYHEDRA), each containing many virions, while the GVs form ellipsoidal or round-ended rod-shaped occlusion bodies (called 'granules' or 'capsules'), each containing only one (rarely two) virions. The matrix proteins of both types of occlusion body (called *polyhedrin*, or polyhedrin in NPVs and granulin in GVs) are closely related in structure and function [review: JGV (1986) 67 1499–1513], but are apparently unrelated to the polyhedrins of the CYTOPLASMIC POLYHEDROSIS VIRUS GROUP. In contrast to the NPVs and GVs, baculoviruses of subgroup *C* do not form occlusion bodies; viruses of this subgroup have been observed in various arthropods (insects, arachnids, crustacea), the type species of the subgroup being *Oryctes rhinoceros* virus (from the coconut palm rhinoceros beetle).

## baculoviruses

An insect becomes infected with an NPV or GV when it ingests an occlusion body; the polyhedrin dissolves in the alkaline contents of the insect's midgut, releasing virions which then infect cells of the midgut. Non-occluded virions produced in these cells bud through the plasma membrane of the midgut cells and are disseminated via the haemolymph, subsequently infecting cells of a wide range of tissues. The virion-containing occlusion bodies are formed late in infection, and are eventually released by the death and dissolution of the insect host.

Baculoviruses have been extensively used for the BIOLOGICAL CONTROL of insect pests; they are particularly suitable for this purpose since they have no apparent relationship with any other known animal or plant viruses (and are therefore deemed unlikely to infect mammals or plants), and they can be lethal for – and spread rapidly among – insects in nature. Thus, e.g., NPVs have been used to control the European pine sawfly (*Neodiprion sertifer*) and European spruce sawfly (*Gilpinia hercyniae*), GVs have been used against the Small White butterfly (*Artogeia* (= *Pieris*) *rapae*, a pest of crucifers), and *Oryctes rhinoceros* virus has been used successfully to control the coconut palm rhinoceros beetle.

Since NPVs and GVs produce large quantities of polyhedrin/granulin in infected cells, the genomes of these viruses are of interest as vectors for the introduction and high-level expression of foreign genes in insects or insect cell cultures; e.g., a recombinant baculovirus containing a human  $\alpha$ -interferon gene linked to the polyhedrin promoter yielded large quantities of  $\alpha$ -interferon in silkworms [Nature (1985) 315 592–594].

**baculoviruses** Viruses of the BACULOVIRIDAE.

**Badhamia** See MYXOMYCETES.

**BaeI** See RESTRICTION ENDONUCLEASE (table).

**baeocyte** A small, spherical reproductive cell (diam. ca. 2–3  $\mu$ m) formed by members of section II of the CYANOBACTERIA. Baeocytes (formerly termed 'endospores') are produced by multiple fission of a vegetative cell which is enclosed in a fibrous layer external to the outer membrane of the cell wall; numerous baeocytes are released on rupture of the fibrous layer. A baeocyte enlarges, without division, until it reaches the size of a vegetative cell, this growth being accompanied by a progressive thickening of the fibrous outer layer. Gliding motility may be exhibited initially by those baeocytes which lack a fibrous outer layer at the time of their release.

**Baeomyces** A genus of LICHENS (order LECANORALES); photobiont: e.g. *Myrmecia*. Thallus: crustose to squamulose, often sorediate. Fruiting bodies are non-lichenized, stalked, convex hymenial discs resembling miniature mushrooms (cf. PODETIUM). Species occur on soil, rocks etc.

**BAF** See SEWAGE TREATMENT.

**bagassosis** An EXTRINSIC ALLERGIC ALVEOLITIS associated with inhalation of the dust of sugar cane waste (bagasse); certain bacteria (e.g. *Thermoactinomyces sacchari*) have been implicated.

**BAHS** (bacterium-associated haemophagocytic syndrome) See HAEMOPHAGOCYTIC SYNDROME.

**bakanae disease** ('foolish seedling disease'; 'foolish rice') A disease of rice caused by *Gibberella fujikuroi* (*Fusarium moniliforme*) and characterized by conspicuous elongation of the plant stems (internodes) followed by wilting. The symptoms are believed to be due to the effects of GIBBERELLINS produced by the pathogen. (See also CEREAL DISEASES.)

**baker's yeast** A specialized strain of *Saccharomyces cerevisiae* which is capable of rapid fermentative activity in dough (see BREAD-MAKING), i.e., under conditions of low oxygen tension, low water activity, and high osmotic pressure. The yeast is manufactured by batch culture (in a medium containing molasses,

vitamins, minerals and a nitrogen source) for 12–18 hours at ca. 30°C with full aeration (to suppress fermentation). The yeast is harvested by centrifugation, washed, and concentrated by pressing or filtration. 'Fresh yeast' is blended, extruded, cut into cakes and wrapped; it can be stored for only a few days. 'Active dry yeast' is usually dried in a stream of warm air and sold as granules (water content ca. 8.0%); it can be stored for up to ca. 18 months in sealed containers.

**baking** See BREAD-MAKING.

**BAL** British anti-Lewisite: 2,3-dimercaptopropanol; in the presence of oxygen BAL acts as a mitochondrial RESPIRATORY INHIBITOR, apparently blocking electron flow between cytochromes *b* and *c*<sub>1</sub> in Complex III of the ELECTRON TRANSPORT CHAIN.

**Balamuthia mandrillaris** A species of amoeba which can cause ENCEPHALITIS in the young, old and immunocompromised. Trophozoites, 15–60  $\mu$ m diam., have a round nucleus and a large, strongly staining nucleolus; cysts are roughly spherical, ca. 6–30  $\mu$ m diam. [*B. mandrillaris* infection: JMM (2001) 50 205–207.]

**balanced growth** See GROWTH.

**balanced salt solution (BSS)** Any of several solutions used (with or without supplement) e.g. in TISSUE CULTURE to provide satisfactory ionic, pH and osmotic conditions for the maintenance and/or growth of cells (see e.g. EARLE'S BSS and HANKS' BSS). Antibiotic(s) may be added to suppress microbial growth. (See also TRANSPORT MEDIUM; DULBECCO'S PBS; EAGLE'S MEDIUM.)

**Balansporida** See STELLATOSPOREA.

**Balansia** See CLAVICIPITALES.

**balantidiasis** See DYSENTERY (c).

**Balantidioides** See HETEROTRICHIDA.

**Balantidium** A genus of parasitic ciliate protozoa of the order TRICHOSTOMATIDA. *B. coli* can cause dysentery (see DYSENTERY (c)) in man, and is the only ciliate known to be pathogenic for man; it normally occurs e.g. as a harmless parasite in the intestinal tract in pigs. The trophozoite is ovoid with a tapering anterior end, ca. 40–70  $\mu$ m in length, and is covered by spirally arranged longitudinal rows of cilia; the organism exhibits a rotatory movement. At the anterior end of the cell there is a deep invagination (the vestibulum) leading to the cytostome, and a smaller invagination (the cytopye) occurs at the posterior end. The cell contains a large, kidney-shaped macronucleus (generally visible only in stained preparations) and a small micronucleus situated close to it; contractile vacuoles may be present. Reproduction occurs by binary fission; conjugation also occurs. Encystment occurs in the gut; the spherical cyst (ca. 50  $\mu$ m diam.) contains a large macronucleus which can be seen in unstained preparations or in preparations stained with a solution of methyl green in dilute acetic acid. Trophozoites can be cultured in media which support the growth of parasitic intestinal amoebae.

**BALB/c mice** An inbred mouse strain predisposed to MYELOMA formation on intraperitoneal injection of e.g. mineral oil. [The BALB/c mouse – genetics and immunology: CTMI (1985) 122 1–253.]

**Ballerup–Bethesda group** (1) Strains of *Citrobacter freundii* which ferment lactose slowly. (2) *Citrobacter freundii*.

**ballistoconidium** See BALLISTOSPORE.

**ballistospore** A spore which, at maturity, is forcibly projected from its site of attachment on the sporophore; ballistospores are formed by many basidiomycetes (cf. BASIDIOSPORE), by some imperfect fungi (e.g. *Sporobolomyces*) and by slime moulds of the PROTOSTELIOMYCETES. (cf. STATISMOSPORE and GASTEROID

BASIDIOSPORE.) An asexually-derived ballistospore is sometimes referred to as a *ballistoconidium*.

The ballistospore of a basidiomycete is formed terminally and asymmetrically on a sterigma; its surface is readily wettable. Shortly before discharge, a drop of liquid appears on the surface of the spore in a region near the attachment site (e.g. the HILAR APPENDIX); the drop grows in size (for ca. 5–40 sec) until, suddenly, both spore and drop are projected from the sterigma. [Proposed mechanisms for ballistospore discharge in *Itersonilia perplexans*: TBMS (1984) 82 13–29.]

**ballotini** Small glass beads, obtainable in a range of sizes, used e.g. for the ballistic disintegration of cells; for this purpose, cells and Ballotini are shaken together in e.g. a BRAUN MSK TISSUE DISINTEGRATOR.

**Baltimore classification** An early system of virus classification, proposed by Baltimore [Bact. Rev. (1971) 35 235–241], based on the nature of the genome and the strategy for viral gene expression (see VIRUS). Six classes (groups) were distinguished. *I.* dsDNA viruses. *II.* ssDNA viruses (only positive-sense ssDNA were known at the time). *III.* dsRNA viruses. *IV.* Positive-sense ssRNA viruses. *V.* Negative-sense ssRNA viruses. *VI.* RNA viruses in which DNA is synthesized (by reverse transcription) from the genome, and mRNA is transcribed from the DNA. (More classes would now be required to accommodate current knowledge of viral strategies.)

**bamboo mosaic virus** See POTEVIRUSES.

**BamHI** A RESTRICTION ENDONUCLEASE from *Bacillus amyloliquefaciens*; G/GATCC.

**banana bunchy top virus** See LUTEOVIRUSES.

**banana leaf spot** (sigatoka disease) A disease of the banana plant (*Musa*) characterized by leaf lesions and imperfect development of the fruit; causal agent: *Mycosphaerella musicola*. The disease has been controlled by spraying with copper compounds or with mineral oil.

**band centrifugation** See CENTRIFUGATION.

**Bangia** See RHODOPHYTA.

**Bang's disease** See BRUCELLOSIS.

**bank** (gene bank) *Syn.* LIBRARY.

**Banji virus** See FLAVIVIRIDAE.

**bar** A unit of pressure equal to 100 kPa (cf. PASCAL).

**barban** 4-Chlorobut-2-ynyl-3-chlorophenylcarbamate: a compound used e.g. for the control of wild oats; it also acts as a NITRIFICATION INHIBITOR.

**barbital** (barbitone) 5,5'-Diethylbarbituric acid. (Barbituric acid = malonylurea.)

**barbone** *Syn.* HAEMORRHAGIC SEPTICAEMIA (2).

**Barbour Stoenner Kelly medium** See BORRELIA (*B. burgdorferi*).

**Barbulanympha** See HYPERMASTIGIDA.

**bark-boring beetles** See SCOLYTIDAE.

**bark necrosis** See CANKER.

**barley B-1 virus** See POTEVIRUSES.

**barley diseases** See CEREAL DISEASES.

**barley stripe mosaic virus** See HORDEVIRUSES.

**barley yellow dwarf virus** See LUTEOVIRUSES.

**barley yellow mosaic virus** See POTYVIRUSES.

**barley yellow striate mosaic virus** See RHABDOVIRIDAE.

**Barmah Forest virus** See ALPHAVIRUS.

**baroduric** *Syn.* BAROTOLERANT.

**barophile** An organism which grows optimally or obligately under elevated hydrostatic pressure; under atmospheric pressure (101.325 kPa) some barophiles (e.g. *Shewanella benthica*) continue to grow (less vigorously) but others (obligate

barophiles) die at a temperature-dependent rate. Barophilic bacteria in seas and oceans occur both in the nutrient-poor seawater and in the relatively nutrient-rich guts of invertebrates (e.g. holothurians – sea cucumbers); those occurring in cold regions (<4°C) are heterotrophic bacteria (cf. HYDROTHERMAL VENT). [Reviews: ARM (1984) 38 487–514; MS (1986) 3 205–211.] (See also BAROTOLERANT.)

**barophilic** Having the characteristics of a BAROPHILE.

**barosensitive** See BAROTOLERANT.

**barotolerant** (baroduric) Refers to an organism which can grow at elevated pressures (up to ca. 400–600 atmospheres; 1 atm = 101.325 kPa) but which grows optimally at atmospheric pressure (cf. BAROPHILE); many bacteria (including e.g. *Escherichia coli* and *Pseudomonas aeruginosa*) are barotolerant, but some (e.g. *Vibrio parahaemolyticus*) cannot survive for long even under relatively low pressures (e.g. ca. 200 atm) and are termed *barosensitive*.

The inhibitory effect on barotolerant organisms of pressures greater than ca. 400–600 atm appears to be due, at least partly, to inhibition of certain aspects of PROTEIN SYNTHESIS – specifically, the binding of amino acyl-tRNAs and translocation. In a number of organisms the susceptibility of protein synthesis to pressure has been linked with the 30S ribosomal subunit; interestingly, increased barotolerance occurs in those strains of *E. coli* which have become resistant to streptomycin owing to a mutation affecting the 30S subunit.

**barren kinetosome** See CILIFEROUS.

**barrier filter** See MICROSCOPY (e).

**Barritt's method** See VOGES-PROSKAUER TEST.

**Barrouxia** See EIMERIORINA.

**Bartonella** A genus of Gram-negative, oxidase-negative bacteria (family BARTONELLACEAE) within the alpha subgroup of Proteobacteria; the cells are small, typically capnophilic, fastidious rods which can usually be grown aerobically on blood-agar in the presence of 5% carbon dioxide [guidelines for the practical identification of isolates: JCM (1993) 31 2381–2386].

The genus now includes several species which have been imported from the (former) genus *Rochalimaea* [JUSB (1993) 43 777–786].

*B. bacilliformis* (the type species) is the causal agent of BARTONELLOSIS in man (the only natural host); the bacterium is a small bacillus or pleomorphic coccobacillus, commonly ca. 1–3 µm in length, which, in culture, bears one or more flagella at one pole and divides by binary fission; it is transmitted by sandflies, and occurs in or on erythrocytes, and in endothelial cells, in infected persons.

*B. clarridgeiae* has been associated with cat scratch disease [JCM (1997) 35 1813–1818].

*B. elizabethae* (formerly *Rochalimaea elizabethae*) has been isolated from a case of endocarditis [JCM (1993) 31 872–881].

*B. henselae* (formerly *Rochalimaea henselae*) has been associated with various types of disease, including e.g. cutaneous bacillary angiomatosis; this disease (which occurs mainly in the immunocompromised) involves reddish-coloured, typically nodular lesions which may ulcerate. (*R. quintana* can also give rise to the disease.)

*B. quintana* (formerly *Rochalimaea quintana*) is the causal agent of TRENCH FEVER; the cells are small rods, and the organism is aerobic and capnophilic.

*B. vinsonii* (formerly *Rochalimaea vinsonii*) is parasitic in voles (the 'Canadian vole agent'); it is not capnophilic.

[Diseases caused by *Bartonella* spp: RMM (1995) 6 155–164.]

## Bartonellaceae

**Bartonellaceae** A family of bacteria which are parasitic or pathogenic in or on erythrocytes (red blood cells), and, in some cases, other cells, in various mammals, including man; the organisms can be grown in cell-free media. Genera: BARTONELLA and GRAHAMELLA.

**bartonellosis** (Carrion's disease) A human disease, occurring in parts of South America, caused by *Bartonella bacilliformis*; it is transmitted by the bites of sandflies of the genus *Phlebotomus*. There are two forms of the disease which usually occur in sequence: the first stage (*Oroya fever*) is characterized by fever and anaemia, the second (*verruca peruana*) by wart-like, ulcerating skin lesions.

**basal body** (a) (prokaryotic) See FLAGELLUM (a).

(b) (eukaryotic) (basal granule; blepharoplast; kinetosome; mastigosome) In some (ciliated or flagellated) cells: an intracellular microtubular structure which resembles a CENTRIOLE and which can serve e.g. as a MICROTUBULE-ORGANIZING CENTRE for the formation of the axoneme of a CILIUM or FLAGELLUM; unlike the prokaryotic basal body, a eukaryotic basal body plays no role in flagellar beating per se: see FLAGELLUM (b). A basal body can develop from a centriole or it can be formed de novo (e.g. during the transition of *Naegleria gruberi* from the non-flagellated to the flagellated form). In at least some cases a basal body can give rise to a centriole. A basal body differs from a centriole e.g. in that it is generally longer, and in that it has a system of microtubular and fibrillar filaments (*rootlets*) which arise from the side of the basal body and which may pass from one basal body to another.

(See also GRAIN CONVENTION; PITELKA CONVENTION.)

**basal granule** Obsolete term for BASAL BODY (b).

**basal medium** See MEDIUM.

**basauxic development** See CONIDIUM.

**base analogues** Reagents which are analogues of – and which can substitute for – normal bases in DNA; they can act as MUTAGENS since, during subsequent replication of the DNA, the base analogue may pair with the wrong normal base to generate a POINT MUTATION. For example, 2-aminopurine (AP) may be incorporated into DNA in place of adenine; during subsequent replication AP can pair with cytosine which, on further replication, pairs with guanine (an A-T-to-G-C transition). (See also 5-BROMOURACIL.) (Some base analogues in DNA may be recognized by the cell as 'damage' and may induce mutation by error-prone repair: see SOS SYSTEM.) (cf. BUDR and DDTTP.)

**base composition** (of DNA) See BASE RATIO and GC%.

**base excision repair** A form of EXCISION REPAIR that follows removal of a base from DNA (see ADAPTIVE RESPONSE and URACIL-DNA GLYCOSYLASE).

After removal of the base, the phosphodiester bond on one side of the AP SITE is cleaved by an AP *endonuclease*. The main AP *endonuclease* in *Escherichia coli* is *endonuclease III*; this is a multifunctional enzyme whose structure suggests that cleavage of phosphodiester bonds involves a nucleophilic attack on the P–3'O link [Nature (1995) 374 381–386]. Once the phosphodiester bond has been cleaved, a DNA polymerase can replace the damaged nucleotide. As well as the damaged nucleotide, several adjacent nucleotides may also be replaced [NAR (1998) 26 1282–1287]. The repair is completed by a ligase.

**base pair** A pair of bases, each in a separate NUCLEOTIDE, in which each base is hydrogen-bonded to the other. A 'classical' (Watson–Crick) base pair always contains one purine and one pyrimidine: adenine pairs specifically with thymine (A–T), guanine with cytosine (G–C), uracil with adenine (U–A); the two bases in a classical base pair are said to be *complementary*

to each other. (Other combinations (A–A, G–T, A–C, G–G, A–G) can occur under certain circumstances [Nature (1976) 263 285–289] but these are less stable than the classical pairs.) Classical base-pairing is responsible for holding together the strands in dsDNA (see DNA) or in dsRNA (e.g. in certain viruses); it is also involved e.g. in ordering the sequence of nucleotides in DNA REPLICATION and TRANSCRIPTION.

**base ratio** (dissymmetry ratio) Of microbial DNA: the ratio (A + T)/(G + C) in which A, T, G and C represent relative molar amounts of adenine, thymine, guanine and cytosine, respectively. (cf. GC%.) Species with a base ratio >1 may be called AT types; GC types have a base ratio <1.

**basic dye** See DYE.

**basic fuchsin** See FUCHSIN.

**basic orange** Syn. ACRIDINE ORANGE.

**basic replicon** (1) The smallest part of a replicon which encodes all the functions necessary for replication.

(2) As (1), above, with the added constraint that replication maintains the wild-type COPY NUMBER [Book ref. 161, p. 202].

**Basidiobolus** See ENTOMOPHTHORALES.

**basidiocarp** A fruiting body of a basidiomycete.

**basidiole** (1) An immature BASIDIUM prior to the appearance of the sterigmata. (2) An aborted basidium. (3) A sterile cell which is similar in appearance to an immature basidium.

**basidiolichen** A lichen (see LICHENS) in which the mycobiont is a basidiomycete.

**basidiomycetes** Fungi of the BASIDIOMYCOTINA.

**Basidiomycotina** (the 'basidiomycetes') A subdivision of fungi (division EUMYCOTA) characterized by the formation of sexually derived spores (BASIDIOSPORES) on *basidia* (see BASIDIUM). The basidiomycetes are typically terrestrial saprotrophs or parasites; they include e.g. mushrooms, puffballs, stinkhorns, and the (parasitic) rust and smut fungi. A few basidiomycetes are marine organisms (see e.g. NIA). In most species the thallus is a well-developed septate mycelium which often has CLAMP CONNECTIONS (see also DOLIPORE SEPTUM); some basidiomycetes can occur in a yeast-like (unicellular) phase (see FILOBASIDIACEAE) – as can certain fungi which appear to be the anamorphs of basidiomycetes (see e.g. SPOROBOLOMYCETACEAE).

In the *typical* life cycle, the germination of a basidiospore leads to the development of a septate mycelium consisting of uninucleate, haploid cells. At some stage the thallus enters DIKARYOPHASE (see also HYPHA), and eventually karyogamy and MEIOSIS occur in the developing basidium – which typically gives rise to four (haploid) basidiospores.

Classes: GASTEROMYCETES, HYMENOMYCETES, UREDINIOMYCETES, USTILAGINOMYCETES.

**Basidiophora** A genus of fungi (order PERONOSPORALES) in which the sporangiohores resemble basidia, and the sporangia are borne on short sterigmata; the organisms include parasites of the ornamental aster and of members of the Compositae.

**basidiospores** Sexually-derived, typically uninucleate and haploid SPORES formed on basidia (see BASIDIUM) by fungi of the BASIDIOMYCOTINA. According to species, basidiospores may be any of various shapes and sizes, and either pigmented or non-pigmented. In many basidiomycetes the basidiospores are BALLISTOSPORES, while in some (e.g. smut fungi) they are STATISMOSPORES. (cf. GASTEROID BASIDIOSPORE.) On germination, a basidiospore commonly gives rise to a germ tube, but in some cases GERMINATION BY REPETITION may occur.

*Dispersal of basidiospores.* In agarics with aequihymeniiferous lamellae (see LAMELLA), the ballistospores are projected more or less horizontally for ca. 0.1–0.2 mm before gravity

initiates a vertical fall; the spores on a given basidium are commonly discharged in rapid succession (within seconds or minutes of one another). In these agarics the shape of the lamella facilitates spore dispersal – spores from the more proximal parts of the lamella being able to fall vertically even when the lamellae are orientated several degrees from the vertical.

In e.g. *Coprinus* spp the inaequihymeniiferous lamellae occur close together on the pileus, and the shape of the lamellae does not facilitate dispersal of the ballistospores. However, in some species cystidia (see CYSTIDIUM) may serve to hold apart adjacent hymenial surfaces. In other species the process of *autodigestion* is an aid to spore dispersal; autodigestion involves the progressive liquefaction of the lamellae, beginning at the free edge of the lamella and progressing towards the pileus as fresh crops of basidia become mature. Thus, spores discharged by a given basidium need fall for only a short distance between adjacent lamellae before becoming free of the fruiting body.

See also e.g. CYATHUS, LYCOPERDALES, SPHAEROBOLUS.

**basidium** (*pl.* basidia) A microscopic, unicellular or multicellular structure which gives rise to the sexually-derived spores (BASIDIOSPORES) in fungi of the BASIDIOMYCOTINA; basidiospores are formed externally, i.e., as extrusions, on the basidium (but see TETRAGONIOMYCETES). In some basidiomycetes (e.g. HYMENOMYCETES) the basidia are formed in a layer on specialized fertile tissue (see HYMENIUM), while in others (e.g. UREDINIOMYCETES) they are formed individually from germinating spores.

In many species the basidium is a simple, cylindrical or clavate structure which gives rise to (usually) four apically and symmetrically situated basidiospores, each basidiospore commonly being borne on a small, narrow protrusion (STERIGMA). In other species the basidium may be apically bifurcate, each fork (sterigma) bearing a single terminal basidiospore (as in members of the DACRYMYCETALES), or it may be divided, apically, into four substantial finger-like protrusions (sterigmata), each bearing a terminal basidiospore (as in members of the TREMELLALES). A basidium which is not divided, internally, by septa is called a *holobasidium*; such basidia are formed by members of the HOLOBASIDIOMYCETIDAE. A basidium which is divided, internally, by transverse or longitudinal septa (as e.g. in *Auricularia* and *Tremella*, respectively) is called a *phragmobasidium*; such basidia are formed by members of the PHRAGMOBASIDIOMYCETIDAE and of the UREDINIOMYCETES and USTILAGINOMYCETES.

**Basidium formation.** A simple holobasidium typically develops from a terminal dikaryotic hyphal cell within a hymenium; the boundary between this cell and the parent hypha is often marked by a CLAMP CONNECTION. Within the developing basidium, karyogamy and MEIOSIS commonly give rise to four haploid nuclei. (See also METABASIDIUM and PROBASIDIUM.) Four small protuberances (sterigmata) then form at the apical (free) end of the developing basidium, and the terminal part of each sterigma swells to form a basidiospore initial; one nucleus migrates into each initial, and the basidiospores are subsequently delimited. In some species mitotic division occurs within the developing basidiospores; in such cases either binucleate basidiospores are formed, or uninucleate basidiospores are formed after one daughter nucleus from each pair has returned to the basidium.

In rust and smut fungi, the basidium typically develops from a short germ tube which arises from the *teliospore*. In some cases a diploid nucleus passes from the teliospore into the germ tube and undergoes meiosis; the structure which develops (the metabasidium, or 'promycelium') is septate in many species and (in rusts, and in many smut fungi) it gives rise to basidiospores both apically and laterally. Rust fungi characteristically form

four basidiospores per basidium; in many smut fungi the basidium may give rise to an indefinite number of basidiospores following mitotic divisions within the metabasidium.

[Review: BBMS (1983) 17 82–94.]

**basionym** (basonym) The name of the species whose specific epithet is included in a new combination (see COMB. NOV.).

**basipetal development** Development from the tip towards the base or point of attachment; e.g., in a chain of basipetally developing spores the first-formed spores occupy positions in the terminal or distal parts of the chain, while spores formed later occupy the more proximal positions. (cf. ACROPETAL DEVELOPMENT.)

**basonym** *Syn.* BASIONYM.

**basophil** A PMN (q.v.) which can respond to certain stimuli e.g. by rapidly secreting vasoactive products; it is primarily a circulatory cell, and is important e.g. in immediate-type hypersensitivity reactions. As in the MAST CELL, with which it shares many characteristics, the basophil surface contains e.g. many high-affinity receptor sites for the Fc portion of IgE antibodies, and its (basophilic) cytoplasmic granules also contain substances such as HISTAMINE and SEROTONIN; stimuli which cause activation and degranulation lead to the secretion of various products and to the formation of e.g. SUPEROXIDE and H<sub>2</sub>O<sub>2</sub>. (See also JONES–MOTTE SENSITIVITY.)

**batch culture** (closed culture) A form of CULTURE (sense 2) in which a given volume of liquid medium is inoculated with cells (e.g. bacteria) capable of growth in that medium, and the inoculated medium is incubated for an appropriate period of time; cells growing under these conditions are exposed to a continually changing environment due e.g. to the gradual consumption of nutrients and the accumulation of metabolic wastes (cf. CONTINUOUS CULTURE and FED BATCH CULTURE).

The growth curve (see GROWTH) obtained by monitoring a batch culture commonly exhibits a sequence of four main phases of growth. In the *lag phase* the growth rate – i.e., the rate of increase in cell numbers (or biomass) – is initially minimal but subsequently rises to a value dictated e.g. by the prevailing conditions (e.g. temperature, concentration of nutrients etc). The length of the lag phase is influenced by the cultural history of the cells in the inoculum. For example, if slowly dividing cells from a nutrient-poor environment are transferred to a nutrient-rich medium which can support a higher rate of growth, there is usually a relatively long lag phase during which time the cells become adapted to the new environment; during this period of adaptation the cells exhibit *unbalanced* GROWTH. Subsequently, growth occurs at a new, higher rate permitted by the higher levels of nutrients. A long lag phase may also occur e.g. if the carbon source in the new medium differs from that previously used by the cells. (cf. DIAUXIE.) When actively dividing cells are transferred to a medium which offers conditions similar to those under which the cells were previously growing, a lag phase is not observed.

At the end of the lag phase the cells enter the *exponential* (= *logarithmic* or *log*) *phase* of growth in which, for a given organism, the growth rate is both constant and maximal for the particular growth conditions. In this phase there is an exponential increase in cell numbers (and biomass); this type of growth is referred to as *balanced* GROWTH. (See also TROPHOPHASE.)

In the *stationary phase* the growth rate declines and eventually reaches zero. (See also IDIOPHASE.)

In the *death phase* the number of viable cells in the culture (maximal in the stationary phase) declines.

## batch retort

**batch retort** In CANNING: a vessel within which filled, sealed cans (or other containers) undergo heat treatment in a batch-type process (cf. COOKER-COOLER). The cans are subjected to saturated steam under pressure or to an air-steam mixture, or (in an *overpressure retort*) are submerged in heated water under an air pressure of up to ca. 250 kPa. In some batch retorts (e.g. the *Konservomat*) the load is agitated to facilitate heat penetration.

**bating** (of hides) See PROTEASES.

**Batrachospermum** See RHODOPHYTA.

**Battarrea** See GASTEROMYCETES (Tulostomatales).

**Battley bacillus** Strain(s) of *Mycobacterium intracellulare* or, loosely, strain(s) of related species (including *M. avium*).

**Bayer's junction** (Bayer's patch) See ADHESION SITE.

**Bayleton** See TRIADIMEFON.

**BB-transhydrogenase** See TRANSHYDROGENASE.

**BCDF** (*immunol.*) See LYMPHOKINES.

**BCF** Bioconcentration factor: a measure of the degree to which a compound (commonly a xenobiotic), present in an aquatic environment, is accumulated in the biomass of organisms (e.g. algae) living in that environment.  $BCF = C_o/C_w$  where  $C_o$  = concentration of the compound in the organisms, and  $C_w$  = the concentration of the compound in the water. (See e.g. TBTO.)

**BCG** Bacille (bacillus) Calmette-Guérin: an attenuated strain of *Mycobacterium bovis* used e.g. as a vaccine against TUBERCULOSIS. The vaccine often gives protection against e.g. tubercular meningitis in childhood – but in a number of studies it has failed to protect against pulmonary tuberculosis [Lancet (1990) 335 1016–1020]; moreover, it may produce disseminated infections in the immunocompromised (e.g. AIDS patients). In some instances, BCG has provided some protection against LEPROSY.

[Mycolic acids in BCG substrains: JGM (1984) 130 2733–2736.]

(See also ESAT-6.)

**BCGF** (*immunol.*) See LYMPHOKINES.

**Bchl** Bacteriochlorophyll: see CHLOROPHYLLS.

**BclI** A RESTRICTION ENDONUCLEASE from *Bacillus caldolyticus*; T/GATCA.

**BCNU** See N-NITROSO COMPOUNDS.

**Bd** (buoyant density) See CENTRIFUGATION and GC%.

**BD-type starter** See LACTIC ACID STARTERS.

**bdelloplast** See BDELLOVIBRIO.

**bdelloplasm** See BDELLOVIBRIO.

**Bdellospora** See ZOOPAGALES.

**Bdellovibrio** A genus of aerobic Gram-negative bacteria which are characteristically predatory on other bacteria (cf. VAMPIROVIBRIO); they occur worldwide in soil and sewage, and in freshwater and marine habitats. On primary isolation all strains are obligately parasitic on certain Gram-negative bacteria, including e.g. *Aquaspirillum serpense*, *Escherichia coli*, *Pseudomonas* spp, and *Rhodospirillum rubrum* – the range of prey species varying with the strain of *Bdellovibrio*; prey-independent, cultivable strains can develop from strictly predatory strains, and some strains are facultatively predatory. The predatory strains exhibit a biphasic life cycle: the predatory phase (in which the non-growing cells search for prey) alternating with a phase of growth and reproduction in the periplasmic space of a host cell. Predatory cells of *Bdellovibrio* are vibrioid,  $0.2\text{--}0.5 \times 0.5\text{--}1.4 \mu\text{m}$ , each having a single polar sheathed flagellum (the sheath being continuous with the outer membrane); cells of prey-independent strains may be larger and non-motile, and may form a yellowish pigment. All strains are chemoorganotrophs. Growth occurs optimally at 28–30°C, and metabolism is respiratory (oxidative). Three species are recognized [Book ref. 22, pp. 118–124]:

*B. bacteriovorus*, *B. starrii* and *B. stolpii*; the genus is divided by phage typing into six groups: groups I–IV consist of strains of *B. bacteriovorus*, group V contains *B. stolpii* strains, and group VI consists of strains of *B. starrii* (for which no phages are currently known). GC%: ca. 33–51. Type species: *B. bacteriovorus*.

**Predation.** A predatory *Bdellovibrio* cell initially attaches, via a 'holdfast' region at its non-flagellar end, to a prey cell. ('Bdello' derives from the Greek for 'leech'.) The predatory cell secretes enzymes (e.g. lysozyme) and enters the periplasmic space of the prey cell via the pore produced by enzymic action. (*Bdellovibrio* can penetrate cells of *E. coli* even when they have a thick capsule [Microbiology (1997) 143 749–754].) The prey cell quickly dies and subsequently rounds up to become a *bdelloplast*; during this process the peptidoglycan sacculus of the prey cell becomes insensitive to lysozyme, thus inhibiting predation by other *Bdellovibrio* cells. Within the periplasmic space of the *bdelloplast*, the predatory cell grows and develops into a long, spiral, non-motile filament; the filament subsequently fragments to form motile predatory cells which, on release, can initiate a new cycle. *Bdellovibrio* strain W can form a resting cell (*bdelloplast*) within the *bdelloplast*; a *bdelloplast* has a thickened peptidoglycan wall and has increased resistance to elevated temperatures and to desiccation.

**Isolation.** *Bdellovibrio* may be isolated from soil infusions etc. e.g. by membrane filtration (membrane pore size ca. 1.2  $\mu\text{m}$ ) – the filtrate being inoculated onto a lawn plate prepared from a sensitive strain of bacteria, or onto a soft agar which incorporates suitable prey cells; on incubation, viable cells of *Bdellovibrio* give rise to macroscopic plaques.

**bdDNA assay** (branched DNA assay) A procedure, based on signal amplification, which is used for quantifying a specific single-stranded DNA or RNA target sequence in a sample; essentially, signal amplification involves (i) the use of a target-specific PROBE for immobilizing the target nucleic acid on a solid support, and (ii) the use of other types of probe for labelling each bound target sequence with an enzyme system that generates (from a suitable substrate) an amplified chemiluminescent signal – the intensity of which is related to the number of target molecules in the sample.

Signal amplification avoids an important problem associated with target amplification methods (such as PCR): the problem of potential contamination of apparatus and environment with copies of the (highly amplified) target nucleic acid. It has the disadvantage that, by failing to provide copies of the target, further investigation of the target molecule (e.g. by sequencing) is precluded.

bdDNA-based commercial kits (Quantiplex™; Bayer Diagnostics, Leverkusen, Germany) have been used e.g. for quantifying hepatitis viruses B and C and the human immunodeficiency virus (HIV). In a given assay, a divalent probe is used initially to bind target molecules to the surface of a microtitre plate. Another divalent probe is then used to link each bound target molecule to a synthetic multi-branched DNA molecule (bdDNA; the 'amplifier'); subsequently, excess enzyme-labelled probes are allowed to bind to (multiple) probe-binding sites on the bdDNA. After washing, addition of the enzyme's substrate (a diacetate) generates the chemiluminescent signal.

A bdDNA assay may be used for detection, as well as quantification, of a given sequence; for example, this method has been used for detecting the *mecA* gene in blood culture bottles [JCM (1999) 37 4192–4193].

**BDProbe Tec™ ET** See SDA.

**beak** (*mycol.*) The tubular neck of a perithecium or pycnidium.

- bean common mosaic virus** See POTYVIRUSES.
- bean golden mosaic virus (BGMV)** A member of the GEMINIVIRUSES. BGMV can cause chlorosis in beans (*Phaseolus vulgaris*); it is transmitted by the whitefly *Bemisia tabaci*, and occurs in tropical America.
- bean paste** *Syn.* MISO.
- bean summer death virus** See GEMINIVIRUSES.
- bean yellow mosaic virus** See POTYVIRUSES.
- beard-lichens** (beard-moss) Lichens of the genera ALECTORIA, BRYORIA, and/or USNEA.
- Beauveria** A genus of fungi of the class HYPHOMYCETES. *B. bassiana* forms a septate mycelium; spheroidal conidia are borne on the sympodially branched, narrow, apical region of each flask-shaped conidiophore. *B. bassiana* causes the SILK-WORM DISEASE *muscardine*, and has been used (e.g. in the former USSR) for the BIOLOGICAL CONTROL of certain crop pests – e.g. Colorado beetle (*Leptinotarsa decemlineata*); for biological control the fungus has been used e.g. in the form of a powder, *Boverin*: a dried mixture of conidia and kaolin. *B. bassiana* forms a depsipeptide toxin, *beauvericin* (see ENNIATINS).
- beauvericin** See ENNIATINS.
- Bebaru virus** See ALPHAVIRUS.
- becampicillin** See PENICILLINS.
- Bedsonia** See CHLAMYDIA.
- bee acute paralysis virus** See PICORNAVIRIDAE.
- bee diseases** ‘Domestic’ hive bees – *Apis mellifera* (the European honey-bee) and *A. cerana* (the Eastern honey-bee) – are subject to a range of diseases of microbial aetiology. In general, larvae are affected more often than adults. Spread of disease is often kept under control by the activity of worker bees which remove diseased and dead larvae from the hive. *Bacterial diseases* include e.g. AMERICAN FOULBROOD and EUROPEAN FOULBROOD (see also SPIROPLASMA). *Fungal diseases* include CHALK-BROOD and STONE-BROOD. *Protozoal* parasites and pathogens of bees include e.g. *Nosema apis*, which develops in the midgut epithelial cells in adult honey-bees (infected bees may show no obvious symptoms, although they have a shortened lifespan), and *Malpighamoeba mellificae* (*Vahlkampfia mellificae*), which infects the lumen of the Malpighian tubules in adult bees [SEM of developmental stages: JP (1985) 32 139–144]. *Virus diseases* include several caused by small unclassified RNA viruses (see PICORNAVIRIDAE) and some caused by iridescent and filamentous viruses. [Book ref. 66.] (See also INSECT DISEASES.)
- bee slow paralysis virus** See PICORNAVIRIDAE.
- bee virus X** See PICORNAVIRIDAE.
- beech bark disease** A European and North American disease of beech trees (*Fagus* spp) caused by *Nectria coccinea*. Infection commonly follows infestation of the tree by beech scale insects (*Cryptococcus fagisuga*). Symptoms: phloem and cambium cells in the bark die in patches, allowing leakage and blackening of sap, and there may be yellowing of the leaves and die-back of the crown; infected trees may die.
- Beechey ground squirrel hepatitis virus** *Syn.* GROUND SQUIRREL HEPATITIS VIRUS.
- beef-steak fungus** *Fistulina hepatica* (see APHYLLOPHORALES).
- beer-making** See BREWING.
- beer spoilage** Off-flavours in beer may be caused by contaminating organisms – e.g. *Acetobacter* spp can produce acetic acid and cause ROPINESS; heterofermentative lactobacilli (which preferentially ferment maltose) can cause off-flavours (e.g. diacetyl), turbidity and/or ropiness. *Sarcina sickness* results from the production of diacetyl by *Pediococcus cerevisiae*. Other spoilage organisms include *Candida* and *Pichia* spp.
- beet cryptic viruses** See CRYPTIC VIRUSES.
- beet curly top virus** See GEMINIVIRUSES.
- beet leaf curl virus** See RHABDOVIRIDAE.
- beet mild yellowing virus** See LUTEOVIRUSES.
- beet mosaic virus** See POTYVIRUSES.
- beet necrotic yellow vein virus (BNYVV)** A virus which can cause severe disease (‘rhizomania’) in sugar beet (*Beta vulgaris*); it is transmitted by the ‘fungus’ *Polymyxa betae* – which is also responsible for the persistence of the virus in the soil. BNYVV may belong to the ‘furovirus’ group – see SOIL-BORNE WHEAT MOSAIC VIRUS. (cf. TOBAMOVIRUSES.) [BNYVV RNA: JGV (1985) 66 345–350.]
- beet western yellows virus** See LUTEOVIRUSES.
- beet yellow net virus** See LUTEOVIRUSES.
- beet yellow stunt virus** See CLOSTEROVIRUSES.
- beet yellows virus group** *Syn.* CLOSTEROVIRUSES.
- Beggiatoa** A genus of GLIDING BACTERIA (see CYTOPHAGALES); species are widespread e.g. in freshwater, estuarine and marine waters and sediments, in the rice rhizosphere, and in activated sludge. The organisms are non-sheathed, non-pigmented, multicellular filaments (trichomes) which form necridia and hormogonia; according to species, the trichomes are 1 to >50 µm in diameter. The organisms appear to be chemoorganotrophic heterotrophs, although at least some strains may be able to grow mixotrophically using sulphide as an electron donor; refractile ‘intracellular’ granules of sulphur (located between cytoplasmic membrane and cell wall) are formed in the presence of sulphide. Metabolism is respiratory, and a complete TCA cycle is present. Most strains can use acetate and/or lactate as the sole source of carbon; none can use hexoses. The main storage product is poly-β-hydroxybutyrate; volutin is also formed. [Review: ARM (1983) 37 341–354.]
- Beggiatoaceae** See CYTOPHAGALES.
- Beijerinckia** A genus (*incertae sedis*) of Gram-negative, aerobic, catalase-positive, chemoorganotrophic, asporogenous bacteria which occur e.g. in the phyllosphere and in soils (particularly in the tropics). Cells: typically round-ended rods, ca. 0.5–1.5 × 1.7–4.5 µm, peritrichously flagellated or non-motile; division involves constriction. Each cell characteristically contains two PHB-containing polar bodies. In some species each cell may be encysted, or several cells may occur within a single capsule. Metabolism is respiratory (oxidative), with O<sub>2</sub> as terminal electron acceptor. NITROGEN FIXATION is carried out under both atmospheric and microaerobic conditions; in many strains N<sub>2</sub> is used in preference to NO<sub>3</sub><sup>-</sup>. All strains can utilize glucose, fructose and sucrose as carbon sources; peptone does not support growth. Slime (sometimes elastic) is commonly formed, particularly on agar under N<sub>2</sub>-fixing conditions. Colonies are often some shade of pink, or orange to pale brown. No pellicle is formed on liquid media. Optimum growth temperature: 20–30°C; no growth at 37°C. Growth can occur within the pH range ca. 3–10. GC%: ca. 55–61. Type species: *B. indica*; other species: *B. dextrii*, *B. fluminensis* and *B. mobilis*. [Book ref. 22, pp. 311–321.]
- bell morels** The fruiting bodies of VERPA spp.
- belladonna mottle virus** See TYMOVIRUSES.
- benalaxyl** See PHENYLAMIDE ANTIFUNGAL AGENTS.
- Beneckea** An obsolete bacterial genus, members of which are now included in the genus VIBRIO.
- benign (med.)** (1) (of disease) Mild; self-limiting; not recurrent. (2) (of tumours) Not MALIGNANT (sense 2).
- benign enzootic paresis** *Syn.* TALFAN DISEASE.
- benign foot-rot** (of sheep) See SCALD.

## benign tertian malaria

**benign tertian malaria** See MALARIA.

**Benlate** See BENOMYL.

**benomyl** (methyl-(1-*n*-butylcarbamoyl)-benzimidazole-2-carbamate; trade name: e.g. Benlate) An agricultural ANTIFUNGAL AGENT (see BENZIMIDAZOLES (a)). Benomyl is a systemic antifungal agent which has both eradicant and protectant properties against a wide range of plant diseases (e.g. many powdery mildews, apple scab, botrytis, eyespot of wheat and barley, black spot of roses); when used as a seed dressing it protects against seed-borne diseases such as smuts and bunts of cereals, and when mixed with a dithiocarbamate such as maneb or mancozeb it gives some control against glume blotch in wheat and against some cereal rusts. It is also used to prevent storage rots of fruit and vegetables (see e.g. GANGRENE sense 2). Benomyl owes its activity to its degradation, in solution, to the fungitoxic substances MBC (see BENZIMIDAZOLES) and butyl isocyanate; it also acts as a cutinase inhibitor, preventing penetration of the plant cuticle by the pathogen (see CUTIN) [Book ref. 58, pp. 94–95]. Benomyl-resistant strains of many fungal pathogens have emerged, reducing the usefulness of the fungicide in agriculture. [Bacterial degradation of benomyl: AvL (1978) 44 283–292, 293–309.]

**benquinox** (1,2-benzoquinone-*N'*-benzoylhydrazone-4-oxime) A QUINONE ANTIFUNGAL AGENT which is used mainly as a seed dressing.

**Benson–Calvin–Bassham cycle** *Syn.* CALVIN CYCLE.

**benthic** Refers to the mud, sand etc, and/or to the indigenous organisms, at the bottom of a lake, sea or other body of water. (cf. PELAGIC; see also LITTORAL.)

**benzalkonium chloride** See QUATERNARY AMMONIUM COMPOUNDS and e.g. KLEINSCHMIDT MONOLAYER TECHNIQUE.

**benzene** Aerobic degradation: see HYDROCARBONS. Degradation in an anoxic environment: see BIOREMEDIATION.

**benzethonium chloride** See entry QUATERNARY AMMONIUM COMPOUNDS.

**benzidine test** A test used to detect bacterial CYTOCHROMES. Colonies of the test strain are flooded with a reagent consisting of benzidine dihydrochloride dissolved in a mixture of acetic acid and ethanol; on addition of an equal volume of H<sub>2</sub>O<sub>2</sub> (5%), cells which contain cytochromes develop a green or blue–green coloration. (cf. OXIDASE TEST.)

**benzimidazoles** (a) (as antifungal agents) An important group of agricultural systemic ANTIFUNGAL AGENTS; they are often called ‘MBC fungicides’ because many of them decompose in aqueous solution (or in the plant) to form methyl benzimidazol-2-yl carbamate (MBC, CARBENDAZIM) – apparently the primary fungitoxic agent. MBC appears to act primarily in the nucleus where it disrupts the formation of spindle microtubules, inhibiting or disrupting mitosis. Single-step resistance to benzimidazoles tends to emerge readily. The group includes BENOMYL, CARBENDAZIM, FUBERIDAZOLE, THIABENDAZOLE and THIOPHANATE-METHYL.

(b) (as antiviral agents) See e.g. ENVIROXIME and HBB.

**benzoic acid** (C<sub>6</sub>H<sub>5</sub>COOH) An antibacterial and antifungal ORGANIC ACID used (as the free acid or as benzoate) as a PRESERVATIVE (e.g. in fruit juices, cordials, sauces, acidic foods, pharmaceuticals) and, with other agents, for the topical treatment of certain fungal infections; it is maximally effective below ca. pH 5, activity decreasing sharply with increase in pH above this value. Benzoic acid can be inactivated by certain colloids (e.g. kaolin). (cf. PARABENZOATES.)

**benzoquinones** See QUINONES.

**benzoyl peroxide** See ACNE.

**benzyl alcohol** See ALCOHOLS.

**2-benzyl-4-chlorophenol** See PHENOLS.

**benzylpenicillin** (penicillin G) One of the first of the natural PENICILLINS to be produced (from e.g. *P. chrysogenum*); R = C<sub>6</sub>H<sub>5</sub>.CH<sub>2</sub>.CO (see β-LACTAM ANTIBIOTICS). It is active against many Gram-positive bacteria which do not produce β-LACTAMASES, but is poorly active against Gram-negative species. It is administered parenterally.

**Berenil** A trypanocidal DIAMIDINE which binds to AT-rich regions of dsDNA (apparently in the same way as does NETROPSIN).

**beriberi** (acute cardiac) See CITREOVIRIDIN.

**Berkefeld candle** See FILTRATION.

**Berne virus** An enveloped RNA virus (proposed family: TOROVIRIDAE) isolated from a horse. The virion is pleomorphic (ca. 120–140 nm diam.) and consists of an elongated, curved nucleocapsid enclosed by a peplomer-bearing envelope. The genome is a single molecule of positive-sense ssRNA (MWt ca. 6 × 10<sup>6</sup>); polyadenylated subgenomic mRNAs are apparently synthesized in infected cells. Maturation apparently involves the budding of preformed tubular nucleocapsids into Golgi vesicles and intracytoplasmic cisternae; the nucleocapsid appears to undergo a morphological change during budding [JGV (1986) 67 1305–1314].

**Berry–Dedrick phenomenon** See NON-GENETIC REACTIVATION.

**Besnoitia** A genus of coccidian protozoa (suborder EIMERIORINA); members are classified by some authors [AP (1982) 20 403–406] in the genus ISOSPORA. The organisms are parasitic in a range of animals – e.g. cattle, horses, sheep, cats, rodents; transmission may occur e.g. via blood-sucking flies or by ingestion of infected tissues. Disporic, tetrazoic oocysts are formed.

**β** (duplex winding number) See DNA.

**β-barrel pore** See PROTEIN SECRETION (type IV systems).

**β-exotoxin** *Syn.* THURINGIENSIN.

**beta interferon** See INTERFERONS.

**beta-lactam antibiotics** See β-LACTAM ANTIBIOTICS.

**beta-lactamases** See β-LACTAMASES.

**β operon** See RIBOSOME (biogenesis).

**beta-rays** See IONIZING RADIATION.

**Betabacterium** See LACTOBACILLUS.

**betacin** A BACTERIOCIN-like, heat-resistant, proteinaceous substance produced by bacteriophage SPβ-containing (or bacteriophage Z-containing) lysogens of *Bacillus subtilis* when growing on agar (but apparently not in broth cultures). Betacin inhibits the growth of non-lysogens but not that of lysogens containing SPβ (or the related phage Z). [Book ref. 170, p. 280.] (cf. BACTERIOPHAGE ΦB41.)

**Betacoccus** Obsolete name for LEUCONOSTOC.

**Betadine** See IODINE (a).

**Betaferon**<sup>™</sup> See INTERFERONS.

**Betaherpesvirinae** (‘cytomegalovirus group’) A subfamily of viruses of the HERPESVIRIDAE (q.v.).

The Betaherpesvirinae formerly consisted of only (i) the *human cytomegalovirus group* – type species human (beta) herpesvirus 5 (= human herpesvirus 5, HHV5; human cytomegalovirus, HCMV) and (ii) *murine cytomegalovirus group* – type species murid (beta) herpesvirus 1 (= murid herpesvirus 1; mouse cytomegalovirus, mouse CMV) [Book ref. 23, pp 49–50]; possible members included suid herpesvirus 2 (pig CMV, causal agent of INCLUSION BODY RHINITIS), murid herpesvirus 2 (rat CMV) and caviid herpesvirus 1 (guinea-pig CMV). Later, certain bovine herpesviruses were classified as ‘bovine cytomegaloviruses’ [JGV (1984) 65 697–706] (see also MALIGNANT CATARRHAL FEVER).

Characteristically, the replication cycle of these viruses is appreciably longer than 24 hours (in contrast to the cycles

of other herpesviruses). In culture they typically give rise to enlarged, rounded cells (cytomegalic cells) and slowly spreading foci of cell lysis. DNA-containing inclusion bodies may be seen in the nuclei and sometimes in the cytoplasm of infected cells. Typically, the host range for a given virus is narrow and is often restricted to a single species. Latent infection can be established in cell cultures and in vivo.

HCMV (often truncated to CMV) is a large herpesvirus with a linear dsDNA genome of MWt ca.  $1.5 \times 10^8$  containing terminal and internal repeated sequences; the genome encodes a number of structural and regulatory proteins. Each virion consists of the DNA-protein core, a capsid, and an external lipoprotein envelope bearing surface projections, the region between envelope and capsid (the 'tegument') containing several virus-encoded proteins.

In the replication cycle of HCMV, the virion initially fuses with the cell membrane of the target cell, and the (unenveloped) virus migrates towards the nucleus. Viral DNA is replicated in the nucleus, and virus-encoded proteins are synthesized in the cytoplasm; the nucleocapsid is assembled in the nucleus.

HCMV genes are transcribed in strict temporal sequence. The 'immediate-early' genes (expressed within 2–4 hours of infection) encode regulatory proteins that are needed for synthesis of 'early' and 'late' genes. The 'early' gene products include a DNA polymerase. 'Late' gene products include capsid proteins.

Culture of human CMV is carried out in human fibroblasts. (See also SHELL VIAL ASSAY.) In vivo, replication appears to occur primarily in epithelial cells (e.g. in salivary glands, kidneys); HCMV is also known to infect peripheral blood leukocytes and haematopoietic progenitor cells.

Infection with HCMV is endemic in human populations world-wide, but in most cases it is asymptomatic; primary infection may be followed by viral persistence which may take the form of low-level replication or latent infection. (The site of latency is currently unknown.) However, the virus is e.g. a common cause of congenital viral infections, and sometimes causes a disease resembling INFECTIOUS MONONUCLEOSIS. HCMV-mediated disease appears to occur most commonly among the immunocompromised (e.g. immunosuppressed transplant patients and AIDS patients) and in those with an immature immune system (e.g. neonates). Typically, HCMV-mediated disease is associated with conditions such as fever, hepatitis and leucopenia. (See also CYTOMEGALIC INCLUSION DISEASE.)

[Epidemiology and transmission of HCMV: JID (1985) 152 243–248. Molecular biology and immunology of HCMV (review): Bioch. J. (1987) 241 313–324. Occupational risk of HCMV: RMM (1994) 5 33–38. HCMV in haematological disease: BCH (1995) 8 149–163.]

The laboratory diagnosis of HCMV can be achieved in <24 hours e.g. by SHELL VIAL ASSAY or by serological or nucleic acid-based techniques [diagnosis of HCMV by detection of antigen and DNA: RMM (1994) 5 265–276]. A NASBA-based procedure has been used for detecting the transcript of a *late* HCMV gene in order to monitor transplant patients at risk from HCMV-related disease [JCM (1998) 36 1341–1346].

In recent years, two more herpesviruses have been added to the Betaherpesvirinae: human (beta) herpesvirus 6 (human herpesvirus 6, HHV6) and human (beta) herpesvirus 7 (human herpesvirus 7, HHV7).

HHV6 has been identified as a causal agent of EXANTHEM SUBITUM, and is able to cause severe morbidity in immunocompromised patients; it is also a possible causal agent of e.g. lymphoma and leukaemia.

HHV6 can infect different types of cell – although replication may not occur in all of them; for example, latent or poorly replicative viruses have been detected in macrophages and peripheral blood mononuclear cells. HHV6 has a tropism for lymphoid cells; in vitro it replicates well in CD4<sup>+</sup> cells. Saliva appears to be a good source of the virus in infected persons.

Interestingly, the HHV6 genome includes two genes with homology to chemokine genes, and a gene resembling that of a chemokine receptor. (Certain other herpesviruses, including HCMV, encode soluble chemokine receptors.)

In cultures of peripheral blood mononuclear cells, HHV6 induces the cytokines IL-1 $\beta$  and TNF- $\alpha$ .

On the basis of (i) restriction patterns (see RFLP), (ii) binding of specific monoclonal antibodies, and (iii) cultural properties, HHV6 has been divided into two variant forms (A and B). Variant A appears to be observed more frequently in HIV-infected patients.

[HHV6 (review): BCH (1995) 8 201–223; Lancet (1997) 349 558–563.]

HHV7 (as well as HHV6) is widespread in the human population; unlike HHV6 it has not been firmly linked to human disease. HHV7 replicates well in CD4<sup>+</sup> cells, and may (unlike HHV6) use the CD4 antigen as a receptor. In culture, HHV7 replicates more slowly than HHV6.

[HHV7 (review): Lancet (1997) 349 558–563.]

Another recently isolated herpesvirus, HHV8, has been placed in the GAMMAHERPESVIRINAE.

**betaine** *N*-Trimethylglycine: (CH<sub>3</sub>)<sub>3</sub>N<sup>+</sup>CH<sub>2</sub>COO<sup>-</sup>. (See also OSMOREGULATION and STICKLAND REACTION.)

**Betaseron**<sup>™</sup> See INTERFERONS.

**Bethell process** A method of TIMBER PRESERVATION in which the timber is first subjected to a vacuum (to withdraw air) and then exposed to a PRESERVATIVE under pressure. (cf. BOUCHERIE PROCESS; SAUG-KAPPE PROCESS.)

**Bethesda–Ballerup group** *Syn.* BALLERUP–BETHESDA GROUP.

**Betsia** A genus of fungi of the ASCOSPHAERALES. *B. alvei* ('pollen mould') apparently occurs only in stored pollen in the combs of bee-hives.

**BF<sub>0</sub>F<sub>1</sub> ATPase** A bacterial F<sub>0</sub>F<sub>1</sub>-type PROTON ATPASE.

**BFNU** See *N*-NITROSO COMPOUNDS.

**BFP** See PATHOGENICITY ISLAND.

**BFPR** (BFP) BIOLOGICAL FALSE POSITIVE REACTION.

**BGAV** Blue-green algal virus (CYANOPHAGE).

**BGG** Bovine  $\gamma$ -globulin.

**bgl operon** (in *Escherichia coli*) See CATABOLITE REPRESSION.

**BglF** (in *Escherichia coli*) See CATABOLITE REPRESSION.

**BglG** (in *Escherichia coli*) See CATABOLITE REPRESSION.

**BglII** A RESTRICTION ENDONUCLEASE from *Bacillus globigii*; the recognition sequence is: GCCNNNN/NGGC.

**BglIII** A RESTRICTION ENDONUCLEASE from *Bacillus globigii*; A/GATCT.

**BGMV** BEAN GOLDEN MOSAIC VIRUS.

**BHIA** Brain–heart infusion agar.

**BHIB** Brain–heart infusion broth.

**BHK-21** AN ESTABLISHED CELL LINE derived from hamster kidney; the cells are heteroploid and fibroblast-like.

**BIAcore** An analytical system in which *surface plasmon resonance* (SPR) is used to study the kinetics, affinities and binding positions in antigen–antibody and other molecular interactions. Specific molecules, in solution, are allowed to bind to an immobilized ligand at a hydrophilic sensor surface; *binding affects the refractive index in the vicinity of the sensor surface*. The refractive index (and, hence, molecular interaction at the surface) can

## biased random walk

be monitored by a beam of polarized light incident on the sensor surface. [Example of use: NAR (2000) 28 1935–1940.]

**biased random walk** See RANDOM WALK.

**Bicine** A zwitterionic pH buffer: *N,N*-bis(2-hydroxyethyl)glycine. Unlike HEPES, Bicine binds divalent cations. At 25°C the pK<sub>a</sub> of Bicine is ca. 8.3.

**Biddulphia** See DIATOMS.

**bifactorial heterothallism** See HETEROTHALLISM.

**bifermentolysin** See THIOL-ACTIVATED CYTOLYSINS.

**bifid** (1) (*adj.*) Forked. (2) (*noun*) A bacterium forked at one or both ends.

**Bifidobacterium** A genus of Gram-positive, asporogenous, anaerobic bacteria which occur e.g. among the GASTROINTESTINAL TRACT FLORA and the VAGINA MICROFLORA, and which carry out a HETEROLACTIC FERMENTATION in which the main products of e.g. glucose fermentation are typically acetic and lactic acids in the ratio 3:2; the key enzyme in the pathway, fructose 6-phosphate phosphoketolase [see Appendix III(b)], is a diagnostic feature of the genus. Cells: non-motile (often pleomorphic) rods and bifids. GC%: ca. 57–66. Type species: *B. bifidum* (formerly e.g. *Lactobacillus bifidus*); other species include e.g. *B. adolescentis*, *B. asteroides* (from bees), *B. breve*, *B. infantis*, *B. suis*, *B. thermophilum*. (See also INDICATOR ORGANISM.) [Isolation and media: Book ref. 46, pp. 1951–1961.]

**bifidus pathway** See HETEROLACTIC FERMENTATION.

**bifonazole** See AZOLE ANTIFUNGAL AGENTS.

**big bone disease** See OSTEOPETROSIS.

**big liver disease** See LYMPHOID LEUKOSIS.

**big T antigen** (large T antigen) See POLYOMAVIRUS.

**biguanides** *Syn.* DIGUANIDES.

**biguttulate** (*mycol.*) Containing two GUTTULES.

**bijou** A glass, screw-cap, 5–7 ml bottle.

**bikaverin** A benzoxanthone quinone produced by *Fusarium* spp (e.g. *F. moniliforme*); it is a wine-red pigment which shows some anti-protozoal activity [Book ref. 131, pp. 223–225].

**Biken test** A precipitin test, based on the ELEK PLATE method, used for detecting the production of heat-labile enterotoxin by ETEC (q.v.) [JCM (1981) 13 1–5].

**bilabiate** (*mycol.*) Refers to those asci in which spore discharge is preceded by the development of a vertical slit in the apex of the ascus.

**bilateral trama** A type of trama in which the hyphae have a bilateral arrangement. In e.g. members of the Amanitaceae, the hyphae diverge from the central plane of the lamella, passing downwards and outwards towards the lamellar surfaces (*divergent* trama). In e.g. members of the Pluteaceae, the hyphae converge towards the central plane (*convergent* trama).

**bile acids** Steroid carboxylic acid – typically hydroxylated derivatives of 5 $\beta$ -cholan-24-oic acid: *cholic acid* has  $\alpha$ -hydroxyl groups at positions 3, 7 and 12, *deoxycholic acid* at positions 3 and 12, *chenodeoxycholic acid* at positions 3 and 7, and *lithocholic acid* at position 3. These compounds occur – usually conjugated via an amide bond with glycine (glycocholic acids) or taurine (taurocholic acids) – in bile, the relative proportions depending on species. Cholates (the salts of bile acids) are surfactants which emulsify dietary fats in the intestine. *Primary* bile acids are synthesized in the liver. *Secondary* bile acids are produced from primary acids by the action of intestinal bacteria; they are absorbed from the intestine and returned to the liver for secretion. In mammals, primary bile acids include cholic and small amounts of chenodeoxycholic acid. (Chenodeoxycholic acid is the main bile acid in fowl.) Lithocholic acid and deoxycholic acid are secondary bile acids; lithocholic acid, formed from chenodeoxycholic acid, is

hepatotoxic and may promote liver disease associated with biliary stasis.

Bile acid salts and amides inhibit many non-enteric bacteria and are useful (e.g. in MACCONKEY'S AGAR) for selecting enteric species. Bile salts promote multidrug-efflux in *Campylobacter jejuni* [JB (2005) 187 7417–7424].

**bile–aesculin agar** See AESCULIN.

**bile solubility** The 'solubility' (i.e., tendency to lyse) shown by most (freshly isolated) strains of *Streptococcus pneumoniae* when exposed (under alkaline conditions) to bile, sodium deoxycholate, sodium taurocholate, or e.g. lauryl sulphate; other similar streptococci do not lyse under these conditions. Lysis appears to result from the activation/stimulation by the bile of an AUTOLYSIN, *N*-acetylmuramyl-L-alanine amidase, which disrupts the cell wall peptidoglycan. Heat-killed pneumococci, and pneumococci in which choline has been replaced by ethanolamine in the wall teichoic acid (by culture in a defined medium), do not lyse with bile.

*Bile solubility test* (one method): 2 drops of 10% sodium deoxycholate solution are added to ca. 1 ml of a 24-hour broth culture or saline suspension of the test organism, the pH is adjusted to 7.4–7.6, and incubation is carried out (10–15 min /37°C). If the organism is soluble in bile, the turbid suspension becomes clear (positive test). [Methods: Book ref. 53, pp. 1437–1438.]

**bilin** See PHYCOBILIPROTEINS.

**biliproteins** *Syn.* PHYCOBILIPROTEINS.

**binapacryl** See DINITROPHENOLS.

**binary fission** FISSION (q.v.) in which two cells – usually of similar size and shape – are formed by the growth and division of one cell. (cf. MULTIPLE FISSION.) In binary fission cytoplasmic division is preceded by DNA REPLICATION in prokaryotes, and e.g. MITOSIS in eukaryotes. (See also CELL CYCLE.) If a cell divides across its longitudinal axis the process is termed *transverse binary fission*; if division occurs along the longitudinal axis it is termed *longitudinal binary fission*. Binary fission is a common mode of asexual reproduction in many types of microorganism.

In bacteria, binary fission is typically of the transverse type, and it usually results in the formation of two morphologically and functionally similar daughter cells; asymmetrical binary fission occurs e.g. in *Caulobacter*. Following binary fission the daughter cells may separate; alternatively, the progeny cells of sequential binary fissions may remain together to form chains, PACKETS, PALISADES etc. (See also BUDDING; GROWTH (a); SEPTUM (a); TERNARY FISSION.)

In protozoa, binary fission in ciliates is typically HOMOTHETOGENIC, and in flagellates it is typically SYMMETROGENIC. (See also STOMATOGENESIS.)

In yeasts, binary fission occurs e.g. in *Schizosaccharomyces* spp; in many yeasts (including e.g. *Saccharomyces*) cell division involves BUDDING (cf. BUD-FISSION).

**binding hyphae** See HYPHA.

**binding protein** (1) (periplasmic binding protein) In e.g. bacteria of the Enterobacteriaceae: a soluble protein, located in the periplasmic region, which binds to a specific substrate and which is involved in a BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM for that substrate; periplasmic binding proteins can also function as chemoreceptors for CHEMOTAXIS.

(2) Any protein which binds, more or less specifically, to other molecules: see e.g. DNA BINDING PROTEIN; SINGLE-STRAND BINDING PROTEIN; PENICILLIN-BINDING PROTEINS.

**binding protein-dependent transport system** (ABC importer; periplasmic transport system; periplasmic permease; osmotic

shock-sensitive permease) In Gram-negative bacteria: an ABC TRANSPORTER in which an essential stage is the binding of (imported) substrate by a soluble *periplasmic binding protein* which transfers the substrate to a membrane complex. (Some binding proteins also function in chemosensing.) Binding proteins can be released by OSMOTIC SHOCK; as membrane-bound components cannot function without their binding proteins, this type of transport system is characterized by its sensitivity to osmotic shock.

In *Escherichia coli* and *Salmonella typhimurium* (for example) various sugars, ions, amino acids, organic acids, oligopeptides etc. (almost half of all imported material) can be transported by binding protein-dependent systems. (See also VITAMIN B<sub>12</sub>.)

One example is the maltose uptake system in *E. coli* which consists of (i) membrane-associated proteins: MalF, MalG and the two (MalK) ABC proteins, and (ii) the periplasmic binding protein, MalE; uptake of maltose via the outer membrane involves a specific PORIN, the LAMB PROTEIN.

Another importer, the *E. coli* ProU system, mediates uptake of the osmoregulatory molecule glycine betaine [FEMS Reviews (1994) 14 3–20].

A further example is the high-affinity histidine uptake system (*histidine permease*) in *Salmonella typhimurium* [e.g. JBC (1997) 272 859–866] – one of a number of distinct histidine transporters in this organism. This importer consists of (i) HisM, HisQ and two copies of the ABC protein, HisP (all membrane-associated), and (ii) the periplasmic binding protein, HisJ. (Genes encoding the J, Q, M and P proteins constitute a single OPERON.) On binding to histidine, HisJ undergoes a conformational change and interacts with the membrane complex; histidine is translocated concomitantly with ATP hydrolysis. [HisP (crystal structure): Nature (1998) 396 703–707.]

In some cases, binding proteins specific for different substrates can interact with the same membrane complex. For example, in *Salmonella typhimurium* the binding protein for histidine and that for lysine, arginine and ornithine (the LAO binding protein: *argT* gene product) both interact with the same membrane-bound complex. In *E. coli*, two binding proteins for branched amino acids – LIV-I (for L-leucine, L-isoleucine and L-valine) and LS (for D- and L-leucine) – also have common membrane-bound components.

**binomial** A designation consisting of two names. For example, a SPECIES is designated by a Latin binomial which consists of the name of the genus to which it belongs (the *generic name*) followed by the name (*specific epithet*) which distinguishes that species from all others in the genus. Thus, e.g. in *Bacillus cereus* 'Bacillus' is the generic name and 'cereus' is the specific epithet.

**bioadsorbents** See LEACHING.

**bioassay** Any quantitative procedure in which a given organism is used for assay purposes. Bioassay is used most often to measure trace amounts of a given substance (e.g. a vitamin) in a sample; this is achieved by using an organism for which the given substance is an essential growth factor, and determining the total amount of growth of that organism in the sample. For example, for the bioassay of PANTOTHENIC ACID, *Tetrahymena pyriformis* is inoculated into a medium containing adequate concentrations of all growth requirements except pantothenic acid – which is present at a known, suboptimal concentration; no pantothenic acid should be carried over in the inoculum. After incubation (under standard conditions) the amount of growth is measured (e.g. in mg dry weight); the amount of growth is proportional to the amount of pantothenic acid in the medium. The procedure is repeated, using different concentrations of pantothenic acid each

time, and a standard curve is constructed by plotting the amount of growth against the concentration of pantothenic acid; the standard curve can then be used to quantify an unknown concentration of pantothenic acid. Clearly, a medium must not contain substance(s) which allow the test organism to bypass the restriction on growth imposed by the limiting concentration of the assayed substance; in the case of BIOTIN bioassay, for example, the presence of pimelic acid in the medium may circumvent the requirement for biotin and permit growth of the test organism. (See also FOLIC ACID; METHANOBREVIBACTER; NICOTINIC ACID; VITAMIN B<sub>12</sub>; cf. BIOAUTOGRAPHY.)

Bioassay is also used e.g. for measuring concentrations of antimicrobial agents, and for assaying the pathogenicity of entomopathogenic microorganisms by determining their effect on susceptible insect populations.

**bioautography** A method for detecting a trace amount of a substance (e.g. a vitamin) in a complex mixture, the given substance being an essential growth requirement for the test organism used. The components of the mixture are initially separated by CHROMATOGRAPHY. The presence of a given substance, in a given chromatographic band, is then determined by extracting the band with an appropriate solvent and adding the extract to a medium which lacks a particular growth factor; the medium is then inoculated with an organism which fails to grow in the absence of the growth factor. On incubation, growth of the test organism indicates the presence of the growth requirement in the original mixture. (cf. BIOASSAY.)

**Biobor** An organoboron preservative used e.g. in various liquid hydrocarbon fuels.

**bioburden** In an industrial sterilization process: the number of contaminating organisms per product unit before sterilization.

**biochemical oxygen demand** See BOD.

**biocide** (1) *Syn.* STERILANT. (2) Sometimes used to refer to a DISINFECTANT or PRESERVATIVE.

**bioconcentration factor** See BCF.

**biocontrol** *Syn.* BIOLOGICAL CONTROL.

**bioconversion** (1) The conversion of a substrate to particular product(s) by cells or by isolated enzymes. (2) The conversion of substrate(s) to cell biomass.

**biocytin**  $\epsilon$ -N-Biotinyl-lysine (see BIOTIN).

**biodegradation** The degradation of a substance as a result of biological (usually microbial) activity. In ecological terms, biodegradation is vital for the recycling of matter (see e.g. CARBON CYCLE). In human terms, biodegradation may be useful e.g. in the disposal of waste materials (see e.g. SEWAGE TREATMENT) and xenobiotics (see BIOREMEDIATION), and in processes such as COFFEE production and RETTING; it can also be a nuisance – see BIODETERIORATION.

**biodeterioration** The deterioration (spoilage) of an object or material as a result of biological – usually microbial – activity. See e.g. CATHODIC DEPOLARIZATION THEORY (of iron corrosion), COAL BIODEGRADATION, FOOD SPOILAGE, GLASS, LEATHER SPOILAGE, PAINT SPOILAGE, PAPER SPOILAGE, PETROLEUM (spoilage of fuels and oils), RUBBER SPOILAGE, TEXTILE SPOILAGE, TIMBER SPOILAGE, WOOL SPOILAGE. (See also PRESERVATIVES; cf. BIODEGRADATION.)

**bioemulsifiers** See BIOSURFACTANTS.

**biofilm** An adherent layer of microbial cells embedded in a polymer matrix secreted by the cells. Biofilms can develop on living tissues (e.g. oral cavity) on catheters, in water pipes [FEMS Ecol. (1997) 22 265–279], and on ships' hulls; pathogens in biofilms (e.g. on prostheses) may be resistant to antibiotics (and to the immune system), but biofilms can be useful e.g. in waste-water treatment systems [TIBtech.(2000) 18 312–320]. (See also EPLITHON.)

## biofilm fluidized-bed reactor

At least some biofilms contain fluid-filled channels which are kept open by rhamnolipid biosurfactants [JB (2003) 185 699–700; 185 1027–1036]. Biofilm development may be controlled by QUORUM SENSING [Microbiology (2001) 147 2517–2528; JB (2004) 186 1838–1850] and (in *Pseudomonas aeruginosa*) may involve three-component regulation—a sensor and two response regulators (cf. TWO-COMPONENT REGULATORY SYSTEM) [JB (2005) 187 1441–1454].

[Symposium/review: JB (2004) 186 4427–4440.]

**biofilm fluidized-bed reactor** A reactor in which the liquid to be treated is pumped upwards through a column ('bed') of small, biofilm-coated particles (e.g. sand grains of 0.5 mm diam.) at a flow rate sufficient to cause *fluidization* of the bed, i.e. a state in which the particles, though retained within the reactor, are able to move relative to one another in the liquid – rather than being sedimented and immobile.

**biofuel cell** A device in which certain redox reactions, catalysed by isolated enzymes or by living cells, are coupled to metal electrodes – thereby generating an electromotive force (emf) between the electrodes.

In a biofuel cell a given redox system may be coupled to an electrode via a mediator substance which facilitates electron flow between the redox system and electrode; for example, 4,4'-dipyridyl can facilitate electron flow between oxidized/reduced cytochrome *c* and a gold electrode [Nature (1980) 285 673–674].

In one type of biofuel cell energy is derived from the metabolism of glucose by *Proteus vulgaris* [JGM (1985) 131 1393–1401]. In another device, energy is derived from the oxidation of carbon monoxide by an isolated CO OXIDASE using e.g. ferrocene monocarboxylic acid ([carboxycyclopentadienyl]cyclopentadienyl-iron) as a mediator [MS (1986) 3 149–153].

More recently, improved results in a microbial fuel cell have been obtained by using neutral red as an electron mediator [AEM (2000) 66 1292–1297].

**biogas** See ANAEROBIC DIGESTION.

**bioinsecticide** See BIOLOGICAL CONTROL.

**bioleaching** Microbial LEACHING.

**biological aerated filter** See SEWAGE TREATMENT.

**biological assay** *Syn.* BIOASSAY.

**biological clock** See CIRCADIAN RHYTHMS.

**biological control** The exploitation, by man, of one species or strain of an organism (or a product of that organism) to control the numbers and/or activities of another organism.

Biological control is used on a commercial scale e.g. in agriculture, forestry and horticulture; it often involves introducing into the environment a microbial pathogen of insects (a microbial insecticide, *bioinsecticide* or *biopesticide*) which can infect and kill, or disable, particular insect pests of certain crop plants. Similarly, weeds may be controlled by the use of plant-pathogenic fungi (*mycoherbicides*). (See also TRICHODERMA.)

Certain strains of *Bacillus thuringiensis* can synthesize a (typically plasmid-encoded) insecticidal crystal protein (ICP); there are several types of ICP – designated Cry types I–IV (and subtypes) – and these important bioinsecticides are widely used against insect pests on a range of crops. Most of the ICPs are formed as a *parasporal crystal* (see DELTA ENDOTOXIN), i.e. they are synthesized only in sporulating cells; synthesis and sporulation are linked because transcription of the relevant ICP genes depends on sporulation-specific sigma factors such as  $\sigma^E$ . ICPs of the Cry III type differ in that they are formed during vegetative growth; overexpression of these ICPs occurs in mutant cells blocked in the phosphorelay (see ENDOSPORE). [ICP production: Mol. Microbiol. (1995) 18 1–12.]

ICPs applied to crops are readily degraded – so that repeat application is necessary. To avoid this problem, *B. thuringiensis* has been genetically modified so that toxin accumulates within the cell; this (partly-protected) toxin is still highly active [Biotechnology (1995) 13 67–71].

Biological control has also been directed against mosquitoes; strains of *B. thuringiensis*, *B. sphaericus* and *Clostridium bifementans* produce toxins which can kill mosquitoes, and considerable effort is being made to develop a product suitable for controlling mosquito-borne diseases such as MALARIA, filariasis and YELLOW FEVER [MR (1993) 57 838–861].

[Biological control by Gram-positive bacteria: FEMS (1999) 171 1–19.]

In a 'competitive' form of biological control, *Pseudomonas fluorescens* reduces frost injury in certain crops by using nutrients which would otherwise be available to ICE-NUCLEATION BACTERIA.

Other biological control agents include e.g. strains of *Agrobacterium* (see AGROCONS), *Bacillus popilliae* (see MILKY DISEASE), fungi (see e.g. ASCHERSONIA, BEAUVERIA, HETEROBASIDIUM, METARHIZIUM, NOMURAEA), protozoa (see e.g. NOSEMA) and viruses (see e.g. BACULOVIRIDAE, CYTOPLASMIC POLYHEDROSIS VIRUS GROUP, MYXOMATOSIS).

**biological false positive reaction (BFPR)** In a serological test: a positive reaction obtained as a result of the occurrence, in the patient, of disease(s) or condition(s) other than those being tested for (see e.g. STANDARD TESTS FOR SYPHILIS).

**biological filter** See SEWAGE TREATMENT.

**biological oxygen demand** See BOD.

**biological safety cabinet** *Syn.* SAFETY CABINET.

**biological transmission** Transmission of a parasite by a *biological* VECTOR.

**biological vector** See VECTOR (1).

**biological warfare** Any form of warfare which exploits the harmful potential of bioactive substance(s) and/or of particular microorganism(s) – use of the latter sometimes being termed *germ warfare*. The topic is discussed in a number of books – e.g. *Superterrorism* by Schweitzer & Dorsch (1998) published by Kluwer Academic Publishers/Plenum.

[Bioterrorism as a public health threat: EID (1998) 4 488–494. Bioterrorism: EID (1999) 5 (special issue) 491–565.]

There are plans to develop a former Russian bioweapons laboratory into an international centre for studying emerging and re-emerging diseases [see Science (2001) 291 2288–2289].

**biological washing powders** See SUBLTILISINS.

**biologicals (med.)** Certain biologically derived therapeutic agents which include e.g. *infiximab* (see TNF).

**bioluminescence** CHEMILUMINESCENCE generated by certain microorganisms and (e.g.) by fireflies and by some crustaceans and jellyfish. (cf. PHOSPHORESCENCE.)

In all cases, bioluminescence requires the presence of free oxygen – although only very low levels may be necessary. However, bioluminescence in different organisms may require different sources of energy (e.g. ATP in fireflies, NAD and FMN in bacteria); moreover, different organisms may produce light of different wavelengths (e.g. 560 nm in fireflies, ~475–505 nm in bacteria).

In some organisms the light-emitting entity has been identified as a particular compound; for example, in the firefly (*Photinus pyralis*) it is 4,5-dihydro-2-(6-hydroxy-2-benzothiazolyl)-4-thiazole carboxylic acid. The various light-emitting compounds/systems from different organisms are referred to by the generic term *luciferin*.

All bioluminescent organisms contain a species-specific thiol-containing oxidoreductase which catalyses oxidation of the light-emitting entity – giving rise to an energized form which produces light as it returns to the unexcited ground state. The generic term for this oxidoreductase is *luciferase*. In *Photobacterium fischeri*, luciferase (EC 1.14.14.3) is a protein of MWt ~80000. (The firefly luciferase (EC 1.13.12.7) is a protein of MWt ~62000.)

**Bioluminescence in bacteria.** The luminescent bacteria include marine and coastal species, e.g. *Alteromonas hanedai* and species of PHOTOBACTERIUM and XENORHABDUS. All the luminescent bacteria appear to generate light by similar reactions, involving the same types of component, and light is emitted continuously (i.e. not in pulses) under appropriate conditions. Bacterial luciferase is an AUTOINDUCIBLE ENZYME. The autoinducer in e.g. *P. fischeri* is *N*-( $\beta$ -ketocaproyl)homoserine lactone (see QUORUM SENSING); above a certain concentration, autoinducer switches on the *lux* operon that encodes luciferase.

Bacterial bioluminescence apparently involves the initial reduction of FMN by NADH, and the formation of a luciferase–FMNH<sub>2</sub> complex. In the presence of (i) free oxygen, and (ii) an aliphatic aldehyde (containing at least seven or eight carbon atoms), a larger complex appears to develop: luciferase–FMNH<sub>2</sub>–O<sub>2</sub>–RCHO; this complex emits light and yields FMN, luciferase, water and a carboxylic acid corresponding to the aldehyde. (The aldehyde may be re-cycled after reduction of the carboxylic acid by NADH.)

Bacterial bioluminescence competes with the respiratory chain for reduced NAD; luminescence is rapidly enhanced following the inhibition of respiration by cyanide.

**Bioluminescence in fungi.** The fruiting bodies and/or mycelium of some agarics (e.g. *Armillaria mellea*, *Mycena* spp) produce a continuous (non-pulsing) light which, in some species, exhibits a diurnal fluctuation in intensity; it is dependent on NAD(P)H and appears to involve two types of enzyme. The emitted light may be bluish-green or green (wavelength ca. 530 nm).

**Bioluminescence in dinoflagellates.** On appropriate stimulation (e.g. acidification, agitation), the cells of some dinoflagellates (e.g. species of *Gonyaulax*, *Noctiluca*, *Pyrocystis*, *Pyrodinium*) emit bluish light (wavelength ca. 480 nm) in flashes of ca. 0.1 second duration. *Gonyaulax* has a system of subcellular, guanine-containing, crystal-like fluorescent structures referred to as ‘scintillons’; the luciferin occurs (together with at least some luciferase) only in the scintillons, although some luciferase may also occur in other parts of the cell [JCB (1985) 100 1435–1446]. Structures similar to scintillons have been observed in non-luminescent dinoflagellates. Bioluminescence in *G. polyedra* (and probably in many other dinoflagellates) exhibits a CIRCADIAN RHYTHM. In *Noctiluca*, luminescence is associated with subcellular organelles, the *microsources*.

Bioluminescence is also exhibited by a number of radiolarians.

The function of microbial bioluminescence, if any, is unknown. It has been suggested that it is the vestige of a system once used for removing low levels of environmental oxygen.

**Applications.** Bioluminescent bacteria have been used for detecting very low concentrations of dissolved oxygen.

The ATP-dependent firefly luciferase–luciferin system is used for detecting/quantifying ATP (e.g. in PYROSEQUENCING, in which pyrophosphate is first converted to ATP). A luciferase reporter system is used e.g. for studying promoter function [AEM (2005) 71 1356–1363] and the efficacy of antisense oligomers [AAC (2005) 49 249–255]. Three different luciferases have monitored the simultaneous expression of three genes [BioTechniques (2005) 38 891–894].

**biomass** The dry weight, or other (usually quantitative) estimation of organisms (commonly microorganisms), in a given habitat (soil, water, culture medium, etc).

**biomimetic technology** Biologically-based systems which can achieve results similar to those hitherto dependent on abiotic electrical/mechanical/chemical methodology. One example involves the ability of a strain of *Pseudomonas stutzeri* to form (in its periplasm) crystalline particles of silver in a nanometre range of sizes; heat treatment (400°C) of a layer of particle-containing cells can form a carbonaceous matrix containing the small, homogeneously embedded particles of silver – a structure which may have applications as a coating for the absorption of solar energy. Silver–carbon films from *P. stutzeri* may also be useful (as a consequence of their high porosity) as electrodes in lithium-ion and other batteries.

In general, certain microorganisms are capable of producing intracellular or extracellular *cermet* (ceramic–metal) or *orgmet* (organic–metal) structures, or composites, which are organized on a nanometre scale and which potentially have a range of applications in materials science.

[Metal-accumulating bacteria and their potential for materials science: TIBtech. (2001) 19 15–20.]

**biomineralization** The deposition of minerals due to biological activity – e.g. the formation of magnetosomes (see MAGNETOTACTIC BACTERIA) and the intracellular or extracellular deposition of sulphur by photosynthetic bacteria. (cf. MINERALIZATION.)

**biomining** See LEACHING.

**Biomyxa** See GRANULORETICULOSEA.

**biont** *Syn.* SYMBIONT.

**biopesticide** See BIOLOGICAL CONTROL.

**biophore** A ‘host’ cell in genetic engineering.

**bioplastics** See BIOPOL.

**Biopol** The trade name (Zeneca, Great Britain) for a range of biodegradable thermoplastics based on POLY- $\beta$ -HYDROXYBUTYRATE (PHB). The homopolymer (PHB) is formed under suitable conditions when *Alcaligenes eutrophus* uses glucose as the sole source of carbon. When the growth medium is appropriately supplemented, *A. eutrophus* forms co-polymers of hydroxybutyrate and hydroxyvalerate; the proportion of hydroxyvalerate (controlled by adjusting the growth medium) determines the properties of these co-polymers. The intracellular granules of polymer (either PHB or co-polymer) are harvested and purified to a fine, white powder.

Biopol can be used for making containers, mouldings, fibres, films and coatings, and can be worked by blow-moulding and injection-moulding processes. While stable in normal use, Biopol is fully degradable after suitable disposal.

To reduce costs, attempts are now being made to develop transgenic plants for the commercial production of bioplastics.

[Review on bioplastics: BAB (1996) 49 1–14.]

**biopsy** (1) The removal of tissue from the living body for examination, culture etc. (2) The tissue specimen referred to in (1).

**biopterin** 2-Amino-4-hydroxy-6-(1',2'-dihydroxypropyl)-pteridine. Biopterin is believed to act as a coenzyme in certain hydroxylation reactions, and is required as a growth factor e.g. by *Crithidia fasciculata* and *Trypanosoma platydictyli* (formerly *Leishmania tarentolae*); the requirement for biopterin may be partially or totally overcome by high concentrations of FOLIC ACID.

**bioreactor (reactor)** A FERMENTER or other apparatus used for BIOCONVERSIONS.

## bioremediation

**bioremediation** Biotechnological (microbe-based) clean-up of pollutants (chemical contaminants) in the environment (aqueous and terrestrial).

As a group, microorganisms are metabolically highly diverse, so that, in theory, it should be possible to degrade any of a wide range of pollutants given a suitable choice of microorganisms(s). Moreover, *microbial* degradation of pollutants may give rise to simple products – such as carbon dioxide and water – whereas alternative approaches (e.g. physical decontamination) may simply transfer the problem from one location to another. Nevertheless, while physical methods are typically rapid, often with a predictable outcome, biological methods frequently have unknown, unpredictable or unquantifiable effects in the environment; for example, the *bioavailability* of a pollutant (its accessibility to microorganisms) may be reduced by adsorption to soil particles, and this may limit or preclude efficient bioremediation.

To be more widely accepted and used, bioremediation must be shown to be both effective and reliable in the environment. The efficacy of a bioremediation process may be gauged e.g. by (i) assaying pollutants of all levels of biodegradability at the polluted site; (ii) assaying the long-lived breakdown products of pollutants; (iii) assessing the levels/states of *normal* constituents of the environment; and (iv) quantifying specific microbial genes involved in the catabolism of pollutants [see e.g. AEM (1996) 62 2381–2386].

[Bioremediation: towards a credible technology (review): Microbiology (1998) 144 599–608.]

Certain types of pollutant are susceptible to anaerobic degradation, and it has been suggested that, in the future, anaerobic microbial processes may have the potential for widespread application in bioremediation technology.

Anaerobic degradation of the perchlorate ion can be carried out by various facultatively anaerobic or microaerophilic bacteria which are capable of dissimilatory perchlorate reduction (a form of ANAEROBIC RESPIRATION); these bacteria include *Wolinella succinogenes* and (particularly) species belonging to two new genera: *Dechloromonas* and *Dechlorosoma* (both members of the beta subclass of Proteobacteria). In dissimilatory perchlorate reduction, the initial (energy-yielding) stage produces chlorite; the chlorite is split (enzyme: *chlorite dismutase*) to chloride and molecular oxygen. [Ubiquity and diversity of (per)chlorate-reducing bacteria: AEM (1999) 65 5234–5241.] Currently (2000), biological methods for perchlorate degradation are based mainly on the use of bioreactors, and there is at present no technique for treating perchlorate contamination in the environment.

Anaerobic degradation of certain hydrocarbons (including BTEX) would be very useful when these pollutants occur e.g. in fuel-contaminated aquifers under anoxic conditions – but BENZENE (for example) typically resists anaerobic degradation. A novel approach to the anaerobic degradation of benzene involves the addition of low levels of chlorite – so that the (ubiquitous) perchlorate-reducers (see above) can convert the chlorite to chloride and (free) oxygen; the oxygen is then available for certain aerobic organisms (e.g. *Pseudomonas*) which are able to degrade cyclic aromatic hydrocarbons [see Nature (1998) 396 730].

[Emerging techniques for anaerobic bioremediation: TIBtech. (2000) 18 408–412.]

Degradation of biphenyls and polychlorinated biphenyls (PCBs) – an important category of environmental pollutants – can be carried out by various types of Gram-negative and

Gram-positive bacteria. Genes encoding the relevant degradative activity for biphenyls/polychlorinated biphenyls form the *bph* operon. [Transcription of the *bph* operon in *Pseudomonas pseudoalcaligenes* strain KF707: JBC (2000) 275 31016–31023.]

The pesticide pentachlorophenol (PCP) can be degraded by strains of the bacterium *Sphingomonas chlorophenolica* – the metabolic potential for such degradation probably having developed during the last few decades [TIBS (2000) 25 261–265].

(See also POLYURETHANASE and TOL PLASMID.)

Wastewater containing terephthalic acid (used e.g. in the manufacture of plastics) can be treated anaerobically (see SEWAGE TREATMENT).

[Heavy metals: FEMS Reviews (2002) 26 327–338.]

The development of genetically engineered bacteria for degrading specific compounds (particularly XENOBIOTICS) is likely to be assisted by information on the way in which signals from various environmental substrates are integrated at gene promoters [EMBO (2001) 20 1–11].

**Bios test** A test used for assessing the integrity of the seams in a can (see CANNING). Essentially, cans are filled with a nutrient medium and are sealed and processed in the normal way – cooling being carried out with water containing a gas-producing organism; the cans are then incubated and examined for the presence of SWELLS. An analogous test is used for testing the integrity of RETORT POUCHES.

**biostratigraphy** The study of the age and structure of stratified rocks in terms of the fossils – e.g. FOSSIL MICROORGANISMS – they contain. [Book ref. 136.]

**biosurfactants** Biological molecules which function as surfactants, i.e., they lower the surface tension of water; however, as commonly used, the term includes *bioemulsifiers*: substances which act as emulsifying agents but which do not necessarily have a significant effect on surface tension. Most biosurfactants/bioemulsifiers are amphipathic cell components such as fatty acids, phospholipids, lipopolysaccharides, lipoteichoic acids, etc. Certain microorganisms produce extracellular biosurfactants or bioemulsifiers which may play a role e.g. in the adhesion of cells to – and/or their detachment from – surfaces (see e.g. EMULCYAN), or in the utilization of hydrophobic substrates such as sulphur and hydrocarbons. For example, organisms growing on HYDROCARBONS may produce extracellular fatty acids, glycolipids (e.g. RHAMNOLIPIDS, SOPHROLIPIDS), high-MWt polymers (e.g. EMULSAN), etc (see also LIPOSAN); such substances may serve e.g. to emulsify the substrate and/or to allow cells to adhere to substrate–water interfaces. (See also SAPONINS and SURFACTIN.) [Potential use of biosurfactants in industry: MS (1986) 3 145–149.]

**biotechnology** In a broad sense: collectively, the various forms of technology that exploit biological sources – usually microorganisms and/or their products and components (for examples see INDUSTRIAL MICROBIOLOGY). (See also BIOMIMETIC TECHNOLOGY and IMMOBILIZATION.) However, the term ‘biotechnology’ refers more commonly to those forms of technology which depend on the use of modern techniques in molecular biology/genetic engineering to construct novel organisms and/or products for industrial, medical or other purposes.

**bioterrorism** See BIOLOGICAL WARFARE.

**biotic** Living; of biological origin.

**biotin** (vitamin H; coenzyme R) A VITAMIN which acts as a cofactor in carboxylation and transcarboxylation reactions, acting as a carrier of CO<sub>2</sub>; biotin is bound via its carboxyl group (see figure) to the ε-amino group of a lysine residue in the apoenzyme. (cf. BIOCYTIN.)

BIOTIN: (a) free, and (b) bound.

Biotin is required as a growth factor e.g. by many fungi (e.g. *Saccharomyces cerevisiae*, *Candida* spp) and bacteria (e.g. species of *Clostridium*, *Lactobacillus*, *Leuconostoc*). Some organisms can synthesize biotin from cysteine, pimelic acid and carbamoyl phosphate. (See also AVIDIN and ABC IMMUNOPEROXIDASE METHOD.)

**biotin enzyme** Any enzyme whose active centre is associated with a BIOTIN residue – e.g. PYRUVATE CARBOXYLASE and oxaloacetate decarboxylase.

**biotope** (1) The environment occupied by an organism or organisms. (2) (*med., vet.*) The location of a particular parasite or pathogen within the body. (3) The spatial distribution of the biomass in a cross-section of a river, lake, etc.

**biotransformation** *Syn.* BIOCONVERSION (1).

**biotroph** An organism which derives nutrients from the living tissues of another ('host') organism. (*cf.* NECROTROPH.)

**biotype** (*biovar*) Any VARIETY distinguished by metabolic and/or physiological properties.

**biovar** *Syn.* BIOTYPE.

**biparental** See PROTOPLAST FUSION.

**biphenyls** (*degradation*) See BIOREMEDIATION.

**biplicity** See FLAGELLUM (a).

**bipolar heterothallism** See HETEROTHALLISM.

**Birbeck granule** See LANGERHANS' CELLS.

**bird flu** An outbreak of disease (Hong Kong, 1997) caused by an avian strain (H5N1) of influenza virus type A (see INFLUENZA-VIRUS).

**bird's nest fungi** See NIDULARIALES.

**birefringence** (*double refraction*) The phenomenon in which a beam of light, on entering certain (optically *anisotropic*) materials (e.g. a calcite crystal), gives rise to two beams of polarized light which travel at different velocities in mutually perpendicular planes and which often (depending on conditions) follow divergent paths.

**Birnaviridae** See IPN VIRUS.

**birth scar** (*mycol.*) See SCAR.

**bisdithiocarbamates** (as antimicrobial agents) Metal ethylene-bisdithiocarbamates (MS.CS.NH.CH<sub>2</sub>CH<sub>2</sub>NH.CS.SM, in which M is a metal ion) are used as agricultural ANTIFUNGAL AGENTS – see e.g. MANCOZEB, MANEB, NABAM and ZINEB; they are believed to be converted, under field conditions, to diisothiocyanate derivatives.

**Bismarck brown** A brown basic diazo DYE used e.g. for VITAL STAINING.

**bismuth sulphite agar** See WILSON AND BLAIR'S AGAR.

**bisphenols** Compounds that contain two phenolic residues/molecule; in bisphenols which are effective ANTISEPTICS or DISINFECTANTS the residues are linked directly (i.e. carbon-carbon) or e.g. via –CH<sub>2</sub>– (*dihydroxydiphenylmethanes*)

or –S– (*dihydroxydiphenylsulphides*). For maximum antimicrobial activity, each phenolic residue must carry an *o*-(2-)hydroxyl. Halogenation increases activity; two di- or trihalogenated phenolic groups generally confer greater activity against Gram-positive than Gram-negative species. Bacteriostatic at low concentrations, bisphenols may be bactericidal at higher concentrations; they appear to affect the cell membrane – e.g. hexachlorophane affects membrane potentials and, at higher concentrations, may (like various antibacterial agents) cause coagulation of the cytoplasm.

Bisphenols are poorly soluble or virtually insoluble in water but are soluble in dilute alkali and/or organic solvents; they are inactivated by non-ionic surfactants. Since bisphenols retain antimicrobial activity in the presence of soaps and are relatively non-toxic to man, they are widely used as antiseptics and preservatives. *Bithionol* (2,2'-dihydroxy-3,5,3',5'-tetrachlorodiphenylsulphide) is an antibacterial and antifungal agent used e.g. in antiseptic soaps. *Bromochlorophane* (3,3'-dibromo-5,5'-dichloro-2,2'-dihydroxydiphenylmethane) is active against Gram-positive bacteria and has been used e.g. in deodorants and toothpastes. *Dichlorophane* (dichlorophene) (5,5'-dichloro-2,2'-dihydroxydiphenylmethane) is active against fungi, bacteria and algae; it is used e.g. as a preservative for paper and textiles. *Fentichlor* (2,2'-dihydroxy-5,5'-dichlorodiphenylsulphide) is active primarily against Gram-positive bacteria (e.g. staphylococci) and fungi (particularly dermatophytes); it has been used to treat infections involving dermatophytes. *Hexachlorophane* (hexachlorophene) (2,2'-dihydroxy-3,5,6,3',5',6'-hexachlorodiphenylmethane) is much more active against Gram-positive than Gram-negative bacteria; it has been used in antiseptic soaps, liquid soaps (e.g. *Ster-zac*) and lotions (e.g. *pHisoHex*). (*cf.* TRICLOSAN; see also PHENOLS.)

**bisterigmat** Having two sterigmata.

**bis(tri-*n*-butyltin) oxide** See TBTO.

**bisulphite** (as a MUTAGEN) Bisulphite (HSO<sub>3</sub><sup>-</sup>) undergoes various reactions with nucleic acids, and can also cause cross-linking between proteins and nucleic acids. The reaction believed to be responsible for mutagenesis is the deamination of cytosine and (at a slower rate) of 5-methylcytosine to give, respectively, uracil and thymine (resulting in G-C-to-A-T transition in either case); bisulphite can apparently act on these bases only in ssDNA. (See also SITE-SPECIFIC MUTAGENESIS.)

**bithionol** See BISPHENOLS.

**Bittner virus** *Syn.* MOUSE MAMMARY TUMOUR VIRUS.

**bitty cream** See MILK SPOILAGE.

**bitunicate ascus** (*fissitunicate ascus*) An ASCUS whose wall consists of a thin, more or less rigid outer envelope (*ectotunica*), and a thicker, extensible inner envelope (*endotunica*); at maturity, the outer envelope ruptures and the inner envelope elongates – the ascospores being discharged via an apical pore in the inner envelope. (*cf.* UNITUNICATE ASCUS.) *Lecanoralean* asci release their ascospores in a similar way; they differ from other bitunicate asci e.g. in that the endotunica protrudes only to a limited extent during ascospore discharge.

**biuret test** A test based on the fact that peptide bond-containing substances (e.g. peptides and proteins) give a violet/pink colour when treated with a dilute, alkaline solution of copper sulphate.

**bivalent** (*noun*) See MEIOSIS.

**Bivalvulida** See MYXOSPOREA.

**BK virus** See POLYOMAVIRUS.

**BL-type starter** See LACTIC ACID STARTERS.

**bla gene** A gene encoding β-LACTAMASE. (See also e.g. Tn3.)

**black beans** *Syn.* HAMANATTO.

## Black beetle virus

**Black beetle virus** See NODAVIRIDAE.

**black bread mould** See BREAD SPOILAGE.

**black cat/white cat principle** The principle that different mechanisms for regulating a given catabolic system are equally efficient if they both (or all) ensure responsiveness to the substrate in the context of the organism's physiological state [EMBO (2001) 20 1–11].

**Black Creek Canal virus** See HANTAVIRUS.

**Black Death** See PLAGUE.

**black disease** (infectious necrotic hepatitis) An acute, toxæmic disease, which affects mainly sheep and cattle (sometimes pigs), caused by infection of the liver by *Clostridium novyi*; the disease is commonly precipitated by invasion of the liver by the liver fluke (*Fasciola hepatica*). Death usually occurs rapidly.

**black fluids** Commercial DISINFECTANTS consisting of certain phenolic coal tar fractions solubilized with soaps; their activity is decreased by electrolytes. (cf. WHITE FLUIDS.)

**black gill disease** A disease of prawns and shrimps (*Penaeus* spp) caused by *Fusarium solani* (cf. BURNED SPOT DISEASE); the gills bear many black spots and may undergo necrosis or collapse.

**black light** Radiation of ca. 300–420 nm.

**black mat syndrome** A disease of the tanner or snow crab (*Chionoecetes bairdi*) caused by the ascomycete *Trichomarix invadens* [CJB (1981) 59 2121–2128]. The fungus forms a dense black nodular encrusting subiculum (bearing partly embedded perithecia) on the crab exoskeleton; non-pigmented hyphae penetrate the tissues beneath [AEM (1983) 46 499–500]. (See also CRUSTACEAN DISEASES.)

**black mildews** (dark mildews) Plant-parasitic fungi of the family Meliolaceae (order DOTYDIALES); the organisms form dark mycelium which, in many species, is setose (see also HYPHOPODIUM). Genera: e.g. *Meliola*. (cf. POWDERY MILDEWS and SOOTY MOULDS.)

**black piedra** A human MYCOSIS in which hairs (e.g. of the scalp) are infected by *Piedraia hortae*. Hard black nodules adhere firmly to infected hairs (mainly on the distal portions). The nodules are composed of masses of dark hyphae which form a stroma containing many uniaxial locules; asci are spherical and contain 8 fusiform ascospores. (cf. WHITE PIEDRA.)

**black pod disease** A CACAO DISEASE caused by species of PHYTOPHTHORA (e.g. *P. palmivora*, *P. megakarya*) and characterized by blackening of the (normally green) pods. Pulp prepared from the beans of infected pods contains subnormal amounts of sugar so that the fermentation process (see COCOA) may be affected; such beans also contain excessive amounts of free fatty acid. The disease is usually controlled by antifungal sprays. [Black pod disease in Nigeria: Phytopathol. Paper number 25 (April, 1981).]

**black pox** (black spot) (*vet.*) Ulcerative lesions, each with a black centre, which occur on the teats, particularly at the orifice, in e.g. cattle. *Staphylococcus aureus* may be isolable from the lesions. *Treatment*: antimicrobial ointments or teat dips. (See also MASTITIS.)

**black queen cell virus** See PICORNAVIRIDAE.

**black rot** (*plant pathol.*) A general term for any of various unrelated plant diseases. For example, *brassica black rot*, caused by *Xanthomonas campestris* pv. *campestris*, is characterized by blackening of leaf-margins and often of leaf-veins, yellowing of leaves, stunting etc. (*Carrot black rot*: see ALTERNARIA.)

**black scours** *Syn.* WINTER DYSENTERY.

**black smoker** See HYDROTHERMAL VENT.

**black spot** (1) (*food microbiol.*) A type of MEAT SPOILAGE which affects red meats at sub-zero temperatures; black spots of fungal

growth develop on the meat surface. Species involved include *Cladosporium cladosporioides*, *C. herbarum* and *Penicillium verrucosum* var. *corymbiferum* (*Penicillium hirsutum*). [JAB (1982) 52 245–250.]

(2) (*vet.*) *Syn.* BLACK POX.

(3) (*plant pathol.*) Any of various plant diseases characterized by the formation of black spots e.g. on the leaves and/or fruit. Black spot of roses is caused by *Diplocarpon rosae*; irregular dark-brown or black patches appear on both surfaces of the leaves, and leaves turn yellow and fall prematurely. Bacterial black spot of mangoes, a serious necrotic disease present in most mango-growing regions, is caused by *Xanthomonas campestris* pv. *mangiferaeindicae* [IJSB (1984) 34 77–79].

**black stem rust** A CEREAL DISEASE, caused by *Puccinia graminis*, which can affect wheat (causing serious economic losses e.g. in the USA) and other cereals; see UREDINIOMYCETES for details of the disease in wheat.

**black wart disease** (of potato) See WART DISEASE.

**black yeasts** Fungi which can form dark, yeast-like cells (e.g. species of *Aureobasidium* and *Cladosporium*).

**blackeye cowpea mosaic virus** See POTYVIRUSES.

**blackfellow's bread** The SCLEROTIUM of *Polyporus mylittae* which is used as food by Australian aboriginals.

**blackhead** (1) (*vet.*) (histomoniasis; infectious enterohepatitis) A disease which affects mainly turkeys but also e.g. chickens and pheasants; it is caused by *Histomonas meleagridis*. Transmission occurs mainly via the caecal nematode *Heterakis gallinae*, in which *H. meleagridis* is transmitted transovarially; the bird is infected on ingestion of nematode eggs passed with the faeces of an infected bird. Symptoms in turkeys: anorexia, lethargy, passage of characteristic yellow faeces; cyanosis or blackening of the head may occur. Initially, small haemorrhagic ulcers occur in the caecum; later the caecal tubes are greatly enlarged. Characteristic circular, yellowish, necrotic lesions occur in the liver, sometimes coalescing to form large areas of necrosis. In the acute form the disease is often rapidly fatal, but it may be chronic in older birds. In chickens, the disease is usually mild (although severe outbreaks may occur under intensive rearing conditions). Chickens are commonly parasitized by *H. gallinae* and can act as a reservoir of *H. meleagridis*; they should therefore not be reared alongside turkeys. *Lab. diagnosis*: *H. meleagridis* may be observed in scrapings from caecal lesions. Furazolidone and dimetridazole are used for prevention/treatment. (See also POULTRY DISEASES.)

(2) (*med.*) See ACNE.

**blackleg** (1) (blackquarter) (*vet.*) In cattle (and occasionally in other animals): an acute (usually) fatal disease, characterized by severe toxæmia and inflammation of leg (and/or other) muscles, caused by *Clostridium chauvoei*; the pathogen is presumed to reach the affected site via the intestine and bloodstream, but trauma to muscles may be a predisposing factor. *Treatment*: parenteral administration of antibiotics. (cf. MALIGNANT OEDEMA.)

(2) (*plant pathol.*) Any of various bacterial or fungal diseases of plants in which the plant stem characteristically becomes blackened and often rots.

In potatoes blackleg is caused by *Erwinia carotovora* subsp. *atroseptica*; symptoms: yellowing of foliage, rotting of stems (which become black and slimy), slimy lesions in the tubers.

In cruciferous plants 'blackleg' may refer to any of several diseases. That caused by *Xanthomonas campestris* involves leaf chlorosis and blackening of the veins; infection is seed-borne or occurs via stomata or wounds. *Leptosphaeria maculans* can be an important cause of blackleg in oil-seed rape and other brassicas.

In beet plants, blackleg may be caused by *Pleospora* (*Phoma*) *hjoerlingii*; in seedlings, the stem blackens and shrivels, while in mature plants brown leaf spots and blackening of root tissues occur. Infection is seed-borne.

*Pelargonium* blackleg is caused by a *Pythium* sp; stems blacken from the base upwards, foliage wilts, etc.

**blackpatch disease** (of clover) See SLAFRAMINE.

**blackquarter** *Syn.* BLACKLEG (1).

**blackwater fever** A complication of falciparum MALARIA characterized by profound haemoglobinuria.

**bladder** (*algol.*) *Syn.* PNEUMATOCYST.

**bladder infection** See CYSTITIS and UPEC.

**bladder wrack** See FUCUS.

**blade** (*algol.*) The flat or crinkled, essentially sheet-like part of the thallus in certain algae (e.g. *Fucus*, *Laminaria*).

**Blakeslea** See MUCORALES.

**blanket weed** See CLADOPHORA.

**BLAST** Basic local alignment search tool, a program for comparing sequences: <http://www.ncbi.nlm.nih.gov/BLAST/>

**blast disease** (of rice) A disease of the rice plant caused by *Pyricularia oryzae* (see PYRICULARIA). Leaf lesions are often e.g. bluish or grey, each having a dark brown margin; bluish lesions may occur in the neck of the culm (i.e., just below the flowering head) – often leading to breakage – and small brown lesions may form on the glumes. The disease is favoured e.g. by high levels of soil nitrogen. (See also HINOZAN, KASUGAMYCIN, KITAZIN and THIOPHANATE-METHYL.)

**blast transformation** Morphological and metabolic changes which occur in B LYMPHOCYTES and T LYMPHOCYTES on exposure to specific antigen or to a MITOGEN; in at least some cases, blast transformation appears to be triggered by the cross-linking of receptors on the surface of the lymphocyte.

In B cells, within ~12–24 hours of stimulation, the cell begins to enlarge and develops a basophilic, ribosome-rich cytoplasm, an enlarged nucleolus, and a large, pale-staining nucleus which contains an increased amount of interchromatinic protein; the transformed cell is known as a *blast cell* (= *blast*), and its formation appears to represent a shift from the G<sub>0</sub> to the G<sub>1</sub> phase of the cell cycle. For ANTIBODY FORMATION, a blast proliferates and forms PLASMA CELLS.

**blastic conidiogenesis** See CONIDIUM.

**Blastobacter** A genus of rod-shaped to spherical, Gram-negative budding bacteria which occur e.g. in ponds and lakes; some strains are flagellated, and some are pigmented.

**Blastocaulis** A subjective SYNONYM of PLANCTOMYCES.

**Blastocladales** An order of fungi (class CHYTRIDIOMYCETES) in which the thallus consists typically of rhizoid-bearing hyphae or mycelium, and in which sexual reproduction involves the fusion of iso- or anisoplanogametes; most species live saprotrophically in water or soil, but *Coelomomyces* spp (which form wall-less, coenocytic hyphae lacking rhizoids) are obligate parasites of certain insects (e.g. mosquito larvae). [*Coelomomyces*: Book ref. 190.] Other genera include ALLOMYCES, *Blastocладиella*, and *Catenaria* (see also NEMATOPHAGOUS FUNGI).

**Blastocладиella** See BLASTOCLADIALES and GAMMA PARTICLE (2).

**blastoconidium** See CONIDIUM.

**Blastocrihidia** A genus of homoxenous parasitic protozoa (family TRYPANOSOMATIDAE) which occur in the gut of bugs and mosquitoes; epimastigotes, approx. 10–70 µm. *B. triatomae* forms desiccation-resistant cysts.

**Blastocystis** A genus of organisms currently regarded as protozoa (formerly as fungi of the Entomophthorales). *B. hominis* occurs in the intestinal tract in man and other animals; it is generally non-pathogenic, but may be associated with diarrhoea when

present in large numbers [Ped. Inf. Dis. (1985) 4 556–557]. Three morphological forms (amoebic, granular and vacuolated) have been described, but the vacuolated form is the most common in human faecal specimens; these cells are non-motile and spherical, oval or ellipsoid, (5–)8–10(–30) µm diam., and may be mistaken for cysts of certain amoebae. Staining of the vacuolated forms with e.g. iodine reveals a thin peripheral layer of cytoplasm containing one nucleus (sometimes 2–4 nuclei) and surrounding a large central or slightly eccentric body or vacuole.

**Blastodinium** See DINOFLAGELLATES.

**Blastomyces** A genus of fungi of the HYPHOMYCETES. *B. dermatitidis* (= *B. zymonema*, teleomorph *Ajellomyces dermatitidis*) is a dimorphic fungus which causes BLASTOMYCOSIS; in mammalian cells and in culture at 37°C it grows in the form of yeast-like, spherical, thick-walled cells (usually ca. 8–15 µm diam.). The cells reproduce by budding, a (usually) single bud being attached to the mother cell by a broad base. When cultured at <30°C the organism grows as a septate mycelium, producing smooth, spherical to ovoid conidia (3–5 µm diam.) on short, straight conidiophores.

**Blastomycetes** A class of fungi (subdivision DEUTEROMYCOTINA) which include the anamorphic yeasts; the class is sometimes divided into two families: CRYPTOCOCCACEAE (species do not form ballistospores) and SPOROBOLOMYCETACEAE (species form ballistospores). In some taxonomic schemes [Book ref. 64, p. 54] the organisms are included in the HYPHOMYCETES.

**blastomycosis** (North American blastomycosis; Gilchrist's disease) An acute or chronic MYCOSIS, affecting man and animals (e.g. dogs), caused by *Blastomyces dermatitidis*; it occurs e.g. in North America, Africa and Israel. Infection apparently occurs by inhalation of spores from the (presumably saprotrophic) fungus, although *B. dermatitidis* has proved difficult to isolate from environmental habitats. The disease occurs in two clinically distinct but variable forms: the cutaneous form (a chronic disease in which granulomatous, suppurative lesions are confined mainly to the skin, although the pathogen is disseminated from a primary pulmonary site), and the pulmonary form (in which lesions develop primarily in the lungs). Pulmonary blastomycosis may be subclinical, may (occasionally) manifest as an acute, self-limiting, influenza- or pneumonia-like disease, or may be chronic and progressive with dissemination to other regions of the body (e.g. bones, genitourinary tract, CNS). Mortality rates associated with untreated systemic blastomycosis may be >80%. *Chemotherapy*: e.g. amphotericin B; 2-hydroxystilbamidine. [Review of human blastomycosis: CRM (1982) 9 139–164.] (cf. PARACOCCIDIOIDOMYCOSIS.)

**blastospore** See CONIDIUM.

**Blattabacterium** A genus of Gram negative-type bacteria which occur as intracellular endosymbionts of the cockroach (*Blatta* spp). Cells: non-motile rods, ca. 1.0 × 1.6–9.0 µm, which may give a Gram-positive or Gram-variable reaction; they occur within the bacteriocytes of the cockroach – and within the oocytes, thus ensuring their transmission to the larvae. GC%: ca. 26–28. Type species: *B. cuenoti*. [Book ref. 22, pp. 830–831.]

**bleach** See HYPOCHLORITES.

**bleaching** Loss of the chromophore from a biological pigment, or loss of pigment(s) from an organism – e.g. loss of chlorophyll from a photosynthetic organism.

**bleeding canker** A CANKER which affects e.g. horse chestnut, lime and apple trees; it is caused by *Phytophthora citricola*. A brownish or reddish gum oozes from the regions of dying bark and dries to form a hard black crust; dieback may occur, and the lesions may be infected with other wood-decaying fungi.

## blending

**blending** Vigorous agitation involving high shear forces.

**bleomycin** An anticancer antibiotic produced by *Streptomyces verticillus*; it is structurally complex, consisting of peptide and disaccharide moieties. Bleomycin binds to DNA and – in the presence of Fe<sup>2+</sup> and O<sub>2</sub> – causes release of free bases and the degradation of the DNA by single- and double-stranded cleavages.

**Blepharisma** A genus of ciliates (order HETEROTRICHIDA). Cells: ovoid to elongate, non-contractile, with uniform somatic ciliature and an oral region extending about half the length of the cell; usually pink to red.

**blepharismín** See GAMONE.

**blepharismone** See GAMONE.

**blepharhormone** See GAMONE.

**Blepharocorythina** See TRICHOSTOMATIDA.

**blepharoplast** (*protozool.*) *Syn.* BASAL BODY (b).

**blewit** The edible fruiting body of *Lepista saeva* (*syn.* *Tricholoma saevum*, *T. personatum*) (= field blewit), or of *Lepista nuda* (*syn.* *Tricholoma nudum*) (= wood blewit).

**blight** (1) (*plant pathol.*) A general term applied to any of a wide range of unrelated plant diseases: see e.g. CANE BLIGHT, CHESTNUT BLIGHT, FIREBLIGHT, FUSARIUM, HALO BLIGHT, LATE BLIGHT.

(2) (*vet.*) *Syn.* INFECTIOUS KERATITIS.

**blister blight** A TEA DISEASE which occurs throughout the Asian tea-growing regions; it is caused by *Exobasidium vexans*. Translucent (sometimes pinkish), circular, concave lesions commonly occur on the upper surfaces of leaves; the convex underside of each lesion (on the lower side of the leaf) becomes white and downy with spores. Only young leaves are susceptible to infection. Control: e.g. copper sprays.

**blister rust** (white pine blister rust) An economically important disease of the western white pine (*Pinus monticola*), and of the Weymouth pine (*P. strobus*), caused by *Cronartium ribicola* (an apparently heterothallic rust [CJB (1985) 63 1086–1088]). The disease develops over a period of years; symptoms include the formation of large orange blisters, and of cankers which may spread until the tree dies. (See also PINE DISEASES.)

**bloat** (ruminal tympany) In ruminants: a (sometimes fatal) condition in which the gaseous products of fermentation become trapped (either as free gas or as a stable foam) in the RUMEN – which thus becomes distended; the cause of bloat is not always clear, but the *pasture* (or *legume*) *bloat* which may occur in cattle grazing legume-rich pasture may be due to the foam-promoting properties of soluble leaf proteins or of lipids present in the feedstuff. *Feedlot* (or *grain*) *bloat* appears to be due to certain factor(s) of microbial origin – e.g. extracellular polysaccharides or slimes. One factor which may be important in both pasture and feedlot bloats is the ability of some bacteria (e.g. *Butyrivibrio fibrisolvens*, *Megasphaera elsdenii*, *Streptococcus bovis*) to digest the salivary mucins which act as antifoaming agents.

**bloater damage** (in cucumbers) See PICKING.

**Blochman bodies** Intracellular, prokaryotic symbionts which occur in mycetomes in insects.

**blocked reading frame** See OPEN READING FRAME.

**blocking antibodies** (1) (non-agglutinating antibodies) Antibodies which fail to agglutinate homologous antigens even though antigen–antibody combination may occur; lack of agglutination may be due e.g. to an insufficiency of effective combining sites on the antibody molecules. By combining with antigen, blocking antibodies prevent ('block') agglutination by homologous agglutinating antibodies. Blocking antibodies can be detected e.g. by an ANTIGLOBULIN CONSUMPTION TEST. (2) IgG antibodies which

combine with allergens and which prevent those allergens from initiating an immediate hypersensitivity reaction.

**blood agar** An agar-based medium containing defibrinated (or whole citrated or oxalated) blood. It is prepared by mixing 5–10% blood (drawn aseptically) with a pre-autoclaved molten agar base (e.g. TRYPTICASE–SOY AGAR) at ca. 50°C; the medium is dispensed e.g. to Petri dishes and allowed to set. (cf. CHOCOLATE AGAR.) Blood agar is used e.g. for the culture of fastidious bacterial parasites of man and animals, and for the detection of HAEMOLYSINS; since a given bacterial haemolysin may be active against the RBCs of only some animals (e.g. horse, sheep), the choice of blood is important.

**blood clotting** See FIBRIN; COAGULASE; ANTICOAGULANT.

**blood culture** A procedure for detecting the presence of viable bacteria in blood. Since blood-borne bacteria may be present only in very small numbers, isolation is attempted only after a blood sample has been incubated in a suitable medium to allow the bacteria to multiply. Blood (5–10 ml), taken aseptically, is immediately added (aseptically) to 50–100 ml of medium (e.g. trypticase soy broth) which usually contains an anticoagulant (e.g. SPS) and sometimes e.g. penicillinase (to inactivate any penicillin in the blood) and/or PABA (to counteract any sulphonamide drugs). (The medium is commonly contained in a plain bottle whose opening is sealed by a rubber disc held in place by a screw-cap with a central hole; blood is injected into the bottle through the rubber disc.) The medium is then incubated. Periodically (e.g. daily for 7 days) the medium is subcultured to a suitable solid medium which is then incubated and examined for bacterial growth. (See also CASTAÑEDA'S METHOD; CLOT CULTURE.) [ARM (1982) 36 467–493.]

**blood DNA isolation kits** Commercial kits used for preparing genomic DNA from samples of blood.

In the DNA Stat™ system (marketed by Stratagene), the blood sample (25–200 µl) is added to a hypotonic solution in a spin cup resting in a 2-ml collection tube; erythrocytes (red blood cells) are lysed in the hypotonic solution. On centrifugation, plasma proteins and lysed RBCs pass through the spin cup into the collection tube; leukocytes are retained within the spin cup. A chaotropic solution is then added to the spin cup; this lyses the leukocytes and releases genomic DNA. DNA binds to the spin cup, and contaminants are removed by two washing steps. DNA can then be eluted into buffer. The resulting DNA is suitable for use as a template in PCR.

**blood parasites** See e.g. ANAPLASMA, BABESIA, ENDOTRYPANUM, LANKESTERELLA, PLASMODIUM and THEILERIA.

**blood poisoning** *Syn.* SEPTICAEMIA.

**blood transfusion** (infection by) See TRANSFUSION-TRANSMITTED INFECTION.

**bloom** (water bloom) An abundant (easily visible and often conspicuous) growth of e.g. planktonic algae (including phytoflagellates), cyanobacteria (particularly GAS VACUOLE-forming species), or occasionally protozoa (e.g. *Stentor*) at or near the surface of a body of water (reservoir, lake, fishpond, ocean, etc). Blooms are often seasonal and may be favoured by particular set(s) of environmental conditions, including e.g. thermal stratification (in lakes and reservoirs), an excess of particular nutrients (e.g. leached nitrogen-rich agricultural fertilizers), an abundance of organic matter, etc; blooms of *Chrysochromulina breviturrita* may be triggered by the deposition of selenium (apparently an essential growth factor for this species) derived from coal-fired power plants [CJFAS (1985) 42 1783–1788]. Blooms may recur cyclically: e.g. when dinoflagellates in a bloom exhaust their nutrient supply and die, their decomposition releases nutrients

which encourage bacterial growth; the bacteria in turn produce VITAMIN B<sub>12</sub> (an essential growth factor for dinoflagellates), thus triggering another dinoflagellate bloom. (See also RED TIDE.)

Blooms can cause various deleterious effects on the habitat in which they occur, as well as causing problems for man. The death and sudden decomposition of the massive microbial populations can cause a severe depletion of dissolved oxygen, often resulting in the asphyxiation of fish and other aquatic animals. Many bloom-forming species produce potent PHYCOTOXINS which may cause illness or death in animals or humans drinking the water or consuming aquatic animals from affected waters. (See also RED TIDE.) Certain species can impart unpleasant tastes and odours to the water: e.g. *Chrysochromulina breviturrita* can cause a 'rotten cabbage' odour, while *Synura petersenii* can cause 'fishy' tastes and odours. (See also GEOSMIN and METHYLLISOBORNEOL.) Excessive algal growth in a reservoir may, in addition to the above problems, block water filters (see WATER SUPPLIES).

The formation of blooms may be discouraged or prevented by e.g. pumping to discourage thermal stratification, adding certain algicides, preventing contamination of waters with fertilizers, etc. ALGICIDES commonly used in this context include e.g. copper sulphate (a few parts per million), although this may actually encourage some smaller, more troublesome species by decimating larger, more susceptible species. Phenanthraquinone and DICHLONE have been reported to be effective against bloom-forming cyanobacteria.

**bloomed lens** (coated lens) A lens coated with a thin layer of e.g. magnesium fluoride to reduce the amount of incident light reflected back from the lens surface; the thickness of the coating is calculated such that *destructive interference* occurs between rays reflected from the bloomed surface and rays reflected at the fluoride-glass interface. In practice, blooming eliminates only that reflected light (usually green or yellow) whose wavelength is about four times the thickness of the fluoride coating. Blooming of a microscope eyepiece lens reduces stray background light in the tube and improves image sharpness.

**blot** (*mol. biol.*) See BLOTTING.

**blotch disease** *Syn.* BROWN BLOTCH.

**blotting** Following gel ELECTROPHORESIS: the transfer of nucleic acid and/or protein molecules from a gel strip to a specialized, chemically reactive paper, or other matrix, to which the transferred molecules may bind in a pattern similar to that present in the original gel. Transfer may be effected by capillary action, in which case the matrix (e.g. nitrocellulose, DEAE paper, APT PAPER) is sandwiched between the gel and a highly absorptive pad. Alternatively, in *electroblotting*, transfer is effected by electrophoresis.

In the earliest (capillary) blotting, DNA was transferred to nitrocellulose in the eponymous *Southern blot* technique (see SOUTHERN BLOT; see also SOUTHERN HYBRIDIZATION); later, blotting of RNA (*Northern blot*) and protein (*Western blot*) was carried out.

After blotting, a particular target molecule on the matrix may be identified or assayed e.g. by labelled probes or by enzyme immunoassay techniques. In *immunoblotting*, the transfer of proteins to a matrix is followed by exposure of the matrix to labelled antibodies; the binding of specific antibodies to a particular protein on the matrix may indicate the corresponding antigen.

(See also SOUTHWESTERN BLOTTING.)

**blower** *Syn.* SWELL.

**blown can** *Syn.* SWELL.

**blue bodies** See EAST COAST FEVER.

**blue cheese** See CHEESE-MAKING.

**blue-eared pig disease** Porcine reproductive and respiratory syndrome (PRRS): a disease of pigs, reported first in the USA and later in Europe, associated with a variety of symptoms, including abortion/stillbirth, agalactia, respiratory distress (particularly in new-born animals) and cyanosis of the ears; some strains can cause encephalitis. The disease may be mild, or may be severe with heavy losses, depending e.g. on the virulence of the causal agent and existing health of infected pigs. Secondary infections may occur.

The causal agent is a virus (genus ARTERIVIRUS), first identified in The Netherlands (the 'Lelystad' virus); it is also referred to as the swine infertility and respiratory syndrome (SIRS) virus.

Infection may occur via the airborne route. The incubation period may be a few days to a week, or much longer. Following experimental infection via the oronasal route, the virus can be detected within 12 hours in alveolar macrophages, in lung lymph nodes within 24 hours, and in spleen within 3–4 days. A reduction in numbers of alveolar macrophages (the major target cell of the virus) may be important in predisposing to secondary infections. Virus is shed in the oronasal secretions, urine and faeces of acutely infected animals.

[PRRS: RMM (1995) 6 119–125.]

**blue-green algae** CYANOBACTERIA.

**blue-light fluorescence** See FLUORESCENCE.

**blue mould** (1) (of tobacco) See PERONOSPORA.

(2) Any blue-spored species of *Penicillium*.

**blue proteins** Copper-containing proteins which characteristically absorb strongly at or near 600 nm; at least some blue proteins are known to have roles in electron transport, and these proteins have been referred to as 'cupredoxins'.

Blue proteins occur in bacteria, e.g. AMICYANIN, AZURIN (sense 1), RUSTICYANIN; in fungi, e.g. LACCASE; in higher plants, e.g. cucumber basic blue protein, stellacyanin, umecyanin; in higher plants, algae and cyanobacteria, e.g. PLASTOCYANIN; and in animals, e.g. ascorbate oxidase (EC 1.10.3.3) and ceruloplasmin (found in mammalian blood plasma).

**blue pus** Pus formed in suppurative infections involving *Pseudomonas aeruginosa*; the pus has a bluish tinge owing to the presence of pyocyanin.

**blue slime disease** See COSTIASIS.

**blue-stain** A form of SAP-STAIN in which timber becomes bluish-grey owing to the deep penetration of fungal hyphae; the bluish-grey 'stain' is due to refraction of light by the hyphae. The commonest causal agents of blue-stain in temperate zones are species of *Ceratocystis*, e.g. *C. pilifera*; *Diplodia* spp are important in the tropics. Blue-stain may reduce the value of timber, but it does not significantly affect its mechanical strength since the cellulose and lignin components of the wood are little affected.

**blueberry shoestring virus** See SOBEMOVIRUSES.

**bluecomb disease virus** See CORONAVIRIDAE.

**bluetongue** An acute SHEEP DISEASE caused by an ORBIVIRUS; other ruminants (e.g. cattle, deer) may be affected, but in these the disease is usually mild or subclinical. Bluetongue occurs mainly in Africa but has occurred e.g. in Europe, Asia, USA. Transmission occurs mainly via a biological vector (especially *Culicoides* spp). Incubation period: 2 days to 2 weeks. Symptoms: fever; inflammation and cyanosis of the mucous membranes of the mouth, nose, and alimentary tract. The lungs and feet may be involved. Mortality (in sheep): e.g. 5–30%.

**blunt-ended DNA** Linear dsDNA with flush ends, i.e., with no 3' or 5' single-stranded extensions. (cf. e.g. STICKY ENDS.)

## blusher

**blusher** *Amanita rubescens*.

**BLV** Bovine leukosis virus: see BOVINE VIRAL LEUKOSIS.

**BOD** (biochemical oxygen demand; biological oxygen demand)

The amount of dissolved oxygen needed for microbial oxidation of soluble, biodegradable matter in an aquatic environment. For example, when discharged to rivers etc., sewage effluents may consume large amounts of dissolved oxygen, and if dilution is inadequate they may give rise, locally, to anaerobic or microaerobic conditions (i.e. exert a high BOD); in such cases there is a risk of asphyxiation for fish and other organisms dependent on appropriate levels of dissolved oxygen.

The BOD test measures the amount of oxygen (mg) consumed per litre of (e.g.) sewage, or a known dilution of it, in 5 days at 20°C.

(See also SEWAGE TREATMENT.)

**BOD test** See BOD.

**Bodanella** See PHAEOPHYTA.

**Bodo** A genus of protozoa (suborder BODONINA); species occur e.g. in organically polluted waters (see SAPROBITY SYSTEM). The cells are ovoid or tapered, sometimes flattened, ca. 5–20 µm in length; two flagella arise at the anterior end (near the cytostome), one being directed posteriorly.

**Bodonina** A suborder of biflagellate protozoa (order KINETOPLASTIDA); some members are free-living, others are parasitic e.g. in the blood or gut of fish. Genera include BODO, *Cryptobia*, *Rhynchomonas*.

**body microflora** Each of the various regions of the body typically harbours a characteristic MICROFLORA (sense 1); for microflora of the human body see e.g. EAR MICROFLORA, EYE MICROFLORA, GASTROINTESTINAL TRACT FLORA, GENITOURINARY TRACT FLORA, MOUTH MICROFLORA, RESPIRATORY TRACT MICROFLORA, SKIN MICROFLORA.

**body odour** See SKIN MICROFLORA.

**boil** (furuncle) A skin lesion due to infection of a hair follicle, sebaceous gland or skin lesion by (usually) *Staphylococcus aureus*. A tender red nodule becomes pus-filled and may either subside or break at the skin surface and drain. (cf. CARBUNCLE; FURUNCULOSIS (2).)

**boil disease** (in fish) See MYXOBOLUS.

**Boivin antigens** *Syn.* O ANTIGENS.

**Bolbitiaceae** See AGARICALES.

**Boletales** An order of fungi (subclass HOLOBASIDIOMYCETIDAE) that typically form mushroom-shaped basidiocarps in which the hymenophore lines a mass of vertically orientated tubules on the underside of the pileus (porous basidiocarp) or forms a layer on lamellae; the porous basidiocarps are fleshy (cf. APHYLLOPHORALES). Genera include e.g. *Boletus* (basidiocarp porous, stipe central), *Paxillus* (lamellate), and *Phylloporus* (lamellate). Some species are edible – e.g. *Boletus edulis* (cèpe or penny bun), some form mycorrhizal associations with trees, and one species, *Boletus parasiticus*, is parasitic on *Scleroderma*. [Classification and spore structure: TBMS (1981) 76 103–146.]

**Boletus** See BOLETALES.

**Boletus virus** See POTEXVIRUSES.

**Bolivian haemorrhagic fever** A VIRAL HAEMORRHAGIC FEVER caused by the Machupo virus (see ARENAVIRIDAE). Mortality: usually ca. 5–30%.

**Bombyx mori NPV** See NUCLEAR POLYHEDROSIS VIRUSES.

**bongkrek** See TEMPEH.

**bongkrekic acid** A toxic, substituted heptaenedioic acid produced by '*Pseudomonas cocovenenans*' in spoiled bongkrek (see TEMPEH); it inhibits (uncompetitively) the ADP/ATP exchange carrier system which operates across the inner mitochondrial membrane. (cf. ATRACTYLOSIDE.)

**booster** (*immunol.*) A second or subsequent dose of a VACCINE administered with the object of eliciting a higher rate of antibody formation (see ANAMNESTIC RESPONSE).

**boot laces** See ARMILLARIA.

**boracic acid** *Syn.* BORIC ACID.

**Bordeaux mixture** (*plant pathol.*) An antifungal preparation first used in Bordeaux in the late 19th century for the treatment of downy mildew of vines; it has since been widely used as an agricultural antifungal agent against various blights, mildews, rusts and leaf-spot diseases, but is now used less frequently owing to its phytotoxicity. It is prepared by mixing a solution of copper sulphate with an aqueous suspension of calcium hydroxide, and appears to contain a mixture of basic copper sulphates (CuSO<sub>4</sub>.xCu(OH)<sub>2</sub>). The freshly-prepared mixture, sprayed onto leaves, stems etc, forms an insoluble deposit which gradually releases COPPER ions as a result of the influence of e.g. atmospheric carbon dioxide and/or plant or fungal secretions.

**border disease** (hairy shaker disease) A congenitally acquired SHEEP DISEASE characterized by an abnormally hairy birth-coat, tremors, and poor growth; it is caused by a PESTIVIRUS. [Review: Adv. Vet. Med. (1982) 36 (90 pp.)]

**Bordet–Gengou agar** An agar-based medium, used for the primary isolation of *Bordetella* spp (especially *B. pertussis*), containing glycerol, soluble starch, and 20–30% fresh horse or sheep blood; peptone (1%) may be added, but certain peptones inhibit the growth of *Bordetella* spp. Penicillin may be added to suppress growth of the nasopharyngeal flora. [Recipes: e.g. Book refs. 2, p. 132; 19, p. 145.]

**Bordetella** A genus of aerobic, chemoorganotrophic, Gram-negative bacteria classified within the beta group of Proteobacteria; the organisms occur as parasites and pathogens in mammals. Cells: non-motile or peritrichously flagellated coccobacilli, ca. 0.2–0.5 × 0.5–2.0 µm. Metabolism: respiratory (oxidative). Carbon sources include e.g. various amino acids; carbohydrates are not used. Growth factors required include organic forms of nitrogen and sulphur. Optimum growth at 35–37°C. GC% ca. 66–70. Type species: *B. pertussis*.

*B. avium*. Proposed name for bacteria causing coryza (rhinotracheitis) in turkey poults [IJSB (1984) 34 56–70].

*B. bronchiseptica*. Cells: motile. Growth can occur on peptone-agar, and may be visible after overnight incubation. Oxidase +ve. Catalase +ve. Urease +ve. This species occurs e.g. in dogs and other animals, and is sometimes a cause of respiratory disease in man and animals.

*B. parapertussis*. Cells: non-motile. Growth on peptone-agar is characterized by the formation of a brown, soluble pigment. Improved growth may be obtained on Moredun medium (see WHOOPING COUGH). Oxidase –ve. Catalase +ve. Urease +ve. *B. parapertussis* is isolated from some cases of WHOOPING COUGH (q.v.).

*B. pertussis*. The primary cause of WHOOPING COUGH (q.v.). Initial isolation is usually carried out by plating a pernasal swab on BORDET–GENGOU AGAR or (better) CHARCOAL BLOOD AGAR. The typical colony (ca. 1 mm after 3–6 days) is smooth and domed with a metallic ('mercury drop') appearance and a butyrous consistency. Growth is inhibited by unsaturated fatty acids or colloidal sulphur. Cells: non-motile. Oxidase +ve. Some strains are catalase +ve. Urease –ve. Citrate is not utilized. (For toxin production see WHOOPING COUGH.) (See also BVG GENES.) *B. pertussis* and *B. parapertussis* can be detected, simultaneously, by a duplex PCR [JCM (1999) 37 606–610].

**boric acid** (boracic acid) (as an antimicrobial agent) Boric acid (H<sub>3</sub>BO<sub>3</sub>) has mild antimicrobial properties, and is widely used

as an ANTISEPTIC for delicate tissues (e.g. eyes) and e.g. as a bacteriostatic agent in urine samples. It is sometimes used, in combination with borax ( $\text{Na}_2\text{B}_4\text{O}_7$ ), as a wood preservative.

**Borna disease** A disease of horses (and rarely sheep) caused by the BORNA DISEASE VIRUS. Symptoms in the horse include fever, pharyngeal paralysis and hyperaesthesia; death usually occurs in 1–3 weeks.

Borna disease virus (BDV) can cause behavioural abnormalities (with aggressive and passive phases) in certain animals, and it has been suggested that BDV could be responsible for certain psychiatric disorders in humans [Arch. Gen. Psych. (1985) 42 1093–1096]; the involvement of BDV in psychiatric disease remains controversial, but immunological and PCR-based studies for BDV in psychiatric patients and blood donors in Japan have suggested that certain individuals are infected with BDV or with a BDV-related virus [JCM (2001) 39 419–429].

**Borna disease virus (BDV)** A neurotropic virus (family Bornaviridae) which is the causal agent of BORNA DISEASE; BDV has a non-segmented, negative-sense ssRNA genome and appears to be a member of the MONONEGAVIRALES. [The coding strategy of BDV: Virology (1995) 210 1–8.]

**Bornholm disease** (epidemic myalgia; devil's grip) A self-limiting, epidemic disease usually caused by a group B coxsackievirus; other enteroviruses (e.g. coxsackieviruses A4, A6, A9, A10, and echoviruses 1 and 6) have sometimes been implicated. Onset is abrupt, with spasmodic, often severe chest pain (pleurodynia) and a brief period of high fever.

**Borrelia** A genus of Gram-negative bacteria (family SPIROCHAETACEAE) which occur as parasites or pathogens in man and other animals (see e.g. RELAPSING FEVER). The cells are motile, helical (3 to 10 loose coils), ca.  $0.2\text{--}0.5 \times 3.0\text{--}20 \mu\text{m}$ , each containing up to 20 periplasmic flagella; they stain well with conventional dyes, and are visible by light microscopy. Some species (including *B. recurrentis*) have been grown in vitro; cultured species require complex media and are microaerophilic.

Species were differentiated by their arthropod vectors: e.g. human-louse-borne borreliæ *B. recurrentis*, tick-borne borreliæ according to tick species. Type species: *B. anserina*.

The 19 species recognized in Book 22 (pages 57–62) included *B. anserina*, *B. brasiliensis*, *B. duttonii*, *B. graingeri*, *B. harveyi*, *B. hermsii*, *B. parkeri*, *B. persica*, *B. recurrentis*, *B. theileri* and *B. venezuelensis*.

*B. burgdorferi* (*sensu lato*) comprises *B. burgdorferi* (*sensu stricto*) and the species *afzelii*, *andersonii*, *bissettii*, *garinii*, *japonica*, *lusitaniae*, *tanukii*, *turdi* and *valaisiana* [Molecular typing of *B. burgdorferi sensu lato*. Clinical Microbiology Reviews (1999) 12 633–653].

*B. burgdorferi* [IJSB (1984) 34 496–497; genome: Nature (1997) 390 580–586] causes LYME DISEASE. This organism can be grown in BSK (Barbour–Stoenner–Kelly) II medium [recipe: Book ref. 219, pp. 570–571], although diagnosis is more often serological (confirmation of a clinical diagnosis by detection of a rising titre of specific IgM during the 3rd–6th week following first symptoms e.g. by an indirect immunofluorescent antibody test). Quantification of *B. burgdorferi* in tissue samples has been achieved with a PCR-based method [JCM (1999) 37 1958–1963]. The outer surface protein C (OspC) of *B. burgdorferi* is possibly involved in the binding of the pathogen to host ligands, and this protein has been examined in some detail [crystal structure of OspC: EMBO (2001) 20 971–978].

**borreliosis** Any disease of man or animals caused by a *Borrelia* sp: see e.g. RELAPSING FEVER and LYME DISEASE.

**Bostrychia** See RHODOPHYTA.

**botches disease** Synonym for freshwater RED PEST.

**bothrosome** See LABYRINTHULAS and THRAUSTOCHYTRIDS.

**botcinis** See BACTERIOCIN.

**Botrydium** A genus of siphonaceous algae (class XANTHOPHYCEAE) in which the mature vegetative organism consists of a globose to elongate (typically pear-shaped) coenocytic vesicle, up to ca. 2 mm diam., anchored to the substratum (mud, damp soil, etc) by colourless branched rhizoids; inside the vesicle is a thin peripheral layer of cytoplasm (containing the chloroplasts and nuclei) surrounding a large central vacuole. Asexual reproduction occurs by the formation of zoospores or aplanospores; resistant cysts are formed under dry conditions.

**Botryobasidium** See APHYLLOPHORALES (Corticaceae).

**botryomycosis** ('bacterial pseudomycosis') A chronic localized infection of the skin and subcutaneous tissues in man and animals. The pathogen (commonly e.g. *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or *Escherichia coli*) forms one or more granules in the centre of an abscess which is surrounded by fibrous tissue. (cf. MADUROMYCOSIS.)

**Botryotinia** See HELOTIALES.

**botrytis** (*plant pathol.*) *Syn.* GREY MOULD.

**Botrytis** A genus of fungi of the class HYPHOMYCETES; many species are known to have teleomorphs in the genus *Botryotinia*. The organisms include many plant-pathogenic species – e.g. *B. aclada* (= *B. allii*) (see ONION ROT), *B. cinerea* (see GREY MOULD, NOBLE ROT), and *B. fabae* (see CHOCOLATE SPOT). (See also SOFT ROT *sensu lato*.) Antifungal agents used against *Botrytis* infections include e.g. BENOMYL, DICARBOXIMIDES, DICHLOFLUANID, DICLORAN, THIRAM and ZINEB.

*Botrytis* spp form septate mycelium; dark, ovoid, non-septate conidia develop in a layer on the swollen, terminal region of each of the small branches of a conidiophore. Sclerotia are formed e.g. by *B. aclada*, *B. cinerea* and *B. tulipae*. [Book ref. 183.]

**bottom-fermenting yeast** See BREWING.

**bottromycins** A group of peptide antibiotics, produced by *Streptomyces* spp, which inhibit bacterial protein synthesis.

**botulinolysin** See THIOL-ACTIVATED CYTOLYSINS. (cf. BOTULINUM TOXIN.)

**botulinum C2 toxin** A powerful toxin, produced by certain strains of *Clostridium botulinum*, which apparently has no neurotoxic activity (cf. BOTULINUM TOXIN) – but which causes e.g. increased intestinal secretion. The C2 toxin consists of two components, the larger of which appears to be involved in cell-surface binding and (possibly) uptake of the smaller component. The smaller component effects ADP-RIBOSYLATION of an ATP-binding ACTIN molecule, G actin, preventing its polymerization to F actin; this disrupts the cell's microfilament cytoskeleton and leads e.g. to rounding of the cell.

**botulinum cook** In the food processing industry: COOKING equivalent to a 12D PROCESS in respect of the endospores of *Clostridium botulinum*. The  $D_{121.1}$  value (see D VALUE) of *C. botulinum* endospores is generally taken to be ca. 0.21 min. (See also CANNING.)

**botulinum toxin** Any of a range of related, powerful protein toxins (MWt ca. 150000) produced mainly by strains of *Clostridium botulinum*.

Botulinum toxins are differentiated antigenically into types A–G, with type C being divided into subtypes C1 and C2. Toxins of types A–F – with the exception of BOTULINUM C2 TOXIN – are powerful neurotoxins which cause BOTULISM in man and animals. The (plasmid-encoded) botulinum toxin G has been isolated e.g. from autopsy material but has not been linked definitively with disease. The botulinum C and D toxins are encoded by genes from two different bacteriophages.

## botulism

All of these toxins can be produced by strains of *C. botulinum*.

Botulinum toxin type F has also been linked with an organism resembling *Clostridium barati*, associated with infant botulism [JCM (1985) 21 654–655]. [See also JCM (2002) 40 2260–2262.] A toxin similar to the botulinum type E toxin is produced by strains of *C. butyricum* isolated from cases of infant botulism. The ability to form type C toxin can apparently be transferred, by phage, from *C. botulinum* type C to *C. novyi*.

All the botulism-causing toxins are similar in structure and mode of action. Proteolytic cleavage into two fragments – a heavy (H) chain and a light (L) chain (connected by a disulphide bond) – activates the toxin; cleavage is mediated by a bacterial protease or an exogenous protease. The activated toxin binds, via the H chain, to the cell membrane of motor neurones at the nerve–muscle junction; toxin is internalized within a vesicle that remains at the nerve–muscle junction. The active part of the toxin (L chain) is translocated from the vesicle to the neurone's cytoplasm. Within the cytoplasm, the toxin acts as a zinc-endopeptidase in a way similar to that of TETANOSPASMIN (q.v. for essential details); in this case, however, the toxin blocks neuroexocytosis of vesicles containing the neurotransmitter *acetylcholine* – i.e. it prevents nervous stimulation of the muscle, leading to a *flaccid* paralysis. (Compare the site and mode of action of TETANOSPASMIN.)

Botulinum toxins differ in their targets: the A and E toxins cleave (inactivate) SNAP-25 (see TETANOSPASMIN); the C toxin cleaves syntaxin; B, D, F and G toxins cleave VAMP/synaptobrevin.

[Mechanism of action of botulinum neurotoxins: Mol. Microbiol. (1994) 13 1–8.]

Purified botulinum toxin is heat-labile, being inactivated e.g. by heating at 100°C/10 minutes.

Botulinum toxin has been used as an alternative to surgery for treating some muscular disorders of the eye (strabismus; = 'squint') [Br. J. Opth. (1985) 69 718–724, 891–896]. [Uses of botulinum and other microbial neurotoxins: MR (1992) 56 80–99. Therapy with botulinum toxin: Book ref. 220. Botulinum toxin for spastic gastrointestinal disorders: BCG (1999) 13 131–143.]

**botulism** A disease of man and animals caused by any strain of *Clostridium* (usually a strain of *C. botulinum*) which forms a (neurotoxic) BOTULINUM TOXIN (q.v.).

(a) *Botulism in man.* The disease is commonly caused by *C. botulinum* types A, B or E, but may be caused by any neurotoxic strain.

'Classical' botulism is a food-borne intoxication which follows ingestion of foods contaminated with pre-formed toxin – although additional toxin may be formed in the gut if viable cells of the pathogen are ingested. In the mouse, the LD<sub>50</sub> of botulinum toxin is reported to be of the order of 0.1–1.0 ng/kg.

Foods of a low-acid, low-salt type are often implicated. *C. botulinum* type A may be associated with e.g. improperly canned vegetables, fish and meat products (Latin *botulus* = sausage), types B and F with e.g. meat products, and type E with e.g. uncooked sea-foods.

Toxin is absorbed from the gut and disseminated via the circulation. The incubation period is typically 12–36 hours, but may be ~2–8 days. The symptoms may include nausea, blurred/double vision (due to effects of toxin on the oculomotor muscles), dysphagia, dysphonia etc.; there is a progressive flaccid paralysis, and death may follow from asphyxia or cardiac failure.

*Wound botulism* is a rare form of the disease resulting from contamination of a wound by a toxigenic strain of the pathogen. Incubation period ~4–14 days. Symptoms are similar to those of food-borne botulism, sometimes with the addition of fever.

*Infant botulism* can follow ingestion of spores of the pathogen which germinate and form toxin in the gut (= *toxicoinfection*). The disease affects mainly infants <6 months of age, and varies from subclinical to rapidly fatal; typical symptoms: e.g. constipation, lethargy, dysphagia and weakness. One source of infection was reported to be honey contaminated with *C. botulinum* spores [JPed (1979) 94 331–338]. Infant botulism may be responsible for some cases of SUDDEN INFANT DEATH SYNDROME; sudden death may be due to weakening or flaccid paralysis of muscles of the tongue and pharynx, leading to obstruction of the airway and asphyxia.

*Botulism of undetermined classification* includes those cases in individuals, older than 1 year, in which 'a specific food cause cannot be implicated'. Botulism in an adult may be due to the synthesis of toxin within the intestine during a gut infection with the pathogen [NEJM (1986) 315 239–241; Lancet (1987) i 357–360; (*C. barati*) JCM (2002) 40 2260–2262].

*Lab. diagnosis* (all forms): assay of serum, faeces and implicated foods for botulinum toxin and organisms.

*Treatment.* Any unabsorbed toxin should be removed from the gut. Polyvalent antitoxin may be administered (avoiding possible hypersensitivity reactions to heterologous components). Guanidine, given orally, may counteract the effects of toxin at the nerve–muscle junction. Supportive care will be needed. (A prophylactic botulinum toxoid vaccine has been given to laboratory personnel working with *C. botulinum*, but such a vaccine is unlikely to be useful for *treatment* owing to the time required to develop an immune response.)

[Botulism (epidemiology, diagnosis, treatment): RMM (1995) 6 58–62.]

(b) *Botulism in animals.* In cattle, the disease may be caused by *C. botulinum* types B, C or D (see e.g. LAMZIEKTE and MIDLAND CATTLE DISEASE). In horses, types B or C may be involved (see e.g. FORAGE POISONING). Birds may be affected by types A or C (see e.g. LIMBERNECK and WESTERN DUCK DISEASE). In farmed salmonid fish the disease has been caused by type E [J. Fish Dis. (1982) 5 393–399]. In animals, the disease is characterized by progressive paralysis without loss of sensibility and without fever.

**Boucherie process** A method of TIMBER PRESERVATION in which the sap of newly felled trees is replaced by a preservative (under pressure) in order to prevent subsequent fungal decay of the timber. (cf. SAUG-KAPPE PROCESS; BETHELL PROCESS.)

**Bouin's fluid** A FIXATIVE: a mixture of picric acid (75 ml saturated, aqueous), formalin (25 ml), and glacial acetic acid (5 ml).

**bound coagulase** See COAGULASE.

**bourbon** See SPIRITS.

**boutonneuse** In man: a mild disease caused by *Rickettsia conorii* and transmitted by tick bite. After an incubation period of 1–2 weeks a characteristic lesion (the *tâche noir*) develops at the location of the bite; this lesion (up to 0.5 cm diam.) consists of a black necrotic centre and a reddened margin. The regional lymph nodes may be affected. Fever, headache and muscular pains are typically followed by a maculopapular rash. Diagnosis may include the WEIL-FELIX TEST.

**Boveria** See SCUTICOCILLIATIDA.

**Boverin** See BEAUVERIA.

**bovid herpesvirus** See under *bovine* herpesvirus.

**bovine cytomegaloviruses** See BETAHERPESVIRINAE.

**bovine diseases** See CATTLE DISEASES.

**bovine ephemeral fever** An infectious CATTLE DISEASE caused by a virus (a probable member of the Rhabdoviridae) and transmitted by insects; it occurs e.g. in Africa and Asia. Incubation period: ca. 2–10 days. Symptoms: e.g. fever, tremors, stiffness, and enlargement of the peripheral lymph nodes; mortality rates are low, but lactation is severely depressed.

**bovine farcy** See FARCY (2).

**bovine farmers' lung** (*vet.*) A chronic ATYPICAL INTERSTITIAL PNEUMONIA of cattle; it occurs, infrequently, in housed adult cattle exposed to mouldy or dusty feedstuffs. Symptoms: coughing, dyspnoea, nasal discharge. (cf. FARMERS' LUNG.)

**bovine herpesvirus 1** See HERPESVIRIDAE.

**bovine herpesvirus 2** See ALPHAHERPESVIRINAE.

**bovine leukosis virus** See BOVINE VIRAL LEUKOSIS.

**bovine mammillitis virus** See BOVINE ULCERATIVE MAMMILLITIS.

**bovine mastitis** See MASTITIS.

**bovine papilloma virus** See PAPILLOMAVIRUS.

**bovine parvovirus** See PARVOVIRUS.

**bovine pustular stomatitis virus** See PARAPOXVIRUS.

**bovine respiratory disease (BRD)** A collective term which includes a range of acute respiratory diseases of diverse aetiology in which the symptoms may include e.g. anorexia, coughing, dyspnoea, nasal discharge, pneumonia; cattle of all ages may be affected, but young animals are generally more susceptible. Treatment generally includes broad-spectrum chemotherapy to combat primary or secondary bacterial pathogens. Specific BRDs include: *pneumonic pasteurellosis* (shipping fever), a disease which is spread by droplet infection, and which can occur with high incidence in young stressed cattle; symptoms: fever, acute bronchopneumonia and toxæmia. The causal agent is usually *Pasteurella haemolytica*, sometimes *P. multocida*. There is usually a good response to early chemotherapy, with recovery in 1–2 days. *Bovine respiratory syncytial virus infection* is an acute bronchiolitis and alveolitis which occurs in (usually) young animals and involves e.g. fever, cough and dyspnoea; the disease can be fatal. (See also ATYPICAL INTERSTITIAL PNEUMONIA; CALF PNEUMONIA; CONTAGIOUS BOVINE PLEUROPNEUMONIA; INFECTIOUS BOVINE RHINOTRACHEITIS.)

**bovine rhinotracheitis** See INFECTIOUS BOVINE RHINOTRACHEITIS.

**bovine spongiform encephalopathy (BSE; mad cow disease)** A TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHY of bovines caused by a PRION; it was reported in Great Britain in 1986. Clinical signs include e.g. nervousness, kicking and locomotor difficulty [clinical picture: VR (1992) 130 197–201]. In Great Britain there were 3.9 confirmed cases per 1000 adult animals up to the end of 1989. Epidemiological studies implicated the meat and bone meal in concentrate feeds as a source of the causal agent; dairy herds were found to be affected more than beef suckler herds, due apparently to different feeding practices. [Epidemiological features: VR (1992) 130 90–94; TIM (1997) 5 421–424.]

Transmission of the BSE prion to humans, via the food chain, is now believed to cause nvCJD (variant, or new variant CREUTZFELDT-JAKOB DISEASE). This aetiological link is supported by various experimental data which have accumulated over the last few years. For example: intracerebral injection of monkeys with brain homogenates from affected cows yields clinically and pathologically similar CJD [Nature (1996) 381 743–744]; transgenic mice which express human PrP proteins react with identical clinical, biochemical and histological changes when exposed to BSE or nvCJD material [Nature (1997) 389 448–450]; the

BSE prion converts human PrP to the prion form in a cell-free system [Nature (1997) 388 285–288]. [Review of BSE: RMM (1998) 9 119–127.]

[Cumulative incidence of BSE in the United Kingdom during the period July 1986–June 1997, animal-associated risk factors influencing age of onset of clinical signs, and effectiveness of control measures: VR (2000) 147 349–354.]

(See also CATTLE DISEASES.)

**bovine syncytial virus** See SPUMAVIRINAE.

**bovine tubercle bacillus** *Mycobacterium bovis*.

**bovine typhus** *Syn.* RINDERPEST.

**bovine ulcerative mammillitis** (bovine herpes mammillitis) A CATTLE DISEASE caused by bovine (alpha) herpesvirus 2 (bovine mammillitis virus – see ALPHAHERPESVIRINAE). The disease involves severe inflammation and ulceration of the skin of the udder and teats; stomatitis and facial infection may also occur, particularly in calves. (See also LUMPY SKIN DISEASE and MASTITIS.)

**bovine viral leukosis** (enzootic bovine leukaemia) A chronic transmissible CATTLE DISEASE caused by the bovine leukosis virus (BLV), an exogenous v-*onc*<sup>-</sup> retrovirus which is closely related to HTLV-I and HTLV-II (see HTLV). [Nucleotide sequence of the BVL genome and its relation to other retroviruses: PNAS (1985) 82 677–681.] Natural infection occurs e.g. in cattle (*Bos taurus* and *Bos indicus*), sheep, and water buffalo. The disease involves systemic malignant neoplasia of the reticuloendothelial system; in a small proportion of infected animals, malignant lymphomas (mainly of the B cell type) may develop in almost any organ, resulting in a variety of clinical manifestations. Transmission occurs horizontally by transfer of infected lymphocytes – most commonly via surgical instruments and needles (e.g. during herd vaccinations, blood-sampling, etc); natural transmission may occur via milk or colostrum or, in tropical countries, possibly via insects or parasites. [Reviews: Book refs 105, pp. 229–260, and 110, pp. 197–216.]

**bovine virus diarrhoea (BVD)** A CATTLE DISEASE caused by the BVD-MD virus (see PESTIVIRUS). BVD may affect cattle (and other ruminants) at any age, and follows infection by ingestion or inhalation; the condition is usually mild and self-limiting. (cf. MUCOSAL DISEASE.)

**Bovista** See LYCOPERDALES.

**bowel oedema** *Syn.* OEDEMA DISEASE.

**Bowie–Dick test** A test used to monitor the performance of an AUTOCLAVE. Essentially, two pieces of AUTOCLAVE TAPE are fixed in the form of an 'X' to a piece of paper which is inserted into the middle of a stack of cotton towels; the towels are autoclaved and the tape is examined. A satisfactory sterilizing regime is deemed to have been achieved only if *all* parts of the tape indicate exposure to sterilizing conditions.

**box-like bacteria** Various shaped, angular bacteria which are found in hypersaline environments and which contain bacteriorhodopsin-like pigments [JB (1982) 151 1532–1542]. (cf. SQUARE BACTERIA.)

**Boyden chamber** A chamber, divided into two sections by a membrane filter, used e.g. to study macrophage migration; the filter initially separates activated T lymphocytes (or their supernatant) and macrophages – the latter subsequently migrating through the filter in response to macrophage chemotactic factor.

**Boyden procedure** Treatment of erythrocytes with tannic acid (see TANNINS) to enable them to adsorb soluble antigens; such tanned cells are used e.g. in PASSIVE AGGLUTINATION. (Chromium salts or e.g. *bis*-diazobenzidine have been used in place of tannic acid.)

bp

**bp** BASE PAIR.

**Bph** BACTERIOPHAEOPHYTIN.

**bph operon** See BIOREMEDIATION

**BPI protein** (bactericidal/permeability-increasing protein) A component of the azurophil granules in human and rabbit NEUTROPHILS; it is bactericidal for some Gram-negative bacteria – in which it increases the permeability of the OUTER MEMBRANE – but it is not active against e.g. POLYMYXIN-resistant enteric bacteria (such as *Proteus*) or Gram-positive bacteria [MR (1992) 56 399]. BPI binds to LPS and can apparently neutralize endotoxigenicity, and it may also attenuate the inflammatory response [see e.g. RMM (1995) 6 101–108].

**BPL**  $\beta$ -PROPIOLACTONE.

**BPV** Bovine papilloma virus; see PAPILOMAVIRUS.

**Brabant mastitis test** See CALIFORNIA MASTITIS TEST.

**Brachiomonas** A genus of unicellular flagellated green algae which are closely related to CHLAMYDOMONAS. The vegetative cells have a distinctive morphology: the posterior end is pointed, and four backward-directed pointed projections extend laterally from the cell body. Motile ‘autospores’ are formed (the daughter cells acquiring the distinctive adult-cell morphology before being released).

**Brachonella** See HETEROTRICHIDA.

**Brachyallomyces** See ALLOMYCES.

**Brachyarcus** A proposed genus of gas-vacuolated, curved rod-shaped bacteria which occur, in groups (coenobia), in microaerobic or anaerobic sulphide-containing aquatic habitats. [Book ref. 22, pp. 137–138.]

**Brachybasidiales** An order of plant-endoparasitic fungi (subclass HOLOBASIDIOMYCETIDAE) which form bisterigmatate basidia either in definite hymenia or in tuft-like fascicles. *Brachybasidium* forms non-septate basidiospores on tufts of basidia which emerge from the host plant’s stomata. Members of the other genera form true hymenia – which emerge through the host’s epidermis and stomata – and basidiospores which sometimes become septate. In *Dicellomyces*, the basidiocarp is gelatinous (when fresh) and the hymenium is of uniform thickness. In *Ceraceosorus* and *Proliferobasidium* the basidiocarp is waxy, and the hymenium is not of uniform thickness; *Ceraceosorus* forms intracellular hyphae, *Proliferobasidium* forms intercellular hyphae [Mycol. (1976) 68 640–654]. (cf. EXOBASIDIALES.)

**Brachybasidium** See BRACHYBASIDIALES.

**bracket fungi** (shelf fungi) Those fungi of the APHYLLOPHORALES (e.g. *Piptoporus betulinus*) whose fruiting bodies jut out like brackets or shelves from infected trees or rotting logs etc.

**bradsot** *Syn.* BRAXY.

**Bradyrhizobium** A genus of Gram-negative bacteria of the RHIZOBIACEAE; strains were formerly included in the genus RHIZOBIUM as ‘slow-growing’ strains (colonies  $\leq 1$  mm diam. in 5–7 days on e.g. yeast extract–mannitol–mineral salts agar). *Bradyrhizobium* spp produce an alkaline reaction in media containing carbohydrate (e.g. mannitol) and mineral salts. Extracellular slime includes a neutral (1  $\rightarrow$  2)- $\beta$ -glucan. Some strains can grow chemolithotrophically with H<sub>2</sub>, CO<sub>2</sub> and low levels of O<sub>2</sub>; some can fix nitrogen under microaerobic conditions in media which contain e.g. a source of fixed nitrogen. Species induce ROOT NODULE formation in certain leguminous plants (mostly tropical, some temperate) – e.g. soybeans, cowpea, siratro, certain *Lotus* spp. One non-leguminous plant, *Parasponia* (Ulmaceae), is also nodulated by a *Bradyrhizobium* strain. GC%: 61–65. Type species: *B. japonicum* (formerly *Rhizobium japonicum*). [Book ref. 22, pp. 242–244.]

**bradyzoite** *Syn.* CYSTOZOITE.

**brain fungus** *Sparassis crispa*.

**brain–heart infusion medium** A medium containing infusions of calf-brain and beef-heart, proteose, D-glucose, NaCl, and Na<sub>2</sub>HPO<sub>4</sub>; it is available commercially in dehydrated form. The medium may be used as a broth or solidified with agar; it may be supplemented with e.g. haemin, menadione, yeast extract etc. It is used for the culture of a range of bacteria and medically important fungi. [Recipe: Book ref. 47, pp. 644–645.]

**branch migration** (*mol. biol.*) See RECOMBINATION (figures 1 and 2).

**branched DNA assay** See BDNA ASSAY.

**branching enzyme** An enzyme which introduces branches into a linear polysaccharide (see e.g. GLYCOGEN and Q ENZYME). (cf. DEBRANCHING ENZYMES.)

**Branchiomyces** A ‘genus’ of fungi of uncertain taxonomic affinity; strains of *Branchiomyces* have features in common with members of the SAPROLEGNIALES, but it is unknown whether they form heterokont zoospores or aplanospores [Book ref. 1, pp. 215–216]. The organisms have been isolated only from the gill tissues of fish (see GILL ROT).

**branchiomycosis** *Syn.* GILL ROT.

**brand spores** See USTILAGINALES.

**Brandenfleckenkrankheit** *Syn.* BURNED SPOT DISEASE.

**brandy** See SPIRITS.

**Branhamella** See MORAXELLA.

**brassica black rot** See BLACK ROT.

**brassica diseases** See CRUCIFER DISEASES.

**Braun lipoprotein** (murein lipoprotein) A small lipoprotein (MWt ca. 7500) which occurs e.g. in *Escherichia coli* (encoded by gene *lpp*) and in other enterobacteria; each cell contains ca. 10<sup>5</sup>–10<sup>6</sup> copies of the lipoprotein – about one-third of which form links (in association with OmpA) between the peptidoglycan layer and the OUTER MEMBRANE (thus stabilizing the cell envelope).

Braun lipoprotein is synthesized as a precursor with a signal sequence (see SIGNAL HYPOTHESIS). The cysteine residue immediately adjacent to the signal peptide cleavage site is modified by substitution with a diacylglycerol, permitting cleavage by the signal peptidase; following cleavage, a fatty acid residue is added to the N-terminal cysteine. Such post-translational modification apparently targets the protein to the outer membrane. [Cell (1990) 61 739–741.]

The activity of the signal peptidase is inhibited by the peptide antibiotic *globomycin* (a structural analogue of the cleavage site).

**Braun MSK tissue disintegrator** An apparatus for CELL DISRUPTION. The sample, together with glass or plastic beads, is placed in a cooled container which is shaken at several thousand oscillations per minute for ca. 5 minutes; cells are broken by shear forces. The apparatus can break e.g. Gram-positive bacteria and endospores.

**braxy** (bradsot) An acute, usually fatal disease of lambs and young sheep; symptoms: fever, anorexia, inflammation of the wall of the abomasum, and toxæmia. Braxy occurs only in winter and appears to be due to the invasion of the abomasum by *Clostridium septicum* – the ingestion of frozen grass being a possible predisposing factor. Death occurs within hours.

**BRD** BOVINE RESPIRATORY DISEASE.

**BrdU** *Syn.* BUDR.

**bread-making** Bread is prepared by mixing flour (usually wheat flour), water, BAKERS’ YEAST and salt to form a dough; other ingredients (e.g. milk, sugar, shortening etc) may be added. After thorough mixing the dough is left to ‘prove’ at ca. 25°C;

during this time the yeast metabolizes sugars (released from the flour starches by AMYLASES present in the flour) and produces bubbles of CO<sub>2</sub> which become trapped in an elastic complex of flour proteins (gluten) – lightening the texture of the dough. (Fungal amylases may be added to increase the availability of fermentable sugars (see also PROTEASES).) In addition to its leavening (lightening) action, the yeast contributes flavour to the product and helps to modify the gluten structure. When the leavened dough is baked the yeast is usually killed and any alcohol produced by fermentation evaporates.

*Sourdough breads* are made by using a starter consisting of flour (usually rye) and water inoculated with dough from a previous batch. In the starter, heterofermentative lactic acid bacteria (*Lactobacillus sanfrancisco*) ferment maltose (released from the starch by amylase action) and produce lactic and acetic acids, ethanol and CO<sub>2</sub>; the pH falls to e.g. ca. 3.8. The acid-tolerant yeast *Saccharomyces exiguus*, which does not use maltose, uses other sugars (glucose, fructose etc) to leaven the bread. The starter may then be mixed with flour, water and salt to make a dough as with ordinary bread.

[Gluten biochemistry: *Biotechnology* (1995) 13 1185–1190.]

**bread mould** See BREAD SPOILAGE.

**bread spoilage** Bread and similar products are very susceptible to spoilage by the growth of moulds, especially *Rhizopus nigricans* (black bread mould), *Neurospora sitophila* (red bread mould), and species of *Penicillium* and *Aspergillus*. Preservatives which may be incorporated in the dough include e.g. propionates, sorbic acid, and potassium sorbate. (See also ROPINESS; ERGOTISM.)

**breakpoint chlorination** See WATER SUPPLIES.

**breakage-and-reunion model** See RECOMBINATION.

**breakbone fever** *Syn.* DENGUE.

**breaking (plant pathol.)** *Syn.* COLOUR-BREAKING.

**Breda virus** An RNA virus which causes diarrhoea in young calves; it is apparently related to the BERNE VIRUS (see TOROVIRIDAE). [Morphological study of Breda virus replication: *JGV* (1986) 67 1293–1304.]

**brefeldin A** A fungal toxin which inhibits the activity of the Golgi apparatus and which, as a consequence, can block certain processes in various types of cell; for example, brefeldin A can block protein secretion and inhibit the development of viruses.

**Breiln strain** A virulent strain of *Rickettsia prowazekii*; unlike the attenuated E strain it can be cultivated in human macrophage cultures.

**Bremia** A genus of fungi (order PERONOSPORALES) which cause DOWNY MILDEWS on members of the Compositae (e.g. *B. lactucae* on lettuce). [*B. lactucae*–lettuce interaction: Book ref. 174, pp. 116–118.]

**Bremiella** See PERONOSPORALES.

**Brettanomyces** A genus of yeasts (class HYPHOMYCETES) which form single spheroidal, cylindrical or elongated budding cells, pseudomycelium, or branched non-septate mycelium. Growth occurs slowly e.g. on malt agar; species may be isolated on cycloheximide-containing malt agar. Most strains can ferment glucose; fermentation is usually stimulated by O<sub>2</sub> and acetoin ('Custers effect', 'negative Pasteur effect'). Under aerobic conditions acetic acid is produced from glucose and from ethanol. Only some species can assimilate NO<sub>3</sub><sup>-</sup>. Species: *B. abstinens*, *B. anomalus*, *B. bruxellensis* (teleomorph: *Dekkera bruxellensis*), *B. clausenii*, *B. custersianus*, *B. custersii*, *B. intermedium* (teleomorph: *Dekkera intermedia*), *B. lambicus*, *B. naardensis*. ('*B. sphaericus*' = *Candida etchellsii*; '*B. versatilis*' = *Candida versatilis*.) Species occur in beers, wines (see WINE SPOILAGE), grape must etc. [Book ref. 100, pp. 562–576.]

**brevetoxins** Polycyclic toxins produced by the dinoflagellate *Ptychodiscus brevis* (see RED TIDE). Brevetoxins A, B and C each consist of 11 contiguous ether rings; they are highly lipid-soluble and are potent neurotoxins, causing depolarization of nerve membranes. [PAC (1986) 58 339–350 (346–347).]

**Brevibacterium** A genus of obligately aerobic, catalase-positive, asporogenous bacteria (order ACTINOMYCETALES, wall type III – see also PEPTIDOGLYCAN) which occur e.g. on certain cheeses. In culture the organisms initially grow as irregular, 'lumpy' rods, but coccoid forms predominate in the stationary phase; colonies vary from yellow to orange-red, though some strains produce pigment only in the light. Growth occurs at ca. 20–25°C e.g. on trypticase–soy agar containing 4% sodium chloride; metabolism is oxidative. GC%: ca. 60–64. Type species: *B. linens*.

**Brewer jar** An ANAEROBIC JAR which consists of a cylindrical glass chamber and a flat, gas-tight lid which is secured by means of a screw clamp. In use, the jar is filled with e.g. a mixture of N<sub>2</sub> (85%), CO<sub>2</sub> (5%) and H<sub>2</sub> (10%), and any residual O<sub>2</sub> is eliminated by means of an electrically-heated platinized catalyst which is fitted inside the lid and which is separated from the interior of the jar by a gauze safety screen. Alternatively, the jar may be used for the evacuation–replacement method as described for the MCINTOSH AND FILDES' ANAEROBIC JAR. Anaerobiosis within the jar is monitored e.g. with a tube containing a METHYLENE BLUE solution.

**Brewer's thioglycollate medium** A liquid medium (pH 7.0–7.2) used e.g. for the culture of ANAEROBES; it includes e.g. glucose, tryptone, agar (ca. 0.1%), sodium thioglycollate (a poisoning agent – see REDOX POTENTIAL), and a redox indicator dye. [Recipe: Book ref. 53, pp. 1409–1410.] The medium is particularly useful for testing the sterility of products which contain mercurial preservatives – the antimicrobial activity of the latter being neutralized by the thioglycollate.

**brewers' yeast** Any of various strains of *Saccharomyces cerevisiae* used for BREWING (q.v.); 'bottom-fermenting' strains (formerly called *Saccharomyces uvarum* or *S. carlsbergensis*; see SACCHAROMYCETES) are usually used in the manufacture of lagers, while 'top-fermenting' strains are usually used for ales. (Top- and bottom-fermenting strains can generally be distinguished by the ability of bottom yeasts to produce an extracellular melibiase (α-galactosidase) and thus to hydrolyse raffinose to glucose, galactose and fructose, whereas top yeasts – which do not produce melibiase – hydrolyse raffinose to melibiose and fructose.) Particular strains of yeast may be selected for particular properties (e.g. flavour production), but all brewers' yeasts must be able to ferment the sugars (particularly maltose and maltotriose) present in wort, and must be able to tolerate the initially high levels of solutes in wort and produce – and tolerate – high levels of ethanol under brewing conditions; the yeast must also be readily separable from the fermented wort (see BREWING) and should retain high viability for re-use in subsequent fermentations. [Selection and modification of brewers' yeast strains: *Food Mic.* (1984) 1 289–302.]

**brewing** The preparation of beer or lager by the fermentation of an aqueous extract of malted barley containing essential oils and bitter resins of the dried female flowers ('cones') of the hop (*Humulus lupulus*). During *malting* the barley is allowed to germinate, and the grain starch and protein are partially degraded by endogenous enzymes. Germination is halted by *kilning*: drying (e.g. to stop respiration, preserve enzymes and substrates etc), followed by heating (e.g. to ca. 80°C). The dried malt is ground (milled) to expose the starchy endosperm; the

## brick cheese

resulting *grist* is made into a *mash* by mixing with water. Other carbohydrate sources (*adjuncts*) may be added at this stage. The mash (pH 5.2–5.5) is subjected to controlled (variable) temperature–time cycles during which starch is broken down to fermentable sugars (glucose, maltose, maltotriose) and non-fermentable dextrins, proteins are degraded to amino acids and peptides, and phytin is hydrolysed to inorganic phosphate (which acts as a buffer) and inositol (an essential yeast growth factor). The liquor (*wort*) is separated from the spent grain and is boiled (with hops) to inactivate enzymes, coagulate proteins, destroy spoilage organisms etc. The hopped wort is cooled, aerated, and inoculated (*seeded* or *pitched*) with a pure culture of yeast: a strain of *Saccharomyces cerevisiae* (see BREWERS' YEAST). A lag period of ca. 12 h is followed by growth of the yeast. As oxygen is used up, metabolism switches from respiratory to fermentative, and sugars in the wort are converted to ethanol and CO<sub>2</sub> primarily via the EMBDEN–MEYERHOF–PARNAS PATHWAY. (Fermentation is exothermic, so the fermentation vessel must be cooled.) The formation of bubbles of CO<sub>2</sub> keeps the wort agitated and the yeast cells in suspension. At the end of the fermentation the yeast cells clump together – see FLOCCULATION (sense 2); in 'top-fermenting' strains of *S. cerevisiae* the clumps rise to the surface of the liquor, while those of 'bottom-fermenting' strains sediment. Most of the yeast is removed (e.g. by surface skimming of top yeasts or collection of sediment for bottom yeasts, and/or by centrifugation), and the beer is *matured* at low temperature (e.g. –1°C); residual yeast cells (a) carry out a 'secondary fermentation' of remaining maltotriose, and (b) reduce levels of diacetyl. H<sub>2</sub>S and acetaldehyde may be removed by purging with CO<sub>2</sub>. Finally, the beer is filtered, bottled or canned, and pasteurized. (See also BEER SPOILAGE.)

**brick cheese** See CHEESE-MAKING.

**Brie cheese** See CHEESE-MAKING.

**bright-field microscopy** See MICROSCOPY (a).

**brightener** See FLUORESCENT BRIGHTENER.

**Brill–Zinsser disease** See TYPHUS FEVERS.

**brilliant green** A yellowish-green TRIPHENYLMETHANE DYE which contains ethyl-substituted amino groups. It has antibacterial activity, inhibiting aerobic spore-formers more than anaerobic spore-formers.

**brilliant green agar** A selective medium used for salmonellae which have a broad host range (e.g. *S. typhimurium*); it contains e.g. lactose, phenol red, and brilliant green (selective agent). Lactose +ve colonies are green, lactose –ve colonies are pink.

**brinase** A fibrinolysin-like PROTEASE, obtained from *Aspergillus oryzae*, which can hydrolyse fibrin and fibrinogen and can lyse blood clots. (cf. STREPTOKINASE.)

**British anti-Lewisite** See BAL.

**brittleworts** See CHAROPHYTES.

**broad bean mottle virus** See BROMOVIRUSES.

**broad bean wilt virus** A virus which may be a member of the COMOVIRUSES but which has a wide host range and is transmitted by aphids.

**broad-range primers** Primers, used in PCR, which bind to highly conserved sequences found in the 16S rRNA gene in *all* bacteria; such primers can therefore be used to detect *any* species of bacterium whose 16S rRNA gene is accessible. Broad-range primers are also referred to as *universal primers*.

Broad-range primers are used e.g. to study bacterial diversity in environmental samples; the products are sequenced, and variable regions within the amplicon (which include species-specific sequences) are checked against the 16S rRNA database of known species in order to attempt identification of bacteria within the sample.

Some PCR-based studies use broad-range primers (simultaneously with other primers) as an amplification control [see e.g. JMM (1997) 46 773–778; JCM (1999) 37 2090–2092].

**broad-spectrum antibiotics** (1) ANTIBIOTICS active against a wide range of bacteria – including both Gram-positive and Gram-negative species. (2) Antibiotics active against a wide range of bacteria which may include Gram-positive species, Gram-negative species, or both.

**broccoli necrotic yellows virus** See RHABDOVIRIDAE.

**Brochothrix** A genus of Gram-positive, facultatively anaerobic bacteria; type species: *B. thermosphacta* (formerly *Microbacterium thermosphactum*) [JJSB (1976) 26 102–104]. *B. thermosphacta* is common e.g. in meat and meat products (see MEAT SPOILAGE). In young cultures cells are rod-shaped (occurring in chains), in older cultures they are small coccobacilli. Growth conditions: 0–30°C (optimum ca. 23–25°C); pH 5–9 (optimum ca. 7.0); all strains can grow in the presence of 6.5% NaCl, many in 10% NaCl. Tests: MR +ve; VP +ve; indole –ve; H<sub>2</sub>S –ve; nitrate is not reduced, catalase +ve e.g. on APT agar at 20°C, usually catalase –ve at 30°C. During aerobic growth *B. thermosphacta* forms cytochromes and can use glycerol or a range of carbohydrates as energy sources. Anaerobically, cytochromes are not formed, and glucose is fermented primarily to L-lactic acid, acetic acid, formic acid, and ethanol in proportions that vary with growth conditions [AEM (1983) 45 84–90]. In *meat* under aerobic conditions *B. thermosphacta* uses glucose and, when glucose is depleted, glutamate; under anaerobic conditions only glucose can be used. (See also STAA MEDIUM.)

[Review: Book ref. 29, pp. 139–173.]

**broken cream** See MILK SPOILAGE.

**bromatia** See FUNGUS GARDENS.

**bromocresol green** A PH INDICATOR: pH 3.8–5.4 (yellow to green); pK<sub>a</sub> 4.7.

**bromocresol purple** A PH INDICATOR: pH 5.2–6.8 (yellow to purple); pK<sub>a</sub> 6.3.

**brome mosaic virus** See BROMOVIRUSES.

**bromelain** A basic glycoprotein thiol PROTEASE (EC 3.4.22.4) obtained from the pineapple plant.

**bromoaplysiatoxin** See LYNGBYA.

**5-bromo-4-chloro-3-indolyl-β-D-galactoside** See XGAL.

**5-bromo-4-chloro-3-indolylphosphate-p-toluidine** See XP.

**bromochlorophane** See BISPHENOLS.

**bromocresol green** *Syn.* BROMOCRESOL GREEN.

**bromocresol purple** *Syn.* BROMOCRESOL PURPLE.

**5-bromodeoxyuridine** See BUDR.

**bromophenol blue** *Syn.* BROMPHENOL BLUE.

**bromothymol blue** *Syn.* BROMTHYMOL BLUE.

**5-bromouracil (BU)** A BASE ANALOGUE which, in the *keto* tautomeric form (which predominates), pairs with adenine (A) but in the *enol* form pairs with cytosine (C). Thus, during DNA synthesis, keto-BU may be incorporated into DNA in place of thymine (T); if it then remains in the keto form, BU will continue to mimic T and no mutation will occur, but if it switches to the enol form just prior to further DNA replication it will pair with guanine (G) instead of A, leading to an A-T-to-G-C transition. Conversely, enol-BU may be incorporated into DNA in place of C, and a subsequent switch to the keto form will result in a G-C-to-A-T transition on subsequent DNA replication.

**bromovinyldeoxyuridine (BVDU; (E)-5-(2-bromovinyl)-2'-deoxyuridine)** An ANTIVIRAL AGENT which is highly active against varicella-zoster virus; it is also active against herpes simplex virus (HSV) type 1 (but less so against HSV type 2) and

e.g. against pseudorabies virus, infectious bovine rhinotracheitis virus, and herpesvirus simiae. It can be administered topically or orally. BVDU is apparently converted to the 5'-monophosphate by the viral thymidine kinase; the monophosphate can be converted to the diphosphate by HSV type 1 thymidine kinase (cf. ACYCLOVIR).

**bromoviruses** (brome mosaic virus group) A group of tripartite ssRNA-containing PLANT VIRUSES, each of which infects a narrow range of plants; mechanical transmission can occur readily, and some members are transmitted by beetles. Type member: brome mosaic virus; other members: broad bean mottle virus; cowpea chlorotic mottle virus.

Virion: icosahedral, ca. 26 nm diam., containing a single species of coat protein. Genome: three molecules of linear, positive-sense ssRNA – RNA1 (MWt ca.  $1.1 \times 10^6$ ), RNA2 (MWt ca.  $1.0 \times 10^6$ ), and RNA3 (MWt ca.  $0.7 \times 10^6$ ); 'RNA4' (MWt ca.  $0.3 \times 10^6$ ), the coat protein mRNA, is also encapsidated. A given bromovirus particle may contain a molecule of RNA1, a molecule of RNA2, or one molecule each of RNA3 and RNA4; these different particles all have about the same  $S_{20}^W$  and all three are necessary for infectivity. The RNAs each have a capped 5' end and a tRNA-like structure (which accepts tyrosine) at the 3' end. Virus assembly occurs in the cytoplasm; crystalline arrays of virus particles and granular cytoplasmic inclusions may be formed.

**bromphenol blue** A PH INDICATOR: pH 3.0–4.6 (yellow to blue);  $pK_a$  4.0.

**bromthymol blue** A PH INDICATOR: pH 6.0–7.6 (yellow to blue);  $pK_a$  7.0.

**bromthymol blue agar** See BTB AGAR.

**bronchiolitis** Inflammation of the bronchioles. The disease occurs mainly in infants and is often due to human respiratory syncytial virus. Spread occurs by droplet transmission. The disease may be self-limiting or may lead to cyanosis, apnoea and death.

**bronchitis** Inflammation of the bronchi; the condition may be acute or chronic and often follows a (usually viral) upper respiratory tract infection. Bronchitis may be caused by bacteria (e.g. *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*), by viruses, or by physical or chemical irritants. Symptoms: chest pain, cough with mucoid to purulent sputum, fever etc.

**bronopol** See ALCOHOLS.

**bronze leaf wilt** *Syn.* HARTROT.

**brood pouch** (marsupium) In certain ciliates: a cavity, formed by invagination of the pellicle, within which 'larval' cells are formed by budding; in suctorians the brood pouch is a temporary structure, but in chonotrichs (in which it is also called a *crypt*) it is permanent. In some species the larval cells are released into the brood pouch, while in others the larval cells detach from the parent cell only after the pouch has everted.

**brooder pneumonia** See ASPERGILLOSIS.

**brosse** (*ciliate protozool.*) A tuft of cilia, of unknown function, which occurs on some gymnostomes.

**broth** In microbiology: any of a variety of liquid media – especially NUTRIENT BROTH or any liquid medium based on nutrient broth and/or hydrolysed protein.

**broth culture** See CULTURE.

**broth dilution test** See DILUTION TEST.

**broth sugars** See PEPTONE-WATER SUGARS.

**brown algae** Algae of the PHAEOPHYTA.

**brown blotch** A MUSHROOM DISEASE caused by *Pseudomonas tolaasii*. Caps and stalks of infected mushrooms are pitted

with wet lesions which become dark chocolate-brown. (cf. GINGER BLOTCH.) [Disease control by disinfection: JAB (1985) 58 259–281.]

**brown bodies** See LEPROSY.

**Brown–Boveri UV-C lamp** A source of high-intensity ULTRAVIOLET RADIATION; the lamp gives a radiation intensity of up to ca.  $1W/cm^2$ . (Conventional sources give up to ca.  $10 \mu W/cm^2$ .)

**Brown–Hopps modification** (of the GRAM STAIN) A procedure used for staining bacteria in deparaffinized, hydrated tissue sections. Essentially, sections are stained with crystal violet; washed; treated with Gram's iodine; washed; differentiated in acetone; washed; stained with basic fuchsin; washed; treated with Gallego's solution (an aqueous solution of formalin and acetic acid); washed; dipped in acetone, picric acid–acetone, and acetone; and finally transferred, via xylene, to the mountant. Gram-positive bacteria stain blue; Gram-negative bacteria stain red. [AJCP (1973) 60 234–240.]

**brown oak** Timber from an oak tree (*Quercus* sp) which has been infected by *Fistulina hepatica*; such infection causes the heartwood of the tree gradually to develop a rich brown colour. The colour appears to derive partly from pigment within the fungal hyphae and partly from extracellular fungal products. Brown oak is somewhat weaker than the normal wood, but it is valued e.g. for furniture-making.

**brown rot** (1) (of timber) A form of fungal TIMBER SPOILAGE in which the CELLULOSE and HEMICELLULOSES of the wood are decomposed while the LIGNIN remains virtually intact (although it may be modified), leaving the wood brown, soft and friable, and subject to cross-grain cracking. The hyphae of brown-rot fungi (e.g. *Piptoporus betulinus*, *Poria placenta*) penetrate the wood cell lumen and lie in contact with the inner surface of the cell wall; a generalized thinning of the wall occurs, suggesting a diffusion of degradative enzymes from the hyphae (cf. WHITE ROT). A novel mechanism has been proposed for the disruption of native cellulose by brown-rot fungi (which do not produce exoglucanases – see CELLULASES):  $H_2O_2$ , generated by the oxidation of hexoses by glucose oxidase, is believed to act in combination with  $Fe^{2+}$  (present in the wood) to oxidize glucopyranosyl residues, causing rupture of the cellulose chains; this could disrupt microfibrils sufficiently to allow access for endoglucanases [Book ref. 26, pp. 28–29; Book ref. 39, pp. 56–59].

(2) (of fruits) A rot which affects a wide variety of fruits – particularly apples, pears and stone fruits (cherries, plums etc) – both on the tree and in storage. Soft brown lesions develop in the fruits, initially beneath an intact epidermis; subsequently, whitish cottony pustules may develop, often in a concentric arrangement, and the fruit eventually shrivels and dries. Brown rots are caused by *Sclerotinia* spp: *S. fructigena* in e.g. apples, pears and almonds, *S. laxa* or *S. fructigena* in cherries, plums, peaches etc.

**brown rust** A disease of wheat and rye caused by *Puccinia recondita*; orange-brown pustules, later becoming dark or black, develop mainly on the upper (adaxial) leaf surface. On barley, a similar disease is caused by *Puccinia hordei*. (See also CEREAL DISEASES.)

**Browne's tubes** Sealed glass tubes containing a fluid which changes (irreversibly) from red to green when exposed to certain temperature/time combinations; they are used to monitor conditions at various positions within an operating AUTOCLAVE or hot-air oven. Type I and type II tubes are used in conventional autoclaves and high-vacuum autoclaves, respectively; type III is used in hot-air ovens, and type IV for monitoring exposures of ca.  $180^\circ C/12$  min. (cf. BROWN'S TUBES.)

## Brownian movement

**Brownian movement** *Random* movements made by small (ca. 1 µm) particles, or organisms, freely suspended in a fluid medium; the movements are due to bombardment of the particles by molecules of the medium. Brownian movement causes *non-motile* organisms to oscillate about more or less fixed positions; by contrast, *motile* organisms change their relative positions.

**Brown's tubes** A set of sealed glass tubes containing aqueous suspensions of barium sulphate in increasing concentrations; the tubes thus exhibit a range of optical densities which vary from transparent to turbid. Brown's tubes are used for standardizing microbial suspensions: the opacity of a given bacterial suspension is matched (visually) with that of a particular tube, and the suspension described e.g. as a Brown's number 2 or a Brown's number 5 suspension etc. (Higher numbers correspond to greater opacities.) The unknown suspension should be examined in a tube of size and thickness equivalent to those containing the standard suspensions.

**Brucella** A genus of Gram-negative, aerobic, chemoorganotrophic, catalase-positive bacteria which occur, typically as intracellular parasites or pathogens, in man and other animals (see BRUCELOSIS). The cells are non-motile bacilli, cocci or coccobacilli, ca. 0.5–0.7 × 0.6–1.5 µm, which stain well with conventional dyes (see also KOSTER'S STAIN). Metabolism is respiratory (oxidative). Growth requirements generally include certain amino acids, nicotinamide and thiamine; 5–10% CO<sub>2</sub> may be essential, particularly in primary isolation. Primary culture may be carried out on e.g. serum–glucose agar or chocolate agar; on primary isolation, 48-hour colonies on serum–glucose agar are typically 0.5–1.0 mm in diameter, shiny, convex and entire. Optimum growth temperature: 37°C. With the exception of *B. neotomae*, no species forms acid from carbohydrates in peptone-water sugars. MR –ve; VP –ve; most strains are oxidase +ve; most strains are urease +ve, but all strains of *B. ovis* are urease –ve (at 24 hours). The organisms are normally killed by pasteurization, are generally sensitive to tetracyclines, and are often sensitive e.g. to chloramphenicol, erythromycin and streptomycin. GC% ca. 55–58. Type species: *B. melitensis*.

Brucellae can be divided into smooth, rough and mucoid strains on the basis of their reaction in ACRIFLAVINE solution (0.1% aqueous): smooth strains are easily emulsifiable, rough strains agglutinate, and mucoid strains form stringy threads.

The brucellae are susceptible to a range of tailed, polyhedral DNA phages which have been divided into five groups that are used in phage typing (see e.g. TBILISI PHAGE, WEYBRIDGE PHAGE); group 5 phages include those which lyse non-smooth brucellae. (*Brucella* phages are sensitive to e.g. cationic detergents and oxidizing agents.)

The sensitivity of some brucellae to certain dyes, e.g. basic FUCHSIN and THIONIN, has been exploited for between-species and within-species differentiation; these dyes inhibit the growth of sensitive strains when incorporated in media at concentrations of ca. 1:50000 (w/v).

Differentiation between species and biovars is also achieved by the use of monospecific antisera prepared against each of the two main somatic antigens in the brucellae: the A and M antigens; an antiserum against rough strains (R) is used for *B. canis* and *B. ovis*.

*B. abortus*. Primarily a pathogen of bovines, but man and other animals can be infected; infection of pregnant animals commonly results in placentitis and abortion. All strains of *B. abortus* are lysed by Tbilisi phage at RTD – a characteristic which distinguishes this species from other brucellae. There are 9 biovars, biovars 1, 2 and 4 being sensitive to thionin,

biovar 2 to fuchsin. Biovars 4, 5 and 9 do not agglutinate in A antiserum; biovars 1, 2, 3 and 6 do not agglutinate in M antiserum. *B. abortus* 'strain 19' is similar to biovar 1 but has reduced virulence; it is used as a live vaccine for cattle.

*B. canis*. Primarily a pathogen of the dog, causing e.g. epididymitis, orchitis, prostatitis and the development of local granulomas; man is occasionally infected. Only rough or mucoid strains occur; these are agglutinated by R antiserum but not by A or M antisera. Insensitive to thionin; most strains sensitive to fuchsin. No biovars.

*B. melitensis*. Typically pathogenic in goats and sheep, but also in bovines, man and pigs. Insensitive to both fuchsin and thionin; biovar 1 is agglutinated by M antiserum, biovar 2 by A antiserum, and biovar 3 by both A and M antisera.

*B. neotomae*. A non-pathogenic or weakly pathogenic species. Acid (no gas) is formed from arabinose, galactose, glucose and xylose. Sensitive to both fuchsin and thionin, and agglutinated by A antiserum. No biovars.

*B. ovis*. A pathogen of sheep, causing epididymitis/orchitis, or abortion in pregnant ewes. Insensitive to thionin; most strains sensitive to fuchsin. No biovars. Smooth strains unknown; agglutination by R antiserum only.

*B. suis*. Primarily a pathogen of pigs, but most or all strains can also infect man; other hosts include e.g. dogs and hares. Insensitive to thionin; most strains sensitive to fuchsin, but biovar 3 is insensitive. Biovars 1–4 are agglutinated by A antiserum; 4 is also agglutinated by M antiserum, and 5 is agglutinated only by M antiserum.

An early proposal to include all strains of *Brucella* in a single species (*B. melitensis*) [JSB (1985) 35 292–295] has not been accepted.

**Brucella ring test** *Syn.* MILK RING TEST.

**brucellin** An antigenic material derived from cultures of *Brucella* spp.

**brucellin test** A SKIN TEST, analogous to the TUBERCULIN TEST, used for detecting *Brucella*-induced hypersensitivity (cf. BRUCELOSIS).

**brucellosis** Any human or animal disease caused by *Brucella* spp. In animals the reproductive organs are generally affected, often resulting in abortion (*contagious abortion*). *B. abortus* is the usual causal agent in cattle, *B. suis* in pigs, *B. melitensis* in goats, *B. ovis* in sheep, and *B. canis* in dogs, but host specificity is not absolute. Contagious abortion in cattle (*Bang's disease*) may follow infection via the mouth, vagina or wounds; the pathogen has a predilection for the udder (resulting in its presence in the milk) and for fetal and placental tissues (its growth apparently being stimulated by erythritol present in these tissues).

In man brucellosis (*undulant fever*, *Malta fever*) is an acute or chronic systemic disease contracted from animals via unpasteurized milk, infected carcasses, etc; *B. abortus*, *B. melitensis* or *B. suis* is most commonly involved. Infection occurs via the mouth, conjunctivae or wounds. Incubation period: days, weeks or months. Symptoms: variable, but typically include headache, malaise, and intermittent periods of fever. Untreated cases may persist for years. (In individuals frequently exposed to *Brucella* spp disease may be due to hypersensitivity to *Brucella* antigens rather than to true infection.) *Lab. diagnosis*: (i) Blood culture (usually positive if blood is taken at the height of the fever). (ii) Culture of bone marrow or lymph node aspirates (may be useful in chronic cases). (iii) Serological assay for specific serum agglutinins. (N.B. Agglutinins against cholera vibrios cross-react

- with those against *Brucella* spp.) *Chemotherapy*: e.g. tetracyclines with streptomycin. (See also BRUCCELLIN TEST and MILK RING TEST.)
- Bryopsis** A genus of siphonaceous green seaweeds (division CHLOROPHYTA) which exhibit a heteromorphic alternation of generations (cf. DERBESIA).
- Bryoria** A genus of fruticose LICHENS (order LECANORALES) separated from ALECTORIA e.g. on the basis of the smaller colourless ascospores (8 per ascus).
- BSA** Bovine serum albumin.
- BS-C-1** An ESTABLISHED CELL LINE derived from the kidney of an African green monkey (*Cercopithecus aethiops*); the cells are heteroploid and epithelioid.
- BSE** BOVINE SPONGIFORM ENCEPHALOPATHY.
- BSS** BALANCED SALT SOLUTION.
- BssHII** See RESTRICTION ENDONUCLEASE (table).
- BstEII** A RESTRICTION ENDONUCLEASE from *Bacillus stearothermophilus*; G/GTNACC.
- BTB agar** (bromthymol blue agar) A medium (used e.g. for enterobacteria) containing e.g. peptone, lactose, glucose, yeast extract, MARANIL, thiosulphate, and bromthymol blue; pH: 7.7–7.8. [Recipe: Book ref. 22, p. 421.]
- BTEX** Benzene, toluene, ethyl-benzene and xylene – a group of compounds which are sometimes present as contaminants in aquifers. (See also BIOREMEDIATION.)
- BtuB protein** In *Escherichia coli*: an OUTER MEMBRANE protein encoded by the *btuB* gene; it acts as a receptor for bacteriophage BF23 and for various colicins, and is involved in the uptake of VITAMIN B<sub>12</sub>.
- BtuC protein** See VITAMIN B<sub>12</sub>.
- BU** 5-BROMOURACIL.
- bubble column fermenter** A FERMENTER in which mixing and circulation of the culture is induced by a stream of bubbles introduced at the base of the column (which lacks a draft tube – cf. LOOP FERMENTER); it may be used e.g. with low-viscosity cultures when efficient mixing is not essential. An increased gas–liquid interface can be achieved by placing mesh sieve plates at intervals in the column.
- bubble diseases** MUSHROOM DISEASES caused by *Verticillium fungicola* (dry bubble) or *Mycogone perniciosa* (wet bubble). [Control by PROCHLORAZ and other antifungals: PP (1983) 32 123–131.]
- bubble point test** A test used to determine the physical integrity of a membrane filter (see FILTRATION). In a wetted membrane, water is retained in the pores by the forces of surface tension, and a considerable pressure of air is needed to dislodge this water and to force air through the pores; the minimum pressure which can do this (the bubble point pressure) increases with decrease in pore size, and is about 55 lb/inch<sup>2</sup> (379 kPa) for a membrane of pore size 0.22 µm. Using the relationship between bubble point pressure and pore size, the integrity of a membrane of given pore size can be tested by determining its bubble point pressure. (cf. DIFFUSION TEST.)
- bubbler** *Syn.* ALL-GLASS IMPINGER.
- bubo** An enlarged, inflamed lymph node (particularly in the axilla or groin) formed e.g. in bubonic PLAGUE.
- bubonic plague** See PLAGUE.
- buccal cavity** In some ciliates: a cavity, chamber or surface depression which is typically open to the environment and which contains, at its base, the CYTOSTOME; the ciliature of the buccal cavity is typically readily distinguishable from the somatic ciliature. (See also e.g. PARORAL MEMBRANE.)
- buccal overture** The entrance (outer or distal region) of the BUCCAL CAVITY.
- buccokinetal stomatogenesis** See STOMATOGENESIS.
- Buchnera** A genus of intracellular bacteria found in the BACTERIOCYTES of aphids; aphids and *Buchnera* are mutually dependent – neither can reproduce without the other.
- The chromosome of *Buchnera* sp APS is one of the smallest to be sequenced so far in bacteria (a total of 640681 base pairs) [Nature (2000) 407 81–86].
- bud-fission** In certain fungi (e.g. *Saccharomyces ludwigii*): a form of BUDDING in which the septum between bud and parent cell is almost as wide as the widest part of the parent cell.
- bud scar** (*mycol.*) See SCAR.
- budding** (1) (*bacteriol., mycol.*) In certain bacteria and fungi: a process of cell division in which a daughter cell (or spore) develops from the mother cell as a localised outgrowth or protrusion (*bud*), the cell wall of the mature daughter cell apparently being composed mainly of newly synthesized material; mother and daughter cells are often physically, and sometimes functionally, distinguishable. (cf. FISSION.) In the BUDDING BACTERIA, budding often – but not always – occurs at one of the poles of the mother cell. In some fungi (e.g. *Saccharomyces cerevisiae*) buds may arise at any of a number of sites on the parent cell (*multipolar budding*); in e.g. *Kloeckera*, buds can develop at both cell poles (*bipolar budding*), while in *Malassezia* they can arise only at one pole (*monopolar budding*). (cf. TRIGONOPSIS; see also BUD-FISSION, SCAR and SPROUT MYCELIUM.)
- (2) (*protozool.*) In some protozoa (e.g. members of the Astomatida, Peritrichia and Suctoria): a reproductive process in which a cell divides unequally to form a large adult and small progeny cells (external or exogenous budding), or in which progeny develop within the cytoplasm of the adult cell (interior or endogenous budding).
- (3) (*virol.*) See ENVELOPE (sense 1).
- budding bacteria** A diverse, non-taxonomic group of bacteria all of which undergo BUDDING; they include e.g. species of BLASTOBACTER, CHAMAESIPHON, ENSIFER, GEMMIGER, GEODERMATOPHILUS, *Hyphomicrobium*, HYPHOMONAS, NITROBACTER, PASTEURIA, PLANCTOMYCES, RHODOMICROBIUM, RHODOPSEUDOMONAS and SELIBERIA.
- budgerigar fledgling disease virus** A virus which causes a commercially important acute, fatal disease in fledgling budgerigars (*Melopsittacus undulatus*) and may also be responsible for a milder, chronic disease ('French moult') in older birds. The virus is apparently a POLYOMAVIRUS – the first non-mammalian polyomavirus to be recorded. [Virology (1986) 151 362–370.]
- BUdR** (BrdU) 5-Bromo-2'-deoxyuridine: the deoxynucleoside corresponding to 5-BROMOURACIL. It can be phosphorylated by THYMIDINE KINASE. (cf. IDOXURIDINE.)
- Buellia** A genus of crustose LICHENS (order LECANORALES). Apothecia: lecideine, black; ascospores brown, one-septate. (cf. DIPLOICIA; see also ENDOLITHIC.)
- buffalopox virus** See ORTHOPOXVIRUS.
- buffy coat** The thin layer of white cells which forms at the surface of the packed red cells when unclotted blood is centrifuged.
- bufotenine** See AMATOXINS.
- bulbil** (*algol.*) See CHAROPHYTES.
- Bulbochaete** A genus of freshwater filamentous green algae related to OEDOGONIUM. The filaments are branched and bear long, colourless 'hairs', each with a bulbous base.
- Bulgaria** See HELOTIALES.
- Bulgarian buttermilk** *Syn.* BULGARICUS MILK.
- Bulgarian milk** (Bulgarian buttermilk) A beverage made by fermenting milk with *Lactobacillus bulgaricus*.

## bulgecin

**bulgecin** A low-MWt glycopeptide which, in combination with a  $\beta$ -lactam antibiotic, causes bulge formation in susceptible bacterial cells [AAM (1986) 31 181–205 (200–201)].

**bullate** With bubble- or blister-like swellings.

**Buller phenomenon** A form of DIKARYOTIZATION in which a dikaryotic cell or mycelium donates a nucleus to a monokaryotic (haploid) cell or mycelium.

**Bullera** A genus of fungi (see SPOROBOLOMYCETACEAE) which form spheroidal, ovoid or elongate, budding vegetative cells, and which may form pseudomycelium or true mycelium; the cell walls contain xylose. On malt agar, the growth is cream-coloured to slightly yellowish or brownish (cf. SPOROBOLOMYCETES). Ballistospores are formed on sterigmata of varying lengths and are rotationally symmetrical, being spheroidal, obovoid, turbinate, apiculate or ampulliform. Metabolism is strictly respiratory.  $\text{NO}_3^-$  is assimilated by *B. piricola* and *B. tsugae*, but not by *B. alba*, *B. dendrophila* or *B. singularis*. Species have been isolated from insect frass and plant material. [Book ref. 100, pp. 577–584.]

**bullous impetigo** See IMPETIGO.

**bumblefoot** An arthritis of poultry due to infection via wounds – particularly in the feet – by *Staphylococcus aureus*. (See also POULTRY DISEASES.)

**bumper primer** See SDA.

**bundle-forming pili** See PATHOGENICITY ISLAND.

**bundlin** The major subunit of bundle-forming pili (see EPEC) – a 19.5 kDa protein encoded by the ‘EPEC adherence factor plasmid’ (EAF plasmid) found in strains of EPEC. (See also PATHOGENICITY ISLAND.)

**bunts** (stinking smuts) See e.g. COMMON BUNT and KARNAL BUNT.

**Bunyamwera supergroup** See BUNYAVIRUS.

**Bunyaviridae** A family of enveloped, ssRNA VIRUSES which infect warm- and cold-blooded vertebrates, arthropods and plants. Some members are important pathogens of man and animals, causing e.g. VIRAL HAEMORRHAGIC FEVERS or pulmonary disease; transmission may occur e.g. via ticks, mosquitoes or sandflies (*Phlebotomus* spp), while some bunyaviruses are transmitted in aerosols. (See also TOMATO SPOTTED WILT VIRUS; cf. ARBOVIRUSES.)

**Virion.** Roughly spherical, enveloped, ca. 90–100 nm diam., containing three major protein species (nucleocapsid protein N, and glycoproteins G1 and G2), one large but minor protein (L), and three molecules/segments of negative sense (or ambisense) ssRNA designated L, M and S (MWts ca. 2–5, 1–2.3 and  $0.3\text{--}0.8 \times 10^6$  respectively); the envelope contains ca. 20–30% by weight of lipid.

**Virion structure.** The lipoprotein envelope, which contains G1 and G2, encloses three circular (but not covalently closed) helical strands of ribonucleoprotein (comprising RNA and N protein); the haemagglutinating activity and neutralizing antigenic determinants are associated with the glycoproteins. Virions can be inactivated by e.g. lipid solvents and detergents.

Transcriptase activity is associated with the virions, and viral replication occurs in the cytoplasm of the host cell.

In the genus *Bunyavirus*, all three genome segments are negative-sense. The S RNA segment encodes (in overlapping reading frames) the N protein and a non-structural protein ( $\text{NS}_s$ ). The M RNA segment encodes G1, G2 and at least one non-structural protein ( $\text{NS}_m$ ). The L RNA appears to encode the L protein. (cf. PHLEBOVIRUS.) During maturation, the virions bud into smooth-surfaced vesicles in or near the Golgi region.

In culture, some bunyaviruses can induce cell fusion.

The family is divided into genera on the basis of e.g. size of RNA segments, size and nature of viral proteins, nature of

arthropod vector (if any) etc.; the genera include BUNYAVIRUS; HANTAVIRUS; NAIROVIRUS; PHLEBOVIRUS and UUKUVIRUS.

**Bunyavirus** (‘Bunyamwera supergroup’) A genus of viruses of the BUNYAVIRIDAE. Host range: various vertebrates; vectors: mainly mosquitoes. MWts of L, M and S RNAs: ca. 2.7–3.1, 1.8–2.3, and  $0.28\text{--}0.50 \times 10^6$ , respectively. MWts of proteins L, G1, G2 and N: ca. 145–200, 108–120, 29–41 and  $19\text{--}25 \times 10^3$ , respectively. The genus comprises at least 16 serological groups, including the Bunyamwera group (e.g. Bunyamwera virus (type species of the genus), Cache Valley virus), the California group (e.g. CALIFORNIA ENCEPHALITIS virus, Inkoo virus, La Crosse virus, snowshoe hare virus), and the Simbu group (e.g. Aino virus, Akabane virus – see AKABANE VIRUS DISEASE).

**bunyaviruses** (1) Viruses of the BUNYAVIRIDAE. (2) Viruses of the genus BUNYAVIRUS.

**buoyant density** See CENTRIFUGATION.

**burdock stunt viroid** See VIROID.

**burdock yellows virus** See CLOSTEROVIRUSES.

**Burdon’s stain** A stain for bacterial intracellular lipid. A heat-fixed smear is stained with SUDAN-BLACK B for 5–10 min, drained, and blotted dry. The smear is washed in xylene, blotted dry, and counterstained for 5–10 sec in 0.5% aqueous safranin. Lipid stains black, cytoplasm red. (See also NILE BLUE A.)

**Burgundy mixture** (*plant pathol.*) An agricultural antifungal preparation which consists of a mixture of copper sulphate and sodium carbonate; it is used in aqueous solution as a spray. Active constituent: the COPPER ion.

**Burgundy truffle** See TRUFFLES.

**Burkard trap** See HIRST SPORE TRAP.

**Burkea** See MICROSPORA.

**Burkholderia** A genus of Gram-negative bacteria initially proposed to accommodate seven (group II) species from the genus PSEUDOMONAS, with *Burkholderia* (formerly *Pseudomonas*) *cepacia* as the type species [Microbiology and Immunology (Tokyo) (1992) 36 1251–1275]; the other species in this proposal were: *P. mallei*, *P. pseudomallei*, *P. caryophylli*, *P. gladioli*, *P. pickettii* and *P. solanacearum*. Two other former species of the genus *Pseudomonas* (*P. plantarii* and *P. glumae*), and a new species, *B. vandii*, have since been added to the genus [IJSB (1994) 44 235–245].

(See also CYSTIC FIBROSIS.)

[*B. cepacia* (surface chemistry and typing methods): RMM (1995) 6 1–9. *B. cepacia* (pathogenicity and resistance to antibiotics): RMM (1995) 6 10–16.]

**Burkitt’s lymphoma** (BL) A malignant monoclonal B-cell lymphoma which is endemic in parts of Africa where it is the most common tumour among children. The tumours commonly develop in the mandibular and maxillary bones, but may also develop in the ovaries, thyroid, kidneys, heart, stomach, and spinal column. BL is associated with EPSTEIN-BARR VIRUS (EBV) infection, but other factors – including the occurrence of malaria – are also important in pathogenesis. BL cells contain multiple copies of the EBV genome, and also show characteristic chromosomal rearrangements involving reciprocal translocations between chromosome 8 and chromosome 14 or, less frequently, chromosome 2 or 22. These translocations apparently result in the juxtaposition of a cellular ONCOGENE (*c-myc*, or possibly *c-mos*) and the immunoglobulin (Ig) genes on chromosomes 14, 2 or 22; *c-myc* may be activated by the Ig gene promoter, resulting in oncogenesis. These chromosomal rearrangements can occur in the absence of EBV; EBV may predispose to oncogenesis by its mitogenic effect on B cells, providing large numbers of transformed cells and thereby increasing the chances

of one of the three chromosomal rearrangements occurring. Chronic malaria depresses EBV-specific cell-mediated immunity and stimulates B cell proliferation, thus potentiating the effects of EBV. 'Burkitt-like' lymphomas occur rarely and sporadically outside the endemic areas, and only ca. 20% of these are associated with EBV infection.

**burned spot disease** (shell disease; *Brandenfleckenkrankheit*) A marine CRUSTACEAN DISEASE which affects the exoskeletons of crabs, lobsters, crayfish etc; it is caused by chitinolytic bacteria and/or fungi which form brown erosive lesions in the calcified chitin of the exoskeleton following damage to the epicuticle (e.g. by abrasion). Once initiated, the lesions may support a varied microbial flora. The disease may be fatal, but recovery may occur if the animal survives to ecdysis. *Fusarium solani* has been associated with the disease in lobsters; the fungus may penetrate the muscles and occasionally the foregut of the lobster [TBMS (1981) 76 25–27]. (cf. BLACK GILL DISEASE.)

**Burnet's clonal selection theory** See CLONAL SELECTION THEORY.

**bursa of Fabricius** In birds, a sac-like organ which develops from the hindgut in the early embryonic stage; within the bursa, precursors of B LYMPHOCYTES appear to undergo maturation. (See also INFECTIOUS BURSAL DISEASE VIRUS.)

**Bursaria** See HETEROTRICHIDA.

**bursattee** *Syn.* EQUINE PHYCOMYCOSIS.

**burst size** The average number of virus particles released per infected cell following the lytic infection of a population of sensitive cells; it may be determined e.g. by the ONE-STEP GROWTH EXPERIMENT (by comparing the latent period plaque count with the plateau plaque count) or by the SINGLE BURST EXPERIMENT.

**burst test** A test used for assessing the strength of the seal in a RETORT POUCH; in the test, the pouch is either inflated or is filled with water and then compressed.

**Bursulla** See MYXOMYCETES.

**Buruli ulcer** A chronic, progressive, granulomatous skin lesion caused by *Mycobacterium ulcerans*; infection occurs via wounds.

**Buschke–Löwenstein tumour** (giant condyloma acuminatum) A large, cauliflower-like, malignant but non-metastasizing genital tumour of humans. The genomes of HPV-6 or HPV-11 (see PAPILOMAVIRUS) have been identified in Buschke–Löwenstein tumour cells [see e.g. JV (1986) 58 963–966]. (cf. PAPILOMA.)

**Busse–Buschke disease** *Syn.* CRYPTOCOCCOSIS.

**Bussuquara virus** See FLAVIVIRIDAE.

**butanediol fermentation** (butylene glycol fermentation) A FERMENTATION (sense 1) carried out e.g. by certain enterobacteria, including species of *Enterobacter*, *Erwinia*, *Klebsiella* and *Serratia*. The main products of glucose fermentation include ethanol, 2,3-butanediol and formic acid or CO<sub>2</sub> and H<sub>2</sub> [Appendix III(f)]; small amounts of DIACETYL (CH<sub>3</sub>.CO.CO.CH<sub>3</sub>) may also be formed from acetolactate. Organisms which form diacetyl or acetoin give a positive VOGES–PROSKAUER TEST. The amount of acid produced in the butanediol fermentation is generally insufficient to give a positive methyl red test (cf. MIXED ACID FERMENTATION).

**butanol fermentation** *Syn.* ACETONE–BUTANOL FERMENTATION.

**butirosin** An AMINOGLYCOSIDE ANTIBIOTIC.

**butoconazole** See AZOLE ANTIFUNGAL AGENTS.

**Bütschli's granules** METACHROMATIC GRANULES observed in diatoms.

**butt** (*microbiol.*) The thickest part of a SLOPE. The butt of a freshly-prepared slope is a microaerobic or anaerobic environment.

**butt rot** A TREE DISEASE in which the base (butt) of the trunk rots. In e.g. elms (*Ulmus* spp) a butt rot may be caused by

*Rigidoporus ulmarius*, while in oaks (*Quercus* spp) it may be caused by *Inonotus dryadeus* (*Polyporus dryadeus*).

**butter** A food consisting mainly of the fatty components of milk; it contains at least 80% fat, up to 16% water, and usually ca. 2% added salt. *Sweet cream butter* is made without a bacterial starter. Cream is pasteurized, cooled, and churned at ca. 8–12°C to destabilize the fat globules in the cream. The butter is then strained from the aqueous phase (buttermilk) and salted; it may be stored for a year or more at ca. –23 to –29°C. *Ripened cream butter* (*cultured creamery butter*) is made from pasteurized cream seeded with a B- or BD-type LACTIC ACID STARTER. The main function of the bacteria is to contribute flavour (LACTIC ACID and DIACETYL). After several hours' incubation, during which the pH falls to ca. 4.6, the cream is cooled, churned etc. Cultured butters are more common in e.g. Europe than in the USA; they have better flavour than sweet cream butter, but they also undergo chemical deterioration faster – the rate of deterioration being higher if salt is added. (See also DAIRY PRODUCTS.)

Butter is generally resistant to microbial spoilage owing to its low water content. However, proteolytic and/or lipolytic psychrotrophs (e.g. *Pseudomonas fragi*, *Ps. fluorescens*) can cause putrid or rancid flavours in refrigerated butter. A cheese-like off-flavour ('surface taint') may be caused by '*Ps. putrefaciens*', and '*Ps. nigrificiens*' can cause a black surface discoloration.

**buttermilk** Originally: the liquid residue formed during BUTTER-making. Currently, the term usually refers to 'cultured buttermilk': a beverage made by fermenting skim milk with lactic acid bacteria; a BD-type LACTIC ACID STARTER is usually used. [Book ref. 8, pp. 140–143.] (See also DAIRY PRODUCTS.)

**button stage** The (early) stage of an agaric fruiting body in which the lamellae are not yet exposed, and the pileus is roughly dome-shaped.

**butyl alcohol fermentation** *Syn.* ACETONE–BUTANOL FERMENTATION.

**butylene glycol fermentation** *Syn.* BUTANEDIOL FERMENTATION.

**butyric acid fermentation** A FERMENTATION (sense 1) carried out e.g. by *Butyrivibrio fibrisolvens*, certain species of CLOSTRIDIUM (e.g. *C. acetobutylicum*, *C. butyricum*, *C. pasteurianum*, *C. perfringens*) and *Fusobacterium nucleatum*. The products of glucose fermentation include acetic and butyric acids, CO<sub>2</sub> and H<sub>2</sub> [Appendix III(g)]; some species (e.g. *C. perfringens*) form lactic acid and/or ethanol in addition to the above products – lactic acid becoming a major product under conditions of iron deficiency. (See also ACETONE–BUTANOL FERMENTATION.)

**butyricins** See BACTERIOCIN.

**Butyrivibrio** A genus of bacteria (family BACTEROIDACEAE) which occur e.g. in the RUMEN and in non-ruminant faeces. Cells: motile or (infrequently) non-motile curved rods, 0.3–0.8 × 1.0–5.0 μm (occurring singly or in chains), or filaments which are sometimes helical; the cells stain Gram-negatively, although the cell wall of *B. fibrisolvens* is of the Gram-positive type (see also TEICHOIC ACIDS). [Heterogeneity in cell envelopes of *Butyrivibrio* strains: JUR (1985) 90 286–293.] Fermentation of e.g. glucose or maltose typically yields butyric acid as the main product (although lactic acid may be the major product under certain conditions). Some strains are cellulolytic, pectinolytic and/or amylolytic. GC%: ca. 36–41. Type species: *B. fibrisolvens*.

*B. crossotus*. Cells are lophotrichously flagellated. Maltose is fermented, but cellobiose, sucrose and xylose are not.

*B. fibrisolvens*. The cells each have one polar or subpolar flagellum. Glucose, maltose, cellobiose, sucrose and xylose are fermented.

**butyrolactone antifungal agents**

**butyrolactone antifungal agents** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**butyrous** Butter-like in consistency.

**BVD** BOVINE VIRUS DIARRHOEA.

**BVD-MD virus** See PESTIVIRUS.

**BVDU** BROMOVINYLDEOXYURIDINE.

**bvg genes** In *Bordetella* spp: genes of a TWO-COMPONENT REGULATORY SYSTEM controlling the synthesis of various virulence factors (adhesins, toxins); *bvgS* encodes the histidine kinase, while *bvgA* encodes the response regulator. It is not known which signal(s) activate the system in vivo; in vitro it can be regulated e.g. by temperature.

**BWD** See PULLORUM DISEASE.

**BWYV** Beet western yellows virus (see LUTEOVIRUSES).

**BYDV** Barley yellow dwarf virus (see LUTEOVIRUSES).

**byssinosis** A human pulmonary disease, associated with the handling of cotton, flax, hemp or sisal, characterized by acute

symptoms of airway obstruction; aetiology may involve e.g. the endotoxins and/or allergens from contaminating Gram-negative bacteria. [AEM (1982) 44 355–362; CIA (1984) 4 45–47.]

**Byssochlamys** A genus of fungi (order EUROTIALES) found e.g. in soil; anamorphs occur in the genus PAECILOMYCES. The mature ascocarp consists of a group of asci surrounded by a few wisps of hyphae. *B. fulva* can cause spoilage of canned foods (see CANNING); the organism forms extracellular pectinases, and its ascospores can withstand ca. 85°C for 30 minutes, and higher temperatures for shorter periods. (See also PATULIN.)

**byssoid** Composed of slender fibrils.

**bystander help** (*immunol.*) Non-specific help; for example, an antigen-stimulated T cell may provide help (in the form of cytokines) for another cell which has been stimulated by a different antigen.

**bystander lysis** *Syn.* REACTIVE LYSIS.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# C

**C** (1) (*immunol.*) COMPLEMENT. (2) (*mol. biol.*) Cytosine (or the corresponding nucleoside or nucleotide) in a nucleic acid. (3) Cysteine (see AMINO ACIDS).

$\bar{c}$  See C VALUE.

**C'** (*immunol.*) COMPLEMENT.

**1-C compounds** See C<sub>1</sub> COMPOUNDS.

**C forms** See AZOSPIRILLUM.

**C loop** See BACTERIOPHAGE P1.

**c-onc** See ONCOGENE.

**C period** See HELMSTETTER-COOPER MODEL.

**C-reactive protein (CRP)** An ACUTE-PHASE PROTEIN, increased amounts of which circulate in the body e.g. during inflammatory processes. CRP is precipitated by so-called *C-reactive substances* which occur in various microorganisms – e.g. *Streptococcus pneumoniae* (the basis of the C-reactive protein diagnostic test) and *Aspergillus fumigatus*. [Binding of CRP to C-reactive substance of *Aspergillus fumigatus*: JMM (1986) 21 173–177.]

Changes in CRP titre may help to distinguish between bacterial and viral infections: a rise in the serum level of CRP is more likely to reflect a bacterial infection because viral infections usually do not produce such a change.

**C-reactive substance** See C-REACTIVE PROTEIN. (cf. C SUBSTANCES.)

**C region (of Ig)** See IMMUNOGLOBULINS.

**C ring** See FLAGELLUM (a).

**c strand (C strand)** Complementary strand, e.g., the strand complementary to the genomic (viral, v) strand in the RF of an ssDNA virus. (cf. CDNA.)

**C substances (of streptococci)** A range of serologically distinct carbohydrates – typically only one of which occurs in a given strain of *Streptococcus*; C substances are used in LANCEFIELD'S STREPTOCOCCAL GROUPING TEST. In the majority of Lancefield groups the C substance is a CELL WALL component. In Lancefield group A streptococci the C substance is a rhamnose polymer with a terminal residue of *N*-acetylglucosamine, the latter being immunodominant; in strains of group B the main determinant appears to be rhamnose, while in those of group C it is a terminal residue of *N*-acetylgalactosamine. [Structure of the C substance in group B streptococci: Biochem. (1987) 26 476–486.] The C substance of group D strains, a glycerol TEICHOIC ACID, occurs in the periplasmic region.

C substances may be extracted from cells by various methods. In the hot-HCl method (Lancefield extraction method), packed (centrifuged) cells of the strain under test are resuspended in ca. 0.3 ml of a solution of sodium chloride (0.85%) containing HCl (at a final concentration of 0.2 N) and one drop of the pH indicator metacresol purple (0.04%); the pH should be ca. 2 (pink coloration). The tube containing the suspension is placed in boiling water for ca. 10 min with periodic shaking. The tube is then centrifuged, and the supernatant is decanted into a clean vessel; NaOH (0.2 N) is added dropwise until the pH is ca. 7.5 (weak purple).

In the simpler autoclave extraction method, packed cells are re-suspended in 0.5 ml of NaCl solution (0.85%), autoclaved (121°C/15 min), centrifuged, and the supernatant is used for the test.

[Methods of preparing antigen extracts for Lancefield grouping: Book ref. 120, pp. 170–172.]

**C-type particles** See TYPE C ONCOVIRUS GROUP.

**C value (C-value;  $\bar{c}$ )** The amount of DNA in a *haploid* genome; it can be measured e.g. in picograms or in terms of the molecular weight or the number of constituent kilobase-pairs.

**C<sub>0</sub>** In the food processing industry: heating (COOKING) for 1 min at 100°C or an equivalent amount of heat processing.

**C<sub>1</sub> cellulase** See CELLULASES.

**C<sub>1</sub> compounds (1-C compounds; one-carbon compounds)** Carbon compounds which contain no carbon-carbon bonds and which are more reduced than is CO<sub>2</sub> – e.g. CO, methane, methanol, formaldehyde, formamide and formate; C<sub>1</sub> compounds may have more than one carbon atom: e.g. dimethyl sulphide [(CH<sub>3</sub>)<sub>2</sub>S], dimethyl sulphoxide [(CH<sub>3</sub>)<sub>2</sub>SO], dimethyl sulphone [(CH<sub>3</sub>)<sub>2</sub>SO<sub>2</sub>], trimethylamine-*N*-oxide [(CH<sub>3</sub>)<sub>3</sub>NO]. (See also METHYLOTROPHY.)

**C1 esterase inhibitor** See COMPLEMENT FIXATION (a).

**C1EI** See COMPLEMENT FIXATION (a).

**C1INH** *Syn.* C1EI – see COMPLEMENT FIXATION (a).

**C<sub>2</sub> carbon oxidation cycle** See PHOTORESPIRATION.

**C2a pathway** See COMPLEMENT FIXATION (d).

**C3 convertase** See COMPLEMENT FIXATION.

**C<sub>3</sub> cycle** *Syn.* CALVIN CYCLE.

**C3bina (C3bINA)** *Syn.* FACTOR I.

**C5 convertase** See COMPLEMENT FIXATION.

**C27 organisms** See PLESIOMONAS.

**C<sub>55</sub> lipid carrier** *Syn.* BACTOPRENOL.

**Ca<sup>2+</sup>-ATPase** See ION TRANSPORT.

**Ca<sup>2+</sup>, Mg<sup>2+</sup>-stimulated ATPase** See ATPASE.

**Ca<sup>2+</sup> transport** See ION TRANSPORT.

**Cabassou virus** See ALPHAVIRUS.

**cabbage B virus** *Syn.* CAULIFLOWER MOSAIC VIRUS.

**cabbage diseases** See CRUCIFER DISEASES.

**cabinet (safety cabinet)** See SAFETY CABINET.

**cacao diseases** For diseases of the cacao plant (*Theobroma cacao*) see e.g. BLACK POD DISEASE, FUSARIUM (*F. decemcellulare*), POD ROT, RED RUST, VASCULAR-STREAK DISEASE and WITCHES' BROOM.

**cacao yellow mosaic virus** See TYMOVIRUSES.

**Cache Valley virus** See BUNYAVIRUS.

**cachectin** An early name for tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ).

**cacodylate** Dimethylarsinate.

**cactus virus 2** See CARLAVIRUSES.

**cactus virus X** See POTEXVIRUSES.

**CAD** See APOPTOSIS.

**cAD1** See PHEROMONE.

**cadang-cadang** See COCONUT CADANG-CADANG VIROID.

**cadaverine** See e.g. DECARBOXYLASE TESTS.

**cadherins** A family of CELL ADHESION MOLECULES. The cadherins are large, transmembrane glycoproteins that mediate calcium-dependent *homophilic* cell-cell adhesion (i.e. cadherin binds to cadherin). The intracellular domain of the cadherin molecule binds to proteins called *catenins* which, in turn, are linked to the cell's actin cytoskeleton.

E-cadherin occurs mainly in epithelial tissue (and in the early stage of mammalian embryogenesis); E-cadherin is used as a receptor for the adhesin *internalin A* of *Listeria monocytogenes* during invasion of the intestinal epithelium. P-cadherin occurs in the placenta and epidermis, and N-cadherin is found e.g. in nerve and heart cells.

## cadmium

**cadmium** See HEAVY METALS.

**caducous** Tending to be shed, or to fall, early.

**Caedibacter** A genus of Gram-negative bacteria which are obligate endosymbionts in strains of *Paramecium aurelia*. Cells: non-motile coccobacilli or rods, ca. 0.4–1.0 µm across and 1.0–4.0 µm in length, which stain well with toluidine blue; some (not all) cells of *Caedibacter* contain an R BODY (or, rarely, two R bodies). Cell division is inhibited in bacterial cells which contain an R body. The possession of R body-containing cells of *Caedibacter* appears to confer on the host *Paramecium* the ability to behave as a killer, or as a MATE KILLER, towards sensitive paramecia (i.e. paramecia which lack endosymbiotic *Caedibacter*); in the 'killer' phenomenon, sensitive paramecia appear to ingest R body-containing bacterial cells (and/or isolated R bodies or toxins?) released by killer paramecia, and are killed as a consequence. The ability of killer paramecia to remain viable while harbouring *Caedibacter* is dependent on certain dominant allele(s). GC%: ca. 40–44. Type species: *C. taeniospiralis*.

The cells of *C. pseudomutans*, *C. taeniospiralis* and *C. vari-caedens* – which occur in the cytoplasm of their hosts, and which confer the killer characteristic – are sometimes called kappa particles. *C. paraconjugatus* (see also MU PARTICLE) is associated with mate killing. Another endosymbiont, which occurs in the macronucleus of *P. caudatum* – and which confers the killer characteristic – may belong to this genus. (See also HOLOSPORA, LYTICUM, PSEUDOCAEDIBACTER, SPIN KILLING.)

[Book ref. 22, pp. 803–806; protein synthesis in kappa particles: JGM (1984) 130 1517–1523.]

**caematoid** (caemoid) Refers to an irregularly-shaped acium which lacks a distinct peridium.

**caesium chloride** See CENTRIFUGATION.

**caffeic acid** 3-(3',4'-Dihydroxyphenyl)-propenoic acid, a compound produced by higher plants (apparently as a precursor of LIGNIN). Caffeic acid may be a factor in the resistance of certain plants to certain diseases; thus, e.g. potatoes resistant to LATE BLIGHT have been found to accumulate caffeic acid on infection with *Phytophthora infestans*. (Caffeic acid inhibits *P. infestans* in vitro.) (See also AUXINS and CHLOROGENIC ACID.)

**caffeine** 1,3,7-Trimethylxanthine, a purine derivative present e.g. in tea leaves and coffee beans. In e.g. certain bacteria caffeine can act as an inhibitor of EXCISION REPAIR OF DNA.

**cag** See PATHOGENICITY ISLAND.

**Cairns' mechanism** ( $\theta$  replication) A mechanism for the replication of a ds cccDNA molecule: replication is initiated at a fixed point, progresses (unidirectionally or bidirectionally) around the circle – both strands being replicated more or less simultaneously – and ends at a defined terminus. (The partly replicated intermediate thus has a  $\theta$ -like structure.) Bidirectional replication occurs e.g. in the chromosome of *Escherichia coli* (see DNA REPLICATION); unidirectional replication occurs e.g. in the COLE1 PLASMID. (cf. ROLLING CIRCLE MECHANISM.)

**Calberla's solution** A mixture of glycerol (5 ml), 95% ethanol (10 ml) and distilled water (15 ml) used as a microscopical mounting medium for the ROTOROD.

**Calcarisporium** See HYPHOMYCETES; see also AUROVERTINS and CONTACT BIOTROPHIC MYCOPARASITE.

**calicolous** Growing preferentially in a calcium-rich environment.

**calcium alginate wool** See ALGINATE.

**calcium nutrient agar** (CNA) NUTRIENT AGAR containing CaCl<sub>2</sub>; a lawn plate prepared from CNA may be used e.g. for the cultivation of certain bacteriophages.

**calcium transport** See ION TRANSPORT.

**calcofluor white** A FLUORESCENT BRIGHTENER which binds by hydrogen-bonding to  $\beta$ -linked fibrillar polysaccharides such as cellulose and chitin; it can be used as a fluorescent marker to locate these polymers in cells (see MICROSCOPY (e)), and can disrupt CELLULOSE and chitin microfibril formation in growing cells (e.g. yeasts: [JGM (1983) 129 1577–1582]).

**caldoactive** Refers to an extreme THERMOPHILE. The term is used more specifically by some authors to refer to an organism with a maximum growth temperature >70°C, an optimum growth temperature >65°C, and a minimum growth temperature >40°C [Sci. Prog. (1975) 62 373–393].

**caldopentamine** See POLYAMINES.

**calf diphtheria** See NECROBACILLOSIS.

**calf pneumonia** (enzootic pneumonia of calves; viral pneumonia of calves) A non-specific calf disease, the causal agent(s) being one or more viruses (e.g. adenoviruses, parainfluenza virus type 3, respiratory syncytial virus) frequently in association with bacteria (e.g. *Chlamydia*, *Mycoplasma* spp); typical symptoms: fever with constipation, followed by a mucopurulent nasal discharge, PNEUMONIA and diarrhoea. Poor hygiene and housing conditions (e.g. poor ventilation) and overcrowding appear to predispose towards the disease. Mortality rates can be high e.g. in acute RSV pneumonia.

Control involves improvements in housing etc. and chemotherapy. (See also danofloxacin in entry QUINOLONE ANTIBIOTICS.)

**calf scours** Scouring (see SCOURS) in young calves due to any of a range of microbial agents, e.g. enterotoxigenic strains of *Escherichia coli*, coronaviruses etc; aetiology may be complex (e.g. mixed bacterial and viral causal agents) and the occurrence and severity of the disease may involve both immunological and environmental factors.

**Calgitez** See ALGINATE.

**Caliciales** A heterogeneous order of (mostly LICHEN-forming) fungi of the ASCOMYCOTINA. Three families [Book ref. 64]:

Caliciaceae. Mostly lichen-forming (photobiont: a green alga). Thallus thin crustose or immersed in the substratum (usually wood or bark). Apothecia (mazaedia) stalked or sessile. Lichen-forming genera include e.g. *Calicium*, *Chaenotheca*, *Coniocybe*, *Cyphellium*.

Mycocaliciaceae. Lichenicolous or fungicolous (possibly also lichen-forming) fungi in which the thallus is immersed in the substratum or absent. Apothecia stalked, asci thick-walled (mazaedia are not formed). Genera: e.g. *Stenocybe*.

Sphaerophoraceae. All lichen-forming (photobiont: a green alga). Thallus foliose or fruticose. Apothecia (mazaedia) often globose, marginal or terminal. Genera: e.g. *Sphaerophorus*.

**Calicium** See CALICIALES.

**Caliciviridae** A family of VIRUSES which infect vertebrates; caliciviruses were formerly classified as a genus in the family Picornaviridae. The virions are non-enveloped, roughly spherical, ca. 35–39 nm diam., and have 32 characteristic cup-shaped surface indentations – arranged with icosahedral symmetry – observable by electron microscopy of negatively stained preparations. The capsid contains a single major polypeptide species (MWt ca. 60000–71000) and a minor polypeptide (MWt ca. 15000). Genome: one molecule of positive-sense ssRNA (MWt ca. 2.6–2.8 × 10<sup>6</sup>) which is apparently polyadenylated at the 3' end but not capped at the 5' end; the RNA is covalently linked (possibly at its 5' end) to a protein (MWt ca. 10000–15000) which is necessary for infectivity. Replication occurs in the cytoplasm; dsRNAs (presumably replicative intermediates), genome-sized ssRNAs, and subgenomic ssRNAs can

be detected in infected cells. Mature viruses are released by host cell lysis. Caliciviruses are not sensitive to lipid solvents or to mild detergents, but are inactivated at pH 3–5.

The family includes VESICULAR EXANTHEMA of swine virus (VESV), FELINE CALCIVIRUS (FCV) and SAN MIGUEL SEA LION VIRUS (SMSV); these three viruses are classified in the genus *Calicivirus* (type species: VESV serotype A). VESV, SMSV and FCV are readily propagated in cell culture and do not cause gastroenteritis (although they are pathogenic); morphologically similar viruses which have not been cultivated and which cause gastroenteritis in calves, piglets and humans (especially young children) are included as 'possible members' of the family [Book ref. 23, pp 133–134] (but see SMALL ROUND STRUCTURED VIRUSES).

**Calicivirus** See CALCIVIRIDAE.

**California encephalitis** (CE) An acute, usually mild, viral ENCEPHALITIS affecting mainly children below ca. 15 years of age; it occurs sporadically in forested areas in parts of North America. The CE virus (genus BUNYAVIRUS) occurs in small mammals and is transmitted by mosquitoes (mainly *Aedes* spp).

**California mastitis test** (CMT; CM test) (*ver.*) A test, used for the indirect detection of MASTITIS, in which the number of white blood cells in milk is estimated. A reagent is added to the milk, causing a degree of gelation which corresponds to the white cell count; test results designated 'negative', 'trace', 1, 2 and 3 correspond to cell counts of ca.  $<10^5$ ,  $3 \times 10^5$ ,  $9 \times 10^5$ ,  $27 \times 10^5$ , and  $81 \times 10^5$ , respectively. The Brabant and Wisconsin mastitis tests also depend on a gelation principle.

**callose** A linear (1 → 3)-β-D-glucan which occurs e.g. associated with sieve-plates and sieve-tubes in higher plants and in algae of the Laminariales (PHAEOPHYTA). Callose may be deposited in plant cell walls e.g. in response to wounding or invasion by pathogens.

**calmodulin** A 16.7 kDa, heat-stable, acid-stable Ca<sup>2+</sup>-binding protein found in eukaryotic cells, including those of certain protozoa and slime moulds. The complex of calmodulin with calcium ions stimulates a number of enzymes (e.g. cyclic nucleotide phosphodiesterase) and activates certain toxins (e.g. CYCLOLYSIN and the EF component of ANTHRAX TOXIN).

**Calocera** A genus of fungi (order DACRYMYCETALES). *C. cornea* forms an erect, columnar, pointed, usually unbranched, yellow, gelatinous basidiocarp, ca. 1 cm high, on various types of wood. *C. viscosa* forms an erect, antler-like, yellow or orange, gelatinous basidiocarp, commonly 3–5 cm high, on coniferous wood.

**calomel** See MERCURY.

**Calonectria** See HYPOCREALES.

**calonectrin** See TRICHOETECENES.

**Caloplaca** A genus of LICHENS (order TELOSCHISTALES) in which the thallus is crustose or placodioid, usually yellow, orange or red (containing PARIETIN) – but grey in some species. Apothecia: usually yellowish or reddish; ascospores: polarilocular in most species. Species grow on rocks and/or on wood.

**Caloramator** See CLOSTRIDIUM.

**Calostoma** See GASTEROMYCETES.

**Calothrix** A genus of filamentous CYANOBACTERIA (section IV) in which the mature trichomes taper from base to apex and are composed of disc-shaped, isodiametric or cylindrical vegetative cells; a terminal heterocyst occurs at the base of the trichome. Hormogonia are uniform in width, and young trichomes from hormogonia each have a heterocyst at one end only. GC%: 40–44. The genus is taken to include members of the family RIVULARIACEAE. Species are common e.g. on coastal rocks in the littoral zone.

**calprotectin** A zinc-chelating protein released from dying NEUTROPHILS at sites of inflammation (e.g. abscesses); it inhibits

bacterial growth (apparently by withholding zinc ions), and this may antagonize certain antibiotics (e.g. β-lactams) used for chemotherapy. [Zinc in antimicrobial defence: RMM (1997) 8 217–224.]

**Calvatia** See LYCOPERDALES.

**Calvin cycle** (Calvin–Benson cycle, or Benson–Calvin–Bassham cycle; reductive pentose phosphate cycle; C<sub>3</sub> cycle) A cyclic pathway used for the fixation of CARBON DIOXIDE by a wide range of AUTOTROPHS (q.v.). (See also METHYLOTROPHY.) The key enzymes in the Calvin cycle are RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE–OXYGENASE (RuBisCO), responsible for the CO<sub>2</sub>-fixing reaction, and phosphoribulokinase (ribulose 5-phosphate kinase, EC 2.7.1.19), responsible for regenerating the CO<sub>2</sub> acceptor: ribulose 1,5-bisphosphate (RuBP). For every three molecules of CO<sub>2</sub> fixed, six molecules of 3-phosphoglycerate are formed; of these, five are required for the regeneration of RuBP, while the remaining molecule is available as a source of carbon for biosynthesis (see figure on page 120). The ATP and reduced NAD(P) required to drive the cycle are supplied by the light reactions of PHOTOSYNTHESIS in phototrophs, or by the oxidation of reduced inorganic compounds in CHEMOLITHOAUTOTROPHS. [Regulation of the Calvin cycle in bacteria: AvL (1984) 50 473–487.] (See also PHOTORESPIRATION.)

**calyciform** Cup-shaped.

**calymma** See RADIOLARIA.

**Calymmatobacterium** A genus (*incertae sedis*) of Gram-negative bacteria which occur as pathogens in man (see GRANULOMA INGUINALE). Cells: non-motile, pleomorphic, capsulated, round-ended rods, 0.5–1.5 × 1.0–2.0 μm. In exudates from diseased tissues the cells are usually seen in the cytoplasm of large mononuclear phagocytes. The organisms can be cultured in the chick embryo yolk sac or on specialized egg yolk-containing media. Optimum growth temperature: 37°C. Type (only) species: *C. granulomatis*. [Book ref. 22, pp. 585–587.]

**Calyptralegnia** See SAPROLEGNIALES.

**CAM** (1) Chorioallantoic membrane: see EMBRYONATED EGG.

(2) CELL ADHESION MOLECULE.

**cam gene** See METHANOGENESIS.

**CAM plasmid** An IncP-2 *Pseudomonas* PLASMID (ca. 500 kb) which encodes the capacity for metabolism of camphor (compare TOL PLASMID).

**cAM373** See PHEROMONE.

**camalexin** A PHYTOALEXIN (a substituted indole) produced by *Arabidopsis*.

**Camarops** See SPHAERIALES.

**Calmarosporium** A genus of fungi of the class COELOMYCETES. (See also LEPTOSPHAERIA.)

**camelpox virus** See ORTHOPOXVIRUS.

**Camembert cheese** See CHEESE-MAKING.

**cAMP** CYCLIC AMP.

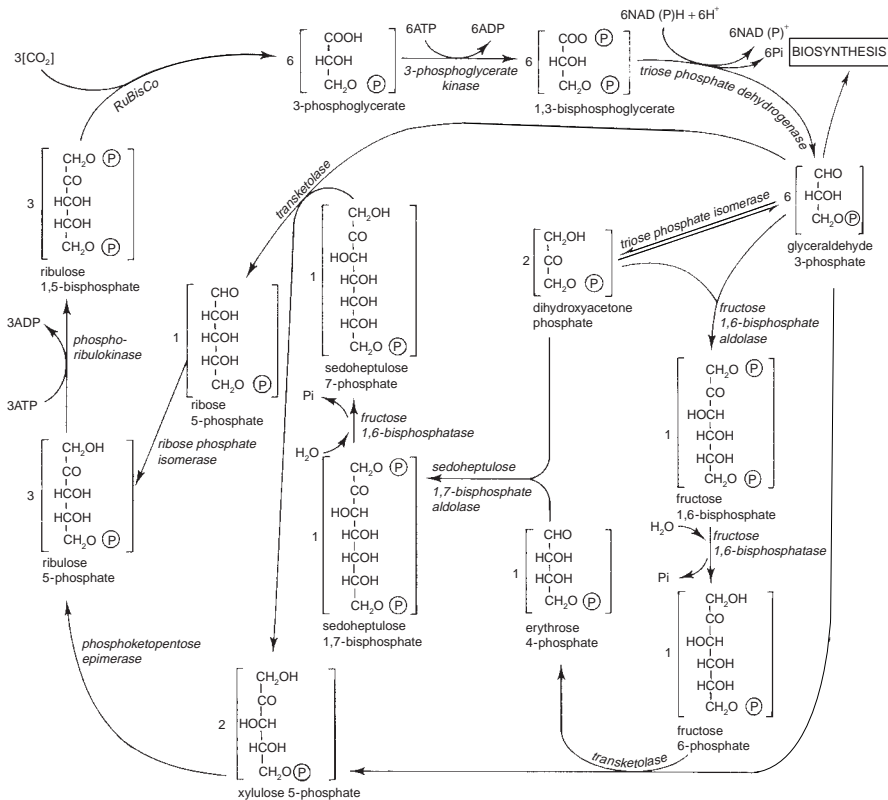

**cAMP–CAP** See CATABOLITE REPRESSION.

**CAMP factor** See CAMP TEST.

**cAMP phosphodiesterase** See ADENYLATE CYCLASE.

**cAMP receptor protein** See CATABOLITE REPRESSION.

**CAMP test** (Christie–Atkins–Munch–Peterson test) A test used for the presumptive identification of group B streptococci. (Some group A streptococci may also give a positive test, particularly under anaerobic conditions [Book ref. 46, pp. 1590–1591].) The organism under test is inoculated in a fine streak on the surface of ox- or sheep-blood agar; a second streak – perpendicular to the first but separated from it by a few millimetres – is made with a culture of a β-HAEMOLYSIN-producing strain of *Staphylococcus aureus*. The plate is then incubated (aerobically) for ca. 12 hours

CALVIN CYCLE. For simplicity, the intermediate withdrawn for biosynthesis is shown as glyceraldehyde 3-phosphate. In reality, other intermediates may be withdrawn. For example, 3-phosphoglycerate is a precursor for the synthesis of various amino acids, fatty acids, purines and pyrimidines; withdrawal of 3-phosphoglycerate rather than glyceraldehyde 3-phosphate reduces the immediate energy cost of the cycle by 1 ATP and 1 NAD(P)H per 3 CO<sub>2</sub> fixed.

or more at 37°. In a positive test, a typical arrowhead- or flame-shaped area of *clear* haemolysis – due to synergy between a streptococcal extracellular polypeptide ('CAMP factor') and staphylococcal β-HAEMOLYSIN – occurs between the two lines of bacterial growth. [Conditions affecting CAMP factor-induced haemolysis: JGM (1985) 131 817–820.]

The CAMP test is used e.g. for the detection of *Streptococcus agalactiae* (a causal agent of bovine MASTITIS) in milk; milk which is moderately or heavily contaminated with *S. agalactiae* may itself give a positive CAMP test if streaked onto the test plate in place of an isolate of the organism, as may a culture filtrate of *S. agalactiae*.

A 'reverse CAMP test', using a known group B streptococcus, can be used for the identification of β-haemolysin-producing staphylococci.

**Campanella** A genus of sedentary ciliate protozoa (subclass PERITRICHIA) found in freshwater and brackish habitats. *Campanella* resembles VORTICELLA (q.v.) but its zooid is larger and it is a colonial organism, one zooid occurring on each branch of a non-contractile stalk.

**Campbell model** A model, originally proposed by Campbell [Adv. Gen. (1962) 11 101–145], in which a circular plasmid

or phage genome integrates into a bacterial chromosome by a single cross-over between the two circular molecules. (See e.g. BACTERIOPHAGE λ; cf. BACTERIOPHAGE φ105.)

**Campylobacter** A genus of Gram-negative, asporogenous bacteria of the family CAMPYLOBACTERACEAE. Cells: slender, spirally curved rods, usually ca. 0.2–0.5 × 1.0–5.0 μm; POLAR MEMBRANES are present. (In old cultures, spherical or COCCOID BODIES may occur.) Motile; a single unsheathed flagellum occurs at one or both poles of the cell. Microaerophilic; growth is optimal in 5% oxygen, 10% carbon dioxide and 85% nitrogen. Metabolism: respiratory. Carbon sources: amino acids or TCA cycle intermediates, but not carbohydrates. Oxidase +ve. Indole –ve. Nitrate is reduced. Lipase –ve. MR –ve. VP –ve. GC%: 30–38. Type species: *C. fetus*.

Campylobacter species occur in the reproductive and intestinal tracts of man and animals. Some species are pathogenic (see CAMPYLOBACTERIOSIS.)

*C. coli*. Closely resembles *C. jejuni*, but e.g. does not hydrolyse hippurate.

*C. concisus*. Cells: small, curved. Catalase –ve. Hydrogen sulphide (TSI) +ve. No growth at 25°C. Hippurate and indoxyl acetate are not hydrolysed. Occurs in the gingival crevice flora

in humans with gingivitis, periodontitis etc., but apparently non-pathogenic.

*C. fetus*. Cells appear comma- or S-shaped or 'gull-winged'. (Loosely wound spiral filaments (up to 8 µm in length) occur in old cultures.) Catalase +ve. Hydrogen sulphide (TSI) -ve. Growth occurs at 25°C but not at 42°C. Hippurate and indoxyl acetate are not hydrolysed. Pathogenic.

*C. jejuni*. Cells: small, tightly coiled spirals. On exposure of cultures to air, coccoid bodies form rapidly. SWARMING occurs on moist agar (the DIENES PHENOMENON does not occur). Catalase +ve. Hydrogen sulphide (TSI) -ve. Growth occurs at 42°C but not at 25°C. Hippurate and INDOXYL ACETATE are hydrolysed. Pathogenic. [PCR-RFLP typing of *C. jejuni*: LAM (1996) 23 163–166; PGFE typing of Penner HS11 strains of *C. jejuni*: JMM (1998) 47 353–357.]

*C. pylori*. Re-classified: see HELICOBACTER.

*C. sputorum*. Cells: slender, curved rods, appearing comma-shaped, 'gull-winged' or occasionally filamentous. Catalase -ve. Hydrogen sulphide (TSI) +ve. Growth occurs at 42°C (except for subsp *bubulus*) but not at 25°C (except for some strains of subsp *bubulus*). Hippurate and indoxyl acetate are not hydrolysed. Subsp *bubulus* and *sputorum* can grow anaerobically with fumarate; subsp *mucosalis* requires hydrogen or formate (as well as fumarate) for anaerobic growth. Subsp *bubulus* occurs in the genital tract in cattle and sheep, apparently as a commensal. Subsp *mucosalis* is found in pigs, apparently as a commensal in the mouth and as a pathogen, causing enteric disease. Subsp *sputorum* occurs in the gingival crevice flora of man but is apparently non-pathogenic.

(See also ARCOBACTER and HELICOBACTER.)

[Book ref. 22, pp 111–118. Culture, media etc.: Book ref. 219, pp 444–446. *Campylobacter* spp (genotyping: mini-review): AEM (2000) 66 1–9.]

**Campylobacteraceae** A family comprising the genera ARCOBACTER and CAMPYLOBACTER.

**campylobacteriosis** (*med., vet.*) Any human or animal disease caused by a strain of CAMPYLOBACTER.

In man, disease is commonly food-borne, and is usually caused by *C. jejuni* or *C. coli*; less frequently isolated pathogens include *C. hyointestinalis* and *C. upsaliensis*. Typically, disease involves diarrhoea/enterocolitis, but disseminated infection can occur in the immunocompromised patient, and meningitis may develop in neonates. The usual sources of infection are inadequately cooked meats, especially poultry, unpasteurized milk and untreated (or contaminated) water; cross-contamination of food, particularly from raw (uncooked) poultry, is an important factor. The incubation period (~1–7 days) may be followed by several days of watery diarrhoea, often with abdominal pain. In severe cases the diarrhoea may be bloody; in some cases, symptoms resemble those of acute ulcerative colitis. In a small number of cases patients subsequently develop reactive arthritis; very rarely they develop the GUILLAIN-BARRÉ SYNDROME.

**Chemotherapy.** For persistent cases: erythromycin or e.g. ciprofloxacin.

[*Campylobacter* infections (reviews): RMM (1997) 8 113–124; Microbiology (1997) 143 5–21.]

In animals, campylobacters are commonly found as commensals in the gut. However, *C. fetus* can cause abortion in sheep (and less often in cattle). The *veneredalis* subspecies of *C. fetus* causes abortion and infertility in cattle, while *C. sputorum* subsp *mucosalis* causes enteric disease in pigs. (See also WINTER DYSENTERY.)

**CaMV** CAULIFLOWER MOSAIC VIRUS.

**Canada balsam** A clear, ethanol-insoluble resin, obtained from fir trees (*Abies* sp), used (dissolved in xylene or benzene) as a MOUNTANT. It takes weeks to dry (harden) at room temperature; the refractive index of the dry resin is ca. 1.53. Canada balsam becomes yellowish with age owing to oxidation. (See also DPX.)

**Canadian vole agent** See BARTONELLA.

**canarypox virus** See AVIPOXVIRUS.

**L-canavanine** 2-Amino-4-guanidinohydroxybutyric acid. (See also CGB AGAR.)

**cancellous** (cancellate) Spongy; reticulated.

**cancer** Any disease of man or animals in which abnormal, unregulated proliferation of cells results in the formation of a malignant tumour (e.g. a CARCINOMA or SARCOMA); as the tumour grows, it tends to invade and destroy adjacent tissues and may shed cancer cells which can then disseminate (metastasize) to other areas of the body, resulting in the formation of secondary tumours.

The causes of cancer are complex and appear to be varied and multifactorial; in general, the detailed mechanisms are not fully understood. Oncogenesis appears commonly to involve an irreversible change in the genome of the cell, such a change ranging from a single point mutation to chromosomal rearrangements. (See also ONCOGENE.) In only relatively few cases have microorganisms been implicated as direct or indirect causes of cancer. Certain viruses are known to induce tumours and e.g. LEUKAEMIAS in animals and man (see DNA TUMOUR VIRUSES and ONCOVIRINAE); others may play an indirect role in predisposing to cancer (e.g. by suppressing the normal host immunological defence mechanisms). (cf. PARVOVIRUS.) [Viruses and cancer: Book ref. 110.]

Certain bacteria and fungi may play an indirect role in causing cancer by producing cancer-promoting substances (CARCINOGENS); e.g., certain MYCOTOXINS (e.g. AFLATOXINS) can be oncogenic, and certain bacteria of the human GASTROINTESTINAL TRACT FLORA may be responsible for the formation of substances which may play a role in the induction of bowel cancer. However, some microbial products have anticancer activity: e.g. ANTHRACYCLINE ANTIBIOTICS, ANTHRAMYCIN, BLEOMYCIN, etc.

See also e.g. IMMUNOTOXINS and NK CELLS; cf. GALLS.

**Candelariella** A genus of LICHENS (order LECANORALES); photobiont: a green alga. Thallus: crustose, yellow, lacking parietin. Apothecia: lecanorine.

**candicidin B** A heptaene POLYENE ANTIBIOTIC produced by *Streptomyces griseus*; its spectrum of activity is similar to that of AMPHOTERICIN B, and it is particularly effective against *Candida albicans*.

**Candida** (formerly e.g. *Monilia*) A large and heterogeneous genus of yeast-like or dimorphic imperfect fungi (class HYPHOMYCETES). (Although *Candida* has been traditionally classified in the Fungi Imperfecti, analysis of the genome of *C. albicans* has indicated a genetic repertoire that could support a sexual cycle [PNAS (2001) 98 3249–3253].) Some species occur as commensals and/or as opportunist pathogens in man and animals (see CANDIDIASIS), and some can be isolated from plants, soil, foods etc. (See also e.g. CIDER, GARI, MEAT SPOILAGE.) The yeast-like cells are e.g. spherical, ovoid, cylindrical or elongate, and reproduce by (usually multilateral) budding. Pseudomycelium may be absent, rudimentary, or well developed, according to species and/or conditions; some species can form a true, septate mycelium. Blastospores and chlamydozoospores may be formed. Carotenoid pigments are not produced. Many species can ferment glucose and other sugars. Inositol and NO<sub>3</sub><sup>-</sup> may or may not be assimilated; inositol-assimilating strains form

## candidate virus

pseudomycelium. The species [196 are described (with keys) in Book ref. 100, pp. 585–844] are distinguished e.g. on the basis of metabolic tests, growth requirements, etc.

*C. albicans* (a species which incorporates e.g. '*C. stelloidea*') occurs as a commensal e.g. in the mouth and in the genital and intestinal tracts in man; *C. albicans* is the commonest cause of CANDIDIASIS. Cells: e.g. ca.  $3-6 \times 5-10 \mu\text{m}$ . On e.g. cornmeal agar, pseudomycelium may be abundant, typically bearing grape-like clusters of blastospores. True mycelium may be formed, and thick-walled chlamydospores are formed e.g. on cornmeal agar at 20°C. *C. albicans* can ferment glucose and maltose, but not e.g. lactose. The ability to form GERM TUBES after incubation in serum for 2 hours at 37°C is presumptive evidence of *C. albicans*. It has been demonstrated that *C. albicans* can switch between at least seven different phenotypes (identified by colony morphology on agar media); the switching is heritable, reversible, and occurs at high frequency (increased further by low doses of UV radiation) [Science (1985) 230 666–669]. Such switching may be important in the role of *C. albicans* as an opportunist pathogen (cf. ANTIGENIC VARIATION), but its mechanism is unknown.

*C. tropicalis* can also cause candidiasis. On e.g. cornmeal agar, pseudomycelium is abundant and consists of long, branched pseudohyphae bearing blastospores singly or in short chains and clusters. True mycelium and chlamydospores may also be formed.

*C. utilis* (= *Torulopsis utilis*; teleomorph: *Hansenula jadinii*) is an important food yeast (see SINGLE-CELL PROTEIN, TORULA YEAST, YEAST EXTRACT). On cornmeal agar an abundant pseudomycelium is formed, consisting of branched chains of short, coarse pseudohyphae and oval cells. True mycelium is not formed.

A few *Candida* spp have basidiomycetous affinities: e.g. *C. frigida*, *C. gelida*, *C. nivalis* and *C. scottii* have teleomorphs in the genus *Leucosporidium*, *C. japonica* in *FILOBASIDIUM*. Many species have teleomorphs among the ascomycetes: e.g., *C. ciferrii* (STEPHANOASCUS), *C. colliculosa* (TORULASPORA), *C. dattila* (KLUYVEROMYCES), *C. domercqii* (WICKERHAMIELLA), *C. globosa* (CLYTEROMYCES), *C. guilliermondii* (PICHIA), *C. holmii* (SACCHAROMYCES), *C. kefir* (= *C. pseudotropicalis*) (KLUYVEROMYCES), *C. krusei* (ISSATCHENKIA), *C. lipolytica* (*Yarrowia lipolytica* – see SACCHAROMYCOPSIS), *C. lusitanae* (CLAVISPORA), *C. pelliculosa* (HANSENULA), *C. pintolopesii* (SACCHAROMYCES), *C. pulcherrima* (METSCHNIKOWIA), *C. reukaufii* (METSCHNIKOWIA), *C. sorbosa* (ISSATCHENKIA), *C. sphaerica* (KLUYVEROMYCES), *C. utilis* (HANSENULA), *C. valida* (PICHIA), *C. variabilis* (PICHIA). (*C. hellenica*, *C. inositophila*, *C. steatolytica*: see ZYGOASCUS.)

**candidate virus** (1) A virus which is of uncertain taxonomic affinity but which may belong to (i.e., is a 'candidate' for) a particular taxonomic group; e.g. a 'candidate calicivirus' is a virus which may belong to the family Caliciviridae.

(2) A virus which might be the causal agent of a particular disease.

**candidiasis** (candidosis; moniliasis) A MYCOSIS, affecting man and animals, caused by a species of *Candida* – usually *C. albicans* (see CANDIDA); other pathogenic species include e.g. *C. parapsilosis* and *C. tropicalis*. Infection is probably endogenous in most cases; predisposing factors include e.g. suppression of the normal body microflora (e.g. by antibiotic therapy), impaired immune responses, etc. In man, candidiasis commonly occurs as a localized infection of the mouth (*oral thrush*) or vagina (*vaginal thrush*), and involves the formation

of whitish mucoid plaques on the mucous membranes. (See also NON-GONOCOCCAL URETHRITIS.) Cutaneous candidiasis tends to occur on skin areas constantly exposed to moisture, regions commonly affected including e.g. the groin and axillae (see also PARONYCHIA); infected skin is swollen, red and pruritic. *Chronic mucocutaneous candidiasis* is a severe condition which occurs in immunocompromised or otherwise abnormal individuals; the skin and mucous membranes of the entire body may be affected, with chronic, granulomatous, inflammatory reactions in the underlying tissues. Other forms of candidiasis include bronchocandidiasis, pulmonary candidiasis (often secondary to other diseases), and systemic candidiasis (involving e.g. fungaemia, endocarditis, nephritis etc – cf. TORULOPSIS). *Lab. diagnosis*: microscopical and cultural examination of material from lesions etc (see CANDIDA).

In animals, candidiasis may involve the intestinal tract, skin, and/or various internal organs (see also MASTITIS); in calves and piglets the intestine is usually involved, and infection can cause watery diarrhoea, anorexia, dehydration, and even death. In birds, candidiasis commonly involves the digestive tract – particularly the crop.

[Book ref. 103.]

**candidosis** *Syn.* CANDIDIASIS.

**candle** (*verb*) To carry out CANDLING.

**candle filter** See FILTRATION.

**candle jar** A container within which cultures etc can be incubated under an increased partial pressure of CO<sub>2</sub>; the CO<sub>2</sub> is provided by placing a lighted candle in the container prior to closure.

**candle-snuff fungus** See XYLARIA.

**candling** (*virol.*) A procedure for observing the contents of an intact egg by transmitted light. An EMBRYONATED EGG is placed over an aperture in a box containing an electric lamp; internal details of the egg – such as the positions of the embryo and blood vessels – can be seen, thus facilitating the inoculation of a particular membrane or cavity of the egg. Candling is best performed in a darkened room, and should be carried out rapidly to avoid overheating the egg.

**cane blight** In raspberry canes: a disease caused by *Leptosphaeria coniothyrium*. Infection occurs mainly via wounds; leaves shrivel and die, dark patches appear on the stem bases, and bark associated with these patches cracks open.

**cane-cutters' disease** LEPTOSPIROSIS caused by *L. interrogans* serotype *australis* A; the disease is common among cane-cutters in N. Queensland, Australia.

**cane gall** A disease of *Rubus* spp (raspberry, blackberry etc) in which small spherical galls or elongated ridges develop on the stems. Causal agent: *Agrobacterium rubi*.

**cane spot** (of raspberry) See ELSINOE.

**canicola fever** LEPTOSPIROSIS caused by *L. interrogans* serotype *canicola*.

**canid herpesvirus 1** See ALPHAHERPESVIRINAE.

**canine distemper** An acute, infectious disease of dogs and other animals (e.g. foxes, mink, raccoons, wolves) caused by a virus of the genus MORBILLIVIRUS. Infection occurs mainly by droplet inhalation, also e.g. by ingestion. Incubation period: ca. 3–30 days. Symptoms initially include fever, nasal and ocular discharge, and listlessness. The fever subsides, then recurs with vomiting, diarrhoea, and often pneumonia; signs of CNS involvement (e.g. fits) may occur. (cf. HARD-PAD.) The disease affects mainly young animals. However, persistent infection may result in 'old dog encephalitis' – a condition characterized by progressive neurological degeneration. The distemper virus

has also been associated (rarely) with a demyelinating disease in man.

Effective anti-distemper vaccines are available.

**canine herpesvirus** See ALPHAHERPESVIRINAE.

**canine parvovirus** A subspecies of the feline parvovirus (genus PARVOVIRUS) which appeared initially in Europe and then spread rapidly in 1978, causing worldwide outbreaks of disease in dogs. Infection may occur via the nasopharynx or via lymphoid tissues, including the tonsils. Viraemia leads to generalized infection of lymphoid tissues. Levels of erythrocytes (red blood cells) are not affected, and panleukopenia is infrequent in the dog (cf. FELINE PANLEUKOPENIA VIRUS). Infection of dividing epithelial cells in the ileum and jejunum impairs osmotic regulation and leads to diarrhoea (often containing blood/mucus); large numbers of virions are shed during the diarrhoeal phase. The disease can be associated with high mortality rates, but the severity varies in individual animals – some infections being mild/subclinical.

In neonatal puppies there is no manifestation of enteritis. In these animals infection may lead to death from myocarditis, often at 3–8 weeks of age (but sometimes up to 4 months of age). Onset of disease is rapid, typically with cardiac arrhythmia, pulmonary oedema and dyspnoea; the myocardium suffers multifocal necrosis. Infrequently, infection of the neonatal animal gives rise to lesions in a variety of tissues.

Canine parvovirus is apparently distinct from the ‘minute virus of canines’ (sometimes also called ‘canine parvovirus’) – a virus which is widespread in canine populations and which can be isolated from the faeces of asymptomatic dogs.

[Pathogenesis of canine parvovirus: BCH (1995) 8 57–71.]

**canker** (*plant pathol.*) An imprecise term usually used for a plant disease which is characterized (in woody plants) by the death of cambium tissue and resulting loss and/or malformation of bark, or (in non-woody plants) by the formation of sharply delineated, dry, necrotic, localized lesions on the stem. (The term ‘canker’ may also be used to refer to the lesion itself, particularly in woody plants.) Cankers may be caused by bacteria (e.g. bacterial canker of cherry and plum is caused by *Pseudomonas syringae* pv. *morsprunorum*) or fungi (see e.g. APPLE CANKER, BEECH BARK DISEASE, BLEEDING CANKER, PITCH CANKER).

**canning** A form of APPERTIZATION in which, typically, suitably prepared foods are put into metal containers (‘cans’, ‘tins’) which are then exhausted, hermetically sealed, and heated; as an alternative, the food may be heat-treated before being placed aseptically in pre-sterilized cans which are then sealed under aseptic conditions. Most cans are made of tinplate (tin-plated steel) – see also TIN – but aluminium or other materials (e.g. lacquered tin-free steel) may be used. (See also RETORT POUCH.)

(a) *The canning process.* Conventional canning involves the following stages.

*Food preparation.* According to the type of food, this may involve grading, cutting, peeling, blanching (see also INDIVIDUAL QUICK BLANCH), washing etc; foods for canning must be as free as possible from microbial contamination because the efficacy of heat treatment is related to the level of contamination.

*Filling the cans.* This process must take into account the fact that the efficiency of subsequent processes depends on the correct volume of free space (*headspace*) between the surface of the food and the top of the can.

*Exhausting the cans.* The removal of air reduces the strain on the can during subsequent heating and inhibits long-term internal corrosion. Exhausting may be carried out by heating immediately prior to sealing, by sealing cold food into the can under vacuum (*vacuumizing*), or by injecting steam into the headspace during the sealing process.

*Sealing.* The can end is added by a double-seaming process in which the edge of the can end is wrapped around the body flange to form a seam of five thicknesses of metal – seven at the side seam, if present. (See also BIOS TEST.) (Concentric rings (*expansion rings*) on the can ends facilitate double-seaming and help to relieve strain on the can seams during the heating process.)

*Heat processing.* Cans may be heated in a BATCH RETORT or a COOKER-COOLER (see also STERIFLAMME PROCESS); in some cases cans are agitated to facilitate heat penetration, and in such cases an adequate headspace is essential. The temperature–time regime used in a particular case depends e.g. on the type and pH of the food. Following heat treatment, the food (i) must not contain *Clostridium botulinum* capable of growth and toxin production under the conditions of storage; (ii) should not contain organisms capable of causing spoilage; and (iii) should retain, as far as possible, its organoleptic properties. For non-acid foods (e.g. potatoes, mushrooms) – except foods containing curing salts – heat processing is usually to a *minimum* F<sub>0</sub> VALUE of 3.0 in order to destroy the spores of *C. botulinum* (see also BOTULINUM COOK); for foods with a pH below 4.5, an F<sub>0</sub> of 0.7 may be satisfactory because growth and toxin production by *C. botulinum* is generally considered not to occur at or below this pH (cf. CLOSTRIDIUM). Large cans of ham and other *cured* meats (pH above 5) are frequently processed at quite low temperatures (e.g. a centre temperature of ca. 70°C for a few minutes); such cans are necessarily stored under refrigeration – consumer safety and preservative action both relying on the combined effects of the curing salts and low temperature. Smaller cans of cured meats generally undergo a higher level of heat treatment and are shelf-stable, without refrigeration, owing to the ability of the curing salts to inhibit growth and toxin production by (heat-injured) pathogens [Book ref. 35]. Some canned foods (e.g. sweetened condensed milk) are not heated after can sealing; this product contains sufficient sugar to lower its WATER ACTIVITY to a level which inhibits most species of bacteria, and pre-PASTEURIZATION of the milk helps to prevent spoilage by fungi. Sweetened condensed milk (like many other – particularly acidic – canned foods) is usually non-sterile (cf. COMMERCIAL STERILITY) and often contains e.g. *Bacillus* spp and micrococci.

*Cooling.* Cans are cooled as rapidly as possible to avoid overcooking; cooling may be carried out under pressure to prevent unnecessary strain on the can seams and possible leakage. Water used for cooling should be bacteriologically clean and generally of potable standard.

(b) *Spoilage of canned foods.* Spoilage of the contents of a can may result from (i) mechanical damage to the can or leakage of imperfectly sealed cans (permitting the ingress of microorganisms), or (ii) the activities of thermophilic organisms or heat-stable enzymes in foods subjected to inadequate heat treatment. The type of spoilage depends on the type of food and the nature of the spoilage organism(s). (See also FLAT SOUR and SWELL.) Organisms which may survive the canning process include e.g. endospore-forming bacteria and certain fungi – e.g. *Byssochlamys* spp can cause pectinolytic softening in certain types of canned fruit (the ascospores of *B. fulva* can survive 87.7°C for 10 min). Canned fruit and vegetables may also be spoiled by heat-stable endopolygalacturonases (see PECTIC ENZYMES) produced by fungal contaminants prior to the canning process.

**Cantharanthus alkaloids** *Syn.* VINCA ALKALOIDS.

**Cantharellales** An order of fungi (subclass HOLOBASIDIOMYCETIDAE) in which the basidiocarp may be e.g. funnel-shaped (as

## Cantharellus

e.g. in *Cantharellus infundibuliformis* and *Craterellus cornucopioides*) or stalked and pileate; the hymenophore may be smooth, wrinkled, or lamella-like. *Cantharellus cibarius* (the 'chanterelle') is an edible species which forms a deep yellow, flat or centrally concave pileus on a stipe which tapers towards the base; the 'gills' are yellow, forked and decurrent, and the basidiospores are ochre, ellipsoidal, ca. 8–10 × 5 µm.

**Cantharellus** see CANTHARELLALES.

**cap** (1) (*mycol.*) The PILEUS of a mushroom-shaped fruiting body.

(2) (*mol. biol.*) See MRNA (b). (3) See CAPPING sense 3.

**CAP** Catabolite activator protein: see CATABOLITE REPRESSION.

**cap-binding protein** See MRNA (b).

**capacity test** A type of test used to determine the capacity of a DISINFECTANT to retain activity in the presence of increasing numbers of bacteria. Essentially, aliquots of a bacterial suspension are periodically added to a fixed volume of disinfectant solution which is subcultured (to detect viable bacteria) at fixed intervals of time after the addition of each aliquot. (See e.g. KELSEY-SYKES TEST.)

**capillitium** A system of (non-cellular) threads or filaments which ramify through the spore mass in the fruiting bodies of certain slime moulds of the MYXOMYCETES and fungi of the GASTROMYCETES. In myxomycetes, the capillitial threads may be solid or hollow, free or interconnected, smooth or ornamented, and in certain species they may bear nodes or encrustations of lime (see e.g. FULIGO); the nature of the capillitium is an important taxonomic feature. At least some types of capillitium may aid in spore dispersal; some are elastic, helping to expose spores when the peridium ruptures, while others are hygroscopic, their movements in response to changes in humidity helping to dislodge and release the spores.

**capneic** *Syn.* CAPNOPHILIC.

**Capnocytophaga** A genus of Gram-negative, capnophilic GLIDING BACTERIA found in the human oral cavity and associated with e.g. PERIODONTITIS, abnormalities in neutrophil function, and – in compromised patients – systemic disease. The organisms are flexible fusiform rods, ca. 0.3–0.5 × 3–8 µm. Metabolism: fermentative (glucose being fermented to succinic and acetic acids) or respiratory (with O<sub>2</sub> as terminal electron acceptor). Although CO<sub>2</sub> may be required for initial isolation, high levels of CO<sub>2</sub> are not necessarily required for fermentation or oxidation of glucose [JUSB (1985) 35 369–370]. Agar is not liquefied. Optimum growth temperature: 37°C. Species: *C. gingivalis*, *C. ochracea* (formerly *Bacteroides ochraceus*), and *C. sputigena*.

**Capnodium** See SOOTY MOULDS.

**capnophilic** Refers to any organism whose growth either requires, or is stimulated by, higher-than-atmospheric levels of carbon dioxide.

**capped mRNA** See MRNA (b).

**capping** (1) See MRNA (eukaryotic).

(2) The binding of a specific protein or agent to the end of an ACTIN microfilament or a microtubule (see MICROTUBULES), resulting e.g. in cessation of polymerization/assembly at that end.

(3) In some types of eukaryotic cell: a process which is initiated when cell-surface molecules are cross-linked by multivalent ligands (e.g. antibodies, lectins). The cross-linked molecules from different regions of the cell surface initially cluster into groups or 'patches' (*patching*); subsequently, all the patches undergo an ATP-dependent translocation to one pole of the cell, forming a 'cap' (*capping*). Capping appears to occur only in cells capable of motility, and it has been suggested that it is the expression of a response similar to that given

by a motile cell on contact with a surface. In *Dictyostelium discoideum*, capping appears to involve interaction between ACTIN microfilaments (which are linked, through the cytoplasmic membrane, to patches of ligand) and cortical MYOSIN [JCB (1985) 100 1884–1893]. (See also DYSENTERY (b).)

**caprine arthritis–encephalitis** (CAE) A disease of goats caused by a retrovirus of the LENTIVIRINAE; symptoms include interstitial pneumonia, leucoencephalitis, inflammatory lesions in the CNS, and a progressive arthritis.

**caprized vaccine** A VACCINE containing live organisms whose virulence for a given host species has been attenuated by SERIAL PASSAGE through goats.

**Capripoxvirus** (sheep-pox subgroup) A genus of viruses of the CHORDOPOXVIRINAE which cause disease in ungulates (see e.g. GOAT POX, LUMPY SKIN DISEASE and SHEEP POX); capripoxviruses can be transmitted mechanically by arthropod vectors. The virions are longer and narrower than those of orthopoxviruses; haemagglutinin is not produced, and infectivity can be destroyed e.g. by ether. The viruses in this group are very closely related serologically [JGV (1986) 67 139–148].

**capsduction** A mode of gene transfer in strains of *Rhodospseudomonas capsulata*: DNA transfer from donor to recipient is mediated by a phage-like particle known as the *gene transfer agent* (GTA). Although the GTA morphologically resembles a tailed bacteriophage (head: apparently icosahedral, ca. 30 nm diam., with short spikes; tail: variable in length, bearing tail fibres) no phage-specific DNA has been detected; the linear dsDNA (MWt ca. 3 × 10<sup>6</sup>) carried by the GTA is derived entirely from the host cell (chromosome or plasmid), and any region of the host genome can be packaged. Strains of *R. capsulata* which do not naturally produce GTA can act as recipients in capsduction but do not acquire the ability to produce GTA in consequence. Capsduction has been useful for mapping and genetic analysis in *R. capsulata*. (cf. TRANSDUCTION.)

**capsid** In a virion: a protein coat or shell which surrounds either the nucleic acid genome or a nucleoprotein CORE; it commonly exhibits ICOSAHERAL SYMMETRY. (See e.g. ADENOVIRIDAE.) In some viruses the capsid is itself surrounded by an ENVELOPE (see e.g. TOGAVIRIDAE). (cf. NUCLEOCAPSID.)

**capsidiol** A PHYTOALEXIN (a derivative of 5-epiaristolochene) produced e.g. by the tobacco and green pepper plants.

**capsomer** (capsomere) See ICOSAHERAL SYMMETRY.

**capsule** (1)(a) In prokaryotes, a layer of material external to but contiguous with the CELL WALL; the term thus includes any polysaccharide and/or protein surface layer(s) (including the bacterial S LAYER) but excludes those S layers which constitute the cell wall proper in members of the Archaea. (cf. GLYCOCALYX.) In some bacteria (e.g. *Beijerinckia*) a capsule may enclose more than one cell.

Capsules are commonly divided into three categories.

(i) *Macrocapsules* or 'true' capsules are sufficiently thick to be easily visible (with negative staining – see CAPSULE STAIN) on light microscopy. (ii) *Microcapsules* cannot be observed by light microscopy, but their presence may be revealed by electron microscopy or by serological techniques (see e.g. QUELLUNG PHENOMENON); some bacteria which have lost the ability to form a macrocapsule may form a serologically identical microcapsule. (iii) *Slime layers* are diffuse secretions which may adhere loosely to the cell surface; slime layers commonly diffuse into the medium when the organism is grown in liquid culture, and may be too permeable to stains to be observable by microscopy. (Since capsules normally contain a high proportion of water, they may not be detectable in specimens dehydrated prior to microscopy.)

Capsule composition varies with species, growth conditions etc; serologically distinguishable capsules may be formed even by different strains of the same species (e.g. strains of *Streptococcus pneumoniae* can be distinguished on this basis). Most capsules consist of polysaccharide – either homopolysaccharide (see e.g. CELLULOSE; COLOMINIC ACID; DEXTRAN; LEVAN) or heteropolysaccharide (see e.g. ALGINATE; COLANIC ACID; HYALURONIC ACID). In virulent strains of *B. anthracis* the capsule consists of a homopolymer of  $\gamma$ -linked poly-D-glutamic acid. *Xanthobacter* spp can form both an  $\alpha$ -polyglutamine capsule and copious polysaccharide slime. (See also M PROTEIN (sense 1).) The nature of the binding between the capsule and cell wall is largely unknown, but may involve ionic and/or covalent bonding. For example, capsular material covalently bound to peptidoglycan has been isolated from *B. anthracis*; in *Azotobacter vinelandii* and some mucoid strains of *Pseudomonas aeruginosa* retention of the alginate capsule depends on the level of  $Ca^{2+}$  in the growth medium, alginate being released into the medium at low  $Ca^{2+}$  levels.

Biosynthesis of polysaccharide capsules generally appears to involve transglycosylation from sugar–nucleotide precursors; the subunits are commonly transferred to the exterior of the cell via phosphorylated isoprenoid lipid carriers in the cell membrane.

In nature, bacterial capsules have various functions: they may act as permeability barriers (protecting e.g. against heavy metal toxicity) and/or as ion exchange systems; they may prevent desiccation, phagocytosis by protozoa, or phage infection (by covering receptor sites and/or by immobilization of the phage); they may promote bacterial adhesion to surfaces (see e.g. DENTAL PLAQUE) and/or play a role in recognition systems in interactions with other organisms (see e.g. ROOT NODULES); and they may act as a nutrient reserve (see e.g. XANTHOBACTER). Among pathogens, capsule formation often correlates with pathogenicity; in an animal host, a capsule may allow the pathogen to evade the host's defence mechanisms (see e.g. PHAGOCYTOSIS) [review: JID (1986) 153 407–415], while in a plant host capsular material may be involved in the infection process (see e.g. CROWN GALL). (See also e.g. VI ANTIGEN.)

In vitro, colonies of capsulated bacteria on solid media are typically mucoid. Capsules may be lost on prolonged in vitro culture, but may be retained if a selective agent (e.g. sublethal levels of a surfactant or antibiotic) is incorporated in the medium.

A number of extracellular bacterial polysaccharides have important commercial applications: see e.g. CURDLAN; DEXTRAN; GELLAN GUM; XANTHAN GUM.

(b) (*mycol.*) Structures analogous to bacterial capsules occur in many fungi: gel-like or mucilaginous layers may surround hyphae or yeast cells and may sometimes diffuse into the surrounding medium. For example, in *Schizophyllum commune* a water-soluble glucan is loosely associated with the hyphal walls and may be released into the medium; the glucan consists of a (1  $\rightarrow$  3)- $\beta$ -D-linked chain with single glucose residues attached by (1  $\rightarrow$  6)- $\beta$ -D-linkages at (on average) every third residue [Book ref. 62, p. 139]. Cells of *Cryptococcus* spp form capsules of an amylose-like polymer e.g. when cultured in media of pH <3.0, or (*C. neoformans*) in the tissues of an infected host animal. In certain plant-pathogenic fungi, capsular material may be involved in the recognition of and/or attachment to a suitable host plant [e.g. *Drechslera (Helminthosporium) oryzae*/rice: Phytopath. (1982) 72 285–292].

(2) (*entomopathol.*) See BACULOVIRIDAE.

(3) (*protozool.*) See e.g. RADIOLARIA and DESMOTHORACIDA.

**capsule stain** Bacterial CAPSULES may be demonstrated e.g. by negative STAINING: bacterial growth is mixed with a loopful of e.g. India ink or aqueous NIGROSIN on a clean slide and overlaid with a cover-glass; under the high-dry or oil-immersion objective the capsule appears as a clear zone between the cell wall and the dark background.

**capsule swelling reaction** *Syn.* QUELLUNG PHENOMENON.

**captafol** (difolatan; *N*-(1,1,2,2-tetrachloroethylthio)-cyclohex-4-ene-1,2-dicarboximide) An agricultural antifungal agent related to CAPTAN; it is used as a PROTECTANT e.g. against late blight of potato.

**captan** An antibacterial and ANTIFUNGAL AGENT (*N*-(trichloromethylthio)-cyclohex-4-ene-1,2-dicarboximide) widely used as an agricultural PROTECTANT; it is effective against a number of fungal plant pathogens, and is used e.g. for the prevention of apple scab and leaf-spot diseases (such as black spot of roses), and as a component of seed dressings. The activity of captan has been attributed to the  $-SCCl_3$  group which may react with essential  $-SH$  groups within the fungal cell. Captan is almost insoluble in water and is often formulated as a WETTABLE POWDER. (cf. CAPTAFOL.)

**carate** *Syn.* PINTA.

**carbamate kinase** See e.g. ARGININE DIHYDROLASE.

**carbamic acid derivatives** (as antimicrobial agents) Antimicrobial derivatives of carbamic acid ( $NH_2COOH$ ) include UREA, derivatives of thiocarbamic acid,  $NH_2.CS.OH$  (e.g. TOLNAFTATE), and DITHIOCARBAMATES. (See also BENOMYL.)

**carbamide** *Syn.* UREA.

**carbanilides** (as antimicrobial agents) Carbanilide (diphenylurea,  $(C_6H_5NH)_2CO$ ) and substituted carbanilides (e.g. 3,4,4-trichlorocarbanilide, TCC, = triclocarban) are active mainly against Gram-positive bacteria; they appear to affect the functioning of the cytoplasmic membrane. TCC is also active against certain fungi (e.g. *Trichophyton* spp).

**carbapenems** A class of  $\beta$ -LACTAM ANTIBIOTICS (q.v. for structure) produced (extracellularly) by *Streptomyces* spp; in addition to possessing antibacterial activity, many carbapenems are inhibitory to  $\beta$ -LACTAMASES. (cf. CLAVULANIC ACID.) Carbapenems are stable in aqueous solution near neutral pH. They include e.g. asparenomyins, epithienamycins, olivanic acids, pluracidomyins, PS-5, and THIENAMYCIN.

**carbendazim** (MBC) An agricultural antifungal agent – the active derivative of many of the BENZIMIDAZOLES. Carbendazim is used e.g. in the treatment of eyespot of wheat and barley and (as a seed treatment) as a protectant against damping off caused by *Rhizoctonia solani*. It is often mixed with other antifungal agents – e.g. PROPICONAZOLE or PROCHLORAZ – for use as a broad-spectrum antifungal preparation.

**carbenicillin** See PENICILLINS.

**carbofuran** A broad-spectrum carbamate insecticide used as a soil treatment for the control of insect pests on a range of crop plants. The persistence of carbofuran in the field is limited owing to the wide range of soil microorganisms which can degrade the compound [FEMS Ecol. (2000) 34 173–180].

**carbofuchsin** A red dye used e.g. in the GRAM STAIN and in ZIEHL–NEELEN'S STAIN. Concentrated carbofuchsin is made by adding 10% *basic* FUCHSIN in 95% ethanol (10 ml) to 5% aqueous phenol (100 ml); the solution is filtered after standing overnight.

**carbolic acid** *Syn.* phenol (see PHENOLS).

**carbolic soap** See SOAPS.

**Carbomyces** See PEZIZAE.

**carbomycin** See MACROLIDE ANTIBIOTICS.

## carbon cycle

**carbon cycle** In nature: the cyclical interconversion of carbon compounds (see figure); carbon in its elemental form appears to play no significant role in biological carbon metabolism (cf. NITROGEN CYCLE and SULPHUR CYCLE).

A major metabolite in the carbon cycle is carbon dioxide – see CARBON DIOXIDE (b). In AUTOTROPHS, carbon dioxide can be ‘fixed’ (i.e. incorporated into biomass) via several distinct pathways; the energy required for carbon dioxide fixation may be light energy (see PHOTOSYNTHESIS) or energy derived from chemical reactions. Carbon dioxide can also be used in a dissimilatory manner: see METHANOGENESIS.

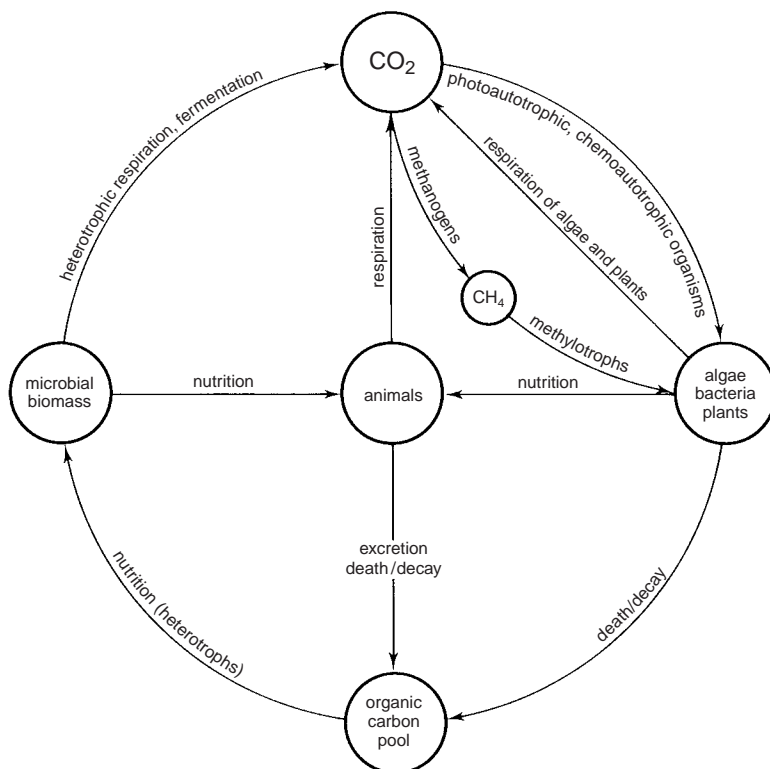

The pool of carbon dioxide is replenished from organic matter by MINERALIZATION, a process in which both oxidative (respiratory) and fermentative forms of metabolism are involved. (See also SAPROTROPH.)

In *aquatic* environments, at least some dissolved organic carbon derives from phytoplANKTON; in the oceans almost all dissolved carbon derives from this source. (See also PRIMARY PRODUCTION.) Some of the dissolved carbon is used for bacterial growth and respiration, and it appears that, at certain times and locations, the amount of carbon dioxide produced by bacterial respiration may exceed that fixed by the phytoplankton; such

an imbalance in carbon cycling may mean that periods of net autotrophy (when autotrophic fixation of carbon dioxide exceeds bacterial respiratory output) may occur at different times of the year to compensate for periods of net heterotrophy [Nature (1997) 385 148–151].

Carbon cycling is relevant to the GREENHOUSE EFFECT. Moreover, the evolution of the carbon cycle is an interesting topic in itself [FEMS Reviews (1992) 103 347–354].

**carbon dioxide (CO<sub>2</sub>)** (a) *CO<sub>2</sub> as a food preservative.* CO<sub>2</sub> (5–50%) inhibits the growth of many types of microorganism and is used in FOOD PRESERVATION – e.g. for meats (see MEAT SPOILAGE), fish, fruit and vegetables (in which CO<sub>2</sub> also extends storage life e.g. by delaying ripening), and for carbonated beverages. In general, CO<sub>2</sub> inhibits moulds more than yeasts, Gram-negative bacteria more than Gram-positive species. CO<sub>2</sub> dissolves in water to form carbonic acid, H<sub>2</sub>CO<sub>3</sub>, which dissociates to form H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> (pK 6.37); some inhibition may thus be due to a pH effect. However, CO<sub>2</sub> also exerts a direct antimicrobial effect which is largely independent of either pH or oxygen concentration. The mechanism of this effect is unknown, but direct inhibitory effects of CO<sub>2</sub> on certain enzymes have been reported; it has also been suggested that CO<sub>2</sub> dissolves

**CARBON CYCLE:** simplified scheme showing some of the major interconversions of carbon in nature (see entry). Bacteria have significant roles, as both autotrophs and heterotrophs, and certain members of the Archaea have unique roles as methanogens; the methylotrophs include methane-utilizing bacteria. Various microorganisms, including bacteria and fungi, are responsible for the essential conversion of ‘dead’ organic carbon to biomass and carbon dioxide; without this process the cycle would stop.

Reproduced from *Bacteria* 5th edition, Figure 10.1, page 256, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

in the cytoplasmic membrane and increases its fluidity, thereby impairing membrane function [Book ref. 29, pp. 335–343]. CO<sub>2</sub> forms complexes with amino groups in proteins, a reaction which is slowly reversible at low temperatures and under low partial pressures of CO<sub>2</sub>; this may account for the observed residual effect in CO<sub>2</sub>-treated meats subsequently exposed to air [Book ref. 29, pp. 369–375].

(b) *CO<sub>2</sub> as a carbon source.* CO<sub>2</sub> is assimilated via several different pathways in AUTOTROPHS (q.v.); in some algae, CO<sub>2</sub>-concentrating mechanisms operate at low CO<sub>2</sub> levels, preventing (energy-wasting) PHOTORESPIRATION. In heterotrophs, CO<sub>2</sub> may be fixed in various carboxylation reactions (see e.g. Appendix II (b) and BACTEROIDES). (See also BIOTIN.)

**carbon disulphide** (CS<sub>2</sub>) CS<sub>2</sub> (b.p. 46°C) is sometimes used as a soil fumigant for the control of *Armillaria mellea* root infections. It also acts as a NITRIFICATION INHIBITOR.

**carbon monoxide** (CO) (a) (as a metabolite) See CARBOXYDOBACTERIA, ACETOGENESIS and METHYLOTROPHY. (b) (as a RESPIRATORY INHIBITOR) Carbon monoxide can bind to the reduced a<sub>3</sub> component of eukaryotic cytochrome oxidase (see ELECTRON TRANSPORT CHAIN), and to many bacterial terminal oxidases, inhibiting the oxidation of the oxidase; a CO-insensitive respiratory chain occurs in the CARBOXYDOBACTERIA. At least some bacterial CO–cytochrome oxidase complexes can be dissociated by strong illumination (*photodissociation*) with light of wavelengths absorbed by the complex – with concomitant release of inhibition.

**carbon monoxide dehydrogenase** See ACETOGENESIS and METHANOGENESIS.

**carbon monoxide oxidase.** See CO OXIDASE.

**carbonic anhydrase** A zinc-containing ENZYME (EC 4.2.1.1) which catalyses the reaction:

Carbonic anhydrases are found in eukaryotes and in members of the domains Bacteria and Archaea [PNAS (1999) 96 15184–15189]. (See also acetate in the figure legend of the entry METHANOGENESIS.)

The carbonic anhydrases are categorized in classes  $\alpha$ ,  $\beta$  and  $\gamma$ ; members of different classes do not share sequence homology.

Tests for the ability to produce carbonic anhydrase have been used e.g. to distinguish between species of MORAXELLA and NEISSERIA.

**carbonylcyanide-*m*-chlorophenylhydrazone** See PROTON TRANSLOCATORS.

**carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone** See PROTON TRANSLOCATORS.

**Carbowax** See POLYETHYLENE GLYCOL.

**Carboxide** See ETHYLENE OXIDE.

**carboxin** (2,3-dihydro-6-methyl-5-phenylcarbamoyl-1,4-oxathiin) An agricultural systemic ANTIFUNGAL AGENT which is active against basidiomycetes, apparently by inhibiting mitochondrial succinate dehydrogenase. Carboxin is used e.g. for the control of *Rhizoctonia solani* and of smuts and rusts in cereals. Oxy-carboxin, the corresponding sulphone, has also been used against cereal rusts.

**carboxydismutase** *Syn.* RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE-OXYGENASE.

**carboxydobacteria** A (non-taxonomic) category of bacteria characterized by the ability to use CARBON MONOXIDE, aerobically, as the sole source of carbon and energy [ARM (1983) 37 277–310]. [Isolation and culture: Book ref. 45, pp. 899–902. Metabolism: Book ref. 132, pp. 131–151. Biotechnological

aspects: MS (1986) 3 149–153. Biochemistry and physiology: FEMS Reviews (1986) 39 161–179.]

The oxidation of carbon monoxide to carbon dioxide is catalysed by an enzyme sometimes referred to as ‘CO dehydrogenase’ (a CO OXIDASE); the cytochrome oxidase of one branch of the respiratory chain is insensitive to inhibition by carbon monoxide. The carbon dioxide produced is assimilated via the CALVIN CYCLE. In at least some cases it appears that the CO oxidase is functional only when attached to a membrane-bound electron acceptor (cytochrome *b*<sub>561</sub>) – the ability of the cells to oxidize carbon monoxide being lower during the stationary phase when some of the enzyme is cytoplasmic [FEMS Reviews (1993) 104 332–336].

Many of all of the carboxydobacteria are able to obtain energy by the oxidation of hydrogen, and can grow more rapidly with hydrogen/carbon monoxide/oxygen mixtures than with mixtures of carbon monoxide and oxygen.

At least some species are facultatively heterotrophic.

The organisms occur e.g. in soil and polluted waters, sewage etc. Species include e.g. *Bacillus schlegelii*, *Pseudomonas carboxydohydrogena*, *P. carboxydovorans* and *P. thermocarboxydovorans*.

The carboxydobacteria were once classified as methylotrophs (users of C<sub>1</sub> compounds) but are now excluded from this category as they do not produce/assimilate formaldehyde.

**carboxymethylcellulose** See CM-CELLULOSE.

**carboxypeptidase** See PROTEASES.

**carboxysomes** Intracellular ‘polyhedral bodies’ (typically ca. 90–500 nm diam.) found in many autotrophic prokaryotes: e.g., in *Thiobacillus intermedius*, *T. neapolitanus*, *T. thiooxidans* and *T. thioparus* (but not in *T. novellus* or *T. versutus*); in *Nitrobacter winogradskyi* and a marine species of *Nitrosomonas* (but not in *Nitrospina gracilis* or *Nitrosococcus mobilis*); apparently in *Rhodocrobium vannielii* (but not in green bacteria or purple non-sulphur bacteria); in most or all cyanobacteria (in vegetative cells and akinetes but not in heterocysts); in *Prochloron*; and apparently in many cyanelles. Carboxysomes from *T. neapolitanus* each consist of a number of doughnut-shaped particles (ca. 10 nm diam.) enclosed within a single-layered membrane or shell; these particles are molecules of RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE-OXYGENASE (RuBisCO). Carboxysomes from other organisms appear to resemble those of *T. neapolitanus*, and RuBisCO has been found in all carboxysomes in which it has been sought (e.g. in those from *Anabaena cylindrica*, *Chlorogloeopsis fritschii*, *Nitrobacter* sp, *Nitrosomonas* sp). The function of carboxysomes is unknown. [Biol. Rev. (1984) 59 389–422.]

**carbuncle** A cluster of interconnected BOILS in which PUS is eventually discharged via several openings. It is usually caused by *Staphylococcus aureus*.

**Carchesium** A genus of sedentary ciliate protozoa (subclass PERITRICHIA). *Carchesium* occurs in various freshwater and marine habitats, and some species (e.g. *C. polypinum*) are common in SEWAGE TREATMENT plants. (See also SAPROBITY SYSTEM and SEWAGE FUNGUS.) In size and shape *Carchesium* resembles VORTICELLA – e.g. it has a bell-shaped zooid; however, *Carchesium* is a colonial peritrich – the mature organism consisting of a number of zooids carried on a branching stalk, each zooid and its individual branch of the stalk being capable of independent contraction.

**carcinogen** (1) Any agent which can cause CANCER. In general, carcinogens appear to exert their effect by interacting with the DNA of the target cell; many carcinogens are also mutagens.

## carcinoma

(See also MUTAGENICITY TEST.) Some apparent carcinogens actually require enzymic conversion within the body to an active form, the 'ultimate carcinogen', before they can cause neoplastic transformation.

(2) *Syn.* oncogen *sensu lato* (see ONCOGENIC).

**carcinoma** Any malignant tumour which arises from epithelial tissue: see e.g. NASOPHARYNGEAL CARCINOMA and HEPATOCELLULAR CARCINOMA. (See also CANCER.)

**cardiac beriberi** See CITREOVIRIDIN.

**Cardiobacterium** A genus of oxidase-positive, catalase-negative, Gram-negative bacteria which occur e.g. in the upper respiratory tract (see also HACEK) and which have been isolated from the blood in cases of bacterial endocarditis. Cells: small, pleomorphic, non-motile, round-ended rods ( $\sim 0.5\text{--}0.75 \times 1\text{--}3 \mu\text{m}$ ), or filaments. Chemoorganotrophic. Aerobic and facultatively anaerobic; apparently capnophilic. On anaerobic blood agar, with 5% carbon dioxide, colonies are smooth and circular, 1–2 mm diam., after 48 hours. Strains are urease –ve but may be weakly indole +ve. Nitrates are not reduced. Optimum growth temperature 30–35°C. Media which have been used for primary isolation include e.g. casein-soy broth and thioglycollate broth (each containing SPS). No growth occurs on MacConkey agar. Acid (but no gas) is formed from the fermentation of fructose, glucose, mannose, sorbitol or sucrose; lactic acid is the main product of glucose fermentation. The organism is typically sensitive to  $\beta$ -lactam and other antibiotics. GC%: 59–62. Type species: *C. hominis*.

**cardioid condenser** See MICROSCOPY (b).

**cardiolipin** Diphosphatidylglycerol. Such lipids occur e.g. in bacterial CYTOPLASMIC MEMBRANES. Cardiolipin prepared by alcoholic extraction of beef heart is used in STANDARD TESTS FOR SYPHILLIS.

**Cardiovirus** A genus of viruses (family PICORNAVIRIDAE) isolated mainly from rodents; the true natural host is uncertain. Cardiovirus virions are generally stable at pH 3–9, but are labile at pH 4.5–6.4 in the presence of 0.1 M halide ions. There is only one serotype, and the various named members of the genus – e.g. Columbia SK virus, mouse (or Maus) Elberfeld virus, mengovirus, MM virus – are regarded as strains of *murine encephalomyocarditis virus* (EMCV). EMCV causes encephalitis and myocarditis in rodents, and a variant can cause a diabetes-like syndrome in certain strains of mice [JGV (1985) 66 727–732].

**carfencillin** See PENICILLINS.

**caries** (dental) See DENTAL CARIES.

**carriogenic** Refers to any factor, substance or organism which promotes DENTAL CARIES.

**carlaviruses** (carnation latent virus group) A group of PLANT VIRUSES in which the virions are slightly flexuous filaments (ca. 600–700  $\times$  13 nm) containing one molecule of linear, positive-sense ssRNA (MWt ca.  $2.7 \times 10^6$ ). Each member has a fairly narrow host range, and some can cause disease in crop plants. Transmission occurs (non-persistently) via aphids in at least some members; mechanical transmission can be achieved under experimental conditions. Type member: carnation latent virus. Other members include e.g. cactus virus 2, hop latent virus, HOP MOSAIC VIRUS, pea streak virus, potato virus M (= potato paracrinkle virus), potato virus S, red clover vein mosaic virus. Possible members include e.g. chicory blotch virus, eggplant mild mottle virus, and groundnut crinkle virus.

**CARNA** See CUCUMOVIRUSES.

**carnation etched ring virus** See CAULIMOVIRUSES.

**carnation Italian ringspot virus** See TOMBUSVIRUSES.

**carnation latent virus** See CARLAVIRUSES.

**carnation mottle virus** See TOMBUSVIRUSES.

**carnation necrotic fleck virus** See CLOSTEROVIRUSES.

**carnation ringspot virus** See DIANTHOVIRUSES.

**carnation vein mottle virus** See POTYVIRUSES.

**carnidazole** See NITROIMIDAZOLES.

**carnivorous** Refers to protozoa which feed on other protozoa, crustacea, etc. (cf. HERBIVOROUS.)

**Carnobacterium** A genus of heterofermentative LACTIC ACID BACTERIA found e.g. on vacuum-stored chilled meats and on meats stored in a carbon-dioxide-rich environment. *Carnobacterium* spp have been studied e.g. as sources of BACTERIOCINS. [Bacteriocin production by *C. piscicola*: JBC (1994) 269 12204–12211. Divercin V41, a new bacteriocin from *C. divergens* V41: Microbiology (1998) 144 2837–2844.]

**Carnoy's fluid** A FIXATIVE: either (a) ethanol (95% or 100%) and glacial acetic acid in the ratio 3:1, or (b) ethanol (95% or 100%), chloroform, and glacial acetic acid (6:3:1).

**carotenes** See CAROTENOIDS.

**carotenoid band shift** A light-induced change in the absorption spectrum of a photosynthetic membrane due, mainly, to a change (of a few nanometres) in the absorption spectra of the carotenoids in the membrane; this change results from the effect on the carotenoids of the light-induced transmembrane pmf (see PHOTOSYNTHESIS) and is sometimes referred to as an 'electrochromic effect'.

**carotenoids** A class of polyene (isoprenoid), aliphatic or alicyclic, commonly yellow or orange pigments; the class includes the *carotenes* (hydrocarbons with usually nine conjugated double bonds) and oxygen-containing derivatives of carotenes (*xanthophylls*) – see figure. Carotenoids are widely distributed in microorganisms, plants and animals; they are present in probably all photosynthetic organisms, in which they function e.g. in LIGHT-HARVESTING COMPLEXES and in protecting CHLOROPHYLLS from photodegradation. (See also SINGLET OXYGEN and ANTIOXIDANTS.) Carotenoids may also be involved in phototaxis (see e.g. EYESPOT), and a carotenoid derivative, RETINAL, occurs in certain bacterial energy-transducing systems (see PURPLE MEMBRANE). The presence of one or more particular carotenoids in a given organism may be an important taxonomic feature, especially in algae.

*Carotenes* include e.g.  $\beta$ -*carotene* ( $R' = R'' = \beta$ -ionone ring, see figure), widely distributed in algae and higher plants, and present in certain bacteria;  $\alpha$ -*carotene* (an isomer of  $\beta$ -carotene), also widely distributed;  $\gamma$ -*carotene* ( $R' = \beta$ -ionone ring,  $R'' = 2,6$ -dimethyl-1,5-heptadienyl), present e.g. in some bacteria of the Chlorobiaceae; *lycopene* ( $R' = R'' = 2,6$ -dimethyl-1,5-heptadienyl), found e.g. in fruits.

*Xanthophylls* include e.g. *antheraxanthin* (found e.g. in green algae (Chlorophyta), in chloromonads, and in plants); *astaxanthin* (see PHAFFIA); BACTERIORUBERINS; *diatoxanthin* (in cryptophytes); *fucoxanthin* (in brown algae (Phaeophyta), chrysophytes, diatoms and prymnesiophytes – see figure); *lutein* (3,3'-dihydroxy- $\alpha$ -carotene, common in plants and green algae); *myxoxanthophyll* (a rhamnosyl-containing xanthophyll found in cyanobacteria); *neoxanthin* (common in green algae and higher plants); *peridinin* (in dinoflagellates); *siphonein* and *siphonoxanthin* (in siphonaceous green algae); *spirilloxanthins* (in anoxygenic photosynthetic bacteria); STAPHYLOXANTHIN; *torularhodin* (in *Rhodotorula*); *violaxanthin* (in green algae and higher plants); *zeaxanthin* (3,3'-dihydroxy- $\beta$ -carotene, an isomer of lutein, found e.g. in green algae and higher plants).

CAROTENOIDS. (a) General structure of a typical carotene. (b)  $\beta$ -Carotene (=  $\beta$ , $\beta$ -carotene). (c) Fucoxanthin (a xanthophyll).

Some bacterial polyene pigments (e.g. FLEXIRUBINS, XANTHOMONADINS) resemble carotenoids but lack the methyl groups on the hydrocarbon chain.

(See also SPOROPOLLENIN.)

**carp erythrodermatitis** (Polish INFECTIOUS DROPSY) A FISH DISEASE affecting carp and certain other fish (e.g. goldfish, bream); aetiology: unknown. The disease is subacute to chronic, with variable mortality. Inflamed skin lesions become necrotic and ulcerative, and generalized oedema follows. Secondary infection with *Aeromonas* and *Pseudomonas* spp is common.

**carp pox** (epithelioma papulosum) A benign FISH DISEASE affecting the common carp (*Cyprinus carpio*) and other cyprinids. Multiple transient hyperplastic nodules (up to several centimetres across) develop on the skin and fins, and occasionally on the eyes and gills; the lesions do not become necrotic. Carp pox is apparently caused by a herpesvirus (see HERPESVIRIDAE).

**carpomycetes** Fungi which form fruiting bodies – particularly the ascomycetes and basidiomycetes.

**Carr medium** A medium used e.g. to distinguish between strains of ACETOBACTER and GLUCONOBACTER; it contains yeast extract (3%), agar (2%), BROMCRESOL GREEN (0.002%) and ethanol (2% v/v). *Gluconobacter* strains (which typically oxidize ethanol to acetic acid) produce colonies each surrounded by a yellow halo; *Acetobacter* strains (which typically carry out 'overoxidation') initially form similar colonies but, on further incubation, the acetic acid is metabolized and the pH indicator reverts to its original colour (i.e. the halo is lost).

**carrageenan** (carrageenin; carrageen) A mixture of sulphated galactans associated with the CELL WALLS of many rhodophycean algae (e.g. *Chondrus crispus*, *Gigartina* spp); they appear to prevent desiccation when the alga is exposed to the atmosphere. Carrageenans have the general structure:  $-\beta$ -A-(1  $\rightarrow$  4)- $\alpha$ -B-(1  $\rightarrow$  3)- $\beta$ -A-, where A = D-galactose 4-sulphate or D-galactose 2-sulphate, and B is any of a range of sulphated galactose or 3,6-anhydrogalactose residues. One component of the carrageenan mixture,  $\kappa$ -carrageenan, is precipitated by KCl; in  $\kappa$ -carrageenan A = D-galactose 4-sulphate, B = 3,6-anhydro-D-galactose.  $\kappa$ -Carrageenan forms gels with e.g.  $K^+$ ,  $NH_4^+$ ,  $Ca^{2+}$ ,  $Mg^{2+}$ ,  $Fe^{3+}$ , and with water-miscible organic solvents;

it is widely used in industry e.g. as a gelling and thickening agent in foods, pharmaceuticals etc, and in supports for IMMOBILIZATION of cells and enzymes. It can also be used as an AGAR substitute in certain bacteriological media [Book ref. 2, pp. 144–145]. The KCl-soluble, non-gelling fraction of carrageenan consists of various polymers in which B = e.g. D-galactose 6-sulphate, D-galactose 2,6-disulphate, 3,6-anhydro-D-galactose 2-sulphate, etc. (The term  $\lambda$ -carrageenan sometimes refers to the whole KCl-soluble fraction, sometimes specifically to the component in which A = D-galactose 2-sulphate, B = D-galactose 2,6-disulphate.)

**carragheen moss** See CHONDRUS.

**Carrel flask** A squat cylindrical glass vessel which opens, at the side, via a straight, upward-sloping tubular neck.

**carrier** (1) (*med., vet.*) An individual who harbours a particular pathogen but shows no clinical signs of disease; such an individual can transmit the pathogen to others. Carriers are important reservoirs of infection in certain diseases – e.g. DIPHTHERIA and TYPHOID FEVER (cf. SMALLPOX). [The carrier state (involving bacteria): JAC (1986) 18 Supplement A 1–81.] (2) (*immunol.*) See HAPTEN. (3) See CARRIER TEST. (4) (*virol.*) See PSEUDOLYSOGENY and CARRIER CULTURE.

**carrier culture** (*virol.*) A cell culture which is persistently infected with a virus (see PERSISTENCE) but in which only a small proportion of the cells in the population is actually infected by the virus. The infected cells may release virus (e.g. by lysis) but only a small proportion of the remaining cells is then infected, and so on. The culture can be 'cured' of the virus e.g. by treatment with virus-neutralizing antiserum or by serial subculture using small inocula. In e.g. mammalian cell cultures a carrier culture may arise e.g. because INTERFERON production may render most of the cells resistant to infection. (See also PSEUDOLYSOGENY; cf. SEMIPERMISSIVE CELLS.)

**carrier gene** See FUSION PROTEIN.

**carrier-specific T helper cell** (CTh) A T LYMPHOCYTE whose TCR recognizes a specific epitope in the 'carrier' part of an antigen – another epitope (the 'hapten') on the same antigen being recognized by a B cell. (See COGNATE HELP.) If an antigen carrying a particular hapten-carrier pair is used for primary

## carrier test

immunization, then the hapten must be paired with the same carrier for an efficient response during secondary immunization.

**carrier test** A type of test used to determine the ability of a given disinfectant to disinfect an object ('carrier') which has been artificially contaminated with microorganisms; the carrier may be e.g. a piece of cloth or an instrument. (See e.g. AOAC USE-DILUTION TEST.) [Evaluation of carriers used in AOAC test methods; AEM (1986) 51 91–94.]

**Carrión's disease** *Syn.* BARTONELLOSIS.

**carboiose** A disaccharide: 3,6-anhydro-4-*O*-( $\beta$ -D-galactopyranosyl)-D-galactose, a degradation product of  $\kappa$ -carrageenan.

**carrot black rot** See ALTERNARIA.

**carrot latent virus** See RHABDOVIRIDAE.

**carrot mosaic virus** See POTYVIRUSES.

**carrot mottle virus** See TOGAVIRIDAE.

**carrot red leaf virus** See LUTEOVIRUSES.

**carrot soft rot** See SOFT ROT (sense 2).

**carrot thin leaf virus** See POTYVIRUSES.

**carrot yellow leaf virus** See CLOSTEROVIRUSES.

**Carr's medium** See CARR MEDIUM.

**Carreria** A genus of green algae which closely resemble CHLAMYDOMONAS but which have four flagella instead of two.

**carvacrol** See PHENOLS.

**Cary-Blair transport medium** See TRANSPORT MEDIUM.

**caryonide** *Syn.* KARYONIDE.

**Caryophanon** A genus of Gram-positive, asporogenous, obligately aerobic, chemoorganotrophic bacteria which form motile (peritrichously flagellate) TRICHOMES of diameter ca. 1.5  $\mu$ m (*C. tenue*) or ca. 2.5–3.2  $\mu$ m (*C. latum*). Both species have been isolated from cattle manure, but their true habitat is unknown. [Book ref. 46, pp. 1701–1707.]

**Caryospora** A genus of protozoa (suborder EIMERIORINA) which form oocysts each enclosing one sporocyst containing 8 sporozoites.

**Caryotropha** See EIMERIORINA.

**casamino acids** Acid-hydrolysed casein.

**caseation** (*med., vet.*) A type of necrosis in which diseased tissue breaks down into a dry, amorphous, cheese-like mass (cf. TUBERCULOSIS).

**casein** A phosphoprotein which occurs in MILK mainly in the form of micelles, each micelle consisting of aggregated molecules of the 3 main types of casein:  $\alpha$ -,  $\beta$ - and  $\kappa$ -casein; the ( $\text{Ca}^{2+}$ -precipitable)  $\alpha$ - and  $\beta$ -caseins in the micelles are stabilized by the  $\kappa$ -casein.  $\kappa$ -Casein can be cleaved by various enzymes – e.g. by pepsin (EC 3.4.23.1), or by rennin (= chymosin; EC 3.4.23.4), an enzyme derived from the abomasum (see RUMEN) of suckling ruminants; these enzymes cleave  $\kappa$ -casein into an insoluble N-terminal fragment, *p*- $\kappa$ -casein, and a soluble C-terminal fragment, 'glycomacropetide'. Cleavage of micellar  $\kappa$ -casein in milk destabilizes micelles and leads to the precipitation of  $\alpha$ - and  $\beta$ -caseins and *p*- $\kappa$ -casein (i.e., the milk *coagulates*). (The proteolytic enzymes of some psychrotrophic bacteria can cleave  $\kappa$ -casein and cause 'gelation' (coagulation) in stored UHT-treated milk.)

Enzyme-independent coagulation ('clotting' – see e.g. LITMUS MILK) occurs when the pH is lowered to ca. 4.6 (i.e., at or near the isoelectric points of the caseins).

$\gamma$ -Casein is a product of the enzymic cleavage of  $\beta$ -casein by a trypsin-like enzyme which occurs in milk in small amounts.

**Caseobacter** A genus of aerobic, non-motile, asporogenous bacteria (order ACTINOMYCETALES, wall type IV) which occur e.g. on certain cheeses. The organisms are pleomorphic or coryneform rods, ca. 1  $\times$  2–4  $\mu$ m, which give rise to coccoid

forms in stationary-phase culture; on yeast extract–glucose agar the colonies are grey-white, pink or red. Up to 12% salt (NaCl) can be tolerated. GC%: 65–67. Type species: *C. polymorphus*.

**caseous necrosis** *Syn.* CASEATION.

**caspsases** See APOPTOSIS.

**cassava common mosaic virus** See POTEXVIRUSES.

**cassava latent virus** See GEMINIVIRUSES.

**cassava vein mosaic virus** See CAULIMOVIRUSES.

**cassette mechanism** (*mol. biol.*) A system for gene regulation in which a particular gene is removed from one site ('active slot'), in which it can be expressed, to another ('inactive slot') in which it cannot be expressed – another gene being inserted into the 'active slot'. (See e.g. MATING TYPE.)

**Castañeda's method** A form of BLOOD CULTURE in which the culture bottle contains an agar slope which projects above the level of the liquid medium when the bottle is standing vertically. The liquid medium is inoculated in the usual way, and the bottle is incubated. After 24/48 h the bottle is tilted so that the medium washes over the exposed agar; the bottle is then incubated, vertically, and subsequently examined for bacterial growth on the agar. Tilting etc may be repeated at intervals of one or two days. By eliminating subculturing this method avoids a source of contamination.

**cat** (parvovirus infection) See FELINE PANLEUKOPENIA VIRUS.

**cat bite fever** A disease caused by *Pasteurella multocida* and transmitted by cat-bites; an abscess develops at the site of the bite. (cf. CAT SCRATCH DISEASE.)

**cat diseases** See under 'feline'.

**cat flu virus** *Syn.* FELINE CALICIVIRUS.

**cat gene** A gene encoding chloramphenicol acetyltransferase: see CHLORAMPHENICOL and Tn9.

**cat scratch disease** (cat scratch fever) A (usually benign) human disease (more common in children) associated with the scratch or bite of a cat or, occasionally, with injuries from thorns, splinters etc. A local inflammatory skin lesion develops after 2–3 days, and this is followed, in days/weeks, by enlargement of regional lymph nodes – which suppurate in some cases. There is often a general malaise with low-grade fever. The condition usually resolves spontaneously within weeks; however, in some cases there are complications – which may involve e.g. liver, brain or eyes.

Various organisms have been proposed as the causal agent of cat scratch disease, including e.g. *Bartonella clarridgeiae* [JCM (1997) 35 1813–1818].

(See also CAT BITE FEVER.)

**catabolism** The metabolic reactions by which exogenous or endogenous organic compounds are degraded to simpler organic or inorganic compounds. (cf. ANABOLISM; AMPHIBOLIC PATHWAY.)

**catabolite activator protein** See CATABOLITE REPRESSION.

**catabolite control protein A** See CATABOLITE REPRESSION.

**catabolite inhibition** See INDUCER EXCLUSION.

**catabolite repression** The repression of certain inducible enzyme systems by the presence of a 'preferred' carbon source (e.g. glucose in enterobacteria and *Saccharomyces cerevisiae*, certain TCA cycle intermediates in *Pseudomonas* spp). For example, in *Escherichia coli*, various operons concerned with the degradation of substrates other than glucose (e.g. ARA OPERON, LAC OPERON, TNA OPERON) are repressed in the presence of glucose, even when their respective inducers are present; thus, when *E. coli* is grown in a medium containing both glucose and lactose, the *lac* operon remains repressed until all the glucose has been used – at which time the *lac* operon becomes derepressed. (See also DIAUXIE, CRABTREE EFFECT.)

Among the bacteria there are several distinct mechanisms for catabolite repression. Thus, e.g. one mechanism is characteristic of *E. coli* and other enterobacteria, while others are typical of AT-rich Gram-positive species (e.g. species of *Clostridium*, *Lactobacillus* and *Staphylococcus*); each of these mechanisms is regulated by signals from components of the PTS (q.v.). Models outlining these mechanisms are described below.

(a) *Catabolite repression in enterobacteria*. In these organisms the key regulatory molecule is the IIA component of glucose permease in the PTS; note that, in this particular permease, IIA is a cytoplasmic (i.e. soluble) protein.

When glucose is *absent*, phosphorylated IIA (IIA~P) does not undergo dephosphorylation via IIB, and under these conditions IIA~P activates the enzyme ADENYLATE CYCLASE – thus stimulating the synthesis of CYCLIC AMP (cAMP). cAMP binds to, and activates, the so-called *cAMP-receptor protein* (CRP) – also called *catabolite activator protein*, CAP, or *catabolite gene activator protein*, CGA protein. (CRP is encoded by the *crp* gene.) The cAMP–CRP complex acts as a transcriptional activator by binding in the vicinity of promoters of certain operons (e.g. *lac*), allowing them to be expressed in the presence of their respective inducers. This explains why the inducibility of the repressed operons can be at least partly restored by the addition of cAMP. The precise way in which cAMP–CRP promotes transcription is still unknown. One early model for the *lac* operon supposed that the binding of cAMP–CRP displaced RNA polymerase from a weak promoter, P2, to the primary promoter, P1; that such a mechanism is unlikely to contribute significantly to the transcription of the *lac* operon has been inferred from the failure of inactivation of P2 to result in activation of P1 [Mol. Microbiol. (1992) 6 2419–2422]. Studies on e.g. the *lac* operon suggest that the presence of cAMP–CRP is not needed after the establishment of a productive open complex, and that only transient interaction is required between cAMP–CRP and RNA polymerase [EMBO (1998) 17 1759–1767].

When glucose (or other rapidly metabolizable substrate) is *present*, unphosphorylated IIA binds to the permeases of various sugars (e.g. lactose), inhibiting uptake of the corresponding sugars; as these sugars are involved in the induction of their respective operons, this phenomenon is called INDUCER EXCLUSION.

Note that, in some cases, cAMP–CRP may repress rather than activate gene expression. For example, in *Rhizobium meliloti* cAMP–CRP blocks transcription of the *dctA* gene whose expression is necessary for symbiotic nitrogen fixation [EMBO (1998) 17 786–796]. (In fact, CRP – originally associated with activation of catabolic operons – is involved in a much wider range of gene-regulatory activities.)

(b) *Catabolite repression in the AT-rich Gram-positive bacteria*. In these bacteria, transcription of some catabolic operons is at least partly regulated by operon-specific regulator proteins, each regulator protein having two phosphorylation sites; each of these two sites is called a PRD (= PTS regulation domain). PRDs can be phosphorylated by certain intermediates in the PTS (IIB~P and HPr~P); one of the PRDs can be phosphorylated by IIB~P, the other by HPr~P. It seems that phosphorylation by IIB~P is inhibitory, causing the regulator protein to inhibit transcription from relevant operons, while phosphorylation by HPr~P promotes transcription from those operons. The activity of a given regulator protein thus depends on the mode of its phosphorylation; thus, when phosphorylated *only* by HPr, the regulator protein promotes transcription from all relevant operons, but phosphorylation by HPr *and* IIB, or a lack of phosphorylation in both PRDs (i.e. in the presence of both inducer

and glucose), causes the regulator protein to function as a repressor of transcription. Induction of operon(s) therefore occurs only under appropriate conditions, i.e. when (i) inducer is present and (ii) glucose is absent. [PTS-dependent control of PRD-containing regulators in induction and repression of catabolic operons: Mol. Microbiol. (1998) 28 865–874.]

A PRD-containing regulator protein in *E. coli*, BglG, is involved in the control of the *bgl* operon (a  $\beta$ -glucoside catabolic system concerned e.g. with the metabolism of salicin); in the *absence* of  $\beta$ -glucoside, BglG is phosphorylated by the IIB component of BglF (the  $\beta$ -glucoside permease) – thus inhibiting transcription of the *bgl* operon.

In AT-rich Gram-positive bacteria, catabolite repression involving HPr and the enzyme *HPr kinase* occurs by ATP-dependent phosphorylation of HPr at a site (Ser-46) which differs from that (His-15) phosphorylated by enzyme I in the PTS; when HPr is phosphorylated at Ser-46 it can form a complex with *catabolite control protein A* (CcpA), and this complex can bind to a regulatory site in target operons, inhibiting transcription. (*In vitro*, phosphorylation of HPr at the Ser-46 site decreases the ability of HPr to accept phosphate from the ‘routine’ donor, enzyme I; thus, phosphorylation of HPr at this site is likely to inhibit uptake of sugars at the PTS permeases.) HPr kinase is a bifunctional enzyme (HPr kinase/phosphatase), and its role as a kinase in phosphorylating HPr under appropriate conditions of carbon availability is not fully understood; it is possible that the kinase function of the enzyme is stimulated by fructose 1,6-bisphosphate (an intermediate in glucose catabolism). Inactivation of the HPr kinase gene (*hprK*) in *Staphylococcus xylosum* resulted in abolition of repression in the three catabolic enzyme activities examined [JB (2000) 182 1895–1902].

**catalase** ( $\text{H}_2\text{O}_2:\text{H}_2\text{O}_2$  oxidoreductase; EC 1.11.1.6) A tetrameric ENZYME, consisting of four ferriprotoporphyrin IX-containing subunits, which catalyses the reaction  $2\text{H}_2\text{O}_2 \rightarrow 2\text{H}_2\text{O} + \text{O}_2$ ; with low concentrations of  $\text{H}_2\text{O}_2$  the enzyme can act as a PEROXIDASE – but this ability may not be common to catalases from all sources [JGM (1983) 129 997–1004]. Catalase plays a vital role in detoxifying HYDROGEN PEROXIDE produced during aerobic metabolism; it occurs in the majority of aerobic organisms and is absent from most obligate anaerobes (though present e.g. in *Bacteroides fragilis*). The enzyme is inhibited by e.g.  $\text{H}_2\text{S}$ ,  $\text{HCN}$  and  $\text{N}_3^-$ , and is inactivated by SUPEROXIDE. Catalase is obtained commercially from e.g. *Aspergillus niger* and *Penicillium* spp; it is used e.g. in the food industry for removing excess  $\text{H}_2\text{O}_2$  (used for cold disinfection) from milk and dairy products and from irradiated foods. (See also CATALASE TEST; METHYL TROPHY; PEROXISOMES; cf. PSEUDOCATALASE.)

**catalase test** A test commonly used with the object of determining whether or not a given bacterial strain produces CATALASE. One drop of  $\text{H}_2\text{O}_2$  is added to a bacterial colony, or to a bacterial emulsion; if the cells contain catalase, bubbles of gas (oxygen) appear immediately or within one or two seconds. Such a (positive) reaction may indicate the presence of catalase or (e.g. in some strains of *Enterococcus faecalis*) the presence of a PSEUDOCATALASE; certain bacteria can synthesize catalase only if they are provided with haem. If, for the test, bacterial growth is obtained from a blood-containing medium, care should be taken to prevent contact between  $\text{H}_2\text{O}_2$  and the medium: erythrocytes, which contain catalase, can give rise to a false-positive reaction.

In carrying out the catalase test care should be taken to avoid exposure to the AEROSOL produced by bursting bubbles; in one method the test is carried out in a non-vented Petri dish: a drop of  $\text{H}_2\text{O}_2$  and a speck of bacterial growth are placed at opposite

## cataloguing

sides of the dish which, with the lid in place, is tilted so that the  $H_2O_2$  runs onto the growth.

(See also SUPEROXOL TEST.)

**cataloguing** (of 16S rRNA) See RRNA OLIGONUCLEOTIDE CATALOGUING.

**Catapyrenium** A genus of LICHENS (order VERRUCARIALES) which differ from *DERMATOCARPON* spp in having a squamulose thallus attached to the substratum by rhizines. The genus includes e.g. *C. lachneum* (formerly called e.g. *Dermatocarpon hepaticum*).

**catarrh** Inflammation of a mucous membrane, with excessive production of mucus.

**catecholamides** (in iron uptake) See SIDEROPHORES.

**catenane** A complex of two or more circular nucleic acid molecules interlocked like links in a chain. (cf. CATENATE; CONCATEMER; see also GYRASE.)

**Catenaria** See BLASTOCLADIALES.

**catenate** (1) (*verb*) To interlock circular nucleic acid molecules to form a CATENANE (hence *noun* catenation). (2) (*adj.*) Of e.g. spores: formed in chains.

**catenins** See CADHERINS.

**catheter-associated infection** INFECTION (sense 3) associated with catheterization of the blood vascular system or of the urinary tract; in general, the risk of such infection increases with the duration of catheterization. Catheter-related infections account for a significant proportion of nosocomial disease.

In catheter-associated bacteraemia, the source of infection can be investigated either with or without withdrawal of the catheter [current methods for the diagnosis of catheter-related bacteraemia: RMM (1997) 8 189–195].

In catheter-associated infection of the urinary tract, a significant reduction in incidence during short-term (<3 weeks) catheterization may be obtained by using catheters that have anti-infection surface activity; such catheters may be either (i) impregnated with e.g. nitrofurazone, or with minocycline and rifampicin, or (ii) coated with a silver alloy–hydrogel [EID (2001) 7 342–347].

**cathodic depolarization theory** A theory proposed to account for the microbial corrosion of iron. In this theory, the spontaneous solubilization of iron (by ionization:  $Fe \rightarrow Fe^{2+} + 2e^-$ ) is promoted by (a) hydrogen formation, the electrons from iron combining with protons derived from water ionization, and (b) utilization of the hydrogen by SULPHATE-REDUCING BACTERIA. However, it has been reported that the primary cause of such corrosion may involve an extracellular (probably phosphorus-containing) product of sulphate-reducing bacteria [Book ref. 155, pp. 619–641].

**cattle diseases** Cattle may be affected by a wide range of diseases, some of which are specific to bovines; different species and breeds of bovines may show differences in susceptibility to a given disease (see e.g. FOOT-ROT). (a) *Bacterial diseases*: see e.g. ACTINOMYCOSIS; ANAPLASMOSIS; ANTHRAX; BLACK DISEASE; BLACKLEG; BRUCELLOSIS; CAMPYLOBACTERIOSIS; CONTAGIOUS BOVINE PLEUROPNEUMONIA; EPERYTHROZONOSIS; FARCY (sense 2); FOOT-ROT; HAEMORRHAGIC SEPTICEMIA (sense 2); INFECTIOUS KERATITIS; JOHNE'S DISEASE; LEPTOSPIROSIS; LISTERIOSIS; MASTITIS; NECROBACILLOSIS; PARATYPHOID FEVER; RED WATER (of calves); TUBERCULOSIS; TULARAEMIA; ULCERATIVE LYMPHANGITIS; WHITE SCOURS. (See also COWDRIA; LAMZIEKTE; MIDLAND CATTLE DISEASE.) (b) *Fungal diseases*: see e.g. ASPERGILLOSIS; ZYGOMYCOSIS. (See also FESCUE FOOT; 4-IPOMEANOL; PASPALUM STAGGERS; PENITREMS; SPORIDESMINS.) (c) *Protozoal diseases*: see e.g. DALMANY DISEASE; EAST COAST FEVER; NAGANA; REDWATER FEVER. (d) *Viral diseases*: see e.g. AKABANE VIRUS DISEASE; ALLERTON

DISEASE; AUJESZKY'S DISEASE; BOVINE EPHEMERAL FEVER; BOVINE ULCERATIVE MAMMILLITIS; BOVINE VIRAL LEUKOSIS; BOVINE VIRUS DIARRHOEA; CALF PNEUMONIA; FOOT AND MOUTH DISEASE; INFECTIOUS BOVINE RHINOTRACHEITIS; JEMBRANA DISEASE; LUMPY SKIN DISEASE; MALIGNANT CATARRHAL FEVER; MUCOSAL DISEASE; PSEUDOCOWPOX; RABIES; RIFT VALLEY FEVER; RINDERPEST; ROTAVIRUS; VESICULAR STOMATITIS. (e) *Diseases of unknown/variable aetiology*: ATYPICAL INTERSTITIAL PNEUMONIA; BOVINE RESPIRATORY DISEASE; CALF SCOURS; WIMMERA GRASS POISONING; WINTER DYSENTERY.

(See also BOVINE SPONGIFORM ENCEPHALOPATHY.)

**cattle plague** *Syn.* RINDERPEST.

**cattle tick fever** *Syn.* REDWATER FEVER.

**Caulerpa** A genus of siphonaceous, tropical and subtropical green seaweeds related to HALIMEDA (q.v.). The thallus consists of a horizontal green rhizome with colourless rhizoids and erect fronds. (See also ELYSIA.)

**caulescent** Becoming stalked or tailed.

**cauliflower fungus** *Sparassis crispa*.

**cauliflower mosaic virus** (CaMV; cabbage B virus) A member of the CAULIMOVIRUSES which infects various brassicas. In e.g. cauliflower (*Brassica oleracea* var. *botrytis*) symptoms of infection typically include vein-banding and/or vein-clearing; enations are occasionally formed. Transmission: chiefly stylet-borne via aphids.

A CaMV virion consists of a capsid (composed of a single type of protein) and the dsDNA genome. In the virion, the dsDNA is circular with three discontinuities at specific sites in the molecule: two in one strand (the  $\beta$  strand), one in the other ( $\alpha$  strand); these discontinuities are neither nicks nor gaps, but are sites of triple-stranded DNA in which the 3' and 5' ends overlap by ca. 8–20 nucleotides [FEBS (1981) 134 67–70]. In the host plant, CaMV DNA appears to occur in the form of covalently closed circular, supercoiled, histone-associated (chromatin-like) 'mini-chromosomes' which are apparently active in transcription but not in replication. Only the  $\alpha$ -strand is transcribed. Viral RNAs (which are capped and polyadenylated) include a large (8.2 kb, 35S) transcript corresponding to the length of the entire genome with an additional 180-nucleotide terminal repeat; this transcript may be an intermediate in DNA replication: a molecule of plant tRNA<sup>met</sup> binds to the 35S transcript at a 14-bp region of homology, and this tRNA may act as a primer for cDNA synthesis by reverse transcription (see RETROID VIRUSES). [Evidence for replicative recombination in CaMV: Virol. (1986) 150 463–468.] Viral transcription occurs in the plant cell nucleus, while virus particle assembly occurs in rounded, amorphous, electron-dense, cytoplasmic viroplasm; the site of DNA replication is unknown.

CaMV is widely studied as a model for transcription, DNA replication etc in higher plants, and as a potential (non-integrating) vector for gene transfer in plants.

[Book ref. 80, pp. 17–48.]

**caulimoviruses** (cauliflower mosaic virus group) A group of PLANT VIRUSES characterized by a dsDNA genome (ca. 8000 bp long). The virions are isometric, ca. 50 nm diam.; the capsid is composed of a single type of polypeptide (MWt ca.  $42 \times 10^3$ ). Type member: CAULIFLOWER MOSAIC VIRUS; other members: carnation etched ring virus, dahlia mosaic virus, figwort mosaic virus, *Mirabilis* mosaic virus, strawberry vein-banding virus; possible members: cassava vein mosaic virus, *Petunia* vein-clearing virus, *Plantago* virus, thistle mottle virus. (See also NON-CIRCULATIVE TRANSMISSION sense 1.)

**Caulobacter** A genus of chemoorganotrophic, strictly aerobic, PROSTHOCATE BACTERIA found e.g. in oligotrophic waters and in

soils poor in organic matter. Type species: *C. vibrioides*. GC%: 64–67.

Most of the studies on this genus have been carried out on *C. crescentus* – to which the following account applies.

The non-motile, mature ('mother') cell is a straight or curved rod, ca. 1–2  $\mu\text{m}$ , which typically has a single polar stalk (PROSTHECA) – the distal end of which is adhesive; cells may adhere, singly, to the substratum – or may occur in groups ('rosettes'), each group consisting of a number of cells radiating from a central mass of adhesive material. Many strains contain carotenoid pigments.

The mother cell gives rise, by asymmetric binary fission, to a daughter cell (*swarmer*) which bears a single polar flagellum. The swarmer subsequently loses its flagellum, develops a prostheca, and can then function as a mother cell. In stained mother cells the prostheca may show one or more cross-striations (*crossbands*), each of which is thought to mark one turn of the cell cycle.

The molecular mechanisms involved in the process of differentiation and asymmetric cell division (essential features of the cell cycle) are beginning to be understood through studies on the intracellular localization of proteins using techniques such as gene fusion. In some cases the targeting, or activation, of a specific protein has been linked to an essential aspect of differentiation or cell division.

Cell cycle regulation involves various TWO-COMPONENT REGULATORY SYSTEMS. One response regulator, CtrA, has an important role in the control of initiation of DNA replication and in the expression of many genes [PNAS (2002) 99 4632–4637].

Following initiation of DNA replication in the mother cell, levels of the phosphorylated form of CtrA (CtrA~P) increase, CtrA~P (and/or CtrA) then promoting transcription of certain genes – including 'early' flagellar genes and those regulatory genes needed for expression of the later flagellar genes. The regulation of flagellar genes may be more complex than was previously supposed [PNAS (2002) 99 4632–4637].

The FliF protein is targeted to a specific polar site in the developing daughter (*swarmer*) cell, i.e. the MS ring in the swarmer cell develops prior to septation; the mechanism responsible for directing FliF to the appropriate location is unknown.

After formation of the septum, the FlbD protein is activated by phosphorylation – the kinase, FlbE, occurring near the septum in the *daughter* cell; the activated FlbD protein (FlbD~P) promotes transcription of 'late' flagellar genes – resulting in the development of a polar flagellum in the daughter cell.

In the daughter cell, CtrA~P binds to the chromosomal origin, thus inhibiting replication; hence, unlike the mother (stalked) cell, the swarmer does not divide until it matures.

Under normal circumstances, the role of CtrA (i.e. the unphosphorylated form) in the mother cell includes activation of the late cell division genes *ftsQ* and *ftsA* – whose expression is necessary for cell division. If DNA replication is inhibited, then CtrA is not synthesized (thus blocking cell division) – lack of synthesis under these conditions reflecting failure of activation of *ctrA*; as activation of *ctrA* is normally dependent on CtrA~P, it has been suggested that inhibition of DNA replication may inhibit phosphorylation of CtrA – constituting a cell cycle 'checkpoint' which blocks cell division in the absence of DNA replication [EMBO (2000) 19 4503–4512].

[Control of differentiation in *C. crescentus*: Science (1997) 276 712–718. Signal transduction mechanisms in *C. crescentus* development and cell cycle control: FEMS Reviews (2000) 24 177–191.]

**Caulococcus** See KUSNEZOVIA.

**caviid herpesvirus 1** See BETAHERPESVIRINAE.

**cavitation** (1) (*med.*) The formation of an (abnormal) cavity or space in the body (as e.g. in certain types of pneumonia). (2) See ULTRASONICATION.

**cavity slide** A slide (somewhat thicker than a normal microscope SLIDE) which has a shallow, circular depression about 1 cm across in the centre of one face. (cf. RING SLIDE.)

**Cavostelium** See PROTOSTELIOMYCETES.

**CBP** Cap-binding protein: see MRNA (b).

**CBS** Centraalbureau voor Schimmelcultures, Oosterstraat 1, Baarn, The Netherlands; yeast division: CBS, Julianalaan 67A, Delft, The Netherlands.

**cca gene** See TRNA.

**cccDNA** Covalently-closed circular DNA.

**CCCP** See PROTON TRANSLOCATORS.

**CCCV** COCONUT CADANG-CADANG VIROID.

**ccd mechanism** See e.g. F PLASMID.

**CcdB toxin** See F PLASMID.

**CCFAS** (compact colony-forming active substance) A heat-stable, acid-labile carbohydrate, present in the cell walls of certain staphylococci, responsible for the compact morphology of colonies growing in serum soft agar. (Strains without CCFAS form diffuse colonies in such media.) CCFAS exerts its effect by interacting with fibrinogen in the serum agar, promoting the formation of fibrin. It is distinct from, but has been confused with, clumping factor (see COAGULASE). [Book ref. 44, pp. 551–552.]

**CCM** Czechoslovak Collection of Microorganisms, J. E. Purkyne University of Brno, Tr. Obrancu Miru 10, 66243 Brno, Czechoslovakia.

**CCNU** See N-NITROSO COMPOUNDS.

**CepA** See CATABOLITE REPRESSION.

**CCPs** Critical control points: see HACCP.

**CCY medium** A medium containing casein hydrolysate and yeast extract; cultures on this medium are commonly incubated under a CO<sub>2</sub>-enriched atmosphere.

**CD** (meaning of) See CELL ADHESION MOLECULE.

**CD2** See IMMUNOGLOBULIN SUPERFAMILY.

**CD3** A T-cell-receptor-associated antigen consisting of three transmembrane polypeptides ( $\gamma$ ,  $\delta$  and  $\epsilon$ ) which occurs in all T cells (both  $\alpha\beta$  and  $\gamma\delta$  types) and which is part of the so-called *T-cell receptor complex*. CD3 is not covalently linked to the T cell receptor, and it does not bind antigen; however, when antigen binds to the T cell receptor, serine and tyrosine residues on the three polypeptides of CD3 undergo phosphorylation, and this initiates part of the intracellular signalling in the T cell which follows the binding of antigen.

**CD4** A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY which occurs on some  $\alpha\beta$  and  $\gamma\delta$  T cells (see also CD8).

CD4 binds to MHC class II ligands on antigen-presenting cells (APCs) when antigen is bound by the T cell receptor; such binding stabilizes T cell–APC contact, and causes CD4 to act as a signal-transducing molecule – this involving phosphorylation of its intracellular domain by a specific kinase.

CD4 also acts as a receptor for the human immunodeficiency virus (HIV), allowing infection of CD4<sup>+</sup> cells.

**CD5** See B LYMPHOCYTE.

**CD8** A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY which occurs e.g. on some  $\alpha\beta$  and some  $\gamma\delta$  T cells (see also CD4). CD8 binds to MHC class I ligands; like CD4, bound CD8 acts as a signal-transducing molecule.

## CD11a/CD18

**CD11a/CD18** (*syn.* LFA-1) A CELL ADHESION MOLECULE of the INTEGRIN family ( $\alpha_L\beta_2$ ) found on most leukocytes; when activated, it binds strongly to ICAM ligands (see e.g. INFLAMMATION). (CD11a refers to the  $\alpha$  subunit, CD18 to the  $\beta$  subunit.)

**CD11b/CD18** (*syn.* Mac-1) See INTEGRINS.

**CD11c/CD18** The CR4 receptor on macrophages; it binds e.g. the C3bi fragment of complement.

**CD14** A protein which occurs either in plasma or membrane-associated on macrophages and fibroblasts. Cell-bound CD14 binds exogenous LIPOPOLYSACCHARIDES (LPS); such binding (indirectly) stimulates the synthesis of cytokines – including pro-inflammatory (e.g. IL-1, TNF) and anti-inflammatory (e.g. IL-6, IL-10) molecules. The activity of LPS is greatly increased by the ACUTE-PHASE PROTEIN *lipopolysaccharide-binding protein* (LBP) which promotes the transfer of LPS to CD14.

**CD15** (sialyl-Lewis x) A carbohydrate CELL ADHESION MOLECULE, found on leukocytes, which binds to ligands of the SELECTIN family (see e.g. INFLAMMATION).

**CD16** (*syn.* Fc $\gamma$ RIII) A CELL ADHESION MOLECULE, found on e.g. PMNs and NK cells, which binds to the Fc portion of antigen-bound antibody and is involved e.g. in ADCC.

**CD18** See CELL ADHESION MOLECULE and INTEGRINS.

**CD21** A CELL ADHESION MOLECULE which occurs e.g. on epithelial cells of the oropharynx; it acts as a receptor for Epstein–Barr virus. CD21 (= CR2) is also found on B lymphocytes, and is involved e.g. in antigen-dependent activation.

**CD23** See EPSTEIN–BARR VIRUS and B LYMPHOCYTE.

**CD28** A cell-surface molecule which occurs on T lymphocytes. During presentation of antigen by an ANTIGEN-PRESENTING CELL to a naive CD4<sup>+</sup> T cell, so-called *co-stimulatory signals* – which promote clonal proliferation of the T cell and secretion of cytokines – are generated when CD28 binds to certain molecules on the APC – e.g. B7.1 (also written B7-1; = CD80) or B7.2 (B7-2; CD86). Co-stimulatory signals generated by such binding (which are necessary for T cell development) lead e.g. to the synthesis of INTERLEUKIN-2 by the T cell.

During presentation of antigen to an *activated* T cell, CD80/CD86 binds preferentially to the cell-surface molecule CD152 (found only on activated T cells) – the affinity of CD80/CD86 for CD152 being greater than that for CD28. (CD152 is also called *cytokine T-lymphocyte-associated antigen-4*, or CTLA-4.) Unlike the binding between CD80/CD86 and CD28, binding between CD80/CD86 and CD152 generates a signal that is inhibitory to the T cell's response, e.g. it inhibits the synthesis of IL-2 in the lymphocyte.

(See also CD40.)

**CD31** (*syn.* PECAM-1) A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY which occurs e.g. on endothelial cells, monocytes and platelets. Binding, apparently homophilic (i.e. CD31–CD31), is believed to be necessary for extravasation in INFLAMMATION.

**CD32** See B LYMPHOCYTE.

**CD34** A marker present on haemopoietic stem cells but not on mature haemopoietic cells.

**CD35** Complement receptor 1 (CR1): a glycoprotein present e.g. in the membranes of erythrocytes (red blood cells, RBCs) and of various nucleated blood cells, including B cells and some T cells; plasma contains low levels of a soluble form of CR1 (sCR1).

CR1 belongs to a family of COMPLEMENT control proteins. The molecules of CR1 on RBCs bind immune complexes, and these complexes are removed as the RBCs circulate through the liver and spleen; CR1 promotes cleavage of the C3b and

C4b components of complement, thus protecting the cell from complement-mediated lysis.

The SI<sup>a</sup> antigen of the CR1 glycoprotein (an antigen of the Knops blood group system) is associated with the phenomenon of 'rosetting' in falciparum MALARIA.

**CD36** See MALARIA (vaccines).

**CD40** A cell-surface molecule which occurs on B lymphocytes. During recognition of a thymus-dependent (TD) antigen by antigen-specific B and T cells, CD40 binds to the T cell's CD40L (gp39) antigen; such binding generates part of the stimulus which results in clonal proliferation of the B cell and class switching of antibody (IgM  $\rightarrow$  IgG etc.). (The physical interaction between T and B cells also generates signals that activate clonal proliferation in the T cell: see CD28.)

(See also RNA EDITING.)

**CD41b** See INTEGRINS.

**CD44** (*syn.* homing-associated cell adhesion molecule, HCAM) A CELL ADHESION MOLECULE found e.g. on monocytes, neutrophils, fibroblasts and memory T cells; it is apparently unrelated to other CAMs. CD44 binds to e.g. collagen and hyaluronate, and is apparently involved in 'lymphocyte homing' (i.e. translocation of lymphocytes between blood and lymph vessels).

**CD46** (membrane co-factor protein, MCP) A cell-surface molecule on macrophages which acts as a receptor for COMPLEMENT component C3b. (CD46 can also act as a receptor for the measles virus; the binding of measles virus to CD46 inhibits the ability of the macrophage to form INTERLEUKIN-12.)

**CD48** A macrophage cell-surface glycoprotein which can bind the type I FIMBRIAE of *Escherichia coli*. In the absence of opsonizing factors, cells of *E. coli* that have type I fimbriae can bind to CD48, initiating uptake into a phagosome which is not acidified in the normal way and in which *E. coli* can survive.

**CD50** See IMMUNOGLOBULIN SUPERFAMILY.

**CD54** (*syn.* ICAM-1) A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY which occurs e.g. on endothelial and epithelial cells, monocytes and fibroblasts. CD54 binds to certain integrins (e.g. LFA-1, Mac-1). (See also INFLAMMATION.)

**CD55** Decay-accelerating factor (DAF): a glycoprotein present in the membranes of blood cells (red and white), endothelial cells, and epithelial cells of the urinary and gastrointestinal tracts; DAF accelerates decay of the C3 and C5 convertases in the classical and alternative pathways of COMPLEMENT FIXATION, thus helping to protect cells from complement-mediated lysis.

The DAF glycoprotein bears antigens of the Cromer blood group system, and also acts as a receptor for *Escherichia coli* and enteroviruses.

**CD56** (*syn.* NCAM) See IMMUNOGLOBULIN SUPERFAMILY.

**CD58** See IMMUNOGLOBULIN SUPERFAMILY.

**CD61** See INTEGRINS.

**CD62E** (*syn.* E-selectin; also known as endothelium–leukocyte adhesion molecule-1, ELAM-1) A CELL ADHESION MOLECULE of the SELECTIN family which is inducible, on endothelial cells, by certain cytokines (e.g. IL-1 $\beta$ , TNF- $\alpha$ ); it binds to sialylated carbohydrate ligands on e.g. monocytes, neutrophils and CD4<sup>+</sup> T cells. CD62E is involved in the tethering stage of INFLAMMATION.

**CD62L** See SELECTINS.

**CD62P** See SELECTINS.

**CD66** A category of cell adhesion molecules (of the IMMUNOGLOBULIN SUPERFAMILY), some of which occur on polymorphonuclear leukocytes (PMNs) and/or e.g. epithelial cells. Specific molecule(s) – CD66a, c, d and/or e (not b) – can

bind neisserial OPA PROTEINS and, in at least some cases, mediate uptake of bacteria by the eukaryotic cell.

**CD69** An antigen detectable on immature T lymphocytes (thymocytes) during the process of maturation in vivo.

**CD77 antigen** A B-lymphocyte differentiation antigen which is structurally equivalent to the globotriosylceramide (Gb<sub>3</sub>) receptor for SHIGA TOXIN and the shiga-like toxins. These toxins selectively kill B cells expressing IgG or IgA – so that the immune response to infection may be actively suppressed by toxin.

**CD80** See CD28.

**CD81** A protein of the tetraspanin family which is found in the cytoplasmic membrane of cells in many human tissues; CD81 acts as a receptor for the E2 envelope glycoprotein of the hepatitis C virus. [Three-dimensional structure of the extracellular domain of CD81: EMBO (2001) 20 12–18.]

**CD86** See CD28.

**CD95** See FAS.

**CD102 (ICAM-2)** A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY found e.g. on endothelial cells, monocytes and some lymphocytes; it binds to the integrin LFA-1, and may be involved in lymphocyte homing.

**CD106 (VCAM-1, vascular cell adhesion molecule-1)** A CELL ADHESION MOLECULE of the IMMUNOGLOBULIN SUPERFAMILY found e.g. on endothelial cells, macrophages and fibroblasts; it binds to ligands of the integrin family, and is involved e.g. in the adhesion of leukocytes to the endothelium during the flattening stage of INFLAMMATION.

**CD120a (p55)** See TNF.

**CD120b (p75)** See TNF.

**CD152** See CD28.

**CDC** Centers for Disease Control, a division of the US Public Health Service.

**cdc mutant** See CELL CYCLE.

**cdl gene** See COLICIN PLASMID.

**cDNA (complementary DNA; copy DNA)** A DNA molecule obtained by reverse transcription of an RNA molecule (commonly an mRNA molecule).

cDNAs prepared from *mature* mRNAs are useful e.g. for CLONING and expressing intron-containing eukaryotic genes; if the genes themselves were cloned in bacteria, the presence of intron(s) would prevent their expression. (Introns are removed during the formation of mature mRNA – see SPLIT GENE.)

Most eukaryotic mRNAs [and some bacterial mRNAs: Microbiology (1996) 142 3125–3133] have a polyadenylate (poly(A)) tail at the 3' end (see MRNA). To synthesize a cDNA molecule, a short oligodeoxythymidine (oligo(dT)) strand is hybridized to the poly(A) tail of the mRNA, and a REVERSE TRANSCRIPTASE, together with a mixture of dNTPs, is then added; using oligo(dT) as a primer, the reverse transcriptase synthesizes a DNA strand on the mRNA template. The mRNA strand can then be removed e.g. by alkaline hydrolysis or by RNase H. The DNA strand synthesized by reverse transcriptase often folds over at the 3' end to form a HAIRPIN structure, thus providing a primer for the synthesis of a complementary DNA strand by an appropriate DNA polymerase; following such synthesis, the hairpin structure can be opened by endonuclease S1 to form a linear dsDNA molecule which is suitable for cloning.

**CDP** Cytidine 5'-diphosphate.

**CDR factor** See METHANOGENESIS.

**CDSC** Communicable Diseases Surveillance Centre, Public Health Laboratory Service, Colindale, London, UK.

**CDTA** A chelating agent, *trans*-1,2-diamino-cyclohexane-*N,N,N',N'*-tetraacetic acid. CDTA complexes a range of cations (e.g.

Ba<sup>2+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>, Zn<sup>2+</sup>); complexes formed with either Ca<sup>2+</sup> or Mg<sup>2+</sup> are more stable than those formed by EDTA or EGTA with these cations.

**cea gene** See COLICIN PLASMID.

**cecidia** See GALLS.

**cecidization** GALL-formation.

**cecropins** A family of PEPTIDE ANTIBIOTICS; cecropins appear in the haemolymph of the Cecropia moth (*Hyalophora cecropia*), and certain other insects, following exposure to bacteria. (cf. SARCOTOXINS.)

**cedar apples** See GYMNOSPORANGIUM.

**Cedecea** A genus of bacteria (family ENTEROBACTERIACEAE) isolated from human clinical specimens (pathogenicity unknown). [Book ref. 22, pp. 514–515.]

**cefamandole** See CEPHALOSPORINS.

**cefazolin** See CEPHALOSPORINS.

**cefepime** A fourth-generation CEPHALOSPORIN. Resistance to cefepime has been associated with diminished permeability of the outer membrane in *Enterobacter aerogenes* [Microbiology (1998) 144 3003–3009] and with hyperproduction of the  $\beta$ -lactamase SHV-5 in *Klebsiella pneumoniae* [JCM (1998) 36 266–268].

**cefixime** A third-generation CEPHALOSPORIN. It has been used e.g. (together with potassium tellurite) as a supplement to SMAC medium (see EHEC); this supplement has been found to increase the rate of isolation of *Escherichia coli* strain O157 by suppressing the growth of other non-sorbitol-fermenters (e.g. strains of *Proteus*).

**cefmenoxime** See CEPHALOSPORINS.

**cefonicid** See CEPHALOSPORINS.

**ceforanide** See CEPHALOSPORINS.

**cefotaxime** See CEPHALOSPORINS.

**cefoxitin** A CEPHAMYCIN which, in e.g. *Escherichia coli*, binds preferentially to PBP-1A (see PENICILLIN-BINDING PROTEINS) and moderately well to other PBPs (but not to PBP-2).

Cefoxitin is active against a range of Gram-negative and Gram-positive bacteria, including anaerobes such as *Clostridium* and members of the *Bacteroides fragilis* group. It is resistant to many  $\beta$ -LACTAMASES, including extended-spectrum  $\beta$ -lactamases, but may be sensitive to metalloenzyme  $\beta$ -lactamases produced by certain strains of anaerobic bacteria.

Cefoxitin is an inducer of  $\beta$ -lactamases, so that it should not be used in combination with another  $\beta$ -lactam antibiotic.

Cefoxitin has been useful e.g. as a systemic prophylactic agent in both gastrointestinal and gynaecological surgery; when combined with doxycycline it has been used for the treatment of pelvic inflammatory disease, while a combination of cefoxitin and an aminoglycoside antibiotic has been useful for treating post-operative infections.

[Cefoxitin (review): RMM (1995) 6 146–153.]

**cefprome** See CEPHALOSPORINS.

**cefsulodin** See CEPHALOSPORINS.

**cefsulodin–Irgasan–novobiocin agar** See CIN AGAR.

**ceftazidime** See CEPHALOSPORINS.

**ceftizoxime** See CEPHALOSPORINS.

**ceftriaxone** See CEPHALOSPORINS.

**cefuroxime** See CEPHALOSPORINS.

**celecoxib** See PROSTAGLANDINS.

**celery crown rot** See CROWN ROT.

**celery mosaic virus** See POTYVIRUSES.

**celery yellow mosaic virus** See POTYVIRUSES.

**celery yellow spot virus** See LUTEOVIRUSES.

## celery yellows

**celery yellows** A YELLOWS disease of celery which may be caused e.g. by an MLO or by the fungus *Fusarium oxysporum*; in the latter case the main symptoms (stunting and yellowing) are due to vascular occlusion by the pathogen.

**celesticetin** See LINCOSAMIDES.

**cell adhesion molecule (CAM)** In man and other animals: a membrane-associated molecule characteristically involved in cell–cell or cell–matrix adhesion and (often) in the signalling between a cell and its environment. In the latter role, incoming signals modulate various signalling pathways within the cell; signals transmitted via CAMs influence various aspects of cell physiology, including the cell cycle.

Most CAMs are proteins which consist of (i) a hydrophobic transmembrane domain; (ii) an extracellular domain – which can bind to a *counter-receptor* (a different type of molecule on another cell) or to another extracellular ligand; and (iii) an intracellular domain (often linked to the cytoskeleton of the cell). A CAM may be normally present in an inactive form; under appropriate conditions, activation may confer the ability e.g. to bind a counter-receptor. The extracellular domain of a CAM may act e.g. as a receptor for invasive bacterial pathogens (see CADHERINS, INTEGRINS), or as a means of cell migration during INFLAMMATION.

In a given cell, the type and number of CAMs depend on factors such as stage of development, function (or change in function), and the presence or absence of viral infection.

A CAM may be referred to by a ‘family’ name (see cross-references, below) or by a CD (‘cluster of differentiation’) number. A given CD number (e.g. CD54) signifies a specific antigen which has been identified by various batches of monoclonal antibodies from different laboratories. An integrin molecule may have *two* CD numbers (e.g. LFA-1 = CD11a/CD18); one number refers to the  $\alpha$  subunit, the other to the  $\beta$  subunit.

See: CADHERINS, IMMUNOGLOBULIN SUPERFAMILY, INTEGRINS, SELECTINS and CD44; see also separate entries under ‘CD’.

**cell-bound antibodies** Antibodies bound by their combining sites to homologous cell-surface antigens, or bound by other sites (see e.g. CYTOPHILIC ANTIBODIES) to cell-surface receptors.

**cell culture** See TISSUE CULTURE.

**cell cycle** In prokaryotic or eukaryotic microorganisms: the sequence of events which occur in a growing cell during the period between the cell’s formation from its parent cell and the division of the cell itself into daughter cells; this period of time includes (i) initiation of DNA replication from at least one chromosomal origin, (ii) the replication of chromosome(s), (iii) the segregation of chromosomes, (iv) the formation of a septum or intercell partition, and (v) cell division. These events always occur strictly in the same order. The events which constitute the cell cycle are regulated by both extracellular (environmental) and cell-associated factors.

One event regarded as an important juncture in the cell cycle is the initiation of DNA replication; earlier workers proposed two main hypotheses to account for the regulation of this stage of the cell cycle.

In the ‘G<sub>1</sub> event model’ (devised primarily for eukaryotic cells), triggering of DNA replication, and subsequent cell division, is dependent on event(s) which occur only during a specific part of the cell cycle (the G<sub>1</sub> phase – see below).

In the ‘continuum model’ (postulated to refer to both prokaryotic and eukaryotic cells), a hypothetical initiator of DNA replication is produced by the cell during all phases of the cell cycle; initiation of DNA replication occurs when the concentration of initiator, per origin of replication in the cell, reaches a certain

critical level – the concentration of initiator (per origin) then falling sharply owing to the abrupt doubling of numbers of available origins at the start of replication. (It follows from this model that a cell can govern its rate of division by regulating the rate of synthesis of the initiator.)

In both models, initiation of DNA replication is a key event which occurs late in an empirically defined phase that follows cell division and precedes the next round of DNA replication. Once DNA replication has begun the cell is normally committed to continue replication to completion; the point at which a cell becomes committed to DNA replication has been called the *restriction point* (= R point, or R) or, simply, *start*.

(a) *The eukaryotic cell cycle*. The typical cell cycle in eukaryotes consists of the following sequence of phases:

*S phase*. DNA replication.

*G<sub>2</sub> phase*. Gap phase 2: the period between the end of DNA replication and the start of mitosis.

*M phase*. MITOSIS and cell division.

*G<sub>1</sub> phase*. Gap phase 1: the period between cell division and the start of DNA replication.

The total period (G<sub>1</sub> + S + G<sub>2</sub>) is called *interphase*. (In some lower eukaryotes, e.g. *Physarum*, the cell cycle apparently lacks a G<sub>1</sub> phase.)

Non-cycling (‘resting’) cells are said to be in the G<sub>0</sub> phase.

A given phase in the cell cycle is characterized e.g. by the cell’s PLOIDY; thus, in a ‘diploid’ cell, the ploidy is 2n in G<sub>1</sub>, 2n–4n in S, and 4n in G<sub>2</sub>.

Typically, when variation occurs in the rate of cell growth and division (due e.g. to nutritional factors) it is the length of G<sub>1</sub> which varies, i.e. the other two phases remain relatively constant in length over a wide range of growth rates.

*Regulation of the eukaryotic cell cycle*. The cell cycle can be regulated by signals from outside the cell; thus, cells exposed to e.g. certain growth-inhibitory factors or sex pheromones become arrested in the G<sub>1</sub> phase. (Those cells which, at the time of exposure, are in the S, G<sub>2</sub> or M phase complete their cycling to the G<sub>1</sub> phase.)

To investigate regulatory mechanisms within the cell, studies have been carried out e.g. on the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. Particularly useful have been the cell-division-cycle mutants (*cdc* mutants) in which the cell cycle is arrested at specific stage(s). The products of some *cdc* genes have been found to influence more than one point in the cycle; for example, the *cdc2* gene product of *S. pombe* (Cdc2) affects the cycle in late G<sub>1</sub> and also in late G<sub>2</sub>.

What kind of internal regulatory mechanisms are involved? At certain points in the cell cycle there are ‘gates’ or ‘checkpoints’ at which the cell makes a decision to either continue through the cycle or stop cycling; one such checkpoint is *start* (mentioned earlier). Continuation through *start* depends e.g. on the nutrient status of the cell’s environment, i.e. the cycle is arrested at the *start* checkpoint if nutrient levels are inadequate.

The effector molecules involved in regulating ‘continue/stop’ decisions are certain types of protein. They include PROTEIN KINASES and PROTEIN PHOSPHATASES; a cyclical element is contributed by the CYCLINS (q.v.) which accumulate intracellularly, prior to checkpoints, and are cleaved on passage through the checkpoints.

(b) *The prokaryotic cell cycle*. In prokaryotes, most studies on the cell cycle have been carried out on bacteria – particularly *Escherichia coli*; the following account is based primarily on the cell cycle in *E. coli*. [Cell cycle in the Archaea: Mol. Microbiol. (1998) 29 955–961.]

In bacteria, the cell cycle typically involves a period of growth followed by division into two similar or identical daughter cells (BINARY FISSION). (An atypical cell cycle occurs e.g. in CAULOBACTER (q.v.).) The daughter cells receive equal numbers of chromosome(s). Chromosome replication and cell division are related in a manner described by the HELMSTETTER-COOPER MODEL (q.v.).

*The cell's dimensions during growth.* Cells that are growing rapidly are larger (in both mass and volume) than those growing more slowly. If the doubling time is less than ~1 hour, the *C* and *D* periods (see HELMSTETTER-COOPER MODEL) are more or less constant; at the beginning of each *C* period the cell's mass (= initiation mass) is also virtually constant for a given rate of growth. Under these conditions, it follows that the faster a cell grows the greater will be the increase in cell mass and volume during the (constant) *C* + *D* interval prior to cell division.

Cells of *E. coli* growing at a constant rate increase in size mainly by elongation (the diameter of the cells remaining largely unchanged). If the growth rate is increased, newly formed cells are larger than those formed at the lower rate. During up-regulation of the growth rate, the cell's diameter increases slowly, but the increase in cell length occurs more rapidly and, in fact, initially 'overshoots' – cells being longer than appropriate for the new, higher rate of growth; during ongoing growth at the new rate, the cell diameter increases to its new value while the cell length decreases to its final value (which is still higher than that at the lower rate of growth). If growth rate falls, the cell's diameter, as before, adjusts more slowly than the cell's length – the latter exhibiting an initial 'undershoot' [JGM (1993) 139 2711–2714].

In *Bacillus subtilis*, determination of the rod shape appears to involve helical, actin-like filaments within the cell. Filaments composed of MreB protein may influence the cell's width. Those of Mbl protein influence longitudinal growth; they seem to guide the cell-wall-synthesizing machinery. These types of protein are found in many species, including *Escherichia coli*. Some bacteria (e.g. *Corynebacterium glutamicum*) lack these proteins; in these bacteria the rod shape may be maintained through polar growth. [Bacterial morphogenesis: Cell (2003) 113 767–776.]

*Synthesis of the cell envelope.* During steady growth, cell envelope material is presumably being synthesized more or less continually throughout the cell cycle. Studies on the turnover of PEPTIDOGLYCAN in growing cells of the (Gram-negative) bacillus *E. coli* suggest that the lateral wall of the cell contains a monolayer of peptidoglycan and that multilayered peptidoglycan may occur at the poles [JB (1993) 175 7–11]. In Gram-positive bacteria, wall growth is believed to follow the INSIDE-TO-OUTSIDE MODEL.

Höltje [Microbiology (1996) 142 1911–1918] described a model for the mode of incorporation of newly synthesized peptidoglycan in the growing sacculus: see THREE-FOR-ONE MODEL.

It has been assumed that synthesis of the CYTOPLASMIC MEMBRANE proceeds passively (secondarily to the growing peptidoglycan sacculus). However, it has been reported that peptidoglycan synthesis is dependent on the synthesis of membrane phospholipids – a finding which suggests a novel mechanism for the regulation of growth of the cell envelope [Microbiology (1996) 142 2871–2877].

*DNA replication.* As mentioned, co-ordination between chromosome (DNA) replication and cell division is described by the HELMSTETTER-COOPER MODEL.

Regulation of the initiation of a round of DNA replication is not understood – although a link between the timing of initiation

and growth rate can be seen in the Helmstetter-Cooper model by comparing the start of the *C* periods in slow-growing and rapidly growing cells.

Although the precise mechanism of initiation is unknown, several factors appear to be important. [Some similarities among the initiators of DNA replication in Bacteria, Archaea and Eucarya: FEMS Reviews (2003) 26 533–554.]

One factor is the intracellular concentration of DnaA protein (or possibly an activated form of it); thus, replication is dependent on the initial binding of a number of DnaA molecules at specific sites (*DnaA boxes*) within the *oriC* region of the chromosome – such binding being followed by localized 'melting' (i.e. strand separation) in the DNA, a prerequisite for replication. The concentration of DnaA molecules within the cell is therefore critical because replication is delayed until the DnaA boxes have been occupied. Studies with in vitro replication systems have identified mutant DnaA proteins defective in opening the duplex at *oriC* [Mol. Microbiol. (2000) 35 454–462].

The link between initiation and growth rate, mentioned earlier, possibly involves guanosine 5'-diphosphate 3'-diphosphate (= 'guanosine tetraphosphate'; ppGpp) – a small molecule whose concentration is inversely proportional to growth rate; the high levels of ppGpp found during slow growth can e.g. inhibit synthesis of DnaA protein (at the level of transcription), and this may result in delayed initiation.

Another factor apparently involved in initiation is the Fis protein (*fis* gene product). Like DnaA, Fis has binding sites in the *oriC* region; moreover, it appears to regulate genes which include those encoding DnaA and the  $\beta$  subunit of DNA polymerase III [JB (1996) 178 6006–6012]. Fis binds at *oriC* in a cell-cycle-specific way [EMBO (1995) 14 5833–5841], forming an 'initiation-preventive' complex [NAR (1996) 24 3527–3532]. Nevertheless, the way in which Fis influences the timing of initiation is unknown.

Initiation may also be influenced by the degree of methylation in the *oriC* region – a certain level of methylation apparently being necessary for a functional *oriC*. It has been suggested that, after a round of replication, the *oriC* region in a daughter cell may be left temporarily hemi-methylated (i.e. methylated in only the template strand), and that the time needed to achieve a functional level of methylation may affect the timing of initiation.

*Decatenation and partition of chromosomes.* Newly synthesized chromosomes are *catenated* (i.e. interlocked, like the links of a chain); clearly, prior to partition, the chromosomes have to be separated, and this process is carried out by TOPOISOMERASES. (If decatenation is prevented, e.g. by mutation in an essential topoisomerase gene, the result may include the formation of filamentous cells, containing interlocked chromosomes, as well as anucleate cells which have no chromosome; this can occur e.g. in cells of *E. coli* which are mutant in the *parC* gene which encodes a subunit of topoisomerase IV.)

On separation, each chromosome forms a compact nucleoid; this may involve the binding of many molecules of HU protein [Mol. Microbiol. (1993) 7 343–350].

The way in which nucleoids are partitioned to daughter cells is unknown. Various mechanisms have been suggested: (i) attachment to the cytoplasmic membrane – the nucleoids being segregated mechanically; (ii) mutual repulsion between nucleoids; (iii) the *extrusion-capture* model, in which extrusion of DNA from the 'replication factory' (replisome) provides the energy for partition [GD (2001) 15 2031–2041].

## cell disruption

In *Bacillus*, the *oriC* regions may be drawn apart *actively* [JB (1998) 180 547–555]. In *B. subtilis* the Smc protein seems to contribute to nucleoid structure – hence promoting normal segregation. [Segregation (primarily in *B. subtilis*): Microbiology (2001) 147 519–526.]

After the report of ‘mitosis-like’ partitioning of plasmid R1 in *E. coli* [EMBO (2002) 21 3119–3127] it was suggested that actin-like filaments of MreB protein (a ‘cytoskeletal’ element associated with the maintenance of cell shape in rod-shaped bacteria) may mediate a similar process in the segregation of nucleoids; dysfunctional MreB inhibits chromosome segregation in *E. coli* [EMBO (2003) 22 5283–5292].

**Septum formation.** In *E. coli*, a cross-wall (septum) eventually divides the growing cell into two daughter cells. This process starts with the formation of a ring-shaped structure composed of FtsZ molecules (encoded by *ftsZ*) circumferentially on the inner surface of the cytoplasmic membrane – mid-way along the length of the cell; this FtsZ ring (‘Z ring’) marks the plane of the forthcoming septum. (Expression of FtsZ may be influenced by ppGpp [JB (1998) 180 1053–1062].) Binding between FtsZ and ZipA (a cytoplasmic membrane protein) is reported to be necessary for cell division [Cell (1997) 88 175–185]. [Interaction between ZipA and a C-terminal fragment of FtsZ (X-ray crystallography): EMBO (2000) 19 3179–3191.]

Assembly of the Z ring apparently begins at a *nucleation site* and proceeds, bidirectionally, around the circumference of the cell; development of nucleation sites themselves may involve the Era protein (product of the *era* gene; a GTPase of the Ras superfamily) which seems to be a key factor in the control of cell division [Mol. Microbiol. (1998) 29 19–26].

During cell division the septum must form mid-way along the cell – not at alternative polar sites; the Z ring is guided by the *min* gene products. In one model for this guidance system, MinE molecules form a circumferential, annular band at mid-cell. This MinE ring oscillates, i.e. it moves alternately towards one pole and then the other; this causes the MinCD proteins to oscillate between opposite poles of the cell – so that the (inhibitory) influence of MinC on FtsZ polymerization is minimal at the mid-cell location, permitting assembly of the FtsZ ring at the mid-cell position [Science (2002) 298 1942–1946]. (During oscillation of MinCD proteins, arrival/departure at the cell’s poles involves binding/hydrolysis of ATP.) One report suggested that the oscillation of MinD may involve ATP-dependent polymerization of MinD into fibres [PNAS (2002) 99 16776–16781].

A fluorescent image of the FtsZ ring has been obtained by means of gene fusion between *ftsZ* and the gene for green fluorescent protein [PNAS (1996) 93 12998–13003].

An FtsZ ring has been reported in anucleate cells, indicating that division sites can develop even in the absence of a chromosome [Mol. Microbiol. (1998) 29 491–503].

The Z ring also occurs in members of the Archaea; this suggests that the apparatus for cell division was similar in an ancestral prokaryote [Mol. Microbiol. (1996) 21 313–319].

In the plane of the Z ring, peptidoglycan grows inwards to form the septum; this begins very early in the development of the division site [JB (2003) 185 1125–1127].

**Cell division.** The septum is split into two layers, each of which forms the new pole (end) of a daughter cell; this process is carried out by the EnvA protein. The OUTER MEMBRANE grows inwards to complete the cell envelope.

The *morphogenes* encode those products, such as EnvA, FtsZ and the MinCDE proteins, which ensure that, during the cell

cycle, proteins are synthesized at the right times and targeted to correct locations within the cell.

**Control of the cell cycle.** The occurrence of a given event in the cell cycle could depend directly on the occurrence of the previous event in the sequence. An alternative view is that the cell cycle is a sequence of independent events that are co-ordinated. Co-ordination was suggested [Mol. Microbiol. (1991) 5 769–774] for reasons that include e.g. (i) The inhibition of certain cell cycle events does not necessarily inhibit others. Thus, cell division *can* occur, for example, without proper partitioning of the nucleoids – i.e. division can proceed in the absence of a ‘signal’ from the event that normally precedes division. (ii) There is no evidence for *direct* coupling between chromosome replication and cell division. However, there is evidence for indirect co-ordination: damage to DNA (which may inhibit chromosome replication) triggers the so-called SOS SYSTEM which, among other effects, inhibits cell division.

More recent studies on e.g. CAULOBACTER show that the cell cycle has *checkpoints*: stages at which, normally, a given event must be completed before the next can begin [see JB (2003) 185 1128–1146 (1135–1136)]. (See also *essential* TWO-COMPONENT REGULATORY SYSTEMS.)

**cell disruption** The breaking of cells – usually for analysis of their components. Methods include: (a) Exposure to physical forces (see e.g. BRAUN MSK TISSUE DISINTEGRATOR, FRENCH PRESS, HUGHES PRESS, ULTRASONICATION). (b) Enzymic digestion of specific cell wall components – e.g. the digestion of PEPTIDOGLYCAN by LYSOZYME or LYSOSTAPHIN; cells thus weakened can be lysed osmotically. The morphology and structure of a cell influence the ease with which it is broken. Cells most resistant to mechanical disruption include yeasts, bacterial endospores, and Gram-positive cocci; Gram-negative bacteria are less resistant, and the least resistant include protozoa and other animal cells. Once cells are broken, their components become susceptible to the action of e.g. AUTOLYSINS. (See also CELL FRACTIONATION.)

**cell envelope (bacteriol.)** The CYTOPLASMIC MEMBRANE together with all layers external to it – including the CELL WALL and/or (where applicable) an S LAYER.

**cell fractionation** The separation of cell components. Fractionation is preceded by some form of CELL DISRUPTION. Methods of fractionation include various forms of CENTRIFUGATION, CHROMATOGRAPHY and ELECTROPHORESIS.

**cell-free ice nuclei** See ICE NUCLEATION BACTERIA.

**cell fusion** See e.g. HYBRIDOMA; see also PROTOPLAST FUSION.

**cell line (tissue culture)** The heterogeneous population of cells resulting from the first subculture of a PRIMARY CULTURE, or from subsequent serial passaging of the cells. (cf. CLONED LINE and ESTABLISHED CELL LINE.)

**cell-mediated cytotoxicity** Lysis of specific or non-specific target cells by certain types of lymphoid cell. Lysis by CD8<sup>+</sup> *cytotoxic* T cells is triggered by *specific* antigen present at the surface of the target cell, is subject to HISTOCOMPATIBILITY RESTRICTION (involving MHC class I antigens), and is independent of both antibody and complement (see T LYMPHOCYTE). Cytotoxicity mediated by CD8<sup>+</sup> T cells is important e.g. as a defence against viral infections (antigen-specific T cells can lyse virus-infected cells which bear virus-specific cell-surface antigens). Lysis of the target cell requires a single collision with a functional cytotoxic T cell – which can kill repeatedly.

For other types of cell-mediated cytotoxicity see ADCC and NK CELLS.

All types of cell-mediated cytotoxicity appear to require divalent cations (Ca<sup>2+</sup>, Mg<sup>2+</sup>).

**cell-mediated hypersensitivity** *Syn.* DELAYED HYPERSENSITIVITY.

**cell-mediated immunity (CMI)** Any form of immunity which can be transferred to a non-immune individual by the transfer of cells (including e.g. LYMPHOCYTES) but not by (cell-free) serum or plasma (see DELAYED HYPERSENSITIVITY), or in which cells are directly involved as effectors (see CELL-MEDIATED CYTOTOXICITY). (cf. HUMORAL IMMUNITY; see also AIDS.)

**cell membrane** *Syn.* CYTOPLASMIC MEMBRANE.

**cell sap** (1) The fluid in a plant cell vacuole. (2) *Syn.* CYTOSOL.

**cell sorter** See e.g. FACS.

**cell wall** In most algae, archaeans, bacteria and fungi: the structure which forms a (usually rigid) layer external to the CYTOPLASMIC MEMBRANE and which is responsible for the shape of the organism; it protects the protoplast from mechanical damage, osmotic lysis etc., and it may also serve as a permeability barrier to ANTIBIOTICS and other substances. Microbial cell walls differ greatly in structure and composition, according to type and species.

(a) *Algal cell walls.* Although a few algae (e.g. DUNALIELLA, PORPHYRIDIUM) lack cell walls, the majority have a cell wall composed of one or more layers of microfibrillar polysaccharide embedded in a matrix of amorphous polysaccharide (cf. CHLAMYDOMONAS); in many species a layer of mucilaginous polysaccharide also occurs external to the cell wall.

The most common microfibrillar component in algal cell walls is CELLULOSE, which occurs e.g. in members of the Phaeophyta and in many members of the Chlorophyta (e.g. *Chaetomorpha*, *Chlorella*, *Scenedesmus*), Rhodophyta and Xanthophyceae (e.g. *Botrydium*, *Vaucheria*). The proportion of cellulose varies from species to species but is often small compared with that of the matrix polymers. In some green algae (e.g. *Bryopsis* (gametothallus), *Caulerpa*, *Halimeda*, *Penicillus*, *Udotea*) and red algae (e.g. *Palmaria palmata*, *Porphyra umbilicalis*) XYLANS replace cellulose as the main microfibrillar component of the wall. A (1 → 4)-β-linked MANNAN is the main structural polysaccharide in the cell walls of e.g. *Acetabularia* and *Codium* spp; a mannan also occurs as an external layer (cuticle) in the red algae *Porphyra umbilicalis* and *Bangia fuscopurpurea*. Xylomannan is a major component of *Prasiola japonica*.

Matrix polymers in algal cell walls are many and varied; they include e.g. AGAR, ALGINATE, CARRAGEENAN and FUCOIDIN.

The walls of some algae contain inorganic materials such as silica (see e.g. DIATOMS) and calcium carbonate (e.g. as a surface encrustation in the CHAROPHYTES); calcium carbonate occurs as calcite in some species, aragonite in others (e.g. HALIMEDA). Many unicellular algae of the CHRYSOPHYTES, PRYMNESIOPHYCEAE and 'PRASINOPHYCEAE' have a cell covering composed of scales, each consisting of an organic base in which silica or calcite may be deposited. In the Prymnesiophyceae and 'Prasinophyceae' these scales are synthesized in the Golgi apparatus and are released to the exterior by fusion of the Golgi vesicles with the cytoplasmic membrane. (See also THECA.)

In those algae which have a heteromorphic alternation of generations, the different phases may have different cell wall structures/compositions; for example, in *Derbesia marina*/*Halicystis ovalis*, the *Derbesia* phase has cell walls containing mannan, while the *Halicystis* phase has walls containing cellulose and glucoxytan. Gametes and spores may lack cell walls.

Many algal walls may be stained for light microscopy with e.g. ALCIAN BLUE (for acidic polysaccharides), PAS, or TOLUIDINE BLUE (which gives a pink colour with carboxyl and sulphate groups).

[Review: Book ref. 38, pp 278–332.]

(b) *Bacterial cell walls.* Although some species are wall-less (see e.g. MYCOPLASMA), a cell wall is present in the majority of bacteria; moreover, there may be layer(s) external to the cell wall proper – see e.g. CAPSULE, M PROTEIN, S LAYER.

Traditionally, bacterial cell walls have been classified into two major types: the Gram-positive type and the Gram-negative type (see also GRAM TYPE). However, while generally classified as Gram-negative organisms, the cyanobacteria commonly have cell walls that exhibit features of both Gram-negative and Gram-positive species [JB (2000) 182 1191–1199].

The bacterial cell wall is a target for certain ANTIBIOTICS (see e.g. β-LACTAM ANTIBIOTICS and VANCOMYCIN).

*Gram-positive-type walls* are relatively thick (ca. 30–50 nm) and appear to be largely homogeneous by electron microscopy. The wall consists mainly of PEPTIDOGLYCAN (up to ~80% dry weight), and this polymer accounts for ~20–40 nm of the wall's thickness. The backbone chains of peptidoglycan run parallel to the cell surface; they are orientated perpendicular to the long axis of the cell. During wall growth, new glycan chains appear to be intercalated between existing chains (see THREE-FOR-ONE MODEL). Various acidic and/or neutral polymers (e.g. TEICHOIC ACIDS, TEICHURONIC ACIDS) are covalently linked (via a phosphodiester bridge) to the C-6 of *N*-acetylmuramic acid residues – either directly or via 'linkage units'. In some genera the cell wall contains lipids (see e.g. MYCOBACTERIUM) or carbohydrates (e.g. C SUBSTANCE). Some compounds (e.g. lipoteichoic acids) are closely associated with, but not covalently linked to, the wall. A hydrophilic trans-wall channel occurs in STREPTOMYCES and in a species of *Corynebacterium* [JB (2003) 185 4779–4786].

The precise composition of the Gram-positive type cell wall may vary with growth conditions and with the degree of maturity of the wall; thus, e.g. in *Bacillus* spp the presence of teichoic and/or teichuronic acids in the cell wall is influenced by environmental levels of phosphate, while (in various genera) the degree of cross-linking is greater in mature than in newly synthesized peptidoglycan. (See also INSIDE-TO-OUTSIDE MODEL.)

*Gram-negative-type walls* are thinner than the walls in Gram-positive species and they have a distinctly layered structure; they are ~20–25 nm in thickness, of which the peptidoglycan layer (the innermost layer of the cell wall) may contribute less than ~6 nm (being less than ~10% dry weight of the cell wall). (It has been suggested that the lateral wall in *Escherichia coli* may contain a monolayer of peptidoglycan [JB (1993) 175 7–11].)

External to the peptidoglycan layer is the OUTER MEMBRANE; some of the BRAUN LIPOPROTEIN molecules of the outer membrane are covalently linked to peptidoglycan; in e.g. *E. coli* the 6-amino group of the C-terminal lysine residue of the lipoprotein is linked by a peptide bond to a DAP residue in peptidoglycan. At a number of sites, the outer membrane apparently fuses with the cytoplasmic membrane to form ADHESION SITES.

(See also CELL CYCLE; L FORMS; PERIPLASMIC REGION; SPHAEROPLAST; ZETA POTENTIAL.)

(c) *Fungal cell walls.* Cell walls are present in most fungi (absent in *Coelomomyces*) and they consist chiefly of polysaccharides which vary e.g. according to taxonomic group.

The architecture of the fungal cell wall seems to be basically similar in many cases: one or more alkali-insoluble, possibly microfibrillar polysaccharides (e.g. CHITIN, CELLULOSE, other β-glucans) form an innermost 'structural' layer, while other (commonly alkali-soluble) components occur throughout the wall – forming an outer layer and also permeating the structural layer. The various wall components may be more or less extensively bonded together by hydrogen, ionic and/or covalent

## cellar fungus

bonds, and the wall may be surrounded by a gel-like or mucilaginous CAPSULE. [Survey of fungal cell walls: Book ref. 38, pp 352–394.]

In (mycelial) *basidiomycetes*, *ascomycetes* and *chytridiomycetes* the main structural components are typically chitin and  $\beta$ -D-glucans (usually containing (1  $\rightarrow$  3)- and (1  $\rightarrow$  6)-linkages in varying proportions); these polymers are closely associated (possibly covalently linked) to form an alkali-insoluble complex. (This association may prevent the formation of crystalline microfibrils of chitin in the native cell wall [Book ref. 38, pp 355–357]; microfibrils of  $\alpha$ -chitin readily form on chemical extraction of the  $\beta$ -glucan.) Alkali-soluble components of these walls include glycoproteins (usually containing mannose and/or galactose in *ascomycetes*, xylose and mannose in *basidiomycetes*) and (1  $\rightarrow$  3)- $\alpha$ -D-glucans.

In *zygomycetes* the cell wall typically contains CHITOSAN closely associated with poly-anionic substances such as polyphosphate and polyglucuronate (cf. MUCORAN); glucans appear to be absent.

In *oomycetes* the main structural component is cellulose, occurring with (1  $\rightarrow$  3)- $\beta$ -D-glucans and/or (1  $\rightarrow$  6)- $\beta$ -D-glucans; in some *oomycetes* (e.g. certain members of the Leptomitales, Peronosporales, Saprolegniales), and in some members of the Hyphochytriomycetes, the walls contain both cellulose and chitin.

In *yeasts* the cell wall tends to reflect taxonomic affinities.

In *Saccharomyces cerevisiae* (an ascomycetous yeast) the wall consists mainly of alkali-insoluble  $\beta$ -glucans and mannan (as phosphomannoprotein) in roughly equal amounts; chitin is only a minor component, occurring mainly in the primary septa and bud scars but also dispersed throughout the wall. The glucan forms the innermost layer which comprises two components. The major component (which apparently provides the rigid framework of the wall) is a  $\beta$ -glucan containing mostly (1  $\rightarrow$  3)-linkages with some (1  $\rightarrow$  6)-linkages, while the minor component contains mainly (1  $\rightarrow$  6)- $\beta$ -linkages with some (1  $\rightarrow$  3)- $\beta$ -linkages. The mannan component in *S. cerevisiae* is an extensively branched polymer (containing (1  $\rightarrow$  6)- $\alpha$ -, (1  $\rightarrow$  2)- $\alpha$ - and (1  $\rightarrow$  3)- $\alpha$ -linkages) covalently bound to protein. This mannoprotein forms a continuous layer at the wall surface and penetrates the inner glucan layer to some depth; it may have a role in determining the porosity of the wall, and it can e.g. protect the glucan from the action of  $\beta$ -glucanases such as the Z-glucanase ZYMOLYASE [JB (1984) 159 1018–1026]. The mannoprotein molecules are linked covalently (e.g. by disulphide bonds) and by hydrogen and ionic bonds to the glucan and to each other. (Mannoproteins with specific functions (e.g. INVERTASE, acid phosphatase, molecules involved in sexual recognition and agglutination) also occur in the cell wall and/or periplasmic space.)

The walls of other yeasts may differ from those of *S. cerevisiae*. For example, while the walls of *Candida albicans* yeast cells are essentially similar to those of *S. cerevisiae*, the alkali-insoluble  $\beta$ -glucans are highly branched, having a higher proportion of (1  $\rightarrow$  6)- $\beta$ -linkages [JGM (1984) 130 3295–3301]. *Schizosaccharomyces pombe* contains no chitin, and little or no mannan; instead, it contains (1  $\rightarrow$  3)- $\alpha$ -D-glucan (PSEUDONIGERAN) and (1  $\rightarrow$  3)- $\beta$ -D-glucan. The yeast *Sporobolomyces* (a basidiomycete) contains mainly chitin and galactomannan in its walls.

Different morphological forms of a given fungus may show differences in wall composition and structure; thus, for example, in *Mucor rouxii* the hyphal wall contains a high proportion of

chitosan but no melanin, while spore walls of this fungus contain much less chitosan, more glucan, and up to ca. 10% by dry weight of MELANIN.

Wall structure also differs between mycelial and yeast forms of DIMORPHIC FUNGI (sense 1); for example, in *Mucor rouxii* the transition from mycelial form to yeast form is accompanied by the appearance of mannan in the walls. In *Paracoccidioides brasiliensis* the yeast-form walls contain (1  $\rightarrow$  3)- $\alpha$ -D-glucan as the sole glucan, while mycelial walls contain (1  $\rightarrow$  3)- $\beta$ -D-glucan/(1  $\rightarrow$  6)- $\beta$ -D-glucan in addition to the  $\alpha$ -glucan.

In addition to their role as structural components, some fungal wall polymers can be used as endogenous sources of nutrient (for example, during carbon starvation or fruiting body formation – see e.g. PSEUDONIGERAN).

Certain antifungal antibiotics function by interfering with cell wall biosynthesis: see e.g. ACULEACIN A; NIKKOMYCINS; PAPULACANDIN B; POLYOXINS.

(See also GROWTH (fungal).)

(d) *Archaeal cell walls*. Distinctive types of cell wall occur in members of the Archaea; there are also wall-less species (e.g. *Thermoplasma*).

Archaeal walls include those which consist mainly or solely of an S LAYER that is closely associated with the cytoplasmic membrane; this type of wall occurs e.g. in species of *Desulfurococcus*, *Halobacterium*, *Methanococcus* and *Thermoproteus*. *Heteropolysaccharides* occur in the cell walls of *Halococcus* and *Methanosarcina*, and PSEUDOMUREIN occurs in the cell wall of *Methanobacterium* and *Methanobrevibacter*.

**cellar fungus** *Coniophora puteana*. (cf. WET ROT.)

**cellobiase** See CELLULASES.

**cellobiohydrolase** Exoglucanase: see CELLULASES.

**cellobiose** A reducing disaccharide:  $\beta$ -D-glucopyranosyl-(1  $\rightarrow$  4)-D-glucopyranose. (See also CELLULASES and LIGNIN.)

**cellobiose:quinone oxidoreductase** See LIGNIN.

**celloextrins** Oligomers of (1  $\rightarrow$  4)- $\beta$ -D-linked glucopyranosyl residues formed by the action of CELLULASES on CELLULOSE.

**cellular** (1) Of or pertaining to a cell or cells. (2) Having the form and characteristics of a (single) cell. (3) Composed of two or more cells. (cf. ACELLULAR; see also UNICELLULAR and MULTICELLULAR.)

**cellular immunity** (1) CELL-MEDIATED IMMUNITY. (2) Aspects of NON-SPECIFIC IMMUNITY mediated e.g. by macrophages and other phagocytic cells.

**cellular microbiology** A branch of microbiology concerned with the interactions between microorganisms and eukaryotic cells at the molecular level. [Science (1996) 271 315–316; Book ref. 218.]

**cellular slime moulds** SLIME MOULDS in which the vegetative phase consists of uninucleate amoeboid cells (myxamoebae) which aggregate to form a multicellular pseudoplasmodium from which the fruiting bodies arise. Classes: ACRASIDIOMYCETES and DICTYOSTELIOMYCETES. (cf. MYXOMYCETES.)

**cellulases** Enzymes which degrade at least some forms of CELLULOSE. *Endoglucanase* (endo-(1  $\rightarrow$  4)- $\beta$ -D-glucanase, endocellulase, (1  $\rightarrow$  4)- $\beta$ -D-glucan 4-glucanhydrolase, EC 3.2.1.4) attacks more or less randomly at sites within (1  $\rightarrow$  4)- $\beta$ -D-glucan chains in amorphous regions of cellulose or at the surfaces of microfibrils. *Exoglucanase* (exo-(1  $\rightarrow$  4)- $\beta$ -D-glucanase, exocellulase, (1  $\rightarrow$  4)- $\beta$ -D-glucan cellobiohydrolase, EC 3.2.1.91) releases cellobiose (and, in some cases, glucose) from non-reducing ends of  $\beta$ -D-glucan chains.  *$\beta$ -Glucosidase* (cellobiase,  $\beta$ -D-glucoside glucohydrolase, EC 3.2.1.21), hydrolyses cellobiose and water-soluble celloextrins to glucose. Many cellulolytic organisms produce a number of isoenzymes.

Many fungi, several bacteria, and a few protozoa (e.g. *Trichonympha*) can degrade cellulose, but their activities depend e.g. on the degree of polymerization and crystallinity of the cellulose and its association with hemicelluloses and LIGNIN (see CELLULOSE). Crystalline cellulose is highly resistant to enzymic attack; most of the glucan chains in microfibrils are inaccessible to enzymes, and any (surface) bonds cleaved by endoglucanase action can readily be re-formed owing to the stable orientation of the (hydrogen-bonded) glucan chains. Degradation of crystalline cellulose requires the synergistic action of both endoglucanase and exoglucanase; the exoglucanase rapidly removes cellobiose units from the newly created ends formed by endoglucanase action, thus preventing the re-formation of glucosidic bonds. The two enzymes may act consecutively or in concert. Alternative pathways probably also occur – e.g. the progressive release of cellobiose and/or glucose by exoglucanase action only. [PTRSLB (1983) 300 283–291.] Both exo- and endoglucanases are inhibited by cellobiose, and  $\beta$ -glucosidase action (which eliminates cellobiose) is often the rate-limiting step in cellulose degradation. (Cellobiose may also be degraded by cellobiose phosphorylase, EC 2.4.1.20, or oxidized by cellobiose oxidase or by cellobiose:quinone oxidoreductase (see LIGNIN).)

Cellulases are subject to induction (in the presence of cellulose) and to catabolite repression; SOPHOROSE (formed e.g. from cellobiose by transglycosylation reactions) is an effective inducer in many (but not all) cellulolytic organisms and may be a natural inducer – at least in some fungi. Repressors include e.g. glucose and other readily utilizable substrates. Cellobiose can act as inducer or repressor, according to concentration.

(Reference is still sometimes made to 'C<sub>1</sub>' and 'C<sub>x</sub>' cellulase activities. These terms derive from the early C<sub>1</sub>–C<sub>x</sub> concept [JB (1950) 59 485–497] but have subsequently been used in different ways by different authors [Book ref. 31, 290–292]. The terms are thus ambiguous and are best avoided.)

*Cellulolytic bacteria* include e.g. many actinomycetes (e.g. *Cellulomonas* spp) and RUMEN bacteria, *Clostridium thermocellum*, *Cytophaga* spp, *Polyangium cellulosum*, *Pseudomonas* spp and *Sporocytophaga myxococcoides*. In general, bacteria produce endoglucanases and  $\beta$ -glucosidases but not exoglucanases; they thus have little activity on highly crystalline native cellulose, but are highly active against amorphous cellulose or soluble cellulose derivatives (e.g. CM-CELLULOSE). The endoglucanases may be cell-bound, extracellular, or both. In e.g. *Cytophaga* and *Sporocytophaga*, which grow in close contact with cellulose fibres, the glucanases are associated with the outer membrane. (See also CELLULOSOME.) In rumen bacteria cellulases are retained in the GLYCOCALYX surrounding the cells, and the products of their action may also be so retained prior to their uptake by the cell [CRM (1981) 8 303–338]. Bacterial  $\beta$ -glucosidases are typically cell-associated (e.g. periplasmic) or intracellular.

*Cellulolytic fungi* include many basidiomycetes (e.g. *Coniophora puteana*), ascomycetes (e.g. *Chaetomium* spp, *Stachybotrys atra*) and deuteromycetes (e.g. *Trichoderma* spp). (See also NEOCALLIMASTIX.) In general, the brown-rot basidiomycetes produce only endoglucanases and  $\beta$ -glucosidases, while ascomycetes, deuteromycetes and the white-rot basidiomycetes produce (extracellular) endoglucanases, exoglucanases, and  $\beta$ -glucosidases (see BROWN ROT and WHITE ROT).

Cellulases are not produced by animals; herbivores must therefore rely on symbiotic cellulolytic microorganisms to digest their dietary cellulose (see e.g. RUMEN, TERMITES–MICROBE ASSOCIATIONS).

Isolated microbial cellulases have relatively low specific activities and are costly to obtain; they currently have only limited commercial use. Pilot schemes include the use of cellulases or cellulolytic organisms for the saccharification of the cellulose in waste materials such as straw, sugarcane bagasse, sawdust, newspaper etc (see e.g. INDUSTRIAL ALCOHOL and SINGLE-CELL PROTEIN). (See also ENZYMES.)

(See also PAPER SPOILAGE.)

**cellulin granules** Granules, composed of CHITIN and (1 → 3)- $\beta$ - and (1 → 6)- $\beta$ -linked glucan, found in the cells of fungi of the LEPTOMITALEA; the granules are composed of alternating concentric layers of chitin and glucan. (cf. CONCENTRIC BODIES.)

**cellulitis** A diffuse, spreading, inflammatory condition affecting (usually) subcutaneous tissues and characterized by oedema, redness and pain. Common causal agents are streptococci and staphylococci. *Orbital cellulitis* (inflammation of the eye-socket) may be caused by *Haemophilus influenzae*. (See also ERYSIPELAS and GAS GANGRENE.)

**cellulolytic** Able to degrade CELLULOSE.

**Cellulomonas** A genus of aerobic or facultatively anaerobic, asporogenous bacteria (order ACTINOMYCETALES, wall type VIII) which occur e.g. in soil. In young cultures the organisms are slender, irregular rods (diam. ca. 0.5–0.6  $\mu$ m) and/or filaments, with or without primary branching, but shorter rods and/or coccoid forms occur in the stationary phase; the cells are Gram-positive, but easily decolorized, and cells which are apparently Gram-negative may predominate. The organisms are non-motile, or motile by one to several polar flagella [JUSB (1984) 34 218–219]. Growth occurs e.g. on peptone meat extract at 30°C; all strains require biotin and thiamine for growth. Typically, a yellow non-diffusible pigment is formed when growth occurs on nutrient agar. Glucose is metabolized to acid both oxidatively and fermentatively. *Cellulomonas* spp are amylolytic and cellulolytic (see CELLULASES). Species include *C. biazotea*, *C. cellasea*, *C. flavigena*, *C. fimi*, *C. gelida*, and *C. uda*. GC%: 71–77. Type species: *C. flavigena*.

**cellulose** A linear (1 → 4)- $\beta$ -D-glucan. Cellulose occurs in plants (it is the main structural component of the cell walls in most plants), in the CELL WALLS of most algae and certain fungi, in certain cellular slime moulds (e.g. in the sheath surrounding the sorocarp stalk, in the spore walls, and in the slime of migrating slugs of *Dictyostelium discoideum*), and in the cyst walls of *Acanthamoeba* spp; extracellular cellulose is produced by certain bacteria: e.g. *Acetobacter xylinum* (see PELLICLE sense 1), *Sarcina ventriculi* (most strains of which form a cellulose microcapsule apparently responsible for the formation of the characteristic packets of cells), strains of *Agrobacterium* and *Rhizobium* (in which extracellular cellulose is involved in the adhesion of bacteria to plants), and various floc-forming bacteria in activated sludge.

Native cellulose occurs largely in the form of (crystalline) *microfibrils* (' $\alpha$ -cellulose') each composed of stacked sheets of parallel, hydrogen-bonded glucan chains. Each chain is in extended form (held rigid by intrachain hydrogen bonds) and contains many glucosyl residues (e.g. 2000–15000, depending on source). In plant cell walls the microfibrils are embedded in a matrix of HEMICELLULOSES, LIGNIN and PECTIC POLYSACCHARIDES; regions of amorphous cellulose, infiltrated with hemicelluloses, also occur. [Plant cell wall structure: Book ref. 38, pp. 9–46.]

Cellulose may be stained for microscopy e.g. with CONGO RED or CALCOFLUOR WHITE – both of which also inhibit microfibril formation during cellulose synthesis. [Biosynthesis of cellulose in microorganisms: Book ref. 62, pp. 85–127.]

## cellulosome

Cellulose is a vast and constantly renewable potential source of fermentable sugars which would be valuable feedstock for various biotechnological processes. However, the lignin–hemicellulose–cellulose (LHC) complex is very stable, and crystalline cellulose is very resistant to enzymic attack (see CELLULASES). Thus, before it can be used as feedstock, cellulose must be released from the LHC complex and its microfibrillar structure disrupted by various (costly) mechanical, physical or chemical procedures – e.g. grinding or treatment with steam, mineral acids or alkalis (cf. IOTEC PROCESS); this has placed a constraint on its extensive use in industry. [Lignocellulose hydrolysis: PTRSLB (1983) 300 305–322.]

**cellulosome** In certain cellulolytic bacteria: a CELLULOSE-binding, multicELLULASE-containing cell-surface organelle. The cellulosome appears to be composed of parallel rows of catalytic units; it has been suggested that these may act together, cleaving cellulose into pieces as small as cellobiose – which can be taken up by the cell [FEMS Reviews (1993) 104 340].

**cellulytic** Able to lyse cells.

**CELO virus** See AVIADENOVIRUS.

**centiMorgan (cM)** A unit for indicating the distance between markers on a chromosome; the number of centiMorgans between two given markers is the (statistically corrected) RECOMBINATION FREQUENCY exhibited by the markers. Thus, e.g., a corrected RF of 10% gives a distance of 10 cM. (cf. MAP UNIT.)

**Centipeda** A genus of Gram-negative, anaerobic, rod-shaped bacteria; *C. periodontii*, which has HELICOTRICHOUS flagellation, occurs e.g. in human periodontal lesions.

**Centraalbureau voor Schimmelcultures** See CBS.

**central capsule (protozool.)** See RADIOLARIA.

**central dogma (mol. biol.)** The dogma that genetic information can be transferred only in the direction DNA → protein. Originally, the dogma specified that information could flow only in the direction DNA → RNA → protein, but with the discovery of REVERSE TRANSCRIPTASE this was modified to DNA ↔ RNA → protein.

**Central European encephalitis virus** See FLAVIVIRIDAE.

**centric** (1) (of a chromosome) Having a CENTROMERE. (cf. HOLOCENTRIC and MONOCENTRIC sense 2.) (2) Refers to that type of nuclear division in which CENTRIOLES are involved. (3) See DIATOMS.

**centrifugation** The use of a centrifugal field for the sedimentation of fine particulate matter – or macromolecules (see *ultra-centrifugation*, below) – in a liquid medium, or for separating different types of particulate matter, or macromolecules, within a given suspension or solution. (See also CELL FRACTIONATION and MAECT.) In the most widely used form of centrifugation, the sample is placed in a suitable container at the end of one arm of a spider-shaped motor-driven metal *rotor* which has a central, vertical shaft; rotation of the shaft at high speed subjects the sample to a centrifugal field which causes particulate matter in the sample to move in an outward (radial) direction, i.e., towards the bottom of the container. (In practice one or more additional samples of equal weight must be carried by the rotor in order to achieve a balanced distribution of weight.) The apparatus described above, suitably enclosed for safety, constitutes a simple *centrifuge*. Specialized forms of centrifuge are used e.g. for refrigerated centrifugation and for continuous centrifugation; in *continuous centrifugation*, which is used for dealing with large volumes of liquid, provision is made for the continual inflow of sample (e.g. through a hollow rotor) and the continual discharge of supernatant (and of sediment in some types of centrifuge).

The strength of a centrifugal field (at a given point) is given by:

$$G = \frac{4\pi^2(\text{revs min}^{-1})^2 r}{3600}$$

in which ‘revs min<sup>-1</sup>’ refers to the number of revolutions per minute (r.p.m.) made by the rotor, and *r* is the distance (cm) between the given point in the sample and the axis of rotation. *G* is given in terms of acceleration (cm sec<sup>-2</sup>); since (for a given mass) acceleration is proportional to the force producing it, *G* gives a measure of the force acting on a body subjected to a given centrifugal field. The centrifugal field may be increased by (a) increasing the number of r.p.m. and/or (b) increasing *r*. Since the acceleration due to gravity (*g*) is ca. 980 cm sec<sup>-2</sup>, *G*/980 gives the number of times by which the given centrifugal field is greater than the gravitational field; *G*/980 is termed the *relative centrifugal field* (= *relative centrifugal force*), RCF. (Since, for a given value of r.p.m., the centrifugal field varies with *r* – i.e., may vary from one centrifuge to another – centrifugation data should be reported in the form *g*/time, e.g., 1000 *g*/10 minutes.)

*G* gives the acceleration which a given centrifugal field would impart to a particle in a *vacuum*. Since particles subjected to centrifugation are suspended in a liquid, factors in addition to the applied field must be taken into account when considering the effect of the field. These factors, which greatly affect the rates of movement of particles, are the size, shape and density of the particles, and the viscosity and density of the liquid in which the particles are suspended. For example, the rate of movement of a *spherical* particle in a given centrifugal field is proportional to:

$$Gr_p^2(\rho_p - \rho)/\text{viscosity of medium}$$

where *r<sub>p</sub>* is the radius of the particle, and *ρ<sub>p</sub>* and *ρ* are the densities of the particle and the suspending medium, respectively. Thus, given a mixed population of particles which differ e.g. in size and/or density, separation into homogeneous populations may be achieved on the basis of their differing sedimentation rates in a centrifugal field (*differential centrifugation*). If particle density (*ρ<sub>p</sub>*) is equal to that of the suspending medium (*ρ*), the rate of movement in the centrifugal field is zero; if *ρ<sub>p</sub>* is *less* than *ρ*, centrifugally accelerated flotation occurs – an effect which has been used e.g. for the purification of GAS VACUOLES. In general, the *time* taken for a spherical particle to move a given distance in a centrifugal field is given by:

$$t = \frac{9}{2} \frac{\eta}{\omega^2 r_p^2 (\rho_p - \rho)} \log_e \frac{R_a}{R_b}$$

in which *ω* is the angular velocity (radians/sec); *η* is the viscosity of the medium; *r<sub>p</sub>* is the radius of the particle; *ρ<sub>p</sub>* and *ρ* are the densities of the particle and medium, respectively; *R<sub>a</sub>* and *R<sub>b</sub>* are the distances from the centre of rotation to the positions where the particle started (a) and stopped (b); and *t* is the time (sec).

**Density gradient centrifugation.** In some types of centrifugation (e.g. isopycnic and rate-zonal centrifugation) the sample is initially layered onto a column of liquid containing a solute whose concentration increases with increasing distance down the column; solutes used to prepare such density gradients (which may be linear or stepped) include e.g. caesium chloride (CsCl), sucrose, and IODINATED DENSITY-GRADIENT MEDIA. An important practical advantage of a density gradient is that it militates against convection – which can disrupt a liquid column in the absence of a gradient.

*Isopycnic centrifugation* (also called *equal density*, *equilibrium density gradient*, or *equilibrium zonal centrifugation*). The

sample is layered onto a density gradient column, and centrifugation is continued until equilibrium is reached, i.e., each particle has reached that part of the gradient which corresponds to its own density (its isopycnic or equal density position). Particles in a heterogeneous sample are thus separated on the basis of their individual densities: particles of different density can be separated even if they are similar in size and shape.

*Rate-zonal centrifugation* (also called *band, gradient differential, s zonal, zonal, or zone centrifugation*). The sample is layered onto a density gradient column, and centrifugation is continued until the various types of particle in the sample form layers or bands at different levels within the column – at which time centrifugation is stopped. The separation of particles into bands is thus achieved on the basis of the differing sedimentation rates of the particles.

*Ultracentrifugation* is used e.g. for the sedimentation of macromolecules, for the determination of molecular weights, for purifying plasmid DNA, for characterizing viruses, and as an indirect method for estimating the GC% of bacterial DNA. The principles involved are similar to those given earlier in the entry; however, while the common laboratory centrifuge can develop a maximum field of ca. 5000 to 10000 *g*, the ultracentrifuge can achieve fields of the order of 500000 *g*. In an ultracentrifuge the rotor is housed in a refrigerated and evacuated chamber, and the instrument incorporates various optical systems (e.g. the SCHLIEREN SYSTEM) and photographic systems so that the progress of sedimentation can be followed and recorded at all times. (See also SVEDBERG UNIT.)

If a species of DNA is subjected to isopycnic ultracentrifugation in a caesium chloride gradient, the DNA forms a band at a region of the gradient corresponding to its *buoyant density* (Bd); the Bd of e.g. chromosomal DNA from *Escherichia coli* is ca. 1.7 g/cm<sup>3</sup>. Since there is a linear relationship between Bd and GC%, the value of Bd can be used for estimating GC% (q.v.).

Ultracentrifugation can also be used to separate cccDNA (e.g. plasmid DNA) from linear DNA or from circular, nicked DNA (e.g. nicked chromosomal DNA). cccDNA can incorporate smaller amounts of certain INTERCALATING AGENTS (e.g. ETHIDIUM BROMIDE) than can equivalent molecules of the other forms of DNA. The incorporation of e.g. ethidium bromide *decreases* the Bd of the DNA molecule. Thus, if e.g. a plasmid-containing bacterial lysate is centrifuged in a caesium chloride–ethidium bromide gradient, cccDNA may form a distinct band of higher Bd; such a procedure has been called *dye–buoyant density centrifugation*.

**centriolar plaque** *Syn.* SPINDLE POLE BODY.

**centriole** In many types of eukaryotic cell: an intracellular microtubular structure (see MICROTUBULES) which is involved in some types of MITOSIS and which, in some cells, can develop into a BASAL BODY; centrioles do not occur in e.g. some types of fungi. Essentially, a centriole is a hollow cylinder, ca. 300–400 nm in length, whose wall is formed of 9 longitudinally arranged triplets of microtubules; one end of the cylinder contains a dense intracentriolar material. The structure appears to lack DNA, but RNA may be present. A centriole is often surrounded by a number of dense *pericentriolar structures* which, collectively, are sometimes referred to as a *centrosome* and which can act as a MICROTUBULE-ORGANIZING CENTRE. ('Centrosome' is also used to refer to the entire structure, i.e., centriole(s) plus pericentriolar structures.) Centrioles are often formed from pre-existing centrioles, but they can also be formed *de novo*.

**Centrohelida** An order of protozoa (class HELIOZOEAE) in which the cell typically has an eccentric nucleus and a central body

(the *centroplast*) from which the axopodial axonemes appear to arise. Some species lack a centroplast but have a large eccentric nucleus. Typically, a centrohelid has an outer 'skeleton' of siliceous plates and/or spines embedded in a gelatinous outer covering; some species have organic spicules. Genera include e.g. *Acanthocystis*, *Gymnosphaera*, *Heterophrys*, RAPHIOPHYRYS.

**centromere** The region of a replicated eukaryotic chromosome where the two CHROMATIDS are joined together; during MITOSIS a KINETOCHORE is formed on both sides of the centromere. [Molecular structure of centromeres: ARB (1984) 53 163–194; chromatin conformation of yeast centromeres: JCB (1984) 99 1559–1568.] (cf. HOLOCENTRIC and MONOCENTRIC (sense 2).)

**centroplast** See CENTROHELIDA.

**Centropyxis** See ARCELLINIDA.

**centrosome** See CENTRIOLE.

**centrotype** In NUMERICAL TAXONOMY: a strain regarded as that which typifies a given species cluster on the basis of its position within that cluster.

**centrum** (*mycol.*) The totality of fertile and sterile structures within a CLEISTOTHECIUM, PERITHECIUM, or locule in an ASCOSTROMA.

**cep** *Syn.* cèpe (see BOLETALES).

**cèpe** (cep) See BOLETALES.

**Cepedea** See OPALINATA.

**Cepedieta** See ASTOMATIDA.

**Cephaleuros** A genus of obligately epiphytic (and/or parasitic) algae (division CHLOROPHYTA) closely related to TRENTEPOHLIA. The heterotrichous thallus is composed of a discoid system of prostrate, compacted, branched filaments and an erect system of sterile, multicellular, uniseriate filaments and specialized zoosporangiophores; the prostrate system grows between the cuticle and epidermis in the leaves, fruits and/or young stems of a host plant, while the erect filaments and gametangia protrude through the host cuticle. Although the alga may cause considerable damage to the host plant (see RED RUST), there is apparently no evidence that it is nutritionally dependent on the plant. (*Cephaleuros* also occurs as the photobiont in certain obligately foliicolous lichens: e.g. *Strigula* spp [Book ref. 129, pp. 190–191].)

**cephalexin** See CEPHALOSPORINS.

**cephaline gregarines** See GREGARINASINA.

**Cephaloascus** See ENDOMYCETALES.

**cephalodium** (*lichenol.*) A discrete group of cyanobacteria occurring in or on the thallus in certain lichens whose main photobiont is a green alga. Cephalodia appear generally to arise by entrapment of free-living cyanobacteria by the mycobiont – usually via the lower cortex of the thallus. The cyanobacteria (usually NOSTOC) carry out NITROGEN FIXATION, fixed nitrogen being transferred to the mycobiont.

*Internal* cephalodia occur e.g. in species of *Lobaria*, *Nephroma* and *Solorina*; they typically consist of colonies of cyanobacteria which lie in the medulla and may be apparent as swellings on the surface of the thallus.

*External* cephalodia occur e.g. in species of *Peltigera* and *Stereocaulon*; they may occur (e.g. as warty protuberances) on the upper or lower surface of the thallus, depending on species.

Some lichens (e.g. species of *Lobaria*, *Peltigera* and *Sticta*) form well-differentiated, fruticose or subfoliose, cyanobacterium-containing structures which arise (usually) from the upper surface of the thallus and which are capable of independent growth. These structures were originally thought to be epiphytes and were assigned to distinct genera (e.g. '*Dendriscoaulon*'), but are now commonly believed to be elaborate cephalodia

## cephaloridine

or different morphotypes ('phycosymbiodemes') of the same mycobiont. [Chimeroid associations in *Peltigera*: Lichenol. (1978) 10 157–170.]

**cephaloridine** See CEPHALOSPORINS.

**cephalosporin C** See CEPHALOSPORINS.

**cephalosporin N** *Syn.* PENICILLIN N.

**cephalosporin P1** A steroid antibiotic structurally related to FUSIDIC ACID.

**cephalosporinase** A  $\beta$ -LACTAMASE active mainly or solely against CEPHALOSPORINS.

**cephalosporins** A class of antibiotics each characterized by a molecular structure which includes a  $\beta$ -lactam ring fused to a dihydrothiazine ring (see  $\beta$ -LACTAM ANTIBIOTICS for structure and mode of action). (cf. CEPHALOSPORIN P1 and PENICILLIN N.)

Cephalosporin C (the first to be prepared) is produced e.g. by *Acromonium kiliense* (= *Cephalosporium acremonium*); this antibiotic has poor antibacterial activity.

A range of semi-synthetic cephalosporins can be prepared from the 7-aminocephalosporanic acid (7-ACA) derivative of cephalosporin C. When introduced, the earlier cephalosporins (collectively) had useful activity against a range of bacteria, and were typically (particularly cefotaxime and cefuroxime) less susceptible than PENICILLINS to  $\beta$ -LACTAMASES; moreover, compared to penicillins, cephalosporins were found to be less frequently allergenic.

When introduced, the first- to third-generation cephalosporins were characterized by antibacterial spectra such as: mainly Gram-positive (cephalexin, cephaloridine); good activity against Gram-positive and moderate activity against  $\beta$ -lactamase-negative Gram-negative species (cephalothin); Gram-positive species and e.g. *Neisseria gonorrhoeae* and *Haemophilus influenzae* (cefuroxime); limited spectrum, but some activity against *Pseudomonas aeruginosa* (cefsulodin); Gram-negative species, including *Haemophilus influenzae* (cefotaxime). (Note that cephalosporins (and e.g. the cephamycin CEFOXITIN) have little or no activity against enterococci.) The earlier cephalosporins (and some of the newer ones) are commonly susceptible to extended-spectrum  $\beta$ -LACTAMASES (q.v.). (See also CEPHAMYCINS.)

Some cephalosporins can be administered orally, while others (e.g. cefuroxime, cefotaxime) are administered parenterally.

*First-generation cephalosporins* include e.g. cefazolin, cephalexin, cephaloridine and cephalothin.

*Second-generation cephalosporins* include e.g. cefamandole, cefonicid [Drugs (1986) 32 222–259], ceforanide, cefsulodin and cefuroxime.

*Third-generation cephalosporins* include e.g. cefixime, cefmenoxime [Am. J. Med. (1984) 77 (supplement 6A)], cefotaxime, ceftazidime [Am. J. Med. (1985) 79 (supplement 2A)], ceftizoxime and ceftriaxone.

*Fourth-generation cephalosporins* include e.g. CEFEPIME and cefpirome.

(*Note.* In the literature, the names of some cephalosporins are spelt with either 'f' or 'ph'.)

**Cephalosporium** See ACREMONIUM. (For *C. lecanii* see VERTICILLIUM.)

**Cephalothamnium** A genus of colonial CHRYSOPHYTES in which a cluster of biflagellate, non-pigmented cells extends from the tip of a single stalk.

**cephalothin** See CEPHALOSPORINS.

**cephamycins** Antibiotics (7- $\alpha$ -methoxyCEPHALOSPORINS) produced by *Streptomyces* spp or prepared from cephalosporins. Compared with those cephalosporins which lack the 7- $\alpha$ -methoxy group, cephamycins (e.g. CEFOXITIN) tend to have

decreased antibacterial activity but increased resistance to  $\beta$ -LACTAMASES and improved penetrability of the Gram-negative outer membrane.

**cephems** Compounds which contain the cephalosporin nucleus (see  $\beta$ -LACTAM ANTIBIOTICS). (cf. OXACEPHEMS.)

**cephradine** See CEPHALOSPORINS.

**Ceraceosorus** See BRACHYBASIDIALES.

**ceramide** See SPHINGOMYELIN.

**Ceramiom** See RHODOPHYTA

**Ceratiomyxa** A genus of SLIME MOULDS formerly classified with the acellular slime moulds (MYXOMYCETES); currently, the genus is placed e.g. in a separate class, Ceratiomyxomycetes, of the MYXOMYCOTA, or – in zoological schemes – is classified with the protostelids e.g. in the subclass Protosteliia (see EUMYCETOZOE). *C. fruticulosa* is a widespread and common species found e.g. on bark and rotting wood. The vegetative PLASMIDIUM is almost hyaline. Prior to fruiting, it produces copious amounts of a mucoid matrix, and plasmodium and matrix become extended to form upright, usually branched white columns (1–10 mm tall) which solidify on drying; sporocarps develop on the surface of these columns, each sporocarp consisting of a long slender stalk bearing a single round or cylindrical spore. The spores are deciduous. On germination of a spore, a quadrinucleate 'thread stage' is produced, and this eventually gives rise to 4, then 8, flagellated haploid cells which can apparently function as gametes; a diploid vegetative plasmodium develops from the zygote formed by fusion of two of these flagellated cells.

**Ceratiomyxella** See PROTOSTELIOMYCETES.

**Ceratiomyxomycetes** See CERATIOMYXA.

**Ceratium** A genus of DINOFLAGELLATES in which the cells typically bear 3 or 4 horn-like thecal extensions: one arising from the epicone, 2 or 3 from the hypococone.

**Ceratobasidiaceae** See TULASNELLALES.

**Ceratobasidium** See TULASNELLALES.

**Ceratocystis** A genus of fungi (order OPHIOSTOMATALES) which include various plant pathogens – see e.g. DUTCH ELM DISEASE and OAK WILT. (See also BLUE STAIN, PINE DISEASES, and IPOMEA-MARONE.)

*C. ulmi* forms erumpent perithecia (see also ASCOSPORE), and in the imperfect (*Pesotum*) state can form individual conidia on simple conidiophores or chains of conidia in a drop of mucus at the tip of a dark, bristle-like synnema (ca. 1 mm high).

*C. coerulea* forms superficial perithecia, and in the *Chalara* state can form cylindrical or ellipsoidal conidia.

**Ceratomyces** See LABOULBENIALES.

**Ceratomyxa** See MYXOSPOREA.

**Cercophora** See SORDARIALES.

**cercopithecine herpesvirus 1** See B VIRUS.

**Cercospora** A genus of fungi (class HYPHOMYCETES) which include many plant-pathogenic species – e.g. *C. beticola* (causal agent of leaf spot of beet), and *C. apii* (e.g. on celery). The organisms form septate mycelium; conidia are characteristically thread-like and multiseptate.

**cereal chlorotic mottle virus** See RHABDOVIRIDAE.

**cereal diseases** Diseases of members of the Gramineae cultivated for their edible grain. Some of the common diseases are listed below. Although some diseases are specific to particular types of cereal, others can also affect certain wild grasses; thus, e.g. the causal agents of HALO SPOT and LEAF BLOTCH can both grow on cocksfoot (*Dactylis glomerata*) and Timothy grass (*Phleum pratense*). (See also GRASS DISEASES.)

*Barley.* See e.g. BROWN RUST, ERGOT, EYESPOT (sense 2), GLUME BLOTCH, HALO SPOT, LEAF BLOTCH ('rhynchosporium'), NET

BLOTCH, POWDERY MILDEW, SMUTS (sense 2), TAKE-ALL, YELLOW RUST; see also LUTEOVIRUSES (barley yellow dwarf virus) and HORDEIVIRUSES (barley stripe mosaic virus).

**Maize.** See e.g. CORN STUNT DISEASE, MAIZE WALLABY EAR DISEASE, SMUTS (sense 2); see also MAIZE STREAK VIRUS.

**Oats.** See e.g. CROWN RUST, ERGOT, SMUTS (sense 2), TAKE-ALL, VICTORIA BLIGHT.

**Rice.** See e.g. BAKANAE DISEASE, BLAST DISEASE, SUFFOCATION DISEASE; see also FIJIVIRUS, RICE DWARF VIRUS, RICE GALL DWARF VIRUS, RICE RAGGED STUNT VIRUS, RICE STRIPE VIRUS GROUP. (cf. YELLOW RICE.) [Engineered resistance to *Rhizoctonia solani* (sheath blight): *Biotechnology* (1995) 13 686–691.]

**Rye.** See e.g. BROWN RUST, COMMON BUNT, ERGOT, HALO SPOT, LEAF BLOTCH ('rhynchosporium'), SNOW MOULD, TAKE-ALL.

**Wheat.** See e.g. BLACK STEM RUST, BROWN RUST, COMMON BUNT, ERGOT, EYESPOT (sense 2), GLUME BLOTCH, HALO SPOT, KARNAL BUNT, POWDERY MILDEW, SMUTS (sense 2), SNOW MOULD, TAKE-ALL, WHEAT SCAB, YELLOW RUST; see also SOIL-BORNE WHEAT MOSAIC VIRUS.

**cereal striate virus** See RHABDOVIRIDAE.

**cereal tillering disease virus** See FIJIVIRUS.

**cerebriform** Brain-like in appearance; convoluted.

**cerebroside** See SPHINGOLIPID.

**cereolysin** See THIOL-ACTIVATED CYTOLYSINS.

**Cerinomyces** See DACRYMYCETALES.

**cermet** See BIOMIMETIC TECHNOLOGY.

**cerulenin** An antibiotic – [(3R)-2,3-epoxy-4-oxo-7,10-dodecadienoyl amide] – obtained from '*Cephalosporium caerulens*'; it has antifungal and antibacterial activity, but is too unstable for clinical use. Cerulenin inhibits fatty acid and sterol biosynthesis, inhibiting e.g. the condensation reaction between acyl and malonyl thioesters and thus preventing fatty acid chain elongation. It also inhibits lipoteichoic acid synthesis in e.g. *Enterococcus faecalis*, prevents the synthesis and secretion of certain extracellular proteins in some bacteria (e.g. glucosyltransferase in oral streptococci [JGM (1983) 129 3293–3302]), and alters morphogenesis and autolytic activity in *Bacillus subtilis* [JGM (1985) 131 591–599].

**ceruloplasmin** See BLUE PROTEINS.

**cervical cancer** (cancer of the cervix) See PAPILLOMA.

**cesspool** A watertight container for the temporary storage of sewage. (cf. SEPTIC TANK.)

**Cetavlon** See QUATERNARY AMMONIUM COMPOUNDS.

**Cetraria** A genus of LICHENS (order LECANORALES); photobiont: a green alga. Thallus: either fruticose and erect or foliose with upturned margins, growing on soil, bark, wood or rocks. Apothecia have reddish-brown discs and are marginal in foliose species.

*C. islandica* ('Iceland moss') has an erect, branched thallus (ca. 2–7 cm in height); the strap-like branches are curved to appear more or less tubular, the inside surface being greenish-grey to dark brown, the outermost surface being paler with a scattering of whitish pseudocyphellae. The thallus margins bear short black spines. This species forms cushions on the ground in heathland, moorland, and acid woodland; it has been used as food e.g. in Scandinavian countries, and serves as fodder for e.g. reindeer and caribou.

**Cetrimide** See QUATERNARY AMMONIUM COMPOUNDS.

**cetylpyridinium chloride** See QUATERNARY AMMONIUM COMPOUNDS.

**cetyltrimethylammonium bromide** See QUATERNARY AMMONIUM COMPOUNDS.

**CF** (1) COMPLEMENT FIXATION. (2) CYSTIC FIBROSIS.

**CF<sub>0</sub>F<sub>1</sub> H<sup>+</sup>-ATPase** See PROTON ATPASE.

**CFA/I, CFA/II** See ETEC.

**CFP-10** See ESAT-6.

**CFT** COMPLEMENT-FIXATION TEST.

**cfu** Colony-forming unit: see COUNTING METHODS.

**CGA protein** See CATABOLITE REPRESSION.

**CGB agar** Canavanine-glycine-bromthymol blue agar: a medium used to distinguish between certain strains of CRYPTOCOCCUS. On this medium, *C. neoformans* var. *gattii* hydrolyses glycine, raising the pH and causing the BROMTHYMOL BLUE to turn blue; the few strains of *C. neoformans* var. *neoformans* which can hydrolyse glycine are inhibited by the L-canavanine. [Recipe and method: Book ref. 100, p. 95.]

**CH region** See IMMUNOGLOBULINS.

**CH<sub>50</sub>** See HD<sub>50</sub>

**Chaenotheca** See CALICIALES.

**Chaetoceros** A large genus of planktonic centric DIATOMS in which the cells are often joined together by long setae.

**Chaetocladium** See MUCORALES.

**Chaetomella** See SPHAEROPSIDALES.

**Chaetomium** A genus of fungi (order SORDARIALES) which form evanescent asci in perithecia which bear long, curved, coiled and/or branched hairs or bristles; the unicellular, commonly dark ascospores are discharged from the perithecium in a gelatinous mass. Most or all species are strongly cellulolytic (see CELLULASES, PAPER SPOILAGE, SOFT ROT (sense 1), TEXTILE SPOILAGE). (See also COMPOSTING and OLIVE-GREEN MOULD.)

**Chaetomorpha** A genus of unbranched, filamentous, siphonocladous green algae (division CHLOROPHYTA).

**Chaetophora** A genus of uniseriate, filamentous (heterotrichous) green algae (division CHLOROPHYTA) which occur in freshwater habitats, usually attached to rocks, plants etc. Long colourless multicellular 'hairs' extend from the ends of the (branched) filaments. Quadriflagellate zoospores and biflagellate isogametes are formed. Related genera include e.g. *Draparnaldia*, *Fritschella*, *STIGEOCLONIUM* and *URONEMA*.

**chaga fungus** The sterile fruiting body of *Inonotus obliquus*.

**Chagas' disease** An acute or chronic, often fatal, systemic TRYPANOSOMIASIS of man which occurs in Central and South America. The causal agent, *Trypanosoma* (SCHIZOTRYPANUM) *cruzi*, is typically transmitted *contaminatively* by blood-sucking TRIATOMINE BUGS (family Reduviidae): metacyclic forms in the bug's faeces infect via wounds, abrasions and mucosal surfaces. (The pathogen can also be transmitted by blood transfusion and, via the milk, to breast-fed infants. Transplacental transmission occurs in over 1% of cases in endemic areas.) Reservoirs of bug-transmissible pathogens exist in domestic animals (e.g. dogs) and wild animals (e.g. anteaters, armadillos, opossums, certain rats and primates). [Book ref. 72, pp 161–182.]

In the patient, *T. (S.) cruzi* occurs as non-dividing trypomastigotes in the blood, and in the reproductive amastigote and epimastigote forms in pseudocysts within host cells. Symptoms may include cardiomyopathy, grossly enlarged colon ('megacolon') and oesophagus, and low levels of certain hormones resulting from damage to endocrine glands. Autoantibodies to heart and skeletal muscles, and to nerve tissue, have been detected. *Lab. diagnosis*: microscopical examination of thick blood films; XENODIAGNOSIS (using e.g. *Dipetalogaster maxima*); a CFT and/or e.g. immunofluorescence tests. *Treatment*: chemotherapeutic agents, e.g. Lampit (a nitrofurantoin) and benznidazole (a 2-nitroimidazole), are commonly used but are associated with significant side-effects; moreover, this treatment may or may not eliminate the intracellular forms of *T. (S.) cruzi*.

## chain-termination method

Dinitroaniline herbicides such as *trifluralin* ( $\alpha,\alpha,\alpha$ -trifluoro-2,6-dinitro-*N,N*-dipropyltoluidine), which inhibit certain protozoan parasites by affecting tubulin polymerization, have been examined for their potential as candidate antimicrobials against *T. cruzi* [TIP (2001) 17 136–141].

[The disease in Mexico: TIP (2001) 17 372–376.]

**chain-termination method** (of DNA sequencing) See DNA SEQUENCING.

**Chainia** See STREPTOMYCES.

**Chalara** See HYPHOMYCETES and CERATOCYSTIS; see also MURAMIDASE.

**chalconycin** See MACROLIDE ANTIBIOTICS.

**chalk-brood** A BEE DISEASE caused by *Ascosphaera apis*. Infected honey-bee larvae become fluffy and swollen, and later shrink and harden; death usually occurs after the larvae have been sealed in their cells. Some of the dead larvae remain chalky-white, others become dark-coloured. Infection occurs by ingestion of spores of *A. apis*. The spores germinate in the gut; mycelium develops in the gut lumen and penetrates the gut wall. Fruiting bodies may form on the outside of the larvae.

*Ascosphaera* spp can also cause chalk-brood in wild bees – e.g. *A. aggregata* in the alfalfa leaf-cutting bee *Megachile rotundata* [life cycle of *A. aggregata*: Mycol. (1984) 76 830–842].

**challenge** (*immunol.*) The exposure of an animal (or other living system) to a pathogen (or other agent) – usually in order to determine the state of immunity or resistance to the pathogen or agent; for example, an animal may be challenged with a pathogen to test the efficacy of a previously administered vaccine.

**challenge virus** See INTERFERENCE (1).

**chalybeate** (of water) Containing iron.

**Chamaesiphon** A genus of unicellular CYANOBACTERIA (section I) in which the cells are ovoid and reproduce by repeated budding at the apical end; the buds were formerly known as ‘exospores’. GC%: ca. 47.

**Chamaesiphonales** See CYANOBACTERIA.

**Chamberland candle** See FILTRATION.

**chamois contagious ecthyma virus** See PARAPOXVIRUS.

**champagne** See WINE-MAKING.

**chancere** A papular lesion formed at the initial site of infection in certain diseases (e.g. SYPHILIS, SLEEPING SICKNESS).

**chancroid** (soft chancre) A VENEREAL DISEASE, caused by *Haemophilus ducreyi*, characterized by one or more ulcerative lesions which are usually confined to the genitalia. Incubation period: 1–14 (usually 4–5) days.

**Changuinola subgroup** See ORBIVIRUS.

**channel catfish virus disease (CCVD)** A FISH DISEASE which affects cultivated channel catfish (*Ictalurus punctatus*) under 4 months of age. Symptoms include e.g. abnormal swimming movements, haemorrhages of gills, skin and internal organs, and necrotic lesions in liver, spleen etc. The causal agent is a herpesvirus (see HERPESVIRIDAE).

**chanterelle** See CANTHARELLALES.

**Chaos** A genus of large, multinucleate, freshwater amoebae of the AMOEBIDA [Book ref. 133, p. 145]. In *C. carolinense* polypodial forms may be 0.7–2.0 mm in diam., monopodial forms up to 3 mm diam.; *C. illinoisense* is generally smaller (ca. 0.5–1.5 mm).

**chaperone** (molecular chaperone) In most cases: a protein that is specialized for folding/stabilization or direction of a (typically newly synthesized) protein. (See also HEAT-SHOCK PROTEINS, FIMBRIAE (type I) and VIRULON.) A chaperone may bind to

a nascent protein either co-translationally [JBC (1997) 272 32715–32718] or following translation.

Although most chaperones are proteins, a membrane lipid acts as a chaperone for the LacY protein in *Escherichia coli* [EMBO (1998) 17 5255–5264].

**Chara** See CHAROPHYTES.

**Charales** See CHAROPHYTES.

**charcoal blood agar** A medium used for the primary isolation of *Bordetella pertussis*; it is reported to yield better growth than that obtained with the traditional BORDET–GENGOU AGAR. Beef extract, starch, peptone, NaCl, nicotinic acid and agar are dissolved in water by heating; charcoal is added before autoclaving. Sterile, defibrinated horse blood is added to the molten agar at ~45°C. [Recipe: Book ref. 219, pp 470, 471.]

**Charcot–Leyden crystals** Microscopic, colourless crystals often present in the stools of patients suffering from certain intestinal diseases (e.g. amoebic dysentery) or in the sputum of patients with asthma or other chest conditions. The crystals are diamond-shaped or shaped like short, double-pointed needles; they stain with iodine.

**charge-shift immunoelectrophoresis** IMMUNOELECTROPHORESIS used e.g. to distinguish amphiphilic from hydrophilic proteins. Differentiation is based on the fact that when amphiphilic proteins bind non-ionic detergent at their hydrophobic sites, their electrophoretic mobility is changed by the addition of (positively or negatively charged) ionic detergent; hydrophilic proteins are unaffected.

**chargerin** See ANISOTROPIC INHIBITOR.

**Charon** A type of CLONING vector derived from the genome of bacteriophage  $\lambda$ ; typically, a Charon is a REPLACEMENT VECTOR.

**charonin** An ATP-dependent protease which may also function as a molecular chaperone.

**Charophyceae** See CHLOROPHYTA.

**Charophyta** See CHAROPHYTES.

**charophytes** A group of macroscopic green algae variously regarded as (a) a distinct division (Charophyta) [e.g. Book ref. 123, pp. 303–330]; (b) a class (Charophyceae) within the division Chlorophyta [e.g. Book ref. 130, pp. 36–132]; or (c) an order (Charales) within a class, Charophyceae, which is broader than that in (b); see CHLOROPHYTA. Charophytes (e.g. *Chara* and *Nitella*) have several features in common with bryophytes (mosses and liverworts); e.g., the plant is structurally complex, being differentiated into root-, shoot- and leaf-like structures; the shoots are divided into nodes (each node bearing a whorl of branches) and internodes; sexual reproduction is oogamous, and an envelope of sterile cells (*shield cells*) surrounds the antheridia and oogonia; asexual reproduction may occur e.g. by the formation of bulbils (‘plantlets’) on the rhizoids, or of AMYLUM STARS on the lower nodes, but apparently never by the formation of zoospores. Charophytes are generally heavily calcified (hence the popular names ‘stoneworts’ or ‘brittleworts’); they occur mainly in fresh water (lakes, ponds, etc.). (See also GYROGONITES.)

**chasmoendolith** See ENDOLITHIC.

**Chattonella** See CHLOROMONADS.

**chauveolysin** See THIOL-ACTIVATED CYTOLYSINS.

**che gene** In e.g. enterobacteria: a gene involved in CHEMOTAXIS.

**checker colony** See DRAUGHTSMAN COLONY.

**Cheddar cheese** See CHEESE-MAKING.

**cheese-making** Cheese is made by the coagulation and fermentation of MILK; differences between the various types of cheese reflect differences in e.g. mode of manufacture, microorganisms employed, and type of milk used (e.g. cows’, goats’ sheep’s).

Initially, the milk may undergo various treatments: e.g. PASTEURIZATION, homogenization (i.e. reduction in size of fat globules), adjustment of fat content. The milk protein is then coagulated to form a solid *curd* in which milk fat and soluble components are trapped. Coagulation is usually achieved primarily by adding rennet (rennin) or microbial PROTEASES; it is aided by stirring, heating ('cooking'), and the addition of cultures of selected strain(s) of LACTIC ACID BACTERIA – which lower the pH by fermenting lactose to lactic acid. Strains of the mesophilic bacterium *Lactococcus lactis* are commonly used, but thermophilic strains (e.g. *Streptococcus thermophilus*, *Lactobacillus bulgaricus*, *L. helveticus*) are used for cheeses cooked at higher temperatures. The bacteria primarily carry out HOMOLACTIC FERMENTATION under the conditions of manufacture, but they also form small amounts of other important flavour components (acetic and propionic acids, ketones, esters etc.).

The curd is cut into pieces, and the liquid (*whey*) is removed by pressing and/or straining; the curd may then be treated to optimize pH, reduce moisture, increase salt content etc., according to the type of cheese. Finally, the cheese is ripened by a controlled storage during which flavour and texture develop due mainly to the action of microorganisms and milk enzymes.

(a) *Blue cheeses* (e.g. *Gorgonzola*, *Roquefort*, *Stilton*). As well as strains of *Lactococcus lactis*, *Penicillium roqueforti* is mixed with the curd before removal of the whey; during ripening, the mould grows through the cheese, giving the characteristic flavour and blue 'veins'.

(b) *Brick cheese* is an American soft cheese. The early stages of manufacture resemble those for Cheddar (see below); subsequently the cheese is *surface-ripened*: the relative humidity is held at 95% to allow a succession of microorganisms to develop on the surface of the cheese. First, yeasts metabolize the lactic acid, raising the pH and synthesizing vitamins etc.; this stimulates the growth of micrococci and *Brevibacterium linens*. The microbial growth is washed off before packaging and a further period of ripening. *Bel paese*, *Limburger*, *Port Salut* and *Tilsit* are made similarly.

(c) *Camembert* is a high-moisture soft, French cheese. In addition to lactic acid bacteria, the mould *Penicillium camemberti* is added either to the milk or to the separated curd. The curd is placed on racks to maximize surface exposure and facilitate growth of the mould – which forms a cottony white mat over the surface of the cheese. Yeasts (e.g. species of *Saccharomyces*, *Kluyveromyces*, *Candida*), and sometimes *Brevibacterium linens*, are also present in the surface flora. *Brie* is made in a similar manner.

(d) *Cheddar* is a hard English cheese made from raw or pasteurized whole milk. The milk is clotted enzymically, inoculated with (usually) strains of *Lactococcus lactis*, and cooked at temperatures of up to ca. 40°C. (A genetically engineered starter culture has been used to control the pathogen *Listeria monocytogenes* in Cheddar cheese [AEM (1998) 64 4842–4845].) The curd is cut into small cubes and allowed to settle in the whey. The whey is drained off, and the curd mass is cut into blocks which are piled and turned (a process called 'cheddaring'). The curd is then cut into smaller pieces, salted, pressed into the desired shape, packaged, and ripened at 2–7°C.

*Edam* and *Gouda* are semi-soft Dutch cheeses made in a similar manner.

(e) *Cottage cheese* is a high-moisture, unripened soft cheese made from skim milk. The milk is clotted with a B- or BD-type LACTIC ACID STARTER. The final cooking temperature is ca. 55°C (cf. QUARG). To improve the safety of cottage cheese, use

has been made of a starter culture containing organisms that produce the BACTERIOCIN lactacin 3147 – which inhibits *Listeria monocytogenes* [JAM (1999) 86 251–256]. *Cream cheese* (for example, *Neufchâtel*) is made in a similar way using cream instead of skim milk; it thus has a higher fat and lower moisture content.

(f) *Mozzarella* is a soft, usually unripened, Italian cheese formerly made from buffalo milk (but now generally made from cows' milk). Its manufacture is similar to that of Cheddar but involves higher temperatures (50–55°C) as well as thermophilic streptococci and lactobacilli.

(g) *Parmesan* is a hard, low-moisture Italian cheese; its manufacture is similar to that of Swiss cheeses (see below), but e.g. propionibacteria are not used.

(h) *Swiss cheeses* (e.g. *Emmentaler*, *Gruyère*) are manufactured in a way basically similar to that used for Cheddar; however, the process involves higher cooking temperatures (50–55°C) and uses thermophilic bacteria (*Streptococcus thermophilus*, *Lactobacillus* spp). Strains of *Propionibacterium* are used in the inoculum; during ripening, these bacteria (i) contribute flavour components (e.g. propionic acid), and (ii) produce carbon dioxide – which collects in pockets, thus forming the characteristic 'eyes' in the cheese.

(See also CHEESE SPOILAGE and DAIRY PRODUCTS.)

**cheese spoilage** High-moisture cheeses (e.g. cottage cheese) are very susceptible to spoilage by a wide range of bacteria and moulds, while low-moisture cheeses (e.g. parmesan) are much more resistant. Surface spoilage of cheeses is commonly due to the growth of moulds – e.g. species of *Aspergillus*, *Cladosporium* and *Penicillium*, and (in high-moisture cheeses) *Geotrichum* spp. Bacteria may produce off-flavours – e.g. H<sub>2</sub>S (produced e.g. by clostridia), rancidity (due e.g. to lipolytic pseudomonads); undesirable holes ('eyes') may be formed during the ripening process by gas-producing bacteria (e.g. coliforms, *Bacillus* spp).

**cheese-washers' lung** An EXTRINSIC ALLERGIC ALVEOLITIS associated with the inhalation of allergens from *Penicillium* spp – e.g. *P. verrucosum* ('*P. casei*').

**CHEF** See PFGE.

**chelating agents** See e.g. CDTA, EDTA, EGTA, NTA.

**chemical shift** See NUCLEAR MAGNETIC RESONANCE.

**Chemiclave** An apparatus used e.g. for sterilizing surgical instruments etc; essentially, it consists of a chamber within which instruments etc are exposed to a mixture of the vapours of alcohol, formaldehyde and water at 132°C, 20 lb/inch<sup>2</sup> (ca. 137 kPa). (cf. AUTOCLAVE.)

**chemiluminescence** The production of light as a result of a chemical reaction. The term is commonly used to refer e.g. to the emission of light by phagocytes and other specialized mammalian cells under appropriate conditions, and to light emission in cell-free experimental systems, while BIOLUMINESCENCE usually refers to the emission of light from whole, living organisms; in all cases the emission of light is O<sub>2</sub>-dependent. In those cases where the mechanism is known, light emission involves the oxidation of a particular type of organic molecule – the resulting unstable, excited molecule spontaneously returning to the (unexcited) ground state with concomitant emission of light. (cf. PHOSPHORESCENCE.) Chemiluminescence in phagocytes is associated with the respiratory burst which occurs in e.g. NEUTROPHILS during PHAGOCYTOSIS.

Experimental chemiluminescence systems employ light-emitting substances such as *lucigenin* (*bis-N*-methylacridinium nitrate), *lophine* (2,4,5-triphenylimidazole) and LUMINOL.

## chemiluminogenic probe

Luminol emits light in an alkaline solution of  $\text{H}_2\text{O}_2$  in the presence of a suitable catalyst; catalysts include e.g. cytochromes, horseradish peroxidase, MICROPEROXIDASE, and even  $\text{Mn}^{2+}$  or  $\text{Ni}^{2+}$  ions. Other agents – e.g. lophine, lucigenin – emit light in alkaline  $\text{H}_2\text{O}_2$  in the absence of a catalyst.

Chemiluminescence involving the (ATP-requiring) firefly luciferin–luciferase system (see BIOLUMINESCENCE) has been used to detect small amounts of ATP; e.g., very small numbers of cells can be quantified by measuring their extractable ATP [e.g. in studies on bacterial adhesion: JGM (1983) 129 621–632]. LUMINOL-dependent chemiluminescence can be triggered in mouse spleen cells by interaction between spleen cell plasma membrane and the HN and (particularly) F glycoproteins of the Sendai virus; such chemiluminescence is apparently associated with the action of unstable oxygen species (e.g., HYDROGEN PEROXIDE, HYDROXYL RADICAL, SUPEROXIDE) on the luminol probe [Book ref. 87, pp. 451–458]. Immunoassay systems using chemiluminescent labels may offer a useful alternative to RADIOIMMUNOASSAY systems [PHLS Digest (1984) 1 58–62]. [Reviews on applications: Book ref. 96; TIBS (1986) 11 104–108.]

**chemiluminogenic probe** See e.g. LUMINOL.

**chemiosmosis** The phenomenon in which an energy-dependent transfer of protons or electrons across an ENERGY-TRANSDUCING MEMBRANE generates, or augments, a transmembrane proton gradient whose inherent energy (*proton motive force, pmf*) can be used for chemical, osmotic or mechanical work. A pmf can be generated e.g. by the operation of an ELECTRON TRANSPORT CHAIN; by the illumination of a PURPLE MEMBRANE; by the hydrolysis of ATP by a PROTON ATPASE; by the hydrolysis of pyrophosphate by a PROTON PPASE; by END-PRODUCT EFFLUX; or by EXTRA-CYTOPLASMIC OXIDATION. A pmf can be used e.g. for ATP (or PYROPHOSPHATE) synthesis (see OXIDATIVE PHOSPHORYLATION); for the concentration of solutes against a concentration gradient (see e.g. ION TRANSPORT); for the regulation of TRANSHYDROGENASE activity; for REVERSE ELECTRON TRANSPORT; and (in flagellated bacteria) for the rotation of the FLAGELLUM. (See also AEROTAXIS and PHOTOTAXIS; cf. SODIUM MOTIVE FORCE.)

Proton motive force is usually represented as the sum of (a) the ‘electrical’ energy, and (b) the ‘chemical’ energy associated with protons by virtue of their distribution across a transmembrane proton gradient – such a gradient being, simultaneously, both an electrical (i.e., charge) gradient and a chemical (i.e., concentration) gradient. The ‘electrical’ component of pmf (= *membrane potential, transmembrane electrical potential difference,  $\Delta\psi$* ) is generally given in millivolts (mV). The ‘chemical’ component of pmf corresponds to the transmembrane pH differential,  $\Delta\text{pH}$ ;  $\Delta\text{pH}$  can be converted to millivolts by multiplying by the factor  $2.3(\text{RT}/\text{F})$  in which R is the gas constant, T is the absolute temperature, and F is the Faraday constant. The factor  $2.3(\text{RT}/\text{F})$  is commonly indicated by the letter Z. The expression for pmf (symbol:  $\Delta\tilde{\mu}_{\text{H}^+}$  or  $\Delta p$ ) is thus:

$$\Delta p = \Delta\psi - Z\Delta\text{pH} \quad (1)$$

Z has a value of ca. 60 at  $30^\circ\text{C}$ . In this equation the minus sign is necessary for the correct summation of energies:  $\Delta\text{pH}$  is itself commonly a negative quantity, being obtained by the subtraction of a higher pH from a lower one. (The equation above refers specifically to *proton* gradients.)

In bacteria, the outward pumping of protons during respiratory pmf generation causes the inner (cytoplasmic) side of the cytoplasmic membrane to become both alkaline and electrically negative relative to the outer (periplasmic) side; in mitochondria it is

the matrix side of the inner membrane which becomes relatively alkaline and electrically negative. By contrast, in the chloroplast thylakoid membrane, protons are pumped inwards during PHOTOSYNTHESIS, so that electrochemical gradients develop in the opposite orientation.

Respiring cells of *Escherichia coli* develop a pmf of the order of 200 mV; thus, e.g.  $\Delta\psi$  may be ca. 100 mV and  $\Delta\text{pH}$  ca.  $-1.75$  ( $\Delta p = 205$  mV). These cells maintain an internal pH of ca. 7.4–7.8 when the extracellular pH ranges from 5.5 to 9.0, i.e., the ‘bulk-phase’ transmembrane  $\Delta\text{pH}$  is highly dependent on the extracellular pH. (By contrast, in *Clostridium pasteurianum* a decrease in extracellular pH from 7.1 to 5.1 corresponds to a decrease in internal pH from 7.5 to 5.9 [Book ref. 82, pp. 137–138].) In respiring *E. coli*, the  $\Delta p$  drops sharply if the external pH rises above ca. 7.8, though  $\Delta p$  can be augmented under these conditions by increasing the extracellular concentration of  $\text{K}^+$  or  $\text{Na}^+$  [JB (1985) 163 423–429]. In chloroplasts, the contribution of  $\Delta\text{pH}$  to  $\Delta p$  is typically much greater than it is in bacteria such as *E. coli*.

In a respiring bacterial cell there is a characteristic *proton circuit*: protons are extruded across the cytoplasmic membrane by the primary pmf generator (electron transport chain) and they re-cross the membrane via an  $\text{H}^+$ -ATPase during ATP synthesis. In such a cell the pmf acts as a thermodynamic back-pressure which opposes further extrusion of protons. However, proton extrusion can occur not only through the operation of an electron transport chain: it can also occur as a result of the tendency of the intracellular reaction ( $\text{ATP} \leftrightarrow \text{ADP} + \text{P}_i$ ) to reach equilibrium; in a respiring cell, the energy derived from metabolism holds this reaction far to the left of its equilibrium position, so that the tendency to reach equilibrium (by ATP hydrolysis) is associated with a large amount of Gibbs free energy ( $\Delta G_{\text{ATP}}$ ;  $\Delta G_{\text{P}}$ ; *phosphate potential*; *phosphorylation potential*).  $\Delta G_{\text{ATP}}$  tends to promote ATP hydrolysis (at the  $\text{H}^+$ -ATPase on the inner side of the membrane) and, hence, to promote proton extrusion in opposition to the pmf.  $\Delta G_{\text{ATP}}$  and pmf may tend to maintain a dynamic balance; however, if pmf is below a certain value ATPases tend to become (reversibly) inactivated: see PROTON ATPASE. Pmf is the primary factor responsible for RESPIRATORY CONTROL.

*Experimental manipulation of  $\Delta p$ ,  $\Delta\psi$  or  $\Delta\text{pH}$ .* Various IONOPHORES can be used to collapse or modify pmf or either of its components. Thus, e.g., VALINOMYCIN can alter  $\Delta\psi$ , without altering  $\Delta\text{pH}$ , by permitting  $\text{K}^+$  influx into the bacterial cytoplasm sufficient to reduce or eliminate  $\Delta\psi$ . By contrast, NIGERICIN can effect an electroneutral exchange of  $\text{K}^+$  for  $\text{H}^+$ , thus altering  $\Delta\text{pH}$  without disturbing  $\Delta\psi$ . UNCOUPLING AGENTS can abolish  $\Delta p$  (or prevent its development) and (as a consequence) can abolish respiratory control. Other agents (e.g. AUROVERTINS, DCCD, efrapeptin, OLIGOMYCIN, QUERCETIN, TENTOXIN and tributyltin chloride) can inhibit ( $\text{F}_0\text{F}_1$ )-type  $\text{H}^+$ -ATPases.

*Measurement of  $\Delta p$ .* The components of  $\Delta p$  ( $\Delta\psi$  and  $\Delta\text{pH}$ ) are estimated separately and added.

$\Delta\psi$  is often estimated by allowing an indicator ion to distribute across the membrane so as to reach electrochemical equilibrium with the membrane potential; at equilibrium, a measurement is made of the concentration of the indicator ion on either side of the membrane, and  $\Delta\psi$  is estimated from the Nernst equation (see equation 3 in ION TRANSPORT). The indicator ion must be permeable only by electrical uniport (so that its equilibrium distribution reflects  $\Delta\psi$ ); it should not be bound or metabolized; it should disturb the membrane

potential only minimally; and it should be measurable with ease. Ions used include the synthetic, lipophilic 'Skulachev' cations (e.g. triphenylmethylphosphonium, TPMP<sup>+</sup>) and anions (e.g. tetraphenylborate, TPB<sup>-</sup>) which disturb the gradient minimally since they can be used in very low concentrations. Methods used for measuring equilibrium concentrations of indicator ions include e.g. continual monitoring of the given ion in the incubation medium.

$\Delta$ pH is usually estimated from the equilibrium distribution of a weak acid (e.g. 5,5-dimethyl-4-oxazolinedione, DMO) or a weak base which permeates the membrane electroneutrally.

One of the unresolved problems in chemiosmosis concerns the precise mode of transmembrane proton translocation; some workers favour the concept of VECTORIAL GROUP TRANSLOCATION, while others favour a model in which proton translocation is associated with conformational changes in the membrane proteins (see ELECTRON TRANSPORT CHAIN). Another problem concerns the extent to which the proton circuit is delocalized into the bulk phases on either side of the membrane; some evidence suggests that the proton circuit is more or less localized at the membrane surface (in accordance with the 'semi-localized' hypothesis) [Nature (1986) 322 756–758].

(See also LUNDEGARDH-TYPE RESPIRATION.)

**chemoattractant** See CHEMOTAXIS.

**chemoeffector** See CHEMOTAXIS.

**chemokines** A category of CYTOKINES which function primarily as chemoattractants for particular type(s) of leukocyte – and which are important in the recruitment of leukocytes to regions of infection and INFLAMMATION.

Chemokines are typically small (8–10 kDa) secreted proteins which are produced by a range of cells that include monocytes, macrophages, fibroblasts, T cells, epithelial cells and endothelial cells.

Chemokines are divided into several families on the basis of e.g. composition and function. Every cytokine molecule contains several conserved cysteine (C) residues, and the sequence of amino acids containing these residues differs in different families. Thus, in the CXC family ( $\alpha$ -chemokines) the two initial cysteine residues are separated by one amino acid residue (X). In the CC family ( $\beta$ -chemokines) the two initial cysteine residues are adjacent. Members of the C family ( $\gamma$ -chemokines) lack some of the cysteine residues present in the  $\alpha$ - and  $\beta$ -chemokines. Yet another family, CX3C, includes the membrane-bound chemokine fractalkine.

The two main families (CXC and CC) differ in the principal types of cell which they attract; thus, typically (though not exclusively), the CXC chemokines attract neutrophils while the CC chemokines attract monocytes.

The cell-surface receptors for chemokines (in most or all cases) are transmembrane molecules of the rhodopsin superfamily. The intracellular domain of such receptors is coupled to G PROTEINS which initiate intracellular signalling when chemokines bind to their cognate receptors; in at least some cases, the intracellular signalling pathway downstream of the G proteins includes protein kinase C (PKC).

Some receptors can bind only one type of chemokine (e.g. the receptor CXC-CKR2 is specific for the CXC-type chemokine IL-8) but other receptors can bind more than one type of chemokine. A receptor on erythrocytes (red blood cells) can bind both CXC and CC chemokines; such binding is non-functional, but it may serve as a 'sink' to prevent inappropriate stimulation of leukocytes.

Chemokines of the CXC family include INTERLEUKIN-8, PF4 (platelet factor 4: produced by the  $\alpha$  granules of platelets,

attractant for e.g. fibroblasts) and IP10 (produced by monocytes and endothelial cells, attractant for e.g. NK cells). (The two latter chemokines are reported to have anti-angiogenic activity, and they may inhibit tumour formation.)

Chemokines of the CC family include eotaxin (produced by macrophages and endothelial cells, attractant primarily for eosinophils) and RANTES ('regulated on activation, normal T cell expressed and secreted': produced by T cells, monocytes and epithelial cells, attractant for e.g. T cells and NK cells).

Chemokines of the C family include lymphotactin: a (murine) protein produced e.g. by activated T cells and a potent attractant for T cells.

**chemoklinokinesis** Klinokinesis (see KINESIS sense 2) in which the stimulus is a change in concentration of a chemical.

**chemolithoautotroph** A CHEMOTROPH with properties of a LITHOTROPH and an AUTOTROPH. The ability to grow chemolithoautotrophically is confined to a relatively small number of prokaryotes; these organisms make important contributions to the cycles of matter, and some are involved in LEACHING processes.

Plasmid-mediated anaerobic chemolithoautotrophic growth has been reported for a strain of *Sulfolobus ambivalens* containing the plasmid pSL10. Aerobically, this organism derives energy from the oxidation of elemental sulphur (with oxygen as the terminal electron acceptor), yielding sulphuric acid; anaerobically it obtains energy from the oxidation of hydrogen (with elemental sulphur as terminal electron acceptor), yielding hydrogen sulphide [Nature (1985) 313 789–791].

**chemolithoheterotroph** A CHEMOTROPH with the properties of a LITHOTROPH and a HETEROTROPH. (See also MIXOTROPHY.)

**chemolithotroph** See CHEMOTROPH.

**chemoorganoheterotroph** A CHEMOTROPH with the properties of an ORGANOTROPH and a HETEROTROPH. The majority of bacteria and fungi are chemoorganoheterotrophs (cf. CHEMOLITHOAUTOTROPH); some such bacteria are facultative chemolithoautotrophs. Taken together, chemoorganoheterotrophs can use a very wide range of organic substrates, though particular species may be able to use only a very limited number of compounds. Because most – if not all – chemoorganotrophs are heterotrophic, the term 'heterotroph' is sometimes used as a synonym of 'chemoorganoheterotroph'.

**chemoorganotroph** See CHEMOTROPH.

**chemoprophylaxis** The use of drug(s) for PROPHYLAXIS.

**chemoreceptor** See CHEMOTAXIS.

**chemorepellent** See CHEMOTAXIS.

**chemorespiration** See PHOTORESPIRATION.

**chemostat** See CONTINUOUS CULTURE.

**chemosynthetic primary production** See PRIMARY PRODUCTION.

**chemotaxigen** Any agent which promotes the formation of a CYTOTAXIN.

**chemotaxis** A TAXIS in which the stimulus is a concentration gradient of a given chemical (a *chemoeffector*). A cell may make a net movement towards higher concentrations of some chemoeffectors (*chemoattractants*) but away from others (*chemorepellents*); a chemoattractant may or may not be a nutrient. Cells may exhibit chemotaxis when they occupy a physiologically suboptimal position within the concentration gradient.

A cell capable of chemotaxis must be able to (i) detect ('sense') changes in the concentration of a chemoeffector, (ii) transmit this information to locomotory organelle(s), and (iii) make the appropriate response; it must also be able to *adapt* by resuming the unbiased mode of motility when in a uniform concentration of chemoeffector, regardless of the actual concentration.

**chemotaxis**

(a) In *Escherichia coli* (and other enterobacteria) FLAGELLAR MOTILITY within a *uniform* concentration of chemoeffector(s) results in a pattern of movements referred to as a RANDOM WALK. If, however, a cell be placed in a concentration gradient of e.g. chemoattractant, the cell will subsequently exhibit a modified pattern of movements; thus, if the cell were initially swimming towards the higher concentration of chemoattractant it will maintain a smooth mode of swimming (counterclockwise flagellar rotation), but if swimming away from the higher concentration

of chemoattractant it will exhibit a greater tendency to tumble (clockwise flagellar rotation) – thus increasing the probability of changing to a more favourable direction.

‘Sensing’ the concentration gradient is achieved by means of specific receptors (in the cytoplasmic membrane) to which the chemoeffector binds; the binding of chemoeffector to a receptor results in the transmission of a signal that promotes either counterclockwise or clockwise flagellar rotation – that is, either smooth swimming or tumbling, respectively.

When a cell is swimming towards a higher concentration of chemoattractant, the receptors will be more likely, within a given period of time, to bind molecules of the chemoattractant than if the cell were moving in another direction; when a molecule of chemoattractant binds to a receptor it induces a signal that promotes smooth swimming. Conversely, if the cell is swimming *down* the concentration gradient, there is likely to be (over a period of time) a net loss of chemoattractant molecules bound to receptors; when a molecule of chemoattractant leaves a receptor it stimulates a signal that promotes tumbling.

The diagram (see accompanying figure) gives an outline of the mechanism of receptor-mediated chemotaxis in *Escherichia coli*. The receptors are designated *methyl-accepting chemotaxis proteins* (MCPs). In *E. coli*, MCPs include the products of genes *tap*, *tar*, *trg* and *tsr*.

Some chemoeffectors bind directly to their MCPs. Thus, e.g. serine and aspartate bind to the Tsr and Tar proteins, respectively. Other chemoeffectors, such as galactose and ribose, initially form a complex with certain periplasmic *binding proteins* before binding to their respective MCPs (see BINDING PROTEIN-DEPENDENT TRANSPORT SYSTEM); thus, e.g. the

maltose complex binds to the Tar protein, and the galactose and ribose complexes bind to the Trg protein. (Uptake and metabolism of these sugars are not necessary for a chemotactic response.)

Cells can also respond chemotactically to substrates taken up by PTS (q.v.). The mechanism is not understood, but one suggestion is that particular PTS component(s) interact – via unknown intermediate(s) – with the CheY protein (see figure), thus influencing flagellar rotation. PTS-mediated chemotaxis differs from the MCP system in several ways – e.g. (i) substrates must be *transported*, not simply bound; (ii) adaptation does not involve methylation; and (iii) the system does not respond to repellents [e.g. JCB (1993) 51 1–6].

The mechanism by which flagellar rotation is switched between counterclockwise and clockwise modes appears to be independent of pmf, although pmf is necessary for driving the flagellar motors (cf. AEROTAXIS and PHOTOTAXIS).

Interestingly, although SWARMING in *E. coli* involves components of the chemotaxis system, the substances that promote swarming appear to differ from the known chemoeffectors in chemotaxis [PNAS (1998) 95 2568–2573].

CHEMOTAXIS in *Escherichia coli*: a model of receptor-mediated chemotaxis involving signal transduction.

(a) The receptors are called *methyl-accepting chemotaxis proteins* (MCPs), and they occur in the cytoplasmic membrane (CM). MCPs have functional regions in both the periplasm and cytoplasm. There are different types of MCP, each type recognizing its own range of chemoeffectors, and there are several hundred molecules of each type of MCP in a given cell. (In *E. coli* the MCPs are encoded by genes *tap*, *tar*, *trg* and *tsr*.) Some chemoeffectors (e.g. aspartate, serine) bind directly to their MCPs, but others (e.g. some sugars, including ribose) first form a complex with certain periplasmic proteins before binding. The binding/release of chemoeffectors by an MCP regulates an intracellular signal that influences the frequency of tumbling.

(b) The intracellular signal originates at the protein CheA (encoded by gene *cheA*). CheA is a HISTIDINE KINASE. In the diagram, CheA is bound to the MCP; CheW is a coupling protein. CheA can transfer phosphate from ATP to a regulator protein, CheY; the phosphorylated (activated) form of CheY (CheY~P) enhances clockwise (CW) flagellar rotation (and, hence, increases the frequency of tumbling) by interacting with the C ring of the flagellar motor (apparently with the FilM component).

[Role of CheY: TIM (1999) 7 16–22.] The basic signal thus consists of the transfer of phosphate from CheA to CheY. This signal is modulated (i.e. regulated) by (i) the binding/release of chemoeffector at the MCP, and (ii) the degree of methylation of the MCP; these two factors are considered below. (Although *phosphorylation* of CheY has been regarded as the essential mode of signalling in chemotaxis, there is some evidence that, in at least some cases, *acetylation* of CheY may be involved in the response to repellents [reported in JB (2000) 182 1459–1471 (1466)].)

The binding of a chemoattractant *inhibits* the kinase activity of CheA, thus inhibiting the transfer of phosphate to CheY. (On binding of chemoattractant, it appears that subunits of the MCP move relative to one another, and that such movement is involved in the inhibition of CheA kinase activity [see e.g. JB (2000) 182 1459–1471 (1465–1466)].) Conversely, the release of chemoattractant from an MCP *stimulates* CheA and promotes the transfer of phosphate to CheY, thus encouraging tumbling.

The cytoplasmic side of an MCP is subject to ongoing methylation by a methyltransferase, CheR, which uses S-adenosylmethionine as methyl donor. Opposing this, a methyl-esterase, CheB, removes the methyl groups; the activity of CheB is enhanced when it is phosphorylated by CheA. The degree of methylation of an MCP thus depends on the activities of both CheR and CheB; increased methylation tends to *enhance* the activity of CheA.

(c) In a low, uniform concentration of chemoattractant ( $C_{\text{attr}}$ ), tumbling occurs at a given rate. When the cell swims *up* a concentration gradient (i.e. towards higher concentrations), there is an increase in the number of molecules of  $C_{\text{attr}}$  bound to MCPs; this results in the inhibition of CheA which, in turn, inhibits phosphorylation of CheY – and thus promotes counterclockwise (CCW) flagellar rotation, i.e. smooth swimming in the same direction. Inhibition of CheA also inhibits CheB, allowing increased methylation of the MCP (as CheR methylates continually); hence, inhibition of CheA, due to binding of  $C_{\text{attr}}$ , is subsequently offset by the stimulatory effect of increased methylation of the MCP – so that the frequency of tumbling returns to its original value. The cell has thus *adapted* to the new, higher, concentration of  $C_{\text{attr}}$  (MCP in the centre).

On swimming *down* the concentration gradient (i.e. away from higher concentrations), there is a decrease in the number of molecules of  $C_{\text{attr}}$  bound to the MCPs. Release of  $C_{\text{attr}}$  stimulates CheA and promotes clockwise (CW) flagellar rotation (more frequent tumbling); at the same time, CheB is stimulated, leading to de-methylation of the MCP until CheA activity has been reduced to its original level – i.e. adaptation to the new, low, uniform concentration of  $C_{\text{attr}}$  (MCP at right-hand side). Such adaptation depends on an appropriate rate of dephosphorylation of CheY~P and CheB~P; CheB~P undergoes autodephosphorylation, while CheY~P levels are regulated by the CheZ protein. (It appears that about 30% of the intracellular pool of CheY molecules are in the phosphorylated state in fully adapted cells [EMBO (1998) 17 4238–4248].)

Note that the degree of methylation of an MCP in an *adapted* cell reflects the extracellular concentration of the chemoattractant (compare first, third and fifth MCPs in the diagram).

Reproduced from *Bacteria*, 5th edition, Figure 7.13, pages 152–153, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

## chemotaxonomy

Experimental modification of the concentration of various components of the chemotaxis system (e.g. CheR) indicates that, whereas variation can occur in factors such as the time taken to adapt (e.g. a >20-fold variation with variation in CheR concentration), the *precision* of adaptation (i.e. the capacity to return to the exact pre-stimulus level of tumbling) is preserved [Nature (1999) 397 168–171].

[Control of chemotaxis: Mol. Microbiol. (1996) 20 903–910. Aspects of chemosensing (including non-enteric bacteria): JB (1998) 180 1009–1022. Signalling components in bacterial locomotion and sensory reception: JB (2000) 182 1459–1471. Signalling in bacterial chemotaxis (review): JB (2000) 182 6865–6873.]

(b) In the immune system (see e.g. INFLAMMATION), chemotaxis refers to the migration of certain types of leukocyte (e.g. MACROPHAGE, NEUTROPHIL) in the direction of higher concentrations of chemoeffectors (= *cytotaxins*); the cytotaxins include certain CYTOKINES and the ANAPHYLATOXIN C5a.

(c) In DICTYOSTELIUM (q.v.) and other cellular slime moulds, chemotaxis is involved e.g. in cell aggregation.

**chemotaxonomy** TAXONOMY based on chemical criteria such as DNA base composition, cell wall lipids, 16S rRNA structure etc.

**chemotherapeutic agent** Any drug used for chemotherapy – e.g. an ANTIBIOTIC.

**chemotherapeutic index** *Syn.* THERAPEUTIC INDEX.

**chemotherapy** The use of drug(s) (e.g. ANTIBIOTICS) for the treatment of disease.

**chemotroph** An organism whose energy is derived from endogenous, light-independent chemical reactions (a mode of metabolism termed *chemotrophy*). (cf. PHOTOTROPH.) A chemotroph which obtains energy by the metabolism of inorganic substrate(s) – i.e. a LITHOTROPH – is called a *chemolithotroph*; one which obtains energy by metabolizing organic substrate(s) – i.e. an ORGANOTROPH – is called a *chemoorganotroph*.

According to the type of compound from which carbon is assimilated, a chemolithotroph may be an AUTOTROPH (i.e. a CHEMOLITHOAUTOTROPH) or a HETEROTROPH (i.e. a chemolithoheterotroph). (See also MIXOTROPHY.) A heterotrophic chemoorganotroph is called a CHEMOORGANOHETEROTROPH.

The mode of metabolism may vary according to growth conditions: e.g., *Thiobacillus* strain A2 can exhibit chemolithoautotrophic, mixotrophic or chemoorganoheterotrophic growth under appropriate conditions [JGM (1980) 121 127–138].

**chemotrophy** A mode of metabolism in which energy is derived from endogenous, light-independent chemical reactions (cf. PHOTOTROPHY). (See also CHEMOTROPH.)

**chemotropism** See TROPISM (sense 1).

**chemotype** Any VARIETY distinguished by structural properties – e.g. a rough mutant.

**chenodeoxycholic acid** See BILE ACIDS.

**cherry leaf roll virus** See NEPOVIRUSES.

**cherry rasp leaf virus** See NEPOVIRUSES.

**Cheshunt compound** An agricultural antifungal preparation which consists of a mixture of copper sulphate (see COPPER) and ammonium carbonate; it is used, in aqueous solution, as a protectant against DAMPING OFF.

**chestnut blight** (chestnut canker) A lethal disease of the American chestnut (*Castanea dentata*) caused by invasion of the vascular cambium by *Endothia parasitica*. The disease has virtually eliminated the American chestnut from parts of America; however, in Italy the disease has been ameliorated by the appearance of hypovirulent strains of the pathogen capable of transferring the HYPOVIRULENCE phenotype to virulent strains ('transmissible hypovirulence'). Hypovirulent strains contain dsRNA which

can be transmitted e.g. by hyphal anastomosis; no capsid has been detected (cf. MYCOVIRUS), but the dsRNA appears to be closely associated with an RNA polymerase and may be packaged within vesicles formed by the host fungus [JGV (1985) 66 2605–2614]. [Potential of the hypovirulence factor for biological control of *E. parasitica*: ARPPath. (1982) 20 349–362; Science (1982) 215 466–471.] (See also DUTCH ELM DISEASE.)

**chi site** (chi sequence) See RECBC PATHWAY.

**chi structure** See RECOMBINATION.

**χ1776** A 'disabled' strain of *Escherichia coli* K12 which e.g. requires various amino acids (including diaminopimelic acid) and is highly sensitive to bile salts and other detergents. It was constructed for use in CLONING experiments to reduce the risk of propagation of potentially dangerous clones should they escape from the laboratory. However, χ1776 is difficult to grow and to transform, and is currently rarely used.

**chiasma** The visible manifestation of CROSSING OVER – e.g. between non-sister chromatids of homologous chromosomes during MEIOSIS.

**chiasma interference** See INTERFERENCE (sense 2).

**chiasmatobasidial** Refers to a *transverse* arrangement of nuclear spindles in a developing BASIDIUM. (cf. STICHOBASIDIAL.)

**chick embryo lethal orphan virus** See AVIADENOVIRUS.

**Chick–Martin test** A SUSPENSION TEST used to determine the PHENOL COEFFICIENT of a (phenolic) disinfectant; it assesses the efficacy of a disinfectant in the presence of organic matter, i.e., under conditions more closely approximating those in practical use (cf. RIDEAL–WALKER TEST). (Many disinfectants are inactivated by organic matter.) In the original test the organic matter used was 3% sterile dry faeces; a modified form of the test uses a sterilized suspension of yeast (5% dry wt/vol.). To each of several serial dilutions of the disinfectant under test are added the yeast and an inoculum of *Salmonella typhi*. After incubation for 30 min, an inoculum from each dilution is added to each of two tubes of broth which, after incubation at 37°C for 2 days, are examined for growth. The same procedure is carried out with phenol. For the *phenol* test two dilutions are identified: (i) that containing the highest concentration of phenol which permitted growth in *both* tubes inoculated from it, and (ii) that containing the lowest concentration of phenol which did not permit growth in *either* tube inoculated from it; the mean of these two concentrations is then calculated ( $P_{\text{mean}}$ ). For the disinfectant under test  $D_{\text{mean}}$  is calculated in the same way. The phenol coefficient of the disinfectant is given by  $P_{\text{mean}}/D_{\text{mean}}$ .

**chicken diseases** See POULTRY DISEASES.

**chicken syncytial virus** See AVIAN RETICULOENDOTHELOSIS VIRUSES.

**chickenpox** (varicella) An acute, highly infectious disease which usually occurs in epidemics affecting mainly young children. The causal agent is human (alpha) herpesvirus 3 (varicella-zoster virus) – see ALPHAHERPESVIRINAE. Infection occurs by direct contact or by droplet inhalation. The incubation period is ca. 2–3 weeks. Symptoms: fever and a rash of erythematous macules which rapidly develop into thin-walled vesicles, finally becoming dry and crusty; successive crops of lesions occur. The disease is usually mild and self-limiting; complications include e.g. pneumonia (usually in adults), encephalitis, and secondary infection of skin lesions with staphylococci and streptococci. In immunosuppressed or CMI-defective patients the disease is much more severe, with extensive rash and severe systemic symptoms (*progressive varicella*) which may be fatal; vidarabine and acyclovir have been used in treatment. A live vaccine has been developed [MS (1985) 2 249–254]. *Lab. diagnosis*: viruses

can be isolated from vesicular fluid during the first 3 days of the rash; scrapings from the base of a vesicle may be stained and examined for typical varicella GIANT CELLS and eosinophilic intranuclear inclusion bodies. (See also HERPES ZOSTER.)

**chiclero's ear** A chronic, ulcerating lesion on the ear-lobe, caused by *Leishmania mexicana*. It occurs in Panama, Honduras, and the Amazon region.

**chicory blotch virus** See CARLAVIRUSES.

**chicory yellow mottle virus** See NEPOVIRUSES.

**chikungunya fever** An acute infectious human disease caused by an ALPHAVIRUS and transmitted by mosquitoes (*Aedes* spp); epidemics occur in Africa, India and S. E. Asia. The disease is characterized by severe joint and back pains with fever; rarely, a severe (often fatal) haemorrhagic form occurs. Wild primates may act as a reservoir of infection.

**childbed fever** *Syn.* PUERPERAL FEVER.

**Chilo iridescent virus** See IRIDOVIRUS.

**Chilodochona** A genus of marine protozoa (subclass HYPOSTOMATIA). Cells: vase-shaped, i.e., the body is narrow at the point of attachment, broadening out before constricting and finally becoming flared and convoluted at the distal end.

**Chilodonella** A genus of ciliates (subclass HYPOSTOMATIA). The cells are flattened both ventrally and in the dorsal anterior region, and are rounded in the dorsal posterior region; there is an anteriolateral point ('break'), and the cytostome is located subterminally in the anteroventral surface. Species occur e.g. as gill parasites of freshwater fish, and are common in stagnant ponds etc and in some SEWAGE TREATMENT plants.

**Chilomastix** A genus of flagellate protozoa of the order RETORTAMONADIDA. *C. mesnili* is a non-pathogen which occurs e.g. in the caecum and colon in man and other animals (e.g. pigs); it is a pear-shaped organism, ca. 10–15 µm in length, with three anteriorly directed flagella arising from the blunt anterior end, and a fourth flagellum within the conspicuous cytostome. The single nucleus is located at the anterior end of the cell. The cysts are lemon-shaped, ca. 6–10 µm; the nucleus and cytostome are usually visible in stained cysts.

**Chilomonas** See CRYPTOPHYTES.

**chimeric plasmid** (1) Any recombinant PLASMID formed from nucleic acids derived from organisms which do not normally exchange genetic information (e.g. *Escherichia coli* and *Saccharomyces cerevisiae*). (See e.g. SHUTTLE VECTOR; cf. HYBRID PLASMID sense 2.)

(2) *Syn.* HYBRID PLASMID sense 1.

**Chinese letter arrangement** An arrangement of the cells of certain bacteria (e.g. *Corynebacterium* spp) as seen in microscopic preparations: the cells are arranged in groups which, to the occipital eye at least, resemble Chinese characters or 'letters'.

**chinoxon** See 8-HYDROXYQUINOLINE.

**Chionosphaera** A genus of fungi (see FILOBASIDIACEAE). Basidia occur in a hymenium covering the enlarged terminal portion of a small (<1 mm), stalked fruiting body. One species: *C. apobasidiales*, isolated from dead tree-limbs. [Book ref. 100, pp. 470–471.]

**chip** (DNA) See DNA CHIP.

**Chironomus luridus EPV** See ENTOMOPOXVIRINAE.

**Chironomus plumosus iridescent virus** See IRIDOVIRUS.

**chitan** CHITIN in which all of the glucosamine residues are *N*-acetylated. In nature, chitan may occur only in diatom spines. (cf. CHITOSAN.)

**chitin** A linear polysaccharide consisting of (1 → 4)-β-linked D-glucosamine residues, most of which are *N*-acetylated (cf. CHITAN; CHITOSAN). Chitin is abundant in nature, occurring e.g.

in arthropod exoskeletons, in the CELL WALLS of most fungi, in certain algae (e.g. in the spines of many planktonic centric diatoms and in the lorica of '*Poteroiochromonas stipitata*' – see OCHROMONAS), and in certain protozoa (e.g. in the cyst walls of ciliates and amoebae); it is apparently never formed by bacteria.

Native chitin occurs in the form of microfibrils in which extended glucan chains are hydrogen-bonded together (antiparallel in α-chitin, parallel in β-chitin) to form sheets which, in turn, associate (by hydrogen-bonding in α-chitin but not in β-chitin) to form microfibrils.

Biosynthesis of chitin involves the enzyme chitin synthase (EC 2.4.1.16) which catalyses the polymerization of *N*-acetylglucosamine from UDP-*N*-acetylglucosamine precursors. The enzyme requires Mg<sup>2+</sup> or Mn<sup>2+</sup> and phospholipids for activity, and is inhibited e.g. by POLYOXINS and NIKKOMYCINS. The location of chitin synthase in fungal cells is controversial; most reports suggest that it occurs in the cytoplasmic membrane [Book ref. 38, pp. 403–405], while evidence has been presented that it is mainly cytoplasmic in *Mucor rouxii* [JGM (1984) 130 1193–1199]. (See also CHITOSOME and GAMMA PARTICLE (sense 2).) Chitin synthase occurs in zymogen and active forms; its activity in the cell may be controlled by regulation of the proteolytic activation of the zymogen at sites of chitin synthesis. [Chitin biosynthesis in microorganisms: Book ref. 62, pp. 85–127.] (See also GROWTH (fungal).)

(See also CHITINASE.)

**chitinase** (poly-[1,4-β-(2-acetamido-2-deoxy-D-glucoside)] glycanohydrolase; EC 3.2.1.14) An enzyme which degrades CHITIN to chitobiose [JGM (1984) 130 1857–1861]; chitobiose can be hydrolysed to *N*-acetylglucosamine by *chitobiase* (*N*-acetyl-β-D-glucosaminidase, EC 3.2.1.30). Chitinases are produced by a wide range of organisms: e.g., chitin-containing fungi; microorganisms parasitic on chitin-containing organisms (e.g. entomopathogens – see also BURNED SPOT DISEASE); insectivorous animals (e.g. spiders); and plant tissues (where they may play a role in resistance to fungal diseases [Nature (1986) 324 365–367]).

**chitinolytic** (chitinoclastic) CHITIN-degrading: see CHITINASE.

**chitobiase** See CHITINASE.

**chitobiose** A disaccharide consisting of two (1 → 4)-β-linked *N*-acetyl-D-glucosamine residues.

**chitosan** (mycosin) A polymer of non-acetylated (1 → 4)-β-linked D-glucosamine residues (cf. CHITIN). It occurs in nature as a CELL WALL constituent in the hyphae of certain zygomycetes (e.g. *Mucor* spp) and as a minor component of the spores of *Fusarium solani* (in which it is a strong elicitor of PHYTOALEXIN production by pea plants [Book ref. 58, pp. 270–271]). [Coordination of chitosan and chitin synthesis: JGM (1984) 130 2095–2102.]

**chitosome** A type of vesicular particle (40–70 nm diam.) comprising a membrane-like shell containing chitin synthase; chitosomes can be isolated from a wide range of fungi and can synthesize CHITIN microfibrils from UDP-*N*-acetylglucosamine in vitro. Initially, coiled microfibrils develop within the chitosome – which then apparently breaks open to release extended microfibrils. It is uncertain whether chitosomes are organelles (serving e.g. in the transport of chitin synthase from its site of synthesis to its site of action) or small vesiculated fragments of cytoplasmic membrane formed during the isolation procedure. Chitin synthase can be released from chitosomes by treatment with digitonin.

**Chl** Chlorophyll: see CHLOROPHYLLS.

## Chlamydia

**Chlamydia** (formerly e.g. *Bedsonia*, *Miyagawanella*; cf. TRIC agents) A genus of Gram-negative bacteria (order CHLAMYDIALES) which occur as obligate intracellular parasites in man and other animals. Strains of *Chlamydia* can cause various types of disease – e.g. CURTIS-FITZ-HUGH SYNDROME, INCLUSION CONJUNCTIVITIS, KERATOCONJUNCTIVITIS, LYMPHOGRANULOMA VENEREUM and TRACHOMA in man, PSITTACOSIS in man and animals, diarrhoea in new-born calves, lambs and piglets, and abortion (see e.g. ENZOOTIC ABORTION) and eye infections in various animals. [Human chlamydial infections: Book ref. 193. Clinical conditions associated with positive COMPLEMENT-FIXATION TESTS for *Chlamydia*: *Epidem. Inf.* (1987) 98 101–108.]

The organisms undergo a development cycle, in only part of which are they infectious for fresh host cells. The cells are non-motile, coccoid and pleomorphic, 0.2–1.5 µm diam., size varying with the phase of development. The chlamydial cell envelope contains little or no muramic acid, but includes a Gram-negative-type OUTER MEMBRANE containing LPS; a heat-stable, genus-specific, KDO-containing antigen occurs in all strains throughout the development cycle and is responsible for positive FREI TEST reactions. The outer membrane contains a major protein species (Mwt ca. 40000) with which is associated species-specific and type-specific antigens. The inner surface of the outer membrane consists of a monolayer of hexagonally arranged protein units [EM studies of the cell wall: *JMB* (1982) 161 579–590]; in the elementary body (see below) the outer surface has a number of hemispherical projections [JB (1985) 164 344–349]. The organisms have been cultured in laboratory animals, in the yolk sacs of chick embryos, and in cell cultures. GC%: ca. 41–44 (T<sub>m</sub>). Type species: *C. trachomatis*.

**Development cycle.** The form infectious for host cells is the *elementary body* (EB): a non-dividing, osmotically-stable disseminative cell, ca. 0.2–0.4 µm diam., which has few ribosomes, and in which the condensed nuclear material occupies a major part of the cell; the cell wall proteins are extensively cross-linked by disulphide bonds [JB (1984) 157 13–20]. EBs are metabolically limited: glucose is not metabolized, although glucose 6-phosphate and certain other substrates may yield CO<sub>2</sub> if ATP, NADP and other cofactors are also supplied. The development cycle begins when EBs adhere to unidentified receptor sites on a host cell and undergo cytochalasin D-sensitive endocytosis. [Mechanisms of endocytosis of *C. trachomatis*: *JGM* (1984) 130 1765–1780.] Phagosomes within which EBs are internalized do not fuse with lysosomes (cf. PHAGOCYTOSIS). The EBs subsequently differentiate, becoming *reticulate bodies* (RBs): osmotically-labile, trypsin-sensitive cells, ca. 0.6–1.5 µm diam., which contain increased numbers of ribosomes and in which the nuclear material is more diffusely distributed; the disulphide inter-protein cross links in the cell wall are reduced. RBs are not infectious for fresh host cells; those of *C. trachomatis* may be capable of glycolysis and of ATP synthesis [Mol. Microbiol. (1999) 33 177–187]. Some chlamydiae synthesize e.g. folic acid and glycogen, and all strains must produce the prokaryotic-type fatty acids and lipids which cannot be supplied by the host cell. [Protein synthesis in host-free RBs: *JB* (1985) 162 938–942.] The RBs undergo binary fission ca. 8–10 hours after the initial infection of the host cell, and continue to divide for up to ca. 20 hours after infection. By about 12–15 hours after infection, the membrane-bounded population of progeny RBs (called an *inclusion* or *microcolony*) is large enough to be visible by light microscopy; the inclusions of glycogen-forming strains can be detected by staining with iodine. From ca. 20 hours after infection RBs begin to give rise to EBs, and by ca. 48–72 hours after

infection the cycle is complete – each infected host cell containing ca. 10–1000 EBs in an inclusion which may occupy a major part of the cell. On release, EBs infect fresh host cells.

**Antibiotic resistance.** Chlamydiae are typically sensitive to e.g. tetracyclines. Penicillins may inhibit the development of EBs from RBs, although the mechanism of such inhibition is unknown. Most strains of *C. trachomatis* are sensitive to sulphonamides.

***C. pecorum.*** A species from ruminants (including sheep and cattle) which can cause e.g. respiratory, intestinal and neurological disease. [Description of *C. pecorum*: *IJSB* (1992) 42 306–308.]

***C. pneumoniae.*** A species first isolated from a suspected case of trachoma in Taiwan (strain TW-183) and subsequently from a case of acute respiratory infection (strain AR-39). These organisms, initially thought to be strains of *C. psittaci*, were referred to as TWAR strains [see Book ref. 193, pp 321–340] but later classified in a new species, *C. pneumoniae* [description of *C. pneumoniae*: *IJSB* (1989) 39 88–90]. [Phylogenetic relationship of *C. pneumoniae* to *C. psittaci* and *C. trachomatis*: *IJSB* (1993) 43 610–612.] *C. pneumoniae* is associated with e.g. epidemics of subacute respiratory disease; re-infection, or chronic infection, can lead to severe disease, apparently involving immunologically-based pathogenesis.

***C. psittaci.*** Hosts: commonly birds and mammals other than man (but see PSITTACOSIS); *C. psittaci* appears to have played a significant role in an epizootic of urogenital and respiratory-tract disease and keratoconjunctivitis in the koala (*Phascolarctos cinereus*) [*AJEBMS* (1985) 63 283–286]. Folic acid and glycogen are not formed.

***C. trachomatis.*** Natural hosts: man and mouse; no strains have been isolated from birds. Folic acid and glycogen are formed. Three biovars: trachoma (typically non-invasive, confined almost exclusively to squamocolumnar epithelial cells), lymphogranuloma venereum (LGV) (typically invasive, infects e.g. lymph nodes), and mouse (isolated only from mice; has an affinity for the lungs). Biovars trachoma and LGV can be distinguished (by means of microimmunofluorescence tests) by virtue of their type-specific antigens: A–K and L<sub>1</sub>–L<sub>3</sub>, respectively. [Complete genome sequence: *Science* (1998) 282 754–759.]

**Chlamydiaceae** See CHLAMYDIALES.

**Chlamydiales** An order of Gram-negative bacteria which are obligate intracellular parasites in eukaryotic cells; the organisms multiply within cytoplasmic vacuoles and exhibit a developmental cycle which includes small, rigid-walled infectious forms (elementary bodies), and larger, non-infectious forms (reticulate bodies, sometimes called initial bodies) which have flexible walls and which divide by fission. One family, Chlamydiaceae, which comprises a single genus, CHLAMYDIA.

**Chlamydomon** See HYPOSTOMATIA.

**Chlamydomonas** A large genus (>500 species) of unicellular, usually flagellated green algae (division CHLOROPHYTA – cf. PHYTOASTAGIOPHOREA) which are widespread and common in a range of freshwater habitats and e.g. on damp soils. (See also RED SNOW.) The vegetative cells are usually pyriform or ovoid, ca. 5–20 µm in length, uninucleate, haploid, and usually motile by means of two similar flagella which project from the anterior end (cf. PALMELLOID PHASE). (See also FLAGELLUM (b) and FLAGELLAR MOTILITY (b).) The cell wall is thin and contains no cellulose, being composed of a complex of hydroxyproline-rich glycoproteins [wall structure: *JCB* (1985) 101 1550–1568, 1599–1607]. The cell contains a single large CHLOROPLAST which may be cup-shaped, stellate, H-shaped, lobed, etc., according to species.

The chloroplast contains an EYESPOT and generally one or more PYRENOIDS. Two (or more) CONTRACTILE VACUOLES are typically present at the anterior end of the cell, and a number of elongated, branched mitochondria occur near the flagellar bases.

**Asexual reproduction** occurs by endodyogeny or endopolygeny: typically, a cell comes to rest, losing or withdrawing its flagella, and the protoplast undergoes one or more longitudinal cleavages within the parental wall. The 2, 4, 8 or 16 daughter protoplasts develop cell walls and flagella, and are then released by enzymic dissolution of the parent cell wall; the enzymes responsible for wall dissolution ('sporangium wall autolysins') are apparently species-specific [Book ref. 123, pp. 409–418]. [Cell cycle: New Phyt. (1985) 99 1–40, 41–56.]

**Sexual reproduction** is isogamous in most species, anisogamous in some. Some species are heterothallic. Vegetative cells may develop into gametes e.g. in response to nitrogen starvation (in *C. reinhardtii*) or to general nutrient stress (in *C. eugametos* [JGM (1985) 131 1553–1560]); gametes differ from vegetative cells in that, when cells of opposite mating types are mixed, they rapidly clump together by agglutination of their flagella. Agglutination results from the presence on the flagella of a glycoprotein (the 'agglutination factor') which is formed by the cell during gametogenesis. Cells within the clumps become sorted into pairs, their flagella separate, and the cells in each pair become joined at their anterior ends (apical papillae) to form a quadriflagellate, motile zygote; this is followed – often after a period of motility – by plasmogamy and karyogamy. The zygote then develops a thick, ornamented wall, and becomes dormant. On germination, meiosis occurs, and four or eight (occasionally 16 or 32) motile cells are released by dissolution of the zygote wall. The mating process may differ in some respects from one species to another. For example, in *C. reinhardtii* a 'fertilization tubule' extends from the apical papilla of one ( $mt^+$ ) gamete, and plasmogamy is initiated when the tip of the tubule contacts a dome-shaped region near the flagellar base of the other ( $mt^-$ ) gamete; by contrast, in *C. eugametos* there are no morphological differences between  $mt^+$  and  $mt^-$  gametes, or between gametes and vegetative cells. In *C. reinhardtii* the gametes shed their cell walls following flagellar contact, while in *C. eugametos* the walls are shed after zygote formation. [Form and location of cell wall lytic enzyme in vegetative cells and gametes of *C. reinhardtii*: JCB (1987) 104 321–329; review of cell–cell interactions in *Chlamydomonas*: ARPphys. (1985) 36 287–315.]

*Chlamydomonas* spp are easily maintained in culture and have been used extensively in research e.g. on ultrastructure, physiology, etc. Mutants of *C. reinhardtii* which are defective in chlorophyll synthesis have been obtained, and these can often grow in the dark on media supplemented with acetate, forming yellow colonies. Such mutants are commonly killed by light, although a mutant has been isolated which, in the presence of acetate, can form yellow colonies both in the light and in the dark [JGM (1983) 129 159–165].

See also e.g. BRACHIOMONAS; CARTERIA; DUNALIELLA; TETRA-SPORA; VOLVOX.

**chlamydospore** A loosely used term usually applied to a thick-walled, asexually-produced resting spore formed by certain fungi; the term is sometimes used to refer specifically to the teliospores of smut fungi: see USTILAGINALES. (cf. THALLOSPORE.)

**chloramine T** See CHLORINE.

**Chloramoeba** See XANTHOPHYCEAE.

**chloramphenicol** (chloromycetin;  $NO_2.C_6H_4.CHOH.CH(CH_2OH).NH.CO.CHCl_2$ ) An ANTIBIOTIC (the D-threo form of four possible stereoisomers) produced by *Streptomyces venezuelae*

and also made synthetically. Chloramphenicol is a broad-spectrum bacteriostatic agent active against a wide range of bacteria; it also inhibits vegetative growth and sporulation in certain fungi [JGM (1983) 129 3401–3410].

Chloramphenicol binds to the 50S subunit of prokaryotic and mitochondrial RIBOSOMES (but apparently not to the ribosomes in at least some archaeans [SAAM (1985) 6 125–131]); it inhibits peptidyltransferase and, hence, PROTEIN SYNTHESIS.

Resistance to chloramphenicol in bacteria is commonly due to a plasmid-specified enzyme – *chloramphenicol acetyltransferase* (CAT; also called chloramphenicol transacetylase) – which catalyses an acetyl-CoA-dependent acetylation of chloramphenicol at the C-3 hydroxy group to form a compound with little or no antibiotic activity. Plasmid-specified CAT is usually or always synthesized constitutively in Gram-negative bacteria but inducibly (see also TRANSLATIONAL ATTENUATION) in e.g. staphylococci and streptococci. (See also Tn9.)

CAT-producing bacteria can be detected by rosanilin dyes [JB (1982) 150 1375–1382].

Non-enzymic resistance to chloramphenicol may be due e.g. to (mutant) ribosomes which fail to bind the antibiotic. *Pseudomonas aeruginosa* is innately resistant, being able normally to tolerate high levels of the drug.

Chloramphenicol antagonizes those antibiotics (e.g. penicillins) which inhibit only actively growing and dividing bacteria. Its clinical usage is limited by its toxicity.

**chloranil** (tetrachloro-*p*-benzoquinone) A QUINONE ANTIFUNGAL AGENT used e.g. as a seed dressing for the prevention of damping off, seed rots etc; it decomposes in the presence of light.

**chlorazol black E** A black amphoteric triazo DYE used e.g. for the VITAL STAINING of *Mycoplasma* spp and L-forms [JB (1969) 99 1–7].

**chlorbutanol** (chlorbutol) Trichloro-*t*-butanol; it is used e.g. as a PRESERVATIVE (at ca. 0.5% w/v) in ophthalmic solutions. At room temperatures chlorbutanol is unstable at alkaline pH, and it can be inactivated by colloids such as bentonite and magnesium trisilicate.

**chlorbutol** *Syn.* CHLORBUTANOL.

**Chlorella** A genus of non-motile, unicellular green algae (division CHLOROPHYTA) which occur in fresh water, on soils, bark etc, and in association with various other organisms (see ZOOCHLORELLAE). (cf. VAMPIROVIBRIO.) The cells are spherical (ca. 2–15  $\mu m$  diam.); each contains a single haploid nucleus and a large, usually cup-shaped chloroplast with or without a pyrenoid. The CELL WALL contains cellulose and e.g. SPOROPOLLENIN. Asexual reproduction occurs by AUTOSPORE formation: the protoplast divides to form 2, 4, 8 or 16 daughter protoplasts which develop cell walls before being released by rupture of the parent wall. Motile cells are never formed. (cf. CHLOROCOCCUM.)

The paucity of morphological features in *Chlorella* spp has led to an increased use of chemotaxonomy in this genus [Book ref. 123, pp. 391–407]. Although primarily photosynthetic, some *Chlorella* spp can ferment glucose to lactate under anaerobic conditions. Most species can reduce  $NO_3^-$ , and a few can produce extracellular gelatin- and/or starch-hydrolysing enzymes.

(cf. PROTOTHECA; see also SINGLE-CELL PROTEIN and YAKULT.)

**chlorguanide** (Paludrine; proguanil)  $N^1$ -*p*-chlorophenyl- $N^5$ -isopropylidguanide: an antimalarial drug (see MALARIA) which, itself, has little activity but which is converted in vivo to a highly active cyclic form ('cycloguanil' – a substituted dihydrotriazine). Cycloguanil binds competitively to the enzyme dihydrofolate reductase (DHFR), inhibiting the synthesis of tetrahydrofolate.

## chlorhexidine

The drug has been used mainly for prophylaxis. However, it exhibits different levels of efficacy in different human populations, so that its usefulness for some groups has been questioned [BJCP (1994) 37 67–70].

Resistance to cycloguanil develops readily. For example, a mutant form of DHFR (presumably with lower affinity for cycloguanil) arises by a serine-to-threonine change at residue 108 and an alanine-to-valine change at residue 16 of the DHFR molecule [PNAS (1990) 87 3014–3017].

**chlorhexidine** (1,6-di-(4'-chlorophenyldiguanido)-hexane) An ANTISEPTIC which is bacteriostatic or bactericidal (depending on concentration) for a wide range of Gram-positive and Gram-negative bacteria; it is not active against bacterial endospores, some fungal spores, or viruses. Chlorhexidine has been reported to inhibit bacterial ATPase activity and damage the bacterial cell membrane; higher concentrations coagulate the cytoplasm. Antimicrobial activity decreases with increasing acidity, becoming very low at ca. pH 5; activity is also decreased in the presence of soaps and anions such as carbonate and chloride. An alcoholic solution of chlorhexidine is used as a skin disinfectant; water-soluble derivatives include the acetate and gluconate (e.g. *Savlon*, used as a skin antiseptic and in throat lozenges, is a mixture of chlorhexidine gluconate (Hibitane) and Cetrimide). [Review: Book ref. 65, pp. 251–270.]

**chlorin** A 7,8-dihydroporphyrin (see PORPHYRINS), derivatives of which occur in e.g. CHLOROPHYLLS, certain CYTOCHROMES, and sirohaem (see DESULFOVIRIDIN).

**chlorinated soda solution** *Syn.* DAKIN'S SOLUTION.

**chlorinator** See WATER SUPPLIES.

**chlorine** (as an antimicrobial agent) Chlorine is an effective microbicidal agent used e.g. for the disinfection of WATER SUPPLIES, swimming pools etc. Chlorine is a strong OXIDIZING AGENT; it can also react directly with certain groups in cells and viruses, and it reacts with water to form the strongly antimicrobial compound hypochlorous acid (see HYPOCHLORITES). (N.B. The word 'chlorine' is often used to refer to an aqueous solution containing Cl<sub>2</sub>, hypochlorous acid and other active chlorine compounds – rather than to elemental chlorine; 'available chlorine' is the oxidizing capacity of a chlorine compound expressed in terms of the equivalent amount of elemental chlorine.) The antimicrobial action of chlorine is decreased by the presence of organic matter and other substances with which it can react.

*Chloramines* exert antimicrobial activity by decomposing slowly to release chlorine; their activity is thus much less rapid than that of hypochlorites. *Monochloramine* (NH<sub>2</sub>Cl) has been used e.g. in the treatment of water supplies. The organic chloramines are less toxic and less irritating to animal tissues and have been used e.g. as antiseptics and/or disinfectants; they include *chloramine T* (sodium *p*-toluenesulphonchloramide) – a white, crystalline, water-soluble solid; *dichloramine T* (*p*-toluenesulphondichloramide) – water-insoluble and less rapidly effective than chloramine T; *halazone* (*p*-carboxy-*N,N*-dichlorobenzene-sulphonamide) – used for the disinfection of small quantities of drinking water.

(See also CHLORINE DIOXIDE and IODINE.)

**chlorine demand** See WATER SUPPLIES.

**chlorine dioxide** (ClO<sub>2</sub>) A microbicidal agent active against e.g. bacteria (including endospores), fungi and viruses; it has been used e.g. for the disinfection of swimming-pool water, and as a disinfectant in water-immersion chilling systems for poultry carcasses.

**Chloriridovirus** (large iridescent insect virus group) A genus of viruses (family IRIDOVIRIDAE) which infect insects; infected

larvae – and purified virus pellets – exhibit a yellow-green iridescence. Virions (ca. 180 nm diam.) are ether-resistant. Type species: mosquito iridescent virus; other members include insect iridescent viruses 3–5, 7, 8 and 11–15 [Book ref. 23, p. 57].

**Chloris striate mosaic virus** See GEMINIVIRUSES.

**chlorite dismutase** See BIOREMEDIATION.

**β-chloroalanine** A synthetic ANTIBIOTIC which acts e.g. as an inhibitor of alanine racemase.

**chlorobactene** See LIGHT-HARVESTING COMPLEX.

**Chlorobiaceae** A family of non-motile photosynthetic bacteria (suborder CHLOROBINEAE); species occur e.g. in anaerobic, sulphide-rich freshwater and estuarine muds. The family includes cocci and rods (some species – e.g. *Prosthecochloris aestuarii* – are prosthecate); GAS VACUOLES occur in *Clathrochloris* and PELODICTYON. In green-coloured species the predominant pigments are Bchl *c* or *d* and the carotenoid chlorobactene; in brown-coloured species Bchl *e* and isorenieratene predominate. The organisms are obligate anaerobic phototrophs; they are primarily photolithotrophic autotrophs (electron donors: e.g. sulphur, sulphide – thiosulphate in some strains) which fix CO<sub>2</sub> by the REDUCTIVE TRICARBOXYLIC ACID CYCLE, but many strains require vitamin B<sub>12</sub>, and all can use simple organic molecules (e.g. acetate) given a suitable electron donor; elemental sulphur, when produced, is deposited extracellularly.

Genera: *Ancalochloris*, CHLOROBIMUM (type genus), *Clathrochloris*, PELODICTYON, *Prosthecochloris*. (cf. CHLOROHERPETON; CHLOROPSEUDOMONAS ETHYLICA; CHLOROCHROMATIUM AGGREGATUM.)

[Evidence for bacteria of the Chlorobiaceae in Palaeozoic seas: Nature (1986) 319 763–765.]

**Chlorobiineae** A suborder of photosynthetic bacteria (order RHODOSPIRILLALES); the organisms contain bacterioCHLOROPHYLL *c*, *d* or *e* in CHLOROSOMES, and their REACTION CENTRES contain Bchl *a*. Families: CHLORABIACEAE and CHLOROFLEXACEAE. The suborder appears to be taxonomically unsound; thus, on the basis of rRNA OLIGONUCLEOTIDE CATALOGUING, the species *Chlorobium limicola*, *C. vibrioforme*, *Prosthecochloris aestuarii* and *Chloroherpeton thalassium* constitute a moderately tight phylogenetic group which has no specific relationship with another, somewhat looser group comprising e.g. *Chloroflexus aurantiacus*, *Herpetosiphon aurantiacus* and *Thermomicrobium roseum* [SAAM (1985) 6 152–156].

**Chlorobium** A genus of photosynthetic bacteria (family CHLORABIACEAE). The cells are rods or vibrios, according to species, ca. 1–2.5 μm long; division occurs by binary fission. The genus includes both green species (*C. limicola*, *C. vibrioforme*) and brown species (*C. phaeobacteroides*, *C. phaeovibrioides*).

**chlorobium chlorophylls** See CHLOROPHYLLS.

**chlorobium vesicles** *Syn.* CHLOROSOMES.

**Chlorochromatium aggregatum** A consortium consisting of an aggregate of cells: a central, colourless, chemoorganotrophic, motile bacterium covered by green bacteria of the family Chlorobiaceae [microanatomy and ecology: JGM (1984) 130 2717–2723]. Similar consortia, which involve species of the Chlorobiaceae, are called *Chlorochromatium glebulum*, *Cylindrogloea bacterifera*, and *Pelochromatium roseo-viride*.

**Chlorochromatium glebulum** See CHLOROCHROMATIUM AGGREGATUM.

**Chlorociboria** See HELOTIALES.

**Chlorococcum** A genus of unicellular green algae (division CHLOROPHYTA) which differ from CHLORELLA spp e.g. in producing biflagellate zoospores as well as autospores. Species occur e.g. on damp soil, brick-work, etc.

**chlorocresol** See PHENOLS.

**Chlorocystis** A genus of unicellular coccoid green algae (division CHLOROPHYTA).

**Chloroflexaceae** A family of filamentous, photosynthetic GLIDING BACTERIA (suborder CHLOROBIINEAE) which includes the genera CHLOROFLEXUS, CHLORONEMA and *Oscillochloris* [ARM (1981) 35 339–364].

**Chloroflexis** See CHLOROFLEXUS.

**Chloroflexus** (formerly *Chloroflexis*) A genus of bacteria (family CHLOROFLEXACEAE). *C. aurantiacus* occurs in hot, neutral to alkaline (pH ca. 8) springs (often in mats in association with cyanobacteria) and grows optimally at ca. 50–55°C. Under anaerobic conditions in the light, *C. aurantiacus* can grow as a photoorganotrophic heterotroph or as a photolithotrophic autotroph (electron donor: e.g. sulphide); sulphur produced by sulphide oxidation is deposited extracellularly. The organisms contain bacterioCHLOROPHYLLS *a* and *c*. (See also CHLOROSOMES.) Aerobically, *C. aurantiacus* does not produce chlorophylls and grows chemoorganotrophically. The filaments of *C. aurantiacus* (ca. 0.45–1.0 µm in width) are bright orange under most conditions but are green when growing photolithotrophically with high sulphide levels or low light intensity. [Photochemistry in *C. aurantiacus*: PNAS (1982) 79 6532–6536.]

**chlorogenic acid** 1,3,4,5-Tetrahydroxycyclohexane-1-carboxylic acid (quinic acid) esterified at the 3-hydroxy position with CAFFEIC ACID. Chlorogenic acid is an antifungal metabolite found in certain higher plants; it may be involved e.g. in the resistance of certain strains of apple to scab (*Venturia inaequalis*). Since chlorogenic acid tends to accumulate around damaged tissues at sites of infection it is sometimes regarded as a PHYTOALEXIN. (See also AUXINS.)

**Chlorogloeopsis** (*Chlorogloea*) A genus of filamentous CYANOBACTERIA (section V) in which the cells divide in more than one plane, producing a multicellular trichome which readily breaks up into irregular *Gloeocapsa*-like aggregates, each surrounded by a sheath (containing heteropolysaccharides and ca. 20% protein [JGM (1982) 128 267–272]). Hormogonia are formed by rapid division of some cells in one plane, and are composed initially of small cylindrical cells which enlarge and become spherical. Heterocysts develop in terminal and intercalary positions, and akinetes are produced. GC%: 42–43. One species: *C. fritschii*.

The genus currently includes the thermophilic organism known as 'high-temperature-form (HTF) *Mastigocladus*'. This organism has an upper temperature limit for growth of 63–64°C and is apparently capable of nitrogen fixation; it occurs in hot springs, and is very sensitive to sulphide.

**Chlorogonium** A genus of unicellular, biflagellated green algae which are closely related to CHLAMYDOMONAS spp. (See also FLAGELLUM (b).)

**Chloroherpeton** A genus of green, photosynthetic, non-filamentous gliding bacteria; one species: *C. thalassium* [Arch. Micro. (1984) 138 96–101], which is apparently closely related to *Chlorobium limicola* and *C. vibrioforme* [SAAM (1985) 6 152–156].

**Chloromonadida** See CHLOROMONADS.

**Chloromonadophyceae** See CHLOROMONADS.

**chloromonads** A group of phytoflagellates (including genera such as *Chattonella*, *Gonyostomum*, *Vacuolaria*) which are variously classified as algae of the class Raphidophyceae (= Rhaphidophyceae or Chloromonadophyceae), as algae within the class XANTHOPHYCEAE, or as protozoa of the order Chloromonadida (see PHYTOMASTIGOPHOREA). The vegetative cell typically has

two flagella: a tinsel flagellum directed anteriorly, and a whiplash flagellum directed posteriorly; a PALMELLOID PHASE commonly occurs e.g. in *Vacuolaria*. The numerous yellow-green chloroplasts contain e.g. chlorophylls *a* and *c*, β-carotene, and antheraxanthin. Chloromonads occur mainly in freshwater habitats.

**chloromyxetin** Syn. CHLORAMPHENICOL.

**Chloromyxum** See MYXOSPOREA.

**chloroneb** (1,4-dichloro-2,5-dimethoxybenzene) An agricultural systemic ANTIFUNGAL AGENT which is taken up by plant roots and is concentrated in the roots and lower stem; it is highly fungistatic for *Rhizoctonia* spp, moderately fungistatic for *Pythium* spp, but shows little activity against *Fusarium* spp. It is used as a seed and soil treatment for the control of damping off etc.

**Chloronema** A genus of filamentous, mesophilic bacteria (family CHLOROFLEXACEAE [ARM (1981) 35 339–364]) which occur e.g. in lakes. In *Chloronema* bacterioCHLOROPHYLL *d* occurs in chlorosomes.

**chloronitrobenzenes** (as antifungal agents) These compounds include several useful agricultural ANTIFUNGAL AGENTS: see e.g. DICLORAN, QUINTOZENE and TECNAZENE. (See also DINITROPHENOLS.)

**chloropeptide** (cyclochlorotine) A hepatotoxic MYCOTOXIN produced by *Penicillium islandicum* (see YELLOW RICE). It appears to bind to actin within cells, modifying the cytoskeleton.

**chlorophenol red** Syn. CHLORPHENOL RED.

**Chlorophyceae** See CHLOROPHYTA.

**chlorophycean starch** See STARCH.

**chlorophylls** A class of pigments involved in PHOTOSYNTHESIS; they may be regarded as derivatives of protoporphyrin IX (see PORPHYRINS) complexed with magnesium (see figure on page 158). (cf. PHAEOPHYTIN.)

*Chlorophylls in algae and cyanobacteria.* Chlorophyll *a* (Chl *a*) – see figure – occurs in all organisms which carry out oxygenic PHOTOSYNTHESIS. Chl *b* (see figure) occurs in euglenoid flagellates and green algae (Chlorophyta), as well as in most higher plants. Chls *c*<sub>1</sub> and *c*<sub>2</sub> occur together in brown algae (Phaeophyta), chrysophytes, diatoms, and prymnesiophytes, while Chl *c*<sub>2</sub> without Chl *c*<sub>1</sub> occurs in cryptophytes and dinoflagellates. Chl *d* occurs in some red algae (Rhodophyta).

*Bacteriochlorophylls* occur in anoxygenic photosynthetic bacteria (Rhodospirillales). Bchl *a* is the sole bacteriochlorophyll in most purple bacteria (Rhodospirillineae); those purple bacteria which lack Bchl *a* (*Ectothiorhodospira abdelmalekii*, *E. halochoris*, *Rhodopseudomonas sulfoviridis*, *R. viridis*, *Thiocapsa pfennigii*) have instead Bchl *b*. Probably all green bacteria (Chlorobiineae) contain Bchl *a* – usually together with Bchls *c* (= 'chlorobium chlorophyll 660 series') or Bchls *d* ('chlorobium chlorophyll 650 series'). Bchl *e* is the major bacteriochlorophyll in *Chlorobium phaeobacteroides* and *C. phaeovibrioides*, occurring together with small amounts of Bchl *a*. Bchl *g* has been identified in *Helio bacterium chlorum* (q.v.). (See also ERYTHROBACTER.)

Chlorophylls generally occur in photosynthetic cells within specialized membranes or organelles: see CHLOROPLAST, CHLOROSOME, CHROMATOPHORE (sense 2), THYLAKOID. Purified chlorophylls are unstable in the presence of light and oxygen.

**Chlorophyta** (green algae) A division of the ALGAE, members of which are characterized by a combination of features: e.g., they contain chlorophylls *a* and *b*, β-carotene, and xanthophylls such as antheraxanthin, lutein, neoxanthin, violaxanthin and zeaxanthin; the chloroplasts are enveloped by a double membrane but lack an additional envelope of endoplasmic reticulum; pyrenoids,

## Chlorophyta

CHLOROPHYLLS: Chlorophyll a (phytyl =  $C_{20}H_{39}$ ). Other chlorophylls differ from chlorophyll a as shown below.

when present, occur within the chloroplast; the main storage polymer is starch which is formed within the chloroplast; motile cells, when formed, bear flagella (commonly 2 or 4) which have a characteristic structure (see FLAGELLUM (b)).

The 'green algae' (which are not necessarily green in colour) are a diverse group of organisms which, in vegetative form, may be unicellular and non-motile (e.g. ANKISTRODESMUS, CHLORELLA, CHLOROCOCCUM, COCCOMYXA, TREBOUXIA; cf. ACETABULARIA and DESMIDS), unicellular and flagellated (e.g. CHLAMYDOMONAS, MICROMONADOPHYCEAE, TETRASELMIS), sarcinoid (e.g. PSEUDOTREBOUXIA), coenobial (e.g. SCENEDESMUS, VOLVOX), filamentous (e.g. APHANOCHAETE, OEDOGONIUM, SPIROGYRA, STIGEOCLONIUM, TRENTEPOHLIA, ULOTHRIX; see also SIPHONOCLOUS), siphonaceous (e.g. CODIUM, DERBESIA, HALIMEDA, OSTREOBIMUM), or thallose/parenchymatous (e.g. ENTEROMORPHA, ULVA) – reaching a relatively high degree of structural complexity and differentiation (CHAROPHYTES). *Asexual reproduction* commonly occurs by the formation of flagellated zoospores, but some species may produce e.g. aplanospores (e.g. *Aphanochaete*, *Stigeoclonium*), AUTOSPORES, or bulbils (charophytes), or may reproduce by fragmentation of the vegetative thallus (e.g. *Spirogyra*, *Stichococcus*). *Sexual reproduction* may be isogamous (e.g.

	4	=CH.CH <sub>3</sub>
	7	phytyl replaced by geranylgeraniol

in *Acetabularia*, *Chaetophora*, most *Chlamydomonas* spp, *Klebsormidium*, *Ulothrix*), anisogamous (e.g. in *Codium* and *Derbesia*), or oogamous (e.g. in *Aphanochaete*, charophytes, *Coleochaete*, *Oedogonium*); sexual reproduction is unknown in e.g. *Chlorella*. An isomorphic ALTERNATION OF GENERATIONS occurs e.g. in CLADOPHORA and ULVA, a heteromorphic alternation of generations occurs e.g. in DERBESIA and MONOSTROMA.

The majority of green algae occur in freshwater habitats, but some are found in the sea (e.g. *Acetabularia*, *Codium*, *Enteromorpha*, *Halimeda*, *Ulva*), some occur in hypersaline waters (e.g. DUNALIELLA), and some are terrestrial – growing on soil (e.g. *Chlorella* spp, *Chlorococcum*, *Friedmannia*), rocks (e.g. some desmids), snow (see e.g. RED SNOW), tree-bark (e.g. *Chlorella* spp, '*Pleurococcus*', *Trentepohlia*), plant leaves (e.g. CEPHALEUROS), etc. Certain green algae form close stable associations with other organisms: see e.g. LICHEN and ZOOCHLORELLAE.

The classification of the green algae has been, and remains, controversial. Some schemes [e.g. Book ref. 130, pp. 86–132] divide the Chlorophyta into two classes: Chlorophyceae (divided into ca. 16 orders containing the vast majority of green algae) and Charophyceae (containing the charophytes). In another scheme [Book ref. 123, pp. 29–72] – based on comparative cytological data such as the structure of flagellated cells, the nature of cell division, etc. – the division Chlorophyta is divided into 5 classes: MICROMONADOPHYCEAE, Charophyceae (containing, in addition to the charophytes, genera such as *Coleochaete*, *Klebsormidium*, *Spirogyra* and the desmids), Ulvophyceae (containing genera such as *Monostroma*, *Ulothrix*, *Ulva*, and the siphonocladous, siphonaceous and dasycladalean algae [Book ref. 123, pp. 121–156]), Pleurostrophyceae (see TETRASELMIS and TREBOUXIA), and Chlorophyceae (containing genera such as *Chaetophora*, *Chlamydomonas*, *Oedogonium*, *Volvox*, etc).

**chloropicrin** Trichloronitromethane, Cl<sub>3</sub>C(NO<sub>2</sub>); a soil fumigant with fungicidal, herbicidal and insecticidal properties.

**chloroplast** A semi-autonomous PLASTID, one or more of which occur in the cells of *eukaryotic* photosynthetic organisms; it is the site of PHOTOSYNTHESIS and of the biosynthesis of e.g. CHLOROPHYLLS and certain proteins and lipids. According to species, *algal* chloroplasts may be cup-shaped, discoid, lobate, spiral, stellate or irregularly shaped, and are commonly 2–20 μm in size.

*Chloroplast structure.* The chloroplast consists essentially of a membrane-bounded matrix (*stroma*) containing a number of flattened, membranous sacs (THYLAKOIDS) which may occur in one or more stacks (*grana* – singular: *granum*); the grana are interconnected by membranous bridges (*intergranal frets*). The stroma contains e.g. DNA (see also CYTOPLASMIC GENES), RIBOSOMES, PLASTOGLOBULI, and a range of proteins – e.g. 'fraction I protein' (= RIBULOSE 1,5-BISPHOSPHATE CARBOXYLASE-OXYGENASE) and other CALVIN CYCLE enzymes. (See also EYESPOT and PYRENOID.) The thylakoids contain the photosynthetic apparatus (e.g. chlorophylls, electron transport components), PROTON ATPASES, and (membrane-bound) ribosomes. The membrane which encloses the stroma is a *double* membrane (the *chloroplast envelope*). In some algae, one or more layers of endoplasmic reticulum (*chloroplast endoplasmic reticulum*) occur external to the envelope: one layer surrounds the chloroplast in DINOFLAGELLATES and EUGLENOID FLAGELLATES, while two layers occur in members of the PHAEOPHYTA and XANTHOPHYCEAE; none occur in members of the CHLOROPHYTA.

Chloroplast DNA (ctDNA) occurs as covalently-closed circular molecules which lack histones; typically, each chloroplast

contains multiple DNA molecules. In at least some higher plants and algae, ctDNA encodes e.g. the large subunit of RuBisCO, various subunits of proton ATPase, several cytochromes, and various rRNAs and ribosomal proteins.

*Chloroplast development.* The following is a provisional summary. Most chloroplast polypeptides are encoded by nuclear genes and synthesized on cytoplasmic ribosomes. Such polypeptides are transported into the chloroplast by a post-translational (rather than co-translational) mechanism. Chloroplast genes, which may encode up to ca. 100 polypeptides, are essential for chloroplast development. Chloroplast-encoded polypeptides and RNAs function within the chloroplast. Light is essential for chlorophyll synthesis in angiosperms but not in most algae, mosses, ferns or gymnosperms. [Book ref. 156, pp. 1–9.]

PROTEIN SYNTHESIS in chloroplasts resembles that in bacteria: 70S-type ribosomes are used, *N*-formylmethionine is the first amino acid incorporated, and the process is inhibited e.g. by chloramphenicol.

Synthesis of galactolipids, the major polar lipids in the chloroplast, appears to occur in the chloroplast envelope [Book ref. 156, pp. 193–224].

*Origin of chloroplasts.* Chloroplasts appear to arise either by the division of existing chloroplasts or by the development of relatively undifferentiated plastids (*proplastids*) which lack e.g. thylakoids and specialized pigments. (See also ETIOPLAST.) The mechanism of coordination of the expression of nuclear and chloroplast genes is not fully understood.

[Chloroplasts of giant-celled and coenocytic algae: Bot. Rev. (1984) 50 267–307.]

**chloroplast endoplasmic reticulum** See CHLOROPLAST.

**Chloropseudomonas ethylica** A species designation [Book ref. 21] which now appears to refer to a syntrophic mixture of green sulphide-oxidizing bacteria (*Chlorobium limicola* and/or *Prosthecochloris aestuarii*) and the sulphur-reducing species *Desulfuromonas acetoxidans*.

**chloroquine** See AMINOQUINOLINES and MALARIA.

**Chloros** See HYPOCHLORITES.

**chlorosis** (*plant pathol.*) The loss of chlorophyll from the tissues of a plant – due e.g. to microbial infection, to the action of certain phytotoxins, to lack of light, to magnesium or iron deficiency, etc. Chlorotic tissues commonly appear yellowish (cf. YELLOWS).

**chlorosomes** (chlorobium vesicles) Elongated, intracellular, membranous vesicles formed in all members of the CHLOROBINEAE grown under appropriate conditions; the vesicles, which contain most of the light-harvesting ('antenna') pigments involved in PHOTOSYNTHESIS, are attached to, but differ in structure from, the cytoplasmic membrane. In members of the Chlorobiaceae the chlorosomes contain bacteriochlorophyll *c*, *d* or *e* and various CAROTENOIDS (e.g. chlorobactene in green cells, isorenieratene in brown cells), while in the Chloroflexaceae they contain bacteriochlorophyll *c* and  $\gamma$ - and  $\beta$ -carotene; a small amount of 'antenna' Bchl *a* is present in the chlorosomes of *Chloroflexus aurantiacus* and appears to occur also in the chlorosomes of members of the Chlorobiaceae. In the Chlorobiineae the cytoplasmic membrane contains the reaction centre Bchl *a* together with a small amount of antenna Bchl *a*. [Biochemistry of light-harvesting systems: ARB (1983) 52 125–157.]

**Chlorosplenium** See HELOTIALES.

**chloroxylenol** See PHENOLS.

**chlorphenol red** A PH INDICATOR: pH 4.8–6.4 (yellow to red); pK<sub>a</sub> 6.0.

**chlortetracycline** See TETRACYCLINES.

## Choanephora

**Choanephora** See MUCORALES.

**Choanephoraceae** See MUCORALES.

**choanoflagellate** A member of the CHOANOFLAGELLIDA.

**Choanoflagellida** An order of free-living, motile or sessile, flagellated protozoa (class ZOOMASTIGOPHOREA) characterized by a ring ('collar') of tentacles (microvilli) surrounding the proximal part of the single, anteriorly directed flagellum; the cell may have an outer membranous sheath (periplast) or a lorica composed of a basket-like arrangement of siliceous costae. Genera: e.g. *Acanthoeca*, *Codonosiga*, *Diplothecca*, *Monosiga*, *Pleurasiga*, *Savillea*, *Stephanoecca*. [Ultrastructure and deposition of silica in loricate species: Book ref. 137, pp. 295–322.]

**choanomastigote** A form assumed by *Crithidia* spp: see TRY-PANOSOMATIDAE.

**chocolate agar** A medium used for the isolation and culture of certain fastidious bacteria (e.g. *Haemophilus* spp, *Neisseria gonorrhoeae*). A medium such as blood agar base or brain-heart infusion agar is autoclaved and cooled to ca. 80°C; defibrinated horse or bovine blood (10%) is added and the medium shaken gently until chocolate-brown in colour. It may be dispensed into plates, slopes etc. [Recipe: Book ref. 46, p. 1375.] Alternatively, a chocolate agar plate may be prepared by heating a set blood-agar plate to ca. 80°C.

**chocolate spot** A disease of beans (particularly broad beans, *Vicia faba*) caused by *Botrytis fabae*. Chocolate-brown, rounded spots develop on all parts of the plant; in severe cases entire organs or plants may be blackened and killed. Infection is usually initiated by conidia from over-wintering plant debris, but may be seed-borne. (See also WYERONE.)

**choke** A GRASS DISEASE (affecting e.g. *Agrostis* and *Festuca* spp) caused by *Epichloë typhina* (see EPICHLÖE). Just before the host plant comes into flower, the sheath of the flag-leaf becomes encircled at its apex by a yellow to orange stroma; conidia are produced on the stromal surface, and perithecia develop within the stroma with their ostiolar pores at the surface. Flowering is partly or completely suppressed.

**cholecystitis** Inflammation of the gall-bladder. Inflammation may be due to bacterial infection (e.g. by bacteria from the bowel) secondary to stagnation of the bile caused e.g. by gallstones.

**cholera** An acute, infectious human disease involving profuse dehydrating diarrhoea; cholera is caused by certain strains of *Vibrio cholerae* (see VIBRIO) which secrete CHOLERA TOXIN. Until 1992, choleraemic strains of *V. cholerae* were associated only with serogroup O1. In 1992, non-O1 choleraemic strains were isolated in India; these strains were assigned to a new serogroup, O139, and were designated O139 Bengal [*V. cholerae* O139 Bengal: RMM (1996) 7 43–51].

Infection occurs by the faecal–oral route, usually via contaminated water. The severity (or occurrence) of disease is influenced e.g. by the number of organisms ingested; low stomach acidity is a predisposing factor. Incubation period: 1–5 (usually 2–3) days. Initially the stools contain faecal material, but they rapidly become pale-grey and watery ('rice-water stools'); 1–30 litres of fluid may be passed per day, resulting in severe dehydration and loss of electrolyte. In untreated cases mortality rates may be high (e.g. 50–75%); death may occur within hours, but usually within 1–2 days. Mild cases also occur, particularly in endemic areas.

Diarrhoeal disease may be caused by O1 strains which do not form cholera toxin; such disease may be due e.g. to the Ace and/or Zot toxins (encoded by bacteriophage CTXΦ).

*V. cholerae* adheres to the small intestine by 'toxin co-regulated pili' – filamentous appendages (encoded by a chromosomal PATHOGENICITY ISLAND) which form a bundle on the

bacterial surface (see also BACTERIOPHAGE CTXΦ). The symptoms of cholera follow secretion and uptake of CHOLERA TOXIN (q.v.).

**Lab. diagnosis.** A stool specimen is incubated in alkaline peptone water for up to 6 hours and the culture used to inoculate TCBS AGAR. Colonies of interest on TCBS agar should be used to inoculate (heavily) a non-selective agar medium; growth on this medium (after ~6 hours) may be used for a slide agglutination test with appropriate antisera. For O139, a rapid screening test has been developed with monoclonal antibodies [JCM (1998) 36 3595–3600].

**Treatment.** Oral or intravenous replacement of fluid and electrolyte (see e.g. ORAL REHYDRATION SOLUTION). Antibiotics (e.g. tetracyclines) may help to reduce the period of shedding and limit the risk of cross-infection (although multidrug-resistant strains of *V. cholerae* have been recorded).

**Vaccines.** A successful live, oral VACCINE against O1 strains was reported in 1995; however, immunity to O1 does not protect against O139. Earlier, live vaccines against O139 were being developed by deletion of certain virulence genes [JID (1994) 170 278–283].

(See also NICED; NON-CHOLERA VIBRIOS; NON-VIBRIO CHOLERA.)

**cholera toxin (cholerae)** A protein ENTEROTOXIN produced by toxigenic strains of *Vibrio cholerae* and responsible for the symptoms of CHOLERA. Cholera toxin (CT) is encoded by genes *ctxA* and *ctxB* of BACTERIOPHAGE CTXΦ (toxigenic strains of *V. cholerae* are thus lysogenic for this phage).

Structurally, CT resembles PERTUSSIS TOXIN in having the AB<sub>5</sub> arrangement of subunits: a pentameric ring of B subunits with the central A subunit to one side of the plane of the ring. (A variant of *V. cholerae* produces B subunits ('choleraeoid') but no A subunits [PNAS (1979) 76 2052–2056].)

The B subunits bind to glycolipid receptors (GM<sub>1</sub> gangliosides) in the brush border membranes of cells lining the small intestine. Internalization of the toxin occurs via a non-clathrin-coated vesicle.

Within the target cell the A subunit is proteolytically cleaved, but the two fragments remain attached, temporarily, by a disulphide bond. When the bond is reduced, the active (catalytic) fragment of the A subunit (responsible for CT activity) acts as an ADP-ribosyl transferase: it ADP-ribosylates a particular G protein, G<sub>s</sub>, which normally stimulates the activity of ADENYLATE CYCLASE (AC). As a result, AC is converted to a permanently active form – thus raising the level of cAMP within the target cell (cf. PERTUSSIS TOXIN). CT activity thus leads to an efflux of water and electrolyte (sodium and chloride ions) into the gut lumen, and the profuse watery diarrhoea characteristic of cholera.

**cholerae** *Syn.* CHOLERA TOXIN.

**choleraeoid** See CHOLERA TOXIN.

**cholesterol oxidase** An enzyme (EC 1.1.3.6) which oxidizes the 3β-hydroxy group of cholesterol. The enzyme is obtained e.g. from various actinomycetes (e.g. *Nocardia* and *Streptomyces* spp) and from *Schizophyllum commune*; it is used in the detection of cholesterol in body fluids. (See also ENZYMES.)

**cholic acid** See BILE ACIDS.

**choline** See e.g. LECTITHIN.

**chondrioids** *Syn.* MESOSOMES.

**chondriosome** *Syn.* MITOCHONDRION.

**Chondrococcus** (1) A genus of algae of the RHODOPHYTA. (2) An obsolete bacterial genus; *C. columnaris* is now *Flexibacter columnaris*.

**Chondromyces** See MYXOBACTERALES.

**chondrosarcoma** See SARCOMA.

**Chondrostereum** See APHYLLOPHORALES (Stereaceae).

**Chondrus** A genus of marine algae (division RHODOPHYTA).

The thallus consists typically of dichotomously branched fronds which attach to rocks etc by means of a holdfast. *C. crispus* ('Irish moss', 'carrageen moss') is used as a source of CARRAGEENAN and, in some countries, as food. [Culture of *C. crispus*: CJFAS (1986) 43 263–268.]

**Chonotrichida** See HYPOSTOMATIA.

**chopped meat medium** See COOKED MEAT MEDIUM.

**Chorda** See PHAEOPHYTA.

**Chordaria** See PHAEOPHYTA.

**Chordopoxvirinae** A subfamily of viruses, family POXVIRIDAE, which infect vertebrates; most members share a common antigen. Six genera are recognized: AVIPOXVIRUS, CAPRIPOXVIRUS, LEPORIPPOXVIRUS, ORTHOPOXVIRUS, PARAPOXVIRUS, SUIPOXVIRUS. The members of a given genus are closely related serologically; genetic recombination can occur between members of a given genus, and NON-GENETIC REACTIVATION can occur between members of the same genus and of different genera.

**Choreocolax** A genus of algae (division RHODOPHYTA).

*C. polysiphoniae* is a parasite of another red alga, *Polysiphonia lanosa*; the nuclei of *C. polysiphoniae* apparently enter the cytoplasm of the host via secondary PIT CONNECTIONS [PNAS (1984) 81 5420–5424].

**chorioallantoic membrane** See EMBRYONATED EGG.

**chorismate** A central intermediate in the biosynthesis of aromatic compounds: see Appendix IV(f).

**Choristoneura EPVs** See ENTOMOPOXVIRINAE.

**Christensen's urea agar** See UREASES.

**Christie–Atkins–Munch–Peterson test** CAMP TEST.

**Chromatiaceae** (purple sulphur bacteria; Thiorhodaceae) A family of photosynthetic bacteria (suborder RHODOSPIRILLINEAE) which occur typically in sulphide-rich aquatic and terrestrial habitats (for example, muddy soils, riverine and estuarine muds); most species contain Bchl *a* (see CHLOROPHYLLS) – the photosynthetic pigments typically occurring in vesicular intracytoplasmic membrane systems. The organisms are primarily photolithotrophic autotrophs which can use e.g. sulphur, sulphide or hydrogen as electron donors, but at least some simple organic compounds (e.g. acetate) can be used by all species under appropriate conditions; sulphur and its compounds are ultimately oxidized to sulphate, though elemental sulphur can be deposited intracellularly. Motile species are polarly flagellate (monotrichous or lophotrichous). GAS VACUOLES occur in some species. Genera: *Amoebobacter*, CHROMATIUM (type genus), LAMPROCYSTIS, THIOCAPSA, *Thiocystis*, *Thiodictyon*, *Thiopedia*, *Thiosarcina*, THIOSPIRILLUM; cf. ECTOTHIORHODOSPIRA.

**chromatic adaptation** In e.g. certain cyanobacteria: adaptation to changes in the wavelength of incident light by changes in the composition of the light-harvesting pigments. For example, '*Fremyella diplosiphon*' produces PHYCOBILIPROTEINS allophycocyanin and phycocyanin when grown in red light (ca. 625 nm), but when grown in green light (ca. 550 nm) the cells also produce phycoerythrin [Book ref. 75, pp. 119–126].

**chromatid** Either of the two longitudinally adjacent threads formed when a (eukaryotic) CHROMOSOME replicates prior to MITOSIS; the chromatids are held together at the CENTROMERE. *Sister* chromatids are derived from the same chromosome.

**ChromaTide®** See PROBE.

**chromatin** The fibrous nucleoprotein complex, containing genomic DNA, HISTONES, NON-HISTONE PROTEINS and RNA, present in the nucleus of most eukaryotic cells. (The term

'chromatin' is sometimes used in a more restrictive sense to refer specifically to the dispersed nucleoprotein material in the interphase nucleus, as distinct from the condensed, discrete CHROMOSOMES evident during mitosis and meiosis.) Two types of chromatin are distinguishable in the interphase nucleus: *heterochromatin*, in which the nucleoprotein fibres are very densely packed, and *euchromatin*, in which the fibres are less densely packed. Heterochromatin may be condensed permanently, i.e., with little variation through the cell cycle (*constitutive heterochromatin*), or temporarily (*facultative heterochromatin*). Euchromatin represents the regions within which gene expression can occur.

Chromatin released from cells appears under certain in vitro conditions as a mesh of fibres (ca. 10 nm diam.) which have a regular beaded appearance in the electron microscope; the beads are called *nucleosomes*. Treatment of these fibres with an endonuclease results in the separation of the nucleosomes, each of which then forms a structure called a *chromatosome*; a chromatosome contains ca. 165 bp (on average) of DNA, one molecule of histone H1, and a *histone octamer* comprising two molecules each of histones H2A, H2B, H3 and H4. Further endonuclease action gives rise to a *core particle*, a disc-shaped structure (ca. 11 nm in diam., 5.7 nm thick) consisting of the histone octamer around which a 146-bp sequence of B-DNA is wrapped in a left-handed superhelix. In the chromatosome, the DNA is believed to form two complete superhelical turns around the histone octamer, the turns being secured by histone H1 which binds to the sequences of DNA entering and leaving the core. In the intact 10-nm chromatin fibre the chromatosome structures are connected to one another via *linker DNA* which may vary from a few (or no) bp to >80 bp, but which is typically ca. 30–40 bp long.

In vivo, the linear chain of nucleosomes (the 10-nm fibre) is itself folded (with consequent further compaction of the DNA) into a *30-nm fibre* in which the nucleosomes are packed together – possibly in a helical arrangement, although the details of the structure are uncertain. The 30-nm fibre is apparently the basic structure both in interphase chromatin and in mitotic chromosomes. The H1 histone is essential for the formation of the 30-nm fibre.

For processes such as replication, transcription and repair, the highly compacted genome must undergo disruption (so-called 'remodelling') in order to expose the DNA to enzymes and binding proteins etc. Various mechanisms are involved. Histone properties (e.g. binding strength) may be modified by post-translational acetylation, phosphorylation, ubiquitylation etc. ATP-dependent remodelling complexes can slide nucleosomes along the DNA and replace histones [COGD (2004) 14 165–173]. *Constitutive* variant histones (which, unlike other histones, are expressed throughout the cell cycle) can e.g. modify nucleosome properties by replacing existing histones [GD (2005) 19 295–316].

**Chromatium** A genus of photosynthetic bacteria (family CHROMATIACEAE). The cells are rod-shaped and may be large (up to 15 µm long) or small (ca. 2–6 µm) according to species; they contain Bchl *a* and various carotenoids (cell suspensions are typically some shade of brown, red or purple). Gas vacuoles are absent. Motility, when it occurs, is mediated by polar flagella. Small-celled species include *C. vinosum*. The large-celled species (*C. buderi*, *C. okenii*, *C. warmingii*, *C. weissii*) are nutritionally fastidious strict anaerobes for which sulphide and vitamin B<sub>12</sub> are essential; other species can grow without sulphide under anaerobic reducing conditions.

## chromatography

**chromatography** The separation of molecules (or ions) in a mixture by any technique which exploits the differing extents to which the different molecules (or ions) become distributed between a stationary phase and a contiguous mobile phase, one of the phases being either a thin film or a surface. Phases may be solid, liquid, or gaseous, according to the type of chromatography. Substances are separated primarily on the basis of their adsorption and/or solubility characteristics (cf. GEL FILTRATION); unlike ELECTROPHORESIS, chromatography does not involve the use of an electrical potential difference. Chromatography is used e.g. for the isolation, purification, and identification of molecules or ions.

In *adsorption chromatography* substances are separated on the basis of quantitative differences in their adsorption onto the surface of a stationary solid phase from a mobile liquid phase. For example, *affinity chromatography* exploits the specificity of binding which occurs between e.g. antibody and antigen, or enzyme and substrate. Essentially, one component (e.g. antigen) is immobilized on an inert support; this adsorbs the other component (antibody) from the liquid phase which flows over it. [Industrial uses: Book ref. 3, pp. 31–66.] *Ion-exchange chromatography* exploits the preferential adsorption of a particular charged species (e.g. ion, nucleic acid) to an insoluble ion-exchange material under particular conditions. (Ion-exchange chromatography is sometimes excluded from the category 'adsorption chromatography' on a mechanistic basis.)

*Partition chromatography* exploits the tendency of different substances to become differently distributed between two fluids in contact. In liquid–liquid chromatography one of the liquids is typically present as a coating on inert particles, or on an inert matrix, over which the mobile liquid phase is passed. For example, in *paper partition chromatography* the stationary phase is typically water which coats the fibres of a paper strip; the mobile phase, usually an organic solvent, flows along the strip by capillary action. If a spot of sample (mixture of substances) is initially applied to one end of the strip, the substances become separated – according to their different partition coefficients – as the solvent flows along the strip. In *gas–liquid chromatography* (GLC) the sample is vaporized in a carrier gas (helium, hydrogen, or nitrogen) which is pumped along a heated tube (up to ca. 350°C) containing inert particles coated with a substance that is liquid at the temperature used. Substances in the sample become partitioned between the gas and liquid; a given substance moves along the tube, in the direction of gas flow, at a characteristic rate which depends on its partition coefficient, and its exit from the tube is recorded e.g. by a thermal conductivity detector.

*High-pressure liquid chromatography* (*high-performance liquid chromatography*; HPLC) uses very high pressures to force a liquid sample through a tightly-packed column of minute particles; separations occur at the surfaces of the particles on the basis of e.g. adsorption processes. The small size of the particles increases the efficiency of interaction between solid and liquid phases; high pressures are necessary to ensure a reasonable rate of flow through the column. *Thin-layer chromatography* (TLC) employs a thin layer of e.g. silica gel on a flat glass support; the (liquid) mobile phase rises up the thin layer by capillary action.

When the substances in a sample have been separated, each may be removed (*eluted*) from the stationary phase by means of a suitable solvent or solution (the *eluent*); for example, in ion-exchange chromatography a suitable eluent may be a solution of a particular electrolyte or a buffer of particular pH. (See also GRADIENT ELUTION.) Alternatively, the separated substances may,

for example, be stained *in situ* on the stationary phase – e.g. using specific stains which allow identification of particular types of molecule.

**chromatoid bodies** (*protozoal*.) Ribonucleoprotein bodies (commonly rod-shaped) which occur within the young cysts of certain amoebae (see e.g. ENTAMOEBEA). Chromatoid bodies stain well with iron-haematoxylin (they do not stain with iodine); one, two or more bodies per cyst may be seen. The nucleoprotein tends to disperse in the cytoplasm as the cyst ages.

**chromatophore** (1) One of a number of small membranous vesicles obtained by the experimental disruption of photosynthetic membranes from bacteria of the Rhodospirillineae; the vesicles are used e.g. for *in vitro* studies on photophosphorylation. (2) A system of vesicular, tubular or lamellar membranous structures which occurs in bacteria of the Rhodospirillineae; chromatophores, which contain bacterioCHLOROPHYLL, CAROTENOIDS, and the electron carriers involved in PHOTOSYNTHESIS, are continuous with the cytoplasmic membrane. (cf. CHLOROSOME.) (3) *Syn.* CHLOROPLAST. (4) *Syn.* CHROMOPLAST.

**chromatosome** See CHROMATIN.

**Chromidina** See HYPOSTOMATIA.

**Chromobacterium** A genus (*incertae sedis*) of chemoorganotrophic, Gram-negative bacteria which occur e.g. in soil and water, and as opportunist pathogens in man and other animals. Cells: round-ended, pigmented (VIOLACEIN-containing) rods, ca. 0.6–0.9 × 1.5–3.5 μm, with one polar and one or more lateral and/or subpolar flagella. Growth occurs on unenriched nutrient media. Most strains attack glucose fermentatively (forming acid but usually no gas); some strains attack glucose oxidatively. Nitrate and nitrite are usually reduced. Growth is inhibited by 6% NaCl. Catalase +ve. Usually oxidase +ve. VP –ve. GC%: ca. 50–68. Type species: *C. violaceum*.

*C. fluviatile*. Optimum growth temperature ca. 25°C, maximum ca. 30°C. GC%: ca. 50–52.

*C. lividum*. See JANTHINOBACTERIUM.

*C. violaceum*. Optimum growth temperature ca. 30–35°C, maximum ca. 40–44°C. GC%: ca. 65–68. (See also MONOBACTAMS and QUORUM SENSING.)

[Book ref. 22, pp. 580–582.]

**chromoblastomycosis** (dermatitis verrucosa; verrucose dermatitis) A chronic human MYCOSIS, occurring mainly in tropical and subtropical areas of South America and Africa, caused by any of several black moulds (e.g. *Cladosporium carrionii*, *Phialophora* spp, *Rhinoctadiella* spp) which are normally saprotrophic e.g. in soil. Infection occurs via wounds, and warty, spreading, often ulcerating lesions develop in the skin and underlying tissue. In the tissues, the fungi occur as thick-walled, dark-brown muriform cells, 5–12 μm ('sclerotic bodies') which multiply by cell separation (not budding); in culture (e.g. on Sabouraud's dextrose agar) they form slow-growing, velvety, dark-brown to greenish-black colonies. Pathogenicity may involve the body's reaction to fungal components: e.g., lipids extracted from the fungi can induce granulomatous reactions on intravenous injection into mice [JGM (1985) 131 187–194].

**chromogenic** Pigment-producing or colour-producing. (cf. ACHROMOGENIC.)

**chromomycin** (chromomycin A<sub>3</sub>) An ANTIBIOTIC and antitumour agent containing an aromatic three-ring chromophore linked to five different sugar residues. *Olivomycin* and *mithramycin* are very similar to chromomycin; all three dyes bind non-covalently and non-intercalatively to dsDNA, inhibiting synthesis of RNA and DNA. Binding requires stoichiometric amounts of Mg<sup>2+</sup> ions, seems to involve the 2-amino group of guanine, and

results in a shift in the absorption spectrum of the dye to longer wavelengths. The dyes are used in cytochemistry as GC-specific fluorochromes, e.g., they produce specific fluorescent banding patterns in metaphase chromosomes [Science (1977) 195 400–402].

**chromomycosis** May refer either to CHROMOBLASTOMYCOSIS or to PHAEOHYPHOMYCOSIS.

**chromophore** That part of a dye molecule which is responsible for the colour of the dye.

**chromoplast** (1) A PLASTID in which the main or sole pigments are CAROTENOIDS. (2) (chromatophore) Any pigmented plastid, e.g. a CHLOROPLAST or a carotenoid-rich plastid in ripening fruit.

**chromosomal fingerprinting** See DNA FINGERPRINTING.

**chromosome** In a prokaryotic cell, or in the nucleus of a eukaryotic cell: a structure consisting of or containing DNA which carries genetic information essential to the cell; the term is also commonly applied to DNA in a mitochondrion or chloroplast and to the genome of a DNA virus, but generally not to the genomic RNA of an RNA virus. (cf. GENOME sense 1 and PLASMID.)

(a) *Bacterial chromosomes.* In most bacteria the chromosome is a ccc dsDNA molecule; in some species (e.g. *Borrelia burgdorferi* [Nature (1997) 390 580–586], species of *Streptomyces*) the DNA is linear. Bacterial chromosomes are not enclosed by a membrane (see PROKARYOTE) but they are apparently linked to the cell's cytoplasmic membrane.

Typically, a cell contains only one type of chromosome; the chromosome may be present in one, several or many copies per cell – depending e.g. on species and on growth conditions; for example, in *Escherichia coli* there may be one or more copies per cell according to the growth rate (see HELMSTETTER–COOPER MODEL). Some species of bacteria appear normally to have multiple copies of the chromosome – e.g. *Azotobacter vinelandii* may have an average of 20–40 'genome equivalents' (apparently separate chromosomes) per cell, *A. chroococcum* contains 20–25, *Deinococcus radiodurans* has four (in resting cells) to ca. 10, while *Desulfovibrio gigas* has ca. 9–17 (in growing cells) [see e.g. JGM (1984) 130 1597–1601, 1603–1612].

The size of the chromosome (in base-pairs) varies considerably among species. One of the smallest is that of *Buchnera*, an obligate intracellular parasite of aphids (~640 kb [Nature (2000) 407 81–86]); larger chromosomes occur e.g. in *Helicobacter pylori* (~1.7 × 10<sup>6</sup> bp) [Nature (1997) 388 539–547] and *Mycobacterium tuberculosis* (~4.4 × 10<sup>6</sup> bp [Nature (1998) 393 537–544]).

In *Vibrio cholerae* the genome consists of two dissimilar circular chromosomes – chromosome 1 (~2961 kb) and chromosome 2 (~1073 kb) [Nature (2000) 406 477–483].

In *E. coli* the chromosome contains ca. 4.7 × 10<sup>6</sup> bp; if opened out, it would be ca. 1.3 mm in length. Within the cell it is extensively folded to form a compact structure variously called a *nucleoid*, *nucleoid body*, *nuclear area*, '*nucleus*' etc. The nucleoid consists mainly of DNA associated with certain types of protein. The DNA is extensively supercoiled (see DNA), the degree of supercoiling being determined by the joint activities of certain enzymes (see TOPOISOMERASE). The supercoiling is segregated into many topologically distinct *domains*; a nick in one domain relaxes the DNA in that domain only. The nucleoid can be unfolded in vitro by treatment with RNase.

(See also CELL CYCLE and DNA REPLICATION.)

[The chromosome of *E. coli*: Book ref. 122, pp. 161–197, 199–227.]

(b) *Eukaryotic chromosomes.* The eukaryotic NUCLEUS typically contains one or more sets of different chromosomes (see

also PLOIDY; each chromosome is believed to contain a single linear dsDNA molecule complexed with protein (see CHROMATIN). Between nuclear divisions (interphase) the chromosomes are dispersed as a mass of 30-nm chromatin fibres occupying much of the volume of the nucleus; during MITOSIS (and MEIOSIS) each chromosome becomes highly condensed to form a discrete structure with a characteristic morphology (see also KARYOTYPE) and structurally and functionally distinct regions (see e.g. CENTROMERE and TELOMERE). Chromosome replication (and transcription) occurs during interphase (see CELL CYCLE), so that at mitosis each chromosome consists of two sister CHROMATIDS.

The 30-nm chromatin fibre in a mitotic chromosome appears to be organized into a series of loops (each ca. 30–90 kb), the ends of the loops being secured by a central proteinaceous *scaffold*; when the chromosome is treated in vitro to remove most of the histones and non-histone proteins, the central scaffold – similar in shape to the sister chromatids – can be seen surrounded by a halo of naked DNA loops.

**chromosome aberration** An abnormality in the number or structure of chromosomes in a cell. Thus, e.g., a HETEROPLOID cell may have the diploid number of chromosomes minus one chromosome (*monosomic* cell) or plus one chromosome (*trisomic* cell). A chromosome may lose a segment (*deletion*); a segment may move from one site to another on the same or on a different chromosome (*translocation*); a segment may take up the reverse orientation in the same site (*inversion*); or a segment may be duplicated.

**chromosome walking** A technique with which an unknown region of a chromosome can be explored. The starting point is a LIBRARY in which the cloned DNA constitutes a series of *overlapping* fragments. A fragment containing a known gene is selected and used as a probe to identify (e.g. by COLONY HYBRIDIZATION) other, overlapping fragments which contain the same gene. The nucleotide sequences of these fragments are then characterized – thus delimiting an overall segment of the chromosome which comprises the span of the overlapping sequences. A fragment at one end of this segment is selected, and the terminal part of this fragment is cleaved and used as a probe to identify a neighbouring set of overlapping fragments, and so on.

**chromotrope** See METACHROMASY.

**Chromulina** A genus of unicellular CHRYSOPHYTES in which each cell has a long tinsel flagellum but only a very short second flagellum. Cysts resemble narrow-necked flasks.

**chronic (med.)** Refers to a disease which persists for a relatively long period of time (e.g. months, years) – terminating in recovery or death. Examples: LEPROSY; TUBERCULOSIS. (cf. ACUTE.)

**chronic bacillary diarrhoea** *Syn.* JOHNE'S DISEASE.

**chronic mucocutaneous candidiasis** See CANDIDIASIS.

**chronic myelogenous leukaemia** See ABL.

**chronic wasting disease** See TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.

**Chroococcales** See CYANOBACTERIA.

**Chroococcidiopsis** A genus of unicellular CYANOBACTERIA (section II) in which growth and binary fission lead to the formation of cubical aggregates of cells; baecocytes are non-motile and have a fibrous outer cell wall layer at the time of their release. GC%: 40–46.

**Chroococcus** A phycological genus of 'blue-green algae' included in the genus GLOEOCAPSA [JGM (1979) 111 1–61 (p. 9)].

**Chroodactylon** See RHODOPHYTA.

**Chroomonas** See CRYPTOPHYTES.

## chrysanthemum chlorotic mottle viroid

**chrysanthemum chlorotic mottle viroid** See VIROID.

**chrysanthemum stunt viroid** See VIROID.

**chrysanthemum white rust** A serious disease of chrysanthemums caused by *Puccinia horiana*; typical early symptoms include pale spots on the upper surfaces of leaves, and raised, buff-coloured pustules on corresponding parts of the lower surfaces – the pustules subsequently becoming white. Common chrysanthemum rust, a less serious disease caused by *P. chrysanthemi*, is characterized by brown powdery masses on the undersides of leaves.

**Chryseomonas** A genus of yellow-pigmented, aerobic, catalase-positive, Gram-negative bacteria. *C. polytricha* was isolated from clinical specimens; cells are round-ended rods, motile by lophotrichous flagella. The organisms are chemoorganotrophs and are reported to be oxidatively saccharolytic but oxidase-negative. GC%: 54–56. [IJSB (1986) 36 161–165.]

**Chrysochromulina** See PRYMNESIOPHYCEAE.

**Chrysoococcus** A genus of unicellular CHRYSOPHYTES in which young cells each have a mucilaginous lorica which, as the cell ages, becomes impregnated with mineral crystals. Cytoplasmic projections extend through pores in the lorica.

**chrysolaminarin** (leucosin; chrysose) A reserve polysaccharide produced by CHRYSOPHYTES, DIATOMS, and members of the PRYMNESIOPHYCEAE. It is a (1 → 3)-β-D-glucan with some branching via (1 → 6)-β-linkages.

**Chrysomonadida** See PHYTOMASTIGOPHOREA.

**chrysomonads** *Syn.* CHRYSOPHYTES.

**chrysophytes** (chrysomonads) A group of eukaryotic, mainly freshwater organisms regarded as algae ('golden, golden-brown or yellow-brown algae', class Chrysophyceae or division Chrysophyta) or as protozoa (see PHYTOMASTIGOPHOREA). Species are either free-swimming (or occasionally sessile) unicellular organisms (e.g. *Chromulina*, *Mallomonas*, *Ochromonas*, *Oikomonas*), or they may form sessile colonies (e.g. CEPHALOTHAMNIUM, DINOBRYON) or motile colonies (e.g. SYNURA, UROGLENA). Most species have two flagella, one of which is directed anteriorly and bears two opposite rows of mastigonemes (see FLAGELLUM (b)), while the other is either smooth and directed posteriorly or is reduced to a short stub (e.g. CHROMULINA) or basal body. FLAGELLAR MOTILITY is achieved primarily by the tinsel flagellum.

According to species, the chrysophyte cell may be naked, may be enclosed by a LORICA (see e.g. CHRYSOCOCCUS, DINOBRYON, OCHROMONAS), or may bear scales – adherent to the outside of the plasmalemma – which may be silicified (e.g. in MALLEMONAS, PARAPHYSOMONAS, SYNURA) or organic (e.g. in *Chromulina placentula*); the scales are produced in special membranous vesicles (SILICA DEPOSITION VESICLES), not in the Golgi apparatus (cf. PRYMNESIOPHYCEAE). [Scale formation in *Synura*, *Mallomonas* and *Paraphysomonas*: JUR (1982) 18 13–26.] Pseudopodium-like cytoplasmic projections are present in many species, and many chrysophytes (e.g. OCHROMONAS) can ingest particulate matter. The majority of chrysophytes are photosynthetic, each cell typically having a few (commonly two) golden-brown chloroplasts containing chlorophylls *a*, *c*<sub>1</sub> and *c*<sub>2</sub>, β-carotene, and fucoxanthin. Mannitol is a major primary product of photosynthesis. Storage compounds include CHRYSOLAMINARIN.

Reproduction occurs by longitudinal binary fission. Palmelloid stages are common in some species. Spherical or bottle-shaped cysts (statospores, resting spores) are commonly formed; each cyst develops within a vegetative cell and has a silica wall which may be smooth or ornamented with e.g. spines.

[Book ref. 197. Silica in chrysophytes: Book ref. 137, pp. 201–230.]

See also SILICOFAGELLATES.

**chrysose** *Syn.* CHRYSOLAMINARIN.

**Chrysosporium** A genus of fungi of the HYPHOMYCETES; most have teleomorphs in the Gymnoascaceae. Hyphae: hyaline, septate. Conidia: non-septate, subglobose to pyriform, 2–2.5 × 4–4.5 μm in culture (cf. ADIASPIROMYCOSIS), typically borne (singly or in pairs) on short, peg-like conidiophores. *C. pruinatum*, a saprotroph, produces adiaspores at high temperatures in vitro.

**chvE gene** See CROWN GALL.

**chymosin** See CASEIN.

**chymotrypsin** A pancreatic serine PROTEASE.

**chytrid** A member of the CHYTRIDIALES.

**Chytridiales** (the 'chytrids') An order of fungi (class CHYTRIDIOMYCETES) which characteristically do not form true mycelium (though some species form a RHIZOMYCELIUM) and in which sexual reproduction, where known, may involve e.g. the fusion of isogametes or gametangial copulation; the organisms include parasites and pathogens of terrestrial plants, aquatic saprotrophs, parasites of algae, and MYCOPARASITES. Genera include *Chytriumyces*, NOWAKOWSKIELLA, OLPIDIUM, *Polyphagus*, RHIZOPHYDIUM, *Rozella* and SYNCHYTRIUM.

**Chytridiomycetes** A class of terrestrial and aquatic, saprotrophic and parasitic fungi (subdivision MASTIGOMYCOTINA) which form sporangiospores having one posteriorly-directed whiplash flagellum. (cf. NEOCALLIMASTIX.) According to species, the thallus ranges from a simple, sac-like, holocarpic structure to a well-developed, branched mycelium; in many species the cell wall contains CHITIN, and in some species the mycelium contains pseudosepta – see SEPTUM (b). Orders: BLASTOCLADIALES, CHYTRIDIALES, Harpochytriales (tropical freshwater saprotrophs), MONOBLEPHARIDIALES.

**Chytridiopsis** See MICROSPORA.

**Chytriumyces** See CHYTRIDIALES.

**Ci** CURIE (q.v.).

**CI** See COLOUR INDEX.

**Ciboria** See HELOTIALES.

**CID** CYTOMEGALIC INCLUSION DISEASE.

**cider** (American: hard cider) A beverage made by the ALCOHOLIC FERMENTATION of apple juice. (In the USA 'cider' refers to unfermented apple juice.) Cider apples are rich in tannin and malic acid (contributing astringent and sharp flavours, respectively). Fermentation may be carried out by the natural apple flora – including e.g. bacteria, yeasts (e.g. *Candida*, *Kloeckera*, *Pichia*, *Saccharomyces*) and other fungi (e.g. *Aspergillus*, *Penicillium*). *Kloeckera* spp begin the fermentation, suppressing both *Candida* and *Pichia*; later, *Saccharomyces* spp predominate. In modern processes the natural flora is usually suppressed (with SULPHUR DIOXIDE) or reduced (by pasteurization, filtration etc) and the juice inoculated with cider yeast – usually '*Saccharomyces uvarum*' (a strain of *S. cerevisiae*); this yeast can degrade de-esterified PECTINS to galacturonic acid. After fermentation is complete, acidity may be reduced by the MALOLACTIC FERMENTATION. The cider may then be carbonated and/or pasteurized and/or filtered.

*Cider spoilage.* The most common microbial spoilage is ACETIFICATION by contaminating acetic acid bacteria. *Cider sickness* is a condition caused by *Zymomonas mobilis* which produces acetaldehyde; this reacts with tannins in the cider to form a milky-white haze and a banana-like off-flavour. 'Oiliness' and ROPINESS may be caused by various lactobacilli.

**cider sickness** See CIDER.

**Cidex** An alkaline GLUTARALDEHYDE solution.

**CIDS** CIRCULAR INTENSITY DIFFERENTIAL SCATTERING.

**CIE** COUNTERCURRENT IMMUNOELECTROPHORESIS.

**ciguatera** A form of toxic FOOD POISONING, involving gastrointestinal and neurological symptoms, which results from the consumption of certain tropical or subtropical fish whose flesh has accumulated certain algal toxin(s); the fish may have fed directly on the algae, or may have consumed other algivorous fish. The dinoflagellate *Gambierdiscus toxicus* has been identified as the toxin producer in cases in the Gambier Islands of Polynesia; the main toxin (*ciguatoxin*) produced by this species is a highly potent neurotoxin [PAC (1986) 58 339–350 (347–348)]. (cf. *Paralytic SHELLFISH POISONING*.)

**ciguatoxin** See CIGUATERA.

**cilia** See CILIUM.

**ciliary corpusele** *Syn.* KINETID.

**ciliate** (1) (*adj.*) Bearing cilia (see CILIUM). (2) (*noun*) A protozoon of the CILIOPHORA.

**ciliature** (*ciliate protozool.*) Collectively, those cilia which occur on a ciliate or on specific region(s) of a ciliate; thus, e.g. 'somatic ciliature' refers to those cilia which occur on the body of the cell – as opposed to those which occur in the oral (buccal) cavity.

**ciliferous** Bearing cilia; a ciliferous kinetosome has an associated cilium, while a 'barren' kinetosome does not.

**Ciliophora** A phylum of PROTOZOA [JP (1980) 27 37–58] in which the organisms are characteristically ciliated (see CILIUM) during at least some stage in their life cycles, and possess two types of nucleus (see MACRONUCLEUS and MICRONUCLEUS). (cf. PHALACROCLEPTES and STEPHANOPOGON.)

Many of the 7000 or so known species are free-living in freshwater, brackish or marine habitats; some occur in the soil (e.g. *Grossglockneria acuta* [SBB (1985) 17 871–875]), in the RUMEN, or in SEWAGE TREATMENT plants. Some species are pathogenic (see e.g. BALANTIDIUM and ICHTHYOPHTHIRIUS) and some (e.g. members of the ASTOMATIDA) are parasitic.

In size, ciliates range from ca. 10 µm to several millimetres. The cells generally have a substantial PELLICLE, one or more CONTRACTILE VACUOLES, and most have a CYTOSTOME; some have EXTRUSOMES. CYSTS are formed by some species. Ciliates are typically colourless, but some (e.g. BLEPHARISMA, STENTOR) are pigmented. Some species have endosymbionts (see e.g. PARAMECIUM). Although typically motile, the ciliates include some sedentary species (see e.g. PERITRICHIA). Ciliates commonly feed holozoically, i.e., by PHAGOCYTOSIS.

Reproduction typically occurs by transverse, perkinetal binary fission; budding or multiple fission occurs in some species. Sexual processes (see AUTOGAMY and CONJUGATION) occur in some species.

In ciliates the GENETIC CODE differs from that previously regarded as the 'universal' code, and huge evolutionary distances are believed to separate ciliates from other organisms [MS (1986) 3 36–40].

Currently, ciliate taxonomy involves criteria such as the nature of STOMATOGENESIS and of the PARORAL MEMBRANE. Three classes: KINETOPHAGMINOPHOREA (regarded as the most primitive); OLIGOHYMENOPHOREA; POLYHYMENOPHOREA.

(See also SILVER LINE SYSTEM.)

[Book ref. 135.]

**Ciliophrys** See ACTINOPHRYIDA.

**cilium** (*pl.* cilia) A thread-like appendage, numbers of which extend from the cells of most members of the CILIOPHORA; the coordinated movements of cilia are involved in locomotion and/or feeding. (Cilia also occur on other organisms and

cells – e.g. ctenophores ('comb jellies') and certain cells in the mammalian respiratory tract.) The structure and ultrastructure of a cilium are similar to those of the eukaryotic FLAGELLUM (q.v.); however, cilia are usually shorter (often 7–10 µm) and they frequently occur in longitudinal rows (see KINETY) or in specialized groups (see COMPOUND CILIATURE). The characteristic rhythmical bending of cilia is achieved by the sliding of the ciliary microtubules relative to one another.

The basic ciliary movement begins with an *effective stroke*, i.e., a rapid swing through a wide angle in a straight, relatively rigid state due to simultaneous activity of the dynein arms on one side of the axoneme; this is followed by a *recovery stroke* in which the cilium returns to its datum position as a result of the propagation of a wave of dynein activity along the other side of the axoneme, from base to tip. Energy is therefore required for both the effective and the recovery strokes. The rhythmical beating of cilia generates currents in the ambient fluid – thus causing the cell to move or, e.g., propelling food particles towards the cytostome. (See also METACHRONAL WAVES.) Many variations of ciliary movement are found among ciliates – including e.g. the ability to change the direction of the ciliary beating. (See also CLAVATE CILIUM; cf. FLAGELLAR MOTILITY (b).) [Mechanism and controls of microtubule sliding in cilia: SEBS (1982) 35 179–201; production of different ciliary beat patterns: SEBS (1982) 35 139–157; regulation of ciliary motility by membrane potential via cAMP in *Paramecium*: Cell Mot. (1986) 6 256–272.]

(2) (*lichenol.*) A vegetative appendage which structurally resembles a RHIZINE but which arises from the margin of a thallus or apothecium or, in some lichens, from the upper surface of the thallus.

**CIN agar** Cefsulodin–Irgasan–novobiocin agar, a medium developed for the isolation of *Yersinia enterocolitica*. At least one strain of *Y. enterocolitica* (biotype 3B, serotype O3) and strains of *Y. pseudotuberculosis* are inhibited on this medium [JCM (1986) 24 116–120].

**cin gene** See BACTERIOPHAGE P1.

**cinchona alkaloids** Alkaloids obtained from the bark of certain tropical trees (especially *Cinchona succirubra*); the alkaloids include e.g. cinchonine and QUININE.

**cinerubin** See ANTHRACYCLINE ANTIBIOTICS.

**cingulum** See e.g. DIATOMS and DINOFLAGELLATES.

**cinnoxacin** See QUINOLONE ANTIBIOTICS.

**CIP** Collection de l'Institut Pasteur, Institut Pasteur, 28 Rue du Docteur Roux, 75724 Paris, Cedex 15, France.

**ciprofloxacin** See QUINOLONE ANTIBIOTICS.

**circadian rhythms** In certain parameters of a cell or organism: rhythmical changes which occur with a periodicity of ca. 24 hours and which may persist for extended periods of time (e.g. days, weeks) even when the cell or organism has been isolated from the natural diurnal fluctuations of the environment; such innate rhythms are often referred to as expressions of a 'biological clock'.

In eukaryotes, parameters that exhibit circadian rhythms include e.g. (according to organism): BIOLUMINESCENCE, cell division, chloroplast ultrastructure, mating type, motility and photosynthetic activity; thus, for example, peak photosynthetic activity in *Acetabularia* occurs with a 24-hour periodicity even when the organism is kept in continual light. (cf. INFRADIAN RHYTHMS and ULTRADIAN RHYTHMS.)

Once believed to occur only in eukaryotes, circadian rhythms have also been detected in some prokaryotes. For example, in the unicellular cyanobacterium *Synechococcus*, gene *psbAI* (which

## circannual rhythms

encodes a component of photosystem II) is expressed least at dawn and maximally at dusk; certain other genes are regulated in the opposite phase. Under conditions of constant light, the *timing* of cell division is influenced by the endogenous ~24-hour biological clock, even when average doubling time is only 10.5 hours [TIM (1998) 6 407–410].

[Molecular bases for circadian clocks (review): Cell (1999) 96 271–290. Circadian programmes in cyanobacteria: ARM (1999) 53 389–409.]

**circannual rhythms** In certain parameters of a cell or organism: rhythmical changes which occur with a periodicity of ca. one year (see e.g. RED TIDE).

**CIRCE** See HEAT-SHOCK PROTEINS.

**Circoviridae** See TT VIRUS.

**circular intensity differential scattering (CIDS)** A phenomenon in which left and right circularly polarized light is scattered in a characteristic way by a given type of cell, virus, or molecule. CIDS has been used for the rapid characterization of microorganisms [AEM (1982) 44 1081–1085].

**circularly permuted** (*mol. biol.*) Refers to nucleic acid molecules in which the bases or genes are arranged in the same sequence but with different starting points: ABCDEFG, BCDEFGA, CDEFGAB, etc; such molecules can arise e.g. by cleavage at different positions in a given type of circular parental molecule. (See e.g. BACTERIOPHAGE T4.)

**circulative transmission** (of viruses) (*plant pathol.*) A mode of transmission in which viruses taken up by an insect VECTOR pass from the alimentary canal to the haemolymph and subsequently to the salivary glands and saliva of the insect; viruses which are transmitted in this way are called *circulative* or *persistent* viruses. Insects involved in circulative transmission typically carry plant-infective virions for long periods, sometimes for life. Circulative transmission characteristically involves a latent period (several hours to a number of days) during which the vector, having acquired virus from an infected plant, is unable to transmit the virus to a healthy plant. (cf. NON-CIRCULATIVE TRANSMISSION.)

Some viruses (e.g. potato yellow dwarf virus, wound tumour virus) replicate in their insect vectors; circulative transmission of such *propagative viruses* is termed *propagative transmission*. Other viruses (e.g. barley yellow dwarf virus) apparently do not replicate in their insect vectors; circulative transmission of such *non-propagative viruses* is accordingly referred to as *non-propagative transmission*.

**circulative viruses** See CIRCULATIVE TRANSMISSION.

**circulins** See POLYMYXINS.

**circumsporozoite protein** See PLASMODIUM.

**cirramycin** See MACROLIDE ANTIBIOTICS.

**cirri** See CIRRUS.

**cirrus** (*pl. cirri*) A discrete group of somatic cilia (several to over 100) which act primarily as a unified locomotive organelle; the typical cirrus is conical. Cirri are characteristic of the HYPOTRICHIDA. (See also COMPOUND CILIATURE.)

**cis-acting** See CIS-DOMINANCE.

**cis-dominance** The phenomenon in which a genetic element (a gene or a non-coding sequence such as a promoter) affects only the DNA molecule in which it occurs; in a COMPLEMENTATION TEST, a mutant form of such a genetic element (which is called a *cis-acting* element) cannot be complemented by (i.e., is dominant over) the wild-type form of the element present in the same cell. The converse of a *cis-acting* element is a *trans-acting* element, an element which encodes a product that can diffuse through the cytoplasm and act on other DNA molecules. For example,

in the LAC OPERON, a mutation in the *lacI* gene may result in an inactive *lac* repressor and hence in the constitutive expression of the *lac* genes; the presence of a wild-type *lacI* gene (e.g. on a plasmid) in the same cell can re-establish repression of the *lac* genes, i.e., the *lacI*<sup>-</sup> allele is recessive to the wild-type *lacI*<sup>+</sup> allele, and the *lac* repressor is said to be *trans-acting*. A mutation in the *lac* operator which renders the operator unable to bind the repressor also results in constitutive expression of the *lac* genes; however, in this case the presence of a functional *lac* operator on a plasmid in the same cell does not alter the mutant (constitutive) phenotype, i.e., the mutant operator is dominant over the wild-type form, complementation cannot occur between mutant and wild-type forms, and the operator is said to be *cis-acting*.

Although in most cases a *cis-acting* element is non-coding (e.g. a promoter, an operator, etc), certain proteins are *cis-acting*; such a protein can function only on the DNA molecule encoding it. For example, certain transposases can act efficiently only on the ends of an appropriate transposable element in the same DNA molecule as the gene which encoded the transposase (see e.g. Tn5). *Cis-acting* proteins are generally strongly basic; it has been suggested that, as soon as it is synthesized (perhaps even before translation is complete), a *cis-acting* protein may bind to the nearby DNA template and may subsequently move along the DNA until it reaches an appropriate site of action (e.g. the ends of a transposon in the case of a *cis-acting* transposase).

**cis-trans test** A form of COMPLEMENTATION TEST which actually comprises two separate tests: a *cis* test and a *trans* test. The terms *cis* and *trans* refer to the arrangement of mutations in the two genomes which are brought together in the same cell to test for complementation; in the *trans* arrangement one mutation occurs in each genome, while in the *cis* arrangement both mutations are located in the same genome, the other genome being wild-type. (The doubly-mutant genome used in the *cis* test is constructed, by recombination, from the two singly-mutant genomes used in the *trans* test, so that the mutations in the *cis* arrangement occupy the same loci as those in the *trans* arrangement.) Positive results in both *cis* and *trans* tests (i.e., the wild-type phenotype is restored in both tests) indicate that the two mutations are in different genes and hence that the phenotypic characteristic under study is determined by more than one gene. A negative *trans* test with a positive *cis* test indicates that the two mutations are in the same gene (organisms in the *cis* test having one doubly-mutant copy and one wild-type copy of the gene, those in the *trans* test having only two mutant copies of the gene). However, if both *cis* and *trans* tests are negative, at least one of the mutations must be dominant (see COMPLEMENTATION TEST), i.e., the mutant phenotype is expressed in the *cis* test organisms despite the presence of a wild-type copy of the gene. The *cis* test thus provides a control to prevent the possible misinterpretation of a negative (*trans*) complementation test as indicative of monogenic control when in fact it could be the result of a dominant mutation in one gene together with a second (dominant or recessive) mutation in another gene.

**cistron** (1) A GENE as defined in terms of the CIS-TRANS TEST: i.e., in a diploid cell or merozygote, either of two homologous sequences in a genetic nucleic acid in which two mutations in *trans* fail to exhibit complete complementation (see COMPLEMENTATION TEST).

(2) *Syn.* GENE.

**Cit plasmid** An enterobacterial plasmid encoding a citrate transport system; the presence of a Cit plasmid in e.g. *Escherichia coli* confers on the (usually citrate-negative) cells the ability to utilize citrate as sole source of carbon and energy (see CITRATE TEST).

**Citeromyces** A genus of yeasts (family SACCHAROMYCETACEAE). Cells reproduce by multilateral budding; neither pseudomycelium nor true mycelium is formed. Asci are persistent and contain one (occasionally two) rough-surfaced spheroidal spores. Glucose is fermented;  $\text{NO}_3^-$  is assimilated. One species: *C. matritensis* (anamorph: *Candida globosa*), isolated from e.g. fruit preserved in syrup, tree exudates etc. [Book ref. 100, pp. 117–119.]

**Citifluor** A photofading retardant and mountant used e.g. for epifluorescence microscopy of soil [SBB (1985) 17 739–746].

**citrate metabolism** See e.g. TCA CYCLE, CIT PLASMID, DIACETYL; see also CITRIC ACID.

**citrate synthase** See Appendix II(a).

**citrate test** An IMVIC TEST which determines the ability of a bacterial strain to use citrate as the sole source of carbon (see e.g. TCA CYCLE). A saline suspension of the test organism is prepared from growth on a solid medium. An inoculum from this suspension is transferred by means of a STRAIGHT WIRE to the test medium (e.g. KOSER'S CITRATE MEDIUM or SIMMONS' CITRATE AGAR); the wire is dipped (ca. 1 cm) into the suspension and then dipped into, or streaked across, the test medium. Such a small inoculum minimizes carry-over of nutrients and avoids causing turbidity in Koser's medium. The inoculated medium is incubated and examined daily for evidence of growth (turbidity in Koser's medium, blue coloration in Simmons' medium); growth is a positive reaction.

**citreoiviridin** A yellow pigment and neurotoxic MYCOTOXIN produced by *Penicillium citreoiviride* growing e.g. on polished rice. (See also YELLOW RICE.) The molecule consists of a hydrofuran ring linked, via a conjugated polyene, to an  $\alpha$ -pyrone chromophore; it emits a brilliant yellow fluorescence on UV irradiation. Consumption, by man, of rice contaminated with citreoiviridin may be responsible for *acute cardiac beriberi*: a fatal disease characterized by ascending paralysis, convulsions, and respiratory arrest; these symptoms can be reproduced in animals by feeding them with citreoiviridin. In vitro, citreoiviridin inhibits PROTON ATPASE isolated e.g. from mitochondrial membranes.

**citric acid** A tricarboxylic acid present e.g. in many fruits (especially citrus fruits) and an important metabolic intermediate in many organisms (see e.g. TCA CYCLE). Citric acid is obtained commercially mainly from strains of *Aspergillus niger* grown e.g. on molasses or starch hydrolysates; the accumulation of citric acid is apparently due to abnormal functioning of the TCA cycle. The citric acid is separated from the fermentation liquor by precipitation as the  $\text{Ca}^{2+}$  salt. Citric acid has many commercial uses – e.g. as an acidifying agent in various foods, beverages and pharmaceuticals. [Production methods etc: Book ref. 8, pp. 709–747.]

**citric acid cycle** *Syn.* TCA CYCLE.

**citrinin** A yellow pigment and MYCOTOXIN produced by *Penicillium* spp in mouldy cereals etc. It is nephrotoxic e.g. in pigs.

**Citrobacter** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: ca.  $1 \times 2\text{--}6 \mu\text{m}$ , usually motile. MR +ve; VP –ve citrate +ve; acid and gas from glucose; lactose +ve or –ve, or fermented slowly. Growth usually occurs on/in selective media such as DCA, SS agar, tetrathionate broth and selenite broth. GC%: 50–52. Type species: *C. freundii*.

*C. amalonaticus* (formerly e.g. *C. intermedius* biotype a; *Levinea amalonatica*). Indole +ve; malonate –ve;  $\text{H}_2\text{S}$  –ve; growth in KCN media.

*C. diversus* (= *C. koseri*; formerly e.g. *C. intermedius* biotype b; *Levinea malonatica*). Indole +ve, malonate +ve and  $\text{H}_2\text{S}$  –ve; no growth in KCN media.

*C. freundii*. Indole –ve; malonate (usually) –ve;  $\text{H}_2\text{S}$  +ve; growth in KCN media. Nitrogen fixation has been reported in some strains. Serotypes may be distinguished on the basis of O and H antigens, some of which are common to serotypes of *Escherichia* and *Salmonella*; *C. freundii* H antigens are monophasic. Certain strains are reported to have a Vi antigen serologically identical to that of *Salmonella typhi* (see VI ANTIGEN), but its presence is not related to virulence. (See also PHASE VARIATION.)

*Citrobacter* spp may be isolated from human or animal faeces, from various clinical specimens, and from food, water, sewage, soil etc; they may be opportunist pathogens. *C. freundii* and *C. diversus* have been associated with cases of human diarrhoea. [Book refs. 22, pp. 458–461, and 46, pp. 1140–1147.]

**citrovorum factor** See FOLIC ACID.

**L-citrulline** See e.g. Appendix IV (a).

**Citrus exocortis viroid** See VIROID.

**Citrus leaf rugose virus** See ILARVIRUSES.

**Citrus leprosis virus** See RHABDOVIRIDAE.

**Citrus tristeza virus** A member of the CLOSTEROVIRUSES which causes 'tristeza disease' of citrus trees; the virus has killed millions of orange trees in Brazil.

**Citrus variegation virus** See ILARVIRUSES.

**CJD** CREUTZFELDT–JAKOB DISEASE.

**CL region** See IMMUNOGLOBULINS.

**Cladobotryum** See HYPHOMYCETES and HYPHYCOMYCES.

**cladogram** Any dendrogram which expresses phylogenetic relationships. (cf. PHENOGRAM.)

**Cladonia** A large genus of LICHENS (order LECANORALES); photobiont: a green alga. Species tend to be variable in appearance. There is a granular or squamulose primary thallus (often evanescent, but predominant in some species) from which may arise hollow podetia (see PODETIUM); according to species, podetia may be awl-shaped, branched and shrubby, or funnel-, cup- or wine-glass-shaped, and may bear brown or red hymenial discs ('apothecia'). Species occur on the ground (particularly on peaty soils in heaths and moors), on walls, on decaying logs, etc. Some species – e.g. *C. portentosa* (formerly *C. impexa*), *C. rangiferina*, *C. stellaris* – form cushions of extensively branched podetia ('reindeer moss') on the ground in mountainous regions of Europe and in Arctic regions, where they may serve as an important source of winter fodder for reindeer and caribou.

**Cladophora** A genus of filamentous, branched, siphonocladous green algae (division CHLOROPHYTA); the filaments are composed of cylindrical, multinucleate cells, the walls of which contain parallel arrays of cellulose microfibrils. An isomorphic alternation of generations occurs; sporophytes produce quadriflagellate, uninucleate zoospores, gametophytes produce biflagellate isogametes. Species occur in freshwater and marine habitats, sometimes free-floating, but usually attached to a substratum by rhizoids; some species often form extensive tangled skeins up to several metres in length ('blanket weed').

**Cladosiphon** See PHAEOPHYTA.

**cladosporiosis** Any human or animal disease caused by a species of CLADOSPORIUM.

**Cladosporium** A genus of fungi (class HYPHOMYCETES) which form septate mycelium and dark-coloured, aseptate or septate, ellipsoidal conidia. The organisms include saprotrophs and pathogens of plants and animals. Species include e.g. *C. carrionii* (see e.g. CHROMOBLASTOMYCOSIS), *C. cucumerinum* (see e.g. GUMMOSIS), *C. herbarum* (teleomorph: *Mycosphaerella tassiana*) (see e.g. BLACK SPOT (sense 1), SAP-STAIN, TEXTILE

## Cladostephus

SPOILAGE), and *C. oxysporum* (a pathogen of homopteran insects). (See also BLACK YEASTS, MEAT SPOILAGE, PAINT SPOILAGE, PAPER SPOILAGE.) For *C. bantianum* see XYLOHYPHA. For *C. fulvum* see FULVIA. For *C. resinae* see HORMOCONIS.

**Cladostephus** See PHAEOPHYTA and PHEROMONE.

**clamp connection** (clamp; clamp cell) In the *dikaryotic* mycelia of many (not all) basidiomycetes: a hyphal structure formed during vegetative cell division for ensuring that the daughter nuclei of a given nucleus are segregated to different cells. Prior to MITOSIS a dikaryotic cell develops a short, angled, lateral branch (the incipient clamp connection) into which *one* of the nuclei migrates. Both nuclei then undergo simultaneous mitotic division (*conjugate division*) – the spindles being orientated such that, subsequently, one end of the cell contains one daughter nucleus from each of the two parental nuclei; this pair of nuclei is then isolated from the rest of the cell by a septum (which thus delimits a heterokaryotic binucleate cell), while a second septum isolates the single daughter nucleus in the developing clamp connection. The clamp hypha now grows towards – and fuses with – the mononucleate compartment of the original (parental) cell, the clamp connection thus being completed, and a second heterokaryotic binucleate cell being concomitantly formed. The clamp connection persists as a hyphal bulge in the region of septation.

A *medallion clamp* (formed e.g. by species of *Lentinus*, *Lenzites*, *Poria* and *Polyporus*) develops when only the terminal part of the clamp hypha fuses with the mononucleate cell, a small space or eyelet remaining between the clamp hypha and the parent hypha.

Parallels have been drawn between clamp connections and the *croziers* formed during ASCUS development.

**clarithromycin** A MACROLIDE ANTIBIOTIC used e.g. as part of a combination of antibiotics for treating disease caused by *Helicobacter pylori*; this macrolide is more acid-stable (and is absorbed more readily) than e.g. erythromycin. In *H. pylori*, resistance to macrolide antibiotics has been associated with point mutations in 23S rRNA [AAC (1996) 40 477–480].

**class** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**class I/class II antigens** See MAJOR HISTOCOMPATIBILITY COMPLEX.

**class I/class II introns** See SPLIT GENE (b) and (c).

**class switching** See ANTIBODY FORMATION.

**clathrin** See PINOCYTOSIS.

**Clathrochloris** See CHLOROBIACEAE.

**Clathrulina** A genus of freshwater protozoa (order DESMOTHRACIDA). The mature organism is attached to e.g. vegetation by a tubular stalk-like extension (ca. 200–350 µm long) of the capsule; the capsule (ca. 60–90 µm diam.) has circular to polygonal perforations through which axopodia protrude. The cell reproduces by the formation of biflagellate zoospores which lack both stalk and capsule. These cells initially form filopodia (rather than true axopodia); subsequently a stalk, a capsule, and finally axopodia, are produced.

**Clathrus** See PHALLALES.

**clavacin** *Syn.* PATULIN.

**clavams** A class of β-LACTAM ANTIBIOTICS which includes CLAVULANIC ACID.

**Clavaria** See APHYLLOPHORALES (Clavariaceae).

**Clavariaceae** See APHYLLOPHORALES.

**clavate** Club-shaped, i.e. thicker at one end.

**clavate cilium** (stereocilium) A short cilium whose axoneme lacks the central pair of microtubules; it does not flex. Clavate cilia occur e.g. in *Didinium* and in the scopula of some peritrichs.

**clavatin** *Syn.* PATULIN.

**clavems** A class of antibiotics; a clavem contains a clavam-like nucleus in which a double bond occurs between C-2 and C-3 (see β-LACTAM ANTIBIOTICS, Figure (f)).

**Clavibacter** A genus of Gram-positive, asporogenous, non-acid-fast, non-motile, obligately aerobic, phytopathogenic coryneform bacteria; *C. xyli* subsp. *xyli* causes ratoon stunting disease of sugarcane, *C. xyli* subsp. *cyndontis* causes Bermuda-grass stunting disease. [IJSB (1984) 34 107–117.]

**Claviceps** A genus of fungi (order CLAVICIPITALES) which are typically parasitic on grasses (see e.g. ERGOT; see also PASPALUM STAGGERS).

*C. purpurea*. The cycle of infection begins when ascospores germinate and infect the ovaries of a susceptible grass. The fungus soon produces small, colourless conidia (the *Sphacelia* stage) which become suspended in a HONEYDEW secretion (possibly produced by the plant in response to infection); insects, attracted by the honeydew, disperse the conidia to the ovaries of uninfected grasses. Later, the fungus produces a SCLEROTIUM (q.v.) (the *ergot*, the overwintering stage) in the position normally occupied by the grain. In spring or early summer the sclerotia germinate, each giving rise to several erect, drum-stick-like stromata; perithecia develop in the surface layer of each stromal head, their ostiolar pores level with the stromal surface. Each ascus contains 8 thread-like ascospores.

**Clavicipitales** An order of fungi (subdivision ASCOMYCOTINA) which include entomogenous species, and species parasitic on other fungi or on grasses. Ascocarp: perithecioid, superficial or immersed in a stroma. Asci: unitunicate, cylindrical, with a thick apical cap. Ascospores: elongated to filiform, often multiseptate, sometimes fragmenting. Genera: e.g. *AcrospERMUM*, *Balansia*, *CLAVICEPS*, *CORDYCEPS*, *EPICHLÖE*, *HypoCERELLA*, *HYPOMYCES*.

**claviformin** *Syn.* PATULIN.

**clavine alkaloids** See ERGOT ALKALOIDS.

**Clavispora** A genus of yeasts (family SACCHAROMYCETACEAE) which reproduce by multilateral budding; pseudomycelium may be formed. Asci are formed following conjugation between cells of different mating type. Ascospores: clavate, minutely warty, 1–4 per ascus. Glucose is fermented; NO<sub>3</sub>– is not assimilated. One species: *C. lusitaniae* (anamorph: *Candida lusitaniae*), isolated e.g. from pigs and from human skin and sputum. [Book ref. 100, pp. 120–122.]

**clavulanic acid** A clavam (see β-LACTAM ANTIBIOTICS for structure). Clavulanic acid, produced e.g. by *Streptomyces clavuligerus* (ATCC 27064), binds to the PENICILLIN-BINDING PROTEINS of *Escherichia coli* (preferentially to PBP-2) but has only weak antibacterial activity; however, it is a potent inhibitor of many β-LACTAMASES from Gram-positive and Gram-negative bacteria and may thus be used in combination with β-lactamase-sensitive antibiotics (see e.g. AUGMENTIN and TIMENTIN). Clavulanic acid is unstable as the free acid and is isolated from aqueous solutions as a salt.

**CLB** (coccidian-like body) An organism linked with prolonged diarrhoea (duration: weeks) in humans; it appears to be water-borne. [Epidemiology: Lancet (1993) 341 1175–1179.]

**cleared lysate** The supernatant obtained when bacteria in suspension are lysed and centrifuged for ca. 10–20 min at ca. 20000 g; it may contain plasmids (if present in the cells) but is generally free of particulate cell debris and chromosomal DNA.

**clearing** In preparing a specimen for microscopy: the stage in which the dehydrating agent (usually ethanol) is replaced by a solvent (*clearing agent*) such as benzene, xylene, or terpineol; if the cleared specimen is to be mounted in a MOUNTANT or impregnated with paraffin wax, the clearing agent must be

miscible with both the dehydrating agent and the mountant or wax solvent. The refractive index of clearing agents is higher than that of ethanol, so that the process of clearing increases the transparency of the specimen.

**CLED medium** Cystine-lactose-electrolyte-deficient medium: a medium used for the culture of organisms in the absence of electrolyte (or NaCl). With added colistin, it may be used for the primary isolation of members of the PROTEAE, since swarming is inhibited in the absence of NaCl.

**cleistocarp** *Syn.* CLEISTOTHECIUM.

**cleistothecium** (cleistocarp) A hollow, closed, typically spherical or spheroid ASCOCARP in which develop one or more asci (see ASCUS and ASCOSPORE). In some species the cleistothecial wall (*peridium*) is a more or less rigid pseudoparenchymatous structure; in others the wall may be little more than an envelope of loosely woven hyphae. In e.g. *Erysiphe* spp the cleistothecia are ca. 100–200 µm in diameter.

**clindamycin** See LINCOSAMIDES.

**Clitocybe** See AGARICALES (Tricholomataceae).

**cloacin DF13** A group A colicin (see COLICINS) (MWt ca. 56000) produced by strains of *Enterobacter cloacae* and *Escherichia coli* which harbour the CloDF13 plasmid. [Proposed role for protein H (the lysis protein) in cloacin DF13 export: JGM (1986) 132 825–834.]

In *E. coli* the receptor for cloacin DF13 is the IutA protein (which also serves as a receptor for iron–aerobactin complexes – see SIDEROPHORES); translocation across the cell envelope of the target cell is reported to require the TolAQR proteins.

Within a sensitive cell, cloacin DF13 acts as an RNase, specifically cleaving 16S rRNA – thereby inhibiting ribosome function and protein synthesis.

**CloDF13 plasmid** See CLOACIN DF13 and COLE1 PLASMID.

**clofazimine** (B663; Lamprene) A lipid-soluble substituted phenazine used e.g. as an anti-LEPROSY drug; in *Mycobacterium leprae* it binds to guanine residues in DNA and may inhibit transcription.

**clonal abortion** (*immunol.*) See IMMUNOLOGICAL TOLERANCE.

**clonal deletion** (*immunol.*) See IMMUNOLOGICAL TOLERANCE.

**clonal expansion** See e.g. T LYMPHOCYTE. (Clonal expansion also occurs in B cells when they react to specific antigen.)

**clonal selection theory** A currently accepted theory of ANTIBODY FORMATION. Essentially, it proposes that particular cells (within a cell population) respond to a specific antigen by binding the antigen on pre-existing specific cell-surface receptors (antibodies); binding promotes proliferation of these cells to form an enlarged clone of cells which are responsive to that antigen – some of the cells secreting antibodies and others acting as ‘memory’ cells which can produce antibodies on later exposure to the antigen. IMMUNOLOGICAL TOLERANCE in respect of certain antigens is explainable as the loss of particular clones due to exposure to self-antigens, or external antigens, at an early stage in the development of the immune system. (cf. INSTRUCTIVE THEORIES OF ANTIBODY FORMATION.)

**clone** (1) (*noun*) A population of cells or organisms derived asexually from a single progenitor. A clone is generally assumed to be genetically homogeneous.

(2) (*verb*) To carry out CLONING (of DNA).

**clonal line** (*tissue culture*) A population of cells descended directly from a single CLONE. (cf. CELL LINE.)

**cloning** (of DNA) A procedure (also called *gene cloning* or *molecular cloning*) used for obtaining millions of copies of a given gene (or other piece of DNA); copies of the (cloned) DNA may be used e.g. for sequence analysis (see DNA SEQUENCING)

or for synthesis of the product encoded by the sequence (see EXPRESSION VECTOR).

Initially, the required gene (or other sequence) is inserted (‘spliced’) into a REPLICON – often a PLASMID or a phage genome. The replicon functions as a *vector* (= *cloning vector*), i.e. a molecule which, on being replicated in a cell, brings about the replication of the given gene (as the latter is an integral part of the vector).

The insertion of a gene into a plasmid vector is carried out in a procedure involving a RESTRICTION ENDONUCLEASE and a ligase (see figure).

Vector molecules, each incorporating the given gene, are introduced into cells in which they can replicate; plasmid vectors are introduced into bacteria by TRANSFORMATION or ELECTROPORATION. The cells, containing vectors, are then cultured; because a bacterial population can reach very high numbers in culture, and because each cell contains one or more copies of the vector, large numbers of vector molecules (each containing the given gene) are obtained – i.e. the gene has been *cloned*.

To harvest the cloned gene, the cells are lysed and the vector molecules are isolated e.g. by isopycnic centrifugation (cf. QIAGEN PLASMID KIT). The cloned gene is then cut from each vector molecule (by means of the original restriction enzyme), and copies of the cloned gene are separated from vector DNA e.g. by gel electrophoresis.

*Cloning with plasmid vectors in bacteria.*

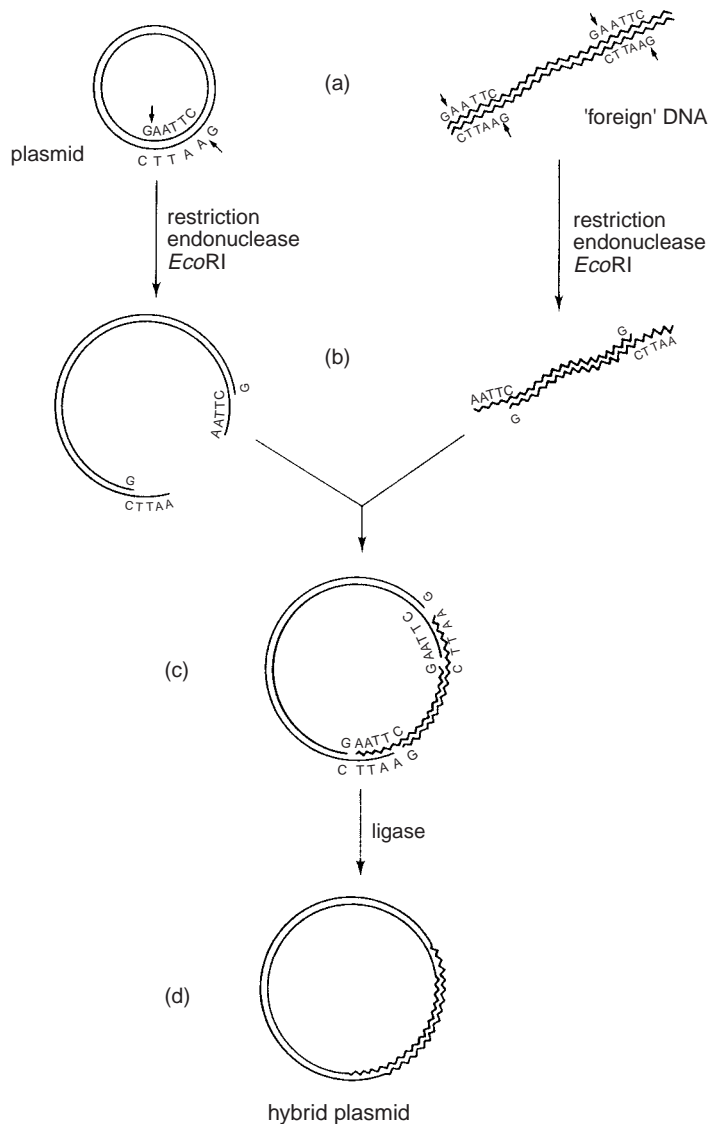

During the initial stage (see figure), one potential problem is that some plasmid molecules may re-circularize without incorporating a copy of the gene; such plasmids may then be taken up by transformation but, lacking the gene insert, they would not contribute to the cloning process. This difficulty may be addressed by pre-treating the cleaved (linearized) plasmids with a phosphatase to remove the 5′-phosphate groups which are necessary for ligase action and re-circularization. When the gene (target) fragments are added, their 5′-phosphate groups can be ligated to 3′-OH ends in the plasmids, resulting in stable, circular hybrid plasmids which contain single-stranded nicks (at the 5′-OH ends). These hybrid plasmids can then be used for transformation – the nick sites being repaired in vivo to yield ccc dsDNA molecules.

Sometimes the target fragment lacks restriction sites, or has incompatible ones. This problem may be addressed as follows. Sticky ends, if present, are changed to blunt ends (see BLUNT-ENDED DNA); this may be achieved by either removing single-stranded overhangs (e.g. with ENDONUCLEASE S1) or by synthesizing a complementary strand on each 5′ overhang (thus converting 5′ overhangs to dsDNA). To each blunt end can now be ligated a short, blunt-ended dsDNA molecule – a *linker* – which contains a suitable restriction site; one example of a linker is:

which contains the *EcoRI* restriction site (see table in RESTRICTION ENDONUCLEASE). Because a linker is a PALINDROMIC SEQUENCE (the 5′-to-3′ sequence is the same in both strands) either end can be ligated. Blunted-ended ligation requires a higher concentration of enzyme, a lower temperature and a longer time. (See also ADAPTOR.)

Following transformation, only cells which have actually received a plasmid can contribute to the cloning process. These cells can be selected for if the plasmid vector contains an antibiotic-resistance gene; thus, if the transformed cells are

CLONING: insertion of a gene (or other 'foreign' DNA) into a plasmid vector (diagrammatic).

(a) A plasmid and a piece of 'foreign' DNA. Both molecules contain the nucleotide sequence GAATTC which is recognized by the RESTRICTION ENDONUCLEASE *Eco*RI; in the foreign DNA, the sequence to be cloned lies between the two restriction sites. *Eco*RI cuts between the guanosine (G) and adenosine (A) nucleotides, as shown by the arrows.

(b) As a result of *Eco*RI activity, the plasmid has been linearized, and both types of molecule now have 'sticky ends', i.e. terminal, single-stranded complementary sequences of nucleotides (5'-AATT).

(c) The foreign DNA has integrated with the plasmid vector molecule through base-pairing between complementary nucleotides in the sticky ends.

(d) An enzyme, DNA ligase, has catalysed a phosphodiester bond between the sugar residues of each G and A nucleotide, forming a hybrid plasmid (recombinant plasmid; also referred to as hybrid DNA, or hDNA). Note that, unless prevented, at least some of the vector molecules may simply re-circularize by base-pairing between their sticky ends; such re-circularization, which would reduce the efficiency of the procedure, may be prevented by treating the linearized plasmids with phosphatase (see entry).

A population of hybrid plasmids can be inserted into bacteria by transformation or electroporation for cloning. Note that, if required, the (cloned) fragment can be cut from the vector by using the same restriction enzyme.

Reproduced from *Bacteria* 5th edition, Figure 8.6, page 182, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

plated on a medium containing the relevant antibiotic, only the plasmid-containing cells (which are resistant to the antibiotic) will form colonies.

Some vectors are particularly useful in that, following transformation, they can signal the uptake of both vector and DNA insert. For example, in plasmid pBR322 (see pBR322), the tetracycline-resistance gene contains a *Bam*HI restriction site, and the ampicillin-resistance gene contains a *Pst*I restriction site; if, for example, *Pst*I is used to insert the gene (analogous to *Eco*RI in the figure), then any transformant which is (i) sensitive to ampicillin but (ii) resistant to tetracycline may be presumed to contain the complete hybrid plasmid.

A different approach to selection is provided by REPRESSOR TITRATION.

If a plasmid vector replicates under *relaxed* control (see PLASMID), the number of plasmids per cell can be greatly increased by treating the cells with chloramphenicol; in this way, the yield of cloned product can be maximized.

*Cloning with phage vectors in bacteria.*

In some phages (e.g. BACTERIOPHAGE LAMBDA) the genome contains a fairly high proportion of 'non-essential' DNA; thus, a sequence may be excised from the genome, using restriction endonucleases, and replaced by the fragment to be cloned. Such a vector is called a REPLACEMENT VECTOR; using the genome of phage lambda as a replacement vector it is possible to clone a fragment of about 20 kb (compared with <10 kb in plasmid pBR322). Even larger fragments, up to ~40 kb, can be cloned in a COSMID.

Phage genomes can be used as vectors only if the recombinant genome (i.e. genome plus insert or fragment) is not too large to fit into the phage head, and only if it contains, where necessary, the appropriate packaging signals.

Once incorporated into a phage particle, the recombinant genome can be injected into bacterial cells and will replicate like a plasmid. (Note that, during construction of a phage vector, any sequences in the phage genome that promote integration into the bacterial chromosome should be removed.)

ssDNA phages may also be used as vectors; filamentous phages have the advantage that their virions can accommodate a wide range of sizes of target DNA. Another option for cloning is a hybrid vector which includes sequences from a phage and a plasmid: see PHAGEMID.

*Characterization of clones.*

Sometimes, clones are prepared from a mixture of DNA fragments or from a LIBRARY, i.e. different cells within the culture will contain vectors that incorporate different fragments of DNA. In such cases one can screen for cells that contain a particular gene or sequence. Screening methods include: COMPLEMENTATION analysis (in which cells are selected when their particular fragment of cloned DNA complements a given chromosomal defect); probing for a specific gene product (e.g. by using labelled antibodies); or hybridization techniques (see e.g. COLONY HYBRIDIZATION).

*Linguistic note.*

The above account of cloning should make it clear that a gene (or other sequence) is *inserted into* a vector, and that a vector (and its insert) is *cloned in* a population of cells. Unfortunately, the expression '*cloned into*...' has become widely used in the literature; this piece of gibberish has been promulgated by mindless repetition. A given sequence of DNA may be cloned *in* a particular vector molecule or cloned *in* a particular type of cell.

**Clostrithrix** A genus of IRON BACTERIA which occur as sheathed, tapering filaments. Type species: *C. fusca*.

**clorobiocin** An ANTIBIOTIC, obtained from *Streptomyces* spp, closely related to NOVIOBIOCIN and COUMERMYCINS – which it resembles in its action.

**closed complex** See TRANSCRIPTION.

**closed culture** *Syn.* BATCH CULTURE.

**closed mitosis** See MITOSIS.

**Closterium** A large, morphologically diverse genus of placoderm DESMIDS. The cells are commonly more or less crescent-shaped; the cell is not constricted (i.e. there is no sinus), but the semicells are separated by a median suture line.

**closteroviruses** (beet yellows virus group) A group of PLANT VIRUSES in which the virions are highly flexuous filaments, typically 1200–2000 × 12 nm (some possible members are ca. 600–800 × 12 nm) containing one type of coat protein and one molecule of linear positive-sense ssRNA (MWt ca. 2.2–4.7 × 10<sup>6</sup>). In general, the viruses have a fairly wide host range, and some are important pathogens of crop plants. At least some members are transmitted semipersistently by aphids; mechanical transmission can be achieved, often with difficulty, under experimental conditions. In the host plant the virions often aggregate in cross-banded masses in phloem cells.

Type member: SUGAR BEET YELLOW VIRUS (SBYV). Other members include e.g. beet yellow stunt virus, burdock yellows virus, carnation necrotic fleck virus, carrot yellow leaf virus, CITRUS TRISTEZA VIRUS, clover yellows virus, *Festuca* necrosis virus, wheat yellow leaf virus. Possible members include e.g. apple chlorotic leafspot virus, apple stem grooving virus, and POTATO VIRUS T.

**Clostridium** A genus of ENDOSPORE-forming, chemoorganotrophic, obligately anaerobic (or, in a few cases, aerotolerant) bacteria which cannot carry out dissimilatory sulphate reduction (cf. DESULFOTOMACULUM). Species occur widely e.g. in soil and mud, and in the intestines of man and other animals; some species are saprotrophic, others are opportunistic pathogens. Cells: typically rod-shaped, ca. 0.3–1.9 × 2–10 μm, but may vary from coccoid to filamentous or (in *C. cocleatum* and *C. spiroforme*) helical; the Gram reaction is typically positive (though it may become negative in old cultures) but some species (e.g. *C. clostridiiforme*, *C. ramosum*) are commonly Gram-negative even in overnight cultures. Most species are peritrichously flagellate; some (e.g. *C. innocuum*, *C. perfringens*, *C. ramosum*) are non-motile. The endospores are usually spherical to ovoid/elongate; they typically distend the sporangium, and may be located terminally or subterminally. Except in rare cases, clostridia are catalase-negative.

Many species grow poorly on basal media and require e.g. *p*-aminobenzoic acid (PABA), biotin and/or pantothenate. Media used for the culture of clostridia include e.g. blood agar, cooked meat medium, and egg-yolk agar. (See also MCCLUNG TOABE EGG-YOLK AGAR and REINFORCED CLOSTRIDIAL MEDIUM.) SWARMING is common in some strains. Metabolism is generally described as 'fermentative'; however, some strains (e.g. of *C. perfringens*) are capable of NITRATE RESPIRATION. (See also STICKLAND REACTION.) The growth of *saccharolytic* clostridia is improved by, or is dependent on, the presence of a fermentable carbohydrate; most saccharolytic species form acetic acid and/or butyric acid as a major product (see also BUTYRIC ACID FERMENTATION), although some form, instead, products such as formic and lactic acids and/or ethanol. [Genetics and biochemistry of *Clostridium* relevant to fermentations: AAM (1986) 31 1–60.] The *proteolytic* clostridia digest cooked meat, casein and/or other protein, and generally grow well in e.g. nutrient broth without the addition of carbohydrate; at least some of these species can derive

## Clostridium

energy by the STICKLAND REACTION, and in some species this is the preferred mode of energy metabolism. Certain species (e.g. *C. perfringens*, *C. sordellii*) are both proteolytic and saccharolytic, while others are restricted to specific substrates (see e.g. *C. cochlearium*, *C. cylindrosporium* and *C. kluyveri*). Some species can reduce nitrate. Some clostridia are thermophilic, others are psychrophilic, but most are mesophilic. GC% range for the genus: ca. 22–55. Type species: *C. butyricum*.

Currently, >80 species (some listed below) – but see end of entry.

*C. acetium*. Saccharolytic; diazotrophic; acetic acid is formed from CO<sub>2</sub> and H<sub>2</sub>. (See also ANAEROBIC DIGESTION.)

*C. acetobutylicum*. Proteolytic and saccharolytic; growth requirements appear to include PABA and biotin. (See also ACETONE–BUTANOL FERMENTATION.)

*C. acidurici*. A species metabolically similar to *C. cylindrosporium* (q.v.)

*C. barati*. Incorporates the former species *C. perenne* and *C. parapreperfringens* [IJSB (1982) 32 77–81]. (See also BOTULINUM TOXIN.) LIPASE –ve, LECTHINASE +ve.

*C. barkeri*. Saccharolytic; butyric and lactic acids, CO<sub>2</sub> and H<sub>2</sub> are formed from carbohydrates.

*C. beijerinckii*. Saccharolytic; butyric and acetic acids and butanol are formed from glucose.

*C. bifementans*. Proteolytic and saccharolytic; requires e.g. biotin, nicotinamide, pantothenate, pyridoxine and various amino acids. Spores: ovoid, subterminal. Indole-positive. The organisms form a lecithinase similar to the  $\alpha$ -toxin of *C. perfringens*.

*C. botulinum*. The causal agent of BOTULISM (see also BOTULINUM TOXIN). Cells: motile, ca. 0.3–1.9  $\times$  3.4–9.4  $\mu$ m; spores: ovoid, subterminal. All strains can ferment glucose (none can use lactose, mannitol or sucrose), and all form metabolic products which include acetic and butyric acids. All strains can hydrolyse gelatin and produce lipases. The organisms are divided into seven types (designated A, B, C, D, E, F and G), strains of a given type producing a BOTULINUM TOXIN which is antigenically distinct from those of the other types; in some cases the strains of a given type are metabolically heterogeneous: e.g., type B strains include some which are saccharolytic as well as some which are both proteolytic and saccharolytic. Minimum growth temperatures: often ca. 10°C, but ca. 3.3° in saccharolytic type B strains and in type E strains. Minimum pH for growth is sometimes reported to be ca. 4.6 for types A and B, and ca. 5.0 for type E; under certain conditions growth and toxin formation may occur at pH values down to ca. 4.0 [Nature (1979) 281 398–399]. The heat-resistance of endospores is strain-dependent; thus, e.g., for types A and B the D<sub>112.8</sub> (see D VALUE) is ca. 0.15–1.32 min, for type C the D<sub>100</sub> is ca. 0.12 min (terrestrial strains) or ca. 0.4–0.9 min (marine strains), and for type E the D<sub>80</sub> is ca. 0.33–3.3 min (in media) or ca. 1.6–4.3 min (in fish) [Book ref. 30, p. 327].

*C. botulinum* type A strains are proteolytic and saccharolytic; they cause botulism in man and other animals (see also LIMBERNECK).

*C. botulinum* type B strains are either saccharolytic or proteolytic and saccharolytic; they cause botulism in man and other animals.

*C. botulinum* type C strains are proteolytic and saccharolytic; they cause botulism in animals: see e.g. FORAGE POISONING, MIDLAND CATTLE DISEASE, WESTERN DUCK DISEASE.

*C. botulinum* type D strains are proteolytic and saccharolytic; they cause botulism in animals (see LAMZIEKTE).

*C. botulinum* type E strains are saccharolytic; they are often associated with fish and fish products, and they cause botulism

in man. [Effect of oxygen and REDOX POTENTIAL on growth of *C. botulinum* type E: Food Mic. (1984) 1 277–287.]

*C. botulinum* type F strains are saccharolytic, or proteolytic and saccharolytic. A comparatively rare cause of botulism in man.

*C. botulinum* type G strains are either proteolytic or neither proteolytic nor saccharolytic; they have been isolated e.g. from autopsy material.

Strains of *C. botulinum* are also divided into three metabolic groups. Group I includes proteolytic strains of types A, B, F and G. Group II includes all strains of types C and D. Group III includes non-proteolytic strains of types B, E and F.

*C. butyricum*. Saccharolytic, requiring biotin for growth. Ferments many carbohydrates, including starch, producing acetic and butyric acids, CO<sub>2</sub> and H<sub>2</sub>. Gelatin is not hydrolysed. No extracellular lecithinases or lipases are formed. Cells: motile. Spores: ovoid, subterminal.

*C. cadaveris*. Saccharolytic, acetogenic; some strains are also proteolytic. Indole-positive. Spores: ovoid, terminal.

*C. carnis*. Saccharolytic; aerotolerant.

*C. cellulolyticum*. Cellulolytic; mesophilic; isolated from decayed grass. Spores: spherical, terminal. [IJSB (1984) 34 155–159.]

*C. chauvoei*. Saccharolytic, forming acetic and butyric acids; some strains hydrolyse gelatin. Spores: ovoid, subterminal. Toxins: e.g.  $\alpha$ -toxin (dermonecrotizing, haemolytic);  $\beta$ -toxin (DNase);  $\gamma$ -toxin (hyaluronidase);  $\delta$ -toxin (a THIOL-ACTIVATED CYTOLYSIN). (See also BLACKLEG and MALIGNANT OEDEMA.)

*C. clostridiiforme*. Saccharolytic, forming acetic and lactic (but not butyric) acids, CO<sub>2</sub> and H<sub>2</sub>. Some strains form indole. Cells typically stain Gram-negatively; spores (ovoid, subterminal) are seldom formed.

*C. cochlearium*. Non-saccharolytic; glutamate, glutamine or histidine are metabolized to acetic and butyric acids, CO<sub>2</sub> and H<sub>2</sub>.

*C. cocleatum*. Saccharolytic; carbohydrates are fermented to acetic (but not butyric) acid. Cells: helical.

*C. colinum*. See QUAIL DISEASE.

*C. cylindrosporium*. Substrates include xanthine and other purines, but not sugars or amino acids; metabolic products include acetic and formic acids and glycine.

*C. difficile*. Saccharolytic; ferments glucose or mannitol, forming e.g. acetic, butyric, isobutyric and isocaproic acids. Indole-negative. No extracellular lecithinases or lipases are formed. Some strains hydrolyse gelatin. Cells: Gram-positive or Gram-variable; on cycloserine–cefoxitin–egg–yolk–fructose agar (used for primary isolation from faeces) colonies exhibit a yellow-green fluorescence under light of wavelength 360 nm. Some strains are non-motile. Ovoid spores are formed subterminally; spores are reported to occur at both ends of the rod to give a ‘dumb-bell’ appearance [Book ref. 107, pp. 327–346]. Toxinogenic strains can cause COLITIS and PSEUDOMEMBRANOUS COLITIS. [PCR ribotyping of *C. difficile* in hospitals in England and Wales: RMM (1997) 8 (supplement 1) S55–S56.]

*C. histolyticum*. Proteolytic; gelatin is hydrolysed, and milk is digested. Indole-negative. Some strains can grow aerobically on blood-agar plates. Spores: ovoid, subterminal. Toxins include the  $\alpha$ -toxin (dermonecrotizing);  $\beta$ -toxin (collagenase);  $\delta$ -toxin (a non-thiol-activated ELASTASE); and  $\epsilon$ -toxin (a THIOL-ACTIVATED CYTOLYSIN). (See also CLOSTRIPAIN.)

*C. innocuum*. Saccharolytic; ferments glucose, mannitol and salicin (and sucrose in some strains), forming acetic and butyric acids. Cells non-motile. Spores: ovoid, terminal.

*C. kluyveri*. Non-saccharolytic, non-proteolytic; a mixture of ethanol, acetic acid and bicarbonate is metabolized to butyric and caproic acids and H<sub>2</sub>. Biotin and PABA are required for growth.

*C. limosum*. Proteolytic; gelatin is hydrolysed, and milk is digested. An extracellular lecithinase is formed. Spores: ovoid, subterminal.

*C. nigrificans*. See DESULFOTOMACULUM.

*C. novyi* (= *C. oedematiens*). Proteolytic and saccharolytic. Types A, B, C and D are distinguished on the basis of the toxins they produce; types A and B are involved in human diseases (see e.g. GAS GANGRENE). (See also BLACK DISEASE and MALIGNANT OEDEMA.) Both A and B types ferment glucose, hydrolyse gelatin, and form the dermonecrotizing  $\alpha$ -toxin. Type A also forms the  $\gamma$ -toxin (a phospholipase C) and  $\epsilon$ -toxin (a lipase), and type B forms the  $\beta$ -toxin (a lethal dermonecrotizing phospholipase C), the  $\zeta$ -toxin (a haemolysin), and the  $\eta$ -toxin (a tropomyosinase). Type D forms e.g. the  $\beta$ - and  $\eta$ -toxins. Some strains are non-motile. Spores: ovoid, subterminal.

*C. oedematiens*. See *C. novyi*.

*C. paraputrificans*. See *C. barati*.

*C. paraputrificum*. Saccharolytic; ferments glucose, lactose, maltose or salicin, forming acetic and butyric acids. Spores: ovoid, terminal.

*C. pasteurianum*. Saccharolytic; many carbohydrates are fermented to acetic and butyric acids, CO<sub>2</sub> and H<sub>2</sub>. Requires e.g. PABA and biotin. Diazotrophic (see NITROGEN FIXATION).

*C. perenne*. See *C. barati*.

*C. perfringens* (formerly *C. welchii*). Proteolytic and saccharolytic; gelatin is hydrolysed, milk is digested, and glucose, maltose, lactose and sucrose are fermented to acetic and butyric acids. Some strains can use nitrate as electron acceptor with consequent increase in growth yield and the production of acetic rather than butyric acid. Indole-negative. Cells non-motile; on blood agar (made with human, rabbit or sheep blood) the colonies of haemolytic strains are each surrounded by a double zone of haemolysis: an inner zone of complete haemolysis, and an outer zone of incomplete haemolysis. Spores: ovoid, subterminal, but rarely formed; the spores have been reported to have a D VALUE (D<sub>90</sub>) of 15–145 min for non-haemolytic strains, and 6–7 min for haemolytic strains [Book ref. 30, p. 327]. Strains of *C. perfringens* collectively form a range of toxins which include: the  $\alpha$ -toxin (PHOSPHOLIPASE C: a LECITHINASE; see also HOT-COLD LYSIS); the  $\beta$ -,  $\epsilon$ - and  $\iota$ -toxins (all dermonecrotizing toxins); the  $\delta$ -toxin (a lethal, haemolytic toxin); the  $\gamma$ - and  $\eta$ -toxins (both lethal, non-haemolytic toxins); the  $\theta$ -toxin (a THIOL-ACTIVATED CYTOLYSIN: see also STREPTOLYSIN O); the  $\mu$ -toxin (a HYALURONATE LYASE); the  $\kappa$ -toxin (a COLLAGENASE). On the basis of toxin production, strains of *C. perfringens* are divided into five types, designated A, B, C, D and E:

*C. perfringens* type A strains form the  $\alpha$ -toxin; they are the commonest cause of clostridial FOOD POISONING, are often present in the lesions of GAS GANGRENE, and can cause haemorrhagic enteritis in young piglets.

*C. perfringens* type B strains form the  $\alpha$ -,  $\beta$ - and  $\epsilon$ -toxins, and cause e.g. LAMB DYSENTERY.

*C. perfringens* type C strains form the  $\alpha$ - and  $\beta$ -toxins, and cause e.g. ENTERITIS NECROTICANS in man, STRUCK in sheep, and a fatal necrotic and haemorrhagic enteritis in young piglets.

*C. perfringens* type D strains form the  $\alpha$ - and  $\epsilon$ -toxins, and cause e.g. PULPY KIDNEY in ruminants.

*C. perfringens* type E strains form the  $\alpha$ - and  $\iota$ -toxins; they are associated with diseases in ruminants.

*C. propionicum*. See PROPIONIC ACID FERMENTATION.

*C. ramosum* (formerly e.g. *Ramibacterium ramosum*). Saccharolytic; ferments glucose, maltose, lactose, sucrose and salicin, forming acetic acid as a main product. Cells frequently stain Gram-negatively and are non-motile; spores: spherical to ovoid, terminal, but seldom observed.

*C. septicum*. Proteolytic and saccharolytic; glucose, maltose, lactose and salicin are fermented with the formation of acetic and butyric acids, and gelatin is hydrolysed. Spores: ovoid, subterminal. Toxins formed:  $\alpha$ -toxin (dermonecrotizing, haemolytic),  $\beta$ -toxin (a DNase),  $\gamma$ -toxin (a hyaluronidase) and  $\delta$ -toxin (a THIOL-ACTIVATED CYTOLYSIN). A causal agent in GAS GANGRENE and in BRAXY and MALIGNANT OEDEMA. (See also NEUTROPENIC ENTEROCOLITIS.)

*C. sordellii*. Proteolytic and saccharolytic; glucose and maltose are fermented to e.g. acetic acid. Gelatin is hydrolysed, and milk is digested. Indole-positive. Urease-positive. Some strains form a lecithinase ( $\alpha$ -toxin) and e.g. a THIOL-ACTIVATED CYTOLYSIN. [Taxonomy of lecithinase-negative strains: JGM (1985) 131 1697–1703.] Spores: ovoid, subterminal. (See also MALIGNANT OEDEMA.)

*C. sphenoides*. Saccharolytic; glucose, maltose, salicin and mannitol are fermented to e.g. acetic acid. Reported to be capable of growth on citrate. Some strains hydrolyse gelatin and some produce indole. Cells typically stain Gram-negatively. Spores: spherical, subterminal to terminal.

*C. spiroforme*. Saccharolytic; carbohydrates are fermented to acetic (not butyric) acid. Cells: helical.

*C. sporogenes*. Proteolytic and saccharolytic; glucose and maltose are fermented to e.g. acetic and butyric acids. Gelatin is hydrolysed, and milk is digested. Spores: ovoid, subterminal.

*C. subterminale*. Proteolytic; gelatin is hydrolysed, and milk is digested. Lysine is fermented to e.g. acetic and butyric acids. Spores: ovoid, subterminal.

*C. tertium*. Saccharolytic; glucose, maltose, lactose, sucrose, salicin and mannitol are fermented to acetic and butyric acids. Spores: ovoid, terminal. Growth occurs aerobically on blood agar.

*C. tetani*. The causal agent of TETANUS. (See also TETANOSPASMIN and THIOL-ACTIVATED CYTOLYSIN.) Proteolytic; gelatin is hydrolysed, and acetic and butyric acids are formed from the fermentation of peptones. No carbohydrates – not even glucose – are fermented. Some strains form indole. Spores: spherical and terminal.

*C. thermoaceticum*. See ACETOGENESIS.

*C. thermocellum*. Saccharolytic; cellobiose, CELLULOSE and hemicellulosic materials are degraded and fermented, the main products being ethanol, acetic acid, CO<sub>2</sub>, and H<sub>2</sub>. (See also CELLULASES and CELLULOSOME.) [Regulation of cellulase formation: JGM (1985) 131 2303–2308.] Pentoses are apparently not utilized. Optimum growth temperature: 55–60°C.

*C. thermolacticum*. Saccharolytic; thermophilic. A wide range of carbohydrates (including xylan) can be fermented, the main product being L(+)-lactate. Some strains are cellulolytic. [SAAM (1985) 6 196–202.]

*C. thermosaccharolyticum*. Saccharolytic; many carbohydrates (including e.g. GLYCOGEN, PECTINS and STARCH) are fermented to e.g. acetic, butyric and lactic acids, CO<sub>2</sub>, and H<sub>2</sub>. Optimum growth temperature: 55–60°C. Spores may have a D VALUE of ca. D<sub>120</sub> = 4 min; the organisms are sometimes responsible for hard SWELL spoilage of canned foods. (See also CANNING.)

*C. thermosulfurogenes*. Saccharolytic. Cells are peritrichous, Gram –ve; filaments may occur. Spores: spherical. Opt. growth

## clostripain

at >60°C. In microbial mats from hot volcanic springs. [JGM (1983) 129 1149.]

*C. villosum*. Isolated from subcutaneous abscesses in cats [IJSB (1979) 29 241–244].

*C. welchii*. See *C. perfringens*.

Other species include e.g. *C. aurantibutyricum*, *C. celatum*, *C. cellobioparum*, *C. coccoides*, *C. durum*, *C. fallax*, *C. felsineum*, *C. formicoaceticum*, *C. glycolicum*, *C. haemolyticum*, *C. indolis*, *C. lituseburense*, *C. oceanicum*, *C. putrefaciens*, *C. putrificum*, and *C. sticklandii*.

The genus *Clostridium* is heterogeneous, and proposals for rationalization have included the creation of a number of new genera (*Caloramator*, *Filifactor*, *Moorella*, *Oxobacter* and *Oxalophagus*) [IJSB (1994) 44 812–826].

**clostripain** A thiol PROTEASE (MWt ca. 50000; EC 3.4.22.8), obtained from *Clostridium histolyticum*, which acts specifically at basic amino acyl (arginyl, lysyl) residues. It also has amidase and esterase activity, cleaving amides and esters of amino acids.

**clot culture** BLOOD CULTURE in which clotted blood, minus serum, is liquefied (e.g. with STREPTOKINASE) and the resulting fluid used as the inoculum. Apparently not widely used – due e.g. to the risk of contamination prior to the inoculation stage.

**clotrimazole** (bis-phenyl-(2-chlorophenyl)-1-imidazole methane) One of the earliest of the clinically useful imidazole antifungal agents (see AZOLE ANTIFUNGAL AGENTS); it is used topically in the treatment of superficial mycoses (e.g. candidiasis, ringworm, pityriasis versicolor).

**clotting** (of blood plasma) See FIBRIN; COAGULASE; ANTICOAGULANT.

**clover blackpatch disease** See SLAFRAMINE.

**clover rot** (clover sickness; sclerotinia crown and stem rot, SCSR)

A disease of clover and other forage legumes caused by *Sclerotinia* spp (particularly *S. trifoliorum*). Leaves and petioles of infected plants turn olive-brown and subsequently rot; the disease progresses from the petioles to the stem and root, leading to the death of the plant. Control by repeated applications of e.g. benomyl or quintozene is effective but economically impracticable. [Review: Bot. Rev. (1984) 50 491–504.]

**clover wound tumour virus** *Syn.* WOUND TUMOUR VIRUS.

**clover yellow mosaic virus** See POTEVIRUSES.

**clover yellows virus** See CLOSTEROVIRUSES.

**cloverleaf structure** (of IRNA) See TRNA.

**cloxacillin** See PENICILLINS.

**club fungi** See APHYLLOPHORALES (Clavariaceae).

**clubroot** A disease of cruciferous plants (cabbages, cauliflowers, turnips etc) caused by *Plasmodiophora brassicae* (see PLASMODIOPHOROMYCETES). The roots of an infected plant become swollen and distorted, developing a single large gall (the 'club' symptom) or clusters of smaller galls ('finger-and-toe disease'). The aerial parts of the plant may be stunted and may wilt in hot weather; the foliage often acquires a reddish tinge. Secondary infection of the galls by SOFT ROT bacteria commonly occurs.

*P. brassicae* causes both hyperplasia and hypertrophy of infected tissues, apparently by inducing hyperauxiny (see AUXINS). Healthy plant tissue normally contains, in separate compartments, an indole compound, *glucobrassicin*, and an enzyme (*glucosinolase*) which hydrolyses glucobrassicin to indoleacetonitrile (IAN), a precursor of indoleacetic acid (IAA). *P. brassicae* apparently interferes with the compartmentalization of glucobrassicin and glucosinolase, resulting in increased levels of IAN (and hence IAA) in infected tissues.

The cysts of *P. brassicae* can remain viable for years in the soil, and it is difficult to eradicate the disease from contaminated

land. Soil 'sterilants' such as dazomet may reduce the numbers of cysts. The disease can be controlled to some extent by dipping the roots of plants into a suspension of calomel, thiophanate-methyl or benomyl before planting.

**clue cells** See BACTERIAL VAGINOSIS.

**clumping factor** See COAGULASE.

**clumping-inducing agent** See PHEROMONE.

**cluster cup** See UREDINIOMYCETES stage I.

**cluster gene** A gene encoding a multifunctional protein. (cf. GENE CLUSTER.)

**cluster of differentiation** See CELL ADHESION MOLECULE.

**CLV** Cassava latent virus (see GEMINIVIRUSES).

**cM** CENTIMORGAN.

**CM** COMPLETE MEDIUM.

**CM-cellulose** (carboxymethylcellulose; CMC) A soluble derivative of CELLULOSE which is readily hydrolysed by most or all cellulolytic organisms. It is used e.g. to determine the ability of an organism or enzyme to degrade non-crystalline cellulose; end-product formation or changes in the viscosity of CMC solutions may be measured. (cf. AVICEL; HE-CELLULOSE; FP-CELLULOSE.)

**CM test** CALIFORNIA MASTITIS TEST.

**CMC** (1) CM-CELLULOSE. (2) Chronic mucocutaneous CANDIDIASIS.

**CMI** (1) CELL-MEDIATED IMMUNITY. (2) Commonwealth Mycological Institute, Kew, Surrey, UK.

**CML** Chronic myelogenous leukaemia (see ABL).

**CMT** CALIFORNIA MASTITIS TEST.

**CMV** Cytomegalovirus (see BETAHERPESVIRINAE).

**CNA** CALCIUM NUTRIENT AGAR.

**cnidosporans** A group of protozoa formerly of the subphylum Cnidospora [JP (1964) 11 7–20], currently included in the phyla MICROSPORA and MYXOZOA.

**CNS** (1) Central nervous system. (2) Coagulase-negative staphylococci.

**CO** See CARBON MONOXIDE.

<sup>60</sup>Co See IONIZING RADIATION.

**CO dehydrogenase** A name used (confusingly) for (i) an enzyme which reduces carbon dioxide to carbon monoxide (see e.g. ACETOGENESIS), and (ii) an enzyme (cf. CO OXIDASE) which oxidizes carbon monoxide to carbon dioxide (see e.g. CARBOXYDOBACTERIA, METHANOGENESIS).

**CO dehydrogenase disulphide reductase** See ACETOGENESIS.

**CO difference spectrum** (of a cytochrome) The absorption spectrum of a given reduced, CARBON MONOXIDE-complexed CYTOCHROME *minus* the absorption spectrum of the same reduced, but non-complexed, cytochrome.

**CO oxidase** (CO:acceptor oxidoreductase) An inducible enzyme which occurs in CARBOXYDOBACTERIA; it catalyses the oxidation of carbon monoxide to carbon dioxide in a reaction in which oxygen is derived from water rather than from air:

In at least some carboxydobacteria the enzyme contains a non-covalently bound molybdenopterin moiety. [Properties of CO oxidases: MS (1986) 3 149–153.]

**CO<sub>2</sub>** See CARBON DIOXIDE.

**CO<sub>2</sub>-stat** See CONTINUOUS CULTURE.

**CoA** COENZYME A.

**coa gene** See STAPHYLOCOCCUS (*S. aureus*).

**Coactin** *Syn.* MECILLINAM.

**co-activator** See OPERON.

**co-agglutination** (1) See PROTEIN A. (2) Joint agglutination (analogous to CO-PRECIPIATION). (3) Agglutination of different strains

or species of microorganism by a given antiserum (see e.g. WEIL-FELIX TEST).

**coaggregation** Cell-to-cell adhesion in which the cells of one species adhere more or less specifically to those of a different species; e.g. *Actinomyces viscosus* and *Streptococcus sanguis* coaggregate by LECTIN-carbohydrate interaction [JGM (1984) 130 1351–1357].

**coagulase** Any bacterial component or product which causes coagulation (clotting) OF PARACOAGULATION IN PLASMA containing an anticoagulant such as citrate, heparin or oxalate. Coagulases are produced e.g. by certain staphylococci and by *Yersinia pestis*.

*Staphylococci* produce two structurally and functionally distinct types of coagulase: *free coagulase* (*staphylocoagulase*, a protein which is released into the medium) and *bound coagulase* (*clumping factor*, a protein component of the cell wall). *Staphylocoagulase* causes a true clotting of plasma (from certain species only); it interacts with a 'coagulase reacting factor', CRF, in the plasma (believed to be prothrombin or a form of it) to form a complex ('staphylothrombin') which acts on plasma fibrinogen, converting it into insoluble fibrin – apparently by limited proteolytic action similar or identical to that of normal thrombin. The resulting clot differs from a normal clot in that e.g. it is not stabilized by Factor XIII (a normal blood-clotting factor) and it is much more resistant to fibrinolysin than is a normal clot. Several antigenically distinct staphylocoagulases are produced by different staphylococcal strains. The property of staphylocoagulase production is often used to distinguish between pathogenic and non-pathogenic strains, since there is a high degree of correlation between staphylocoagulase production and virulence (although coagulase-negative staphylococci are not necessarily harmless). However, although it can apparently exert its effect freely in vivo, the role of staphylocoagulase – if any – in pathogenesis is unknown. In vitro, the activity of staphylocoagulase is inhibited by various chemicals, particularly oxidizing agents, and by certain antibiotics (e.g. some penicillins).

Staphylococcal *clumping factor* does not form a true clot in plasma; rather, it induces clumping of the cells (*para-coagulation*) in the presence of fibrinogen. When mixed with plasma, cells with clumping factor bind fibrinogen near the C-terminal ends of its  $\gamma$ -chains – this apparently being responsible for the clumping of the cells [Biochem. (1982) 21 1407–1413, 1414–1420]. The role of clumping factor in pathogenesis (if any) is unknown. (cf. CCFAS.) [Isolation of clumping factor from *S. aureus*: Inf. Immun. (1985) 49 700–708.]

Staphylocoagulase and clumping factor may be detected by different forms of the COAGULASE TEST.

[Review of staphylococcal coagulases: Book ref. 44, pp. 525–557.]

**coagulase test** Any procedure used to determine whether or not a given bacterial strain produces a COAGULASE. The tests described below are used for staphylococci.

The *tube test* (which detects *staphylocoagulase*) simply involves incubating the test organism with a suitable plasma sample. In one of many methods, 0.5–1.0 ml of plasma is mixed with an equal (or smaller) volume of an 18–24-hour broth culture of the organism, and the tube is incubated at 35–37°C; the tube is examined at hourly intervals, and after overnight incubation, for clot formation – a firm clot which does not move when the tube is shaken being regarded as a positive result [Book ref. 44, pp. 526–527]. Known coagulase-positive and coagulase-negative strains should be used as controls. Plasma containing anticoagulants such as citrate, oxalate, EDTA, or heparin may be used, although heparin has been reported to delay clot formation;

any organism tested for coagulase formation should be unable to metabolize the anticoagulant: citrated plasma, for example, may be clotted by coagulase-negative citrate-utilizing bacteria. Preservatives (e.g. thiomersal) may inhibit staphylocoagulase. Purified fibrinogen, or freeze-dried plasma, may be used instead of fresh plasma. Staphylocoagulases from strains pathogenic for man exhibit maximum activity in human or rabbit plasma.

Strains which produce large amounts of fibrinolytic enzymes (see FIBRINOLYSIS) may not form clots, or may lyse any clot formed; such strains are more commonly found among isolates from human infections than among isolates from animals. (See also PSEUDOCOAGULASE.)

The *slide test* detects clumping factor (see COAGULASE). A thick, saline suspension is prepared (on a slide) from a colony of the test strain grown on a non-selective medium; a loopful of citrated or oxalated human or rabbit plasma (not sheep or guinea-pig plasma) is stirred into the suspension. (Fibrinogen may be used instead of plasma e.g. to avoid any antibody-mediated agglutination of the bacteria.) Clumping of cells within ca. 5 sec indicates the presence of clumping factor. (A false-negative result may be obtained with capsulated strains [Book ref. 44, p. 505].) Controls should be used (cf. AUTO-AGGLUTINATION). (See also STAPHYLOSLIDE.)

There is a high, though not total, correlation between positive results in the tube and slide tests; however, a positive slide test should not be regarded as evidence of staphylocoagulase production.

A *plate method* may be used to detect staphylocoagulase-positive organisms. The test organism is inoculated onto the surface of an agar growth medium containing citrated plasma or purified fibrinogen and prothrombin. After overnight incubation, coagulase-positive colonies are each surrounded by a dense zone of precipitated fibrin. This method is useful for estimating numbers of coagulase-positive staphylococci in e.g. foods, but is too slow and prone to misleading results for use in routine clinical diagnosis.

**coal biodegradation** Certain fungi are capable of growing on coal – particularly lignite ('brown coal', a form which is relatively low in carbon and rich in volatile compounds) – as the sole source of nutrients; such fungi include e.g. the basidiomycetes *Polyporus versicolor* and *Poria monticola* [AEM (1982) 44 23–27] and various other species (e.g. *Aspergillus terreus* and species of *Candida*, *Mucor*, *Paecilomyces* and *Penicillium* [SAAM (1985) 6 236–238]). Growth generally appears to be restricted to the surface of the coal; the nature of the substrates utilized is unknown.

Coal *products*, such as benzene and toluene (derived from coal tar), may be degraded e.g. by combinations of bacteria [Nature (1998) 396 730]. [Aerobic and anaerobic degradation of toluene by *Thauera*: AEM (2004) 70 1385–1392.]

(See also LEACHING.)

**CoASH** (CoA-SH) Uncombined COENZYME A.

**coated lens** See BLOOMED LENS.

**coated pit** See PINOCYTOSIS.

**coated vesicle** See PINOCYTOSIS.

**cobalamin** See VITAMIN B<sub>12</sub>.

**cobamide coenzymes** See VITAMIN B<sub>12</sub>.

**cobinamide** See VITAMIN B<sub>12</sub>.

**cobra venom factor** (CVF) Either of the two proteins, derived from cobra venom, which affect the alternative pathway of COMPLEMENT FIXATION. CVFs mimic C3b. CVF from *Naja naja* binds Factor B and promotes its cleavage (by Factor D) to form a C3 convertase; it can also give rise to a C5 convertase. CVF

## cobweb disease

from *Naja haje* can also give rise to a C3 convertase but not to a C5 convertase. Unlike C3b, CVF is not inactivated by Factors I and H; it therefore forms a C3 convertase which is not subject to regulation.

**cobweb disease** A MUSHROOM DISEASE caused by *Hypomyces rosellus*; it can be controlled e.g. by BENOMYL or PROCHLORAZ [PP (1983) 32 123–131].

**cocarboxylase** See THIAMINE.

**coccal** Pertaining to a COCCUS.

**cocci** See COCCUS.

**coccidia** The common name for protozoa of the suborder EIMERIORINA.

**Coccidia** (1) A subclass of protozoa (class Telosporea) later incorporated, with the TOXOPLASMEA, in the subclass COCCIDIASINA. (2) A subclass of protozoa (class Sporozoa [JP (1980) 27 37–58]) equivalent to the COCCIDIASINA.

**Coccidiascus** A genus of yeasts (family METSCHNIKOWIACEAE). Cells: spherical to ovoid (5–15 µm diam./length), with a large vacuole and nucleus; neither pseudomycelium nor mycelium is formed. *C. legeri* (sole species) occurs as a parasite in intestinal epithelial cells of *Drosophila* spp; it has not been cultured in vitro. [Book ref. 100, pp. 123–124.]

**Coccidiiasina** A subclass of protozoa (class SPOROZOASIDA) parasitic mainly in vertebrates but also in invertebrates. In members of this subclass the mature gametocytes typically occur intracellularly in the host (cf. GREGARINASINA). Orders: Agamococcidiorida, EUCOCCIDIORIDA, Protococcidiorida.

**coccidiiasis** Any subclinical or very mild infection with a coccidian parasite – as distinct from clinical COCCIDIOSIS.

**Coccidioides** A genus of fungi (class HYPHOMYCETES); *C. immitis* is a saprotroph in desert soils in hot, arid regions of the American continent, and is the causal agent of COCCIDIOIDOMYCOSIS. In mammalian tissues it occurs mainly as multinucleate, thick-walled, spherical (ca. 20–80 µm) cells (*spherules* or *sporangia*). The spherule protoplasm divides into multinucleate *protospores* and then into uninucleate sporangiospores (*endospores*) which are released on rupture of the spherule wall and develop into new spherules. *C. immitis* grows readily on various types of media, forming a mycelium which fragments into barrel-shaped arthroconidia which are highly infective and very easily dispersed by air currents.

**coccidioidin** Any antigenic preparation derived from *Coccidioides immitis* and used in a diagnostic SKIN TEST for COCCIDIOIDOMYCOSIS.

**coccidioidomycosis** (San Joaquin Valley fever; desert fever) A disease of man and animals caused by *Coccidioides immitis*; it occurs in hot, arid regions of the American continent. Infection usually occurs by inhalation of wind-borne spores (especially arthroconidia); person-to-person transmission does not occur. Infection may be asymptomatic or may result in an acute, self-limiting respiratory disease resembling a common cold or influenza – often with severe chest pain. Rarely, mycetomas ('fungus balls') may develop in the lungs. Less common symptoms include joint pains ('desert rheumatism') and/or skin lesions. The primary infection occasionally leads to progressive, often fatal, disseminated disease (coccidioid granuloma) with lesions in e.g. skin, joints, meninges. *Lab. diagnosis*: serological tests; SKIN TESTS using COCCIDIOIDIN or SPHERULIN; demonstration of the fungus by histology, culture and/or animal inoculation. *Treatment*: ketoconazole, amphotericin B. [Book ref. 25.]

**coccidiosis** Any disease of man and other animals caused by protozoa of the suborder EIMERIORINA. Coccidiosis are typically contracted via the oral route and may involve the intestinal

tract and/or various other tissues; they may be mild to fatal. Coccidiosis of domestic animals and poultry are often of economic importance.

(a) Poultry. In chickens, *Eimeria necatrix* causes severe haemorrhage in the small intestine, and *E. tenella* causes haemorrhage and necrosis in the caecum; other pathogens include e.g. *E. acervulina* and *E. brunetti*. In ducks, *Tyzzzeria pernicioosa* causes haemorrhagic intestinal disease. In turkeys, severe inflammation of the intestine is caused by e.g. *E. adenoides* and *E. meleagriditis*.

(b) Domestic animals. In cattle, haemorrhagic lesions in the intestine are caused e.g. by *E. bovis* and *E. zürnii* (*E. zuernii*); an increased incidence of disease may occur during cold weather ('winter coccidiosis'). In sheep, intestinal disease may be caused e.g. by *E. ahsata*, *E. ovina* or *E. ovinoidalis*. In pigs, enteritis, severe diarrhoea and emaciation are caused e.g. by *E. scabra*. In rabbits, intestinal disease (often fatal) is caused e.g. by *E. magna* and *E. irresidua*; *E. stiedae* (*E. stiedai*) causes diarrhoea, enlargement of the liver and bile ducts, and emaciation. In cats, intestinal symptoms may be due to infection by *Isospora* spp (which may also infect dogs) or *Toxoplasma* (see TOXOPLASMOSIS). (cf. SARCOsporIDIOSIS; see also EQUINE PROTOZOAL MYELOENCEPHALITIS.)

(c) Man. Infections involving *Isospora belli* and *I. hominis* are believed to be commonly asymptomatic, but intestinal symptoms may occur. (See also CRYPTOSporIDIOSIS, SARCOsporIDIOSIS and TOXOPLASMOSIS.)

Diagnosis of animal coccidiosis involves e.g. SPORULATION of oocysts concentrated from fresh faeces.

[Identification of *Eimeria* spp: Book ref. 7, pp. 7–30. Identification of coccidia: Book ref. 18, pp. 80–91. Coccidian pathogenicity: Book ref. 18, pp. 287–327. Pathology, lab. diagnosis, and therapy in cryptosporidiosis, isosporiasis, sarcosporidiosis and toxoplasmosis: Book ref. 118, pp. 211–236.]

**coccidium** An individual, or a particular strain, of an organism of the suborder EIMERIORINA.

**coccobacillus** A bacterial cell intermediate in morphology between a COCCUS and a BACILLUS.

**Coccodiscus** See RADIOLARIA.

**coccolith** More or less spherical: cf. COCCUS.

**coccolith bodies** Thin-walled coccolith forms which develop from the helical or vibrioid cells in old cultures of e.g. *Aquaspirillum*, *Campylobacter* and *Oceanospirillum* spp; their formation is enhanced by treatment with mitomycin or UV light. Coccolith bodies resemble sphaeroplasts but are resistant to osmotic lysis; the majority are apparently viable, 'germinating' to form normal cells when transferred to a fresh medium. (cf. MICROCYST.)

**coccolith** A calcified scale, generally measuring a few micrometres or less in diam., present on the cell surface in certain cells of the COCCOLITHOPHORIDS. Coccoliths contain crystals of calcite – either of a single type (in *holococcolithis*) or, more commonly, of different shapes and sizes (in *heterococcolithis*); coccoliths are often elliptical in shape (but may be round, polygonal, etc) and they commonly exhibit intricate patterns and ornamentations which are species-specific. The coccoliths of present-day coccolithophorids form a significant proportion of some deep-sea oozes; however, coccolithophorids were even more abundant in previous geological ages, particularly in the Cretaceous, and the coccoliths of these organisms are major constituents of Mesozoic (Jurassic and Cretaceous) and Cenozoic chalks and marls. Coccolith morphology apparently changed rapidly over the ages, making fossil coccoliths useful markers in the biostratigraphy of sedimentary rocks [Book ref. 136,

pp. 329–426 (Mesozoic coccoliths), pp. 427–554 (Cenozoic coccoliths)]. (See also FORAMINIFERIDA.)

**coccolithophorids** Those algae of the PRYMNESIOPHYCEAE in which the cell bears a covering of one to several layers of COCCOLITHS during at least some stage of the life cycle. For example, *Emiliana huxleyi* – the commonest living coccolithophorid – has a life cycle in which two distinct types of cell are formed: the motile ‘S cell’, which is biflagellated and covered with one or several layers of organic scales, and the non-motile ‘C cell’, which lacks flagella and organic scales but is enclosed by a shell-like *coccosphere* consisting of one or several layers of coccoliths. Life cycles involving motile and non-motile phases also occur in other genera (e.g. *Coccolithus*, *Cricosphaera*, *Hymenomonas*). Coccolithophorids are planktonic marine organisms which are particularly common in tropical waters.

**Coccolithus** See COCCOLITHOPHORIDS.

**Coccomyces** See RHYTISMATALES.

**Coccomyxa** A genus of unicellular, non-motile green algae (division CHLOROPHYTA) which occur as photobionts in certain lichens (see e.g. NEPHROMA, PELTIGERA, SOLORINA). The cells are small, ovoid, and contain a single parietal chloroplast with no pyrenoid; flagellated stages and sexual reproduction have never been observed. (See also RIBBITOL and SPOROPOLLENIN.)

**Cocconeis** See DIATOMS.

**coccosphere** See COCCOLITHOPHORIDS.

**coccus** (*pl.* cocci) A spherical (or near-spherical) bacterial cell. According to species, cocci may occur singly, in pairs (see DIPLOCOCCUS), in regular groups of four or more (see TETRAD and PACKET), in chains, or in irregular clusters. (cf. BACILLUS *sense* 2.)

**Cochliobolus** See DOTHIDEALES.

**Cochliopodium** A genus of amoebae (order ARCELLINIDA) which have a type of test known as a *tectum*: a more or less flexible, closely adherent covering of small scales (distinguishable only by electron microscopy); in some species the scales bear spines which may be visible by light microscopy, while in others sand grains and other debris may adhere to the scales. Species occur in fresh water, activated sludge, etc. [Book ref. 133, pp. 76–82.]

**Cochlonema** See ZOOPAGALES.

**cocksfoot mottle virus** See SOBEMOVIRUSES.

**cocksfoot streak virus** See POTYVIRUSES.

**cocoa** Cocoa and chocolate are made from the seeds (beans) of the cacao plant *Theobroma cacao*. The cacao fruit is a pod containing up to 50 beans covered by a white mucilage. After harvesting, the pods are opened and the beans are extracted, piled up (e.g. in perforated boxes or on plantain leaves) and covered (e.g. with leaves). A fermentation then occurs: initially, various yeasts carry out an ALCOHOLIC FERMENTATION, and this is rapidly followed by ACETIFICATION by acetic acid bacteria – the production of acetic acid and heat inhibiting further yeast action. Other bacteria (e.g. lactic acid bacteria) and moulds are also present. During the process, which lasts ca. 6 days, the beans darken in colour (owing to oxidation) and the mucilage gradually disappears. The beans are then dried. The characteristic cocoa flavour develops only after the beans are roasted. [Book ref. 5, pp. 275–292.] (cf. COFFEE; see also CACAO DISEASES.)

**cocoa necrosis virus** See NEPOVIRUSES.

**coconut cadang-cadang viroid** (CCCV) A VIROID which infects coconut palms; infected palms may be killed, and the viroid has caused severe economic losses e.g. in the Philippines (cf. TINANGAJA DISEASE). The natural mode of transmission is unknown. CCCV is unique among known viroids in that it exists

as four different RNA species. Two RNAs – designated RNA-1 small or RNA-1 fast (246 nucleotides) and RNA-2 small or RNA-2 fast (492 nucleotides) – occur in infected palms during the early stages of cadang-cadang disease; later, two additional RNAs – RNA-1 large or RNA-1 slow (287 nucleotides) and RNA-2 large or RNA-2 slow (574 nucleotides) – appear and eventually predominate. The RNA-1 small is regarded as the unit CCCV RNA; the other three RNAs are apparently derived from RNA-1 small by sequence duplication. [Nature (1982) 299 316–321.]

**coconut hartrot** See HARTROT.

**coconut lethal yellowing** A YELLOWS disease of the coconut palm caused by an MLO. The disease is controlled, commercially, by the use of oxytetracycline hydrochloride.

**coconut palm rhinoceros beetle** (biological control) See BACULOVIRIDAE.

**co-conversion** (*mol. biol.*) See RECOMBINATION.

**codecarboxylase** See PYRIDOXINE.

**coding strand** A term which (like non-coding strand) is frequently used with opposite meanings by different authors. Originally, the term was generally used to refer to that strand of a gene which acts as the template on which mRNA is synthesized during transcription – the strand whose sequence is *complementary* to that of mRNA. Currently, there appears to be a consensus for the opposite meaning, i.e. that strand of a gene which is *not* transcribed (i.e. not used as a template) and whose sequence is homologous to that of mRNA. (Even so, given the confusion present in the literature, it may be wise to define the term, in relation to mRNA, whenever it is used.) The coding strand is also called the *sense* strand or the *plus* (+) strand.

The non-coding strand of a gene (which is complementary to the coding strand) is thus the template strand; it is also called the *antisense* strand or the *minus* strand.

Interestingly, a certain gene in the fruitfly (*Drosophila*) has been shown to contain protein-encoding information in *both* of the strands [Nature (2001) 409 1000].

**Codium** A genus of siphonaceous green seaweeds (division CHLOROPHYTA). The thallus is terete and dichotomously branched; it is composed of a colourless central medulla of interwoven filaments from which arises a surrounding layer of inflated green branchlets (‘utricles’). Anisogametes are produced in the utricles; these are initially non-motile, later becoming biflagellate. (See also CELL WALL; ELYSIA; NITROGEN FIXATION.)

**codominant gene** One of two (or more) genes which, when present together, specify a phenotype unlike that specified by either (or any) of the genes individually.

**codon** See GENETIC CODE.

**codon bias** In the expression of a heterologous (i.e. ‘foreign’) gene (e.g. a mammalian gene in *Escherichia coli*): inefficient translation due to the presence of certain codon(s) for which the host cell has insufficient numbers of the corresponding tRNA(s); codon bias can be a problem e.g. when high-level expression in *E. coli* is required from a heterologous gene containing a high frequency of codons such as the proline codon CCC and/or the arginine codon AGG – codons which occur rarely in homologous (*E. coli*) genes. Attempts at high-level expression of genes containing relatively high frequencies of codons that are ‘rare’ for the host cell may lead e.g. to slowing or termination of translation and the degradation of mRNA. One solution to the problem is to insert into the host cell extra (plasmid-borne) copies of the relevant tRNA-encoding gene(s).

Codon bias may also arise as a result of a same-sense mutation which replaces a common or ‘routine’ codon with a synonymous but infrequent codon (see SILENT MUTATION).

## Codonella

**Codonella** See TINTINNINA.

**Codonosiga** See CHOANOFAGELLIDA.

**Coe virus** Coxsackievirus A21: see ENTEROVIRUS.

**coelichelin** A tripeptide siderophore, encoded by *Streptomyces coelicolor*, which is synthesized by a non-ribosomal synthetase [see e.g. FEMS (2000) 187 111–114].

**Coelomomyces** See BLASTOCLADIALES.

**Coelomycetes** A class of fungi (subdivision DEUTEROMYCOTINA) which form septate mycelium and in which the conidiophores line a discrete saucer-shaped, cupulate, flask-shaped or loculate conidioma – e.g. an ACERVULUS or a PYCNIDIUM. (cf. HYPHOMYCETES.) Orders [Book ref. 64, pp. 87–88]; MELANCONIALES, PYCNOTHYRIALES and SPHAEROPSIDALES.

**Coeloseira** See RHODOPHYTA.

**Coelosphaerium** A phycological genus of unicellular 'blue-green algae' (Chroococaceae) in which the cells occur in a single layer at the periphery of a spherical colony; the cells are ellipsoidal, divide longitudinally, and contain GAS VACUOLES. The organisms are planktonic e.g. in freshwater lakes. (See CYANOBACTERIA.)

**coelozoic** Refers to a parasite which lives within its host in body fluids – e.g. in the gall bladder, bloodstream (*outside* blood cells), urinary tract, etc. (cf. HISTOZOIC.)

**Coemansia** See KICKXELLALES.

**coenobium** (1) (*bacteriol.*) A MICROCOLONY (sense 1) in which, following cell division, the cells of a clone form a regular array. Thus, e.g. *Thiopedia* typically forms a coenobium which consists of a flat sheet of 16 contiguous cells in a '4 × 4' arrangement – but coenobia containing up to ca. 64 cells may be formed. In *Brachyarcus* the coenobia consist of symmetrically arranged cells embedded in a matrix.

(2) (*algol.*) In certain types of algae: a colonial form which consists of a number of cells arranged in a specific way; the number of cells in a coenobium is usually a stable feature of a given species or genus. Coenobia are formed e.g. by *Scenedesmus* and *Volvox*.

**coenocyte (microbiol.)** A multinucleate cell, structure, or organism, formed by the division of an existing multinucleate entity or by nuclear division without the formation of dividing walls or septa. (cf. SYNCYTIUM.) Coenocytes occur e.g. in SIPHONACEOUS and SIPHONOCLOUDOUS algae; the hyphae of many fungi may be regarded as coenocytic.

**coenzyme** (1) Any low-MWt, non-protein, freely dissociable organic molecule which is necessary for the activity of a given enzyme (cf. PROSTHETIC GROUP); e.g., dehydrogenases require electron acceptors such as NAD<sup>+</sup> or NADP<sup>+</sup>

for catalysis of redox reactions. (2) Any low-MWt, non-protein organic molecule – whether freely dissociable or firmly bound – necessary for the activity of a given enzyme.

**coenzyme F<sub>420</sub>** See METHANOGENESIS.

**coenzyme F<sub>430</sub>** See METHANOGENESIS.

**coenzyme I** NAD (q.v.).

**coenzyme II** NADP: see NAD.

**coenzyme A (CoA)** A coenzyme, derived from PANTOTHENIC ACID (see figure), which functions as a carrier of acyl groups – with which it forms thioesters (CoA.S.CO.R). (Uncombined coenzyme A may be represented as CoA-SH or CoASH.) Acyl-coenzyme A thioesters have a high free energy of hydrolysis and are commonly involved in SUBSTRATE-LEVEL PHOSPHORYLATIONS.

**coenzyme B** See METHANOGENESIS.

**coenzyme B<sub>12</sub>** See VITAMIN B<sub>12</sub>

**coenzyme F** See FOLIC ACID.

**coenzyme M** See METHANOGENESIS.

**coenzyme Q** See QUINONES.

**coenzyme R** *Syn.* BIOTIN.

**cofactor** (1) Any low-MWt, non-protein (organic or inorganic) factor which is necessary for the activity of a given enzyme (cf. COENZYME; PROSTHETIC GROUP). (2) (*Syn.* activator) Any *inorganic* component (e.g. metal ion) necessary for the activity of a given enzyme. (3) Any organic or inorganic factor necessary for the activity of an enzyme or enzyme complex.

**coffee** The commercial preparation of coffee from ripe coffee fruits ('cherries') requires the removal of the sticky mucilaginous mesocarp which surrounds the two beans in each fruit. This may be achieved mechanically or chemically, but the preferred method is by fermentation – which also improves the quality and appearance of the beans. The coffee fruits are pulped to disrupt the skins and then allowed to ferment either under water or 'dry'. The mucilage is degraded both by enzymes in the fruit itself and by microbial extracellular enzymes. (Commercial preparations of mould enzymes have also been used.) Various bacteria, yeasts and moulds are associated with the fermenting coffee, the most important probably being pectinolytic species of e.g. *Bacillus*, *Erwinia*, *Aspergillus*, *Fusarium* and *Penicillium*. After the fermentation, the beans are washed, dried, blended, roasted and ground before use. (cf. COCOA.)

**coffee berry disease** A disease of the coffee plant characterized by sunken, anthracnose lesions on the berries; causal agent: *Colletotrichum coffeanum*. [Review: Phytopathol. Paper number 20, March 1977.]

COENZYME A (CoA-SH)

**coffee diseases** For diseases of the coffee plant (*Coffea* spp) see e.g. COFFEE BERRY DISEASE, COFFEE RUST, FUSARIUM WILT, PHLOEM NECROSIS, RED RUST.

**coffee ringspot virus** See RHABDOVIRIDAE.

**coffee rust** A COFFEE DISEASE caused by *Hemileia vastatrix*. Yellowish spots, which become orange, appear on the undersides of the leaves, corresponding dark patches appearing on the upper surfaces; infected leaves are shed, and yields of berries are greatly reduced.

**cognac** See SPIRITS.

**cognate** In (e.g.) immunology, a word commonly used to mean 'corresponding' or 'matching'.

**cognate help** (linked recognition) (*immunol.*) The binding of a helper T cell to an antigen which is also bound by a B cell; the B and T cells are thus physically linked via the antigen. Such joint binding of antigen is accompanied by contact between various receptors and ligands on the two cells; this leads to activation and proliferation of both types of cell and formation of antibodies by the B cell. (See also ANTIBODY FORMATION.)

The determinant (epitope) bound by the B cell is sometimes referred to as the 'hapten', that bound by the T cell as the 'carrier' – terminology that derives from earlier hapten-carrier studies.

**cohesive ends** *Syn.* STICKY ENDS.

**cointegrate** The (circular) product of fusion between two circular replicons (e.g. two plasmids, or a plasmid and a bacterial chromosome) mediated by a TRANSPOSABLE ELEMENT (TE). Cointegration may occur as a result of a transposition event between a replicon containing a TE and one containing a target sequence for that TE. The transposition is accompanied by duplication of both the TE and a sequence at the target site: see entry TRANSPOSABLE ELEMENT. An alternative mechanism of cointegrate formation involves *recA*-dependent reciprocal recombination between homologous TEs in each of two replicons. (Some authors reserve the term 'cointegration' for the transposition event only.) (See also Tn3.)

(The term 'cointegrate' has also been used for any product of fusion between two replicons, regardless of the mechanism by which fusion occurred.)

**coital exanthema** See EQUINE COITAL EXANTHEMA.

**col factor** See COLICIN PLASMID.

**col plasmid** See COLICIN PLASMID.

**Colacium** A genus of EUGLENOID FLAGELLATES. The organisms differ from other euglenids in that they generally form dendroid or palmelloid colonies; flagellated cells, when formed, resemble those of EUGLENA. *C. libellae* overwinters in association with damselfly nymphs, becoming established in the rectum of the insect.

**colanic acid** A capsular heteropolysaccharide (the 'M antigen') produced e.g. by strains of *Escherichia coli* and *Salmonella*. K12 strains of *E. coli* produce colanic acid and form mucoid colonies at 30°C but not at 37°C; certain mutants (*lon* or *capR*) produce colanic acid and appear mucoid at 37°C.

Colanic acid consists of repeating trisaccharide units of (-glucose-fucose-fucose-), the central fucose residue of each unit carrying a trisaccharide branch (galactose-glucuronic acid-galactose-). Non-carbohydrate substituents (e.g. acetyl and pyruvyl groups) may be present, the nature and position of such groups varying e.g. with strain.

[Organization of the *E. coli* K12 gene cluster responsible for production of colanic acid: JB (1996) 178 4885–4893.]

**Colcemid** (trade name) DEMECOLCINE.

**colchicine** An alkaloid found e.g. in the meadow saffron (*Colchicum autumnale*); the colchicine molecule consists of a tricyclic skeleton which includes an aromatic ring (substituted with three methoxy groups) and a tropolone ring. At low concentrations colchicine can e.g. bind to TUBULIN and prevent the in vitro or in vivo assembly of tubulin into MICROTUBULES; colchicine can thus e.g. inhibit MITOSIS in mammalian, plant, and other cells. (However, some complex microtubular structures – e.g. CENTRIOLES, and the ciliar and flagellar axonemes – are normally resistant to colchicine.) The in vitro effect of colchicine on microtubule assembly can be abolished e.g. by ultraviolet radiation (which converts colchicine to lumicolchicine).

COLCHICINE

**cold** See COMMON COLD.

**cold abscess** See ABSCESS.

**cold agglutinins** Agglutinins which combine maximally with homologous or cross-reacting antigens at low temperatures (e.g. 4°C) but not at e.g. 37°C. Cold agglutinins may be detectable e.g. in the serum of patients suffering from PRIMARY ATYPICAL PNEUMONIA (sense 2), and they can be assayed by their ability to agglutinate human group O RBCs. Cold agglutinins occur also in certain other diseases – e.g. pneumonia caused by adenoviruses.

**cold enrichment** ENRICHMENT of psychrophilic or psychrotrophic organisms by incubation at low temperatures (see e.g. *Yersinia enterocolitica*).

**Cold plasmid** See COLICIN D and COLICIN PLASMID.

**cold shock** See OSMOTIC SHOCK.

**cold-shock response** In prokaryotes and eukaryotes: an apparently adaptive response to a down-shift in temperature (e.g. 37 → 10°C or, in general, a down-shift of at least 13°C) characterized by (i) initial cessation of growth, with resumption after a lag period; (ii) induction or increased synthesis of *cold-shock proteins*; (iii) repression of heat-shock proteins; (iv) generalized inhibition of protein synthesis, but ongoing synthesis of certain proteins involved in transcription and translation.

In *Escherichia coli*, the cold-shock proteins include CspA, RecA, IF-2 (initiation factor 2, which mediates binding of *N*-formylmethionine-charged tRNA to the 30S ribosomal subunit), NusA (involved in the last stage of transcription), and the  $\alpha$ -subunit of DNA gyrase. So far, no cold-inducible sigma factor has been identified.

CspA is a small (70 amino-acid) protein which is inducible immediately (at the level of transcription) on temperature down-shift. It appears to interact with nucleic acids. Suggested functions of CspA include: (i) a low-temperature activator of translation; (ii) an 'RNA chaperone' that inhibits secondary structures in RNA and which may be important e.g. for efficient translation of mRNA at low temperatures [JBC (1997) 272 196–202]; (iii) an agent which inhibits translation from specific mRNAs. (It has been reported that CspA is normally produced

## cold sore

during early exponential growth at 37°C in *E. coli* – i.e. under non-stress conditions [EMBO (1999) 18 1653–1659].)

The cold-shock response can also be triggered by certain inhibitors of translation – for example, the antibiotics chloramphenicol, erythromycin and tetracycline; this has suggested that a decrease in translational capacity may be an important factor in the induction of the cold-shock response [Mol. Microbiol. (1994) 11 811–818].

**cold sore** (fever blister) (1) The lesion associated with labial herpes (see HERPES SIMPLEX). (2) The recurrent thin-walled vesicular mucocutaneous lesion associated with any of the various forms of HERPES SIMPLEX.

**cold stability factor** See MICROTUBULE-ASSOCIATED PROTEINS.

**cold water disease** (peduncle disease; low temperature disease)

A FISH DISEASE affecting young salmonids below 10°C. The tail and peduncle undergo slow progressive necrosis. Causal agent: *Flexibacter psychrophila* ('*Cytophaga psychrophila*').

**ColE1 plasmid** A small (MWt ca.  $4.2 \times 10^6$ ), non-conjugative, ccc dsDNA COLICIN PLASMID which is normally maintained in the host cell at a copy number of ca. 10–30.

In ColE1, DNA REPLICATION occurs by the CAIRNS MECHANISM. Replication is initiated from a fixed origin and (in contrast to chromosomal replication in *Escherichia coli*) proceeds unidirectionally from the origin; it is not dependent on plasmid-encoded proteins but requires the cell's RNA polymerase, DNA polymerases I and III and components of the PRIMOSOME. The first several hundred nucleotides of the leading strand are synthesized by DNA polymerase I from an RNA primer synthesized by RNA polymerase; subsequent DNA chain elongation is carried out by DNA polymerase III.

Initiation of plasmid replication is regulated at the level of primer formation. During the initiation process, *two* RNA transcripts are synthesized, one on each DNA strand, at the same region ca. 500 nt upstream from the origin (*ori*). The transcript on the H strand (RNA II) can – unless prevented (see later) – extend to the origin and give rise to a primer for synthesis of the leading strand; the transcript on the L strand (RNA I, 108 nt long) is complementary to the 5' terminal region of RNA II and behaves as a *trans*-acting repressor of plasmid replication.

According to a current model, the 5' end of RNA II is synthesized as a free (single-stranded) transcript, but as the RNA polymerase approaches *ori* the transcript and template form a DNA/RNA hybrid; the RNA strand in this hybrid is cleaved by RNASE H to form a free hydroxyl (–OH) terminal suitable for extension by DNA polymerase, i.e. the cleaved end of the RNA transcript, at *ori*, functions as a primer. (Although RNase H is essential for replication of ColE1 *in vitro*, its role *in vivo* has been questioned [JB (1986) 166 143–147].)

Whether or not a functional primer is formed from the RNA II transcript, as described above, is influenced by several factors – factors which, by regulating the initiation of replication, determine the COPY NUMBER of the plasmid.

One regulatory factor is RNA I. RNA I and RNA II each form several stem-and-loop structures which, because the two transcripts are complementary, can undergo mutual base-pairing; when this happens, it inhibits development of a functional primer at the RNA/DNA hybrid in the *ori* region. (*In vitro*, RNA I can inhibit primer formation only if it binds to RNA II some time before the complete RNA II–DNA hybrid has been formed; once the nascent RNA II transcript has reached a length of ~360 nt it becomes resistant to RNA I.) The hybridization of RNA I with RNA II is facilitated/accelerated by a small protein (63

amino acids) encoded by the plasmid gene *rop* (= *rom*); the Rop/Rom protein (which acts as a rigid dimer exhibiting exact two-fold symmetry) thus enhances the inhibitory effect of RNA I on primer formation.

The ability of RNA I to inhibit primer formation depends on its intracellular concentration. (This, in turn, can be influenced e.g. by the host cell's RNASE E which can cleave and inactivate RNA I.) It appears that only when the copy number of ColE1 has reached its maximum is the concentration of RNA I high enough to inhibit further replication.

Interestingly, the copy number of ColE1 is affected by mutations in the *pcnB* gene (see MRNA (a)).

A similar mechanism for the regulation of plasmid replication occurs e.g. in CloDF13, p15A, pBR322, pMB1 and RSF1030 plasmids. In pBR322, RNA I is synthesized five times more often than RNA II, and it has been estimated that only 1 in 20 pre-priming event results in plasmid replication [JB (1987) 169 1217–1222].

**Coleochaete** A genus of freshwater epiphytic green algae (division CHLOROPHYTA). Some species are filamentous and dichotomously branched, others are discoid; cell division is confined to apical/marginal cells. Characteristic of the genus is the formation by certain cells of long, fine, unbranched, sheathed 'hairs' (setae). Motile cells are scaly. Zoospores are biflagellate, one being formed per cell. Sexual reproduction is oogamous; an envelope of sterile cells may surround the reproductive cells. Plants may be homothallic or heterothallic.

**Coleosporium** See UREDINIOMYCETES.

**Coleps** A genus of freshwater and marine ciliates (subclass GYMNOSTOMATIA). Cells: typically barrel-shaped, ca. 50–100 µm in length, with an anterior (apical) cytostome; a semirigid endoskeleton (formed by the deposition of calcium phosphocarbonate in the pellicular alveoli) gives the appearance of a regular series of platelets forming a grid-like pattern over the entire body surface. Posteriorly directed spines may occur at the posterior edge of the cell. The organisms feed on other protozoa and algae.

**colibacillosis** (*vet.*) Any of certain diseases, caused by strains of *Escherichia coli*, which occur primarily in very young animals and which typically involve septicaemia and/or mild to severe diarrhoea. (See also ETEC; cf. WHITE SCOURS; OEDEMA DISEASE.)

**colicin A** A pore-forming colicin (see COLICINS) (MWt ca. 63000) which binds to the OmpF/BtuB protein [mechanism of action: JMB (1986) 187 449–459].

**colicin B** A pore-forming colicin (see COLICINS) (MWt ca. 80000–90000) which binds to the FEPA PROTEIN.

**colicin D** A colicin (see COLICINS) (MWt ca. 87000) which binds to the FEPA PROTEIN and subsequently inhibits protein synthesis in sensitive cells. [Physical and genetic analysis of the ColD plasmid: JB (1986) 166 15–19.]

**colicin E** A category of COLICINS (MWt ca. 64000–66000) each of which binds to the BtuB protein. E colicins are divided into nine immunity groups (E1...E9); colicins of a given group (e.g. E1) are not active against cells which contain a (repressed) plasmid encoding the *same* colicin and which are synthesizing the corresponding immunity protein. In a sensitive cell, colE1 forms pores; colE2, colE7, colE8 and colE9 are DNases; and colE3 and colE6 are RNases which cleave 16S rRNA.

**colicin I** A category of COLICINS (MWt ca. 80000); colIa and colIb are group B pore-forming colicins.

**colicin K** A group A, pore-forming colicin (see COLICINS) (MWt ca. 70000) which binds to the TSX PROTEIN; uptake across the cell envelope of the target cell is reported to require OmpFA and the TolABQR proteins.

**colicin L** See COLICINS.

**colicin M** A colicin (see COLICINS) (MWt ca. 23000) which binds to the TONA PROTEIN (= FhuA); it inhibits the synthesis of PEPTIDOGLYCAN.

**colicin N** A pore-forming colicin (see COLICINS) MWt ca. 39000 which binds to the OmpF protein.

**colicin plasmid** (col factor, or col plasmid) A PLASMID which encodes one or more COLICINS. Some col plasmids (type 1) are small, MULTICOPY PLASMIDS, while others (type 2) are large, low-copy-number plasmids. The type 1 col plasmids are non-conjugative; type 2 col plasmids are often conjugative (see CONJUGATIVE PLASMID). Conjugative col plasmids occur in various INCOMPATIBILITY (Inc) groups (e.g. ColV is an IncFI plasmid, ColB-K98 is an IncFIII plasmid, and ColB-P9 is an IncI $\alpha$  plasmid). Some non-conjugative plasmids have been found to exhibit incompatibility [e.g. incompatibility between ColE plasmids: JGM (1986) 132 1859–1862].

Col plasmids contain three essential genes: (i) the colicin structural gene (= 'activity' gene); (ii) a gene encoding the immunity protein (see COLICINS); and (iii) a gene encoding the lysis protein. These genes are designated *cdl* (colicin D lysis gene), *cea* (colicin E activity gene), *cui* (colicin U immunity gene) etc.

In a population of colicinogenic bacteria only a small proportion of the cells is de-repressed for colicin synthesis; however, the immunity gene is usually expressed constitutively so that cells with repressed genes for the colicin and lysis protein are protected from the given colicin produced by their derepressed neighbours.

A col plasmid typically encodes only that type of immunity protein which protects the host cell against the particular colicin encoded by the plasmid. However, ColE9-J encodes two types of immunity protein: one protecting against colE9 and one protecting against colE5 [JGM (1986) 132 61–71].

Transcription of col plasmids is repressed by the LexA protein so that synthesis of colicins is promoted by those agents which trigger the SOS SYSTEM.

**colicin typing** BACTERIOCIN TYPING with COLICINS.

**colicin U** A pore-forming colicin (see COLICINS) (MWt ca. 66300) produced by *Shigella boydii*; colicin U binds to sensitive cells via the OmpA and OmpF proteins, and uptake occurs via the TolABQR proteins [JB (1997) 179 4919–4928].

**colicin V** The designation of a bacteriocin (MWt 6000) which acts by disrupting the membrane potential of sensitive cells [JB (1984) 158 757–759]; it is not inducible by conditions which trigger the SOS system (cf. COLICINS), and at least some authors now classify this bacteriocin as a MICROCIN [e.g. TIM (1998) 6 66–71].

**colicin X** The designation of a small bacteriocin subsequently classified as a MICROCIN.

**colicin Y** A recently isolated pore-forming colicin (see COLICINS) encoded by plasmid pCol-Let [complete coding sequence: Microbiology (2000) 146 1671–1677].

**colicinogenic** Able to produce COLICINS.

**colicinogenic plasmid** *Syn.* COLICIN PLASMID.

**colicins** A category of high-MWt (~25–90 kDa) BACTERIOCINS produced by colicinogenic bacteria of the family Enterobacteriaceae (e.g. *Escherichia coli*, *Shigella boydii*) and active against (sensitive) strains of the same family; most colicins are encoded by plasmid genes (see COLICIN PLASMID), one exception being the chromosomally encoded 'bacteriocin 28b' – a bacteriocin (similar to colicin L) produced by strains of *Serratia marcescens*.

A given colicin is associated with a cluster of three genes: (i) the structural gene for the colicin; (ii) the immunity gene,

encoding a protein which protects the cell against molecules of the *same* colicin produced by other cells in the vicinity; and (iii) a lysis gene, encoding a protein involved in the release of the colicin.

Under normal conditions the colicin and lysis genes are not expressed, but the immunity gene is expressed constitutively. The product of the immunity gene (the *immunity protein*) inhibits the activity (but not the adsorption) of any molecules of the given colicin that bind to the cell surface.

In a population of colicinogenic cells, synthesis of the colicin and lysis protein is promoted under conditions which trigger the SOS SYSTEM (see COLICIN PLASMID). However, in a colicinogenic population a small proportion of the cells (at any given time) may be derepressed for colicin synthesis, and these cells will be able to produce and externalize colicins.

Colicins synthesized in a given cell leave the cell following the activity of the lysis protein. The lysis protein localizes in the cell envelope; earlier studies indicated that this causes a non-specific increase in the permeability of the cell envelope – allowing release not only of the colicin molecules but also of various other constituent of the cell's cytoplasm [EMBO (1987) 6 2463–2468]. During the externalization of colicin molecules, a cell may not appear to be undergoing extensive disintegration, but it becomes leaky (releasing various ions and molecules) and it fails to take up essential substrates. Synthesis and externalization of colicins is characteristically linked to the death of the colicin-producing cell.

Cells in the vicinity of a colicin-producing cell are insensitive ('immune') to the given colicin if they contain the same (repressed) colicin system and a functional immunity protein. In some cases, however, such immunity may be lost (*immunity breakdown*) in the presence of high concentrations of the given colicin; this presumably occurs because there are too many molecules of colicin for the cell's immunity system to deal with.

Externalized colicin molecules bind to specific receptors on the surface of sensitive cells, and it appears that internalization of the colicin molecule is usually or always an energy-dependent process; in at least some cases (e.g. colicin A), the colicin unfolds on binding to the receptor, such unfolding being essential for translocation through the cell envelope.

The specific receptors used by colicins include the BtuB, FepA, FhuA, IutA and Tsx proteins and the OmpF porin.

After binding, group A colicins (A, E1–E9, K, L, N, cloacin DF13 and bacteriocin 28b) are internalized via a complex of envelope proteins that include TolA, TolB, TolQ and TolR.

After binding, group B colicins (B, D, Ia, Ib, M, 5 and 10) are internalized via a complex of proteins that include the TONB PROTEIN, ExbB and ExbD.

[Colicin import into *Escherichia coli* cells: JB (1998) 180 4993–5002.]

Within the target cell, a given colicin may act as a lethal agent by (i) forming pores in the cytoplasmic membrane, thereby collapsing proton motive force and allowing leakage of cytoplasmic constituents; (ii) functioning as a non-specific DNase; (iii) functioning as an RNase specifically against 16S rRNA; or (iv) inhibiting the synthesis of PEPTIDOGLYCAN.

A given colicin is associated with a particular mode of lethal activity. Thus, e.g. pore-formers include the group A colicins E1, A, N and K and the group B colicins B, Ia, Ib, 5 and 10; RNases include group A colicins DF13 and E6; DNases include the group A colicins E2 and E8; inhibitors of peptidoglycan synthesis include the group B colicin M.

(See also separate entries for colicin A, B, D, E, I, K, M, N, U, V, X and Y, and CLOACIN DF13.)

## coliform

**coliform** In general: any Gram-negative, non-sporing, facultatively anaerobic bacillus which can ferment lactose, with acid and gas formation, within 48 hours at 37°C. For water bacteriologists (in the United Kingdom), a coliform is defined as any member of the family Enterobacteriaceae which grows at 37°C and which normally encodes β-galactosidase [for further information see Report 71 (1994) HMSO, London (ISBN 0 11 753010 7)].

*Escherichia coli* is a typical coliform.

**coliform mastitis** See MASTITIS (b).

**coliform test** A test used to detect the presence of COLIFORM organisms in e.g. water (see INDICATOR ORGANISM and WATER SUPPLIES); the test was originally designed to reveal faecal contamination (hence the designation 'faecal coliform test'). In the test, aliquots of sample are used to inoculate a number of tubes (see MULTIPLE-TUBE METHOD), each of which contains e.g. MACCONKEY'S BROTH and a DURHAM TUBE; incubation is carried out at 37°C. A 'positive' test (i.e. lactose fermentation) is shown by acidification (pH indicator) and gas production (Durham tube). The 'most probable number' of coliforms in the original sample can be calculated from the number of positive tubes and the use of statistical tables. The count thus obtained is actually a *presumptive coliform count* because, in any given tube, a 'positive' result could be due to certain endospore-forming bacteria (which also ferment lactose and form gas); this possibility is particularly important when testing chlorinated water samples because spore-forming bacteria are more resistant than coliforms to chlorine. Confirmation that each 'positive' result is, in fact, due to *thermotolerant* (= 'faecal') coliforms involves two further 24-hour tests at 44°C: the INDOLE TEST and the EIJKMAN TEST.

**coli-granuloma** *Syn.* HJÄRRE'S DISEASE.

**coliphage** A BACTERIOPHAGE that infects *Escherichia coli*. (For 'coliphage λ', 'coliphage T4' etc see BACTERIOPHAGE λ, BACTERIOPHAGE T4, etc.)

**colisepticaemia** A respiratory and septicaemic disease of poultry caused by strains of *Escherichia coli*. Incidence of the disease has increased greatly with the advent of modern intensive rearing methods, and often occurs secondarily to e.g. poor ventilation, vaccination of birds with live vaccines (e.g. live Newcastle disease vaccines), or various other respiratory diseases (e.g. AIR SACCULITIS, AVIAN INFECTIOUS BRONCHITIS, NEWCASTLE DISEASE). Infection occurs mainly via the respiratory tract; characteristic post-mortem findings include fibrinous pericarditis and perihepatitis.

**colistins** See POLYMYXINS.

**colitis** Inflammation of the colon. (cf. ENTERITIS.) Colitis occurs e.g. in certain infectious diseases (e.g. amoebic and bacillary DYSENTERY; see also SHIGA TOXIN). *Antibiotic-associated colitis* sometimes occurs when the normal bowel flora is suppressed by broad-spectrum antibiotic therapy; this condition ranges from mild diarrhoea to PSEUDOMEMBRANOUS COLITIS, and is commonly due to growth and toxin formation by *Clostridium difficile* (an organism normally rare in adults, but common in the bowel in infants). *C. difficile* produces at least two distinct hydrophobic protein toxins, A (an enterotoxin) and B (a cytotoxin) [JMM (1984) 18 385–391]; toxin A causes fluid accumulation in the intestinal lumen (but *not* by activating adenylate cyclase – cf. e.g. CHOLERA TOXIN), and the B toxin disaggregates filamentous actin in tissue culture cells [GE (1984) 86 1212 (abstr.)]. [Purification and properties of cytotoxin B: JBC (1986) 261 1316–1321.] *Chemotherapy*: e.g. vancomycin.

**colitose** (3,6-dideoxy-L-galactose) A sugar, first isolated from *Escherichia coli*, which occurs in the O-specific chains

of the LIPOPOLYSACCHARIDE in certain *Salmonella* serotypes (contributing to O antigen 35 in group O salmonellae – see KAUFFMANN-WHITE CLASSIFICATION) and in the LPS of *E. coli* serotypes of the O111 group.

**collagen** The main protein component of bone, cartilage and other connective tissues; it is a microfibrillar protein whose subunit, *tropocollagen*, consists of three polypeptide chains in which the amino acid sequences are essentially (glycine-X-Y)<sub>n</sub> where X and Y are often proline and hydroxyproline, respectively. Collagen is generally resistant to enzymic degradation (cf. COLLAGENASE). Collagenolytic organisms may cause LEATHER SPOILAGE. (See also GELATIN.)

**collagenase** A COLLAGEN-degrading enzyme; collagenases are produced e.g. by *Clostridium histolyticum* (the β-toxin) and *C. perfringens*. The collagenase of *C. histolyticum* appears to have maximum activity at the peptide bond preceding a glycine-proline sequence.

**collarette** See CONIDIUM.

**Collema** A genus of LICHENS (order LECANORALES); photobiont: *Nostoc*. The thallus lacks a cortex and is homoimerous, foliose to fruticose, brownish- to greenish-black, pulpy and gelatinous when wet, firm and cartilaginous when dry. The apothecia, when formed, generally have reddish-brown discs. According to species, globular, cylindrical, coralloid or scale-like isidia may be formed. Species occur on bark, rocks, calcareous soils, etc.

**Colletotrichum** A genus of fungi (order MELANCONIALES) which include some important plant pathogens (see e.g. ANTHRACNOSE, COFFEE BERRY DISEASE, RED ROT and SMUDGE). Conidiophores characteristically develop on setose acervuli (see SETA); the conidia, which lack appendages, are typically elongated, rounded and colourless.

**Collospheera** See RADIOLARIA.

**Collybia** See AGARICALES (Tricholomataceae).

**Colominic acid** The capsular polysaccharide of *Escherichia coli* K1 strains; it is a linear polymer of *N*-acetylneuraminic acid residues linked by (2 → 8)-α-ketosidic bonds. [Biosynthesis: JB (1984) 159 321–328.] An apparently identical polysaccharide occurs in strains of *Neisseria meningitidis* (groups B and C). Colominic acid is resistant to most neuraminidases; however, it can be hydrolysed by an enzyme from *Clostridium perfringens*, and a neuraminidase associated with a bacteriophage (coliphage E) specifically depolymerizes colominic acid [JV (1985) 55 374–378].

**colon microflora** See GASTROINTESTINAL TRACT FLORA.

**colonization factor antigens** See ETEC.

**colony** (*microbiol.*) A number of cells or organisms (of a given species) which, during their growth, have developed as a discrete aggregate or group in which there is commonly direct contact or continuity between the cells.

*Algal colonies*. Some algal colonies are of more or less stable size and form (see COENOBIVM sense 2; cf. PALMELLOID PHASE). In some species the colony is the only form in which the organism occurs. See e.g. SCENEDESMUS and VOLVOX.

*Bacterial colonies* are usually formed only on, or within, a solid MEDIUM (such as an agar gel); each usually consists of a compact mass of individual cells, although certain bacteria (e.g. *Streptomyces* spp) form mycelial colonies. A discrete colony commonly comprises the progeny of a single cell (see also STREAKING). Many species of bacteria can form macroscopic colonies on appropriate media under suitable conditions; on a given medium, a colony's shape, colour, consistency, surface appearance and size (for a given incubation time) are often highly characteristic, and these features are often of use in the

identification of particular bacterial species. The full description of a colony can be very detailed. Thus, e.g. the *elevation* of a (surface) colony may be flat, low convex, domed, umbonate etc; its *edge* may be e.g. entire (i.e., circular and unbroken), crenate (scalloped), lobed or fimbriate; its *texture* may be butyrous, friable or mucoid; its *surface* may be matt or glossy; it may be whitish or pigmented, or it may contain a dye taken up from the medium. When the colonies of certain species develop on blood agar, each colony is surrounded by a zone in which the blood has been lysed or greened (see HAEMOLYSIS). (See also DAISY HEAD COLONIES, DRAUGHTSMAN COLONY, fried egg colony in MYCOPLASMA, MOTILE COLONIES, SMOOTH-ROUGH VARIATION.)

Although a bacterial colony has been traditionally regarded as an aggregate of independent cells, some studies have provided evidence that the behaviour of a given cell in a colony is influenced by its position within the colony, i.e., the behaviour of a cell can be subject to 'multicellular' regulatory mechanisms [see Book ref. 198, pp. 27–69].

Other types of bacterial colony include e.g. the rosettes of CAULOBACTER spp, the arrays of *Hyphomicrobium* and RHODOMICRIBIUM spp, and the networks of PELODICTYON.

**Fungal colonies.** Some fungi (e.g. certain yeasts) form colonies which resemble those typical of bacteria. Mycelial fungi often form circular 'fluffy' colonies, each consisting of a mass of MYCELIUM which may or may not include reproductive structures (see e.g. PENICILLIUM). (See also PELLET sense 2; PETITE MUTANT.)

**Protozoal colonies.** In the (few) colonial protozoa, the colony typically consists of SESSILE (sense 1) organisms which form a group of variable size (see e.g. CARCHESIUM). Chain-like colonies are formed by some members of the ASTOMATIDA.

**colony-forming unit** See COUNTING METHODS.

**colony hybridization** (modified Grunstein–Hogness procedure)

A method for screening bacterial colonies for the presence of a specific sequence of DNA (e.g. among colonies containing a gene LIBRARY). As in a REPLICA PLATING procedure, cells are transferred from colonies on the master plate to a nitrocellulose (or other) filter. The cells on the filter are lysed with alkali – the alkali also serving to denature the DNA (i.e. to separate the strands of the duplex); the alkali is then neutralized, any protein is digested e.g. with proteinase K, and the filter is baked at 70–80°C under vacuum to bind the (single-stranded) DNA to the filter. The filter is then exposed to labelled probes (see PROBE) which are complementary to the sequence of interest. After washing away unhybridized probes, the given sequence, if present, is indicated by the label on bound (hybridized) probes; any probe-positive sites on the filter are then used to identify the corresponding (positive) colonies on the master plate.

A probe labelled with a radioactive isotope is detected by AUTORADIOGRAPHY.

In the original procedure [Book ref. 177, pp. 172–174], cells transferred from the master plate were allowed to grow and form colonies on the filter (which was overlaid on a plate of nutrient medium); subsequent steps were similar to those described.

This technique can also be used for yeast cells, but these cells must be converted to sphaeroplasts (with e.g. ZYMOLYASE) before lysis.

**colony-stimulating factors** (CSFs) CYTOKINES involved in the maturation of LEUCOCYTES. CSFs include e.g. granulocyte–macrophage colony-stimulating factor (GM-CSF), an agent which stimulates proliferation of progenitors of various blood cells (including granulocytes and macrophages), and macrophage colony-stimulating factor (M-CSF; also referred to as CSF-1), an agent formed mainly by monocytes and

macrophages which, among other functions, stimulates the development of macrophages from precursor forms such as monoblasts and monocytes.

**Colorado tick fever** An acute human disease caused by a virus and transmitted by the tick *Dermacentor andersoni*; it occurs in the Rocky Mountain regions of the USA. Symptoms include fever, leucopenia, headache and myalgia, but no rash; CNS complications occasionally occur in young children. Wild rodents (e.g. ground squirrels) may act as a reservoir of infection. The causal agent has been regarded as an ORBIVIRUS, but has been shown to contain 12 dsRNA molecules [Virol. (1981) 112 361–364] and may thus represent a distinct taxonomic group.

**colostrum** A secretion of the mammary gland produced before lactation proper; it contains e.g. immunoglobulins (mainly IgA and IgG). In man, the immunoglobulin content of colostrum is relatively low, but in some animals – e.g., ruminants (in which immunoglobulins do not cross the placenta) – large amounts are normally present. (See also PASSIVE IMMUNITY.)

**colour-breaking** (breaking) The development of VARIEGATION in flower petals; colour-breaking may occur as a result of virus infection (e.g., in tulips infected with tulip breaking virus, a member of the POTYVIRUSES). Flowers affected in this way are often prized for their attractive appearance.

**Colour Index** (CI) A comprehensive reference publication on dyes and pigments published by The Society of Dyers and Colourists, Bradford, Yorkshire BD1 2JB, England. It consists of a number of volumes which are periodically updated.

**coloured field illumination** *Syn.* RHEINBERG ILLUMINATION.

**colourless sulphur bacteria** Those non-photosynthetic SULPHUR BACTERIA which obtain energy by the oxidation of sulphur and/or reduced inorganic sulphur compounds (e.g. sulphide); although referred to as 'colourless', some strains can exhibit pigmentation owing to their content of cytochromes. The colourless sulphur bacteria include e.g. species of *Beggiatoa* and *Thiobacillus*. [Ecology of colourless sulphur bacteria: Book ref. 115, pp. 211–240.]

**Colpidium** A genus of ciliates (order HYMENOSTOMATIDA) which occur e.g. in freshwater habitats containing decomposing organic matter. Cells: ovoid or reniform, ca. 50–150 µm, with uniform somatic ciliation and a single macronucleus, micronucleus and contractile vacuole. In *C. colpoda* (at least) asexual reproduction occurs within a cyst.

**Colpoda** A genus of soil and freshwater ciliates (order COLPODIDA). Cells: typically reniform, ca. 40–120 µm in length, with uniform somatic ciliation; the cytostome is lateral. *C. steini* is a small species, ca. 20–60 µm, with a conspicuous tuft of cilia (the 'beard') projecting from the region of the vestibulum. Food consists of other protozoa, algae and bacteria. Asexual reproduction occurs within CYSTS – in which four or more individuals may be formed.

**Colpodida** An order of protozoa (subclass VESTIBULIFERIA) in which the vestibular ciliation tends to be highly organized. Cysts are common. The organisms are typically free-living, sometimes associated with molluscs. Genera: e.g. COLPODA, *Woodruffia*.

**Colpomonia** See PHAEOPHYTA.

**Colsargen** See SILVER.

**Columbia SK virus** See CARDIOVIRUS.

**columella** An axial or central, unicellular or multicellular structure within a fruiting body in certain fungi and in certain slime moulds of the MYXOMYCETES; in some cases it is simply an extension of the sporangiophore into the cavity of a sporangium, while in others it may be a spherical, conical or cylindrical structure extending upwards from the base of a sporangium. Although

## column fermenter

columellae are commonly described as STERILE (sense 2), the columellae of *Mucor piriformis* have been reported to germinate and give rise to secondary sporangia under certain cultural conditions [Mycol. (1985) 77 353–357]. (cf. PSEUDOCOLUMELLA.)

**column fermenter** See FERMENTER.

**columnaris disease** (cotton wool disease; ‘mouth fungus’) An acute, often fatal freshwater FISH DISEASE caused by *Flexibacter columnaris*. Necrotic lesions occur on the skin and gills; cottony tufts of epithelium and bacteria appear around the mouth.

**ColV plasmid** Any of a heterogeneous group of IncFI COLICIN PLASMIDS which encode COLICIN V; many also encode e.g. the aerobactin iron-uptake system (see SIDEROPHORES).

**ColV, I-K94 plasmid** An IncFI COLICIN PLASMID which encodes COLICINS V and Ia; it occurs e.g. in *Escherichia coli* and is derepressed for conjugal transfer.

**ColX plasmid** See COLICIN PLASMID.

**ComA** See QUORUM SENSING.

**Comatricha** See MYXOMYCETES.

**comb. nov.** (*combinatio nova*; new combination) In NOMENCLATURE: the name of a species which has been moved from one genus to another but which has retained the specific epithet (suitably modified, when necessary, to agree with the form of the new genus name).

**combinatio nova** See COMB. NOV.

**combined gold standard** See GOLD STANDARD.

**combined residuals** See WATER SUPPLIES.

**combining site** (*immunol.*) That part of an ANTIBODY (or a FAB PORTION) which can combine with a determinant of the homologous antigen or hapten; it is located at the variable (N-terminal) ends of the heavy chain and light chain in an Ig molecule (see IMMUNOGLOBULINS and HYPERVARIABLE REGION). Monomeric antibodies have a VALENCY of two. (See also CYTOPHILIC ANTIBODIES and AFFINITY LABELLING.)

**come-up time** In the CANNING process: the time needed for the correct processing temperature to be reached in the retort.

**comedone** See ACNE.

**co-metabolism** The phenomenon in which a substrate (the *co-substrate*) which does not support the growth of a given microorganism can nevertheless be modified or degraded by that organism in the presence of a second, growth-supporting substrate. Co-metabolism is believed to result from the action of an enzyme of relatively low substrate specificity which has a different physiological function in the cell; for example, METHANE MONOOXYGENASE can oxidize certain short-chain alkanes and alkenes as well as methane, and such hydrocarbons can be oxidized by methane-grown cells (*co-oxidation*) which may be unable to use the oxidation products. In nature, co-metabolism may be important in the degradation of XENOBIOTICS.

**commensal** See COMMENSALISM.

**commensalism** SYMBIOSIS (sense 1) in which one symbiont (the *commensal*) derives benefit from the association, and the other (sometimes called the *host*) derives neither benefit nor harm. (cf. MUTUALISM.)

**commercial sterility** A term used when referring to the condition of a substance following APPERTIZATION.

**common bunt** A seed-borne wheat disease caused by *Tilletia caries* or *T. foetida* (*T. laevis*). (Rye and certain other grasses may also be affected.) Symptoms include retarded growth and the formation of long, narrow ears which have a bluish tinge; grains are filled with grey or black powdery masses of teliospores which, when released during harvesting, give off a characteristic ‘rotten fish’ odour (trimethylamine). *Dwarf bunt* is a similar (soil- and seed-borne) disease caused by *Tilletia contraversa*

(*T. brevivaciens*); affected plants show severe stunting and chlorotic flecks on the leaves. (cf. KARNAL BUNT; see also CEREAL DISEASES.)

**common cold** An acute disease of the upper respiratory tract in man; the causal agent may be any of a range of viruses – usually a rhinovirus, coronavirus, influenza virus (type A, B or C), parainfluenza virus (types 1–4) or human respiratory syncytial virus. Incubation period: usually ca. 48–72 hours. Symptoms typically include coryza and nasal obstruction, sore throat, cough, sneezing, but little or no fever. Direct contact may be an important mode of transmission of rhinoviruses [AIM (1978) 88 463]; the other viruses are probably transmitted mainly by aerosols (see DROPLET INFECTION). Transmission of rhinoviruses can be interrupted (experimentally) by the use of virucidal (citric acid-treated) paper handkerchiefs [JID (1986) 153 352–356]. Colds are usually self-limiting, but occasional complications include e.g. OTITIS MEDIA, PNEUMONIA or SINUSITIS. (cf. INFLUENZA.) [Review: Lancet (2003) 361 51–59.]

**common fimbriae** Type 1 FIMBRIAE.

**common pili** (1) *Syn.* FIMBRIAE. (2) *Syn.* Type 1 fimbriae.

**common scab** (of potato) See POTATO SCAB.

**communicable disease** *Syn.* INFECTIOUS DISEASE.

**comoviruses** (cowpea mosaic virus group) A group of PLANT VIRUSES in which the bipartite positive-sense ssRNA genome is encapsidated in (separate) icosahedral particles; both parts are necessary for infection. Most comoviruses cause systemic mosaic or mottling and stunting – occasionally with wilting, necrotic ring formation, etc. – in various plants, including e.g. cowpea (*Vigna unguiculata*), beans, red clover etc; the host range of individual members is narrow. Most comoviruses are transmitted by leaf-feeding beetles, particularly of the Chrysomelidae (e.g. *Cerotoma* and *Diabrotica* spp); seed transmission occurs in some comoviruses, and mechanical transmission can occur readily under experimental conditions. Type member: COWPEA MOSAIC VIRUS (SB isolate). Other members: e.g. cowpea severe mosaic virus, quail pea mosaic virus, red clover mottle virus, squash mosaic virus. (cf. BROAD BEAN WILT VIRUS.)

**ComP** See QUORUM SENSING.

**compact colony-forming active substance** See CCFAS.

**comparative single intradermal tuberculin test** (comparative test; single intradermal comparative tuberculin test) (*vet.*) A form of TUBERCULIN TEST, applied to cattle, in which two intradermal injections are given (on a single occasion – cf. STORMONT TEST) at different sites on the same side of the neck; PPD derived from *Mycobacterium bovis* is injected at one site, PPD derived from *M. avium* is injected at the other site. After 72 hours any increase in skin thickness at the injection sites is measured. If the response to PPD from *M. bovis* (increase in skin thickness) is greater than that to PPD from *M. avium* by a certain minimum amount then the animal is designated a ‘reactor’. A positive reaction to PPD from *M. avium* together with a negative reaction to PPD from *M. bovis* suggests contact with *M. avium* and/or mycobacteria other than *M. bovis*.

The use of a defined antigen (ESAT-6), compared with PPD, has been associated with lower sensitivity but higher specificity [VR (2000) 146 659–665].

**comparative test** (*vet.*) *Syn.* COMPARATIVE SINGLE INTRADERMAL TUBERCULIN TEST.

**comparator** See WATER SUPPLIES.

**compatibility** (1) (of plasmids) See PLASMID. (2) (in fungal sexuality) The ability, or otherwise, of a given cell or thallus to interact sexually with itself and/or with other cells or thalli of the same species. In general, the genetic constraints on mating increase, both in number and complexity, from the lower

fungi, through the ascomycetes, to the basidiomycetes. HOMOTHALLISM is common in all the major groups of fungi. Bipolar HETEROTHALLISM occurs in some lower fungi (e.g. species of *Mucor* and *Rhizopus*), in many ascomycetes (including e.g. *Saccharomyces*), and in many of the rust and smut fungi. Tetrapolar heterothallism occurs in a number of basidiomycetes – including e.g. *Schizophyllum commune* and *Ustilago maydis*. (See also MATING TYPE and PARASEXUAL PROCESSES.)

**compatible** (*plant pathol.*) Refers to a plant–pathogen interaction which results in the development of disease in the plant. (cf. INCOMPATIBLE.)

**compatible solute** Any low-MWt compound which, when present intracellularly in high concentration, is compatible with metabolism and growth. Compatible solutes involved in OSMOREGULATION include: L-glutamate, GLYCEROL, ISOFLORIDOSIDE, MANNITOL, L-proline, glycine betaine [in *Escherichia coli*: FEMS Reviews (1994) 14 3–20; in *Staphylococcus aureus*: Microbiology (1994) 140 3131–3138], and certain sugars.

**compensation level** See PHOTIC ZONE.

**competence** See TRANSFORMATION (1).

**complement** (C or C'; historical *syn.* alexin or alexine) (*immunol.*)

A group of functionally related proteins present in normal plasma, tissue fluids and the (freshly isolated) serum of vertebrates. (In serum, the activity of complement is abolished by exposure to room temperature for a few days, by heating to 56°C for 30 minutes, or by the action of chelating agents such as EGTA or oxalate.) When activated, the complement system is responsible for a number of important physiological activities (see e.g. COMPLEMENT FIXATION).

Before activation, many of the components exist as proenzymes and/or inactive forms (cf. FACTOR D) which, on activation, complex with, or act on, other components to form physiologically active entities.

In man, complement consists of nine numbered components (C1–C9, MWts ca. 80000–200000) together with various proteins involved e.g. in stabilization or control functions: see e.g. FACTOR B; FACTOR D; FACTOR H; FACTOR I; PROPERDIN and S PROTEIN. Component C1 is a complex macromolecule which consists of three parts: C1q, C1r and C1s; C1q itself consists of a bundle of six elongated subunits, and the macromolecule as a whole depends on Ca<sup>2+</sup> for its structural integrity.

Gene-based deficiencies in the complement system are associated with various adverse effects – which depend e.g. on the particular component(s) involved. One important role of complement is the removal of immune complexes (via the liver), and deficiencies in C1, C4 and C2 may give rise to forms of disease reflecting the accumulation of such complexes. A deficiency in C3 (with reduced capacity for opsonization) may result in recurrent infections. A deficiency in MBL (lectin pathway) is associated with increased susceptibility to infection in children. Deficiencies in C5–C8 generally cause increased susceptibility to infection – particularly with *Neisseria*.

**complement activation** *Syn.* COMPLEMENT FIXATION.

**complement fixation** (complement activation) Activation of the COMPLEMENT system, i.e. promotion of the sequence ('cascade') of reactions in which various components of complement are activated in turn. In vivo, complement fixation is involved e.g. in certain immune responses and in INFLAMMATION; in vitro it provides a sensitive system for various COMPLEMENT-FIXATION TESTS. (Complement fixation is sometimes referred to as complement *inactivation* – an allusion to the fact that components of complement are 'used up' during fixation.)

Complement fixation can be triggered in various ways, the type of trigger determining which pathway is followed; four pathways are shown in the figure.

(a) *Classical pathway.* This pathway is activated e.g. when antigens bind to COMPLEMENT-FIXING ANTIBODIES in the presence of complement. When such binding occurs, sequentially activated components may bind at or near the antigen–antibody complex; according to the antigen involved, this may result in e.g. phagocytosis of the antigen–antibody complex or, if a cell-surface antigen is involved, it may lead to cell lysis (see later). The cascade of reactions which occur in the (antigen-triggered) classical pathway is as follows.

The sequence is triggered when two or more subunits of C1q (in the complement C1 molecule) bind to the FC PORTION of antigen-bound IgG or IgM antibodies. Such binding (dependent on calcium ions) activates the C1r component of C1 which, in turn, activates the C1s component. C1s has serine protease and esterase activity.

(Note that antibody-independent activation of C1 can be promoted by certain non-specific activators – e.g. C-reactive protein (an ACUTE-PHASE PROTEIN) and various proteases.)

Activated C1s cleaves C4, forming C4a and C4b; as one molecule of C1s can cleave many molecules of C4, this reaction provides initial amplification. C4b molecules can bind to bacterial or other surfaces; like C3b (see later), C4b is an OPSONIN: C4b-coated cells or particles bind (via C4b) to the CR1 receptor on the surface of phagocytes.

Surface-bound C4b may also bind C2. C2 is cleaved (in a process involving C1s) to C2a and C2b; the complex formed between the larger fragment, C2a (referred to as C2b in some sources), and C4b (C4b2a) is a C3 *convertase*: an enzyme which cleaves C3 to C3a and C3b (this being a major phase of amplification in the complement cascade). (A low level of C3 cleavage normally occurs spontaneously ('C3 tickover') but the resulting fragments are rapidly degraded.)

C3a is an ANAPHYLATOXIN.

C3b is an important OPSONIN, promoting e.g. the phagocytosis of pathogens (IMMUNE ADHERENCE); C3b-bound antigens bind (via C3b) to CR1 receptors on phagocytes.

C3b can also form a complex with C3 convertase: C4b2a3b; this complex is a C5 *convertase*, i.e. it cleaves C5 into the small fragment C5a and a larger fragment, C5b.

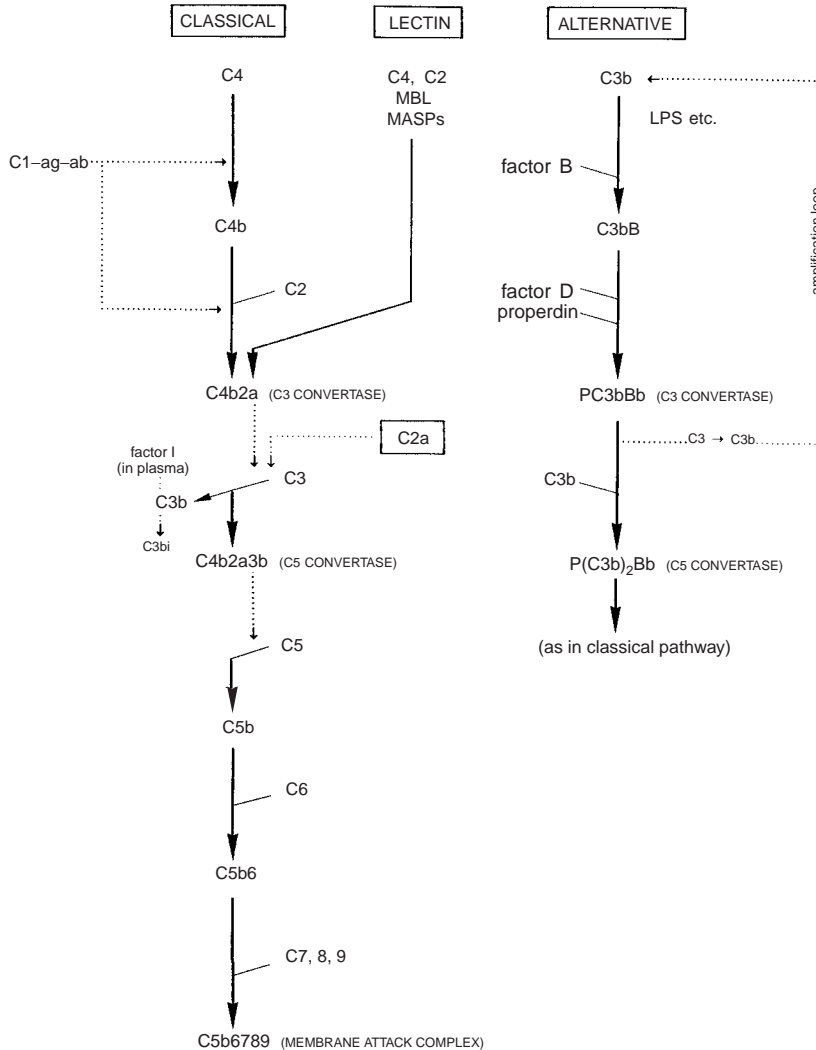

C5a is an ANAPHYLATOXIN and a chemoattractant for phagocytes (e.g. neutrophils).

C5b, C6 and C7 form a complex (C5b67) which binds to cell membranes – typically at the site of the initial triggering event. Component C8 binds to the complex; this promotes polymerization of a number of C9 molecules within the membrane – the C9 molecules forming a pore or channel which, in some types of cell (or even LIPOSOMES), can lead to lysis (*immune cytolysis*). C5b678 and the C9 molecules collectively form the so-called *membrane attack complex*, MAC. (Even in the absence of C9, the complex C5b678 can bring about slow lysis e.g. in erythrocytes.)

For certain pathogens (e.g. trypanosomes), MAC-inflicted damage can be lethal. In Gram-negative bacteria, pores formed by the MAC in the OUTER MEMBRANE can promote cell lysis by giving LYSOZYME access to cell-wall peptidoglycan; thus, e.g. a Gram-negative bacterium on the conjunctiva would be at risk of lysis because the tear film normally contains both complement and lysozyme.

Sometimes, C5b67 binds to a cell other than that which triggered the cascade; MAC-inflicted lysis in such a cell is called

**complement fixation**

COMPLEMENT FIXATION: four pathways (simplified scheme; see text). C1, C2 etc. denote particular components of the complement system; 'a' and 'b' denote fragments of components produced by enzymic cleavage during the activation process. For clarity, the diagram does not show *all* the cleavage products; for example, C4 is cleaved to C4a and C4b, but only the C4b fragment is considered here. Dotted lines indicate those cases in which a given complex or component acts enzymically to cleave certain components of the system.

Reproduced from *Bacteria* 5th edition, Figure 11.1, page 292, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

*bystander lysis* or *reactive lysis*. Reactive lysis may thus damage cells adjacent to a site of infection, and to limit such damage the plasma contains factors inhibitory to the C5b67 complex (see e.g. S PROTEIN).

Because complement fixation creates highly potent physiological agents, and as it includes various stages of amplification, regulatory mechanisms are essential to prevent the system becoming an uncontrolled avalanche of physiological destruction. In fact, there are specific inhibitors at key stages in the process; these include C1EI (C1 esterase inhibitor; also called

C1INH), which inhibits initial activation of the classical pathway, and FACTOR I, which cleaves C3b to an inactive form, C3bi. (C3bi, although inactive in the cascade, can nevertheless behave as an opsonin – binding e.g. to the CR4 receptor on macrophages.) Other regulatory factors are involved in the control of the alternative pathway (see later).

(b) *Alternative pathway*. In evolutionary terms, this pathway is apparently older than the classical pathway. In man, fixation via the alternative pathway is initiated by e.g. bacterial LIPOPOLYSACCHARIDES, rabbit (but not sheep) erythrocytes, aggregates of

human myeloma proteins, inulin and ZYMOSAN. (In the human complement system, this pathway can be activated by sheep erythrocytes if the cell-surface sialic acids have been removed.) The sequence of reactions in this pathway is as follows.

On a suitable surface (e.g. OUTER MEMBRANE LPS), component C3b ('tickover' C3b – see above) binds FACTOR B (in the presence of  $Mg^{2+}$ ) to form C3bB. The bound factor B is then cleaved by FACTOR D; this creates a C3 convertase (C3bBb) which is stabilized by binding to PROPERDIN (P). The C3 convertase (C3bBb) cleaves C3, forming more C3b and giving rise to an amplification loop (see figure).

The C3 convertase can bind a molecule of C3b to form a C5 convertase (P(C3b)<sub>2</sub>Bb); the cascade then continues as in the classical pathway.

Regulators of the alternative pathway include the plasma protein FACTOR I and the cell-bound *decay-accelerating factor* (DAF) (see CD55). Other cell-surface-associated inhibitory proteins include CR1, which can displace Bb from surface-bound C3bBb, and the *membrane co-factor protein* (MCP), which facilitates cleavage of C3b by factor I; collectively, these cell-surface factors help to protect *host* cells from the ongoing complement cascade (including the MAC) by inhibiting the cascade at the C3 convertase/C3b level.

For experimental work on the alternative pathway, COBRA VENOM FACTOR is used as an activator, while COMPLESTATIN and HEPARIN are used as inhibitors. (See also SURAMIN.)

When the *classical* pathway is stimulated, some of the C3b can bind Factor B and give rise to an alternative-pathway C3 convertase; in this way the alternative pathway can augment the classical pathway, and this sequence of reactions is sometimes called the *amplification pathway*.

The alternative pathway can be studied independently of the classical pathway by using the  $Ca^{2+}$  chelator EGTA (the latter pathway being dependent on the presence of calcium ions).

(c) *The lectin pathway.* This pathway effectively bypasses the C1 stage of the classical pathway: when the lectin pathway is triggered, a C3 convertase (C4b2a) is formed directly from C4 and C2.

The lectin pathway involves several components of normal plasma: mannose-binding lectin (MBL) and the MBL-associated *serine proteases* (MASPs) (cf. component C1s in the classical pathway); the system is triggered when MBL binds to certain groups on the microbial cell envelope. [Mannose-binding lectin: IT (1996) 17 532–540.]

The lectin pathway may be particularly useful in the young during the 'window' period of ~12–18 months between loss of maternal antibody cover (IgG) and the development of an effective immune system. However, triggering of this pathway by a bacterial pathogen may be greatly inhibited if the pathogen has a capsule (e.g. *Neisseria meningitidis*).

(d) *The C2a pathway* (= '*salvage pathway*'). This pathway, reported in 1997, may be important in the context of pathogenic mycobacteria. In the C2a pathway, C2a acts as a C3 convertase when it binds to the mycobacterial surface. [See TIM (1998) 6 47–49; TIM (1998) 6 49–50.]

**complement-fixation test (CFT)** Any of a range of sensitive, *in vitro* tests in which COMPLEMENT FIXATION is used to indicate the presence or absence (or quantity) of a specific antigen or COMPLEMENT-FIXING ANTIBODY. *Principle:* antigen and antibody are allowed to interact in the presence of complement, and the amount of complement used up (a measure of the amount of antigen–antibody interaction) is estimated, indirectly, by the addition of a HAEMOLYTIC SYSTEM; the proportion of erythrocytes

lysed indicates the amount of free (unfixed) complement remaining. *Practice:* to detect or quantify e.g. a given antibody in a sample of serum, SERIAL DILUTIONS of the INACTIVATED SERUM are prepared, and known, fixed quantities of COMPLEMENT and antigen are added to each dilution; the quantity of complement added (determined by titration) should be sufficient to cause lysis of ca. 90% of the erythrocytes in the haemolytic system when *no* complement-fixation has occurred. Incubation is carried out for ca. 18 hours at ca. 4°C. (Low-temperature incubation is used because some components of complement are labile at room temperature.) A fixed volume of the haemolytic system is then added to each dilution, and the whole is incubated for 15–30 min at 37°C; the test dilutions are then left at ca. 4°C to permit non-lysed erythrocytes to settle. In any given dilution, the extent of haemolysis will be inversely proportional to the extent of complement fixation in that dilution. If maximum haemolysis is observed in the lowest serum dilution (i.e. the highest serum concentration) the test is *negative* – i.e. the serum contains no detectable antibody. In a *positive* test, no haemolysis occurs in (at least) the lowest serum dilution; a test may be regarded as positive either (i) when no haemolysis has occurred in a specified number of serum dilutions (e.g. all dilutions up to 1:8 or 1:16 initial serum dilution), or (ii) when an *increase* in the titre of complement-fixing antibodies is recorded in a second serum sample taken some time after the first.

In all CFTs, controls are essential e.g. to check that the test system is functioning correctly and to preclude false-positive interpretations based on the effects of ANTICOMPLEMENTARY substances.

**complement-fixing antibodies** Antibodies which 'fix' or 'activate' COMPLEMENT when they combine with their homologous antigens. IgG (subclasses 1 and 3) and IgM can bring about complement fixation via the classical pathway; aggregates of IgA (subclasses 1 and 2) can activate the alternative pathway. (See also FC PORTION.)

**complement receptor 1** See CD35.

**complementarity-determining regions** (*immunol.*) Those HYPERVARIABLE REGIONS which occur at the surface of the COMBINING SITE of an antibody.

**complementary bases** See BASE PAIR.

**complementation** The ability of a gene (or protein) to compensate for (i.e., to 'complement') a functional defect in a homologous gene (or protein) when present in the same organism or cell. For example, a wild-type gene necessary for the synthesis of a given amino acid may, when introduced into a mutant organism auxotrophic for that amino acid, complement the mutant gene (by supplying an active form of the defective gene product) and restore the wild-type (prototrophic) phenotype. (See also COMPLEMENTATION TEST; *IN VITRO* COMPLEMENTATION ASSAY; NON-GENETIC REACTIVATION.)

**complementation test** A test used to determine whether or not COMPLEMENTATION will occur in a cell with a given mutant phenotype when another mutant genome, encoding the same mutant phenotype, is introduced into that cell. The test involves bringing together, into the same cell, the two (haploid) mutant genomes (or a genome and part-genome – see MEROZYGOTE) and determining the resulting phenotype. The expression of a wild-type phenotype (a *positive* complementation test) indicates that the mutations are in different genes in the two genomes, i.e., one wild-type form of each gene can be supplied by each of the mutant genomes (*intergenic* or *intercistronic* complementation); this indicates that at least two genes are involved in the expression of that phenotype. (If the mutations were in the

## complementing diploids

same gene in each genome, no wild-type form of that gene would be present and the mutant phenotype would continue to be expressed; if such a negative result is consistently obtained with a range of mutants of the same phenotype, then the phenotypic characteristic under study may be presumed to be under monogenic control.)

Interpretation of the results of a complementation test can be complicated by several factors. (a) In some cases two mutant copies of a gene – each by itself encoding an inactive polypeptide – may be able to complement one another when present together in the same organism. This may occur e.g. when the normal active gene product is a monomer of an oligomeric protein, and the two types of defective monomer encoded by the two mutant alleles can somehow interact to give an oligomer with some activity (*intragenic, intracistronic or interallelic* complementation). The resulting phenotype usually has characteristics qualitatively or quantitatively intermediate between the wild-type and mutant phenotypes. (b) Certain mutant genes are dominant over their wild-type alleles: e.g., an inactive product of a mutant gene may bind to the active product of the wild-type gene to produce an inactive hybrid oligomer (*negative complementation*: see e.g. LAC OPERON); such dominant mutations can be detected by a CIS–TRANS TEST. (c) Recombination between two mutant copies of a gene may result in the restoration of a functional gene; this possibility can be minimized by using recombination-deficient strains (e.g. *recA*<sup>−</sup> bacteria). (d) Complementation can occur only if the genes under study produce diffusible products; it cannot occur e.g. if the mutation is in a control region (e.g. a promoter) which can affect the expression only of adjacent genes in the same genomic molecule. (See also CIS-DOMINANCE.) (e) A POLAR MUTATION can give a misleading result since a single mutation can inactivate two or more adjacent genes.

(See also CISTRON.)

**complementing diploids** See PROTOPLAST FUSION.

**complestatin** A substance, produced by *Streptomyces lavendulae*, which inhibits the alternative pathway of COMPLEMENT FIXATION by combining with Factor B and preventing its binding to C3b.

**complete Freund's adjuvant** See FREUND'S ADJUVANT.

**complete medium** (CM) A type of culture medium which contains nutrients sufficient to support the growth of both PROTOTROPHS and AUXOTROPHS. (cf. MINIMAL MEDIUM.)

**complete transduction** See TRANSDUCTION.

**complex flagellum** See FLAGELLUM (a) and FLAGELLIN.

**complex-mediated hypersensitivity** *Syn.* TYPE III REACTION.

**composting** A process involving the aerobic biological degradation of waste plant matter (e.g. straw, cotton waste, corn-cobs etc) or other organic waste (e.g. paper, dewatered sewage sludge, municipal refuse); composting reduces the bulk of the waste material and converts it to an innocuous form ('compost') which can be used e.g. as a soil conditioner. (See also MUSHROOM CULTIVATION.) Composting involves the activities of a succession of microorganisms whose nature depends to some extent on the nature of the material being composted.

In the composting of e.g. wheat-straw: the damp straw is piled loosely (to allow free circulation of air); inorganic nitrogen and phosphorus – or animal or poultry manure – may be added. The activities of mesophilic bacteria generate heat, and the temperature in the centre of the heap may rise to ca. 60°C or more within a few days, creating conditions in which thermophilic actinomycetes predominate [ARM (1983) 37 198–200]. Air circulation is maintained by convection,

and the heap may be turned and mixed at intervals. The pH may rise substantially (e.g. to 8–9), due e.g. to ammonia production, but later falls to ca. 6–7. After several days the temperature may fall to ca. 30–50°C and may remain at this level for several weeks; during this stage fungi become dominant. Initially, thermophilic members of the Mucorales (e.g. *Rhizomucor pusillus*) develop; these are then replaced by thermophilic hyphomycetes (e.g. *Humicola* spp. *Thermomyces lanuginosus*) and ascomycetes (e.g. *Chaetomium thermophilum*). Finally, basidiomycetes such as *Coprinus cinereus* (often accompanied by the zygomycete *Mortierella wolfii*) become dominant [Book ref. 39, pp. 263–305]. During composting, most or all of the free soluble substrates, much of the CELLULOSE, HEMICELLULOSES and PECTIC POLYSACCHARIDES, and some of the LIGNIN, are degraded, and the loss in dry weight may reach 50% or more.

**compound II** See SIDEROPHORES.

**compound ciliature** Any form of somatic or oral ciliature which involves a discrete group of cilia (several to many) acting as a functional unit; examples: the CIRRUS, MEMBRANELLE, PARORAL MEMBRANE and SYNCILIUM.

**compound trichocyst** *Syn.* FIBROCYST.

**Compsopogon** See RHODOPHYTA.

**co-mutagenesis** The generation of two or more mutations at closely linked loci: see e.g. MNGG.

**ComX** See QUORUM SENSING.

**con gene** See OMP.

**concanavalin A** (con A; jack bean lectin) A mitogenic LECTIN (tetrameric form: MWt 102000) from the jack bean, *Canavalia ensiformis*; it can stimulate T cells and, if cross-linked (e.g. by anti-con A antibody), B cells. Con A binds e.g. to terminal  $\alpha$ -D-mannopyranosyl and  $\alpha$ -D-glucopyranosyl residues (binding requires Ca<sup>2+</sup> and Mg<sup>2+</sup>), and can thus agglutinate e.g. bacteria whose cell wall TEICHOIC ACIDS contain  $\alpha$ -linked glucosyl substituents.

**concatemer** Two or more identical linear nucleic acid molecules (e.g. copies of a viral genome) in tandem, i.e., covalently linked end to end in the same orientation. (cf. CATENANE.)

**concatenate** (1) (*verb*) To form a concatenate (sense 2). (2) (*noun*) *Syn.* CATENANE or CONCATEMER. (3) (*adj.*) Of e.g. spores: formed in chains.

**concentration exponent** (of a disinfectant) See DILUTION COEFFICIENT.

**concentric bodies** (*mycol.*) Rounded or ellipsoidal intracellular structures (ca. 300 nm diam.) which have a transparent core surrounded by concentric layers of varying optical density; they occur in almost all lichenized ascomycetes and in a few non-lichenized ascomycetes. Their origin and function are unknown. Similar structures ('concentric granules') are found in *Allomyces* and related genera; these may play a role as septal pore plugs [Mycol. (1987) 79 44–54]. (cf. CELLULIN GRANULES.)

**conceptacle** (*mycol.*) A hollow structure within which spores are formed – e.g. a locule (see ASCOSTROMA).

**conchate** Having the shape of one-half of a bivalve shell.

**Conchocelis stage** See e.g. PORPHYRA.

**concolorous** Similarly coloured.

**concomitant immunity** *Syn.* PREMUNITION.

**condenser** (substage condenser) In a microscope: a system of lenses which concentrates light and directs it onto the specimen (see MICROSCOPY, Fig. 1). Correct adjustment of the condenser is important for optimum image formation: see e.g. KÖHLER ILLUMINATION. The *numerical aperture* of a condenser (see RESOLVING POWER) should be at least as great as that of the objective lens with which it is used; an oil-immersion

condenser should be used with an oil-immersion objective. Before entering the condenser, the light passes through an iris diaphragm (*aperture diaphragm, substage diaphragm*) which, by controlling the amount of light entering the condenser, controls the apical angle of the cone of light which illuminates the specimen. Hence, the aperture diaphragm should *not* be used as a means of reducing the intensity of illumination because this reduces the NA of the condenser (see RESOLVING POWER). (See also ABBE CONDENSER; CRITICAL ILLUMINATION.)

**condensing enzyme** *Syn.* citrate synthase (EC 4.1.3.7) [see Appendix II(a)].

**conditional lethal mutant** A mutant organism (e.g. a bacterium or virus) in which the mutation does not significantly affect the phenotype under one set of conditions (*permissive* conditions) but is lethal or inhibitory to the organism under another set of conditions (*restrictive* or *non-permissive* conditions). See e.g. TEMPERATURE-SENSITIVE MUTANT and HOST-DEPENDENT MUTANT.

**conduction** (*mol. biol.*) See CONJUGATION (1b)(i).

**condyloma** (*pl.* condylomas or condylomata) An elevated, wart-like lesion of the skin. *Condyloma acuminatum* = genital wart (see PAPILLOMA); *condyloma latum* = a wide, flat condyloma occurring chiefly in the anogenital region in secondary SYPHILIS.

**Condylostoma** See HETEROTRICHIDA.

**confluent growth** See CULTURE.

**confocal scanning light microscopy (CSLM)** A form of light MICROSCOPY in which linear resolution is superior to that obtainable with conventional light microscopes. Essentially, rays from a laser-illuminated pin-hole are focused in the plane of the specimen and collected by a lens system which rapidly scans the specimen in synchrony with the illuminating source. As the optical system scans the specimen the rays entering the collector lens are continually modulated by the specimen; the modulated rays are focused onto a detector plate – generating a signal which modulates a cathode ray tube and forms a visual display of the image.

**congeneric** Of the same genus.

**congenital** Present at birth.

**conglutinated** ‘Glued together’ – used e.g. of hyphae in certain prosenchymatous fungal or lichen tissues.

**conglutination** See CONGLUTININ.

**conglutinin** A protein, present in normal bovine serum, which can bind to a cleavage product of complement component C3b (see COMPLEMENT FIXATION); conglutinin can agglutinate particles/cells to which the cleavage product has adhered – a phenomenon termed *conglutination*.

**conglutininogen** Potential activity associated with complement component C3b; cleavage of C3b by FACTOR I exposes a site which can bind CONGLUTININ.

**conglutininogen-activating factor** *Syn.* FACTOR I.

**Congo – Crimean haemorrhagic fever** See VIRAL HAEMORRHAGIC FEVERS.

**Congo red** A red acid diazo DYE used e.g. as a PH INDICATOR (pH 3.0–4.5, blue to red) and for staining  $\beta$ -linked fibrillar polysaccharides (e.g. cellulose); Congo red disrupts CELLULOSE and CHITIN microfibril formation in growing cells (cf. CALCOFLUOR WHITE).

**conidia** Plural of CONIDIUM.

**conidial head** (*mycol.*) The expanded terminal portion of the conidiophore in certain fungi – see e.g. ASPERGILLUS.

**conidiation** The phenomenon in which conidia function as gametes.

**Conidiobolus** See ENTOMOPHTHORALES.

**conidiogenesis** See CONIDIUM.

**conidiogenous cell** See CONIDIUM.

**conidioma** Any plectenchymatous structure which bears conidia – e.g. a pycnidium, sporodochium or synnema.

**conidiophore** A hypha which bears one or more conidiogenous cells (see CONIDIUM). In e.g. some species of *Colletotrichum*, setae (see SETA) can function as conidiophores.

**conidiospore** *Syn.* CONIDIUM.

**conidium** (*mycol.*) An asexually-derived, non-motile SPORE formed in a blastic or thallic mode (see below) from a specialized conidiogenous (i.e., conidium-producing) cell (cf. SPORANGIOSPORE). Conidia are formed e.g. by many fungi of the DEUTEROMYCOTINA and by a few lower fungi (e.g. species of *Bremia* and *Peronospora*). The two basic modes of conidiogenesis (conidium formation) are as follows.

*Blastic conidiogenesis.* An apical or lateral part of a conidiogenous cell expands and develops into a mature conidium, becoming delimited from the parent cell by a septum. Such a blastic conidium (= *blastoconidium* or blastospore) secedes (i.e., breaks away) from the conidiogenous cell by centripetal splitting of the septum (*schizolysis*) – half the septum becoming the base of the conidium, the other half forming the apex of the conidiogenous cell. If the conidiogenous cell subsequently elongates from a basal growing region it is said to exhibit *basauxic* development. (Cessation of *hyphal* tip growth – see GROWTH (b) – preceding blastic conidiogenesis may depend on changes in ion gradients across the envelope of the conidiogenous cell.)

*Thallic conidiogenesis.* A septum-delimited part of a hypha becomes converted to a single, terminal or intercalary, conidium (a *holothallic* conidium) or to a chain of conidia (*arthric* conidia). (cf. ARTHROSPORE.) Seccession of a terminal, holothallic conidium commonly occurs by *rhexolysis*: the circumferential splitting of the wall of the penultimate cell (which ruptures) a little below the septum of the conidium; arthric conidia may separate by rhexolysis (alternate cells being sacrificed) or by schizolysis. [Formation and germination of fungal arthroconidia: CRM (1986) 12 271–292.]

There are various ways in which the conidiogenous cell can produce a succession of conidia or give rise to a crop of simultaneously formed conidia; some examples are given below.

(a) *Ampullate development.* The apex of the conidiogenous cell becomes globose (‘ampullate’) and gives rise, simultaneously, to a number of blastoconidia. Ampullate development occurs e.g. in *Gonatobotrys*.

(b) *Annellidic development.* After the first, terminal blastoconidium has been delimited by a septum (and either before or after its seccession) a new wall is laid down on the inner surface of the old wall in the distal region of the conidiogenous cell; this new, annular wall, in conjunction with the apical septum, forms an inverted cup-like structure at the free end of the conidiogenous cell. (The formation of the new wall is referred to as *enteroblastic* proliferation of the conidiogenous cell.) Subsequently, the cup-like structure expands to form the next conidium; such a process, in which the new wall becomes continuous with the conidial wall, is referred to as *holoblastic* conidial development. Septum formation then delimits the second blastoconidium – which (sooner or later) secedes by schizolysis; the position of this septum is such that, following seccession of the blastoconidium, part of the new wall remains in the conidiogenous cell, extending a little beyond the rim of the old wall. Thus, after a number of blastoconidia have been produced, the conidiogenous cell (*annellide*) exhibits a succession of bands (*annellations*) at the apical end, each annellation being the remnant of a layer of wall formed inside the previous layer.

## Coniocybe

Annellidic development occurs e.g. in *Scopulariopsis*. (See also PERCURRENT PROLIFERATION.)

(c) *Phialidic development* is very similar to annellidic development, the essential difference being that, in phialidic development, successive septa are formed at or near the level of the rim of the old wall; annellations are therefore not formed, although the edges of successive wall layers in the conidiogenous cell (*phialide*) may be visible just within the apical rim (*collarete*) formed by the original wall of the conidiogenous cell. Phialidic development occurs e.g. in *Phialophora* and *Trichoderma*.

(d) *Retrogressive development* is similar to annellidic and phialidic development but differs in that each blastoconidium formed takes with it, on secession, a part of the original cell wall of the conidiogenous cell; the conidiogenous cell thus progressively shortens. It occurs e.g. in *Cladobotryum*.

(e) *Tretic (porogenous) development*. The wall of the conidiogenous cell contains a narrow pore or channel; materials for conidial growth pass through this channel during the formation of the blastoconidia ('poroconidia' or 'porospores') – which arise either solitarily or in acropetally formed chains. Tretic development occurs e.g. in *Alternaria*.

[Reviews: MS (1984) 1 86–89 and MR (1986) 50 95–132.]

Conidiophores may arise individually or in discrete masses: see e.g. ACERVULUS, COREMIUM, PYCNIDIUM and SYNNEMA.

**Coniocybe** See CALICIALES.

**Coniophora** A genus of fungi of the APHYLLOPHORALES (family Coniophoraceae). *C. puteana* (= *C. cerebella*, 'cellar fungus'), a cause of WET ROT, forms a thin, resupinate fruiting body which is initially cream-coloured but later olivaceous; the basidiospores are brownish. (See also CELLULASES.)

**Coniophoraceae** See APHYLLOPHORALES.

**coniosporiosis** *Syn.* MAPLE BARK STRIPPERS' DISEASE.

**Coniothyrium** See SPHAEROPSIDALES.

**conjugate** (1) (*verb*) Carry out CONJUGATION (sense 1). (2) (*noun*) See CONJUGATION (sense 2).

**conjugate division** See CLAMP CONNECTION.

**conjugate vaccine** A VACCINE containing a *polysaccharide* antigen linked (conjugated) to a protein; such vaccines are useful for young children whose immune system does not respond adequately to (unconjugated) polysaccharide antigens. Some diseases are caused by pathogens with polysaccharide capsules, and conjugate vaccines containing such polysaccharides can elicit protective antibodies in young children. For example, a conjugate vaccine is used against diseases (epiglottitis, meningitis etc.) caused by *Haemophilus influenzae* type b [RMM (1996) 7 231–241]. [Responsiveness of infants to capsular polysaccharides: RMM (1996) 7 3–12.] [Vaccine against group B streptococci IV and VII: JID (2002) 186 123–126. Meningococcal C vaccine (in teenagers): Lancet (2003) 361 675–676.]

**conjugation** (1) ('mating') Any of various processes in which gene transfer (or, exceptionally, complete fusion) follows the establishment of direct contact between two or more microbial cells (which may exhibit little or no morphological differentiation in comparison to vegetative cells).

(a) (*algol.*) Conjugation occurs in several groups of algae (e.g. DESMIDS, certain DIATOMS, SPIROGYRA) and generally involves cell–cell contact followed by protoplast fusion.

(b) (*bacteriol.*) In bacterial conjugation, DNA is transferred from a 'male' (*donor*) bacterium to a 'female' (*recipient*) bacterium while the cells are in physical contact; a recipient which has received DNA from a donor is called a *transconjugant*. (cf. RETROTRANSFER.)

The donor phenotype is commonly conferred on a cell by the intracellular presence of a CONJUGATIVE PLASMID (sense 1);

TRANSPOSON-mediated conjugation is considered separately in the entry CONJUGATIVE TRANSPOSITION.

Any of various plasmid-borne genes (and, in some cases, chromosomal genes) may be transferred during conjugation; such genes include those conferring resistance to antibiotic(s).

Conjugation occurs in both Gram-positive and Gram-negative bacteria; however, as the process differs in Gram-positive and Gram-negative species it is discussed under separate headings for the two categories.

(i) *Conjugation in Gram-negative bacteria*. Much of the information on this topic has derived from studies on the transfer of the F PLASMID (q.v.), and other IncF plasmids, between strains of *Escherichia coli*; the following account is based largely on this information. It is important to note that the general features of the F plasmid–*E. coli* transfer system are not common to all transfer systems found in Gram-negative bacteria.

The stages of conjugation are outlined below, in sequence, on the basis of current models and data.

*Initial cell–cell contact*. The presence of a (plasmid-encoded) pilus (see PILI) is believed to be essential for the donor phenotype. Moreover, different types of pilus mediate conjugation under different physical conditions, and they may function in different ways; for example, some types of pilus mediate conjugation only on moist (but not submerged) solid surfaces (e.g. agar plates), while others mediate conjugation either within the liquid phase or on a solid surface (see PILI) [see also Book ref. 177, pp 33–59 (42–45)].

In the F plasmid–*E. coli* conjugal system, initial donor–recipient contact is believed to occur when the tip of the pilus binds to a site on the surface of the recipient; the pilus is then believed to retract so that the cells achieve wall-to-wall contact. Stable cell–cell contact, involving specific plasmid-encoded proteins, is established after an initial period of unstable contact (during which donor and recipient are easily separated by mild shearing forces). (Mutant *E. coli* recipients defective in the OmpA protein (see OMP) form unstable contacts with donor cells, although this deficiency may be overcome by mating on a moist solid surface.) (See also SURFACE EXCLUSION.)

An understanding of the initial donor–recipient interaction would require a detailed knowledge of the structure and mode of action of the pilus – from initial contact to the putative retraction. This information is currently unavailable; indeed, the conjugal transfer of DNA, even in the well-studied F plasmid–*E. coli* system, and particularly in the initial stages of cell–cell contact, has been described as a 'black box' [Mol. Microbiol. (1997) 23 423–429].

Some authors report that the region of contact between donor and recipient is characterized by a specific, electron-dense *conjugal junction* [JSB (1991) 107 146–156; JB (2000) 182 2709–2715]. The composition of this electron-dense layer is unknown but one suggestion is that, in F plasmid-mediated matings, it may consist of, or contain, F-pilin (the subunit of the F pilus) [Mol. Microbiol. (1997) 23 423–429]; however, results from recent studies on RP4-mediated matings indicated that conjugal junctions are not composed of pilin [JB (2000) 182 2709–2715].

On establishment of effective cell–cell contact, a 'mating signal' (nature unknown) promotes the *mobilization* of donor DNA.

*Mobilization and transfer of DNA*. Mobilization is the process in which (in at least some cases, including the F plasmid) a single, specific strand of donor DNA is prepared for transfer to the recipient.

In the F plasmid, an essential prerequisite for mobilization is the formation of a NICK at a specific site (designated *nic*), in a specific strand, within the origin of transfer (*oriT*); nicking occurs in that strand which is to be transferred to the recipient (the *T-strand*). Nicking is mediated by an endonuclease (a *relaxase*) that forms part of a so-called *relaxosome* (previously called a *relaxation complex*). The relaxosome associated with the F plasmid is a nucleoprotein complex consisting of the transfer origin (*oriT*), the relaxase, and certain other proteins. (Relaxases are encoded e.g. by the F plasmid *tral* gene, the *tral* gene of plasmid RP4, and the *nikA* gene of *Salmonella* plasmid R64.) As well as endonuclease activity, the *Tral* protein of the F plasmid also has (ATP-dependent) helicase activity and is referred to as *helicase I*.

Components of the relaxosome are assembled in a specific order: *Tral* binds after the INTEGRATION HOST FACTOR and the *TraY* protein [JBC (1995) 270 28381–28386]. Recent studies confirm that *TraY* is required for in vivo nicking [JB (2000) 182 4022–4027].

The relaxase is believed to mediate an ongoing cycle of nicking and ligation at the *nic* site, i.e. nicking appears not to be triggered by donor–recipient contact.

Following the mating signal in F plasmid–*E. coli* systems, it appears that the nicked strand enters the recipient in the 5'-to-3' direction. (Single-strand transfer in the 5'-to-3' direction is believed to occur in at least some other cases.)

Transfer of the nicked strand from donor to recipient requires that the strand be unwound from its complementary strand, and this is thought to involve helicase I (*Tral*); if helicase I is involved, and if it is immobilized in relation to the cell envelope, then the unwinding of the transferred strand may provide energy for strand transfer.

One early study indicated that the transferred strand could pass *through* an extended pilus to the recipient [JB (1990) 172 7263–7264]. A later study – which used video-enhanced light-microscopy and electron microscopy – concluded that DNA is transferred while donor and recipient are in close wall-to-wall contact [JSB (1991) 107 146–156].

The precise mode of transfer of DNA from donor to recipient is not known. For F plasmid-mediated systems, it has been postulated that the relaxosome may be coupled, via *TraD*, to a transport apparatus (*transferosome*) consisting of a protein complex located in the cell envelope at the base of the pilus.

In RP4-mediated mating, the transfer apparatus in the donor may include a structure that bridges the cytoplasmic and outer membranes [JB (2000) 182 1564–1574], although this was not detected in another study on RP4-mediated mating [JB (2000) 182 2709–2715].

*DNA synthesis in the recipient cell.* When a cell receives the transmitted strand of an F plasmid, a complementary strand is synthesized to form a circularized dsDNA molecule; this *recA*-independent process is called *replication*. Complementary strand synthesis apparently involves the recipient's DNA polymerase III and other host-encoded enzymes.

For certain *IncI* and *IncP* plasmids (e.g. *ColIb*, RP4), synthesis of DNA in the recipient is initiated by a donor-plasmid-encoded PRIMASE, i.e. during conjugation, primase, as well as ssDNA, is transferred from donor to recipient. In such cases, DNA synthesis is initiated from primers which are formed at various locations on the transferred strand. [Plasmid DNA primases in conjugation: Book ref. 161, pp 585–603.] Matings with *ColIb*-P9 involve the transfer, from donor to recipient, of molecules which include the product of the *sog* gene, which has primase activity [EMBO (1986) 5 3007–3012].

When chromosomal genes have been conjugally transferred (following mobilization of the chromosome), recombination between donor and recipient DNA appears to involve the RECBC PATHWAY.

*DNA synthesis in the donor cell.* In the donor cell a complementary strand is synthesized on the non-transmitted strand in order to reconstitute the dsDNA plasmid; this synthesis, carried out by DNA polymerase III, is referred to as *donor conjugal DNA synthesis* (DCDS). DCDS is generally believed to be carried out by the ROLLING CIRCLE MECHANISM (although earlier claims that primers are needed for DCDS had made this uncertain). More recently, a study using recombinant plasmids containing two tandemly repeated R64 *oriT* sequences (one initiation-proficient but termination-deficient, the other initiation-deficient but termination-proficient) has provided evidence of rolling circle synthesis [JB (2000) 182 3191–3196].

[DNA processing reactions in bacterial conjugation: ARB (1995) 64 141–169.]

*Mobilization of non-conjugative plasmids.* The term 'mobilization' commonly includes instances in which (a) a non-conjugative plasmid (or part of the bacterial chromosome) is conjugally transferred by becoming covalently linked to a conjugative plasmid (transfer being initiated at *oriT* in the conjugative plasmid), or (b) a non-conjugative plasmid is conjugally transferred independently of (that is, without covalent linkage to) a conjugative plasmid by means of cell–cell contacts established by the conjugative plasmid; mobilization of the latter type does not necessarily involve co-transfer (i.e. concomitant transfer) of the conjugative plasmid. (Some authors [ARG (1979) 13 99–125 (106)] have referred to (a) and (b) as *conduction* and *donation*, respectively.) (See also HFR DONOR and INTERRUPTED MATING.)

The F plasmid can mobilize certain non-conjugative plasmids, e.g. the COLE1 PLASMID, in a way that does not require covalent linkage. Plasmid *ColE1* is associated with a relaxosome which can be activated to promote mobilization and transfer of plasmid DNA; the in vivo mechanism of activation is unknown. During F-mediated mobilization and transfer of *ColE1*, one of the proteins of the relaxosome apparently remains covalently bound to the 5' end of the transferred strand, and it has been suggested that this protein may act as a 'pilot protein', interacting with membrane protein(s) and guiding the 5' terminal into the recipient.

Mobilization of the non-conjugative plasmid R1162 involves at least four *trans*-acting plasmid-encoded products and a *cis*-acting site (*oriT*), *oriT* being distinct from *oriV* [JB (1986) 167 703–710].

*Effects of physicochemical parameters on conjugation.* Relatively few studies have been carried out on the effects of variation in the physicochemical conditions under which cell–cell contact occurs. However, a number of early studies were conducted on the effects of variation in basic parameters such as pH, temperature, electrolyte concentration and osmotic pressure; one purpose of these studies was to characterize the response of the conjugal process to changes in 'external' conditions, thus obtaining data potentially useful e.g. for optimizing transfer in the laboratory. These studies found e.g. that transfer of the *IncFII* plasmid R1*drd*19 could be greatly stimulated by higher levels of electrolyte [FEMS (1983) 20 151–153]; that the plasmid could be transferred between 37 and 17°C [AEM (1981) 42 789–791]; that the effects of non-optimal pH and non-optimal temperature are synergistic [AEM (1983) 46 291–292]; that transfer is subject to osmotic constraint [FEMS (1984) 25 37–39]; and

## conjugational junction

that transfer is inhibited by particles of colloidal clay [AEM (1983) 46 756–757]. Transfer of the IncN plasmid R269N-1, which mediates surface-obligatory mating (see PILI), appears to need, or be assisted by, surface tension [FEMS (1983) 19 179–182; JGM (1983) 129 3697–3699].

Some early experiments [e.g. JGM (1987) 133 3099–3107] purported to demonstrate the possibility of plasmid transfer in natural aquatic environments but were flawed by extreme artificiality.

(ii) *Conjugation in Gram-positive bacteria.* Conjugal transfer is known to occur in organisms from various genera, including *Bacillus*, *Enterococcus*, *Lactococcus*, *Staphylococcus* and *Streptomyces*. As in conjugation in Gram-negative bacteria, some plasmids can be transferred across a broad host range; for example, plasmid pAM $\beta$ <sub>1</sub>, which encodes resistance to erythromycin, can be transferred from streptococci to e.g. *Bacillus subtilis* and *Lactobacillus casei*.

There are two main types of plasmid-mediated conjugation in Gram-positive species: PHEROMONE-mediated and (apparently) pheromone-independent mating; pili have not been demonstrated in either category.

Pheromone-mediated conjugation in e.g. strains of *Enterococcus faecalis* (see PHEROMONE) occurs in liquid (broth) cultures, and the plasmids involved commonly contain genes conferring resistance to antibiotics. Some of these plasmids also encode a peptide which antagonizes the corresponding pheromone; such a peptide may have the function of ensuring that a mating response in the donor cell is not triggered unless the relevant pheromone is in a sufficiently high concentration, i.e. conditions under which there is a good chance of a random collision between donor and recipient cells. [Review: JB (1995) 177 871–876.]

Pheromone-independent conjugation requires that the donor and recipient be present on a solid surface (e.g. a nitrocellulose filter) – rather than in a liquid medium. Conjugation of this type occurs e.g. in strains of *Staphylococcus* and *Streptococcus*. The plasmids, which encode e.g. resistance to antibiotics, are commonly >15 kb in size.

In *Bacillus subtilis*, recombinants may be obtained by co-incubation of two apparently plasmid-less parent strains for extended periods of time (e.g. 20 hours); in such crosses most exconjugants contain the entire genome of both parent strains, and the process is believed to resemble a form of temporary cell fusion [Book ref. 199, pp 25–39]. (cf. PROTOPLAST FUSION.)

As in Gram-negative bacteria, certain plasmids may be mobilized by other plasmids, and some of the small multicopy plasmids encode function(s) which specifically promote their own mobilization. Mobilization of the streptococcal plasmid pMV158 has been studied in *Escherichia coli* using R388 or RP4 as the auxiliary plasmid [Microbiology (2000) 146 2259–2265].

(c) *(ciliate protozoal.)* Conjugation occurs in many ciliates; it involves either the temporary association of two individual cells (as e.g. in *Paramecium* or *Tetrahymena*) or the complete fusion of conjugal partners (as e.g. in peritrichs). In some ciliates (e.g. *Blepharisma*) conjugation is promoted by soluble substances (see GAMONE) which are released by the cells; in other ciliates (e.g. *Paramecium*) the chemical signals remain bound to the cell.

In *Paramecium aurelia*, two individuals of appropriate mating type (see SYNGEN) pair with their ventral surfaces in contact, and an intercellular cytoplasmic bridge forms in the cytostomal region. In each conjugant (i.e. partner) the MACRONUCLEUS disintegrates, and both of the micronuclei (see MICRONUCLEUS) undergo meiosis to form eight haploid *pronuclei*; seven *pronuclei* disintegrate. (In *Paramecium caudatum* the fate of a given

*pronucleus* depends on its position within the cytoplasm; the nucleus which survives is located in the cytostomal region [JCS (1985) 79 237–246].) The surviving *pronucleus* (= *gonal nucleus*) divides mitotically to form a pair of gametic nuclei, one of which passes to the conjugal partner and fuses with the stationary nucleus to form a zygotic nucleus (= *syngony*). Subsequently, mitotic divisions of each *syngony* lead to the formation of four diploid nuclei in each conjugant – the conjugants by now having separated; two of the nuclei give rise to two new micronuclei, while the other two form two new macronuclei. During the first binary fission after conjugation, the micronuclei (but not the macronuclei) undergo mitotic division; each daughter cell receives one macronucleus and two micronuclei – thus restoring the normal nuclear constitution of the species. In *P. aurelia* conjugation takes ca. 12–18 hours.

[DNA synthesis, methylation and degradation during conjugation in *Tetrahymena thermophila*: NAR (1985) 13 73–87.]

In peritrichs, two morphologically dissimilar conjugants are formed: a female *macroconjugant* and a smaller, motile, ciliated *microconjugant* which swims in search of, and fuses with, a *macroconjugant*.

(See also AUTOGAMY and CYTOGAMY.)

(d) (*mycol.*) See e.g. MATING TYPE and PHEROMONE.

(2) (*immunol.*) The process of covalently linking two or more species of molecule to form a hybrid molecule (a *conjugate*); for example, a dye may be linked to a protein (as in fluorescein-conjugated antiglobulin), or glutaraldehyde may be used to link two different antibodies to form a hybrid antibody [SAB (1984) 22 73–78]. (See also CONJUGATE VACCINE.)

**conjugational junction** See CONJUGATION (1b)(i).

**conjugative pili** See PILI.

**conjugative plasmid** (1) (self-transmissible plasmid) As commonly used: a PLASMID which encodes all the functions needed for its own intercellular transmission by CONJUGATION (sense 1b); in e.g. the F PLASMID (q.v.) these functions include pilus formation (see PILI) and the formation of proteins involved in the initial preparation of plasmid DNA for transfer. Such a plasmid may also bring about the *mobilization* of a (mobilizable) NON-CONJUGATIVE PLASMID or the mobilization of the donor's chromosome. (cf. SEX FACTOR; see also ANDROPHAGE and PROMISCUOUS PLASMIDS.)

(2) According to some authors [ARG (1979) 13 99–125 (105–106)]: a plasmid which encodes e.g. pilus formation but which may or may not be capable of mobilization; only if such a plasmid is mobilizable is it self-transmissible.

**conjugative transposition** In bacteria: CONJUGATION mediated by a *conjugative transposon*, i.e. independently of a conjugative plasmid, the transposon being transferred from the *donor* cell to the *recipient* cell. First reported in Gram-positive bacteria, it is now well established in Gram-negatives (e.g. *Bacteroides*); indeed, it may permit gene transfer between Gram-positives and Gram-negatives [e.g. AEM (2001) 67 561–568; AEM (2003) 69 4595–4603].

A model for Gram-positive conjugative transposition was as follows. Contact between donor and recipient triggers excision of the transposon in the donor, this involving a transposon-encoded recombinase (product of gene *int*). Each end of the excised transposon carries single-stranded host DNA called a *coupling sequence*. The excised transposon then circularizes through base-pairing (albeit mis-matched) between coupling sequences. A *single* strand may be transferred to the recipient, the complementary strand being synthesized in the recipient prior to insertion. Insertion of the (double-stranded) transposon into the target site is neither

site-specific nor random; each target site seems to contain an A-rich sequence of nucleotides and a T-rich sequence, the two sequences being separated by about six nucleotides.

In *Bacteroides* (Gram-negative) excision and transfer of the conjugative transposon CTnDOT (which is found in many strains of *Bacteroides*) is governed by an OPERON that may be regulated by a TRANSLATIONAL ATTENUATION mechanism [JB (2004) 186 2548–2557].

A recipient which has received a conjugative transposon is a *transconjugant*; receipt confers the donor phenotype. (Interestingly, strains of *Lactobacillus lactis* can receive conjugative transposons but, apparently through lack of particular host function(s), transposons cannot be excised – so that *L. lactis* cannot act as a donor.)

Characteristically, conjugative transposons are resistant to restriction. It may be relevant that the *orf18* gene in Tn916 has been found to encode a product similar to the antirestriction proteins encoded by some plasmids.

All conjugative transposons from pathogenic bacteria carry the tetracycline-resistance *tet(M)* gene [mechanism of Tet(M): JB (1993) 175 7209–7215], and some carry other types of antibiotic-resistance gene(s). These transposons are mobile among a wide range of host species, and are often responsible for antibiotic resistance in plasmid-less Gram-positive pathogens; they have been identified in e.g. *Enterococcus faecalis*, *E. faecium* and *Streptococcus pneumoniae*.

Conjugative transposons occur in e.g. plasmids and chromosomes, and range in size from about 18 kb (Tn916) to >50 kb; some of the larger ones (e.g. Tn5253) apparently consist of a Tn916-like entity within another transposon (each being able to transpose independently).

Conjugative transposons include Tn916, Tn925, Tn1545, Tn3710 and Tn5253. They differ from the ‘classical’ transposons in several ways: (i) they mediate conjugation; (ii) when they insert, they do not duplicate the target site; (iii) when excised, the transposon forms a cccDNA intermediate; (iv) the recipient duplex is characteristically in another cell.

**conjunctivitis** Inflammation of the conjunctivae. It may be due e.g. to physical or chemical irritation, allergic reaction, or to infection by bacteria (e.g. *Haemophilus influenzae*, *Moraxella lacunata*) or viruses (e.g. adenoviruses). (See e.g. ACUTE HAEMORRHAGIC CONJUNCTIVITIS; EPIDEMIC KERATOCONJUNCTIVITIS; GONORRHOEA; INCLUSION CONJUNCTIVITIS; PHARYNGOCONJUNCTIVAL FEVER; PINK-EYE; TRACHOMA.)

**conk** A colloquial name for the fruiting body of a wood-rotting basidiomycete (particularly a polypore).

**Conocybe** See AGARICALES (Bolbitiaceae).

**conocyst** An EXTRUSOME of the gymnostome *Loxophyllum*.

**conoid** A hollow cone of spirally arranged fibrils or tubules, open at the apex, found at the extreme anterior end in certain members of the APICOMPLEXA; it may assist in the penetration of the host cell.

**consensus sequence** (*mol. biol.*) Of the variant forms of a given type of genetic element (e.g. a PROMOTER): a theoretical ‘representative’ nucleotide sequence in which each nucleotide is the one which occurs most often at that site in the various forms of the genetic element which occur in nature. The phrase is also used to refer to an actual sequence which approximates the theoretical consensus.

**conserved name** In NOMENCLATURE: a name retained (by a recognized taxonomic body) even though it may contravene rule(s) of the relevant code.

**consolidation** (*med.*) See e.g. PNEUMONIA (a).

**consortium** A more or less stable physical association between the cells of two or more types of microorganism – advantageous to at least one of the organisms; SYNTROPHISM seems to characterize many (perhaps all) consortia. One example is CHLOROCHROMATIUM AGGREGATUM. [Review: ME (1996) 31 225–247.]

**conspecific** Of the same species.

**constant region** (of Ig) See IMMUNOGLOBULINS.

**constitutive** Refers either to a gene which is expressed constantly, or to the product of such a gene. The level of expression of a constitutive gene depends largely on the efficiency of its PROMOTER.

**constitutive heterochromatin** See CHROMATIN.

**consumption** Pulmonary TUBERCULOSIS.

**consumption test** (*serol.*) Any test in which a measurement is made of the amount of antibody or antigen which is used up (consumed) by antigen–antibody combination in a test system; the amount consumed is determined by titrating the residual (unconsumed) antibody or antigen and comparing it with the quantity initially present. (See e.g. ANTIGLOBULIN CONSUMPTION TEST.)

**contact biotrophic mycoparasite** A fungus which parasitizes other fungi by means of specialized cells which make contact with – but do not penetrate or cause obvious damage to – mycelium of the (living) host; most of the known species (including e.g. *Calcarisporium parasiticum*) require biotin, thiamine, and an unidentified substance, ‘mycotrophen’, for growth. (See also MYCOPARASITE.)

**contact-dependent secretion** See type III systems in PROTEIN SECRETION.

**contact dermatitis** *Syn.* CONTACT SENSITIVITY.

**contact inhibition** See *transformation* in TISSUE CULTURE.

**contact sensitivity** (contact dermatitis) A form of DELAYED HYPERSENSITIVITY in which the subject is primed by cutaneous exposure to certain protein-binding substances – e.g. dinitrofluorobenzene, certain metals (e.g. nickel) and antibiotics (e.g. neomycin) – which bind skin proteins to form neoantigens; subsequent challenge, after ca. 1 week, with the sensitizing substance results in a typical lesion in 24–48 hours. (See also LANGERHANS’ CELLS.)

**contagious abortion** See BRUCELOSIS.

**contagious acne** *Syn.* CONTAGIOUS PUSTULAR DERMATITIS (2).

**contagious bovine pleuropneumonia** In cattle: acute lobar PNEUMONIA, with pleuritis, caused by a strain of *Mycoplasma mycoides*; infection occurs mainly by droplet inhalation. Incubation period: 3–6 weeks (sometimes longer). Onset is sudden, with fever and anorexia; subsequently there is a deep cough and dyspnoea. Death from anoxia may occur within days or weeks (mortality rate up to ca. 50%); survivors may become asymptomatic carriers. *Treatment*: antibiotic and/or other therapy is generally given only where the disease is enzootic. (See also BOVINE RESPIRATORY DISEASE.)

**contagious disease** (1) *Syn.* INFECTIOUS DISEASE. (2) A disease normally transmissible only by direct physical contact between infected and uninfected individuals – as e.g. in many VENEREAL DISEASES.

**contagious ethyma** *Syn.* CONTAGIOUS PUSTULAR DERMATITIS (1).

**contagious equine metritis** (CEM) A sexually transmitted HORSE DISEASE (first recognized in Suffolk, UK, in 1977) characterized by endometritis with mucopurulent vulval discharge and temporary infertility; clinical symptoms usually resolve rapidly. A symptomless carrier state occurs in both mares and stallions. The causal agent is a previously unknown bacterial species. It is a Gram-negative coccobacillus (occasionally filamentous); catalase +ve; oxidase +ve; asaccharolytic; gives –ve reactions in

## contagious hypovirulence

most biochemical tests; grows slowly e.g. on chocolate agar at 37°C (optimum temperature); GC%: 36.1. [Book ref. 181, pp. 49–96.]

**contagious hypovirulence** See HYPOVIRULENCE.

**contagious pustular dermatitis** (1) (orf; contagious ecthyma; scabby mouth) A disease which affects mainly sheep (especially lambs) – in which pustular, scab-forming lesions form on the lips and face and in the mouth; the causal agent, a PARAPOXVIRUS, is presumed to infect via abrasions. Morbidity may be high, but mortality rates are generally very low. In cattle, lesions may be formed on the teats. In man, the disease is localized and self-limiting, involving the formation of lesions e.g. on the hands, arms or eyelids.

(2) (*syn.* contagious acne) A HORSE DISEASE characterized by the formation of pustules, particularly where the skin is in contact with harness; causal agent: *Corynebacterium pseudotuberculosis*.

**contaminative infection** (1) (*parasitol.*) Infection by pathogens derived from the POSTERIOR STATION of the vector. (cf. INOCULATIVE INFECTION.) (2) Infection brought about by the ingestion of material containing pathogens.

**context** (*mycol.*) In basidiomycetes: the sterile (i.e., non-generative) structural tissue which forms the main bulk of a fruiting body, particularly that of the pileus. (cf. TRAMA.)

**continuous cell line** *Syn.* ESTABLISHED CELL LINE.

**continuous centrifugation** See CENTRIFUGATION.

**continuous cooker-cooler** See COOKER-COOLER.

**continuous cultivation** *Syn.* CONTINUOUS CULTURE.

**continuous culture** (continuous-flow culture; continuous cultivation; open culture; open-system culture) The culture of microorganisms, in a liquid medium, such that the organisms can exhibit continual exponential or near-exponential growth (balanced GROWTH) for an extended period of time. (cf. BATCH CULTURE.) Essentially, the procedure involves a continual inflow of fresh medium to the culture (with which it is well mixed) and the simultaneous outflow of an equal volume of fluid consisting of a mixture of old and fresh medium and a proportion of biomass; under 'steady-state' conditions the concentration of biomass in the culture vessel remains constant. In continuous culture, growth can occur, ideally, under defined and effectively invariant conditions; for this reason continuous culture is used e.g. for studies of microbial metabolism: data from continuous culture are generally more reproducible than are those from batch culture. The commonest forms of apparatus used in continuous culture are the chemostat and the turbidostat (see also GRADOSTAT).

In the *chemostat* a culture normally grows at a *sub-maximal* growth rate, and a steady state (at a given growth rate) is achieved by controlling the concentration (always at growth-limiting levels) of an essential substrate in the incoming medium (and, hence, in the culture vessel). (By using very low concentrations of a given essential substrate it is possible to achieve very low rates of growth – similar to those believed to occur e.g. in certain aquatic habitats.) Under steady-state conditions, the growth rate and the concentration of the growth-limiting substrate often have the relationship predicted by the Monod equation (see SPECIFIC GROWTH RATE), and the specific growth rate is numerically equal to the DILUTION RATE. Under steady-state conditions the concentration of biomass in the chemostat is governed by the rate at which the growth-limiting substrate is supplied to the culture, and (for a given rate of supply of that substrate) the concentration of biomass cannot be varied by the operator. (See also YIELD COEFFICIENT.) The conditions

in a chemostat tend to be unstable at or near the maximum growth rate.

In the *turbidostat* a culture normally grows at or near the *maximum* growth rate, and all substrates are usually present in excess; within certain limits, the concentration of biomass in the turbidostat can be selected by the operator, and a steady state is achieved by adjusting the dilution rate such that cell growth is matched by the rate of loss of cells from the culture vessel. Control of culture density (i.e. number of cells per unit volume) may be achieved e.g. by a photosensitive device which monitors the opacity of the culture and automatically adjusts the flow rate; however, this method may suffer from inaccuracies due e.g. to foaming and to 'wall growth' (see later). Alternatively, culture density can be controlled by monitoring other parameters which are closely linked to specific growth rate – e.g. pH (in a 'pH-stat'), CO<sub>2</sub> evolution (in a 'CO<sub>2</sub>-stat'), or oxygen uptake.

In continuous culture, deviations from ideal (predictable) operation are common. Such deviations may arise e.g. as a result of the inability to achieve perfect (100%, instantaneous) mixing of the inflowing medium with the culture fluid; imperfect mixing may be indicated by a stable dilution rate which exceeds  $D_c$ . Changes in the rate of agitation can affect the mean cell volume of the cultured cells [JGM (1985) 131 725–736]. Wall growth (adherence to, and growth of, the cultured cells on the walls of the culture vessel) may give an effect similar to (but usually greater than) that of imperfect mixing. Another type of deviation may occur when cells are cultured at low rates of growth; for example, under carbon-limited conditions a major part of the carbon source may be used to provide MAINTENANCE ENERGY (thus giving a lower-than-predicted yield of biomass), while under carbon-excess conditions the yield of biomass may be greater than predicted owing to the accumulation of intracellular reserve polymers (e.g. PHB). A different type of problem involves the emergence of mutants during the (extended) periods of culture – an effect which can change the character of the biomass if particular mutant(s) can outgrow the parent strain; nevertheless, it is possible to take advantage of this effect – e.g. when it is desired to isolate mutants which synthesize more (or more effective) enzyme(s) or which can take up the growth-limiting substrate more efficiently than can the parent strain.

**continuous-flow culture** *Syn.* CONTINUOUS CULTURE.

**continuum model** See CELL CYCLE.

**Contophora** Algae *except* members of the RHODOPHYTA. (cf. ACONTA.)

**contour-clamped homogeneous electric field electrophoresis** (CHEF) See PFGE.

**contractile vacuole** An osmoregulatory organelle, one or more of which may occur in the cytoplasm in most freshwater (and some saltwater) eukaryotic microorganisms (cf. PUSULE); basically, it is a membrane-limited region which, under normal environmental conditions, alternately fills with fluid (*diastole*) and then discharges the fluid to the exterior (*systole*). During diastole, the contractile vacuole may be fed by a surrounding layer of small vesicles which appear to coalesce with the main vacuole (as in amoebae), and/or – depending on species – it may be fed by a system of collecting tubules which ramify in the cytoplasm (forming the *spongione*, = *spongioplasm*, = 'nephridial network') and apparently drain areas remote from the vacuole (a system characteristic of ciliates). In some protozoa (e.g. *Paramecium*, *Tetrahymena*) discharge occurs at a fixed site (pore) in the pellicle.

The mechanism of contractile vacuole activity is not known. Systole may involve cytoplasmic turgor pressure; at least in

ciliates, the vacuole wall may be inherently contractile. In general, the length of the diastole–systole cycle (seconds, minutes or hours) appears to depend on temperature, on the size of the cell (being shorter in smaller cells), and on the osmolarity of the medium.

[Review: Biol. Rev. (1980) 55 1–46.]

**convalescent serum** SERUM from a patient in the convalescent stage of a disease; in some cases it may be used to provide PASSIVE IMMUNITY.

**convergent trama** See BILATERAL TRAMA.

**Convoluta** A genus of flatworms (platyhelminths), found on sandy sea shores in the intertidal zone, which form a symbiotic association with certain unicellular green algae. On hatching, the young flatworms ingest cells of *TETRASELMIS*; the algal cells lose their flagella, theca and eyespot, and reside between the cells of the subepidermal tissues in the flatworm where they continue to photosynthesize. The flatworm eventually ceases to feed, its digestive organs degenerate, and it becomes completely dependent on the photosynthate produced by *Tetraselmis*. Eventually, the algal cells themselves are digested, and the animal then dies. (cf. ELYSIA; see also ZOOCHLORELLAE.)

**cooked meat medium** (chopped meat medium; Robertson's cooked meat medium) Any of a range of media containing boiled, de-fatted, minced lean beef, and used e.g. for the growth of ANAEROBES, for the sporulation of clostridia, and as maintenance media for e.g. clostridia and streptococci; in some formulations the medium incorporates a reducing agent (e.g. L-cysteine or thioglycollate) and e.g. haemin, vitamin K<sub>1</sub> and yeast extract. The medium is sterilized by autoclaving, and the final pH is about 7.4; it is stored in screw-cap bottles, and is sometimes equilibrated under O<sub>2</sub>-free conditions at room temperature before the cap is tightened. [Recipe: (e.g.) Book Ref. 53, pp. 1423–1424.]

**cooker–cooler** (continuous cooker–cooler) In CANNING: a vessel within which filled, sealed cans (or other containers) undergo heat treatment in a continuous-type process (cf. BATCH RETORT). In rotary-type cooker–coolers, the cans enter and leave, through self-sealing valves, a chamber containing steam under pressure. In hydrostatic-type cooker–coolers, pressure in the steam chamber supports vertical columns of water through which the cans enter and leave the chamber.

**cooking** (*industrial microbiol.*) (1) In the food processing industry: heat treatment used for APPERTIZATION. (See also c<sub>0</sub>.) (2) A stage in CHEESE-MAKING.

**Coomassie brilliant blue** A sensitive stain for proteins. The red (anionic) form of the dye becomes blue when bound to protein amino groups.

**Coombs' reagent** (*serol.*) *Syn.* ANTIGLOBULIN.

**Coombs' test** (*serol.*) *Syn.* ANTIGLOBULIN TEST.

**Cooper–Helmstetter model** *Syn.* HELMSTETTER–COOPER MODEL.

**cooperative binding** A mode of binding (e.g. of protein molecules to a DNA strand) in which the binding of one molecule facilitates binding of the next.

**co-oxidation** See CO-METABOLISM.

**cop gene** A gene involved in the control of the COPY NUMBER of a plasmid. (See e.g. R1 PLASMID.)

**cophenetic correlation coefficient** In NUMERICAL TAXONOMY: a measure of the accuracy with which a phenogram represents a given S matrix.

**copiotroph** Any organism which grows only in the presence of high concentrations of nutrients. (cf. OLIGOTROPH.)

**copper** (as an antimicrobial agent) Copper is a HEAVY METAL which is essential (in trace amounts) for the activity of a number of microbial proteins (e.g. cytochrome *aa*<sub>3</sub>, tyrosinase).

However, in effective concentrations, copper and certain of its compounds are useful antimicrobial agents; toxicity to microorganisms appears to reside in the cupric ion.

*Copper sulphate* has been used as an anti-algal agent in e.g. swimming pools and as a constituent of various agricultural antifungal agents (see e.g. BORDEAUX MIXTURE, BURGUNDY MIXTURE, CHESHUNT COMPOUND). *Copper naphthenate* is a greenish, waxy solid, soluble in various organic solvents, which is used as an antifungal preservative for e.g. cellulosic textiles. *Copper soaps* are copper salts of certain fatty or oleoresinous acids (e.g. copper stearate, copper tallate) which have antifungal activity similar to that of copper naphthenate. *Cuprammonium hydroxide* is used in aqueous solution for rot-proofing fabrics. Cupric ions are complexed by 8-HYDROXYQUINOLINE (one atom of copper to two molecules of 8-hydroxyquinoline) to form *copper 8-quinolinolate* (copper-oxine; copper oxinate) which is a highly effective antifungal agent used e.g. in agriculture and as a preservative for textiles. (Copper compounds are not used in rubber products since they catalyse the oxidation of rubber.)

**copper 8-quinolinolate** See COPPER.

**copper soaps** See COPPER.

**co-precipitation** (*serol.*) The precipitation of otherwise non-precipitating molecules etc. as part of, or enmeshed with, an immune complex.

**Coprinaceae** See AGARICALES.

**Coprinus** A genus of humicolous, lignicolous or coprophilous fungi (AGARICALES, Coprinaceae) in which, in most species, the lamellae undergo rapid autodigestion at maturity (see LAMELLA and BASIDIOSPORE). (See also INK-CAP FUNGI.)

**coproantibodies** Antibodies produced by the intestinal mucosa and found in the lumen of the gut; they are mainly of the secretory IgA class.

**Coprococcus** A genus of Gram-positive, asporogenous, anaerobic bacteria which occur e.g. in the human gut; the organisms ferment carbohydrates with the production of butyric and acetic acids. Cells: cocci, occurring in pairs or chains. GC%: ca. 39–42.

**coprogen** See SIDEROPHORES.

**Copromyxa** See ACRASIOMYCETES.

**Copromyxella** See ACRASIOMYCETES.

**coprophilic** (coprophilous) Refers to an organism which grows preferentially or exclusively on or in animal faeces. For example, certain fungi (e.g. species of *Coprinus*, *Pilobolus* and *Sordaria*) grow more or less specifically on dung – particularly that of herbivorous animals.

**co-protease** (coprotease) A type of molecule which, acting non-enzymically, can promote autocatalytic cleavage of a protein; an example is RecA\* in the SOS SYSTEM.

**coprozoic** Refers to e.g. protozoa which are COPROPHILIC.

**copy-choice model** See RECOMBINATION.

**copy-mutant** (copy-number mutant; *cop* mutant) A mutant PLASMID whose COPY NUMBER differs from that of the wild-type plasmid. In copy mutants the copy number is usually higher than that of the wild-type plasmid, but in some cases it is lower.

**copy number** (1) (of a bacterial plasmid) The number of copies of a given PLASMID, per chromosome, in a cell; copy number depends on the replication control system encoded by the plasmid, on the strain or species of cell in which the plasmid occurs, and on growth conditions. In plasmid-containing bacteria in the exponential phase of growth, a given plasmid occurs with a characteristic copy number; any perturbation in copy number tends to be corrected by a rise or fall in the frequency of plasmid replication. Mutations in a plasmid (and/or chromosome) may give rise to a COPY MUTANT.

## CoQ

Copy number is determined primarily by the regulation of initiation of plasmid replication; thus, e.g. a particular mutant of pBR322 (a plasmid related to the COLE1 PLASMID – q.v.) which encodes an altered (less effective) negative regulatory molecule (RNA I) exhibits an 8-fold increase in copy number [JGM (1986) 132 1021–1026]. Other factors which govern copy number include the PARTITION system (if any) of the plasmid. In some plasmids the *ccd* system contributes to the stability of plasmid inheritance (see F PLASMID).

(See also INCOMPATIBILITY and MULTICOPY PLASMID.)

(2) The number of copies of e.g. a given gene product per copy of that gene (or per cell), or the number of copies of a given gene per cell etc.

**CoQ** Coenzyme Q: see QUINONES.

**coral fungi** See APHYLLOPHORALES (Clavariaceae).

**coral spot** See NECTRIA.

**coral symbiosis** See ZOOXANTHELLAE.

**Corallina** See RHODOPHYTA.

**Corallococcus** See MYXOBACTERIALES.

**Corallomyxa** See ACARPOMYXEA.

**cord factor** Any of the MYCOLIC ACID diesters of TREHALOSE found in the cell walls of *Mycobacterium* spp and in other mycolic acid-containing species. The name 'cord factor' was originally given to a glycolipid (6,6'-dimycolyl- $\alpha,\alpha'$ -D-trehalose) derived from tubercle bacilli characterized by growth in the form of 'cords'. Certain mycolic acid esters (e.g. 6,6'-dimycolyl- $\alpha,\alpha'$ -D-trehalose, or 5-mycolyldiaraboside) from the walls of *M. tuberculosis* can potentially act as ENDOTOXINS (sense 2) by uncoupling mitochondrial electron transport and oxidative phosphorylation [Ann. Mic. (1983) 134B 233–239].

**cordycepin** (3'-deoxyadenosine) An inhibitor of RNA synthesis; it is obtained e.g. from *Cordyceps militaris*.

**Cordyceps** A genus of fungi (order CLAVICIPITALES) which include parasites of insects and of other fungi. At least some entomogenous species can form CHITINASES, and infection appears to be initiated via the cuticle and haemolymph rather than via the gut; the fungus subsequently forms, on the dead insect, an erect, cylindrical or clavate stroma which contains perithecia in the surface layer. The dead host is resistant to decay – apparently due to the presence of CORDYCEPIN. *C. militaris* ('scarlet caterpillar fungus') forms orange stromata (ca. 2–5 cm high) on the larvae and pupae of butterflies and moths. *C. canadensis* is parasitic on *Elaphomyces* spp.

**core** (1) (*virol.*) Any of various internal structures within a virion – commonly a protein–nucleic acid complex; the core may be enclosed within a CAPSID (see e.g. HERPESVIRIDAE), a membrane (see e.g. POXVIRIDAE) or an ENVELOPE (see e.g. RETROVIRIDAE). (cf. NUCLEOCAPSID.)

(2) (*bacteriol.*) See ENDOSPORE sense 1(a).

**core oligosaccharide** See LIPOPOLYSACCHARIDE.

**core particle** (of chromatin) See CHROMATIN.

**coremium** In some fungi (e.g. *Penicillium expansum*): an erect bundle of spore-bearing hyphae, the hyphae being associated more loosely than those in a SYNNEMA. (For some authors the terms coremium and synnema are synonymous.)

**corepressor** See OPERON.

**coriaceous** Leathery in texture.

**Coriolius** A genus of fungi of the APHYLLOPHORALES (family Polyporaceae) which form non-stipitate, typically semicircular, bracket-type basidiocarps on deciduous wood; the context is trimitic, usually leathery, rubbery or woody, and the hymenophore is porous. In *C. versicolor* (sometimes called *Trametes versicolor*) the upper surface of the basidiocarp is often

velvety, exhibiting a number of dark bands concentric about the region of attachment, while the lower surface is pale; basidiospores: cream-coloured, ca.  $6 \times 2 \mu\text{m}$ . (See also WHITE ROT and LIGNIN.)

**corn oil test** (for lipase) See LIPASE.

**corn stunt disease** A leafhopper-transmitted YELLOWS disease of maize, characterized by stunting and leaf striping/discoloration, caused by the MAIZE CHLOROTIC DWARF VIRUS or by certain strains of *Spiroplasma citri*. [Proposal to regard the corn stunt spiroplasmas as a distinct species, *S. kunkelii*: IJSB (1986) 36 170–178.]

**cornmeal agar** A mycological medium. Essentially, cornmeal (4% w/v) is heated in distilled water for 1 hour at 60–65°C; agar (1.5% w/v) is added to the filtrate, and the medium is autoclaved. Cornmeal agar is used e.g. to demonstrate chlamydospore formation in *Candida albicans* – which is reported to be encouraged by the addition to the medium of Tween 80.

**cornute** *Syn.* ROESTELIOID.

**Coronaviridae** A family of pleomorphic, enveloped, non-segmented ssRNA viruses which infect man, animals or birds. One genus (*Coronavirus*) is currently recognized. Members include AVIAN INFECTIOUS BRONCHITIS VIRUS (IBV; type species), human coronavirus (a causal agent of the COMMON COLD), murine hepatitis virus (MHV), porcine haemagglutinating encephalitis virus (see VOMITING AND WASTING DISEASE), and porcine TRANSMISSIBLE GASTROENTERITIS VIRUS; probable members include e.g. coronavirus enteritis of turkeys virus (= turkey bluecomb disease virus), and neonatal calf diarrhoea coronavirus. 'Possible members' include feline infectious peritonitis virus (= feline coronavirus) and human enteric coronavirus (a possible causal agent of human FOOD POISONING).

Virion: ca. 75–160 nm diam., consisting of a helical nucleocapsid surrounded by the envelope; characteristic club-shaped glycoprotein projections (peplomers, 'spikes') 12–24 nm long extend from the outer surface of the envelope. Genome: positive-sense ssRNA, MWt typically ca.  $6-7 \times 10^6$  ( $8 \times 10^6$  has been reported for IBV). The RNA is polyadenylated at the 3' end. Proteins associated with the virion include (at least) S ('spike'), M (membrane) and N (nucleocapsid). The virions are inactivated e.g. by lipid solvents and by detergents.

Virus replication occurs in the host cell cytoplasm. In IBV, 6 subgenomic mRNAs (A–F) are formed, all of which are 3'-coterminal with the genomic RNA (a so-called 'nested set' of mRNAs); each 5' end has a common leader sequence (ca. 70 bases long) derived from the 5' end of genomic RNA [possible mechanism: JGV (1986) 67 221–228]. (MHV forms a 'nested set' of 7 subgenomic mRNAs, designated RNA1–RNA7.) The virions mature by budding through the endoplasmic reticulum into vesicles.

[Molecular biology of coronaviruses: AVR (1983) 28 35–112.]

**Coronavirus** See CORONAVIRIDAE.

**Coronie wilt** *Syn.* HARTROT.

**correction collar** A part of a microscope objective lens which is used to adjust the lens to work with cover-glasses of various thicknesses.

**corrinoids** See VITAMIN B<sub>12</sub>.

**Corriparta subgroup** See ORBIVIRUS.

**corrosive sublimate** See MERCURY.

**cortex** (1) Any of various external or outer layer(s) of a structure or organism – e.g. the outer differentiated tissue of certain LICHENS; in *ciliates* 'cortex' refers to the PELLICLE together with the INFRAILCIATURE. (2) See ENDOSPORE.

**corticate** Having a CORTEX.

**Corticaceae** See APHYLLOPHORALES.

**corticicolous** *Syn.* CORTICOLOUS.

**corticolous** (corticicolous) Growing on and/or in bark. (cf. EPIPHLOEODAL and ENDOPHLOEODAL.)

**Corticosteroid synthesis** See STEROID BIOCONVERSIONS.

**corticotype** (*ciliate protozool.*) The morphological features of the CORTEX determined by staining (particularly silver staining) techniques. (See also SILVER LINE SYSTEM.)

**Corticoviridae** (PM2 phage group) A family of icosahedral, lipid-containing, non-enveloped BACTERIOPHAGES which contain supercoiled ds cccDNA. Type species: BACTERIOPHAGE PM2. Possible member: bacteriophage 06N 58P (host: *Vibrio*).

**Corticovirus** Currently the sole genus of the CORTICOVIRIDAE.

**cortina** A remnant of the PARTIAL VEIL (q.v.) in a mature fruiting body. ('Cortina' is also used to refer to an intact partial veil.)

**Cortinariaceae** See AGARICALES.

**Cortinarius** See AGARICALES (Cortinariaceae) and MYCETISM.

**cortisol synthesis** See STEROID BIOCONVERSIONS.

**Corynebacterium** A genus of Gram-positive, aerobic, facultatively anaerobic, chemoorganotrophic, non-acid-fast, non-motile, asporogenous bacteria (order ACTINOMYCETALES, wall type IV). The genus contains saprotrophic species found e.g. in soil and vegetable matter (including e.g. some species previously classified in the genera *Arthrobacter*, *Brevibacterium* and *Microbacterium*), and a number of species which are parasitic or pathogenic in man and other animals; all the plant-pathogenic species have been reclassified in other genera (e.g. CURTOBACTERIUM, RHODOCOCOCCUS). *Corynebacterium* spp exhibit certain features common to all nocardioform actinomycetes – e.g. the presence of cell wall MYCOLIC ACIDS. The organisms are straight or curved, pleomorphic, often coryneform rods. Metabolism can be oxidative or fermentative. Catalase-positive. GC%: ca. 51–59. Type species: *C. diphtheriae*.

*C. autotrophicum*. See XANTHOBACTER.

*C. betae*. See CURTOBACTERIUM.

*C. bovis*. Occurs e.g. associated with the cow's udder. Unlike other *Corynebacterium* spp it contains tuberculostearic acid.

*C. diphtheriae*. Cells rod-shaped, 0.3–0.8 × 0.8–8.0 μm. Toxinogenic strains of *C. diphtheriae* are the causal agents of DIPHTHERIA (see also DIPHTHERIA TOXIN and CROUP); the organisms may be isolated e.g. on tellurite–blood agar (see TELLURITE MEDIA) and subcultured to Loeffler's serum. (Growth from Loeffler's serum is used for the determination of cell morphology; cells grown on tellurite media have an atypical morphology.) The optimum growth temperature is 37°C. *C. diphtheriae* occurs in three main varieties, *gravis*, *intermedius* and *mitis*, which can be distinguished by cell and colonial morphology and by biochemical activity. All three varieties are urease-negative, and none can hydrolyse pyrazinamide; all produce acid (but no gas) from glucose, maltose and mannose, and some *mitis* strains can ferment sucrose [Book ref. 46, p. 1831]. *Gravis* strains typically form DAISY HEAD COLONIES (ca. 3 mm diam. at 24 hours/37°C) on blood–tellurite media; haemolysis is uncommon. Typically, starch is fermented in 24–48 hours. Very few cells contain METACHROMATIC GRANULES.

*Intermedius* strains typically form small colonies (<1 mm diam. at 24 hours/37°C) on blood–tellurite media, the colonies usually being dull greyish-black with a slightly crenated edge; haemolysis does not occur. The cells rarely contain metachromatic granules; stained cells exhibit a characteristic 'barred' appearance due to uptake of the stain (polychrome methylene blue) in a series of transverse bands. *Mitis* strains

typically form shiny, greyish-black, entire colonies, 1–2 mm at 24 hours, on blood–tellurite media; haemolysis is very common. Each cell typically contains several metachromatic granules. The *ulcerans* variety [Book ref. 46, p. 1831] (= *C. ulcerans*) produces urease and gelatinase, and ferments starch and trehalose as well as glucose, maltose and mannose; haemolysis is common. Pyrazinamide is not hydrolysed. (See also ULCERACIN 378.)

*C. equi*. See RHODOCOCOCCUS.

*C. fascians*. See RHODOCOCOCCUS. (See also FASCIATION.)

*C. flaccumfaciens*. See CURTOBACTERIUM.

*C. glutamicum*. A species which occurs e.g. in soil and vegetable matter; certain strains are used for the industrial production of GLUTAMIC ACID. *C. glutamicum* is nutritionally fastidious; biotin is necessary for growth, and some strains are reported to need B vitamins.

*C. haemolyticum*. See ARCANOBACTERIUM.

*C. hydrocarboclastus*. See CORYNECINS.

*C. minutissimum*. A species [*incertae sedis*: Book ref. 21, p. 605] which is the causal agent of ERYTHRASMA; the organisms ferment glucose, maltose, mannose, and usually sucrose [Book ref. 46, p. 1831].

*C. oortii*. See CURTOBACTERIUM.

*C. ovis*. See *C. pseudotuberculosis*.

*C. parvum*. See PROPIONIBACTERIUM.

*C. poinsettiae*. See CURTOBACTERIUM.

*C. pseudotuberculosis* (formerly *C. ovis*). The causal agent of pyogenic infections in e.g. cattle, horses and sheep (see e.g. CONTAGIOUS PUSTULAR DERMATITIS (2), and ULCERATIVE LYMPHANGITIS). The organisms typically form yellow colonies; acid is produced from glucose, maltose and mannose, and urease is formed. Some strains are haemolytic. Pyrazinamide is not hydrolysed.

*C. pyogenes*. See ACTINOMYCES.

*C. renale*. A species isolated e.g. from urinary tract infections in cattle. Colonies are typically cream to yellow; glucose and mannose (but not maltose) are fermented, and urease is formed. Pyrazinamidase and caseinase are formed.

*C. salmoninus*. See RENIBACTERIUM.

*C. ulcerans*. See *C. diphtheriae*.

*C. xerosis*. A species which occurs e.g. on the conjunctivae and in the throat in man; usually non-pathogenic, but cases of endocarditis following aortic valve replacement have been reported. Colonies are greyish; typically, glucose, maltose, mannose and sucrose are fermented, and pyrazinamidase is formed. Urease-negative.

**corynecins** Compounds analogous to chloramphenicol in which the *N*-dichloroacetyl substituent is replaced with non-halogenated acyl groups; corynecins have been isolated from '*Corynebacterium hydrocarboclastus*'. (A type strain of *C. hydrocarboclastus* has been shown to have the properties of a species of *Rhodococcus* [JGM (1982) 128 2503–2509].)

**coryneform** (1) ('club-shaped') Essentially rod-shaped with one end thickened or bulbous. (2) A name applied, loosely, to any Gram-positive, asporogenous, pleomorphic rod-shaped bacterium; as such it covers bacteria from a range of genera. (cf. DIPHTHEROID.)

**Coryneliales** See ASCOMYCOTINA.

**corynephage** A BACTERIOPHAGE which infects *Corynebacterium* spp. (See also DIPHTHERIA TOXIN.)

**corynomycolic acids** MYCOLIC ACIDS of *Corynebacterium* spp.

**coryza** Discharge from the nasal mucous membranes – a symptom of e.g. the COMMON COLD and the prodromal phase of MEASLES.

*cos*

*cos* See BACTERIOPHAGE LAMBDA; BACTERIOPHAGE P2; COSMID.

*Coscinodiscus* See DIATOMS.

*Cosmarium* A large genus of placoderm DESMIDS. The cells are elliptical or angular in outline, with a deep sinus; the semicells may be ornamented but lack prominent projections or spines (cf. XANTHIDIUM). (See also SINGLE-CELL PROTEIN.)

**cosmid** A PLASMID into which has been inserted the *cos* site of BACTERIOPHAGE LAMBDA. Cosmids can be used as CLONING vectors for large fragments of DNA (e.g. ca. 25–40 kb), and have been useful e.g. in the construction of genomic libraries.

The use of a cosmid is shown diagrammatically in the figure. (See also PHASMID.)

**costa** (1) Any rib-like structure. (2) A deeply-staining, curved, endoskeletal rod in trichomonads; its location coincides with the region where the undulating membrane adjoins the cell. (cf. AXOSTYLE.)

*Costaria* See PHAEOPHYTA.

*Costia* A genus of flagellated protozoa. *C. necatrix* is parasitic in fish (see COSTIASIS); the cell is dorsoventrally flattened and bears two long and two short flagella. The longer flagella are used for locomotion, the shorter flagella for attachment of the organism to a host.

**costiasis** (blue slime disease) A freshwater FISH DISEASE caused by *Costia necatrix*. The skin and gills are affected, and large

COSMID (diagrammatic). The cosmid (*top*) is a plasmid containing (i) a *cos* site (*solid black square*) from bacteriophage lambda, and (ii) the cutting site (*short vertical bar*) of a RESTRICTION ENDONUCLEASE.

Cosmids are cut at the single restriction site, yielding linearized molecules with an internal *cos* site (*top, left*). Linearized cosmids are mixed with DNA fragments (*dashed lines*) which have been cut by the same restriction enzyme.

Cosmids and fragments bind randomly via sticky ends, and in some cases a fragment will be flanked by two cosmids (*centre*). If, in such a molecule, the distance *cos*-to-*cos* is approximately 40–50 kb, then the *cos*-*cos* sequence is the right size for packaging into a phage lambda head (the phage lambda genome is ~48 kb). Enzymic cleavage at the *cos* sites (*arrowheads*) creates sticky ends, and packaging of the recombinant molecule occurs, *in vitro*, in the presence of phage components.

The completed virions can inject their recombinant molecules into suitable bacteria. Within a bacterium the DNA circularizes, via the *cos* sites, and replicates as a plasmid; its presence in the cell can be detected e.g. by the expression of plasmid-encoded antibiotic-resistance genes.

Screening for specific sequences in cosmids is carried out in a way similar to that used for plasmid vectors.

Reproduced from *Bacteria* 5th edition, Figure 8.15, page 197, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

amounts of slime are secreted over the body. Mortality may be massive in fish hatcheries.

**co-substrate** See CO-METABOLISM.

**cot death** *Syn.* SUDDEN INFANT DEATH SYNDROME.

**cotransduction** The TRANSDUCTION of two or more donor genes in the same transducing virion.

**co-transfer** (of plasmids) See CONJUGATION (1b) (i).

**co-transport** *Syn.* SYMPORT.

**cotrimoxazole** See FOLIC ACID ANTAGONIST.

**cottage cheese** See CHEESE-MAKING.

**cotton anthocyanosis virus** See LUTEOVIRUSES.

**cotton blue** *Syn.* METHYL BLUE.

**cotton wilt** Any VASCULAR WILT of cotton plants (*Gossypium* spp.). Common causal agents include *Fusarium oxysporum* f. sp. *vasinfectum* ('Frenching disease') and *Verticillium dahliae*.

**cotton wool** A fibrous, cellulosic material from seed coats of the cotton plant (*Gossypium*). *Non-absorbent* cotton wool contains substances (e.g. unsaturated fatty acids) inhibitory to certain organisms; *absorbent* cotton wool has been treated with solvents and bleached so that the inhibitory substances have been largely or completely removed. Plugs of non-absorbent cotton wool are often used as stoppers in tubes of bacteriological media. (See also SWAB.) (cf. cotton wool substitute in the entry ALGINATE.)

**cotton wool disease** See COLUMNARIS DISEASE.

**cottontail rabbit papilloma virus** See PAPILLOMAVIRUS.

**cotype** *Syn.* SYNTYPE.

**cou gene** See GYRASE.

**cough plate** A method for isolating *Bordetella pertussis* from a suspected case of WHOOPING COUGH. A plate of BORDET-GENGOU AGAR is exposed to droplet inoculation from the patient's cough and is then incubated and examined for growth of *B. pertussis*. Many clinicians now use a pernasal swab (optimally, with an ALGINATE tip) in preference to the cough plate method.

**Coulter counter** An instrument used for counting particles (cells, spores etc) in a suspension. Essentially, it consists of two chambers separated by a partition of (electrically) insulating material which is perforated by a single hole of size similar to that of the particles to be counted. Each chamber contains an electrode. The sample is placed in one chamber and forced, under pressure, into the other; during this transfer the suspension acts as a conducting path (via the hole) between the two electrodes. As each cell passes through the hole, it momentarily decreases the electrical conductivity between the electrodes; this momentary change in conductivity is recorded as a pulse by an electronic counting circuit controlled by the two electrodes. The cell count is indicated on a digital display. (See also COUNTING METHODS.)

**coumermycins** A group of compounds structurally related to NOVOBIOCIN. Coumermycin A<sub>1</sub> inhibits ATP-dependent GYRASE activity in the same way as NOVOBIOCIN, but is much more effective both *in vivo* and *in vitro*.

**Councilman body** A cluster of hyaline, necrotic, eosinophilic cells in the liver of an individual suffering from YELLOW FEVER.

**counter-receptor** (to a CAM) See CELL ADHESION MOLECULE.

**counter transport** *Syn.* ANTIPORT.

**countercurrent immunoelectrophoresis (CIE)** IMMUNOELECTROPHORESIS (used for only certain types of antigen) in which antibodies and antigens (in separate wells in a gel strip) move towards each other when subjected to the same electric field; the antibodies move towards the cathode (see ELECTROENDOSMOSIS) while the antigens – because of their size, charge, and other physico-chemical characteristics – move towards the anode.

**counterstain** (1) A second, contrasting, stain used on a microscopical preparation with the object of staining those features

which have not taken up the first stain. (2) In the GRAM STAIN: a stain used to stain those organisms or tissues which have been decolorized. (3) In the AURAMINE-RHODAMINE STAIN: the solution of potassium permanganate used to eliminate background fluorescence.

**counting chamber** (haemocytometer) An instrument used for determining the total cell count, viable cell count, or spore count etc. of a suspension of cells or spores (see COUNTING METHODS). A typical counting chamber is illustrated on p. 200. A grid, etched on the central plateau of the glass block, typically consists of a square of side 1.0 mm divided into 400 squares, each 0.0025 mm<sup>2</sup>; the distance between grid and cover-slip may be 0.1 mm (as in the Thoma chamber) or 0.02 mm (as in the Helber chamber). When the cover-slip is correctly positioned, Newton's rings should be visible through those parts of the cover-slip in contact with the glass shoulders – indicating close contact. The suspension is introduced (with a Pasteur pipette) into the space between cover-slip and central plateau; the troughs should remain empty. The cells are allowed to settle and are counted under the microscope; since the volume between grid and cover-slip is known, the count per unit volume can be calculated. For viable cell counts, cells are subjected to VITAL STAINING.

(See also FACS.)

**counting methods** Methods for counting microorganisms may be divided into two categories according to the type of organism considered.

(a) *Organisms other than viruses, viroids etc.* The total number of living and dead cells in a given volume (or on a given area) of a sample is termed the *total cell count*; usually, total cell counts refer to bacteria, spores or yeasts (single-celled organisms). A total cell count may be determined by direct (visual) counting, i.e., by MICROSCOPY (see also COUNTING CHAMBER), or by the use of electronic or other instruments (see e.g. COULTER COUNTER, NEPHELOMETRY, TURBIDIMETRY); both direct and electronic methods may permit the counting of specific types of cell – e.g. by IMMUNOFLUORESCENCE microscopy and FACS (q.v.), respectively. Liquid samples containing small numbers of cells can be membrane-filtered (see FILTRATION) and the (stained) cells counted *in situ*. (See also DEFT.) Cell numbers in a given suspension may be estimated by comparison with standard suspensions (see BROWN'S TUBES).

*Viable cell count* refers to the number of living cells (per volume or area) in a given sample; viable cell counts usually refer to single-celled organisms, and they can obviously include only those organisms which are detectable by the particular method used. A viable cell count may be determined in several ways. (i) Direct examination, in a counting chamber, of a sample stained with a vital stain (see VITAL STAINING) – living and dead cells being distinguished by their different reactions to the dye. (ii) Statistical methods: see e.g. MULTIPLE-TUBE METHOD. (iii) Colony counts: the number of viable cells in a sample (or aliquot) is assessed from the number of colonies which develop on incubation of a solid medium which has been inoculated with the sample or aliquot; in such methods it is assumed that each colony developed from a single cell. The selectivity of the medium and the conditions of incubation may significantly affect the number of viable cells which give rise to colonies. For colony-counting methods see e.g. DIP-SLIDE METHOD, MILES AND MISRA'S METHOD, POUR PLATE, ROLL-TUBE TECHNIQUE and SPREAD PLATE (sense 1).

Some types of cell tend to form clumps or to grow in chains or filaments or in microcolonies. An accurate viable count of such organisms cannot be obtained by the above methods, and

COUNTING CHAMBER (Thoma chamber). The instrument – seen from one side at (a) – consists of a rectangular glass block in which the central plateau lies precisely 0.1 mm below the level of the shoulders on either side. The central plateau is separated from each shoulder by a trough, and is itself divided into two parts by a shallow trough (seen at (b)). On the surface of each part of the central plateau is an etched grid (c) consisting of a square which is divided into 400 small squares, each  $1/400 \text{ mm}^2$ . A thin glass cover-slip is positioned as shown at (b) and pressed firmly onto the shoulders of the chamber; to achieve proper contact it is necessary, while pressing, to move the cover-slip (slightly) against the shoulders. Proper contact is indicated by the appearance of a pattern of coloured lines (Newton's rings), shown at (b).

*Using the chamber.* A small volume of a bacterial suspension is picked up in a Pasteur pipette by capillary attraction; the thread of liquid in the pipette should not be more than 10 mm. The pipette is then placed as shown at (b), i.e., with the opening of the pipette in contact with the central plateau, and the side of the pipette against the cover-slip. With the pipette in this position, liquid is automatically drawn by capillary attraction into the space bounded by the cover-slip and one-half of the central plateau; the liquid should not overflow into the trough. (It is sometimes necessary to tap the pipette, *lightly*, against the central plateau to encourage the liquid to enter the chamber.) A second sample can be examined, if required, in the other half of the counting chamber. The chamber is left for 30 min to allow the cells to settle, and counting is then carried out under a high power of the microscope – which is focused on the grid of the chamber. Since the volume between grid and cover-slip is accurately known, the count of cells per unit volume can be calculated.

*A worked example.* Each small square in the grid is  $1/400 \text{ mm}^2$ . As the distance between grid and cover-slip is  $1/10 \text{ mm}$ , the volume of liquid over each small square is  $1/4000 \text{ mm}^3$ , i.e., (for all practical purposes)  $1/4,000,000 \text{ ml}$ .

Suppose, for example, that on scanning all 400 small squares 500 cells were counted; this would give an average of  $500 \div 400 (= 1.25)$  cells per small square. Thus, since 1.25 cells occur in  $1/4,000,000 \text{ ml}$ , the sample must contain  $1.25 \times 4,000,000$  cells per ml, = 5,000,000 cells per ml.

If the sample was diluted before examination in the counting chamber, the count obtained must be multiplied by the dilution factor: e.g., if the sample was diluted 1 in 10, the count must be multiplied by 10.

in these cases counts may be given as the number of *colony-forming units* (cfu) per unit volume or area of the sample; a cfu can be any entity – e.g. a single cell or a chain of cells – capable of giving rise to a single colony.

The above methods are generally applicable e.g. to most bacteria and spores, and some of the methods may be used for certain algae, fungi (e.g. yeasts) and protozoa. The counting of rapidly moving microorganisms can be facilitated by the use of a viscous suspending medium – e.g. FICOLL, methylcellulose (2–5% aqueous) or poly(ethylene oxide).

(b) *Viruses*. Viruses may be counted by electron microscopy, and the largest viruses (e.g. some entomopoxviruses) may be counted by light microscopy after suitable staining; however, such methods are seldom used since e.g. they do not distinguish between infective and non-infective virions. In the plaque method of assay, serial dilutions of a viral suspension are initially prepared, and a known volume of each dilution is examined for its content of infectious, plaque-forming virions: see PLAQUE (1) and PLAQUE ASSAY. An alternative procedure is the END-POINT DILUTION ASSAY. Plant viruses may be assayed on LOCAL LESION hosts.

**coupled cell division** See F PLASMID.

**coupling sequences** See CONJUGATIVE TRANSPOSITION.

**cover-glass** (cover-slip) A small round or rectangular sheet of thin glass used primarily to cover a specimen on a microscope SLIDE. When a slide is viewed with a HIGH-DRY OBJECTIVE lens, the image quality is optimum only when the cover-glass is of a particular thickness (specified by the lens manufacturer); thicker or thinner cover-glasses effectively increase spherical aberration. Cover-glass thickness is relatively unimportant with low-power objectives and (usually) with oil-immersion objectives. Cover-glasses are made in thickness ranges designated No. 0 (ca. 0.1 mm), No. 1 (ca. 0.15 mm), No. 1½ (ca. 0.175 mm), No. 2 (ca. 0.2 mm), and No. 3 (ca. 0.3 mm). Most objectives are designed for use with No. 1½ cover-glasses. (See also CORRECTION COLLAR.)

**cover-slip** *Syn.* COVER-GLASS.

**covered smut** See SMUTS (sense 2).

**covirus** *Syn.* MULTICOMPONENT VIRUS.

**Cowan I, II & III strains** Strains of *Staphylococcus aureus* used e.g. for the production of standard TYPING antisera.

**Cowdria** A genus of Gram-negative bacteria of the tribe EHRLICHIEAE. Cells: coccoid to rod-shaped, pleomorphic, non-motile, maximum dimension ca. 0.5 µm. Growth occurs intracytoplasmically in the vascular endothelial cells of ruminants, but does not occur in cell-free media. Type species (sole species): *C. ruminantium*, the causal agent of 'heartwater' (a tick-borne, septicaemic disease of ruminants which occurs in Africa); *C. ruminantium* is transmitted trans-stadially, but not transovarially, in the tick vector. [Book ref. 22, pp. 709–710.]

**cowpea aphid-borne mosaic virus** See POTYVIRUSES.

**cowpea chlorotic mottle virus** See BROMOVIRUSES.

**cowpea mosaic virus** (CPMV) The type member of the COMOVIRUSES. Three types of particle can be distinguished and are designated T, M and B ( $S_w^{20}$  58, 98 and 118, respectively); each is icosahedral, ca. 28 nm diam., the capsid consisting of 60 subunits of each of two structural proteins (MWts 22000 and 42000). T particles appear to consist only of protein. B particles contain a single molecule of RNA-1 (B-RNA, MWt ca.  $2 \times 10^6$ ) while the M particles contain one molecule of RNA-2 (M-RNA, MWt ca.  $1.2 \times 10^6$ ). Both RNAs are polyadenylated at the 3' end and have a small polypeptide (VPg, MWt ca. 4000) covalently bound to the 5' end. RNA-1 can be replicated

and expressed in cowpea protoplasts in the absence of RNA-2, but requires RNA-2 for encapsidation and for cell-to-cell spread; expression of RNA-2 is completely dependent on the expression of RNA-1. Both RNAs appear to be translated (in the cytoplasm) into large POLYPROTEINS which are cleaved to form functional proteins. RNA-1 encodes at least 6 proteins, including VPg and a protease apparently involved in cleavage of the polyprotein [EMBO (1987) 6 549–554]; RNA-2 carries genes for the capsid proteins. Cells infected with CPMV contain characteristic inclusion bodies: membranous, vesicular structures, usually adjacent to the nucleus, which contain dsRNA corresponding to RNA-1 and RNA-2, complementary (minus-strand) RNA, and replication complexes containing RNA-DEPENDENT RNA POLYMERASE molecules. (Although uninfected cowpea cells contain an RNA-dependent RNA polymerase, the activity of which increases by 10-fold or more on infection with CPMV, this enzyme appears not to be involved in CPMV replication [Book ref. 80, pp. 120–125].) Progeny CPMV particles accumulate in the host cell cytoplasm, sometimes forming crystalline arrays.

**cowpea ringspot virus** See CUCUMOVIRUSES.

**cowpea severe mosaic virus** See COMOVIRUSES.

**cowpox** A mild disease which primarily affects cows but which is transmissible (by direct contact) to human handlers; it is caused by the COWPOX VIRUS. In cows, lesions (which progress from papules through vesicles and pustules to crusts – cf. SMALLPOX) develop mainly on the udder and teats; other animals (e.g. cats [VR (1985) 117 231–233]) may be affected. In man the lesions occur mainly on the hands and arms and may be accompanied by local oedema and lymphangitis.

**cowpox virus** A virus of the genus ORTHOPOXVIRUS; it is the causal agent of COWPOX. The virus has a relatively broad host range, including e.g. cattle, man, and many other animals; it has been recovered from wild rodents, and rodents may be the natural reservoir host. Cowpox virus forms large, haemorrhagic pocks on the CAM, and is highly lethal for chick embryos. Both A- and B-type inclusion bodies are formed in infected cells. DNA MWt: ca.  $145 \times 10^6$ .

**coxibs** See PROSTAGLANDINS.

**Coxiella** A genus of Gram-negative bacteria of the RICKETTSIAE. Cells: highly pleomorphic, non-motile rods, ca. 0.2–0.4 × 0.4–1.0 µm, which stain well with the GIMÉNEZ STAIN; *C. burnetii*, the sole species, undergoes a developmental cycle in which ENDOSPORES are formed. Glucose, glutamate and pyruvate are metabolized (more readily at low pH). *C. burnetii* is not invariably killed at 63°C/30 min or 90°C for a few sec (cf. PASTEURIZATION). GC%: ca. 43.

*C. burnetii* is an obligate intracellular parasite in vertebrate and arthropod hosts, and is the causal agent of Q FEVER in man; in man, growth occurs e.g. in phagolysosomes (see PHAGOCYTOSIS) within mononuclear phagocytes (e.g. macrophages). Lab. culture is carried out (at ca. 35°C) e.g. in chicken embryos (by inoculating the yolk sac in hen's eggs), or in monolayer tissue cultures prepared from chicken embryos. On repeated passage, the organisms gradually change from phase I (= phase 1) – i.e., 'smooth', hydrophilic cells which are stable in suspension and are not phagocytosed in the absence of specific antibodies – to phase II (= phase 2) – i.e., 'rough', hydrophobic, autoagglutinable, readily phagocytosed cells; rapid reversion to phase I occurs when phase II cells are injected into lab. animals. [Book ref. 22, pp. 701–704.]

**coxsackieviruses** See ENTEROVIRUS.

**cozymase** NAD (q.v.).

## **cpd gene**

**cpd gene** In e.g. *Escherichia coli*: the gene encoding cAMP phosphodiesterase (see CYCLIC AMP).

**CPE** CYTOPATHIC EFFECT.

**CPV group** CYTOPLASMIC POLYHEDROSIS VIRUS GROUP.

**CR1** See CD35.

**CR2** (on B lymphocytes) See CD21.

**Crabtree effect** In certain yeasts: the occurrence of high levels of fermentative metabolism under aerobic conditions in the presence of high concentrations of a fermentable sugar (e.g. glucose in the case of *Saccharomyces cerevisiae*). When growing in batch culture with high concentrations of glucose under aerobic conditions, *S. cerevisiae* carries out a predominantly fermentative metabolism, converting glucose to ethanol (see ALCOHOLIC FERMENTATION); when the levels of glucose have been depleted, the ethanol can be used as a substrate for respiratory metabolism. Studies with continuous cultures have suggested that cells exposed to high concentrations of glucose under aerobic conditions respond by 'short-term' and 'long-term' regulatory processes. In the short term, respiratory enzymes are apparently not repressed, but ethanol is nevertheless formed; this is apparently because the cells have only a limited respiratory capacity, i.e., more pyruvate is formed than can be oxidized, and the excess pyruvate is decarboxylated to form ethanol. Long-term regulation is a process of metabolic adaptation involving repression of the synthesis of e.g. certain TCA cycle enzymes, cytochromes, and gluconeogenic enzymes, together with proteolytic inactivation of enzymes. [JGM (1985) 131 47–52.] (See also CATABOLITE REPRESSION.)

**Craigie's tube method** A method used e.g. for separating motile from non-motile organisms, and for isolating strains of *Salmonella* in the alternative flagellar phase. A piece of glass tubing (internal diam. ca. 3 mm) is placed in a test-tube of semi-solid nutrient agar such that the tubing projects above the level of the medium; the lower end of the tubing is cut obliquely, thus permitting free communication between the agar in the tubing and that in the remainder of the test-tube. If the medium inside the tubing is inoculated with motile and non-motile organisms, motile organisms may migrate into the medium in the test-tube – from which they may be subsequently isolated.

For the isolation of alternative-phase strains of *Salmonella* (see PHASE VARIATION) the medium is supplemented with antiserum to the flagella antigens of the currently predominant phase; the antiserum inhibits motility in strains of the predominant phase, but alternative-phase strains can swim out into the test-tube from where they can be subsequently isolated.

**Craterellus** See CANTHARELLALES.

**crayfish plague** (*Krebspest*) A disease of European crayfish (e.g. *Astacus astacus*) caused by *Aphanomyces astaci*; the American crayfish (*Pacifastacus leniusculus*) is normally resistant but may be able to carry the pathogen. The disease involves mainly the exoskeleton and CNS; mortality rates are very high. (See also CRUSTACEAN DISEASES.)

**cre gene** See BACTERIOPHAGE P1.

**cream cheese** See CHEESE-MAKING.

**Crédé procedure** See GONORRHOEA.

**Crenarchaeota** See ARCHAEA.

**crenate** Scalloped.

**Crenothrix** A genus of IRON BACTERIA (q.v.) which occur as sheathed, sometimes terminally swollen filaments. Type species: *C. polyspora*.

**creosote** A highly effective antifungal wood preservative for outdoor use. It consists of a complex mixture of coal tar distillation products which include phenol, cresols, xylenols,

pyridine, quinoline, anthracene and naphthalene. (See also LENTINUS.)

**creosote fungus** See HORMOCOONIS.

**Crepidotaceae** See AGARICALES.

**Crepidotus** A genus of fungi (AGARICALES, Crepidotaceae) which grow e.g. on fallen twigs and leaves, forming typically shell-shaped or lobed fruiting bodies up to 2 or 3 cm across.

**crescent** (*protozool.*) The mature, crescent-shaped gametocyte formed by certain species of *Plasmodium* (e.g. *P. falciparum*).

**cresol red** A PH INDICATOR; pH 7.2–8.8 (yellow to red).

**cresols** (as disinfectants) See PHENOLS.

**creylic acid** A mixture of methyl-, dimethyl- and ethyl-phenols used e.g. as an industrial biocide.

**Creutzfeldt–Jakob disease** (CJD) A human TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHY in which the symptoms at onset typically include dementia (but which, in some patients, are limited to ataxia or to e.g. psychiatric disorders); death commonly occurs within 1 year (sometimes <6 months) of onset, but may not occur for up to 4 years in a minority of patients. Some cases involve *inherited* CJD – in which the *PRNP* gene (encoding PrP) contains particular mutations; brain extracts from such patients can transmit the disease to mice (indicating that, in these cases, the causal prion is endogenous, i.e. produced within host cells).

CJD can be transmitted e.g. via contaminated neurosurgical instruments (despite 'sterilization' with 70% ethanol and formaldehyde vapour), via transplanted corneas from infected donors, and by the administration of contaminated human growth hormone.

Several variant forms of CJD are distinguished on the basis of (i) the nucleotide sequence of the *PRNP* gene, and (ii) the particular strain of prion protein involved. Thus, cases of 'sporadic' CJD can be placed into four groups – cases in a given group differing from those in other groups e.g. by differences in initial symptoms and the rapidity with which the disease progresses.

Most or all of the strains of CJD prion can be transmitted to chimpanzees and other primates, but only some strains can be transmitted to other animals (e.g. cats, guinea pigs, mice). Goats (but not sheep) inoculated with brain tissue containing CJD prions develop a disease indistinguishable from scrapie.

A new variant form of CJD (designated nvCJD) was reported in the United Kingdom [Lancet (1996) 347 921–925]. Cases of nvCJD have some unique features. For example, patients have died in their 2nd–5th decades, i.e. earlier than typical CJD patients. Clinical features that distinguish nvCJD from the typical CJD pattern also include psychiatric conditions, sensory abnormalities and pain preceding the more usual signs of ataxia, myoclonus and cognitive impairment; the electroencephalogram is unlike that obtained in most other cases of CJD. Moreover, histopathology includes multiple 'florid' amyloid plaques (rare in other cases of CJD) – as well as the changes that are typical of prion diseases; each of these plaques is encircled by a ring of spongiform vacuoles.

It is now believed that nvCJD is caused by a prion derived from meat or meat products from animals with BOVINE SPONGIFORM ENCEPHALOPATHY (q.v.). It has been suggested that – *before* the appearance of nvCJD – at least some cases of 'sporadic' CJD were caused by a prion derived from cattle with a rare spongiform disease, and that the BSE prion is a novel variant of this agent which, in humans, gives rise to nvCJD [RMM (1998) 9 119–127]. Studies with transgenic mice have provided evidence in favour of the transmission of bovine prions to humans [PNAS

(1999) 96 15137–15142] (see BOVINE SPONGIFORM ENCEPHALOPATHY for further supporting evidence).

Diagnosis may be facilitated by immunohistochemistry and/or Western blot analysis of tonsil biopsies [Lancet (1999) 353 183–189].

At present, there is no chemotherapy for CJD. Various chemical agents have been examined for their ability e.g. to increase the incubation period of the disease in animals [therapeutic strategies (review): RMM (1998) 9 135–151].

The causative prion of BSE has been shown to be transmissible from a sheep in the initial symptom-free phase of experimental infection to another sheep via a whole-blood transfusion; it has been suggested that symptom-free pre-nvCJD individuals may represent a risk of spread to other humans via blood transfusion [Lancet (2000) 356 999–1000.]

[UK distribution of CJD 1994–2000: Lancet (2001) 357 1002–1007; nvCJD (UK deaths): Lancet (2003) 361 751–752.]

Some similarities between CJD and Alzheimer's disease have led to attempts to demonstrate a transmissible agent in the latter disease; however, to date, there is no evidence of such an agent.

**crevicular fluid** A serum-like fluid which enters the mouth via the gingival crevice (= gingival sulcus) – i.e., the shallow crevice at the tooth–gum margin. It contains e.g. IMMUNOGLOBULINS (including IgA, IgG and IgM), COMPLEMENT, and various cells (e.g. LEUCOCYTES).

**CRF** COAGULASE reacting factor.

**crib death** *Syn.* SUDDEN INFANT DEATH SYNDROME.

**Cribraria** See MYXOMYCETES.

**Cribrostomum** See FORAMINIFERIDA.

**cricket paralysis virus** See PICORNAVIRIDAE.

**Cricosphaera** See COCCOLITHOPHORIDS.

**Crimean–Congo haemorrhagic fever** See VIRAL HAEMORRHAGIC FEVERS.

**Crinipellis** See AGARICALES (Tricholomataceae) and WITCHES' BROOM.

**crista** (1) See CRISTISPIRA. (2) See MITOCHONDRION.

**Cristispira** A genus of bacteria (family SPIROCHAETACEAE) which occur e.g. in the digestive tract and/or crystalline style in freshwater and marine molluscs, and in other aquatic organisms. Cells are motile, helical, ca. 0.5–3.0 × 30–180 μm, and each cell has 100 or more periplasmic flagella which may distend the outer sheath – giving rise to a longitudinal ridge, the *crista*; cells divide by transverse fission. Type species: *C. pectinis*. [Book ref. 22, pp. 46–49.]

**Crithidia** (*Strigomonas*) A genus of homoxenous parasitic protozoa (family TRYPANOSOMATIDAE) in which the choanomastigote form occurs; species typically occur in the gut of insects (e.g. *C. fasciculata* occurs worldwide in *Anopheles* and *Culex* mosquitoes).

**crithidial form** Obsolete *syn.* EPIMASTIGOTE.

**critical control points** See HACCP.

**critical dilution rate** See DILUTION RATE.

**critical illumination** (Nelsonian illumination) In MICROSCOPY: illumination in which the light source (e.g. lamp filament) is focused by the CONDENSER to form an image in the plane of the specimen. With electric coiled filaments critical illumination tends to give uneven illumination. (cf. KÖHLER ILLUMINATION.)

**critical initiation mass** See CELL CYCLE.

**critical point drying** A method used e.g. for dehydrating and drying specimens prior to their examination by ELECTRON MICROSCOPY; in this method the specimen is not exposed to a liquid–gas boundary and is thus not subjected to the damage caused by surface tension in air-dried specimens. In a typical

schedule, the water in a fixed and washed specimen is initially replaced by an 'intermediate fluid' (e.g. ethanol or acetone), and the specimen, totally immersed in the intermediate fluid, is placed in a strong metal pressure chamber. The chamber is then closed, cooled to ca. 15–18°C, and the intermediate fluid is replaced by the 'transitional fluid' (usually liquid CO<sub>2</sub>) by means of a valve system; the specimen remains below the liquid–gas boundary throughout. The liquid CO<sub>2</sub> is then partially drained and fresh liquid CO<sub>2</sub> is added; this is repeated several times to dilute out the intermediate fluid, the specimen always remaining fully covered by liquid CO<sub>2</sub>. When the last traces of intermediate fluid have been replaced by liquid CO<sub>2</sub> the temperature of the (closed) chamber is slowly raised (e.g. 1°C/min) above 31°C: the *critical point* above which CO<sub>2</sub> cannot exist as a liquid. The gas is then bled off *slowly* (to avoid e.g. turbulence in the chamber).

In an alternative schedule, various halocarbons (e.g. certain Freons) may be used to displace the ethanol or acetone. Thus e.g. ethanol may be displaced by two different halocarbons, used sequentially: the first acts as an additional intermediate fluid, while the second acts as the transitional fluid. (cf. FREEZE-DRYING.)

**critical temperature zone** See FREEZING.

**CRM** Cross-reacting material: protein which cross-reacts serologically with a given biologically active protein; CRM may lack the biological activity of the given protein, e.g., it may be a product of a mutant gene or a precursor form of the given protein.

**cro gene** See BACTERIOPHAGE λ.

**Crohn's disease** A (typically) chronic human disease of the intestinal tract which is characterized by granulomatous/ulcerative lesions; diarrhoea and intestinal pain are common. The acute form may resemble appendicitis.

The aetiology is not known. Possibly, mutations affecting certain intracellular molecules in the intestinal epithelium (e.g. Nod2) may affect the normal protective response to bacterial infection [JBC (2003) 278 5509–5512, 8869–8872].

**chromoglycate** A therapeutic agent which stabilizes sensitized MAST CELLS, inhibiting the release of histamine; it is administered *before* the patient is exposed to antigen/allergen in order to prevent anaphylactic reactions.

**Cronartium** A genus of rust fungi (class UREDINIOMYCETES) which include some important parasites of pine trees (*Pinus* spp); see e.g. BLISTER RUST. (See also PERIDERMOID.)

**cross-feeding** (1) *Syn.* SYNTROPHISM. (2) A particular type of SYNTROPHISM in which each organism derives essential growth factors from the other(s).

**cross-linking quantitative assay** A type of assay which has been used for detecting and quantifying hepatitis B virus (HBV) in serum. The assay, carried out in the solution phase, involves probes which incorporate a derivative of 7-hydroxycoumarin – a cross-linking agent that can be photo-activated by ultraviolet radiation such that each probe can be covalently bound to its target sequence in HBV DNA. Essentially, probes complementary to sequences in the major subtypes of HBV are allowed to hybridize to target sequences in the sample and are then photo-cross-linked to their targets; by means of biotin tags, the cross-linked probes are captured on streptavidin-coated DYNABEADS and subsequently labelled with alkaline phosphatase. The addition of a suitable substrate for the enzyme gives rise to a fluorescent signal. [Cross-linking assay for HBV DNA: JCM (1999) 37 161–164.]

**cross-reacting antibody** Antibody which can combine with non-homologous antigen (i.e. antigen not identical to that which

## cross-reacting material

elicited the antibody) as well as with homologous antigen. Such cross-reaction requires that the homologous and non-homologous antigens have a certain degree of stereochemical similarity. Cross-reacting antibodies often have a much lower affinity for the non-homologous antigen (cf. HETEROCLICITY.) (See also MONOCLONAL ANTIBODIES.)

Antibodies raised against a particular microorganism may combine with related (or even unrelated) species (see e.g. WEIL-FELIX TEST); such organisms may share a common antigenic determinant or may have CROSS-REACTIVE ANTIGENS.

**cross-reacting material** See CRM.

**cross-reactivation** See REACTIVATION.

**cross-reactive antigens** Antigens which differ from one another but which can combine with antibodies raised against either (or any) one of them. In *type 1 cross-reactivity*, different cross-reactive ligands bind with different affinities to a given site on a given antibody molecule; in *type 2 cross-reactivity* a cross-reactive ligand reacts with *some* of the antibodies in a POLYCLONAL ANTISERUM raised against the homologous ligand [Mol. Immunol. (1981) 18 751–763].

**cross resistance** The phenomenon in which the resistance of an organism to one antibiotic correlates with resistance to one or more other antibiotics.

**cross-wall** *Syn.* SEPTUM.

**crossband** (in prosthecae) See CAULOBACTER.

**crossed immunoelectrophoresis** See TWO-DIMENSIONAL ELECTROPHORESIS.

**crossing over** A RECOMBINATION process in which, e.g., exchange of double-stranded sequences occurs between two linear duplexes. In effect, crossing over involves a break in each of the two strands in both (linear) duplexes, exchange of parts of the duplexes, and ligation to form two recombinant duplexes (see RECOMBINATION). Thus, if the two duplexes carry alleles ABCD and abcd, crossing over results in recombinant molecules Abcd and aBCD, ABcd and abCD, or ABCd and abcD, depending on the site of the cross-over. In e.g. MEIOSIS, crossing over occurs between non-sister chromatids in homologous chromosomes (cf. PARASEXUAL PROCESSES).

If crossing over occurs between two *circular* molecules the result is a single larger circular molecule; conversely, crossing over between regions within a single circular molecule results in two smaller circular molecules. (See also CAMPBELL MODEL.)

**crotoxin** See TRICHOCECENES.

**croup** A type of laryngotracheitis with hoarseness, resonant cough, stridor, and respiratory obstruction. Croup occurs mainly in young children and may be of non-microbial causation (e.g. allergy) or due to infection by e.g. human respiratory syncytial virus, parainfluenza viruses, *Corynebacterium diphtheriae*.

**crown gall** A plant neoplasm, sometimes bearing root-like, stem-like and/or leaf-like structures, which is formed at the crown (stem–root junction) – or, less commonly, on stems or roots – in a wide range of gymnosperms and dicotyledonous angiosperms (although in few monocotyledonous angiosperms); crown gall follows infection of a wound with virulent strains of certain species of *Agrobacterium*, commonly *A. tumefaciens* (see AGROBACTERIUM). Infected plants may be stunted or even killed; the disease can cause important economic losses (for example, in stone-fruit trees and vines) e.g. in parts of Australia, Europe and the USA. Crown gall of grape is caused by strains of *Agrobacterium* which have been assigned to a new species, *A. vitis* [crown gall of grape (biology and disease management): ARPPATH. (1999) 37 53–80]. (See also GALLS.)

*A. tumefaciens* attaches to the host plant at the site of a wound, attachment being reported to occur via the bacterial

lipopolysaccharides and via epicellular cellulose microfibrils formed by the bacteria [Book ref. 55, pp 33–54].

Virulence in *A. tumefaciens* (and in *A. vitis*) depends on the presence of a large CONJUGATIVE PLASMID called the Ti (tumour-inducing) plasmid (ca. 150–230 kb). Genes responsible for tumorigenesis are located in a small subregion of the Ti plasmid termed the T-region or T-DNA (ca. 15–24 kb); in the infection process, single-stranded T-DNA is excised from the plasmid and transferred to the plant.

Transfer of T-DNA to the plant requires certain products of the virulence (*vir*) regulon – ~25 genes in regions of the Ti plasmid outside the T-DNA; transfer is regulated by a TWO-COMPONENT REGULATORY SYSTEM consisting of the proteins VirA (sensor) and VirG (response regulator), both expressed constitutively. [Two-component regulatory system in *A. tumefaciens*: FEMS Reviews (1998) 21 291–319 (301–303).] VirA appears to respond (directly or indirectly) to certain types of phenolic compound (e.g. *acetosyringone*) released by plant wounds; the activity of phenolics is enhanced by monosaccharides such as glucose, and it has been suggested that such enhancement results from the binding, to VirA, of a complex consisting of monosaccharide and the product of the bacterial virulence gene *chvE*. (As well as being a sensor protein, VirA may also function as a host-range determinant [EMBO (1987) 6 849–856]; thus, different (variant) forms of VirA may differ in their response to particular plant signals.)

On activation, VirG promotes transcription in the *vir* regulon. The *virD* operon encodes a site-specific endonuclease complex which makes nicks in one strand of the plasmid at unique sites within a pair of 24-bp DIRECT REPEATS that flank the T-DNA; the (single-stranded) copy of T-DNA, with protein VirD2 covalently attached to the 5' end, is then transferred to the plant cell nucleus. (So-called *nuclear localization signals*, associated with one of the proteins accompanying the T-DNA, appear to be required for targeting.) [Molecular signals in the interaction between plants and microbes: Cell (1992) 71 191–199.] Pili appear to be necessary for transfer of T-DNA to plants [Science (1996) 273 1107–1109].

Within a plant cell the processed T-DNA can apparently insert at multiple sites in the nuclear DNA, sometimes forming tandem repeats. While T-DNA is transcribed only weakly in the bacterium, in the plant cell it is transcribed into both polyadenylated and non-polyadenylated RNA [Plasmid (1981) 6 17–29].

Genes within T-DNA encode enzymes involved in the formation of CYTOKININS [PNAS (1984) 81 4776–4780, 5994–5998] and IAA (see AUXINS), resulting in persistently raised levels of these phytohormones which are apparently responsible for tumorigenesis.

T-DNA also carries genes which specify the production, by tumour cells, of a number of tumour-specific substances called *opines*. A given Ti plasmid may encode opines of the OCTOPINE family (e.g. octopine, histopine, lysopine, octopinic acid) or of the NOPALINE family (e.g. nopaline, nopalinic acid). Octopine Ti plasmids may also encode agropine; agropine (formerly 'null type') Ti plasmids and nopaline Ti plasmids also encode AGROCINOPINES. The different plasmids may specify tumours of different types. (cf. HAIRY ROOT; see also AGROCINS.)

A Ti plasmid carries genes for the degradation of those opine(s) synthesized by the tumour induced by its T-DNA; moreover, the pathogen – but not plant cells or other microorganisms – can use opines as the sole source of carbon and nitrogen.

The availability of nutrients (opines) promotes growth and development of a population of the pathogen. Conjugal transfer

of the Ti plasmid from Ti<sup>+</sup> cells to Ti<sup>-</sup> agrobacteria involves initial transcriptional activation of the regulatory gene *traR* (present in the Ti plasmid) – apparently by a gall-derived opine; a second signal, derived from a QUORUM SENSING system (based on the density of *donor* cells), is also needed to initiate the transfer process. [Tra system in *A. tumefaciens*: FEMS Reviews (1998) 21 291–319 (299–301).]

Ti plasmids may be used as vectors for the insertion of DNA sequences into the genome of dicotyledonous plants [EMBO (1985) 4 277–284]. (See also AGROINFECTION.) Non-oncogenic Ti plasmids and plant protoplasts may be used so that hormone levels are not disturbed, and whole plants can be regenerated from the protoplasts using standard plant cell culture techniques. Transformed protoplasts can be detected by screening for opine synthesis.

**crown rot** Any plant disease in which the ‘crown’ (i.e., the region between the root and stem) rots as a result of microbial infection; causal agents include e.g. *Erwinia rhapontici* in rhubarb, *Mycocentrospora acerina* in carrots and celery, *Phytophthora cactorum* in strawberries. (cf. FOOT-ROT (2).)

**crown rust** A disease of members of the Gramineae. Crown rust of oats (*Avena* spp) is an economically important disease caused by *Puccinia coronata avenae*; orange, typically elongated, ureal pustules occur on leaves and sometimes on culms. (See also CEREAL DISEASES.)

**crozier** See ASCUS.

**CRP** (1) C-REACTIVE PROTEIN. (2) cAMP receptor protein: see CATABOLITE REPRESSION.

**crp gene** See CATABOLITE REPRESSION.

**Crucibulum** See NIDULARIALES.

**crucifer diseases** See e.g. ALBUGO (for white rusts), BLACKLEG (sense 2), CLUBROOT and FUSARIUM WILT.

**crucifer white blister** See ALBUGO.

**cruciform** (1) (*adj.*) Cross-shaped. (2) (*noun*) In a nucleic acid molecule: two HAIRPINS (or STEM-AND-LOOP STRUCTURES), opposite one another, forming a cross-shaped structure. A cruciform can be formed in a double-stranded molecule or in a double-stranded region of a single-stranded molecule. (See PALINDROMIC SEQUENCE.)

**crude oil** See PETROLEUM.

**crustacean diseases** See e.g. BLACK GILL DISEASE; BLACK MAT SYNDROME; BURNED SPOT DISEASE; CRAYFISH PLAGUE; GAFFKAEMIA; PARAMOEBA. (See also LAGENIDIALES and SAPROLEGNIALES (ATKINSIELLA and *Leptolegnia baltica*.) (See also INVERTEBRATE DISEASES.)

**crustaceous** *Syn.* CRUSTOSE.

**crustose** (crustaceous) Forming or resembling a crust. Of a lichen: having a thallus which generally lacks a lower cortex, being attached to the substratum (over the whole of its lower surface) by hyphae of the medulla. A crustose thallus may be e.g. AREOLATE, PLACODIOID, etc. (cf. FOLIOSE; FRUTICOSE.)

**cryo-** Prefix meaning *cold*.

**cryoelectron microscopy** See ELECTRON MICROSCOPY (d).

**cryofixation** The FREEZING of living cells preparatory to e.g. FREEZE-ETCHING; the aim is similar to that of FIXATION but cells may or may not be killed during the process. [Cryofixation techniques for soil fungi: MS (1985) 2 225–230.]

**cryogen** Any agent which is used for FREEZING a specimen – e.g. liquid nitrogen. (See also FREON.)

**cryopreservation** See FREEZING.

**cryoprotectant** See FREEZING.

**cryosectioning** *Syn.* FREEZE-SECTIONING.

**cryostat** *Syn.* cryotome (q.v.).

**cryosubstitution** FREEZE-SUBSTITUTION.

**cryotome** See FREEZE-SECTIONING.

**Cryoxidic** A STERILANT containing ETHYLENE OXIDE (11%), trichlorofluoromethane (79%), and dichlorodifluoromethane (10%).

**crypt** (*ciliate protozoal.*) See BROOD POUCH.

**cryptic mutant** A cell which lacks one or more components of a TRANSPORT SYSTEM so that a particular substrate, or substrates, cannot enter the cell – and hence cannot be utilized, even though the cell may possess all the enzymes necessary for its utilization. For example, the failure of a cell to produce enzyme I (see PTS) – as a result of a (pleiotropic) mutation – would prevent that cell (a cryptic mutant) from taking up and metabolizing a range of sugars.

**cryptic plasmid** A PLASMID which has no apparent effect on the phenotype of the cell in which it occurs.

**cryptic viruses** Virus-like isometric particles which have been detected in a wide range of symptomless plants; the particles are generally ca. 30 nm in diameter, are present in low concentrations, and appear to be seed-borne. Some have been shown to contain dsRNA [e.g. beet cryptic viruses: JGV (1986) 67 363–366].

**cryptidin** See DEFENSINS.

**Cryptobia** See BODONINA.

**cryptobiosis** See DORMANCY.

**Cryptocaryon** A genus of cyst-forming ciliates related to ICHTHYOPHTHIRIUS; the sole species, *C. irritans*, causes WHITE SPOT in marine fish.

**Cryptococcaceae** A family of fungi of the class BLASTOMYCETES. The genera include CANDIDA, CRYPTOCOCCUS, KLOECKERA, RHODOTORULA and TRICHOSPORON.

**cryptococcosis** (torulosis; also European blastomycosis or Busse–Buschke disease) A disease of man and animals caused by *Cryptococcus neoformans* (q.v.); infection occurs on inhalation of dust contaminated with the fungus. Pulmonary infection may be mild or inapparent. However, particularly in individuals with e.g. defective CMI or certain leukaemias, the disease may become disseminated to almost any tissue (liver, bones, skin etc) but especially to the meninges (*cryptococcal* MENINGITIS – commonly fatal). *Diagnosis*: demonstration of the fungus by culture or microscopy; latex particle test for cryptococcal capsular polysaccharide. *Chemotherapy*: e.g. amphotericin B, flucytosine, possibly miconazole or ketoconazole. [Book ref. 17, pp. 180–186.]

**Cryptococcus** A genus of non-fermentative imperfect yeasts (class HYPHOMYCETES). The cells are spheroidal, ovoid, elongate, or polymorphic, and reproduce by multilateral budding. Pseudomycelium is rudimentary or absent. The vegetative cells usually have capsules, the composition of the capsule and the abundance of capsular material depending on growth conditions; under certain conditions the capsule contains starch-like polysaccharides which may be released into the medium. Colonies on e.g. malt agar are typically mucoid and are commonly cream- to tan-coloured, or red in some species (e.g. *C. hungaricus* and *C. macerans*). Inositol can be assimilated as sole carbon source. NO<sub>3</sub><sup>-</sup> is assimilated by some species.

Most *Cryptococcus* species have basidiomycetous affinities: *C. albidus* var. *albidus* and *C. uniguttulatus* are anamorphs of FILOBASIDIUM spp, *C. neoformans* of FILOBASIDIELLA sp. Three species have ascomycetous affinities: *C. cereanus* and *C. lactivorius*, which are anamorphs of SPOROPACHYDERMIA, and *C. melibiosum* (teleomorph unknown). [Book ref. 100, pp. 845–872.]

## cryptoendolith

*C. neoformans* is the causal agent of CRYPTOCOCCOSIS and may also be associated with e.g. bovine mastitis. Cells (e.g. in malt extract after 3 days at 25°C) are spherical, ca. 3–8 µm diam., occurring singly, in pairs, or in small groups. Pseudomycelium is not formed, and extracellular polysaccharide may be abundant. *C. neoformans* is the only *Cryptococcus* sp which can grow well at 37°C (certain other species or strains – e.g. *C. melibiosum* – may be capable of weak growth at 37°C). *C. neoformans* has two varieties, var. *neoformans* and var. *gattii* (= '*C. bacillisporus*'), distinguished e.g. on the basis of the ability of var. *gattii* (but not var. *neoformans*) to give a blue colour on CGB AGAR within 2–5 days.

Other *Cryptococcus* spp (not mentioned above) include e.g. *C. ater*, *C. dimennae*, *C. elinovii*, *C. flavus*, *C. gastricus*, *C. heveanensis*, *C. infirmo-miniatus*, *C. kuetzingii*, *C. laurentii*, *C. luteolus*, *C. magnus*, *C. skinneri*, *C. terreus*. Strains have been isolated from a wide range of habitats, including e.g. soil, plants, dew-retted flax, seawater, clinical specimens, foods and beverages, etc. Another species, *C. friedmannii*, has been isolated from rock fragments containing cryptoendolithic lichens from a dry desert area of the Antarctic [Mycol. (1985) 77 149–153].

**cryptoendolith** See ENDOLITHIC.

**cryptogam** A plant which does not produce true flowers or seeds; cryptogams traditionally include the ALGAE, FUNGI, bryophytes (e.g. mosses) and pteridophytes (e.g. ferns).

**cryptogram** (virol.) A descriptive code used to summarize, in symbolic form, certain basic properties of a given virus.

**Cryptomonadida** See PHYTOMASTIGOPHOREA.

**cryptomonads** *Syn.* CRYPTOPHYTES.

**Cryptomonas** See CRYPTOPHYTES.

**cryptophytes** (cryptomonads) A category of unicellular, biflagellated, marine or freshwater organisms variously regarded as algae (class Cryptophyceae) or as protozoa (see PHYTOMASTIGOPHOREA); most cryptophytes are photosynthetic (including e.g. *Chroomonas* and *Cryptomonas*), but some (e.g. *Chilomonas*, *Cyathomonas*) are colourless and heterotrophic. The cryptophyte cell is typically flattened and dorsiventral, lacks a cell wall (having instead a plasma membrane with an internal lining of proteinaceous plates), and possesses EJECTOSOMES. In photosynthetic species each cell has a single bilobed chloroplast containing a pyrenoid, paired thylakoids, chlorophylls *a* and *c*<sub>2</sub>,  $\alpha$ -carotene, diatoxanthin, and PHYCOBILIPROTEINS. Storage products are starch and lipid. Reproduction occurs by longitudinal binary fission; sexual reproduction is unknown. [Taxonomic aspects (including genus descriptions): *New Phyt.* (1984) 98 627–646.]

**cryptosporidiosis** A COCCIDIOSIS (q.v.) of man and other animals caused by a species of CRYPTOSPORIDIUM; the pathogen is commonly transmitted (as sporulated oocysts) via the direct or indirect faecal–oral route.

The disease in man is typically mild and self-limiting; it may involve diarrhoea, abdominal cramps, low-grade fever and headache. In the severely immunocompromised it is a life-threatening disease: usually severe, persistent watery diarrhoea; other sites (e.g. respiratory, biliary) may be affected. No effective chemotherapy is available [IJP (1995) 25 139–195]. [The treatment dilemma: *JMM* (2000) 49 207–208.]

*Cryptosporidium* is a cause of diarrhoea, pneumonia and disseminated infections in calves foals, lambs and piglets; it can also cause diarrhoea, inappetence and weight loss in the domestic cat [VR (1985) 116 73–74].

[Cryptosporidiosis in animals and humans: *MR* (1983) 47 84–96.]

Outbreaks of disease can be transmitted via water as thick-walled oocysts of *Cryptosporidium* are resistant to the level of chlorination normally used in WATER SUPPLIES. The viability of *C. parvum* oocysts in water has been examined by staining them with fluorescent dyes (SYTO-9, SYTO-59); oocysts which stained above a certain intensity could not establish infection in mice, but those which displayed little or no fluorescence could readily establish infection [AEM (2000) 66 406–412].

**Cryptosporidium** A genus of parasitic (homoxenous) protozoa (suborder EIMERIORINA – q.v.) which are pathogenic for man and other animals (see CRYPTOSPORIDIOSIS); the organisms typically develop in the intestinal microvilli. The oocysts are very small (ca. 4–6 µm); following ENDOSPORULATION, each oocyst contains four banana-shaped sporozoites. Two types of oocyst are formed; thin-walled oocysts which release sporozoites into the host's intestine, causing re-infection ('autoinfection') of the host, and acid-fast thick-walled oocysts (ca. 80% of the total) which are voided in the faeces.

[Complete development of *Cryptosporidium* in cell cultures: *Science* (1984) 224 603–605.]

The taxonomy of the genus is unsettled. It has been suggested that only 4 species should be recognized e.g. on the basis of host range: *C. crotali* (infecting reptiles), *C. meleagridis* (infecting birds), *C. muris* (infecting mammals) and *C. nasonum* (infecting tropical fish) [JP (1984) 31 94–98]. However, '*C. parvum*', the organism which appears to be the cause of most cases of cryptosporidiosis, is apparently distinct from *C. muris* [J. Parasitol. (1985) 71 625–629]. [*C. baileyi* from chickens: JP (1986) 33 289–296.]

**Cryptostroma** See HYPHOMYCETES; see also MAPLE BARK STRIPPERS' DISEASE and SOOTY BARK.

**crystal toxin** (of *Bacillus thuringiensis*) See DELTA-ENDOTOXIN.

**crystal violet** A violet basic TRIPHENYLMETHANE DYE used e.g. in the GRAM STAIN.

**CS protein** See PLASMODIUM.

**CS1, CS2, CS3** See ETEC.

**CSF** (1) Cerebrospinal fluid. (2) COLONY-STIMULATING FACTOR. (3) Cold stability factor (see MICROTUBULE-ASSOCIATED PROTEINS). (4) A pheromone of *Bacillus subtilis* (see QUORUM SENSING).

**CSLM** CONFOCAL SCANNING LIGHT MICROSCOPY.

**CSP reaction** Shedding of CS proteins by the sporozoites of *Plasmodium* spp (see PLASMODIUM) following cross-linking of the CS proteins by anti-CS antibodies. (cf. Capping phenomenon in DYSENTERY (b).)

**CspA** See COLD-SHOCK RESPONSE.

**CSPD**<sup>®</sup> Trade name (Tropix, Bedford, MA, USA) of a 1,2-dioxetane substrate which gives rise to CHEMILUMINESCENCE when activated by the enzyme alkaline phosphatase. (See also AMPPD.)

**CSSD** Central sterile supply department.

**CTAB** See QUATERNARY AMMONIUM COMPOUNDS.

**ctDNA** Chloroplast DNA (see CHLOROPLAST).

**CTEM** Conventional transmission ELECTRON MICROSCOPY.

**CTh** CARRIER-SPECIFIC T HELPER CELL.

**CTLA-4** See CD28.

**CTP** Cytidine 5'-triphosphate [see Appendix V(b)].

**ctxA, ctxB genes** See CHOLERA TOXIN.

**cucumber 4 virus** See TOBAMOVIRUSES.

**cucumber green mottle mosaic virus** See TOBAMOVIRUSES.

**cucumber mosaic virus** See CUCUMOVIRUSES.

**cucumber necrosis virus** See TOBACCO NECROSIS VIRUS.

**cucumber pale fruit viroid** See VIROID.

**cucumbers** (pickled) See PICKLING.

**cucumoviruses** (cucumber mosaic virus group) A category of ssRNA-containing PLANT VIRUSES which infect e.g. cucurbits and solanaceous plants; transmission occurs (non-persistently) via aphids and, in some hosts, via seeds, and can also occur mechanically. Type member: cucumber mosaic virus, CMV (S isolate). Other members: peanut stunt virus (PSV) and tomato aspermy virus (TAV); possible member: cowpea ringspot virus.

Virion: icosahedral, ca. 29 nm diam., containing a single type of coat protein and linear, positive-sense ssRNA. Three types of virion exist, differing in the nature of the RNA they contain; a particle may contain one molecule of RNA-1 (MWt ca.  $1.27 \times 10^6$ ), one molecule of RNA-2 (MWt ca.  $1.13 \times 10^6$ ), or one molecule each of RNA-3 (MWt ca.  $0.82 \times 10^6$ ) and RNA-4 (coat protein mRNA). Some isolates of CMV and PSV also contain SATELLITE RNAs designated (respectively) CARNA (CMV-associated RNA) and PARNA (PSV-associated RNA). CARNA 5, the best-known example, consists of 335 nucleotides and is capped at the 5' end; it can code for two polypeptides. The presence of a CARNA attenuates the symptoms of CMV infection in many plants, but may enhance disease severity in others. For example, in tomato plants infection with CMV (only) may cause leaf chlorosis with some leaf distortion, but infection with both CMV and CARNA 5 causes a lethal necrosis. 'White leaf' of tomatoes and 'brilliant yellowing' of tobacco are also examples of diseases caused by CARNA strains. The presence of a CARNA in a host plant also reduces the yield of CMV – apparently as a result of competition for virus replication machinery.

**Cucurbitaria** See DOTHIDEALES.

**cud** See RUMEN.

**cudbear** A purple dye obtained from *Ochrolechia tartarea*.

**Culex** A genus of mosquitoes (order Diptera, family Culicidae);

*Culex* spp are vectors of certain diseases: see e.g. MURRAY VALLEY FEVER.

**Culiciniomyces** A genus of fungi of the HYPHOMYCETES; *C. clavisporus* is pathogenic in mosquito larvae [Mycol. (1984) 76 614–625].

**Culicoides** A genus of biting midges (order Diptera, family Ceratopogonidae); *Culicoides* spp are vectors of certain diseases: e.g. AFRICAN HORSE SICKNESS and BLUETONGUE.

**culmination** See DICTYOSTELIOMYCETES.

**cultivar** (cv.) A commercial or cultivated 'variety' of a given species of plant or fungus.

**culture** (1) (*noun*) A liquid or solid MEDIUM on or within which has grown a population of particular type(s) of microorganism or cell as a result of the prior INOCULATION and INCUBATION of that medium. The following refers primarily to microbial cultures – cf. TISSUE CULTURE. On a solid medium, microorganisms may grow as a continuous layer or film of surface growth (*confluent growth*) or as discrete (individual) colonies (see COLONY) – depending e.g. on the method of inoculation (cf. LAWN PLATE and STREAKING). Cultures in liquid media may be turbid or clear, and may or may not have a PELLICLE.

*Aerobic culture.* A culture prepared under AEROBIC (sense 1) conditions.

*Anaerobic culture.* One prepared under ANAEROBIC (sense 1) conditions. (See also ANAEROBE.)

*Axenic culture.* Pure culture (see below).

*Batch culture.* See BATCH CULTURE.

*Broth culture.* One prepared with NUTRIENT BROTH or with any similar liquid medium.

*Closed culture.* *Syn.* BATCH CULTURE.

*Contaminated culture.* One which has been exposed (usually unintentionally) to non-STERILE conditions and which has become contaminated with extraneous organisms.

*Continuous culture.* See CONTINUOUS CULTURE.

*Fed batch culture.* See FED BATCH CULTURE.

*Mixed culture.* One containing two or more species or strains of organism.

*Old culture.* One which has been incubated or stored for an excessive period of time and in which, as a consequence, degenerative changes may have occurred – see e.g. INVOLUTION FORMS.

*Open culture.* *Syn.* CONTINUOUS CULTURE.

*Plate culture* ('plate'). One prepared using a solid medium (e.g. nutrient agar) in a PETRI DISH.

*Primary culture.* See PRIMARY CULTURE.

*Pure culture* (AXENIC culture). One in which all the organisms are of the same species or strain.

*Shake culture.* See SHAKE CULTURE.

*Slant culture.* Slope culture (see below).

*Slope culture* (slant culture). One prepared using a SLOPE.

*Stab culture.* One produced by deep inoculation of a solid medium (e.g. the butt of an agar or gelatin slope) with a STRAIGHT WIRE; the wire is pushed vertically into the medium so that the INOCULUM (on the tip of the wire) is distributed along the length of the stab.

*Subculture.* See SUBCULTURE.

*Synchronous culture.* See SYNCHRONOUS CULTURE.

(2) (*noun*) The process of preparing a culture (sense 1).

(3) (*verb*) To encourage the growth of particular type(s) of microorganism under controlled conditions. Cultures of bacteria or fungi are usually started by seeding (inoculating) a medium with viable cells or spores from another culture, or by inoculating the medium with material expected to contain particular type(s) of viable organism; the type of MEDIUM and the incubation conditions required differ widely among the different types of microorganism. Certain organisms (e.g. *Rickettsia* spp, *Treponema pallidum*) can be cultured only in living systems. (See also ASEPTIC TECHNIQUE; ENRICHMENT; LOOP.)

**culture collections** Collections of characterized microorganisms.

*General collections:* see e.g. ATCC, CBS, CCM, CIP, DSM, JCM, LMD, and NCTC; *agricultural* (including dairy and phytopathological organisms): see e.g. ICPB, NCDO, NCPPB, NRRL and UW0; *algae:* see e.g. SAG; *fungi* (including yeasts): see e.g. CBS and CMI; *industrial and applied:* see e.g. IAM, IFO and NCIB; *marine bacteria:* NCMB; *medical:* see e.g. CDC.

**cultured** (of bacteria etc.) Grown.

**cultured butter** See BUTTER.

**cultured buttermilk** See BUTTERMILK.

**Cummings' disease** See AVIAN INFECTIOUS BRONCHITIS.

**Cunninghamella** See MUCORALES.

**Cunninghamellaceae** See MUCORALES.

**cup fungi** Ascomycetes which form cup-like fruiting bodies, particularly members of the PEZIZALES.

**cup lichens** Species of CLADONIA whose podetia have conspicuous scyphi.

**cuprammonium hydroxide** See COPPER.

**cupredoxin** See BLUE PROTEINS.

**cupulate** Cup-Shaped. (See also AECIDIROID.)

**curdlan** A class of extracellular, water-insoluble, linear (1 → 3)-β-glucans formed e.g. by *Alcaligenes faecalis* 'var. *myxogenes*' and by strains of *Agrobacterium* and *Rhizobium*. When aqueous suspensions of curdlans (e.g. 2% w/v) are heated to >90°C and then cooled slowly, they form very elastic, resilient gels.

## curie

Curdans have potential applications in the food industry (e.g. as non-caloric gelling, thickening or stabilizing agents) and in other industries (e.g. in the formation of films and fibres for use e.g. as molecular sieves and/or as supports for immobilized enzymes). [Book ref. 62, pp. 201–229.]

**curie** (*abbr.* Ci) A unit of activity of a radioactive source equal to  $3.7 \times 10^{10}$  disintegrations per sec.

**Curie point pyrolysis** PYROLYSIS in which a ferromagnetic wire (coated with the sample) is heated inductively by means of a high-frequency alternating magnetic field; the temperature of the wire increases (within e.g. 0.1 sec) to the Curie point: a temperature which the inducing field maintains – but cannot increase owing to the wire's thermally promoted paramagnetic state. The Curie point depends on the chemical composition of the wire; iron-nickel wires with a Curie point of 510°C are often used.

**curing** (1) (of meats) A method of FOOD PRESERVATION in which meat (particularly pig meat) is permeated with a solution typically containing NaCl, NaNO<sub>2</sub> and NaNO<sub>3</sub> at a temperature of e.g. 4°C. Preservation is due mainly to the NaCl (which e.g. lowers the WATER ACTIVITY) and to the nitrite which, under appropriate conditions of e.g. a<sub>w</sub>, pH (ca. 5.6) and temperature, inhibits the growth of vegetative bacteria and the germination and/or outgrowth of bacterial endospores. Nitrite also enhances the colour and flavour of cured meats. Brines used for curing hams contain a characteristic microflora which reduces nitrate to nitrite, lowers the pH by producing acid from carbohydrates, and (possibly) produces flavour components. The presence of these bacteria (principally halophilic, psychrotolerant *Vibrio* spp) reduces the spoilage of the cured hams; the organisms may be added to the brine as a starter culture or may derive from the meat itself.

(2) (of plasmids in bacteria) Elimination of a PLASMID without loss of bacterial viability. Sublethal doses of e.g. certain INTERCALATING AGENTS (e.g. ACRIDINES) or NOVOBIOCIN can cause preferential inhibition of plasmid replication; hence, a growing, plasmid-containing bacterial population which is exposed to these agents will give rise to an increasing number of plasmid-free progeny cells. MITOMYCIN C is often used for curing plasmids in *Pseudomonas* spp. Other curing agents include rifampicin (see RIFAMYCINS).

**curling factor** See GRISEOFULVIN.

**Curtis–Fitz-Hugh syndrome** A syndrome, observed most commonly in women, which includes acute PERIHEPATITIS in association with genital tract infection; it can be due e.g. to *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. [Perisplenitis and perinephritis in the Curtis–Fitz-Hugh syndrome: Br. J. Surg. (1987) 74 110–112.]

**Curtobacterium** A genus of aerobic, asporogenous bacteria (order ACTINOMYCETALES, wall type VIII – see also PEPTIDOLYCAN) which occur in soil and plant litter; some species are phytopathogenic. In culture the organisms are short rods, coccobacilli or coccoid forms; they are non-motile, or motile with a few lateral flagella. Growth occurs optimally at ca. 25°C on e.g. media containing peptone, yeast extract, and glucose; the organisms are non-cellulolytic. GC%: ca. 66–73. Type species: *C. citreum*. [Re-classification of *Corynebacterium betae*, *C. flaccumfaciens*, *C. oortii* and *C. poinsettiae* (collectively) as *Curtobacterium flaccumfaciens*: JGM (1983) 129 3545–3548.]

**Curvularia** See HYPHOMYCETES.

**Custers effect** (negative Pasteur effect) A phenomenon in which, apparently, the fermentative metabolism of a substrate is stimulated by the presence of O<sub>2</sub>. (See e.g. BRETTANOMYCES; cf. PASTEUR EFFECT.)

**cut-and-paste mechanism** (of transposition) See e.g. Tn10.

**cutaneous basophil hypersensitivity** *Syn.* JONES–MOTE SENSITIVITY.

**cutaneous herpes** See HERPES SIMPLEX.

**cutaneous leishmaniasis** LEISHMANIASIS of man and other animals in which the pathogen primarily infects the skin and gives rise to self-healing or metastasizing lesions; the causal agents (which are transmitted by sandflies), and the patterns of disease, vary with geographical location.

Old World cutaneous leishmaniasis (mainly in Africa and Asia) are typically caused by *Leishmania aethiopica*, *L. major* or *L. tropica*. In man, a papule develops (after several weeks) at the site of a sandfly bite, becoming necrotic at the centre and forming a moist, ulcerative lesion (*L. major*) or a dry lesion (*L. aethiopica*, *L. tropica*) which eventually heals. (These lesions have been called e.g. *Aleppo boil*, *Delhi boil*, *oriental sore*.) *L. aethiopica* and *L. major* infections are zoonotic, animal reservoirs including populations of e.g. the great gerbil, *Rhombomys opimus* (for *L. major*), and the rock hyrax, *Procavia capensis* (for *L. aethiopica*); *L. tropica* infections appear to be anthroponotic.

New World cutaneous leishmaniasis (in South America) are caused by *L. braziliensis* or *L. mexicana*; they are zoonotic diseases in man, animal reservoirs including rodents and sloths. The clinical picture in man may resemble the Old World pattern; however, following an apparent cure the disease may re-appear at a site remote from the original lesion, and in some cases the infection may metastasize to the oral/nasal mucous membranes (see MUCOCUTANEOUS LEISHMANIASIS).

(See also CHICLERO'S EAR and PIAN BOIS.)

Diagnosis of cutaneous leishmaniasis may involve e.g. microscopical examination of exudate from lesions, culture of lesion material (in e.g. NNN MEDIUM), and the MONTENEGRO TEST; treatment may involve e.g. pentavalent ANTIMONY compounds and/or antibiotics.

(cf. VISCERAL LEISHMANIASIS.)

**cutaneous T-cell lymphoma** See MYCOSIS FUNGOIDES and SEZARY SYNDROME; see also ADULT T-CELL LEUKAEMIA.

**cuticle** (*mycol.*) *Syn.* PELLIS.

**cutin** An insoluble polymer which, embedded in waxes, forms the cuticle which covers the epidermal cell walls in the aerial parts of higher plants. (cf. SUBERIN.) Cutin is a polyester formed from C<sub>16</sub> and C<sub>18</sub> hydroxy fatty acids. It functions as a physical barrier, protecting against water loss, entry of pathogens, etc. Many plant-pathogenic fungi produce enzymes (*cutinases*) which can breach the cutin barrier prior to infection. [Book ref. 58, pp. 79–100; enzymic penetration of the plant cuticle by fungal pathogens: ARPPATH. (1985) 23 223–250.]

**cutinase** A CUTIN-degrading enzyme.

**cutis** (*mycol.*) *Syn.* PELLIS.

**Cutleria** See PHAEOPHYTA.

**cv.** CULTIVAR.

**CVF** COBRA VENOM FACTOR.

**C<sub>x</sub> cellulase** See CELLULASES.

**CY agar** A medium which includes pancreatic digest of casein, yeast autolysate, and (sometimes) CaCl<sub>2</sub>.

**cya gene** See ADENYLATE CYCLASE.

**cyaA gene** See CYCLOLYSIN.

**cyanelles** Endosymbiotic CYANOBACTERIA which occur in various eukaryotes: e.g. in the testate amoeba PAULINELLA, in the 'algae' *Cyanophora paradoxa* and *Glaucocystis* spp, and in certain sponges; many contain CARBOXYSOMES. A number of authors consider that cyanelles were the evolutionary precursors of CHLOROPLASTS. (See also GLAUCOPHYTA.)

**cyanide** (CN<sup>-</sup>) (1) (as a RESPIRATORY INHIBITOR) Cyanide binds to and inhibits both the oxidized and reduced forms of CYTOCHROME OXIDASES of the *aa<sub>3</sub>*-type. Cytochrome oxidases of the *o*-type are also generally inhibited, but those of the *d*-type are insensitive to cyanide.

(2) (as a metabolite) Cyanide is formed from glycine by certain microorganisms, e.g. a basidiomycetous fungus [JGM (1980) 116 9–16] and various bacteria, including *Chromobacterium violaceum* [JGM (1984) 130 521–525]; at least some of these organisms can degrade cyanide – e.g. to CO<sub>2</sub> or to β-cyanoalanine. A strain of *Pseudomonas fluorescens* has been reported to utilize cyanide as a source of nitrogen for growth, converting cyanide to ammonia and CO<sub>2</sub> in an oxygen-dependent reaction [FEMS (1983) 20 337–341].

(3) (as an enzyme inhibitor) Cyanide inhibits e.g. CO dehydrogenase (see METHANOGENESIS).

(See also AMYGDALIN and LEACHING.)

**cyanide broth** See KCN BROTH.

**cyanide test** (KCN test) A test used to determine the ability of an organism to grow in the presence of cyanide; it is used in the identification of certain species of bacteria, particularly members of the Enterobacteriaceae. A suitable medium, e.g. KCN BROTH, is inoculated with the strain under test, and the medium is examined for growth after 24 and 48 hours; growth constitutes a positive reaction.

**Cyanidium** See RHODOPHYTA.

**cyanobacteria** ('blue-green algae') A large and varied group of prokaryotic, photosynthetic organisms which differ from other bacteria in possessing chlorophyll *a* (but not bacteriochlorophylls) and in carrying out oxygenic PHOTOSYNTHESIS. (cf. RHODOSPIRILLALES and ALGAE; see also OXYPHOTOBACTERIA and CYANOBACTERIALES.) The organisms are unicellular (cells occurring singly or in aggregates) or filamentous (usually uniseriate and unbranched, sometimes multiseriate and branched); they may form more or less well-defined and distinctive colonies in nature (see e.g. COELOSPHAERIUM, GLOEOTRICHIA, NOSTOC, TRICHODESMIUM). The essentially Gram-negative-type CELL WALL frequently has features typical of the Gram-positive-type wall [JB (2000) 182 1191–1199]; one or more layers external to the outer membrane may be present, forming a firm or diffuent mucilaginous sheath (which may be calcified in some species) or a fibrous outer layer (see section II, below). No cyanobacterium has flagella at any stage, but many strains are capable of GLIDING MOTILITY; a novel type of motility has been reported in SYNECHOCOCCUS (q.v.). Within the cell, the photosynthetic pigments (CHLOROPHYLL *a*, CAROTENOIDS and PHYCOBILIPROTEINS) are typically attached to THYLAKOIDS (cf. GLOEOBACTER); the relative proportions of these pigments determine the colour of the organisms (blue-green, olive-green, yellow-green, red, purple, or almost black – depending on organism and environmental conditions: see also CHROMATIC ADAPTATION). Cells may also contain e.g. CARBOXYSUMES, GAS VACUOLES, and granules of CYANOPHYCEAN STARCH, CYANOPHYCIN, (occasionally) POLY-β-HYDROXYBUTYRATE, and/or POLYPHOSPHATE. In many species, cells or filaments (trichomes) may undergo differentiation in response to particular environmental conditions: see e.g. AKINETE, HETEROCYST, HORMOGONIUM.

In general, cyanobacteria are primarily aerobic, oxygenic photoautotrophs which fix CO<sub>2</sub> via the CALVIN CYCLE; during photosynthesis, cells accumulate storage polysaccharide which, during periods of darkness, is catabolized (via the HEXOSE MONOPHOSPHATE PATHWAY and an aerobic respiratory electron transport chain) to provide maintenance energy. *Oscillatoria limnetica*

can also catabolize endogenous polysaccharide under anaerobic conditions – either by anaerobic respiration using sulphur as terminal electron acceptor (resulting in sulphide formation) or by a fermentative pathway in which lactic acid is produced. Some cyanobacteria can grow on exogenous organic compounds – either photoheterotrophically or chemoorganotrophically. [Carbon metabolism: Ann. Mic. (1983) 134B 93–113.]

Certain species (e.g. *Cyanothece halophytica*, *Dactylococcopsis salina*, *Oscillatoria limnetica*) can, in the presence of sulphide, carry out facultative *anoxygenic* PHOTOSYNTHESIS using photosystem I with H<sub>2</sub>S as electron donor; in *O. limnetica* the resulting sulphur accumulates extracellularly. NITROGEN FIXATION occurs in many species, usually in specialized cells called HETEROCYSTS (cf. GLOEOTHECE and TRICHODESMIUM): see also NITROGENES. In some species (e.g. *Anabaena variabilis*) diazotrophy can occur in the dark under heterotrophic conditions [energy requirement: JGM (1983) 129 2633–2640]. [General metabolic aspects: Book ref. 76.]

Cyanobacteria occur in a wide range of habitats, from tropical to polar regions; however, they are rare or absent in habitats of pH < ca. 5. Depending on species, they may be found in fresh, brackish, marine and hypersaline waters, where they may be planktonic, benthic, epiphytic etc (see also BLOOM and OSMOREGULATION); in hot springs; on soils (including hot arid desert soils), muds, sediments and salt-marshes (where they may form extensive and conspicuous mats); on rocks (where they may be endolithic or epilithic); etc. (See also STROMATOLITE.) In many such environments (including rice fields) free-living cyanobacteria may be important providers of fixed nitrogen, and certain nitrogen-fixing cyanobacteria form symbiotic associations with eukaryotic organisms (see e.g. ANABAENA and NOSTOC). Heterocystous cyanobacteria of several genera (*Anabaena*, *Cylindrospermum*, '*Gloeotrichia*', *Nostoc*) occur in colonies attached to the lower epidermis or in the reproductive pockets in the leaves of floating duckweed plants (Lemnaceae), possibly supplying much of their nitrogen requirement [CJM (1985) 31 327–330]. (See also CYANELLE; RHIZOLENIA; RHOPALODIA.) No species appears to be directly pathogenic in any organism, but some freshwater bloom-forming strains produce potent toxins which may cause illness or death in animals drinking the water (see e.g. ANABAENA, APHANIZOMENON, MICROCYSTIS, NODULARIA; cf. LYNGBYA), and cyanobacterial blooms in reservoirs may cause tainting of the WATER SUPPLIES (see e.g. GEOSMIN). [Toxins and health: RMM (1994) 5 256–264.] Cyanobacterial toxins (= cyanotoxins) include e.g. (i) neurotoxins such as the anatoxins (see ANABAENA) and SAXITOXIN; (ii) hepatotoxins such as microcystins (produced by strains of MICROCYSTIS and of e.g. *Anabaena*, *Nostoc* and *Oscillatoria*); (iii) dermatotoxins such as aplysiatoxin (produced by strains of LYNGBYA and of e.g. *Oscillatoria*). [Ecological and molecular investigations of cyanotoxin production (review): FEMS Ecol. (2001) 35 1–9.]

Fossil organisms resembling cyanobacteria are among the oldest fossils known; from the fossil record and other data it is believed that cyanobacteria may have dominated the Earth's biota during the middle to late Precambrian (Proterozoic, ca. 2500–570 million years ago), and were probably responsible for the generation of oxygen in the atmosphere. [Book ref. 76, pp. 543–564.]

The taxonomy of the cyanobacteria is confused. Until quite recently they were regarded as algae and were therefore subject to the Botanical Code of nomenclature. Thus, herbarium specimens, or descriptions and illustrations, were used as type materials (living cultures not being recognized as valid types

## Cyanobacteriales

according to the Botanical Code), and emphasis was given to 'field' characteristics (e.g. colony form, pattern and frequency of false branching, presence, absence and/or consistency of sheath material) in organisms growing in nature. On this basis >150 genera and >1000 species were described. However, many of these 'field' characteristics were found to be indeterminate in culture: e.g., colony forms may be lost, mucilage production and false branching may be variable, etc. Hence, a new scheme for generic assignments, based on properties of the organisms in pure culture, was proposed [JGM (1979) 111 1–61] and widely accepted. The genera were grouped into five sections:

Section I. Unicellular; cells occur singly or in colonies. Reproduction occurs by equal binary fission (GLOEOBACTER, GLOEOCAPSA, GLOEOTHECE, SYNECHOCOCCUS, SYNECHOCYSTIS) or by budding (CHAMAESIPHON). This section includes organisms formerly of the Chroococcales, with *Chamaesiphon* from the Chamaesiphonales.

Section II. Unicellular; cells always enclosed by a fibrous layer (F layer) external to the outer membrane. Reproduction occurs by multiple fission only (DERMOCARPA, XENOCOCCUS) or by multiple fission and binary fission (CHROOCOCCIDIOPSIS, DERMOCARPELLA, MYXOSARCINA, PLEUROCAPSA GROUP). Multiple fission occurs by rapid repeated binary fissions (unaccompanied by growth) within the F layer, resulting in the formation of BAEOCYTES which are released by rupture of the F layer. In species capable of binary fission, a series of divisions produces an aggregate of vegetative cells cemented together by their F layers; some or all of the cells in the aggregate eventually undergo multiple fission to form baeocytes. Motility, if it occurs, is restricted to baeocytes prior to the development of an F layer. [Developmental patterns: Book ref. 34, pp. 203–226.] This section includes the Chamaesiphonales (except *Chamaesiphon*) and the Pleurocapsales.

Section III. Filamentous; growth occurs by intercalary cell division in one plane only (at 90° to the long axis of the trichome), giving rise to uniseriate, unbranched trichomes (cf. FALSE BRANCHING) composed only of vegetative cells (i.e., heterocysts and akinetes are not formed). The trichomes may be helical (SPIRULINA) or straight (LPP GROUP, OSCILLATORIA, PSEUDANABAENA). This section includes some genera of the former order Nostocales.

Section IV. Filamentous; growth occurs by intercalary cell division in one plane only (at 90° to the long axis of the trichome), giving rise to uniseriate, unbranched trichomes (cf. FALSE BRANCHING); heterocysts are formed in the absence of combined nitrogen, and akinetes are produced by some members. Reproduction occurs by random breakage of trichomes, or by germination of akinetes if formed; hormogonia are produced by CALOTHRIX, NOSTOC and SCYTONEMA, but not by ANABAENA, CYLINDROSPERMUM or NODULARIA. Section IV includes those genera of the Nostocales not included in section III.

Section V. Filamentous; growth occurs by intercalary cell division which may occur in more than one plane, i.e., some cells in the mature trichome may divide in a plane parallel to the long axis of the trichome. Thus, the mature trichome may be partly multiseriate with uniseriate lateral (true) branches (FISCHERELLA), but may readily break up into cell aggregates (CHLOROGLOEOPSIS). Heterocysts are formed in the absence of combined nitrogen; akinetes are formed by some members. Reproduction occurs by random breakage of trichomes, by the formation of hormogonia, and (in some species) by the formation and germination of akinetes. Section V is taxonomically equivalent to the former order Stigonematales.

Many genera have yet to be incorporated in this scheme: see e.g. APHANIZOMENON, COELOSPHAERIUM, DACTYLOCOCCOPSIS, MICROCYSTIS, STARRIA, TRICHODESMIUM.

[Isolation, media etc: Book ref. 45, pp. 212–246.]

**Cyanobacteriales** An order proposed for the CYANOBACTERIA [JBSB (1978) 28 1–6] but not accepted as legitimate owing to the lack of a genus named *Cyanobacterium*; however, the proposal of a new genus *Cyanobacterium* [Ann. Mic. (1983) 134B 21–36] paves the way for legitimization of the order.

**Cyanobacterium** See SYNECHOCOCCUS and CYANOBACTERIALES.

**cyanobiont** A cyanobacterial symbiont: see e.g. ANABAENA and NOSTOC. (cf. PHYCOBIONT.)

**Cyanobium** See SYNECHOCOCCUS.

**cyanocobalamin** See VITAMIN B12.

**Cyanocyta** See GLAUCOPHYTA.

**cyanogen bromide (CNBr)** A reagent used e.g. for the IMMOBILIZATION of a protein on the surface of a support; CNBr binds to the support (forming a 'CNBr-activated' support) and then binds spontaneously to primary amino groups on the protein. The instability of the isourea bond (between the activated support and protein) may lead to some loss of the immobilized protein; this may be avoided e.g. by cross-linking the protein with glutaraldehyde.

**cyanogenic** Having the capacity to produce cyanide (see also CYANIDE sense 2).

**cyanoguanidine** Dicyandiamide, a NITRIFICATION INHIBITOR.

**cyanomycin** An antibiotic produced by *Streptomyces cyanoflavus* and reported to be identical to PYOCYANIN [J. Antibiot. (1969) 22 49–54 cited in JB (1980) 141 156–163].

**cyanophage** Any VIRUS whose host is a cyanobacterium ('blue-green alga'). (cf. PHYCOVIRUS.) Cyanophages may be virulent or temperate, and have been isolated from filamentous and unicellular species – including members of the LPP group (cyanophages LPP-1, LPP-2), *Nostoc* (N1, N2), and *Anabaena* (A1, A2); lysis of infected intercalary cells in filamentous species results in progressive fragmentation of the filament. [Ann. Mic. (1983) 134B 43–59; classification and nomenclature: Interviol. (1983) 19 61–66.]

**cyanophilic** Having an affinity for blue dyes such as LACTOPHENOL COTTON BLUE.

**Cyanophora** See GLAUCOPHYTA.

**cyanophycean starch** A glycogen-like storage polysaccharide found in cyanobacteria; the polysaccharide occurs as granules or rods located between the thylakoids.

**cyanophycin** (multi-L-arginyl-poly(L-aspartic acid); arg-poly(asp)) A high-MWt polymer consisting of equal amounts of L-aspartic acid and L-arginine; the L-aspartic acid residues occur in a linear chain, and each residue is linked via its free carboxyl group to the  $\alpha$ -amino group of an arginine residue. Granules of cyanophycin ( $\alpha$  granules, 'structured granules') occur in most cyanobacteria. The polymer is synthesized independently of ribosomes and serves primarily as a nitrogen reserve in both vegetative cells and heterocysts. Under CO<sub>2</sub>-limiting conditions, cyanophycin may also serve as a source of carbon and energy by an ARGININE DIHYDROLASE pathway, at least in some species. [Review: ARM (1984) 38 13–16.]

**cyanophytes** CYANOBACTERIA.

**cyanosis** (*med.*, *vet.*) A bluish discoloration or darkening of the skin and mucous membranes due to inadequate oxygenation of the blood.

**cyanosomes** Cyanobacterial PHYCOBILISOMES.

**Cyanotheca** See SYNECHOCOCCUS.

**cyanotoxin** Any toxin produced by a member of the CYANOBACTERIA (q.v. for examples).

**Cyathomonas** See CRYPTOPHYTES.

**Cyathus** A genus of fungi (order NIDULARIALES) in which the basidiocarp is funnel-shaped (ca. 1 cm across), the opening of the funnel being closed by a membrane (*epiphragm*) in the immature fruiting body. Each of the flattened, discoid peridioles is attached to the lower, inner surface of the peridium (i.e., funnel) by means of a complex structure which consists essentially of three components joined end to end. Attached directly to the peridium is the *sheath* (a short cord of aggregated hyphae) to which is joined the *middle piece* (a narrow extension of the sheath); the middle piece is attached to an elongated sac (the *purse*) to the outside of which is attached the peridiole. The purse contains a long thread of coiled hyphae (the *funiculus* or *funicular cord*), one end of which is firmly attached to the peridiole while the other (unattached) end carries a strongly adhesive body (the *hapteron*). When drops of rain fall into the funnel-shaped peridium (or 'splash cup') the peridioles are ejected by the strong upthrust of water on their undersurfaces; each peridiole flies through the air, trailing its funiculus, until the hapteron adheres to e.g. a blade of grass.

**cycad symbioses** See NOSTOC.

**cyclaridine** AN ANTIVIRAL AGENT – the carbocyclic analogue of vidarabine; its activity resembles that of VIDARABINE in cell cultures, but it is resistant to deamination by adenosine deaminase.

**cycles of matter** See CARBON CYCLE, NITROGEN CYCLE and SULPHUR CYCLE.

**cyclic AMP (cAMP)** Adenosine 3',5'-cyclic monophosphate: a cyclic nucleotide synthesized from ATP by ADENYLATE CYCLASE; cAMP is degraded to AMP by cAMP phosphodiesterase (EC 3.1.4.17).

CYCLIC AMP (cAMP)

cAMP is an important regulatory molecule in various types of cell. In prokaryotes, cAMP is involved in CATABOLITE REPRESSION and e.g. in stimulating fruiting in the MYXOBACTERIALES.

[cAMP in prokaryotes: MR (1992) 56 100–122.]

In eukaryotes, cAMP is involved in various regulatory and developmental processes (see e.g. DICTYOSTELIUM); it apparently functions mainly by regulating the activity of PROTEIN KINASES. cAMP-dependent protein kinase A (PKA) consist of two types of subunit: the catalytic (C) and regulatory (R) subunits; the inactive form of PKA consists of a dimer of R subunits to which are bound two C subunits. cAMP activates PKA by binding to the R subunits; this causes the release of both C subunits – which (separately) are then able to carry out their catalytic roles. The active C subunits have a wide range of functions in both cytoplasm and nucleus – including e.g. regulation of certain transcriptional events in the nucleus.

**cyclic octadepsipeptide antibiotics** QUINOXALINE ANTIBIOTICS.

**cyclic transmission** A mode of transmission of a parasite by a VECTOR (sense 1) in which the parasite undergoes one or

more essential stages of its life cycle in the vector. (See e.g. PLASMODIUM and TRYPANOSOMA.)

**Cyldidium** A genus of ciliates (order SCUTICOCILIATIDA) which occur e.g. in soil, fresh water (including hot springs) and marine habitats. Cells: typically ovoid and generally small, ca. 15–40 μm; the cell surface is typically not densely ciliated, but those cilia which are present tend to be long, and there is often one or more longer caudal cilia.

**cyclin** A type of protein involved in the regulation of the eukaryotic CELL CYCLE. During the cycle, molecules of cyclin accumulate intracellularly at specific stages and form complexes with certain PROTEIN KINASES. Phosphorylation of the kinase part of the complex – and subsequent (partial) dephosphorylation at an appropriate point in the cycle – leads to activation of the kinase. The activated kinase phosphorylates certain proteins which then promote onward cycling; it can also bring about UBIQUITIN-dependent degradation of the cyclin – so that the intracellular concentration of cyclin falls sharply on passage through the checkpoint.

There are various types of cyclin, and different types may form complexes with protein kinases at different cell-cycle checkpoints; for example, different types of cyclin form complexes with the yeast protein kinase Cdc2 in order to mediate passage through (a) the *start* checkpoint, and (b) the G<sub>2</sub> → M checkpoint.

**cyclitol antibiotics** ANTIBIOTICS which contain a cyclic alcohol – e.g. AMINOGLYCOSIDE ANTIBIOTICS (which contain a substituted INOSITOL).

**cycloalkanes** See HYDROCARBONS.

**cycloamyloses** *Syn.* SCHARDINGER DEXTRINS.

**cyclochlorotine** *Syn.* CHLOROPEPTIDE.

**cyclodextrins** *Syn.* SCHARDINGER DEXTRINS.

**cycloguanil** See CHLORGUANIDE.

**cyclohexane metabolism** See HYDROCARBONS.

**cycloheximide** (Actidione; β-[2-(3,5-dimethyl-2-oxocyclohexyl)-2-hydroxyethyl]-glutarimide) An ANTIBIOTIC produced by certain strains of e.g. *Streptomyces griseus*; it is a by-product of streptomycin manufacture. Cycloheximide is active against many fungi and other eukaryotes (bacteria are not affected), acting primarily by inhibiting PROTEIN SYNTHESIS; e.g., it prevents translocation by binding to the 60S subunit of 80S ribosomes. Ribosomes from different organisms may differ in sensitivity. Only the yeast-like forms of certain dimorphic fungi (e.g. *Blastomyces dermatitidis*, *Histoplasma capsulatum*) are susceptible to cycloheximide.

Certain stereoisomers of cycloheximide (e.g. naramycin B) have been isolated from *Streptomyces* cultures; these are generally less active than cycloheximide against fungi. *Streptoviticins* are monohydroxyl-substituted cycloheximides produced by *S. griseus*; streptovitamin A appears to resemble cycloheximide in its mode of action.

**cyclolysin** An RTX TOXIN produced by species of *Bordetella*. The ~177 kDa protein is encoded by gene *cyaA*; activity of the toxin depends on post-translational modification in which a long-chain fatty acid is linked covalently at a specific lysine residue. The toxin is secreted by an ABC EXPORTER.

Cyclolysin has ADENYLATE CYCLASE, haemolysin and pore-forming activity. A range of eukaryotic cells are susceptible; within the target cell cyclolysin is activated by CALMODULIN.

The principal role of cyclolysin in WHOOPING COUGH may involve inhibition of the activity of phagocytic cells (e.g. macrophages) by raising their intracellular levels of cAMP. Moreover, by suppressing anti-bacterial activity in phagocytes,

## cyclo-oxygenase

the pathogen may be able to establish an intracellular carrier state. The raised levels of cAMP in epithelial cells may account for the secretion of fluid/mucus.

**cyclo-oxygenase** See PROSTAGLANDINS.

**cycloparaffins** See HYDROCARBONS.

**cyclophosphamide** See IMMUNOSUPPRESSION.

**cyclopiazonic acid** A MYCOTOXIN produced by species of *Aspergillus* and *Penicillium* (e.g. *A. flavus*, *A. oryzae*, *P. verrucosum* ('*P. cyclopium*') and *P. griseofulvum* ('*P. patulum*').) It is toxic e.g. for chickens [AEM (1983) 46 698–703], rats and calves.

**D-cycloserine** (D-4-amino-3-isoxazolidone) A broad-spectrum ANTIBIOTIC obtained from strains of *Streptomyces* spp or synthesized chemically. It acts as an analogue of D-alanine, competitively inhibiting the two enzymes (alanine racemase and D-alanyl-D-alanine synthetase) involved in the biosynthesis of PEPTIDOGLYCAN. D-Cycloserine is actively taken up by the D-alanine/glycine transport system of the cell, and a mutation which alters this transport system can result in resistance to the antibiotic. (*Methanococcus vannielii* lacks peptidoglycan but is nevertheless susceptible to D-cycloserine [Book ref. 157, p. 529].)

**cyclosis** *Syn.* CYTOPLASMIC STREAMING.

**Cyclospora** A genus of protozoa (suborder EIMERIORINA) which form disporic, dizoic oocysts. [*C. cayetanensis* as a diarrhoeal agent: RMM (1996) 7 143–150.]

**cyclosporin A** A hydrophobic peptide obtained from certain hyphomycetes (*Cylindrocarpon lucidum*, *Tolypocladium inflatum*); it is a powerful immunosuppressive drug (see IMMUNOSUPPRESSION) which appears to act mainly on T cells.

**Cyclotella** See DIATOMS.

**Cydia pomonella** GV See GRANULOSIS VIRUSES.

**Cylindrocarpon** A genus of fungi (class HYPHOMYCETES) which include organisms previously classified as species of *Fusidium*. Some species have teleomorphs in the genus *Nectria*. (See also CYCLOSPORIN A and FUSIDIC ACID.)

**Cylindrocystis** A genus of saccoderm DESMIDS.

**Cylindrogloea bacterifera** See CHLOROCHROMATIUM AGGREGATUM.

**Cylindrospermum** A genus of filamentous CYANOBACTERIA (section IV) in which the heterocysts occur only at the ends of the trichomes; akinetes are always adjacent to heterocysts. Hormogonia are formed by fragmentation of whole trichomes. GC%: 42–47.

**Cylindrosporium** See MELANCONIALES.

**Cylindrotheca** See DIATOMS.

**Cymbella** See DIATOMS.

**Cymbidium mosaic virus** See POTEXVIRUSES.

**Cymbidium ringspot virus** See TOMBUSVIRUSES.

**Cymbomonas** See MICROMONADOPHYCEAE.

**Cyniclomyces** A genus of fungi (family SACCCHAROMYCETACEAE) which form budding yeast cells and pseudomycelium; elevated levels of CO<sub>2</sub> are needed for growth. One species, *C. guttulatus*, isolated from the faeces and stomach of rabbits. [Book ref. 100, pp. 125–129.]

**Cyphellium** See CALICIALES.

**cyphella** (*lichenol.*) A round depression or pore – visible as a small white pit ca. 0.5–2.0 mm diam. – in the lower surface of the thallus in *Sticta* spp. The lower cortex forms a protruding rim around the edge of the cyphella, a medullary layer of rounded fungal cells lining the depression. Cyphellae are believed to facilitate gas exchange. [New Phyt. (1981) 88 421–426]. (cf. PSEUDOCYPHELLA.)

**Cypovirus** *Syn.* CYTOPLASMIC POLYHEDROSIS VIRUS GROUP.

**cypofuram** See PHENYLAMIDE ANTIFUNGAL AGENTS.

**Cyrtophorida** See HYPOSTOMATIA.

**cyrtos** (cytopharyngeal basket; nasse; pharyngeal basket) A (frequently curved) type of CYTOPHARYNGEAL APPARATUS whose walls are strengthened by longitudinal nematodesmata (which arise at apical kinetosomes) and are lined with extensions of POSTCILINARY MICROTUBULES; toxicysts are absent. The cyrtos is characteristic of the HYPOSTOMATIA. (cf. RHABDOS.)

**cyst** A specialized microbial cell produced either in response to adverse environmental conditions or as a normal part of the life cycle. During cyst formation (*encystment*), an organism produces a thick or thin wall within which it becomes totally enclosed. Cysts are usually resistant to desiccation, and may be resistant to e.g. ultraviolet radiation and/or heat.

(a) (*bacteriol.*) Cyst formation is uncommon among bacteria; most studies on bacterial cyst formation have been carried out on species of AZOTOBACTER, particularly *A. vinelandii*.

In *Azotobacter* spp, encystment can be promoted *in vitro* by the provision of substrates such as  $\beta$ -hydroxybutyrate, and it has been generally supposed that the intracellular accumulation of PHB is a necessary pre-requisite for cyst formation; however, it has been proposed that the stimulus for encystment may be related to the extracellular levels of both carbon and nitrogen sources [SBB (1986) 18 23–28]. During encystment, cells lose their flagella and become spheroidal; these heavily encapsulated cells ('precysts') typically accumulate PHB. Membranous blebs develop at the cell surface, and these subsequently detach and coalesce – forming the fragmented outer layer (*exine*) of the cyst wall. Later, the cyst wall develops an electron-transparent inner layer (*intine*). The cyst wall contains ALGINATE together with protein and lipid; the exine is particularly rich in polyguluronic acid (and Ca<sup>2+</sup>), while the intine is richer in polymannuronic acid. *Azotobacter* cysts are metabolically dormant, and they can remain viable in dry soil for many years; they are more resistant than the vegetative cells to desiccation, sonication and ultraviolet radiation, but they are not significantly more resistant to heat.

*Azotobacter*-like 'lipid cysts' are formed by some members of the Methylococcaceae.

(See also MICROCYST.)

(b) (*protozool.*) Cysts are formed e.g. by some amoebae, ciliates and phytoflagellates. During encystment, structures such as cilia or flagella are lost or resorbed, and considerable reorganization of internal structures may occur; the cell becomes enclosed by a thin or thick, commonly multilayered wall, the outer-most layer(s) being termed the *ectocyst* or *exocyst*, the innermost layer(s) the *endocyst*, and intermediate layer(s) the *mesocyst*. Cyst walls vary in composition, according to species; they commonly contain a high proportion of protein, while e.g. cellulose occurs in the endocyst of *Acanthamoeba* spp, chitin apparently occurs in *Entamoeba* cysts [BBRC (1982) 108 815–821], and sulphated glycosaminoglycans occur in the mesocyst in *Histiculus similis* [JGM (1983) 129 829–832]. Cysts of CHRYSOPHYTES have silica walls. (In certain loricate or testate organisms – e.g. *Euglypha* spp – a cyst is formed when the organism withdraws into its lorica/test and plugs the aperture.) *Excystment* (the release of one or more vegetative cells from the cyst) may involve rupture of the cyst wall (possibly as a result of the intake of water) and/or enzymic dissolution of the wall; in e.g. *Naegleria gruberi* the cell leaves the cyst via a pore which becomes unplugged, while in *Acanthamoeba* a lid-like operculum is removed from an exit aperture in the cyst wall.

In many protozoa the cyst serves a protective function, allowing the organism to survive e.g. the absence of food,

desiccation, and/or unfavourable temperatures. Such 'resistant cysts' are generally dormant and may remain viable for years under appropriate conditions. Many such cysts (e.g. those of some euglenoid flagellates) are highly resistant to desiccation; however, those of e.g. *Didinium* and *Euplotes* cannot withstand drying, but can remain viable in water for long periods. Resistant cysts may allow dissemination of the organism e.g. by wind or by birds or animals. In parasitic protozoa – e.g. ENTAMOEBIA, coccidia, GIARDIA – cysts are the form in which the parasite is transmitted from one host to another.

In some protozoa *reproductive cysts* are formed as a normal part of the life cycle; these may not be more resistant than the vegetative cell to adverse environmental conditions. For example, *Colpoda* spp form thin-walled cysts within which asexual fission occurs, and can also form thick-walled resistant cysts under adverse conditions. (See also e.g. ICHTHYOPHTHIRIUS.) Some protozoal cysts may serve both reproductive and protective (and disseminative) functions (e.g. the oocysts of the EIMERIORINA). (See also ACTINOPHRYS and ACTINOSPHAERIA.)

**cystathione** See e.g. Appendix IV(d).

**cysteamine** 2-Mercaptoethylamine (=  $\beta$ -aminoethanethiol): see e.g. PANTOTHENIC ACID.

**L-cysteine biosynthesis** See Appendix IV(c).

**cysteine protease** (1) See APOPTOSIS. (2) *Syn.* thiol PROTEASE.

**cystibiotics** Class IIa BACTERIOCINS (q.v.).

**cystic fibrosis (CF)** An inheritable disease [Review: Lancet (1998) 351 277–282] usually involving defective transmembrane transport of chloride by an ABC TRANSPORTER.

Typically, the lungs are congested with a viscid dehydrated mucus (containing e.g. raised levels of calcium and magnesium ions) which may become infected with organisms such as *Burkholderia* (formerly *Pseudomonas*) *cepacia* [review: RMM (1995) 6 1–16], mycobacteria and *Pseudomonas aeruginosa*; such infections often persist. Patients with CF are frequently given prolonged antibiotic therapy, but this may not prevent colonization of the lungs with e.g. mucoid (ALGINATE-forming) strains of *Pseudomonas aeruginosa* [mucoidy of *P. aeruginosa* in CF: JB (1996) 178 4997–5004]; this is associated with a poor prognosis because the alginate may protect the bacteria from phagocytosis, pulmonary surfactant and antibiotics. It has been reported that high levels of salt (NaCl) on CF airway epithelia may permit bacterial colonization by inhibiting anti-bacterial activity normally associated with this habitat [Cell (1996) 85 229–236]. (See also QUORUM SENSING.)

Results of studies on the molecular epidemiology of *P. aeruginosa* in a CF outpatient clinic indicate that cross-infection is not common within the clinic, and that acquisition of infection from a common source is unlikely [JMM (2001) 50 261–267].

It was suggested that long-term colonization of the lungs of CF patients with *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*) may be a significant factor in prognosis [RMM (1997) 8 15–19]. This environmentally common, Gram-negative, non-glucose-fermenting bacillus [description: IJBS (1993) 43 606–609] is now frequently isolated from the respiratory specimens of CF patients (and is also associated with disease in immunocompromised individuals, cancer patients and recipients of transplants). [Identification/detection of *S. maltophilia* by a PCR-based approach: JCM (2000) 38 4305–4309.]

[Genetic basis, treatment etc. of CF: Book ref. 214.]

**cystidium (mycol.)** A large, elongated, sterile cell which occurs among the basidia in the hymenia of certain basidiomycetes. Cystidia vary greatly in size and form, but they usually project

some way beyond the tips of the basidia. Their function is largely unknown; however, those which arise from the surfaces of the lamellae of certain species of *Coprinus* appear to function as 'spacers' – maintaining a small but significant distance between adjacent lamellae, thus facilitating spore dispersal.

**cystine–lactose–electrolyte-deficient medium** See CLED MEDIUM.

**cystine–tellurite–blood agar** See TELLURITE MEDIA.

**cystitis** Inflammation of the urinary bladder. Symptoms: frequent, painful micturition, sometimes with haematuria, fever etc. Cystitis may result from the spread of an infection upwards from the urethra or downwards from the kidney. The former is more common, with *Escherichia coli* (see UPEC) and *Proteus* spp being the most common causal agents; other causal agents include enterococci and *Staphylococcus saprophyticus*. Treatment may involve e.g. copious fluid intake and therapy with broad-spectrum antibiotics.

Certain adenoviruses (e.g. type 11) have been associated with haemorrhagic cystitis (mainly in children).

(See also URINARY TRACT INFECTION.)

**Cystobacter** See MYXOBACTERALES.

**Cystodinium** A genus of DINOFLAGELLATES in which the vegetative cells are unicellular and non-motile, and reproduce by the formation of zoospores.

**Cystomyces** See UREDINIOMYCETES.

**Cystoseira** See PHAEOPHYTA.

**cystosorus** A cluster of cysts: see e.g. PLASMODIOPHOROMYCETES.

**Cystotheca** See ERYSIPIHALES.

**Cystoviridae** ( $\phi 6$  phage group) A family of BACTERIOPHAGES containing one genus (*Cystovirus*) and one member: BACTERIOPHAGE  $\phi 6$ .

**Cystovirus** See CYSTOVIRIDAE.

**cystozoite** (bradyzoite) In certain coccidia: a stage within host tissues (see e.g. TOXOPLASMOSES).

**cytarabine** (1- $\beta$ -D-arabinofuranosylcytosine; ara-C; cytosine arabinoside) An ARABINOSYL NUCLEOSIDE originally investigated as a possible systemic ANTIVIRAL AGENT for disseminated herpesvirus infections; toxicity has limited its clinical use.

**cytidine** See NUCLEOSIDE and Appendix V(b).

**cytidine deaminase** See RNA EDITING.

**cytoadherence** See MALARIA.

**cytoadhesin subfamily** A category within the INTEGRIN family which includes CD41b/CD61.

**cytobiosis** SYMBIOSIS in which one symbiont occurs within the cells of the other.

**cytochalasins** A family of fungal secondary metabolites (POLYKETIDE derivatives) – cytochalasins A, B, C etc. – which are formed e.g. by species of *Aspergillus*, *Helminthosporium* and *Phomopsis*. Cytochalasins bind to one end of an ACTIN microfilament (the fast-growing or 'barbed' end) and inhibit the addition of further monomers – thus inhibiting e.g. phagocytosis, amoeboid movement, the intracellular development of certain viruses, and other microfilament-dependent functions. (Cytochalasin B apparently slows, but does not prevent, the addition of actin monomers [JCB (1986) 102 282–288].) Cytochalasins A and E enhance branching in certain fungi (see GROWTH (fungal)).

**cytochrome** See CYTOCHROMES.

**cytochrome oxidase** In an ELECTRON TRANSPORT CHAIN a (terminal) cytochrome which transfers electrons to molecular oxygen, reducing it to water. Cytochrome oxidases include cyts *aa<sub>3</sub>*, *a<sub>1</sub>*, *d* and *o* (see CYTOCHROMES). Bacteria typically have more than one type of cytochrome oxidase. The electron transport chain in the animal MITOCHONDRION appears to have only one type

## cytochrome oxidase test

of cytochrome oxidase, cyt *aa<sub>3</sub>*, which resembles the bacterial cyt *aa<sub>3</sub>* in containing two haem *a* molecules and two copper atoms; in at least some plant mitochondria there is an additional CYANIDE-resistant cytochrome oxidase. (See also RESPIRATORY INHIBITORS.)

**cytochrome oxidase test** See OXIDASE TEST.

**cytochromes** A class of *haemoproteins* in which the HAEM (sense 1) is usually linked to the protein via the 5th and 6th coordinate positions of the haem iron; cytochromes participate in many types of electron transfer reaction (see e.g. ELECTRON TRANSPORT CHAIN and PHOTOSYNTHESIS), such reactions involving the alternate oxidation and reduction of the haem iron. The  $E_{m,7}$  (see REDOX POTENTIAL) of most cytochromes falls within the approximate range  $-100$  to  $+500$  mV.

**Cytochrome nomenclature.** Cytochromes are classified primarily by the nature of their haem group(s); individual cytochromes within a given class may be distinguished by subscripts (e.g. *c*<sub>1</sub>, *c*<sub>2</sub>, *c*<sub>3</sub> etc) or – see later – they may be designated by certain of their absorption characteristics. Cytochromes *a* (cyts *a*) contain haem *a* (which has a formyl group at the C-8 position, and a long hydrophobic chain at the C-2 position of the PORPHYRIN). Cytochromes *b* contain haem *b* (= *protohaem*: see HAEM). Cytochromes *c* contain haem *c* (a *mesohaem*), the haem being linked to the protein via thioether bonds (between the ethyl substituents of the haem and cysteine residues in the protein) as well as via the coordinate bonds. Some *c*-type cytochromes (e.g. cyts *c*<sub>2</sub>, *c*<sub>555</sub>) have a single haem attached near the N-terminal of the protein, while others have a single haem attached near the C-terminal; the latter, which include the *c'* cytochromes (= *cytochromoids*), differ chemically and spectroscopically from other *c*-type cytochromes. Cytochromes *d* contain a CHLORIN.

Certain cytochromes have more than one haem group, while others may contain e.g. a flavin group.

Some cytochromes are often referred to by their original names, even though such names do not reflect current classification; thus e.g. cyt *a*<sub>2</sub> is now cyt *d*, and cyt *o* is a *b*-type cytochrome.

**Identification of cytochromes.** Cytochromes may be identified/quantified by various methods, often e.g. by spectrophotometry – in which a given type of cytochrome may be detected, *in situ*, by its characteristic absorption pattern in the visible regions of the spectrum. Commonly a *difference spectrum* is determined: e.g., the absorption spectrum of a given cytochrome in the reduced state minus its absorption spectrum in the oxidized state (cf. CO DIFFERENCE SPECTRUM); such a spectrum often exhibits a maximum absorption peak in each of three bands: the  $\alpha$ -band (ca. 540–650 nm), the  $\beta$ -band (ca. 510–530 nm) and the  $\gamma$ -band (= *Soret band*) (ca. 400–450 nm). In some cases a cytochrome may be designated by its absorption peak (in the reduced state) within the  $\alpha$ -band – e.g., cyt *b*-557 (= cyt *b*<sub>557</sub>).

Spectroscopy can sometimes lead to an incorrect *in situ* identification of a cytochrome [see e.g. JGM (1984) 130 3055–3058]. In some cases it may be necessary to extract the haem, bind to it (coordinately) two pyridine molecules per molecule, and examine by spectroscopy the resulting *dipyridine ferrohaemochrome* (= *pyridine haemochrome*) – reduced e.g. with sodium dithionite – in an alkaline pyridine solution. For each class of cytochromes, the corresponding dipyridine ferrohaemochrome  $\alpha$ -absorption peak falls within a narrow waveband: cyts *a* 580–590 nm; cyts *b* 556–558 nm; cyts *c* 549–551 nm; cyts *d* 600–620 nm. [Analysis of cytochromes: Book ref. 138, pp. 285–328.]

**Cytochrome–ligand binding.** See e.g. AZIDE, CARBON MONOXIDE and CYANIDE.

**Cytochromes in eukaryotes.** Cytochromes occur e.g. in the mitochondrial ELECTRON TRANSPORT CHAIN (q.v.) and in photosynthetic systems (see PHOTOSYNTHESIS). Many cells also contain e.g. certain *b*-type cytochromes – such as cyt *b*<sub>5</sub> and a cyt P-450 – associated with the endoplasmic reticulum. The mammalian cyt P-450 – the cytochrome–carbon monoxide complex absorbs at 450 nm – occurs in liver cells and mediates in hydroxylation reactions involving sterols and other lipid-soluble substances; an analogous cyt P-450 occurs e.g. in many fungi (see e.g. AZOLE ANTIFUNGAL AGENTS and HYDROCARBONS). Cytochromes appear to be absent in e.g. certain parasitic protozoa – including bloodstream forms of trypanosomes and intracellular stages of *Leishmania donovani*.

**Cytochromes in prokaryotes.** Cytochromes occur in both aerobic and anaerobic respiratory chains in the CYTOPLASMIC MEMBRANE; they also occur in the cytoplasm and/or periplasmic region in some cells, and appear to occur in certain photosynthetic REACTION CENTRES. In bacteria, cytochromes vary – qualitatively and quantitatively – from one species to another, and even in a given species under different growth conditions. [Cytochromes in *Escherichia coli* under different growth conditions: JGM (1982) 128 1685–1696.] Various cytochromes may act as CYTOCHROME OXIDASES, and it is usual for a given bacterium to have more than one type of cytochrome oxidase.

Generalized patterns of cytochromes occur in the various categories of bacteria. Gram-positive aerobic chemoheterotrophs typically have a pattern of the *bca<sub>3</sub>o* type, i.e., including two types of cytochrome oxidase; exceptions include e.g. *Brochothrix thermosphacta* which has only one cytochrome oxidase (*aa<sub>3</sub>*). Gram-negative chemoheterotrophs (including e.g. enterobacteria and pseudomonads) are, by comparison, more heterogeneous in their cytochrome patterns under aerobic conditions; typically, cyt *aa<sub>3</sub>* is not formed (though it is in e.g. some pseudomonads, many methylotrophs, and *Rhizobium* spp), the cytochrome pattern frequently being of the *bcoa<sub>1</sub>d* type, but often without cyt *c*. Cyts *a* and *d* are not formed e.g. by *Pseudomonas fluorescens*, or by certain other pseudomonads, so that these organisms may have patterns of the *bco* or *bo* type. Cytochrome oxidases are often absent or greatly decreased during anaerobic respiration. In at least some pseudomonads (and e.g. *Thiobacillus denitrificans*) which carry out DENITRIFICATION, cyt *d*<sub>1c</sub> (= *cd*<sub>1</sub>) acts as a nitrite reductase. Chemolithotrophs often have cytochrome patterns of the *bca<sub>3</sub>o* type. All members of the RHODOSPIRILLALES appear to contain *c*-type cytochromes, and most or all appear to have *b*-type cytochromes.

Specialized cytochromes or cytochrome patterns occur in some bacteria; thus, e.g. *Pseudomonas putida* contains a soluble cyt P-450 which, together with an iron–sulphur protein and an FAD-containing reductase, effects hydroxylation of e.g. camphor in a cyclic reaction sequence. [Structure and chemistry of cyt P-450 from *P. putida*: Book ref. 146, pp. 157–206.] (See also METHYLOTROPHY and RHP.)

Cytochromes appear to be absent from some facultative and obligate anaerobes.

[Structure, function and evolution of cytochromes (review): Prog. Biophys. Mol. Biol. (1985) 45 1–56.]

(See also BENZIDINE TEST and OXIDASE TEST.)

**cytochromoids** See CYTOCHROMES.

**cytotoxic (adj.)** Able to kill cells.

**cytoductant** See CYTODUCTION.

**cytoduction** A cross in which two cells undergo cytoplasmic fusion but do not undergo nuclear fusion (karyogamy) owing to a chromosomal mutation; each haploid progeny cell (*cytoductant*,

*heteroplasmon*) contains the nucleus of one parent cell but may contain cytoplasmic elements from both parent cells.

**cytofluorometry** FLOW CYTOMETRY which involves the detection of specific fluorescence or FLUOROCHROME markers.

**cytogamy** (selfing) (*ciliate protozoal.*) The occurrence of AUTOGAMY (instead of conjugation) in each of two ciliates which have paired.

**cytohet** (cytoplasmic heterozygote) A *eukaryotic* cell which is HETEROZYGOUS for one or more CYTOPLASMIC GENES.

**cytokines** In the human and animal body: a heterogeneous population of (glyco)proteins which form a dynamic network of intercellular messenger molecules that regulate various aspects of physiology, including the immune response to infection. (This describes, but does not define, cytokines; workers in the field have not yet indicated the essential difference(s) between those molecules which are currently regarded as cytokines and certain other regulatory molecules – thus precluding a formal definition at the present time.) Cytokines may be distinguished from the (protein) hormones in that (i) a given cytokine may be synthesized by different types of cell and/or may act on different types of cell; (ii) cytokines typically act on target cells near the source of cytokine – although if secreted into the circulatory system they may act on distant cells; (iii) cytokines may cause diverse effects (e.g. when acting on different cells under different conditions); (iv) different types of cytokine may give rise to the same physiological effect; and (v) some cytokines can act as mitogens.

Two sources [Book refs 218 and 226] recognize the following as cytokines: COLONY-STIMULATING FACTORS, INTERFERONS, INTERLEUKINS, cytotoxic agents such as tumour necrosis factor (see TNF), growth factors and CHEMOKINES.

Cytokines are synthesized mainly by leukocytes (white blood cells); some cytokines are synthesized by stationary cells (e.g. endothelial cells). Although most cytokines are soluble (secreted) products, some are, or can be, membrane-associated.

In general, transcription of cytokine-encoding genes is inducible by appropriate exogenous or endogenous stimuli. An example of an exogenous stimulus is the binding of lipopolysaccharide to CD14 receptors on macrophages (see CD14); endogenous stimuli can arise e.g. during viral infection.

On release, cytokines bind to specific receptors on target cells.

Cytokine receptors are divided into a number of families which differ e.g. in structure. (Some of the receptors found on macrophages and T lymphocytes can act as receptors for human immunodeficiency virus (HIV). Cytokine receptors have also been reported to act as binding sites for certain other viruses, including human (alpha) herpesvirus 1.) Interestingly, receptor molecules can be shed from cells; such isolated receptors can e.g. bind to (and antagonize) the corresponding cytokine, or they can bind to other cells – which may then be stimulated by the given cytokine.

The binding of a cytokine to its cognate receptor initiates an intracellular signal, the nature of which depends e.g. on the type of cell and cytokine and on the environmental and intracellular conditions under which binding takes place. Cytokine–receptor binding characteristically results (either directly or indirectly) in the activation of kinase(s) at certain stage(s) within the signalling pathway. In one intracellular signalling pathway (triggered by many of the interleukins), the binding of cytokine leads to activation of a tyrosine kinase of the JAK (Janus kinase) family which, when activated, transmits the signal by phosphorylating a molecule of the so-called 'signal transducers and activators of transcription' (STATs); STATs exist in different forms, and

a given type of STAT relays the signal for only some type(s) of cytokine – thus permitting different cytokines to initiate different signals in the same cell. Phosphorylated STATs form homo- or heterodimers that enter the nucleus and promote transcription of particular gene(s). [STATs: TIBS (2000) 25 496–502.]

As mentioned, a given cytokine may cause diverse effects. For example, the binding of tumour necrosis factor (TNF) to its receptor can result in activation of caspases (and APOPTOSIS) – or e.g. transcription of specific genes through activation of a major transcription factor: nuclear factor- $\kappa$ B (NF- $\kappa$ B). In the latter pathway, the binding of TNF to its receptor promotes phosphorylation (and consequent degradation) of a certain protein (I $\kappa$ B $\alpha$ ) which, by binding to NF- $\kappa$ B, inactivates it; that is, phosphorylation (degradation) of I $\kappa$ B $\alpha$  results in the activation of NF- $\kappa$ B. NF- $\kappa$ B is important e.g. in the development of an inflammatory response; it promotes transcription of a range of genes – including those encoding TNF- $\alpha$ , IL-1 $\beta$  and IL-8.

In general, the binding of cytokines to their receptors may initiate cellular responses that range from secretion (of cytokines etc.), differentiation or proliferation to chemotaxis or apoptosis; currently, many of the signalling pathways in eukaryotic cells are incompletely understood. [Signalling mechanisms in prokaryotes and eukaryotes: Book ref. 218, pp 89–162; Book ref. 226, pp 111–140.]

*Note regarding nomenclature of cytokines.* The name of a cytokine does not necessarily correlate with its primary function(s) in vivo. For example, tumour necrosis factor was initially identified as an anti-tumour agent but is now known to be a central mediator in host defence and inflammation. Again, some interleukins, initially thought to mediate only leukocyte–leukocyte interactions, are now known to involve other types of cell; thus, e.g. interleukin-8 is secreted by endothelial cells and is classified as a chemokine.

*Cytokines as factors in health and (infectious) diseases.* Various roles have been attributed to cytokines in normal physiology and development. However, the contribution of individual cytokines in vivo has been difficult to establish experimentally – not least because of the complexity of the system and the existence of biochemical redundancy among cytokines; hence, in some cases, the function(s) of a cytokine have been inferred from the effects attributed to inherited deficiencies in the synthesis or activity of that cytokine (and/or its receptor). In other cases, the role(s) of cytokines have been inferred from studies on knockout mice in which genes of particular cytokine(s) have been rendered non-functional.

In diseases of microbial aetiology, cytokines typically have protective roles – e.g. in processes such as ANTIBODY FORMATION and INFLAMMATION. However, dysregulation of cytokines (enhanced production, imbalance, inhibition) may be a major factor in pathogenesis.

In some cases, the severity of, or susceptibility to, disease has been found to vary in different individuals according to the nature of the TNF- $\alpha$  gene promoter – particular polymorphisms in the promoter region of the gene being associated with enhanced production of the cytokine; this has been reported in cerebral MALARIA [Nature (1994) 371 508–510] and in ENDOGENOUS SHOCK [JAMA (1999) 282 561–568]. Again, polymorphisms in the gene encoding IL-1 $\beta$  have been associated with an increased risk of gastric cancer from *Helicobacter pylori* infection [Nature (2000) 404 398–402].

In pyelonephritis caused by *Escherichia coli*, the cytokines IL-6 and IL-8 appear to be prominent – levels of IL-6 correlating

## cytokines

with the severity of disease [e.g. PNAS (2000) 97 8829–8835 (8833–8834)].

During infection with *Yersinia*, the pathogen's secreted YopP/YopJ (see VIRULON) down-regulates the pro-inflammatory response – e.g. inhibiting the formation of both TNF- $\alpha$  and IL-8; the mechanism involves inhibition of the kinase that phosphorylates (and inactivates) I $\kappa$ B $\alpha$ , thus inhibiting transcription of NF- $\kappa$ B-dependent genes [PNAS (2000) 97 8778–8783 (8781–8782)].

Viruses may inhibit cytokines in various ways; for example, soluble forms of TNF and IL-8 receptors are encoded by Shope fibroma virus and CMV, respectively. (See also INTERLEUKIN-18.)

(See also DISSEMINATED INTRAVASCULAR COAGULATION; DNA VACCINE; HAEMOPHAGOCYTIC SYNDROME; JARISCH–HERXHEIMER REACTION; LEPROSY; MODULIN; NITRIC OXIDE; P FIMBRIAE; SUPER-ANTIGEN; TOXIC SHOCK SYNDROME.)

Many infections elicit an immunological response in which a particular subset of T LYMPHOCYTES – either Th1 or Th2 – is dominant. For example, Th1-type responses are typical in certain bacterial and protozoan infections, while Th2-type responses are common e.g. when infection involves helminths [IT (1996) 17 138–146]; moreover, in at least some cases, an 'inappropriate' response (e.g. Th2 instead of Th1) is associated with increased susceptibility to the infection.

Naive CD4<sup>+</sup> T cells (i.e. those not previously exposed to antigen) may develop as either Th1 or Th2 cells on exposure to antigen; the mechanism that selects one or other subset of T cells is unknown, but the decision to develop one way or the other is influenced by the microenvironment of cytokines which are present during activation of the T cell by antigen – e.g. IL-12 promotes the Th1 response, while IL-4 promotes differentiation to Th2 cells. (A newly reported cytokine receptor, designated TCCR, appears to be necessary for the Th1-type immune response in mice [Nature (2000) 407 916–920].) Interestingly, glucocorticoids from stress metabolism may suppress IL-12 (the main inducer of the Th1-type response); that is, stress-derived glucocorticoids may shift the balance of the immune response from Th1-type toward Th2-type [BCEM (1999) 13 583–595].

One important difference between Th1- and Th2-type responses is that Th1 and Th2 cells secrete different types of cytokine (see table) and so have correspondingly dissimilar physiological roles. (In this context, it is interesting to note that when the molecule ICAM-1 was co-expressed with antigen (on the antigen-presenting cell) the Th2 cytokine IL-4 was found

to be down-regulated in naive CD4<sup>+</sup> cells [PNAS (1999) 96 3023–3028].)

Studies carried out in vitro and in vivo suggest that the cytokines secreted by (Th1 or Th2) cells are responsible for various aspects of the immune response observed during infections. Thus, 'inflammatory' Th1 cells secrete pro-inflammatory cytokines that are associated with important roles in cell-mediated immunity. For example, IFN- $\gamma$  activates macrophages which may then (i) exhibit enhanced antimicrobial activity in phagosomes, (ii) secrete IL-8, attracting immune cells to the site of infection, and (iii) secrete IL-12, promoting further development of the Th1 subset. Moreover, IFN- $\gamma$  can promote class switching to complement-fixing, opsonizing antibodies (human IgG1, IgG3; murine IgG2a). Th1 cytokines can e.g. upregulate expression of E selectins (see INFLAMMATION) and they can also upregulate MHC class II antigens. DELAYED HYPERSENSITIVITY is one manifestation of the characteristically cell-mediated Th1-type immune response.

Th2 cells are typically T-helper cells in ANTIBODY FORMATION. Th2 (anti-inflammatory) cytokines down-regulate macrophages and promote B cell activation, thus being important in the 'humoral' (antibody-mediated) immune response to infection by e.g. extracellular bacteria and helminths etc. IL-4 promotes class switching to non-complement-fixing IgG (human IgG4; murine IgG1) as well as to IgE in both man and mice. IL-5 promotes eosinophilia which may give activity against e.g. helminths and other parasites. IL-6 may contribute to antimicrobial activity by stimulating B cell proliferation and/or inducing ACUTE-PHASE PROTEINS.

*Therapeutic uses of cytokines.* Because cytokines regulate so many aspects of the immune defence system they are attractive as candidate therapeutic agents; for example, INTERFERONS have been useful in various contexts. However, some cytokines (e.g. TNF), though potentially useful, may be unsuitable for therapy owing e.g. to instability or toxicity in vivo; interestingly, a non-toxic TNF-mimetic peptide has been found to prevent recrudescence of *Mycobacterium bovis* (BCG) infection in CD4<sup>+</sup> T cell-depleted mice [JLB (2000) 68 538–544]. Inhibition of TNF- $\alpha$  can be achieved by monoclonal antibodies or by soluble TNF- $\alpha$  receptor molecules. [New perspectives on the design of cytokines and growth factors: TIBtech. (2000) 18 455–461.]

[Molecular biology of the cytokines: Book ref. 226.]

**cytokinesis** Those events, excluding nuclear division, which occur during the division of a eukaryotic cell into progeny cells; they include the apportionment of the cytoplasm and organelles, and may include e.g. synthesis of new material for the cell wall of each progeny cell.

**cytokinins** (kinins, phytokinins) PHYTOHORMONES which stimulate metabolism and cell division; the cytokinins are 6-*N*-substituted adenines which are synthesized mainly at the root apex and translocated via the xylem. (Cytokinin-like activity is exhibited by certain urea derivatives, e.g. diphenylurea (found in coconut milk); it is believed that such compounds act by promoting the 6-*N*-substitution of endogenous adenine.) The mechanism by which cytokinins promote cell division is unknown; one suggestion is that cell division is encouraged by an increase in the level of endogenous cAMP brought about by the inhibition of cAMP phosphodiesterase by cytokinins.

Compounds similar or identical to cytokinins are produced by certain microorganisms; such compounds may account for the formation of ROOT NODULES and for the development of symptoms in e.g. FASCINATION.

CYTOKINES: some of the cytokines secreted by Th1 and Th2 subsets of T lymphocytes

Cytokine	Th1	Th2
Interleukin-2	+	
Interleukin-3	+	+
Interleukin-4		+
Interleukin-5		+
Interleukin-6		+
Interleukin-10		+
Interleukin-13		+
Interferon- $\gamma$	+	
TNF- $\alpha$	+	+ <sup>a</sup>
TNF- $\beta$	+	

<sup>a</sup> Secretion from Th2 cells reported to be lower than that from Th1 cells.

Interestingly, cytokinins are incorporated in specificity-determining positions in a small proportion of tRNA molecules. (See also KINETIN and ZEATIN.)

**cytolysin** A toxin which lyses (usually eukaryotic) cells.

**cytolytic** Able to lyse cells.

**cytolytic T cell** See T LYMPHOCYTE.

**cytomegalic inclusion disease (CID)** A disease caused by human cytomegalovirus (CMV) – see BETAHERPESVIRINAE. CMV can infect almost any tissue; infected cells are characteristically enlarged with large intranuclear inclusion bodies. Virus transmission occurs e.g. by direct contact, by transfusion of blood from an infected donor, or via the placenta. Congenital CID is commonly asymptomatic, but can be a severe condition with e.g. hepatosplenomegaly, encephalitis with irreversible CNS damage, and increased incidence of congenital deformities (see also TORCH DISEASES). Postnatal and adult infections are probably largely asymptomatic; in some cases the disease resembles INFECTIOUS MONONUCLEOSIS ('CMV mononucleosis', Paul-Bunnell test negative). In immunodeficient patients CMV infection may lead to e.g. pneumonia, transplant rejection, and/or death; infection may be primary or may result from reactivation of latent CMV. Patients at risk from CMV-related disease may be monitored by a NASBA-based assay of cytomegalovirus late gene *UL65* (which encodes the pp67 protein) [JCM (1998) 36 1341–1346]; a commercial form of the assay for CMV was introduced by Organon Teknika. Known antiviral agents are not effective against CID.

**cytomegaloviruses** See BETAHERPESVIRINAE.

**cytomegaly** See CYTOPATHIC EFFECT.

**cytomembranes** *Syn.* INTRACYTOPLASMIC MEMBRANES.

**cytomere** A multinucleate structure which is formed by fragmentation of a schizont and which subsequently gives rise to merozoites.

**cytopathic effect (CPE) (*virol.*)** A change or abnormality in cells due to virus infection. CPEs may include e.g. INCLUSION BODY formation, cytoplasmic vacuolation (see e.g. SPUMAVIRINAE), cell enlargement (cytomegaly) (see e.g. BETAHERPESVIRINAE), SYNCYTIUM formation (see e.g. PARAMYXOVIRUS), the formation of discrete foci of cell proliferation (see e.g. FRIEND VIRUS and MCF VIRUSES), cell death (see also PLAQUE), etc. The CPEs produced by a given virus in a given cell system are often characteristic and may be useful in the identification of the virus; some viruses characteristically fail to give rise to CPE even when viral replication occurs (see e.g. RUBIVIRUS).

**Cytophaga** A genus of GLIDING BACTERIA of the CYTOPHAGALES; species occur in soil and in freshwater, estuarine and marine habitats. The organisms are rods or filaments, up to ca. 50 µm long, containing carotenoid pigments ranging from yellow to red; they are chemoorganotrophs and may be aerobic (respiratory metabolism using oxygen – or, in at least one strain, nitrate – as electron acceptor) or facultatively anaerobic (facultatively fermentative). Typically, *Cytophaga* spp can attack polysaccharides such as AGAR, ALGINATE, CELLULOSE and CHITIN. GC%: ca. 28–39.

**Cytophagaceae** See CYTOPHAGALES.

**Cytophagales** An order of GLIDING BACTERIA which do not form fruiting bodies (cf. MYXOBACTERIALES); constituent species, all of which are Gram-negative, occur e.g. in soil and in freshwater, estuarine and marine habitats. In an early taxonomic scheme [Book ref. 21, pp. 99–119] four families were distinguished: motile rods or filaments containing carotenoid pigments (Cytophagaceae); motile filaments lacking carotenoid pigments (Beggiatoaceae); flat, non-pigmented, motile filaments found in

the oral cavity in vertebrates (Simonsiellaceae); non-pigmented filaments, attached (at one end) to other filaments or to the substratum, which form gliding gonidia (Leucotrichaceae). Genera include ALYSIELLA, BEGGIATOA, CYTOPHAGA, FLEXIBACTER, HERPETOSIPHON, LEUCOTHRIX, SAPROSPIRA, SIMONSIELLA, SPORO-CYTOPHAGA, THIOPLOCA, THIOTHRIX and VITREOSCILLA.

In another taxonomic scheme [ARM (1981) 35 339–364 – cf. FLEXIBACTERIAE], of the above genera only *Cytophaga*, *Flexibacter* and *Sporocytophaga* are included in the Cytophagales; the other genera are classified as apochlorotic cyanobacteria.

**cytopharyngeal apparatus (*ciliate protozool.*)** Skeletal and certain other elements of the CYTOPHARYNX. Two main types of cytopharyngeal apparatus have been distinguished: the CYRTOS and the RHABDOS; this taxonomically important distinction is believed to reflect evolutionary differences in the different ciliate groups – those having a rhabdos-type structure being regarded as the more primitive.

**cytopharyngeal basket** *Syn.* CYRTOS.

**cytopharynx (*ciliate protozool.*)** An invagination of the cytoplasmic membrane which is supported, within the cytoplasm, by a tubelike system of microtubules and/or microfibrils. (See also CYTOPHARYNGEAL APPARATUS and CYTOSTOME.) Food particles which pass into the (non-ciliated) cytopharynx are taken up by PHAGOCYTOSIS through the cytoplasmic membrane at its inner end.

**cytophilic antibodies** Antibodies which can bind to a cell surface without involving their COMBINING SITES; the bound antibody can therefore still bind homologous antigen. (See e.g. REAGINIC ANTIBODIES.)

**cytoplasmic genes** (extrachromosomal genes; extranuclear genes) Genes which are not located on a bacterial CHROMOSOME or in a (eukaryotic) NUCLEUS; in eukaryotic organisms the term commonly refers to the genes in a CHLOROPLAST or a MITOCHONDRION, while in prokaryotes it has been used to refer to the genes carried by a PLASMID. (See also CYTOPLASMIC INHERITANCE.)

**cytoplasmic heterozygote** See CYTOHET.

**cytoplasmic inheritance** (extrachromosomal inheritance; non-Mendelian inheritance) Inheritance governed or influenced by CYTOPLASMIC GENES – which are not subject to the Mendelian laws of segregation and assortment; see e.g. MATERNAL INHERITANCE.

**cytoplasmic membrane (CM; cell membrane; plasma membrane; plasmalemma; protoplast membrane)** The lipid- and protein-containing, selectively permeable membrane which encloses the cytoplasm in prokaryotic and eukaryotic cells; in most types of microbial cell the CM is bordered externally by the CELL WALL. In microbial cells the precise composition of the CM may depend on growth conditions and on the age of the cell.

The structure of all biological membranes appears to conform to the basic *fluid mosaic model*. In this model the lipid molecules form a bilayer within which the protein molecules are partly or wholly embedded – some spanning the entire width of the bilayer; the lipid molecules are orientated such that their polar groups form the outer, hydrophilic surfaces of the bilayer while their hydrocarbon chains form the hydrophobic interior of the bilayer. (cf. UNIT MEMBRANE.) The membrane proteins are sometimes categorized as either *peripheral* (= *extrinsic*) proteins (bound to the membrane e.g. by electrostatic forces, and easily removable by electrolytes or chelating agents) or *integral* (= *intrinsic*) proteins (bound more strongly by hydrophobic bonds and extractable, with difficulty, by detergents or organic solvents). Cytoplasmic membranes are characteristically asymmetrical, i.e. the components of the outer (externally facing)

## cytoplasmic membrane

side of the membrane are not identical to those of the inner (cytoplasmic) side.

Membrane 'fluidity' primarily involves lateral and rotational motion of whole lipid molecules as well as motion of the hydrocarbon chains of the lipid molecules (rather than movement of whole lipid molecules from one layer of the membrane to the other layer). The hydrocarbon chains may be disordered and flexible (the  $\alpha$ -conformation) or ordered, rigid and perpendicular to the plane of the bilayer (the  $\beta$ -conformation). Fluidity greater than a certain level is essential for the normal physiological role of the CM. The degree of fluidity is governed by temperature and e.g. by the length and structure of the hydrocarbon chains; membranes containing unsaturated chains are generally more 'fluid' than are membranes containing saturated chains of the same length.

Previously, it was thought that only rarely do lipid molecules move from one side of the bilayer to the other. It is now known that such transmembrane movement (*flip-flop*) occurs with a much greater frequency than was originally supposed; in at least one case evidence has been obtained for a 'flippase' which may facilitate such translocation [Cell (1985) 42 51–60].

Although it is believed that the membrane lipids are normally present as a bilayer, results of nuclear magnetic resonance (NMR) and other studies have indicated the presence of transient, temperature-dependent, localized non-bilayer lipid phases within biological membranes. In one of these phases, termed *hexagonal II* (or  $H_{II}$ ), the lipid molecules form an array of fine (~20 Å diam.) water-filled cylinders whose walls are composed of the polar heads of lipid molecules; the array of cylinders is hexagonal in cross-section, the space between the cylinders containing the hydrocarbon chains of the lipid molecules. [Lipid structure of biological membranes: TIBS (1985) 10 418–421.]

The CM has various functions, one of which is to regulate the cytoplasmic milieu by controlling the inward and outward passage of ions and molecules. Some uncharged and/or lipophilic molecules can pass relatively freely through the CM; these include e.g. water, carbon dioxide, oxygen, ammonia (but not ammonium ions), acetic acid (undissociated form) and ethanol. However, ions and most molecules cannot pass freely through the CM, so that their transmembrane translocation requires more or less specific TRANSPORT SYSTEMS. (Specific mechanisms also exist for OSMOREGULATION.) Transport commonly occurs at the expense of metabolic energy, and some systems depend on the presence of a transmembrane electrochemical gradient – e.g. proton motive force (pmf: see CHEMIOSMOSIS) or SODIUM MOTIVE FORCE – such gradients being a general feature of CMs.

According to species, the CM is also the site of RESPIRATION (and, in some organisms, photosynthesis).

The CM is involved in the synthesis of external structures, such as the cell wall and capsule, and also in the synthesis of components of the CM.

(a) *Bacterial cytoplasmic membranes.* In transmission electron micrographs the CM, ca. 7–8 nm thick, typically appears as a trilaminar structure: an electron-translucent layer sandwiched between two electron-dense layers. In Gram-negative bacteria, localized regions of the CM may be involved in ADHESION SITES. In many species of bacteria it has been demonstrated that the inner (cytoplasmic) face of the CM bears minute, spherical, 'stalked' particles (see PROTON ATPASE) which are involved in energy conversion. In many (not all) species, CYTOCHROMES and other components of an ELECTRON TRANSPORT CHAIN occur in the CM. (See also PURPLE MEMBRANE.)

Lipid components of bacterial CMs are mainly phospholipids; in many or all cases, these are synthesized within the membrane itself.

*Phosphatidylglycerols* (PG) appear to occur in all bacteria, while *phosphatidylethanolamine* (PE) is more common and more abundant in Gram-negative species; *phosphatidylcholine* is absent in Gram-positive cells and is rare in Gram-negative bacteria. *Phosphatidylinositol* occurs in some bacteria (e.g. *Mycobacterium* spp). PLASMALOGENS are found in the cytoplasmic membrane in some anaerobes. In *Escherichia coli* the main phospholipid is PE – PG and *diphosphatidylglycerol* (DPG, cardiolipin) being relatively minor components.

*Glycolipids* are common in small quantities; in some Gram-positive bacteria molecules of glycolipid may be covalently linked to glycerol TEICHOIC ACIDS, forming *lipoteichoic acid*.

*Sphingolipids* are rare in bacterial membranes.

*Sterols* are absent in most species (cf. MYCOPLASMATACEAE).

*Hopanes* (triterpene derivatives which resemble sterols in size, rigidity and amphiphilicity) are present in some bacteria [JGM (1985) 131 1363–1367].

*Lipoamino acids* (*O*-aminoacylphosphatidylglycerols) occur in the membranes of some Gram-positive bacteria (e.g. *Bacillus* spp, *Clostridium* spp, *Staphylococcus aureus*). These are esters of PG and basic amino acids such as arginine, lysine or ornithine; the proportion of lipoamino acids varies according to growth phase and to the pH of the medium.

The CM *fatty acids* may be straight-chained or branched (the latter more common in Gram-positive species), saturated or unsaturated; some contain a cyclopropane ring (which is formed by methylation at a double bond). Phospholipids often contain one saturated and one unsaturated fatty acid residue per molecule.

In *E. coli* the main saturated fatty acids are hexadecanoic (palmitic) and tetradecanoic (myristic) acids, minor components including e.g. octadecanoic (stearic) and dodecanoic (lauric) acids; the main unsaturated fatty acids (all of which are *cis*-monoenes) include e.g. *cis*- $\Delta^9$ -hexadecenoic (palmitoleic) acid.

In general, the CM varies in its fatty acid composition according to growth conditions (e.g. temperature, pH). Thus, in some species the proportion of unsaturated fatty acids increases when the growth temperature decreases – e.g. in *E. coli* the proportion of unsaturated fatty acids increases from 16% to 49% when the growth temperature falls from 36°C to 25°C; such a change appears to be a compensatory response which helps to maintain optimum membrane fluidity. In contrast, almost no increase in monoenoic fatty acids occurs in the CM of *Staphylococcus aureus* when the growth temperature drops from 37°C to 25°C [Book ref. 44, p 402]. In some bacteria, adaptation to lower growth temperatures involves an increase in the length of fatty acid chains rather than an increase in the degree of unsaturation [JGM (1985) 131 2293–2302].

The *lipids* of the CM clearly contribute to the essential feature of selective permeability. However, the lipids also have other functions; for example, in *E. coli* phosphatidylethanolamine can behave as a 'molecular chaperone', being required for the correct folding (maturation) of the membrane protein LacY [EMBO (1998) 17 5255–5264].

*Proteins* in the bacterial CM include a variety of enzymes (involved e.g. in the synthesis of phospholipids and cell wall components); for example, penicillin-binding proteins (involved in the synthesis of PEPTIDOGLYCAN) may form part of a protein complex in the CM [FEMS Reviews (1994) 13 1–12]. There are also components of TRANSPORT SYSTEMS, energy-converting

systems (see e.g. ELECTRON TRANSPORT CHAIN and EXTRACYTOPLASMIC OXIDATION) and sensing systems (see e.g. CHEMOTAXIS).

CM proteins also include the molecular water channels called *aquaporins* (see MIP CHANNEL). (See also MECHANOSENSITIVE CHANNEL.)

[Structural dynamics of the CM of *E. coli*: Book ref. 122, pp 121–160.]

The bacterial CM is the target for a variety of ANTISEPTICS and DISINFECTANTS (see e.g. QUATERNARY AMMONIUM COMPOUNDS) and ANTIBIOTICS (see e.g. DEPSIPEPTIDE ANTIBIOTICS, GRAMICIDINS, POLYMYXINS and TYROCIDINS).

(b) *Fungal cytoplasmic membranes*. The CMs in fungi (and in other eukaryotes) differ significantly from those in bacteria. In fungal CMs the major lipids typically include phosphatidylcholine and phosphatidylethanolamine (with smaller amounts of phosphatidylinositol and phosphatidylserine) together with SPHINGOLIPIDS; as a rough generalization, the fatty acids of sphingolipids in higher fungi tend to contain even numbers of carbon atoms and to be saturated or mono-unsaturated, while those of lower fungi tend to have odd numbers of carbon atoms and to be polyunsaturated. (Changes in the degree of fatty acid saturation can have interesting physiological effects; for example, when *Saccharomyces cerevisiae* strain Y185 becomes de-repressed for general amino acid permease, a higher degree of fatty acid unsaturation in the CM correlates with a more rapid expression of the permease [JGM (1985) 131 57–65].) Most fungal membranes also contain sterols (e.g. ergosterol), so that fungi are generally susceptible to POLYENE ANTIBIOTICS (see also AZOLE ANTIFUNGAL AGENTS); vegetative cells of members of the Pythiaceae have been reported to lack sterols, although sterols are required during the reproductive phase.

Proteins in fungal CMs include those involved in transport processes, components of ATPase complexes, and various enzymes – such as those needed for the synthesis of walls and membranes.

In addition to lipids and proteins, fungal CMs contain small amounts of carbohydrate. In e.g. some slime moulds, certain CM carbohydrates are important LECTIN receptors and are involved in cell–cell recognition and/or adhesion.

(c) *Archaeal cytoplasmic membranes*. In members of the ARCHAEA the CM contains lipids of a kind which do not occur in bacteria. Unlike the ester-linked glycerol–fatty acid bacterial lipids, archaeal lipids are characteristically ether-linked molecules that contain e.g. isoprenoid or hydro-isoprenoid components. Some of the archaeal lipids are structurally analogous to those of bacteria; for example, the di-ether and di-ester lipids both have a single polar end. However, some archaeal lipids (e.g. tetra-*O*-di(biphytanyl) diglycerol) contain one ether-linked glycerol residue at *each* end of the molecule; having two polar ends, such molecules may span the width of the CM. Given the extreme habitats typically occupied by these organisms, it seems likely that some or all of the archaeans will be found to contain membrane components whose characteristics reflect an adaptation to the environment.

Some archaeans contain MIP CHANNELS.

**cytoplasmic petite** See PETITE MUTANT.

**cytoplasmic polyhedrosis virus group** (CPV group; *Cypovirus*)

A genus of entomopathogenic viruses of the REOVIRIDAE. Genome: 10 dsRNA molecules which may be linked together by protein in the virion. CPVs are pathogenic in a wide range of insects of the Diptera, Hymenoptera and Lepidoptera; and can also infect certain crustaceans (*Simocephalus spinosus*); the type member, a CPV from the silkworm (*Bombyx mori*),

has caused significant economic losses in the silk industry. A CPV is commercially available in Japan for the BIOLOGICAL CONTROL of the pine caterpillar *Dendrolimus spectabilis*. (cf. BACULOVIRIDAE; see also INSECT DISEASES.) CPV infection is usually chronic and is generally restricted to the columnar epithelial cells of the midgut. The mature virions occur embedded in POLYHEDRA in the cytoplasm of infected cells (cf. NUCLEAR POLYHEDROSIS VIRUS). The polyhedra may be polyhedral, cuboid, triangular etc, depending on virus and host. The infected insect shows symptoms of starvation due to reduced feeding and a reduction in the absorptive capacity of the gut cells; diarrhoea is common, with large numbers of polyhedra in the faeces. Infected larvae commonly reach adulthood, but the adults are generally small and often malformed, with greatly diminished reproductive capacity. CPVs are apparently transmitted to the larvae via the surface of the egg. [Review: Book ref. 83, pp. 425–504.]

**cytoplasmic streaming** (cyclosis) The intracellular flow of protoplasm which occurs in various types of eukaryotic cell; such a flow ensures e.g. that intracellular reactions are not dependent on simple diffusion. In e.g. the green alga *Chara*, cytoplasmic streaming appears to result from the interaction between peripheral ACTIN microfilaments and MYOSIN, the relative movement between actin and myosin being reflected in the flow of cytosol and organelles. In amoebae, the characteristic amoeboid movement may involve local actin–myosin-mediated contractions in the cell cortex accompanied by cytoplasmic streaming due to gel–sol interconversions in the microfibrillar networks.

**cytoplast** A eukaryotic cell from which the nucleus has been removed (i.e., an ENUCLEATED CELL). (cf. KARYOPLAST.)

**cytoproct** (cytopyge) In some protozoa: a permanent pore through which is voided particulate non-digestible material.

**cytopyge** *Syn.* CYTOPROCT.

**cytosegresome** An intracellular, membrane-limited vacuole within which a cell has enclosed some of its own constituents. Cytosegresomes are formed during AUTOPHAGY.

**cytosine arabinoside** *Syn.* CYTARABINE.

**cytoskeleton** In a eukaryotic cell: the framework, composed primarily of proteinaceous tubules and fibrils, which ramifies throughout the cytoplasm (binding e.g. to the cytoplasmic membrane and to various organelles) and which is responsible e.g. for the shape and internal organization of the cell, the intracellular transport of vesicles and organelles, and (where applicable) cell motility; in a living cell the cytoskeleton probably undergoes continual modification – being disassembled in some regions and reassembled in others, according to the needs of the cell. (cf. NUCLEOSKELETON.)

The main structural components of the cytoskeleton are microfilaments (see ACTIN), MICROTUBULES, and INTERMEDIATE FILAMENTS. Microtubules contribute e.g. to cell shape, to the correct location and orientation of intracellular structures and organelles, to certain types of motility (see e.g. axoneme in FLAGELLUM (b)), and to the formation of the spindle in MITOSIS; they can also serve as a temporary scaffolding e.g. during intracellular rearrangements. [Role of microtubules during the cell cycle in *Stephanopyxis turris*: JCB (1986) 102 1688–1698.] Microfilaments are involved e.g. in those parts of the cytoskeleton concerned with intracellular movements (see e.g. CYTOPLASMIC STREAMING), amoeboid movement (see PSEUDOPodium), PHAGOCYTOSIS, and CAPPING (sense 3). Intermediate filaments may e.g. fulfil a strengthening role. There is some evidence that, in multicellular organisms and tissues, cytoskeletal elements may extend from one cell to another by penetrating cytoplasmic membranes and the intercellular matrix.

## cytosol

[Molecular biology of the cytoskeleton: Book ref. 166; in vitro translocation of organelles along microtubules: Cell (1985) 40 729–730; reviews: JCS (1986) Supplement 5; the cytoskeleton in protists: Int. Rev. Cytol. (1986) 104 153–249.]

**cytosol** The fluid (non-particulate) fraction of cytoplasm. (cf. CELL SAP; HYALOPLASM.)

**cytostome** In certain protozoa (including many ciliates and some others, e.g. *Noctiluca*, *Paranema*): the cell mouth, a specific region of the cell through which particulate food is ingested. (See also AMOEBOSTOME.)

In ciliates the cytostome is regarded as a two-dimensional aperture at the level of the PELLICLE; in this region the pellicle lacks both cilia and pellicular alveoli, and is typically invaginated within a supportive collar or tube-like structure of microtubules and/or microfibrils in the cytoplasm (see also CYTOPHARYNX and CYTOPHARYNGEAL APPARATUS). In advanced ciliates (e.g. *Paramecium*) that part of the pellicle which includes the

cytostome typically occurs at the base of a concavity in the body (BUCCAL CAVITY); in the more primitive ciliates (e.g. the gymnostomes) the cytostome-containing region of the pellicle is typically not recessed in this way, and is characteristically situated apically or subapically in the cell. In some ciliates the ciliature surrounding the cytostome is readily distinguishable from the somatic ciliature (see e.g. AZM and PARORAL MEMBRANE).

**cytotaxin** Any agent chemotactic for cells.

**cytotoxic hypersensitivity** *Syn.* TYPE II REACTION.

**cytotoxic T cell** See T LYMPHOCYTE.

**cytotropism** See TROPISM (sense 2).

**cytozoic** Living (parasitic) within cells.

**Cytriales** See ASCOMYCOTINA.

**Czapek–Dox medium** (Czapek's medium) A medium containing sucrose, NaNO<sub>3</sub>, K<sub>2</sub>HPO<sub>4</sub>, MgSO<sub>4</sub>, KCl and FeSO<sub>4</sub>; it may be solidified with agar. It is used for culturing e.g. saprotrophic fungi, soil bacteria etc.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Words to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# D

**D** (1) Dihydrouridine (see TRNA). (2) Aspartic acid (see AMINO ACIDS).

**D** (in continuous culture) DILUTION RATE.

**d-factor** See DUTCH ELM DISEASE.

**D loop** (*mol. biol.*) (1) (displacement loop) A single-stranded loop formed when a short ssDNA molecule pairs with a complementary region of one strand of a dsDNA molecule, displacing the corresponding region of the homologous strand (the D loop). For example, under certain (non-physiological) conditions in vitro a negatively supercoiled ccc dsDNA molecule can spontaneously take up a short complementary single (linear) strand to give rise to a D loop in a reaction driven by the energy of supercoiling; the resulting 'joint molecule' is more relaxed than the original supercoiled DNA. D-loop formation is promoted e.g. by the RECA PROTEIN; it may occur e.g. during RECOMBINATION (Fig. 2), and may be involved in the priming of certain types of DNA replication (see e.g. BACTERIOPHAGE G4). (See also SITE-SPECIFIC MUTAGENESIS; cf. R LOOP.)

(2) The loop of the 'D arm' in a tRNA molecule (see TRNA).

**D period** See HELMSTETTER-COOPER MODEL.

**12D process** In food processing: heating, at a given temperature, for a period equal to twelve times the D VALUE at that temperature. (See also BOTULINUM COOK.)

**D-type particles** See TYPE D RETROVIRUS GROUP.

**D-type starter** See LACTIC ACID STARTERS.

**D value** (1) ( $D_{10}$  value; decimal reduction time) The time required, at a given temperature, to reduce the number of viable cells or spores of a given microorganism to 10% of the initial number; it is usually quoted in minutes. The temperature ( $^{\circ}\text{C}$ ) at which the D value is determined may be indicated by a subscript, e.g.,  $D_{112}$ . (In the synonym of D value,  $D_{10}$  value, the subscript refers to the 10% survival value.) (cf.  $F_0$  VALUE; Z VALUE; see also 12D PROCESS.)

(2) (of animal feed) The percentage of digestible organic matter in the 'dry matter' (DM) – DM (in g/kg) being determined by oven-drying of feed samples and correction for e.g. loss of volatile fatty acids. (See also SILAGE.)

**$D_{10}$  value** *Syn.* D VALUE (1).

**Da** DALTON.

**dacA gene** See PENICILLIN-BINDING PROTEINS.

**dacB gene** See PENICILLIN-BINDING PROTEINS.

**dacC gene** See PENICILLIN-BINDING PROTEINS.

**Dacrymyces** A genus of fungi (order DACRYMYCETALES). *D. deliquescens* forms bright orange, gelatinous, globular asexual fruiting bodies (each up to ca. 5 mm diam.) on decaying wood; each fruiting body consists of a mass of radiating hyphae which, at the surface, break up into oidia. Subsequently, basidia develop at the surface of the same fruiting body, which concurrently becomes yellow.

**Dacrymycetales** An order of typically lignicolous fungi (subclass HOLOBASIDIOMYCETIDAE) which form the so-called 'tuning fork' type of basidium – i.e., a two-spored basidium which is apically bifurcate (forked) and Y-shaped, the two arms of the 'Y' (the sterigmata) curving inwards to become more or less parallel. The basidiocarp may be e.g. crust-like, pulvinate, cup-like and stipitate, or columnar and branched or unbranched; it may be gelatinous or waxy, and in many species it is brightly coloured (e.g. yellow, orange) due, apparently, to

carotenoid pigments. Genera include CALOCERA, *Cerinomyces*, DACRYMYCES, *Dacryopinax*, *Guepiniopsis*.

**Dacryopinax** See DACRYMYCETALES.

**dactinomycin** *Syn.* ACTINOMYCIN D.

**Dactylaria** See HYPHOMYCETES; see also NEMATOPHAGOUS FUNGI and PHAEOHYPHOMYCOSIS.

**Dactylella** See HYPHOMYCETES and NEMATOPHAGOUS FUNGI.

**Dactylococcopsis** A genus of unicellular CYANOBACTERIA in which the cells are elongate with tapering ends, sometimes occurring in short chains. *D. salina* is a gas-vacuolate species which is blue-green when grown at low light intensities but deep orange under high light intensities; it is planktonic in hypersaline environments. Although sensitive to concentrations of  $\text{H}_2\text{S}$  > ca. 10  $\mu\text{M}$ , at lower concentrations *D. salina* is capable of limited anoxygenic photosynthesis using  $\text{H}_2\text{S}$  as electron donor. [Ecophysiology of *D. salina*: JGM (1983) 129 1849–1856.]

**Dactylosoma** See PIROPLASMASINA.

**Dactylosporangium** A genus of mycelial bacteria (order ACTINOMYCETALES, wall type II) which occur e.g. in soil. The organisms form finger-like sporangia each containing a single row of three or more zoospores; non-motile spores are also formed, singly, on the substrate mycelium. Aerial mycelium is not formed. Type species: *D. aurantiacum*.

**Dactylostoma** See SUCTORIA.

**DAEC** See ENTEROADHERENT E. COLI.

**Daedalea** A genus of fungi of the APHYLLOPHORALES (family Polyporaceae) which occur as perthotrophs (PERTHOTROPH sense 2) and saprotrophs on various types of wood. Basidiocarp: non-stipitate, often hoof-like, commonly corky, the upper surface brown to grey-brown; hymenophore: labyrinthiform ('maze-like'), consisting of elongated pores with thick dissepiments. *D. quercina*, which grows e.g. on oak, may form imbricated basidiocarps with a trimitic context; basidiospores: ellipsoidal, hyaline, ca.  $6 \times 3 \mu\text{m}$ . (See also WOOD WASP FUNGI.)

**DAF** See CD55.

**dahlia mosaic virus** See CAULIMOVIRUSES.

**dairy products** Many dairy products are made by a LACTIC ACID FERMENTATION of milk using selected strains of lactic acid bacteria (see e.g. LACTIC ACID STARTERS): see ACIDOPHILUS MILK; BUTTER; BUTTERMILK; CHEESE-MAKING; KEFIR; KOUMISS; LEBEN; QUARG; SOUR CREAM; TAETTE; VILIA; YOGHURT. (See also MILK.)

**daisy head colonies** Colonies of the type commonly formed by *Corynebacterium diphtheriae* (*gravis* type) on blood-tellurite agar; after 24 hours at  $37^{\circ}\text{C}$ , each colony is 2–3 mm in diameter, dull, with a grey to black centre, translucent margin, crenated edge, and radial striations.

**Dakin's solution** (chlorinated soda solution) A solution of sodium hypochlorite and sodium bicarbonate used e.g. as an antiseptic for the cleansing of wounds.

**Daldinia** A genus of fungi (order SPHAERIALES). *D. concentrica* grows on dead or fallen branches of certain trees, particularly ash (*Fraxinus*), forming hemispherical or subglobose, superficial stromata ca. 2–10 cm across; when young, each stroma has a surface layer of branched conidiophores bearing brown conidia, but the mature stroma is a hard, brittle, shiny black structure which, in vertical cross-section, exhibits alternating light and dark bands concentric about the centre of the base of the stroma. Perithecia develop in the superficial layer of the stroma with their

## Dalman plate technique

ostiolar pores at the surface. The bulk of the stromal tissue may act as a reservoir for water. (See also ASCOSPORE.)

**Dalman plate technique** A technique used e.g. for studying the formation of pseudomycelium or true mycelium by a yeast. A streak and two point-inoculations of the test strain are made at well-separated locations on a surface-dried plate of e.g. CORNMEAL AGAR; the centre of the streak and one of the point-inoculations are then each overlaid with a sterile cover-glass. After incubation at 25°C for ca. one week the preparation is examined under the microscope.

**Dalmeny disease** A disease of cattle which results in e.g. abortion or death; the causal agent is believed to be a species of SARCOCYSTIS.

**dalton (Da)** *Syn.* ATOMIC MASS UNIT.

**Dalyellia viridis** See ZOOCHLORELLAE.

**Dam-directed mismatch repair** See MISMATCH REPAIR.

**dam gene** In e.g. *Escherichia coli*: a gene which encodes a DNA adenine methylase (Dam methylase), i.e. an enzyme that methylates DNA at the N-6 position of adenine in the nucleotide sequence 5'-GATC-3' ('Dam site'); a strand of DNA is methylated soon after its synthesis (see DNA METHYLATION).

Dam methylation is involved e.g. in MISMATCH REPAIR in *E. coli*. It is also involved in regulating certain genes. For example, transposition of the transposon Tn10 (q.v.) is inhibited by Dam methylation of a sequence in the transposase gene promoter (reducing transposase synthesis) and of a sequence in IS10 (reducing transposase activity); Tn10 transposition is thus apparently coupled to DNA replication: it occurs just after the replication fork has passed but before Dam methylation has occurred.

Other genes which contain Dam sites in their promoters, and whose expression is sensitive to Dam methylation, include e.g. the *trpR* gene of *E. coli*, the *cre* gene of BACTERIOPHAGE P1, and the *mom* gene of BACTERIOPHAGE MU. The chromosomal origin, *oriC*, in *E. coli* contains more than 10 Dam sites which may be important in regulating the initiation of DNA replication (see CELL CYCLE (b)).

[Minireview: JB (1985) 164 490–493.]

Dam methylation apparently occurs in various other Gram-negative bacteria (including certain cyanobacteria) and in some members of the Archaea.

**Dam methylation** See DAM GENE.

**damping off (plant pathol.)** A microbial disease of seedlings in which e.g. roots may rot, or the hypocotyl (lower stem) may either collapse or become wiry ('wire stem'); seedlings may die before or after they emerge from the soil (pre-emergence and post-emergence damping off, respectively). Common causal agents include species of PYTHIUM and RHIZOCTONIA. Aerial parts are often secondarily affected by GREY MOULD. Damping off may be controlled e.g. by CARBENDAZIM, CHESHUNT COMPOUND, CHLORONEB or ETRIDIAZOLE. (cf. FOOT-ROT (sense 2) and BLACK-LEG (sense 2).)

**Dane particle** See HEPATITIS B.

**Danielli–Davson model** See UNIT MEMBRANE.

**Danish agar** *Syn.* FURCELLARAN.

**danofloxacin** See QUINOLONE ANTIBIOTICS.

**dansyl chloride** A reagent, 5-(dimethylamino)naphthalene-1-sulphonyl chloride, which reacts with amino acids and proteins to form derivatives that exhibit an intense yellow fluorescence under UV irradiation.

**Danysz' phenomenon** The phenomenon in which the residual toxicity in a mixture of diphtheria toxin and antitoxin varies according to the method of admixture. Thus, if toxin is added to

an equivalent amount of antitoxin in one stage (i.e., all at once) the resulting mixture is non-toxic; however, if the same quantity of toxin is added in two halves (the second ca. 30 min after the first), the resulting mixture contains free (non-neutralized) toxin. In the second method of admixture, the first portion of toxin combines with more than its equivalent of antitoxin – leaving insufficient free antitoxin to neutralize the second portion of toxin.

**DAP pathway** DIAMINOPIMELIC ACID PATHWAY.

**DAPI** 4',6-Diamidino-2-phenylindole: a FLUOROCHROME used e.g. as a DNA-specific stain. [Limn. Ocean. (1980) 25 948–951.] (See also DIAMIDINES.)

**dapsone (DDS)** A drug used e.g. in the treatment of LEPROSY and MALARIA; 4,4'-diaminodiphenylsulphone; DDS may inhibit FOLIC ACID metabolism. [Book ref. 54, p. 422.] (cf. CLOFAZIMINE.)

**daptomycin** A lipopeptide antibiotic which, in vitro, is bactericidal for a range of clinically important Gram-positive bacteria, including e.g. MRSA and vancomycin-resistant enterococci (VRE); daptomycin apparently interferes with the function of the bacterial cytoplasmic membrane.

[Resistance studies with daptomycin: AAC (2001) 45 1799–1802.]

**dark-field microscopy** See MICROSCOPY (b).

**dark-ground microscopy** See MICROSCOPY (b).

**dark mildews** *Syn.* BLACK MILDEWS.

**dark reaction** See PHOTOSYNTHESIS.

**dark repair** (1) Light-independent DNA REPAIR: e.g. EXCISION REPAIR or RECOMBINATION REPAIR (as opposed to PHOTOREACTIVATION). (2) *Syn.* EXCISION REPAIR.

**Darling's disease** *Syn.* HISTOPLASMOSES.

**Darmbrand** ENTERITIS NECROTICANS.

**dasycladalean algae** A small group of tropical and subtropical marine green algae (division CHLOROPHYTA) which typically grow in shallow waters. The vegetative thallus is uninucleate and is radially symmetrical, composed of an erect axis with whorls of branches and a rhizoid-like holdfast which contains the nucleus; the thallus becomes multinucleate during gametangial development. Fossil dasyclads are known from the Lower Palaeozoic onwards [Book ref. 123, pp. 297–302]; modern genera include ACETABULARIA.

**Dasyscyphus** See HELOTOALES.

**Dasyscypha** See UREDINIOMYCETES.

**Dasytricha** A genus of ciliates (order TRICHOSTOMATIDA) which occur e.g. in the RUMEN. Cells: ovoid, with dense, uniform somatic ciliature and a cytostome located posteriorly.

**DAT (serol.)** Differential agglutination test: any in vitro diagnostic test in which the result consists of two agglutination titres – that of the test proper and that of the control; the titres may be quoted in full or expressed as a ratio.

**daughter-strand gap repair** See RECOMBINATION REPAIR.

**daunomycin** See ANTHRACYCLINE ANTIBIOTICS.

**daunorubicin** See ANTHRACYCLINE ANTIBIOTICS.

**Davson–Danielli model** See UNIT MEMBRANE.

**dazomet** A soil fumigant (3,5-dimethyltetrahydro-2H-1,3,5-thiadiazine-2-thione) used as a fungicide and nematocide; in soil it breaks down to form e.g. formaldehyde and *N*-methylisothiocyanate. (cf. METHAM SODIUM.)

**DBMIB** An inhibitor of PHOTOSYNTHESIS.

**D<sub>c</sub>** Critical DILUTION RATE.

**DCA (deoxycholate–citrate agar)** An agar medium used for the primary isolation of e.g. *Salmonella* and *Shigella*; most strains of *Escherichia* and of the Proteaceae (cf. PROVIDENCIA) fail to grow on DCA. DCA generally contains meat extract, peptone, lactose,

sodium citrate, ferric ammonium citrate, sodium deoxycholate, and neutral red; pH ca. 7.3. DCA should not be sterilized by autoclaving.

**DCCA** See DICHLOROISOCYANURATE.

**DCCD** *N,N'*-Dicyclohexylcarbodiimide; under weakly alkaline conditions DCCD binds covalently to the 'DCCD-binding protein' of  $F_0$  in ( $F_0F_1$ )-type  $H^+$ -ATPases and inhibits both the synthesis and hydrolysis of ATP, while under weakly acidic conditions it binds to the  $\beta$  subunit of  $F_1$ , inhibiting the hydrolysis of ATP.

**DCDS** See CONJUGATION (1b) (i).

**DCMU** (Diuron) *N*-(3,4-dichlorophenyl)-*N'*-dimethylurea; this agent acts as a mitochondrial RESPIRATORY INHIBITOR, blocking electron flow between cytochromes *b* and *c*<sub>1</sub> in Complex III of the ELECTRON TRANSPORT CHAIN (cf. BAL), and as an inhibitor of electron flow between photosystems I and II (see PHOTOSYNTHESIS).

**dda gene** (in bacteriophage T4) See HELICASES.

**DDMR** See MISMATCH REPAIR.

**DDS** DAPSONE.

**ddTTP** 2',3'-Dideoxythymidine triphosphate: an analogue of thymidine triphosphate; it inhibits DNA synthesis since, when incorporated in a growing DNA strand in place of thymidine, it provides no 3'-OH for further polymerization. In mammalian cells it specifically inhibits DNA polymerase  $\beta$  action; the  $\alpha$  enzyme is apparently unable to incorporate the analogue in a growing DNA strand. (cf. APHIDICOLIN.)

**de-acetylase** See ANTIBIOTIC.

**dead man's fingers** See XYLARIA.

**Dean and Webb titration** A serological titration in which a constant volume of a given antiserum is added to each of a number of serial dilutions of the homologous antigen; precipitation occurs most rapidly in that dilution in which antibody and antigen are present in OPTIMAL PROPORTIONS.

**death cap fungus** See AMANITA.

**death phase** See BATCH CULTURE.

**death rate constant** See STERILIZATION (b).

**Debaryomyces** A genus of yeasts (family SACCHAROMYCETACEAE) which reproduce by multilateral budding; pseudomycelium may be formed. Ascus formation is generally preceded by conjugation between bud and mother cell; conjugation between separate cells also occurs. Ascospores: spherical or oval, minutely warty or ridged, usually 1 or 2 (up to 4 in some species) per ascus. Fermentation occurs (weakly) in some species.  $NO_3^-$  is not assimilated. Species (*D. castellii*, *D. coudertii*, *D. hansenii*, *D. marama*, *D. melissophilus*, *D. polymorphus*, *D. pseudopolymorphus*, *D. tamarii*, *D. vanriji*) have been isolated from soil, foods etc. [Book ref. 100, pp. 130–145.]

**debranching enzyme** (1) (amylo-1,6-glucosidase) An enzyme which hydrolyses the (1  $\rightarrow$  6)- $\alpha$  branch points in e.g. amylopectin, glycogen, and/or related polysaccharides. There are two types: *pullulanase* ('limit dextrinase', pullulan 6-glucanhydrolase, EC 3.2.1.41), which can degrade PULLULAN, and *isoamylase* (glycogen 6-glucanhydrolase, EC 3.2.1.68), which has no action on pullulan. Pullulanases are obtained commercially from e.g. *Klebsiella aerogenes* ('*Aerobacter aerogenes*') and *Bacillus cereus* var. *mycoides*; the enzyme from *K. aerogenes* can debranch amylopectin and its  $\beta$ -limit dextrin (see AMYLASES) but has little or no activity on native glycogen, while that from *B. cereus* var. *mycoides* has little or no activity on amylopectin but can degrade its  $\beta$ -limit dextrin [Book ref. 31, pp. 133–137]. Isoamylases are obtained e.g. from *Pseudomonas* sp. (cf. BRANCHING ENZYME.)

(2) (*mol. biol.*) An enzyme which 'debranches' the lariat form of an excised intron (see SPLIT GENE).

**débridement** The removal of necrotic/infected tissue and/or foreign material from a wound.

**debromoaplysiatoxin** See LYNGBYA.

**decarboxylase tests** Tests used to determine the ability of a given bacterial strain to decarboxylate arginine, lysine and/or ornithine. Three tubes of MØLLER'S DECARBOXYLASE BROTH, each containing one of the three amino acids, are inoculated with the test organism; each broth is overlaid with a layer of sterile paraffin, incubated at 37°C, and examined daily for 4 days. Initially, in both positive and negative tests, glucose is metabolized to acidic products causing the pH indicator bromocresol purple (in the medium) to turn yellow. In a positive test the amino acid is cleaved by a specific decarboxylase in a reaction requiring pyridoxal phosphate (see PYRIDOXINE); the product is a polyamine (see POLYAMINES) which raises the pH of the medium, causing bromocresol purple to turn purple. Arginine, lysine and ornithine are decarboxylated to agmatine, cadaverine and putrescine, respectively.

**decay-accelerating factor** See CD55.

**Dechloromonas** See BIOREMEDIATION.

**Dechlorosoma** See BIOREMEDIATION.

**decimal code** (for growth stages of cereals) See ZADOKS' CODE.

**decimal reduction time** *Syn.* D VALUE (1).

**declomycin** See TETRACYCLINES.

**decoy receptor** See e.g. INTERLEUKIN-1.

**decorynine** See PSICOFURANINE.

**decurrent** (*mycol.*) Refers to hymenium-bearing structures (e.g. lamellae in agarics, the layer of 'teeth' in *Hydnum*) whose region of attachment to the fruiting body extends at least partly down the stipe.

**Dee disease** See KIDNEY DISEASE.

**deep** (*noun*) (1) Any solid medium present (in a tube) at a depth sufficient to permit stab inoculation. (2) A SHAKE CULTURE (sense 1).

**deep rough mutant** See SMOOTH-ROUGH VARIATION.

**defaunation** The removal of the fauna (animal life) from a given environment – especially the removal of protozoa from a mixed microbial population (e.g. that of the RUMEN).

**defective interfering particle** (DI particle; defective interfering virus) A DEFECTIVE VIRUS which typically arises as a result of mutation (usually deletion mutation) in an originally non-defective virus (the *standard virus*); a DI particle can replicate only in the presence of the standard virus, and its presence reduces the yield of infectious standard virus (i.e., it exhibits INTERFERENCE). (The preferential production of DI particles at the expense of standard virus is known as *enrichment*.) The generation of DI particles and their ability to cause interference depend, at least to some extent, on the nature of the host cell. The mechanisms of DI particle generation, enrichment and interference are poorly understood. [Primary structure of poliovirus DI particle genomes and possible mechanism for their generation: *JMB* (1986) 192 473–487.]

DI particles commonly accumulate in stocks of animal viruses which have been passaged at high multiplicity of infection (moi). (Passage at low moi minimizes the chances of a cell being coinfecting with both DI and standard viruses, so that any DI particles which arise are unlikely to be able to replicate.) DI particles can attenuate the pathological effects of a virulent standard virus (and in some cases of other closely related viruses) both in cell cultures and in animals under experimental conditions; however, the presence of DI particles may also allow

## defective virus

the establishment of a persistent infection of cells or animals by a virus which does not normally exhibit PERSISTENCE [e.g. Semliki Forest virus in mice: JGV (1986) 67 1189–1194]. The role of DI particles – if any – in attenuating disease or in establishing persistent infections under natural conditions is unknown.

**defective virus** A virus which – inherently or e.g. as a result of mutation – lacks one or more genetic functions necessary for its replication; such a virus can produce progeny in the presence of another (non-defective) HELPER VIRUS which can provide the missing functions. (See also e.g. DEFECTIVE INTERFERING PARTICLE; RETROVIRIDAE; SATELLITE VIRUS; TRANSDUCTION.)

**defensins** PEPTIDE ANTIBIOTICS, produced e.g. by mucosal epithelial cells and macrophages, which are active against a range of bacteria, including both Gram-positive and Gram-negative species; examples: the *tracheal antimicrobial peptide* found in bovines, *cryptdin* in mice, and *human neutrophil peptide*. [See e.g. Nature (2003) 422 522–526.]

**defined medium** See MEDIUM.

**definitive host** *Syn.* FINAL HOST.

**DEFT** Direct epifluorescent filter technique: a technique used e.g. for the rapid detection and/or quantification of microorganisms in water, milk etc. Essentially, the sample is passed through a membrane filter (see FILTRATION), and the cells retained on the filter are counted by epifluorescence MICROSCOPY – the cells having been stained with a fluorescent dye either before or after filtration. For the examination of MILK, the sample is pretreated with a protease (e.g. trypsin) and a detergent (e.g. Triton X-100) to disrupt, respectively, the casein micelles and fat globules which would otherwise block the membrane filter.

**degeneracy** (*mol. biol.*) See GENETIC CODE.

**degerming** *Syn.* ANTISEPSIS.

**DegP protease** See FIMBRIAE (P fimbriae).

**degradosome** In *Escherichia coli*: a multicomponent complex which includes RNASE E and certain other proteins involved in the degradation/processing of RNA molecules; degradosomes are associated with the cytoplasmic membrane of the cell via the N-terminal part of RNase E. Proteins which have been identified in degradosomes include polynucleotide phosphorylase, enolase, RhlB (RNA helicase), polynucleotide phosphate kinase, DnaK and GroEL. [RNA degradosomes in vivo: PNAS (2001) 98 63–68.]

(See also PROTEASOME.)

**degranulation** (*immunol.*) See MAST CELL.

**degron** Any feature of a protein which acts as a signal for that protein's *in vivo* degradation. One example is the identity of the protein's N-terminal amino acid residue: see N-END RULE.

**dehiscence** Opening on maturity.

**dehydration** (1) (of specimens) The replacement of water, in a specimen, by a non-aqueous medium, e.g. ethanol. (See also ELECTRON MICROSCOPY; CRITICAL POINT DRYING.) (2) (of foods) See FOOD PRESERVATION (c). (3) (of microorganisms) See DESICCATION.

**dehydroemetine** See EMETINE.

**dehydrogenase** An OXIDOREDUCTASE which catalyses the removal of hydrogen atom(s) from a substrate – the hydrogen being donated to an acceptor *other than* molecular oxygen; hydrogen acceptors include pyridine nucleotides and flavin nucleotides. (*cf.* OXIDASE.)

**Deinococcus** A genus of GRAM TYPE-negative (GRAM REACTION-positive) bacteria. *D. radiodurans* (formerly *Micrococcus radiodurans*) is highly resistant to IONIZING RADIATIONS; the cells are red-pigmented cocci in which the outer layers of the cell wall (external to the peptidoglycan) include an OUTER MEMBRANE and

an S LAYER. Carbohydrate chains originating at the outer membrane pass through the S layer and form the outermost surface of the cell. The S layer – also called the HPI (= hexagonally packed intermediate) layer – is composed of a single polypeptide species. [Three-dimensional structure of the HPI layer: JMB (1986) 187 241–253.] *D. radiodurans* does not contain phosphatidylglycerol or phospholipids derived from it. [Polar lipid profiles of *Deinococcus*: IJSB (1986) 36 202–206.] The genome is toroidal [Science (2003) 299 254–256].

**Dekkera** A genus of yeasts (family SACCHAROMYCETACEAE) which reproduce by budding; pseudomycelium is usually formed. Asci are evanescent and are formed directly from (diploid) vegetative cells; ascospores are more or less bowl-hat-shaped, 1–4 per ascus. NO<sub>3</sub><sup>-</sup> may or may not be assimilated. Two species: *D. bruxellensis* (anamorph: *Brettanomyces bruxellensis*) and *D. intermedia* (anamorph: *B. intermedius*), found in beers, wines etc. (See also BRETTANOMYCES.) [Book ref. 100, pp. 146–150.]

**delavirdine** See ANTIRETROVIRAL AGENTS.

**delayed enrichment method** See AUXOTROPH.

**delayed hypersensitivity** (DH; delayed-type hypersensitivity; cell-mediated hypersensitivity; type IV reaction) (*immunol.*) In a PRIMED individual: a HYPERSENSITIVITY (sense 1) response which (i) follows the second (or subsequent) exposure to the given antigen, (ii) is mediated by antigen-specific T LYMPHOCYTES, and (iii) involves a local inflammatory reaction that reaches maximum intensity ~24–48 hours after antigenic challenge. (*cf.* IMMEDIATE HYPERSENSITIVITY.)

Priming and subsequent antigenic challenge may occur in the skin or elsewhere. Initial priming (or 'sensitization'), in which the individual is initially exposed to the given antigen, involves interaction between an ANTIGEN-PRESENTING CELL (e.g. a DENDRITIC CELL) and an antigen-specific CD4<sup>+</sup> T cell. The T cell forms a Th1 clone: when activated by antigen it proliferates and secretes CYTOKINES that include INTERLEUKIN-2. Hence, a primed individual contains an expanded clone of specifically reactive T cells (referred to as T<sub>DH</sub>, T<sub>DTH</sub> or T<sub>dth</sub>). Sensitization may require a period of ~1–2 weeks.

Following sensitization, a DH reaction can be elicited by further exposure to specific antigen; as before, antigen is presented by an APC, but in this instance the (primed) individual contains an expanded clone of specifically reactive T cells. The secreted cytokines include e.g. interleukin-2, INTERLEUKIN-12 and IFN-γ (see INTERFERONS); the cytokines (i) promote expansion of the Th1 subset of T cells (which secrete more pro-inflammatory cytokines) and (ii) bring about the accumulation of activated MACROPHAGES at the site of antigenic challenge. In the skin, the result is typically an indurated (hard), erythematous (red) nodule which develops in 24–48 hours of antigenic challenge.

The lesion commonly resolves slowly. However, when there is a failure to eliminate the antigen (or pathogen) the ongoing presence of a concentration of activated macrophages can result in damage to the host's tissues. In some diseases aggregations of macrophages give rise to epithelioid cells and, subsequently, GIANT CELLS within lesions called GRANULOMAS; *tubercles* are granulomas formed in tuberculosis.

DH to a given antigen can be transferred to a non-primed subject only by the transfer of *cells*, not serum or plasma alone. (*cf.* JONES-MOTE SENSITIVITY.)

DH reactions can be modified by various drugs; for example, glucocorticosteroids can inhibit DH reactions, and certain anti-tumour agents, such as mitomycin C, have been found to stimulate DH reactions in mice.

DH reactions form the basis of certain diagnostic SKIN TESTS. Thus, an individual suffering from a given microbial disease may be primed in respect of certain antigens of the pathogen; hence, if the patient is given a cutaneous injection of specific antigen, the primed state may be revealed by a DH inflammatory response (a *positive* skin test) at the site of the injection. (cf. ANERGY.)

(See also CONTACT SENSITIVITY.)

**delayed-type hypersensitivity** *Syn.* DELAYED HYPERSENSITIVITY.

**deletion mutation** A type of MUTATION in which one or more nucleotides are lost from the genome; if the number of nucleotides lost is not divisible by 3, the mutation will be a FRAMESHIFT MUTATION. (cf. INSERTION MUTATION.)

**Deleya** A genus which accommodates the marine species *Alcaligenes aestus*, *A. pacificus*, *A. cupidus* and *A. venustus*, and *Pseudomonas marina* [IJSB (1983) 33 793–802]; another species, *D. halophila*, was isolated from hypersaline soils [IJSB (1984) 34 287–292].

**Delhi boil** See CUTANEOUS LEISHMANIASIS.

**Δ** (delta plasmid; also: delta transfer factor) An IncIα, low-COPY-NUMBER enterobacterial CONJUGATIVE PLASMID. [Structure of the delta plasmid: JGM (1986) 132 3261–3268.]

**delta agent** *Syn.* DELTA VIRUS.

**δ antigen** HDAg: see DELTA VIRUS.

**delta chain** (*immunol.*) See HEAVY CHAIN.

**δ-endotoxin** A glycoprotein entomotoxin produced by *Bacillus thuringiensis*. Synthesis of the toxin is typically associated with sporulation, the toxin appearing as a (commonly bipyramidal) crystal, the *parasporal crystal*, near the spore within a sporulating cell; in *B. thuringiensis* subsp. *yunnanensis* crystals are apparently produced only in asporogenous cells [J. Inv. Path. (1986) 48 254–256]. (Genes concerned with toxin synthesis are apparently plasmid-borne.) The crystal is composed of subunits of a *protoxin*, the subunits generally being linked by disulphide bonds (which can be disrupted by reducing conditions or by alkaline pH). When crystals and spores are ingested by an insect larva, the crystals dissolve in the alkaline contents of the insect's midgut to release the protoxin subunits; the subunits are converted by midgut proteases to one or more toxic components which cause paralysis of the gut and degeneration of the midgut epithelium. This may kill the insect directly, or may allow *B. thuringiensis* to invade the insect and cause a lethal septicaemia. Larvae may be killed within hours of ingesting the toxin.

Different strains of *B. thuringiensis* are effective against different host ranges: those of 'Group A' – e.g. *B. thuringiensis* subsp. *kurstaki* – are pathogenic primarily in lepidopteran larvae (caterpillars of butterflies and moths), while those in 'Group B' – subsp. *israelensis* – are pathogenic e.g. in mosquito larvae (Diptera); subsp. *tenebrionis* is pathogenic in some coleopteran (beetle) larvae [δ-endotoxin in subsp. *tenebrionis*: FEMS (1986) 33 261–265].

Strains of *B. thuringiensis* have been used, worldwide, as 'microbial insecticides' for the BIOLOGICAL CONTROL of various lepidopteran pests. Preparations containing spores and crystals (prepared by deep-tank culture of *B. thuringiensis*) are applied e.g. to crops; repeated applications are necessary because, e.g., both spores and (to a lesser extent) crystals tend to be inactivated by the ultraviolet component of sunlight. (To avoid the need for repeated applications, *B. thuringiensis* has been genetically modified so that toxin accumulates within the toxin-producing cells; the partly protected (intracellular) toxin is still highly active [Biotechnology (1995) 13 67–71].) *Plodia interpunctella*, an important lepidopteran pest of stored grain, has been reported

to develop stable and heritable resistance to *B. thuringiensis* crystals within a few generations [Science (1985) 229 193–195]. (cf. THURINGIENSIN.)

[Reviews: Book ref. 171, pp. 185–209 (commercial aspects), pp. 211–249 (genetics of *B. thuringiensis*); MR (1986) 50 1–24.]

(cf. MILKY DISEASE.)

**δ-factor** See RNA POLYMERASE.

**delta hepatitis virus** See DELTA VIRUS.

**delta herpesvirus** A herpesvirus which is antigenically related to human varicella-zoster virus (see ALPHAHERPESVIRINAE) and which causes a varicella-like disease in non-human primates.

**delta particles** See TECTIBACTER.

**delta plasmid** See DELTA.

**δ sequence** See TY ELEMENT.

**delta transfer factor** See DELTA.

**delta virus** (delta agent; hepatitis D virus; hepatitis delta virus)

A defective RNA virus which can replicate only in the presence of a helper virus of the HEPADNAVIRIDAE – usually HEPATITIS B VIRUS (HBV), although under experimental conditions the delta virus can replicate in woodchucks infected with WOODCHUCK HEPATITIS VIRUS. The delta virus virion (as derived from the serum of an HBV-infected patient) is ca. 35–37 nm in diam.; it consists of a core containing the delta virus RNA genome (MWt ca.  $5.5 \times 10^5$ ) and a delta virus-encoded protein antigen (HDAG) surrounded by an (HBV-encoded) HBsAg-containing envelope. The genome is circular ssRNA [PNAS (1986) 83 8774–8778]. [Protein composition of the delta virus virion: JV (1986) 58 945–950.]

In humans, the delta virus can infect an individual either simultaneously with HBV or subsequent to the establishment of an HBV infection; delta virus infection may itself be acute or chronic. The presence of the delta virus may exacerbate the symptoms of HBV infection, in some cases inducing an acute, severe or fulminant hepatitis – particularly when an acute delta virus infection is superimposed on a pre-existing chronic HBV infection. HDAG can be detected in the serum of the patient only very early in infection, but anti-HDAG antibodies apparently persist indefinitely in chronically infected patients; evidence of active delta virus replication requires immunohistological staining for HDAG in the hepatocytes.

**ΔG<sub>ATP</sub>** See CHEMIOSMOSIS.

**ΔG<sub>p</sub>** See CHEMIOSMOSIS.

**Δμ<sub>H+</sub>** See CHEMIOSMOSIS.

**Δp** See CHEMIOSMOSIS.

**ΔpH** See CHEMIOSMOSIS.

**Δψ** See CHEMIOSMOSIS

**dematiaceous** (*mycol.*) Darkly pigmented.

**demeclocycline** See TETRACYCLINES.

**demecolcine** Deacetyl-*N*-methyl-COLCHICINE.

**Demerec convention** A widely-followed convention for bacterial genetic nomenclature [Genetics (1966) 54 61–76].

**demethylchlortetracycline** See TETRACYCLINES.

**demicyclic rusts** Those rust fungi (see UREDINIOMYCETES) which form all types of spore except uredospores; they include e.g. most species of *Gymnosporangium*.

**demyelination** (demyelination) The removal or destruction of the myelin sheath of one or more nerve fibres. (See also MULTIPLE SCLEROSIS; PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY; VISNA.)

**denaturing gradient gel electrophoresis** See DGGE.

**Dendriscoaulon** See CEPHALODIUM.

**dendritic cells** Motile, non-phagocytic ADHERENT CELLS, derived from the bone marrow, which are present e.g. in spleen and

## dendrodochiotoxiosis

lymph nodes. Dendritic cells are irregularly shaped, smooth-surfaced cells which contain pulsatile nuclei and many spherical mitochondria; they bear class II MHC antigens (cf. LANGERHANS' CELLS) and can act as ANTIGEN-PRESENTING CELLS (see e.g. DELAYED HYPERSENSITIVITY) and as accessory cells for cytotoxic T cells. [Minireviews: Cell (2001) 106 255–274.]

**dendrodochiotoxiosis** (myrotheciotoxiosis) A MYCOTOXICOSIS, affecting domestic animals and man, caused by roridin and verrucarin TRICHOCECENES produced by *Myrothecium* spp.

**Dendrophoma** See SPHAEROPSIDALES.

**Dendrosoma** See SUCTORIA.

**dengue** (breakbone fever) An acute, tropical and subtropical human disease caused by any of four serotypes of dengue virus (family FLAVIVIRIDAE) and transmitted by mosquitoes (usually *Aedes aegypti*). (The genetic diversity of dengue virus is reported to be increasing, and strains of the virus may now, or in the future, exhibit differences in virulence [TIM (2000) 8 74–77].) Replication of the virus may occur chiefly in macrophages.

In most cases the disease is benign and self-limiting (*dengue fever*). After an incubation period of ~5–10 days, typical symptoms include fever, headache, joint and muscular pains, and (often) a rash; bleeding (e.g. haematuria or gingival bleeding) is present in some cases. Mortality rates for this 'classical' form of the disease are very low.

Less often, a more severe form of disease may develop: *dengue haemorrhagic fever* (DHF). The manifestations of DHF include high fever, haemorrhagic phenomena, hepatomegaly and thrombocytopenia. The severity of disease is influenced by the extent of plasma leakage (as indicated by the rise in haematocrit reading). The most severe forms of DHF (World Health Organization grades III and IV) are designated *dengue shock syndrome* (DSS). DSS develops suddenly, after several days' fever, with signs of circulatory failure/hypovolaemic shock (rapid, weak pulse, narrowed pulse pressure or hypotension, and cold clammy skin); death may occur in 12–24 hours without suitable treatment, but recovery may be rapid following volume-replacement therapy.

[Dengue haemorrhagic fever (review): RMM (1995) 6 39–48.]

In common with many other diseases caused by arthropod-borne viruses, various manifestations of dengue infection (including those in which there is little or no haemorrhage) are characterized by a transient leukopenia [dengue-induced suppression of bone marrow: BCH (1995) 8 249–270]. [Haematology of dengue fever and dengue haemorrhagic fever: BCH (2000) 13 261–276.]

Detection of dengue virus in samples of serum can be achieved by rPCR; in primary infection, detection of viral RNA seems to be optimal prior to seroconversion (soon after onset of symptoms) [JCM (1999) 37 2543–2547].

**denitrification** Energy-yielding (respiratory) metabolism in which nitrate or nitrite (as terminal electron acceptor) is sequentially reduced to gaseous products, mainly dinitrogen and/or nitrous oxide (cf. DISSIMILATORY NITRATE REDUCTION). It is generally stated that denitrification occurs only under anaerobic or microaerobic conditions; however, aerobic denitrification has been reported [AvL (1984) 50 525–544; denitrification in *Rhizobium*: SBB (1985) 17 1–9].

In some DENITRIFYING BACTERIA (e.g. *Paracoccus denitrificans*) electrons from e.g. NADH are transferred to NO<sub>3</sub><sup>-</sup> via a *b*-type cytochrome, and to NO<sub>2</sub><sup>-</sup> and N<sub>2</sub>O via *c*-type cytochromes; electron flow to NO<sub>3</sub><sup>-</sup>, NO<sub>2</sub><sup>-</sup> and N<sub>2</sub>O apparently generates proton motive force. Nitrate reductase is a MOLYBDOENZYME; in some species cytochrome *d<sub>1c</sub>* acts as a nitrite reductase.

(See also NITROGEN CYCLE).

**denitrifying bacteria** Those bacteria capable of DENITRIFICATION; they occur e.g. in soil and in marine and freshwater environments. (Some species can be useful in the elimination of nitrate from waste water.) Examples include e.g. *Bacillus licheniformis*, *Hyphomicrobium* sp., *Paracoccus denitrificans*, *Pseudomonas stutzeri* and *Thiobacillus denitrificans*.

**density gradient centrifugation** See CENTRIFUGATION.

**denisonucleosis viruses** See DENSOVIRUS.

**Densovirus** (insect parvovirus group; also: denisonucleosis viruses, DNVs) A genus of autonomous (helper-independent) viruses (family PARVOVIRIDAE) which infect insects of the Lepidoptera (and probably of the Diptera and Orthoptera). Both positive- and negative-strand ssDNA molecules are encapsidated (in separate virions). Replication occurs in most tissues of host larvae, nymphs and adults; hypertrophy of the nucleus occurs in infected cells, and virions accumulate in dense intranuclear inclusions. Infected insects may die. Type species: densovirus of *Galleria mellonella* (the greater wax moth, whose larvae – known as wax-worms – feed on pollen and wax in beehives). Other members include densovirus of *Junonia* (a genus of butterflies); similar viruses have been detected in e.g. *Aedes* (mosquitoes), *Bombyx* (silk-moth), and butterflies of the Nymphalidae.

**dental caries** Tooth decay: typically, a process in which acids (particularly lactic acid), formed by plaque microorganisms, cause localized breakdown (demineralization) of tooth enamel, thus exposing the dentine; an important factor in the development of caries is the formation of water-insoluble extracellular microbial glucans which promote adhesion of cariogenic bacteria to the tooth surfaces (see DENTAL PLAQUE). Various bacteria, including e.g. lactobacilli and *Streptococcus mutans*, can be cariogenic in man; the development of caries may depend on factors such as the nature of the plaque microflora, diet, and the level of immunity in the host (see also CREVICULAR FLUID).

Fluoride is a potent anti-caries agent. It converts the apatite in tooth enamel to the more stable (acid-resistant) fluorapatite, and this is believed to be the primary mode of fluoride anti-caries activity. Fluoride can also inhibit bacterial metabolism e.g. by blocking the uptake of sugars by the PEP-dependent phosphotransferase system (see FLUORIDES). However, in some oral streptococci (including *S. mutans*) there is an alternative, fluoride-insensitive, pmf-dependent uptake system for glucose; this is a low-affinity uptake system compared to the high-affinity PTS system (the latter operating as a scavenger system under conditions of substrate limitation). At low pH (e.g. 5.5) the fluoride-insensitive system appears to be more important than the PTS system for the uptake of glucose.

**dental plaque** On the surfaces of teeth: a thin film (up to ca. 0.5 mm thick) consisting of a mixed microbial flora embedded in a matrix composed largely of extracellular (capsular) bacterial polysaccharides and salivary polymers; it is a predisposing factor in DENTAL CARIES and PERIODONTITIS.

Early colonizers of a clean enamel surface (in man) include species of *Neisseria* and *Streptococcus* (particularly *S. sanguis*). If plaque is allowed to build up, the nature of the microflora changes with time; although streptococci tend to remain dominant, anaerobes and filamentous bacteria begin to appear in significant numbers after several days or a week. Organisms present in well-established plaque include e.g. species of ACTINOMYCES (particularly *A. viscosus*), BACTEROIDES and VEILLONELLA; there is a general correlation between the numbers of *Streptococcus mutans* (see STREPTOCOCCUS) and the dietary intake of sucrose. The nature of the plaque microflora varies e.g. from one individual to another, and from one site to another on a given tooth.

Bacterial polymers typically present in plaque include MUTAN and LEVANS.

The presence of plaque can be detected by rinsing the mouth with a solution of a dye ('disclosing agent') such as erythrosin.

**Dentalina** See FORAMINIFERA.

**deodorants** (skin) See SKIN MICROFLORA.

**5'-deoxyadenosylcobalamin** See VITAMIN B<sub>12</sub>.

**deoxycholate** A salt of deoxycholic acid (see BILE ACIDS).

**deoxycholate-citrate agar** See DCA.

**deoxycholic acid** See BILE ACIDS.

**deoxycoformycin** *Syn.* pentostatin (see VIDARABINE).

**2'-deoxy-2'-fluoro-5-methyl-1-β-D-arabinosyluracil** See FMAU.

**deoxyhemigossypol** A terpenoid PHYTOALEXIN produced by the cotton plant. [Role of terpenoid phytoalexins in the resistance of a cultivar of *Gossypium barbadense* to *Verticillium dahliae*-induced wilt: PPP (1985) 26 209–218.]

**deoxynivalenol** See TRICHOCECENES.

**deoxyribonuclease** (DNase; DNAase) An enzyme which depolymerizes DNA. A DNase is designated DNase I (EC 3.1.21.1) or DNase II (EC 3.1.22.1) according to whether the mono- or oligonucleotide products of its action have (terminal) 5'- or 3'-phosphate groups, respectively. DNases are produced e.g. by the pancreas and by many microorganisms.

In *staphylococci*, production of a thermostable, Ca<sup>2+</sup>-requiring, extracellular DNase ('thermonuclease': a 5'-phosphodiesterase with both endo- and exonuclease activity, yielding 3'-nucleotides) correlates closely with the production of COAGULASE; thermonuclease also has Ca<sup>2+</sup>-dependent RNase activity. (Many coagulase-negative staphylococci produce a DNase which is generally heat-labile.) DNase activity may be detected/assayed e.g. by measuring changes in turbidity, or increasing levels of acid-soluble nucleotides (measured by spectrophotometry at 260 nm), induced in a suspension of DNA. For the detection of DNase production on solid media, an agar medium (e.g. trypticase-soy agar) containing DNA and a calcium salt is inoculated with the test strain and incubated for 18–24 hours. The plate is then flooded with 1 N HCl to precipitate DNA. A clear zone (in which the DNA has been hydrolysed) surrounds each DNase-producing colony. Certain dyes – e.g. methyl green (which combines only with highly polymerized DNA) – may be used instead of HCl, in which case cell viability may be preserved. [Book ref. 44, pp. 757–768.]

Certain *Clostridium* spp produce DNases: e.g. the β-toxins of *C. chauvoei* and *C. septicum*.

See also STREPTODORNASE.

**deoxyribonucleic acid** See DNA.

**deoxyribonucleoside** See NUCLEOSIDE.

**deoxyribophage** A BACTERIOPHAGE with a DNA genome.

**deoxyribovirus** A VIRUS with a DNA genome.

**2-deoxystreptomine** 2-Deoxy-1,3-diaminoinositol, a component of many AMINOGLYCOSIDE ANTIBIOTICS.

**DEPC** DIETHYLPYROCARBONATE.

**Dependovirus** (adeno-associated viruses, AAVs; adeno-satellite viruses) A genus of defective viruses (family PARVOVIRIDAE) which are totally dependent on functions of a co-infecting helper adenovirus (or herpesvirus) for their replication. Dependoviruses can infect a wide range of vertebrate hosts. Type species: AAV-1 (AAV type 1), which infects mainly monkeys; other members: AAV-2 and AAV-3 (which can infect man), AAV-4 (common e.g. in African green monkeys), avian AAV, bovine AAV and canine AAV. (Equine AAV and ovine AAV are probable members of the genus.) In vitro, a given AAV seems able to replicate in any type of cell culture which can support the replication of a suitable helper virus.

Genome: linear ssDNA, 4675 bases long in AAV-2 [sequence in AAV-2: JV (1983) 45 555–564]. Both positive and negative strands are encapsidated (in separate virions). The DNA has terminal INVERTED REPEATS 145 bases long. Within each repeat, the first 125 bases include a PALINDROMIC SEQUENCE in which bases 1–41 are complementary to bases 125–85; between bases 41 and 85 are two shorter palindromic sequences (bases 42–62 and 64–84). Folding which permits maximum base-pairing thus results in a T-shaped structure. (cf. PARVOVIRUS.)

Initial stages of AAV infection are independent of helper virus; the virions adsorb to a host cell and subsequently enter the nucleus, where the DNA is uncoated. In the presence of a co-infecting helper virus, the DNA is replicated and transcribed, its mRNA is translated, and infectious virions are formed. DNA replication appears to be initiated at the hairpin structures and is independent of RNA primers. In the absence of a helper virus, the AAV establishes a latent state by integrating into the host DNA as a provirus. Subsequent infection of the latently infected cell by a helper virus 'rescues' the AAV DNA, allowing the formation of infectious AAV virions.

AAVs appear not to cause disease in their hosts. In vitro, they may have a strong inhibitory effect on the replication of their helper viruses, but in vivo they seem not to ameliorate symptoms of adenovirus infection to any significant extent (although AAVs have been shown to reduce the oncogenic potential of adenoviruses in hamsters and of herpes simplex virus in cell cultures). AAV-2 infecting cell cultures co-infected with human cytomegalovirus (HCMV) as helper apparently exacerbates HCMV-induced CPE [Virol. (1985) 147 217–222].

[Reviews in Book ref. 97.]

**depside** An ester formed by the condensation of two or more phenolcarboxylic acids; e.g., COOH.ArO.CO.ArOH is a generalized didepside where Ar = a phenolic group. Depsides occur e.g. as 'lichen substances' (see LICHEN) and as components of TANNINS (e.g. digallic acid).

**depsipeptide antibiotics** ANTIBIOTICS which are derivatives of depsipeptides (molecules containing both ester and peptide bonds). They include the cyclic octadepsipeptide intercalating agents (QUINOXALINE ANTIBIOTICS) and the cyclic depsipeptide ionophores (see e.g. ENNIATINS and VALINOMYCIN). (See also DIDEMNINS.)

**Derbesia** A genus of siphonaceous, tropical or temperate, epilithic or epiphytic green seaweeds (division CHLOROPHYTA) which exhibit a heteromorphic alternation of generations. The sporophyte and gametophyte are so distinct morphologically that they have been described as separate plants: e.g. *Halicystis*, with a bulbous vesicular thallus, is the gametophyte of a filamentous *Derbesia* sporophyte; some species of *Bryopsis* have also been shown to have *Derbesia* sporophyte stages. *Derbesia* sporophytes produce stephanokont zoospores, while gametophytes produce biflagellate anisogametes. (See also CELL WALL.)

**derepressed** (*mol. biol.*) Refers to the state of a repressible gene or operon when it is not repressed, i.e., when the gene or operon is expressed. Derepression may be brought about e.g. by the presence of a specific inducer: see OPERON. (See also DRD PLASMID.)

**dermatitis** Inflammation of the skin. It is commonly due to mechanical or chemical irritants or to allergic reactions, but may occur in certain infectious diseases (e.g. RINGWORM.) (cf. ECZEMA.)

**dermatitis verrucosa** *Syn.* CHROMOBLASTOMYCOSIS.

**Dermatocarpon** A genus of foliose LICHENS (order VERRUCARIALES); photobiont: a green alga. Thallus: small, more or less

## dermatomycosis

lobed, attached to the substratum (rocks) by a central holdfast (umbilicus – cf. UMBILICARIA). Pseudothecia occur immersed in the thallus, their ostioles visible as black dots in the thal-  
lus surface. Some species – e.g. *D. rivulorum*, *D. weberi* (for-  
merly *D. fluviale*) – occur on rocks in or adjacent to unpolluted  
streams or lakes. (cf. CATAPYRENIUM.)

**dermatomycosis** Any MYCOSIS affecting the skin – see e.g. CAN-  
DIDIASIS, PITIRIASIS VERSICOLOR, RINGWORM.

**dermatophilosis** A disease of animals, transmissible (by direct  
contact) to man, caused by *Dermatophilus congolensis* (see e.g.  
LUMPY WOOL and STRAWBERRY FOOT-ROT). In man, self-limited  
pustular lesions develop on the skin. (cf. PITTED KERATOLYSIS.)

**Dermatophilus** A genus of aerobic or facultatively anaerobic,  
catalase-positive bacteria (order ACTINOMYCETALES, wall type III)  
which occur as pathogens of man and other animals (see DER-  
MATOPHILOSIS). In culture the organisms initially form filaments  
( $<1 \mu\text{m}$  in diameter) which become branched and undergo trans-  
verse and longitudinal septation to form long, tapering hyphae,  
up to  $5 \mu\text{m}$  in diameter, which bear a tough gelatinous capsule.  
Further septation gives rise to coccoid forms which develop into  
zoospores (up to ca.  $1 \mu\text{m}$  in diameter), each having a single  
tuft of flagella. Growth occurs at  $37^\circ\text{C}$  on enriched media (e.g.  
brain–heart infusion medium), and is enhanced by increased  
partial pressures of  $\text{CO}_2$ ; the colonies are initially dry and  
greyish-white but later become mucoid and yellowish-orange.  
Clear haemolysis occurs in media containing sheep blood but  
not in media containing horse blood. Casein, gelatin and starch  
are metabolized. GC%: ca. 57–59. Type species: *D. congolensis*.  
[Morphology, ecology, isolation: Book ref. 46, pp. 2011–2015;  
differentiation between *Dermatophilus* and *Geodermatophilus*  
by 16S rRNA oligonucleotide cataloguing: JGM (1983) 129  
1831–1838.]

**dermatophytes** A group of fungi which can infect and degrade  
keratinized tissues (skin, nails, hair etc) in living animals (includ-  
ing man), causing RINGWORM. Dermatophytes belong to the  
HYPHOMYCETES, and many have teleomorphs in the GYMNOAS-  
CALES; the three main genera are *Epidermophyton*, *Microsporium*  
(teleomorph *Nannizzia*), and *Trichophyton* (teleomorph *Arthro-*  
*derma*). The organisms form a hyaline, septate mycelium which  
in many species tends to fragment to form arthrospores. (See also  
RACQUET MYCELIUM.) When infecting hair, some dermatophytes  
(e.g. *T. tonsurans* and *T. violaceum*) form both hyphae and  
arthrospores largely or wholly within the hair shaft (*endothrix*  
infection); other species (e.g. *T. mentagrophytes*, *Microsporium*  
spp) may also form hyphae within the hair shaft, but arthrospores  
develop only on the surface of the hair (*ectothrix* infection). In  
culture, most dermatophytes produce both single-celled micro-  
conidia and septate macroconidia. (*Epidermophyton* spp do not  
form microconidia.) Microconidia are generally oval or pyr-  
iform, borne singly or in grape-like clusters along the sides of  
the hyphae. Characteristics of the macroconidia are used in the  
classification of genera and species. In *Epidermophyton* spp,  
macroconidia are produced abundantly and are smooth-surfaced,  
2–4-septate, ca.  $6\text{--}8 \times 15\text{--}40 \mu\text{m}$ , and borne in groups of 2  
or 3. In *Microsporium* spp, macroconidia are usually numer-  
ous (but rare in *M. audouinii*) and are rough-surfaced, usually  
thick-walled, 3–15-septate, ca.  $3\text{--}8 \times 40\text{--}120 \mu\text{m}$ , and borne  
singly. In *Trichophyton* spp, macroconidia are usually sparse  
and are smooth-surfaced, usually thin-walled, 2–8-septate, ca.  
 $4\text{--}6 \times 10\text{--}50 \mu\text{m}$ , borne singly.

Some (anthropophilic) dermatophytes occur mainly or only  
as human pathogens; these include e.g. *E. floccosum* (ATHLETE'S  
FOOT), *M. audouinii* (tinea capitis), and *T. schoenleinii* (tinea

capitis, FAVUS). Zoophilic dermatophytes commonly show some  
degree of host specificity: e.g., *M. canis* (e.g. cats and dogs),  
*T. verrucosum* (e.g. cattle, horses, pigs, goats), *T. equi* (horses);  
most or all zoophilic species can also infect man. Certain species  
(e.g. *M. gypseum*, *T. ajelloi*) are said to be 'geophilic': they  
apparently grow as saprotrophs (e.g. in soil, birds' nests), but  
can also infect man and animals under certain conditions.

**dermatophytosis** *Syn.* RINGWORM.

**Dermocarpa** A genus of unicellular CYANOBACTERIA (section II)  
in which the vegetative cells are rounded and variable in size;  
baeocytes initially lack a fibrous outer cell wall layer and are  
motile (by gliding). GC%: ca. 38–44.

**Dermocarpales** *Syn.* Chamaesiphonales (see CYANOBACTERIA).

**Dermocarpella** A genus of unicellular CYANOBACTERIA (sec-  
tion II) in which growth and binary fission result in pear-shaped  
aggregates consisting of one or two basal cells and a larger apical  
cell; multiple fission of the apical cell yields baeocytes which  
initially lack a fibrous outer cell wall layer and are motile (by  
gliding). GC%: ca. 45.

**Dermocystidium** See PERKINSUS.

**dermonecrotic** Causing necrosis of the skin.

**dermonecrotic toxin** A TOXIN produced by species of *Bordetella*;  
its role (if any) in the pathogenesis of WHOOPING COUGH has not  
been determined, but it is known to cause e.g. re-arrangement  
of actin filaments within eukaryotic cells.

**dermotropism** See TROPISM (sense 2).

**Derrick's method** See IMMUNOSORBENT ELECTRON MICROSCOPY.

**Derxia** A genus (*incertae sedis*) of Gram-negative, aerobic,  
catalase-negative, chemoorganotrophic, facultatively chemoli-  
thoautotrophic bacteria which occur e.g. in acidic tropical soils  
(e.g. in Brazil, China, Indonesia, West Bengal). Cells: typically  
round-ended pleomorphic rods, ca.  $1.0\text{--}1.2 \times 3.0\text{--}6.0 \mu\text{m}$ , with  
a single flagellum at one pole (or sometimes at each pole).  
Metabolism is respiratory (oxidative), with  $\text{O}_2$  as terminal  
electron acceptor. Carbon sources include glucose, fructose,  
ethanol and mannitol; little or no growth occurs on acetate,  
lactate, malate or succinate. NITROGEN FIXATION can occur  
under atmospheric conditions. Chemolithoautotrophic growth  
can occur with mixtures of  $\text{H}_2$ ,  $\text{CO}_2$  and  $\text{O}_2$  ( $\text{CO}_2$  being fixed  
via the Calvin cycle),  $\text{N}_2$  or  $\text{NH}_4^+$  serving as a source of  
nitrogen; growth on  $\text{CH}_4$  or  $\text{CH}_3\text{OH}$  (see METHYL TROPHY)  
has been reported. A pellicle is formed in liquid media;  
broth cultures become gelatinous. Colonies are slimy, becoming  
raised, wrinkled, and subsequently dark brown. Optimum growth  
temperature:  $25\text{--}35^\circ\text{C}$ . Growth occurs within the pH range 5.5-  
ca. 9.0. GC%: ca. 69–73. Type species: *D. gummosa*.  
[Book ref. 22, pp. 321–325.]

**desensitization** (*syn.* hyposensitization) (*immunol.*) The repeated  
administration of known quantities of allergen to an individual  
in whom it usually provokes an immediate or delayed  
HYPERSENSITIVITY reaction; in some cases this treatment  
temporarily reduces or abolishes hypersensitivity to the given  
allergen. In one method used for treating allergy to mould(s),  
an aqueous extract of the allergen(s) – up to 100-fold weaker  
than that required to produce an intradermal hypersensitivity  
reaction – is administered subcutaneously; the dose, initially  
given weekly, is gradually increased and administered after  
longer intervals of time for a total period of several years [Book  
ref. 51, pp. 187–201].

Little is known about the mechanism(s) of desensitization.  
Possible mechanisms include e.g. (i) the formation of BLOCKING  
ANTIBODIES (sense 2), and (ii) the stimulation of suppressor T  
cells.

**desert fever** *Syn.* COCCIDIOIDOMYCOSIS.

**Desert Shield virus** See SMALL ROUND STRUCTURED VIRUSES.

**desferrioxamine** A hydroxamate SIDEROPHORE formed e.g. by *Streptomyces pilosus*. It is used e.g. in the treatment of patients with iron overload.

**desiccation** (of microorganisms) The removal of water: a process used e.g. for the PRESERVATION of viable populations of certain types of microorganism (including enterobacteria and spore-forming bacteria). However, the method described below is lethal for many types of microorganism, including various pathogens (e.g. *Neisseria gonorrhoeae*, *Treponema pallidum*) and many aquatic organisms; some organisms that are killed by this procedure can be preserved by FREEZE-DRYING.

Initially, the organisms are suspended in an appropriate medium (e.g. broth, serum, or 5–10% nutrient gelatin). Drops of the suspension are then placed, singly, onto a sterile filter paper (or a piece of waxed paper) which is inserted into a glass ampoule. The ampoule is placed in a desiccator which contains phosphorus pentoxide (as drying agent) and which is subsequently evacuated. The use of a vacuum is essential because it reduces the time for which cells are exposed to the deleterious effects of high concentrations of solute. When the sample is completely desiccated the ampoule is sealed. Under optimal conditions the organisms remain viable for years; spores may remain viable for decades.

In general, desiccation is tolerated to different degrees by different organisms; many do not survive for long in the air-dried state. [Desiccation tolerance of prokaryotes: MR (1994) 58 755–805.]

**desmarestene** See PHEROMONE.

**Desmarestia** See PHAEOPHYTA.

**Desmidium** A genus of placoderm DESMIDS.

**desmids** A group of freshwater, basically unicellular green algae (division CHLOROPHYTA) which reproduce sexually by conjugation and which never form flagellated cells of any kind. In most species the cells are solitary, although in a few they are joined end-to-end to form filaments (see e.g. HYALOTHECA). The cells are generally more or less bilaterally symmetrical and may be cylindrical, fusiform, crescent-shaped, etc, sometimes bearing elaborate ornamentations. Many species are highly variable, occurring in a range of growth forms – a feature which has caused considerable confusion in speciation and nomenclature [Book ref. 123, pp. 251–269].

In *placoderm desmids* each cell is divided into two 'semi-cells' either by a median suture line (e.g. in *Closterium* and *Penium*) or, more commonly, by an equatorial constriction (*sinus*) – the narrow region joining the semicells being called the *isthmus*. The cell wall is perforated by pores through which mucilage may be secreted; the mucilage may allow the desmid to adhere to substrata, and is apparently necessary for the GLIDING MOTILITY often exhibited by these cells. Genera of placoderm desmids include e.g. CLOSTERIUM, COSMARIUM, *Desmidium*, *Euastrum*, HYALOTHECA, *Micrasterias*, PENIUM, STAUSTRUM, *Staurodesmus*, and XANTHIDIUM.

In *saccoderm desmids* the cells do not have a median suture line or sinus and have smooth walls without pores. They nevertheless produce mucilage, often in copious amounts, and some can exhibit gliding motility. Genera include e.g. *Ancylonema* (short cylindrical cells joined end-to-end to form short filaments), *Cylindrocystis* (cells cylindrical, round-ended, containing a stellate chloroplast at each end), and *Mesotaenium* (cells short, cylindrical, solitary, containing a single chloroplast).

Sexual reproduction in desmids involves a process of conjugation analogous to that in SPIROGYRA. Essentially, cells come

together in pairs, a conjugation tube is formed between them, and the protoplasts function as amoeboid gametes, fusing to form a zygote which then develops a thick, resistant wall.

Desmids occur in various freshwater habitats, particularly in acidic, unpolluted pools, bogs etc; some (e.g. *Cylindrocystis*, *Mesotaenium*) may occur in mucilaginous, amorphous colonies on damp soil, wet rocks etc.

[Book ref. 128.]

**Desmococcus** See PLEUROCOCCUS.

**desmodexy** See RULE OF DESMODEXY.

**desmosome** One of a number of differentiated regions which occur e.g. where the cytoplasmic membranes of adjacent epithelial cells are closely apposed; it consists of a circular region (ca. 0.5  $\mu\text{m}$  diam.) of each membrane together with associated intracellular microfilaments and an intercellular material which may include e.g. mucopolysaccharides. Desmosomes can be disrupted e.g. by hyaluronidase and  $\text{Ca}^{2+}$  chelators. (See also TRYPANOSOMA.)

**Desmothoracida** An order of protozoa (class HELIOZOEAE) in which the cell is enclosed in a reticulate, basket-like capsule which is usually spherical and generally composed of an organic matrix often impregnated with silica; axopodia project through perforations in the capsule. In some species a stalk from the capsule attaches the organism to the substratum. There is no centroplast (cf. CENTROHELIDA). Uniflagellate or biflagellate zoospores may be formed. Genera include e.g. CLATHRULINA.

**desmotubule** In plant cells: an extension of the endoplasmic reticulum which is continuous from one cell to the next via the PLASMODESMA.

**desoxy-** A prefix equivalent to 'deoxy-'; thus, e.g., for desoxycholate see DEOXYCHOLATE.

**desquamation** The shedding of skin, cuticle etc in sheets or flakes.

**destroying angel** See AMANITA.

**destruxins** See METARHIZIUM.

**Desulfobacter** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in aquatic habitats (primarily brackish and marine). (See also ANAEROBIC DIGESTION.) Cells: non-motile or motile (polarly monoflagellate), rod-shaped to ellipsoidal, ca. 1.0–2.0  $\times$  1.7–3.5  $\mu\text{m}$ . Chemoorganotrophic. Acetate can be used as a source of carbon and energy, and is oxidized to  $\text{CO}_2$  using sulphate (or another oxidized sulphur compound) as terminal electron acceptor (see DISSIMILATORY SULPHATE REDUCTION and TCA CYCLE). The organisms contain *b*- and *c*-type cytochromes; they lack desulfovirdin. Growth is inhibited by elemental sulphur. Typically, at least 0.5% NaCl and 0.1%  $\text{MgCl}_2$  are required for growth. Optimum growth temperature: 28–32°C. Optimum pH: 7.3. GC%: ca. 46. Type species: *D. postgatei*. [Book ref. 22, pp. 674–676.]

**Desulfobolus** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in freshwater, brackish and marine habitats, and in the RUMEN. Cells: ellipsoidal, ca. 1.0–1.3  $\times$  1.5–2.0  $\mu\text{m}$ ; in many strains there is a single polar flagellum. Chemoorganotrophic. Lactate, propionate, pyruvate or certain alcohols are used as sources of carbon and energy, and are oxidized to e.g. acetate using sulphate (or another oxidized sulphur compound) as terminal electron acceptor (see DISSIMILATORY SULPHATE REDUCTION); the organisms contain *b*- and *c*-type cytochromes. Lactate or pyruvate can be fermented in the absence of an external electron acceptor. Optimum growth temperature: 28–39°C. GC%: ca. 60. Type species: *D. propionicus*. [Book ref. 22, pp. 676–677.]

## *Desulfococcus*

***Desulfococcus*** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in aquatic habitats (freshwater, brackish and marine) and in anaerobic sewage digesters. Cells: cocci, ca. 1.5–2.2 µm in diameter. Chemoorganotrophic. Benzoate, other aromatic compounds, acetate, lactate, pyruvate and alcohols etc are used as sources of carbon and energy; these substrates are oxidized to CO<sub>2</sub> using sulphate (or another oxidized sulphur compound) as terminal electron acceptor (see DISSIMILATORY SULPHATE REDUCTION). The organisms contain *b*- and *c*-type cytochromes. Lactate or pyruvate can be fermented in the absence of an external electron acceptor. GC%: ca. 57. Type species: *D. multivorans*. [Book ref. 22, pp. 673–674.]

***Desulfomonas*** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in the human intestinal tract. Cells: non-motile rods. The organisms, which carry out DISSIMILATORY SULPHATE REDUCTION, contain both *b*- and *c*-type cytochromes and desulfovibrin; pyruvate is oxidized to acetate and CO<sub>2</sub>. GC%: ca. 66–67. Type species: *D. pigra*. [Book ref. 22, pp. 672–673.]

***Desulfonema*** A genus of SULPHATE-REDUCING BACTERIA which occur e.g. in marine sediments. Cells: gliding filaments, ca. 2.0–7.0 µm in width, several millimetres in length, each being uniseriately multicellular; the organisms stain Gram-positively. Acetate, benzoate and other substrates are oxidized to CO<sub>2</sub>. The organisms carry out DISSIMILATORY SULPHATE REDUCTION and contain *b*- and *c*-type cytochromes; desulfovibrin occurs in strains of *D. limicola* but not in those of *D. magnum*. At least some strains have been reported to grow autotrophically. GC%: ca. 34–42.

**desulforubidin** A (red) sirohaem-containing sulphite reductase which occurs e.g. in *Desulfovibrio desulfuricans* strain Norway 4. (cf. DESULFOVIRIDIN.)

***Desulfosarcina*** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in brackish and marine waters. Cells: irregularly shaped and sarciniform, or coccoid to ellipsoidal single cells, ca. 1.0–1.5 × 1.5–2.5 µm, occasionally motile by means of a single polar flagellum. Chemoorganotrophic, and reported to be facultatively chemolithoautotrophic. Carbon and energy sources include e.g. acetate, lactate, pyruvate, formate, propionate, and various alcohols and fatty acids; these substrates can be oxidized to CO<sub>2</sub> using sulphate (or another oxidized sulphur compound) as terminal electron acceptor (see DISSIMILATORY SULPHATE REDUCTION). Lactate or pyruvate can be fermented in the absence of an external electron acceptor. Growth requires at least 1% NaCl and 0.2% MgCl<sub>2</sub>·6H<sub>2</sub>O. Optimum growth temperature: 28–33°C. GC%: ca. 51. Type species: *D. variabilis*. [Book ref. 22, pp. 677–679.]

***Desulfotomaculum*** A genus of Gram-negative, endospore-forming SULPHATE-REDUCING BACTERIA which occur e.g. in soil and in the RUMEN. Cells: motile (peritrichously flagellate) rods up to ca. 9 µm in length. Chemoorganotrophic. For most species the carbon and energy sources include lactate and pyruvate; *D. acetoxidans* can oxidize acetate. The organisms carry out DISSIMILATORY SULPHATE REDUCTION and contain *b*-type cytochromes; no species contains desulfovibrin. In addition to electron transport-coupled phosphorylation, *Desulfotomaculum* spp can carry out a substrate-level phosphorylation in which PPI (see PYROPHOSPHATE) reacts reversibly with acetate (enzyme: acetate:PPI phosphotransferase) to form acetyl phosphate and Pi; acetyl phosphate and ADP can then yield acetate and ATP in the presence of acetokinase. GC%: ca. 37–49. Type species: *D. nigrificans* (formerly *Clostridium nigrificans*); other species: *D. acetoxidans*, *D. antarcticum*, *D. orientis*, *D. ruminis*.

***Desulfovibrio*** A genus of Gram-negative SULPHATE-REDUCING BACTERIA which occur e.g. in mud and sediments in freshwater, brackish and marine habitats. Cells: motile, typically curved (sometimes S-shaped or helical) rods, ca. 0.5–1.5 × 2.5–10.0 µm, each having one polar flagellum or a tuft of polar flagella. Metabolism is chemoorganotrophic or mixotrophic, primarily respiratory, and the cells contain *c*-type (and usually *b*-type) cytochromes; sulphate (or another oxidized sulphur compound) is used as a terminal electron acceptor and is reduced to H<sub>2</sub>S. (See also DISSIMILATORY SULPHATE REDUCTION; cf. FERMENTATION sense 1.) Most species give a positive DESULFOVIRIDIN TEST. In the absence of oxidized sulphur compounds some strains can use fumarate and/or nitrate as terminal electron acceptor. Substrates used by most species include one or more of the following: lactate, malate, pyruvate and glycerol; these substrates are typically oxidized to acetate and CO<sub>2</sub>, the acetate not being oxidized further. (*D. baarsii* can oxidize e.g. acetate, butyrate or formate to CO<sub>2</sub>; it can also grow as an AUTOTROPH (q.v.)) [Use of amino acids by marine strains of *Desulfovibrio*: FEMS Ecol. (1985) 31 11–15.] In the absence of a reducible sulphur compound some species can gain energy from e.g. pyruvate (see PHOSPHOROCLASTIC SPLIT). Most strains contain HYDROGENASE, and some can gain energy by the oxidation of H<sub>2</sub> (using SO<sub>4</sub><sup>2-</sup> as terminal electron acceptor) while using acetate and CO<sub>2</sub> as carbon sources. (See also EXTRACYTOSOLIC OXIDATION.) [Hydrogenase, electron-transfer proteins and energy coupling in *Desulfovibrio*: ARM (1984) 38 551–592.] Some strains can carry out NITROGEN FIXATION. [Diazotrophy in *Desulfovibrio*: JGM (1985) 131 2119–2122.] GC%: ca. 46–61. Type species: *D. desulfuricans*; other species: *D. africanus*, *D. baculatus*, *D. gigas*, *D. salixigens*, *D. sapovorans*, *D. thermophilus*, *D. vulgaris*. [Book ref. 22, pp. 666–672.] (For *D. sulfodismutans* see FERMENTATION sense 1.)

**desulfovibrin** A (green) sulphite reductase which occurs e.g. in the cytoplasm in species of *Desulfovibrio* and which is involved in DISSIMILATORY SULPHATE REDUCTION. The enzyme (MWt ca. 200000) contains several 4Fe–4S clusters and two sirohaem groups per molecule (each sirohaem consisting of an iron-containing porphyrin-like molecule, sirohydrochlorin). In vitro the products of sulphite reduction include trithionate (S<sub>3</sub>O<sub>6</sub><sup>2-</sup>) and sulphide (S<sup>2-</sup>). (cf. DESULFORUBIDIN and P582.)

**desulfovibrin test** A test used to detect DESULFOVIRIDIN in certain SULPHATE-REDUCING BACTERIA. The pellet from a centrifuged culture (15 ml) is resuspended in growth medium, one drop of NaOH (2 M) is added, and the whole is examined under ultraviolet light (wavelength 365 nm); in a positive test the suspension gives a red fluorescence due to the presence of the free sirohydrochlorin chromophore of desulfovibrin.

***Desulfurococcus*** A genus of chemolithoheterotrophic archaeans (order THERMOPROTEALES) which occur e.g. in Icelandic solfataras; they metabolize peptides and obtain energy by SULPHUR RESPIRATION, although at least one species can apparently survive by means of a (sulphur-independent) fermentation. The cells are cocci, ca. 1 µm diam.; *D. mobilis* is motile (flagellated), *D. mucosus* is not. GC%: 51.

***Desulfuromonas*** A genus of Gram-negative, obligately anaerobic bacteria which occur e.g. in freshwater, brackish and marine sediments or muds. Cells: motile, round-ended rods, ca. 0.4–0.9 × 1.0–4.0 µm, which typically have a single lateral or subpolar flagellum. The organisms are chemoorganotrophs; acetate, L-malate and other substrates (e.g. alcohols in some strains) can be utilized. Metabolism is primarily respiratory, and

the organisms contain *c*-type cytochromes; elemental sulphur, which acts as terminal electron acceptor, is reduced to H<sub>2</sub>S (dissimilatory sulphur reduction), and acetate (or other substrate) is completely oxidized to CO<sub>2</sub>. (See also ANAEROBIC DIGESTION.) (Sulphate, sulphite or thiosulphate cannot be used as terminal electron acceptor.) Fumarate or L-malate can be fermented to acetate and succinate. Optimum growth temperature: 30°C. Optimum pH: 7.2–7.5. Colonies are pink or peach-coloured, translucent to opaque. GC%: ca. 50–63. Type species: *D. acetoxidans*. Strains which are ovoid, with a polar or subpolar flagellum, and which do not use alcohols as substrates have been referred to as '*D. acetexigens*'. [Book ref. 22, pp. 664–666.]

**determinant** (1) (antigenic determinant; determinant group; epitope) (*immunol.*) Of an antigenic macromolecule: any region of the macromolecule with the ability or potential to elicit, and combine with, specific antibody. Determinants exposed on the surface of the macromolecule are likely to be *immunodominant*, i.e. more immunogenic than other (*immunorecessive*) determinants which are less exposed, while some (e.g. those within the molecule) are non-immunogenic (*immunosilent*). (See also ANTIGEN.)

(2) (*genetics*) A gene or functional gene group.

**detritivore** Any organism (e.g. earthworm, lugworm, bivalve mollusc) which feeds by ingesting detritus (such as soil particles), removing and digesting e.g. adherent microorganisms, and voiding the residue.

**Detroit-6** An ESTABLISHED CELL LINE derived from human sternal bone marrow; the cells are heteroploid and epithelioid.

**Dettol** See PHENOLS.

**Dettol chelate** A disinfectant which contains chloroxylenol (see PHENOLS) and EDTA; EDTA potentiates the action of chloroxylenol on Gram-negative bacteria by increasing cell permeability. It is active against e.g. many strains of *Pseudomonas aeruginosa*.

**deuteromycetes** See DEUTEROMYCOTINA.

**Deuteromycotina** (deuteromycetes; Fungi Imperfecti) A non-phylogenetic category originally created for fungi with no known sexual stage; the category still includes fungi with no known sexual stage (and some fungi which form neither conidia nor sexual structures: see AGONOMYCETALES), but it also includes the asexual (= anamorphic, conidial or imperfect) stages of various fungi which are now known to have a sexual (= teleomorphic or perfect) stage in the Ascomycotina or the Basidiomycotina.

For convenience, 'Deuteromycotina' is generally treated as a subdivision within the EUMYCOTA. The conidium-forming deuteromycetes are arranged into form genera (see FORM GENUS) primarily on the basis of the characteristics of their conidia and their modes of conidiogenesis (see CONIDIUM). (See also SACCARDOAN SYSTEM.) The inclusion of a number of form species in a given form genus means only that those fungi have similar asexual stages; such fungi are not necessarily related (and are often unrelated) in an evolutionary sense (as determined by the sexual characteristics of the organisms, when known). Thus, a given form genus may contain e.g. anamorphs corresponding to the teleomorphs of different genera together with ANAHOLOMORPHS. (For convenience, the word 'form' is generally omitted when referring to a form genus, form species etc.) Classification of the deuteromycetes on the basis of their asexual stages facilitates the identification of those members in which the asexual stage is that which is most commonly encountered in nature (and which may form the sexual stage only rarely).

Two classes [Book ref. 64, p. 112]: COELOMYCETES and HYPHOMYCETES.

**deuterosome** In a eukaryotic cell: a dense region in the cytoplasm which can act as a MICROTUBULE-ORGANIZING CENTRE for the de novo assembly of a BASAL BODY.

**deutomerite** In a cephaline gregarine: the posterior of the two main regions of the (septate) cell (cf. PROTOMERITE); it usually contains the nucleus.

**DEV** Duck embryo vaccine (see RABIES).

**Devarda's alloy** An alloy containing aluminium (45%), copper (50%) and zinc (5%); it is used e.g. to reduce nitrite and/or nitrate to ammonia.

**devil's grip** *Syn.* BORNHOLM DISEASE.

**dew retting** See RETTING.

**dexioplectic metachrony** See METACHRONAL WAVES.

**dextrans** D-Glucans in which the glucose residues are linked mainly by (1 → 6)-α-glucosidic bonds; branches are formed by occasional (1 → 4)-α- and, less frequently, (1 → 3)-α-linkages. The size of the molecule and the nature and extent of branching depend on the source of the dextran. Extracellular dextrans are produced by a range of microorganisms, sometimes in copious amounts (see e.g. ROPINESS); they are obtained commercially from strains of *Leuconostoc mesenteroides* grown anaerobically on sucrose-containing media [Book ref. 62, pp. 1–44]. Dextrans of MWt ca. 75000 are used as plasma volume extenders for blood transfusions; they may be obtained by acid hydrolysis of higher-MWt dextrans. Artificially cross-linked dextrans (e.g. 'Sephadex') are used in GEL FILTRATION. Dextrans are relatively inert and can withstand autoclaving.

**dextrins** Products of the partial degradation of STARCH or GLYCOGEN by heat, acid hydrolysis, or enzyme action. *Limit dextrins* are those formed by enzymes that are unable to effect complete hydrolysis (see AMYLASES). (See also SCHARDINGER DEXTRINS.)

**dextrose** Dextrorotatory glucose (D-glucose).

**DFD meat** Dark, firm, dry meat: red meat from animals stressed before slaughter. DFD meat contains less glucose and has a higher pH (>ca. 6.0) than normal meat; during stress, muscle glycogen in the living animal is converted to lactic acid (cf. MEAT SPOILAGE) which is subsequently lost when the animal is bled. DFD meat is more susceptible than normal meat to spoilage. Increased susceptibility to aerobic spoilage appears to be due to the deficiency of glucose rather than to the high pH; since little or no glucose is available, spoilage organisms attack amino acids earlier than in normal meat and, hence, produce off-odours and off-flavours after a shorter period of storage [Book ref. 30, pp. 240–244]. Anaerobic spoilage (e.g. in vacuum packs) may be due to organisms (e.g. *Aeromonas putrefaciens*, *Serratia liquefaciens*) which are inhibited by the low pH of normal meat. *S. liquefaciens* produces off-odours. *A. putrefaciens* forms H<sub>2</sub>S which reacts with e.g. myoglobin to produce a green compound: sulphmyoglobin ('greening') – cf. MEAT SPOILAGE (b); since *A. putrefaciens* is inhibited at pH below 6.0, greening can be prevented by treating the meat with citrate buffer. Vacuum-packed DFD meat may also support the growth of large populations of *Yersinia enterocolitica*, although these seem not to cause significant spoilage (cf. FOOD POISONING).

**DFMO** (DL-α-difluoromethylornithine) See SLEEPING SICKNESS.

**DFP** Diisopropylfluorophosphate – see PROTEASES.

**DGGE** Denaturing gradient gel electrophoresis: a method for comparing samples of related double-stranded DNA (generated e.g. by PCR or restriction) by two-dimensional electrophoresis (cf. SSCP). In DGGE [Biotechnology (1995) 13 137–139], fragments are separated by size in the first phase of electrophoresis. Then, in the same gel, the fragments are moved electrophoretically at right-angles to their original path. In this second phase,

## DHBG

fragments move through an increasing concentration of DNA-denaturing agents (e.g. formamide + urea) so that, at certain levels in the gradient, localized *sequence-dependent* melting (i.e. strand separation) occurs within part(s) of the fragments (base-pairing being stronger in GC-rich sections); such localized melting affects the electrophoretic speed of those fragments in which it occurs and allows separation of fragments in the gel.

[Example of use of DGGE (differentiation of isolates of *Escherichia coli* by analysis of the 16S–23S intergenic spacer region): FEMS Ecol. (2001) 35 313–321.]

Other uses of DGGE include e.g. characterization of organisms by comparing PCR-amplified sequences of their 16S rRNA genes [AEM (1996) 62 340–346] and detection of *Rhizobium* spp [LAM (1999) 28 137–141].

Another method, based on the same principle, replaces the chemical denaturing gradient of DGGE with an ongoing increase in temperature during the second phase of electrophoresis; thus, at certain levels of temperature, localized sequence-dependent melting occurs in specific part(s) of the fragments – affecting electrophoretic mobility and allowing separation within the gel. This method is referred to as *temporal temperature gradient gel electrophoresis* (TTGE).

[Comparison of DGGE with TTGE: LAM (2000) 30 427–431.]

**DHBG** (9-(3,4-dihydroxybutyl)-guanine) An ANTIVIRAL AGENT which is active, both in cell cultures and in vivo, against herpes simplex viruses (HSV-1 and -2); the (*R*)-enantiomer is more effective than the (*S*)-enantiomer. The mechanism of action resembles that of ACYCLOVIR, but DHBG has higher affinity for HSV thymidine kinase.

**DHBV** DUCK HEPATITIS B VIRUS.

**Dhori virus** An unclassified virus (see ORTHOMYXOVIRIDAE) which has been isolated from ticks; antibodies to the virus have been found in man and domestic animals.

**DHPA** ((*S*)-DHPA; (*S*)-9-(2,3-dihydroxypropyl)-adenine) An ANTIVIRAL AGENT which acts as an analogue of adenosine; it is a potent inhibitor of 5-adenosyl homocysteine hydrolase. DHPA is active e.g. against vaccinia, herpes simplex, varicella-zoster and measles viruses; it acts synergistically with VIDARABINE. (The (*R*)-enantiomer is inactive.)

**DHPG** (9-(1,3-dihydroxy-2-propoxymethyl)-guanine; 2'-nor-2'-deoxyguanosine, 2'-NDG) An ANTIVIRAL AGENT which has potent activity against herpes simplex viruses (HSV-1 and -2); it is not effective against e.g. Epstein–Barr virus, varicella-zoster virus or cytomegaloviruses. The mechanism of action resembles that of ACYCLOVIR. The isomer (*S*)-9-(2,3-dihydroxy-1-propoxymethyl)-guanine is also active against HSV-1 and -2.

**DI particle** DEFECTIVE INTERFERING PARTICLE.

**diacetoxyscirpenol** See TRICHOTHECENES.

**diacetyl** (dimethylglyoxal; CH<sub>3</sub>.CO.CO.CH<sub>3</sub>) A water-soluble compound formed e.g. by certain lactic acid bacteria; it may also be derived by oxidation of acetoin in the BUTANEDIOL FERMENTATION. (See also VOGES–PROSKAUER TEST.)

Diacetyl produced by certain lactic acid bacteria is responsible for the characteristic 'buttery' flavour and aroma in many fermented DAIRY PRODUCTS. The diacetyl is formed from pyruvate – see Appendix III(c) – but levels of diacetyl are low if the pyruvate is derived from hexoses only. Additional pyruvate (and hence diacetyl) can be produced from citrate by certain strains of lactic acid bacteria ('aroma bacteria', 'flavour bacteria') – e.g. *Lactococcus lactis* and *Leuconostoc cremoris* (see LACTIC ACID STARTERS). (Citrate is naturally present in cows' milk at levels of ca. 0.2%, with seasonal fluctuations; it may also be added to

the milk to enhance diacetyl production.) *L. lactis* produces both lactic acid and diacetyl in milk. However, *Leuconostoc cremoris* by itself grows poorly in milk, producing little lactic acid; it can take up citrate only at pH below ca. 6.0, so that diacetyl production by this organism requires the activities of a lactic acid producer such as *L. lactis*. The ability to produce diacetyl from citrate is apparently plasmid-linked in at least certain strains of *L.* ('*Streptococcus*') *lactis* [AvL (1983) 49 265–266]. The ratio of flavourful products (e.g. diacetyl) to flavourless products (e.g. acetoin) depends e.g. on the redox potential of the system.

Diacetyl has some antimicrobial activity [AEM (1982) 44 525–532], being more effective against Gram-negative bacteria, yeasts and moulds than against Gram-positive bacteria.

**diacridine** A compound containing two ACRIDINE moieties (linked e.g. by a hydrocarbon bridge); it may act as a *bis* INTERCALATING AGENT.

**diagnosis** (1) In NOMENCLATURE: a list of descriptive characteristics which distinguish a proposed new taxon from other taxa. (2) (*med.*) In general, a statement of the identity of a given disease, deduced from symptoms etc., or the procedure used for arriving at such a statement.

**diagnostic window** See TRANSFUSION-TRANSMITTED INFECTION.

**diakinesis** See MEIOSIS.

**Dialister pneumosintes** See BACTEROIDES (*B. pneumosintes*).

**dialkylnitrosamines** See *N*-NITROSO COMPOUNDS.

**diamidines** Compounds with two amidine [NH<sub>2</sub>.C(=NH)–] groups. Aromatic diamidines bind to DNA, and a number of them are trypanocidal agents which bind to kinetoplast DNA and cause structural changes in the kinetoplast; however, there is evidence that at least part of the trypanocidal effect in vivo is due to inhibition of ornithine decarboxylase, leading to depletion of putrescine. (See e.g. BERENIL; DAPI; 2-HYDROXYSTILBAMIDINE; PENTAMIDINE ISETHIONATE.)

**diaminopimelic acid pathway** (DAP pathway) A pathway for lysine biosynthesis [Appendix IV(e)] which occurs in bacteria, certain lower fungi (Hyphochytriales, Leptomitales, Saprolegniales) and e.g. in green plants. (cf. AMINOADIPIC ACID PATHWAY.)

**diaminopyrimidine drugs** See FOLIC ACID ANTAGONIST.

**diamond skin disease** *Syn.* SWINE ERYSIPELAS.

**dianemycin** See MACROTETRALIDES.

***o*-dianisidine** (fast blue B) A (carcinogenic) substance, 3,3'-dimethoxybenzidine, used e.g. in assays for HYDROGEN PEROXIDE: the peroxidase-dependent oxidation of *o*-dianisidine causes increased absorbance at 500 nm.

**dianthoviruses** (carnation ringspot virus group) A category of PLANT VIRUSES which have a wide host range and are transmitted mechanically and via the soil. Virion: icosahedral, ca. 31–34 nm diam., containing two molecules of positive-sense ssRNA (MWts ca. 1.5 and 0.5 × 10<sup>6</sup>) and one type of coat protein (MWt 40000). Virus replication appears to occur in the cytoplasm. Type member: carnation ringspot virus; other members: red clover necrotic mosaic virus, sweet clover necrotic mosaic virus.

**diapedesis** See INFLAMMATION.

**diaphorase** Any enzyme which can catalyse the oxidation of reduced NAD or NADP by an artificial electron acceptor.

**diaphoromixis** Bipolar or tetrapolar *multi* allele HETEROPLASMY.

**diaplectic metachrony** See METACHRONAL WAVES.

**Diaporthales** An order of fungi (subdivision ASCOMYCOTINA) which include saprotrophic and plant-parasitic species. Ascomycarp: perithecioid, often immersed; hamothecium: absent or evanescent. Asci: unitunicate, evanescent. Genera: e.g. *Diaporthe*, ENDOTHIA, GAEUMANNOMYCES, *Gnomonia* (see also ZYTHIA).

**Diaporthe** See DIAPORTHALES.

**diarrhoea** (*American*: diarrhea) Frequent passage of fluid stools: a symptom of many types of illness. (cf. DYSENTERY; see also SCOURS.) Diarrhoea may be due to e.g. (i) the effect on the gut mucosa of particular microbial toxins which cause hypersecretion of fluid into the lumen; (ii) failure of the gut to absorb small molecules (peptides, sugars – especially lactose) due e.g. to damage to, or non-functioning of, the mucosa, leading to an osmotic effect in the gut lumen; (iii) abnormal activity of the smooth musculature of the gut wall.

Severe diarrhoea may lead to dehydration and loss of electrolyte; treatment includes rehydration with solutions containing  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Ca}^{2+}$ , bicarbonate ions and glucose.

Some causes of persistent diarrhoea include e.g. CLB and EAGGEC. (See also CRYPTOSPORIDIOSIS and ETEC.)

**Diaspora** See EIMERIORINA.

**diaspore** *Syn.* PROPAGULE.

**diastase** *Syn.* AMYLASE.

**diastatic** Able to metabolize starch.

**diastole** See CONTRACTILE VACUOLE.

**Diatoma** See DIATOMS.

**diatomaceous earth** (diatomite; *kieselguhr*) A siliceous material composed largely of fossil diatom frustules (see DIATOMS), large natural deposits of which are mined in various parts of the world (particularly Lompoc, California). Diatomaceous earth is used e.g. as a mild abrasive (in toothpastes, polishes etc), as an absorbent, as a heat-insulating material, and in various types of filter (including certain microbiological filters: see FILTRATION).

**diatomite** *Syn.* DIATOMACEOUS EARTH.

**diatoms** A large group (>10000 species) of ALGAE (often regarded as a distinct division – Bacillariophyta) which are essentially unicellular (some are colonial, some form filaments) and which have a characteristic type of CELL WALL consisting typically of a siliceous structure (the *frustule*) encased in an organic layer. Most cells have brownish chloroplasts containing chlorophylls *a*, *c*<sub>1</sub> and *c*<sub>2</sub> and e.g. fucoxanthin; storage products include CHRYSOLAMINARIN. Many species are facultatively heterotrophic in the dark; a few marine benthic species are obligately heterotrophic. Diatoms are unusual, if not unique, in having an absolute requirement for silicon – not only for the construction of their walls but also for general metabolism (e.g. in *Cylindrotheca fusiformis* silicon affects gene expression both directly and indirectly [JGM (1985) 131 1735–1744]). Species occur in aquatic environments, including fresh, brackish and marine waters (where they may be benthic, planktonic, epiphytic etc. – see also AUFWUCHS), and in terrestrial environments such as soil, damp rocks, and even dry rocks and desert sands. *Achnanthes exigua* is a thermophile (optimum temperature for photosynthesis: 42°C) found in hot springs. Psychrophilic species form a major component of the ‘ice algae’ present on the lower surfaces of ice in polar seas [JGM (1983) 129 1019–1023]. Diatoms occur as endosymbionts e.g. in members of the FORAMINIFERIDA. (See also RHIZOSOLENIA and RHOPALODIA.)

The diatom frustule consists of two *valves* – which, according to species, may each be saucer-shaped, bowl-shaped, boat-shaped etc. – held together by two or more siliceous bands (*girdle bands*) which, collectively, form the *cingulum*. In many species one valve (the *epivalve* or *epitheca*) is slightly larger than the other (*hypovalve* or *hypotheca*); the *cingulum*, which is attached to the edges of the valves, may overlap the hypovalve to a greater or lesser extent. The valves are characteristically elaborately ornamented with pores, slits, ribs, tubes, projections,

etc which are usually arranged in symmetrical, species-specific patterns. The degree of cell wall silicification may vary to some extent with environmental conditions, and exceptionally the wall may be predominantly or entirely organic (e.g. in *Phaeodactylum tricorutum* – see PHAEODACTYLUM – and in *Cylindrotheca fusiformis*). [Details of wall structure: Book ref. 137, pp. 129–156.]

Two main groups of diatoms are commonly recognized: *centric diatoms*, in which the valve is radially symmetrical, and *pennate diatoms*, in which the valve is bilaterally symmetrical. (Some diatoms do not fit easily into either category: e.g. *Triceratium* spp may have 3-, 4- or 5-fold rotational symmetry; see also HEMIDISCUS.)

Centric diatoms are mostly marine and planktonic, are non-motile, and commonly exhibit oogamous sexual reproduction in which the male gametes each bear a single tinsel flagellum. Genera include e.g. *Arachnoidiscus*, *Bacteriastrum*, *Biddulphia*, *CHAETOCEROS*, *Coscinodiscus*, *Cyclotella*, *Hemiaulus*, *MELOSIRA*, *Skeletonema*, *Stephanodiscus*, *Stephanopyxis*, *Thalassiosira*, *Zygoceros*.

Pennate diatoms occur in various habitats; many are capable of gliding motility, and many exhibit isogamous sexual reproduction involving cell–cell contact (conjugation). All species which are capable of GLIDING MOTILITY (q.v.) have a *raphe*: basically, a slit which (usually) runs the length of the valve, interrupted by a *central nodule*. Such ‘raphid’ species are generally benthic or occur attached to a solid substratum. In a few genera (e.g. *Achnanthes*, *Cocconeis*) a raphe occurs in only one of the two valves, but in most a raphe occurs in both valves. Pennate diatoms which lack a raphe (‘araphid’ diatoms: e.g. *Fragilaria*, *Striatella*, *Tabellaria*) cannot glide; these organisms may have a central line, ridge, or unornamented central area called a *pseudoraphe*. (Other pennate diatoms include e.g. AMPHORA, *Anomooneis*, *Bacillaria*, *Cylindrotheca*, *Cymbella*, *Diatoma*, *GOMPHONEMA*, *Gyrosigma*, *NAVICULA*, *Nitzschia*, PHAEODACTYLUM, *Pinnularia*, *Pleurosigma*, *Stauroneis*, *Surirella*.)

In many centric and pennate diatoms the cells adhere to one another to form filaments or characteristic groupings (see e.g. ASTERIONELLA and MELOSIRA); the cells may be held together by mucilage secreted via tubular projections in the frustule and/or by the interlocking of spines present on the margins of the valves. Secreted mucilage may also serve to attach some forms to the substratum, and apparently serves an essential role in GLIDING MOTILITY.

Asexual reproduction occurs by binary fission. The nucleus (which is diploid in vegetative cells) moves from its position near the epivalve to the cell centre, and the protoplast expands, pushing the two valves apart. New girdle bands are formed, and mitosis occurs. The original parent hypovalve becomes the epivalve of one daughter cell, and both daughter cells synthesize a new hypovalve. Thus, the epivalve is always the older of the two valves in a cell, and – in species in which the epivalve is larger than the hypovalve – one of the daughter cells must be smaller than the parent cell. When division is complete, the nucleus in each cell returns to its position near the epivalve face. The new siliceous structures (valves and cingulum) are synthesized in SILICA DEPOSITION VESICLES beneath the plasmalemma, reaching the exterior by fusion between the silicalemma and plasmalemma. [Diatom wall formation: Book ref. 137, pp. 157–200; silicon ‘biomineral’ synthesis in diatoms: TIBS (1987) 12 151–154.]

Since, in many species, the average size of cells in a population progressively decreases with increasing numbers of

## diatoxanthin

divisions, maximum cell size must eventually be re-established; this may be achieved by the formation of resting spores or auxospores. *Resting spores* generally have thick ornamented walls; on germination, the protoplast expands to maximum cell size prior to wall formation. *Auxospores* are usually or always formed as a result of fusion of gametes, after which the zygote protoplast escapes from the parent wall, expands, and then synthesizes a wall which is initially organic; a siliceous wall is then synthesized.

(See also DIATOMACEOUS EARTH.)

**diatoxanthin** See CAROTENOIDS.

**diatretyne nitrile** See POLYACETYLENES.

**Diatrypales** See ASCOMYCOTINA.

**diauxie** The phenomenon in which, when provided with two sources of carbon, an organism preferentially metabolizes one source (completely) before starting to metabolize the other; the two phases of growth are commonly separated by a lag phase in which the organism produces enzyme(s) necessary for the utilization of the second source of carbon. (See also CATABOLITE REPRESSION.)

**diauxy** *Syn.* DIAUXIE.

**diazaborines** A range of antibacterial agents [JB (1989) 171 6555–6565] which apparently inhibit fatty acid biosynthesis by inhibiting the enzyme enoyl-acyl carrier protein reductase (ENR).

**diazomycin A** See DON.

**6-diazo-5-oxo-L-norleucine** See DON.

**diazotroph** Any organism capable of NITROGEN FIXATION.

**dibromomethylisatoxin** See LYNGBYA.

**dibromomethylisopropyl-p-benzoquinone** An inhibitor of PHOTOSYNTHESIS.

**dibromopropamidine** An aromatic diamidine used as an anti-septic; it is active mainly against asporogenous Gram-positive bacteria.

**DIC** DISSEMINATED INTRAVASCULAR COAGULATION.

**dicarboximides** A group of agricultural ANTIFUNGAL AGENTS which are effective against *Botrytis cinerea*; they are used on a wide range of crops, functioning primarily as surface protectants. Dicarboximides include e.g. iprodione and vinclozolin.

**Dice–Leraas diagrams** Diagrams that are used for identifying and describing trypanosomes on the basis of their measurements (e.g. length, distances between organelles).

**Dicellomyces** See BRACHYBASIDIALES.

**dicentric** (of a eukaryotic chromosome) Having two CENTROMERES.

**dichlofluanid** A sulphur-containing ANTIFUNGAL AGENT used e.g. for the control of *Botrytis cinerea* in plants, and in antifungal washes for the prevention of mould in buildings.

**dichlone** (2,3-dichloro-1,4-naphthoquinone) A QUINONE ANTIFUNGAL AGENT used as a seed dressing (e.g., for the seeds of legumes or cotton) and as a foliar spray; it is effective against a range of diseases, including apple scab, damping off, etc. Dichlone is toxic to certain plants, and is also effective in controlling BLOOMS of certain cyanobacteria.

**dichloramine T** See CHLORINE.

**dichloroisocyanurate** (DCCA) (as an antimicrobial agent) Sodium or potassium dichloroisocyanurate, available in powder or tablet form, hydrolyses in water to form hypochlorous acid (see HYPOCHLORITES). When dry, DCCA salts are stable at room temperature.

**dichlorophane** (dichlorophene) See BISPHENOLS.

**3-(3,4-dichlorophenyl)-1,1-dimethylurea** See DCMU.

**Dichothrix** See RIVULARIACEAE.

**Dick test** A SKIN TEST used to determine whether or not an individual is susceptible to SCARLET FEVER. The test procedure (similar to that used in the SCHICK TEST) involves an intradermal injection of the erythrogenic toxin of *Streptococcus pyogenes*. A *positive* Dick test (indicating susceptibility) consists of an inflammatory response (at the site of the injection) which becomes evident within ca. 12 hours and reaches peak intensity within ca. 24 hours of the injection. In immune individuals the toxin is neutralized by antitoxin, thus giving a *negative* test.

**dicloran** An agricultural antifungal agent (2,6-dichloro-4-nitroaniline) which is used against various *Botrytis* infections. It is water-insoluble – hence very persistent – and is usually formulated as a dust; it has very low phytotoxicity. (cf. CHLORONITROBENZENES.)

**dicloxacillin** See PENICILLINS.

**Dictyocha** See SILICOFAGELLATES.

**Dictyoglomus** A genus of bacteria. One species: *D. thermophilum*, an anaerobic, caldoactive, asporogenous chemoorganotroph; cells: rod-shaped, occurring in large spherical bodies consisting of a few to many separate cells. [JJSB (1985) 35 253–259.]

**Dictyosiphon** See PHAEOPHYTA.

**dictyosome** (1) One of the stacks of membranous vesicles which form a GOLGI APPARATUS. (2) *Syn.* Golgi apparatus.

**dictyosporae** See SACCARDOAN SYSTEM.

**Dictyostelia** See EUMYCETOZOA.

**dictyostelids** See DICTYOSTELIOMYCETES.

**Dictyosteliia** See EUMYCETOZOA.

**Dictyosteliomycetes** (dictyostelid cellular slime moulds; dictyostelids) A class of cellular SLIME MOULDS (division MYXOMYCOTA). (cf. EUMYCETOZOA.) The organisms occur mainly in soil, humus and dung, particularly in tropical regions. The vegetative phase consists of myxamoebae which form filose sub-pseudopodia; flagellated cells are not formed. The life cycle involves a feeding stage, during which myxamoebae ingest food (mainly bacteria) and divide mitotically. When the food supply is exhausted, the amoebae stop growing and, after a period of starvation (*pre-aggregation phase* or ‘interphase’), the *aggregation phase* begins: numerous myxamoebae converge (chemotactically – see ACRASIN) and join together to form one to many multicellular, macroscopic pseudoplasmodia. In most species, the pseudoplasmodium can migrate over the surface of the substratum and can show tactic responses. Eventually, the pseudoplasmodium stops moving and differentiates to form a multicellular, multispored, stalked fruiting body, the *sorocarp* (a process known as *culmination*); the sorocarp stalk consists of a cellulosic ‘stalk tube’ which, when mature, is either hollow or filled with dead cells. The spores are dispersed by wind, rain, etc; on germination, each spore releases a myxamoeba, thus initiating a new cycle. (In some species myxamoebae may not always pass through this life cycle, forming instead MICROCYSTS and/or MACROCYSTS.) Genera: e.g. ACYTOSTELIUM, DICTYOSTELIUM, POLYSPHONDYLUM.

[Dictyostelids – natural history, life cycles, cultivation: Book ref. 144.]

**Dictyostelium** A genus of slime moulds (class DICTYOSTELIOMYCETES) in which the sorocarp stalk tube is filled with a mesh of empty cell walls (cf. ACYTOSTELIUM) and bears a spherical sorus of spores at its apex. In e.g. *D. discoideum* the sorocarp consists of a single unbranched stalk that tapers from base to tip; the proximal end is flared into a basal attachment disc, and the distal end bears a single, more or less spherical, white to yellowish mass (sorus) of ellipsoidal to reniform spores (each typically ca. 2.5–3.5 × 6.0–9.0 μm). In some species the sorocarp may

be sparingly and irregularly branched (cf. POLYSPHONDYLUM); in *D. polycephalum* several sorocarps occur in a coremium-like cluster in which the stalks are fused over much of their length, becoming free at their distal, spore-bearing ends. Sorocarps of *Dictyostelium* spp vary in size from e.g. ca. 0.2–0.6 mm in *D. deminutivum* to 30 mm or more in *D. giganteum*; those of *D. discoideum* may reach a maximum height of ca. 4.0–4.5 mm, but are usually smaller. [Species descriptions and key: Book ref. 144, pp. 246–367.]

During the feeding stage of the life cycle, *Dictyostelium* myxamoebae feed mainly on bacteria, but sometimes ingest other myxamoebae of the same species ('cannibalism'); *D. caveatum* is unusual in that it feeds extensively on the myxamoebae of other slime moulds as well as on bacteria. [Self/non-self recognition in *D. caveatum*: JCB (1986) 102 298–305.]

*D. discoideum* is the best-known species, being widely used in studies on differentiation and cell-cell interactions. It is easily cultured in the laboratory (e.g. on hay infusion agar or SM MEDIUM, with *Escherichia coli* or *Klebsiella pneumoniae* as food); some strains can be grown in cell-free media. (The main natural habitat of *D. discoideum* is apparently deciduous forest soils and leaf-litter.) The vegetative amoebae are commonly ca. 13–16 × 9–11 μm; they are haploid and uninucleate, and contain one or more contractile vacuoles, food vacuoles, etc. They are attracted to their prey by CHEMOTAXIS, chemoattractants apparently including e.g. folic acid released by the bacteria. When food is exhausted, cells enter the *pre-aggregation phase* (see DICTYOSTELIOMYCETES) during which the myxamoebae discharge their food vacuoles, become smaller, show altered staining properties, and lose the ability to respond chemotactically to folic acid but acquire the ability to be attracted by cyclic AMP (cAMP). Each cell contains six chromosomes, the largest being chromosome 2 (about 25% of the genome). [Sequence and analysis of chromosome 2: Nature (2002) 418 79–85.]

In *D. discoideum* the aggregation phase begins when a subset of myxamoebae begins to secrete cAMP (an ACRASIN) in slow, rhythmic pulses. The cAMP diffuses out from these cells and binds to cell-surface cAMP receptors on nearby myxamoebae. Binding of cAMP to the receptors triggers several responses in the cell: e.g., it (transiently) stimulates adenylate cyclase activity within the cell, resulting in greatly increased production and release of cAMP from the cell, and it triggers migration of the cell towards the source of the cAMP. Thus, the pulses of cAMP are progressively amplified and relayed from the initial subset of cAMP-producing cells throughout the population, resulting in the formation of converging streams of cells which move in regular steps with intervening 'rest' periods. In order to maintain the cAMP gradient and to prevent swamping of the receptors by excess cAMP, the concentration of extracellular cAMP is strictly controlled by regulation of the relative proportions of (at least) two proteins: a cAMP phosphodiesterase (which occurs in both soluble extracellular and membrane-bound forms, and which hydrolyses cAMP), and a glycoprotein phosphodiesterase inhibitor (which binds to and inactivates the soluble – but not the bound – form of the enzyme). The aggregated cells adhere to one another, eventually forming a pseudoplasmodium.

The multicellular, elongated pseudoplasmodium (called a 'slug' or 'grex') consists of a mass of cells enclosed within a slime sheath which is composed of cellulose microfibrils embedded in a protein- and carbohydrate-containing matrix. The slug varies in size (e.g. ca. 0.5–2.0 mm long) depending on the number of cells it contains. It migrates over the surface of the

substratum, exhibiting e.g. aerotaxis, phototaxis and thigmotaxis. The slime sheath does not move relative to the substratum, and may provide traction against which the cells within can move; thus, as the slug moves forwards, a slime trail of collapsed sheath material remains behind. New sheath material is synthesized along the length of the slug, so that the sheath is thinnest at the anterior end, becoming progressively thicker towards the posterior. A migrating slug can split into two smaller slugs, or two slugs can merge to form a larger slug; the size (but not the proportions) of the sorocarp which eventually develops depends on the size of the slug at culmination.

The fates of the cells during culmination are apparently determined at the slug migration stage (i.e., before culmination begins): the cells making up the anterior third of the slug are *prestalk cells*, destined to form the sorocarp stalk, while the cells of the posterior two-thirds are *prespore cells*. [Patterns of cell differentiation within the slug: Book ref. 67, pp. 255–274.] The culmination process begins when the slug stops moving and reorients such that the leading (anterior) tip is raised vertically above the rest of the cell mass, forming a nipple-like apical projection. A short cellulosic 'stalk tube initial' is secreted by cells near the apex; the entire cell mass then flattens, bringing the tube down through the cell mass to the substratum. Prestalk cells within the lower end of the tube enlarge, become vacuolated and compacted, and eventually die; the stalk lengthens upwards – the remaining prestalk cells progressively undergoing vacuolation and death to result eventually in the characteristic mesh of cellulose cell walls which fills the cellulose stalk tube. Meanwhile, the mass of prespore cells is gradually elevated on the growing stalk, becoming progressively differentiated into spores from the periphery to the centre of the mass. Differentiation is complete when all the cells have become either stalk cells or spores.

The sorocarp is usually orientated such that the sorus is at the maximum distance from the substratum or from adjacent objects (including other sorocarps); this orientation is believed to be due to a tropism regulated by an (unidentified) gas or vapour produced by the developing sorocarp.

The spores have thick cellulosic walls and are resistant to e.g. desiccation. Germination generally occurs only in the presence of an adequate supply of amino acids. Spores in masses fail to germinate owing to the presence of an autoinhibitor apparently produced during culmination.

In *D. discoideum* macrocysts may be formed, but microcysts have not been observed.

**Dictyota** See PHAEOPHYTA.

**Dictyuchus** See SAPROLEGNIALES.

**dicyandiamide** (DCD; Didin) Cyanoguanidine, a NITRIFICATION INHIBITOR. [Mineralization of DCD in acid soils: SBB (1985) 17 253–254.]

**N,N'-dicyclohexylcarbodiimide** See DCCD.

**didanosine** See NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS.

**didemnins** Cyclic depsipeptide ANTIVIRAL AGENTS isolated from Caribbean tunicates (sea-squirts); they are probably too cytotoxic for therapeutic use.

**dideoxy fingerprinting** See TUBERCULOSIS (antibiotic resistance testing).

**dideoxy sequencing** See DNA SEQUENCING.

**dideoxyribonucleotide** See NUCLEOTIDE (figure legend).

**dideoxythymidine triphosphate** See DDTP.

**Didemnis** See GYMNOSTOMATIA.

**Didin** See DICYANDIAMIDE.

**Didinium** A genus of freshwater ciliates (subclass GYMNOSTOMATIA). Cells: radially symmetrical, ovoid or barrel-shaped, ca.

## **Didymella**

60–200 µm in length; the flattened apical region has a prominent cone-shaped ‘proboscis’ at the apex of which is the cytostome. The cytopharyngeal region is reinforced with nematodesmata. The cell may be encircled by two pectinellae: one somewhat posterior of the midline, the other surrounding the base of the proboscis. The macronucleus is U-shaped. *Didinium* feeds primarily or exclusively on *Paramecium*; in the absence of food *Didinium* encysts. (See also TOXICYST.)

**Didymella** A genus of saprotrophic and plant-parasitic fungi of the order DOTHIDEALES; anamorphs occur in the genera ASCOCHYTA and PHOMA. [Taxonomy: CJB (1981) 59 2016–2042.]

**Didymium** See MYXOMYCETES.

**didymosporae** See SACCARDOAN SYSTEM.

**Dienes phenomenon** (Dienes reaction) The failure of two swarms of different strains of *Proteus* growing on the same nutrient agar plate to penetrate each other, with the result that a sharp line of demarcation always occurs between them; the phenomenon does not occur between two swarms of the same strain. The Dienes phenomenon is used to distinguish between strains of *Proteus* in epidemiological studies – the presence of a demarcation line (a positive reaction) being regarded as evidence for strain difference. (The results of a *negative* Dienes reaction may not be entirely reliable [Book ref. 22, p. 491].) The Dienes phenomenon appears to result from the production of BACTERIOCINS.

**Dientamoeba** A genus of protozoa of the TRICHOMONADIDA. *D. fragilis* occurs in the large intestine in man; it is non-pathogenic. The trophozoites (5–20 µm diam.) contain numerous vacuoles and (usually) two nuclei, each nucleus lacking peripheral chromatin and containing (usually) four closely grouped karyosomes. Pseudopodia are blunt and are formed slowly. Cysts are not formed.

**Dieterle silver stain** (Dieterle silver impregnation stain) A complex, non-specific, silver-impregnation staining procedure used e.g. for staining spirochaetes, cells of *Legionella* in tissue sections, etc.; stained bacteria appear brown or black. [Method: Book ref. 53, p. 1388.]

**N,N-diethyl-p-phenylenediamine (DPD)** See WATER SUPPLIES.

**diethylpyrocarbonate (DEPC; C<sub>2</sub>H<sub>5</sub>.O.CO.O.CO.C<sub>2</sub>H<sub>5</sub>)** DEPC is an effective inhibitor of yeasts and moulds once used as a preservative in wines etc.; owing to toxicity (and suspected carcinogenicity) it is no longer a permitted preservative in the USA and UK.

In molecular biology, DEPC is useful as a reagent for the carbethoxylation of exposed N-7 groups of (unpaired) adenine residues in DNA or RNA. It also (covalently) inactivates RNases, and is used for treating water, solutions, glassware etc. to prevent degradation of sample RNA by extraneous RNases; whenever possible, water or solutions should be treated with DEPC (0.1%) for a minimum of 1 hour at 37°C and subsequently autoclaved to eliminate any remaining DEPC.

**Dieudonné alkaline blood agar** A medium, containing defibrinated ox blood and sodium hydroxide, formerly used for the primary isolation of *Vibrio cholerae*. (cf. MONSUR MEDIUM.)

**difference spectrum** (of cytochromes) See CYTOCHROMES and CO DIFFERENCE SPECTRUM.

**differential centrifugation** See CENTRIFUGATION.

**differential display** A technique for detecting those (primarily eukaryotic) genes which are expressed only under specific conditions; it involves isolation, and comparison, of mRNAs from two or more populations, each population having been exposed to different conditions. Initially, mRNAs from each population are converted to cDNAs; this is done by using, as a primer-binding

site, the 3'-AAA... tail on polyadenylated mRNA molecules. The task is made manageable by converting only *some* of the (many) mRNAs from each population; selectivity is achieved with a primer such as 5'-TT...TTGG-3' which permits conversion of only those mRNAs in which a cytosine (C) residue occurs in the appropriate position after the 3'-AAA... tail.

cDNAs from each of the populations are then fingerprinted by subjecting them to ARBITRARILY PRIMED PCR and separating the products by gel electrophoresis. When fingerprints from different populations are compared, any band(s) of interest – such as band(s) present in one fingerprint but not in other(s) – can be further examined by removal from the gel and amplification by the same arbitrary primer; the amplified fragments may be e.g. sequenced and/or used to probe a library.

[Differential display methodology: NAR (1998) 26 5537–5543; review: Biotechniques (2002) 33 338–346.]

**differential host** (*plant pathol.*) A plant host which, on the basis of disease symptoms, serves to distinguish between various strains or races of a given plant pathogen.

**differential interference-contrast microscopy** See MICROCOPY (d).

**differential medium** See MEDIUM.

**diffluent** Readily dissolving or breaking up in water.

**Diffugia** A genus of testate amoebae (order ARCELLINIDA) in which the test is reinforced with sand grains, diatom frustules, sponge spicules etc which are initially ingested by the cell. *D. urceolata* is multinucleate and has a rounded test (ca. 200–230 × 150–200 µm) with a pointed top and a rim around the ventral aperture through which several narrow, round-ended pseudopodia emerge. *Diffugia* spp occur in ponds, swamps, bogs, soil etc.

**diffusely adherent E. coli** See ENTEROADHERENT E. COLI.

**diffusion-coupled gradostat** See GRADOSTAT.

**diffusion test** (1) In ANTIBIOTIC-sensitivity testing: any test which involves the diffusion of antibiotic(s) through agar. See e.g. DISC DIFFUSION TEST and AGAR DIFFUSION TEST.

(2) (for membrane filters) A test used to determine the physical integrity of a membrane filter (see FILTRATION). If a wetted membrane is subjected to a pressure lower than its bubble point pressure (see BUBBLE POINT TEST), some air can pass through the pores by simple diffusion; the amount of air transmitted in this way can be significant in filters of large surface area. In the diffusion test a wetted filter is subjected to pressure at ca. 80% of its bubble point pressure, and the volume of air transmitted is determined; the integrity of the filter is assessed by comparing this volume with that expected from an intact filter.

**DL-α-difluoromethylornithine** See SLEEPING SICKNESS.

**difolatan** *Syn.* CAPTAFOL.

**DIG** Abbreviation for DIGOXIGENIN.

**digenic** Refers to a parasite which carries out part of its life cycle in each of two different host species. (cf. HETEROXENOUS.)

**di George syndrome** (congenital thymic aplasia) The condition, resulting from an undeveloped thymus gland, which is characterized by a lack of T LYMPHOCYTES; those with this syndrome are susceptible to a range of infections, especially by intracellular pathogens. The condition has been treated by transplantation of fetal thymus gland (using tissue from a fetus at <14 weeks' gestation).

**digitonin** A mixture of steroid SAPONINS found in the seeds of the purple foxglove (*Digitalis purpurea*).

**digoxigenin (DIG)** A (poisonous) steroid obtained from species of the plant *Digitalis*. Digoxigenin is used e.g. as a ‘tag’ for non-radioactive labelling of oligonucleotide probes (both RNA and DNA) – see e.g. DOT-BLOT.

Incorporation of digoxigenin into RNA probes can be carried out by *in vitro* transcription on a DNA template of the target sequence using DIG-UTP in the reaction mixture; the DNA template itself may be prepared e.g. as a cloned (then linearized) target sequence carrying a promoter at the 3' end.

DIG-dUTP is incorporated into DNA probes during synthesis; this tagged nucleotide can be used as a substrate by a range of polymerases, including e.g. the KLENOW FRAGMENT, *Taq* DNA polymerase, phage T4 DNA polymerase, and at least some reverse transcriptases.

DIG-dUTP can also be covalently bound to the 3' end of DNA strands using the enzyme terminal nucleotidyltransferase.

**diguanides** (as antimicrobial agents) See e.g. CHLORGUANIDE and CHLORHEXIDINE.

**dihydrofolate reductase** See FOLIC ACID.

**dihydrofolate reductase inhibitor** See FOLIC ACID ANTAGONIST.

**dihydromocimycin** See POLYENE ANTIBIOTICS (b).

**dihydroxyerol** See WYERONE.

**dihydroxyacetone fermentation** A commercial aerobic FERMENTATION (sense 2) in which GLYCEROL is oxidized to dihydroxyacetone by strains of *Gluconobacter oxydans* ('*Acetobacter suboxydans*'). The product is used in the pharmaceutical industry and e.g. as a sun-tanning agent.

**dihydroxyacetone pathway** *Syn.* XMP PATHWAY.

**9-(3,4-dihydroxybutyl)-guanine** See DHBG.

**9-(1,3-dihydroxy-2-propoxymethyl)-guanine** See DHPG.

**(S)-9-(2,3-dihydroxy-1-propoxymethyl)-guanine** See DHPG.

**(S)-9-(2,3-dihydroxypropyl)-adenine** See DHPA.

**diiodohydroxyquin** See 8-HYDROXYQUINOLINE.

**diisopropylfluorophosphate** See PROTEASES.

**dikaryon** (dicaryon) (1) A binucleate cell, or a mycelium composed of binucleate cells, in which the two nuclei are haploid and are genetically dissimilar. (See also *secondary* HYPHA.)

(2) A pair of (usually genetically dissimilar) nuclei.

**dikaryophase** In the life cycles of some fungi: a phase characterized by dikaryotic mycelium (see DIKARYON sense 1).

**dikaryotization** Any process which leads to the formation of a DIKARYON (sense 1); it typically involves SOMATOGAMY or SPERMATIZATION in which one mononucleate cell donates its nucleus to another. (See also BULLER PHENOMENON.)

**Dileptus** A genus of carnivorous, cyst-forming ciliates (subclass GYMNOSTOMATIA). Cells: elongate, up to ca. 500  $\mu$ m in length, the anterior end having a long TOXICYST-bearing 'neck' region at the base of which is the cytostome and its associated nematodesmata; the posterior end is pointed.

**diloxanide** A synthetic amoebicide which, as e.g. diloxanide furoate ('furanide'), is effective in the treatment of some forms of amoebiasis.

**dilution coefficient** (concentration exponent;  $\eta$ ) Of a given DISINFECTANT: a number which indicates the effect of dilution on the rate of disinfection under standardized conditions. The concentration and killing rate of a disinfectant are related by the equation:

$$tc^\eta = k$$

where  $t$  is the time required for 100% kill of cells in a test suspension,  $c$  is the concentration of the disinfectant,  $\eta$  is the dilution coefficient, and  $k$  is a constant. For example, if a given undiluted disinfectant with an  $\eta$ -value of 4 is diluted by a factor of 2, the expression  $c^\eta$  becomes  $(1/2)^4$ , i.e. 1/16; thus  $t$  must increase 16-fold in order for  $tc^\eta$  to remain numerically constant. Disinfectants with high dilution coefficients – e.g. ethanol ( $\eta = 10$ ) and phenol ( $\eta = 6$ ) – lose activity with dilution more

than those with lower coefficients – e.g. chlorhexidine ( $\eta = 2$ ), QACs ( $\eta = 1$ ).

**dilution end-point assay** See END-POINT DILUTION ASSAY.

**dilution rate** ( $D$ ) In CONTINUOUS CULTURE: the parameter  $F/V$  in which  $F$  is the rate at which medium enters (and leaves) the culture vessel, and  $V$  is the volume of liquid in the vessel. Dilution rate has the same dimensions as SPECIFIC GROWTH RATE (i.e., 1/time) and its unit is hour<sup>-1</sup>. Under steady-state conditions dilution rate is numerically equal to specific growth rate. The *critical dilution rate* ( $D_c$ ) is the dilution rate which corresponds to  $\mu_{max}$ ; if the dilution rate exceeds  $D_c$  the culture is eventually diluted to extinction and is said to have undergone 'wash-out'.

**dilution test** In ANTIBIOTIC-sensitivity testing: a procedure in which an organism is tested for its ability to grow in the presence of certain fixed concentrations of a given antibiotic. (cf. DIFFUSION TEST.)

In the *agar dilution test* (= *plate dilution test*) a series of agar plates containing progressively lower concentrations of a given antibiotic (and an antibiotic-free control plate) are each surface-inoculated with the test organism and incubated; the MIC (q.v.) is indicated by the lowest concentration of antibiotic at which growth does not occur.

The *broth dilution test* (= *tube dilution test*) is essentially similar (in principle and interpretation) to the agar dilution test except that growth of the test organism is attempted in each of a series of broths containing progressively lower concentrations of antibiotic. If each broth is ca. 0.2 ml or less the process may be called a *microdilution broth test*; otherwise it is a *macrodilution broth test*.

**Dimargaritales** See ZYGOMYCETES.

**Dimastigamoeba gruberi** A former name of *Naegleria gruberi*.

**dimension** (1) (*serol.*) In GEL DIFFUSION procedures: the mode in which antibody and antigen come together in order to form precipitate. In *single dimension* tests, antigen and/or antibody diffuse through the gel in a single direction – i.e., parallel to the long axis of a gel column. In *double dimension* tests, a given reactant (antigen and/or antibody) diffuses radially outwards from a hole or 'well' cut into the gel. (See also SINGLE DIFFUSION and DOUBLE DIFFUSION.)

(2) Either stage of TWO-DIMENSIONAL ELECTROPHORESIS.

**Dimerella** See GYALECTALES.

**dimethirimol** (5-*n*-butyl-2-dimethylamino-4-hydroxy-6-methylpyrimidine) A HYDROXYPYRIMIDINE ANTIFUNGAL AGENT which is active against powdery mildews of chrysanthemums, cucurbits and sugar beet.

**dimethyldithiocarbamate** See DMDC.

**dimethylglyoxal** *Syn.* DIACETYL.

**dimethylloxazolidinedione** (DMO) See CHEMIOSMOSIS.

**dimethylsulphoxide** (DMSO; (CH<sub>3</sub>)<sub>2</sub>SO) A non-ionized polar solvent used e.g. as a cryoprotectant in FREEZING. Both hydrophilic and lipophilic substances are soluble in DMSO.

**dimetridazole** (Emtryl) 1,2-Dimethyl-5-nitro-imidazole: a NITRO-IMIDAZOLE antimicrobial agent used in veterinary medicine e.g. for the prevention and treatment of BLACKHEAD in turkeys and of SWINE DYSENTERY.

**dimictic** Of, or pertaining to, DIMIXIS.

**dimidiate** (1) Split into two. (2) Lacking – or appearing to lack – one half (applied e.g. to a semicircular, non-stipitate fungal fruiting body).

**dimitic** See HYPHA.

**dimixis** (1) *Morphological* HETEROTHALLISM. (2) One-locus two-allele physiological heterothallism.

## dimorphic fungi

**dimorphic fungi** (1) Those fungi (e.g. species of *Blastomyces* and *Candida*) which – according to environmental conditions – can grow in either of two distinct vegetative states: a unicellular ('yeast-phase') state or a mycelial state. (See GROWTH (fungal); MORPH.) (See also QUORUM SENSING.)

(2) Fungi which exhibit DIPLANETISM.

(3) *Syn.* DIOECIOUS fungi.

**din genes** In *Escherichia coli*, DNA damage-inducible genes: genes inducible in the SOS SYSTEM. For *dinB* see DNA POLYMERASE IV.

**dinactin** See MACROTETRALIDES.

**dinitrogen fixation** *Syn.* NITROGEN FIXATION.

**dinitrogenase** *Syn.* NITROGENASE.

**2,4-dinitrophenol** See PROTON TRANSLOCATORS.

**dinitrophenols** Dinitrophenols exhibit antifungal, insecticidal and herbicidal properties. AS ANTIFUNGAL AGENTS they are used mainly for the treatment of powdery mildews; they include *binapacryl* (2,4-dinitro-6-*sec*-butyl-phenyl-3-methylcrotonate), which is also an acaricide, *dinobuton* (2,4-dinitro-6-*sec*-butyl-phenylisopropylcarbonate), and *dinocap* (a mixture of three isomers of each of the compounds 2,4-dinitro-6-*sec*-octylphenol and 2,6-dinitro-4-*sec*-octylphenol in which the octyl group may be 1-methylheptyl, 1-ethylhexyl or 1-propylpentyl). *Dinocap* is generally used as the crotonate; it functions as an antifungal ERADICANT and PROTECTANT. (See also PROTON TRANSLOCATORS.)

**Dinobryon** A genus of loricate, generally colonial CHRYSOPHYTES. Each cell has two flagella of unequal length, and sits in a stalked, vase-shaped LORICA composed of helical bands of cellulose microfibrils which are laid down by the slowly rotating cell within. Following cell division, one daughter cell becomes attached to the rim of the parent lorica and secretes a new lorica around itself, so that eventually a branching, fan-shaped colony is formed.

**dinobuton** See DINITROPHENOLS.

**dinocap** See DINITROPHENOLS.

**dinoflagellates** A large group of photosynthetic and/or heterotrophic organisms regarded either as algae (e.g. class Dinophyceae, division Dinophyta) or as protozoa (see PHYTOMASTIGOPHOREA). Most dinoflagellates are unicellular and biflagellated (but cf. e.g. CYSTODINIUM, DINOTHRIX and GLOEODINIUM). The cell typically has a *theca* composed essentially of a layer of flattened membranous vesicles beneath the plasmalemma; these vesicles may be empty (in 'unarmoured' dinoflagellates such as *Gymnodinium*, *Gyrodinium*, and *Oxyrrhis*) or may each contain a cellulosic plate varying from very thin (e.g. in *Katodinium* and *Woloszynskia*) to thick (in 'armoured' dinoflagellates such as *Ceratium* and *Peridinium*). The edges of thick plates are commonly bevelled, allowing the plates to move freely relative to each other. The number of plates per cell ranges from two (e.g. in PROROCENTRUM) to several hundred, the number, form and arrangement of plates being characteristic for a given dinoflagellate. (See also e.g. CERATIUM; ORNITHOCERCUS.) On cell division, the thecal plates may be shared between the daughter cells, each cell then synthesizing new plates to replace those taken by the other; in e.g. *Gonyaulax* shedding of the theca ('ecdysis') by the parent cell occurs prior to cell division.

In the majority of dinoflagellates (including e.g. *Amphidinium*, *Ceratium*, *Glenodinium*, *Gonyaulax*, *Gymnodinium*, *Oxyrrhis*, *Peridinium* and *Woloszynskia*) the vegetative cell is divided by a transverse groove (the *girdle*, *cingulum* or *annulus*) into two parts: the *epicone* and the *hypocone*. (The corresponding thecal regions in armoured dinoflagellates are termed the *epitheca* and *hypotheca*.) A longitudinal groove, the *sulcus*, extends

perpendicularly from the girdle into the hypocone. One of the two flagella (the *transverse* flagellum) lies in the girdle and encircles the cell, while the other (*longitudinal*) flagellum arises from the sulcus and may project beyond the cell. The transverse flagellum [form and function: JP (1985) 32 290–296] is longer than the longitudinal one, is helical in shape, contains a PARAXIAL ROD, and bears a single row of fine hairs; the longitudinal flagellum may be smooth or may bear two rows of stiffer hairs. (cf. e.g. PROROCENTRUM; see also PUSULE.) Dinoflagellate cells contain contractile, non-actin filaments which are apparently responsible for cell contraction and shape changes in at least some species (*Kofoidinium* and related genera [Cell Mot. (1985) 5 1–15]).

The dinoflagellate nucleus contains chromosomes which are unique among eukaryote chromosomes in lacking centromeres and containing little or no protein; dinoflagellate nuclear organization has been considered to be intermediate between prokaryotic and eukaryotic, and has been termed 'mesokaryotic' or 'dinokaryotic'. During MITOSIS the nuclear membrane remains intact; the spindle is typically extranuclear – spindle MTs passing through the nucleus via channels lined with nuclear membrane – but in *Oxyrrhis marina* the spindle is wholly intranuclear [JCS (1986) 85 161–175].

The majority of dinoflagellates are photosynthetic, typically possessing several chloroplasts per cell and containing chlorophylls *a* and *c*<sub>2</sub>, β-carotene, and peridinin (replaced by fucoxanthin in *Glenodinium foliaceum*). Other dinoflagellates (e.g. NOCTILUCA) are colourless and heterotrophic. Both heterotrophic and photosynthetic species can apparently ingest particulate matter in the region of the sulcus.

Resistant 'resting spores' (cysts, hypnospores) are produced in some species. [Cyst formation in *Gonyaulax tamarensis*: JEMBE (1985) 86 1–13.] (cf. HYSTRICHOSPHAERIDS.) Sexual reproduction has been observed in some species.

The majority of dinoflagellates are free-living in marine, brackish or freshwater habitats, sometimes forming extensive blooms (see e.g. RED TIDE). Some dinoflagellates (e.g. species of *Gonyaulax*, *Noctiluca*, *Pyrocystis*, *Pyrodinium*) exhibit BIOLUMINESCENCE, and some produce potent toxins (see e.g. SAXITOXIN). Dinoflagellates also occur in association with other organisms: e.g. *Blastodinium* is parasitic in the intestines of copepods, *Oodinium* is a parasite of fish (see VELVET DISEASE), and '*Symbiodinium*' is an endosymbiont in various invertebrates (see ZOOXANTHELLAE).

**Dinoflagellida** See PHYTOMASTIGOPHOREA.

**dinokaryotic** See DINOFLAGELLATES.

**Dinophyceae** See DINOFLAGELLATES.

**Dinotrix** A genus of marine DINOFLAGELLATES in which the cells are non-motile and are joined together to form branching filaments.

**Diodoquin** See 8-HYDROXYQUINOLINE.

**dioecious** Refers to an organism in which the male and female reproductive structures occur in different individuals. (cf. MONOE-CIOUS.)

**dioecism** Morphological HETEROTHALLISM.

**1,2-dioxetane** A type of substrate which gives rise to CHEMILUMINESCENCE when activated by certain enzymes (examples: AMPDP and CSPD).

**dioxygenase** See OXYGENASE.

**dip-slide method** (agar-slide method) A method for detecting or estimating microbial populations on solid surfaces and in various fluids (e.g. machine-tool cooling fluids, urine samples). The dip-slide, a plastic slide coated with a sterile nutrient agar, is attached

to the inside of the cap in a screwcap cylindrical tube; for use, the cap is unscrewed and the slide is dipped into, or pressed against, the sample and it is subsequently incubated. Microbial numbers can be estimated from the number of colonies which develop on the slide. (See also COUNTING METHODS.)

**diphasic medium** Any MEDIUM, e.g. NNN MEDIUM, in which a solid (usually agar-based) component is at least partly covered by a liquid 'overlay'.

**diphasic serotypes** See H ANTIGEN (*Salmonella*).

**diphenyliodonium chloride** See IODONIUM COMPOUNDS.

**diphenylthiourea** See THIOUREA DERIVATIVES.

**diphenylurea** See CARBANILIDES.

**diphosphopyridine nucleotide** See NAD.

**diphthamide** See DIPHTHERIA TOXIN.

**diphtheria** (membranous croup) An acute infectious human disease, usually affecting children, caused by toxinogenic strains of *Corynebacterium diphtheriae*. Infection occurs by droplet inhalation or ingestion of contaminated food, milk etc. Asymptomatic carriers are often sources of infection. Incubation period: 1–10 (usually 2–5) days. Symptoms: fever, sore throat, headache, and the development of a characteristic whitish or grey membrane at the site of infection – usually the tonsils but sometimes e.g. the nasopharynx, larynx, or nose; the membrane and swelling of adjacent tissues can cause respiratory obstruction and difficulty in swallowing. Other sites occasionally affected include skin lesions or wounds (*cutaneous diphtheria*) and the genitals. The membrane results from the local effects of the DIPHTHERIA TOXIN which causes cell death and subsequent deposition of fibrin, blood cells, cellular debris, and *C. diphtheriae* cells. Local secondary infection with e.g. *Streptococcus pyogenes* (*septic diphtheria*) may occur. *C. diphtheriae* normally remains localized at the membrane, but the toxin is disseminated via the blood and lymph and can cause severe, often fatal, systemic effects – including myocarditis and nerve demyelination. *Treatment*: primarily with antitoxin. Penicillin G or erythromycin may be used in treatment and for eradication of *C. diphtheriae* from carriers. *Lab. diagnosis*: culture of *C. diphtheriae* (see CORYNEBACTERIUM) from swabs, and/or identification of the toxin (e.g. by gel diffusion tests).

[Review: RMM (1996) 7 31–42.]

**diphtheria toxin** A heat-labile protein exotoxin (MWt ca. 60000) produced by certain lysogenic strains of *Corynebacterium diphtheriae* and responsible for the symptoms of DIPHTHERIA; it is lethal for many animal species and is also cytotoxic in some types of cell culture – e.g. Vero cells are highly susceptible, though murine cells are almost totally resistant. (cf. EXOTOXIN A.)

Diphtheria toxin (DT) is encoded by *tox*, a gene carried by various temperate CORYNEPHAGES (e.g.  $\beta$ ,  $\omega$ ,  $\gamma$ ) [*tox*<sup>+</sup> corynephages (DNA relationships): Inf. Immun. (1985) 49 679–684].

The toxin is synthesized as a single polypeptide chain. The Y-shaped molecule consists of three domains: translocation domain, receptor-binding domain (RBD) and catalytic domain (CD).

Uptake of toxin involves initial binding of the RBD to a receptor protein, and internalization of the toxin within a vesicle via a clathrin-coated pit (PINOCYTOSIS). In the vesicle, CD is proteolytically cleaved but remains attached via a disulphide bond; the translocation domain undergoes an acid-induced conformational change in which it inserts into the membrane of the vesicle – apparently forming a pore through which CD is translocated into the cytoplasm of the target cell. The disulphide link undergoes reduction (scission) – releasing CD into the target cell's cytoplasm.

CD is a heat-stable fragment with resistance to cellular proteolysis. It has ADP-ribosyltransferase activity, and, in the cell,

inhibits PROTEIN SYNTHESIS by catalysing the ADP-RIBOSYLATION (inactivation) of elongation factor EF-2. (One molecule of CD can kill a sensitive cell.) In EF-2, the target for ADP-ribosylation is a rare amino acid, 'diphthamide', (2-[3-carboxyamido-3-(trimethylammonio)propyl]-histidine); diphthamide appears to occur only in EF-2 – a single residue lying within a sequence which is highly conserved in eukaryotes. [Review: TIBS (1987) 12 28–31.]

Elongation factors in members of the Archaea (formerly Archaeobacteria) appear also to contain a single diphthamide residue, and are characteristically sensitive to diphtheria toxin [Book ref. 157, pp. 379–410]. Bacteria are not susceptible to the toxin.

Synthesis of DT is repressed while the intracellular concentration of iron remains above a certain level. Repression of *tox* is mediated by a repressor protein, DtxR, which, when activated by transition metal ions, binds to the operator of the *tox* gene and blocks transcription [see Nature (1998) 394 502–506].

**diphtheroid** (1) Any non-pathogenic strain of *Corynebacterium*, particularly one isolated from the skin or mucous membranes. (2) Any strain of *Corynebacterium* other than those of *C. diphtheriae*. (3) *Syn. CORYNEFORM* (2).

**diphtheroid stomatitis** A disease of adult chickens, apparently caused by '*Spirillum pulli*' (see SPIRILLUM). Yellowish-white, firm lesions (ca. 2–20 mm), adherent to the underlying tissues, occur in the mouth, larynx and pharynx. (See also POULTRY DISEASES.)

**dipicolinic acid** (DPA) Pyridine-2,6-dicarboxylic acid; DPA occurs in bacterial ENDOSPORES, and has been reported e.g. in *Penicillium citreoviride*. In bacteria, dipicolinic acid is synthesized via a branch of the diaminopimelic acid pathway [see Appendix IV(e)]. [Characterization of spores of (mutant) *Bacillus subtilis* which lack dipicolinic acid: JB (2000) 182 5505–5512.]

**dipplanetism** In certain OOMYCETES: the phenomenon in which two types of morphologically distinct zoospore are formed at separate stages (*swarm periods*) in the asexual life cycle. *Primary zoospores* are formed in the first swarm period; in e.g. *Achlya* and *Saprolegnia*, primary zoospores are pyriform with two flagella arising at the apex. After release from the sporangium, primary zoospores may encyst directly (e.g. in *Achlya*) or may swim for some time before encysting (e.g. in *Saprolegnia*). A cyst subsequently gives rise to a *secondary zoospore*; in e.g. *Achlya* and *Saprolegnia*, secondary zoospores are reniform with two flagella arising from the concavity. After a period of swarming, secondary zoospores encyst and subsequently germinate to form a vegetative thallus. (cf. MONOPLANETISM and POLYPLANETISM.)

**Diplocalyx** See SPIROCHAETALES.

**Diplocarpon** A genus of fungi of the order HELOTIALES; anamorphs occur in the genera *Marssonina* and *Entomosporium*. *D. earlianum* causes strawberry leaf scorch. *D. rosae* causes BLACK SPOT (sense 3) of roses; the blackish acervuli of the *Marssonina* stage, bearing uniseptate conidia (the main disseminative spore), develop on leaves and/or on overwintering lesions on the shoots. The ascigerous stage can occur in overwintering leaves.

**Diplocarpon rosae virus** See MYCOVIRUS.

**diplococcin** An antibiotic, structurally related to NISIN, produced by *Lactococcus* sp.

**diplococcus** A pair of cocci (see COCCUS) – the form commonly assumed by e.g. *Enterococcus faecalis* and *Streptococcus pneumoniae* and by species of *Neisseria*.

## *Diplococcus pneumoniae*

***Diplococcus pneumoniae*** Incorrect name for *Streptococcus pneumoniae*.

**Diplodia** See SPHAEROPSIDALES.

**Diplodinium** A genus of ciliates (order ENTODINIOMORPHIDA) which occur e.g. in the RUMEN. The cytostome is close to the anterior pole of the cell; somatic ciliature is limited, cilia occurring in tufts in the oral and anteriodorsal regions. (See also DZM.) The pellicle may be drawn out posteriorly into one or more spines.

**Diploicia** A genus of placodioid LICHENS (order LECANORALES). Apothecia: lecideine, black; ascospores: brown, one-septate. *D. canescens* (formerly *Buellia canescens*) has a whitish thallus bearing whitish-grey farinose soralia; this species is common in Atlantic regions of Europe, growing on rocks, wood, bark etc. – particularly in light shade.

**diploid** Having a PLOIDY of two. (cf. HAPLOID and POLYPLOID.) In a prokaryotic cell, *partial diploid* or *merodiploid* refers to the possession of extra copies of only some of the chromosomal genes – see MEROZYGOTE.

**Diplomastigomycotina** See OOMYCETES.

**Diplomonadida** An order of protozoa (class ZOOMASTIGOPHOREA); cells contain either one (suborder Enteromonadina) or two (suborder Diplomonadina) KARYOMASTIGONTS, those containing two exhibiting twofold rotational symmetry or (in *Giardia*) bilateral symmetry. Each karyomastigont has 1–4 flagella. Mitochondria and Golgi apparatus are absent.

Members of the Enteromonadina are parasitic; cysts are formed in at least one genus. Genera: e.g. *Enteromonas*, *Trimitus*.

In the Diplomonadina each karyomastigont has four flagella, one of which is recurrent. Cysts are formed by at least some species. The suborder includes free-living and parasitic species. Genera: e.g. GIARDIA, HEXAMITA, *Trepomonas*.

**Diplomonadina** See DIPLOMONADIDA.

**diplont** (1) (*noun*) An organism in whose life cycle only the gametes are haploid. (cf. HAPLONT.) (2) The diploid form of an organism, e.g. a sporophyte (see ALTERNATION OF GENERATIONS). (3) (*diploantic*) (*adj.*) Refers to either (1) or (2) above.

**diphophage** A bacteriophage which infects *Streptococcus* ('*Diplococcus*') *pneumoniae*.

**diplophase** In organisms which reproduce sexually: the diploid phase of the life cycle (between syngamy and MEIOSIS).

**Diplonaviridae** A family proposed for all dsRNA-containing viruses; the family has not been accepted since differences in genome structure, replication and expression among dsRNA viruses are too great to be encompassed in a single family.

**Diploschistes** See GRAPHIDALES.

**diplostichomonad membrane** See PARORAL MEMBRANE.

**diplovene stage** See MEIOSIS.

**Diplothecha** See CHOANOFLAGELLIDA.

**Dipodascaceae** See ENDOMYCETALES.

**Dipodascus** See ENDOMYCETALES and GEOTRICHUM; see also AMBROSIA FUNGI.

**dipyridine ferrohaemochrome** See CYTOCHROMES.

**direct epifluorescent filter technique** See DEFT.

**direct immunofluorescence** See IMMUNOFLUORESCENCE.

**direct repeat (DR)** Either of two (or more) regions of a nucleic acid molecule in which the sequences of bases or base pairs are similar or identical and have the same polarity and orientation, e.g.:

The repeated sequences may or may not be contiguous. (cf. INVERTED REPEAT.)

**direct repeat (DR) locus** (in *Mycobacterium tuberculosis*) See SPOLIGOTYPING.

**directly observed therapy, short-course (DOTS)** See TUBERCULOSIS.

**disc** (lichenol.) The hymenial layer of an apothecium; it may be circular (flat or convex), elongated (lirelliform), or irregular in shape.

**disc diffusion test** (also: agar disc diffusion test) In ANTIBIOTIC-sensitivity testing: a DIFFUSION TEST in which the entire surface of an agar plate is inoculated with the organism under test, and several small absorbant paper discs – each impregnated with a different antibiotic – are placed at different locations on the agar surface; on subsequent incubation, antibiotics diffuse from the discs, and a zone of growth inhibition develops around each disc which contains an antibiotic to which the organism is susceptible. Precise details of the test (e.g. inoculum size, medium) commonly conform to the so-called 'Kirby–Bauer technique' [AJCP (1966) 45 493–496].

Strains of *Staphylococcus aureus* containing an *inducible*  $\beta$ -LACTAMASE commonly form zones of inhibition around discs containing an antibiotic sensitive to the enzyme; these zones are typically bordered by relatively heavy growth containing discrete colonies. (Zones formed by sensitive bacteria generally exhibit a gradual or abrupt transition between regions of growth and non-growth.) Cells close to the disc are killed before adequate amounts of  $\beta$ -lactamase can be synthesized. Cells at the periphery of the zone are exposed to gradually increasing concentrations of the (outwardly diffusing) antibiotic; such cells can synthesize sufficient  $\beta$ -lactamase to permit survival, and they give rise to relatively large colonies by using nutrients forfeited by inactivated cells in their immediate vicinity.

(cf. AGAR DIFFUSION TEST.)

**disclosing agent** See DENTAL PLAQUE.

**discocarp** *Syn.* APOTHECIUM.

**discoidins** See LECTINS.

**Discomycetes** A class of ascomycetes in which the ascocarp is typically an apothecium (though some members, e.g. *Tuber* spp. form closed, hypogean ascocarps). The class is not recognized in most modern taxonomic schemes.

**Discorbis** See FORAMINIFERIDA.

**disease** A term used loosely for any state of an individual (human, animal or plant) characterized by a deviation from the condition regarded as normal or average for members of the species or type, and which is usually wholly detrimental; exceptionally, a disease may be associated with some benefit: see e.g. sickle-cell anaemia in the entry MALARIA. A disease may be due e.g. to a metabolic or genetic defect, to infection by a PATHOGEN, or to the ingestion of a TOXIN or other poison – but not (in conventional use) to physical wounds. By custom, the term 'disease' is generally applied only to multicellular organisms – including certain multicellular microorganisms (such as mushrooms); however, analogous states occur in unicellular organisms: e.g., a bacterium may suffer metabolic or genetic lesion(s), it may be infected e.g. by a virulent bacteriophage, or it may be affected adversely by an antibiotic, a bacteriocin, or some other toxic substance.

**disinfectant** Any chemical agent used for DISINFECTION; disinfectants which are non-injurious to human or animal tissues may also be used as ANTISEPTICS. (cf. PRESERVATIVES.) Disinfectants for general use should be active against a wide range of common pathogens and should be microbicidal rather than microbistatic at the concentrations used; microbistatic disinfectants may become microbistatic when diluted, and at low concentrations some disinfectants can be metabolized by certain

organisms – e.g. *Pseudomonas* spp can metabolize phenol. A given disinfectant may be effective against only one particular category of organisms (e.g. Gram-negative bacteria), but is not necessarily effective against all species in that category. Most disinfectants are primarily antibacterial, but some are also (or primarily) antifungal or antiviral; most disinfectants have little or no activity against bacterial ENDOSPORES. (See also ACRIDINES; ALCOHOLS; BISPHENOLS; CHLORINE; FORMALDEHYDE; HEAVY METALS; HYPOCHLORITES; IODINE; OXIDIZING AGENTS; PHENOLS; PINE DISINFECTANTS; QUATERNARY AMMONIUM COMPOUNDS; SALICYLIC ACID.)

Different disinfectants may require different conditions for maximum effectiveness. Important factors include e.g. pH (cf. CHLORHEXIDINE and HYPOCHLORITES), the presence or absence of organic matter (cf. CHLORINE and ACRIDINES), and humidity (see e.g. FORMALDEHYDE). The detergent properties of QUATERNARY AMMONIUM COMPOUNDS permit them to penetrate grease barriers which may protect organisms from non-detergent disinfectants. In general, the activity of a disinfectant rises with temperature (see TEMPERATURE COEFFICIENT) and concentration (see DILUTION COEFFICIENT). The action of some disinfectants is reversible; thus e.g. endospores inactivated by mercuric ions may germinate after exposure to hydrogen sulphide (which combines with mercuric ions). The efficacy of a disinfectant may be estimated by certain tests – see e.g. CAPACITY TEST; CARRIER TEST; CHICK–MARTIN TEST; KELSEY–SYKES TEST; PHENOL COEFFICIENT; RIDEAL–WALKER TEST; SUSPENSION TEST; USE-DILUTION TEST.

**disinfection** The destruction, inactivation or removal of those microorganisms likely to cause infection or other undesirable effects (e.g. spoilage); disinfection does not normally involve STERILIZATION. The term ‘disinfection’ commonly refers to the use of chemical agents (DISINFECTANTS) for the treatment of inanimate objects and surfaces; however, it is sometimes also used to refer to ANTISEPSIS.

Disinfection can also be achieved by physical procedures such as PASTEURIZATION and TYNDALLIZATION. (See also ULTRAVIOLET RADIATION and LOW-TEMPERATURE STEAM DISINFECTION.) A PULSED ELECTRIC FIELD technique may have applications e.g. in the food industry; this approach has been used e.g. to reduce significantly the numbers of viable cells of *Mycobacterium paratuberculosis* in milk [AEM (2001) 67 2833–2836].

[Disinfection kinetics: JAM (2001) 91 351–363.]

**disjunctor cells** Cells which occur between spores in a chain of spores; their disintegration may aid spore release. (cf. NECRIDIUM.)

**disk** See DISC.

**dislodgement** (*mol. biol.*) The phenomenon (mechanism unknown) in which the introduction of a second, compatible, plasmid into a cell sometimes causes the elimination of the resident plasmid.

**disodium phosphonoacetate** See PHOSPHONOACETIC ACID.

**displacement loop** See e.g. D LOOP and R LOOP.

**displacement vector** *Syn.* REPLACEMENT VECTOR.

**disporic** Of a coccidian oocyst: containing two sporocysts.

**disseminated intravascular coagulation** (DIC) A condition characterized by an imbalance between pro- and anticoagulant activities within the blood vascular system, resulting in the formation of disseminated clots; DIC is usually a result of sepsis, but other causes include tissue necrosis, hypothermia and some types of snake bite.

DIC is incited when bacterial components (such as LIPO-POLYSACCHARIDE) bind to specific receptors on endothelium and leukocytes; this stimulates the release of a number of CYTOKINES – including the pro-inflammatory TNF- $\alpha$ , IL-1 and IL-6.

Cytokine activity appears to promote coagulation and also to inhibit anticoagulant activity. Additionally, cytokines upregulate CELL ADHESION MOLECULES on the endothelial membrane; adhesion molecules contribute to coagulopathy by binding monocytes and platelets. Activated platelets are degranulated, releasing various products (including fibrinogen); moreover, the platelet membrane gives rise to the potent vasoconstrictor thromboxane A<sub>2</sub>.

Initiation of coagulation apparently involves cytokine-mediated upregulation of an endothelial membrane protein, *tissue factor* (TF), which is believed to play a key role in triggering the coagulation cascade. In an animal model, anti-TF antibodies were able to limit coagulopathy in the presence of *Escherichia coli* sepsis.

In vivo, the inhibitor of TF is a protein synthesized in the endothelium: *tissue factor pathway inhibitor* (TFPI); in at least some studies, the level of TFPI appears to be reduced in cases of DIC.

[Disseminated intravascular coagulation: BCH (2000) 13 179–197.]

**dissepiment** In a polypore: the tissue which lies between, and supports, the pores. (cf. TRAMA.)

**dissimilatory nitrate reduction** Energy-yielding (respiratory) metabolism in which nitrate is reduced to e.g. nitrite, nitrous oxide, dinitrogen or ammonia, the product(s) typically being excreted: see DENITRIFICATION and NITRATE RESPIRATION. (cf. ASSIMILATORY NITRATE REDUCTION.)

**dissimilatory perchlorate reduction** See BIOREMEDIATION.

**dissimilatory reduction of nitrate to ammonia** A respiratory process carried out by certain bacteria (e.g. species of *Enterobacter* and *Vibrio*) and reported to occur in habitats such as marine sediments. The process appears to occur more readily when the concentration of nitrate is low – higher concentrations of nitrate being reduced to nitrite and correspondingly smaller amounts of ammonia [FEMS Ecol. (1996) 19 27–38]. (cf. DISSIMILATORY NITRATE REDUCTION.)

**dissimilatory sulphate reduction** (sulphate respiration) The use of sulphate (or other oxidized compound of sulphur) as terminal electron acceptor in the anaerobic respiratory metabolism of the SULPHATE-REDUCING BACTERIA. Initially, sulphate is ‘activated’, i.e., converted to adenosine-5’-phosphosulphate (APS) in an energy-requiring reaction (enzyme: sulphate adenylyl transferase):

This reaction is encouraged by the hydrolysis of PPi; the pyrophosphatase involved is inactivated under aerobic conditions, so that ATP is conserved when growth cannot occur.

The reduction of APS is catalysed by adenylyl sulphate reductase in the reaction:

Sulphite is reduced to sulphide by an enzyme complex which, in many species of sulphate-reducing bacteria, includes e.g. DESULFOVIRIDIN. Different intermediates (e.g. thiosulphate, trithionate) have been reported from in vitro studies on sulphite reduction; these intermediates may or may not occur in vivo – or may occur in only some species. A small amount of reduced sulphur is assimilated, but nearly all is eliminated as H<sub>2</sub>S (cf. ASSIMILATORY SULPHATE REDUCTION).

The reduction of APS and sulphite involves electron transport via e.g. *c*- and/or *b*-type cytochromes, and is accompanied by OXIDATIVE PHOSPHORYLATION. In many species electrons are

## disassimilatory sulphur metabolism

derived from the oxidation of certain organic substrates to e.g. acetate; in e.g. *Desulfovibrio postgatei* and *Desulfovibrio baarsii* electrons can be derived from the oxidation of acetate to CO<sub>2</sub>. Some sulphate-reducing bacteria can grow mixotrophically, gaining energy from the oxidation of H<sub>2</sub> (at the expense of sulphate) and using acetate and CO<sub>2</sub> as sources of carbon.

In vitro inhibition of sulphate reduction can be achieved e.g. with chromate, molybdate, monofluorophosphate or selenate ions; molybdate appears to form an analogue of APS, thus depleting the cell of ATP.

(See also SULPHUR CYCLE.)

**disassimilatory sulphur metabolism** See DISSIMILATORY SULPHATE REDUCTION, SULPHUR-OXIDIZING BACTERIA, SULPHUR-REDUCING BACTERIA and THIOBACILLUS.

**dissociation** (*bacteriol.*) A phenotypic change in a given strain (see e.g. SMOOTH-ROUGH VARIATION). (cf. SALTATION.)

**dissymmetry ratio** See BASE RATIO.

**distamycin A** See NETROPSIN.

**distemper** (*vet.*) (1) *Syn.* CANINE DISTEMPER. (2) *Syn.* STRANGLES.

**Distigma** See EUGLENOID FLAGELLATES.

**distoseptum** See SEPTUM (b).

**Distrene-80** A high-MWt polystyrene (see DPX).

**distromatic** Refers to a structure which is two cells thick (see e.g. ULVA). (cf. POLYSTROMATIC.)

**ditalimfos** See ORGANOPHOSPHORUS COMPOUNDS.

**dithanes** See MANEB (dithane M-22), NABAM (dithane D-14) and ZINEB (dithane Z-78).

**dithianon** (2,3-dicyano-1,4-dihydro-1,4-dithia-anthraquinone) A QUINONE ANTIFUNGAL AGENT used e.g. for the control of apple scab and other fungal diseases of apples and related fruits; it is not effective against apple mildew.

**dithiocarbamates** Dithiocarbamates (salts of dithiocarbamic acid derivatives: R<sub>2</sub>N.CS.SH) include several agricultural ANTIFUNGAL AGENTS (e.g. METHAM SODIUM) and preservatives for paper and board; the antifungal activity of at least some dithiocarbamates appears to depend on their conversion to substances which are more highly fungitoxic – methylisothiocyanate in the case of metham sodium. (See also BISDITHIOCARBAMATES; DMDC; THIURAM DISULPHIDES.)

**dithiothreitol** See MUCOLYTIC AGENT.

**Diuron** *Syn.* DCMU.

**divercin V41** A 43-amino-acid BACTERIOCIN produced by *Carnobacterium divergens* strain V41 [Microbiology (1998) 144 2837–2844].

**divergent trama** See BILATERAL TRAMA.

**divergent transcription** Transcription of different genes (on the same DNA molecule) in opposite directions. When divergent transcription occurs from closely spaced promoters, the (transcription-dependent) generation of negative supercoiling behind each advancing polymerase causes an increase in negative superhelicity in the region between the active polymerases; this increase in superhelicity may affect the expression of genes or operons [Mol. Microbiol. (2001) 39 1109–1115].

**division** A taxonomic rank (see TAXONOMY and NOMENCLATURE).

**dizoo** Of a coccidian oocyst: containing two sporozoites per sporocyst.

**DLVO theory** See ADHESION.

**DMDC** DimethylDITHIOCARBAMATE; DMDCs have antifungal (and antibacterial) activity and are used in agriculture as broad-spectrum antifungal agents – e.g. for the treatment of fruit and vegetables and as a constituent of seed and turf dressings. DMDCs include *ferbam*, [(CH<sub>3</sub>)<sub>2</sub>.N.CS.S]<sub>3</sub>Fe, and *ziram*, [(CH<sub>3</sub>)<sub>2</sub>.N.CS.S]<sub>2</sub>Zn. Oxidation of dimethyldithiocarbamic acid gives THIRAM.

**DMO** 5,5-Dimethyl-4-oxazolidinedione: see CHEMIOSMOSIS.

**DMSO** DIMETHYLSULPHOXIDE.

**DNA** Deoxyribonucleic acid: a NUCLEIC ACID consisting of deoxyribonucleotides, each of which typically contains one of the bases adenine, guanine, cytosine and thymine (cf. e.g. BACTERIOPHAGE and DNA METHYLATION). (See also RNA.) DNA is the repository of genetic information in all cells and in many VIRUSES (see GENETIC CODE). In eukaryotes DNA occurs chiefly in CHROMOSOMES but also in organelles: see MITOCHONDRION (mtDNA), CHLOROPLAST (ctDNA) and KINETOPLAST; in prokaryotes DNA constitutes the CHROMOSOME. (See also PLASMID.) DNA can be detected in situ by specific STAINING (see e.g. ACRIDINE ORANGE, DAPI, FEULGEN REACTION).

A single chain of deoxyribonucleotides (*single-stranded DNA*, = ssDNA) occurs in some viruses, usually as a covalently closed 'circle' (ss cccDNA) (see e.g. SSDNA PHAGE; cf. PARVOVIRIDAE).

In cells and in many viruses DNA is normally *double-stranded* (dsDNA, duplex DNA): the two strands are held together by Watson–Crick BASE PAIRING between bases on opposite strands; thus, the base sequence of each strand is *complementary* to that of the other. The two strands in dsDNA are *antiparallel*, i.e., orientated 'head-to-tail' (5'...3' adjacent to 3'...5'). Under physiological conditions the two strands are usually twisted around a common axis to form a *double helix*. In its commonest form (the Watson–Crick double helix, or B-DNA) the helix is right-handed (i.e., when viewed from one end it winds away from the viewer in a clockwise direction) with on average ca. 10.4 base pairs (bp) per turn, each turn being ca. 3.4 nm long and ca. 2 nm in diameter. The (planar) bases are stacked roughly perpendicular to the helix axis but with a propeller twist of ca. 11.5–17.3° between the bases in each pair. Two spiral grooves are discernible in B-DNA: the *minor groove*, located between the two strands, and the *major groove*, which runs between the turns of the helix. Substituents on the bases protrude into these grooves and are thus accessible e.g. for recognition by enzymes. B-DNA is now thought to have local variations in conformation which seem to reflect the nature of the local base sequences; this may further assist specific recognition of particular base sequences by proteins. In vivo the double helix is stabilized by hydrophobic interactions between the stacked bases, and by neutralization of the charges on the phosphate groups by e.g. divalent metal ions or (possibly) POLYAMINES in bacteria, or by HISTONES in eukaryotes.

dsDNA may adopt different helical conformations under different conditions [review: ARB (1982) 51 395–427]. For example, A-DNA is a right-handed helix with ca. 11 bp/turn and bases tilted at an angle to the helix axis; the bases are relatively inaccessible, the sugar–phosphate backbone being the most prominent part of the molecule. A-DNA occurs in vitro e.g. at low (75%) relative humidity in the presence of Na<sup>+</sup>, K<sup>+</sup> or Cs<sup>+</sup> as counterion; in vivo a similar conformation occurs e.g. in DNA–RNA hybrid duplexes and probably also in dsRNA. (cf. Z-DNA; see also HAIRPIN; CRUCIFORM.)

In most bacterial chromosomes and plasmids, certain viruses, mitochondria and chloroplasts, the DNA is double-stranded and covalently closed 'circular' (ds cccDNA), i.e., it has no free 3' or 5' ends. Such DNA can occur in distinct topoisomeric forms (see TOPOISOMER). *Relaxed* cccDNA can be regarded as linear B-DNA with covalently joined ends, i.e., the molecule can theoretically lie in a plane, without strain, with a pitch (*p*) of ca. 10.4 bp/turn. The number of times one strand winds around the other in any ds cccDNA molecule *lying in a plane*

is called the *linking number* (= *topological winding number*) of that molecule and is designated  $Lk$  (or  $\alpha$ ); by convention, linking numbers are designated positive in right-handed helices. In a relaxed molecule, the linking number is the same as that of an equivalent B-DNA molecule (ca.  $N/10.4$  where  $N$  = the number of base pairs in the molecule) and is called the *duplex winding number*,  $Lk_0$  (or  $\beta$ ). The linking number of any cccDNA molecule is a topological property of that molecule; it cannot change without strand breakage. If a relaxed molecule is broken and the broken ends are twisted (in either direction) before rejoining, the linking number of the resulting molecule will be greater or less than  $Lk_0$ . Such a molecule is under strain (envisaged as a tendency to restore the stable pitch of ca. 10.4 bp/turn); a nick in one strand would allow rotation of the intact strand at the site of the nick and, hence, relaxation of the molecule. Unlike a relaxed molecule, the strained molecule can lie in a plane only if forced to do so, such constraint necessarily causing a deviation in pitch from 10.4 bp/turn. When such a molecule is *unconstrained*, the pitch of the helix is kept as nearly as possible to 10.4 bp/turn by contortion of the molecule such that the axis of the double helix itself becomes helical; this contortion is termed *writhe*, and the molecule is said to be *supercoiled* or *superhelical*. (See also DNA I, DNA II, etc.) Supercoiled DNA is much more compact than equivalent relaxed or linear DNA and thus has a much higher sedimentation coefficient and lower viscosity.

When all the strain of supercoiling is accommodated by writhe, the amount of writhe (*writhing number*,  $Wr$  – i.e., the number of superhelical turns) in a given cccDNA molecule is indicated by the *superhelix winding number*,  $\tau$ , given by the difference between the linking number of the supercoiled molecule and that of the equivalent relaxed molecule:  $\tau = Lk - Lk_0$ . If the molecule has *fewer* turns than the equivalent relaxed molecule (i.e., the molecule is *underwound*),  $Lk < Lk_0$ , and  $\tau$  is negative (i.e., the molecule is negatively supercoiled). If the molecule is *overwound*,  $Lk > Lk_0$ ,  $\tau$  is positive. (When  $Lk = Lk_0$ ,  $\tau = 0$ , and the molecule is relaxed.) In general, naturally occurring supercoiled DNA is negatively supercoiled (cf. REVERSE GYRASE). The *superhelical density*,  $\sigma$ , of a given molecule is the number of superhelical turns per turn of the helix in relaxed DNA, i.e.,  $\sigma = 10.4\tau/N$ .

The equation  $\tau = Lk - Lk_0$  assumes that the pitch of the double helix, and hence the number of turns in the helix, remains constant (at the value for the relaxed molecule,  $Lk_0$ ), so that any supercoils are accommodated entirely by writhe. However, the strain of supercoiling may force a change in pitch, and hence a change in the number of turns in the double helix – the actual number of turns, the *twist* ( $Tw$ ), being related to the pitch ( $p$ ) of the helix by the expression  $Tw = N/p$ ; by convention,  $Tw$  is positive for a right-handed helix. Pitch, and hence twist, can also be altered by the insertion of an INTERCALATING AGENT. Twist differs from the linking number in that, in a given cccDNA molecule, the amount of twist can vary depending on the amount of writhe; the linking number is invariable and is the sum of twist and writhe. Thus,  $Wr = Lk - Tw$ , and, since  $Lk$  is constant for a given molecule, any change in writhe must be accompanied by an equal and opposite change in twist, and vice versa; when  $Tw = Lk_0$ ,  $Wr = \tau$ , and when  $Wr = 0$ ,  $Tw = Lk$ . [PNAS (1976) 73 2639–2643.]

The positive free energy associated with negative supercoiling has a number of important consequences for the biological behaviour of DNA. It facilitates the formation of certain secondary structures (e.g. HAIRPINS, CRUCIFORMS, localized regions

of z-DNA) and also the unwinding of DNA strands e.g. during DNA REPLICATION, RECOMBINATION, TRANSCRIPTION, etc. The degree of supercoiling of DNA in vivo is controlled by enzymes called TOPOISOMERASES.

Normal cellular function requires that the degree of supercoiling be maintained within certain limits. In some circumstances – e.g. during the transition from aerobic growth to anaerobic growth – there is a fall in the cell's energy charge and a corresponding, transient fall in 'global' (i.e. overall) superhelical density; such changes in superhelicity alter the expression of a range of genes (e.g. by affecting the activity of their promoters). *Local increases* in superhelicity (i.e. in specific regions of the DNA molecule) can be brought about by divergent transcription from closely spaced promoters; such increased negative superhelicity may affect the expression of particular genes/operons [Mol. Microbiol. (2001) 39 1109–1115].

Pure linear dsDNA clearly cannot be supercoiled. However, linear dsDNA (and discrete regions or *domains* within linear or ccc dsDNA) can maintain a superhelical conformation if there is a constraint on the rotation of the double helix to prevent unwinding of the supercoils (see CHROMATIN and CHROMOSOME (bacterial)).

Certain drugs exert their toxic effects by binding to DNA; the drug may bind e.g. to the major or minor grooves of dsDNA (see e.g. NETROPSIN) or may intercalate between the base-pairs (see INTERCALATING AGENTS). [DNA structure and its perturbation by drug binding (review): Bioch. J. (1987) 243 1–13.]

See also GC%; DNA HOMOLGY; THERMAL MELTING PROFILE.

**DNA I** Supercoiled ds cccDNA (see DNA).

**DNA I'** *Syn.* DNA IV (q.v.).

**DNA II** Nicked relaxed circular dsDNA formed by an ss 'nick' in DNA I.

**DNA III** Linear dsDNA derived from DNA I or DNA II by strand breakage.

**DNA IV** (DNA I') Relaxed (intact) ds cccDNA (see DNA).

**DNA base composition** See e.g. BASE RATIO and GC%. (See also DNA HOMOLGY.)

**DNA binding protein** (1) *Syn.* SINGLE-STRAND BINDING PROTEIN. (2) In general: *any* non-enzymic protein which binds to ssDNA or dsDNA – e.g. a repressor protein, or a single-strand binding protein.

**DNA blotting** See BLOTTING.

**DNA chip** A microarray of short, single-stranded DNA molecules – having diverse (but known) sequences – immobilized on a small piece ('chip') of glass, silicon or plastic. The immobilized DNA molecules commonly function as PROBES. A chip can be used e.g. to determine the sequence of an unknown, labelled, single-stranded fragment of nucleic acid by testing the ability of the fragment to hybridize with a *particular* probe in the array, hybridization being detected by the fragment's label – using e.g. confocal epifluorescence microscopy.

A large microarray of probes can cover all possible combinations of nucleotides for a strand of given length. For example, a complete set ( $4^8$ ) of nucleotide combinations for an 8-nucleotide probe – 65536 different probes – can be synthesized on a 1 cm<sup>2</sup> glass chip.

Chips are useful e.g. for detecting mutations, including those that confer resistance to antibiotics. Thus, that section of a genome in which mutations confer resistance to particular antibiotic(s) can be amplified (e.g. by PCR using fluorophore-labelled primers), and the amplicons tested against a microarray which includes all possible mutations (as well as the wild-type sequence). For example, the protease gene in clade B

## DNA cloning

isolates of the human immunodeficiency virus (HIV-1) has been investigated in this way with the object of linking particular mutations with resistance to protease inhibitors [Nature Medicine (1996) 2 753–759].

Chip technology can also be used for examining the differential expression of genes: with an array of immobilized, single-stranded cDNAs (which bind mRNAs of expressed genes), fluorophore-labelled probes (with binding sites elsewhere on the mRNA molecules) can be used to detect those genes which are active under specific conditions.

Chips can be made by (i) immobilizing pre-existing molecules, or (ii) 'on-chip synthesis' – in which high-speed robotic devices can synthesize a vast range of nucleotide combinations on a single chip.

One problem with microarrays is that (single-stranded) DNA probes have a tendency for intra-strand base-pairing – which may obscure target sequences. A possible solution may be the use of microarrays containing PNA probes because PNA–DNA hybridization can occur in the absence of salts (that is, under conditions which inhibit intra-strand base-pairing in ssDNA).

Among the growing number of published uses, high-density arrays have been used to identify species of *Mycobacterium* and (*simultaneously*) to test for resistance to rifampicin [JCM (1999) 37 49–55].

The need to include a sufficiently comprehensive range of probes for a given investigation has been demonstrated in another study in which non-clade-B strains of HIV-1 were examined for resistance to antiretroviral agents using an assay system designed for clade B isolates of HIV-1; the assay was unsatisfactory for non-clade-B isolates – indicating the need to ensure that future assays can accommodate newly emergent strains of HIV-1 [JCM (1999) 37 2533–2537].

[DNA chips (reviews): Nature Biotech. (1998) 16 27–31 & 40–44; TIBtech. (1999) 17 127–134. Biomedical discovery with DNA arrays (review): Cell (2000) 102 9–15.]

**DNA cloning** See CLONING.

**DNA delay mutant** A mutant of BACTERIOPHAGE T4 which, on infection of a host cell, shows delayed synthesis of T4 DNA (particularly in *Escherichia coli* B strains) and a reduced burst size. The mutation occurs in genes 39, 52 or 60 – genes encoding subunits of the T4 TOPOISOMERASE; a DNA delay mutant requires a functional host GYRASE for replication, the gyrase presumably replacing T4 topoisomerase in an essential function in the initiation of early DNA replication.

**DNA-dependent RNA polymerase** See RNA POLYMERASE.

**DNA–DNA hybridization** See DNA HOMOLOGU.

**DNA fingerprinting** (chromosomal fingerprinting; also: restriction enzyme analysis, restriction endonuclease analysis, REA) A method used for TYPING. Essentially, chromosomal DNA, isolated from a culture of the given strain, is first cleaved by a RESTRICTION ENDONUCLEASE; the fragments (of many different lengths) are then separated by gel electrophoresis into a series of bands – which are stained. The pattern of bands, reflecting the cutting sites of the given RE in the chromosome, is the *fingerprint* of the strain. Strains which differ e.g. through loss or gain of a restriction site (perhaps through a point mutation) will give different fingerprints; similarly, insertion or deletion mutations (or e.g. insertion/excision of phage DNA) will alter the length of particular fragments and will also give rise to changes in the fingerprint. Hence, strains can be typed on the basis of their fingerprints.

One problem with this method is that it may yield too many fragments – giving a complex fingerprint which is difficult to

interpret. One solution to the problem is to use a 'rare-cutting' RE (see table in RESTRICTION ENDONUCLEASE); this gives fewer, larger fragments that can be analysed e.g. by PFGE.

Alternatively, the original procedure can be carried out with additional use of a labelled probe that reveals only those (few) fragments to which the probe binds; an example of this approach is RIBOTYPING (q.v.).

[Evidence from DNA fingerprinting of endoscopic cross-infection in post-endoscopic acute gastritis (*Helicobacter pylori*): JCM (2000) 38 2381–2382.]

(See also FINGERPRINTING.)

**dna genes** In *Escherichia coli*: those genes whose products are involved in at least some types of DNA REPLICATION. See separate entries for genes *dnaA*, *dnaB*, *dnaC* (= *dnaD*), *nrpA* (= *dnaF*), *dnaI*, *dnaJ*, *dnaK*, *dnaP* and *dnaT*. For *dnaE*, *dnaN*, *dnaQ*, *dnaX* and *dnaZ* (= *dnaH*) see DNA POLYMERASE. For *dnaG* see PRIMASE. For *dnaW* see *adk* gene.

**DNA glycosylase** See ADAPTIVE RESPONSE and URACIL-DNA GLYCOSYLASE.

**DNA gyrase** *Syn.* GYRASE.

**DNA helicases** *Syn.* HELICASES.

**DNA homology** The degree of similarity ('relatedness') between base sequences in different DNA molecules (or in different parts of the same DNA molecule); two DNA molecules which are 100% homologous have identical sequences of nucleotides.

In microbial TAXONOMY the degree of homology between samples of chromosomal DNA from different organisms can be used to indicate the taxonomic relationship of the organisms. The homology between two samples of dsDNA can be assessed by various indirect methods (as well as by sequencing each sample and making a direct comparison of the nucleotides); two approaches are outlined below.

In *DNA–DNA hybridization*, single-stranded (heat-denatured) chromosomal DNA from one test strain (strain A) is bound to a membrane (e.g. nitrocellulose). Chromosomal DNA from another test strain (strain B) is fragmented (for example, by ULTRASONICATION) and the fragments denatured by heat to single-stranded pieces. Similar, single-stranded fragments are also made from *labelled* DNA of strain A. Under appropriate conditions, the unlabelled, single-stranded DNA from strain A (which is bound to the membrane) is then exposed to the single-stranded fragments from strains A and B; the concentration of B fragments is very much higher than that of the A fragments. This allows the fragments to hybridize, by base-pairing, with complementary sequences in the bound DNA.

The fragments from strains A and B compete for sequences on the bound DNA. However, the concentration of B fragments is very much higher than that of A fragments; consequently, if strains A and B are very similar, few (if any) of the (*labelled*) A fragments will hybridize. On the other hand, if strains A and B are very different many of the A fragments will hybridize. Thus, the similarity between strains A and B is indicated by the number of A fragments which hybridize; this can be determined by measuring the label on the A fragments after all unbound fragments have been washed away. Such an assay requires controls; in one control, the assay is carried out with only labelled A fragments – this indicating the maximum amount of binding by A fragments. Results are meaningful only if the A fragments hybridize stably; the stability of binding can be assessed by monitoring the dissociation of A fragments from the bound DNA as the temperature is gradually raised.

Homology may also be assessed by comparing the *thermal stability* of HETERO-DUPLEXES formed from two samples of DNA

with the thermal stability of the corresponding homoduplexes. This involves determining the mid-point temperature [ $T_m$ ] of the thermal melting curve of both the homoduplexes and heteroduplexes (see THERMAL MELTING PROFILE). The homology of DNAs from strains A and B are then assessed by comparing the  $T_m$  of the A homoduplexes with that of A–B heteroduplexes – the difference between the two values of  $T_m$  [=  $\Delta T_m$ ] indicating the degree of base pair mis-matching in the heteroduplex.

[Methods for determining the homology of nucleic acids: Book ref. 138, pp 33–74.]

**DNA ligase** A LIGASE which can make a phosphodiester bond between the 3'-OH end of one ssDNA strand and the (physically juxtaposed) 5'-phosphate end of the same or another ssDNA strand; thus, e.g., a DNA ligase can repair a NICK in one strand of a dsDNA molecule, the ends being held in position by base-pairing with the intact strand. (See also e.g. DNA REPLICATION.)

**DNA looping** (transcriptional control) See OPERATOR.

**DNA methylation** Methylation of certain bases in DNA: a normal process which occurs in many or most organisms. In prokaryotes, methylation typically occurs at the N-6 position of adenine and/or at the C-5 position of cytosine, while in most eukaryotes methylation occurs mainly at the C-5 position of cytosine; the bases which are methylated generally occur in a specific sequence of nucleotides – e.g. the second cytosine residue in the sequence CC(A/T)GG is methylated in *Escherichia coli* strain C. (See also DAM GENE and FROG VIRUS 3.)

Methylation serves various functions: see e.g. RESTRICTION-MODIFICATION SYSTEM. It also promotes a certain type of SPONTANEOUS MUTATION. (See also MISMATCH REPAIR.)

[DNA methylation: molecular biology and biological significance: Book ref. 222.]

**DNA modification** A physiological process in which bases in DNA are substituted with methyl or other groups – commonly shortly after synthesis of the DNA (see e.g. DNA METHYLATION; cf. BACTERIOPHAGE MU and BACTERIOPHAGE T4). Modification may occur as part of a RESTRICTION-MODIFICATION SYSTEM or may be involved e.g. in the regulation of gene expression (cf. DAM GENE).

**DNA photolyase** See PHOTOREACTIVATION.

**DNA polymerase** A type of enzyme which forms a polymer of deoxyribonucleotides by condensing deoxyribonucleoside triphosphates (dNTPs) with the elimination of pyrophosphate. A DNA polymerase adds nucleotides to the 3'-OH end of a pre-existing strand of DNA or an RNA primer; the order in which the nucleotides are added is dictated by the nucleotide sequence of a template strand of DNA (see DNA REPLICATION) or, in some cases, RNA (see REVERSE TRANSCRIPTASE). DNA polymerases function processively (see PROCESSIVE ENZYME).

*Prokaryotic DNA polymerases.* The bacterium *Escherichia coli* encodes three main DNA polymerases which are designated I, II and III (see also DNA POLYMERASE IV and DNA POLYMERASE V). All three main polymerases have exonuclease activity as well as polymerase activity; all can remove nucleotides sequentially from the 3' end of a strand, and polymerases I and III can also cleave nucleotides from the 5' end. (See also KLENOW FRAGMENT.) The 3'-to-5' exonuclease activity of a DNA polymerase is required for proof-reading during DNA REPLICATION.

*Polymerase I* (Kornberg enzyme, product of gene *polA*) is active in DNA repair (see EXCISION REPAIR); it is also involved in the removal of RNA primers during DNA replication, and is needed for the replication of certain plasmids (e.g. ColE1). Polymerase I can act as an RNA-dependent DNA polymerase (i.e. a reverse transcriptase) but it exhibits poor processivity in

this capacity and requires longer incubation times compared with a reverse transcriptase [EMBO (1993) 12 387–396].

*Polymerase II* (*polB* product) is induced in the SOS SYSTEM (q.v.).

*Polymerase III* is the main replicative enzyme in *E. coli* and is responsible for replication of the chromosome and of phage DNA etc. 'DNA polymerase III' refers to a *core enzyme* consisting of three different subunits: (i) subunit  $\alpha$  (product of *dnaE/polC*), which is involved in polymerization; (ii) subunit  $\epsilon$  (product of *dnaQ/mutD*), which has 3'-to-5' exonuclease activity and is apparently involved in proof-reading [PNAS (1983) 80 7085–7089] (see also MUTATOR GENE); and (iii)  $\theta$  (of unknown function).

The core enzyme of polymerase III can catalyse limited DNA synthesis on single-stranded gaps in dsDNA, but for full efficiency, accuracy and processivity on longer templates it requires a number of additional subunits which include: (i) the  $\beta$  subunit (*dnaN* product; ?'Factor I'), which apparently contributes to processivity; (ii) the  $\gamma$  subunit (*dnaZ* product), which apparently also contributes to processivity; (iii) the  $\delta$  subunit (*dnaX* product; ?'Factor III'), which apparently enhances processivity; and (iv) the  $\tau$  subunit (product of the *dnaX-Z* region), which acts as a link between two core enzymes. The core enzyme together with the *full range* of subunits is called *DNA polymerase III holoenzyme*. (DNA polymerase III\* refers to the holoenzyme minus the  $\beta$  subunit. DNA polymerase III' refers to a complex of core enzyme plus the  $\tau$  subunit.)

In a current model of DNA replication, the holoenzyme functions as a dimer – the enzymes being physically linked via their  $\tau$  subunits; during replication, one enzyme forms the leading strand while the other forms the lagging strand, i.e. they work in opposite directions.

In other bacteria, DNA polymerases appear to be essentially similar to those in *E. coli*. In the Archaea, DNA polymerases may be significantly different (see e.g. APHIDICOLIN).

In some prokaryotes (those that inhabit high-temperature environments), the DNA polymerases are thermostable, and this feature is exploited in various techniques used for the amplification of nucleic acids in vitro (e.g. PCR); these enzymes include:

(a) *Taq* DNA polymerase. An enzyme (from the bacterium *Thermus aquaticus*) which has been widely used in PCR (particularly during the early years); this enzyme lacks 3'-to-5' exonuclease activity and (therefore) has no proof-reading capacity.

(b) Stoffel fragment. A modified, recombinant form of the *Taq* polymerase (the C-terminal region of the protein) which is more thermostable than the parent enzyme; it lacks 5'-to-3' (in addition to 3'-to-5') exonuclease activity. This enzyme is active in a wide range of concentrations of magnesium ions, and has been found useful e.g. in those forms of PCR which use arbitrary primers.

(c) UITma™ DNA polymerase (Perkin-Elmer). This recombinant form of the DNA polymerase of *Thermotoga maritima* has 3'-to-5' exonuclease activity and can repair 3' mismatches during PCR – such proof-reading ability making the enzyme useful for high-fidelity copying.

(d) *Pfu* DNA polymerase™ (Stratagene). This highly thermostable enzyme from *Pyrococcus furiosus* retains 95% activity after 1 hour at 98°C; it has excellent proof-reading ability.

*Eukaryotic DNA polymerases.* Eukaryotes also have a number of DNA polymerases, including (in most eukaryotic cells) polymerases  $\alpha$ ,  $\beta$  and  $\gamma$ . Each type of polymerase appears to

## DNA polymerase I

be associated with a particular function – for example, the  $\gamma$  polymerase carries out DNA replication in mitochondria.

Some *viruses* (e.g. bacteriophage T4) encode their own DNA polymerases; others (e.g. phages  $\phi$ d,  $\phi$ X174, G4) use host enzymes.

**DNA polymerase I** (Kornberg enzyme) In *Escherichia coli*: an enzyme associated e.g. with EXCISION REPAIR and with the removal of RNA primers during DNA replication. (See also DNA POLYMERASE.)

**DNA polymerase II** In *Escherichia coli*: a polymerase induced in the SOS SYSTEM. (See also DNA POLYMERASE.)

**DNA polymerase III** In *Escherichia coli*: the major DNA polymerase; it is involved in chromosomal replication and e.g. synthesis of phage DNA. For further details see entry DNA POLYMERASE.

**DNA polymerase IV** In *Escherichia coli*: the product of gene *dinB* (induced in the SOS SYSTEM), a protein which has DNA polymerase activity and which appears to be involved in mutagenesis; DinB has no proof-reading activity.

**DNA polymerase V** In *Escherichia coli*: a protein complex, consisting of two UmuD' proteins and one UmuC protein, which has DNA polymerase activity and which may carry out some instances of DNA repair (translesion synthesis) during induction of the SOS SYSTEM.

**DNA polymorphism** See POLYMORPHISM (sense 3).

**DNA primase** *Syn.* PRIMASE.

**DNA repair** Any physiological process in which damaged DNA within a cell is recognized and repaired; *damage* in this context generally means any alteration or distortion of the normal double-helical structure of dsDNA resulting e.g. from the presence of abnormal bases or base pairs, nicks or gaps in one strand, covalent linkages between bases etc. (but *not* from replacement of one normal base pair with another: cf. MUTATION). *Repair* may involve e.g. direct reversal of the damage (e.g. Ada protein in ADAPTIVE RESPONSE) or removal of the damaged region followed by its replacement with normal DNA (e.g. EXCISION REPAIR).

Repair systems may be constitutive or inducible.

See e.g. ADAPTIVE RESPONSE, BASE EXCISION REPAIR, EXCISION REPAIR, MISMATCH REPAIR, PHOTOREACTIVATION, RECOMBINATION REPAIR and SOS SYSTEM.

**DNA replication** The process in which a copy (i.e. a *replica*) of a double-stranded DNA molecule is synthesized.

In *vivo*, circular, dsDNA molecules may be replicated by the CAIRNS' MECHANISMS or the ROLLING CIRCLE MECHANISM; the following refers mainly to the replication of circular dsDNA molecules by the Cairns' mechanism (replication of linear dsDNA is also considered briefly). (For replication of DNA in *vitro* see e.g. PCR and SDA.)

During replication, a new strand of DNA is synthesized on each of the two pre-existing strands, each pre-existing strand being used as a pattern or *template*; a template dictates the sequence of nucleotides in a new strand, thus conserving the genetic information encoded in the template strand. Essentially, molecules of deoxyribonucleoside triphosphate (dNTPs) base-pair with complementary nucleotides in each template strand and are sequentially polymerized (with elimination of pyrophosphate) by a DNA POLYMERASE. Note that each newly synthesized strand is complementary to – not a copy of – the template strand on which it is synthesized; thus, each of the two new daughter duplexes produced from a given parent duplex consists of one parent strand and one newly synthesized strand. (This type of replication is called *semiconservative replication* because only *one* strand in each daughter duplex has been newly synthesized.)

Initiation of DNA replication occurs at one or more special sites, called *origins* (designated *ori*); any DNA molecule which lacks an origin cannot be replicated *in vivo*. (See also REPLICON.)

Initiation of replication involves the recognition of an *ori* site by various initiation factors and enzymes. An essential prerequisite for replication is separation of the two strands of dsDNA (so-called 'melting') in the *ori* region (see CELL CYCLE (b)).

As no known DNA polymerase can *initiate* synthesis of a new strand of DNA on a template, initiation of DNA replication (by the Cairns' mechanism) requires the provision of a 'starter' sequence of nucleotides (a *primer*) which the DNA polymerase can elongate (in the 5'-to-3' direction) to form a new strand of DNA; DNA synthesis is usually primed by a short strand of RNA which is transcribed on the DNA template strand in the *ori* region.

Chain elongation (i.e. ongoing strand synthesis) involves ongoing separation (unwinding) of the two strands of the parental duplex.

Termination of DNA synthesis usually occurs when the entire duplex has been replicated (cf. ROLLING CIRCLE MECHANISM); it involves dissociation of the replicating machinery, joining of the two ends of each daughter strand (in the case of circular dsDNA molecules), and separation of the two circular daughter molecules (*decatenation*).

Newly synthesized strands usually undergo modification before the next round of replication can begin (see RESTRICTION-MODIFICATION SYSTEM).

*Replication of the chromosome in Escherichia coli.* The way in which a round of replication is *initiated* (i.e. triggered) is not known, but various factors appear to be relevant; regulation of the initiation of DNA replication in *E. coli* is discussed in the entry CELL CYCLE.

Once triggered, replication of the ccc dsDNA CHROMOSOME of *E. coli* occurs by the Cairns' mechanism: replication begins at the origin – *oriC* (see ORIC) – and proceeds bidirectionally, both template strands being replicated more or less simultaneously. Thus, two migrating, Y-shaped *replication forks* (in which the stem of the Y is the parental duplex, and the arms the daughter duplexes) move in opposite directions around the chromosome (see figure).

Because the strands of the parent duplex are antiparallel, and because both new strands are synthesized more or less simultaneously in the direction of movement of a replication fork, one daughter strand is synthesized in the 5'-to-3' direction while the other is synthesized from the 3' direction. The strand synthesized in the 5'-to-3' direction (the *leading strand* – see figure) is synthesized continually, but the other strand (*lagging strand*) cannot be synthesized continually because no known DNA polymerase can synthesize DNA in the 3'-to-5' direction. The lagging strand is actually synthesized as a series of fragments (*Okazaki fragments* – see figure), each fragment being synthesized in the 5'-to-3' direction from a separate RNA primer. Primers are subsequently excised and replaced with DNA (by extension from the preceding fragment) and the ends are joined together by a DNA LIGASE.

Chromosomal replication is a complex process requiring a number of different proteins. These proteins include the *dnaA* gene product (see DNAA GENE); a dimer of DNA polymerase III (see DNA POLYMERASE); GYRASE; topoisomerase I (see TOPOISOMERASE); HU PROTEIN; the DNAB GENE product (a helicase); PRIMASE and RNA POLYMERASE. At least some of these proteins are components of an initiation complex (earlier name:

DNA REPLICATION (Cairns-type): disposition of template and newly synthesized strands at a replication fork (diagrammatic; see entry). In a circular DNA duplex the strands have separated, locally, in the *ori* region. Only one half of this region is shown; in this half, the strands of the duplex will continue to separate in a left → right direction (i.e. the replication fork is moving to the right). On one template strand (top) an RNA *primer* (zigzag line) has been synthesized (see text); ongoing addition of deoxyribonucleotides to the 3' end of this primer will form the 'leading' strand of DNA. Synthesis of the leading strand is continuous in the 5'-to-3' direction.

On the other template strand (below), the 1st primer has been synthesized (by a primase), and this (RNA) primer has been extended as a strand of DNA by sequential addition of deoxyribonucleotides from the 3' end. This new strand of DNA may form the first Okazaki fragment of the lagging strand; alternatively, it may act as a primer for leading strand synthesis in the *other* replication fork (not shown). Following synthesis of the 1st primer, the replication fork has moved further to the right – opening up the duplex to the extent shown in the diagram. The 2nd primer has been synthesized and has been extended as a strand of DNA (Okazaki fragment) as far as the 5' end of the first primer. As the replication fork moves even further to the right additional template will become available, and the 3rd, 4th, 5th ... etc. primers synthesized on this template will (like the 2nd primer) be extended as Okazaki fragments; the sequence of Okazaki fragments will be joined together (forming the lagging strand) when the (RNA) primers are replaced by DNA.

Modified from *Bacteria*, 5th edition, Figure 7.8(a), page 116, Paul Singleton (1999) copyright John Wiley & Sons Ltd, Chichester, UK (ISBN 0471-98880-4) with permission from the publisher.

'orisome'). (During strand synthesis, parts of the parent DNA molecule – around the replication forks – necessarily exist in a single-stranded state, and these ssDNA sequences are stabilized by SINGLE-STRAND BINDING PROTEINS.)

A short RNA primer, synthesized on one of the template strands, is elongated by DNA polymerase III in the 5'-to-3' direction to form the leading strand (see figure); synthesis of the primer may be mediated by RNA polymerase (RNA polymerase is needed for initiation of DNA replication).

Exposure of the other template strand permits synthesis of the lagging strand. Primers for the lagging strand are synthesized by a PRIMASE (*dnaG* gene product) that forms part of a PRIMOSOME. Each primer is elongated in the 5'-to-3' direction to form an Okazaki fragment (~1000–2000 nt in length) that extends to the 5' end of the previous primer. (Primers are subsequently removed and replaced by DNA; this involves the enzyme DNA polymerase I.) As the first replication fork moves away, the first fragment of the lagging strand may act as a primer for leading strand synthesis in the opposite direction. At 37°C a replication fork moves at about 1000 nt per second.

In a current model for DNA replication, a processive complex of proteins ('replisome') is associated with each replication fork. The complex includes a DNA polymerase III *dimer* (the two enzymes physically linked via their  $\tau$  subunits and orientated in opposite directions) – one enzyme synthesizing the leading strand while the other synthesizes the lagging strand. The complex also contains a PRIMOSOME which, in turn, includes a helicase and the DnaG protein (a primase); the helicase is described as a hexamer (a ring-shaped structure of six DnaB proteins) which unwinds the duplex [Cell (1996) 86 177–180]. In this model, a section of lagging-strand template (liberated by ongoing leading-strand synthesis) forms a loop at the replication fork. This allows primer synthesis for the lagging strand (by primase) followed by extension of the primer by DNA polymerase III; when a newly synthesized fragment approaches the 5'-end of the previous fragment, the new (double-stranded) section is released by the complex, and the process is repeated on the next region of exposed lagging-strand template. Thus, the complex synthesizes both leading and lagging strands concurrently as it moves along with the replication fork.

## DNA restriction

The physical link between the two enzymes in the DNA polymerase III dimer is apparently needed for co-ordination of synthesis of the leading and lagging strands. It appears that coupling is also needed between the helicase and the polymerases – loss of such coupling being associated with a drastic reduction in efficiency of the helicase [Cell (1996) 84 643–650].

Moving in opposite directions, the two replications forks meet at the *ter* site on the chromosome, 180° from *oriC*.

During replication, the DNA polymerase appears to recognize only the overall shape of a base-pair, i.e. the same active site of the enzyme must serve for all four possible base-pair combinations. The accuracy of DNA synthesis therefore depends initially on base-pairing specificity between incoming nucleotides and template DNA. This might be expected to result in a relatively high frequency of errors because tautomerism in the bases can interfere with the accuracy of base-pairing. However, the overall error rate in *E. coli* DNA replication has been estimated to be ca. one mistake in  $10^8$ – $10^{10}$  nucleotides polymerized – a much higher level of accuracy than can be accounted for by base-pairing and polymerase specificities. This level of accuracy is achieved by ‘proof-reading’ and ‘editing’ systems which recognize and correct errors in a newly synthesized strand. The 3′-to-5′ nuclease activity of DNA polymerase III holoenzyme serves a proof-reading function, removing mispaired nucleotides from the growing (3′) end of the chain before continuing chain elongation. Errors which escape this system may be detected and corrected subsequently by the post-replicative MISMATCH REPAIR system.

In growing cells, chromosomal replication must be coordinated with cell division in order that daughter cells each receive the full genetic complement; the rate of DNA replication in *E. coli* is increased during faster growth by the initiation of additional rounds of synthesis (see HELMSTETTER–COOPER MODEL). Conditions which inhibit DNA replication may cause inhibition of cell division (see SOS SYSTEM).

**Replication of linear genomes.** In some bacteria a linear chromosome is replicated bidirectionally from an internal origin of replication. This raises the question of how the replication machinery avoids leaving the 3′ end of the template strand (in each daughter duplex) as single-stranded DNA. In one of several models, DNA synthesized on the new strand (at the fully duplexed end) displaces the 5′ terminal nucleotide sequence of the template strand – which is then transferred to (complementary) single-stranded DNA on the other daughter duplex (thus filling the single-stranded gap). [Replication of linear DNA molecules: TIG (1996) 12 192–196.]

In some viruses, replication of the linear dsDNA genome involves so-called *protein priming* – in which a nucleotide, bound covalently to a (virus-encoded) ‘terminal protein’, forms the 5′ terminus of a new strand; this system is found e.g. in BACTERIOPHAGE  $\phi$ 29 [protein priming in phage  $\phi$ 29: EMBO (1997) 16 2519–2527] and in members of the ADENOVIRIDAE.

**Chromosomal replication in eukaryotes.** Replication of eukaryotic CHROMOSOMES occurs during the S phase of the cell cycle. DNA synthesis is initiated at many separate sites along the chromosome, and replication forks proceed bidirectionally until they meet and fuse. Each DNA molecule is replicated only once in a cell cycle. [Eukaryotic DNA replication (minireview): Cell (1987) 48 7–8.]

**Plasmid and phage replication.** Mechanisms of replication in PLASMIDS and (DNA) PHAGES may differ significantly from chromosome replication in the corresponding host cell, but in

most or all cases at least some of the components involved in host chromosomal replication are required.

In plasmid ColE1, replication is of the Cairns’ type – but it occurs *unidirectionally* from the origin; in the F PLASMID replication is bidirectional (as in the *E. coli* chromosome).

Many of the small circular plasmids in Gram-positive bacteria replicate by means of a ROLLING CIRCLE MECHANISM [replication control in rolling circle plasmids: TIM (1997) 5 440–446].

Plasmid replication, and the partitioning to daughter cells, seems likely to involve some kind of association between the plasmid and the cytoplasmic membrane of the host cell [Mol. Microbiol. (1997) 23 1–10].

Replication of the (linear) genome of bacteriophage  $\phi$ 29 was mentioned above.

In certain phages the rolling circle mechanism is involved in replication (see e.g. SSDNA PHAGE, BACTERIOPHAGE  $\lambda$ , BACTERIOPHAGE  $\phi$ X174).

[The enzymology of DNA replication (historical perspective): JB (2000) 182 3613–3618.]

**DNA restriction** See RESTRICTION–MODIFICATION SYSTEM.

**DNA sequencing** Any procedure for determining the sequence of nucleotides in a sample of DNA. Sequencing is important in taxonomy, identification and characterization.

In the ‘chemical’ (Maxam–Gilbert) method, end-labelled copies of an unknown sequence are cleaved by base-specific reagents; analysis follows electrophoresis of the fragments. The dideoxy (Sanger’s) method is described in the figure on page 249. (See also PYROSEQUENCING.)

Automated DNA sequencing is often based on the dideoxy method. Primers are labelled with fluorescent dyes, a different dye being used for each of the four reactions. The products from all four reactions are combined and then subjected to electrophoresis from a single well in a polyacrylamide gel. On excitation by an argon laser, fragments from each reaction mixture can be distinguished from those of other reaction mixtures by their dye-specific emission characteristics; emissions from the fragments of all four reaction mixtures are detected automatically and stored e.g. in digital form.

Sequencing provides definitive information on a given sample of nucleic acid. For duplex DNA, greater accuracy is obtained if both strands of the duplex are sequenced.

RNA can be retrotranscribed into cDNA; the (single-stranded) cDNA is then amplified, and the amplified product is sequenced. The sequence of nucleotides in the RNA sample is then deduced. Amplified DNA copies of an RNA sample may be obtained by reverse-transcriptase PCR (rtPCR).

**DNA splicing** See CLONING (of DNA).

**DNA Stat™** See BLOOD DNA ISOLATION KITS.

**DNA synthesis** See DNA REPLICATION.

**DNA topoisomerase** *Syn.* TOPOISOMERASE.

**DNA toroid** A highly compacted genomic DNA, found e.g. in *Deinococcus radiodurans* and ENDOSPORES, which may account at least partly for resistance to DNA-damaging agents (e.g. radiation). Toroidal structure may facilitate repair of double-stranded breaks in a RecA- and template-independent way [JB (2004) 186 5973–5977].

**DNA tumour viruses** Oncogenic DNA-containing animal viruses; they include members of the ADENOVIRIDAE, Hepadnaviridae (see e.g. HEPATITIS B VIRUS), Herpesviridae (subfamily GAMMAHERPESVIRINAE), and PAPAPOVIRIDAE.

**DNA unwinding protein** Any protein capable of unwinding and separating the strands of double-helical DNA. (See HELICASES; cf. SINGLE-STRAND BINDING PROTEIN.)

DNA SEQUENCING: determining the nucleotide sequence of a cloned DNA fragment by the dideoxy method (Sanger's chain-termination method) (diagrammatic). Initially, the fragment to be sequenced is obtained in single-stranded form (e.g. by cloning in a phage M13 vector). Regardless of the cloning method used, the unknown sequence will be flanked on its 3' side by single-stranded DNA of *known* sequence derived from the vector molecule; this permits the design of a labelled primer which can bind at a site next to the unknown sequence such that the first nucleotide to be added to the primer will pair with the first 3' nucleotide of the unknown sequence. In the diagram, the 'unknown sequence' is TCTGACGTAAGC; a primer (short line), which carries a label (black disc), has bound at a site flanking the 3' end of the unknown sequence.

DNA synthesis *in vitro* is normally carried out with a reaction mixture that includes (i) templates (in this case, single-stranded fragments containing the unknown sequence); (ii) primers; (iii) the four types of deoxyribonucleoside triphosphate (dATP, dCTP, dGTP and dTTP); and (iv) DNA polymerase. When base-paired to the template strand, the primer is extended (5'-to-3') by the sequential addition of nucleotides as dictated by the template.

In sequencing, there are four separate reaction mixtures (G, C, T, A), each containing all the constituents mentioned above (including millions of copies of the unknown sequence, and of the primer). In addition, each mixture contains a given *d*ideoxynucleoside triphosphate (ddNTP); thus, the G mixture contains dideoxyguanosine triphosphate (ddG), the C mixture ddC, the T mixture ddT, and the A mixture ddA.

When a dideoxynucleotide is added to a growing strand of DNA it prevents addition of the *subsequent* nucleotide because dideoxynucleotides lack the 3'-OH group necessary for making the next phosphodiester bond. Thus, primer extension will stop (= chain termination) at any location where a dideoxynucleotide has been incorporated. In each reaction mixture the concentration of ddNTP is such that, in most growing strands, synthesis will be stopped, at some stage, by the incorporation of a dideoxynucleotide; because a ddNTP may pair with *any complementary base* in the template, chain termination can occur at different sites on different copies of the template strand – so that product strands of different lengths will be formed. For example, with ddG (see diagram) the three products are of different lengths because, during extension of the primers, ddG has paired with cytosine residues at three different locations in the template; note that, in this case, *the length of a given product strand is related to the location of a particular cytosine residue in the unknown sequence*. Analogous comments apply to reaction mixtures containing the other ddNTPs.

At the end of the reaction, product strands are separated from templates by formamide. Each reaction mixture is then subjected to electrophoresis in a separate lane of a polyacrylamide gel. Short product strands move further than longer ones, in a given time; products that differ in length by only one nucleotide can be distinguished, the shorter product moving just a little further.

The gel contains urea; this inhibits base-pairing between product strands and templates. It also inhibits *intra*-strand base-pairing in the product strands. This is essential: to deduce the sites of a particular base in the template it is necessary to compare the *lengths* of all product strands in the given reaction, and this requires proportionality between strand length and electrophoretic mobility; were intra-strand base-pairing to occur it could alter electrophoretic mobility – in which case a product's length would not necessarily be indicated by the position of its band in the gel. (Continued on page 250.)

## DNA uptake site

**DNA uptake site** (in *Haemophilus*) See TRANSFORMATION (1).

**DNA vaccine** Any parenterally administered VACCINE consisting of DNA. A DNA vaccine consists e.g. of copies of a PLASMID that encodes specific antigen(s); the encoded antigen(s) are synthesized in vivo (i.e. within the recipient of the vaccine) and may then induce both humoral (antibody) and cell-mediated responses. A DNA vaccine may have prophylactic and/or therapeutic uses. The possibility of using DNA vaccines against the major diseases (malaria, tuberculosis etc.) has attracted much interest.

It is known that a DNA vaccine encoding e.g. the 65 kDa heat-shock protein (Hsp65) of *Mycobacterium tuberculosis* can protect mice against infection by this pathogen; the vaccine appears to stimulate an antigen-specific subset of Th1 T cells which (i) have cytotoxic activity against infected cells, and (ii) secrete interferon- $\gamma$  (IFN- $\gamma$ ).

More recently, it has been shown that a DNA vaccine encoding Hsp65 can act therapeutically in mice during an experimentally established infection with *Mycobacterium tuberculosis* [Nature (1999) 400 269–271]. In this study, virulent cells of *M. tuberculosis* H37Rv were injected intravenously and the infection allowed to develop for 8 weeks. DNA vaccine was then administered in four intramuscular doses at 2-week intervals; each dose of vaccine consisted of 50  $\mu$ g plasmid DNA in 50  $\mu$ l saline. Different types of vaccine were used in different groups of animals; the vaccine encoding Hsp65 was found to be significantly more effective than other vaccines encoding different mycobacterial antigens (Hsp70 and ESAT-6). The therapeutic effect of the Hsp65 vaccine (manifested by a marked decrease in the numbers of live tubercle bacilli in lung and spleen) was associated with a switch from a Th-2-dominated to a Th-1-dominated response in the mice.

Interestingly, non-methylated CpG regions in the DNA itself can induce secretion of INTERLEUKIN-12 (IL-12) from antigen-presenting cells (such as macrophages). IL-12 is known to promote the development of the Th-1 phenotype in T cells exposed to antigen. Because IL-12 is one of the factors essential for effective immunity to *M. tuberculosis* in mice, a plasmid encoding IL-12 (rather than a mycobacterial antigen) was tested in the same study [Nature (1999) 400 269–271]; this vaccine was found to cause the maximum reduction in tubercle bacilli by 11 weeks, i.e. its performance exceeded that of the mycobacterial antigens.

A DNA vaccine has also been used against Ebola virus: see FILOVIRIDAE.

Any future large-scale development/use of DNA vaccines is dependent on appropriate technology for preparing pure plasmid DNA (e.g. free of contaminating chromosomal DNA) in sufficient quantity. [Biochemical engineering approaches to the

challenges of producing pure plasmid DNA: TIBtech. (2000) 18 296–305.]

[Plasmids for Therapy and Vaccination: Book ref. 225.]

(See also GENE GUN.)

**DNA boxes** See CELL CYCLE (b).

**dnaA gene** A DNA GENE whose product is necessary for the initiation of DNA REPLICATION in *bacteria*; in archaeans the Orc1 and Cdc6 proteins carry out the same function. DnaA proteins bind to 9-bp sequences ('DnaA boxes') in the *oriC* region during initiation (see CELL CYCLE (b)) and this is followed by localized strand separation. Defective (mutant) DnaA proteins have been reported [Mol. Microbiol. (2000) 35 454–462].

DnaA was earlier reported to be needed for the replication of certain plasmids (e.g. pSC101) but is now seen to be specific to the replication of *chromosomal* DNA. In eukaryotes, the DnaA function is carried out by six proteins (Orc1–6). [Initiators of DNA replication: FEMS Reviews (2003) 26 533–554.]

**DNAase** DEOXYRIBONUCLEASE.

**dnaB gene** A DNA GENE whose product is necessary for many cases of primer formation; in a current model of DNA REPLICATION in *Escherichia coli*, a hexamer of DnaB proteins functions as a HELICASE – forming part of the PRIMOSOME and unwinding the parent duplex as the primosome migrates with the replication fork.

It appears that ATP *binding* is necessary for the binding of DnaB to ssDNA, while ATP *hydrolysis* permits its release. In the absence of single-strand binding protein (SSBP), DnaB–ATP can bind to many sites on ssDNA, and interaction with primase leads to the formation of a short RNA primer at each site (*general priming*); general priming is inhibited by SSBP. *Specific priming* occurs in the presence of SSBP and depends on the presence of other proteins of the PRIMOSOME.

**dnaC gene** (*dnaD* gene) A DNA GENE whose product is required for PRIMOSOME formation.

**dnaD gene** *Syn. dnaC* gene (q.v.).

**dnaE gene** *Syn. polC* gene (see DNA POLYMERASE).

**dnaF gene** *Syn. nrdA* gene (q.v.).

**dnaG gene** See PRIMASE.

**dnaH gene** *Syn. dnaZ* gene (see DNA POLYMERASE).

**dnaI gene** A DNA GENE whose function is required for initiation of DNA REPLICATION at the replication origin.

**dnaJ gene** A DNA GENE which is closely linked to the *dnaK* gene (q.v.) and which, like *dnaK*, is necessary for viability of *Escherichia coli* at high temperatures and apparently for phage  $\lambda$  DNA replication.

**dnaK gene** A DNA GENE whose function is essential for the viability of *Escherichia coli* at high temperatures, and which is also reported to be required for phage  $\lambda$  DNA replication. The product of *dnaK* was identified as protein B66.0, a HEAT-SHOCK PROTEIN. [Properties of DnaK: JBC (1984) 259 8820–8825.]

## DNA SEQUENCING (*continued*)

Bands in the gel are revealed e.g. by staining or chemiluminescence; if the primers carry a radioactive label, the gel is examined by autoradiography following electrophoresis.

The locations of bands indicate the relative lengths of product strands – shorter products having moved further down the gel (from top to bottom in the diagram). Note that the first unknown 3' nucleotide (C) is identified by (i) the shortest product strand (which has moved the furthest), and (ii) the fact that this product is from the ddG mixture – indicating a base that pairs with G, i.e. C. Similarly, the next unknown (G) is the next shortest product strand which came from the ddC mixture, thus indicating G. The entire unknown sequence can be deduced in this way.

The figure also shows part of an autoradiograph of a sequencing gel (courtesy of Joop Gaken, Molecular Medicine Unit, King's College, London).

Figure reproduced from *Bacteria*, 5th edition, Figure 8.23, pages 222–223, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

- dnaL gene** An uncharacterized DNA GENE.
- dnaM gene** An uncharacterized DNA GENE.
- dnaN gene** See DNA POLYMERASE.
- dnaP gene** A DNA GENE whose function is required for initiation of DNA REPLICATION at the replication origin.
- dnaQ gene** See DNA POLYMERASE.
- DNase** DEOXYRIBONUCLEASE.
- dnaT gene** A DNA GENE whose product may interact with DnaC protein *in vivo*; *dnaT* mutants cannot destabilize the replication complex at chain termination.
- dnaW gene** *Syn. adk gene* (q.v.).
- dnaX gene** See DNA POLYMERASE.
- dnaZ gene** See DNA POLYMERASE.
- dNTP** Deoxyribonucleoside-5'-triphosphate.
- Dobiella** See EIMERIORINA.
- Dobrava-Belgrade virus** See HANTAVIRUS.
- DOC** Dissolved organic carbon. (cf. POC.)
- docking protein** See SIGNAL HYPOTHESIS.
- Döderlein's bacilli** Aciduric, Gram-positive bacilli, probably *Lactobacillus* sp(p), observed by Döderlein (1892) in human vaginal secretions.
- dodine** (dodine acetate; *n*-dodecylguanidine acetate) An agricultural (non-systemic) ANTIFUNGAL AGENT used e.g. for the control of apple scab – against which it has eradicant as well as protective action. Dodine has the properties of a cationic surfactant.
- dog** (parvovirus infection) See CANINE PARVOVIRUS.
- dog lichen** *Peltigera canina*.
- dolichol** A polyprenol consisting of 14–24  $\alpha$ -saturated isoprene units; phosphorylated dolichols function in eukaryotes as membrane-bound sugar carriers, assisting the transfer of hydrophilic sugar residues from soluble nucleotide precursors through membranes (e.g. of the rough endoplasmic reticulum and Golgi apparatus) to polymers such as polysaccharides, glycoproteins etc. (see e.g. PALADE PATHWAY). (cf. BACTOPRENOL.)
- Dolichomastix** See MICROMONADOPHYCEAE.
- doliiform** (doliiform) Barrel-shaped.
- dolipore septum** A type of SEPTUM present in the hyphae of most basidiomycetes (cf. AMBROSIOZYMA). The central portion of the septum is thickened and barrel-shaped, the septal pore forming a small tunnel (ca. 0.1  $\mu$ m diam.) through this thickened region. A curved double membrane (the *septal pore cap* or *parenthesome*) typically occurs on each side of the septum, these structures appearing (in cross section) as brackets (parentheses) around the septa. The parenthesomes appear to be formed from the endoplasmic reticulum and may be perforate or imperforate; they may serve as screens, regulating the passage of cellular structures between adjacent cells. Parenthesomes are lacking e.g. in *Filobasidiella*.
- dollar spot** A disease of turf grasses (particularly red fescue, *Festuca rubra*) caused by *Sclerotinia homeocarpa*; yellowish-brown patches, up to ca. 8 cm across, develop on the turf in mild, wet weather.
- domain** (*immunol.*) Any one of the several compact, globular sections of a heavy chain or a light chain in an IMMUNOGLOBULIN molecule; each domain consists of a part of the polypeptide chain which forms a loop (closed by an intra-chain disulphide bond) and which is extensively folded. In IgG the heavy chain domains, in sequence, are designated V<sub>H</sub> (variable region), and C<sub>H1</sub>, C<sub>H2</sub> and C<sub>H3</sub> (constant region); the light chain domains are designated V<sub>L</sub> and C<sub>L</sub>. (Domains are also written as e.g. CH1, CH2 etc. or as CH<sub>1</sub>, CH<sub>2</sub> etc.)
- domain** (*taxon.*) A category ranked above kingdom [origin of term: PNAS (1990) 87 4576–4579] – see e.g. ARCHAEA and BACTERIA.
- Domestos** See HYPOCHLORITES.
- dominance** (genetics) In a diploid (or merodiploid) heterozygous cell or organism; the tendency of certain (*dominant*) alleles to be expressed in preference to their corresponding (*recessive*) alleles. (cf. EPISTASIS.) The complete dominance of one allele over another occurs in only some cases; in such cases the phenotype of the heterozygote Aa is identical to that of the homozygote, AA (A being dominant). When partial dominance is exhibited the Aa phenotype is intermediate between the AA and aa phenotypes.
- dominant allele** See DOMINANCE.
- Domiphen bromide** See QUATERNARY AMMONIUM COMPOUNDS.
- DON** (1) (6-diazo-5-oxo-L-norleucine; CO<sub>2</sub>H.CHNH<sub>2</sub>.(CH<sub>2</sub>)<sub>2</sub>.CO.CH=N<sup>+</sup>=N<sup>-</sup>) AN ANTIBIOTIC and antitumour agent obtained from *Streptomyces* sp; its mode of action resembles that of AZASERINE. Other antitumour DON derivatives are produced by *Streptomyces* spp: e.g. diazomycin A (*N*-acetyl-DON) and alazopeptin (apparently comprising one alanine and two DON residues). (cf. HADACIDIN.)
- (2) Deoxynivalenol – see TRICHOTHECENES.
- donation** (*mol. biol.*) See CONJUGATION (1b) (i).
- donor** Any cell or organism which donates genetic information to another cell or organism (the *recipient*): see CONJUGATION, TRANSDUCTION and TRANSFORMATION.
- donor conjugal DNA synthesis** See CONJUGATION (1b) (i).
- donor site** (of a ribosome) See PROTEIN SYNTHESIS.
- donor splice site** See SPLIT GENE (a).
- donor-suicide model** (for transposition) See e.g. Tn10.
- Donovan bodies** See GRANULOMA INGUINALE.
- donovanosis** *Syn.* GRANULOMA INGUINALE.
- L-dopa** See MELANIN.
- Dorisa** See EIMERIORINA.
- Dorisella** See EIMERIORINA.
- dormancy** (hypobiosis) The state of an organism or spore which exhibits minimal physical and chemical change over an extended period of time; when *no* physical or chemical change can be detected the state is sometimes referred to as *cryptobiosis*. (See also ENDOSPORE (sense I(a)) and SPORE.)
- dorsal zone of membranelles** See DZM.
- Dorset's egg** A MEDIUM used e.g. for the maintenance of *Mycobacterium* spp; it consists of a saline suspension of homogenized whole hens' eggs which has been inspissated in sloped bijoux or universal bottles.
- dorsiventral** Having two unlike (upper and lower) surfaces.
- dosa** A traditional fermented food in India; it is prepared from milled rice and black gram (cf. IDLI). [Microbiology of dosa: Food Mic. (1986) 3 45–53.]
- dosage** (of genes) See GENE DOSAGE.
- dot-blot** A PROBE-based method for detecting or quantifying a specific sequence of nucleotides in a given sample. A drop of the sample is added to a suitable membrane and treated so that any nucleic acids present in the sample bind to the membrane in single-stranded form. The membrane is then exposed to probes (which are complementary to the target sequence) under conditions permitting probe–target hybridization; when unbound probes are removed by washing, the presence of bound probes indicates the presence of the required target sequence. If, for example, the probe had been tagged with DIGOXIGENIN, the bound probe is detected by treating the membrane with a *conjugate* consisting of anti-digoxigenin (antibody to digoxigenin) covalently linked to an enzyme (such as alkaline phosphatase); the binding of conjugate to digoxigenin is determined by adding a colour-generating substrate for the enzyme after all unbound conjugate has been removed by washing.

## dot genes

Alternatively, a radioactive probe can be used.

For quantification, serial dilutions of the sample are examined as described above; the quantity of target present in the sample can then be assessed by noting the strength of label (i.e. colour, radioactivity etc.) in comparison with that of controls of known concentration.

**dot genes** (of *Legionella pneumophila*) See end of section (a) in PHAGOCYTOSIS.

**Dothidea** See DOTHIDEALES.

**Dothideales** The largest order of fungi in the subdivision ASCOMYCOTINA; the organisms include saprotrophs, plant parasites and lichenized fungi. Ascocarp: ascocloacal (see ASCOCARP and ASCOSTROMA), ostiolate or closed. Asci: bitunicate, cylindrical to spheroidal. Some species exhibit one or more asexual (conidial) stages. Genera: e.g. ARTHOPYRENIA, *Cochliobolus* (see also DRECHSLERA), *Cucurbitaria* (syn. *Phialospora*), DIDYMELLA, *Dothidea*, ELSINOÉ, LEPTOSPHERA, MYCOSPHAERELLA, *Myriangium* (see also ASCOSPORA and ASCOSTROMA), *Ophiobolus*, PIEDRAIA, *Pleospora* (see also BLACKLEG sense 2), *Pyrenophora* (see also DRECHSLERA and NET BLOTCH), *Sphaerulina* (see also NORMANDINA), VENTURIA. (See also BLACK MILDEWS and SOOTY MOULDS.)

**DOTS** Directly observed therapy, short-course: see TUBERCULOSIS.

**double diffusion (serol.)** GEL DIFFUSION in which antigen and antibody both diffuse through the gel (cf. SINGLE DIFFUSION). In one procedure, this is achieved by placing antibody and antigen at opposite ends of a gel column; in the *Oakley–Fulthorpe test* (double diffusion, single DIMENSION) antibody is incorporated in a layer of gel, and this is separated by a layer of plain gel from the aqueous solution of antigen which is placed on top. (cf. OUCHTERLONY TEST.)

**double dimension (serol.)** See DIMENSION.

**double fixation** See ELECTRON MICROSCOPY (a).

**double helix** See DNA.

**double lysogen** See e.g. TRANSDUCTION.

**double-negative T cells** See T LYMPHOCYTE.

**double recessive** HOMOZYGOUS for a given recessive allele, or alleles.

**double refraction** Syn. BIREFRINGENCE.

**double-strand break–repair model** See RECOMBINATION Fig. 2. (See also RECOMBINATION REPAIR.)

**double thymidine blockade** See SYNCHRONOUS CULTURE.

**double-vial** See FREEZE-DRYING.

**doubling dilutions** See SERIAL DILUTIONS.

**doubling time** See GROWTH (a).

**Doulton filter** See FILTRATION.

**dourine** (mal du coit) A chronic or subacute, often fatal, sexually transmitted disease of equines caused by *Trypanosoma equiperdum*; it occurs in parts of Africa, America, Asia and Europe. Initial symptoms include oedematous, inflamed lesions of the genitalia, and transient skin lesions (*plaques*) up to 5 cm in diameter; later symptoms include anaemia and neurological involvement (e.g. paralysis). Quinapyramine and suramin have been used therapeutically. A carrier state occurs.

**down mutation** (down-promoter mutation) A MUTATION in a PROMOTER which results in a decreased level of transcription from that promoter. (cf. UP MUTATION.)

**downcomer** In a LOOP FERMENTER: the descending column of liquid or that part of the fermenter which contains it. (cf. RISER.)

**downstream (mol. biol.)** In, or in relation to, the direction in which a nucleic acid strand or a polypeptide chain is synthesized; the converse of 'downstream' is referred to as 'upstream'. (See e.g. PROMOTER.)

**downstream box** In certain prokaryotic and phage genes: a sequence of nucleotides, downstream from the start site, which has been regarded as a translation enhancer. The ribosomal 16S rRNA may contain a complementary region (called the *anti-downstream box*), although suggestions that this may bind to the downstream box have been disputed [JB (2001) 183 3499–3505].

**downstream promoter element** In some RNA polymerase II PROMOTERS: a region downstream of the start site with a role apparently similar to that of the TATA box.

**downy mildews** Plant diseases caused by certain members of the PERONOSPORALES (e.g. BREMIA, PERONOSPORA, PLASMOPARA); downy mildews are characterized by the formation of superficial hyphal growth in which, typically, individual spore-bearing structures can be distinguished under low magnification. (cf. POWDERY MILDEWS.) Downy mildews can be controlled e.g. with copper-based antifungals or ZINEB.

**doxycycline** See TETRACYCLINES.

**D<sub>p</sub>** Pattern difference. In the comparison of two strains by NUMERICAL TAXONOMY: a coefficient which indicates the degree of *dissimilarity* corrected for any difference(s) due solely to inter-strain differences in metabolic vigour. (cf. entry S<sub>p</sub>.)

**DP** Degree of polymerization: the number of monomeric units per molecule of a polymer.

**DPD** *N,N*-diethyl-*p*-phenylenediamine (see WATER SUPPLIES).

**DPN** Diphosphopyridine nucleotide: see NAD.

**DPT** A MIXED VACCINE containing diphtheria toxoid, pertussis vaccine and tetanus toxoid.

**DPX** A neutral, synthetic MOUNTANT of refractive index ca. 1.53 when dry; it consists of *Distrene* and a plasticizer (tritolyl phosphate) dissolved in xylol.

**DR** DIRECT REPEAT.

**Dr adhesins** A category that includes both fimbrial and non-fimbrial adhesins, members of which are found e.g. on UPEC strains of *Escherichia coli*; the Dr adhesins bind to CD55 (at a site corresponding to the Dr<sup>a</sup> blood group antigen).

**draft tube** In a LOOP FERMENTER: a wide, vertical tube typically situated coaxially within the column so as to leave an annular space between itself and the wall of the fermenter; when the fermenter is operating, the draft tube is completely submerged in the culture. Culture is made to flow up (or down) the draft tube in order to generate a circulatory flow in the column – culture flowing down (or up) the annulus.

**DraI** See RESTRICTION ENDONUCLEASE (table).

**Draparnaldia** See CHAETOPHORA.

**draughtsman colony** (checker colony) The form of COLONY typically (though not invariably) produced by *Streptococcus pneumoniae* growing on blood agar: round and raised, with steep sides and a flat top, i.e., resembling one of the pieces used in a game of draughts (= checkers); after overnight growth under a raised partial pressure of CO<sub>2</sub> the colonies are each ca. 1 mm in diameter and surrounded by a zone of  $\alpha$ -haemolysis. Very young colonies of *S. pneumoniae* are typically convex (domed); the flattened colony form apparently results from autolysis of the constituent cells on continued incubation, and further incubation may result in the development of a concavity in the upper surface of the colony.

**draw tube** In some microscopes: a tube coaxial with the body tube (see MICROSCOPY) used to adjust the tube length.

**drd plasmid** A mutant CONJUGATIVE PLASMID in which the TRANSFER OPERON is permanently DEREPRESSED.

**Drechslera** A genus of fungi of the HYPHOMYCETES; teleomorphs occur in the genera *Cochliobolus* and *Pyrenophora*.

The organisms form septate mycelium and pigmented, septate, commonly cylindrical conidia; conidiogenesis is tretic (see CONIDIUM). *Drechslera* spp are typically graminicolous (cf. e.g. PHAEOHYPHOMYCOSIS). Species which have been transferred from HELMINTHOSPORIUM to this genus include e.g. *D. gramineae*, *D. maydis*, *D. oryzae* (causal agent of brown spot disease of rice), and *D. victorinae* (see also VICTORIN).

**Dreyer's tube** A small, conically-based glass test-tube with a flared rim and an internal diameter of ca. 5 mm; it is used in serology for the clear observation of reactions involving agglutination or precipitation.

**drift** See GENETIC DRIFT and ANTIGENIC DRIFT.

**DRNA** DISSIMILATORY REDUCTION OF NITRATE TO AMMONIA.

**drop plate method** *Syn.* MILES AND MISRA'S METHOD.

**droplet infection** INFECTION (sense 1) by inhalation of an AEROSOL of saliva, mucus etc. (contaminated with pathogens) from an infected individual.

**dropsy** *Syn.* OEDEMA. (See also INFECTIOUS DROPSY.)

**Drosophila A virus** See PICORNAVIRIDAE.

**Drosophila C virus** See PICORNAVIRIDAE.

**Drosophila P virus** See PICORNAVIRIDAE.

**Drosophila X virus (DXV)** A virus which causes anoxia sensitivity and death in *Drosophila melanogaster* and which can be cultivated in *Drosophila* cell lines [JGV (1979) 42 241–254]. DXV closely resembles IPN VIRUS in morphology, genome etc. (See also SIGMA VIRUS.)

**drug resistance** *Syn.* ANTIBIOTIC RESISTANCE.

**dry bubble** See BUBBLE DISEASES.

**dry rot** (1) (of timber) A BROWN ROT of structural (and other) timbers caused by the cellulolytic fungus *Serpula lacrymans*; only wood having a moisture content greater than about 20% (see TIMBER SPOILAGE) can be attacked initially, but water produced during metabolism can be transported via moisture-conducting rhizomorphs, enabling the fungus to spread to drier regions of wood (or across brickwork etc). Infected timbers often exhibit longitudinal and cross-grain cracking and a surface growth of whitish mycelium containing yellow and/or lilac patches; the leathery fruiting bodies bear a mass of rust-coloured spores. Control of dry rot involves removal of decayed wood and disinfection of remaining timbers by heat and/or the application of fungicides (see TIMBER PRESERVATION). Infections similar to dry rot may be caused e.g. by *Poria* spp. (cf. WET ROT.)

(2) A storage rot of potato tubers caused e.g. by *Fusarium coeruleum* (= *F. solani* var. *coeruleum*) and *F. sulphureum*. The tubers develop dark, sunken lesions which develop into mycelium-filled cavities; affected tubers lose water and shrink, becoming wrinkled and eventually drying into a hard mass. Under humid conditions, however, infection by SOFT ROT organisms may result in rapid decomposition of the tubers. (See also TECNAZENE.)

**dryad's saddle** *Polyporus squamosus* (q.v.).

**drying** (1) (of foods) See FOOD PRESERVATION (c). (2) (of plates) See PLATE. (3) (of microorganisms) See DESICCATION.

**ds** (of DNA or RNA) Double-stranded.

**dsb genes** See PROTEIN SYNTHESIS (protein folding).

**ds(c)DNA** Double-stranded circular DNA.

**DSI stain** See DIETERLE SILVER STAIN.

**DSM** Deutsche Sammlung von Mikroorganismen (culture collection of microorganisms), Grisebachstr. 8, D-3400 Göttingen, Germany.

**DTH** Delayed-type hypersensitivity: see DELAYED HYPERSENSITIVITY.

**dTMP** Deoxythymidine 5'-monophosphate [see Appendix V(b)].

**DTP** *Syn.* DPT.

**dualtropic** (polytropic) Refers to a recombinant retrovirus derived from an ecotropic virus and a xenotropic virus; the recombinant virus has an extended host range and can, like AMPHOTROPIC viruses, replicate in both homologous and heterologous cells. However, a dualtropic murine virus differs from an amphotropic murine virus in that it possesses *env* glycoprotein antigenic determinants in common with those of the parental ecotropic and xenotropic murine viruses, and may thus be neutralized by antiserum to the *env* glycoprotein of either or both of these viruses. [Book ref. 114, p. 73.] (See also MCF VIRUSES.)

**duck diseases** See POULTRY DISEASES.

**duck embryo vaccine (DEV)** See RABIES.

**duck hepatitis B virus (DHBV)** A virus of the HEPADNAVIRIDAE which infects Pekin ducks (*Anas domestica*) and other domestic ducks; strains of DHBV have also been detected in wild mallard [JGV (1986) 67 537–547]. DHBV can be transmitted vertically via the egg. Infected ducks commonly exhibit persistent viraemia and may develop chronic liver disease; integrated DHBV DNA has been detected in a hepatocellular carcinoma in a domestic duck [PNAS (1985) 82 5180–5184] (cf. HEPATITIS B VIRUS).

**duck infectious anaemia virus** See AVIAN RETICULOENDOTHELIOSIS VIRUSES.

**duck plague** *Syn.* DUCK VIRUS ENTERITIS.

**duck virus enteritis** (duck plague) An acute, highly infectious disease of ducks, geese and swans; it is caused by anatid (or anserid) herpesvirus 1 (see HERPESVIRIDAE). Symptoms: loss of appetite, thirst, nasal and ocular discharge, neurological signs; multiple haemorrhages occur in internal organs. Transmission is believed to occur mainly via pond-water.

**duck virus hepatitis (DVH)** An acute disease of young ducklings, caused by an ENTEROVIRUS; older ducks and other birds are not susceptible. Infection occurs by ingestion of food contaminated with faeces of infected birds. Incubation period: 24–48 hours. The disease progresses rapidly and death may occur within one or a few hours. On postmortem examination the liver is found to be enlarged and haemorrhagic. Vaccines are available for prevention; immune serum has been used in treatment.

**Dulbecco's PBS** Phosphate-buffered saline originally formulated to contain (g/l): NaCl (8.0), KCl (0.2), Na<sub>2</sub>HPO<sub>4</sub> (anhydrous) (1.15), CaCl<sub>2</sub>·2H<sub>2</sub>O (0.132), KH<sub>2</sub>PO<sub>4</sub> (0.2), and MgCl<sub>2</sub>·6H<sub>2</sub>O (0.1).

**dulcitol** *Syn.* GALACTITOL.

**dulse** See PALMARIA.

**Dunaliella** A genus of unicellular, naked (wall-less), halotolerant, biflagellated green algae (division CHLOROPHYTA) which closely resemble CHLAMYDOMONAS spp except for their lack of cell wall. *Dunaliella* spp can grow in aquatic environments of a wide range of salinities, up to and including saturated brines, and are common e.g. in hypersaline environments (salt lakes etc) throughout the world – often forming extensive red or green blooms. The organisms have an exceptional osmoregulatory capacity, using glycerol as an osmoregulator (see OSMOREGULATION); the intracellular concentration of glycerol can be varied rapidly to compensate for changes in the osmotic strength of the surrounding medium. The glycerol can be formed either from stored starch or as a direct product of photosynthetic carbon fixation; a reduction in glycerol concentration apparently occurs by glycerol degradation.

When certain species are subjected to hypo-osmotic shock, the cells swell, change shape (from elongated to spherical),

## Duncan disease

and lose motility. (In *D. salina* expansion of the cytoplasmic membrane during swelling is apparently achieved by fusion of the membrane with numerous small membranous vesicles present in the cytoplasm [JCB (1986) 102 289–297].) Some of the shocked cells lose buoyancy and sink; they may then continue to reproduce slowly or remain dormant, but they recover their motility when transferred to a medium of more favourable salinity. It has been suggested that this is a survival strategy whereby the organism can escape from the upper layers of (potentially damaging) low salinity resulting e.g. from rain or land drainage [JEMBE (1985) 91 183–197].

(See also SINGLE-CELL PROTEIN.)

**Duncan disease** *Syn.* XLP SYNDROME.

**Duovirus** *Syn.* ROTAVIRUS.

**duplex DNA** Double-stranded DNA.

**duplex PCR** See MULTIPLEX PCR.

**duplex winding number** See DNA.

**Durham shelter** (gravity slide sampler) An instrument used for sampling airborne particles, particularly pollen. (See also AIR). Essentially it is an adhesive-coated microscope slide mounted horizontally inside a 'shelter' consisting of two parallel metal discs joined together by three equidistant 10-cm struts; the upper disc acts as a rain shield. Particle deposition is greatly affected by e.g. the speed and direction of the wind and by turbulence, and the volume of air sampled is unknown.

**Durham tube** A transparent glass tube (2–4 cm long, internal diam. ca. 3–4 mm), closed at one end, used to detect gas production by microorganisms during growth in a liquid medium. An *inverted* Durham tube is placed in a test-tube of liquid medium before sterilization; when the medium is autoclaved all the air is driven from the Durham tube which thus sinks to the bottom of the test-tube. On inoculation and incubation, any gas formed is trapped in the Durham tube.

**Durvillaea** See PHAEOPHYTA.

**Dutch elm disease** A disease of elm trees (*Ulmus* spp) caused by *Ceratocystis ulmi*. In the 1970s/1980s a new aggressive strain of *C. ulmi* caused massive epiphytotic, destroying millions of elms throughout Europe, SW Asia and North America. The disease is spread by bark beetles of the Scolytidae (commonly *Scolytus* spp) in a complex series of interactions [review: Book ref. 77, pp. 271–306]. Essentially, adult beetles, carrying *C. ulmi* propagules, emerge during the spring and summer and feed in the tops of healthy trees; the beetles feed in the crotches of young twigs, and some of the resulting wounds become contaminated with *C. ulmi*. The pathogen develops and spreads within the xylem vessels ('pathogenic phase') and infected twigs wilt and show characteristic streaks or spots; TYLOSES are formed, and the whole tree may die within months. The inner bark (phloem) of dying and dead trees becomes a suitable breeding ground for the scolytid beetles. Female beetles excavate extensive breeding galleries in the bark. *C. ulmi* colonizes these galleries ('saprotrophic phase') and sporulates abundantly (forming conidia, including synnematospores, and ascospores) during the autumn and winter when the larvae are developing. The new generation of adult beetles, carrying spores of *C. ulmi*, emerges the following year to feed in the twigs of healthy trees, thus completing the cycle.

Various 'diseased' strains of *C. ulmi*, characterized by abnormal or reduced growth and impaired reproductive fitness, have been isolated. The disease is apparently caused by an infectious agent, called a 'd factor' (for disease factor), which is spread between mycelia by hyphal fusion during the bark stage of the fungus; it has been found that certain diseased isolates contain

10 distinct dsRNA segments whereas healthy isolates contain 0–4 dsRNA segments, suggesting that specific dsRNA segments may be associated with the development of disease [PP (1986) 35 277–287]. (See also CHESTNUT BLIGHT and MYCOVIRUS.)

**Duttonella** A subgenus of TRYPANOSOMA within the SALIVARIA; species include parasites and pathogens of a range of wild and domestic animals (see e.g. NAGANA). The trypomastigote form typically has a large, terminal kinetoplast and a free flagellum.

*T. (D.) vivax* occurs in the vertebrate in the trypomastigote form (ca. 20–30 µm in length) which divides by longitudinal binary fission; it is transmitted cyclically by *Glossina* spp – in which epimastigotes and metacyclic forms develop solely in the proboscis. Mechanical transmission by other biting flies (e.g. *Tabanus*) occurs outside the tsetse belt.

*T. (D.) uniforme* is similar to *T. (D.) vivax*, though somewhat smaller.

**Duval's bacillus** *Shigella sonnei*.

**Duvenhage virus** See LYSSAVIRUS.

**DVH** DUCK VIRUS HEPATITIS.

**dw** Dry weight.

**dwarf bunt** See COMMON BUNT.

**DWELL** See ETRIDIAZOLE.

**dyad symmetry** See e.g. PALINDROMIC SEQUENCE.

**dye** A water-soluble, aromatic compound which has coloured anions and/or cations that can bind to particular substance(s); binding may be primarily ionic but may involve e.g. hydrogen-bonding. (See also AUXOCHROME; CHROMOPHORE; LEUCO COMPOUND.) (In microbiology 'dye' is often used interchangeably with 'stain' to refer not only to dyes, as defined, but also to other substances – e.g. LYSOCHROMES – used for STAINING; 'stain' may also refer to a *mixture* of dyes and/or to the process of using a dye or stain.) An *acid dye* has a coloured anion which combines with cationic groups. A *basic dye* has a coloured cation which combines with anionic groups. A *neutral dye* is a compound of acid and basic dyes in which each ion contains a chromophore. (The pH of a solution of such dyes does not necessarily indicate whether the dye is acid, basic or neutral.) An *amphoteric dye* is either acidic or basic according to pH. Although dyes are commonly used for STAINING, some have additional uses: see e.g. ACRIDINES, ETHIDIUM BROMIDE, METHYLENE BLUE, TRIPHENYL-METHANE DYES; see also PH INDICATORS, RESAZURIN TEST.

Dyes are classified according to the nature of their chromophores. Those based on a (*para*- or *ortho*-) quinonoid ring include the TRIPHENYLMETHANE DYES, xanthene dyes (e.g. EOSIN, pyronin), azine dyes (e.g. JANUS GREEN, NEUTRAL RED, NIGROSIN), azine-related dyes (oxazines, e.g. NILE BLUE A; thiazines, e.g. METHYLENE BLUE, thionin, toluidine blue), and HAEMATEIN. Dyes with a chromophore of one or more azo groups (–N=N–) include BISMARCK BROWN, CHLORAZOL BLACK E, CONGO RED and TRYPAN BLUE; Janus green also contains an azo group. Dyes with a nitro group as chromophore include 2,4,6-trinitrophenol (picric acid).

**dye-buoyant density centrifugation** See *ultracentrifugation* in the entry CENTRIFUGATION.

**dye test** *Syn.* TOXOPLASMA DYE TEST.

**Dynabeads**<sup>®</sup> Microscopic beads used in *magnetic separation*: a technique in which a particular type of cell or molecule is separated from a mixture (in the liquid phase) by allowing the required cells or molecules to bind to beads coated with a specific ligand – the beads then being segregated by use of a magnetic field.

Dynabeads<sup>®</sup> (Dynal, Skøyen, Oslo, Norway) are microscopic spheres that contain a mixture of iron oxides; they are *super-paramagnetic*, i.e. they do not exhibit magnetic properties until

placed in a magnetic field. The beads can be coated with any of a variety of ligands – the particular type used depending on the required cell or molecule. For example, if beads are coated with the oligonucleotide T-T-T-T-T-T they will bind the poly-A tails of mRNA molecules; this approach can be used to separate mRNAs from total RNA.

Essentially, the beads are well dispersed within the sample by thorough mixing; the required cells or molecules bind to the beads – which are then drawn to one side of the vessel by a magnetic field. Unwanted material is discarded, and the required cells/molecules can be washed etc. prior to use. (Note that permanently magnetic beads would not be suitable: they would clump together rather than disperse within the sample.)

Beads coated with specific antibodies are useful for isolating particular pathogens – *E. coli* O157, *Salmonella* spp, *Listeria monocytogenes* etc. – from food or other specimens; the bead–pathogen complex can be plated on a suitable medium. This approach can also be used to isolate a specific type of eukaryotic cell from a mixture of cells. This method is called *immunomagnetic separation* (IMS).

Examples of use include: enrichment of *Mycobacterium paratuberculosis* in milk [AEM (1998) 64 3153–3158]; detection of *E. coli* O157 in meat [LAM (1998) 26 199–204]; preparation of human glomerular endothelial cells for use in tests with *E. coli* verocytotoxin [Kidney International (1997) 51 1245–1256]; detection of specific mycobacterial DNA prior to PCR ('sequence capture' PCR) [JCM (1996) 34 1209–1256].

**dynein** See FLAGELLUM (b).

**dysentery** A disease characterized by inflammation of the intestine (particularly the colon), abdominal pain, and frequent passage of fluid stools that may contain blood, mucus and/or pus. 'Dysentery' (rather than DIARRHOEA) is the term generally used to refer to a diarrhoeal condition in which (i) blood/mucus is typically present in the stool, and (ii) the intestinal epithelium is actively *invaded* by the causative organism (as is the case with e.g. *Shigella dysenteriae*, enteroinvasive *E. coli* and *Entamoeba histolytica*).

(1) (*med.*) (a) *Bacillary dysentery*. The classical (severe) form of dysentery is caused by *Shigella dysenteriae* serotype 1 (found mainly in tropical countries); somewhat less severe disease is caused by *S. sonnei* (a common causal agent in temperate zones), *S. boydii* (mostly tropical) and *S. flexneri*. As well as the *shigellosis*, caused by *Shigella* spp, bacillary dysentery can be caused e.g. by EIEC.

Dysentery caused by *S. dysenteriae* type 1 is transmitted via the faecal–oral route – commonly via food or water contaminated with faeces from patients with dysentery (or from a carrier of the pathogen). Incubation period: 1–6 days. Onset is abrupt, with fever followed by diarrhoea and abdominal cramps. *S. dysenteriae* proliferates in the gut lumen and invades the epithelium of the terminal ileum and colon. While dysentery due to *S. sonnei* and *S. boydii* is typically self-limiting (lasting days), that caused by *S. dysenteriae* may cause ulceration of the intestinal mucosa and may last for weeks, leading to exhaustion and anaemia; mortality may be high in untreated cases.

In animal studies, *Shigella* is taken up via the so-called 'M cells' in Peyer's patches [M cells in infection (review): TIM (1998) 6 359–365]; from this location the bacteria can spread from cell to cell within the epithelial layer. Such spreading (an essential feature of dysentery) depends on the presence of a (plasmid-encoded) outer membrane protein: IcsA (= VirG). (IcsA is the  $\alpha$ -domain of an autotransporter: see type IV secretory systems in PROTEIN SECRETION. An analogous

protein occurs in EIEC.) IcsA promotes *actin-based motility*: i.e. it induces polymerization of actin filaments at one pole of the cell – forming a growing 'tail' of actin which propels the bacterium (through the host cell cytoplasm) in a direction opposite to that of the developing tail. The tail remains stationary within the host cell: ongoing deposition of actin causes bacterial motility. The motile bacterium pushes into the wall of the adjacent cell, either forming a pocket or becoming enclosed within a vacuole (bounded by a double membrane); *Shigella* lyses the membranes, thus entering the adjacent cell. Mutants lacking a functional IcsA do not spread, and do not cause dysentery.

*Shigella* taken up by M cells may be engulfed by macrophages which occur beneath the M cells. *Shigella* can kill macrophages (see APOPTOSIS), and in the resulting inflammatory response PMNs may migrate *between* epithelial cells to reach the gut lumen; such migration is likely to expose basolateral surfaces of epithelial cells to invasion by *Shigella* [TIM (1997) 5 201–204].

*Shigella* can induce uptake by the so-called 'trigger mechanism', invasion apparently occurring via the basolateral surfaces of epithelial cells; the bacterial adhesin(s) are unknown, but epithelial cell receptors may include integrins (which occur on basolateral surfaces). Invasion involves a type III secretory system (see PROTEIN SECRETION) encoded by the plasmid-borne *mxi-spa* genes. The same plasmid also encodes IpaA; this protein is translocated to the epithelial cell where it induces certain changes (e.g. actin polymerization) needed for uptake. During uptake (*macropinocytosis*), the bacterium is engulfed by extrusions of host cell membrane which are supported by actin microfilaments. The bacterium thus induces its own uptake; moreover, the host cell's GTPase 'Rho' also appears to be required. Following uptake (into a vacuole), *Shigella* lyses the membrane and escapes into the host cell's cytoplasm; such lysis may involve the (plasmid-encoded) IpaB protein. Cell-to-cell translocation within the epithelial layer can then occur as described above.

[Invasion of host cells by *Shigella* and subsequent inflammation: FEMS Reviews (2001) 25 3–14.]

*Shigella dysenteriae* serotype 1 produces SHIGA TOXIN (q.v.); the role of this toxin in dysentery is not fully understood, but it may be at least partly responsible for the vascular damage and bloody stools.

*Lab. diagnosis*. Culture from stool, or rectal swab, followed by serological typing; colicin and/or phage typing may also be useful.

*Treatment*. Antibiotics (when indicated, and in accordance with results from susceptibility tests); fluid and electrolyte replacement. (See also ORAL REHYDRATION SOLUTION.)

(b) *Amoebic dysentery* (amoebiasis) is caused by *Entamoeba histolytica* (see ENTAMOEBA). Infection follows ingestion of cysts from the faeces of patients or carriers. Following excystment, the organisms localize in the large intestine and attack the mucosa; establishment of infection apparently requires the presence of normal gut bacteria (see GASTROINTESTINAL TRACT FLORA). Symptoms range from mild, intermittent diarrhoea to severe, and occasionally fatal, dysentery with blood and mucus in the stools. (Trophozoites produce cyto/enterotoxin(s) [Inf. Immun. (1985) 48 211–218].) Chronic relapsing cases, particularly in endemic regions, may be associated with the development of tumour-like granulomatous masses (called *amoebomas*) in the large intestine. Severe amoebic dysentery may be associated with *amoebic hepatitis* (apparently *not* due to amoebic invasion of the liver). The parasite may also cause abscesses, usually in the liver but also in the lungs, brain etc.; the presence of viable

## dysgonic

amoebae in patients with high titres of antibodies may be at least partly explained by the ability of amoebae to shed aggregates of absorbed antibodies ('caps' – see CAPPING sense 3) [JID (1986) 153 927–932].

*Lab. diagnosis* involves e.g. demonstration of trophozoites and/or cysts in stools or lesions. (See also FLOTATION.)

*Chemotherapy*: see AMOEBICIDE.

(c) *Balantidial dysentery* (balantidiasis) is a severe, sometimes fatal, dysentery caused by *Balantidium coli* (see BALANTIDIUM). Infection follows ingestion of cysts in food or water contaminated with infected swine faeces. Excystment occurs in the gut; trophozoites cause extensive ulceration of the colon mucosa.

*Lab. diagnosis*: identification of trophozoites or cysts in faeces.

*Chemotherapy*: e.g. diiodoHYDROXYQUINOLINE.

(2) (*vet.*) See e.g. LAMB DYSENTERY, SWINE DYSENTERY, WINTER DYSENTERY. (cf. SCOURS.)

**dysgonic** See EUGONIC.

**dyskinetoplasty** In e.g. certain naturally-occurring strains of *Trypanosoma evansi*: the absence of a normal KINETOPLAST – the mitochondrion containing, instead, a small, spherical, electron-dense body, the 'kinetoplast remnant', which is not visible in Giemsa-stained preparations. Dyskinetoplastic strains of *T. evansi* and other trypanosomes can be obtained by exposure to e.g. Berenil.

**dysphotic zone** See PHOTIC ZONE.

**dyspnoea** (dyspnea) Difficult or laboured breathing.

**Dysteria** See HYPOSTOMATIA.

**DZM** Dorsal zone of membranelles: a SYNCILIUM (or syncilia) occurring in the anteriodorsal region of some ciliates, e.g. *Diplodinium*, *Epidinium*.

1. Words in SMALL CAPITALS are cross-references to separate entries.
2. Keys to journal title abbreviations and Book ref. numbers are given at the end of the Dictionary.
3. The Greek alphabet is given in Appendix VI.
4. For further information see 'Notes for the User' at the front of the Dictionary.

# E

**E** (1) See REDOX POTENTIAL. (2) Glutamic acid (see AMINO ACIDS).

**E-cadherin** See CADHERINS.

**E. coli** An abbreviation which usually refers to the bacterium *Escherichia coli* (see entry ESCHERICHIA) but which is also used e.g. for the protozoan *Entamoeba coli*. (This illustrates the need to ensure that the name of a genus is spelt out in full – on first usage – before using an abbreviated form.)

**E\* precursor cells** (*immunol.*) Cells on whose surface COMPLEMENT FIXATION has occurred, at 4°C, but which do not lyse unless the temperature is raised; lysis can be further inhibited, even at higher temperatures, by EDTA or zinc or uranyl salts.

**E protein** See F PLASMID.

**E-selectin** *Syn.* CD62E.

**E site** (of a ribosome) See PROTEIN SYNTHESIS.

**E test** A diffusion test for determining the MIC of a given bacterial strain with respect to particular antibiotic(s). One side of a plastic strip (placed in contact with the inoculated plate) carries a given antibiotic, the concentration of which decreases uniformly from one end of the strip; the other side of the strip is graduated with the concentration of antibiotic. Following incubation, the MIC is read by noting the lowest concentration of antibiotic (on the scale) which corresponds to inhibition of growth. Several strips, each with a different antibiotic, can be used simultaneously on a standard-sized plate.

The E test has been used for various bacteria, including *Pseudomonas aeruginosa* [JCM (1991) 29 533–538] and [*Helicobacter pylori*] [JCM (1997) 35 1842–1846]. [*Mycobacterium tuberculosis*]: JCM (2002) 40 2282–2284.]

**E<sub>0</sub>** (E<sup>0</sup>) See REDOX POTENTIAL.

**E<sub>0</sub>'** See REDOX POTENTIAL.

**(E<sub>1</sub>E<sub>2</sub>)-type H<sup>+</sup>-ATPase** See PROTON ATPASE.

**e14 element** See RECOMBINATIONAL REGULATION.

**E5531** See ENDOTOXIC SHOCK.

**EA** Erythrocyte–antibody (see e.g. HAEMOLYTIC SYSTEM). (cf. EAC.)

**EAC** Erythrocyte–antibody–complement. EAC 142... indicates that COMPLEMENT components 142... have been fixed. (cf. EA.)

**eaec gene** See PATHOGENICITY ISLAND.

**EAEC** (1) ENTEROADHERENT *E. COLI* [RMM (1995) 6 196–206].

(2) Enteroaggregative *E. coli* (see EAGGEC) [MR (1996) 60 167–215 (p. 186)].

**EAF plasmid** See PATHOGENICITY ISLAND and BUNDLIN.

**EAggEC** Enteroaggregative *Escherichia coli*: strains of *E. coli* associated with persistent diarrhoea – usually (though not exclusively) in children in the developing countries. (See also ENTEROADHERENT *E. COLI*.) The organisms form toxins and adhesins, but the mechanism of pathogenesis is unknown. EAggEC may be particularly important as pathogens for undernourished/immunosuppressed patients. [Enteroaggregative and diffusely adherent *E. coli*: RMM (1995) 6 196–206.]

Strains of O111:H12 in Brazil were reported to have the properties of EAggEC [FEMS (1997) 146 123–128].

(See also EAEC and EAST 1.)

**Eagle's medium** Any of a number of growth or maintenance media (used in TISSUE CULTURE) consisting basically of EARLE'S BSS or HANKS' BSS supplemented with e.g. amino acid(s), vitamin(s), antibiotic(s), serum etc.

**ear microflora** The microflora of the human ear (external auditory canal) commonly includes e.g. strains of *Staphylococcus*,

*Corynebacterium*, *Mycobacterium* and various yeasts. (See also BODY MICROFLORA.)

**Earle's BSS** Earle's BALANCED SALT SOLUTION; it contains (g/l): NaCl (6.8), KCl (0.4), MgSO<sub>4</sub>·7H<sub>2</sub>O (0.2), NaH<sub>2</sub>PO<sub>4</sub>·2H<sub>2</sub>O (0.158), CaCl<sub>2</sub>·2H<sub>2</sub>O (0.264), NaHCO<sub>3</sub> (2.2), glucose (1.0), and phenol red (0.01); pH: 7.6–7.8.

**early blight** (of potato) A POTATO DISEASE caused by *Alternaria solani*. Small dark spots appear on leaves, each spot having concentric rings of necrotic tissue which give a characteristic 'target' appearance; tubers may exhibit a superficial brown, dry, corky rot.

**early genes** See VIRUS.

**earth balls** See SCLERODERMATALES.

**earth stars** See LYCOPERDALES.

**earth tongues** Fruiting bodies of species of e.g. *Geoglossum* or *Trichoglossum*.

**East Coast fever** An East African tick-borne disease of cattle caused by species of THEILERIA; *T. parva* and *T. lawrencei* cause a febrile disease which is usually fatal, while *T. mutans* typically causes non-febrile anaemia which may be fatal. After the tick vector has ingested blood from an infected bovine host, sexual stages of *Theileria* appear in the tick's gut; zygotes develop in the gut, and each forms a motile kinete which migrates to the tick's salivary glands and undergoes schizogony to form infective sporozoites. The tick can then infect a fresh bovine host. In the new (vertebrate) host the parasite grows in fixed and/or circulating lymphoid cells and forms *macroschizonts* ('Koch's blue bodies'; 'blue bodies'); schizonts, 10–20 µm in size, whose cytoplasm stains blue with Giemsa's stain. Subsequently, intra-erythrocytic forms ('piroplasms') of *T. parva* (or *T. mutans*) become common, but may be scanty/undetected in *T. lawrencei*. *T. parva* and *T. lawrencei* infections usually kill after 15 days. [Life cycles of *Babesia* and *Theileria*: AP (1984) 23 37–103. Anti-*T. parva* vaccine: Annals New York Acad Sci (2000) 916 464–473.]

**EAST 1** A heat-stable toxin secreted e.g. by EAGGEC, many strains of EHEC O157:H7, and by *Yersinia enterocolitica*; it is an analogue of the endocrine hormone *guanylin* (which stimulates fluid outflow from the intestinal mucosa by activating guanylyl cyclase).

**eastern equine encephalomyelitis** (EEE; eastern equine encephalitis; eastern encephalitis) An acute ENCEPHALITIS (or encephalomyelitis) of man and horses, caused by an ALPHAVIRUS; it occurs in eastern North America, the Caribbean, and parts of Central and South America. EEE virus can also cause disease in domestic birds (pigeons, pheasants). The virus occurs in wild birds, in which transmission occurs mainly via *Culiseta melanura*; other mosquitoes (e.g. *Aedes* spp) may be responsible for the sporadic transmission of EEE to animals and man. In man, the mortality rate may be ca. 25–70% or higher. Epizootics in horses may be controlled by vaccination.

**Eaton's agent** *Mycoplasma pneumoniae*.

**EB** ELEMENTARY BODY.

**EB virus** EPSTEIN–BARR VIRUS.

**EBERs** (EBV) See EPSTEIN–BARR VIRUS.

**ebna genes** (EBV) See EPSTEIN–BARR VIRUS.

**Ebola virus** See FILOVIRIDAE.

**EBV** EPSTEIN–BARR VIRUS.

## EC

**EC** (1) Energy charge (See ADENYLATE ENERGY CHARGE). (2) Enzyme Commission (see ENZYME).

**ECA** ENTEROBACTERIAL COMMON ANTIGEN.

**ecad** A distinct population, within a given species, which has adapted phenotypically to its environment. (cf. ECOTYPE.)

**ecchymosis** See PURPURA.

**Eccrinales** See TRICHOMYCETES.

**ecdysis** The shedding of an outer layer: e.g., the exoskeleton of an invertebrate, or the theca in certain DINOFLAGELLATES.

**Echinamoeba** See AMOEBIDA.

**echinocandin B** See ACULEACIN A.

**echinomycin** See QUINOXALINE ANTIBIOTICS.

**Echinosporangium** See MUCORALES.

**Echinosteliales** See MYXOMYCETES.

**Echinosteliopsidales** See MYXOMYCETES.

**Echinosteliopsis** See MYXOMYCETES.

**Echinostelium** A genus of slime moulds (class MYXOMYCETES) which form protoplasmodia and small, stalked sporangia (<0.5 mm tall). *E. lunatum* is the smallest known myxomycete, forming stalked sporangia <50 µm tall and bearing only 4–8(–14) spores. [Encystment of myxamoebae and protoplasmodia in *E. minutum*: Mycol. (1985) 77 253–258.]

**echinulate** Covered with small spines.

**echoviruses** See ENTEROVIRUS.

**eclipse complex** See TRANSFORMATION (1).

**eclipse period** See ONE-STEP GROWTH EXPERIMENT.

**EcoB** A type I RESTRICTION ENDONUCLEASE.

**EcoK** A type I RESTRICTION ENDONUCLEASE.

**econazole** See AZOLE ANTIFUNGAL AGENTS.

**Economo's encephalitis** *Syn.* VON ECONOMO'S ENCEPHALITIS.

**EcoPI** A type III RESTRICTION ENDONUCLEASE.

**EcoRI** A RESTRICTION ENDONUCLEASE from *Escherichia coli*; G/AATTC.

**EcoRV** See RESTRICTION ENDONUCLEASE (table).

**ectotropic** Refers to a (endogenous or exogenous) retrovirus which can replicate only in hosts of the species in which it originated. (cf. XENOTROPIC, AMPHOTROPIC.)

**ecotype** A distinct population, within a given species, which has adapted genetically to its environment. (cf. ECAD.)

**ectendomycorrhiza** See MYCORRHIZA.

**ectocarpene** See PHEROMONE.

**Ectocarpus** See PHAEOPHYTA.

**ectocyst** See CYST (b).

**ectomycorrhiza** See MYCORRHIZA.

**ectoparasite** See PARASITE.

**ectoplasm** See e.g. SARCODINA.

**ectoplasmic net** See LABYRINTHULAS and THRAUSTOCHYTRIDS.

**ectosymbiont** An organism which lives on another organism in a symbiotic association (SYMBIOSIS sense 1); an ectosymbiont remains external to the cells and tissues of a host, although it may live e.g. within the gut cavity of the host. (cf. ENDOSYMBIONT.)

**Ectothiorhodospira** A genus of photosynthetic bacteria originally placed in the family CHROMATIACEAE but later proposed as type genus of a new family, Ectothiorhodospiraceae [JISB (1984) 34 338–339]. Cells: spiral, vibrioid or rod-shaped; they contain Bchl *a* or Bchl *b* (according to species – see CHLOROPHYLLS) and various CAROTENOIDS (cell suspensions are typically brown to brown-red). The pigments occur in lamellar intracytoplasmic membrane systems which are continuous with the cytoplasmic membrane. Motility is mediated by a single polar flagellum or by a polar tuft of flagella. Gas vacuoles occur in some strains. The organisms occur typically in alkaline sulphide-containing saline habitats; they grow optimally at pH 7.5–9.1

with a salt concentration of ca. 3–30%, sulphide being oxidized to elemental sulphur which is deposited extracellularly. Species include e.g. *E. abdelmalekii*, *E. halochloris*, *E. halophila* and *E. vacuolata*.

**ectothrix infection** See DERMATOPHYTES.

**ectotrophic mycorrhiza** See MYCORRHIZA.

**ectotunica** See BITUNICATE ASCUS.

**Ectrogella** See SAPROLEGNIALES.

**ectromelia virus** (mousepox virus) A virus (genus ORTHOPOXVIRUS) which infects mice, causing a disease (mousepox) in which internal organs (mainly liver and spleen) are involved, and characteristic lesions develop on the skin. Ectromelia virus replicates slowly on the CAM, forming small, white, irregularly shaped pocks.

**eczema** An inflammatory condition of the skin involving redness, itching, development of papules and vesicles etc; it is usually an allergic reaction. *Eczema herpeticum* and *eczema vaccinatum* are severe, sometimes fatal, generalized conditions resulting from disseminated infection with herpes simplex virus and vaccinia virus, respectively; they occur most commonly in patients with atopic dermatitis or certain immunodeficiency syndromes.

(See also PROBIOTIC)

**ED pathway** ENTNER–DOUDOROFF PATHWAY.

**ED<sub>50</sub>** Effective dose (50%): that dose of a given agent which, when given or applied to each of a number of experimental test animals or systems, affects 50% of those animals or systems under given conditions.

**Edam cheese** See CHEESE-MAKING.

**edaphic** Of or pertaining to terrestrial habitats – particularly soil, but also e.g. leaf litter and the surfaces of living plants.

**EDDA** An iron chelator: ethylenediamine-di(*o*-hydroxyphenylacetic acid).

**edeines** A group of basic linear peptide antibiotics produced e.g. by *Bacillus brevis*; they are effective against a broad spectrum of organisms, including Gram-positive and Gram-negative bacteria, fungi, and some mammalian cells. At low concentrations edeines are bacteriostatic, selectively and reversibly inhibiting DNA synthesis; at higher concentrations they may be bactericidal, inhibiting the synthesis of proteins but apparently not of RNA.

**Edefäule** (German) *syn.* NOBLE ROT.

**edema** *Syn.* OEDEMA.

**edifenphos** See HINOZAN.

**editing (RNA)** See RNA EDITING.

**EDTA** Ethylenediaminetetraacetic acid: (CH<sub>2</sub>.N(CH<sub>2</sub>COOH)<sub>2</sub>)<sub>2</sub>. EDTA strongly chelates divalent metal ions (e.g. Zn<sup>2+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup>); it is used e.g. as an ANTICOAGULANT (preventing clotting by complexing plasma Ca<sup>2+</sup>) and as a potentiating agent in certain antibacterial preparations (see e.g. DETTOL CHELATE). EDTA causes a non-specific increase in the permeability of Gram-negative bacteria, and under certain conditions it can inhibit or lyse many Gram-negative species – *Pseudomonas aeruginosa* being particularly susceptible; the antibacterial activity of EDTA may involve one or more of several phenomena: e.g., loss of structural integrity of the OUTER MEMBRANE due to chelation of membrane-stabilizing divalent cations, and potentiation of peptidoglycan-degrading autolysins. EDTA has been used in the preparation of SPHAEROPLASTS of Gram-negative bacteria (see also OSMOTIC SHOCK). (The susceptibility of *P. aeruginosa* to EDTA can be decreased by growth in Mg<sup>2+</sup>-limited media owing to changes in the outer membrane proteins [JGM (1983) 129 509–517].) (cf. CDTA; EGTA; NTA.)

**Edwardsiella** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: ca. 1 × 2–3 µm, motile (except

*E. ictaluri*). VP –ve; acid (commonly with gas) from glucose; lactose –ve; phenylalanine deaminase –ve; arginine dihydrolase –ve; lysine decarboxylase +ve. Vitamins and amino acids are required for growth. Optimum temperature: 37°C (ca. 25°C for *E. ictaluri*). The organisms are usually resistant to colistin but sensitive to other antibiotics (including penicillins); R plasmids are rare. GC%: 53–59. Type species: *E. tarda*.

*E. anguillimortifera*. *Nomen dubium* [Book ref. 22, pp. 488–489].

*E. hoshinae*. Indole usually –ve; MR +ve; H<sub>2</sub>S –ve (on TSI); acid from e.g. sucrose, D-mannitol and trehalose. *E. hoshinae* occurs in the intestines of animals (including mammals, fish and reptiles).

*E. ictaluri*. Non-motile. Indole –ve; MR –ve; H<sub>2</sub>S –ve (on TSI); no acid from sucrose, D-mannitol or trehalose. Causal agent of ENTERIC SEPTICAEMIA in channel catfish.

*E. tarda*. Indole +ve; MR +ve; H<sub>2</sub>S +ve (on TSI); usually no acid from sucrose, D-mannitol or trehalose. A few strains ('biogroup 1') produce acid from e.g. sucrose and D-mannitol but not from trehalose. *E. tarda* occurs in the intestines of animals (including mammals, fish and reptiles). It can be an opportunist pathogen in man, and may be a cause of diarrhoea; it can also cause localized and generalized sepsis in fish.

[Book ref. 22, pp. 486–491.]

**EEE** EASTERN EQUINE ENCEPHALOMYELITIS.

**Eel Virus European** See IPN VIRUS.

**EES** Ethylethane sulphonate: a mutagenic ALKYLATING AGENT.

**EF** (1) Elongation factor: see PROTEIN SYNTHESIS. (2) Oedema (edema) factor: see ANTHRAX TOXIN.

**efavirenz** See ANTIRETROVIRAL AGENTS.

**EF<sub>0</sub>F<sub>1</sub> H<sup>+</sup>-ATPase** See PROTON ATPASE.

**effective publication** See NOMENCLATURE.

**efficiency of plating** See EOP.

**efflux mechanism** (of antibiotic resistance) In some microorganisms: any of various systems (usually or always energy-dependent) which can mediate resistance to an ANTIBIOTIC (or to more than one antibiotic) by extruding such agent(s) through the cytoplasmic membrane or the cell envelope; efflux involves a TRANSPORT SYSTEM that often consists of a complex of proteins but which, in some cases, comprises a single protein. Efflux transporters are classified according to their overall structure and e.g. the homology of amino acid sequences in component proteins; some efflux systems are ABC TRANSPORTERS, while others are found e.g. in the major facilitator superfamily (MFS) or resistance–nodulation–division (RND) superfamily. (See also MATE.)

For examples of efflux-dependent antibiotic resistance (and/or references) see e.g. entries ABC TRANSPORTER, MACROLIDE ANTIBIOTICS, QUINOLONE ANTIBIOTICS, TETRACYCLINES.

**effused-reflexed** (*mycol.*) Refers to a sheet-like fruiting body which lies flat against the substratum except at the edge(s), the latter growing outwards from the substratum.

**EF-G** See PROTEIN SYNTHESIS (elongation).

**efornithine** See SLEEPING SICKNESS.

**efrapeptin** A lipophilic polypeptide which binds non-covalently to and inhibits (F<sub>0</sub>F<sub>1</sub>)-type PROTON ATPASES.

**efrotomycin** See POLYENE ANTIBIOTICS (b).

**EF-Ts, EF-Tu** See PROTEIN SYNTHESIS (elongation).

**EGF** Epidermal growth factor. (See e.g. ONCOGENE.)

**egg** (for cultivating viruses) See EMBRYONATED EGG.

**egg-drop syndrome** In general: any fall in egg production in poultry, due e.g. to poor housing, incorrect nutrition, various POULTRY DISEASES, etc. 'Egg-drop syndrome 1976' is a specific syndrome which came into prominence in the UK and Ireland in

1976; it is caused by an adenovirus which can agglutinate fowl RBCs, and which may be indigenous in duck populations [Book ref. 116, pp. 535–536]. In this syndrome egg-drop is preceded by egg abnormalities – e.g. eggs may be soft-shelled or shell-less.

**egg wrack** *Ascophyllum nodosum*.

**egg-yolk agar** (EYA; lecithovitellin (LV) agar) An agar-based medium incorporating the yolks of hens' eggs (which contain the lipoprotein lecithovitellin). It is used e.g. to test for bacterial extracellular LECITHINASE activity; on EYA the colony of a lecithinase-producing strain is surrounded by a zone of opacity due to the deposition of insoluble diglycerides resulting from lecithin cleavage. (See also NAGLER'S REACTION.) On EYA, strains which produce LIPASES form colonies which are each surrounded by a pearly or iridescent zone due to a thin film of free fatty acids.

**eggplant mild mottle virus** See CARLAVIRUSES.

**eggplant mosaic virus** See TYMOVIRUSES.

**eggplant mottled crinkle virus** See TOMBUSVIRUSES.

**eggplant mottled dwarf virus** See RHABDOVIRIDAE.

**EGME** Ethylene glycol monomethyl ether; it is used e.g. as a BIOCIDES (and antifreeze) in aircraft fuel.

**EGS** (*mol. biol.*) External guide sequence: see SPLIT GENE (a).

**EGTA** A chelating agent, ethyleneglycol-bis(β-aminoethylether)-N,N,N',N'-tetraacetic acid. EGTA complexes a range of cations (e.g. Ca<sup>2+</sup>, Mg<sup>2+</sup>, Zn<sup>2+</sup>); Mg<sup>2+</sup> is complexed much less strongly than is Ca<sup>2+</sup>.

**Egtved disease** (viral haemorrhagic septicaemia; haemorrhagic septicaemia of trout) A FISH DISEASE affecting mainly rainbow trout (*Salmo gairdneri*); the causal agent is a virus (a probable member of the RHABDOVIRIDAE). Symptoms may include skin darkening, bulging of the eyes, and abdominal swelling, or there may be few external symptoms; mortality may be high. The disease was first observed in Egtved, Denmark.

**eguttulate** Lacking GUTTULES.

**E<sub>h</sub>** See REDOX POTENTIAL.

**EHC** See OPTOCHIN.

**EHEC** Enterohaemorrhagic *Escherichia coli*: pathogenic strains of *E. coli* which secrete (at least) one or both shiga-like toxins (see SHIGA TOXIN). Shiga-like toxins are also called *verocytotoxins* (VT1, VT2) because they are toxic for Vero cells (kidney cells of the African green monkey); hence, EHEC is sometimes referred to as verocytotoxic *E. coli* (VTEC). A minority of authors refer to EHEC as shiga-toxin-producing *E. coli* (STEC).

EHEC is not an invasive, intracellular pathogen (cf. EIEC; see also EAGGEC, EPEC, ETEC).

EHEC is typically a food-borne pathogen which produces symptoms ranging from mild diarrhoea to severe bloody diarrhoea (*haemorrhagic colitis*); particularly (though not exclusively) in children, infection can give rise to HAEMOLYTIC URAEMIC SYNDROME. Vascular damage has been associated with the shiga-like toxins.

Strains of EHEC typically contain the LEE PATHOGENICITY ISLAND, and many secrete EAST 1; these factors may be relevant to the inflammatory and secretory symptoms of EHEC-mediated disease [MR (1996) 60 167–215 (pp 186–188)]. It has been reported that the expression of openness on the LEE pathogenicity island is regulated by QUORUM SENSING (q.v.).

Any of >25 serotypes of EHEC may cause disease, but, world-wide, O157:H7 is the serotype isolated most often in haemorrhagic colitis; O157:H<sup>–</sup> is also quite common. [Genome sequence of O157:H7: Nature (2001) 409 529–533; erratum:

## Ehrlichia

Nature (2001) 410 240.] EHEC occurs e.g. in undercooked meat (particularly minced beef), milk and dairy products, and water (both drinking and recreational); the minimum infective dose is apparently <100 cells. In the UK (at least), farm animals (cattle, sheep) appear to constitute the main reservoir of infection. [EHEC (VTEC) O157 and other strains in England and Wales, 1995–1998 (epidemiology): JMM (2001) 50 135–142.]

Under starvation conditions, strains of *E. coli* O157:H7 have been found to lose antigenicity corresponding to the O157 antigen – but to retain the ability to produce shiga-like toxins; this has suggested that immunological methods based on O157 antigenicity may be unsuitable for detecting toxin-producing strains which have been under starvation conditions for a long time [AEM (2000) 66 5540–5543].

**Lab. diagnosis.** Culture on sorbitol–MacConkey agar (SMAC medium) is based on the inability of (most) O157 strains to ferment sorbitol; these strains form pale colonies, while most strains of *E. coli* (which ferment sorbitol) form pink colonies. Increased sensitivity of detection may be achieved by pre-culture enrichment of samples with DYNABEADS [detection of *E. coli* O157 in food [LAM (1998) 26 199–204]. [Sorbitol-fermenting EHEC: JMM (2002) 51 713–714.]

[Lab diagnosis: JCM (2002) 40 2711–2715.]

Molecular methods include a PCR-based assay for the *rfb* gene whose product is essential for synthesis of the O157 lipopolysaccharide [JCM (1998) 36 1801–1804]. This method would not distinguish non-toxigenic strains of O157, but it could form part of a multiplex PCR which also assayed for the toxin gene.

A LATEX PARTICLE TEST for the O157 serotype is available from Oxoid (Basingstoke, UK; product number DR620).

Detection of ‘free’ toxin in patients’ faeces may be achieved by a ‘reversed passive latex agglutination test’ (see LATEX PARTICLE TEST); this test involves observation of latex particles (conjugated with anti-toxin antibodies) in the presence of various dilutions of sample (faecal extracts) [LAM (2001) 32 370–374].

Serotypes other than O157 may be identified by serotyping; probe-based tests can be used to detect toxigenicity.

(See also STARFISH and SYNSORB PK.)

**Ehrlichia** A genus of Gram-negative bacteria of the tribe EHRLICHIEAE. Cells: coccoid, often pleomorphic, non-motile, ca. 0.5–1.0 µm. Growth occurs intracellularly in circulating leucocytes; the bacteria are commonly seen as a group of cells within a membrane-limited inclusion body (‘morula’). Growth does not occur in cell-free media. Type species: *E. canis*.

*E. canis* is the causal agent of canine ehrlichiosis: a disease which occurs worldwide and which is characterized by fever, nasal discharge and anorexia; a severe haemorrhagic form of the disease (‘tropical canine pancytopenia’) occurs in some dogs – particular breeds (e.g. German shepherd) being more susceptible than others. *E. phagocytophila* causes ehrlichiosis in cattle and sheep; *E. equi* causes equine ehrlichiosis; *E. risticii* causes POTOMAC HORSE FEVER (and can be transmitted experimentally to cattle [VR (2001) 148 86–87]); *E. sennetsu* (formerly *Rickettsia sennetsu*) causes ‘sennetsu rickettsiosis’ in man: a disease which, in the severe form, involves fever, anorexia and lymphadenopathy; the disease, which occurs in Japan, has been called ‘glandular fever’, ‘Hyuga fever’, ‘infectious mononucleosis’ and ‘Kagami fever’. (cf. INFECTIOUS MONONUCLEOSIS.)

**Ehrlichieae** A tribe of bacteria of the family RICKETTSIACEAE; species are primarily pathogens of animals (including cattle, dogs, goats and sheep), though *Ehrlichia sennetsu* is pathogenic in man. The genera: COWDRIA, EHRLICHIA, NEORICKETTSIA.

**ehrlichiosis** Any human or animal disease caused by a species of EHRLICHIA.

**Ehrlich’s reagent** An INDOLE TEST reagent: *p*-dimethylaminobenzaldehyde (1 g) is dissolved in 95–100% ethanol (95 ml), and conc. HCl (20 ml) is added; stored at 4°C in the dark.

**EIA** (*serol.*) (1) ENZYME IMMUNOASSAY. (2) ERYTHROIMMUNO-ASSAY.

**EIAV** Equine infectious anaemia virus: see SWAMP FEVER and LENTIVIRINAE.

**eicosanoids** Polyunsaturated fatty acids which contain 20 carbon atoms; examples include ARACHIDONIC ACID and LEUKOTRIENES.

**EIEC** Enteroinvasive *Escherichia coli*: strains of *E. coli* which can invade and destroy epithelial cells in the ileum/colon, causing watery diarrhoea (or (bacillary) DYSENTERY. Invasiveness is dependent on virulence genes carried by a plasmid (*pInv*). EIEC encodes a cell-surface protein analogous to the IcsA protein of *Shigella* (which promotes actin-based motility within epithelial cells: see DYSENTERY); the presence of this protein (in EIEC and *Shigella*) is associated with the absence of a specific cell-surface protease (OmpT in EIEC and SopA in *Shigella*) [Mol. Microbiol. (1993) 9 459–468]. EIEC produces at least one enterotoxin: SHET2 (named after *Shigella* enterotoxin 2: a similar toxin produced by *S. flexneri*); this toxin is encoded by the *sen* gene – a (plasmid) gene formerly referred to as *set2*. [Toxins produced by EIEC: MR (1996) 60 167–215 (p. 188).]

At least part of the secretory (diarrhoeal) effect brought about by invasive organisms (such as EIEC and *Shigella dysenteriae*) is likely to be due to their ability to upregulate cyclooxygenase activity in the intestinal mucosa – this leading to increased expression of PROSTAGLANDINS (such as PGE<sub>2</sub>) with resulting increase in fluid secretion.

EIEC causes disease in both children and adults – outbreaks occurring e.g. in schools, hospitals and institutions. EIEC typically resembles *Shigella* – often being non-motile, and giving negative results in tests for lactose utilization and lysine decarboxylase.

**Eijkman test** An IMVEC TEST which determines the ability of an organism to produce gas from lactose at 44°C ± 0.2°C; the test is often used to confirm the presence of coliforms in a water sample (see COLIFORM TEST) – for which purpose use is made of a medium such as lauryl tryptose lactose broth that includes an agent which inhibits endospore-forming bacteria.

**Eikenella** A genus (*incertae sedis*) of anaerobic, facultatively aerobic, oxidase-positive, catalase-negative, chemoorganotrophic, Gram-negative bacteria which occur e.g. in the human mouth and intestine, and which can be opportunistic pathogens. Cells: non-motile, round-ended rods (0.3–0.4 × 1.5–4.0 µm) or short filaments; rods may exhibit TWITCHING MOTILITY. Growth occurs e.g. on blood agar; haemin is required for aerobic growth of freshly-isolated strains. Plate cultures have a ‘bleach-like’ odour. Optimum growth temperature: 35–37°C. No acid is formed from carbohydrates. Nitrate is reduced to nitrite. Urease –ve. GC%: ca. 56–58. Type species: *E. corrodens*. [Book ref. 22, pp. 591–597.]

**Eimeria** A genus of parasitic, homoxenous protozoa of the suborder EIMERIORINA (q.v. for life cycle). *Eimeria* spp form tetrasporic, dizoic oocysts (cf. e.g. ISOSPORA). No species is known to be pathogenic in man, but many cause disease e.g. in domestic animals (see COCCIDIOSIS).

**eimeriid** Of the suborder EIMERIORINA.

**Eimeriina** (1) A suborder of protozoa (order Eucoccida) later incorporated – together with organisms of the TOXOPLASMEA – in the suborder EIMERIORINA. (2) A suborder of protozoa (order

Eucoccidiida [JP (1980) 27 37–58]) equivalent to the EIMERIORINA.

**Eimeriorina** ('the coccidia') A suborder of parasitic protozoa (order EUCCOCCIDIORIDA) in which syzygy generally does not occur (cf. ADELEORINA) and in which motile zygotes are not formed (cf. HAEMOSPORORINA); sporozoites are typically enclosed within SPORO CYST(S). Genera include e.g. BESNOTIA, CRYPTOSPORIDIUM, EIMERIA, FRENKELIA, ISOSPORA, LANKESTERELLA, SARCOCYSTIS, TOXOPLASMA and TYZZERIA. (Other genera include *Aggregata*, *Angeiocystis*, *Arthrocystis*, *Atoxoplasma*, *Barrouxia*, *Caryospora*, *Caryotropha*, *Cyclospora*, *Diaspora*, *Dobiella*, *Dorisa*, *Dorisella*, *Grasseella*, *Hoarella*, *Mantonella*, *Mero-cystis*, *Octosporella*, *Ovivora*, *Pfeifferinella*, *Pseudoklossia*, *Pythonella*, *Schellackia*, *Selenococcidium*, *Selysina*, *Sivatoshella*, *Skrjabinella*, *Wenyonella*.) Generalized life cycles are given below.

(a) *Homoxenous species* (e.g. *Eimeria* spp). The disseminative forms (*oocysts*) are ingested by a new host, and excystation occurs in the intestine: the oocyst breaks down and liberates a number of banana-shaped, non-flagellated (but motile by flexion) *sporozoites* ca. 5–20 µm in length. Sporozoites penetrate and usually grow within cells of the intestinal mucosa, each sporozoite rounding up and becoming a feeding cell (*trophozoite*). Each trophozoite undergoes SCHIZOGONY and subsequently ruptures its host cell to release many *merozoites* (small cells resembling sporozoites). Merozoites penetrate fresh host cells, become trophozoites, and schizogony is repeated; several schizogonous cycles may occur. Later, intracellular merozoites develop into *gametocytes*. Some gametocytes become large, uninucleate female *macrogametes* which remain in situ; others undergo repeated division and produce small, uninucleate, flagellated cells, the male *microgametes*, which escape from the (ruptured) host cell. Each macrogamete is fertilized in situ, and the zygote encysts to form an *oocyst*. Oocysts are often spherical or oval, ca. 10–40 µm according to species; a MICROPYLE may be present. The oocyst is liberated from the host cell and voided in the faeces. Outside the host the oocyst undergoes SPORULATION (cf. ENDOSPORULATION) in which the zygote gives rise to a number of (haploid) sporozoites. In many species the sporozoites are formed within one or more sacs (*sporocysts*) within the oocyst; the number of sporozoites per sporocyst, and the number of sporocysts per oocyst, are taxonomically important features. The sporulated oocysts are able to infect fresh hosts and complete the life cycle.

(b) *Heteroxenous species*. In these species the asexual and sexual phases of the life cycle typically occur in different host species – referred to as the *intermediate host* and *final (definitive) host*, respectively; some species (e.g. *Toxoplasma gondii*) are facultatively heteroxenous, others (e.g. most or all species of *Sarcocystis*) are obligately heteroxenous. These coccidia often parasitize extra-intestinal tissues – particularly in the intermediate host. In *Sarcocystis* spp the intermediate host becomes infected on ingestion of oocysts and/or sporocysts, and the parasite typically undergoes extra-intestinal schizogony, forming cysts in the muscles (see SARCOCYSTIS); when sarcocysts (or sporocysts) are ingested by the final host, sexual reproduction (only) occurs in the intestinal tissues and sporulated oocysts, or sporocysts, are shed in the faeces. (See also TOXOPLASMO-SIS.)

[See also Book ref. 18, pp. 102–165 (ultrastructure), pp. 229–285 (growth in tissue culture and avian embryos).] (See also COCCIDIOSIS.)

**ejectosome** ('protrichocyst') A type of EXTRUSOME present in CRYPTOPHYTES. Ejectosomes occur just below the cell surface in

the region of the anterior depression (when present) and around the cell periphery; each consists of two interconnected, tightly coiled ribbon-like structures enclosed by a single membrane. On appropriate stimulation of the organism ejectosomes are discharged, the coiled structures of each being ejected to form a long tube. Ejectosomes appear not to be toxic; their function is unknown.

**EI Tor vibrio** See VIBRIO (*V. cholerae*).

**EL1–EL34 proteins** See RIBOSOME.

**elaioplast** A lipid-storing PLASTID.

**ELAM-1** *Syn.* CD62E.

**Elaphomyces** See ELAPHOMYCETALES.

**Elaphomycetales** An order of ectomycorrhizal, hypogean fungi of the ASCOMYCOTINA. The dark, globose ascocarp lacks a hamathecium. Asci: globose and unitunicate; evanescent. The ascocarp of *Elaphomyces* can be parasitized e.g. by *Cordyceps* spp.

**Elasmomycetaceae** See RUSSULALES.

**elastase** A protease which cleaves the protein *elastin* (the main component of elastic fibres in e.g. arterial walls and ligaments). An elastase is formed e.g. by *Clostridium histolyticum* (the δ-toxin) and by *Pseudomonas aeruginosa*; the enzyme formed by *P. aeruginosa* (a zinc metalloenzyme) can also degrade human IgG in vitro (i.e., it can act as an 'IgG protease'), and it appears capable of degrading mouse IgG in vivo [CJM (1984) 30 1118–1124].

**elastictaxis** The tendency, observed in many species of GLIDING BACTERIA, to become orientated parallel to stress lines induced in an agar medium.

**electrical transport** A term used by some authors to include both ELECTROGENIC TRANSPORT and ELECTROPHORETIC TRANSPORT.

**electricity generation** See BIOFUEL CELL.

**electroblotting** See BLOTTING.

**electrochromic effect** See CAROTENOID BAND SHIFT.

**electroendosmosis** (electro-osmosis) The movement of a charged fluid, relative to a fixed medium carrying the opposite charge, under the influence of an electrical gradient. Electroendosmosis occurs e.g. during the IMMUNOELECTROPHORESIS of serum in agar gels. In this procedure (often carried out at pH 8.6) some negatively charged proteins (e.g. γ-globulins) migrate towards the negative pole (cathode). This is due to the ionization of the AGAR; the agar carries a net negative charge, and the fluid contains an excess of positive ions. The fluid thus moves towards the cathode – the flow being sufficiently strong to overcome the attraction of the anode for some negatively charged proteins and to carry them towards the cathode.

**electrofocusing** *Syn.* ISOELECTRIC FOCUSING.

**electrofusion** A wholly electrical method for bringing about the fusion of microbial or plant protoplasts, or animal cells (cf. HYBRIDOMA); essentially, protoplasts or cells are aggregated by a high-frequency alternating electric field and then fused by a short pulse (e.g. 1 ms) of direct current. (cf. ELECTRO-TRANSFECTION.)

**electrogenic transport** Transport across an energy-transducing membrane resulting in the generation of, or change in, a transmembrane electrical potential difference. (cf. ELECTRICAL TRANSPORT and ELECTRONEUTRAL TRANSPORT.)

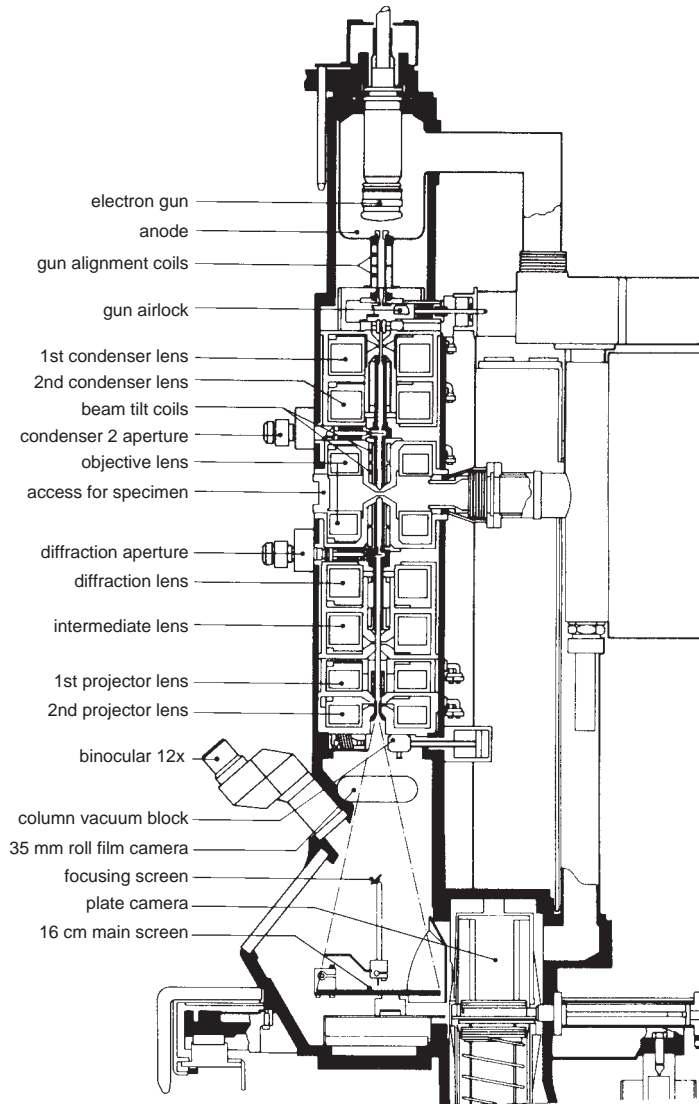

**electroimmunoassay** (1) *Syn.* ROCKET IMMUNOELECTROPHORESIS. (2) Loosely, any form of IMMUNOELECTROPHORESIS.

**electrokinetic potential** *Syn.* ZETA POTENTIAL.

**electron microscopy** MICROSCOPY in which an electron beam interacts with a specimen and subsequently contributes, directly or indirectly, to the formation of an image of the specimen. (The specimen observed may be the original biological specimen

electron microscopy

ELECTRON MICROSCOPY. Cross section of a transmission electron microscope (the Philips EM400). (Courtesy of N. V. Philips' Gloeilampenfabrieken, Eindhoven, Holland.)

or a replica of it.) Electron microscopy can give magnifications within the range ca.  $10\times$  to  $1000000\times$ . Resolving power depends e.g. on the nature of the specimen and on the type of instrument used. The best resolving power is obtained with the transmission electron microscope (see (a) below) which has resolved a structure of ca. 1 nm periodicity in the purple membrane of *Halobacterium salinarium*; for non-periodic biological specimens the best resolution may be ca. 3–5 nm.

Electron microscopy is used e.g. for examining viruses, macromolecules, and the ultrastructure of cells, and for determining the intracellular locations of e.g. specific enzymes and ions (see also IMMUNOELECTRON MICROSCOPY). Although living

material has been examined in the electron microscope (EM), it is usual to examine non-living specimens which have undergone various pre-treatments; treatments vary according to e.g. the nature of the specimen and the purpose of the investigation.

(a) *Transmission electron microscopy.* In the transmission electron microscope (TEM) an electron beam passes *through* the specimen which deflects or scatters some of the electrons; electrons whose paths are slightly deviated by the specimen are focused onto a fluorescent screen to form an image of the specimen. In general, electrons undergo little or no deflection when they pass through thin layers of biological material; hence, unless specially treated, such materials do not yield images in

the electron microscope. However, biological materials can be 'stained' with certain heavy metal compounds which become localized in specific regions of the specimen; this enhances the electron-deflecting properties of those regions and/or increases contrast between the specimen and its background.

*Preparation of thin sections for the TEM.* Typically, a tissue or cell initially undergoes *double fixation*, e.g. pre-FIXATION with GLUTARALDEHYDE and post-fixation with OSMIUM TETROXIDE. The fixed specimen is *dehydrated*, e.g. by equilibration in increasing concentrations of ethanol (or acetone) in water. From 100% ethanol the specimen is commonly transferred to, and equilibrated with, propylene oxide before being *embedded*, i.e., impregnated with an epoxy resin (e.g. SPURR'S MEDIUM) or a methacrylate – substances which polymerize and harden without significant change in volume. (Equilibration of the specimen with propylene oxide between dehydration and embedding is advantageous since propylene oxide is more miscible than ethanol with epoxy resins.) The embedded specimen is then *sectioned* (see MICROTOME) to obtain ultrathin sections of maximum thickness ca. 100 nm. A section is placed on a specimen holder (*grid*): a metal (usually copper) disc, 2–3 mm in diameter, perforated by rows of square holes each ca. 0.1 × 0.1 mm. Before receiving the section the surface of the grid may be coated with a *support film*: a sheet of e.g. FORMVAR or nitrocellulose 20–50 nm thick; such materials have a low, uniform electron-scattering power. (A support film is sometimes omitted when the section is resin-embedded; however, it is essential for a liquid specimen – see e.g. negative staining below.) The support film itself may be coated with a film of carbon (ca. 20 nm thick) which stabilizes it and improves resolution at high magnifications. The section, on the prepared grid, is now *stained*, i.e., immersed in a solution of a heavy metal compound (e.g. uranyl acetate, lead acetate, or a salt of phosphotungstic acid) which combines or complexes with particular components (e.g. lipids, proteins) – a type of staining called *positive staining*; images subsequently formed in the EM thus reflect the distribution of heavy metal atoms and the groups with which they combine. (Staining is sometimes carried out *before* the embedding stage by subjecting the specimen to prolonged exposure to e.g. osmium tetroxide or uranyl acetate; this is called 'in-block' staining.) The section is allowed to dry and is then ready for examination in the TEM.

*Negative staining (negative contrast)* is used to reveal the outlines and surface contours of particulate specimens (e.g. macromolecules, viruses, bacteria). Essentially, the particles are immersed in a thin film of electron-opaque stain on a prepared grid; the stain penetrates the interstices of each particle and forms a thin background layer but usually does not permeate the particles themselves. Electrons are more readily transmitted through those regions occupied by the (relatively) electron-transparent particles, so that in the image these regions appear bright against a dark background; the presence of stain in surface hollows and grooves indicates surface topography. For example, the TOBACCO MOSAIC VIRUS virion appears as a light rod in which a dark, central, axial line indicates the presence of stain in the hollow core. To examine bacterial morphology, one drop of (fixed or unfixed) bacterial suspension is left on a prepared grid for one or more minutes (determined by trial and error) so that cells adhere to the surface; most of the drop is then drawn off with the edge of a filter paper. One drop of stain (e.g. 2% aqueous phosphotungstic acid or 2% aqueous ammonium molybdate) is then placed on the grid; after 30–60 seconds this is drawn off, as before. The fine film on the grid is left to dry and is examined in the TEM. (Alternatively, stain and suspension can be mixed, and the stained suspension applied to the grid.)

*Shadowing (shadow-casting)* is used e.g. to study the morphology and/or dimensions of e.g. viruses and bacteria, and is also involved in the KLEINSCHMIDT MONOLAYER TECHNIQUE for examining nucleic acids. Essentially, the particles (e.g. viruses) on a prepared grid are exposed to a point source of the vapour of a heavy metal; the point source is so placed that metal is deposited on only one side of each particle – leaving a non-metallized (electron-transparent) 'shadow' on the remainder of the particle and on that part of the support film shielded (by the particle) from the vapour. The image of a shadowed particle can give information on the shape and size of the particle; its size can be calculated from the length of the shadow and the angle at which the metal vapour was incident on the particle.

*Replicas* of e.g. a freeze-etched specimen (see FREEZE-ETCHING) may be examined in the TEM. Essentially, this involves shadowing the surface of the frozen specimen with a heavy metal under vacuum; commonly, shadowing is effected at an angle of ca. 30° with a mixture of platinum and carbon vapours. Shadowing throws into relief the features of an irregular surface. Areas protected from the vapour remain non-metallized and are therefore structurally weak; the *primary replica* is therefore strengthened by deposition of a layer of carbon from a vapour source placed directly above the specimen. The replica is cleaned by digesting away the specimen with strong oxidizing and hydrolysing agents (e.g. bleach, sulphuric acid, chromic acid). The replica is mounted on a grid and examined in the TEM.

*The transmission electron microscope (TEM).* A typical TEM is shown in the figure. The electron beam originates at a heated metal filament in the electron gun. The electrons are accelerated through a hole in the anode and pass down through the axis of the instrument; acceleration is caused by a large potential difference ('accelerating voltage') maintained between the anode (at 'earth' or zero potential) and the filament (commonly –100 kV to –500 kV). The accelerating voltage determines the wavelength of the electron beam which, in turn, determines the resolving power; in general, higher accelerating voltages give better resolving power. (Some specimens can be damaged more than others by high accelerating voltages; resolving power is therefore partly determined by the nature of the specimen.) The various magnetic lenses each consist basically of a soft-iron reel on which are wound many turns of copper wire; current passing through the wire generates a magnetic field which controls the electron beam passing axially through the lens. The specimen, on a grid, is placed in the path of the electron beam; electrons which pass through the specimen are focused to form an image on a screen consisting of a metal plate coated with a fluorescent material. During operation, the interior of the tube-like body ('column') of the microscope must be evacuated to prevent e.g. deflection and scattering of the electrons by molecules of gas; pressure in the column is usually less than ca.  $6.5 \times 10^{-5}$  Pa ( $5 \times 10^{-7}$  torr; 0.5 nm Hg).

(b) *Scanning electron microscopy* is used to examine the *surface* of a specimen. The specimen is scanned by an electron beam which moves in a zig-zag raster; a second electron beam synchronously scans a cathode ray tube (CRT) with a similar raster. Electrons which are secondarily emitted from the specimen are collected and used to control the intensity of the beam in the CRT. Since the secondarily emitted electrons vary in quantity from point to point on the specimen's surface (according to surface topography) the electron beam in the CRT will be continually modulated as the specimen is scanned; hence, the CRT screen will display a pattern of bright and less-bright spots corresponding to the surface topography of the specimen.

## electron paramagnetic resonance

The scanning electron microscope (SEM) can give magnifications of ca.  $10\times$  to  $100000\times$ ; for biological specimens it is commonly used at magnifications below ca.  $10000\times$ . Resolution is usually ca. 10–20 nm. The SEM provides a great depth of field, thus giving valuable three-dimensional images.

*Preparation of specimens for the SEM.* Completely untreated specimens have been examined in the SEM. However, specimens (particularly plant material) are often given the following sequence of treatments. (i) Fixation and dehydration – as for TEM thin sections described above. (ii) Drying (removal of all liquid); this is sometimes achieved by FREEZE-DRYING (simultaneous dehydration and drying) but more usually by CRITICAL POINT DRYING. (iii) Attachment of the specimen to a metal (often aluminium) specimen holder (*stub*) by means of a ‘glue’ (e.g. SILVER DAG) which conducts both heat and electricity. (iv) Coating of the specimen, under vacuum, with carbon and/or metal – usually by SPUTTER-COATING; this prevents thermal and electrical build-up on the specimen when it is placed in the electron beam (thus avoiding image distortion and damage to the specimen) and enhances secondary electron emission. (As an alternative to coating, the specimen may be thoroughly impregnated, before dehydration, with e.g. osmium tetroxide.) The specimen is then ready for the SEM.

*Replicas* of a specimen may be made e.g. if repeated observations are to be made of the same specimen. Essentially, fluid plastic or latex is poured over the specimen and allowed to harden. This gives a negative replica which is peeled off and lined with a suitable material that hardens to form the positive replica; the latter is sputter-coated and examined in the SEM.

(c) *Scanning transmission electron microscopy.* In the scanning transmission electron microscope (STEM) electrons pass through the specimen, and the energies of the emergent electrons are measured in an analyser. The pattern of energies of the emergent electrons is used to construct an image of the specimen. The resolving power of the STEM can be similar to that of the TEM. [Introduction to STEM: JUR (1984) 88 94–104; imaging biological structures: JUR (1984) 88 105–120, 177–206.]

(d) *Low temperature electron microscopy (cryoelectron microscopy).* A type of electron microscopy in which very small specimens are cooled rapidly to very low temperatures, without prior dehydration, such that the water in the specimen forms a ‘glass-like’ solid without undergoing crystallization – a phenomenon called *vitrification* [review: TIBS (1985) 10 143–146].

(e) *Three-dimensional electron microscopy.* A procedure intended for three-dimensional examination of biological structures at atomic resolution. [ARBB (1981) 10 563–592.]

**electron paramagnetic resonance** *Syn.* ELECTRON SPIN RESONANCE.

**electron spin resonance** (ESR; electron paramagnetic resonance, EPR) The absorption and consequent emission of electromagnetic radiation by unpaired electrons in certain types of atom in the presence of a strong magnetic field; in general principle ESR resembles NUCLEAR MAGNETIC RESONANCE (q.v.).

Molecules in which atom(s) contain unpaired, ESR-detectable electrons are paramagnetic and are commonly called ‘free radicals’. In biological materials free radicals are produced during many types of metabolic process but they are typically short-lived; however, a stable, paramagnetic probe (*spin label*) can be introduced into an experimental system – e.g. by biosynthetic incorporation or by covalent linking to specific compounds. Most spin labels contain the nitroxide (NO) group; they include derivatives of fatty acids, of the steroids androstane and cholestane, and of 2,2,6,6-tetramethylpiperidine. (In some studies on membrane

systems the presence of the spin label at high concentration can cause significant perturbation of the membrane characteristics.) In ESR the exciting electromagnetic radiation may involve frequencies in the *X-band* (ca. 9.3 GHz) or the *Q-band* (ca. 35 GHz). (1 GHz =  $10^9$  cycles per second.)

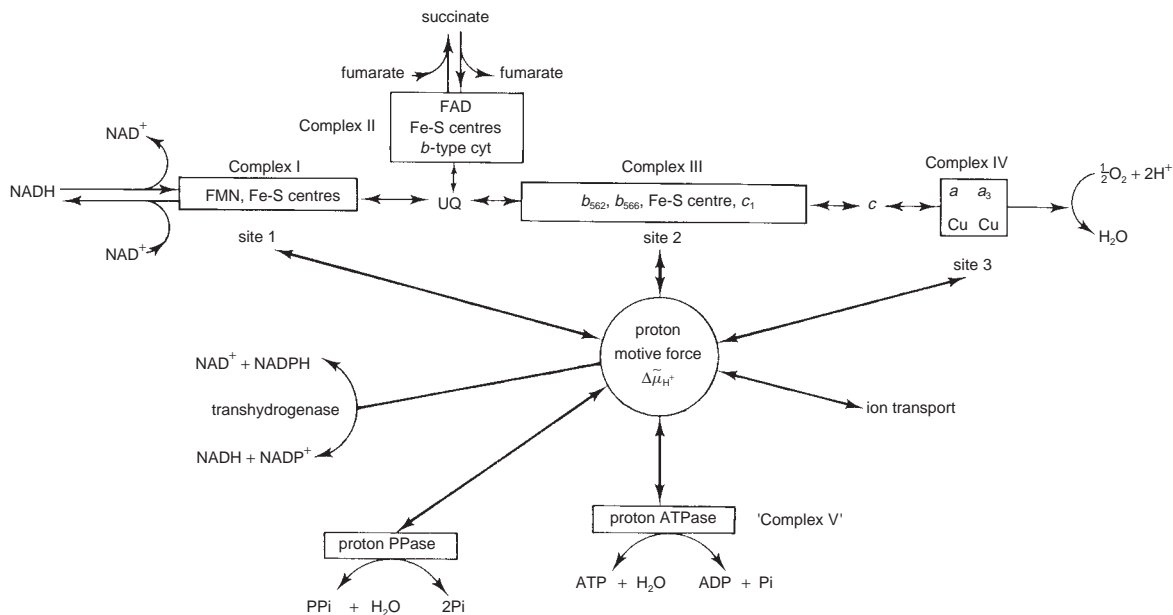

[Book ref. 151.]

**electron transport chain** (ETC; electron transfer chain) A sequence of redox agents along which electrons can be translocated with concomitant conversion of energy; an ETC occurs within an ENERGY-TRANSDUCING MEMBRANE, the redox agents forming a series of redox couples which, collectively, span a REDOX POTENTIAL gradient. In many cases an ETC operates as a *proton pump*: energy yielded during the flow of electrons towards a less negative (or more positive) redox potential is used to extrude protons across the membrane; the transmembrane proton gradient thus formed can be used as a source of energy (see CHEMOSMOSIS). (In some organisms an ETC acts as an  $\text{Na}^+$ -pump: see SODIUM MOTIVE FORCE.) An ETC which is used in the respiratory metabolism of a substrate (see RESPIRATION) is often called a *respiratory chain*; ETCs are also involved in PHOTOSYNTHESIS.

Components of ETCs typically include flavoproteins (see RIBOFLAVIN), CYTOCHROMES, IRON-SULPHUR PROTEINS, QUINONES, and copper-containing proteins (e.g. PLASTOCYANIN); atypical ETCs include e.g. those of *Mycoplasma* spp which lack both cytochromes and quinones. The best-studied ETCs include those which occur in the inner membrane of the MITOCHONDRION – particularly the mitochondria of certain types of mammalian cell (e.g. bovine heart, rat liver). Although the mitochondrial ETCs in many other types of cell are often presumed to be essentially similar to those in mammalian cells, those in e.g. plant mitochondria characteristically exhibit some important differences (see later).

*Mitochondrial ETCs.* The mammalian mitochondrial ETC consists of four groups of functionally interrelated components (Complexes I–IV) arranged in a sequence (see figure). *Complex I* (NADH–UQ oxidoreductase) contains a flavoprotein which is believed to transfer electrons from NADH (formed e.g. in the TCA CYCLE) to the Fe–S centres (see IRON-SULPHUR PROTEINS) and thence to UQ; electron flow between NADH and UQ can be inhibited by e.g. AMYTAL, PIERICIDIN and ROTENONE. *Complex II* (succinate–UQ oxidoreductase) contains succinate dehydrogenase (an FAD-containing enzyme), Fe–S centres, and a *b*-type cytochrome (e.g. *b*<sub>560</sub> in bovine heart, *b*<sub>559</sub> in *Neurospora* sp) of unknown function. In reconstituted ETCs, electron flow between Complex II and UQ is inhibited by TIFA. *Complex III* (UQ–cytochrome *c* oxidoreductase) contains (at least) two *b*-type haems (which appear to be bound to a single polypeptide): *b*<sub>562</sub> (formerly *b*<sub>K</sub>) and *b*<sub>566</sub> (formerly *b*<sub>T</sub>); an Fe–S protein (a RIESKE PROTEIN); cytochrome *c*<sub>1</sub>; and, in at least some species, semiquinones (believed to be ubisemiquinones). Electron flow through Complex III is inhibited by e.g. ANTIMYCIN A, BAL, DCMU and HYDROXYQUINOLINE-N-OXIDES (HOQNOs). (See also XANTHOMEGNIN.) *Complex IV* (cytochrome oxidase; cytochrome *aa*<sub>3</sub>; ferrocycytochrome *c*–O<sub>2</sub> oxidoreductase) contains two haems and two protein-bound copper atoms per functional unit; the haems (*a*, *a*<sub>3</sub>) are chemically identical but have different spectroscopical and other properties owing to differences in the way in which they are bound to protein. Complex IV catalyses the irreversible reduction of oxygen (the terminal electron acceptor) to H<sub>2</sub>O; it is inhibited by e.g. AZIDE, CARBON MONOXIDE, sulphide and CYANIDE.

Transmembrane translocation of protons can occur at three ‘sites’ which correspond to Complexes I, III and IV. The

**ELECTRON TRANSPORT CHAIN.** A scheme for electron transport in an animal-type mitochondrion, showing electron transfer from NADH and/or succinate to the terminal electron acceptor, oxygen. (Electron transport is believed to be similar in the mitochondria of many types of microorganism.) Sites 1, 2 and 3 indicate sites of transmembrane proton translocation during electron flow. Thick lines indicate energy conversion (or regulation in the case of transhydrogenation). FMN = flavin mononucleotide; Fe-S centre = iron-sulphur centre; FAD = flavin adenine dinucleotide;  $b_{562}$ ,  $c_1$  etc = cytochromes; UQ = ubiquinone; proton PPase = proton pyrophosphatase.

mechanism of proton translocation is not understood; moreover, even the stoichiometry of proton translocation has not yet been settled: in Complex I the  $H^+/2e^-$  ratio (q.v.) is believed, by various authors, to be 2, 3 or 4. Proton translocation is the subject of two main types of model: the LOOP MODEL and the conformational pump model; in the latter model, proton translocation involves changes in the pK of ionizable groups on certain proton-binding ETC components brought about by electron-dependent redox and conformation changes in those components. (See also ANISOTROPIC INHIBITOR and Q-CYCLE.) [Mitochondrial electron transport: ARB (1985) 54 1015–1069.]

*Plant mitochondrial ETCs* are characteristically branched at the ubiquinone, one branch terminating with a conventional cytochrome oxidase, the other terminating with a cyanide-resistant oxidase; the latter branch is apparently non-proton-translocating, so that respiration via this branch is less efficient in terms of energy transduction.

*Bacterial ETCs* are generally located in the CYTOPLASMIC MEMBRANE; in at least some cyanobacteria, however, respiratory electron transport pathways occur in both the cytoplasmic membrane and the thylakoid membranes [Book ref. 75, pp. 199–218]. The composition of bacterial ETCs exhibits wide variability among the various species – and even in a given species under different growth conditions or in different physiological states (e.g. vegetative and sporulating cells of *Bacillus cereus* [JB (1984) 160 473–477]). Moreover, many bacteria have branched ETCs and may use different pathways for different terminal electron acceptors. Although the components of ETCs in aerobically grown bacteria may resemble those in mitochondrial ETCs, the order in which they occur is typically unlike that in mitochondria.

In a given species of bacterium more than one type of cytochrome may be used as a terminal oxidase. For example, in *Escherichia coli* the major terminal oxidase under aerobic conditions is a *b*-type cytochrome, *cyt o*, while under oxygen-limited conditions it is *cyt d*. During NITRATE RESPIRATION, *E. coli* uses an inducible cytochrome which functions specifically as part of the nitrate reductase enzyme system; this cytochrome is designated  $nr^b$  or  $b_{556}^{NO_3^-}$ . [Respiratory chains in *E. coli*: MR (1984) 48 222–271.] Cytochromes specific for different terminal electron acceptors may coexist in the same cell [JB (1983) 154 708–727] and, under certain conditions, two terminal electron acceptors may be used simultaneously [JGM (1979) 112 379–383].

**electron-transport particle** See ETP.

**electron transport phosphorylation** The phosphorylation of ADP to ATP, or the formation of PYROPHOSPHATE from inorganic phosphate, in a reaction driven by the energy of a transmembrane gradient of ions generated by means of an ELECTRON TRANSPORT CHAIN. (In all known cases of electron transport phosphorylation, the ETC generates a transmembrane gradient of protons (proton motive force – see CHEMIOSMOSIS); although some respiratory chains generate a SODIUM MOTIVE FORCE, as yet there have been no reports of an  $Na^+$ -motive respiratory chain being used for the synthesis of ATP.) Electron transport phosphorylation can occur in respiratory metabolism (see OXIDATIVE PHOSPHORYLATION), in PHOTOSYNTHESIS, and in certain types of FERMENTATION (sense 1) (q.v.).

‘Electron transport phosphorylation’ excludes not only SUBSTRATE-LEVEL PHOSPHORYLATION but also those modes of

## electroneutral transport

phosphorylation dependent on a transmembrane ion gradient that is not produced by electron transport; such ion gradients can be derived e.g. by direct proton pumping (as in the PURPLE MEMBRANE) or by END-PRODUCT EFFLUX. With the exception of substrate-level phosphorylation, these forms of phosphorylation resemble electron transport phosphorylation in that they are dependent on ion-motive force and involve a membrane-bound ATP- or PPI-synthesizing enzyme system; all forms of phosphorylation which have these two characteristics may be referred to as *ion-motive force phosphorylation* (imf phosphorylation).

**electroneutral transport** Transport across an energy-transducing membrane of charged or uncharged species resulting in no net transfer of charge across the membrane; it occurs when an uncharged species is carried by a UNIORTER, during the SYMPORT of two ions of opposite charge, or during the ANTIORT of two ions of the same charge. (cf. ELECTROGENIC TRANSPORT.)

**electro-osmosis** *Syn.* ELECTROENDOSMOSIS.

**electropherotype** (*virol.*) A virus type (see TYPING) recognized on the basis of ELECTROPHORESIS of e.g. its genome. (See also OLIGONUCLEOTIDE FINGERPRINTING.)

**electrophoresis** Any procedure by means of which the members of a heterogeneous population of charged particles can be translocated or separated (or, exceptionally, brought together: see COUNTERCURRENT IMMUNOELECTROPHORESIS) by virtue of their mobility in an electric field.

Electrophoresis is used e.g. for identifying or quantifying proteins, nucleic acids etc., for molecular weight determinations (e.g. SDS-PAGE), for preparing fingerprints in various forms of TYPING, and for identifying/confirming products in nucleic-acid-amplification methods. (See also CHROMATOGRAPHY and ISOELECTRIC FOCUSING.)

In *free electrophoresis* the molecules to be separated are present in a liquid medium (usually water). In one form (*moving-boundary electrophoresis*) a mixed population of molecules is subjected to electrophoresis in a U-tube, each limb of which contains a column of buffer above the test suspension; the electric field is applied by placing a positive electrode in one limb and a negative electrode in the other. During electrophoresis the different types of molecule begin to separate into distinct zones, boundaries between the homogeneous and heterogeneous populations moving as the process continues.

In *surface electrophoresis* the molecules in a sample move through a thin film of buffer on the surface of a strip of paper or e.g. cellulose acetate; the mobility of a given molecule may therefore be influenced by interaction with the solid phase. Essentially, a droplet of sample is applied near the centre of a strip which has equilibrated with the vapour of an appropriate buffer solution in a closed chamber; an electrical potential difference is then applied between the two ends of the strip. After electrophoresis, the strip may be stained to reveal discrete zones, bands or spots corresponding to the various components in the sample.

In *gel electrophoresis* the molecules in a sample move through a gel composed, usually, of agarose (see AGAR) or polyacrylamide. Essentially, the sample is placed in a well cut into one end of a gel strip, and an electrical potential difference is applied between the two ends of the strip; after electrophoresis, the separated components may be e.g. stained *in situ*, extracted for further study, or transferred to another medium (see BLOTTING and SOUTHERN HYBRIDIZATION).

(See also ELECTROENDOSMOSIS, IMMUNOELECTROPHORESIS, PAGE, SDS-PAGE, TWO-DIMENSIONAL ELECTROPHORESIS, ZYMOGRAM.)

**electrophoretic transport** Transport of a charged species across an energy-transducing membrane in response to a pre-existing transmembrane electrical potential difference. (cf. ELECTRICAL TRANSPORT.)

**electroporation** An *in vitro* method for increasing the efficiency of TRANSFORMATION. Essentially, a mixture of cells and e.g. plasmids is exposed to an electric field (up to ~16 kV/cm) for a fraction of a second; the mechanism of uptake is unknown, but the frequency of transformation varies linearly with the concentration of DNA over a wide range of values, and the efficiency of transformation varies with cell concentration.

[Electroporation in *Helicobacter pylori*: AEM (1997) 63 4866–4871; in *Escherichia coli*: NAR (1999) 27 910–911.]

'Electrocompetent' (electroporation-competent) cells with high-level transformation efficiency are available commercially. The electrocompetent cells marketed by Stratagene (ElectroTen-Blue™) are electroporated at 1.7 kV and 600 ohms resistance.

**ElectroTen-Blue™** See ELECTROPORATION.

**electro-transfection** Electrically-assisted TRANSFECTION; thus, e.g. tobacco protoplasts have been transfected with RNA from the tobacco mosaic virus under the influence of 50-µsec pulses of DC current at 550–800 V/cm [JGV (1986) 67 2037–2042]. (cf. ELECTROFUSION.)

**Elek plate** An *in vitro* method for detecting the formation of a diffusible toxin by a given strain of microorganism, e.g. *Corynebacterium diphtheriae*. A plate of suitable medium is inoculated, in a straight line, with the strain under test; the streak is then overlaid, perpendicularly, with a strip of paper which has been impregnated with relevant antitoxin. After incubation (24–48 hours), toxin production is indicated by the development of lines of whitish precipitate which approximately bisect each of the four right angles formed by the paper strip and the line of microbial growth; the precipitate results from the combination of toxin and antitoxin following their diffusion from the line of growth and paper strip, respectively. Non-specific lines of precipitate may be formed, so that known negative and positive strains must be used as controls.

Several unknown strains, and the controls, may be examined on a standard-size Petri dish.

In a modified form of the test, an antitoxin-impregnated disc is placed at the centre of the plate, and the test strain(s), together with positive and negative controls, are inoculated in a circular pattern at a fixed radius; this form of test can be read after 16 hours [JCM (1997) 35 495–498].

Diphtheria toxin can also be detected – directly from clinical specimens – by a PCR-based method which detects the A and B subunits of the toxin; a result can be available within hours of collecting the specimen. This assay is used in the Diphtheria Laboratory at the Centers for Disease Control in the USA [JCM (1997) 35 1651–1655].

**elementary body (EB)** (1) See CHLAMYDIA. (2) An archaic name for a virion.

**ELISA** (enzyme-linked immunosorbent assay) A highly sensitive IMMUNOASSAY for specific antibodies or antigens. For the assay of specific antibodies, the antiserum (or other test material) is allowed to react with homologous antigens which have been adsorbed e.g. to the inner surface of a plastic tube; uncombined antibodies are removed by washing. Antibodies which have combined with the immobilized antigens are then detected by treating the test system with a *conjugate* (see CONJUGATION sense 2) consisting of anti-immunoglobulin antibodies each covalently linked to an enzyme of a particular type; the test system is washed free of any uncombined conjugate and examined for bound enzyme

by incubating with an appropriate substrate and assaying for the products of enzymic cleavage.

Antigen may be detected or quantified e.g. by a procedure similar to that used for antibody except that the *antibody* is adsorbed, and enzyme is conjugated to anti-antigen antibody. In an alternative procedure, antigen is detected/quantified by its ability to sequester added antibody – the amount of antibody sequestered (an indirect measure of antigen) being assessed by measuring the amount of free antibody remaining in the test mixture; free antibody is measured by allowing it to bind to immobilized antigen, and detecting the bound antibody with enzyme-linked anti-Ig antibodies.

[Developments in ELISA and other solid-phase immunoassay systems; JIM (1986) 87 1–125.]

**ELISPOT assay** (enzyme-linked immunospot assay) A type of assay, based on the ELISA principle, for detecting and quantifying specific molecules or cells. For example, blood has been assayed to quantify those T cells which respond to the tuberculosis-associated antigen ESAT-6 (q.v.) by secreting the cytokine interferon-gamma (IFN- $\gamma$ ; see INTERFERONS). Any ESAT-6-specific T cells (present in a blood sample in the well of an assay dish) react to (added) ESAT-6 antigen by secreting IFN- $\gamma$ . Such IFN- $\gamma$  (which is present in high concentration in the immediate vicinity of a secreting T cell) is detected by adding a conjugate consisting of an enzyme linked to a molecule that binds to IFN- $\gamma$ ; enzymic activity (on an appropriate substrate) then leads to the formation of a visible ‘spot’ on the floor of the well in the location of a secreting T cell. Hence, each spot corresponds to an ESAT-6-specific T cell. Enumeration of ESAT-6-specific T cells has been used in epidemiological studies (contact tracing) in the context of tuberculosis [Lancet (2001) 357 2017–2021].

**Ellobiophrya** See PERITRICHIA.

**elm butt rot** See BUTT ROT.

**Elokomín fluke fever** See NEORICKETTSIA.

**Elphidium** See FORAMINIFERIDA.

**elsinan** A water-soluble, essentially linear glucan, consisting of blocks of (1  $\rightarrow$  4)- $\alpha$ -linked maltotriose units connected by (1  $\rightarrow$  3)- $\alpha$ -bonds, isolated from culture fluids of *Elsinoë leucospila*.

**Elsinoë** A genus of fungi (order DOTHIDEALES) which include some important plant pathogens – e.g. *E. veneta*, which causes purple-bordered, sunken grey lesions (‘cane spot’) on the canes of e.g. raspberry (*Rubus* sp). *Elsinoë* spp form uniascal locules at various levels in a pseudoparenchymatous ASCOSTROMA (the overwintering stage); the ascospores are septate, colourless or pale yellow. Anamorphs occur in the genus *Sphaeloma*.

**eltor vibrio** See VIBRIO (*V. cholerae*).

**elution** (*serol.*, *virol.*) The dissociation of an adsorbed particle.

**Elysia** A genus of marine molluscs which feed on siphonaceous green algae (e.g. CAULERPA, CODIUM) by piercing the cells and sucking out the cytoplasm; the algal chloroplasts are retained intact within the cells of the digestive gland (hepatopancreas) where they continue to photosynthesize for a time. The chloroplasts do not divide in the animal, and are sooner or later digested. [Book ref. 129, pp. 97–107.] (cf. CONVOLUTA.)

**Elytrosporangium** See STREPTOMYCES.

**EM** Electron microscope.

**E<sub>m,7</sub>** See REDOX POTENTIAL.

**emarginate** (*mycol.*) *Syn.* SINUATE (sense 2).

**EMB agar** (eosin–methylene blue agar) An agar-based medium used e.g. for the primary isolation of – and for differentiating between – enterobacteria. The medium contains (w/v): peptone (1%); lactose and sucrose (each at 0.5%) or lactose only (at 1%);

K<sub>2</sub>HPO<sub>4</sub> (0.2%); eosin Y (0.04%); methylene blue (0.0065%); agar (ca. 1.5%). Final pH: ca. 7.2. Colonies of *Escherichia coli* usually have dark centres and a greenish metallic sheen, those of *Enterobacter aerogenes* are usually mucoid, brownish in the centre, and only occasionally show a metallic sheen, while those of *Salmonella* and *Shigella* are usually colourless and translucent.

**Embden–Meyerhof–Parnas pathway** (EMP pathway; Embden–Meyerhof pathway; hexose biphosphate pathway; glycolysis) A sequence of reactions in which glucose is broken down to pyruvate\*. The EMP pathway occurs in a wide range of organisms, both prokaryotic and eukaryotic, and can operate under both aerobic and anaerobic conditions. By this pathway one molecule of glucose yields two molecules each of pyruvate and NADH and two (net) of ATP (from SUBSTRATE-LEVEL PHOSPHORYLATION); if glucose 6-phosphate is derived from GLYCOGEN, the net yield of ATP is 3 molecules. [See Appendix I(a).] In respiratory modes of metabolism (see RESPIRATION) the pyruvate is commonly converted to acetyl-CoA which enters the TCA CYCLE; NADH is oxidized via a respiratory chain (see ELECTRON TRANSPORT CHAIN). In fermentative modes (see FERMENTATION) the fate of pyruvate depends on species and/or conditions, but must always involve regeneration of NAD<sup>+</sup> from NADH by reduction of an endogenous substrate (see e.g. ALCOHOLIC FERMENTATION, HOMOLACTIC FERMENTATION, and Appendix III).

The initial step of the EMP pathway, the formation of glucose 6-phosphate from glucose, is catalysed by hexokinase in e.g. yeasts and some bacteria, while in other bacteria (e.g. enterobacteria, streptococci) glucose is phosphorylated during its uptake by a PTS (q.v.). *Phosphofructokinase* is a key enzyme in the EMP pathway, and the presence of this enzyme in an organism is generally taken as evidence that the EMP pathway occurs in that organism. In yeasts (and e.g. mammals) phosphofructokinase is inhibited by high levels of ATP and citrate, and is stimulated by high levels of AMP; in e.g. *Escherichia coli* phosphofructokinase is inhibited by phosphoenolpyruvate (but not by citrate), and is stimulated by ADP and GDP (but not by AMP). (See also ADENYLATE ENERGY CHARGE.) (In certain organisms fructose 6-phosphate is phosphorylated by a pyrophosphate:phosphofructose dikinase – see PYROPHOSPHATE.)

The EMP pathway functions not only in energy-yielding metabolism but also in supplying intermediates for biosynthesis: e.g., dihydroxyacetone phosphate can be reduced to glycerol phosphate for use in the biosynthesis of lipids; phosphoenolpyruvate may be drawn off for aromatic amino acid biosynthesis [Appendix IV(f)], 3-phosphoglycerate for cysteine, glycine and serine biosynthesis [Appendix IV(c)], and pyruvate for alanine, leucine and valine biosynthesis [Appendix IV(b)]. (See also GLUCONEOGENESIS.)

(See also ENTNER–DOUDOROFF PATHWAY; GLYCOSOMES; HEXOSE MONOPHOSPHATE PATHWAY; METHYLGLYOXAL BYPASS.)

\*The terms ‘EMP pathway’ and ‘glycolysis’ are often used for the complete pathway for glucose degradation: e.g. glucose  $\rightarrow$  lactate (i.e., HOMOLACTIC FERMENTATION) or glucose  $\rightarrow$  ethanol (i.e., ALCOHOLIC FERMENTATION).

**embedding** See MICROTOME and ELECTRON MICROSCOPY.

**embryonated egg** (embryonating egg) An egg (usually a hen’s or duck’s egg) which contains a live, developing embryo. Such eggs are used in virology e.g. for the identification, culture, and/or assay of certain viruses (see e.g. POCK sense 2), and as a source of cells for TISSUE CULTURE.

An embryonated egg is prepared by incubating a fertile egg in a humid atmosphere for ca. 5–14 days at e.g. 37–39°C – the

## EMCV

period and temperature of incubation depending e.g. on the region of the egg to be inoculated, the virus to be used, etc. Essentially, an egg is candled (see CANDLING) and inoculated (aseptically) with the virus via a small hole drilled in the shell; inoculations may be made into the yolk sac (egg pre-incubated ca. 5–8 days), the chorioallantoic membrane (CAM) (pre-incubation 11–13 days), the allantoic cavity (pre-incubation 9–12 days), or the amniotic cavity (pre-incubation 10–14 days). Following inoculation, the hole is sealed and the egg is incubated (at an appropriate temperature and humidity) for e.g. 1–7 days; the egg can then be opened and material removed for examination etc.

**EMCV** See CARDIOVIRUS.

**Emicella** A genus of fungi (order EUROTIALES) which include the teleomorph of *Aspergillus nidulans*. The ascocarp is a globose, red or violet cleistothecium containing spherical or ovoid evanescent asci; it is surrounded by a layer of *hülle cells*: thick-walled cells which develop from the hyphae that envelope the cleistothecium. The ascospores are typically reddish or violet.

**Emicellopsis** See EUROTIALES.

**Emerson enhancement effect** See ENHANCEMENT EFFECT.

**emetine** A toxic alkaloid, obtained from *ipecaquanha* root, used in the treatment of amoebic DYSENTERY. Emetine inhibits eukaryotic protein synthesis [Book ref. 14, pp. 453–454]; at clinical doses it is effective against trophozoites but not cysts. 2-Dehydroemetine is said to cause fewer clinical side-effects.

**Emiliana** See COCCOLITHOPHORIDS.

**Emmentaler cheese** See CHEESE-MAKING.

**Emmonsia** See ADIASPIROMYCOSIS.

**Emmonsella** *Syn.* AJELLOMYCES.

**EMP pathway** EMBDEN–MEYERHOF–PARNAS PATHWAY.

**empty magnification** See MAGNIFICATION.

**empyema** Accumulation of pus in a body cavity (usually the lungs).

**EMRSA** Epidemic MRSA clone. Each distinct EMRSA is given a number (e.g. EMRSA-1, EMRSA-2).

**EMS** Ethylmethane sulphonate: see ALKYLATING AGENTS.

**EMTA** A pH buffer based on 3,6-endomethylene-1,2,3,6-tetrahydrophthalic acid.

**Emtryl** See DIMETRIDAZOLE.

**emulcyan** An extracellular amphipathic polymer produced by stationary-phase filaments of a strain of *Phormidium* – a benthic organism which normally adheres to surfaces by virtue of hydrophobic interactions, and which does not produce hormogonia. In the presence of cations, emulcyan acts as an emulsifying agent; it is believed to mask cell-surface hydrophobicity, thus serving to detach filaments and allow their dispersal. [FEMS Ecol. (1985) 31 3–9.] (See also BIOSURFACTANTS.)

**emulsan** An extracellular, macromolecular bioemulsifier (see BIOSURFACTANTS) produced by *Acinetobacter calcoaceticus* RAG-1 during growth on e.g. hexadecane, ethanol or acetate. Emulsan (MWt ca. 10<sup>6</sup>) consists of a polysaccharide (containing *N*-acetyl-D-galactosamine and an *N*-acetylhexosaminuronic acid) esterified with fatty acids [FEBS (1979) 101 175–178]. Emulsan initially accumulates on the surface of the growing cells, forming a ‘minicapsule’, and is released into the medium e.g. as the cells approach the stationary phase; only the free extracellular form has emulsifying activity. An esterase which interacts with emulsan has been detected on the cell surface and free in the medium; this enzyme may play a role in the release of emulsan from the cell surface [JB (1985) 161 1176–1181].

**emulsification** (1) (*bacteriol.*) The process of preparing a suspension of bacteria in water, saline etc; using a loop, bacterial

growth is transferred to, and mixed with, a drop of the liquid on a slide.

(2) The formation of an emulsion, i.e., a suspension of droplets of one liquid in another with which it is non-miscible (e.g. oil in water). Substances which stabilize emulsions are called emulsifying agents. (See also BIOSURFACTANTS.)

**enanthem** A rash on a mucous membrane (cf. EXANTHEM).

**enation** (*plant pathol.*) A localized proliferation of leaf tissue caused e.g. by viral infection.

**encapsidation** During virion assembly; the process in which nucleic acid becomes incorporated in the viral capsid or – e.g. in certain bacteriophages – in a head/capsid precursor.

**encephalitis** Inflammation of the brain; it is often accompanied by inflammation of the brain meninges (*encephalomeningitis*, MENINGOENCEPHALITIS) or the spinal cord (*encephalomyelitis*) or both (*meningoencephalomyelitis*). Symptoms range from mild (fever, headache, malaise, myalgia, stiffness of the neck and back) to severe (irritability or somnolence, coma, death). Causes of encephalitis are many and varied. *Toxic encephalitis* results from severe toxæmia early in the course of an acute infectious disease. *Post-infective encephalitis* occurs after the onset of certain diseases (e.g. CHICKENPOX, MEASLES, MUMPS, WHOOPING COUGH). *Post-vaccinal encephalitis* may follow active immunization against e.g. rabies, smallpox, whooping cough, yellow fever. *Viral encephalitis* may be caused by any of a range of viruses: see e.g. B VIRUS; CALIFORNIA ENCEPHALITIS; EASTERN EQUINE ENCEPHALOMYELITIS; HERPES SIMPLEX; JAPANESE B ENCEPHALITIS; POWASSAN ENCEPHALITIS; RUSSIAN SPRING–SUMMER ENCEPHALITIS; ST LOUIS ENCEPHALITIS; SUBACUTE SCLEROSING PANENCEPHALITIS; VENEZUELAN EQUINE ENCEPHALOMYELITIS; WESTERN EQUINE ENCEPHALOMYELITIS. *Amoebic encephalitis* may involve e.g. certain species of ACANTHAMOEBA or NAEGLERIA – or BALAMUTHIA MANDRILLARIS.

(See also MENINGITIS, Talfan disease, Teschen disease; TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES.)

**Encephalitozoon** A genus of protozoa (class MICROSPOREA). *E. cuniculi* (= *Nosema cuniculi*) is parasitic (but generally non-pathogenic) in rodents and other animals, and has been recorded as the cause of a case of human encephalitis; it has also been isolated from eye, intestine, kidney, liver and peritoneum. [Mechanism of resistance to *E. cuniculi* in mice: J. Imm. (1984) 133 2712–2719.] The spores of *E. cuniculi* (ca. 2.5 × 1.5 µm) can be isolated from the urine of infected animals.

*E. intestinalis* can cause travellers’ diarrhoea [PCR-based identification of *E. intestinalis*: JCM (1998) 36 37–40].

**encephalomeningitis** See ENCEPHALITIS.

**encephalomyelitis** See ENCEPHALITIS.

**encephalomyocarditis virus** (murine) See CARDIOVIRUS.

**encystment** The formation of a CYST.

**end-point dilution assay** (*virol.*) A method of quantifying a given type of virus in a given sample, i.e., measuring the ‘infectivity’ of that virus in the sample. In this method, infectivity is measured by determining the extent to which the sample must be diluted in order that a given volume of the dilution corresponds to the LD<sub>50</sub>, TCID<sub>50</sub> or (more generally) the ED<sub>50</sub> of the virus. Initially, log (or semi-log) dilutions of the sample are prepared. Each dilution is then examined, individually, by inoculating each of a number of similar test units with a fixed volume (dose) of that dilution; test units may be e.g. susceptible laboratory animals or tissue cultures which undergo detectable forms of degeneration when infected with the virus. After incubation, each test unit is examined. Animals or cultures inoculated with a dose from the lower dilutions (i.e. higher concentrations

of virus) may react positively in every case; of those inoculated with a dose from the higher dilutions some may react positively while others are unaffected. The important dilution is that which corresponds to the ED<sub>50</sub>; such a '50% end point' is not always obtained experimentally, but it may be calculated from the experimental data – provided that some test units have given a negative reaction. The 50% end-point dilution may be calculated by the Reed–Muench method or the Kärber method; however, these methods can be used only if the dilutions are in a regular logarithmic sequence, and only if a similar number of test units is used for each dilution. Examples of the use of these methods are given below with reference to the specimen data in the accompanying table.

END-POINT DILUTION ASSAY: specimen data

Column A: dilution of virus	Column B: mortalities in 5 test animals	Column C: cumulative mortalities	Column D: cumulative survivors	Column E: C/(C + D)%
10 <sup>-6</sup>	0/5	0	9	0
10 <sup>-5</sup>	2/5	2	4	33.3
10 <sup>-4</sup>	4/5	6	1	85.7
10 <sup>-3</sup>	5/5	11	0	100

*Reed–Muench method.* The logarithm (to base 10) of the 50% end-point dilution lies between -5 and -4, and is obtained by linear interpolation – appropriate values from column E being substituted in the following equation:

$$\log_{10} 50\% \text{ end point} = -5 + \frac{50 - 33.3}{85.7 - 33.3}$$

The logarithm of the 50% end point is thus 10<sup>-4.68</sup>; since the antilog of 4.68 is ca. 48000 a dose from the 1/48000 dilution of the sample will contain the LD<sub>50</sub>.

*Kärber method.* Substitutions are made in the following equation:

$$\log_{10} 50\% \text{ end point} = L_1 - L(S - 0.5)$$

in which L<sub>1</sub> = logarithm of lowest dilution tested; L = log interval between dilutions; S = sum of the proportion of positive reactions at each dilution; 0.5 is a constant. In the accompanying table, S = 0 + 0.4 + 0.8 + 1.0 = 2.2; hence, the required value is 10<sup>-4.7</sup>.

An estimate of the number of infectious virions in the original (undiluted) sample can be derived from the expression:

$$n = -\log_e(1 - p)$$

in which n = average number of infectious virions per dose; p = proportion of positive reactions in the test units inoculated from a given dilution; e = 2.7183. The value of n (calculated for one of the dilutions) multiplied by the dilution factor gives an estimate of the viral titre of the sample; such an estimate is less reliable than that made from a PLAQUE ASSAY.

**end-point titration** (*serol.*) A method of assaying the concentration of a specific antibody or antigen, in a given sample, by determining the highest dilution of the sample which gives a reaction regarded as positive under the conditions of the test. For example, in an agglutination test the end point may be regarded

as the highest dilution which exhibits agglutination in the test system. (See also TITRE.)

**end-product efflux** The outflow, from a growing cell, of the end products of metabolism; in some cases such efflux involves end-product–proton SYMPORT (e.g. lactate–proton symport) capable of generating, or augmenting, a proton motive force (see CHEMIOSMOSIS). Such a mechanism for energy conversion may be particularly important e.g. in at least some obligately fermentative bacteria. In these organisms (which lack a respiratory chain) the pmf required e.g. for certain TRANSPORT SYSTEMS can be generated by ATP hydrolysis at a PROTON ATPASE – though this process is likely to consume much of the ATP generated by substrate-level phosphorylation; pmf generation by end-product efflux has been reported e.g. in *Lactococcus lactis* (formerly *Streptococcus cremoris*) [AvL (1984) 50 545–555; JB (1985) 162 383–390].

**Endamoeba** A genus of cyst-forming amoebae (order AMOEVIDA) parasitic in the gut of invertebrates (e.g. *E. blattae* in cockroaches). The nucleus lacks a karyosome.

**endemic** (1) Of a disease: commonly or constantly present in a given location or geographical region; typically, a relatively low proportion of the local population exhibits clinical signs of the disease. (2) Constantly present in a given location or geographical region.

**Endemosarca** A genus of endoparasitic, plasmodium-forming eukaryotic organisms which are parasitic in ciliates (*Colpoda* spp); they appear to be related to members of the PLASMODIOPHOROMYCETES. [Book ref. 147, pp. 203–206.]

**endergonic reaction** Any reaction requiring an uptake of energy. (cf. EXERGONIC REACTION.)

**endobiotic** Living within a host organism.

**endocarditis** Inflammation of the endocardium, i.e. the tissue lining the cavities of the heart.

*Infective (infectious) endocarditis* may be due to infection by any of a range of microorganisms – e.g. *Haemophilus* sp, *Staphylococcus aureus*, *S. epidermidis* (especially in patients with prosthetic heart valves), *Enterococcus faecalis*, viridans streptococci (see also NUTRITIONALLY VARIANT STREPTOCOCCI), *Neisseria gonorrhoeae*, *Candida*, *Aspergillus*, *Histoplasma*. Infrequently, the causal agent is one of the more recently described species of coagulase-negative staphylococci: *S. lugdunensis* [RMM (1995) 6 94–100]. (See also CARDIOBACTERIUM.)

Infective endocarditis may be acute or subacute; *S. aureus* may cause either acute or subacute endocarditis. Infection occurs via the bloodstream. Organisms may gain access to the bloodstream e.g. during dental treatment (e.g. oral viridans streptococci), catheterization or insertion of an intrauterine contraceptive device (e.g. faecal streptococci), intravenous injection (e.g. staphylococci) etc.

Symptoms: e.g. fever, malaise, heart murmurs, weight loss, clubbing of fingertips, embolism; late symptoms of subacute bacterial endocarditis (SBE) include vasculitis, petechial rash, and (almost pathognomonic) small, tender, often bluish swellings on the skin (Osler's nodes). Damage to heart valves may lead to heart failure.

Endocarditis may occur as a complication of other infectious diseases – e.g. Q FEVER, SYPHILIS, TUBERCULOSIS. (See also RHEUMATIC FEVER.)

**Endocarpon** See VERRUCARIALES.

**endocellulase** See CELLULASES.

**endocyst** See CYST (b).

**endocytobiosis** *Syn.* CYTOBIOSIS.

**endocytosis** The ingestion of materials, by a cell, by PHAGOCYTOSIS and/or PINOCYTOSIS.

## endodyogeny

**endodyogeny** Asexual reproduction (found e.g. in *Chlamydomonas*, *Sarcocystis*, *Toxoplasma*) in which two daughter cells form within the parent cell (which is destroyed during the process).

**endoenzyme** An ENZYME which cleaves bonds within a polymer chain: see e.g.  $\alpha$ -AMYLASES. (cf. EXOENZYME.)

**endoflagellum** See SPIROCHAETALES.

**endogenote** See MEROZYGOTE.

**endogenous infection** Infection by an organism which is part of the normal body microflora. (See e.g. CANDIDIASIS; cf. OPPORTUNIST PATHOGENS.)

**endogenous retrovirus** A retrovirus (see RETROVIRIDAE) which occurs, in provirus form, in the DNA of all normal cells of the host species or strain, and which is transmitted genetically via the germ line from one generation to the next. Endogenous retroviruses have been detected in a very wide range of vertebrates (including man [see e.g. JV (1986) 58 955–959]); they are believed to have arisen by exogenous infection of germ line tissue in the (recent or possibly ancient) ancestors of the host. Many endogenous retroviruses are related to horizontally transmissible EXOGENOUS RETROVIRUSES. Most endogenous proviruses are transcriptionally silent. Many appear to be defective, but some can be activated under certain conditions (e.g. by host hormones, or by exposure to radiation or certain chemicals – e.g. BUDR), when expression may range from transcription of selected virus genes to production of complete virus particles which may be infectious or non-infectious, ECOTROPIC or XENOTROPIC, etc. (See also MOUSE MAMMARY TUMOUR VIRUS.)

**endoglucanase** See e.g. CELLULASES.

**Endogonales** An order of fungi (class ZYGOMYCETES) which form zygospores and in which asexual reproduction involves the formation of chlamydospores, azygospores or sporangiospores. Many species are involved in MYCORRHIZA formation (see also RHIZOSPHERE). Genera include *Acaulospora*, *Endogone*, *Gigaspora*, *Glomus* and *Sclerocystis*.

**Endogone** See ENDOGONALES.

**Endolimax** A genus of protozoa (order AMOEBIDA) parasitic in vertebrates and invertebrates. *E. nana* occurs in the human large intestine; it is non-pathogenic. Trophozoites of *E. nana* (ca. 6–12  $\mu$ m diam.) contain numerous vacuoles and form blunt pseudopodia slowly; the single nucleus lacks peripheral chromatin but contains a large, eccentrically located karyosome. Cysts are usually ovoid, 4–8  $\times$  8–16  $\mu$ m, and contain four nuclei when mature; chromatoid bodies are usually absent.

**endolithic** Growing within rock, stone etc (cf. SAXICOLOUS). For example, certain cyanobacteria, lichens and microfungi can grow endolithically in environments too extreme (e.g. too hot or too cold) to allow normal EPILITHIC growth. Endolithic organisms (endoliths) have been categorized into three principal groups: *chasmoendoliths*, which colonize fissures and cracks in the rock; *cryptoendoliths*, which colonize structural cavities within porous rocks; and *euendoliths*, which actively penetrate the rock (e.g. by releasing substances which dissolve the rock). [J. Sed. Pet. (1981) 51 475–478.] In e.g. hot desert regions, cyanobacteria and other bacteria are generally the dominant cryptoendoliths, while in the dry desert valleys of the Antarctic chasmoendolithic and cryptoendolithic lichens (mainly *Acarospora*, *Buellia*, *Lecanora* and *Lecidea* spp) are dominant [Science (1982) 215 1045–1053]. These organisms generally inhabit a narrow zone below the rock surface, any fruiting structures being formed at the surface. (See also e.g. ARTHOPYRENIA; LECANORA; OSTREOBIMUM.)

**endolysin** A PEPTIDOGLYCAN-degrading enzyme (e.g. LYSOZYME) encoded by many types of bacteriophage; the function of an

endolysin is to lyse the host cell's envelope to release phage progeny. In many or all cases, endolysins (which lack a 'signal sequence') are enabled to cross the cytoplasmic membrane (to reach peptidoglycan) by means of a LYSIS PROTEIN.

**endometritis** Inflammation of the endometrium. In humans and animals it may result from infection of the endometrium by various opportunist pathogens (e.g. *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, group A streptococci). (See also CONTAGIOUS EQUINE METRITIS.)

**endomitosis** Chromosome replication without nuclear division. (cf. MITOSIS.)

**Endomyces** See ENDOMYCETALES.

**Endomycetaceae** See ENDOMYCETALES.

**Endomycetales** An order of mainly saprotrophic fungi of the ASCOMYCOTINA; the organisms include both unicellular and dimorphic species. Ascocarps are not formed. Asci (which develop from individual cells, or from cells within hyphae): protunicate, cylindrical to spheroidal. Families: Dipodascaceae (genera: e.g. *Dipodascus*, *Phialoascus*), Endomycetaceae (formerly Ascoidaceae; genera: e.g. *Cephaloascus*, *Endomyces*), METSCHNIKOWIACEAE, SACCHAROMYCETACEAE.

**Endomycopsis** An obsolete fungal genus; species are now included e.g. in SACCHAROMYCOPSIS.

**endomycorrhiza** See MYCORRHIZA.

**endonuclease** A NUCLEASE which cleaves phosphodiester bonds within a nucleic acid strand. See also RESTRICTION ENDONUCLEASE; cf. EXONUCLEASE.

**endonuclease III** See BASE EXCISION REPAIR.

**endonuclease S<sub>1</sub>** (nuclease S<sub>1</sub>, endonuclease S1, etc) A zinc-containing ENDONUCLEASE, first obtained from *Aspergillus oryzae*, which specifically cleaves ssDNA and ssRNA to yield mainly 5'-nucleoside monophosphates. It can cleave local regions of ssDNA in a dsDNA molecule.

**endonucleobiosis** SYMBIOSIS in which one symbiont occurs within the nucleus of the other (see e.g. HOLOSPORA). [Endonucleobiosis in ciliates: Int. Rev. Cytol. (1986) 102 169–213.]

**endoparasite** See PARASITE.

**endoparasitic slime moulds** See PLASMIDIOPHOROMYCETES.

**endopectate lyase** See PECTIC ENZYMES.

**endopectin lyase** See PECTIC ENZYMES.

**endopeptidase** See PROTEASES.

**endoperidium** See LYCOPERDALES.

**endoperoxide synthase** *Syn.* cyclo-oxygenase (see PROSTAGLANDINS).

**endophloeodal** (endophloedal; hypophloeodal) Growing within bark (cf. CORTICOLOUS).

**Endophyllum** See UREDINIOMYCETES.

**endophyte** (1) An organism parasitic partly or wholly within a plant.

(2) Any of certain fungi parasitic in grasses; such fungi include e.g. *Epichloë typhina*. Infection with certain endophytes can have beneficial and harmful effects on the growth and utilization of pasture grasses. [Artificial infection of grasses with endophytes: Ann. Appl. Biol. (1985) 107 17–24.]

**endoplasm** See e.g. SARCODINA.

**endoplasmic reticulum** (ER) Within a eukaryotic cell: a system of membranes which ramifies through the cytoplasmic region and forms the limiting boundaries of compartments and channels whose lumina are completely isolated from the cytoplasm; the ER membrane is a protein-containing lipid bilayer. In some regions the outer surface of the ER membrane (i.e., that surface in contact with the cytoplasm) bears many ribosomes; such regions are called *rough* ER (RER), while those regions

which lack ribosomes are called *smooth* ER (SER). A given compartment or channel may be bounded partly by rough ER and partly by smooth ER. Within the lumina of the ER occur e.g. the early stage(s) of glycosylation of proteins in the PALADE PATHWAY – typically the addition of mannose and/or glucosamine residues. (See also GOLGI APPARATUS; MICROSOME.)

**endopolygalacturonase** See PECTIC ENZYMES.

**endopolygalacturonate lyase** *Syn.* endopectate lyase (see PECTIC ENZYMES).

**endopolygeny** Asexual reproduction (found e.g. in *Chlamydomonas* and *Toxoplasma*) in which many daughter cells form within the parent cell (which is destroyed during the process).

**endoral membrane** (in *Paramecium*) See PARORAL MEMBRANE.

**endoribonuclease** See RNASE.

**endosome** (1) A phagosome or pinosome. (2) (*ciliate protozoal*.)

A Feulgen-positive body which occurs within the paramere of a heteromorous MACRONUCLEUS in some hypostomes. (3) In euglenoid flagellates: a type of NUCLEOLUS which persists, and divides, during mitosis.

**endospore** (1) A type of SPORE formed *intracellularly* by the parent cell or hypha. (cf. EXOSPORE.)

(a) (*bacteriol.*) Endospores are formed under conditions of nutrient limitation by species of e.g. *Bacillus*, *Clostridium*, *Coxiella*, *Desulfotomaculum*, *Sporolactobacillus*, *Sporomusa* and *Thermoactinomyces* (see also SPOROSPIRILLUM). In general, endospores are considerably more resistant than vegetative cells to heat, desiccation, antimicrobial agents and radiation; their irreversible inactivation can be ensured only by the procedures used for STERILIZATION (sense 1). Endospores can remain dormant for long periods of time: the age of some specimens may be measurable on a geological scale [Microbiology (1994) 140 2513–2529]. Studies on the formation and germination of endospores have been carried out mainly with *Bacillus subtilis*.

*Sporulation in Bacillus subtilis.* When growth becomes limited through depletion of nutrients, the cell re-organizes its metabolism. This involves the induction and repression of certain genes – although there is no abrupt switch from active growth to active sporulation; during this *transition state* the decision is made to either (i) maintain the vegetative condition, with low-level metabolism but without cell division, or (ii) initiate sporulation. [Transition state in *B. subtilis*: PNARMB (1993) 46 121–153.]

The cell's decision whether to sporulate or not is influenced by various environmental and intracellular signals which must be integrated and interpreted. For example, sporulation is inhibited if calcium levels drop to 2  $\mu$ M; this reflects the need for calcium during development of the endospore, and may be seen as a mechanism that prevents sporulation from aborting at an intermediate stage.

The (unknown) signals that initiate sporulation appear to stimulate at least two types of sensor molecule which are designated kinase A and kinase B (KinA and KinB). On receipt of appropriate signals, these kinases undergo ATP-dependent autophosphorylation and initiate a so-called *phosphorelay* (see figure, part (a)); Spo0F appears to act as the main junction through which are channelled various external and internal signals. The key factor which determines the decision between ongoing vegetative growth and sporulation appears to be the intracellular level of Spo0A~P.

Spo0A~P is de-phosphorylated (i.e. negatively regulated) by the phosphatase Spo0E (see figure). Indirect regulation of Spo0A~P involves other phosphatases, the RapA and RapB proteins, which de-phosphorylate Spo0F~P; RapA and RapB

are themselves regulated at the level of transcription by factors dependent on the cell's physiological state. Thus, whether or not sporulation occurs appears to depend on the opposing influences of kinases (promoting sporulation) and phosphatases (inhibiting sporulation) [TIM (1998) 6 366–370].

During the process of sporulation, gene expression is regulated, at least partly, at the level of transcription – relevant genes being transcribed in a specific temporal sequence; such regulation involves certain SIGMA FACTORS (see figure).

Elucidation of the mechanism of sporulation has been assisted by the isolation of various mutants, each blocked at a specific stage of the process. Such *spo* mutants are designated according to the stage beyond which endospore development does not progress in the mutant cell; mutations which affect the same stage but which occur at different loci are designated A, B etc. Various mutations at *spo0* loci prevent the development of the asymmetrical septum. No stage I mutants have been detected. In general, *spo* mutations have little or no effect on vegetative growth.

The figure (part b) outlines the stages of development of an endospore.

*Dormancy.* Freshly formed endospores usually enter a period of DORMANCY in which little or no metabolic activity can be detected.

*Activation.* This is a commonly reversible process in which a dormant endospore prepares for subsequent germination and differentiation into a vegetative cell; it appears to involve changes in the configuration of the endospore's macromolecules – presumably early steps in the mobilization of metabolic potential. Activation may be brought about e.g. by a short period of sublethal heating, by 'ageing', or by subjecting the endospores to low pH or to certain chemicals. The mode of activation in nature is apparently unknown.

*Germination* is an irreversible process in which an endospore becomes metabolically active. The process is largely degradative; it involves e.g. hydrolysis and de-polymerization of certain constituents of the endospore, and is characterized by the release of dipicolinic acid, calcium ions, and the breakdown products of cortical peptidoglycan. Concurrently there is a loss of resistance to heat, and a fall in optical density.

Germination requires, or is promoted by, certain substances (*germinants*) such as L-alanine, L-proline, certain sugars (e.g. glucose), ions (e.g. potassium, calcium, manganese, strontium), and surfactants; a given germinant may be effective for the endospores of some species but not for those of others. Germination is also affected by factors such as pH, and may be promoted by mechanical damage to the spore wall.

Certain substances (e.g. D-alanine, sodium bicarbonate) inhibit germination of the endospores of certain species.

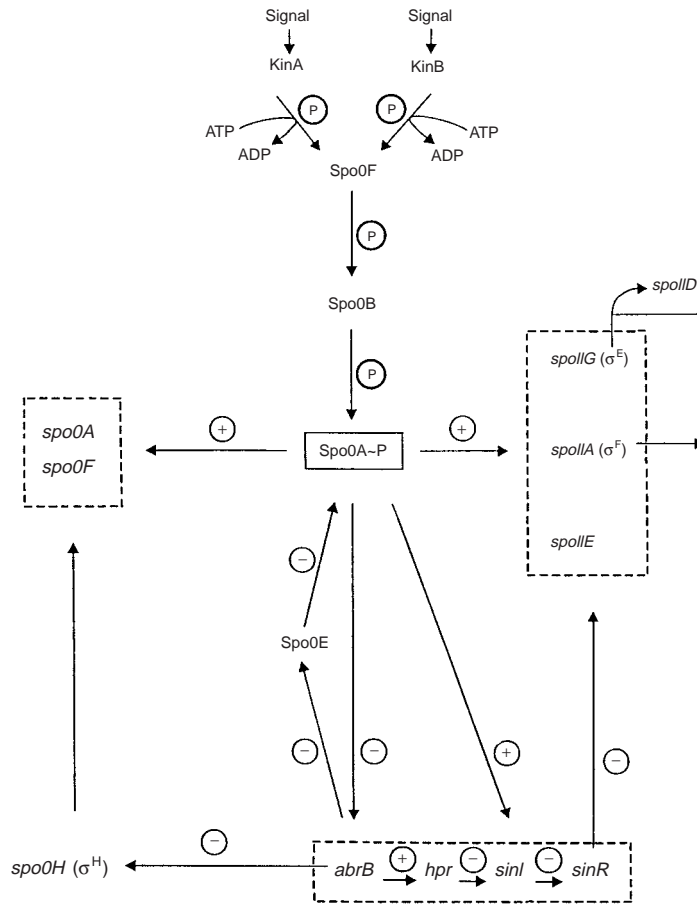

*Outgrowth* is the process in which a vegetative cell develops from a germinated endospore. (See also MICROCYCLE SPORULATION.)

(b) (*cyanobacteriol.*) See BAEOCYTE.

(c) (*mycol.*) See e.g. COCCIDIOIDES, OOSPORIDIUM, RHINOSPORIDIUM, SARCINOSPORON, TRICHOSPORON.

(2) (*mycol.*) (*syn.* endosporium) The innermost layer of a fungal spore wall.

**endospore stains** Bacterial endospores stain poorly (or not at all) with simple staining procedures in the cold. They can be stained e.g. by a modified form of ZIEHL-NEESEN'S STAIN in which ethanol (only) is used for decolorization. In another method (Schaeffer-Fulton stain) an air-dried, heat-fixed smear is flooded with 0.5% (w/v) aqueous malachite green and heated to near-boiling for 5 min; the smear is then washed in running water,

ENDOSPORE (a): simplified scheme for the regulation of gene expression during the initiation of sporulation in *Bacillus subtilis*.

The mechanism for initiating sporulation appears to recognize both external (environmental) and internal (intracellular) signals. These signals are believed to promote ATP-dependent autophosphorylation of certain kinases – shown in the diagram as KinA and KinB. The kinases transfer phosphate (symbol  $\text{P}$ ) to a sequence of proteins: Spo0F  $\rightarrow$  Spo0B  $\rightarrow$  Spo0A (the so-called *phosphorelay*) [COGD (1993) 3 203–212; JCBiochem. (1993) 51 55–61]. The intracellular concentration of the phosphorylated form of Spo0A (Spo0A~P) appears to be the key factor in initiating sporulation; this protein is a transcription factor which promotes the expression of certain sporulation-specific genes (dashed box, centre right) and also regulates genes shown in the two other dashed boxes.

In the diagram, inhibitory influences are indicated by the symbol  $\ominus$ ;  $\oplus$  indicates that the expression of a given gene is promoted. Control is commonly exercised at the level of transcription.

Spo0A~P promotes the expression of genes *spo0F* and *spo0A* (dashed box, left) by a positive feedback loop [Mol. Microbiol. (1993) 7 967–974]. Also, by repressing *abrB* (lower dashed box), Spo0A~P promotes the expression of *spo0H* – whose product (the SIGMA FACTOR  $\sigma^H$ ) is required e.g. for the transcription of *spo0F* and *spo0A*.  $\sigma^H$  is produced at low level during vegetative growth, but its production is greatly enhanced following the initiation of sporulation. During sporulation,  $\sigma^H$  is needed for transcription of the *ftsZ* gene (see FtsZ in CELL CYCLE) from a special promoter, *p2*, which is distinct from the *ftsZ* promoter used during exponential growth; FtsZ is required for the formation of the asymmetrical septum.

Spo0E is a negative regulator of the phosphorelay [PNAS (1994) 91 1756–1760]; it is an enzyme which de-phosphorylates (and thus inactivates) Spo0A~P and which may therefore help to prevent the initiation of sporulation until the cumulative effect of the various (extracellular and intracellular) signals dictates that sporulation is necessary.

Development of the asymmetrical septum (i.e. at a polar rather than a mid-cell location) initially involves the formation of a mid-cell Z ring (see CELL CYCLE) – i.e. as occurs during vegetative cell division. Later, this Z ring develops into a helical structure that extends into both poles of the cell and eventually forms two separate polar Z rings; these developments require the SpoII $\epsilon$  protein. Only one polar site is used – initiation of septation at one site blocks the other site. [Science (2002) 298 1942–1946.]

During vegetative growth, SinR (encoded by *sinR* in the lower dashed box) represses expression of the *spoll* genes (dashed box, centre right). During sporulation, Spo0A~P represses *abrB* (lower dashed box) – thus (indirectly) inhibiting expression of SinR and helping to promote expression of the *spoll* genes; SinR is repressed at the protein–protein level, i.e. inhibited by the SinI protein. Note that Spo0A~P also directly promotes the transcription of *sinI*. (Continued on page 273.)

ENDOSPORE (a) (continued)

The product of *spoIIG* (dashed box, centre right) is a sigma factor,  $\sigma^E (= \sigma^{29})$ , which is needed for transcription of (i) the *spoIID* gene, and (ii) certain genes in the mother cell. SpoIID is one of several products (others are SpoIIM, SpoIIP and SpoIIB) which are involved in the degradation of peptidoglycan in the asymmetric septum – a necessary preliminary to the engulfment of the prespore by the mother cell (early stage II).

The product of *spoIIE* localizes on the prespore side of the asymmetrical septum where, through its phosphatase activity, it can activate  $\sigma^F$  [GD (1998) 12 1371–1380]. The product of *spoIIA* ( $\sigma^F$ ) is needed for transcription in the forespore.

Figure reproduced from *Bacteria*, 5th edition, Figure 7.14, page 154, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

ENDOSPORE (b): stages in the development of an endospore (diagrammatic).

**Stage 0.** Prior to sporulation, a (vegetative) cell is said to be in stage 0.

**Stage I.** The cell contains an *axial filament* composed of two chromosomes. (Some authors consider that sporulation proper begins at stage II.)

**Stage II.** Initially, an asymmetric (polar) septum divides the cell into two protoplasts. The smaller protoplast (= *prespore*, *forespore*), which contains a single chromosome, is the precursor of the endospore; the other protoplast is referred to as the *mother cell*. Before further development, peptidoglycan in the asymmetric septum must be degraded; this involves SpoIID and other proteins (see legend of figure (a)). The cytoplasmic membrane of the mother cell then begins to engulf the smaller protoplast so that the latter subsequently becomes bounded by a double membrane; the final stages of this process (in *Bacillus subtilis*), in which the mother cell membrane fuses to complete the outermost membrane, may involve the SpoIIIE protein [PNAS (1999) 96 14553–14558].

**Stage III.** Completion of development of the double membrane.

**Stage IV.** Modified PEPTIDOGLYCAN is laid down between the two membranes to form a rigid layer called the *cortex*. The peptidoglycan differs from that in vegetative cell walls in that e.g. it contains fewer cross-links, and in that the lactyl groups of some muramic acid residues form lactam rings by displacing the *N*-acetyl group. A loose protein envelope called the *exosporium* may begin to develop at about this time.

**Stages V–VI.** A multilayered protein *spore coat* is deposited outside the outermost membrane (stage V). The spore coat is rich in e.g. cystine residues, and it is strongly hydrophobic. The spore matures (stages V–VI) to develop its characteristic resistance to heat and its bright, refractile appearance under the light microscope; during this period, calcium dipicolinate (see DIPICOLINIC ACID) accumulates in the protoplast ('core'). The endospore reaches maturity.

**Stage VII.** The endospore is released by lysis of the mother cell. (In some species the mature endospore carries a loose outer membrane (*exosporium*) external to the spore coat; the origin and composition of the exosporium appear to be unknown.)

Figure reproduced from *Bacteria*, 5th edition, Figure 4.2, page 61, Paul Singleton (1999) copyright John Wiley & Sons Ltd, UK (ISBN 0471-98880-4) with permission from the publisher.

## endosporium

counterstained with safranin (0.5% aqueous) for ca. 30 sec, washed again with water, and blotted dry. Endospores stain green, cells red-brown.

**endosporium** *Syn.* ENDOSPORE (sense 2).

**endospore** In coccidia: SPORULATION which occurs *within* the host. Endospore occurs e.g. in all species of *Sarcocystis* and in *Cryptosporidium*, and it has been reported to occur in certain coccidia parasitic in fish (e.g. *Eimeria carpelli*).

**ENDO-STAPH** See TEICHOIC ACIDS.

**Endostelium** See PROTOSTELIOMYCETES.

**endosymbiont** An organism which lives within the cells or tissues of another organism in a symbiotic association (SYMBIOSIS sense 1). (cf. ECTOSYMBIONT.)

**endothelial cells** Cells which form a lining (one-cell thick) in the blood vessels, heart and lymphatic system.

**endothelium-leukocyte adhesion molecule** *Syn.* CD62E.

**Endothia** A genus of fungi of the order DIAPORTHALES. *E. parasitica* [ultrastructure: CJB (1982) 61 389–399] causes CHESTNUT BLIGHT (q.v.). (See also PROTEASES.)

**endothrix infection** See DERMATOPHYTES.

**endotoxic shock** (septic shock) An often-fatal condition (mortality rate  $\geq 50\%$ ) associated with blood-borne ENDOTOXINS of Gram-negative bacteria (Gram-positive bacteria are reported to provoke a similar or identical condition); in the USA alone, the number of deaths from endotoxic shock is over 100000 per year. Microbial components act on e.g. monocytes/macrophages and promote the secretion of CYTOKINES such as IL- $1\beta$  and (particularly) TNF- $\alpha$ ; these agents can recruit others, leading to symptoms such as fever, a marked fall in blood pressure and occlusion of blood vessels by white cells. Death may result from a progressive failure of organs.

Individuals with the *TNF2* allele appear to be particularly susceptible to endotoxic shock; this allele, which contains a variant form of the TNF- $\alpha$  promoter, correlates with enhanced production of TNF- $\alpha$ , spontaneously or under stimulation, both *in vitro* and *in vivo*. [Association of *TNF2*, a TNF- $\alpha$  promoter polymorphism, with septic shock susceptibility and mortality: JAMA (1999) 282 561–568.]

Experimental vaccination against endotoxic shock with anti-endotoxin monoclonal antibodies has been tried unsuccessfully [RMM (1994) 5 183–190].

Some recent candidate antibiotics – for example compound L-573,655 [Science (1996) 274 980–982] – are directed against lipid A biosynthesis, and it seems possible that such antibiotics may reduce the risk of endotoxic shock because their activity decreases the levels of lipid A. A possible treatment for endotoxic shock follows the discovery of various molecules with endotoxin antagonist activity; one of these, E5531 (a synthetic analogue of lipid A from *Rhodobacter capsulatus*), has been found to block endotoxin challenge in human trials. [Anti-bacterial and anti-inflammatory agents that target endotoxin: TIM (1998) 6 154–159.]

**endotoxin** (1) Traditionally, the LIPOPOLYSACCHARIDES (LPS) of Gram-negative bacteria; the toxic component of LPS is lipid A – although the polysaccharide moiety may contribute to toxicity by conferring water-solubility.

(2) Although many authors [e.g. RMM (1994) 5 183–190] equate endotoxin with LPS, others [Book ref. 218, p 26] have used the term to refer to a complex that consists of LPS and outer-membrane protein(s); using this nomenclature, the protein associated with LPS is designated either lipid A-associated protein (LAP) or endotoxin-associated protein (EAP).

(3) Any microbial toxin which is released only on cell lysis. (See also DELTA ENDOTOXIN.)

(See also ENDOTOXIC SHOCK.)

**endotrophic mycorrhiza** See MYCORRHIZA.

**Endotrypanum** A genus of protozoa (family TRYPANOSOMATIDAE) parasitic in the erythrocytes of sloths (in Central and South America) and in sandflies (*Lutzomyia* spp) – which transmit the protozoon to sloths. One species (*E. schaudinni*) forms intraerythrocytic epimastigotes, the other (*E. montergei*) forms intraerythrocytic trypomastigotes; in culture both species form promastigotes.

**endotunica** See BITUNICATE ASCUS.

**endoxylanase** See XYLANASES.

**endozoite** (tachyzoite) In certain coccidia: a stage within host tissues (see e.g. TOXOPLASMOSES).

**energy charge (EC)** See ADENYLATE ENERGY CHARGE.

**energy-transducing membrane** Any biological membrane which contains components that are involved in the conversion of one form of energy (e.g. light, ATP) to another (metabolically usable) form of energy. Such membranes are involved e.g. in RESPIRATION and PHOTOSYNTHESIS; they include the bacterial CYTOPLASMIC MEMBRANE (and the CHLOROSOME and CHROMATOPHORE membranes), the inner membrane of the MITOCHONDRION, the THYLAKOID membranes of cyanobacteria and CHLOROPLASTS, and the PURPLE MEMBRANE in certain halobacteria. (In cyanobacteria, respiratory electron transport occurs in the cytoplasmic membrane and, in at least some species, may occur also (in addition to photosynthetic electron transport) in the thylakoids [Book ref. 75, pp. 199–218].) (See also CHEMOSMOSIS.)

**enFeLV viruses** See FELINE LEUKAEMIA VIRUS.

**enhancement effect** (Emerson enhancement effect) In algae and green plants illuminated with light of wavelength above ca. 680 nm: an increase in PHOTOSYNTHESIS which occurs when the illumination is augmented with an additional beam of light of shorter wavelength. (cf. RED DROP.)

**enhancer** A *cis*-acting DNA sequence, present in the genomes of higher eukaryotes and of various animal viruses, which can greatly increase transcription; an enhancer can generally function in either orientation and at various distances (upstream or downstream) from a given promoter. (cf. UAS.) The enhancer of e.g. simian virus 40 (SV40) can function in a wide variety of animal cells, but enhancers of certain other viruses and of cellular genes show more or less strict specificity for particular cell or tissue types. Enhancer function requires the participation of *trans*-acting protein factors; for example, the SV40 enhancer apparently consists of multiple elements, each of which is recognized and bound by specific transcription factors [Book ref. 189, pp. 19–26]. Interactions between protein factors bound to enhancers and to other genetic elements (e.g. PROMOTER) may be important; in yeast, DNA looping between enhancer and promoter suggests that apposition of these elements is involved in enhancer action [NAR (2005) 33 3743–3750].

**enhancer** (translational) See DOWNSTREAM BOX.

**enhancer-dependent sigma factor** ( $\sigma^{54}$ ) See SIGMA FACTOR.

**enniatiins** Cyclic DEPSIPEPTIDE ANTIBIOTICS, obtained e.g. from *Fusarium* spp, which behave as IONOPHORES (for monovalent cations) and which are active against certain Gram-positive bacteria, e.g. *Mycobacterium tuberculosis*. The enniatin molecule includes three residues of D- $\alpha$ -hydroxyisovaleric acid, each occurring between two residues of N-methyl-L-isoleucine (*enniatin A*), N-methyl-L-valine (*enniatin B*), N-methylleucine (*enniatin C*), or N-methylphenylalanine (*beauvericin*, produced by *Beauveria bassiana*); the residues are linked by alternating peptide and ester bonds.

**enokitake** (winter mushroom) *Flammulina velutipes*, a mushroom cultivated for food e.g. in Japan. Enokitake is grown on

sawdust supplemented with rice bran; the mycelium is grown at 20–25°C, and fruiting is induced by lowering the temperature to 10–12°C. The cultivated fruiting bodies differ from those which develop in nature, the mushroom being whitish or cream-coloured with a long slender stipe. [Mycol. (1983) 75 351–360.]

**enoxacin** See QUINOLONE ANTIBIOTICS.

**enoyl-acyl carrier protein reductase (ENR)** See DIAZABORINES and TRICLOSAN.

**enriched medium** Any (liquid or solid) basal MEDIUM which has been supplemented (enriched) with serum or blood etc – or with any of a range of nutrients or growth factors – in order to enable it to support or enhance the growth of particular type(s) of organism. Examples: BLOOD AGAR, serum sugars (see PEPTONE-WATER SUGARS). (cf. ENRICHMENT MEDIUM.)

**enrichment** Any process which increases the proportion of a given microorganism in a mixed population. For example, faeces from a typhoid case can be cultured in an enrichment medium (e.g. SELENITE BROTH) which suppresses growth of the normal faecal flora while permitting growth of the pathogen, *Salmonella typhi*; *S. typhi* is therefore ‘enriched’ so that its detection is facilitated. (See also DEFECTIVE INTERFERING PARTICLE.)

**enrichment medium** Any medium used for ENRICHMENT; it may contain substance(s) which encourage growth of the required organism and/or inhibit the growth of other type(s) of organism. (See e.g. SELENITE BROTH and TETRATHIONATE BROTH; cf. ENRICHED MEDIUM.)

**Ensifer** A genus of Gram-negative, aerobic, chemoorganotrophic and facultatively predatory, soil-inhabiting BUDDING BACTERIA; cells: rod-shaped (ca. 0.7–1.1 × 1.0–1.9 µm), motile by means of a subterminal tuft of 3–5 flagella. The cells of *E. adhaerens* (the type species) attach, end on, to a suitable prey bacterium (e.g. *Micrococcus luteus*), forming a palisade arrangement; under certain conditions the prey cell may be lysed. [IJSB (1982) 32 339–345.]

**ensiform** Sword-like; narrow and pointed.

**ensilage** (1) The process of making SILAGE. (2) The silage itself.

**Ent plasmid** Any plasmid carrying genes for the ST and/or LT enterotoxins of ETEC (q.v.).

**entA gene** (*Staphylococcus aureus*) See ENTEROTOXIN.

**entA–entG genes** (in *Escherichia coli*) See SIDEROPHORES.

**Entamoeba** A genus of protozoa (order AMOEBIDA) characterized by the presence of beaded chromatin on the inner surface of the nuclear membrane. Most species (not *E. gingivalis*) form cysts which may contain CHROMATOID BODIES and glycogen-containing vacuoles. All species except *E. moshkovskii* occur as parasites/commensals in the alimentary tract in animals.

*E. coli*. A non-pathogen found in human faeces. Trophozoites are ca. 10–50 µm diam., contain numerous vacuoles, and slowly form blunt, granular pseudopodia; the single karyosome is located eccentrically, and the peripheral chromatin is coarsely and irregularly beaded. Mature cysts contain 8 nuclei.

*E. gingivalis*. A non-pathogenic, non-cyst-forming species found in the mouth in man and other animals. Trophozoites: ca. 5–35 µm diam., morphologically similar to those of *E. histolytica*.

*E. hartmanni*. A non-pathogenic species found in human faeces. It resembles *E. histolytica*, but both trophozoites (5–10 µm diam.) and cysts (<10 µm diam.) are smaller.

*E. histolytica*. A parasite and potential pathogen in the human intestine; it can cause amoebic DYSENTERY. Non-invasive trophozoites living in the gut lumen are ca. 20 µm in diam.; invasive forms which penetrate and develop in the gut mucosa are usually 20–50 µm diam. The cells contain few vacuoles, but may

contain ingested red blood cells (an almost pathognomonic feature); finger-shaped, hyaline pseudopodia are produced rapidly. The (single) nucleus contains a small central karyosome, and the peripheral chromatin is finely and regularly beaded. In the gut lumen, some trophozoites expel their food particles and shrink to become rounded, non-motile *precysts*; a precyst secretes a resistant wall and becomes a spherical CYST (usually >10 µm and <20 µm diam.). A cyst initially contains a single nucleus, but two nuclear divisions result in four nuclei in the mature cyst; each nucleus contains a central karyosome. Young cysts may contain round-ended chromatoid bodies in the cytoplasm. Trophozoites, precysts and cysts may all be found in the faeces of the host, but only the cysts are infective for another host. Cysts are resistant to various environmental conditions – and to normal chlorination levels in water supplies – but are sensitive to temperatures >40°C and <–5°C and to desiccation. Cysts may be stained with iodine (cytoplasm yellow, glycogen vacuoles reddish-brown); trophozoites stain well with e.g. iron–haematoxylin after fixation in PVA (cytoplasm grey or pale violet, nuclear structures black). *E. histolytica* may be cultured anaerobically on media containing e.g. inspissated horse serum, rice starch, or egg albumen, together with bacteria or flagellate protozoa; it has also been cultured in sterile media. Strains have been classified on the basis of growth characteristics (‘classical’ strains grow best at 37°C, while atypical, less pathogenic ‘Laredo-type’ strains grow well at 37°C and at 25°C), or by the presence or absence of the enzyme phosphoglucomutase (present in organisms from patients with clinical amoebiasis, but not in those from asymptomatic carriers). (See also PYROPHOSPHATE.)

*E. moshkovskii*. A non-pathogen found in sewage; it resembles *E. histolytica* morphologically, but apparently occurs only in the free-living state.

*E. paulista*. A hyperparasite found in the cytoplasm of *Opalina ranarum* in frogs.

Other species include e.g. *E. bovis* (from cattle), *E. invadens* (pathogenic in reptiles), *E. muris* (from rats and mice), and *E. polecki* (from pigs).

[Biochemistry and functional morphology of *Entamoeba*: JP (1985) 32 221–240.]

**enteric** Of or relating to the intestine (particularly the small intestine). ‘Enteric bacteria’ may refer to any or all bacteria normally found in the (small or large) intestine, or may refer specifically to members of the ENTEROBACTERIACEAE.

**enteric adenoviruses** See MASTADENOVIRUS.

**enteric fever** Any typhoid-like human salmonellosis – caused e.g. by *Salmonella paratyphi* (cf. PARATYPHOID FEVER), *S. typhimurium* etc. – as distinct from *Salmonella* FOOD POISONING. Some authors include TYPHOID FEVER among the enteric fevers.

**enteric redmouth** (red vent disease) A disease of rainbow trout (*Salmo gairdneri*) caused by *Yersinia ruckeri*. Symptoms include e.g. haemorrhagic lesions in and around the mouth and vent. (cf. RED MOUTH.)

**enteric septicaemia** (of fish) A disease of the channel catfish (*Ictalurus punctatus*) caused by *Edwardsiella ictaluri*; the disease has become an important problem in the intensive cultivation of catfish. Naturally infected fish often have a characteristic erosive lesion on the head (‘hole-in-the-head’); chronic cases may involve enteritis, hepatitis, meningoencephalitis, etc. Primary infection can apparently occur via the gut or via the nares. [Pathogenesis: CJFAS (1986) 43 36–42.] (See also FISH DISEASES.)

**Enteridium** See MYXOMYCETES.

## enteritis

**enteritis** Inflammation of the lining of any part of the intestine – particularly the small intestine; it may result from the same causes as GASTROENTERITIS. (cf. COLITIS.)

**enteritis necroticans** (necrotizing enteritis; 'pig bel'; *Darmbrand*) A rare, severe (often fatal), haemorrhagic enteric disease caused by ingestion of food (commonly pig meat) contaminated with *Clostridium perfringens* type C. (cf. FOOD POISONING.) The organisms adhere to the intestinal mucosa and produce the necrotizing  $\beta$ -toxin, causing necrosis of the mucosa. Diet influences disease development: the  $\beta$ -toxin is normally readily inactivated by digestive proteases; however, high-carbohydrate, low-protein diets reduce the secretion of proteases, and e.g. sweet potatoes contain a trypsin inhibitor which further lowers proteolytic activity – factors which allow the  $\beta$ -toxin to persist.

**enteroadherent *E. coli*** Diarrhoeagenic strains of *Escherichia coli* characterized by their ability to adhere to (mammalian) HEP-2 cells; strains can be differentiated on the basis of their patterns of adherence: 'diffusely adherent *E. coli*' (DAEC) adheres primarily as isolated, individual cells in a diffuse manner, while enteroaggregative *E. coli* (EAggEC; see EAGGEC) forms a pattern of scattered aggregates in which most of the cells are obviously grouped with other cells. (EPEC adheres to HEP-2 in a localized manner, forming microcolonies.) The category 'enteroadherent' has been discontinued: strains of HEP-2-adherent *E. coli* (excluding EPEC) are now divided into the two main groups EAggEC and DAEC (each of which, though still heterogeneous, is associated with distinct virulence factors and epidemiology) [RMM (1995) 6 196–206].

(See also EAEC.)

**enteroaggregative *E. coli*** See EAGGEC.

**Enterobacter** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: ca.  $0.6\text{--}1.0 \times 1.2\text{--}3.0 \mu\text{m}$ , motile (generally 4–6 peritrichous flagella). Most strains possess fimbrial haemagglutinins [JGM (1983) 129 2175–2180]. Typical reactions: indole –ve; MR –ve; VP +ve; citrate +ve;  $\text{H}_2\text{S}$  –ve; acid and gas from glucose at  $37^\circ\text{C}$  (no gas at  $44.5^\circ\text{C}$ ); lactose +ve. Optimum growth temperature: ca.  $30^\circ\text{C}$ . GC%: 52–60. Type species: *E. cloacae*.

*Enterobacter* spp occur e.g. in the intestines of man and animals, in soil, water and sewage, in foods (e.g. dairy products), on plants etc. Most species can be opportunist pathogens, causing nosocomial infections (e.g. meningitis, pneumonia, septicaemia, UTI).

*E. aerogenes*. Lysine and ornithine decarboxylases +ve; arginine dihydrolase –ve; D-sorbitol +ve; non-pigmented. (It has been proposed that *E. aerogenes* be transferred to the genus *Klebsiella* as '*K. mobilis*' [see Book ref. 22, p. 463, 466 and 469].) (cf. AEROBACTER.)

*E. agglomerans*. A heterogeneous species comprising organisms alternatively included in *Erwinia herbicola* (see ERWINIA). Lysine and ornithine decarboxylases –ve; arginine dihydrolase –ve; lactose –ve. Some strains are yellow-pigmented.

*E. cloacae*. Lysine decarboxylase –ve; ornithine decarboxylase +ve; arginine dihydrolase +ve; D-sorbitol +ve; DNase –ve at  $25^\circ\text{C}$ . Non-pigmented. Naturally resistant to ampicillin.

*E. sakazakii* includes yellow-pigmented strains previously included in *E. cloacae*. D-Sorbitol –ve; DNase delayed +ve at  $25^\circ\text{C}$ .

Other species: *E. amnigenus*, *E. gergoviae*, *E. intermedium*. (*E. hafniae* and *E. alvei*: see HAFNIA; *E. liquefaciens*: see SER-RATIA.)

[Book refs. 46, pp. 1173–1180; and 22, pp. 465–469.]

**enterobacteria** Bacteria of the ENTEROBACTERIACEAE.

**Enterobacteriaceae** A family of Gram-negative, asporogenous, facultatively anaerobic bacteria. Cells: rod-shaped, typically ca.  $0.3\text{--}1.0 \times 1\text{--}6 \mu\text{m}$  (cf. OBESUMBACTERIUM), motile (peritrichously flagellate – cf. TATUMELLA) or non-motile. Metabolism is chemoorganotrophic and may be respiratory or fermentative, depending e.g. on conditions. Most species can reduce nitrate to nitrite. All species are oxidase –ve and (except for *Shigella dysenteriae* serotype 1 and *Xenorhabdus nematophilus*) catalase +ve. Reproduction occurs by binary fission. Type genus: *Escherichia*.

Enterobacteria occur e.g. as parasites, pathogens or commensals in man and/or animals, as saprotrophs or pathogens in plants (see ERWINIA), or as saprotrophs (or faecal contaminants) in soil and water. Many are important opportunist causes of nosocomial infections.

Enterobacteria typically grow readily on a range of basal media (e.g. NUTRIENT AGAR). Media selective for enterobacteria commonly contain a sugar (often lactose), bile salts (as selective agents), and a pH indicator (see e.g. MACCONKEY'S AGAR).

Genera and species are traditionally differentiated on the basis of biochemical tests – e.g. the IMVIC TESTS, the ability to produce certain enzymes (e.g. UREASE, ARGININE DIHYDROLASE), to utilize particular sugars (mono- and disaccharides, polyols etc), to decarboxylate or deaminate certain amino acids (see e.g. DECARBOXYLASE TEST), to produce HYDROGEN SULPHIDE from thiosulphate (see e.g. TSI AGAR), etc. [Identification tests: Book ref. 184.] Reactions to such tests may be affected e.g. by mutation or by the presence of a metabolic PLASMID, and in some cases are strongly dependent on the reaction conditions (see e.g. YERSINIA). DNA HOMOLOGY ('DNA relatedness') studies have been widely used to indicate degrees of relatedness between strains, species and genera. However, the genera *Escherichia* and *Shigella*, for example, continue to be recognized even though they have been shown to be sufficiently closely related genetically to be regarded as a single genus (or even as a single species). [Book ref. 46, pp. 1108–1112.]

Many enterobacteria can be serotyped (see TYPING) on the basis of O ANTIGENS, H ANTIGENS, K ANTIGENS and/or VI ANTIGENS; cross-reactions between members from different genera are quite common (see e.g. CITROBACTER). All enterobacteria (except *Erwinia chrysanthemi*) possess the ENTEROBACTERIAL COMMON ANTIGEN. Colicin, bacteriophage and antibiotic TYPING may be used for particular genera. [Serology/serotyping in enterobacteria: Book ref. 68.]

Genera: CEDECEA; CITROBACTER; EDWARDSIELLA; ENTEROBACTER; ERWINIA; ESCHERICHIA; EWINGELLA; HAFNIA; KLEBSIELLA; KLUYVERA; KOSERELLA; LEMNORELLA; MOELLERELLA; MORGANELLA; OBESUMBACTERIUM; PROTEUS; PROVIDENCIA; RAHNELLA; SALMONELLA; SERRATIA; SHIGELLA; TATUMELLA; XENORHABDUS; YERSINIA. (See also SODALIS.)

**enterobacterial common antigen** (ECA; Kunin antigen) A heteropolysaccharide antigen found in the outer membrane in all wild-type strains of the Enterobacteriaceae (excluding *Erwinia chrysanthemi*) and e.g. in strains of PLESIOMONAS. It consists of alternating residues of (1  $\rightarrow$  4)-linked *N*-acetyl-D-glucosamine and *N*-acetyl-D-mannosaminuronic acid which may be esterified with small amounts of e.g. palmitic and acetic acids. ECA may be linked to phospholipid (when it is poorly immunogenic), or it may be bound e.g. to the core region of LPS (when it is highly immunogenic); it is readily accessible to homologous antibodies in non-capsulated rough strains, but may be inaccessible e.g. in smooth, capsulated strains [JGM (1982) 128 1577–1583].

**enterobacterial repetitive intergenic consensus sequence** See ERIC SEQUENCE.

**enterobactin** See SIDEROPHORES.

**enteroblastic proliferation** (*mycol.*) See CONIDIUM.

**enterochelin** See SIDEROPHORES.

**enterochromaffin cells** Cells in the mammalian gut epithelium which secrete certain hormones – e.g. SEROTONIN (a stimulator of intestinal secretion).

**enterocin P** A broad-spectrum BACTERIOCIN produced by *Enterococcus faecium* strain P13 and secreted by a *sec*-dependent pathway; it inhibits strains of e.g. *Listeria monocytogenes*, *Staphylococcus aureus*, *Clostridium perfringens* and *C. botulinum*. [Biochemical and genetic characterization of enterocin P: AEM (1997) 63 4321–4330.]

**enterococci** (1) Members of the genus ENTEROCOCCUS. (2) A term which has been used very loosely to refer to some or all of the organisms referable to the genus ENTEROCOCCUS.

**Enterococcus** A genus of Gram-positive, asporogenous, chemo-organotrophic, facultatively anaerobic, coccoid bacteria; the genus was originally proposed to accommodate organisms previously classified as *Streptococcus faecalis* and *Streptococcus faecium* [proposal to transfer *S. faecalis* and *S. faecium* to the genus *Enterococcus* as *E. faecalis* and *E. faecium* respectively: IJSB (1984) 34 31–34]. [Proposal to transfer other streptococci to this genus: *S. avium* (as *Enterococcus avium*), *S. casseliflavus* (*E. casseliflavus*), *S. durans* (*E. durans*), *S. faecalis* subsp. *malodoratus* (*E. malodoratus*) and *S. gallinarum* (*E. gallinarum*): IJSB (1984) 34 220–223.]

Members of the genus occur in the animal and human intestine; they can usually grow at 10°C and 45°C, and can grow in 6.5% sodium chloride and at pH 9.6. Metabolism: typically fermentative, but at least some strains can carry out respiratory metabolism when provided with haemin under aerobic conditions. (See also PYR.) GC% 37–45. Type species: *E. faecalis*.

*E. faecalis*. Organisms formerly classified as *Streptococcus faecalis* (Lancefield group D). Cells: ovoid, occurring singly or in pairs or short chains; motile strains are rare. Non-haemolytic or, rarely,  $\beta$ -haemolytic. *E. faecalis* can survive 60°C/30 min. Various sugars are fermented (e.g. D-tagatose, but not e.g. D- or L-arabinose), and acid is formed from glycerol both aerobically and anaerobically. Energy can be obtained from pyruvate, citrate and malate. Growth can occur in the presence of 0.02% sodium AZIDE, 0.04% tellurite, or 0.01% TETRAZOLIUM. Some strains form a PSEUDOCATALASE.

Some strains of *E. faecalis* can transmit/receive plasmids that confer resistance to antibiotic(s) (see CONJUGATION). A current problem is the acquisition of (plasmid-borne) resistance to VANCOMYCIN; the appearance of vancomycin-resistant enterococci (VRE) is important because enterococci are frequent causal agents of nosocomial bacteraemia. It has been estimated that ~15% of enterococci are resistant to vancomycin [EID (1998) 4 239–249]. Vancomycin resistance may be conferred by one or more plasmid-borne *van* genes; *vanA* and *vanB* both confer resistance to vancomycin, while *vanA* also confers resistance to teichoplanin. (These two genes have been reported in both *E. faecalis* and *E. faecium*.) Multiplex PCR has been used for rapidly detecting *vanA* and *vanB* in presumptive colonies of VRE [JCM (1999) 37 2090–2092].

[Vancomycin-resistant *E. faecium* with a VanB phenotype in a Warsaw hospital: JCM (2001) 39 1781–1787.]

*E. faecium*. Organisms formerly classified as *Streptococcus faecium* (Lancefield group D). The organisms resemble *E. faecalis* in morphology and general characteristics, including resistance to heat, high pH and salinity; some strains are  $\alpha$ -haemolytic. Acid is formed from arabinose but not from tagatose.

Unlike *E. faecalis*, *E. faecium* cannot use citrate, malate or pyruvate as sources of energy. Hydrogen peroxide may accumulate under aerobic conditions.

**Enterocytozoon** A genus of protozoa (phylum MICROSPORA); *E. bienersi* has been reported from the gut of a human AIDS patient [JP (1985) 32 250–254].

**enterodiol** See LIGNANS.

**enterohaemorrhagic *E. coli*** See EHEC.

**enteroinvasive** Refers to pathogenic organisms which invade the intestinal mucosa (see e.g. EIEC).

**enteroinvasive *E. coli*** See EIEC.

**enterolactone** See LIGNANS.

**Enteromonadina** See DIPLOMONADIDA.

**Enteromonas** See DIPLOMONADIDA.

**Enteromorpha** A genus of macroscopic green algae, closely related to *ULVA* spp, in which the thallus consists of hollow tubes one cell thick; species occur in coastal waters and on estuarine mudflats, often flourishing in conditions which also favour *Ulva lactuca*.

**enteropathogenic** Pathogenic for the intestine. (See also FOOD POISONING; for enteropathogenic *Escherichia coli* see EPEC.)

**Enteropogon** See TRICHOMYCETES.

**enterotoxigenic** (enterotoxinogenic) Refers to an organism that produces one or more ENTEROTOXINS. (See also ETEC; cf. ENTEROINVASIVE and ENTEROPATHOGENIC.)

**enterotoxigenic *E. coli*** See ETEC.

**enterotoxin** A TOXIN which acts on the intestine, either when ingested or when produced by an organism within the intestine (see e.g. CHOLERA TOXIN and ETEC). [Enteric bacterial toxins (review): MR (1996) 60 167–215.]

The enterotoxins of *Staphylococcus aureus* (A, B, C1–C3, D and E) are SUPERANTIGENS, and their ability to stimulate the production of cytokines may account for at least some of the observed symptoms of staphylococcal FOOD POISONING; gut epithelial cells express MHC class II molecules and may present enterotoxin to submucosal T cells [MR (1996) 60 195]. [See also Clinical Microbiology Reviews (2000) 13 16–34.]

Staphylococcal enterotoxins are small proteins (~25–30 kDa) with similar biological activities; they may be encoded by chromosomal, plasmid-borne or phage-borne genes – in at least some strains, the gene encoding enterotoxin A (*entA*) is phage-borne. Each toxin is a single polypeptide chain which is resistant to many proteolytic enzymes, and can generally withstand boiling for up to 30 minutes. The toxins are produced during active growth.

(See also TSST-1 under TOXIC SHOCK SYNDROME.)

**Enterotube II** See MICROMETHODS.

**Enterovioform** See 8-HYDROXYQUINOLINE.

**Enterovirus** A genus of viruses (family PICORNAVIRIDAE), most of which replicate primarily in the mammalian intestinal tract – although subsequently other tissues may become infected. The virions are stable at pH 3–9 and at or below room temperature, and are resistant to e.g. ethanol (70%), Lysol (5%), quaternary ammonium compounds, detergents and bile salts; they are generally inactivated by heat (e.g. 50°C), formaldehyde (3%), HCl (0.1 N), or chlorine (ca. 0.3–0.5 ppm free residual Cl<sub>2</sub>). They can be protected against heat inactivation by 1 M MgCl<sub>2</sub>. Many enteroviruses can be propagated in primary cultures of human or monkey kidney cells and in some cell lines (e.g. HeLa, Vero, WI-38).

Most human enteroviruses are classified into one of three groups (see below) on the basis of e.g. pathogenicity and host range; enterovirus infections are commonly or usually

## Entner–Doudoroff pathway

subclinical, but may result in various diseases ranging from mild to severe or fatal [review: Book ref. 148, pp. 739–794].

*Coxsackieviruses* (first isolated in Coxsackie, New York) are generally pathogenic for newborn mice: *group A* coxsackieviruses cause a widespread inflammation of skeletal muscles (myositis) resulting in flaccid paralysis, *group B* coxsackieviruses cause a focal myositis with necrotizing inflammation of fatty tissues and e.g. encephalitis, pancreatitis, etc. In humans, coxsackieviruses can cause e.g. aseptic MENINGITIS; BORNHOLM DISEASE; HAND, FOOT AND MOUTH DISEASE; HERPANGINA; paralysis (very rare); pericarditis and myocarditis (mainly coxsackieviruses B1–B5) which may result in chronic cardiovascular disease; PHARYNGITIS; PNEUMONIA; URTIs (e.g. A21, = ‘Coe virus’), can cause a disease resembling the COMMON COLD). (The causal agent of SWINE VESICULAR DISEASE is apparently closely related to human coxsackievirus B5.)

*Echoviruses* (‘enteric cytopathogenic human orphan viruses’) are generally non-pathogenic in newborn mice; in humans they can cause e.g. aseptic MENINGITIS, encephalitis, paralysis, URTIs, etc.

*Polioviruses* are the causal agents of POLIOMYELITIS in man. There are three serotypes: Brunnhilde (type 1), Lansing (type 2), and Leon (type 3). [Molecular biology of polioviruses: Book ref. 162; antigenic structure of polioviruses: JGV (1986) 67 1283–1291.]

Unclassified *human enteroviruses* may cause e.g. bronchiolitis (type 68); ACUTE HAEMORRHAGIC CONJUNCTIVITIS (type 70); MENINGITIS and paralysis (types 70 and 71), and hepatitis (type 72, = HEPATITIS A virus).

*Porcine enteroviruses* cause e.g. SWINE VESICULAR DISEASE and TESCHEN DISEASE. In breeding animals porcine enteroviruses (‘SMEDI viruses’) can cause stillbirth, mummification of the fetus, embryonic death, and infertility, depending e.g. on the period of gestation at which infection occurs.

Other animal enteroviruses include bovine enteroviruses, simian enteroviruses, THEILER’S MURINE ENCEPHALOMYELITIS VIRUS, and the causal agents of AVIAN ENCEPHALOMYELITIS and DUCK VIRUS HEPATITIS.

**Entner–Doudoroff pathway (ED pathway)** A metabolic pathway [Appendix I(c)] for the degradation of glucose in a wide range of bacteria (e.g. species of *Acetobacter*, *Agrobacterium*, *Pseudomonas*, *Rhizobium*, *Serratia*, *Xanthobacter*, *Xanthomonas* and *Zymomonas*); some bacteria (e.g. *Escherichia coli*) which metabolize glucose mainly via the EMBDEN–MEYERHOF–PARNAS PATHWAY can metabolize gluconate and other aldonates via reactions of the ED pathway.

The fates of pyruvate and glyceraldehyde 3-phosphate (GAP) produced in the ED pathway depend on organism and conditions. In some bacteria GAP may be converted to pyruvate via phosphoenolpyruvate, as in the latter part of the EMP pathway [Appendix I(a)]; in pseudomonads, GAP is recycled (via fructose 1,6-bisphosphate, fructose 6-phosphate and glucose 6-phosphate – see GLUCONEOGENESIS) to 6-phosphogluconate (which can enter the ED pathway). Some of the 6-phosphogluconate may be diverted into the HEXOSE MONOPHOSPHATE PATHWAY. In aerobic bacteria, pyruvate can generally be metabolized via acetyl-CoA and the TCA CYCLE. In (fermentative) ZYMONONAS species, pyruvate is largely decarboxylated to acetaldehyde – which is then reduced to ethanol.

In addition to the (phosphorylative) pathway for glucose metabolism, many pseudomonads can oxidize glucose directly (i.e. without phosphorylation) to gluconate – see EXTRACYTOSOLIC OXIDATION. A proportion of the resulting gluconate is

taken into the cell by specific transport systems and then phosphorylated to form 6-phosphogluconate (which can then be metabolized via the ED pathway and/or the HMP pathway).

[ED pathway (history, physiology, molecular biology): FEMS Reviews (1992) 103 1–28. ED pathway in *E. coli*: JB (1998) 180 3495–3502.]

**Entodiniomorpha** An order of protozoa (subclass VESTIBULIFERIA) in which the cells are naked except for tufts or bands of oral and (often) somatic syncytia. STOMATOGENESIS is apparently apokinetal. In some species the pellicle is drawn out into terminal spikes or spines. The organisms occur e.g. in the alimentary canal in herbivorous mammals. Genera: e.g. DIPLODINIUM, ENTODINIUM, *Epidinium*, *Metadinium*.

**Entodinium** A genus of ciliates (order ENTODINIOMORPHIDA) related to DIPLODINIUM. Typically, the anterior pole of the cell is flattened and bears a conspicuous tuft of cilia; there is no DZM, and the posterior end of the cell may or may not be drawn out into spines.

**entomo-** Prefix denoting insect – e.g. entomopathology: the study of INSECT DISEASES; entomopathogenic: pathogenic for insects.

**entomogenous** Growing in or on insects.

**entomopathogenic** Pathogenic for insects (see INSECT DISEASES).

**Entomophaga** See ENTOMOPHTHORALES.

**Entomophthora** A genus of fungi (order ENTOMOPHTHORALES) which include saprotrophs and parasites of insects. The vegetative thallus is commonly an aseptate or septate mycelium with a tendency to fragment; the ‘conidia’ are forcibly discharged. AZYGOSPORES are formed by some species. [Key to *Entomophthora* (sens. lat.): BBMS (1982) 16 113–143; infection of houseflies by *E. muscae*: TBMS (1983) 80 1–8; ultrastructural studies of primary spore formation and discharge in *Entomophthora*: J. Inv. Path. (1986) 48 318–324.]

**Entomophthorales** An order of fungi (class ZYGOMYCETES) which include a number of parasites of insects and mammals. Asexually derived spores – often called ‘conidia’ – are forcibly discharged in members of the families Basidiobolaceae and Entomophthoraceae. (Members of the ZOOPAGALES are sometimes included as a third family in this order.) Genera include *Basidiobolus* (see also ZYGOMYCOSIS and EQUINE PHYCOMYCOSIS) and (in the family Entomophthoraceae) *Conidiobolus* (see also ZYGOMYCOSIS), *Entomophaga*, ENTOMOPHTHORA, ERYNIA, *Goni-mochaete* (see NEMATOPHAGOUS FUNGI), and *Zoophthora*. (See also LOBOA and HYPHAL BODY; cf. BLASTOCYSTIS.)

**entomophthoromycosis** See ZYGOMYCOSIS.

**Entomopoxvirinae** (entomopoxviruses, EPVs) A subfamily of viruses, family POXVIRIDAE, which infect insects – including members of the Coleoptera (beetles etc), Diptera (flies etc), Lepidoptera (butterflies and moths), and Orthoptera (locusts, crickets, grasshoppers etc). EPV virions are brick-shaped or ovoid, ca. 300–450 × 170–250 nm, with a characteristic ‘mulberry-like’ appearance in negatively stained preparations – the globular surface ‘units’ apparently being folds of the outer membrane. The viruses multiply in the cytoplasm of (mainly) leucocytes and adipose cells of the host. Late in the replication cycle infected cells may contain one or two types of inclusion body: *spheroids* (= ‘spherules’, each consisting of mature virions occluded within a matrix of protein, *spheroidin*) and *spindles* (virus-free, spindle-shaped structures composed of a protein which is apparently distinct from spheroidin). A new host is infected when it ingests a spheroid and the virions are released in the alkaline contents of the gut. EPVs apparently vary in their pathogenicity, but at least some can cause diseases (‘spheroidoses’) in their hosts; they are currently little used for biological control of insect pests.

Three genera of EPVs have been proposed on the basis of virion morphology, host range, and genome MWt [Book ref. 23, pp. 44–46]; members of different genera show no serological relationship either to each other or to other poxviruses.

**Genus A** (coleopteran EPVs). Type species: *Melolontha melolontha* (cockchafer) EPV. Virion: ovoid, ca. 450 × 250 nm, containing a kidney-shaped (unilaterally concave) core with one lateral body (cf. POXVIRIDAE) and bearing surface globular units ca. 22 nm diam.; DNA MWt: ca. 170–240 × 10<sup>6</sup>. Similar viruses have been isolated from other coleopteran insects – e.g. *Phyllopertha horticola* (the garden chafer). Spindles are formed by most of these viruses.

**Genus B** (lepidopteran and orthopteran EPVs). Type species: *Amsacta moorei* EPV. Virion: ovoid, ca. 350 × 250 nm, containing a cylindrical core and a ‘sleeve-shaped’ lateral body, and bearing surface globular units ca. 40 nm diam.; DNA MWt: ca. 132–142 × 10<sup>6</sup>. Similar viruses have been isolated from various lepidopteran insects – e.g. *Choristoneura biennis* (the eastern spruce budworm) and other *Choristoneura* spp – and from the orthopteran *Melanoplus sanguinipes* (a short-horned grasshopper). Spindles are formed by most of these viruses.

**Genus C** (dipteran EPVs). Type species: *Chironomus luridus* EPV. Virion: brick-shaped, ca. 320 × 230 × 110 nm, with a biconcave core and two lateral bodies; DNA MWt: ca. 165–250 × 10<sup>6</sup>. Similar viruses have been isolated from other dipteran insects, including other *Chironomus* spp (non-biting midges) and *Aedes aegypti* (see AEDES). Spindles are not formed in cells infected with any of the viruses in this genus.

[Review: AVR (1984) 29 195–213.]

**entomopoxviruses** See ENTOMOPOXVIRINAE.

**Entomosporium** See MELANCONIALES.

**entomotoxin** A TOXIN effective against insects.

**Entorrhiza** A genus of smut fungi (order USTILAGINALES) which are parasitic on the roots of rushes and sedges.

**Entosiphon** A genus of EUGLENOID FLAGELLATES closely related to PERANEMA.

**entry exclusion** *Syn.* SURFACE EXCLUSION.

**Entyloma** A genus of smut fungi (order USTILAGINALES) which form pale-coloured spores; the host plants range from rice to spinach.

**enucleated cell** A CYTOPLAST, or a (eukaryotic) cell in which the nucleus has been inactivated by a ‘chemical enucleator’.

**enumeration of microorganisms** See COUNTING METHODS.

**env gene** See RETROVIRIDAE.

**EnvA** See CELL CYCLE (b).

**envelope** (1) (peplos) (*virol.*) A lipoprotein membrane which forms the outermost layer of the virion in certain ANIMAL VIRUSES, PLANT VIRUSES and BACTERIOPHAGES. Animal virus envelopes have been the most extensively studied, and the account below refers to them.

In general, the lipid components of the viral envelope are derived from host cell membranes, while the protein components (typically glycoproteins) are virus-encoded; many of the proteins project from the surface as ‘spikes’ or *peplomers*. Envelope proteins play important roles in the infection process; they are responsible for the attachment of the virion to receptor sites on the host cell surface, and they bring about the release of the nucleocapsid into the host cell cytoplasm by triggering fusion between the envelope and host membranes. In most enveloped animal viruses (but not in e.g. PARAMYXOVIRUSES) the activity of the membrane-fusing envelope proteins requires a low pH (ca. 5–6), and hence in these viruses fusion generally cannot occur between the viral envelope and the host plasmalemma *in vivo*.

Such viruses are taken up (intact) by the host cell by receptor-mediated endocytosis, and only when the contents of the endosome become sufficiently acidic does fusion occur between the viral envelope and the endosomal membrane – resulting in the release of the nucleocapsid into the cytoplasm. [Review of endocytosis of enveloped viruses: Bioch. J. (1984) 218 1–10.]

In many enveloped viruses (e.g. influenza viruses) the individual virions do not share a common structure or composition; for example, the envelope glycoproteins in influenza viruses do not occur in a fixed number in all the virions. By contrast, a defined structure is found in the virions of alphaviruses and flaviviruses [see e.g. Cell (2001) 105 5–8].

In most cases a virus acquires its envelope (during virion assembly) by a process of *budding* (cf. FLAVIVIRIDAE). The virus-encoded envelope proteins each contain an anchor peptide (see SIGNAL HYPOTHESIS) and become anchored in the appropriate cell membrane (e.g. endoplasmic reticulum, plasmalemma, nuclear membrane – according to virus); these proteins then interact with proteins in the preformed nucleocapsid, causing the associated region of membrane to wrap around the nucleocapsid. This region of membrane eventually becomes detached from the host membrane, completing the assembly process.

Enveloped virions are typically readily inactivated by lipid-disrupting reagents and procedures: e.g. organic solvents such as ether and chloroform, detergents, heat, etc.

[Membranes in animal viruses: Book ref. 148, pp. 45–67.]

(2) (*bacteriol.*) *Syn.* CELL ENVELOPE.

**environmental clean-up** See BIOREMEDIATION.

**environmental pollution** See e.g. BIOREMEDIATION, GREENHOUSE EFFECT, SEWAGE TREATMENT, WATER SUPPLIES and XENOBIOTIC. (See also AEROSOL and AIR.)

**enviroxime** (2-amino-1-(isopropylsulphonyl)-6-benzimidazolyl-phenyl ketone oxide) An ANTIVIRAL AGENT which specifically inhibits rhinovirus replication in cell cultures; it does not appear to be effective in preventing or treating human rhinovirus infections *in vivo*.

**EnvZ** See OSMOREGULATION.

**enzootic** Refers to an ENDEMIC animal disease.

**enzootic abortion** (enzootic ovine abortion) Abortion in sheep caused by *Chlamydia psittaci*. Laboratory diagnosis may involve e.g. detection by microscopy of elementary bodies in stained placental smears, or culture of placental material [VR (1983) 113 413–414]. (cf. INFECTIOUS ABORTION.)

**enzootic bovine leukaemia** *Syn.* BOVINE VIRAL LEUKOSIS.

**enzootic ovine abortion** See ENZOOTIC ABORTION.

**enzootic pneumonia of calves** See CALF PNEUMONIA.

**enzyme** A protein which acts as a highly efficient and specific biological catalyst. (Certain RNA molecules are capable of catalytic activity in the absence of protein, and these are sometimes called enzymes (cf. RIBOZYME); the account below refers specifically to *protein* catalysts.) An enzyme increases the *rate* of a (thermodynamically feasible) reaction by decreasing the activation energy; it cannot alter the equilibrium constant of a reaction. Many enzymes require non-protein COENZYMES, PROSTHETIC GROUPS, or metal ions/atoms for activity. (See also ZYMOGEN.)

Most enzymes have trivial names which usually indicate the nature of the substrate(s) and/or the reaction catalysed (e.g. *urease* splits urea, *alcohol dehydrogenase* dehydrogenates alcohol). However, a systematic scheme for the classification and precise nomenclature of enzymes has been established by the IUB Commission on Enzymes. The *classification* involves the division of all known enzymes into six general classes

## enzyme I, II and III

(numbered 1–6): 1 = OXIDOREDUCTASES; 2 = TRANSFERASES; 3 = HYDROLASES; 4 = LYASES; 5 = ISOMERASES; 6 = LIGASES. According to the nature of the reaction catalysed, each class is divided into (numbered) subclasses and sub-subclasses; within a given sub-subclass, each individual enzyme is given a specific (arbitrarily assigned) serial number. Thus, any enzyme has a unique classification number (EC number) consisting of four figures. For example, pyruvate kinase has the number EC 2.7.1.40, where 'EC' = Enzyme Commission, '2' means that the enzyme is a transferase, '7' that a phosphate group is transferred, and '1' that an alcohol group accepts the phosphate; '40' is the arbitrarily assigned serial number for pyruvate kinase. The systematic *nomenclature* is intended to reflect the nature of the substrate(s), the reaction catalysed, and any coenzyme involved. Thus, e.g., 'alcohol dehydrogenase' (EC 1.1.1.1) is *alcohol:NAD oxidoreductase*, 'pyruvate kinase' is *ATP: pyruvate 2-O-phosphotransferase*.

Microbial enzymes have a number of commercial applications, although their use is still restricted in many cases by e.g. economic factors, stringent safety regulations, and problems of finding suitable enzymes which are stable under the required conditions. Enzymes have a number of advantages over purely chemical processes: they can, under mild conditions, efficiently catalyse reactions which might otherwise require extreme conditions of e.g. temperature, pressure, pH etc; they are usually highly specific (and stereospecific); and they can (at least in theory) be extensively re-used. Either whole microbial cells or purified enzymes may be used. Purified enzymes may be costly, but they generally convert a higher proportion of the substrate (living cells may use some for maintenance energy and biomass production), and fewer side-reactions generally occur; however, isolated enzymes are often unstable. Enzymes from thermophiles are considerably more stable than those from mesophiles and are preferred when available. (See also IMMOBILIZATION sense 1.) For examples of commercial applications of microbial enzymes see AMYLASES, ASPARAGINASE, CATALASE, CELLULASES,  $\beta$ -GALACTOSIDASE, GLUCOSE ISOMERASE, GLUCOSE OXIDASE, GLYCEROKINASE, INVERTASE, LIPASE, PECTIC ENZYMES, PROTEASES, STEROID BIOCONVERSIONS.

[Industrial and diagnostic enzymes: PTRSLB (1983) 300 237–434.]

Enzymes from 'extremophiles' are reported to have unique structures and/or to be stabilized by factors such as thermoprotectants; these enzymes are valuable for studies on enzyme stability, and they have potential applications in biotechnology [TIM (1998) 6 307–314].

In certain pathogenic microorganisms enzymes may play an important role in pathogenesis – see e.g. HYALURONATE LYASE, LECITHINASE, PECTIC ENZYMES, SPHINGOMYELINASE, STREPTOKINASE.

**enzyme I, II and III** See PTS.

**enzyme-catalysed interesterification** See INTERESTERIFICATION.

**enzyme-coupled probes** Small, biotinylated probes labelled with a STREPTAVIDIN–alkaline phosphatase conjugate *prior* to hybridization [NAR (1999) 27 703–705].

**enzyme immunoassay (EIA)** Any IMMUNOASSAY in which an enzyme (e.g. a peroxidase) is used (as a marker) to indicate the presence of specific antigens, antibodies etc: see e.g. ELISA and IMMUNOPEROXIDASE METHOD.

**enzyme-linked immunosorbent assay** See ELISA.

**Eocyta** See ARCHAEBACTERIA.

**Eocytes** A sub-category of PROKARYOTES which share with the eukaryotes a similar sequence of 11 amino acids in the (protein

synthesis) elongation factor EF-1 $\alpha$ , suggesting that the eocytes and eukaryotes are sister taxa with a common ancestor [Science (1992) 257 74–76].

**EOP** Efficiency of plating: the PLAQUE TITRE of a given type of virus expressed as a proportion of the total number of viruses of that type, per unit volume, in a given suspension. Under ideal conditions the EOP of some bacteriophages may exceed 90%; the EOP of animal viruses is often less than 10%.

**eosin (eosin Y)** TetrabromoFLUORESCENIN: a water-soluble red acidic FLUOROCHROME used e.g. as a cytoplasmic stain; it fluoresces greenish-yellow. (See also PHOTODYNAMIC EFFECT.)

**eosin–methylene blue agar** See EMB AGAR.

**eosinophil** A PMN (q.v.) in which cytoplasmic granules contain basic polypeptides that stain strongly with acidic dyes (e.g. eosin).

*Eosinophilia* (an increase in the number of eosinophils in the blood) may be seen e.g. in coccidioidomycosis and allergic pulmonary aspergillosis (sometimes tuberculosis), but, in general, *acute* infections of bacterial, fungal or viral aetiology tend to cause a fall in the number of blood eosinophils (i.e. *eosinopenia*). Protozoan pathogens (e.g. *Entamoeba histolytica*) generally do not give rise to eosinophilia, but eosinophilia is commonly associated with metazoan parasites (such as flatworms and flukes) [eosinophilia and helminthic infections: BCH (2000) 13 301–317].

Eosinophils can participate in ADCC (see also HEPARIN); they can also be phagocytic, but this is not their main function. Eosinophils have cell-surface receptor sites for e.g. IgG, IgE and certain components of COMPLEMENT (e.g. C3b) – sites which may be involved in cell stimulation and release of (cytotoxic) granule contents. Eosinophils are stimulated e.g. by interleukins 3 and (particularly) 5.

**eotaxin** (chemokine) See CHEMOKINES.

**Epalxella** See ODONTOSTOMATIDA.

**Epalxis** See ODONTOSTOMATIDA.

**EPEC** Enteropathogenic *Escherichia coli*: a food-borne and water-borne pathogen which causes diarrhoea primarily in infants (sometimes severe outbreaks: 'infantile gastroenteritis') – particularly under conditions of poor hygiene. EPEC is a major cause of infant mortality in developing countries.

Strains of EPEC characteristically do not invade the gut epithelium (cf. EIEC), do not form ST or LT toxins (cf. ETEC), and do not form shiga-like toxins (cf. EHEC). They attach to the intestinal mucosa and produce characteristic lesions termed *attaching and effacing* (A/E) lesions. Each lesion involves an initial loss of local microvilli and the subsequent development of a 'pedestal': an actin-based, columnar protrusion from the eukaryotic host cell which extends into the gut lumen for several micrometres; the distal end of a pedestal may carry one EPEC cell or a small microcolony of such cells. (An early account noted that strains of EPEC destroy the brush border microvilli "... fashioning for themselves in the process a cup-like pedestal of bare plasma membrane in which individual bacteria sit like eggs in egg-cups" [ADC (1984) 59 395–396].)

The ability of EPEC to produce A/E lesions is encoded by genes on the 35 kb chromosomal LEE PATHOGENICITY ISLAND (q.v.). (Note. Many strains of EHEC can produce EPEC-like lesions *in vitro*; at least some strains of *E. coli* O157:H7, and other EHEC, are known to contain the LEE pathogenicity island. A/E lesions are also produced by certain other Gram-negative bacteria, including *Hafnia alvei*.) The expression of operons on the LEE pathogenicity island is reported to be regulated by QUORUM SENSING (q.v.).

Initial binding of EPEC to the intestinal epithelium was thought, by some authors [TIM (1997) 5 109–114; Book ref. 218], to be mediated by plasmid-encoded bacterial *bundle-forming pili* (BFP; type IV fimbriae). However, in one study, BFP did not adhere to cultures of (paediatric) small intestine – even though they adhered to (mammalian) HeLa cells. In another study, adherence to HeLa cells by (LEE-containing) EHEC apparently depended on filamentous bacterial appendages containing the (LEE-encoded) EspA protein [Mol. Microbiol. (1998) 30 147–161].

One model [TIM (1998) 6 169–172] of EPEC pathogenesis is outlined below. When EPEC comes into contact with an intestinal cell, products of the (LEE-encoded) *esc* genes, and of the *espA* gene, together form a type III secretory system (see PROTEIN SECRETION) – the EspA proteins forming short, filamentous links between the two cells. The Tir and EspB proteins (at least) are secreted directly into the eukaryotic cytoplasm. (Energy requirements may derive from ATP hydrolysis at a putative ATPase, EscN, associated with the type III assembly.) Within the eukaryotic cell, Tir is inserted into the cell membrane – where it acts as a receptor for the bacterial cell-surface adhesin *intimin*. (Intimin may also bind to other host receptors, e.g.  $\beta_1$  integrins.) Phosphorylation of Tir (in the eukaryotic cell) stimulates the polymerization of cytoskeletal elements (e.g. actin) in preparation for pedestal development. (EPEC cells subsequently adherent at the free end of each pedestal may bind to other EPEC, via BFP, to form microcolonies.)

EspB also has regulatory roles in the epithelial cell; it activates various enzymes, resulting e.g. in increased secretion of chloride ions into the gut lumen. The activation of myosin light-chain kinase leads to an opening of ‘tight junctions’ between epithelial cells (increasing the permeability of the intestinal mucosa).

Diarrhoea may result from e.g. (i) stimulation of  $\text{Cl}^-$  secretion (through several mechanisms); (ii) increased permeability of the epithelium (due to opening of tight junctions); and/or (iii) reduced absorptive capacity due to loss of microvilli.

EPEC strains commonly belong to serogroups O26, O55, O86, O114, O119, O125, O126, O127, O128 and O142. O111 is also often listed in this context; however, in Brazil, strains of O111:H12 were reported to have the properties of EAaggEC [FEMS (1997) 146 123–128].

**EPEC adherence factor plasmid** See PATHOGENICITY ISLAND.

**eperezolid** See OXAZOLIDINONES.

**Eperythrozoon** A genus of Gram-negative bacteria within the family ANAPLASMATACEAE. Cells: pleomorphic cocci (diam. ca. 0.5–1.0  $\mu\text{m}$ ) which occur in the blood of the infected host – either free or loosely attached to the outer surface of erythrocytes. *Eperythrozoon* spp (*E. coccoides*, *E. ovis*, *E. parvum*, *E. suis* and *E. wenyonii*) have a wide host range (including ruminants and non-ruminants) and occur worldwide. (See also EPERYTHROZONOSIS.)

**eperythrozoonosis** Any disease caused by an *Eperythrozoon* sp; the pathogen is transmitted e.g. by biting insects. In stressed feeder pigs, *E. suis* can cause acute icterohaemia which involves e.g. mild fever, paleness of the mucosae, wasting, and (often) jaundice; *E. suis* can also cause anaemia in newborn pigs. Similar types of disease can occur in cattle and sheep (caused by *E. wenyonii* and *E. ovis*, respectively). [Book ref. 33, pp. 878–879.]

**ephemeral fever** See BOVINE EPHEMERAL FEVER.

**epicellular** At or on the surface of a cell.

**Epichloë** A genus of fungi (order CLAVICIPITALES) which include parasites and pathogens of grasses. Perithecia are formed within

a stroma, the asci each containing eight filiform ascospores which often fragment in the ascus. *E. typhina* causes CHOKE. (See also FESCUE FOOT and ENDOPHYTE.)

**epicone** See DINOFLAGELLATES.

**epidemic** In a human population within a given geographical region: an outbreak of an infectious disease in which, for a limited period of time, a high proportion of individuals in the population exhibits overt symptoms of the disease (cf. ENDEMIC); epidemics are characterized by a sudden onset. (An analogous outbreak of disease among animals or plants is called an *epizootic* or *epiphytotic*, respectively.) (See also PANDEMIC and EPIDEMIOLOGY.)

Currently, the term ‘epidemic’ is often used in a broader sense to include the occurrence of any disease – either infectious or non-infectious – whose incidence in a given population clearly exceeds that common in other populations.

**epidemic encephalitis** *Syn.* VON ECONOMO’S ENCEPHALITIS.

**epidemic haemorrhagic fever** *Syn.* KOREAN HAEMORRHAGIC FEVER.

**epidemic hepatitis** *Syn.* HEPATITIS A.

**epidemic keratoconjunctivitis** (‘shipyard eye’) A highly infectious KERATOCONJUNCTIVITIS caused by an adenovirus (commonly Ad8: see MASTADENOVIRUS). Infection appears to require direct inoculation of the eye and is typically acquired from inadequately disinfected ophthalmological instruments, contaminated eye ointments etc. (The virus is resistant to organic solvents such as alcohol.) Conjunctivitis with oedema, pain, photophobia and a watery discharge may be followed by erosion of the cornea – sometimes resulting in permanent visual impairment.

**epidemic meningitis** Meningococcal MENINGITIS.

**epidemic myalgia** *Syn.* BORNHOLM DISEASE.

**epidemic spread** (infectious spread) (of plasmids) An effect which occurs when a population of conjugal donor cells (see CONJUGATION sense 1b), carrying a plasmid that is repressed for transfer, is mixed with a population of recipient cells. Initially, a small proportion of the donor cells – becoming spontaneously DEREPRESSED for transfer – donate their plasmids to recipient cells (*low frequency transfer*; LFT). In each of these recipient cells, the newly acquired plasmid remains derepressed owing to the absence of repressor molecule(s); such a cell, and/or progeny derived from it, can transmit the plasmid to a fresh recipient. This effect is cumulative, resulting in the rapid (‘epidemic’) spread of the plasmid throughout the population (*high frequency transfer*; HFT). Cells in the HFT state gradually (over several generations) become repressed for transfer as the intracellular concentration of repressor molecule(s) builds up.

**epidemic tremor** *Syn.* AVIAN ENCEPHALOMYELITIS.

**epidemic vomiting disease** See FOOD POISONING (i).

**epidemiology** The study of the interrelationships between a given pathogen, the environment, and *groups* or *populations* of the relevant hosts; the object is to investigate the factors and mechanisms which govern the spread of disease within a community or population. Three main factors are involved. (a) The virulence of the pathogen. Since the observed virulence of a pathogen is related to host susceptibility (a variable) it is difficult to define virulence in absolute terms. (b) Herd immunity. This may be regarded as the *collective* immunity or resistance to a given disease exhibited by a community or population (human or animal) in the setting of its own environment. (Immunity in individual members of a population may result from e.g. VACCINATION or recovery from the disease.) An important feature of herd immunity is the ratio of *immunes* (individuals resistant to the disease) to *susceptibles* (those

## epidermin

able to contract the disease); a high proportion of immunes reduces the probability of contact between an infectious case and a susceptible, thus impeding the spread of disease. The proportion of susceptibles may often be drastically reduced by vaccination, and the risk to remaining susceptibles may be decreased by placing in quarantine any individuals who have contracted the disease; under such conditions CARRIERS (sense 1) may be important factors in the persistence of disease within the community. (c) Environmental conditions (extrinsic factors) play an important part in the containment or spread of disease. Particularly important are those features of society which favour or impede the transmissibility of the pathogen – e.g., standards of personal hygiene, overcrowding, the quality of communal WATER SUPPLIES, and the general state of sanitation (see e.g. SEWAGE TREATMENT); for a disease transmitted by a VECTOR, the prevalence of the vector and the measures taken to reduce its numbers are important factors. Because, in the present context, a population and its environment are inseparable, these extrinsic factors determine, in part, the observed herd immunity of a given population. The totality of factors which determines the transmissibility of disease and the distribution of immunes and susceptibles within a population has been termed the *herd structure* of that population.

An increase in the proportion of susceptibles in a population may lead from an ENDEMIC to an EPIDEMIC situation; an epidemic may also be initiated when a population immune to certain strains of a given pathogen is exposed to a different strain of that pathogen (see also ANTIGENIC DRIFT).

In a given outbreak of disease, the causal organism isolated from each patient may be examined by TYPING procedures in order to detect any variation which may help to establish the source(s) of infection and route(s) of transmission.

**epidermin** A 21-amino-acid, pore-forming LANTIBIOTIC secreted by *Staphylococcus epidermidis* and active against a range of Gram-positive bacteria.

**epidermodysplasia verruciformis (EV)** A rare, chronic, human skin disease involving the formation of flat, wart-like lesions on the face, neck, hands and feet, and sometimes also on the body. The lesions have a tendency to become malignant, ca. 30–50% of EV patients developing malignant squamous cell carcinoma; exposure to sunlight is believed to be a potentiating factor in the conversion to malignancy. The disease depends on genetic and immunological factors together with infection by certain human papilloma viruses (HPVs – see PAPILOMAVIRUS). Many HPVs have been detected in EV lesions, only some of which are specific to EV. HPV-5 DNA has been detected in EV carcinoma cells, and HPV-5 is believed to be involved in carcinogenesis; HPV-17 has also been implicated in EV carcinogenesis [Virol. (1985) 144 295–298].

**epidermolytic toxin (ET; exfoliative toxin; exfoliatin)** A protein toxin produced by strains of *Staphylococcus aureus* responsible for staphylococcal SCALDED SKIN SYNDROME (SSSS), and also e.g. by many of the strains which cause IMPETIGO. There are (at least) two serologically distinct ETs, variously designated ETA and ETB, TA and DI, type i and type ii, etc. ETA appears to be specified chromosomally, ETB is apparently plasmid-specified. ET-producing staphylococci may produce either or both types of toxin. Both toxins have the same histological effect: neither is cytolytic, but both cause separation of cells of the stratum granulosum from underlying tissue in the skin of only certain species (including humans, mice and monkeys, but not e.g. rats), resulting in a positive NIKOLSKY SIGN. ET apparently plays a role in the pathogenesis of SSSS, but its mechanism of action

is unknown; neither is it known why toxin-producing strains produce localized lesions (impetigo) in some individuals and extensive, spreading ‘scalding’ lesions in others. [Book ref. 44, pp. 599–617.]

**Epidermophyton** See DERMATOPHYTES.

**Epidinium** A genus of ciliates related to DIPLODINIUM.

**epifluorescence microscopy** See MICROSCOPY (e).

**epigean** Occurring on the surface of the ground (cf. HYPOGEAN).

**epiglottitis** Inflammation of the epiglottis. Acute epiglottitis is a life-threatening condition caused primarily by *Haemophilus influenzae*; it occurs mainly in small children. Fever and sore throat are followed rapidly by inspiratory stridor and dysphagia; the epiglottis becomes oedematous and cherry-red, and may cause complete respiratory obstruction.

**epilimnion** The surface layer of a lake which, due to thermal effects and wind, is well-mixed and aerobic and approximately uniform in temperature. (cf. METALIMNION.)

**epilithic** Growing on the surface of rock or stone etc. (cf. SAXICOLOUS.)

**epilithon** The community of sessile organisms which grow on the surfaces of underwater stones. [Composition of epilithon: Oikos (1984) 42 10–22.]

**epimastigote** A form assumed by the cells of species of *Blas-tocitridia*, *Endotrypanum* and *Trypanosoma* during at least certain stages of their life cycles: see TRYPANOSOMATIDAE.

**epimerite** In cephalineregarines: a differentiated region of the PROTOMERITE, delineated by a septum, by means of which the developing parasite remains attached to the host cell (cf. MUCRON).

**epimicroscopy** See MICROSCOPY (g).

**epinasty (plant pathol.)** The downward curvature of a plant structure (particularly a leaf petiole) due to the faster growth of the dorsal side of the structure relative to the ventral side. Epinasty can be induced e.g. by ETHYLENE, and is an early symptom in certain plant diseases.

**epinephrine** *Syn.* ADRENALIN (q.v.).

**epineuston** See NEUSTON.

**epipelic** Growing on mud.

**epiphloeodal (epiphloedal)** Growing on the surface of bark (cf. CORTICOLOUS).

**epiphragm** See CYATHUS.

**epiphyte** A plant or ‘plant-like’ organism (e.g. a lichen) which grows upon another plant but does not derive nutrients from it – i.e., an epiphyte is non-parasitic. (cf. ENDOPHYTE.)

**epiphytotic** See EPIDEMIC.

**epiplan objective** A FLAT-FIELD OBJECTIVE LENS used for bright-field epimicroscopy (see MICROSCOPY (g)).

**epiplasm** (1) (*protozool.*) See PELLICLE. (2) (*mycol.*) That cytoplasm in an ASCUS which is not incorporated into ascospores.

**epidodophyllotoxins** See PODOPHYLLOTOXIN.

**epipolythiapiperazinediones** A group of fungal ANTIBIOTICS. Some (e.g. aranotin, GLIOTOXIN, hyalodendrins, sirodesmins) inhibit the replication of certain RNA viruses – apparently by binding to and inhibiting viral RNA-dependent RNA polymerase; however, they are too toxic for therapeutic use.

**episome** (1) A PLASMID which can exist either in an autonomous (extrachromosomal) state or integrated in the host cell’s chromosome.

(2) *Syn.* PLASMID.

**episporium** See EXOSPORIUM (sense 2).

**epistasis** The dominance of one (*epistatic*) allele over a *non-allelic (hypostatic)* allele. (cf. DOMINANCE.)

**Epistylis** See PERITRICHIA.

**epitheca** (1) See DINOFLAGELLATES. (2) See DIATOMS.

**epithecium** In the hymenium of some ascomycetes: a layer of prosenchymatous tissue which covers the surface of the layer of asci; it consists of the interwoven, branched tips of paraphyses. (cf. PSEUDOEPITHECIUM.)

**epithelioma papulosum** *Syn.* CARP POX.

**epitheliotropism** See TROPISM (sense 2).

**epithienamycins** CARBAPENEM antibiotics.

**epitope** *Syn.* antigenic DETERMINANT.

**epitunica** *Syn.* EXOSPORIUM (sense 2).

**epivalve** See DIATOMS.

**epixyloous** Growing on wood. (cf. CORTICOLOUS.)

**epizootic** See EPIDEMIC.

**epizootic haemorrhagic disease subgroup** See ORBIVIRUS.

**epizootic lymphangitis** (pseudoglanders; equine histoplasmosis; equine blastomycosis; African farcy) A chronic cutaneous and subcutaneous disease of horses and other equines, caused by *Histoplasma farciminosum* (cf. HISTOPLASMOSIS); it occurs in Asia, Africa and Mediterranean countries. Nodules and suppurating ulcers develop on the skin – commonly on the shoulders, neck and limbs – and spread along lymph vessels; associated lymph nodes become inflamed. Small yeast-like cells can be detected – either free or within macrophages – in the pus.

**EPR** See ELECTRON SPIN RESONANCE.

**EPS** Extracellular polysaccharide.

**epsilon chain** (*immunol.*) See HEAVY CHAIN.

**Epstein–Barr virus** (EBV) Human (gamma) herpesvirus 4, the prototype of the subfamily GAMMAHERPESVIRINAE (q.v.). [DNA sequence and expression of the type strain (B95-8) of Epstein–Barr virus: *Nature* (1984) 310 207–211.]

EBV is ubiquitous in human populations; it is transmitted horizontally, mainly via saliva (e.g. by kissing). (Large numbers of infectious virions can occur in saliva.) In developing countries, primary (i.e. initial) infection generally occurs in early childhood, and in almost all cases these infections are subclinical. In developed countries, primary infection generally does not occur until adolescence, and a significant proportion of infected individuals develop INFECTIOUS MONONUCLEOSIS. The reasons for the difference in impact of EBV in developing and developed countries are not known.

EBV infection results in a life-long carrier state in which the virus occurs in latent form within circulating B cells. In some individuals a productive infection results in virus shedding, thus permitting horizontal transmission of EBV.

Although the target cells of EBV were believed to be limited to B lymphocytes and epithelial cells, they are now known to include e.g. T lymphocytes, monocytes, macrophages and endothelial cells. This extended range of host cells may help to explain the fact that EBV is associated with a wide spectrum of diseases.

Infection of epithelial cells characteristically leads to viral replication and the release of infectious virions. By contrast, infection of B cells is usually followed by viral latency and the development of a permanent proliferative state in the B cells.

The B cell receptor for EBV is CD21. In cultured cells, a protein, EBV nuclear antigen-1 (EBNA-1), is detectable within several hours of viral infection. Subsequently, DNA synthesis occurs in the B cells – which then proliferate continually (i.e. so-called ‘immortalization’). In proliferating B cells, the viral genome exists within the cell nucleus in a circular, ‘plasmid’ form; EBNA-1 binds to oriP (in the viral origin of replication), such binding apparently being necessary to keep the plasmid

within the nucleus. EBNA-1 also appears to be required for replication of the plasmid form of EBV. (See also ZEBRA.)

The *ebna-1* gene is only one of nine or ten viral genes (out of ~80) which may be expressed during viral latency. The *ebna-2* gene is reported to be necessary for transactivation of *lmp-1* and *lmp-2* whose products (the latency membrane proteins 1 and 2) are incorporated into the B cell membrane.

The products of *ebna-2*, *ebna-3A* and *ebna-3C* may also be expressed at the cell surface.

In addition to proteins, latent EBV gives rise to two small polyadenylated RNA molecules called EBV-encoded RNAs (EBER-1 and EBER-2); these molecules are expressed at high levels, but their function is unknown. The EBERs have been used as targets for detection of EBV.

Certain genes in latent EBV are also involved in the transactivation of some of the B cell genes; these B cell genes encode e.g. ICAM-1 (see CD54), LFA-1 (see INTEGRINS) and LFA-3 (see IMMUNOGLOBULIN SUPERFAMILY). CD23, a B-cell-encoded activation-related marker, is also produced; this molecule is reported to act as an autocrine B-cell growth factor when shed from the cell surface.

In vivo, proliferating B cells (with cell-surface molecules of EBNA-2, EBNA-3A, EBNA-3C and LMP-1) are normally targeted by a subset of EBV-specific cytotoxic T cells; moreover, these virus-infected immortalized B cells are targets for NK (natural killer) cells, and are also susceptible to interferons. Thus, the number of proliferating B cells is normally controlled in immunocompetent individuals.

Cells containing latent EBV do not necessarily express all of the proteins referred to above; in some cases, however, all of these proteins (and others) may be expressed. In fact, several different types of EBV latency have been distinguished. In *type I latency* only EBNA-1 is produced. Cells which express only EBNA-1 are found e.g. in some gastric carcinomas; as these cells lack the targets for EBV-specific cytotoxic T cells (see above) they escape this form of immune control. In *type II latency* the cell expresses EBNA-1 and LMPs 1 and 2; this pattern is found e.g. in some T-cell lymphomas and in nasopharyngeal carcinoma. In *type III latency* the cell expresses the full complement of these proteins; this pattern is found e.g. in B cells from the acute phase of infectious mononucleosis. (EBERs appear to be expressed in all forms of latency.)

EBV-associated diseases include: BURKITT'S LYMPHOMA; HAIRY LEUKOPLAKIA; INFECTIOUS MONONUCLEOSIS; NASOPHARYNGEAL CARCINOMA; XLP SYNDROME, gastric carcinoma and diffuse polyclonal B-cell lymphomas. In both Burkitt's lymphoma and nasopharyngeal carcinoma, pathogenesis seems to depend on proliferation of host cells latently infected with EBV, whereas in hairy leukoplakia the main pathogenic mechanism appears to involve viral replication; in infectious mononucleosis, the immune response of the host appears to be a major factor in pathogenesis.

Diagnosis of EBV-associated diseases involves laboratory tests (see e.g. INFECTIOUS MONONUCLEOSIS) and clinical observation. Levels of positivity of anti-EBV antibodies have been well documented, so that serology may help to distinguish e.g. between a primary (initial) infection (or a previous infection) and reactivation – in the latter case higher levels of antibodies are formed against viral capsid antigen (VCA), early antigen (EA) and EBNA. The EBERs may be detected e.g. by in situ hybridization or by RNA-amplification techniques.

Treatments for various EBV-associated diseases include antivirals (such as ACYCLOVIR), immunosuppressants (e.g.

## *Epulopiscium fishelsoni*

cyclophosphamide), anti-B cell monoclonal antibodies and interferon-gamma (IFN- $\gamma$ ).

[Haematological associations of EBV: BCH (2000) 13 199–214.]

***Epulopiscium fishelsoni*** See BACTERIA.

**EPV** Entomopoxvirus: see ENTOMOPOXVIRINAE.

**equal density centrifugation** See CENTRIFUGATION.

**equid (alpha) herpesvirus 1** See ALPHAHERPESVIRINAE.

**equid herpesvirus 3** *Syn.* EQUINE COITAL EXANTHEMA VIRUS.

**equilibrium density gradient centrifugation** See CENTRIFUGATION.

**equilibrium zonal centrifugation** See CENTRIFUGATION.

**equine abortion virus** See ALPHAHERPESVIRINAE.

**equine arteritis virus** See ARTERIVIRUS.

**equine blastomycosis** *Syn.* EPIZOOTIC LYMPHANGITIS.

**equine coital exanthema** An acute, usually mild, usually venereally transmitted HORSE DISEASE caused by equid herpesvirus 3 (see ALPHAHERPESVIRINAE). Typically, vesicular or papular lesions develop on the external genitalia (sometimes also on the conjunctivae, lips or nasal mucosa); the lesions progress rapidly to pustules (which may ulcerate), and generally heal in ca. 2 weeks.

**equine diseases** See HORSE DISEASES.

**equine encephalosis subgroup** See ORBIVIRUS.

**equine herpesvirus 2** See GAMMAHERPESVIRINAE.

**equine histoplasmosis** *Syn.* EPIZOOTIC LYMPHANGITIS.

**equine infectious anaemia** *Syn.* SWAMP FEVER.

**equine monocytic ehrlichiosis** *Syn.* POTOMAC HORSE FEVER.

**equine phycomycosis** (hyphomycosis *destruens*; swamp cancer; bursattee; Florida horse leech) A tropical and subtropical HORSE DISEASE characterized by ulcerating, spreading, granulomatous lesions on the skin and mucous membranes; the lesions contain masses of yellow-grey necrotic tissue ('grains', 'leeches') which may calcify. The causal agent is '*Hyphomyces destruens*', a *Pythium* sp. In Australia, outbreaks are associated with grazing in areas of permanent standing water [TBMS (1983) 80 13–18]. Clinically similar conditions are caused e.g. by *Basidiobolus haptosporus* and by certain helminthic parasites. (See also ZYGOMYCOSIS.)

**equine protozoal myeloencephalitis** (equine protozoal myelitis) A HORSE DISEASE which affects young and old horses of both sexes; it occurs in certain areas of the USA. The symptoms are those typical of CNS involvement; they include stumbling and falling, sometimes with partial paralysis of the face and/or tongue, muscle atrophy, and lameness. The causal agent is believed to be a member of the coccidia (suborder EIMERIORINA) [IJP (1987) 17 615–620].

**equine rhinoviruses** See PICORNAVIRIDAE.

**equivalence** (*serol.*) *Syn.* OPTIMAL PROPORTIONS.

**ER** ENDOPLASMIC RETICULUM.

**Era protein** See CELL CYCLE (b).

**eradicator** (*plant pathol.*) Any chemical agent which eliminates particular pathogen(s) from diseased plants treated with that agent. (cf. PROTECTANT.)

**erb** An ONCOGENE originally identified as the transforming determinant in avian erythroblastosis virus (AEV: see AVIAN ACUTE LEUKAEMIA VIRUSES). In AEV, *v-erb* consists of two contiguous genes, *v-erb-A* and *v-erb-B*; the cellular homologues (*c-erb-A* and *c-erb-B*) are not linked in the chicken genome.

The cellular homologue of *v-erb-A* (*c-erb-A*) encodes the *thyroid hormone receptor*. This protein lacks tyrosine kinase activity and is apparently not tumorigenic on its own.

The cellular homologue of *v-erb-B* (*c-erb-B*) encodes a membrane protein that functions as the *epidermal growth factor*

*receptor* (EGF receptor); unlike the *v-erb-A* product, this protein does have tyrosine kinase activity.

The oncogenic activity of the virus appears to depend on more than one gene. Thus, the product with which the avian erythroblastosis virus transforms cells is apparently a fusion protein that includes the *erb-B* product.

***Eremothecium*** See METSCHNIKOWIACEAE; see also RIBOFLAVIN.

**erf gene** See BACTERIOPHAGE P22.

**ergine** See ERGOT ALKALOIDS.

**ergobasine** See ERGOT ALKALOIDS.

**ergochromes** (secalonic acids) Pigments present in ERGOT sclerotia and also produced e.g. by *Penicillium oxalicum*; they are mostly weakly acidic, yellow xanthone derivatives, and at least some (e.g. secalonic acid D) are MYCOTOXINS.

**ergocristine** See ERGOT ALKALOIDS.

**ergocryptine** See ERGOT ALKALOIDS.

**ergolines** *Syn.* ERGOT ALKALOIDS.

**ergometrine** See ERGOT ALKALOIDS.

**ergonovine** See ERGOT ALKALOIDS.

**ergopeptines** See ERGOT ALKALOIDS.

**ergosome** *Syn.* polyribosome: see PROTEIN SYNTHESIS.

**ergot** A CEREAL DISEASE, caused by *Claviceps purpurea* (see CLAVICEPS), which can affect e.g. rye, wheat, barley and oats; it affects only the flowering parts. The earliest infections in the year are initiated by ascospores; conidia initiate later infections. Elongated, hard, black sclerotia ('ergots') become conspicuous in the ripening ears. The sclerotia overwinter and give rise in the following year to stromata and ascospores. (See also ERGOT ALKALOIDS and ERGOTISM.)

**ergot alkaloids** (ergolines) Alkaloids obtained primarily from *Claviceps* spp; they are also produced by other fungi (e.g. *Aspergillus*, *Penicillium*, *Rhizopus* spp) and by certain plants. Natural ergot alkaloids stimulate smooth muscle, especially that of peripheral blood vessels (causing vasoconstriction) and of the pregnant uterus at term; certain hydrogenated derivatives have the reverse effect, causing vasodilation. Ergot alkaloids have several important clinical uses (cf. ERGOTISM).

There are two classes of ergot alkaloids: the clavine alkaloids and the lysergic acid derivatives; the clinically useful alkaloids belong to the latter class, and may be simple amides or cyclic tripeptide derivatives. The amides include e.g. *ergine* (lysergic acid amide) and *ergometrine* (also called *ergonovine* or *ergobasine*: lysergic acid L-2-propanolamide); ergometrine is used to control postpartum bleeding. Cyclic tripeptide derivatives (*ergopeptines*) include *ergotamine*, used (as ergotamine tartrate) in the treatment of migraine, and *ergotoxine* (a mixture containing *ergocristine*,  $\alpha$ -*ergocryptine* and *ergocornine*); hydrogenated derivatives of ergotoxine are used for the treatment of peripheral and cerebral vascular disorders and of essential hypertension. Synthetic derivatives of ergot alkaloids include e.g. the hallucinogen *lysergic acid diethylamide* (LSD).

Commercial production of ergot alkaloids originally involved extraction from sclerotia of *C. purpurea* in naturally infected rye; later, fields of rye were inoculated with selected strains of *C. purpurea*. Currently, many lysergic acid derivatives are obtained from *C. paspali* grown in submerged culture.

**ergotamine** See ERGOT ALKALOIDS.

**ergotism** (St Anthony's fire) A MYCOTOXICOSIS caused by the ingestion of ERGOT ALKALOIDS present e.g. in bread made from ergotized grain; outbreaks of ergotism have been responsible for numerous deaths in Europe – especially during the Middle Ages and the 18th century. Mild cases may involve a prickling

sensation in the skin, with numbness, fatigue, and e.g. diarrhoea and vomiting. Severe ergotism may take one of two forms, depending on the relative proportions of the ergot alkaloids ingested. The convulsive type is characterized by neurological symptoms, with spasms, epilepsy-like convulsions, and severe pain. In the gangrenous type the fingers and toes – or whole limbs – become blackened and gangrenous and are eventually lost. Severe cases are usually fatal, and in non-fatal cases complete recovery is rare. In animals, ergotism may result e.g. from grazing any of a wide range of fodder grasses infected with *Claviceps* spp. (See also PASPALUM STAGGERS.)

**ergotoxine** See ERGOT ALKALOIDS.

**ERIC-PCR** See REP-PCR.

**ERIC sequence** Enterobacterial repetitive intergenic consensus sequence (also called intergenic repeat unit): one of the repeated intergenic sequences of nucleotides in the genomic DNA of enteric and other bacteria; an ERIC sequence contains a highly conserved PALINDROMIC SEQUENCE. ERIC sequences are distinct from REP SEQUENCES (they do not share significant homology). [ERIC sequences: Mol. Microbiol. (1991) 5 825–834.] ERIC sequences have been exploited in typing [see e.g. JCM (1999) 37 103–109; JCM (1999) 37 2473–2478; JCM (1999) 37 2772–2776].

**ericoid mycorrhiza** See MYCORRHIZA.

**Erlenmeyer flask** A conical flask.

**error-prone repair** See SOS SYSTEM.

**ertapenem** A broad-spectrum 1- $\beta$ -methylCARBAPENEM antibiotic with a long serum half-life (up to 4.5 hours). [In vitro activity of ertapenem against a range of bacteria from clinical specimens: AAC (2001) 45 1860–1867.]

**erumpent** Bursting through.

**Erwinia** A genus of Gram-negative bacteria of the ENTEROBACTERIACEAE (q.v.). Cells: 0.5–1.0  $\times$  1–3  $\mu$ m, motile (except *E. stewartii*). Growth occurs e.g. on nutrient agar or YGC AGAR; optimum temperature: 27–30°C. Acid (little or no gas) is produced from glucose, fructose, galactose, sucrose, and  $\beta$ -methylglucoside. GC%: 50–58. Type species: *E. amylovora*.

*Erwinia* spp typically occur as saprotrophs or pathogens in or on plants; some may also occur in insects, and certain strains are opportunist pathogens in man and animals.

The genus is commonly divided into three groups. The *Amylovora* group includes species (e.g. *E. amylovora*) which require organic nitrogen for growth and cause dry-necrotic or VASCULAR WILT diseases in plants. The *Carotovora* group (sometimes regarded as a separate genus, *Pectobacterium*) includes strongly pectinolytic species (e.g. *E. carotovora*) which reduce nitrate to nitrite and cause SOFT ROT (sense 2) in a variety of plants. The *Herbicola* group includes species (e.g. *E. herbicola*) which typically form yellow (carotenoid) pigments and are not normally primary pathogens.

*E. amylovora*. Non-pectinolytic. Causes FIREBLIGHT. Colonies on sucrose nutrient agar are mucoid (due to levan production). Anaerobic growth is weak. *E. amylovora* transfers virulence proteins into target cells by means of a type III PROTEIN SECRETION system; it has been shown that secreted proteins are guided along the Hrp pilus assembly that forms between the pathogen and the eukaryotic target cell [Mol. Microbiol. (2001) 40 1129–1139].

*E. carotovora*. Pectinolytic. Subspecies *atroseptica* causes BLACKLEG (sense 2) of potato plants and storage rot of potato tubers. Subspecies *carotovora* causes SOFT ROT (sense 2) in a wide range of plants. Subspecies *betavasculorum* causes soft rot of sugar-beet.

*E. chrysanthemi*. Pectinolytic. Causes vascular wilts in a wide range of plants. Some strains produce a blue bipyridyl pigment, indigoidine, on YGC agar.

*E. herbicola*. Common as saprotrophs on the surfaces of land plants; some strains can fix nitrogen. May act as secondary invaders in plant lesions. (See also HERBICOLIN A.) Some strains can cause GALL formation. Certain strains are opportunist parasites or pathogens in man and animals; such strains are regarded by clinical microbiologists as *Enterobacter agglomerans*. [Attempted classification of strains of the *Herbicola*-*Agglomerans* group: IJSB (1984) 34 45–55.]

*E. nigrifluens*. Causes bark necrosis of Persian walnut (*Juglans regia*).

*E. rhapontici*. Causes e.g. crown rot of rhubarb (*Rheum rhaponticum*) and pink grain of wheat; it can also grow saprotrophically in plant lesions. A pink diffusible pigment is formed on sucrose–peptone agar.

*E. rubrifaciens*. Pectinolytic. Causes phloem necrosis (bark canker) of Persian walnut (*Juglans regia*). A pink pigment is produced on YGC agar.

*E. salicis*. Pectinolytic. Causes WATERMARK DISEASE in willows (*Salix* spp). Produces yellow pigment on autoclaved potato tissue.

*E. stewartii*. Non-motile. Causes vascular wilt of e.g. maize (*Zea mays*); overwinters primarily in the flea beetle *Chaetocnema pulicaria*.

*E. tracheiphila*. Causes vascular wilt in *Cucurbita* spp; overwinters in cucumber beetles (*Diabrotica* spp).

*E. uredovora*. A parasite of the uredia and uredospores of *Puccinia graminis*. Produces yellow pigment on nutrient agar.

Other recognized species: *E. ananas* (causes pineapple rot), *E. cypripedii*, *E. mallotivora*, *E. quercina*.

[Taxonomy: Book ref. 22, pp. 469–476. Habitats, culture etc: Book ref. 46, pp. 1260–1271.]

See also COFFEE; PECTIC ENZYMES.

**Erynia** A genus of fungi (order ENTOMOPHTHORALES) which include parasites of insects; *E. neophidis* is a pathogen of aphids. [Persistence of infectious spores of *E. neophidis*: Ann. Appl. Biol. (1985) 107 365–376.]

**erysipelas** Typically, well-demarcated lesions of erythema – often affecting the face, although other areas may be involved; fever, prostration and sepsis may occur. The causal agent is usually a strain of *Streptococcus pyogenes*, and infection generally occurs via wounds or abrasions.

(cf. ERYSIPELOID; SWINE ERYSIPELAS.)

**erysipeloid** A disease involving localized inflammation or CELLULITIS of skin (usually on the fingers and hands); it is caused by *Erysipelothrix rhusiopathiae* and is contracted mainly by handlers of fish and meat products. Infection occurs via wounds etc. Rarely, septicaemia or endocarditis may occur.

**Erysipelothrix** A genus of Gram-positive, asporogenous, non-motile bacteria; sole species (type species): *E. rhusiopathiae* (formerly *E. insidiosa*). Cells may be slightly curved, rounded rods (ca. 0.2–0.4  $\times$  0.8–2.0  $\mu$ m) which form smooth, (initially) transparent colonies (S-form), or occur mainly as filaments (up to 60  $\mu$ m long) which form rough, opaque colonies (R-form). S-forms show a strong tendency to become R-forms. (See also PEPTIDOGLYCAN.) The organism is microaerophilic (facultatively aerobic or anaerobic). Growth occurs at 15–42°C (optimum 37°C). Indole –ve; catalase –ve; urease –ve; VP –ve; MR –ve; H<sub>2</sub>S +ve; aesculin not hydrolysed. In gelatin stab cultures S-forms produce a typical ‘pipe-cleaner’ (becoming a ‘test-tube brush’) form of growth, with little or no gelatin liquefaction. GC%: 38–40.

## Erysiphaceae

*E. rhusiopathiae* is parasitic in man, animals, birds and fish, and can be found e.g. in animal faeces, abattoir effluents etc. Some strains are pathogenic (see e.g. ERYSIPELOID, JOINT-ILL, SWINE ERYSIPELAS). The organism is resistant e.g. to salting, pickling, smoking, and low concentrations of phenol; in dried form (e.g. in fish-meal, soil) it can remain viable for years.

[Book ref. 46, pp. 1688–1700.]

**Erysiphaceae** See ERYSIPIHALES.

**Erysiphales** An order of homothallic and heterothallic plant-parasitic fungi of the subdivision ASCOMYCOTINA (see also POWDERY MILDEWS); all species are placed in the family Erysiphaceae. The organisms form at least partially superficial, septate mycelium which is typically colourless and which commonly exhibits numerous haustoria. (*Dark* mycelium is formed e.g. by *Sphaerotheca lanestris*; cf. BLACK MILDEWS.) Ascocarp (ca. 50–350 µm diam.): cleistothecioïd with hamathecium lacking, often dark and rounded, and often with surface appendages; uniascal or containing a small number of asci. Asci: bitunicate, clavate or pyriform. Ascospores: aseptate, ellipsoidal, colourless. Anamorphs occur e.g. in the genera *Oidiopsis*, *Oidium* and *Ovulariopsis*; conidia are often formed in abundance, basipetally, on straight, unbranched conidiophores. Genera: e.g. *Cystotheca*, ERYSIPIHE, *Leveillula*, *Microsphaera*, *Phyllactinia*, *Podosphaera*, *Sphaerotheca*, *Uncinula*.

[Book ref. 187.]

**Erysiphe** A genus of homothallic and heterothallic fungi (order ERYSIPIHALES) which include parasites and pathogens of grasses and other plants (e.g. *E. betae* on beet crops, *E. graminis* on cereals). *Erysiphe* spp form superficial mycelium on host plants; most species form globose haustoria, but those of *E. graminis* are digitate (see also TRIFORINE). The organisms give rise to dark-coloured cleistothecia. The cleistothecial surface appendages (when present) are hypha-like, not dichotomously branched or terminally coiled; each cleistothecium contains more than one ascus. The ovoid to elongated conidia of *E. graminis* and *E. polygoni* are highly vacuolated; the conidiophores of *E. graminis* are distinctive in that in each the basal cell is slightly swollen. Conidia germinate by a germ tube which forms an appressorium.

**erythema** Redness of the skin due e.g. to INFLAMMATION or infection.

**erythema infectiosum** (fifth disease; slapped cheek syndrome) A benign, infectious disease, affecting mainly children, characterized by exanthem which begins on the face and gives a 'slapped cheek' appearance. The causal agent is parvovirus B19. (cf. EXANTHEM SUBITUM.)

**erythema nodosum leprosum** See LEPROSY.

**erythrasma** A chronic skin infection caused by *Corynebacterium minutissimum*. The reddish-brown lesions occur in the groin and armpits and fluoresce coral-pink under Wood's lamp.

**erythritol** The POLYOL corresponding to erythrose. It occurs e.g. in certain fungi, particularly in the Ustilaginales and Agaricales (where it apparently functions as a storage carbohydrate), and as a major photosynthetic product in certain unicellular and filamentous green algae (e.g. *Phycopeltis*, *Trentepohlia*). It can be metabolized e.g. by many yeasts.

**Erythrobacter** A genus of Gram-negative, aerobic, halophilic, ovoid to rod-shaped, orange- or pink-pigmented bacteria which are motile by subpolar flagella. The cells contain bacteriochlorophyll *a* which is synthesized only under aerobic conditions (cf. RHODOSPIRILLALES). Metabolism appears to be chemoorganotrophic (mainly respiratory); autotrophic growth does not occur. Strains have been isolated from seaweeds growing near high-tide

levels (e.g. *Enteromorpha*, *Porphyra*). Type species: *E. longus*. [IJSB (1982) 32 211–217.]

**erythroblastosis** The presence of erythroblasts (nucleated precursors of erythrocytes) in the blood.

**erythrocyte** A red blood cell.

**erythroimmunoassay** (EIA) A sensitive IMMUNOASSAY for detecting and quantifying specific antigens or antibodies. For the detection of antibodies, the inner surface of a well (or tube) is coated with homologous antigen, and the patient's serum – pre-absorbed with sheep erythrocytes (see ABSORPTION) – is added to the well; a hybrid antibody conjugate (see CONJUGATION sense 2) is then added – each hybrid antibody having combining sites for both human immunoglobulins and sheep erythrocytes. Hybrid antibodies bind to any antigen-antibody complexes on the surface of the well, and the presence of bound hybrid antibodies is detected by the addition of sheep erythrocytes. [SAB (1984) 22 73–78.]

**erythromycin** A MACROLIDE ANTIBIOTIC (q.v. for mode of action etc.); it is produced by *Streptomyces erythreus*. (In some strains of group A streptococci, resistance to erythromycin has been associated with the ability to invade, and survive within, epithelial cells of the human respiratory tract [Lancet (2001) 358 30–33].) (See also POLYKETIDE.)

**erythrose** An aldotetrose; erythrose 4-phosphate is an important intermediate e.g. in the CALVIN CYCLE and HEXOSE MONOPHOSPHATE PATHWAY, and is a precursor for the synthesis of aromatic amino acids [Appendix IV(f)].

**Erythrovirus** A genus of autonomous viruses (family PARVOVIRIDAE) which infect primates. The genus was originally created for the only parvovirus known to be pathogenic for man, i.e. parvovirus B19; some authors also include the *simian parvovirus* [Viro. (1995) 210 314–322]. The following details refer to B19 parvovirus. (B19 was formerly referred to as 'human parvovirus' (abbreviated to HPV), but this terminology has been abandoned owing to confusion with human papillomavirus. The designation 'B19' derives from the laboratory number of the sample in which the virus was first detected.)

The B19 virion is 22–26 nm, icosahedral, and contains a single copy of the linear, ssDNA genome (~5.5 kb); identical PALINDROMIC SEQUENCES (383 nt) occur at the two ends of the genome. In a given population of B19 virions, some capsids enclose a negative-sense strand while others enclose a positive-sense strand. B19 virions are stable at 56°C/60 minutes, and (in high concentration) are reported to be stable at 80°C/72 hours; lacking an envelope, they are insensitive to lipid solvents. The virions can be inactivated by e.g. oxidizing agents, formalin and γ-radiation.

For viral DNA replication see entry PARVOVIRUS.

Transcription of the genome yields a number of overlapping RNA transcripts, all of which originate from a single, strong promoter, P6; the function of some of the encoded products is unknown.

Proteins encoded by the genome include capsid proteins VP1 and (the smaller) VP2; VP2 is the major capsid protein, accounting for >95% of the capsid. (Recombinant VP2 proteins self-assemble into capsids within various mammalian and insect cell lines.)

The major non-structural protein, NS1, can be detected in the nucleus of infected cells; it may be associated with the cytotoxicity of B19. One hypothesis supposes that NS1 acts as a positive regulator of viral DNA replication during the early stage of infection and that, subsequently, high concentrations of NS1 bring about cell death and lysis.

B19 has been cultured in the erythroid cells from human bone marrow and fetal liver; *in vitro* propagation of the virus depends on the presence of the hormone erythropoietin (which is specific to erythroid cells). The cell-surface receptor for B19 is the red cell P antigen (*globoside* – a tetrahexose ceramide), the virus binding with high affinity to the carbohydrate moiety. P antigen is expressed e.g. on erythroid progenitors, mature red cells, megakaryocytes, endothelial cells and heart cells. (Individuals with the rare *p phenotype*, who do not express P antigen, are not susceptible to B19.)

Viral replication is dependent on mitotically active cells, the virus being highly tropic for human erythroid cells in the late S phase of the cell cycle.

B19 DNA can be demonstrated in the nasal secretions of individuals with B19 viraemia, and the respiratory route is believed to be important in virus transmission. Infection can also be transmitted via blood and blood products.

Clinical manifestations of infection appear to depend primarily on host factors such as immunocompetence. In immunocompetent persons with a normal erythroid turnover, infection may lead to a short-term (~4–8 days) halt in red cell production without development of anaemia. However, given a high turnover of red cells, even a temporary loss of red cell production may bring about an *aplastic crisis*. In immunocompromised patients infection may lead to chronic anaemia. In the fetus, infection may result e.g. in HYDROPS FETALIS. Other manifestations of B19 infection include arthralgia and rash. (See also ERYTHEMA INFECTIOSUM.)

Among adults, seroprevalence of B19 IgG antibody is high, and the proportion of seropositives increases with age; IgG antibody develops within ~2 weeks of infection and persists for life.

[Persistent B19 infection: RMM (1995) 6 246–256. Molecular epidemiology of parvovirus B19: RMM (1997) 8 21–31. Haematological consequences of parvovirus B19 infection: BCH (2000) 13 245–259.]

#### ES1–ES21 proteins See RIBOSOME.

**ESAT-6** A 6 kDa secreted protein (early secreted antigenic target) encoded by *Mycobacterium tuberculosis* and by *M. bovis* and *M. africanum* (members of the '*M. tuberculosis* complex') but apparently not encoded by any of the (vaccine) strains of *M. bovis* BCG. (The operon encoding ESAT-6 is also reported to encode a novel, low-molecular-weight protein which has been designated CFP-10 [Microbiology (1998) 144 3195–3203].)

Yet another secreted protein, MPT64, appears to be encoded by all strains of *M. tuberculosis* and BCG Tokyo but not by strains of BCG Danish 1331 [BCID (1997) 4 157–172 (167–168)].

Antigens such as ESAT-6 may be useful e.g. in SKIN TESTS for distinguishing between sensitization due to (i) tubercle bacilli, (ii) vaccination strains of BCG, or (iii) 'environmental' mycobacteria (cf. TUBERCULIN TEST).

A test using ESAT-6 has been compared with a PPD-based test for the diagnosis of bovine tuberculosis; ESAT-6 was associated with a lower sensitivity but with increased specificity – useful e.g. for testing in areas which have a low incidence of tuberculosis [VR (2000) 146 659–665].

The specificity of ESAT-6 for the *M. tuberculosis* complex has been exploited (by means of an *ex-vivo* ELISPOT ASSAY) for the enhanced tracing of contacts in epidemiological studies on human tuberculosis [Lancet (2001) 357 2017–2021].

#### ESBLs Extended-spectrum $\beta$ -LACTAMASES.

**esc genes** See PATHOGENICITY ISLAND.

**eschar** Dead tissue which separates (sloughs) from the underlying living tissue. An eschar is formed e.g. in SCRUB TYPHUS.

**Escherichia** A genus of Gram-negative bacteria of the family ENTEROBACTERIACEAE (q.v. for general features); in molecular taxonomy, *Escherichia* is placed in the gamma group of the Proteobacteria. GC% ~50. Type species: *E. coli*.

*E. coli* has long been the principal 'guinea pig' of the microbiologist, and has been studied more extensively than any other species. (Nevertheless, *E. coli* should not be regarded as 'the typical bacterium'; the great diversity of bacteria makes such a concept meaningless.) The following refers specifically to *E. coli* (other species are mentioned at the end of the entry).

Cells are typically straight, round-ended rods, ca. 0.5–0.8  $\times$  1–4  $\mu$ m, normally occurring singly or in pairs; they stain well with ANILINE DYES.

The cell has a typical Gram-negative-type CELL WALL consisting of an OUTER MEMBRANE and a layer of PEPTIDOGLYCAN. The CYTOPLASMIC MEMBRANE contains e.g. various TRANSPORT SYSTEMS, energy-converting systems and chemosensors as well as components of osmoregulatory systems (see OSMOREGULATION); the latter include MECHANOSENSITIVE CHANNELS [mechanosensitive channels in *E. coli*: ARP (1997) 59 633–657], *aquaporins* and *glycerol facilitators* (see MIP CHANNELS).

Cells are typically motile (peritrichously flagellate) [second flagellar system in *E. coli*. JB (2005) 187 1430–1440]. FIMBRIAE are usually present. Type I fimbriae (the most common type) may be suppressed by P FIMBRIAE (q.v.).

Some cells have a CAPSULE or microcapsule (see e.g. COLANIC ACID, COLOMINIC ACID; cf. TEICHOIC ACIDS).

Numerous strains of *E. coli* are distinguished serologically (on the basis of their O ANTIGENS, H ANTIGENS and K ANTIGENS), or by PHAGE TYPING, colicin typing, antibiotic-resistance patterns etc.

*E. coli* exhibits CHEMOTAXIS; the Tsr protein (an MCP in chemotaxis) may also function as a pmf-dependent sensor in aerotaxis [PNAS (1997) 94 10541–10546]. [Ecological role of energy taxis: FEMS REVIEWS (2004) 28 113–126.]

The chromosome (cccDNA) is about 4.7 million base-pairs in length. [Complete sequence: Science (1997) 277 1453–1474.] Replication occurs by the Cairns-type mechanism (bidirectionally from the origin, *oriC*). [Localization of chromosomal segments during the cell cycle: GD (2000) 14 212–223.] There are several systems for DNA REPAIR. (See also SOS SYSTEM.)

Many of the genes occur within OPERONS which may encode e.g. metabolic enzymes and/or components of TRANSPORT SYSTEMS (e.g. LAC OPERON).

TRANSCRIPTION of most genes involves the SIGMA FACTOR  $\sigma^{70}$ ; other sigma factors include  $\sigma^{32}$  (see HEAT-SHOCK PROTEINS). A proportion of mRNA transcripts are polyadenylated at the 3' end [characterization of the *E. coli* poly(A)polymerase: NAR (2000) 28 1139–1144].

Gene transfer can occur *in vivo* by CONJUGATION or TRANSDUCTION. Competence in TRANSFORMATION can be induced in the laboratory in ice-cold solutions of calcium chloride [possible mechanism: JB (1995) 177 486–490]. High-efficiency transformation can be achieved by ELECTROPORATION [NAR (1999) 27 910–911].

Metabolism is respiratory under aerobic conditions (see RESPIRATION). FERMENTATION (sense 1) or ANAEROBIC RESPIRATION occurs anaerobically. Glucose, mannitol and various other substrates are taken up by the PTS (q.v.). Lactose is taken up by proton–lactose symport, and melibiose by Na<sup>+</sup>/melibiose symport (see SODIUM MOTIVE FORCE). Glucose is fermented (usually aerogenically) by a MIXED ACID FERMENTATION (cf. ALKALESCENS-DISPAR GROUP).

## *escN* gene

Sulphur requirements may be obtained from sulphate; sulphate is reduced, intracellularly, to sulphide – which is incorporated into *O*-acetylserine, forming cysteine. Nitrogen may be taken up as ammonia (see AMMONIA ASSIMILATION).

Typical results of 'biochemical' tests: MR +ve; VP –ve; indole +ve; citrate –ve; lactose +ve; malonate –ve; urease –ve; LDC +ve; hydrogen sulphide (on TSI) –ve; no growth with KCN; gelatin hydrolysis –ve.

Some strains give atypical reactions which, in at least some cases, are plasmid-mediated; for example: citrate utilization (Cit plasmid), hydrogen sulphide production (Hys plasmid [FEMS (1983) 20 7–11]), HAEMOLYSIN production (Hly plasmid, often associated with Ent and K88 plasmids in ETEC strains), urease production etc.

Growth occurs on a range of media (e.g. NUTRIENT AGAR, EMB AGAR, MACCONKEY'S AGAR) but (usually) not on e.g. DCA. The optimum growth temperature is 37°C, and the minimum doubling time is ~20 minutes. Colonies of *E. coli* on nutrient agar (37°C/24 hours) are 1–3 mm in diameter and may be smooth, entire, low-convex, greyish-translucent, butyrous and easily emulsifiable – or rough, dry, and not easily emulsifiable (see SMOOTH–ROUGH VARIATION). Mucoid and slime-forming strains also occur. Identification can be aided by the MUG TEST.

Strains of *E. coli* have various modes of PROTEIN SECRETION (q.v.).

*E. coli* and its components (e.g. RESTRICTION ENDONUCLEASES) are widely used in biotechnology (see e.g. OVERPRODUCTION).

*E. coli* is a member of the GASTROINTESTINAL TRACT FLORA in man and animals, and may occur in soil and water as a result of faecal contamination. (It is often regarded as an INDICATOR ORGANISM for faecal pollution.)

Pathogenic strains of *E. coli* include EAGGEC, EIEC, EPEC, ETEC and UPEC (for *E. coli* O157:H7 see EHEC). (See also COLIBACILLOSIS; COLISEPTICAEMIA; CYSTITIS; HAEMOLYTIC URAEMIC SYNDROME; HJÄRRE'S DISEASE; MENINGITIS; OEDEMA DISEASE; OSTEOMYELITIS; PNEUMONIA; URINARY TRACT INFECTION.)

[PCR-based detection of *E. coli* O157: JCM (1998) 36 1801–1804.]

[Target genes for virulence assessment of *Escherichia coli* isolates from food, water and the environment: FEMS Reviews (2000) 24 107–117.]

Other species within the genus. *E. blattae* is an apparently harmless commensal in the hindgut of the cockroach (*Blatta orientalis*). Test reactions: indole –ve; malonate +ve; lactose –ve.

Other proposed species include *E. fergusonii* [JCM (1985) 21 77–81], *E. hermanii* [JCM (1982) 15 703–713] and *E. vulneris* [JCM (1982) 15 1133–1140].

*escN* gene See PATHOGENICITY ISLAND.

esculin *Syn.* AESCULIN.

E $\sigma$  An RNA POLYMERASE holoenzyme.

*espA* gene See PATHOGENICITY ISLAND.

*espB* gene See PATHOGENICITY ISLAND.

EspB protein See PROTEIN SECRETION (type III systems).

*espE* gene See PATHOGENICITY ISLAND.

EspE protein See PROTEIN SECRETION (type III systems).

espundia See MUCOCUTANEOUS LEISHMANIASIS.

ESR ELECTRON SPIN RESONANCE.

*estA* gene See ETEC.

established cell line (continuous cell line) A population of cells – derived either from a tumour, or from a TISSUE CULTURE following transformation – which appears to be capable of unlimited in vitro propagation. See e.g. BHK-21, BS-C-1, DETROIT-6, HELA, HEP-2, VERO AND WISH.

*estB* gene See ETEC.

ET EPIDERMOLYTIC TOXIN.

$\eta$ -value (of a disinfectant) See DILUTION COEFFICIENT.

etamycin *Syn.* VIRIDOGREISEIN.

etanercept See TNF.

ETC ELECTRON TRANSPORT CHAIN.

ETEC Enterotoxigenic *Escherichia coli*: strains of *E. coli* which adhere to the small intestine in man and/or animals and form 'heat-labile' ENTEROTOXIN (LT-I/LT-II: inactivated at ~60°C/30 min) and/or 'heat-stable' enterotoxin (ST-I/ST-II: not inactivated at 100°C/30 min). Strains of ETEC cause mild to severe (cholera-like) diarrhoea in humans of all ages and/or similar disease in animals. (See also COLIBACILLOSIS and FOOD POISONING; cf. EAGGEC, EIEC, EHEC and EPEC.)

The ability to adhere to (i.e. colonize) the small intestine – crucial for virulence – involves various plasmid-encoded FIMBRIAE. Strains from humans have non-fimbrial and fimbrial colonization factors, e.g. CS6 and 'colonization factor antigens' CFAI (F2) and CFADII (F3); CFADII has three components: CS1, CS2 and CS3 (CS = 'coli surface'). Strains of ETEC from animals have e.g. K88 or K99 FIMBRIAE (see also F6 FIMBRIAE). [Fimbriae of human strains of ETEC and their possible use in vaccines: RMM (1996) 7 165–177.]

LT-I closely resembles the CHOLERA TOXIN in structure: both toxins have the AB<sub>5</sub> arrangement of subunits (found also e.g. in SHIGA TOXIN), and there is an ~80% homology in amino acids. LT-I and CT cross-react antigenically, and they also have similar binding sites and a common mode of action; however, for unknown reasons, disease produced by LT-I is generally less severe, and of shorter duration, than that due to CT.

LT-II occurs e.g. in pigs, rarely in humans. The A subunit is <60% homologous to that of LT-I, and the B subunits are essentially non-homologous (so that the binding site differs); the basic mode of action is similar to that of LT-I [MR (1996) 60 167–215 (pp 191, 192)].

Genes encoding the LT toxins are carried on 'Ent plasmids'.

ST-I (= STa) is a (methanol-soluble) peptide containing 18 or 19 amino acids produced from a 72-amino-acid precursor; following cleavage, three disulphide bonds are catalysed in the peptide by the protein DsbA prior to secretion. ST-I binds to receptors in the brush border membrane; the receptors have guanylate cyclase activity, and binding by ST-I activates the cyclase – leading to increased levels of intracellular cyclic GMP that apparently stimulate secretion of chloride and/or inhibit the absorption of NaCl. The net result is believed to be secretion of fluid into the gut. An alternative view of the mode of action of this toxin involves interruption of the luminal acidification mechanism (apparently through inhibition of the Na<sup>+</sup>/H<sup>+</sup> exchanger in the brush border membrane) leading to a reduction in the absorption of fluid [JAM (2001) 90 7–26]. Interestingly, the receptor sites for ST-I are the same as those used by *guanylin* – an endocrine hormone (a peptide of 15 amino acid residues) whose normal function apparently involves regulation of NaCl and water homeostasis in the gut. (The number of receptor sites has been reported to decrease with age – infants having a large number of receptors; this may give a reason for the increased severity of diarrhoea in infants and young children with ST-I infection.) [MR (1996) 60 167–215 (pp 190, 191); MP (1998) 24 123–131.]

ST-II (STb) is a (methanol-insoluble, trypsin-sensitive) polypeptide containing 48 amino acid residues (derived from a precursor of 71 amino acid residues). The toxin does not cause secretion in the small intestine of mice or rats owing to its

inactivation by trypsin. It is apparently without effect on human intestine under in vitro (USSING CHAMBER) conditions; strains secreting ST-II are infrequently involved in human disease. The mode of action is unknown but apparently does not involve cyclic nucleotides (i.e. the mode of action differs from that of ST-I). [ST-II: Microbiology (1997) 143 1783–1795.]

ST-I is encoded by *estA* – a plasmid-borne gene located within a transposon (Tn1681). ST-II is encoded by the plasmid-borne gene *estB*.

[Heat-stable enterotoxin associated with resistance to colon cancer: PNAS (2003) 100 2695–2699.]

ETEC strains commonly belong to serogroups O6, O8, O15, O25, O27, O63, O78, O115, O148, O153 and O159.

**ethambutol** (Myambutol) A synthetic drug, *d*-(2,2'-(ethylene diimino)-di-1-butanol), used (e.g. in combination with ISONIAZID) in the treatment of TUBERCULOSIS; it inhibits growing cells of *Mycobacterium tuberculosis* and *M. bovis*. Major adverse effects include optic neuritis and a loss of the ability to discriminate red/green (particularly in patients on a high-dose regimen) [BCID (1997) 4 53–54].

**ethanol** (as an antimicrobial agent) See ALCOHOLS.

**ethanol fermentation** See ALCOHOLIC FERMENTATION and INDUSTRIAL ALCOHOL.

**ethazole** (5-ethoxy-3-trichloromethyl-1,2,4-thiadiazole) An agricultural systemic ANTIFUNGAL AGENT used e.g. as a seed dressing for protection against *Pythium*, *Phytophthora* and *Rhizoctonia*.

**ethidium bromide** (2,7-diamino-10-ethyl-9-phenylphenanthridinium bromide) A trypanocidal, bacteriostatic dye. It is an INTERCALATING AGENT ( $\phi = 26^\circ$ ) which inhibits transcription and DNA replication; it binds specifically to dsDNA (or to base-paired regions of ssDNA) with no apparent preference for particular base sequences. In eukaryotes it is highly selective for mtDNA and kinetoplast DNA. Ethidium bromide can induce nuclease attack and (non-enzymic) photochemical nicking of DNA.

Owing to their limited capacity to unwind, small cccDNA molecules can bind less ethidium bromide than can equivalent linear or nicked DNAs, and hence show a smaller reduction in density in the presence of ethidium bromide; this is exploited in methods for separating ccc from linear/nicked DNA by isopycnic ultracentrifugation.

**ethirimol** (5-*n*-butyl-2-ethylamino-4-hydroxy-6-methylpyrimidine; trade names: e.g. Milstem, Milgo) A HYDROXYPYRIMIDINE ANTIFUNGAL AGENT which is used as a seed dressing and as a foliar spray for the control of powdery mildews in cereals; it also controls powdery mildew in e.g. sugar beet.

**ethyl stibamine** See ANTIMONY.
