```

```
species occur sparingly within modern reefs of Enewetak (formerly
Eniwetok) Atoll in the central Pacific Ocean. Ranging over 4-35m
depths, the sclerosponges occupy both the outer reef wall and lagoonal
coral knolls at Enewetak. The species encountered are described as seen
in standard paleontologic preparations; these forms can thus be readily
compared with various important fossil groups. The sclerosponge
Acanthochaetetes wellsi is of finely tubular construction, the
sclerosponge Astrosclera willeyana is densely labyrinthine, the celetia
crypta consists of successively stacked hemispherical shells. [original

Hexactinellid Sponge Reefs on the Canadian Continental Shelf: A Unique
&#034;Living Fossil&#034;.- Geoscience Canada 28, 2: 71-78.-
<b>FC&#038;P 30-2</b>, p. 34, ID=1602^<b>Topic(s): </b>reefs, ecology;
Porifera reefs; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Canada^Globally unique hexactinellid
(siliceous) sponge reefs, found in deep (200m), glacially scoured
troughs of the western Canadian continental shelf, have been explored
by a manned submersible. Submersible observation and geophysical data
allow examination of the physical and biological processes that have
shaped the sponge reefs, which began to form about 9 thousand years
(k.y.) ago. The mounds (bioherms) and sheet-like accumulations
(biostromes) cover a low-angle, non-depositional, iceberg-scoured
seafloor, relict since the deglaciation of the region. Biohermal
structures are up to 19 m in height, and are covered with hexactinosan
sponges up to 1.5 m tall, creating a benthic habitat that
discontinously covers roughly 700 km2. Similar to extinct siliceous
sponge reefs, mud mounds, and reef mounds that were widespread during
the Mesozoic, the modern reefs are like a &#34;living fossil&#34; and
provide a unique modern analogue. Fishing activities, especially
trawling or bottom dragging, have damaged the slow-growing reefs in
some areas.^1";

Discovery of a &#034;Living Dinosaur&#034;: Globally Unique Modern
Hexactinellid Sponge Reefs off British Columbia, Canada.- Facies 44, 1:
265-282.- <b>FC&#038;P 30-2</b>, p. 36, ID=1604^<b>Topic(s): </b>reefs;
Porifera reefs; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Canada W^Globally unique hexactinellid
sponge reefs occur on the continental shelf off British Columbia,
Canada. They cover about 425 km2 of seafloor on the continental shelf
off British Columbia (Canada) in water depths between 165 and 240
metres and occur on a low-angle deep shelf, iceberg scoured seafloor,
characterized by very low sedimentation rates and very stable
environmental conditions. The sponge bioherms are up to 19 metres high
with steep flanks, whereas the biostromes are 2-10 metres thick and
many kilometres wide. They all consist of dense populations of only
seven hexactinellid species. Three of them, all hexactinosan species
(Aphrocallistes vastus, Heterochone calyx, Farrea occa) are the main
frambuilders, composing a true rigid framework of sponge skeletons
encased in a organic rich matrix of modern clay baffled by the sponges.
Growth rates of hexactinosan sponges range in the order of 0-7
centimetres per year. The base of the oldest sponge reefs date from
approximately 9000 years b.p. Different invertebrate and fish faunas
occupy the reefs than occur on adjacent seafloor areas and some species
appear to use the sponge reef complex structures as refugia where they
can hide. Sidescan sonar data and direct observation by manned
submersible clearly show that large areas of sponge reefs have been
heavily damaged by seafloor trawling in the past decade. These unique
extant siliceous sponge reefs can be used as a modern analogue for a
better understanding and interpretation of fossil siliceous sponge
reefs, known from many ages and many locations world wide.^1";

Great Barrier Reef^Cymbastela hooperi sp.nov. is described from the
Great Barrier Reef, Australia. This species belongs to the recently
erected genus of stalked sponges, Cymbastela Hooper &#038; Bergquist,
1992. The new species is the eighth member of this Australasian genus.
Cymbastela hooperi sp.nov. is distinguished from other Cymbastela
species, by its unique growth form (stalkless and flattened on
substrate), its yellow to brown colour, its loose skeletal morphology,
the often telescope spicule shape and its chemistry. The new species
produces a large number of structurally related diterpene isonitrile
derivatives which demonstrate significant in vitro antimalarial
activity. One of these compounds, di-isocyano-adociane, is also found
in Amphimedon terpenensis Fromont, 1993. In addition both species
present similar skeletal characters and spicule size. Considering this,
a new combination is proposed: Cymbastela terpenensis (from
Amphimedon). [original abstract]^1";

Dolomites extend from the island surface to a depth of 100m below the ground surface (mbgs). Strontium isotope
```

```
stratigraphy indicates that subsurface Units C1 (0-49.7 mbgs) and C2
(49.7-103.4 mbgs) were dolomitized at 5.5 Ma and 2.0 Ma, respectively,
and that island-surface dolomites are products of dolomitization at
1.6-2.0 Ma. X-ray diffraction analysis indicates that the
island-surface and borehole dolomites comprise variable mixtures of
four and three dolomite crystal phases, respectively. Each of these
phases is distinguished by a different Ca and Mg content. Three
textural types can be recognized in the Kita-daito-jima dolomites,
fabric-preserving crystalline nonmimetic (CNM), crystalline mimetic
(CM), and fabric-preserving microsucrosic (MS). CNM dolomites contain
more calcian phases, whereas MS dolomites commonly are richer in more
stoichiometric phases. Backscattered electron images indicate that
calcian dolomite phases were precipitated earlier than the more
stoichiometric dolomite phases and that there is no significant hiatus
between the phases, although they are diachronous. Both the island
surface and borehole cores dolomites show linear relationships between
whole-rock d18O composition and Mg contents and between whole-rock
trace element concentrations (Sr and Na) and Mg contents. These
covariances result from phase mixing, not stoichiometric effects.
Deconvolution of whole-rock isotopic and elemental compositions based
on the relative abundance of phases reveals that each phase has a
distinct chemical and isotopic composition. Oxygen isotopic
compositions of the island surface and borehole dolomites suggest that
all dolomite phases formed in seawater and that dolomitization
primarily occurred during glacio-eustatic sea-level lowstands and
cooler ocean temperatures.^1";

<b>Geography: </b>Australia, Great Barrier Reef^Shelf sediments were
collected immediately before (8-20 January 1986), immediately after
(9-10 February 1986) and one year after (27 February 1987) cyclone
```

```
Winifred crossed the central Great Barrier Reef shelf on 1 February
1986. The storm produced a normally graded, mixed terrigenous-carbonate
storm bed more than 11 cm thick, covering an area at least 1,200 km2,
and extending more than 30 km offshore to water depths greater than 40
m. The storm layer encompasses two lithologically distinct
shelf-parallel facies belts. The nearshore (0-25 m depth) storm bed is
3-11 cm thick, thins offshore, and grades upward from medium sand to
silty clay. Offshore (25-43 m depth) the storm bed thickens to more
than 11 cm and consists of normally graded, well sorted, relict quartz
and skeletal, gravelly sands capped by thin mud veneer. The cross-shelf
distributions of grain size, mineralogy, carbonate content, and carbon
isotope ratios were very similar before and after Winifred, suggesting
the storm bed did not result from offshore-directed storm currents,
rather, in situ resuspension and settling of the shelf sand with
shoreward transport of mud. In contrast to storm sedimentation models
which predict thinning and fining offshore, Winifred created a layer
that becomes thicker and coarser grained in deeper water in response to
cross-shelf substrate changes. After one year the Winifred storm layer
was well preserved nearshore (<20 m water depth), but completely
bioturbated offshore (>30 m water depth) below fairweather wave base.
Preservation may not be a matter of insulating the layer from physical
reworking below fairweather wave base but of burying it where rates of
sediment accumulation outpace bioturbation. The effects of storms
similar in size to Winifred may be well concealed in ancient shelf
sequences subject to rapid biological remixing of storm layers.^1";

59, ID=2681^<b>Topic(s): </b>reef complexes, sedimentation; reef
complex, sedimentation; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Australia, Great Barrier Reef^Sediments
in the 5-25 m deep lagoon of Davies Reefs, a typical mid-shelf reef in
the Central Great Barrier Reef, are described, based on data gleaned
from 19 soft sediment cores (75 mm diameter, up to 7.5 m penetration),
22 surface sediment samples and air lift surveys. The Holocene sediment
pile, which averages 5-10 m thickness, is entirely skeletal in origin
and has a very poorly sorted, coral gravel-rich base which grades up
into poorly sorted muddy sands with infaunal molluscan gravel. These
muddy sands (mainly derived from the reef rim as opposed to being
produced in situ on the lagoon floor) have been intensely bioturbated
by callianassid shrimps, leaving the infaunal molluscan gravel patently
distributed and the bivalves disarticulated and preferentially oriented
subhorizontally, concave-up. There are no vestiges of primary
depositional sedimentary structures such as bedding or cross-bedding.
Radiocarbon dating suggests that significant accumulation of muddy-sand
in the center of the lagoon did not begin until about 2,500-3,000 yr
BP; and that sediment accumulation rates have increased through time
from an average of 1.4 mm &#47; yr between 2,400 and 640 yr BP, to 3.4
mm &#47; yr over the past 640 years. Interpreting these data, the coral
gravel-rich base to the sediment pile represents a period of prolific
coral growth across the top of Davies Reef Platform following flooding
by the Holocene transgression but before the outer reef rim caught up
with sea level to form a lagoon. When the rim did reach sea-level
(about 3,000-4,000 yr BR?), it started to shed large quantities of mud
and sand grade sediment into the center of the reef platform and this,
combined with decreased water circulation, led to the demise of coral
```

```
growth in the newly formed lagoon. As the area of reef rim at sea level
increased, so too did the supply of sediment to the lagoon, which
explains the observed increase in sediment accumulation rate through
time. Using previously published data to aid speculation into the
future development of the lagoon, a shallowing-upwards model for reef
lagoon sedimentation is developed. In this model, a complete sequence
consists of a fining-upwards base (reflecting the gradation from coral
gravel up into bioturbated muddy sands) and a coarsening-upwards top
(reflecting a gradation from bioturbated muddy sands up into a zone of
shallow subtidal coral nibble and patch reefs, then inter- and
supratidal windward storm shingle ramparts and leeward sand cays).^1";
s[4145] = "DELOS REYES M., MARTENS R. (1995).- Low-cost artificial reef
program in the Philippines: an evaluation in the management of a
tropical coastal ecosystem.- Beiträge zur Paläontologie 20: 1-6.-
<b>FC&#038;P 25-2</b>, p. 65, ID=3167^<b>Topic(s): </b>reefs
artificial, reefs management; reefs conservation; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Philippines^This paper
evaluates a 15-year program on low-cost artificial reefs (LCAR) in the
Philippines resulting in an eco-economic analysis of reefs. The most
common and popular materials used in the construction of artificial
reefs are discarded tires and bamboos. Concrete cement is rarely used
due to the high cost of its materials. Available data reveals that
there is a low biological productivity in bamboo and tire artificial
reefs with an average of 0.154kgm-3wk-1 and 0.010kgm-3wk-1,
respectively, compared with the natural reefs having 0.256kgm-3wk-1.
Likewise, findings show that fishermen earn a lower income of PHP
6.16kgm-3wk-1 from using bamboo reefs and PHP .40kgm-3wk-1 from tire
reefs in comparison with the earnings from natural reefs which is PHP
10.24kgm-3wk-1. Preliminary researches on the ecology of artificial
reefs (i.e., bamboo and tires) showed that the substrates of such reefs
are not conducive to reef organism encrustation, and as rubber tires
decay they produce toxic chemicals adding more problems to the
ecosystem Recommendations for the tropical coastal ecosystem management
are presented.^1";
s[4146] = "COLLINS L.B., ZHU Z.-R.WYRWOLL K.-H., HATCHER B.G., PLAYFORD
P.E. CHEN J.-H., EISENHAUER A., WASSERBURG G.J., (1993).- Late
Quaternary evolution of coral reefs on a cool-water carbonate margin;
the Abrolhos Carbonate Platforms, southwest Australia.- Mar. Geol. 110:
203-212.- <b>FC&#038;P 22-1</b>, p. 51, ID=3423^<b>Topic(s): </b>reefs,
cool climates; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Quaternary; <b>Geography: </b>Australia SW^Late Quaternary coral
reefs have developed on the southwestern Australian margin, which has
otherwise been characterized by cool-water carbonates since the Eocene.
The Houtman Abrolhos coral reefs are at the limits of existence,
extending, with the assistance of the Leeuwin Current, a
poleward-flowing, warm water stream, into a region dominated by more
temperate communities. Coring in the Easter Group reefs, supported by
high precision dating, by both U/Th TIMS and 14C methods, has shown
vigorous coral growth, with reefs over 26m thick in the Holocene and
over 15m thick in the Last Interglacial. Each of the three Abrolhos
platforms consists of a central platform composed of Last Interglacial
reefs, about which windward and leeward Holocene reefs developed
asymmetrically. Reef, peritidal and eolian facies comprise the emergent
Last Interglacial limestones which are extensively calcretized, with
reef facies up to 5m above MSL. The Last Interglacial highstand lasted
for at least 10ka from 130 to 120ka, and possibly 15ka, from 132 to
117ka. Holocene reef facies are also emergent by 0.5m, and are overlain
by peritidal and storm ridge facies in an upward-shallowing sequence.
Windward (10m thick) and leeward (26m thick) Holocene reefs in the
Easter Group show contrasting lithofacies. The wave-exposed windward
reefs consist of a slow-growing association of coralline algal
bindstones and coral framestones, whereas fast-growing coral
framestones dominate the more protected leeward reefs. The leeward
```

```
reefs commenced growth 10,000 years ago and grew to the present sea
level by 6500 years ago, generating Holocene constructional topography
consisting of &#034;blue-hole&#034; terrain in the leeward parts of the
platforms.^1";

Geological reconstruction of Fangataufa atoll (South Pacific).- Mar.
Geol. 110: 377-391.- <b>FC&#038;P 22-1</b>, p. 52, ID=3426^<b>Topic(s):
</b>reefs, geological history; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Quaternary; <b>Geography: </b>Pacific S,
Fangataufa Atoll^Several boreholes drilled by the Commissariat à
l&#39;Energie Atomique have reached and passed through the volcanic
bedrock of Fangataufa atoll. The sampled volcanic rocks under the coral
ring were produced during both aerial and submarine activity, whereas
rocks drilled under the lagoon were erupted during submarine volcanism
only. The bathymetric data show that the atoll has a &#34;starfish&#34;
shape. The rift zones are elongated in N-S, N70-80 and N120 directions;
these three main directions are also the directions of structural
discontinuities in the lithosphere. Reconstruction of the atoll&#39;s
topography before erosion using a slope angle of about 16º shows that
the maximum height reached by the volcano was about 1300m above sea
level. For comparison, the maximum height of Mehetia island (southeast
of Tahiti) is approximately 435m. The successive construction stages
are: (1) initiation of volcanism along the rift zones and construction
of a central volcano; (2) production of brecciated lavas; (3) emergent
volcanism; and (4) central and aerial activity. The present day
position of the aerial volcanic rocks under the coral reef and the
submarine products under the lagoon is discussed with reference to two
hypotheses. The first is based on sea level changes and the second on a
tectonic origin (collapse of the atoll&#39;s flanks). Using recent
geochronological data, the submarine construction of the atoll related
to the hot-spot activity lasted about 1.1Ma. The accumulation rate was
approximately 0.7 cm/yr (1.5 x 10-3km3/yr) and the aerial volcanic
activity lasted about 2Ma (1.5 x 10-3km3/yr).^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>Australia, Great Barrier Reef^The post-glacial sealevel rose to ca.
3m above the present in the northern Great Barrier Reef ca. 6,000 yrs
BP. It oscillated with at least one younger highstand ca. 3,500 yrs BP,
and two intermittent lowstands. The present level was reached only a
few hundred years ago. The younger sealevel highstand has left marine
encrustations on the exposed granite of the Lizard Island Group, coral
colonies on the shore platforms around Lizard Island, and shingle
terraces and storm beaches on Nymph Island and in the Turtle Group of
Low Wooded Isles. This sealevel history is consistent with the one
derived from Rottnest Island, Western Australia. In contrast, the
Caribbean experienced a single-phased sealevel rise without highstands
above present datum. The marked contrast in overall structure and
zonation between the Pacific and the Atlantic barrier reefs may be
attributed to these different sealevel histories.^1";

```

```
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography: </b>Polynesia, Tahiti^Drill cores from Holocene reefs on Tahiti (French Polynesia) reveal a framework composed of massive branching acroporids encrusted by coralline algae associated with sessile vermetid gastropods and arborescent foraminifers. Laminated micritic crusts form coatings over coral branches or, more commonly, over related encrusting organisms throughout the cored reef sections; these crusts appear as a major structural and volumetric component of the reef framework. The microbial nature of these micritic crusts is inferred from their typical organic growth forms and geometry, the occurrence of microbial remains and stable isotope measurements. The reef communities accumulated at depths less than 5m below mean sea level in a high energy environment throughout vertical growth from 7140 ± 170 yr BP to the present. The nature of the involved benthic communities, stable isotope data and high calcification rates of microbially encrusted corals strongly suggest that local environmental conditions have been optimal for reef development for the last 7000 years. The causes of the predominance of microbial communities over actual encrusters (red algae, foraminifers) remain problematic and could be related to short term fluctuations in ecological parameters. Microbial micritic crusts seemingly played a prominent role in protecting the coralgal colonies from bioeroders and grazers and, possibly, in strengthening the framework, due to rapid lithification. The record of similar microbial crusts in other Quaternary reef tracts suggests that microbial communities may have played a more prominent role in Quaternary reefs than presently recognized.^1";
s[4151] = "CHAZOTTES V., LE CAMPION-ALSUMARD T., PEYROT-CLAUSADE M. (1995).- Bioerosion rates on coral reefs: interactions between macroborers, microborers and grazers (Moorea, French Polynesia).- Palaeogeography, Palaeoclimatology, Palaeoecology 113: 189-198.- <b>FC&#038;P 24-1</b>, p. 84, ID=4518^<b>Topic(s): </b>reefs, bioerosion; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Polynesia French^A two-year experimental study of bioerosion at Moorea Island, French Polynesia, clearly demonstrated the importance of microborers in the initial stages of the establishment of infaunal boring communities. Rates of erosion by micro- and macroborers and by grazers were estimated from measurements of carbonate removal from experimental substrates, using Image Analysis. The studied substrates have been exposed for 2, 6, 12 and 24 months. After 2 months of exposure, the only borers present in the substrates were cyanobacteria and one chlorophyte (Phaeophila sp.) and their bioerosion rate was estimated at 0.6kg CaCO3 m-2 yr-1. In the course of the 2 years of exposure, recruitment of macroborers occurred and their estimated rates of erosion increased during this period from 2.15 to 90g CaCO3 m-2 yr-1. Carbonate removal by grazers was the dominant agent of erosion, responsible for 89% of the total bioerosion: 2.6kg CaCO3 m-2 yr-1, as recorded in substrates exposed for 2 years. The measurable rates of bioerosion by microborers apparently decreased with the time of exposure from 0.6 to 0.2kg m-2 yr-1, but these values are underestimations which need to be corrected by including the intensity of microboring in substrate layers removed by grazing. Bioerosion is dependent on numerous environmental factors such as depth, light availability, and nutrient supply. A good knowledge of bioerosional processes in modern environments could highlight bioerosion significance in the fossil record.^1";
s[4152] = "PEYROT-CLAUSADE M., LE CAMPION-ALSUMARD T., HARMELIN-VIVIEN M., ROMANO J.-C., CHAZOTTES V., PARI N., LE CAMPION J., (1995).- La bioerosion dans le cycle des carbonates: essais de quantification des processus en Polynesie francaise.- Bulletin de la Societe geologique de France 166, 1: 85-94.- <b>FC&#038;P 24-1</b>, p. 91, ID=4526^<b>Topic(s): </b>bioerosion; bioerosion quantification; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Polynesia French^The contribution to bioerosion of the major boring
```

```
and grazing species on coral reefs was estimated on French Polynesia by
three methods: (1) experimental models using dead coral samples exposed
for 5 years. Bioerosion was mainly due to microboring organisms during
the first two months, and to macroborers after 6 months of experiment.
Grazing was the dominant process since one year and accounted for 66%
of the total bioerosion which reached 2.6kg CaCO3 m-2y-1 after two
years of exposure: (2) bioerosion rates of grazers. The quantity of
carbonate eroded from the reef framework by echinids and scarid fishes
was determined through the study of gut contents production. On Moorea
barrier reef flat, bioerosion was estimated to 4.5kg CaCO3 m-2y-1 for
echinids and to 1.7kg CaCO3 m-2y-1 for scarids; (3) influence of reef
communities upon carbonate budget. On the reef studied calcification
processes dominated over dissolution processes (2kg CaCO3 m-2y-1. In
laboratory experiments, the living corals depleted the carbonate
content of seawater (3.7g CaCO3 m-2y-1) which is in turn highly
restored by the activity of boring organisms and grazers. These results
demonstrated the great importance of bioeroders and grazers in
determining the calcium carbonate budget of coral reefs.^1";

</b>Recent; <b>Geography: </b>Galapagos Isls^Le présent travail
constitue une étude descriptive et synthétique de l&#039;écologie
marine littorale dans l&#039;Archipel des Galapagos. * Les facteurs du
milieu dépendent de la géomorphologie et de la nature du substrat,
cependant la plupart d&#039;entre eux sont influencés par l&#039;océan
environnant. * Dans une première partie du travail, la géomorphologie
de l&#039;archipel, la météorologie et l&#039;hydrologie sont décrites.
Une étude saisonnière de l&#039;hydrologie à Bahia Academia (Santa
Cruz) est abordée. * Dans le domaine littoral, le faciès rocheux
domine. Les substrats meubles sont peu nombreux, peu étendus et
dispersés dans tout l&#039;archipel. On trouve, également quelques
biotopes particuliers: les coraux, lés mangroves et les réseaux
souterrains d&#039;eaux saumâtres. Une description de la zonation
intertidale èn faciès rocheux est faite à Bahia Academia. Le schéma
général de cette zonation est représentatif de l&#039;ensemble des
côtes rocheuses de l&#039;archipel.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Quaternary; <b>Geography:
</b>Pacific^L&#039;Océan Pacifique a été, à la fin du XIXème siècle et
au début du XXème siècle l&#039;enjeu de rivalités économiques très
grandes et le champ clos de courses maritimes entre les puissances
riveraines ou européennes. En effet, de petites îles, d&#039;un
diamètre de quelques kilomètres seulement, se révélèrent, en général à
la suite de découvertes dues au hasard, être recouvertes de phosphates
dont l&#039;exploitation s&#039;avérait chaque fois très facile, par
suite de l&#039;absence de terrains de couverture. * Les phosphates
océaniens constituent une sorte d&#039;exception dans les dépôts de
phosphates mondiaux et cela pour plusieurs raisons. Ils sont
d&#039;abord opposés systématiquement aux autres dépôts phosphatés par
suite de leur origine dite &#34;de guano&#34;. Du point de vue
gisement, d&#039;après 3 gisements observés, le minerai de phosphate se
trouve piégé dans un karst, souvent complexe et profond. Ce karst est
en général creusé dans une roche dolomitique. Du point de vue
particules, au contraire, ils apparaissent formés de particules
sédimentaires identiques aux autres particules phosphatées visibles
dans les autres gisements (par exemple tunisien, marocain), oolithes,
pisolithes, pelotes foecales et bioclastes phosphatisés. [introductory

<b>Stratigraphy: </b>; <b>Geography: </b>Pacific^Les études
océanographiques, menées depuis plus d&#039;un siècle, ont montré que
les sédiments marins carbonates actuels se répartissent schématiquement
en deux groupes; les boues à globigérines recouvrent les plaines
abyssales tandis que les plates-formes sous-marines ou les plateaux
continentaux intertropicaux entre les isobathes 0 et 200m, voient
l&#039;élaboration et l&#039;accumulation de sédiments, à granulométrie
variable, des lutites aux rudites, mais dont la minéralogie est à
dominante aragonitique. * D&#039;autre part, les roches carbonatées
sédimentaires anciennes, quelle que soit leur origine paléogéographique
et paléobathymétrique, se présentent sous deux faciès minéralogiques
apparemment monotones et constants, calcaires ou dolomies. On appelle
donc diagenèse le passage, d&#039;une part, du sédiment meuble à la
roche consolidée, et, d&#039;autre part, l&#039;ensemble des phénomènes
et des mécanismes physiques, chimiques, minéralogiques ou biologiques
qui fait passer un sédiment meuble, aragonitique, dans le cas des
faciès intertropicaux peu profonds, à une roche cohérente, massive,
calcaire ou dolomitique. [introductory chapter]^1";

s[4199] = "KLEEMANN K. (1995).- Associations of coral and boring
bivalves: Lizard Island (Great Barrier Reef, Australia) versus Safaga
(N Red Sea).- Beiträge zur Paläontologie 20: 31-39.- <b>FC&#038;P
25-2</b>, p. 70, ID=3176^<b>Topic(s): </b>boring bivalves; corals,
boring bivalves; <b>Systematics: </b>Cnidaria Mollusca; Anthozoa
Bivalvia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia, Red
Sea^Associations of coral and boring bivalves from Lizard Island (Great
Barrier Reef, Australia) are reviewed and compared with those from
Safaga, northern Red Sea. Although certain coral and Lithophaga species
are present in both areas, the respective associations differ
regionally distinctively in L. laevigata and L. simplex. Hosts for L.
laevigata at Lizard include Astreopora, Coscinaraea, Cyphastrea,
Goniopora, Montipora, Porites, and Psammocora, at Safaga, Favia,
Leptastrea, Porites, and P. (Synaraea), rarely Cyphastrea and Montipora
```

```
in co-occurrence with L. purpurea. Hosts of L. simplex, at Lizard
include Acanthastrea, Astreopora, Echinopora, Favia, Goniastrea,
Lobophyllia, and Symphyllia, at Safaga Astreopora, Goniastrea, and
Pavona. At Lizard, L. lima, found in single or few speciments per coral
colony, occurs alone or together with L. laevigata (in Porites), or L.
simplex (in Acanthastrea, Astreopora, and Favia). Most bivalve species
have a variety of hosts, a few seem to be restricted to a single coral
genus. Different genera of bivalves may be found in the same host
specimen, e.g., Pedum and Lithophaga in Montipora (at Safaga, Red Sea)
and Porites (at Lizard, GBR). At Lizard, Pedum was found only in
Porites, including P. (Synaraea), while it occupies at least 12 host
genera in the norhtem Red Sea, particularly Montipora. In contrast to
coral rock, where several different boring bivalves can occur next to
each other, rarely more than one Lithophaga species is foundper hsot
colony, although it happens in both areas. On the other hand, the same
coral species may be inhabited by one species of Lithophaga in one area
and (mainly) by another in the other area. In Lithophaga, more
associations are established at Lizard than at Safaga, while in Pedum
it is the other way round. Alltogether, more different associations can
be noted than equal ones. Generally, coral-bivalve associations are
regionally stable and do not overlap. Thus, host determination should
yield the bivalve identity, too.^1";
s[4200] = "GEISTER J. (1992).- Modern Reef Development and Cenozoic
Evolution of an Oceanic Island &#47; Reef Complex: Isla de Providencia
(Western Caribbean Sea, Columbia).- Facies 27: 1-70.- <b>FC&#038;P
21-2</b>, p. 54, ID=3354^<b>Topic(s): </b>reefs, history; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Paleogene - Recent;
<b>Geography: </b>Colombia, Caribbean^Providencia Island in the SW
Caribbean is 4,5 to 8,5km across (including Sta. Catalina Island). In
contrast to nearby San Andres, which is an elevated Tertiary atoll,
Providencia is formed by an extinct Miocene Volcano. This lies far off
the Middle American mainland, and therefore its geological history is
somewhat unique among other western Caribbean islands. The submarine
basement of Providencia rises with steep to vertical slopes from an
ocean of approximately 2,000m depth. This island itself is rugged with
peaks reaching up to more than 360m above present sea-level. It is
surrounded by a wide carbonate insular shelf protected towards the NE
and SE by the second largest barrier reef (after that of Belize) of the
Caribbean Sea. The entire reef complex forms a carbonate shelf, which
consists of a 32km long windward bank-barrier reef with lagoonal
environments in its lee, dotted with patch reefs and minor fringing
reefs. [...] The contemporary shelf morphology is the product of a
complex history of sea-level oscillations accompanied by terracing at
different levels, renewed reef growth and erosion. Of this history, at
present, only a few evolutionary stages may be recognized. Volcanic
activity did not contribute to the geomorphologic evolution of the
island and shelf in post-Miocene time. The shelf was last exposed to
subaerial weathering during the sea-level lowering that accompanied the
late Wisconsinian glaciation. It appears that since reflooding in the
early Holocene some 5,000 years ago, renewed reef growth and
sedimentation have only partly concealed or modified the pre-existing
shelf topography. [first and last fragment of extensive summary]^1";
s[4201] = "GEISTER J. (1975).- Riffbau und geologische

</b>Neogene Quaternary; <b>Geography: </b>Colombia, Caribbean^San
Andres, a small high standing limestone, situated near the western
margin of the Caribbean Sea is formed by uplifted reef rock of Tertiary
(San Andres Formation) and Pleistocene age (San Luis Formation) as well
as by Holocene terrestrial and beach deposits (Bay Formation). It is
surrounded by a recent reef complex. * The recent reef complex consists
```

```
of barrier, fringing and patch reefs. Most reefs show rich coral growth
with a clearly discernible coral zonation. Off the west coast, the
shelf is formed by two submarine terraces at 4 and 20m of depth. A
detailed description of the whole reef complex is given and the process
of reef development and erosion are analyzed. * The zonal distributions
of benthic environments within the reef complex have been analyzed and
interpreted leading to a more general scheme of zonation and
classification of Recent Western Caribbean reef complexes. Three facies
areas may be defined according to the type of substrate and the related
bottom communities. [first part of extensive summary]^1";

Scleractinia, Dendrogyra; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Colombia,
Caribbean^Submarine observations around San Andres Island indicate that
quiet backreef and leeward reef waters from 1 to 20m deep, are the most
favorable habitat for the pillar coral Dendrogyra cylindrus. It thrives
even at the submarine terraces along the calm west coast of the Island,
where abrasive action by coral fragments is heavy during occasional
storm surges. Besides a few minor incrusting and hemispherical species,
Dendrogyra seems to be the only major scleractinian to resist abrasion
and break-down without permanent damage in this environment. Dendrogyra
initiates colony growth with a broad incrustation followed by upgrowth
of pillars. Unstable basement may cause tumbling of the whole coral and
subsequent pillar growth at approximately right angles to old columns.
This process may be repeated, resulting in the formation of a third
generation of pillars.^1";
s[4204] = "GEISTER J. (1986).- Book review: Colombia - Corales y

<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Colombia, Caribbean^The windward reef complex NE and E of San
Andres Island is briefly described in terms of submarine topography,
sediments and the distribution of corals and other benthonic organisms.
The breaker zone of the San Andres barrier and other exposed Western
Caribbean reefs characteristically exhibits a profuse growth consisting
almost exclusively of Millepora. In this respect they are different
from most other described West Indian reef localities, where Acropora
palmata is the dominating species in this part of the reef. The
replacement of Acropora palmata by Millepora is interpreted as an
adaptation of the reef crest community to high energy environments due
to long swell prevailing at the Western end of the Caribbean Sea. A few
short reef sections exposed to the maximum degree of wave energy show
conspicuous algal ridges.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Triassic;
<b>Geography: </b>Tethys^After the extinction near the Permian-Triassic
boundary scleractinian corals first appear in Anisian reefs. They are
the only new order in the Triassic reef associations. Until now 313
species belonging to 90 genera are known from the Triassic. During the
Triassic the scleractinians show a continuous diversification, along
there was an extinction of nearly 90% of the species near the
Carnian-Norian boundary. The highest number of taxa occurs in the
Norian. In the Rhaetian the number of taxa diminishes. Until the end of
the Triassic all scleractinians became extinct. To examine
morphological trends the Triassic scleractinian corals have been
subdivided into three types of growth forms: solitary, dendroid and
cerioid. From the Anisian to the Rhaetian the number of the solitary
types diminishes, whereas the amount of the cerioid taxa increases. The
portion of the dendroid taxa is nearly constant during the Triassic.
The shifts in the composition of the growth forms are explained by
general trends in the evolution of the scleractinians, and by changes
in the availability of nutrients near the Carnian-Norian boundary. From
the Anisian to the Carnian corals play a subordinate role in Triassic
reefs. Only in some small and favourable places they could contribute
to the reef fauna. Since the Norian scleractinians are one of the most
important groups of reef organisms. Dendroid taxa like Retiophyllia
contribute most to the mass of reef organisms. The higher abundance of
corals in Norian and Rhaetian reefs is explained by several factors:
the more common occurrence of grazing organisms (snails, echinoderms)
which probably prey on algae, thus providing free space for corals to
settle; the symbiosis of the corals with zooxanthellae facilitating the
conquest of the light zone and providing better conditions in nutrient
poor environments.^1";
s[4213] = "RONIEWICZ E. (2010).- Uniform habit spectrum vs. taxonomic
discrepancy between two succeeding Triassic coral faunas: A proof of
the intra-Norian faunal turnover.- Palaeoworld 19, 3-4: 410-413.-
<b>FC&#038;P 36</b>, p. 132, ID=6591^<b>Topic(s): </b>extinctions;
faunal turnover, corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Triassic Nor; <b>Geography: </b>Tethys^Triassic
coral fauna from the Tethys Ocean contains, besides colonial cerioid,
meandroid and thamnasterioid corals, a high percentage of solitary and
pseudocolonial, phaceloid corals with exclusively epithecal walls,
about one-fifth of the genera with micromorphology of septa having
pennules or menianes. These features are significant indications of
moderate depth environments of low energy level and reduced
illumination. Despite a uniform spectrum of growth forms,
microstructural criteria allow discriminating a middle Anisian-early
Norian (A2-N1)fauna from the middle/late Norian-Rhaetian (N2/3-R) one.
Taxonomy of the two faunas shows meaningful differences: of four
families that dominated in A2-N1 fauna, Volzeiidae, Conophylliidae, and
```

```
Tropiastraeidae are absent from the N2/3-R fauna and Margarophylliidae
are present in a considerably reduced volume. As a consequence of
reduction of the earlier corals, particular morphologies were
eliminated. In the N2/3-R fauna, five families are abundant: the
solitary and phaceloid Reimaniphyllidae and Stylophyllidae, along with
colonial Cuifastraeidae, Pamirosehidae and Astraeomorphidae, all known
as rare and rudimentary elements in the earlier fauna.This change in
faunal content in the Tethys during the Norian was controlled by
environmental factor(s) hardly identifiable by simple observation, as
this is not connected with any obvious facies or change in coral growth
form. [original abstract]^1";
s[4214] = "RONIEWICZ E., STANLEY G.D.jr (2009).- Noriphyllia, a new
Tethyan Late Triassic coral genus (Scleractinia).- Paläontologische
Zeitschrift 83, 4: 467-478.- <b>FC&#038;P 36</b>, p. 104,
ID=6534^<b>Topic(s): </b>new genus; Scleractinia Noriphyllia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>Tethys^Noriphyllia gen. n. is a
distinctive coral representing the Coryphylliidae, a group of Late
Triassic scleractinian corals. Coral faunas of this age are poorly
known. The new coral is distinguished from related corals belonging to
the reimaniphylliids by key features of septal microstructure as
discerned in thin sections. This microstructure consists of a
straight/wavy midseptal zone and lateral septal stereome organized into
thin fascicles of fibres, producing a fine and sharp micromorphology of
the septal sides. The solitary genus Noriphyllia gen. n. contains two
Early Norian species: N. anatoliensis sp. n. chosen as the type species
and N. dachsteinae sp. n., and a Carnian species referred to as N.
monotutoensis sp. n. The new genus is widely distributed in the Late
Triassic, Early Norian reef facies of the Tethys region (Northern
Calcareous Alps, Austria; Taurus Mountains, Turkey) and it also occurs
in the Carnian of Timor. Noriphyllia gen. n. is unique and details of
its microstructural features add new understanding to the composition
of both Late Carnian and Early Norian corals. [original abstract]^1";

and South Tethys: distribution, setting, and biotic composition.-
Facies 51, 1-4: 442-453.- <b>FC&#038;P 34</b>, p. 71,
ID=1307^<b>Topic(s): </b>distribution; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Triassic U; <b>Geography: </b>Tethys^The
paleolatitudinal distribution patterns during Ladinian and Carniantime
are characterized by an increasing expansion of reefs from thenorthern
to the southern hemisphere. The optimum of reef diversity andfrequency
in the Norian is associated with the development of extendedattached or
isolated carbonate platforms. Norian-Rhaetian sponge andcoral reefs of
the Northern Calcareous Alps developed (1) as reef beltcomposed of
patch reefs in platform-edge positions facing the
openmarinenorthwestern Tethys basins and (2) as patch reefs
inintraplatform basins as well as in ramp positions.Carnian and
Norian-Rhaetian sponge and coral reefs of the ArabianPeninsula are
formed (1) as reef complexes at the margins of carbonateplatforms on
the tops of volcanic seamounts in the southern Tethyan ocean, as small
biostromes on these isolated platforms, and (2) astransgressive reef
complexes on the attached platform of the Gondwanamargin. The Norian
Gosaukamm reefal breccia of the NW Tethys is acounterpart of Jabal Wasa
reefal limestone of the Gondwana marginwith similarities in geological
setting and biotic composition. Rhaetiancoral biostromes of low
diversity known from the Austrian Koessenbasin resemble to the time
equivalent Ala biostromes of the isolatedKawr platform in the southern
Neo-Tethys by forming a discontinuouslayer in shallow intraplat form
basin setting.^1";

(Jurassic, Tethys).- Palaios 25, 11: 721-729.- <b>FC&#038;P 36</b>, p.
117, ID=6557^<b>Topic(s): </b>coral reefs, stable isotopes,
paleoclimate; coral reefs; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Jurassic Oxf; <b>Geography: </b>Tethys^Stable
isotope studies were carried out on shells of reef-dwelling brachiopods
and oysters to evaluate the impact of climate changes on coral
communities during the Oxfordian (Late Jurassic) in western Europe and
northwestern Africa. Low to medium diversities observed in coral
associations in the pioneering and terminal reef phases correlate well
with average seawater paleotemperatures of &#060;20.3 °C. The reef
climax coincides with optimum environmental conditions, reflected by a
high coral diversity and an average seawater temperature between 22 and
30 °C. The results of this study show that water temperatures set the
physiological limits for the distribution of corals and coral reefs in
Oxfordian time.^1";
s[4218] = "GILL G.A., SANTANTONIO M., LATHUILIERE B. (2004).- The depth
of pelagic deposits in the Tethyan Jurassic and the use of corals: an
example from the Apennines.- Sedimentary Geology 166, 3-4: 311-334.-
<b>FC&#038;P 33-2</b>, p. 27, ID=1147^<b>Topic(s): </b>bathymetry;
Scleractinia, ecology; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic; <b>Geography: </b>Tethys^Assessing the
palaeobathymery of pelagic deposits is rather speculative, as proof
through lithology or fossils significant for depth estimates is sparse.
This is unfortunate as the bathymetric history of pelagic successions
allows to conceive the evolution of continental margins and oceanic
basins. Discoveries in coral biology bring an unexpected impact on
basin analysis. Evidence strongly suggests that pennular corals, fossil
and modern, constitute a zooxanthellate group with an outstanding
specialization in colonizing deeper parts of the marine photic zone.
This adaptation includes light amplification by autofluorescent
pigmented cells, and particular feeding, witnessed by peculiar gastric
ducts and skeletal features. Such corals occur in the Umbria-Marche and
Sabina Apennines on top of Late Jurassic submarine highs and at basin
margins. Values of palaeodepth relative to pelagic deposits are
provided by corals and other environmental data. Because depth
reconstruction involves classical Tethyan facies, such as Ammonitico
Rosso, Aptychus limestone and radiolarian cherts, we must note that
these results do not meet with actualistic models relying on carbonate
dissolution for estimating depth. Deposits viewed as bathyal to abyssal
could also have accumulated within, or just below, the photic zone.
Thus, a new insight opens on Mesozoic bathymetries, regarding vast
areas (Middle East to Caribbean) and on subjects ranging from platform
drowning to regional extension styles.^1";

inferred from oxygen isotopesand paleoclimatic simulations are tested
```

```
against fossil and facies data. ALate Callovian-Early Oxfordian crisis
in carbonate production isindicated by the widespread absence of Lower
Oxfordian reefalformations. There is a gap (hiatus) in deposition on
epicontinentalplatforms, with Middle Oxfordian deposits resting
paraconformably onUpper Callovian, while shales accumulated in adjacent
intracratonicbasins. Simultaneously, in Mediterranean Tethys,
radiolaritesaccumulated in deep troughs while Rosso Ammonitico facies
formed onpelagic swells. However, deposition on swells was also
discontinuouswith numerous gaps (hiatuses) and sequences that are much
reduced inthickness. Middle Callovian deposits are generally overlain
by MiddleOxfordian limestones. The dearth of carbonates is consistent
with acooling event lasting about 1 My. By the middle Oxfordian a
warming,leading to &#034;greenhouse&#034; type conditions, is suggested
on the basis ofboth biogeographical (mostly coral reef distribution)
and geochemicaldata. Carbonates spread onto an extensive European
platform whileradiolarites reached a maximum development in the
MediterraneanTethys. Two distinct latitudinal belts, with seemingly
different accumulation regimes, are therefore inferred. Similar
latitudinal belts were also present in the late Oxfordian, when
carbonates were widespread. The distribution of reefal facies in the
late Oxfordian-early Kimmeridgian fits relatively well with GCMs
simulations that imply low rainfall in the Tethyan Mediterranean area
and slightly higher precipitation in central and northern Europe. Local
salinity variations, reflecting more arid or humid conditions, may bias
the paleotemperature signal inferred from d18O values. Biogeographical
and facies distributions, combined with d18O values, unravel the
ambiguity and support a Late Callovian-Early Oxfordian cooling followed
by warming in the later Oxfordian.^1";

```

```
thin-section material from the Aptian of Albania sheds light not only
on its biogenic nature but also the morphological variability of this
taxon. In fact, Carpathoporella represents the debris of colonial,
bushy, most likely gorgonid octocorals with tuberculated spheroids that
maybe fused at least near the basal root-like holdfast. Colony
branching originates from longitudinally grooved calcareous branches or
internodes. Possible relationships to other Upper Cretaceous to
Palaeogene genera are discussed and a revised critical inventory of
Cretaceous octocorals is presented. Due to the evidenced morphological
features, Carpathoporella could either represent an ancestral isidid
octocoral of the order Alcyonacea such as Moltkia Steenstrup or, due to
the likely primary aragonitic skeletal mineralogy, a representative of
Epiphaxum Lonsdale of the order Helioporacea. Due to morphological
analogies, the new combination Carpathoporella elliotti is proposed. In
any case, the Lower Cretaceous record from Tethyan peri-reefal
shallow-water carbonates is highlighted since numerous skeletal
findings of fossil gorgonid Octocorallia were so far only known from
Upper Cretaceous and younger strata of outer shelf environments of the
boreal realm. The origin of deep-water Upper Cretaceous octocorals from
Lower Cretaceous shallow-water taxa such as Carpathoporella is proposed
as a possible further example of onshore/offshore evolutionary pattern.

s[4223] = "GILL G.A., LAFUSTE J.G. (1987).- Structure, repartition et
signification paleogeographique d&#039;Aspidiscus, hexacoralliaire
cenomanien de la Tethys [structure, distribution and paleogeographic
significance of Aspidiscus, a Cenomanian scleractinian coral of the
Tethys].- Bulletin de la Societe geologique de France 1987, 8, III, 5:
921-934.- <b>FC&#038;P 18-1</b>, p. 22, ID=2218^<b>Topic(s): </b>;
Scleractinia, Aspidicus; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Cen; <b>Geography:
</b>Tethys^Aspidiscus is a coral of a particularly attractive form,
easily recognizable by field geologists. Therefore the numerous
citations in the literature and the frequency in many collections
favour the setting of a distribution map for the species of this
Cenomanian genus. Apart from a single non-confirmed mention from
Uruguay, all the specimens collected to date come from around the
Mediterranean with an exceptional abundance in North Africa. Lesser
concentrations are known from the Middle East, Spain, France and
Greece. In North Africa the localities which yielded Aspidiscus are
alined from eastern Algeria via Tunisia to Tripolitania in a narrow
belt (less than 100 km) over 1000 km. This belt, directed NW-SE, cuts
obliquely the structural lines. The various outcrops along this strip
seem to gather in groups (7 to 8) recalling the pattern suggested, by
Freund (1961) for the distribution of ammonites in the Middle East
during the Lower Turonian - that of parallel troughs (with ammonites)
separated by ridges and directed NE-SW. The recognition of
&#034;faulted-tilting blocks&#034; announced by Bureau (1983, 1984,
1986) may also be attempted in explaining the layout of the Aspidiscus
localities in North Africa, which coincides rather well with satellite
photogeological alinements (Biju-Duval et al. 1976). The enigmatic
mention of this coral in Uruguay raises the question of sea links -
Atlantic or Trans-Saharian (Collignon and Lefranc 1974) - between North
Africa and South America during the Cenomanian.^1";

corals; reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Miocene; <b>Geography: </b>Red Sea NW^Coral reefs developed within
the Gulf of Suez - northern Red Sea region during a relatively brief
time interval which corresponds to the Middle Miocene maximum of
worldwide marine transgression associated with a global warm climate.
The mixed carbonate - siliciclastic sequences including reefs belong to
the marine Miocene syn-rift unit (Group B or Upper Rudeis - Kareem
Formations) and possibly extend from Langhian to early Serravallian. *
Various sites where coral reefs occur are presented with description of
reef geometries and their relationships to local structural framework
together with diversity of coral fauna and associated organisms.
Studied reef locations extend along the Egyptian coast of the Gulf of
Suez and northwestern Red Sea from north of Hurghada to the Abu Ghusun
- Ras Honkorab area. [...] Mediterranean reef corals and coral reefs
became definitively extinct within the Gulf of Suez - northern Red Sea
region at the latest during the Serravallian, as a result from the
increasing restriction of marine water inducing the evaporite
sedimentation. This regional restriction is interpreted as directly
related to the gradual closure of the Suez Isthmus likely due to both
eustatic and tectonic movements and finally leading to the isolation of
the Gulf of Suez - Red Sea from the main basin of the Mediterranean
i.e. much earlier than the extinction of the reef corals within the
Mediterranean at the end of the Miocene. [excerpts from an abstract]^1";

<b>Geography: </b>Red Sea^Facies patterns within the Pleistocene reef
terraces along the Red Sea coast exhibit lateral changes over short
distances. These changes reflect either transitions within the
depositional environment or they are related to minor or major sea
level fluctuations. On the basis of quantitative distribution of biota
in the field as well as in thin section it is possible to establish and
map these lateral patterns. Important biota are framebuilders and
secondary reef encrusters (foraminifers, coralline algae). Frequency
distributions of sessile foraminifera and scleractinians are strikingly
```

```
similar to those of the recent environment within diagenetically
unaltered terraces. The main reef terraces occur in different elevated
levels above the present sea level. Morphological steps are caused by
onlap during different sea levels, by tectonics, or by erosion during
transgression. Although several morphological steps exist which obscure
the terrace stratigraphy, only three reef units can be distinguished.
Each unit exhibits a lateral facies development, which begins at the
shore, covering the whole lagoonal facies and ends at the upper reef
slope. Besides this lateral facies pattern vertical patterns occur as
well, showing a transgressive sequence in the youngest (lower) and
oldest (upper) unit and a regressive one in the middle unit. In top
quality outcrops, like wadi sections, it is possible to differentiate
within the youngest reef unit between three onlaping reef cycles. Such
cycles, however, can not be seen in the middle and oldest formations.
The three reef cycles within the youngest unit and the three units as
well, exhibit different degrees of diagenetic alterations, which are
strongly reflected by a gradual reduction in the number of biota. This
reduction may be best described as a process of &#034;sieving&#034;.
Where these differences in diagenesis are recorded, they correspond to
the age of the reef units. U/Th datations of the investigated terraces
reveal an age for the youngest unit between 86.000 and 118.000 years
B.P. During this time three major sea level high stands have occurred,
which explain the existence of three reef cycles. The age of the middle
formation is around 205.000 years, while the age of the oldest
formation can only be assumed to fit in the time span between 290.000
and 340.000 years B.P. All these data correspond to other published
datations along the Red Sea coast.^1";

</b>Aden Gulf^Les côtes du Golfe d&#039;Aden de la Mer Rouge au Golfe
de Tadjoura présentent des dépôts calcaires coralliens pleistocenes.
Ces formations, de faciès variés, permettent de définir une unité
chronostratigraphique datée à environ 125000 ans largement étendue qui
constitue un repère précis de la stratigraphie du Pleistocene. Les
affleurements en position topographique élevée présentent des traces de
lessivage et de recristallisation responsables de la transformation en
calcite de l&#039;aragonite des coraux. Pour cette raison, ils ne
peuvent être datés et ne peuvent pas toujours être rattachés avec
certitude au même cycle. Ils pourraient comprendre des niveaux plus
anciens. Le repère daté permet de chiffrer les déformations subies par
la bande littorale du golfe depuis 125000 ans. Les déformations
dépassent 20 ou 50m (peut-être 100m pour un repère non daté). Elles se
traduissent par des failles de 8m de rejet mesurable et un mouvement
d&#039;ensemble positif qui atteint son maximum le long du méridien
d&#039;Obock. Vers le SO et le N, les déformations s&#039;atténuent et
la surface du niveau marin de 125000 ans se rapproche progressivement
du niveau actuel de la mer.^1";

Whereas all biota show more or less the same amount of diagenetic reduction in numbers, aragonitic mollusks are more reduced in number. Although the skeletons of many organisms and also marine cements, consist of aragonite, their reaction to diagenesis in the vadose environment differs. The diagenetic alteration of aragonite cements into calcite occurs earlier than that of aragonitic coral skeletons. The diagenesis of aragonitic mollusks begins only after the complete replacement by calcite of aragonite in corals and cements. In this stage the diagenetic environment can be already so well advanced that leaching predominates with little concomitant calcite precipitation. This leads to a major loss of aragonite mollusks. This diagenetic sequence can be related to the differing influence of organic matrices formed during aragonite precipitation; to the density of the crystal fabric; and also to the degree of undersaturation of the meteoric water with respect to CaC03.^1";

Sea level and coral atolls: Late Holocene emergence in the Indian
Ocean.- Geology 18: 62-66.- <b>FC&#038;P 19-1.1</b>, p. 61,
ID=2686^<b>Topic(s): </b>reefs, atolls, eustacy; reefs; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>Cocos Isls^The Cocos (Keeling) Islands in the eastern Indian Ocean
were visited by Charles Darwin, who described geomorphological evidence
that he considered supported his subsidence theory of coral-reef
development. However, several other accounts of the reef islands have
questioned Darwin&#039;s interpretation, and have suggested that a
conglomerate platform that underlies most of the reef islands may
indicate recent emergence of the atoll. Radiocarbon ages of corals from
this conglomerate platform, reported here, indicate that it formed in
the late Holocene. Fossil in situ microatolls above present upper coral
growth limits, the levation of associated beachrock, and the
morphological similarity of the conglomerate platform to the present
reef-flat deposits indicate a late Holocene sea level above the present
relative to the atoll. The atoll has undergone at least 0,5 m of
emergence since about 3000 yr B.P. This represents the first
radlometrically dated evidence of Holocene emergence from islands in
the eastern or central Indian Ocean.^1";
s[4241] = "RIEGL B., COOK P.A. (1995).- Is damage susceptibility linked
to coral community structure? A case study from South Africa.- Beiträge
zur Paläontologie 20: 65-73.- <b>FC&#038;P 25-2</b>, p. 73,
ID=3180^<b>Topic(s): </b>ecology, damage susceptibility; coral
biocoenoses; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Africa S^Africa&#039;s southernmost coral
communities are situated in northern Natal, South Africa (27°50&#039;
S), within the Maputaland and St. Lucia Marine Reserves. Growing
concern about the possible impact of recreational activities on the
health of the coral ecosystem prompted the present study on the
structure and health of the reefs. Coral community studies by means of
line transects identified three basic coral community types, which
correlated with the geomorphology of the sandstone outcrops on which
corals grew. 1) Fossil dunes were dominated by alcyonacea in depths
between 8 and 24m. 2) Flat outcrops between 18 and 24m depth were
dominated by scleractinia (mainly Acropora). Within these community
types, a further small-scale differentiation into sub-communities
inside and outside of gullies occurred. 3) Deep hard substrata between
25 and 34 m depth were dominated by sponges, ascidians and sea-fans.
Quantitative damage assessment was used to correlate community
structure to damage susceptibility. The flat-outcrop Acropora community
was considered most fragile, while the other community types (dominated
by leathery alcyonaceans or by sponges) were considered more robust.
Such quantitative assessments can be of value to the development of
zoning schemes for marine reserves.^1";
s[4242] = "SCHUHMACHER H., KOHL D.K., REINICKE G.B. (1995).- Long-term
fluctuations of coral communities at Aqaba and on Sanganeb-Atoll
(northern and central Red Sea) over more than a decade.- Beiträge zur
Paläontologie 20: 89-97.- <b>FC&#038;P 25-2</b>, p. 75,
ID=3182^<b>Topic(s): </b>ecology, decadal scale fluctuations; coral
biocoenoses, fluctuations; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea N &#47;
central^Quantitative analyses of coral communities had been carried out
on test squares in a fore reef area of a fringing reef near Aqaba
(northern Red Sea) and on inner and outher reef slopes on
Sanganeb-Atoll (central Red Sea) in 1976 (Mergner &#038; Schuhmacher
1981) and 1980 respectively (Mergner &#038; Schuhmacher 1985). Further
investigations at Aqaba in 1989 and on Sanganeb in 1991 yielded
information on the growth and mortality of individual colonies as well
```

```
as data on long-term fluctuations of community parameters. Near Aqaba,
data of the test square U-7 (5 x 5m in size) at a depth of some 10m
showed that significant changes occurred in the composition of the
coral reef community between 1976 and 1989: xeniid soft coral colonies
completely disappeared during this time, in total, 112 species of
Cnidaria including 88 Scleractinia were found in the test square in
1976 and 1989. The diversity (H1 = 3.23 in 1989- H1 = 3.42 in 1976,
based on Cnidaria-coverage) compared to the highest in the world. On
Sanganeb-Atoll coral communities of four test squares (TQ-FV) of 5 x 5m
were analyzed. The data of 1991 for four TQs comprised a total of 3034
colonies of 130 species of stony corals, soft corals and hydrocorals,
among them 86 species of Scleractinia. A mean diversity of H1 = 2.80 in
1991 and H1 = 2.58 in 1980 (based on Cnidaria-coverage) was recorded.
The comparison of the qualitative analyses of the Sanganeb TQs in 1980
and 1991 proved the constancy of the coral communities. The analysis of
the TQs near Aqaba and on Sanganeb-Atoll, however, showed significant
differences when compared latitudinally. On Sanganeb-Atoll the data
suggest that the stable abiotic coniditions support a relative
constancy of the coral communities in the reef areas studied, whereas
near Aqaba considerable alterations become evident over a decade.
Higher fluctuations of abiotic conditions (light, temperature) near the
boundary of the geographical reef belt as well as grazing by sea
urchins may account for retarded regeneration after occasional
disturbances.^1";
s[4243] = "RIEGL B., PILLER W.E. (1997).- Distribution and
Environmental Control of Coral Assemblages in Northern Safaga Bay (Red
Sea, Egypt).- Facies 36, 1: 141-162.- <b>FC&#038;P 26-1</b>, p. 90,
ID=3659^<b>Topic(s): </b>ecology; coral biocoenoses; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Egypt, Red Sea^Coral assemblages in northern Safaga Bay, Red Sea,
Egypt, are qualitatively described. Nine distinct assemblages were
found, which correspond to quantitatively defined community types
previously described from the area off Hurghada, northern Red Sea.
Their distribution within northern Safaga Bay was mapped. Strong
gradient and/or steep relief assemblages were: Acropora assemblage on
windward (exposed) reefs, Porites assemblage on leeward (sheltered)
reefs, Porites assemblage on leeward (sheltered) reefs, Millepora
assemblage on current exposed reefs, Stylophora assemblage on reef
flats. Low gradient and/or low relief assemblages were: Acropora
dominated coral patches in areas of good circulation to a depth of 15m,
Stylophora/Acropora coral patch assemblages in shallow sheltered
environments, faviid carpet in low relief areas between 10 and 25m
which with increasing turbidity turns into a depauperate faviid carpet,
Porites carpet in low relief areas between 5 and 15m with clearest
water, Sarcophyton carpet in low relief areas with high suspension
load, platy scleractinian assemblage in deeper water (>25m) with low
light intensity. The distribution of coral assemblages depends
basically on 1) topography 2) hydrodynamics 3) light and 4) suspension
load.^1";
s[4244] = "RIEGL B., PILLER W.E. (1999).- Coral frameworks revisited -
reefs and coral carpets in the northern Red Sea.- Coral Reefs 18:
241-253.- <b>FC&#038;P 28-2</b>, p. 20, ID=4017^<b>Topic(s): </b>reefs,
coral frameworks; reefs; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea N^Coral
communities were investigated in the northern Red Sea, the Gulfs of
Suez and Aqaba, for their framework building potential. Five types of
coral frameworks were differentiated: Acropora reef framework, Porites
reef framework, Porites carpet, faviid carpet, and Stylophora carpet.
Two non-framework community types were found: Stylophora-Acropora
community, and soft coral communities. Reef frameworks show a clear
ecological zonation along depth and hydrodynamic exposure gradients,
with clear indicator communities for each zone. By definition, coral
carpets build a framework and lack a distinct zonation since they only
```

```
grow in areas without pronounced gradients. In the northern Red Sea they show a gradual change with depth from Porites to faviid dominance. A Stylophora carpet is restricted to shallow water in the northern Gulf of Suez. Although growth rates of carpets may be somewhat smaller than those of reefs, the carbonate accumulation is considered to be higher in carpet areas due to their significantly higher areal extension. In addition, reef and carpet have different sediment retention characteristics - the carpet retains, the reef exports. The in situ fossilization potential of coral carpets is expected to be higher than that of reef frameworks.^1";
s[4245] = "CARBONE F., MATTEUCCI R., ROSEN B.R., RUSSO A. (1994).- Recent Coral Facies of the Indian Ocean Coast of Somalia with an Interim Check List of Corals.- Facies 30: 1-14.- <b>FC&#038;P 23-1.1</b>, p. 85, ID=4198^<b>Topic(s): </b>reefs, facies, coral lists; reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Somalia^From a study of two areas, Jesira and the Bajuni Archipelago, about 400 km apart, a general pattern can be established for the Recent facies, together with the morphological and taxonomic features of the corals. Present day coral development is characterized by true fringing reefs in the Bajuni Archipelago and by scattered patches and knolls in the Jesira area. The coral fauna, consisting of 27 genera and 63 species so far (including all uncertainties, but not sight records), is rather poor, though coral communities are locally well developed. These figures probably reflect incomplete study and sampling. Although comparison with other areas may therefore be premature, a preliminary biogeographical analysis suggests that this fauna is more closely related to that of the Red Sea than to East Africa and the Seychelles. This differs from other published biogeographical work on Indian Ocean coral faunas, but further study of the corals in this and neighboring areas of the Indian Ocean is needed in order to resolve this apparent anomaly.^1";

&#034;Seychelles Coral Reef Conservation Expedition&#034; operated in
the Seychelles from 25th July to 12th September 1971 and brought home
from Baie Ternay, on the north-west of the island of Mahé, a coral
collection which was handed over to the Hessian State Museum,
Darmstadt. * The expedition divided the investigated bay into zones: 1,
sand and algae; 2, marine angiosperms; 3, sand; 4, sand with isolated
patch reefs containing live corals; 5, reef flat consisting mainly of
dead coral fragments and algae; 6, reef slope with living corals,
gradually increasing to 10m followed by a steeper slope to 25m depth;
7, sand with isolated corals sloping gently from 20m to 30m. * Corals
were collected at four points: on a patch reef 1.5m deep, and on the
reef slope at 10, 17 and 25m, using SCUBA. The coral composition of the
different points is described and listed in a table. The difference in
coral composition between Baie Ternay and other coral reefs at the east
side of Mahé is discussed and it is suggested that the particularly
sheltered position of Baie Ternay, open to NW and sheltered from the
prevailing SE monsoon winds accounts for these differences. * In a
systematic section the 29 collected coral species from 21 genera are
listed, partly described and supplied with notes about geographical
distribution. One species, Caulastrea furcata, is new for the
Seychelles.^1";

reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Maldives^The present paper is
supplementary to the paper submitted to the Symposium on Corals and
Coral Reefs held at Mandapam, South India, in 1969, in which the basic
ideas of a coral sociology, founded upon the elements of
phytosociology, were explained. In the present paper the more essential
principles, somewhat modified, are repeated. The Rasdu Atoll in the
Maldives is taken as an example to show how coral reefs can be examined
with coral sociological methods. On eight sample quadrats of the inner
reef flat, on ten of the outer reef flat and on six of the lagoon
bottom, abundance-dominance and gregariousness of the corals occurring
there were determined and listed in tables. The corals were arranged
according to their frequency. Frequency diagrams and variation curves
of the species numbers of the different stands were drawn, and
reference is made to the differences in the composition of the sample
quadrats. The reefs of Rasdu Atoll are compared with other reefs of the
Maldives. * Basic viewpoints of classification of coral communities in
terms of dominant, differential and characteristic species are
explained. Provided that detailed and unequivocal keys of
```

```
identification exist, particularly for the difficult coral genera, it
should be possible to establish coral associations and characteristic
species by co-operative effort.^1";

[in German, with English summary].- Natur u. Mensch, Jmitt. 1982:
109-115.- <b>FC&#038;P 12-2</b>, p. 41, ID=6238^<b>Topic(s): </b>reefs,
aragonite diagenesis; aragonite diagenesis; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Quaternary; <b>Geography:
</b>Red Sea^The diagenetic alteration of aragonite cements into calcite
happens earlier than that one of aragonitic coral skeletons within the
vadose environment. The diagenesis of aragonitic molluscs starts after
the complete replacement of aragonite by calcite in corals and cements.
This diagenetic sequence can be referred to the different influence of
organic substances during aragonite precipitation, to the density of
the crystal fabric, as well as to the degree of saturation of the
meteoric water with respect to CaCO3 within the diagenetic environment.
[original summary]^1";
s[4266] = "GEISTER J. (1984).- Film review: &#034;Die Korallengarten
von Shadwan&#034; von H. Fleissner &#038; G. Fleissner.- FC&P 13, 2:
60.- <b>FC&#038;P 13-2</b>, p. 60, ID=6374^<b>Topic(s): </b>coral
reefs; coral reefs; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^Der Film wurde
in den Jahren 1964 bis 1967 im nordlichen Roten Meer gedreht, und zwar
im Bereich der Inseln der Strasse von Cubal (hauptsachlich bei Shadwan)
und an der agyptischen Festlandkuste zwischen Hurghada und Koseir. Er
besteht aus etwa 2 gleich langen Teilen. Teil 1 behandelt die
Organisation und Ausrustung der Expedition zum Roten Meer und die
Herstellung der fur die Aufnahmen wichtigen Hilfsmittel. Teil 2 ist als
Lehr- und Dokumentarfilm konzipiert und gibt einen umfassenden
Uberblick uber biologische und geologische Zusammenhange in rezenten
Korallenriffen. * Die Szenerie und die Handlung des Riff-Films wird
aussschliesslich durch die Korallen und die Mitglieder der
Faunengemeinschaft der Riffe bestimmt. Ein breiter Raum wird der
Darstellung von Wechselbeziehungen zwischen den Rifforganismen sowie
von ihrem Verhalten eingeraumt. Daneben machen technisch perfekte
mikroskopische Nahszenen die Zooxanthellen und Nesselkapseln der
Riffkorallen sichtbar. Sehr spektakulare Zeitlupen-Nahaufnahmen zeigen
die Explosion einzelner Cniden. Als Beispiel fur die Ernahrung der
```

```
Korallen sieht der Zuschauer, wie die Polypen kleine Amphipoden fangen,
und wie die Beute zum Mund der Polypen transportiert wird. Eine
Zeitrafferszene demonstriert daruberhinaus anschaulich, wie die Polypen
ihren Korallenstock selbst von Sedimentuberdeckung reinigen. * Der Film
wurde speziell als Lehrfilm für Universitaten und Schulen sowie fur das
Fernsehen gedreht. Obschon die Feldarbeiten nun fast 20 Jahre
zuruckliegen, gibt er nach Ansicht des Rezensenten unter allen
vergleichbaren, offentlich ausleihbaren Riff-Filmen die abgerundetste
Einfuhrung in den Themenkreis des rezenten Korallenriffes. Deshalb
bietet er gerade auch dem Riffpalaontologen und Palaookologen, der
keine Gelegenheit hat, in rezenten Riffen zu tauchen, notwendige
Einblicke in das heutige Riffokosystem sowie Anschauungsmaterial fur
die wichtigsten geologischen Prozesse und damit wertvolle Anregungen
fur die Interpretation von fossilen Riffablagerungen. Auch fur den
Laien ist die Vorfuhrung des Filmes wegen der ausserordentlich schonen
und mit technischer Perfektion gedrehten Unterwasserszenen ein grosser
Genuss.^1";

</b>Timor Sea^Es wurden 150 Gastropodenarten und 70 Pelecypodenarten
aufgesammelt. Die reprasentativsten 70 Gastropodenarten und 35
Pelecypodenarten werden unter Angabe ihrer Verteilung uber 37
Sammelstationen in Reihenfolge ihrer Haufigkeit aufgelistet. Die
Sammelstationen reichen bis in 10m Tiefe. Die quantitative Verbreitung
der Gesamtfauna sowie diejenige von ausgewahlten Arten im Bereich der
Bank werden graphisch dargestellt und diskutiert. Ferner werden die
Grossen- und Altersstruktur, die vielfach beobachtete Zertrummerung der
Schalen, sowie die unterschiedliche Verteilung der rechten und linken
Klappen erortert. Betrachtungen uber die allgemeinen okologischen
Bedingungen auf der Bank sowie uber den moglichen Einfluss des
ostlichen Timor-Stromes auf die Bildung der
Molluskenvergesellschaftungen runden den Artikel ab.^1";
s[4271] = "LATYPOV Yu.Ya. (1983).- Physiographische Zonierung und
Verteilung der Scleractinia. [in Russisch].- Biologiya korallovykh
rifov. Issledovaniya na banke Fantom (Timorskoye morye). Sbornik
nauchnykh trudov: 36-42; AN SSSR, Dal&#039;nevostochnyi Nauchnyi
Tsentr, Vladivostok.- <b>FC&#038;P 13-2</b>, p. 62,
ID=6379^<b>Topic(s): </b>coral reefs, physiographic zonation; coral
reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Timor Sea^Die Phantom-Bank hat fast
elliptischen Umriss und besteht aus einem System felsiger Walle und
sandiger Becken. Diese bilden eine Struktur, welche einem ringformigen
Riff mit zentraler Lagune sehr ahnlich ist. Der Abfall von der
Oberkante der Walle zum Boden der Becken betragt 3-5m. Vergleiche von
Tiefenmessungen uber der Bank mit 65 Jahre alten Messungen ergaben eine
seitherige Absenkung der Bank um 5-6 cm. * Auf der Phantom-Bank wurden
folgende physiographische Zonen ausgeschieden und anhand der
Korallenfauna charakterisiert: (1) Aussenabhang, bestehend aus
Steilabhangen und senkrechten Felswanden. Umgibt die Bank allseits und
ist in Tiefen zwischen 16 und 20m sowie 40 und 60m ausgebildet. Er wird
grosstenteils besiedelt von dunnen, schildformigen und seltender von
verzweigten und massigen Kolonien. An Steilstufen wurde eine dichte
Besiedlung durch Halimeda beobachtet, an den Steilhangen Gerolle,
bestehend aus Halimeda-Sand. Im oberen Teil des Abhanges wurden gut
ausgebildete Brandungsrinnen-Systeme festgestellt. Die Bedeckung durch
Riffbildner erreicht in diesem Bereich bis zu 100% und besteht vor
allem aus blattformigen und astigen Kolonien von Acropora sowie astigen
Porites, dickastigen Millepora und Heliopora. (2) Aussenrand der Bank
im Uebergangsbereich zum Hang. Es ist 10 bis 20m breit, eben bis leicht
geneigt, mit verstreuten bis zu 1m hohen Buckeln und grossen
abgestorbenen Acropora-Kolonien. Auf den Konvexformen des Reliefs
beobachtet man eine intensive Besiedlung durch Heliopora coerulea,
Porites nigrescens, Acropora cytherea, A. palifera, grosse, massige
Poritiden und Faviiden sowie Kalkalgen (v.a. Halimeda). (3) Durch
Erosion uberpragte Zone, mit einem Relief, das stark durch Ausbildung
zahlreicher Buckel und Spitzen gegliedert ist. Letztere erreichen 2 bis
3m Hohe und erscheinen stark von der Erosion &#034;zerfressen&#034;.
Sie werden in mehreren Etagen von Korallen besiedelt, insbesondere von
Acropora, Heliopora, grossen, laibformigen Kolonien von Porites, Favia
und Leptoria. Grosse Blocke aus Riffkalk bilden hier
Pseudo-Fleckenriffe. (4) Zone der &#034;blauen Lagunen&#034;. Sie
umfasst die Depressionen vor allem im Ost- und Sudostteil der Bank. Der
Meeresboden ist hier weithin mit Kalksediment bedeckt, vor allem von
Sand, uber dem das Wasser blau erscheint. Korallenbesiedlung
(Helioporen, Milleporen, Acroporen und Weichkorallen) sowie vereinzelte
Ansammlungen von Fungien sind ausschliesslich auf den Bereich von
Erhebungen beschrankt. * Die beobachtete, physiographisch-okologische
Riffzonierung und der Artenreichtum der Korallen ist mit typischen
indopazifischen Riffen vergleichbar. Die Acroporen sind auch hier
Hauptriffbildner, treten in zahlreichen Wuchsformen auf und reichen bis
```

```
in 10m Tiefe. Sie reprasentieren 1/3 des Artenbestandes.^1";
s[4272] = "KRASNOV Ye.V., SILINA A.V. (1983).- Korallobionten der Steinkorallen. [in Russisch].- Biologiya korallovykh rifov. Issledovaniya na banke Fantom (Timorskoye morye). s[4288] = "REINICKE G.B., SCHUHMACHER H. (1996).- Significance of Different Traits of Soft-Coral Assemblages (Octocorallia, Alcyoniina) in benthic Reef Communities of the Red Sea.- Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 27, ID=3572^<b>Topic(s): </b>ecologic assemblages; Octocorallia Alcyoniina; <b>Systematics: </b>Cnidaria; Octocorallia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^Different types of soft-coral assemblages in Red Sea benthic reef communities were investigated with regard to spatial distribution patterns, dynamics in abundance and persistence as well as hermatypic (or &#34;anti-hermarypic&#34;) properties. The detailed patterns of 12 by species predominantly preferred depth ranges and fluctuations in abundance were mapped for the Xeniidae, a group of rapid colonizers of denuded substrates. Further qualitative observations included the other alcyoniid and nephtheid genera Sarcophyton, Lobophytum, Sinularia, Litophyton and Dendronephthya. The results were used to define and describe &#34;Xenia-aspects&#34; for the predominant scleractinian species assemblages along the reef slope depth gradient of reefs near Aqaba (northern Red Sea) and at the Sanganeb-Atoll (central Red Sea). The hermatypic properties of two species of Sinularia are presented. The skeletal values for porosity, compressive and bending strength of S. leptoclados resemble those of common scleractinian taxa. These soft corals considerably contribute to the reef framework in lagoonside and windward slope habitats of the Sanganeb-Atoll. With regard to characteristics of colonizing behavior, competition and persistence, predominant soft-coral taxa capable of high areal occupation in Red Sea reefs are grouped into four types of assemblages, which demonstrate the wide spectrum of alcyonacean life history traits. It is suggested that these different types can describe variable soft-coral assemblages with regard to their functional significance in benthic reef communities.^1";

corals as pollution indicators, Red Sea Coast, Egypt.- Neues Jahrbuch
fur Geologie und Palaontologie, Monatshefte 2003, 11: 641-644.-
<b>FC&#038;P 32-2</b>, p. 52, ID=1402^<b>Topic(s): </b>pollution
indicators; Scleractinia, enviroment; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Egypt^The
analysis of trace elements of thirty-four specimens of scleractinian
corals from the Red Sea Coast indicates an enrichment in Cu, Pb, Ni, Zn
and Co in Recent skeletons in comparison with their Pleistocene
counterparts which were deposited in a pristine environment unaffected
by human activities. Differences in the distribution patterns of trace
elements among the Recent specimens are attributed in general to
differences in microstructure and microarchitecture of the examined
species. The highest concentrations are generally found in skeletons
with loose crystal packing and high intergranular porosity (suborder
Fungiina and occasionally Astrocoeniina), whereas the lowest
concentrations are mostly recorded in skeletons with tight crystal
packing as well as lower reactive surface area and intercrystalline
porosity. The high concentrations of trace elements in Recent skeletons
of scleractinian corals may be attributed to the increase of landlifts,
domestic sewage, phosphate mining and tourism activities in the
Hurghada area.^1";

The biota of these four test areas were counted according to frame building scleractinians and reef dwellers, including calcareous algae. The species diversity of the scleractinians was evaluated using the Shannon Wiener Theory Index. This index is small in landward patches, increasing towards the inner microatoll zone with a maximum almost at the beginning of the rear reef. Here, this index becomes zero, probably owing to decreasing water depths that limit vertical patch reef growth within the lagoonal environment. The interaction between the substrate preparation by coralline algae and reef destruction by sea urchins are additionally important factors influencing this species diversity pattern.^1";

```

```
recent Porites colonies of Mauritius Island (Indian Ocean) was dated by
sclerochronological methods. Couples of high-density and low-density
bands represent the annual growth rate of the corals and allow the
growth pattern of every year in the corallum to be counted. The growth
and structure of the skeletons of Porites solida and Porites lutea were
investigated. Older parts of the aragonitic skeleton in these 10 to 20
year old corals show various secondary microstructures resulting from
alterations and thickenings of the elements of the skeleton. The
primary needle-like aragonite crystals are absent in older parts of the
corallum and blocky aragonitic cements can occur. Pores and primary
skeletal elements are overgrown by new microstructures. These
microstructures are caused by secondary cementation and exhibit frontal
zones (Stirnzonen), zigzag-like and pseudolamellar-structures. The
lamellar structures can be compared with similar structures in the
exoskeleton of some Rugosa. A very short early diagenesis within the
recent corals is responsible for the thickening and alteration of
skeletal elements. It occurs only 4 to 5 years after formation of the
skeleton and tends to increase in importance in older parts of the
corallum. Nevertheless, there is no proof for any alteration of
aragonite to calcite.^1";
s[4301] = "WALLACE C.C. (1997).- New species and new records of
recently described species of the coral genus Acropora (Scleractinia:
Astrocoeniina: Acroporidae) from Indonesia.- Zoological Journal of the
Linnean Society 120, 1: 27-50.- <b>FC&#038;P 26-2</b>, p. 74,
ID=3760^<b>Topic(s): </b>taxonomy, new taxa; Scleractinia, Acropora;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Indonesia^Six new species of the coral
genus Acropora are described from Indonesia. These include a species
which is remarkable for tubercular coenosteal structures similar to
those of the confamilial genus Montipora. The new species include three
regional endemics (A. togianensis and A. batunai from central east
Sulawesi and A. derawanensis from east Kalimantan), one species with
broad distribution across the southern island chains (A. sukarnoi) and
two species which occur throughout most of the Indonesian archipelago
(A. indonesia and A. hoeksemai). A further two species described from
Western Australia and Papua New Guinea in 1994 (A. turaki and A.
jacquelineae respectively) are recorded from Indonesia for the first
time, as common members of an unusual assemblage type in the Togian
Islands. The range of another species described from Lombok in 1994 (A.
suharsonoi) is extended into Bali. With A. desalwii, A. lokani and A.
indiana, this brings to 12 the number of Acropora species newly
recorded as being endemic to the Indonesian archipelago or to Indonesia
and one adjoining region (either the Indian Ocean or the western
Pacific). [original abstract]^1";
s[4302] = "HEISS G.A., DULLO W.-C. (1997).- Stable isotopes from recent
and fossil Porites sp. in the Northern Red Sea.- Coral Research
Bulletin 05: 161-169.- <b>FC&#038;P 27-1</b>, p. 51,
ID=3806^<b>Topic(s): </b>stable isotopes; stable isotopes;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Red Sea N^The stable isotopic composition
of scleractinian corals (PISOTOPESorites sp.), two recent and one
fossil, from the Egyptian Red Sea coast was studied. The oxygen isotope
record proves the assumption that recent sea surface temperatures are
comparable to the time of last sea level highstand in Eemian (stage 5e,
125.000yBP). Deposition of high-density and low-density bands in
respect to season shows the same patterns as today with high-density
band deposition in winter (low water temperatures) and low-density band
deposition in summer (high water teperatures). &#948;18O is negatively
correlated with &#948;18C with a shift in phase of 1 to 2 month. Thus,
acoupling of carbon isotopes to light intensity and oxygen isotopes to
water temperature is suggested. To get an overview on seasonal patterns
of stable isotope composition a sampling technique with a resolution of
four samples per year is of sufficient precision.^1";

from the Nicobar Islands.- Zoologica 42, 3, 122: 1-75; Stuttgart.-
<b>FC&#038;P 4-1</b>, p. 24, ID=5079^<b>Topic(s): </b>; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Nicobars^A short historical review shows
that only very few corals are known from the Nicobars, though about 40
genera should occur there. During the &#34;Xarifa&#34; Expedition
1957/58 (led by Dr. Hans Hass) an extensive amount of coral was able to
be collected from the north coast of the island of Great Nicobar and
from the south-east of the island of Tillanchong. The corals are
deposited in the Hessian State Museum at Darmstadt. * On the north
coast of Great Nicobar collections had been made at two places in the
Ganges Harbour, and off Tillanchong especially in the Castle Bay and
there at the fringing reef, on the bottom of the bay and on steep rocky
cliffs at the exit of the bay. A description of the reefs is given and
the different collecting places characterized. * The systematic section
deals with 110 species of 45 genera and 14 families. They are described
and compared with related species and are followed by notes on their
distribution. Many species are shown in photographs. The corals are
systematically grouped in a list showing which species were collected
at which station. * Two species are new, one genus was given a new
name. 20 species were found to be also present in the Indian Ocean.^1";

et Amsterdam (sud de l&#039;Océan Indien).- Tethys 05, 4: 747-778.-
<b>FC&#038;P 4-1</b>, p. 27, ID=5087^<b>Topic(s): </b>; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Indian Ocean S^Etude de 11 espèces de
Scléractiniaires récoltées en partie par la &#34;Valdivia&#34;
(1898-1899), en partie récemment lors de campagnes de pêche à la
langouste. Cinq espèces vivant en général à des profondeurs bathyales
sont communes à l&#039;Atlantique nord-oriental et aux îles Saint Paul
et Amsterdam (Desmophyllum cristagalli, Lophelia pertusa, Madrepora
oculata, Solenosmilia variabilis, Stenocyathus vermiformis). Certaines
de ces espèces sont connues encore plus loin dans l&#039;Océan Indien
et même dans le Pacifique. Une espèce minuscule, interstitielle, et
plutôt typique des faibles profondeurs, est étroitement apparentée à
une forme de l&#039;Atlantique nord-oriental (Sphenotrochus sp.).
Caryophyllia profunda, espèce connue seulement dans les mers australes
entre l&#039;archipel Tristan da Cunha (sud de l&#039;Atlantique) et
les îles Chatham (sud-ouest du Pacifique) est comparée en détail à
Caryophyllia cyathus de l&#039;Atlantique nord-oriental. Compte tenu
des méthodes de prélèvement et du nombre d&#039;opérations effectuées
dans des fonds probablement peu variés, un nombre assez réduit
d&#039;espèces de Scléractiniaires vivant dans les parages des îles
Saint Paul et Amsterdam a été récolté. On ignore, en particulier, la
faune de Scléractiniaires des fonds rocheux à faible profondeur.^1";

<b>Systematics: </b>Foraminifera algae; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^Autochthonous organic frameworks from the deeper fore reef (-50 m to -110 m) of the Red Sea are composed predominantly of incrusting calcareous algae and foraminifera. This foralgal crust facies is represented by three types. The first is a pure foralgal crust community which forms small buildups with bumpy surfaces. Calcareous red algae and incrusting foraminifera comprise more than 60% of the biogenous fabric. The second type is a framework in which foralgal crusts are secondary binders around the hermatypic deep water scleractinian Leptoseris fragilis. The third type occurs on drowned reefs, exhibiting a mixture of Pleistocene shallow water and present day deep water binding species. Therefore, the morphology of this subfacies is more governed by an inherited relief, characterized by pinnacles and barrel shaped towers. This present day deep water foralgal community started to develop within the Cretaceous in shallow water environments, composed predominantly of corallinaceans, peyssoneliaceans, and subordinately of acervulinid foraminifera. With the beginning of the Neogene, the shallow water community of reef binding foraminifera and calcareous algae changed and became dominated by the foraminifera Acervulina. The living foralgal crust of the deeper fore reef in the Red Sea represent a binding community of Upper Cretaceous and Palaeogene shallow water environments which has shifted in greater water depths with time. ^1";

Basal U/Th dates demonstrate that the sclerosponges analyzed [Astrosclera willeyana] are 85-100 years old. Isotopic records from the Indonesian specimens suggest a strong subsurface cooling over the past 20 years that is not manifested in either surface instrumental or shallower coral proxy records. However, analysis of observed subsurface temperatures in Indonesia, observed winds in the west Pacific, and simulated subsurface temperatures from a steady state general circulation model hindcast forced by observed winds combine to suggest that thermocline adjustments could account for at least part of the recent cooling inferred from the Indonesian sclerosponges. If so, the sclerosponge data suggests that, on average, the west Pacific thermocline has
```

The modern coral colonization of the Bajuni Barrier Island (Southern
Somalia): A facies model for carbonate-quartzose sedimentation.-
Geologica Romana 35: 111-149.- <b>FC&#038;P 30-1</b>, p. 30,
ID=1553^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Somalia^The Somali coast
south of Kisimayo has been investigated and a modern depositional model
is proposed. Several evolutive phases have been identified,
corresponding to eustatic sea-level variations starting from isotope
stage 5e, which led to the present coastal setting, characterized by
mixed carbonate-terrigenous sedimetation and conditioned by climatic
factors. The sea level fall below the continental shelf edge during the
last glacial period caused subaerial exposure, erosion and weathering
of the sedimentary substratum. As a consequence a braided fluvial net
developed on the coastal belt and coastal dune ridges migrated toward
the shelf edge, influencing the distribution pattern of the modern
sedimentary and ecological environments. The Holocene inundation of the
shelf caused the drawning of the channels, the overflowing of the
interdune areas, the formation of the Bajuni barrier island, of which
coastal lagoons and channelized tidal flats. The relation among
inherited morphology, supply of terrigenous material and development of
coral communities is shown in a series of ecological profiles and
sketch maps of facies distribution. The depositional systems of outer
shelf, marine passes, coastal sound and braided channels have been
investigated in detail in some key areas. The types of coral
```

```
colonization as well as their interactions with seagrass meadows have
been examined. In outer shelf corals grow in form of fringing reefs and
coral carpets around the abraded flat of the islands and along some
mophological steps corresponding to old sea-level stillstands. In the
marine passes crossing the barrier island, the hard substrate is
colonized by fringing and pinnacle reefs, coral carpets and knobs and
their distribution is controlled by the energy dispersion of the tidal
currents. In the coastal sound corals grow to form at places small
fringing reefs and carpets along the protected edges of the islands and
near the channel mouths, whereas patch and table reefs are found on
isolated erosion remnants inside wide Thalassodendron meadows. The
braided channelized area of the coastal belt is characterized by the
development of mangal and salt flat depositional systems where the
facies distribution is controlled by the extension of the tidal
prism.^1";

complexes, facies; reef complexes; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Egypt, Red
Sea^Topographically the Northern Bay of Safaga can be subdivided into 4
parts: the &#34;East area&#34; with water depths down to 55 m exposed
towards the open sea, the shallow &#34;North area&#34;, the &#34;West
area&#34; with a central basin of 30 to 38 m depth, and the Southwest
&#34;channel&#34;, which is connected to the Southern Bay. Mapping of
the sea bottom allowed several bottom facies to be distinguished: 1)
Coral reefs, which can be subdivided into fringing reefs, patch reefs
(platform reef, miniatoll, pinnacle reefs), and coral patches. 2) Rock
bottom, representing subtidal rocky substrate without or with sparse
sediment cover and lack of dense stony coral settlement. 3) Coral
carpet, showing areal covering of hard bottom by abundant stony corals
without vertical zonation. 4) Sand bottom, where in addition to pure
sands several other subtypes occur (sand with coral patches, sand with
seagrass, sand with macroids, muddy sand). 5) Mud bottom, rich in
infauna and lebensspuren. 6) Rocky tidal flats. 7) Mangrove. The bottom
facies distribution is mainly controlled by the underlying morphology
and by water currents.^1";

```

```
carbonates; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^Holocene reef growth, present date bioerosion and recorded carbonate production were studied in the fringing reef at Aqaba, Red Sea. Water depth, wave impact as well as nutrient availability were considered. The carbonate production was measured for several coral samples. Samples of Porites colonies were collected from several depths and sites near the Marine Science Station at Aqaba. Growth rate depends on water depth, size and age of colonies. Within the coral optimum of water depth growth rates vary between 5 and 16 mm/yr. Coral carbonate production was calculated on the base of annual growth increments and skeletal density using transects from shallow subtidal down to 40 m water depth. High resolution stable isotope data were measured to prove the origin of growth increments. Long-term trends of sea surface temperature and carbon isotope shift (1800-today) fit to the known global deviations. Bioerosion rates were determined using standard dead coral substrates exposed in different water depths and environmental settings. Rates vary between 0.6 and 1.4 kg/m2yr. Sediment export evaluated by means of simple sediment traps ranges between 0.3 and 0.7 kg/m2yr. Gross carbonate production, mainly built up by scleractinian corals, amounts to ca. 1.57 kg/m2yr. Bioerosion alters approx. 1.3 kg/m2yr of hard substrates into sediment. Sediment export is estimated to be ca. 0.4-0.6 kg/m2yr. Thus a net production of ca. 0.7 to 0.9 kg/m2yr should remain in the present reef, which is proved by the recorded carbonate production (reef drillings). Net production preserved in the reef can be given with ca. 800 kg/m2kyr (=0.8 kg/m2yr).^1";

On top of the wall, drowned reefs occur. Dated corals may reveal the history of sealevel changes indicating reef growth during isotope stage 3 (50-26 kyrs BP) at a present-day water depth that is deeper than 80 m and also has developed a coeval reef talus facies. A maximum sealevel drop of 150 m occurred during the last glacial maximum followed between 22-18 kyrs BP. This lowering of sealevel is documented by karst features such as small caves and corroded and jagged surfaces. The phase of deglaciation is recorded by two give-up reef levels at 100 m &#47; 90 m water depth and 65 m &#47; 55 m water depth which we may relate to the Belling (14 kyrs BP) and post Younger Dryas (11.5 kyrs BP) meltwater pulses, known from the deep-sea record.^1";
s[4336] = "DULLO W.-C., EISENHAUER A., HEISS G.A., WISCHOW D., CAMOIN G.F., COLONNA M., MONTAGGIONI L., (1996).- Coral and Reef Growth in the Western Indian Ocean (La Reunion, Mayotte, and Seychelles).- Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 24, ID=3565^<b>Topic(s): </b>reefs, reef growth, sclerochronology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography: </b>Indian Ocean W^The present day coral growth and stable isotopic record from three latitudinal different islands in the Western Indian Ocean were analyzed. All colonies grow at a water depth between 2m and 7m. Stable isotope records were obtained with a sampling distance of 1mm from the upper part of the cores that comprise between 3 and 6 years of coral growth. For the core from
```

```
Mayotte additional annual samples were taken. Their record reaches back
to the year 1920. From the southernmost location off La Reunion the
most accentuated seasonal oxygen isotopic signal was found, indicated
also by Sr/Ca ratios. The Mayotte samples showed a clear seasonal
signal, where deposition of HD-bands is linked to rising seawater
temperatures. From Mahe the oxygen isotopic signal is less clear than
at the other sites. Cores through the Holocene reefs of La Reunion and
Mayotte indicate a reef growth of about 20m during the 9,000 years.
There is a pronounced change in reef growth strategy, starting with a
catch up mode in the order of 7m/1,000 years followed by a decreased
reef growth after 5,000 years BP in the order of 1m/1,000 years. This
difference in growth is related to the early Holocene Climatic Optimum
and the fact that sealevel reached its present position about 3,000
years BP.^1";
s[4337] = "ZUSCHIN M., HOHENEGGER J. (1998).- Subtropical Coral-reef
Associated Sedimentary Facies Characterized by Molluscs (Northern Bay
of Safaga, Red Sea, Egypt).- Facies 38, 1: 229-254.- <b>FC&#038;P
27-1</b>, p. 123, ID=3881^<b>Topic(s): </b>reef mollusc facies; reef
molluscs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Red Sea^The shallow marine subtropical Northern Bay
of Safaga is composed of a complex pattern of sedimentary facies that
are generally rich in molluscs. Thirteen diver taken bulk-samples from
various sites (reef slopes, sand between coral patches, muddy sand,
mud, sandy seagrass, muddy seagrass, mangrove channel) at water depths
ranging from shallow subtidal to 40m were investigated with regard to
their mollusc fauna >1mm, which was separated into fragments and whole
individuals. * Fragments make up more than 88% of the total mollusc
remains of the samples, and their proportions correspond to
characteristics of the sedimentary facies. The whole individuals were
differentiated into 622 taxa. The most common taxon, Rissoina
cerithiiformis, represented more than 5 % of the total mollusc content
in the samples. The main part of the fauna consists of micromolluscs,
including both small adults and juveniles. Based on the results of
cluster-, correspondence-, and factor analyses the fauna was grouped
into several associations, each characterizing a sedimentary facies:
(1) &#034;Rhinoclavis sordidula - Corbula erythraeensis - Pseudominolia
nedyma association&#034; characterizes mud. (2) &#034;Microcirce sp. -
Leptomyaria sp. association&#034; characterizes muddy sand. (3)
&#034;Smaragdia spp. - Perrinia stellata - Anachis exilis -
assemblage&#034; characterizes sandy seagrass. (4) &#034;Crenella
striatissima - Rastafaria calypso - Cordites akabana - assemblage&#034;
characterizes muddy seagrass. (5) &#034;Glycymeris spp. - Parvicardium
sueziensis - Diala spp. - assemblage&#034; characterizes sand between
coral patches. (6) &#034;Rissoina spp. - Triphoridae - Ostreoidea -
assemblage&#034; characterizes reef slopes. (7) &#034;Potamides conicus
- Siphonaria sp. 2- assemblage&#034; characterizes the mangrove. The
seagrass fauna is related to those of sand between coral patches and
reef slopes with respect to gastropod assemblages, numbers of taxa and
diversity indices, and to the muddy sand fauna on the basis of bivalve
assemblages and feeding strategies of bivalves. The mangrove assemblage
is related to those of sand between coral patches and the reef slope
with respect to taxonomic composition and feeding strategies of
bivalves, but has a strong relationship to those of the fine-grained
sediments when considering diversity indices. Reef slope assemblages
are closely related to that of sand between coral patches in all
respects, except life habits of bivalves, which distinctly separates
the reef slope facies from all others.^1";
s[4338] = "KUHLMANN D.H.H. (1994).- Tongue Island - an atoll in the
making: among others Alexander von Humboldt was right.- Courier
Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.)

ID=4085^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
```

```
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea, Tongue Isl^In
the southern Red Sea lies the tiny Tongue Island. It is a small
circular parasitic volcano derived from the large neighbouring island
Djeoel Sukar. It is irregular in height, some parts are above, some
beneath sea level. The rocks consist of dark brown lava and tuff-like
breccia. It encloses a 40 m deep lagoon, about 555 m in diameter. The
upper submerged parts of the crater are typically overgrown by corals.
To depths of 2 to 11 m they include mainly Acroporidae (22 species),
Poritidae (13) and Faviidae (25). In contrast, on the rubble of the
fore-reef, in quieter waters 10 to 25 m deep, among others there are
mainly mushroom corals (9) as well as rolling coral lumps of Cyphastrea
serailia and Siderastrea savignyana. These same species lived in both
habitats, although they differ in their growth form. This circular isle
with its recent coral communities is reminiscent of an atoll. According
to Alexander Von Humboldt (1806) atolls were formed on the scoria of
volcanoes. Should the remaining parts of this crater ring become
submerged in the future, Tongue Island would become a circular reef
according to Humboldt&#039;s theory. This is quite a rare type of reef,
distinct from the true atolls in Darwin&#039;s sense.^1";

Les facteurs du milieu pris en considération sont: les vents, la houle et les marées. Les courants de flot et de jusant ont des actions différentes sur les édifices récifaux particulièrement si l&#039;on considère leurs actions sur les transferts sédimentaires. Ces facteurs déterminent différents types d&#039;édifices récifaux. Leurs particularités sont définies si l&#039;on considère les positions relatives des axes topographiques, morphologiques et de croissance par rapport aux directions de la houle et du vent. * Pour les analyses
```

```
sédimentologiques, les valeurs des indices sont obtenues par
calculatrice IBM 360/44. Je considère d&#039;abord les faciès
sédimentaires à l&#039;intérieur de chaque zone morphologique. Ils sont
déterminés en appliquant une nouvelle technique mathématique.Celle-ci
est basée sur les propriétés d&#039;une nouvelle représentation
graphique qui est une spirale logarithmique. Par rapport aux autres
représentations graphiques des sédiments, la spirale est définie par
son équation mathématique. Les indices sédimentologiques des
échantillons de faciès ont des valeurs déterminées qui ont une
signification hydrodynamique. Un nouvel indice: le facteur
hydrodynamique (FH) est aussi défini. Pour chaque unité morphologique
de ces récifs, je donne rapidement la description des traits
morphologiques et j&#039;explique l&#039;évolution sédimentaire en
relation avec les houles et les courants de marée. * Cette étude
précise la sédimentation et les mouvements des &#034;sables fins&#034;
qui recouvrent la pente interne des édifices récifaux de ce secteur.^1";
s[4351] = "MERGNER H., SCHEER G. (1974).- The physiographic zonation
and ecological conditions of some south Indian and Ceylon coral reefs.-
In Proceedings of the Second International Symposium on Coral Reefs
(22nd June to 2nd July 1973, Brisbane); Published by The Great Barrier
Reef Committee; vol. 2: 3-30.- <b>FC&#038;P 4-2</b>, p. 47,

<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>India, Sri Lanka^On the occasion of the First International
Symposium on Coral Reefs, 1969 in Mandapam Camp, South India, the
ecological and sociological conditions of nine different reef sections
off the coast of South India and Ceylon were examined with special
emphasis on their morphological and structural aspects, their water
movement and their light intensity. Coral growth and species
distribution of corals were analyzed as well as the growth and
distribution of the most abundant and predominant sea weeds and benthic
animals. The results of these investigations were combined and compared
with one another, and therefore allow characterization of typical
physiographic zones, especially within three carefully analyzed reef
areas: one reef composed of numerous small patches along Manauli Island
near Mandapam Camp, one fringing reef plate with three steps to the
open sea south of Hikkaduwa, Ceylon, and one typical small lagoon reef
in front of the same place. All these investigations are part of a
greater program concerning the influence of different abiotic
ecological factors, especially of water exchange, lighting and
substrate, on coral growth and reef zonation.^1";

Tulear^L&#039;analyse de la disposition et de la morphologie des
édifices récifaux de la région de Tuléar et du modelé continental
élaboré au début du Quaternaire, permettent de retracer les grandes
lignes de la morphologie de cette période. Les édifices récifaux de la
première génération (récifs externes), c&#039;est-à-dire contemporains
de la première transgression (tatsimienne), se sont implantés en
suivant étroitement le canevas imposé par le réseau hydrographique.
Cette implantation ne s&#039;est pas faite uniformément sur le rebord
du plateau continental mais uniquement selon les interfluves des
vallons. Il s&#039;est ainsi constitué une chaîne d&#039;unités
récifales qui, ultérieurement, sont devenues coalescentes. Les récifs
internes et les bancs récifaux ont suivi, mais à un degré moindre, le
canevas imposé par l&#039;érosion fluviatile.^1";

<b>Geography: </b>Red Sea^Reefs in the North Towartit and Shambaya
Groups of the Sudanese Red Sea rest on major blocks which have been
defined by large-scale fault movement. The dominant surface features in
these areas have been formed by the sub-aerial sculpting of the
Tertiary and later limestones during late Pleistocene periods of low
sea-level stand. This has resulted in the formation of large numbers of
closed depressions reaching -60m depth. These punctuate a surface lying
between -20 and -30m which is itself probably a residual of an older,
undulating, higher level surface. The margins of depression are
submarine cliffs, the smooth floors are blanketed with Recent sediments
```

```
while the intervening ridges have become the sites for reef accretion.

builders, stable isotopes C O; reef builders; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^The isotopic
composition of the carbonates in skeletons of ecologically significant,
benthonic genera (mainly corals) derived from Red Sea fringing reefs
and coral islands was studied. Between genera and biozones distinct
differences were noticed in the O18/O16 and C13/C12 ratios. Corals from
the reef edges have &#34;lighter&#34; carbonates (down to -2‰ &#948;C13
and 4‰ &#948;O18) than organisms from the lagoons (up to +4‰ &#948;C13
and -2‰ &#948;O18). * This trend was noticed everywhere and is
explained by higher salinities in the lagoons (increase of &#948;C13)
and strong evaporation on the reef flats (decrease in &#948;O16). The
regional depression of the &#948;O18 ratios for about 1‰ in lagoonal
carbonates is related to the general rise in surface water temparatures
from North (Egypt) to South (Saudi Arabia). * In view of the isotope
fractionations on the reef flats and within the lagoons an indication
of the temperatures should be restricted to carbonates from corals of
the reef edges. * Fossil reef organisms (Pleistocene fringing reefs)
have similar O18/O16 and C13/C12 ratios as their living counterparts.
In spite of diagenetic changes, the facies remains isotopically marked.

<b>Geography: </b>Maldives^Based on rotary drilling and radiometric and
U-series dating, we present the first comprehensive data on Holocene
reef anatomy and sea-level rise as well as nature and age of underlying
Pleistocene limestone in the Maldives. Holocene reefs in Rasdhoo Atoll,
central Maldives, are composed of four facies including (1)
robust-branching coral facies, (2) coralline algal facies, (3) domal
coral facies, and (4) detrital sand and rubble facies. Branching coral
and coralline algal facies predominate the marginal reefs and domal
corals and detrital facies preferentially occur in a lagoon reef. In
addition, microbialite crusts are found in lower core sections of
```

```
marginal reefs. Microbialites formed during the early Holocene in reef
cavities. Holocene reef thickness ranges from 14.5 m to &#062; 22 m.
Reef growth started as early as 8.5 kyr BP. Marginal reefs accreted in
the keep-up mode with rates of &#062; 15 m/kyr. Rate of sea-level rise
significantly slowed down from 7-6 kyr BP and subsequently gradually
rose with rates &#060; 1 m/kyr. The lagoon reef accreted in the
catch-up mode with rates of around 4 m/kyr. Even though no indications
of a higher than present sea level were found during this study, it is
not entirely clear from the data whether the sea gradually rose to or
exceeded present level in the late Holocene. Submarine cementation in
Holocene reefs studied is rather weak, presumably as a consequence of
high accretion-rates, i.e., short time available for consolidation.
Pleistocene coral grainstone was encountered in one core at 14.5 m
below present level and three U-series dates indicate deposition during
marine isotope stage 5e ca. 135 kyr BP. [original abstract]^1";

faunal stasis; reef corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Quaternary; <b>Geography: </b>Indo-Pacific^Faunal
stasis among Indo-Pacific reef-building corals is explained as the
result of chronic environmental disruptions preventing evolutionary
processes from approaching completion since the Late Pliocene. The
model assumes shallow reefal habitats (<20m) on the continental shelves
are major sites of scleractinian evolution and explores ecological and
evolutionary consequences of high-frequency sea-level fluctuations and
their associated transgression-regression cycles. Because single
generations, dominated by a few large clonal genotypes, may persist
indefinitely, local populations may not have experienced enough
generations to approach evolutionary equilibrium with their
environments during the estimated average duration (ca. 3200 yr) of
existence of shallow habitats. Persistent consequences of chronic
evolutionary disturbance may be the extensive intraspecific variation
so characteristic of the dominant genera of shallow Indo-Pacific corals
```

```
and the apparent paucity of recently evolved endemic species. The same
disturbances may have accelerated speciation rates among reefal
organisms with much shorter generation times. (Original summary)^1";

environments of colonial reef corals.- Biologiya korallovykh rifov
[B.V. Preobrazhenskiy &#038; E.V. Krasnov (eds)]: 159-175, 3 figs, 7
tabs.- <b>FC&#038;P 10-1</b>, p. 62, ID=6033^<b>Topic(s):
</b>hermatypic, growth rates; reef corals; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Indo-Pacific^The paper offers a literature survey of different
physical and chemical methods of determination of annual linear growth
rates. There is comparison of results and an estimation of influence of
ecological factors on the form and annual increase of colonial reef
corals in paper. The best results were obtained using method of X-ray
in combination with staining of alizarine red in living corals. This
method permits determination not only of annual growth rate, but as
well to measure density of skeleton matters and of seasonal growth rate
of good preservation modern and fossil corals. * Seasonal layers
skeletal matter of the high density are formed in more high
temperatures, but layers of low density - in minimum temperature of sea
water. Layers with low density of skeleton matter are broader then
layers with high density. The greatest linear growth is observed on the
depths 9-10m. In the presence of zoochorella in endoderm the process of
polyp&#039;s calcification is more rapid in light than in the darkness
as well as at branches and at massive colonies.^1";

reefs, cryptic habitats; <b>Systematics: </b>Porifera Monera;
Corallina; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Indo-Pacific^The results on distribution patterns of the three most
important coralline sponge taxa and related microbialites from
Indo-Pacific coral reef caves are presented. The stromatoporoid taxon
Astrosclera, the chaetetid Acanthochaetetes, and the thalamid Vaceletia
are not equally distributed throughout the investigated areas.
Distinctive distribution patterns were observed. All taxa are living in
cryptic habitats, but Astrosclera was also found in dim-light zones and
shaded overhangs. The related microbialites vary in relation to the
sedimentological setting of the environment. Very well developed
microbialites were found in environments influenced by the weathering
of crystalline basement rocks (e.g. Lizard Island) and deep large caves
within a carbonate basement (e.g. Marigondon Cave, Cebu &#47;
Philippines). Poorly developed microbialites were observed in open
oceanic environments with carbonate basement rocks (e.g. Osprey Reef
and reefs of the outer Great Barrier Reef).^1";

Astrosclera; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Indo-Pacific^Astrosclera
willeyana Lister 1900 is a pyriform-half spherical, predominantly
bright orange colored, coralline demosponge with a mean size of about
20 mm in height and maximum head diameter. The habitat of Astrosclera
is generally restricted to cryptic and light reduced environments of
the Indo-Pacific, found mainly in reef caves, but sometimes also in the
dim-light areas of cave entrances and overhangs, where it is green
colored at the side towards the light. Caves of Indo-Pacific coral
reefs were divided into four major facies zones, named 1 to 4 with
decreasing light intensities. Astrosclera occurs in reef caves on a
carbonate basement in Zone 2, 3, and 4, reaching maximum abundance in
Zone 3 and the proximal part of Zone 4, but rare in the distal, very
dark areas of Zone 4. Other abundant coralline sponges in reef caves
are Spirastrella (Acanthochaetetes) wellsi and Vaceletia crypta.
Astrosclera is the most common coralline sponge throughout the studied
sites of the Indo-Pacific.^1";

Previously known Indo-Pacific species of this genus mostly have broad distributions. The newly described species have been overlooked because they have more restricted distributions and in some cases they occur in deeper, rarely sampled, habitats; they thus contribute new information for assessment of the ecology and distribution patterns of the genus. Seven of the new species have low numbers of radial corallites relative to axial corallite number, a
```

```
phenomenon uncommon amongst wellknown (and widely distributed) species.
It is suggested that this character would result in low reproductive
output and may be responsible for the limited range of the species
concerned. The new species are assigned to existing species-groups and
a new species-group is suggested to accommodate two new species and
three other valid species.^1";
s[4387] = "STEFANI F., BENZONI F., PICHON M., CANCELLIERE C., GALLI P.
(2008).- A multidisciplinary approach to the definition of species
boundaries in branching species of the coral genus Psammocora
(Cnidaria, Scleractinia).- Zoologica Scripta 37, 1: 71-91.-
<b>FC&#038;P 36</b>, p. 107, ID=6538^<b>Topic(s): </b>molecular data,
taxonomy; Scleractinia Psammocora; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Indo-Pacific^The Indo-Pacific coral genus Psammocora Dana (1846)
has never been formally revised, and its phylogeny has only been
partially explored. Several synonymies have been proposed for the 11
nominal species which have highly plastic branching growth forms. In
the present study, the definition of genetic and morphologic boundaries
among three currently recognized branching morpho-species, Psammocora
stellata, Psammocora contigua and Psammocora obtusangula, is addressed
through a joint morphometric and molecular study using corallite and
branch measurements, and a portion of the &#946;-tubulin gene as a
marker. The results show a morphological and partial phylogenetic
distinction between P. stellata specimens and a complex composed of P.
contigua and P. obtusangula, which is interpreted as a synonym species
of P. contigua. Among the factors that could be responsible for the
lack of reciprocal monophyly of the three species, hybridization is
considered the most likely, due to the presence of interspecific
recombinant sequences. Type material of nominal species of branching
Psammocora is examined and classified based on genetically defined
groups, and compared with synonyms in the literature. Among the
morphological characters used, corallite variables were best for
discriminating between the two lineages and allow recognition of
putative hybrid specimens. Psammocora stellata is reported for the
first time in the western Indian Ocean (Mayotte), thus greatly
extending its known distribution range. Finally, a hybrid swarm is
identified in the Arabo-Persian Gulf, while no genetic structure is
detected elsewhere in the Indo-Pacific region. [original abstract]^1";

Scleractinia Mussidae; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Atlantic, Pacific^Recent
molecular analyses have challenged the traditional classification of
scleractinian corals at all taxonomic levels suggesting that new
morphological characters are needed. Here we tackle this problem for
the family Mussidae, which is polyphyletic. Most of its members belong
to two molecular clades composed of: (1) Atlantic Mussidae and Faviidae
(except Montastraea) and (2) Pacific Mussidae (Cynarina, Lobophyllia,
Scolymia, Symphyllia) and Pectiniidae. Other Pacific mussids (e.g.
Acanthastrea) belong to additional clades. To discover new characters
that would better serve as phylogenetic markers, we compare the
skeletal morphology of mussid genera in different molecular-based
clades. Three sets of characters are considered: (1) macromorphology
(budding; colony form; size and shape of corallites; numbers of septal
cycles), (2) micromorphology (shapes and distributions of septal teeth
and granules), and (3) microstructure (arrangement of calcification
centres and thickening deposits within costosepta). Although most
traditional macromorphological characters exhibit homoplasy, several
new micromorphological characters are effective at distinguishing
clades, including the shapes and distribution of septal teeth and
granules, the area between teeth, and the development of thickening
deposits. Arrangements of calcification centres and fibres differ among
clades, but the fine-scale structure of thickening deposits does not.

Scientific Results from Investigations of Microbial Borers and
Bioerosion in Reef Environments.- Goettinger Arbeiten zur Geologie und
Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038;
Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation
I. Reef Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 30,
ID=3581^<b>Topic(s): </b>reef complexes, microbial borers, bioerosion;
reef complexes; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Atlantic, Pacific^Experimental investigations at
research sites in the Atlantic and Pacific have been designed to assess
the factors that influence the distribution and abundance of
microborers in reef environments. Results from the Bahamas indicate
that site, depth, substrate type, and length of exposure period are
important in controlling microborer populations and their rates of
bioerosion. Cyanobacteria dominate intertidal limestones, a diverse
assemblage of chlorophytes and cyanobacteria characterizes sites at
depths between 2-30m, and the chlorophyte Ostreobium quekettii and
heterotrophs are present from 100 to 300m water depth. Macrobioerosion
by grazers and borers also show site and depth differences.
Investigations of experimental nutrient enrichment on the Great Barrier
Reef suggest that the impact of the treatments on bioeroders may be
masked by the natural nutrient levels within the endolithic habitat.^1";

middle, odp site 639^1) The generic identification suggested for the
corals studied in thin section from hole 639D includes Stylosmilia,
Enallhelia, Pseudocoenia, Trocharea, Microsolena, cf. Calamoseris, cf.
Dimorphastraea, Fungiastraea, cf. Thecosmilia, cf. Calamophylliopsis,
cf. Dermosmilia, Lochmaeosmilia, and Intersmilia. 2)The sampling,
though limited, emphasizes the importance of pennular and stylinid
corals in the diversified coral collection. 3) The presence of
Stylosmilia pumila (Quenstedt) indicates a Late Jurassic age, which
does not contradict the presence of the other genera recorded. 4) The
occurrence of the corals at hole 639D is episodical. At the base (cores
103-639D-13R through 103B-639D-11R, 103B-639D-8R, and 103-639D-7R), the
corals are rare, tiny fragments that occur as oncoid nuclei or
micritized grains. Their appearance indicates corrosion through
transport from small colonies in muddy environments. In cores
103-639D-4R and 103-639D-5R, corals are common and are associated with
calcareous and siliceous sponges, echinoderms, agglutinated benthic
foraminifers, bivalves, and some calpionellids. They are in situ and
although commonly heavily bored, definitely indicate that they were not
transported. 5) The microfacies of the corals from cores 103-639D-4R
and 103-639D-5R are characterized by a high content of mud; this mud
seems to have been initially calcitic. 6) The corals do not reveal the
proximity of a reef environment; rather, they were dwellers of soft
muddy substrates below wave activity. In cores 103-639D-4R and
103-639D-5R, the associated organisms suggest a depth range from 30 to
70 m below sea level.^1";

s[4401] = "De MOL B., KOZACHENKO M., WHEELER A., ALARES H., HENRIET
J.-P., OLU le ROY K. (2007).- Therese Mound: a case study of coral bank
development in the Belgica Mound province, Porcupine Seabight.-
International Journal of Earth Sciences (Geologische Rundschau) 96, 1:
103-120.- <b>FC&#038;P 35</b>, p. 96, ID=2419^<b>Topic(s): </b>reefs,
deep marine; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Oligocene - Quaternary; <b>Geography: </b>Atlantic, Porcupine
Bight^High-resolution seismic profiles, swath bathymetry, side-scan
sonar data and video imageries are analysed in this detailed study of
five carbonate mounds from the Belgica mound province with special
emphasis on the well surveyed Therese Mound. The selected mounds are
located in the deepest part of the Belgica mound province at water
depths of 950 m. Seismic data illustrate that the underlying geology is
characterised by drift sedimentation in a general northerly flowing
current regime. Sigmoidal sediment bodies create local slope breaks on
the most recent local erosional surface, which act as the mound base.
No preferential mound substratum is observed, neither is there any
indication for deep geological controls on coral bank development.
Seismic evidence suggests that the start-up of the coral bank
development was shortly after a major erosional event of Late
Oligocene-Quarternary age. The coral bank geometry has been clearly
affected by the local topography of this erosional base and the
```

```
prevailing current regime. The summits of the coral banks are
relatively flat and the flanks are steepest on their upper slopes.
Deposition of the encased drift sequence has been influenced by the
coral bank topography. Sediment waves are formed besides the coral
banks and are the most pronounced bedforms. These seabed structures are
probably induced by bottom current up to 1m/s. Large sediment waves are
colonised by living corals and might represent the initial phase of
coral bank development. The biological facies distribution of the coral
banks illustrate a living coral cap on the summit and upper slope and
decline of living coral populations toward the lower flanks. The data
suggest that the development of the coral banks in this area is clearly
an interaction between biological growth processes and drift deposition
both influenced by the local topography and current regime.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Cenozoic; <b>Geography:
</b>Atlantic E^This paper presents the results of a synthetic
compilation of the studies of Neogene marine deposits recognized on the
northeastern Atlantic coast from Morocco to northern France. The
shoreline fluctuations as well as the tectonic and climatic events are
discussed [...] * Marine Upper Chattian is well represented in the
Acquitaine Basin (France), with various facies formed in a tropical
climate. * During the Aquitanian and the Burdigalian, the
transgressions extended in wide neritic gulfs in France, Portugal,
Spain and North of Morocco. * The Middle Miocene transgression is well
pronounced in the different areas. In the Betico-Rifian realm,
overthrusts are established and the flysch resorption is concluded at
the end of that time. * During the Upper Miocene, the marine realm is
locally back from the preceding one; outstanding events occured in the
tectonic Betico-Rifian basin, the eastern part of which was affected by
the Mediterranean salinity crisis during the Messinian. * Finally, in
the Pliocene, most of the features of the modern palaeogeography are
evidenced, even when the coastal frontage of several areas is still
affected by little transgressions. [excerpts from original abstract]^1";

</b>Bermuda^Records of skeletal &#948;18O in monthly and Sr/Ca ratios
in half-yearly resolution were obtained from a Bermuda coral (Diploria
labyrinthiformis) for the time period 1520-1603 (± 15 yr) AD within the
Little Ice Age. Annual and decadal averages of both sea-surface
temperature proxis indicate temperature variabilities of 0.5°C
(standard deviation) and 0,3°C, respectively. Both numbers are close to
recent instrumental observations. Approximately 30% of the interannual
time series variance of &#948;18O is concentrated in broad bands
centered at periods of ~ 30, 16 and 7.8 yr, the last two reflecting the
influence of the North Atlantic Oscillation. Although this large-scale
climate signal is present in the record, there is no correlation with
other contemporaneous northern hemisphere proxy data, resulting from
spatial differences in climate variability.^1";
s[4411] = "MOL B.de, RESBERGEN P.van, PILLEN S., HERREWEGHE K.van,
ROOIJ D.van, McDONELL A., HUVENNE V., IVANOV M., SWENNEN R., HENRIET
J.P. (2002).- Large deep-water coral banks in the Porcupine Basin,
southwest of Ireland.- Marine Geology 188, 1-2: 193-231.- <b>FC&#038;P
32-1</b>, p. 33, ID=1738^<b>Topic(s): </b>reefs coral banks; coral
buildups; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Atlantic E^The Porcupine Basin, southwest
of Ireland, was one of the earliest sites from where the deep-water
corals Lophelia sp. and Madrepora sp. were recovered. These deep-water
corals have since been found all along the Atlantic margins of Europe,
in water depths ranging from 50 to more than 2000m. Recent geophysical
studies have demonstrated the mound-building potential of deep-water
corals. Available data indicate that three major provinces of coral
bank occurrences can be identified in the Porcupine Basin: (1)
high-relief surface mounds which have a dimension of 1 by 5km and a
height up to 200m (&#039;Hovland&#039; mounds), flanked to the north by
(2) a swarm of buried mounds, somewhat smaller (up to 90m), and with
more irregular shapes than those recognised in area 1
(&#039;Magellan&#039; mounds), and (3) outcropping or buried, conical
mounds (single or in elongated clusters, up to 150m high) occurring on
the southeastern slope of the basin (&#039;Belgica&#039; mounds). As
far as can be inferred from shallow cores, the surface lithology
predominantly consists of an upper layer rich in foraminiferal sand and
terrigenous silty clay with intercalations of biogenic rubble. The
banks host a remarkable number of colonies of living and dead Lophelia
pertusa and Madrepora oculata. The living and dead assemblages are
underlain by a significant layer of coral debris in a muddy matrix.
Deep-water coral debris together with a living association of the same
species covers the surface of the &#039;Belgica&#039; and
&#039;Hovland&#039; mounds, which may suggest that these corals have
played a significant role in the development of the mound structures.
The capacity for mound formation by scleractinian corals in the aphotic
zone has been known for some time. Examples are found at different
locations along the shelves and the continental margins of the North
Atlantic. The role of the corals in these deep-water build-ups is still
a point of debate. Though the genesis and initial control of mound
settings in this basin might be related to hydrocarbon seeps, it
appears that the major development of the Porcupine coral banks in
recent geological times has most likely been controlled by oceanic
circulation and dynamics in water masses and nutrient supply. [original
abstract]^1";

carbonate mounds, owing their presence mainly to the framework building
```

```
coral Lophelia pertusa and the activity of associated organisms, are
common along the European margin with their spatial distribution
allowing them to be divided into a number of mound provinces. Variation
in mound attributes are explored via a series of case studies on mound
provinces that have been the most intensively investigated: Belgica,
Hovland, Pelagia, Logachev and Norwegian Mounds. Morphological
variation between mound provinces is discussed under the premise that
mound moprhology is an expression of the environmental conditions under
which mounds are initiated and grow. Cold-water coral carbonate mounds
can be divided into those exhibiting &#34;inherited&#34; morphologies
(where mound moprhology reflects the moprhology of the colonised
features) and &#34;developed&#34; moprhology mainly reflecting dominant
hydrodynamic controls). Finer-scale, surface morphological features
mainly reflecting biological growth forms are also discussed.^1";

1880. Pourtalès did not designate a holotype for A. tanacetum, nor did
he indicate which form he thought was the most &#34;typical&#34; of the
species. Because of the similarities of some of the syntypes with other
nominal species, it is necessary to select a lectotype from one of the
two groups with predominantly uniserial pinnulation. A specimen with
short curved primary pinnules was chosen because it has a very
distinctive pinnulation pattern that has been previously associated
with Tanacetipathes tanacetum. With a lectotype of T. tanacetum
designated, potential new species of Tanacetipathes can now be
evaluated and compared directly with the type species. This is the case
for T. paula n.sp., which is described here from the littoral of
Archipelago of Saint Peter and Saint Paul (Brazil). This species has a
corallum pseudo-dichotomously branched, with primary pinnules arranged
in four rows and in alternating biserial groups of two pinnules each.
The primary pinnules are up to 1.9cm in length. The secondary pinnules
usually occur bilaterally, on both sides of the primary pinnules, and
often in subopposite pairs, especially near the base of the primary
pinnules. There are usually 3-9 secondary pinnules per lateral primary
pinnules. The anterior primary pinnules always with only two secondary
pinnules arranged in subopposite pair nearer the base of primary. The
axial spines are relatively large, conical, acute and slightly
papillose; the polypar spines up to 0.25mm tall and abpolypar spines up
to 0.17mm. Polyps are not present on the type specimen.^1";
s[4415] = "URIZ M.-J., MALDONADO M. (1996).- The genus Igernella
(Demospongiae: Dendroceratida) with description of a new species from
the central Atlantic.- Bulletin de l&#039;Institut royal des sciences
naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.):
Recent advances in sponge biodiversity inventory and documentation]:
153-163.- <b>FC&#038;P 25-2</b>, p. 30, ID=3110^<b>Topic(s): </b>new
taxa; Porifera Demospongiae; <b>Systematics: </b>Porifera;
Demospongiae; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Atlantic
central^The genus Igernella Topsent, 1905 includes those dendroceratid
sponges characterised by an irregularly reticulate skeleton arising
from a spongin plate and the presence of diactinal, triactinal, or
tetractinal spiculoids. To date, two species of this genus are
```

```
described : Igernella mirabilis Levi from the Indo-Pacific and
Igernella notabilis (Duchassaing and Michelotti) from the central
Atlantic. A re-examination of material previously assigned to the
genera Igernella and Darwinella allowed us to detect the existence of a
second species of Igernella in the central Atlantic. Igernella
vansoesti sp.nov. is erected to include the specimens from the Cape
Verde Islands assigned to I. notabilis by Van Soest (1993), and one
specimen from the Gulf of Mexico formerly recorded under the name
Darwinella muelleri Schulze by De Laubenfels. The specimen described as
Darwinella joyeuxi Tosent by Little (1963) probably belongs to this
species as well. The new species is distinguishable from I. notabilis
by its massive growth habit -without conspicuous tubes-, a minutely
conulose surface, small oscules, and a skeletal network, made of narrow
primary and secondary fibres, denser than that of I. notabilis. There
is an important amount of foreign material embedded in the mesohyl
whereas it is scarce within the fibres or even absent. The absence of
debris in the fibres of some species of Igernella suggests a close
relationship between this genus and other genera of the family
Darwinellidae. This is in agreement with a recent proposal of moving
the genus Igernella from the family Dictyodendrillidae to the family
Darwinellidae on the basis of their chemical affinities. [original
abstract]^1";
s[4416] = "HAJDU E., SOEST W.M.van (1992).- A revision of Atlantic
Asteropus Sollas 1888 (Demospongiae), including a description of three
new species, and with a review of the family Coppatiidae Topsent 1898.-
Bijdragen tot de Dierkunde 62, 1: 3-19.- <b>FC&#038;P 22-2</b>, p. 91,
ID=3537^<b>Topic(s): </b>taxonomy; Porifera Demospongiae;
<b>Systematics: </b>Porifera; Demospongiae; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Atlantic^Various records of A. simplex
Carter 1879 from the Atlantic are assigned to three new species of the
sponge genus Asteropus Sollas 1888, viz.: A. brasiliensis sp.n., A.
vasiformis sp.n., and A. niger sp.n., whereas A. simplex s.s. is
restricted to the Indo-Pacific. A worldwide study of Asteropus
specimens resulted in the conclusion that two species groups exist,
namely &#34;simplex&#34;-like species (with true sanidasters), and
&#34;sarasinorum&#34;-like species (with spiny microrhabds), as
previously observed by Bergquist (1965, 1968). A newly discovered
microsclere complement of trichodragmata in the first group strengthens
the need for generic distinction of both lineages, and accordingly the
name Melophlus Thiele 1899 is reinstated for the &#34;sarasinorum&#34;
species group. A key to the west Atlantic species of Asteropus is
provided. The family allocation of Asteropus and associated genera in
the Coppatiidae Topsent 1898 is discussed, with the conclusion that the
family is undoubtedly a polyphyletic assemblage related to various
astrophorid groups (Hooper 1986; van Soest 1991).^1";
s[4417] = "MEHL D., REITNER J., REISWIG H.M. (1994).- Soft tissue
organization of the deep water hexactinellid Schaudinnia arctica
Schulze 1900 from the Arctic Seamount Vesterisbanken (Central Greenland
Sea).- Berliner geowissenschaftliche Abhandlungen E13: 301-313.-
<b>FC&#038;P 23-2.1</b>, p. 60, ID=4416^<b>Topic(s): </b>histology;
Porifera Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Arctics
Vesterisbanken^Histology and ultrastructure of the hexactinellid arctic
deep sea sponge Schaudinnia arctica are investigated. Various
techniques of fluorescence microscopy proven to be very informative for
the study of pofiferan soft tissues are applied. These methods for use
in sponge research are explained in detail. The histology shows that
Schaudinnia arctica on the whole corresponds with earlier models of
hexactinellid organization. However, the collagenous mesolamella are
surprisingly thick compared with those of other hexactinellids
described so far. Spectacular accumulations of granular cells with
larger inclusions are observed throughout the entire sponge body.
Transitional cell types indicate an ontogenetic succession from
```

```
archaeocytes to granular cells in Schaudinnia arctica. According to
observations in UV-fluorescence microscopy with different staining
methods, the large inclusions of these granular cells contain little
glycogen, but high Ca2+-contents. According to comparisons with similar
cells of demosponges, it is suggested that the granular cells may
function as storage cells for lectins, which play an important role in
the metabolism of sponges.^1";
s[4418] = "WISSHAK M., LOPEZ CORREA M., ZIBROWIUS H., JAKOBSEN J.,
FREIWALD A. (2009).- Skeletal reorganisation affects geochemical
signals, exemplified in the stylasterid hydrocoral Errina dabneyi
(Azores Archipelago).- Marine Ecology Progress Series 397: 197-208.-
<b>FC&#038;P 36</b>, p. 135, ID=6598^<b>Topic(s): </b>geochemical
signals; Hydrozoa, Errina; <b>Systematics: </b>Cnidaria; Hydrozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Azores^The pure white
fans of the stylasterid Errina dabneyi are a conspicuous feature on the
upper bathyal slopes in Azorean waters and were documented and
recovered alive with the aid of a submersible in the southern Faial
Channel. Etched vacuum-epoxy-casts of the aragonite skeleton, studied
by scanning electron microscopy, reveal the 3-dimensional internal
architecture comprising coenosarc canal meshwork, dactylopores,
gastropores and ampullae. Near the surface, the canals are narrow and
interconnected in a regular 3-dimensional meshwork. Deeper inside, the
canals are less abundant, more irregular and wider. This pattern
implies that the skeletal architecture is modified during growth, with
more central canals being enlarged by dissolution, and other canals,
gastropores and dactylopores in turn being filled with aragonite
reprecipitates. The skeleton is primarily composed of irregular
spherulitic aggregates and overprinting during growth is evident from
ghost structures in the form of successive semi-spherulitic infill of
former canals. Due to differential dissolution and reprecipitation,
this internal rebuild process inevitably involves an alteration of
initial geochemical signatures such as stable isotope ratios (d18O and
d13C), trace element signals and the distribution of radiogenic
isotopes of carbon and uranium. This has to be taken into account when
applying radiometric dating techniques and when using stylasterids as a
geochemical archive. [original abstract]^1";
s[4419] = "ZIBROWIUS H., THORSEN M. (1992).- The Stylasteridae
(Cnidaria, Hydrozoa) of the BIOFAR project.- Northurlandahusith arsrit
1991-92: 78.- <b>FC&#038;P 22-1</b>, p. 44, ID=3413^<b>Topic(s):
</b>taxonomy; Hydrozoa, Stylasteridae; <b>Systematics: </b>Cnidaria;
Hydrozoa; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Faroe
Isls^Stylasteridae are calcified colonial hydroids. Their polyps are
differentiated into gastrozooids (feeding polyps) and dactylozooids
(defensive polyps) that are housed in the corresponding gastro- and
dactylopores of the skeleton. Taxonomy is essentially based on these
and other skeletal characters. There has been confusion of
Stylasteridae with Bryozoa, and vice versa. Previous records of
stylasterids are rare from around the Faroe islands and adjacent areas,
where the earliest records date back to 19th century expeditions.
BIOFAR has now provided abundant new information on the stylasterid
fauna of Faroese waters. Four species have been collected from 54
stations (depth 133-1099m) around the islands: Pliobothrus symmetricus
Pourtales 1868, Stylaster erubescens Pourtales 1868, S. gemmascens
(Esper 1794), S. norvegicus (Gunnerus 1768). The two genera are
morphologically very different, Pliobothrus having gastro- and
dactylopores randomly arranged, Stylaster having gastro- and
dactylopores arranged in cyclosystems. Although containing only these
few species (previously recorded by the Danish INOOLF expedition in
1895/96 and studied by Broch in 1914), the BIOFAR collection is the
richest and includes all species ever obtained in high latitudes of the
N Atlantic. S. gemmascens and S. norvegicus occur only from Norway to
Denmark Strait, Rockall plateau being the southern outpost. On the
contrary, P. symmetricus recorded from Norway to SE of Iceland and S.
```

```
erubescens recorded from the Faroes to Denmark Strait, also occur at much lower latitudes in the N Atlantic and are even amphiatlantic in distribution, a pattern rare in this group of corals if compared with the scleractinians. The high latitude populations of S. erubescens differ in some details from the typical low latitude ones of the W Atlantic (Yucatan through Florida to South Carolina). Polynoid polychaetes and Pedicularia gastropods, known to be frequent symbionts of stylasterids world-wide, are absent from the high latitudes (northernmost occurrence of Pedicularia on P. symmetricus and S. erubescens at 48°38&#039;N in the Celtic Sea). Distribution of stylasterids in relation with water masses in the N Atlantic deserves special attention. Previously available data on occurrence in high latitude suggested that stylasterids do not occur deep in the Arctic basin beyond a line connecting, roughly, Norway, the Faroes, Iceland and Greenland. [fragment of extensive abstract] ^1";

E. Verrill. Verrill (1839-1926) was one of the most prolific and influential marine invertebrate zoologists of the late nineteenth and early twentieth centuries, having published over 350 papers in which he described over 1000 new species pertaining to almost every marine group. When he died at the age of 87 he left behind an unfinished monograph on the western Atlantic octocorals consisting of over 1000 pages of text and 156 meticulously drawn plates, much of the artwork done by Verrill&#039;s son Alpheus Hyatt Verrill. The text was lost, but over the years Dr. Frederick (Ted) Bayer, curator emeritus in the Department of Zoology, accumulated a unique, complete set of plates and a copy of Verrill&#039;s captions to those plates, in which Verrill alludes to the names of several hundred new taxa. Bayer painstakingly reassembled the plates, transcribed and annotated the captions, and then had 55 copies of the work published for general distribution. Thus, 78 years after his death, at least a part of Verrill&#039;s magnum opus can be used to help illustrate the deep-water western Atlantic octocorals, this work constituting the last publication of this prolific naturalist. The plates alone constitute an invaluable resource on the taxonomy of this group, and should be consulted by any serious student of the group.^1";

Specimens from a number of localities have been analyzed for oxygen and stable carbon isotope composition and 14C age. Stable isotope ratios of recent corals provide information on growth rate and seasonality of oceanographic conditions. Lophelia can be useful in paleoenvironmental reconstructions. 14C dates of fossil Lophelia from Dribak in the Oslofjord, collected from 20 m above and 40 m below present day sea-level, indicate regional extinction between 8700 and 7800 years ago. We suggest that the extinction resulted from the cut-off of deep waters by a rising sill in connection with the postglacial shoreline displacement. Radiocarbon dating of coral bushes suggests a fairly rapid growth rate as older and younger parts of recent corals do not reveal any difference in activity despite the short time scale of the history of bomb-produced 14C in the oceans.^1";

</b>hydrocarbons seepage; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Norway^Large (up to 31-meter high) coral banks (or bioherms) occur
on the continental shelf off mid-Norway at water depths between 220 and
310 meters. They are built up by the cold-water, ahermatypic,
scleractinian coral Lophelia pertusa (L.). A 3-km-wide and 200-km-long
traverse was mapped geophysically across a large part of the mid-Norway
shelf. A total of 57 suspected individual banks were found. Although
they occur in local clusters of up to 9 banks per km2, the mean density
along the whole transect is only 0.09 suspected banks per km2, with the
highest regional density (1.2 banks per km2) occuring above subcropping
presumed Paleocene bedrock. A detailed investigation employing an ROV
(remotely operated vehicle) was conducted of a cluster consisting of 9
individual banks. Based on geophysical, visual, geochemical,
radiocarbon, and other analyses, we conclude that at least some of the
coral banks have been forming at the same locality for over 8,000
years, and that there is a strong correlation between coral-bank
occurrence and relatively high values of light hydrocarbons (methane,
ethane, propane, and n-butane) in near surface sediments. To explain
the structure and distribution of these coral banks, we propose a model
where they form as a consequence of local fertilization that results
from focused hydrocarbon micro-seepage of deep thermogenic hydrocarbons
migrating to the surface along inclined, permeable sedimentary strata.
A direct corollary of this model is that if and when the source of
local fertilization is shut off, the bioherms die out. This possibly
could be the reason why extinct bioherms are more common than live ones
in some areas of the ocean.^1";
s[4434] = "ZIBROWIUS H. (1974).- Redescription of Sclerhelia hirtella
from Saint Helena, South Atlantic, and remarks on Indo-Pacific species

considérations générales sur les Flabellidae (Scléractiniaires).-
Bulletin Inst. Océanogr. 71, 1429: 1-48.- <b>FC&#038;P 4-1</b>, p. 27,
ID=5089^<b>Topic(s): </b>review; Scleractinia, Flabellidae;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Azores^Des représentants du genre
Javania, essentiellement bathyaux, sont très répandus dans la faune
actuelle du monde entier. Une nouvelle espèce, J. pseudoalabastra, est
décrite d&#039;après du matériel des Açores (récolté en partie en 1888,
par le Prince Albert Ier de Monaco). Confondu longtemps avec le genre
Desmophyllum, le genre Javania doit être attribué à la famille des
Flabellidae. Jusqu&#039;à présent, l&#039;absence d&#039;exosarque
avait été considérée comme un caractère principal de cette famille. Or,
cette conception est à modifier. Chez Javania, la fixation au substrat
est renforcée par des couches massives concentriques de sclérenchyme
qui entourent le pédoncule original. Un exosarque doit être à
l&#039;origine de ce sclérenchyme. * Les genres précédemment reconnus
par les auteurs dans la famille des Flabellidae sont commentés; une
proposition pour redistribuer en neuf groupes les formes actuelles de
cette famille est faite. Un tableau comparatif résume les caractères

Bahia^Contrasting with what is known about the growth of coral reefs in
clear waters with minimal runoff of fresh water and sediment from land,
the coastal reefs of Abrolhos, the fringing reefs around the Itaparica
Island and the coral constructions at the Guarajuba Beach are
surrounded and even infilled with muddy terrigenous sediments.
Radiocarbon dates from a Holocene core boring revealed that the reefs
accumulated at an average comparable with the average of growth of
coral reefs in clear waters. This surprisingly demonstrated that the
reef organisms, of the studied areas, are adapted to the previous
accepted conditions of an unhospitable environment for reef growth.
Yet, the growth forms of the reefs, the strong endemism of their coral
fauna as well as the effects of the Quaternary history of the area,
make these reefs quite different from the well known Caribbean
models.^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Brazil, Bahia^The Itaparica reef, in very shallow waters, has a
flat top which stays exposed during low tides. The reef front lacks the
&#34;Spur and Groove&#34; system and the back reef zone is represented
by extremely shallow lagoons without patch reefs. Millepores and
coralline algae contribute more to this reef than in the Caribbean
reefs. In contrast with the predominance of carbonate sediments
surrounding most reefs in the North Atlantic, the Itaparica reef is
surrounded by sediments with a high amount of siliciclast components.
An intensive activity of burrow and boring organisms is detected in the
reef area, between the localities of Gamboa and Penha. Molluscs,
annellids, sipunculids and arthropods produce distinctive boring
structures on the reef structure and rock outcrops in the studied area.
Communities of Decapoda (Crustacea), Gastropoda and Polychaeta are the
major organisms responsible for excavations, pellets, fecal pipes and
track dirts on the sandy and muddy substrates. The limitation of every
of these communities can be easily defined, however, superpositions
exist in the intertidal zone. [abridged original abstract]^1";

```

```
the aphotic zone of deep shelf and continental margin settings in the
Northeast Atlantic are produced by deep-water coral reefs with Lophelia
pertusa as the major framework builder. Through a compilation of side
scan sonar, airgun and manned submersible surveys from several cruises
to the mid-Norwegian Sula Reef Complex (SRC), the facies pattern and
zonation of one of the largest deep-water reefs in the Northeast
Atlantic is described in realation to the overall seabed topography.
The late glacial to early postglacial iceberg scour on the crest and
shoulder of the Sula Ridge provides settling ground for the
scleractinian corals already in the early Holocene. Since then coral
growth continues until today but was supposed to be disturbed by an
environmental hazard, the so-called second Storegga event. The distinct
distribution pattern of individual Lophelia reefs on the Sula Ridge has
stimulated a discussion on intrinsic environmental controls such as the
bentho-pelagic coupling and the alternative hydrocarbon-based nutrition
hypothesis.^1";

accretion along a steep, shelf-edge reef, St. Croix, U.S. Virgin
Islands.- Journal of Sedimentary Petrology 56, 6: 848-861.-
<b>FC&#038;P 16-1</b>, p. 72, ID=2008^<b>Topic(s): </b>reef accretion;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>USA, Virgin Islands^Seven horizontal cores were taken from the
reef-dominated margins of Salt River submarine canyon, St. Croix, U.S.
Virgin Islands at water depths of 14-30 m. The pattern of east-to-west
sediment transport in the area exerts a major control on present-day
reef morphology, as well as accretionary styles recorded in the cores.
Coral growth is inhibited by sedimentation on much of the eastern
(heavily stressed) margin, and slopes are gentle. The regular pattern
of alternating reef growth and sedimentary infill in the eastern cores
reflects this highly variable environment. On the west wall, away from
the source of incoming bedload sediment, coral cover is much greater,
and a vertical reef wall forms the canyon margin. Slumping of the steep
reef face has caused numerous repetitions of section and, in some
instances, accretion rates higher than the growth rates of calcifying
organisms occupying the present or past reef surface. This slumping
process, along with the highly dissected character of the reef, results
in larger sections of reef framework separated by open or
sediment-filled vugs and caverns. 14C dates indicate that this complex
constructional history has resulted in at least 24 m of lateral
accretion during Holocene time. Average lateral-accretion rates in the
cores varied from 0.84 to 2.55 m/1,000 yr, with the highest rate
occurring in the core from deepest water. Intervals of rapid accretion
within the cores were not generally related to patterns of in situ
coral growth, but rather with intervals of allochthonous material
slumped from the shallower portions of the reef complex. The character
of the cores illustrates the potential importance of detrital material
and late-stage reworking in the accretion of shelf-edge reefs. The high
rates of accretion at depth highlight potential problems with reef
models based on net accretion paralleling the abilities of the
present-day surface organisms to produce calcium carbonate.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Quaternary; <b>Geography:
</b>Atlantic, Porcupine Bight^High resolutions studies from the
Propeller Mound, a cold-water coral carbonate mound in the NE Atlantic,
show that this mound consists of &#62; 50% carbonate justifying the
name &#039;carbonate mound&#039;. Through the last ~ 3000,000 years
approximately one third of the carbonate has been contributed by
cold-water corals, namely Lophelia pertusa and Madrepora oculata. This
coral bound contribution to the carbonate budget of Propeller Mound is
```

```
probably accompanied by an unknown portion of sediments buffered from
suspension by the corals. However, extended hiatuses in Propeller Mound
sequences only allow the calculation of a net carbonate accumulation.
Thus, net carbonate accumulation for the last 175 kyr accounts for only
less than 0,3 g/cm2/kyr, which is even less than for the off-mound
sediments. These data imply that Propeller Mound faces burial by
hemipelagic sediments as has happened to numerous buried carbonate
mounds found slightly to the north of the investigated area.^1";
s[4452] = "LOGAN A. (1988).- Holocene Reefs of Bermuda.- Sediments 11:
1-62.- <b>FC&#038;P 18-2</b>, p. 49, ID=2515^<b>Topic(s): </b>reefs;

<b>Geography: </b>Bermuda^Reefs of the Bermuda Pedestal, well north of
the Carribean reef province, have interested scientists since Darwin.
The attributes of these reefs, unique to the Atlantic-Carribean area,
are well documented in this new guidebook. The text of this slim volume
begins with six single spaced pages of introduction, regional geology,
and previous studies followed by seven pages of description outlining
the nature of the reefs themselves, their coelobite communities, and
their relationship to Carribean reefs and concludes with six pages
discussing the biotic factors which affect the reefs, their diagenesis,
and their associated sediments. This is followed by a welcome 12 pages
of references. The eight diagrams and 29 photographs (underwater and
aerial closeups of the reefs) are on glossy paper and grouped together
after the references. Appendix I outlines three whole-day reef trips
with a description of each stop. Appendix II is a list of the corals in
Bermuda while Appendix III is a key to the corals together with
pictures of 18 corals which can be used for identification. This is a
clearly printed and easily readable book. It is a scholarly work, an
excellent source of up-to-date information on Bermuda reefs by someone
who has studied these reefs for over a decade. As such it is both a
handy guide and a handy reference. I would have liked slightly larger
photographs and interwoven text and figures/photographs, but at this
price who can complain. I am writing this review at the Bermuda
Biological Station in the final days of a field trip with students and
so have &#034;field tested&#034; this guide. If you are planning such a
trip this book is a must, if you are at all interested in living reefs
I highly recommend this inexpensive publication. [revieved by Noel P.
James]^1";

Lophelia pertusa around the Faroes.- Northurlandahuith arsrit 1991-92:
79 pp.- <b>FC&#038;P 22-1</b>, p. 39, ID=3399^<b>Topic(s): </b>reefs,
biology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Faroe Isls^Banks of Lophelia pertusa have been
recorded at several localities round the Faroe islands concentrated on
the edges of the banks and the Faroe shelf at depths between 250 and
400m.Coral formations can exceed hundreds of metres in width and tens
of metres in height. Lophelia pertusa is a colonial, branching,
ahermatypic coral. The coral bank is inhabited by a rich associated
fauna. We have examined more than 5700 individuals belonging to 301
species from 18kg of coral. Of the list of 301 associated species, 97
```

```
are new to &#34;The Zoology of the Faroes&#34;. The associated fauna
has a calculated Shannon-Wiener diversity index of 5,26. This is
similar to that found on tropical coral species. This indicates that
Lophelia coral banks has a link to productive high energy areas. The
living part and the dead part of Lophelia pertusa house different
species. Specialized species are capable of resisting the defence of
the living coral. Typically, the number of individuals is much higher
on dead coral blocks. Polychaete are the dominating group on the coral
bank. We found 72 species and more than 1800 individuals. Sessile
epibionts are the most numerous organisms on Lophelia pertusa. A lot of
these are colonial species, which we have not quantified. The active
filter feeders are the most numerous group of feeding types on the
coral bank. Decomposition of the corals is carried out primarily by 2
species of boring sponges that erode the coral branches from inside.
Comparing the fauna from Lophelia pertusa in the Faroe area with other
studies on Lophelia fauna we find about the same number of species on
Norwegian and French Lophelia banks. It appears that the associated
fauna is rather facultative than being an obligate Lophelia fauna.^1";

A., STEINMETZ S., DIETRICH P., THIEDE J., (1992).- Facies belts and
communities of the Arctic Vesterisbanken Seamount (Central Greenland
Sea).- Facies 27: 71-104.- <b>FC&#038;P 22-1</b>, p. 53,
ID=3427^<b>Topic(s): </b>carbonates; carbonates; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Greenland Sea^The Arctic
Vesterisbanken Seamount, situated far offshore in the central Greenland
Sea, provides a unique facility for studying modern cold water
siliceous carbonate deposits. A nearly year round sea ice cover, which
retreats on average only during two months, and a rather constant
temperature and salinity structure of the water column characterize the
Arctic conditions of the area. Despite predominantly oligotrophic
conditions with a pronounced food supply from the pelagic realm only
during the ice-free season, the seamount is covered extensively by
extended sponge-bryozoan constructions. Three distinct facies belts
reveal a pronounced depth zonation which depends on variations in
downslope food transfer and which is specifically effective due to the
development of a Taylor current regime over the seamount. i) the crest
facies from the summit at -133m to -260m, ii) the shallow slope facies
from -260m to -400m, iii) the deep slope facies from -400m down to the
abyssal plain at about -3000m. Different biogenic structures and
communities are found within these facies belts, including widely
extended biogenic mats, sponge-bryozoans-serpulid buildups with mounds,
hedges, spurs and flatcake-like structures, bryozoan thickets and
sponge-crinoid mounds. Depth zonation, internal structure and
controlling parameters in the formation of these biogenic structures
are discussed in the context of their significance as a modern end
member of the Foramol facies and their implications for the fossil
record. In addition, the younger volcanic and hydrothermal history of
the seamount is presented with special reference to its bearing on
Holocene biogenic colonization patterns.^1";

C., ZANKL H., (1996).- Nordic Cold-Water Carbonates: Occurrences and
Controls.- Goettinger Arbeiten zur Geologie und Palaontologie, Special
Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and
Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp
???.- <b>FC&#038;P 26-1</b>, p. 24, ID=3567^<b>Topic(s):
</b>carbonates; carbonates; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Atlantic N^Along a latitudinal transect
from cool-temperate to Arctic environments, various carbonate
production zones were investigated. Biogenic carbonate sediments formed
on high latitudinal shelves of the northern Hemisphere became
established during the last glacial to interglacial transition. Major
sites of production are: 1) rocky coastal platforms with a complex
morphology providing habitats for coralline algae and kelp forests, 2)
the shallow shelf where intense mixing of nourished waters favors the
formation of bryozoan- or barnacle-dominated biocoenoses, 3) the deep
aphotic zone where topographically-guided gyres promote the development
of azooxanthellate coral mounds. True polar carbonate factories exist
along the flanks of the seamount Vesterisbank. Due to local
downwelling, bryozoan-siliceous sponge buildups benefit from the
bentho-pelagic coupling of food particle transfer. The largest open
shelf carbonate platform, the Spitsbergenbank, western Barents Sea, is
fringed by a distinct oceanographic frontal system, the Polar Front.
This oceanographic boundary is a local high-productivity area releasing
large fluxes of digestible particles which maintain huge quantities of
filter feeding communities especially barnacles, bivalves, benthic
foraminifera and bryozoans. Although carbonate production rates of
specific framework-producing organisms, such as coralline algae and
azooxanthellate scleractinians, fall in the magnitude of tropical reef
systems, the accumulation rate of bioclastic carbonates is much lower.
Generally, cool-temperate to Arctic carbonates consist of bioclastic
sands and gravels and sometimes mud. Cementation of carbonate particles
is sparsely developed and precipitation of internal sediments is almost
linked to decay of organic matrixes. Therefore, the hydrodynamic regime
and various forms of bioerosion play an intrinsic role in shaping the
skeletal carbonate particles postmortally.^1";

of coral reef zonation by terrigenous sediment stress.- Palaios 04:
92-100.- <b>FC&#038;P 23-2.1</b>, p. 64, ID=4423^<b>Topic(s):
</b>reefs, ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Puerto Rico^Four coral reefs near Ponce,
Puerto Rico were examined for the effects of terrigenous influx into a
reef environment. The four coral reefs are successively farther from a
point source of frequently occurring, westward-moving terrigenous
sediment plumes which are generated by resuspension of fine-grained
sediments. The coral cover was measured from linear photographic
transects parallel to each 5 meter depth. Living coral was marked on
each photograph, the species identified, and area of cover was measured
with a Jandel digitizer pad and SigmaScan program. Statistics were
compiled for percent cover by species, total cover, and number of
colonies. Total coral cover was reduced near the source of terrigenous
sediment influx. Coral cover and diversity increased with distance from
the source and amounts of sediment trapped on the reefs decreased,
suggesting that the plume influx was an important factor contributing
to the deterioration of these reefs. Sediment stress has drastically
reduced the coral cover and number of species. The reefs with high
sediment inputs showed decreased coral species diversity and percent
cover. Sediment-resistant coral species tolerated this adverse
environment and their percent of cover remained relatively constant.
The effects from sediment influx include partial or total burial of
coral colonies, bleaching, and colonization of the coral surface by
filamentous blue-green algae and sponges. The reduced light levels
resulted in domination of the community by deeper fore-reef coral.^1";

Considerably less numerous in species, they are also less known than scleractinian corals. Some stylasterids resemble bryozoans and other colonial scleractinians, convergences that have caused confusion in recent and ancient faunas, and may also have limited our knowledge of their geological record. 20 species in 6 genera are known in the northeastern Atlantic, only one of which also
```

```
occurs in the Mediterranean. All are described in detail, with abundant
illustrations of the colony shape and of the minute structures
essential for identification (illustrations include SEM stereo views).
In the study area various symbionts leave characteristic traces on the
stylasterid skeleton or cause modifications: the gastropod Pedicularia
(on 8 species) and polynoid and eunicid polychaetes (each on one
species). The reliable record of fossil Stylasteridae is scarce in
Europe and the Mediterranean basin (as it is elsewhere). It ranges from
the Lower Paleocene to the Plio-Pleistocene whereas Pedicularia, an
obligate symbiont of Stylasteridae, is known from the Messinian (Upper
Miocene) and from the Lower Pleistocene.^1";

N^From the northern margin of the Adriatic platform 22 species of
Paleocene corals belonging to 15 genera were systematically described.
Two species (Rhizangia padricensis and Goniopora hrpeljensis) are new.
* The most convenient circumstances for the beginning of coral growth
were at the edge of the platform near to the open sea. Here in Dolenja
was as first the local dendroid-phaceloid coral association thrived.
Then, toward the hinterland, perhaps in more stages, toward Sopada,
Padriciano, Hrpelje-Kozina, Golez to Breg, new generations of massive
and phaceloid corals settled which built smaller or larger patch reefs.
* Corals found in Adriatic platform can be compared with similar
findings of species in the wide area from Greenland to Volga and
Egypt.^1";

Oligocene-Miocene sea-surface temperatures: An approach based on coral
taxonomic richness.- Palaeogeography, Palaeoclimatology, Palaeoecology
258, 1-2: 71-88.- <b>FC&#038;P 35</b>, p. 103, ID=2433^<b>Topic(s):
</b>biodiversity, paleotemperatures; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Oligocene Miocene;
<b>Geography: </b>Mediterranean^During the Oligocene and Miocene,
shallow-water carbonates of the Mediterranean region were rich in
scleractinian corals thriving within various depositional settings,
including different reef types. Their diversity patterns, although
related to a complex interplay between a suite of environmental factors
and palaeobiogeography, are considered to be strongly controlled by
climate variability and changes in sea-surface water temperature. By
using the quantitative relationship between present-day coral taxonomic
richness and prevailing sea-water temperature, underlined by the
so-called &#034;energy hypothesis&#034;, we test zooxanthellate-coral
generic richness values from a selection of 102 Oligocene-Miocene
localities of the Mediterranean region as a proxy for relative
```

```
palaeotemperatures. For each Oligocene-Miocene stage, generic richness
values per z-coral site are firstly examined, together with variations
of the Mediterranean z-coral generic pool. For better testing the
method and assessing its potential application, patterns of generic
richness and inferred palaeotemperatures are then compared with global
palaeoclimatic curves based on marine oxygen stable isotopes data or
other climate proxies, such as palaeoclimatic records from European
continental floras and from fossil coral linear extension rate.Results
clearly show that fluctuations of coral richness-derived
palaeotemperatures correspond relatively well with global changes of
sea-water temperature especially for the entire Oligocene, the
Chattian-Aquitanian boundary and the Late Miocene. The well known
Mid-Miocene Climatic Optimum, however, is not recorded, suggesting that
regional factors, acting together with important palaeogeographical
changes, exerted a strong control on the generic richness of
Mediterranean z-coral communities.A remarkable decline of taxonomic
richness is recorded after the Burdigalian, together with a gradual
decrease of palaeotemperatures in the region. From the Middle Miocene
onwards to the Messinian, however, an increase in the temperature range
of z-coral localities is clearly visible, indicating that z-coral
communities were able to thrive and adapt to a wider temperature range,
as the Mediterranean was gradually migrating northwards, outside the
tropical belt.The &#034;energy hypothesis&#034;, if used at global or
regional scale, can be considered a promising and reliable method for
estimating Cenozoic palaeotemperatures, from coral or other suitable
fossil assemblages of shallow-water carbonates.^1";
s[4470] = "BUDD A.F., BOSELLINI F.R., STEMANN T.A. (1996).- Systematics
of the Oligocene to Miocene reef coral Tarbellastraea in the northern
Mediterranean.- Palaeontology 39, 3: 515-560.- <b>FC&#038;P 25-2</b>,
p. 52, ID=1475^<b>Topic(s): </b>variability, numerical analysis;
Scleractinia, numerical analysis; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Oligocene Miocene; <b>Geography:
</b>Mediterranean N^Multivariate statistical analyses are used to
distinguish species of the common reef-building coral Tarbellastraea at
Oligocene and Miocene localities within the Aquitaine Basin, western
Mediterranean, and central Paratethys regions; and to trace their
distributions through geological time. Thirteen measurements or counts
are made on thin sections of 126 colonies collected at 13 widely
scattered localities, whose geological ages are newly updated, The data
are analyzed using average linkage cluster analysis and canonical
discriminant analysis to distinguish clusters of colonies representing
morphometric species. Names are assigned by qualitatively comparing
measurements on the statistically recognized species with those of
primary types of all previously described species of Tarbellastraea.
The results show that Tarbellastraea originated during the Oligocene
(Rupelian) and became extinct during the Early Messinian. A total of 12
species (including two new species from the Italian Oligocene, and two
species described previously as varieties) lived in the investigated
areas during Oligocene and Miocene time. Except during the Oligocene,
all but one species (T. ellisiana) were widespread. Although species
richness within the genus remained constant at 5-7 species throughout
much of its stratigraphical range, morphological disparity decreased
significantly through tune. The observed constancy in richness
contrasts with the decrease reported overall in the Mediterranean reef
coral fauna. Species originations were highest during the Burdigalian,
when temperatures across the region increased. Species extinctions
remained constant until the latest Miocene, when the extinction rate
increased as cold Atlantic waters entered the Mediterranean. New
species described are Tarbellastraea bragai, T. chevalieri, T. russoi
and T. salentinensis.^1";

Tarbellastraea (Scleractinia): A new stable isotope archive for Late
Miocene paleoenvironments in the Mediterranean.- Palaeogeography,
Palaeoclimatology, Palaeoecology 257, 3: 294-307.- <b>FC&#038;P 35</b>,
p. 109, ID=2442^<b>Topic(s): </b>stable isotopes, temperatures
salinity; Scleractinia, stable isotopes; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Miocene; <b>Geography:
</b>Mediterranean^Geochemical proxy records of sea surface temperature
(SST) or sea surface salinity (SSS) variability on intra- and
interannual time-scales in corals from geological periods older than
Pleistocene are extremely rare due to pervasive diagenetic alteration
of coralline aragonite. Very recently, however, stable isotope data
(&#948;18O, &#948;13C) from specimens of Porites of Late Miocene age
(10 Ma) have been shown to preserve original environmental signatures.
In this paper we describe new finds of the zooxanthellate corals
Porites and Tarbellastraea in exceptional aragonite preservation from
```

```
the island of Crete in sediments of Tortonian (ca. 9 Ma) and Early
Messinian (ca. 7 Ma) age. Systematic, comparative stable isotope
analysis of massive Tarbellastraea and Porites sampled from the same
beds and localities reveal identical stable isotope fractionation
patterns in both genera. Therefore, extinct Tarbellastraea represents
an additional environmental archive fully compatible and mutually
exchangeable with Porites. Provided that seasonal variations in
&#948;18O reflect SST changes only, seasonal SST contrasts of 7.3 ºC
for the Tortonian and 4.8 ºC for the Early Messinian are inferred,
implying warmer summer and cooler winter SSTs during the Tortonian than
during the Messinian. [first fragment of extensive summary]^1";
s[4476] = "ZIBROWIUS H. (1995).- The &#034;Southern&#034; Astroides
calycularis in the Pleistocene of the northern Mediterranean - an
indicator of climatic changes (Cnidaria, Scleractinia).- Geobios 28, 1:
9-16.- <b>FC&#038;P 24-1</b>, p. 72, ID=4502^<b>Topic(s): </b>climate
indicator; Scleractinia ?, Astroides; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>Mediterranean^Although presently limited at 37°38&#039;N on the
coast of Spain and 40°48&#039;N on the coast of Italy, Astroides
calycularis lived on the continental coast of France at
43°42&#039;-44&#039;N and on the coast of Corsica at 42°58&#039;N
during part of the Pleistocene. Thus it has been found at Nice in the
Upper Silician and at Monaco in the Upper Tyrrhenian (interstages,
respectively, of the Riss and Wuerm glaciations), and at Cap Corse in
the Tyrrhenian (Riss-Wuerm interglacial). The species apparently took
advantage of slightly higher surface water temperatures than those
prevailing now in the northern Mediterranean. Although present-day
temperatures allow survival, for many years, of transplanted colonies,
they are not suitable for successful reproduction.^1";

scléractiniaires hermatypiques dans les plates-formes carbonatées
méditerranéennes au Miocene supérieur.- Geodiversitas 30, 1: 181-209.-
<b>FC&#038;P 36</b>, p. 88, ID=6497^<b>Topic(s): </b>; scleractinian
reefs; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Miocene Mess; <b>Geography: </b>Mediterranean^This work consists in
a systematic revision of upper Miocene Mediterranean hermatypic
scleractinian corals, concerning the whole perimediterranean area. An
abundant material allowed an accurate and reliable analysis of the
taxonomic characters. Eighteen specific attributions, belonging to
eight genera, are proposed. Nomenclatural revisions were required
because of the abundant, dispersed and qualitatively diverse literature
on this subject. Comparisons with older works were made dificult
because of ancient identifications and datations by precedent authors.
The biogeographic and stratigraphic distributions are detailed.
Discussions about paleoecological features allow a better understanding
of this coral fauna evolution, particularly regarding the so-called
&#034;salinity crisis&#034; that affected the Mediterranean area at the
end of the Miocene. [original abstract]^1";

They are epigenic structures produced by an episkeletozoan and therefore, they are described as Fixichnia. Here we propose Sulcichnus as a new ichnogenus, with three new ichnospecies (Sulcichnus maeandriformis, S. helicoidalis, and S. sigillum) to name these traces. Sulcichnus is attributed to the activity of polychaetes. Similar structures are recently produced by Lumbrineris flabellicola, a symbiotic eunicid which maintains a commensalistic relationship with solitary corals. In the fossil record, Sulcichnus occurs associated to shallow marine environments whereas their Recent counterparts are described on deep-marine corals. We interpret this as a consequence of
```

Demospongiae; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Mediterranean^The
taxonomic status of some Cliona species living sympatrically in two
Ligurian localities has been studied on the basis of morphological
(spicule shape and size, boring pattern, arrangement of choanocyte
chambers studied by corrosion casts) and genetic analyses. Results from
this study indicate a remarkable specificity in the choice of substrata
by the Cliona larvae. This comprehensive approach confirmed distinct
differences between C. viridis and C. nigricans. C. viridis is a
superficial species boring only calcareous algae (alpha-stage), whereas
the electrophoretic data demonstrate the identity of different growth
forms of C. nigricans boring biogenic substrata or living in massive
form on detritic bottoms and on Posidonia rhizomes (beta- and
gamma-stages). The calcareous veins embedded in sedimentary rocks along
the Ligurian coast are generally bored by C. celata but, in the same
habitat, another species has been detected. This species, that shall be
described afterwards on a wider lot of specimens coming from different
localities, is very close to C. celata in spicule shape, but the
spicules are smaller. Moreover the two species are clearly
distinguishable on the basis of their boring pattern. Finally the
genetic analysis ascertained that there is no gene flux between the two
species. [original abstract]^1";

ID=3100^<b>Topic(s): </b>systematics; Porifera Demospongiae;
<b>Systematics: </b>Porifera; Demospongiae; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Mediterranean^We describe in this study a
new Mediterranean species of the genus Sphinctrella Schmidt.
Sphinctrella aberrans sp.nov. is characterized by the presence of
malformed ortho-plagiotriaenes and pseudocalthrops, a category of
spirasters with a very thick central axis, microxeas with attenuate
ringed ornamentation, and a very fine, pore-like fenestration of the
ectosome of the exhalant sieves. Apart from S. aberrans, three other
species of Sphinctrella are known from the Mediterranean according to
the literature : Sphinctrella gracilis Sollas, Sphinctrella horrida
Schmidt and Sphinctrella verrucolosa Pulitzer-Finali. However, the
reexamination of the single Mediterranean individual claimed to be S.
horrida made evident that this specimen was misidentified and the
species actually does not exist in the Mediterranean. [original

Octocorallia, Gorgonaria; <b>Systematics: </b>Cnidaria; Octocorallia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Italy, Ligurian
Sea^C.R.E. studied the gorgoniarian facies of the coastal bottoms of
&#034;Cinque Terre&#034;. for scientific and practical reasons; this
zone was chosen by the Italian legislation for the creation of a Marine
National Park. Gorgonians can be considered as the most important
systematic group of the Cnidaria for the characterisation of the
coralligenous and the presence of their different species allows
environmental inferences (on irradiation, sedimentation rate, etc.).
These benthic assemblages are of great importance for tourism (i.e.
SCUBA divers) and, for a correct coastal management, they must be
located with accuracy. This work analyses the main factors of
distribution and the dangers that threaten the gorgonians in the area
studied. Some proposals are made in order to guarantee the protection
of the gorgonian facies in the Western Mediterranean Sea.^1";

stock densities varying between 1,9 and 4 colonies . m-2. Laboratory
```

```
measurements of volume, skeleton weight, surface and number of
corallites per colony, coupled with mean annual growth rates evaluated
through sclerochronology, allowed for the estimation of biomass,
skeleton bulk density, calcimass (carbonate standing stock) and
secondary production (both organic and inorganic) of two C. caespitosa
beds at 4 and 9 m depth. The mean colony biomass varied between 0,73
and 0,99 kg dw . m-2, corresponding to a calcimass between 2 and 5 kg
CaCO3 . m-2. Organic secondary production was 215.5 - 305.4 g dw of
polyps . m-2 . y -1, while the potential (mineral) production was 1.1 -
1.7 kg CaCO3 . m-2 . y-1, for the year 11996-1997.These values show
that C. caespitosa is one of the major carbonate producers within the
Mediterranean and one of the major epibiontic species originating
stable carbonate frameworks both in recent and past times.^1";

Present-day bioconstructions of the hard coral Cladocora caespitosa
(L.) (Anthozoa. Scleractinia), in the Eastern Ligurian Sea (NW
Mediterranean).- Biologia Marina Meditteranea 1, 1: 371-372.-
<b>FC&#038;P 25-1</b>, p. 53, ID=3069^<b>Topic(s): </b>reefs; reefs,
Cladocora; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Italy, Ligurian Sea^Cladocora caespitosa
is the only hermatypic coral living in the Mediterranean. Large-sized
formations were recorded between 1700 and 1900m in the Marseille region
but presently this coral is found chiefly in the eastern Mediterranean:
Gulf of Gabes, Tunisia, Aegean Sea, Jonian coasts of Calabria. During
1992, two massive bioconstructions of C. caespitosa were found in two
Ligurian localities: Bonassola and Riomaggiore. Both were on
coralligenous bottoms 26 to 29 m deep, with large amounts of siltation
due to natural and &#47; or anthropogenic causes. These
bioconstructions have been mapped by Scuba diving using photomosaic
techniques. In situ examination of the two structures and the analysis
of the photographic maps led to estimate their surface area, volume,
and carbonate mass. The two bioconstructions differ greatly in their
morphology: that of Bonassola is oblong in shape and reaches a total
length of over 3.5m, whereas that of Riomaggiore is smaller and looks
like a stout pillar about 0.6m high. The inferred developmental
patterns also differ. At Bonassola, the bank progresses chiefly in a
horizontal way, through coalescence and fusion of satellite colonies,
its growth in height is enhanced by the cementing action of sediment,
filling interstices among corallites. The Riomaggiore formation has a
prominent vertical growth through accretion of subsequent colonies,
which makes its upper surface irregular. Both environmental (high
turbidity) and topographic features (both bioconstructions occur in
small grooves conveying sediments and currents) at the two sites are
consistent with data from literature (Laborei 1961, Lumare 1966,
Zibrowius 1980) which, however, always concern shallower zones.^1";
s[4494] = "KUHLMANN D.H.H. (1996).- Preliminary Report on Holocene
Submarine Accumulations of Cladocora caespitosa (L. 1767) in the

Scleractinia; <b>Stratigraphy: </b>Holocene; <b>Geography: </b>Aegean
Sea^In the sublitoral of the North and Middle Aegean investigations of
Cladocora caespitosa (L. 1767) (Anthozoa, Scleractinia, Faviidae) as
scaffolder of sedimental hard structures were undertaken by diving from
1990 to 1994. The structures appeared in two forms: first as ledges,
which had been formed by many colonies of the coral (bioherms) around
5,900 to 3,200 years before present (yrs BP) according to AMS
14Cdatings and secondly as blocks which consisted of only one colony of
coral (biochores) and had been formed 2,000 to 100 yrs BP. Both
structures were exclusively formed by the densely dendroid, hemispheric
growing form of C. caespitosa, whose corallites landing together
```

```
functioned as centers of sedimentation, where silt and biogenic hard
particles could be established in between. On the Cladocora caespitosa
ledges, living colonies of the same species are growing at present
which show a continuous growth of the ledge surface. However, the
ledges themselves already died out more than 3,000 yrs BP. For the
so-called Atlantic time these ledges can be pointed as transitional
structures between merhmatypic [?] single corals and tropical coral
reefs. Due to deteriorated environmental conditions in the
Mediterranean, at present no more recent transitional structures exist
compared to tropical coral reefs.^1";
s[4495] = "PEIRANO A., MORRI C., BIANCHI C.N. (1999).- Skeleton growth
and density pattern of the temperate, zooxanthellate scleractinian
Cladocora caespitosa from the Ligurian Sea (NW Mediterranean).- Marine
ecology progress series 185: 195-201.- <b>FC&#038;P 28-2</b>, p. 20,
ID=4016^<b>Topic(s): </b>skeletal growth, x-radiography; Scleractinia,
Cladocora; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Mediterranean^X-radiographs of corallites
of the zooxanthellate coral Cladocora caespitosa (L.), collected in the
Ligurian Sea between 3 and 27m depth, were examined. C. caespitosa
deposits 2 bands yr-1; the high density band is deposited during winter
(November to March) while the low density band is deposited in summer.
Average growth rates ranged from 1.36 ± 0,58 to 4.42 ± 1,61 mm yr-1. No
differences in the timing of band deposition were found between shallow
and deep colonies. A comparison of the band pattern with monthly
temperature-irradiance measurements from the Ligurian Sea, and with
literature data on the photosynthetic efficiency of zooxanthellae, led
us to hypothese a mechanism of growth with low dependency on
autotrophy. ^1";

hermatypique introduit en Méditerranée.- Helgolaender wiss.
Meeresunters. 26: 153-173.- <b>FC&#038;P 4-1</b>, p. 28,
ID=5090^<b>Topic(s): </b>introduced; Scleractinia Oculina;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Mediterranean^A large colony of Oculina
patagonica growing on a cliff (depth 0,5 to 2m) about 1km from Savona
harbour (Gulf of Genoa, Italy) was discovered in 1966 and was found
prosperous and spreading when surveyed again in 1971 and 1972. Water
temperature in the area was found to vary from about 11°C to about
26°C; during the greater part of the year it remains far below
temperatures generally considered necessary for growth and even
survival of hermatypic scleractinians. In spite of the local pollution
which favours dense and prosperous populations of barnacles and
ascidians, the encrusting colony of O. patagonica (now measuring 1,2m x
1,5m) tends to cover these other organisms. The Savona record of O.
patagonica is the first one of a living colony since nothing was known
on the actual range of the species, probably living on the Atlantic
coast of South America. Previously, O. patagonica was known only from
worn fragments, fossil or sub-fossil, from Argentina. Liberation of
larvae (one of which settled on the surveyed cliff) by a mature colony
that came to Savona waters on a ship bottom, is the only acceptable
```

```
explanation for the highly surprising arrival of the exotic
scleractinian in the Northwestern Mediterranean. Transplantation of
samples of O. patagonica broken off the Savona colony to clean water
off Marseilles has proven very successful. The discovery of O.
patagonica in the Mediterranean has provided material for a detailed
redescription of the species and an opportunity for a systematic and
biogeographic survey of the genus Oculina, as well as for remarks on
hermatypic corals in extra tropical waters.^1";

s[4501] = "ROSELL D., URIZ M.-J. (2002).- Excavating and endolithic
sponge species (Porifera) from the Mediterranean: species descriptions
and identification key.- Organisms, Diversity &#038; Evolution 2:
55-86.- <b>FC&#038;P 31-1</b>, p. 76, ID=1660^<b>Topic(s): </b>boring
&#038; endolithic, taxonomy, identification key; Porifera boring &#038;
endolithic; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Mediterranean^The present study is a review of the
excavating and endolithic sponges present in the Mediterranean. A
dichotomic key to 22 species is presented. Detailed species
descriptions are provided based on newly collected material and
previous descriptions from the literature. In the case of Cliona
viridis (Schmidt, 1862), an in-depth histological study has also been
performed. Discussions on problematic taxonomic issues are also
included. Dotona pulchella Carter, 1880 subspecies mediterranea
n.subsp. n. is described. The previously enacted synonymy between Pione
vastifica Hancock, 1849 and Pione lampa (de Laubenfels, 1950) is
restricted to those specimens identified as &#034;forma occulta&#034;.
Cliona amplicavata Rützler, 1974 is recorded for the first time in the
```

```
Mediterranean. Clionba cretensis Pulitzer-Finali, 1983 is proposed to
be synonymous to Cliona thoosina Topsent, 1887. Cliona copiosa Sarr,
1959 and Cliona tremitensis Sarr, 1961 are considered synonymous to C.
viridis. The spicule complement of Scantilleta levispira (Topsent,
1898), D. pulchella and C. amplicavata, is enlarged, and some spicule
types are better described based on light microscopy and SEM
observation. Pione vastifica shows great variability in the
microrhabds, seemingly related to depth.Regarding excavating patterns,
several species appear to selectively excavate particular substrate
types, whereas others are not selective among calcareous material.A.
labyrinthica, P. vastifica, Cliona janitrix Topsentr, 1932, C. viridis
and C. lobata Hancock,1849 have asexual reproduction. Excavating
ability, bud production and the way the sponge genus grows inside the
substrate are biological features common to distant taxa such as
Clionidae and Aka ssp. That may constitute convergent (analogous)
characters.^1";

dwellers; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Mediterranean^Submarine caves share
several ecological features with deep-sea habitats and could be
considered as a natural mesocosm of the bathyo-abyssal zone, in spite
of differences in temperature. A unique Mediterranean cave which
entraps a cold water mass, resulting in stable temperature conditions
throughout the year, is a specially interesting &#34;bathyal
island&#34; in the littoral zone. It has been colonized by deep-sea
invertebrates, the likely source of propagules of which being a nearby
canyon, 100 to 3000m deep. The example of sponges shows that various
general problems of deep-sea biology could be successfully addressed to
```

```
in the cave. A representative of the deep-sea hexactinellid sponges
reproduces here year round - enabling the first observations of larval
behaviour and ultrastructure to be carried out on this phylogenetically
important group of invertebrates, and opening the unknown area of
larval ecology of deep-sea sponges. The presence of a species of the
deepest known genus of sponges, Asbestopluma (at 8840m depth in the
Central Pacific) is a fascinating opportunity to investigate the
biology of the strange deep-sea cladorhizid sponges, which can live in
the most oligotrophic abyssal basins. A highly unexpected result is
that cladorhizids are non-filter-feeding &#39;sponges&#39; with a
carnivorous feeding habit.^1";

<b>Geography: </b>Mediterranean E^This first study of soft bottom
sponges from the Levantine bathyal employed a device comprising a
plankton net secured atop a Marinovich type semi-balloon trawl. All of
the nearly 500 specimens collected were identified to four sponge
species. All four species are of a very small body size. Sponges were
not retained by the larger mesh Marinovich trawl net. The study
describes a new polymastiid species Tentorium levantinum n.sp., and a
new Rhizaxinella shikmonae n.sp. in addition to two Calcareans: Sycon
faulkneri n.sp. and a Plectroninia sp. that appears to be a new
species. These sponges, which inhabit soft bottom environments, have
evolved morphological features such as unattached ground-based cones
with a broad base (Tentorium levantinum), or a basal anchoring tuft
(Rhizaxinella shikmonae). The absence of these species from previous
records of the Mediterranean bathyal may have resulted either from
overlooking the small sized species in soft bottom environments for
lack of adequate collecting technique or scarcity of studies. It was
thus impossible to confirm or reject the pattern of wide geographical
distribution of deep-water sponges seen elsewhere, including the
western Mediterranean. The new calcareous species was found at greater
```

```javascript
depths than most other calcareous sponges published so far, while
Plectroninia sp. was found at greater depth than all but one record for
this genus. It is expected that other small, benthic species may be
discovered using the appropriate equipment. [original abstract]^1";

Hadromerida Cliona; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Mediterranean^Massive specimens of Cliona
viridis, collected off the coast of Blanes (North-Western Mediterranean
Sea) in January, 1987, were exposed to different light (natural
day-night irradiance/constant darkness) and substrata
(calcareous/siliceous) conditions to assess their influence on growth,
survival and attachment rates. Sponges cultured under natural
irradiance displayed higher growth rates with increasing temperature;
those cultured in the dark did not respond to increased temperature,
but adapted faster to laboratory conditions. Differences in growth
rates between these two culture conditions are ascribed to the presence
of a healthy symbiotical zooxanthellae population on individuals
cultured under conditions of natural irradiance. Attachment rates of
the hut sides of the sponges which were in direct contact with the
substratum, also increased with increasing temperature, whilst sponge
survival was not significantly dependent on temperature. The chemical
nature of the substratum clearly affected survival rates, which were
higher on calcified than on siliceous substrata.^1";

</b>Caribbean^Thirty-four geologists and biologists participated in a
symposium of 22 papers on Caribbean reef systems: Holocene and ancient,
in Guadeloupe, French West Indies, in early July. The Symposium was
arranged by S.H. Frost and M.P. Weiss, of Northern Illinois University,
as part of the Vllth Caribbean Geological Conference convened by the
French government and chaired by Roger Causse. Gatherings of geologists
to consider carbonate materials and their genesis are a commonplace of
recent years; although important and constructive, many failed to treat
reefs as wholes. Modern treatments of reef morphology and history are
also numerous, but many are only geologic and/or refer to the
Indo-Pacific region. Much more cooperation is needed between geologists
and biologists, one 2-day symposium cannot do the job, but a start was
overdue. We also hoped to increase participation and interest in both
modern and fossil reefs all over the Caribbean. [first part of a
report, sent also to Geotimes]^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous L;
<b>Geography: </b>Caribbean^Although ten species are currently assigned
to the Early Cretaceous coral genus Holocoenia, its characteristics are
poorly known. Using both material from the type locality of the type
species Astrea micrantha along with described and undescribed material
from France, Mexico, Poland and Spain, the genus is revised. It has a
cerioid form with small calices, compact septa, a styliform columella,
and an incomplete septothecal to synapticulothecal wall. Provisionally,
it is assigned to the family Thamnasteriidae, being closely related to
Mesomorpha and Thamnasteria. The genera Stereocaenia and Paretallonia
```

```
are considered junior synonyms of Holocoenia. According to the present
revision the genus contains only two species, which range from the
Valanginian to the Aptian. Holocoenia micrantha is restricted to the
central Tethys whereas Holocoenia jaccardi extends geographically from
South America (Aptian of Argentina) and southern North America (Aptian
of Puebla, Mexico) to the eastern Tethys (Hauterivian of Georgia). The
indication of the genus in the San Juan Raya area in Puebla is the
first indication in Central America. While the genus has been indicated
in only eleven outcrop areas, making it rather rare, in many of these
localities samples of Holocoenia are common. [original abstract]^1";

Caribbean reef corals: A unique fauna from the Gatuncillo Formation of
Panama.- Journal of Paleontology 66, 4: 570-594.- <b>FC&#038;P
21-2</b>, p. 42, ID=3340^<b>Topic(s): </b>hermatypic, taxonomy; reef
corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Eocene; <b>Geography: </b>Panama, Carribean^Forty-three species of
25 genera are described in a collection of 170 large, massive reef
corals from the upper Eocene Gatuncillo Formation near Lago Alahuela in
central Panama. Comparisons with type material for other Eocene
Caribbean reef corals suggest that 27 of these species are new.
Twenty-four of these species are named herein. Like other Eocene
Caribbean reef-coral faunas, the fauna is rich in Astrocoenia,
Actinacis, and Astreopora however, unlike other faunas, plocoid and
meandroid members of the family Faviidae (e.g. Montastrea,
Agathiphyllia, Goniastrea, and Colpophyllia) are abundant. Also present
are the oldest known representatives of the genera Meandrina,
Coscinaraea, Alveopora, Heliopora, and Pocillopora, as well as the only
recorded occurrences of Coscinaraea and Cyathoseris from the Caribbean.
Comparisons with Oligocene and Recent Caribbean reef-coral faunas
suggest that the generic composition of Cenozoic Caribbean reefs became
established during the Eocene. With exception of the family Mussidae,
much of the post-Oligocene history of the Caribbean is one of
extinction at the generic level (19 of the 28 Eocene genera became
extinct) and proliferation of species within the surviving genera.^1";

Extinction and Geographic Restriction of Caribbean Corals: Roles of
Turbidity, Temperature, and Nutrients.- Palaios 9: 576-598.-
<b>FC&#038;P 24-1</b>, p. 55, ID=4462^<b>Topic(s): </b>extinctions,
biogeography; Anthozoa extinction; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Oligocene Miocene; <b>Geography:
</b>Caribbean^About half the Caribbean hermatypic corals died out in
the Caribbean during the latest Oligocene through Early Miocene, about
24-16 Ma. The majority of those corals that died out in the Caribbean
are extant in the Indo Pacific, i.e., they suffered geographic
restriction, rather than extinction. The coral and coral associate
faunas of three Upper Oligocene and three Middle Miocene fossil reefs
in western Puerto Rico were compared. Coral genera at these sites
suffered 50% regional extinction (extinction or restriction),
equivalent to earlier reports of this Caribbean coral
extinction/restriction event. Nearly all coral genera tolerant of both
turbidity and cool water survived; those tolerant of cool water or
turbidity alone survived in much lesser proportions. Corals occurring
on both patch reefs and shelf edge reefs survived in much greater
proportions than those occurring on only patch reefs or only shelf edge
reefs. There are no shelf edge barrier reef complexes documented from
the Early or Middle Miocene in the Caribbean; the uppermost Miocene
shelf edge reefs of Mona Island are the only known Miocene shelf edge
reef deposits in the Caribbean. Coral associates, the endolithic
sponges, bivalves, worms, and barnacles that live in coral skeletons,
were almost completely unaffected by this event. Likewise, reef and
off-reef gastropods, bivalves, and echinoids suffered only
insignificant reductions in diversity. Only corals and large benthic
foraminifera were strongly affected by the extinction. It is
significant that zooxanthellate organisms were the primary victims of
this extinction. Miocene endolithic sponge borings are significantly
larger than their Oligocene counterparts, suggesting more intense
bioerosion on Miocene than Oligocene reefs. Bioerosion is generally
correlated with nutrient levels, and the apparently more intense
bioerosion of Miocene corals may indicate enhanced nutrient
availability on Miocene Caribbean reefs. Extensive Miocene phosphorites
throughout the Caribbean indicate enhanced upwelling in the region
during the time of the coral extinction/restriction. Biogeographic
evidence from corals, coral associates, and molluscs corroborates this
pattern, along with the evidence from bioerosion levels. Enhanced
upwelling could account for the extinction/restriction by generally
increasing nutrient levels and cooling Caribbean coastal surface
waters, thus restricting reef development to on-shelf patch reefs,
where corals would be subject to more intense sedimentation. Modern
reefs of the Eastern Pacific may provide a modern analogue to Miocene
Caribbean reefs. This regional extinction was important in dividing a
previously cosmopolitan reef fauna into several modern provincial
faunas. This biogeographic separation was completed in the mid-Pliocene
with the rise of the isthmus of Panama. Coral associates, which
universally survived the Oligocene-Miocene event, also have much more
cosmopolitan distributions than do corals.^1";

gastropods in the Oligocene-Miocetie Bluff Formation of Grand Cayman
```

```
Island contain casts of Entobia (nine ichnospecies including the new
ichnospecies E. dendritica), Trypanites (three ichnospecies),
Gastrochaenolites (two ichnospecies), Maeandropolydora (one
ichnospecies), Talpina (one ichnospecies), and Caulostrepsis (one
ichnospecies) as well as the new ichnogenus Uniglobites, indeterminate
ichnogenus A, and a problematical boring. Entobia accounts for about 75
percent of the borings, while Uniglobites and Trypanites together
account for 15 percent of the borings. Comparison of Uniglobites with
modern borings of known affinity suggests that it was produced by
adociid and &#47; or clionid sponges while indeterminate ichnogenus A
was probably formed by bivalves. The amount of boring, which ranges
from 0 to 75 percent, varies from skeleton to skeleton or, in some
cases, from branch to branch of the same coral colony. The branching
coral Stylophora was particularly susceptible to boring, probably
because of its small size and high surface area. The average boring of
about 38 percent compares favourably with the amount of boring found in
modern corals. Analysis of the borings suggest that sponges were
responsible for most of the borings in the corals from the Bluff
Formation. Comparison with bioerosion in modern reefs suggests that
similar patterns of bioerosion were also occurring in Oligocene-Miocene
times.^1";
s[4523] = "EDINGER E.A., RISK M.J. (1995).- Preferential survivorship
of brooding corals in a regional extinction.- Paleobiology 21, 2:
200-219.- <b>FC&#038;P 24-2</b>, p. 76, ID=4553^<b>Topic(s):
</b>extinctions; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Cenozoic; <b>Geography:
</b>Caribbean^Approximately half of the Caribbean Oligocene reef coral
fauna became locally extinct during the Early Miocene; roughly two
thirds of the genera driven to local extinction still survive in the
Indo-Pacific. Coral genera with lecithotrophic larvae (brooders)
preferentially survived, over those with planktotrophic larvae
(broadcasters). Among 37 genera for which we inferred reproductive
mode, 73% of brooding genera survived the Oligocene &#47; Miocene
extinction events, while only 29% of the broadcasting genera survived.
The proportion of brooders to broadcasters also increased markedly.
During the late Oligocene, 47% of Caribbean reef coral genera were
broadcasters, but in the middle Miocene, only 32% of the genera were
broadcasters. Survivorship in Puerto Rican reefs was correlated with
tolerance of cold and turbid conditions. Genera tolerant of both cold
water and turbidity had much higher survival rates than those tolerant
of turbidity alone. Only 25% of the genera that could tolerate neither
cold water nor turbidity survived. Most of the eurytopic genera were
brooders, while most of the stenotypic genera were broadcasters. We
present two hypotheses that may account for the preferential
survivorship of brooders: the recruitment hypothesis, and the dispersal
hypothesis. The recruitment hypothesis holds that brooders survive
preferentially because lecithotrophic larvae have higher recruitment
success than do planktotrophic larvae in marginal habitats, such as
upwelling zones. This is supported by the correlation of brooding and
eurytopy. The dispersal hypothesis suggests that brooders survive
preferentially because lecithotrophic larvae, which typically inherit
zooxanthellae from the egg, have a longer larval lifespan and, hence, a
wider potential dispersal range, than planktotrophic larvae, which
typically capture zooxanthellae from the water column. Biogeographic
range data, however, do not support this second hypothesis: modern
Indo-Pacific brooding and broadcasting genera have nearly identical
ranges, and many brooding species have narrower longitudinal ranges
than do broadcasting species. Preferential survivorship of brooding
corals contrasts sharply with survivorship patterns among molluscs
during extinction events; among molluscs, broadcasters are favored over
brooders. A major increase in upwelling at the Oligocene &#47; Miocene
boundary was probably responsible for this extinction &#47; geographic
restriction event. Preferential survival of brooding and mixed mode
```

```
coral genera appears to be a product of their being better able to
recruit and survive in marginal conditions such as upwelling zones.^1";
s[4524] = "FROST S.H. (1972).- Evolution of Cenozoic Caribbean coral
Faunas.- Memoirs of the VIth Conf. Geol. Carib., Margarita, Venezuela:
461-464.- <b>FC&#038;P 4-1</b>, p. 43, ID=4824^<b>Topic(s):
</b>phylogeny; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Cenozoic; <b>Geography: </b>Caribbean^Examination
of extensive new coral collections from the Lower Eocene-Lower Miocene
of Chiapas, Mexico and the Middle Eocene-Pliocene of Jamaica plus the
reevaluation of published studies of Duncan, Vaughan, Wells, and others
allows some generalizations to be made about ecological distribution
and evolution of Caribbean Tertiary coral faunas: (a) Paleocene and
Lower Eocene hermatypic and ahermatypic corals are rare in the
Caribbean. In addition to the dominantly ahermatypic faunas of the Gulf
Coast Paleocene and Lower Eocene, sparse Paleocene hermatypic corals
occur in northern British Honduras (Belize) and in the Lower Eocene of
Chiapas, Mexico; (b) Middle Eocene reefs existed in Chiapas, Mexico,
possibly in Jamaica, and mixed hermatypic-ahermatypic assemblages are
present in collections from St. Bartholomew and the Gulf Coast. Tethyan
genera dominate the assemblages. (c) Upper Eocene mixed herrnatypic
&#47; ahermatypic basin-slope faunas existed in Chiapas, Mexico, Gulf
Coast and sparsely at other localities. By the end of the Eocene, most
of the older elements of the Caribbean coral fauna had disappeared,
leaving groups which still exist on modern reefs. (d) The greatest
development of Tertiary hermatypic corals occurred in the Oligocene,
where cosmopolitan genera such as Diploastrea and Antiguastrea of
Vaughan&#039;s &#034;Antiguan coral fauna&#034; built fringing reefs in
Chiapas, Mexico, and possibly Antigua, and patch reefs on the Gulf
Coast, Puerto Rico, Cuba, Northeastern Mexico and Panama. This fauna is
closely comparable to contemporaneous faunas which existed in the
Mediterranean and Pacific. (e) Cosmopolitan elements of the hermatypic
&#034;Antiguan coral fauna&#034; disappeared in latest Oligocene time.
This apparently due to the cut off of access of the Caribbean to the
Eastern Pacific equatorial counter current by the establishment of land
barriers across Central America. Lower Miocene hermatypic faunas are
dominated by Montastrea and Porites although some genera, now extinct
in the Caribbean but living in the Indo-Pacific, persisted. (f) Middle
Miocene through Upper Pliocene faunas are marked by the steady
disappearance of genera still living in the Indo-Pacific. Many of the
classic Miocene and Pliocene assemblages are hermatypic &#47;
ahermatypic deep fore-reef faunas and do not provide much insight into
the species composition of reef-crest hermatypic assemblages. A change
in the composition of reef-crest or reef-buttress assemblages is marked
by the evolution of wave-resistant Acropora palmata in latest Pliocene
or earliest Pleistocene time. Rapidly growing species of Acropora,
Porites, and other genera appear to have increased greatly in species
diversity and abundance since the Late Pliocene and appear to be well
on their way to dominate the shallow water-high wave energy habitats of
modern Caribbean reefs.^1";
s[4525] = "BUDD A.F. (2010).- Tracing the long-term evolution of a
species complex: Examples from the Montastraea &#034;annularis&#034;
complex.- Palaeoworld 19, 3-4: 348-356.- <b>FC&#038;P 36</b>, p. 85,

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cenozoic; <b>Geography: </b>Caribbean^Recent molecular work has
revealed numerous species complexes of scleractinian reef corals.
Although species within complexes are distinct through much of their
distribution, hybridization has been discovered at species margins, and
has been hypothesized as playing an important role in mediating
responses to changing environments. In the present study, I examine the
long-term evolution of the Montastraea &#34;annularis&#34; complex over
the past 5 million years to determine when speciation, extinction, and
hybridization took place over the past 6.5 million years, with the
```

```
eventual aim of understanding how these events corresponded with
environmental changes in the Caribbean region. The material consists of
colonies collected in the Mio-Pliocene of the Dominican Republic and
the Plio-Pleistocene of Costa Rica and Panama. Genetically
characterized colonies from the Recent of Panama are included in the
analyses for comparison. Species are distinguished in the fossil
material using a landmark-based morphometric approach that focuses on
the size and shape of architectural features within corallites in
transverse thin sections. Evolutionary relationships among species are
examined using phylogenetic analyses based on parsimony. Phylogenetic
characters are derived from the results of multiple comparisons tests,
which statistically evaluated differences among species using
morphometric data. * The results show that the Montastraea
&#34;annularis&#34; complex originated during late Miocene time, and
consisted of &#062;12 species during the Pliocene, with a maximum of
4-5 species co-occurring at any one time. The three modern species do
not form a monophyletic group but belong to separate clades within the
complex. The ranges of two of the three modern species may extend back
to 2.9-3.5 Ma, indicating that they are survivors of the
Plio-Pleistocene extinction event in which &#126;80% of Caribbean reef
coral species became extinct. Morphologic differences among species
(disparity) were higher during the Pliocene than they are today.

s[4526] = "KLAUS J.S., BUDD A.F. (2003).- Comparison of Caribbean coral
reef communities before and after Plio-Pleistocene faunal turnover:
analyses of two Dominican Republic reef sequences.- Palaios 18, 1:
3-21.- <b>FC&#038;P 32-1</b>, p. 31, ID=1737^<b>Topic(s): </b>;
Anthozoa communities; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Pliocene &#47; Pleistocene; <b>Geography:
</b>Caribbean^The extent to which origination and selective extinction
influenced the structure and dynamics of Caribbean coral reef
communities is evaluated by comparing the diversity and distributional
patterns of coral species in two Dominican Republic reef sequences
prior to an following late Cenozoic Caribbean faunal turnover. The two
sequences consist of late Miocene Arroyo Bellaco reef of the Cibao
Valley, northern Dominican Republic, and the late Pleistocene 125.ka
reef terraces of the southern Dominican Republic. Samples were
collected along 20-meter transects (10 Miocene, 10 Pleistocene),
species identifications were made using standard sets of characters and
morphometrics. In particular, species of Montastraea annularis-like
corals were distinguished within each sequence using a 2-dimensional
landmark technique involving average linkage cluster analysis,
discriminant analyses, and non-parametric tests. Four Miocene and four
Pleistocene species were recognized. Subsequent community analysis was
two-fold: (1) whole coral community, and 2) distribution of Montastraea
&#034;annularis&#034; complex. [first fragment of extensive summary]^1";

Anthozoa; <b>Stratigraphy: </b>Miocene; <b>Geography: </b>British West
Indies^Three common coral assemblages have been quantitatively
identified in the middle Miocene Anguilla Formation of Anguilla (Lesser
```

```
Antilles) using cluster analysis on three-dimensional coordinates
derived from nonmetric multidimensional scaling. The data consisted of
tallies of coral species identified at 25 points within 178
1-meter-square quadrats placed haphazardly across vertical exposures of
coral-rich lenses at five localities. Eighteen species were recorded.
The resulting clusters intergrade and are characterized by moderately
high diversities which are not significantly different. They include:
1) a thick-branched assemblage dominated by Porites porloricensis, 2) a
mound-shaped assemblage including Porites waylandi, Siderastrea
conferta, Goniopora hilli, and G. imperatoris, and 3) a
platy/thin-branched assemblage composed of Porites macdonaldi and
Porites baracoaensis. The results of chi-square tests show that the
assemblages are randomly distributed, both in space and in
stratigraphic sequence. The patchy, intergradational distribution of
the assemblages, their equally variable but high diversities, and their
association with calcareous sand lenses suggest that they probably all
developed as small patch reefs or thickets of varying composition on a
shallow, gently sloping backreef platform. The three assemblages
developed under similar environmental conditions in one major reef zone
on a platform subjected to frequent abiotic disturbance by shifting
sand. The mere existence of distinctive assemblages of reef-building
corals having different shapes, therefore, needs not in itself imply
ecological succession or large-scale physical environmental gradients,
as is commonly interpreted in many similar fossil reef sequences.^1";
s[4529] = "JONES B., PEMBERTON S.G. (1988).- Lithophaga borings and
their influence on the diagenesis of corals in the Pleistocene
Ironshore Formation of Grand Cayman Island, British West Indies.-
Palaios 03: 3-21.- <b>FC&#038;P 23-2.1</b>, p. 72, ID=4441^<b>Topic(s):
</b>bioerosion; bioerosion; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>Cayman Isls^Corals
in the Pleistocene Ironshore Formation of Grand Cayman Island have been
infested by Lithophaga sp. that formed borings up to 15 cm long and 4
cm in diameter. Although some of the borings were probably generated
while the corals were alive most were formed after the corals had died.
Some of the large coral heads (up to 1.5m diameter) of Montastrea
annularis and Diploria labyrinthiformis have had a 14 to 15cm wide
outer band almost totally transformed by the Lithophaga borings. The
borings, which have a distinct clavate form, are assigned to the
ichnospecies Gastrochaenolites torpedo Kelly &#038; Bromley 1984. Many
of the borings are lined with laminated, fluorescent cryptocrystalline
calcite that may have been formed by the merger of peloids. Similar
material also encrusts many of the Lithophaga shells. After death the
borings were filled with (1) cryptocrystalline calcite, (2) porous
cryptocrystalline calcite, (3) honeycombed cryptocrystalline calcite,
(3) pelsparite, and (4) pelmicrite which locally contains small
calcitic ostracod(?) shells. The cryptocrystalline calcite is always
fluorescent and thus contrasts sharply with the nonfluorescent calcite
of the shells and the spar cement. The corallites around the Lithophaga
borings are partly or totally occluded by (1) first generation,
non-fluorescent aragonite cement, (2) second generation,
non-fluorescent spar calcite, (3) fluorescent peloids, and (4)
featureless, fluorescent cryptocrystalline calcite. The fact that the
cryptocrystalline calcite in the corallites has the same fluorescent
character as the cryptocrystalline calcite in the Lithophaga borings
suggests that the two may be genetically related. The infestation of
the coral heads by Lithophaga played a major role in the evolution of
the diagenetic fabric in the coral heads. It is evident that the
Lithophaga borings can (1) substantially weaken the coral heads thereby
making them more susceptible to erosion, (2) serve to bind the
substrate together by virtue of the dense calcareous linings in the
borings, (3) liberate substantial amounts of calcium carbonate from the
coral heads, (4) increase the rock-area available for further
bioerosion by sponges, algae and fungi, and (5) by virtue of the empty
```

```
borings provide protected sites for sediment accumulation.^1";
s[4530] = "JOHNSON K.G., BUDD A.F., STEMANN T.A. (1995).- Extinction
selectivity and ecology of Neogene Caribbean reef corals.- Paleobiology
21, 1: 52-73.- <b>FC&#038;P 24-2</b>, p. 78, ID=4556^<b>Topic(s):
</b>extinctions, selectivity; extinctions selectivity; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Neogene; <b>Geography:
</b>Caribbean^We analyze a new compilation of Neogene to Recent (22-0
Ma) Caribbean coral occurrences to determine how ecological and life
history traits at the population level affect long-term evolutionary
patterns. The compilation consists of occurrences of 175 species and 49
genera in one continuous (> 5 m.y.) sequence and 22 scattered sites
across the Caribbean region. Previous study of evolutionary rates using
these data has shown that both extinction and origination were
accelerated between 4 and 1 Ma, resulting in large-scale faunal
turnover. Categories for three morphological and two reproductive
variables (colony size, colony shape, and corallite size; and sex, and
mode of embryonic development; respectively) are assigned to each
species in the compilation. Comparisons of the ecological variables
with evolutionary rates using randomization procedures and modified
analysis of variance show that only colony size was strongly related to
rates of extinction and origination during either normal background
times or times of accelerated extinction. Extinction rates were lower
in species with large colonies, because species with small massive
colonies tend to live in small, short-lived populations with highly
fluctuating recruitment rates. During turnover, extinction rates
increased disproportionately in species with small colonies.
Origination rates are found to be less related to ecological variables,
although species with small massive colonies originated at higher rates
prior to turnover. Accelerated turnover may have therefore involved an
increase in local population extinction rates that caused increased
rates of both species extinction and origination across the entire
fauna. Since extinction rates accelerated disproportionately with
respect to colony size, the overall result was a relative increase in
species with large colonies. After severe disturbance, one might expect
that populations of species with large colonies and high rates of
fragmentation would be more likely to escape extinction, because of
larger population sizes, longer generation times, and more constant
rates of population increase. The modern Caribbean reef-coral fauna is
therefore structured by large, long-lived colonies that are robust to
regional environmental change. Many of the very taxa that allowed reef
communities to escape collapse in the past are declining today in
response to anthropogenic disturbances, suggesting that Caribbean reef
communities may be less resilient in the future in response to ongoing
environmental perturbations.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Neogene; <b>Geography: </b>Caribbean^Regression analysis has been
used to study the relationship between age,size, shape, and surface
area in two ancestral-descendant populations of the Neogene Caribbean
coral Trachypora bilobata. Analyses of the relationship between size
and age show that the relationship is isometric and that little
difference occurs between populations in mean corallite length or
height and in their rates of growth. Onset of columella growth is
significantly earlier, however, in the descendant population. Studies
of the relationship between size and shape show that growth is
allometric, with shape change occurring in both corallum elongation and
pinching of the corallite wall during ontogeny. In the descendant
population, pinching and elongation initiate earlier in the ontogeny of
the coral. These results suggest that the evolutionary development of
the meandroid form in freeliving corals has been accomplished by
heterochrony, involving a complex set of disassociated peramorphic
changes in ontogeny accompanied by paedomorphic changes in astogeny.
Further analyses show that the observed heterochronic changes serve to
decrease corallum surface area which may in turn enhance sediment
removal and nutrition in unstable habitats.^1";

the subaerial vadose environment.- Journal of Paleontology 48, 4:
785-799.- <b>FC&#038;P 3-2</b>, p. 33, ID=4919^<b>Topic(s):
</b>diagenesis; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>Barbados^Exoskeletons of scleractinian corals in the elevated late
Pleistocene reefs on northern Barbados illustrate a series of
diagenetic textures that document aragonite coral alteration under
subaerial vadose conditions. Two major solution-precipitation processes
are recognized: (1) concomitant solution - precipitation on a fine
scale leading to preservation of coral microstructure, and (2) total
leaching and destruction of the microstructure followed by later
precipitation of void-filling spar. * The pathway of aragonite solution
is similar in both processes, and is controlled by the original coral
microstructure. Solution begins in the fine equant crystallites forming
the axis (center of calcification) of each trabecula and moves outward
into the surrounding zone of closely packed aragonite needles by
preferential solution along the linear intercrystalline contacts
between needles. This results in the friable aragonite &#34;chalk&#34;
commonly observed in Pleistocene corals. * Aragonite &#34;chalk&#34; is
also observed as a zone between aragonite and calcite in corals
undergoing solution-precipitation on a fine scale. The coral
microstructure is preserved by concomitant precipitation of calcite
between separated aragonite needles adjacent to the calcite alteration
front, incorporating minor impurities and irregularities of the
original structure into the calcite crystals. This result is a new
calcite texture that mimics the original aragonite one. * Corals
completely altered to calcite by concomitant solution-precipitation on
a fine scale exhibit a coarse mosaic of blocky calcite with a relict
fibrous texture. The once dark trabecular axes are preserved as a clear
central canal. A similar calcite trabecular texture is observed in
certain Devonian tabulate corals and other fossil calcareous organisms,
suggesting that their skeletons may have been aragonite, altered to
calcite in a manner similar to that described above.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Neogene; <b>Geography: </b>Caribbean^The coral genus Isopora, a
sister group of the modern dominant Acropora until now only known from
the Pliocene to Recent of the Indo-Pacific, is recorded in the
Caribbean for the first time. Two new species, Isopora ginsburgi and
```

```
Isopora curacaoensis, are described from the Neogene Seroe Domi
Formation of Curaçao, Netherlands Antilles. Study of large collections
made systematically through the sequence indicates that Isopora first
occurred in the Caribbean during the Mio-Pliocene, at approximately the
same time as the origination of many modern Caribbean reef coral
dominants including Acropora cervicornis. It last occurred in the
region during the late Pliocene as part of a pulse of extinction, in
which several genera that live today in the Indo-Pacific became extinct
in the Caribbean. Throughout its Caribbean duration, Isopora
co-occurred with the two abundant modern Caribbean species of Acropora,
A. cervicornis and A. palmata. Comparisons with Neogene collections
made elsewhere in the Caribbean indicate that Isopora was restricted in
distribution to the southern Caribbean. Isopora species are viviparous,
while Acropora are oviparous, and this difference in reproductive
strategy may have played a role in the extinction of Isopora in the
Caribbean. The occurrences of Isopora reported in this study are the
oldest records to date of Isopora worldwide, and are important for
understanding the biogeographic separation between reef coral faunas in
the Caribbean and Indo-Pacific regions. [original abstract]^1";
s[4540] = "PANDOLFI J. (2007).- A new, extinct Pleistocene reef coral
from the Montastraea &#034;annularis&#034; species complex.- Journal of

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Pleistocene; <b>Geography: </b>Caribbean^A new species of the
Montastraea &#034;annularis&#034; species complex is herein described
from Pleistocene coral reefs of the Caribbean Sea. The species,
Montastraea nancyi n.sp., had a broad geographic distribution at mainly
insular sites 125Ka. It has a fossil record extending from 600Ka
(thousand years) to 82Ka, both first and last occurrences exclusively
on the island of Barbados. It also had a broad environmental tolerance,
occurring in fringing, windward back-reef and reef-crest, leeward
reef-crest, and lagoonal patch-reef environments. In every habitat in
which it lived, there are examples that it either dominated the coral
fauna or shared dominance with Acropora palmata, a dominant shallow
water coral in high-energy Pleistocene and modern reefs. The extinction
of Montastraea nancyi resulted in evolutionary and ecological change in
surviving members of the M. &#034;annularis&#034; species complex.

distributions of genera and species of Neogene to Recent Caribbean Reef
corals.- Journal of Paleontology 68, 5: 951-977.- <b>FC&#038;P
24-1</b>, p. 67, ID=4489^<b>Topic(s): </b>hermatypic, distribution;
reef corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Neogene Recent; <b>Geography: </b>Caribbean^To document
evolutionary patterns in late Cenozoic Caribbean reef corals, we
compiled composite Stratigraphic ranges of 49 genera and 175 species
using Neogene occurrences in the Cibao Valley sequence of the northern
Dominican Republic and faunal lists for 24 Miocene to Recent sites
across the Caribbean region. This new compilation benefits in
particular from increased sampling at late Miocene to early Pleistocene
sites and from increased resolution and greater taxonomic consistency
provided by the use of morphometric procedures in species recognition.
Preliminary examination and quantitative analysis of origination and
extinction patterns suggest that a major episode of turnover took place
between 4 and 1 Ma during Plio-Pleistocene time. During the episode,
extinctions were approximately simultaneous in species of all
reef-building families, except the Mussidae. Most strongly affected
were the Pocilloporidae (Stylophora and Pocillopora), Agariciidae
(Pavona and Gardineroseris), and free-living members of the Faviidae
and Meandrinidae. At the genus level, mono and paucispecific as well as
more speciose genera became regionally extinct. Many of the extinct
genera live today in the IndoPacific region, and some are important
components of modem eastern Pacific reefs. Global extinctions were
concentrated in freeliving genera. During the turnover episode, no new
genera or higher taxa arose. Instead, new species originated within the
surviving Caribbean genera at approximately the same time as the
extinctions, including many dominant modem Caribbean reef-building
corals (e.g., Acropora palmata and the Montastraea annularis complex).
Excluding this episode, the taxonomic composition of the Caribbean
reef-coral fauna remained relatively unchanged during the Neogene.
Minor exceptions include. 1) high originations in the Agariciidae and
free-living corals during late Miocene time; and 2) regional or global
extinctions of several important Oligocene Caribbean reef builders
during early to middle Miocene time.^1";

récifs actuels des Caraïbes: Conséquences pour l&#039;interprétation
des récifs fossiles.- Géologie et paléoécologie des récifs [J. Geister
&#038; R. Herb (eds)]: 1.1-1.14.- <b>FC&#038;P 13-1</b>, p. 10,
ID=6314^<b>Topic(s): </b>coral reefs; coral reefs; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Caribbean^Les géologues et paléontologues qui abordent la recherche
dans les récifs actuels, le font avec l&#039;intention de pouvoir mieux
interpréter les récifs fossiles après. Mais un des premiers résultats
qui émergent de tels recherches est que les récifs récents se comparent
assez mal avec la plupart des récifs fossiles. Pour être plus précis: *
il existe une ressemblance assez étroite sur le plan structurel et
géomorphologique entre recifs pleistocenes et actuels; * mais il existe
aussi une dissemblance marquée entre récifs actuels et récifs
pré-quaternaires. * La cause de ce changement brusque de la structure
et de la géomorphologie des récifs est à chercher dans un changement du
milieu marin dès le début du Quaternaire. Le changement le plus marqué
était certainement dû aux oscillations abruptes et fréquentes du niveau
de la mer associées aux glaciations et déglaciations du Quaternaire.
Ces oscillations eustatiques ont connu des amplitudes de plus de 100 m.
* Retenons que la plupart des récifs actuels se sont formés vers la fin
de la transgression holocène. Pour cette raison les âges des récifs
```

```
holocènes dépassent rarement les 6000 années, ce qui contraste avec une durée de plus d&#039;un million d&#039;années chez beaucoup de complexes récifaux mésozoïques qui peuvent comprendre plusieurs zones biostratigraphiques. [original introduction]^1";

The key to the species is mostly based on colonial features that are recognized in the field, although some closely related species can only be differentiated by microscopic skeletal features. Each species is illustrated with one or more photos showing the size and shape of the colony; many photos were taken in the natural environment to facilitate underwater identification. Additionally, a short description is provided of each species and their microscopic diagnostic characters are illustrated with the aid of the Scanning Electron Microscope (SEM). Fifteen black coral species are found in relatively shallow-water in the Caribbean, Gulf of Mexico, and other parts of the tropical western Atlantic; these belong to the families Myriopathidae [Tanacetipathes hirta (Gray), T. tanacetum (Pourtales), T. barbadensis (Brook), T. thamnea (Warner), and Plumapathes pennacea (Pallas)]; Antipathidae [Antipathes lenta Pourtales, A. rubusiformis Warner and Opresko, A. furcata Gray, A. umbratica Opresko, A. atlantica Gray, A. gracilis Gray, A. caribbeana Opresko, Stichopathes lutkeni Brook, and S. occidentalis (Gray)]; and Aphanipathidae [Rhipidopathes colombiana (Opresko and Sánchez)]. We hope that this guide will facilitate research on black corals on Caribbean reefs, where population surveys are urgently needed to evaluate or modify conservation policies.^1";
s[4554] = "WILLENZ P., POMPONI S.A. (1996).- A new deep sea coralline sponge from Turks and Caicos Islands: Wllardia caicosensis gen. et sp.nov. (Demospongiae: Hadromerida).- Bulletin de l&#039;Institut royal des sciences naturelles de Belgique, Biologie 66, suppl. 1996 [Willenz P. (ed.): Recent advances in sponge biodiversity inventory and documentation]: 205-218.- <b>FC&#038;P 25-2</b>, p. 31, ID=3114^<b>Topic(s): </b>new taxa; Porifera corallina; <b>Systematics: </b>Porifera; Corallina; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Turks &#038; Caicos Isls^A new coralline sponge, Willardia caicosensis, assigned to the family Timeidae, is described from the deep fore reef off the Turks and Caicos islands, tropical western Atlantic ocean, where it is common at depths ranging from 100 to 119m. Individuals vary up to 15-20cm in width. The relatively thin aragonitic skeleton is covered with delicate pillars up to + 1mm. The living tissue is restricted to the spaces between pillars and a thin sheet lying above the calcareous skeleton. Exhalant canals converge upon regularly spaced central oscules on the sponge surface. Siliceous spicules include tylostyles and amphiasters which are secondarily embedded in the aragonitic moiety of the skeleton. In addition, ultrastructural characters of the choanocytes, such as periflagellar sleeves are typical of the Order Hadromerida. Two types of cells with dense spherules are abundant in the mesohyl: spherulous cells packed
```

```
with large heterogeneous inclusions, protruding at the surface of the
sponge, and glycocytes with smaller ovoid corpuscles, mainly grouped
along the basal calcareous skeleton. Rough collagen fibrils extend in
tracts from the base of the sponge to the ectosome. Sparse bacteria are
scattered in the mesohyl. [original abstract]^1";

cryptic scleractinian reef corals from Bonaire, NA.- Palaios 02:
205-218.- <b>FC&#038;P 23-2.1</b>, p. 50, ID=4387^<b>Topic(s):
</b>cryptic corals; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Netherlands Antilles^At 14 sites along the west coast of the
southern Caribbean island of Bonaire, Netherlands Antilles, 5045 living
scleractinian corals in 1101 reef-growth-framework cavities over the
depth range 12 m to 43 m were identified and counted. The sample
comprises 28 hermatypic coral taxa, the ahermatype Tubastrea coccinea,
and the hydrozoan Millepora alcicornis. Although there is no known
fossil record of scleractinian reef corals in cavities, there is a
record for the taxa living on the reef surface that also inhabit modern
reef cavities. This permits speculation that the modern Caribbean
cryptic scleractinian coral assemblage may have roots extending into
the Tertiary, and at the family level, possibly into the Mesozoic. The
common presence of 8 genera, amounting to 44% of the southern Caribbean
cryptic coral assemblage, in reef cavities in both the southern
Caribbean and the southwestern Pacific, supports the antiquity of the
cryptic coral biota, by suggesting that at least those genera may have
already been in cavities before the rise of the Isthmus of Panama.^1";

</b>structures; Porifera Sclerospongiae; <b>Systematics: </b>Porifera;
Sclerospongiae; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Caribbean^Fine structural analysis of living tissue of the
sclerosponges Ceratoporella nicholsoni (Hickson) and Stromatospongia
norae Hartman collected near Discovery Bay, Jamaica, between 1984 and
1996, was carried out using transmission and scanning electron
microscopy (TEM and SEM). The thick dermal membrane of these spongiae
is covered by exopinacocytes having a &#34;T&#34; shape in sections
perpendicular to the surface. A dense complex glycocalyx is produced at
the surface of these cells. Choanocyte chambers are diplodal and
unusually small. The inhalant and exhalant canals of both species are
characterized by the presence of valvules, made by transverse
lamellipodial processes of the endospinatocytes lining them. An
abundant and diversified bacterial community occupies almost 20% of the
mesohyl. A single layer of active basipinacocytes lines the mesohyle at
the interface between the living tissue and the aragonitic skeleton.
Sclerocytes and spongocytes are abundant in the vicinity of the
siliceous spicules. Typical lophocytes releasing smooth collagen
fibrils are common in the dermal membrane as well as in the choanosome
where they can be grouped in bundles. Uniquely, C. nicholsoni elaborate
rough intercellular fibrils [are] characterized by periodically spaced
thickenings. The endolithic algae Ostreobium sp. is present in the most
apical zones of the aragonitic skeleton, but does not seem to interfere
with its development. The striking micromorphological resemblances
between both species are discussed and compared to demosponges.^1";

</b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Caribbean^A lush and picturesque shallow-water coral
patch at Little Reef, San Andres Island (western Carribean Sea,
Colombia) has been revisited and photographed episodically for over 30
years. The corals were observed to be flourishing between 1969 and
1979. A return visit to the site in 1994 showed heavy degradation with
extreme mortality rates, especially among the Acropora palmata
colonies. At the time of this visit Diploria strigosa was under full
attack by the &#34;Blackband Desease&#34;. Coral mortality increased
further until 1996, as indicated by the demise of most of the remaining
Porites porites stands. In 1998 more corals were found dead, with their
skeletons attacked by boring organisms and heavily overgrown by soft
algae. However, encouraging signs of local recovery of reefs since 1993
(especially of Acropora palmata thickets) from elsewhere on the San
Andres shelf suggest that degradation has essentially come to an end
and we may look forward to a decade of renewal and restructuring of the
local reef ecosystem. The sequence of events that led to the extensive
destruction of this formerly flourishing coral patch is recorded by a
time series of underwater photographs. These were taken from the site
from westerly and southwesterly directions. Two major Diploria strigosa
colonies are marked on the pictures for better comparison of
differently orientated shots. The life and death chronicle of the coral
patch at &#34;Riffstation C&#34; between spring 1969 and summer 1998
are fixed by &#34;word and picture&#34;.^1";

Symposium on Fossil Cnidaria and Porifera]: 114-124.- <b>FC&#038;P
30-1</b>, p. 20, ID=1611^<b>Topic(s): </b>reefs, ecology, geohistory;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Caribbean^A series of underwater photographs, taken between 1968
and 1999, at five reef stations of San Andres Island (western Caribbean
Sea, Colombia), document and date the following biotic changes and
processes in the reef environment: the presence and absence of corals
and accompanying reef fauna, increase and decrease of live coral
coverage, partial and total coral mortality, impact of coral diseases,
storm fragmentation of corals, growth and regeneration of coral
colonies, bioerosion of coral heads and invasion of soft algae into the
reef environment. * The photographs indicate that degradation of
Acropora palmata and Acropora cervicornis thickets had already begun in
the 1970s, considerably preceding the well recorded mass bleaching
events of the 1980s. Encroachment by soft algae in the reef and lagoon
environment was first noticed in 1973, but increased in the following
years. Extensive algal proliferation witnessed in Caribbean reefs since
the 1980s was apparently not caused by, but was accelerated by the 1983
die off of the grazing urchins Diadema antillarum. A series of
photographs of reef biotopes over time permits retrospective analysis
of changes that otherwise would go unnoticed. [original abstract]^1";

<b>FC&#038;P 18-2</b>, p. 42, ID=2495^<b>Topic(s): </b>reefs, ecology,
current velocities; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>British Virgin Isls^The effects of
predominant currents on the morphology of coral reefs has been studied
in the leeward patch reefs of Anegada, British Virgin Islands.
Measurements of current velocity and direction and sediment
characteristics together with mapping of approximately 31 patch reefs
within a 2 km2 area suggest that even under relatively low but constant
velocities (surface current to 20 m sec-1) the major reef-building
corals show definite distribution patterns on the reef. The currents
also appear to be responsible, in part, for marked orientation and
elongation of patch reefs in a north-west &#47; south-east direction
and for a gradation of patch-reef type across the study area.^1";

s[4585] = "KOBLUK D.R., LYSENKO M.A. (1992).- Storm features on a
southern Caribbean fringing coral reef.- Palaios 7: 213-221.-
<b>FC&#038;P 23-2.1</b>, p. 66, ID=4428^<b>Topic(s): </b>reefs, storm
impacts; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Caribbean^Although there have been many studies that
have documented various effects of storms in coral reefs, to date there
have been no systematic studies of the depth distribution of storm
features and few discussions of the potential for preservation of
evidence of storm activity in reefs. After hurricane Gilbert and
tropical storm Joan passed through the Caribbean late in 1988, an
opportunity became available to study storm features and to relate them
to water depth in the leeward reefs of the southern Caribbean island of
Bonaire. In January 1989, sixty indicators of storm impact on the reefs
of Bonaire were found over the depth range 1.5m to 37m at 5 localities.
These are grouped in 3 broad categories, comprising effects on
sediment, effects on reef-dwelling organisms, and the deposition of
terrestrial vegetation on the reef. Damage to the reef consisted of
direct damage due primarily to wave impact and surge, and indirect
damage by secondary factors such as burial by sediment. The evidence of
direct physical damage was pronounced in the shallow parts of the reef,
and indirect damage dominated in the middle and deeper parts of the
reef. Taking all storm features together 3 to 4 months after the
storms, the greatest number of storm-related features (66%) was in the
```

```
11m to 20m depth range, so that although during the storms the greatest
physical damage to the reef was in the shallower parts, the post-storm
distribution of identifiable storm-related features did not reflect
this. The depth distribution of potentially preservable storm features
(45% of the total) is almost the same as the depth distribution of all
storm features. However, the proportion of potentially preservable
features is greatest in the shallowest (83%) and deepest (60%) parts of
the reef. Therefore, following a short period of adjustment after
storms Gilbert and Joan: 1) the remaining storm-related features were
not evenly distributed with respect to depth, 2) the greatest number of
storm-related features remaining were in intermediate water depths, 3)
the greatest number of potentially preservable storm features were also
in intermediate depths.^1";
s[4586] = "MAZZULLO S.J., ANDERSON-UNDERWOOD K.E., BURKE C.D., BISCHOFF
W.D., (1992).- Holocene coral patch reef ecology and sedimentary
architecture, northern Belize, Central America.- Palaios 7: 591-601.-
<b>FC&#038;P 23-2.1</b>, p. 66, ID=4429^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>Belize^The biotic composition, growth and relationship to sea level
history, and diagenetic attributes of a representative Holocene patch
reef (&#34;Elmer Reef&#34;) in the Mexico Rocks complex in northern
Belize are described, and compared to those of Holocene patch reefs in
southern Belize. Elmer Reef has accumulated in shallow (2.5m) water
over the last 420 yr, under static sea level conditions. Rate of
vertical construction is 0.3-0.5 m/100 yr, comparable to that of patch
reefs in southern Belize. A pronounced coral zonation exists across
Elmer Reef, with Montastrea annularis dominating on its crest and
Acropora cervicornis occurring on its windward and leeward flanks. The
dominance of Montastrea on Elmer Reef is unlike that of patch reefs in
southern Belize, in which this coral assumes only a subordinate role in
reef growth relative to that of Acropora palmata. Elmer Reef locally is
extensively biodegraded and marine, fibrous aragonite and some bladed
high-magnesium calcite cements occur throughout the reef section,
partially occluding corallites and interparticle pores in associated
sands. Patch reefs in southern Belize have developed as catch-up and
keep-up reefs in a transgressive setting. In contrast, the dominant
mode of growth of Elmer Reef, and perhaps other patch reefs in Mexico
Rocks, appears to be one of lateral rather than vertical accretion.
This style of growth occurs in a static sea level setting where there
is only limited accommodation space because of the shallowness of the
water, and such reefs are referred to as &#34;expansion reefs&#34;.
[original summary; comments on this paper are given by William F.
Precht in Palaios 8, 1993: 499-502]^1";
s[4587] = "GISCHLER E. (1994).- Sedimentation on Three Caribbean
Atolls: Glovers Reef, Lighthouse Reef and Turneffe Islands, Belize.-
Facies 31: 243-254.- <b>FC&#038;P 24-1</b>, p. 85, ID=4520^<b>Topic(s):
</b>reefs, sedimentation; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Caribbean^The chief mode of carbonate
sedimentation on the Belizean atolls Glovers Reef, Lighthouse Reef and
Turneffe Islands is the accumulation of organically-derived particles.
Variations in the distribution of the composition and grain-sizes of
surface sediments, collected along transects across the atolls, are
environmentally controlled. Two major sediment types may be
distinguished. (1) Reef and fore reef sediments are dominated by
fragments of coral, coralline algae and Halimeda. Mean grain-sizes
range from 1-2mm. (2) Back reef sediments contain more mollusk
fragments, more fine-grained sediment (&#60;125µm) and appear to have
fewer Halimeda fragments. In addition, sediments from inner platforms
and shallow lagoonal parts of Glovers and Lighthouse Reefs comprise
non-skeletal grains, namely fecal pellets. Sediments from lagoonal
patch reefs may contain up to 20% coral fragments. Mean grain-sizes
range from 0.1-1mm and are finest on the inner platform and lagoon
floor of the backreef environment. Within the reef and fore reef
```

```
environments, it is not possible to distinguish sub-environments on the
basis of textural and compositional differences of the sediments.
Sediments from patch reefs contrast with those from back reef lagoons
and inner platforms and are similar in terms of grain-sizes and
compositions to reef and fore reef surface sediments. Non-skeletal
grains forming in shallow parts of the back reef in Glovers and
Lighthouse Reefs are interpreted to be indurated by interstitial
precipitation of calcium carbonate from warm, supersaturated water
flushing the sediment. The lack of hardened non-skeletal particles in
the back reef sediments of Turneffe Islands is most probably due to the
abundance of muddy, organic-rich sediment in the well protected lagoon.
Fine sediment is less permeable and organic films prevent cement
overgrowth on particles.^1";

shallow-subtidal dolomitization by near-normal seawater, northern
Belize.- Geology 23, 4: 341-344.- <b>FC&#038;P 24-2</b>, p. 101,
ID=4611^<b>Topic(s): </b>dolomitization, normal seawater;
dolomitization; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>Belize^Calcic dolomite cements compose an average of
5% of the upper 4.3m of subtidal deposits &#60;5600 yr old in the
Cangrejo shoals in Belize. Mean &#948;18O (+2‰) compositions of the
high-Sr dolomites (mean 1000 ppm), together with near-normal salinity
and inherently normal Mg/Ca ratio of pore fluids, suggest precipitation
from near-normal seawater. Tidal and wind-driven circulation of
seawater through the sediments supplies most of the Mg for
dolomitization, which appears to be promoted by elevated pore-water
alkalinity resulting from bacterially mediated oxidation of organic
matter and, locally, early stages of methanogenesis. Rapid
dolomitization here supports the idea that significant quantities of
dolomite can form syndepositionally, from normal seawater, in shallow
subtidal deposits. ^1";

</b>Recent; <b>Geography: </b>Caribbean, Pacific S^Stable isotope
records of demosponges from the Caribbean and Coral Sea are described
for the purpose of studying the influence of fossil fuel CO2 on the
carbon isotopic composition of dissolved inorganic carbon (DIC) in
surface water. The slow-growing sponges precipitate calcium carbonate
in isotopic equilibrium with ambient sea water and are used to detect
changes in &#948;13CDIC from pre-industrial times (early 19th century)
to the present. We observed similar shapes and ranges in &#948;13C
curves measured on Caribbean specimens collected from water depths of
25, 84 and 91m as well as [in] a specimen collected in shallow waters
off New Caledonia. The records reveal a highly significant correlation
with atmospheric &#948;13CCO2. &#948;13CDIC values for Caribbean and
Coral Sea surface waters were calculated using the &#948;13C sponge
records. While &#948;13C of atmospheric CO2 decreased by about 1.4‰
from the early 19th century to 1990, &#948;13CDIC of Caribbean and
Coral Sea surface waters decreased by 0.9±0.2‰ and 0.7±0.3‰,
respectively. No isotopic equilibrium between surface water DIC and
atmospheric CO2 was observed, either during the pre-industrial steady
state or during the last 100 years. The lower amount of depletion in
the surface water &#948;13CDIC with respect to the atmospheric
anthropogenic signal is explained by the dilution of the surface waters
by biologically altered subsurface water DIC. The lower &#948;13C
decrease in the Coral Sea points to a stronger influence of the
subsurface water source compared to the Caribbean. [original

(1995).- Cenozoic biogenic mounds and buried Miocene(?) barrier reef on a predominantly cool-water carbonate continental margin - Eucla basin, western Great Australian Bight.- Geology 23, 5: 427-430.- <b>FC&#038;P 25-1</b>, p. 52, ID=3063^<b>Topic(s): </b>reefs, cool water; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Cenozoic; <b>Geography: </b>Australia, Great Australian Bight^The southern continental margin of Australia is the largest area of cool-water carbonate shelf deposition on the globe. Interpretation of 5495km of air gun seismic-reflection data in the western part of the Great Australian Bight indicates that the 700m thick Cenozoic section of the offshore Eucla basin was deposited largely as a prograding cool-water, middle- to high-latitude carbonate ramp, characterized by widespread development of broad, low-relief, biogenic (bryozoan? - sponge), shelf and upper-slope mounds. The succession also contains a spectacular and extensive (>475km long) buried middle Miocene barrier reef (the Miocene Little Barrier Reef) parallel to the modern shelf edge. This rimmed carbonate platform margin represents an episode of warm-water sedimentation during a global climatic optimum, probably coupled with strong eastward flow of a proto-Leeuwin Current. The late Miocene eustatic seal-level fall produced an areally restricted debris-apron sequence at the foot of the reef escarpment. The carbonate platform is capped by a Neogene cool-water carbonate ramp succession typified by aggradational to sigmoidal sequences, punctuated by periods of cold-water, sea-floor erosion. Interpretation of this succession in the light of global and local tectonic and oceanographic events illustrates the dominant influence of water temperature on carbonate platform and reef growth throughout the Cenozoic.^1";
s[4611] = "JANUSSEN D., TABACHNICK K.R., TENDAL O.S. (2004).- Deep-sea Hexactinellida (Porifera) of the Weddell Sea.- Deep-Sea Research Part II: Topical Studies in Oceanography 51, 14-16: 1857-1882.- <b>FC&#038;P 33-2</b>, p. 42, ID=1192^<b>Topic(s): </b>taxonomy; Porifera Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Antarctica^New Hexactinellida from the deep Weddel Sea are described. This moderately diverse hexactinellid fauna includes 14 species belonging to 12 genera, of which five species and one subgenus are new to science: Periphragella antarctica n.sp., Holascus pseudostellatus n.sp., Caulophacus (Caulophacus) discohexactinus n.sp., C. (Caulodiscus) brandti n.sp., C. (Oxydiscus) weddelli n.sp., and C. (Oxydiscus) n.subgen. So far, 20 hexactinellid species have been reported from the deep Weddell Sea, 15 are known from the northern part and 10 only from here, while 10 came from the southern area, and five of these only from there. However, this apparent high &#034;endemism&#034; of Antarctic hexactinellid sponges is most likely the result of severe undersampling of the deep-sea fauna. We find no reason to believe that a division between an oceanic and a more continental group of species exists. The current poor database indicates that a substantial part of the deep hexactinellid fauna of the Weddell Sea is shared with other deep-sea regions, but it does not indicate a special biogeographic relationship with any other ocean. [original abstract]^1";
s[4612] = "SALOMON D., BARTHEL D. </b>taxonomy; Porifera Hexactinellida; <b>Systematics: </b>Porifera;
Hexactinellida; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Australia, Great Australian Bight^The four species of
Hexactinellida described are the first members of the class reported
from southern Australian shelf and slope waters. The large vasiform
Pheronema amphorae n.sp. is the first known member of the genus outside
the Atlantic region bearing a well-developed annulus. Euplectella
regalis, previously known only from the holotype, is represented by two
new individuals. A very large specimen of Regadrella okinoseana,
exhibiting the extremely rare feature of sieve plate fusion, offers new
data which permits synonymization of all stauractin-bearing
regadrellids.^1";
s[4614] = "BARTHEL D., TENDAL O.S. (1994).- Antarctic Hexactinellida.-
Theses Zoologicae 23 [Weagele J. W &#038; Sieg J. (eds): Synopsis of
the Antarctic Benthos, Vol. 6]; 154 pp., 53 text-figs., 20 plates;
Champaign (Koeltz Scientific Books), ISBN 3-87429-3 59-9.- <b>FC&#038;P
24-1</b>, p. 93, ID=4530^<b>Topic(s): </b>biology; Porifera
Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Antarctic seas^This
handy book gives a very good introduction into the topical knowledge
about biology and terminology, e.g. spicule types, of the recent
Hexactinellida. The taxonomic system followed is that of Ijima (1927)
with some revisions from Bergquist (1978), Burthon (1929), Hartman
(1982), and Levi (1964) included. The diverse antarctic assemblage of
Hexactinellida described here includes 16 genera with 26 species
distributed in 8 families. The descriptions are illustrated with
drawings after Schulze and Kirkpatrick and supplied with maps of
antarctic distribution of the various species. This book is a must for
anyone working with Antarctic fauna, or with Hexactinellida. By far the
largest number of samples of Antarctic hexactinellids comes from the
shelf. There are only two records from the slope (800-2000m), and 17
from depths around 2000m and downwards. The Antarctic hexactinellid
fauna comprises 28 species as treated here, and a further 10 may be
considered in the distribution analysis because they have been recorded
close to the Antarctic convergence, mainly in deep water. There is a
distinct vertical division into a shelf group of species and a deep
water group. The relatively few species on the shelf are present in
high numbers and give rise to large biomasses. By species number,
however, hexactinellids are a predominantly deep-see group in
Antarctica, as they are in other oceans.^1";

<b>Geography: </b>Antarctica^Thirty one species of Archaeocyaths are
described from measured sections of the Nimrod Glacier area, which
confirm earlier correlations of Shackleton limestone faunas with the
Botomian stage of Siberia. Archaeocyatha from a section in Byrd Glacier
area are Botomian or early Toyonian in age. Ten further archaeocyath
species are added to the six species already known to be common both
for Antarctica and Australia, confirming the existence of a Gondwana
supercontinent in early Palaeozoic.^1";
s[4622] = "DEBRENNE F., KRUSE P.D. (1989).- Cambrian Antarctic
archaeocyaths.- Geological Society Special Publication 47: 15-28.-
<b>FC&#038;P 19-1.1</b>, p. 18, ID=2563^<b>Topic(s): </b>biogeography;
Archaeocyatha; <b>Systematics: </b>Porifera; Archaeocyatha;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>Antarctica^Most
Antarctic archaeocyaths have been collected as allochthonous blocks,
```

```
but some in situ collections provide stratigraphic control. All
existing collections are taxonomically revised. Strong faunal
affinities are evident at the species level with in situ Early Cambrian
faunas in South Australia and allochthonous faunas in South Africa and
Antarctica. This allows the recognition of an Early Cambrian Gondwana
province and confirms the existence of a Gondwana supercontinent
throughout the Paleozoic.^1";
s[4623] = "WRONA R., ZHURAVLEV A.Yu. (1996).- Early Cambrian
archaeocyaths from glacial erratic of King George Island, West
Antarctica.- Palaeontologia Polonica 55 [Gazdzicki A. (ed.):
Palaeontological Results of the Polish Antarctic Expedition. Part H.]:
pp?.- <b>FC&#038;P 25-2</b>, p. 23, ID=3086^<b>Topic(s): </b>erratics;
Archaeocyatha; <b>Systematics: </b>Porifera; Archaeocyatha;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>Antarctica, King
George Isl^Twenty six species of archaeocyaths, including one
Naimarkcyathus elenae gen. et sp.nov. representing a new family
Naimarkcyathidae, are described from the Cambrian limestone erratics of
the glacial-marine sediments of the Oligocene Polonez Cove and Early
Miocene Cape Melville formations on King George Island (South Shetland
Island, West Antarctica). They are accompanied by coralomorphs and
calcified cyanobacteria. The archaeocyathan assemblage closely
resembles allochthonous ones from the Weddel Sea and Whicaway Nunataks.
Current reconstructions of icestream movement and iceberg drift and
similarities in species composition suggest the source of these
erratics to be the Argentina Range limestone. Some species, namely,
Stapicyathus stapipora, Prethmophyllum subacutum, Aporosocyathus
mucroporus, &#34;Mennericyathus&#34; dissitus, Paranacyathus sarmaticus
and Archaeopharetra irregularis are added to the list of common species
for Antarctica and Australia. The archaeocyaths of King George Island,
and all other allochthonous and in situ Early Cambrian Antarctic
archaeocyathan assemblages (with exception for the Mt Egerton in the
Byrd Glacier area) are of the uppermost Botomian age (Syringocnema
favus beds) as found in South Australian strata. This means that
archaeocyaths did not reach Antarctica untill latest Botomian time.
Blocks containing archaeocyaths represent different reef facies
comparable to the Kooliwurtie Limestone Member of the Yorke Peninsula.
The occurrence of small shelly fossils typical of the upper Kulpara
Formation-lower Parara Limestone, of archaeocyaths of Syringocnema
favus beds, and of Hadimopanella antarctica and certain brachiopods in
erratics of different lithologies suggests a very similar faunal and
facies succession for Antarctica and South Australia and therefore
probably a comparable basin history.^1";

tube-builder hydractinian, symbiotic with hermit crabs, from the
Cretaceous of Antartica.- Journal of Paleontology 68, 6: 1169-1182.-
<b>FC&#038;P 24-1</b>, p. 73, ID=4503^<b>Topic(s): </b>symbiosis,
hermit crabs; Hydrozoa; <b>Systematics: </b>Cnidaria; Hydrozoa;
<b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>Antarctica^An Upper
Cretaceous (early Maastrichtian) tube-building hydractinian
(Psammoactinia antarctica n.gen. and sp.) from Sanctuary Cliffs, Snow
Hill Island, believed to live in association with hermit crabs, is
described for the first time from Antarctica. Psammoactinia forms
thick, concentric, globular colonies that encrust gastropod shells and
extend the shell aperture by forming an open spiral tube. The colony
consists of concentric layers with chambers and pillars made of silt
and very fine sand grains agglutinated by cellophane, which is
interpreted as a diagenetic modification of an original chitinous
phosphatic material. On the basis of the additional finding of isolated
claws of pagurid crabs, assigned to Paguristes sp., the functional
analysis of the hydractinian structure, and a comparison with modern
and fossil analogous structures it is concluded that the peculiar
hydractinian tube is a carcinoecium that housed a symbiotic hermit
crab. Paleoenvironmental and paleoecological inferences suggest that
the Psammoactinia-Paguristes association is mainly controlled by a
fine-grained substrate and by a lack of abundant gastropod shells of
different sizes. These factors do not necessarily correlate with
absolute water depth, and favorable environments could include either
offshore, relatively deep water or shallow restricted depositional
settings. ^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Jurassic M;
<b>Geography: </b>India, Kachchh^The current classification of
scleractinian corals based upon gross morphological features has been
found unsatisfactory due to additional information from skeletal
microarchitecture and microstructure. It is necessary to investigate
microstructural details and limits in morphologic variation within and
between different coral clades before a revised classification is
```

```
constructed. Variations in morphologic characters and microstructural
details from a population of Dimorpharaea de Fromentel, 1861 (Family
Microsolenidae) from Upper Bathonian (Jumara Dome) strata in Kachchh
are described. The data used include the diameter (D) and height (U) of
the corallum, number of corallites in the colony (NC), number of septa
in the mother corallite at the center of the colony (NS), minimum
distance between centers of central corallite and corallite of the
inner ring (CI), minimum distance between corallite centers of the
outer ring (C2), septal density (DS) and trabecular density (DT). The
principal components analysis reveals that most of the variation is
explained by &#034;size&#034; related characters (D and H) while
corallite density (NC and CI) and septal structures (DS and DT)
contribute to the second and third principal component axes,
respectively. The microarchitecture and distribution of characters
observed in the Kachchh Dimorpharaea require a re-evaluation of
familial-specific concepts and suggest that the population belongs to a
single species, Dimorpharaea stellans Gregory, 1900, rather than four
nominal species (D. stellans, D. disctincta, D. continua and D. orbica)
as has been assumed. [original abstract]^1";

distribution of scleractinian corals in the Jurassic of Kachchh,
Western India.- Journal of the Geological Society of India 57:
479-495.- <b>FC&#038;P 30-2</b>, p. 28, ID=1583^<b>Topic(s):
</b>environmental distribution; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Jurassic Bath - Oxf;
<b>Geography: </b>India, Kachchh^Scleractinian corals commonly occur at
specific horizons and localities, in carbonate and in siliciclastic
sediments, throughout the Jurassic (Bajocian to Oxfordian) of Kachchh
as meadows, biostromes, boulder beds and as scattered specimens. In
many cases they are part of the autochthonous benthic fauna and in
others they suffered short intra-basinal transport. Cerioid forms of
low diversity (Amphiastraea, Isastraea, etc.) abound in high-energy
siliciclastic sediments. High diversity coral faunas, which include
thamnasterioid (Microsolena, Dimorpharaea and Kobya) and solitary
(Trocharaea and Trochoplegma) taxa with fenestrate septa and plocoid
forms (Stylina), dominate in carbonate sediments deposited in low
energy, deeper-water environments. The solitary Montlivaltia exhibits a
great physiological tolerance of environmental stress. In all, eight
coral assemblages have been recognized within the ?Early Bajocian to
Late Callovian sediments of the Kachchh basin. * The distribution of
scleractinian coral assemblages has been governed mainly by the rate of
sedimentation and particularly by the influx of coarse siliciclastic
material. As a consequence the distribution pattern reflects
onshore-offshore gradients and the general deepening of the Kachchh
basin towards the Oxfordian. [original abstract]^1";
s[4642] = "PANDEY D.K., LATHUILIERE B. (1997).- Variability in
Epistreptophyllum from the Middle Jurassic of Kachchh, Western India:

ID=6501^<b>Topic(s): </b>geology, reefs; geology, reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic; <b>Geography:
</b>India, Kachchh^Marine Jurassic sediments (Bajocian-Tithonian) of
the Kachchh Basin were deposited in a ramp setting. Except during the
Middle and Late Bathonian, when a carbonate regime became established,
the fill of the basin consists predominantly of siliciclastics. The
sediments represent environments that range from coastal plains (rivers
and associated flood plains with caliche nodules), deltas, brackish
water lagoons, nearshore sand and iron-oolite bars of the inner ramp,
generally situated above fair-weather wave-base, to the middle ramp
influenced by storm-waves and by storm-generated currents, and finally
to the outer ramp which is characterised by low energy, fine-grained
sediments. Changes in relative sea level produced a cyclic
sedimentation pattern. The rich benthic fauna of macroinvertebrates is
dominated by bivalves, followed by brachiopods, gastropods, corals,
serpulids, and sponges. The analysis of 370 statistical samples and
more than 27, 000 specimens produced more than 40 benthic associations
and assemblages. They show a relationship to several environmental
parameters, two of which, salinity and climate, are briefly discussed.
The spatial distribution of the facies and biota is outlined for two
time slices, the Bathonian and the Callovian-Oxfordian, respectively.

Biological and Paleontological Evidence that Eumetazoa, Including
Porifera (Sponges), are of Monophyletic Origin.- In: Watanabe Y.
Fusetani N. (Eds.): Sponge Sciences. Multidisciplinary Perspectives:
133-156.- <b>FC&#038;P 27-2</b>, p. 65, ID=3934^<b>Topic(s): </b>early
phylogeny; Eumetazoa monophyly; <b>Systematics: </b>Animalia;
<b>Stratigraphy: </b>Proterozoic; <b>Geography: </b>^The phylogenetic
relationships of the kingdom Animalia (Metazoa) have long been
questioned. Initially, detailed descriptions of animal embryology and
adult morphology were used to solve the evolutionary origins of distant
groups such as phyla. Focusing on the lowest eukaryotic multicellular
organisms, the metazoan phylum Porifera (sponges), it remained unclear
if they independently evolved multicellularity from a separate protist
lineage (polyphyly of animals) or derived from the same protist group
as the other animal phyla (monophyly). Based on constituent characters
of the sponges a monophyletic origin of the Porifera can be deduced.
The oldest complete fossil sponge has been described from the Early
Cambrian, while the earliest spicules date from the late Proterozoic,
about 600 million years ago. It is suggested that the first sponges did
not contain spicules. After having analyzed those genes from the sponge
Geodia cydonium which are typical for multicellularity, e.g., those
coding for adhesion molecules/receptors and a nuclear receptor, it has
to be concluded that all animals, including sponges, are of
monophyletic origin. Based on the elaborated molecular biological data
we suggest not subdividing Metazoa into Parazoa (including the sponges)
and Eumetazoa. In addition it was estimated that the adhesion
molecules/receptors from sponges diverged from a common ancestor in the
Precambrian, about 800 million years ago.^1";

<b>Systematics: </b>Animalia; <b>Stratigraphy: </b>Proterozoic;
<b>Geography: </b>^To understand the early evolution of the Metazoa, it
is necessary to determine the correct phylogenetic status of
diploblastic animals. Despite cladistic studies of morphological
characters and recent molecular phylogenetic studies, it remains
uncertain whether diploblasts are monophyletic or paraphyletic, and how
the phyla of diploblasts are phylogenetically related. The heat shock
protein 70 (Hsp70) sequences, because of their ubiquity and high degree
of conservation, could provide a useful model for phylogenetic
analysis. We have sequenced almost the entire nucleic acid sequence of
cytoplasmic Hsp70 from eight diploblastic species. Our data support the
monophyly of diploblastic animals. However, the phylogenetic
relationships of the diploblast groups were not significantly resolved.
Our phylogenetic trees also support the monophyly of Metazoa with high
bootstrap values, indicating that animals form an extremely robust
clade.^1";

Phylogenomics Revives Traditional Views on Deep Animal Relationships.-
Current Biology 19, 8: 706-712.- <b>FC&#038;P 36</b>, p. 130,
ID=6587^<b>Topic(s): </b>early phylogeny; early phylogeny;
<b>Systematics: </b>Animalia; <b>Stratigraphy: </b>Proterozoic;
<b>Geography: </b>^The origin of many of the defining features of
animal body plans, such as symmetry, nervous system, and the mesoderm,
remains shrouded in mystery because of major uncertainty regarding the
emergence order of the early branching taxa: the sponge groups,
ctenophores, placozoans, cnidarians, and bilaterians. The
&#34;phylogenomic&#34; approach [1] has recently provided a robust
picture for intrabilaterian relationships [2, 3] but not yet for more
early branching metazoan clades. We have assembled a comprehensive 128
gene data set including newly generated sequence data from ctenophores,
cnidarians, and all four main sponge groups. The resulting phylogeny
yields two significant conclusions reviving old views that have been
challenged in the molecular era: (1) that the sponges (Porifera) are
monophyletic and not paraphyletic as repeatedly proposed [4-9], thus
undermining the idea that ancestral metazoans had a sponge-like body
plan; (2) that the most likely position for the ctenophores is together
with the cnidarians in a &#034;coelenterate&#034; clade. The Porifera
and the Placozoa branch basally with respect to a moderately supported
&#34;eumetazoan&#34; clade containing the three taxa with nervous
system and muscle cells (Cnidaria, Ctenophora, and Bilateria). This new
phylogeny provides a stimulating framework for exploring the important
changes that shaped the body plans.^1";

Paleobiology 18, 4: 378-382.- <b>FC&#038;P 22-1</b>, p. 30,
ID=3382^<b>Topic(s): </b>problematica, polypoid?; Cnidaria ?,
Dickinsonia; <b>Systematics: </b>Cnidaria; <b>Stratigraphy:
</b>Neoproterozoic; <b>Geography: </b>^Dickinsonia is reconstructed as
a benthic polypoid of generally cnidarian design. The oral surface was
without tentacles but contained a median oral slit that probably led
through a pharynx into an enteron, which was divided into digestive
diverticulae by radiating mesenteries; feeding may have been via
ciliary tracts. The mesenteries and the body wall contained a stiff
form of mesogloea. There seems to be no need to postulate a novel
constructional grade for this organism, bringing the concept of the
Vendozoa into question.^1";

75, ID=3765^<b>Topic(s): </b>monophyly; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Neoproterozoic - Recent;
<b>Geography: </b>^The monophyly of the Porifera is well established.
According to our hypothesis the Hexactinellida are the adelphotaxon of
the Pinacophora (new taxon = Calcarea + Homoscleromorpha +
Demospongjae). The Porifera are the adelphotaxon of the Eumetazoa &#47;
Placozoa. Sponge spicules are considered not to be a constituent
character of the Porifera. Mineralized spicules developed independently
within the three poriferan main taxa the Hexactinellida, Calcarea, and
Demospongiae. Demospongian microscleres are not derived from
```

```
megascleres in contrast to those of Hexactinellida. Accordingly,
spicules probably developed several times within the Demospongiae.
Remains of Porifera are known since the late Proterozoic.^1";

Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Ediacaran
- Cambrian; <b>Geography: </b>^The taxon Porifera as the earliest
definite Metazoan phylum is documented from ca. 543-549 Mio. Y. old
sediments, e.g. of Ediacara lagerstaetten: Palaeophragmodictya, a
hexactinellide-like early sponge from these strata may not have
possessed any mineralized spicules at all. Tiny fossils from the ca.
580 Mio. Y. old Duoshantuo-phosphorite have been interpreted as
juvenile sponges, in which case they belong to the Demospongiae.
However, the clade Porifera most probably separated from the Eumetazoa
at least 200 Mio. Y. earlier. During the earliest Cambrian the
Hexactinellida were predominant, but already from the Atdabanian, the
taxon Pinacophora has become highly diverse, e.g. the demospongide
group Astrophora, including the ecologically flexible Geodiidae. [first

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>fossil;
<b>Geography: </b>^Microstructures in Palaeozoic corals are discussed
```

```
in a comprehensive survey resulting from current examinations. It is
considered that diagenetic alterations are more common than hitherto
assumed. This bears consequences for taxonomic purposes as well as for
phylogenetic inferences. In principal, three fundamental types of
diagenetical changes, concerning pseudoskeletal. i.e. diagenetic
altered microstructures, have to be distinguished: (1) skeletogenic
recrystallization, (2) aggrading neomorphism and (3) calcite twinning.
* The latter includes zigzag patterns and pseudolamellar structures,
both of which are due to the same mineralogical regularities of
calcite. The occurrence of cyanobacteria in the coralla of Favosites
specimens from the Eifel Hills, Germany, shows that the overprinting of
the skeleton by aggrading neomorphism and formation of cleavages most
probably succeeded cyanobacterial settlement. Therefore,
&#34;Stirnzonen&#34;, zigzag patterns, and microlamellar structures
cannot be primary in origin. [original abstract]^1";

paleotemperature records, and the aragonite-calcite transformation.-
Geology 23, 4: 333-336.- <b>FC&#038;P 25-1</b>, p. 30,
ID=3003^<b>Topic(s): </b>paleotemperatures, calcite - aragonite;
Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>fossil; <b>Geography: </b>^Oxygen isotopic records from corals play
an increasing role in paleoclimatic research and climatic modeling.
Proxy records of sea-surface temperature are produced by isotopically
analyzing samples drilled from aragonitic (CaCO3) coral skeletons.
However, drilling aragonite causes a polymorphic inversion to calcite
accompanied by 18O) enrichment. The isotopic enrichment may occur
through atmospheric exchange, CO2 degassing, or fractionation during
digestion. Regardless of the mechanism, dry drilling produced isotopic
shifts as large as 0.8‰, corresponding to an erroneous temperature
decrease of 3°C. This error is larger than the global temperature rise
since the Industrial Revolution, and a substantial part of the global
temperature variation over the past 10 ka. Because the isotopic shift
is inconsistent and can occur without the production of measurable
calcite, detecting and correcting the isotopic shift may be
difficult.^1";

haplosclerida appeared. An important boundary for the demosponges is
the late Devonian extinction event, which caused a complete overhaul of
demosponge communities. The Late Permian and the Triassic, especially
the Late Triassic, are the main eras for coralline sponge radiation and
dominance, in which some modern taxa occur for the first time
(Ceratoporella, Astrosclera, Vaceletia). In the Late Jurassic the
freshwater environments were occupied by certain (marine) demosponges,
mostly Haplosclerida. The importance of coralline demosponges as
primary reef-builders decreases up to the Late Cretaceous.^1";

Porifera Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>fossil; <b>Geography: </b>^Rauff (1893/94) was the
first author to pay attention to the very special shape of nodes in
some hexactinellid principal spicules. The principals concerned show
the usual regular triaxial symmetry (a constituent character of the
Hexactinellida), but in addition they are provided with 12 oblique
cross-beams closely surrounding the axial cross. According to these
latern-like nodes Rauff (1893/94) invented the name lychnisk for this
kind of spicules. Since the lychniscs are very common within the
Mesozoic Hexactinellida, Schrammen (1902: 7) erected a taxon
&#034;Unterordnung Lychniskophora&#034; to comprise all hexactinellids,
whose principal supporting skeleton consists of lychniscs.

</b>misidentification cases; corals, vs, belemnites; <b>Systematics:
</b>Mollusca; <b>Stratigraphy: </b>fossil; <b>Geography: </b>^In some
genera of the coral order Pennatulacea Verrill 1865, spicules or
sklerodermites and horny tissue form mesodermal solid calcareous axes
or tubes with transverse tabulae. A well-preserved fossil example of
Pennatulacea was described by Zittel (1924, p. 130, fig. 205) under the
name Graphularia desertorum Zittel. Although clearly corals, such
fossils could mislead palaeontologists into interpreting them as
coleoid remains. Thus, carbonaceous Graphularia axes show some
resemblance to internal structures of belemnite rostra, and
unfortunately, certain Graphularia stems seem to have an orthoconic
cavity at one end similar to the belemnite&#039;s alveolus. Conversely,
the internal structures of some coleoids could lead to their
interpretation as corals. [first fragment of a short note]^1";

Cnidaria; <b>Systematics: </b>Cnidaria; <b>Stratigraphy: </b>fossil;
<b>Geography: </b>^The later Precambrian and early Phanerozoic record
of cnidarian or supposed cnidarian fossils is reviewed. The first
reliable records are considered to be among the Ediacaran fauna of
Vendian age and most cnidarian groups with a significant fossil record
had appeared by the Ordovician. The relationship of some important
fossil groups of disputed or doubtful affinities are discussed. The
Stromatopora and Chaetetida are considered to be closer to the Porifera
than the Cnidaria, in agreement with most recent work. The Conulata are
of uncertain relationship but may form a separate class of cnidarians.
The Hydroconozoa are also accepted as a provisional cnidarian class. A
suggestion that some or all tabulate corals may be more closely related
to the Porifera is disputed. * Cambrian coral records are reviewed and
some are regarded as very doubtful or not of cnidarian affinities. The
relationship of the remainder to the Ordovician records are discussed
and possible phylogenetic schemes for the early diversification of the
tabulate and rugose corals are outlined. No post-Cambrian direct
phyletic link between Tabulata and Rugosa is considered likely but a
common ancestor for the two orders may have existed in the late
Precambrian or early Cambrian. * Various opinions on the origin and
phylogeny of the Cnidaria are briefly outlined. Doubts concerning the
completeness of the fossil record and uncertainties over the
interpretation of Precambrian material weakens the contribution of the
palaeontological evidence to the debate on the nature of the earliest
cnidarians. [original abstract]^1";

p. 136, ID=6600^<b>Topic(s): </b>medusae; cnidarian medusae;
<b>Systematics: </b>Cnidaria; <b>Stratigraphy: </b>fossil;
<b>Geography: </b>^Fossils of cnidarian medusae are extremely rare,
although reports of fossil medusoids, most of which do not represent
medusae, are rather common. Our previous inability to distinguish these
fossils has hampered attempts to investigate patterns and processes
within the medusozoan fossil record. Here we describe criteria for the
recognition of bona fide fossil medusae and use them to assess the
evolutionary, paleoenvironmental, and taphonomic history of the
Medusozoa. Criteria include distinctive sedimentologic and taphonomic
features that result from transport, stranding, and burial of hydrous
clasts, as well as unequivocal body structures comparable to those of
extant animals. Because the latter are uncommon, most fossil medusae
remain in open nomenclature; many are assigned to stem-group
scyphozoans. The majority of described medusae are associated with
coastal depositional environments (such as tidal flats or lagoons).
They rarely occur in oxygen-poor deeper-water facies. All medusan
groups have long geologic histories. Scyphozoa are known from the
Cambrian, but more derived scyphomedusae were not demonstrably present
until the Carboniferous; Mesozoic scyphozoans are rather diverse.
Hydromedusae are known from the Ordovician but may extend back to the
Cambrian. The record of cubozoans is shorter and sparser; the oldest
definite cubozoan is Carboniferous in age. [original abstract]^1";

```

```
the most diverse ecosystems on our planet. Historical and ecological
factors are discussed as potential causes of the extremely high species
richness ranging to hundreds of thousands. The extreme depletion of
nutrients, the spatial complexity and the common but moderate
disturbances of the reef building is well documented in the fossil
record but quantitative fluctuations of reef diversity are only roughly
known. The best available diversity curves for the last 550 million
years exhibit strong variations of both species richness within reefs
and the global diversity of reef builders. These fluctuations are often
related to mass extinctions but also occur independently of
evolutionary crises. The most important factor governing secular
fluctuations of reef diversity is probably the nutrient concentration
in the oceans. Climate change, while influencing the biological
composition of reefs, had only limited effect on reef diversity.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>fossil; <b>Geography:
</b>^Most fossil coral reefs are not readily comparable to modern reefs
in terms of ecology and framework structure because both fossil and
recent reefs formed in a wide range of particular environmental
settings resulting in diverging aspects of individual bioherms. The
most important environmental parameters are the type of substratum
available for settlement of larvae and the influence of sea level
fluctuations. Effects of both on reef formation are discussed. Reefs
that formed with taxonomically divergent coral faunas and at different
geological times under broadly comparable environmental settings may
show surprising geomorphological and ecological similarities. Such reef
formations are termed &#34;analogous reefs&#34;. Comparative studies of
couplets of analogous reefs, one recent and one fossil may be an
efficient tool for better understanding of both fossil and recent reef
```

```
environments. A few selected examples of such analogous reefs,
established on unstable substrata, are discussed from basinal and
deltaic deposits and from turbiditic environments.^1";

collapse.- Coral Reefs 13, 1: 3-11.- <b>FC&#038;P 23-1.1</b>, p. 7,
ID=4048^<b>Topic(s): </b>reef ecosystems, geohistory; reef ecosystems;
<b>Systematics: </b>; <b>Stratigraphy: </b>fossil; <b>Geography:
</b>^Platform carbonate and, particularly, reef ecosystem development
(with reefs representing the acme of carbonate platform growth) were
highly cyclical in early to mid Paleozoic time, especially in relation
to known or postulated times of global warming or cooling. These cycles
do not appear to correspond to postulated 26 Ma rhythms seen in
diversity patterns, nor were they regular. There were major periods of
worldwide reef expansion (e.g. mid-Silurian-Late Devonian),
corresponding to global warming well above present day norms, and
periods of complete global reef collapse (e.g., mid-Cambrian to
mid-Ordovician, Late Devonian) corresponding to global perturbations.
At times of major reef expansion in the Paleozoic, areas covered by
equatorial reef and inter-reef carbonate platforms are conservatively
estimated to have periodically exceeded 5 million sq. km, nearly ten
times that in the modern ocean. At times of global reef collapse, e.g.
the Famennian (Late Devonian), reef complexes were completely absent
or, at best, covered &#060;1000 sq. km. The chief factors relating to
periodic collapse and mass extinction of reef biotas appear to be
related to climatic change and possibly ocean anoxic events, in turn as
a response to large scale, geologically disruptive factors such as
plate collisions, plate movement across equatorial belts and volcanism.
Stress &#034;signals&#034; in Cambrian through Cretaceous reef
ecosystems appear to be comparable to those of today: whether these
relate to physical versus biological stress is uncertain. Reef stress
is evident in globally reduced areas and thicknesses of reef carbonate
production, the absence of large scale barrier reef systems and
reduction to smaller patch reef complexes (or, periodically, following
mass extinctions, no reefs at all), reduced species and genus
diversity, small skeletons or colonies, limited or no biotic zonation
along reef transects, and arrested succession and ecologic replacement
of complex, more highly evolved taxa by &#034;simpler&#034;,
stress-resistant disaster taxa at the genus to ordinal (or even phylum)
level. [original abstract]^1";
s[4738] = "COPPER P. (1994).- Reefs under stress: the fossil record.-
Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.)
Proceedings of the VI. International Symposium on Fossil Cnidaria and
Porifera, Vol. 2]: 87-94.- <b>FC&#038;P 23-1.1</b>, p. 15,
ID=4066^<b>Topic(s): </b>stress; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>fossil; <b>Geography: </b>^Reef ecosystems under
stress are those which operate at much less than or below optimal
environmental conditions. Stressed habitats are reflected in reduced
reef thickness and diameters, absence of large scale barrier and atoll
systems, general failure to develop clear biotic zonation, lowered
diversity, stunted size of colonial corals, partial replacement by
solitary corals and stress tolerant taxa, and arrested ecologic
successions. Stressed reef communities typically occur today at the
fringes of coral reef development in higher latitudes, where coral
dominated faunas are replaced by
bryozoan-foraminiferan-serpulid-sa-bellariid-mollusc dominated
communities. In tropical belts, stress factors include high input of
siliciclastics, especially clay minerals and laterites, unstable soft
substrates, brackish environments in areas of high runoff around
deltas, poorly lighted waters due to large amounts of fines in
suspension, high surface plankton productivity (due to surplus
nutrients) and increased water depth at the margins of the
photosynthetic abilities of symbionts. Examples of Ordovician through
Permian reefs under stress include especially the calcareous and
```

```
siliceous sponge reef communities inhabiting slope environments,
offshore mudmounds and lithoherms (including Waulsortian mounds), and
small reefs with impoverished and aberrant faunas. Though stressed reef
communities are usually considered a response to less than optimal
conditions at a local level, such conditions may also be a response to
global deterioration of climates, especially at times of mass
extinction. Reef recovery following mass extinction phases, such as the
Late Ordovician and Late Devonian, apparently favoured re-invasion and
repopulation of the reef habitat by Lazarus taxa which were preserved
in deeper or colder (high latitude) water refugia: thus, these may
represent offshore-onshore or onshore cold-onshore warm patterns. This
contradicts the general pattern of onshore to offshore migration and
evolution of benthic communities which set the style for the warmer
Phanerozoic intervals. Similarly, deeper or cooler water reefs
(mudmounds, lithoherms, etc.) emigrated to shallower water
subequatorial habitats during mass extinction phases. Recovery periods
for the reef ecosystem following mass extinction phases are measured in
millions of years. ^1";

Boring Activity.- Palaios 1987, 2: 323-331.- <b>FC&#038;P 17-1</b>, p.
20, ID=2118^<b>Topic(s): </b>sclerochronology; Anthozoa growth rates;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>fossil
&#038; living; <b>Geography: </b>^Modern corals from Lizard Island, in
Australia&#039;s Great Barrier Reef, show pronounced dark gray zones
parallel to growth surfaces. These color bands are caused by increased
activity of boring algae during the dry sunny season, and hence are
annual. Cyclicity in algal boring activity may therefore be used to
determine growth rates and life spans of some fossil organisms, and
possibly the seasons of spat settling and death. Samples of Devonian
stromatoporoids from Bathurst Island in the Canadian Arctic show cycles
in boring intensity which suggest growth rates of about 1 cm/yr. These
results are questionable, however, because the borings cross through
```

```
both the lamellae and calcite cement in the interlamellar spaces. This implies early infilling of the stromatoporoid skeleton, a process which is still in debate. Ordovician solitary rugose corals from Kentucky and southern Manitoba show marked cyclicity in intensity of algal borings preserved in the epitheca. Growth rates are estimated to have been about 2 cm/yr. Both the apices and distal portions of these corals are relatively unbored. Perhaps the larvae settled during the cloudy monsoon season, and the adults died (2-3 years later) as a result of overturning and transport by monsoonal storms. Both the stromatoporoid and rugosan growth rates are as high as those shown by modern hermatypic corals, reinforcing previous suggestions that some Early Paleozoic marine invertebrates possessed zooxanthellae.^1";

enigmatic coral reefs.- Mercian Geologist 9, 1: 1-30; Nottingham.-
<b>FC&#038;P 12-2</b>, p. 42, ID=6239^<b>Topic(s): </b>reefs; reefs
structures; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>fossil &#038; living; <b>Geography: </b>^Although by no means
monomineralic, reefs are often enigmatic structures because the
superficial homogeneity of their carbonate components renders their
complex internal histories obscure to many forms of detection. This is
particularly evident in the case of seismic studies of subsurface
phenomena which tend to yield misleadingly uniform lensoid
interpretations resulting from refraction at the shale:carbonate and
sandstone:carbonate interfaces beyond the margins of the reef sensu
stricto. But studies of random sections through reefs can be equally
baffling in the field. The reasons for the ensuing confusion often
results from attempting to compare different diagenetic grades of the
same geological age. This account stresses the interdisciplinary nature
of reef analysis irrespective of time by means of models and by analogy
with present day tropical coral reefs. By drawing on case histories
from Zanzibar and the Seychelles and comparing them with data from
Bermuda, Bahamas, Florida and the Australian Great Barrier Reef, the
oceanic provinciality of sediments is highlighted, and their local
variability is related to their oceanographic and geomorphological
setting and consequent settlement pattern which is often wind
dominated. Then emphasis is placed on integrating ecosystem analysis of
the biota and associated sediments with chemical predictions on the
preservability of the fabric following burial in the vadose zone and
subsequent loading. Intimate details of present day and vadose
Pleistocene reef fabrics are illustrated by scanning electron
micrographs which draw attention to the fact that quantitative data are
only as good as the natural constraints put upon them. Thus one coral
clast featuring no less than eleven adhesive dinoflagellates indicates
that all the published sediment budgets are preferentially biased
against the interstitial biota, the base of the food chain and the role
of organic matter so limiting their potential for ecosystem analysis
and biasing their palaeoecological utility. Though more readily
quantified, this limitation is no worse than the geochemical parameters
encountered during burial diagenesis: hence reefs range from the
obvious to the obscure. [original abstract]^1";

Calcarea; <b>Systematics: </b>Porifera; Calcarea; <b>Stratigraphy:
</b>living &#038; fossil; <b>Geography: </b>^Two different skeletal
types occur within the Recent Calcarea. One type bears calcareous
spicules only, and the other type shows rigid basal skeleton in
addition to the spicular skeleton. Basal skeletons are characteristic
of most fossil examples. Some of the observed basal skeletons are
convergent with those of certain demosponges. Stromatoporoid, thalamid
and adapted chaetetid skeleton types are observed besides other types
not observed within the calcified demosponges. Basal skeletons are
probably a plesiomorphic feature of the coralline Calcarea. Three
phylogenetic models, based on phylogenetic systematics, are discussed.
It is possible to distinguish two main phylogenetic lineages. The
Minchinella-lineage and the closely related Barroisia-lineage are
probably the stock of the Recent non-calcified Calcaronea. Most of the
Recent species of coralline Calcarea are classified within this
subclass. The second lineage (Murrayona-lineage) is probably the stock
of the modern Calcinea. The new species Barroisia gandaraensis n.sp. is
described. Verticillites extensus Lang is shown not to be a demosponge
and a new genus name is created (Muellerithalamia).^1";

polychaete symbiosis; scleractinian, polychaete symbiosis;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>living
&#038; fossil; <b>Geography: </b>^Dredging at the edge of the
continental shelf at various stations between Eire and Morocco and
again off the Natal coast of South Africa and Madagascar has revealed
an interesting association between a polychaete and various cnidarians.
The polychaete Lumbrineris flabellicola Fage (1936) is re-described,
and its relationship to various species of ahermatypic corals is
discussed. The worm forms grooves around the skeleton and the
examination of fossil material shows that similar grooves occur on
corals from the Miocene and later deposits in Italy. Surprisingly,
dredging in the Mediterranean has revealed no living specimens. The
worldwide distribution of the Lumbrineris-coral association is
discussed.^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>fossil &#038; living;
<b>Geography: </b>^In connection with a study of the history of
Mesozoic coral research (Turnsek &#038; Loser, in press) a data bank on
coral genera cited in the literature (1940-1990) was compiled by D.
Turnsek (Ljubljana). This data bank comprises over 4,000 items, each
consisting of the source of the citation, the name of the genus as well
as the higher taxa (subfamily, family, superfamily, suborder) to which
the genus was assigned. * In order to obtain information on the current
state of the systematics of Scleractinia the data bank was subjected to
various transactions. For this purpose it was examined under two
aspects: the classification of genera into families and of families
into suborders (subfamilies and superfamilies were left out of
consideration owing to their rare usage). * The following list shows
the systematics as it emerges from the literature published between
1940 and 1990.The allocations given (of genera to families and of
families to suborders) and the publications quoted are always the
latest ones. * Two things become evident: for one, there seems to be
little justification for certain suborders and families with hardly any
subordinate taxa. Also, it is striking to note the large number of
genera which were never cited again after their first description. As a
product of data bank transactions, the systematics obtained presents an
entirely objective picture. Although, of course, the literature
evaluated lays no claim to completeness. * In conjunction with B.
Lathuiliere (Nancy) the authors of the various families were verified
on the basis of the International Rules of Zoological Nomenclature and
were in part corrected (e.g. Thamnasteriidae Reuss not Vaughan,
Latomeandriidae Fromentel not Alloiteau). * I thank my colleagues

<b>Systematics: </b>Cnidaria Porifera; <b>Stratigraphy: </b>fossil
&#038; living; <b>Geography: </b>^The International Association for the
Study of Fossil Cnidaria and Porifera has played a leading role in the
communication of cnidarian and poriferan research since its creation in
1971 at the First International Symposium in Novosibirsk, USSR, This
paper presents a review of the changes in and accomplishments of the
Association during the past quarter century. Research reports published
in symposium proceedings are based toward topics currently popular
among the leaders of research and among the more affluent countries. As
the Association approches the 21st century, it faces new challenges
posed by an aging and shrinking membership. Analysis of data on fossil
Cnidaria and Porifera specialists reveals trends that are reshaping our
science as we approach the next century: 1) a dramatic decline in the
size of the workforce, 2) a shift away from government research
institutions toward universities and museums as the main workplaces, 3)
a shift away from the dominance of a few large countries toward a more
equitable geographic distribution of the workforce, 4) a declining
emphasis on Paleozoic Zoantharia as the principal object of study
within the Cnidaria, and 5) a declining relative emphasis on
Stromatoporata and Archeocyatha as the principal objects of study
within the Porifera. In this changing scene, the Association can be
even more important than before in promoting, organizing and
communicating the science of fossil Cnidaria and Porifera.^1";

```

```
ISBN 0-306-47260-0.- <b>FC&#038;P 31-2</b>, p. 32, ID=7131^<b>Topic(s):
</b>systematics; Porifera; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>living &#038; fossil; <b>Geography: </b>^Research
whilst compiling this book has uncovered a fauna about twice the size
as that previously published in the literature and consequently Systema
Porifera revises and stabilizes the systematics of the phylum to
accommodate this new knowledge in a contemporary framework. Practical
tools (key illustrations, descriptions of character) are provided to
facilitate the assignment of approximately 680 extant and 100 fossil
genera. * Systema Porifera is unique making sponge taxonomy widely
available at the practical level of classification (genera, families,
order). It is a taxonomic revision of sponges and spongiomorphs (such
as sphinctozoans and archaeocyathans) based on re-evaluation of type
materials and evidence. It is also a practical guide to sponge
identification providing descriptions and illustrations of characters
and interpretation of their importance to systematics. Systema Porifera
addresses many long standing nomenclatural problems and provides a
sound baseline for future debate on sponges and their place in time and
space. * Systema Porifera describes 3 classes, 7 subclasses, 24 orders,
127 families and 682 valid genera of extant sponges (with over 1600
nominal generic names and an additional 500 invalid names treated).
Treatment of the fossil fauna is less comprehensive or critical,
although 6 classes, 30 orders, 245 families and 998 fossil genera are
mentioned. Keys to all recent and many fossil taxa are provided.^1";
s[4772] = "BRUNTON F.R., DIXON O.A. (1994).- Siliceous sponge-microbe
biotic associations and their recurrence through the Phanerozoic as
reef mound constructors.- Palaios 9: 370-387.- <b>FC&#038;P 23-2.1</b>,
p. 59, ID=4414^<b>Topic(s): </b>mud mounds; mud mounds; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Phanerozoic; <b>Geography: </b>^The
association between mound-building, benthic microbial communities and
siliceous sponges is characteristic of some reef mounds of Early
Cambrian, Early-Middle Ordovician, Late Silurian, Late Devonian, Late
Mississippian, Late Permian, Late Triassic and Late Jurassic age.
Significant episodes of siliceous sponge-microbe reef mound
construction, each lasting 5-15 Ma, generally recurred at intervals of
approximately 70-100 Ma. Each was a time when thrombolite-forming
and/or stromatolite-forming calcimicrobes flourished as constructors,
and associated demosponges and hexactinellid sponges diversified as
bafflers and binders, and even constructors on the reef mounds. The
siliceous sponge-microbe biotic association flourished in
subtropical/tropical marine, generally low turbulent, nutrient-rich,
deeper subtidal environments (largely below storm wave base). This
biotic association shows a temporal change in paleoenvironmental
preference through the Phanerozoic from generally inner- to mid-shelf
Cambrian and Ordovician examples to both mid-shelf and foreslope
environs in the Silurian, Devonian and Carboniferous to predominantly
distal shelf and slope settings in Permian, Late Triassic and Late
Jurassic examples. The occurrences of these episodes of reef mound
construction near the culminations of substantial marine transgressions
indicates that extrinsic controls associated with sea level change,
such as their spatial association with stratified basin waters and
fluctuating oxygen-minimum zones, may have been important in microbial
reef mound establishment. During successive sea level highstands the
deeper water siliceous sponge-microbe reef mound community appears to
have flourished in proximal fore-slopes and extensive drowned shelves
and ramps in areas where, at lowstand, reef-building metazoans such as
stromatoporoids, corals and calcareous sponges usually predominated.
The resurgence of the siliceous sponge-microbe community suggests the
recurrence of similar conditions of depth, nutrient conditions, and
other subtle physical and chemical controls. These were, in part,
controlled by tectonic influences during the evolution of Paleozoic and
early Mesozoic seas.^1";

(1999).- Paleoreef Maps: Evaluation of a Comprehensive Database on Phanerozoic Reefs.- American Association of Petroleum Geologists Bulletin 83, 10: 1552-1587.- <b>FC&#038;P 28-2</b>, p. 46, ID=1508^<b>Topic(s): </b>distribution, data base; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Phanerozoic; <b>Geography: </b>^To get a better understanding of controls on reef development through time, we created a comprehensive database on Phanerozoic reefs. The database currently comprises 2470 reefs and contains information about geographic position &#47; paleoposition, age, reef type, dimensions, environmental setting, paleontological and petrographical features, and reservoir quality of each buildup. Reef data were analyzed in two qualitatively different ways. The first type of analysis was by visualization of paleogeogrpahic reef distribution maps. Five examples (Late Devonian, Early Permian, Late Triassic, Late Jurassic, middle Miocene) are presented to show the potential of paleoreef maps for paleogeographic and paleoclimatological reconstructions. The second type of analysis was a numerical processing of coded reef characteristics to realize major trends in reef evolution and properties of reef carboantes. The analysis of paleolatitudinal reef distributions through time shows pronounced asymmetries in some time slices, probably related to climatic asymmetries rather than controlled by plate tectonic evolution alone. The dominance of particular reef builders through time suggests that there are seven cycles of Phanerozoic reef development. First curves for the Phanerozoic distribution of bioerosion in reefs, bathymetric setting, and debris potential of reefs are presented. The
```

```
observed pattern in the temporal and spatial distribution of reefs with
reservoir quality may assist in hydrocarbon exploration Statistical
tests on the dependencies of reefal reservoir quality suggest that
large size, high debris potential, low paleolatitude, high amount of
marine aragonite cement, and a platform/shelf edge setting favor
reservoir quality. Reefal reservoirs are significantly enhanced in
times of high evaporite sedimentation, elevated burial of organic
carbon, low oceanic crust production, low atmospheric CO2 content, and
cool paleoclimate, as well as when they are present in aragonite
oceans.^1";
s[4778] = "KIESSLING W. (2001).- Paleoclimatic significance of
Phanerozoic reefs.- Geology 29, 8: 751-754.- <b>FC&#038;P 30-2</b>, p.
32, ID=1612^<b>Topic(s): </b>ecology, climatic tracers; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Phanerozoic; <b>Geography:
</b>^A database of pre-Quarternary Phanerozoic reefs is used to test
the significance of ancient reefs as paleoclimatic tracers. The
compilation of reef paleolatitudes through time and comparison with
published paleoclimate curves shows that neither the width of the
tropical reef zone nor the total latitudinal range of reefs is
correlated with published estimates of paleotemperature. However, reefs
trace paleoclimatic indirectly: Algal reefs tend to prevail during
icehouse climatic intervals, and distinct high-latitude reefs are only
developed in the cold intervals, whereas during greenhouse episodes,
the reef zone usually ended abruptly at a particular latitudinal
boundary in the subtropics. Additionally, different biotic reef types
tended to be concentrated in different latitudes. The lowest latitudes
have usually been occupied by coralline sponge or microbial reefs,
coral reefs tend to grow in intermediate latitudes, and bryozoan reefs
constantly occupied the highest latitudinal position.^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Phanerozoic;
<b>Geography: </b>^An updated data base is a matter of importance and
urgency in order for encouraging a process-oriented approach to the
study of reef evolution. The evolution of reefs is a major section of a
Priority Program of the Deutsche Forschungsgemeinschaft devoted to
&#039;Global and regional controls of biogenic sedimentation&#039;.
Biological, paleontological and geological approaches in the study of
ancient and modem reefs are needed for providing a better understanding
of the following basic questions: - Biological and non biological
processes responsible for the construction and destruction of recent
reefs. Studies should be focused on those processes which might also be
regarded as important controls in the history of fossil reefs. -
Paleontological data describing the changes in the biological controls
of reef development over time. Studies should aim for a better
understanding of major crises in the reef ecosystem during the
Earth&#039;s history. - Geological factors governing the short-term and
long-term development of reefs. Studies should be concentrated on the
controls of reef accretion by sea-level fluctuations, climatic changes
and possible changes in early diagenetic factors. The Reef Bibliography
presented includes more than 4000 references dealing with Cambrian to
Pleistocene reefs and more than 750 references referring to processes
relevant to the interpretation of ancient reefs. The constraints of
reef evolution will become clearer through intensifying comparative
studies of reefs of different ages. The new data base should encourage
this comparative research approach. ^1";

<b>Stratigraphy: </b>fossil &#038; living; <b>Geography: </b>^In
contrast to the well studied tropical carbonate environments, interest
in non-tropical carbonate deposition was rather low until the basic
ideas of the Foramol-concept were outlined by Lees &#038; Buller
(1972). In the following two decades studies on non-tropical carbonate
settings evolved as a new and exciting branch of carbonate
sedimentology (see Nelson 1988). This is achieved in a great number of
publications dealing on temperate carbonate deposits from numerous
coastal and open shelf settings on both hemispheres. The existence of
wide extended carbonate depositional systems and even reefal frameworks
in Subarctic and Arctic seas which are in focus by our research group
made it possible to study modern non-tropical carbonate settings along
a latitudinal transect from the warm-temperate Mediterranean Sea to the
cold Nordic Seas. Because of increasing seasonality in environmental
conditions towards high latitudes, the major controls in biogenic
carbonate production can be more clearly addressed in these areas.
After the initiation of the priority program &#034;Global and regional
controlling processes of biogenic sedimentation - evolution of
reefs&#034; by the German Science Foundation four years ago, a set of
modern case studies were comparatively analysed specifically with
regard to their principle controlling processes: (1) Modern and
Holocene coralline algal reefs and rhodolith pavements formed in
wave-protected shallow waters along the coast of the Brittany and
northern Norway. Their fine-tuned interaction with herbivores resulted
in the development of widespread but low-diverse, slowly growing
coralline algal frameworks with high competitive value against the
rapid-growing phaeophytic communities. (2) The Mediterranean Cladocora
caespitosa banks provide an instructive example of non-tropical
```

```
hermatypic coral framework construction out of the subtropical-tropical
coral reef belt. (3) The geometry and environmental controls of several
kilometer long coral reefs formed by the azooxanthellate Lophelia
pertusa and Madrepora oculata are studied in more than 250m water depth
in mid and northern Norway. (4) Modern Bryomol-sediments are widely
distributed on non-tropical deeper shelf settings. The formational
processes converting bryozoan-thickets into huge piles of sand and
gravel dunes are recently studied on the outer shelves off northern
Brittany and off northern Norway. (5) Arctic sponge-bryozoan buildups
on the seamount Vesterisbank in the Greenland Sea and (6)
balanid-dominated open shelf carbonates on the Spitsbergen Bank form
the Arctic end members of modern Foramol-deposits. Seasonal ice-edge
phytoplankton blooms and efficient mechanisms of pelagic-benthic food
transfer characterize these depositional settings. Fossil counterparts
of each of these modern case studies are discussed in context with
their paleoceanographic and environmental settings.^1";

scleractinian reef corals and fossil analogues.- Geol. Rundschau 61, 2:
551-564.- <b>FC&#038;P 2-1</b>, p. 13, ID=4711^<b>Topic(s): </b>cavity
formation; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>fossil
&#038; living; <b>Geography: </b>^Shifts in community structure and
concomitant cavity formation may be rapidly effected by subtle
environmental changes; as secretion rates vary from organism to
organism. The experimental rates, placed in declining order are:
encrusting worms, encrusting red algae, bivalve, coral. The worms, with
their organic coatings, secreted a maximum extension of 12mm per month,
and the red algae 3mm, whereas the bivalve and coral only achieved a
matter of microns. Thus, in the aquarium, the coral would have been
effectively smothered by the worms and algae in the foreseeable future.

ecological interpretations; reef builders, shapes; <b>Systematics:
</b>; <b>Stratigraphy: </b>fossil &#038; living; <b>Geography:
</b>^Paleoecologists studying Paleozoic reef-builders have interpreted
their growth forms as responses to conditions of depth and turbulence
in reef complexes. Comparison of the shapes of Paleozoic
stromatoporoids and corals with the growth forms of modern
scleractinians has been used to reconstruct Paleozoic conditions. A
review of shape zonation on modern reefs indicates that no general
pattern is applicable to all reefs and variations in shape are the
result of the interaction of many environmental factors with the
genetically dictated growth pattern of the coral. In most zones of a
reef a wide range of shapes co-exist. The growth forms of corals on
modern reefs are not a simple vegetative response to the many
environmental parameters that have been shown to influence form, but
arc constrained by phylogenetic and developmental influences as well as
functional ones. * Interpretations of the environments of western
Canadian and other mid-Paleozoic reefs have been based on the growth
forms of stromatoporoids. The environmental significance of the shapes
has been deduced from comparison with the shapes of modern
scleractinians, functional morphology, nature of the enclosing
sediment, position of growth, position within the reef, and diversity
gradients. The validity of these criteria is open to question and
considerable doubt remains concerning the significance of the growth
forms. The shapes of reef animals are not specific guides to
```

```
environments of modern reefs and should not be expected to be guides
for ancient ones. [original abstract]^1";
s[4788] = "BOSENCE D.W.J. (1983).- Coralline algal reef framework.- J.
geol. Soc. London 140: 365-376.- <b>FC&#038;P 12-2</b>, p. 41,
ID=6237^<b>Topic(s): </b>reef frameworks; reef framework;
<b>Systematics: </b>; <b>Stratigraphy: </b>fossil &#038; living;
<b>Geography: </b>^Published and unpublished accounts of coralline
algal reef frameworks are reviewed. The descriptions are divided into
frameworks constructed from crustose coralline algae and those
constructed from branching corallines. Crustose frameworks are briefly
described and illustrated from the Miocene of Malta. Recent
&#039;coralligene&#039; from the Mediterranean, Eocene reefs from
Spain, Recent algal reefs of St. Croix, U.S. Virgin Is. and algal reefs
from Bermuda. Branching frameworks are briefly described and
illustrated from the Recent mearl of the NE Atlantic. Recent mud mounds
from Florida, Recent algal reefs from St. Croix and Recent algal ridges
on Pacific reefs. Crustose and branching frameworks show an increase in
strength of construction, early submarine cements and macro-borers and
a decrease in erodibility from low to high energy environments. The
occurrence of genera in coralline frameworks is primarily controlled by
their geographic and water-depth ranges. The construction of coralline
frameworks is seen as the result of competition for living space on
shallow marine hard substrates. [original summary]^1";

buildups.- Géologie et paléoécologie des récifs [J. Geister &#038; R.
Herb (eds)]: 16.1-16.15.- <b>FC&#038;P 13-1</b>, p. 11,
ID=6329^<b>Topic(s): </b>stromatolites; stromatolites; <b>Systematics:
</b>; <b>Stratigraphy: </b>living &#038; fossil; <b>Geography: </b>^In
these brief course notes the analogy between ancient and recent
stromatolites is stressed. Stromatolites are considered to represent
mainly the response of algal and bacterial communities to environmental
conditions. The fact that stromatolites may have evolved through time
according to Russian authors, allowing a zonation of the Proterozoic,
raises the question &#034;Is the Present the (only) key to the
Past?&#034;. Nonetheless, stromatolites considerably influenced
sedimentation for hundreds of millions of years by their ability to
form wave-resistant structures and, more importantly, to bind
sedimentary material and prevent it from being displaced into the
deeper parts of the seas. Thus, stromatolites were largely responsible
for the construction of major carbonate platforms throughout much of
the Proterozoic into the Lower Palaeozoic. [conclusions of the paper]^1";

of Evolution and Sources of Biodiversity in the Phanerozoic.- Science
327, 5962: 196-198.- <b>FC&#038;P 36</b>, p. 116, ID=6554^<b>Topic(s):
</b>biodiversity; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Phanerozoic; <b>Geography: </b>^Large-scale biodiversity gradients
among environments and habitats are usually attributed to a complex
array of ecological and evolutionary factors. We tested the
evolutionary component of such gradients by compiling the environments
of the geologically oldest occurrences of marine genera and using
sampling standardization to assess if originations tended to be
clustered in particular environments. Shallow, tropical environments
and carbonate substrates all tend to have harbored high origination
rates. Diversity within these environments tended to be preferentially
generated in reefs, probably because of their habitat complexity. Reefs
were also prolific at exporting diversity to other environments, which
might be a consequence of low-diversity habitats being more susceptible
to invasions.^1";

<b>Geography: </b>^Biological interactions among clonal marine
```

```
organisms are an important aspect of their behavior and are important
in the construction of biological reefs. The interactions addressed
here are among crustose and erect coralline algae, sponges, corals, and
bryozoans and may involve clones of the same species (conspecific), or
different species (heterospecific). Conspecific interactions may be
either between modules or clones that are produced asexually from one
propagule, genetically identical, or between clones that are sexually
produced from two or more propagules that may or may not be genetically
identical. Juxtaposed genetically identical clones generally fuse
whereas non-identical clones may or may not fuse, depending on their
relatedness and histocompatibility. Most heterospecific clonal
interactions are spatially competitive and result in overgrowths or
stand-offs. Clone fission/fragmentation may occur as a result of biotic
or abiotic processes that initially degrade but may eventually restore
or even enhance ability to gain space and/or nutrients.
Self-overgrowths also occur, usually over dead, diseased, or senescent
parts of the same clone. [original abstract]^1";

Palaeontologica Polonica 30, 3-4: 115-135. [imprint 1985].-
<b>FC&#038;P 15-2</b>, p. 11, ID=6743^<b>Topic(s): </b>skeletal Ca; Ca
ions; <b>Systematics: </b>; <b>Stratigraphy: </b>Phanerozoic;
<b>Geography: </b>^Knowledge on transport and regulation of free
calcium in the living cell is used in support of the theory
(Kazmierczak et al. 1985) linking the onset of biocalcification at
about the Precambrian &#47; Cambrian boundary to a rise in Ca2+
concentrations in the shelf seas to levels toxic to biota. Following
this event, fluctuating Ca2+ levels in the Phanerozoic seas are
supposed to have challenged a variety of protists and invertebrates to
respond by depositing no, thin, or thick skeletons respectively.
Changes in type and extent of calcification, as observed in the
stratigraphical record, are interpreted to reflect the pulsating flow
of Ca2+ ions through crust, sea, and biota. Some implications of that
theory to (i) the history of sea water, (ii) the global carbon cycle,
(iii) stable carbon isotope geochemistry, and (iv) sedimentation of
suspended clays, are briefly discussed.^1";

Archaeocyatha; <b>Systematics: </b>Porifera; Archaeocyatha;
<b>Stratigraphy: </b>Cambrian; <b>Geography: </b>^Archaeocyaths are
Cambrian sponges with calcareous skeletons. They are stenothermal
organisms, limited to the intertropical climatic conditions. They were
stenohaline: when salinity increases they are represented only by their
simplest forms. They were stenobathic, living anchored in soft
substrata in intertidal to subtidal zones, but did not overpass the
photic one. Turbidity and water movements influenced the morphological
face of an archaeocyath community. Archaeocyaths are associated to the
reefal environments. They were facultative reef-builders (mainly
binders and bafflers) and associated with reefal buildups as a
substratum for the calcified cyanobacteria and cements. Buildups were
essentially microbially mediated mud mounds dominated by solitary or
low modular soft-substrate dwelling filter-feeders (archaeocyaths).^1";

</b>Porifera; Archaeocyatha; <b>Stratigraphy: </b>Cambrian L;
<b>Geography: </b>^Since the end of Upper Proterozoic, carbonate
platforms progressively settle down. At the beginning of the Lower
Cambrian, calcimicrobes expanded, later accompanied by benthic
filter-feeders as cobuilders, i.e. archaeocyaths, whose development is
strictly controlled by salinity, turbidity, bathymetry and temperature,
corresponding to intertropical climatic conditions. The &#34;reef
mounds&#34; (sensu James) are placed on the most recent
palaeogeographic maps, controlled by palaeomagnetic data on one hand
and fossil (trilobites and archaeocyaths) and facies distribution on
the other. The archaeocyaths reef mounds are distributed within a belt,
extending on both sides to the Equator (latitude 0° to 30°). Even
between these latitudes, when the environment is hypersaline
(dolomites) or turbidic (siliciclastic sediments) the archaeocyaths did
not develop. The extension of the intertropical zone at the Cambrian is
comparable with the present one; this is confirmed by the presence of
siliciclastic deposits of the same Lower Cambrian age in Avalonia which
are, according to palaeomagnetic data, situated at 45°-50° latitude,
and by the ocurrence of some small bioclastic carbonate levels
deposited in temperate conditions. The demise of archaeocyaths at the
end of the Lower Cambrian is a consequence of the alteration of their
environment, due to a generalized extensional phase, corresponding to
gradual opening of the Iapetus Ocean, and to a displacement of
continents towards the South Pole, disturbing all the previous global
palaeogeographic, palaeoenvironmental and climatic conditions.
Uniformitarism principles, at least for intertropical and temperate
zones, could be applied as far back as the Lower Cambrian time.^1";

archaeocyath-calcimicrobial bioconstructions on the Early Cambrian
shelves.- Palaeoworld 19, 3-4: 222-241.- <b>FC&#038;P 36</b>, p. 30,
ID=6394^<b>Topic(s): </b>reefs; archaeocyathan buildups;
<b>Systematics: </b>Porifera; Archaeocyatha; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>^The differences and variety of
structural, depositional, and compositional features observed in the
Early Cambrian microbial-archaeocyath buildups preserved in the
present-day continents, suggest a direct correlation between the
physico-chemical factors of deposition and the structural architecture
of the buildups. This can be explained in terms of their
palaeogeographic collocation on the shelves (depth, energy), and hence
of the areal distribution of epeiric basins and
perioceanic/pericontinental platforms. * Data on the analysis of
biohermal communities and their architectures indicate that the
relative development of the main reef-building components, as well as
their evolution within the reef communities, reflects the dominant
physico-chemical factors, mainly temperature and nutrient availability,
and the physiography of the primary depositional setting. The
bioaccumulations show different reef building styles, defined by the
types of associated facies and by the early diagenetic features. They
are represented by (i) mud-supported simple (Kalyptrae) to compound
```

```
mounds locally with stromatactis-like cavities; (ii) dendrolitic
bioherms and crustose buildups with large shelter cavities and low
synoptic relief; (iii) cement-supported skeletal reefs with wave
resistant frameworks often associated with oolitic shoals, and (iv)
bioclastic sands, developed at photic and shallow sub-photic depths on
low-angle/low-energy ramps (i-ii) or on high-energy conditions on
platforms distally rimmed (iii) or occasionally swept by storm currents
(iv). The results of the analysis provide information on the spatial
conditions of the primary depositional settings of the first metazoan
involved in reef building in the history of the Earth, and suggest that
the architecture of the bioconstructions was controlled not only by the
physiography of the depositional setting and global/astronomic climate
but also by local climatic conditions constrained by the latitudinal
distribution of the Early Cambrian continental blocks. [original

</b>microstructures, radiation; Cnidaria; <b>Systematics: </b>Cnidaria;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>^Radiation and
diversification of early Cnidaria, at the beginning of the Cambrian are
documented here, with special attention to the skeletal
microstructures, investigated by means of electron microscope and
ultra-thin sections, each time on the same specimen for direct
comparison. Three centers are recognized: Siberia (Tommotian to
mid-Botomian), Australia (mid-Botomian to Toyonian), North America
(Upper Botomian to Toyonian), but without cosmopolitan forms.
Corallomorphs of the Cambrian were represented by slender irregular
polygonal tubes, mostly solitary in the Tommotian and Atdabanian and
mainly modular in the later stages (Botomian and Toyonian). They
acquired in their evolution multilayered walls and septum-like
structures which are absent in the oldest forms. Out of the 10 Early
Cambrian corallomorphs, 8 at least have different microstructures, none
of them fully identified with one of the post-Cambrian Corals. The
diversification of Early Cambrian corallomorphs, according to their
microstructure, had their acme in the Botomian and decreased during the
Toyonian; the Precambrian &#034;medusoids&#034;, now thought plasmoid
unicellulars, could not be considered the ancestor of Cambrian
corallomorphs. For cnidarians, the Early Cambrian represents an unique
stage in the development of the phylum with short-lived branches of
high taxonomic level among which it is not possible to recognize an
&#034;ancestor&#034; of true corals which will appear in the
Ordovician.^1";

Early Cambrian extinction.- Geological Society Special Publication 102
[Hart M.B. (ed.): Biotic Recovery after Mass Extinction Events]:
79-96.- <b>FC&#038;P 25-2</b>, p. 23, ID=3085^<b>Topic(s):
</b>recovery; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Cambrian; <b>Geography: </b>^Revised and new stratigraphic data
indicate a complex extinction event in the late Early Cambrian which
consisted of two, temporally, separate, but related phases. The earlies
phase (mid-Botomian, Sinsk Event) may be related to widespread anoxia
due to eutrophication and phytoplankton blooms. The later event (early
Toyonian, Hawke Bay Event), is connected to a world wide regression.
This double extinction event severely injured the reefal biota which
has undergone a further rejuvenation during the remainder of the
Cambrian. As a result of the lowering of grazing pressure and unhealthy
metazoan-calcimicrobial interactions, the remaining metazoan
reef-builders were eliminated by the end of the Early Cambrian.
Consequent reduction of space heterogenity led to the decline of
calcified microbes (Renalcis, etc.) in both diversity and abundance
which gave the way to the thrombolite-stromatolite community. The
recovery of the reefal biota occurred during the very end of the Late
Cambrian-Early Ordovician and may be attributed to Elvis-taxa, with the
exception of the spicular demosponges. These recovering biota intruded
```

```
into the thrombolite-stromatolite community and created a space for the
more successful encrusting reef dwellers of Middle-Late Ordovician
time.^1";

reefs, cryptic communities; <b>Systematics: </b>; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>^During the Lower Cambrian, cryptic
communities were more abundant than previously thought. They offered a
habitat of reduced environmental stress and housed a substantial
proportion of the total biodiversity of early reefs. Cryptic
communities were composed of solitary organisms with no evidence of
succession compared with most modern reefal crypts. This may be a
result of the small size and short-lived nature of both crypts and
their occupants. The rapid growth of synsedimentary cements in crypts
may have reduced the time avalaible for both colonization and growth of
the cryptos as they did not remain open for long before partial or
total occlusion. Solitary archaeocyathids, solitary chambered forms
(coscinocyathids and kazachstanicyathids), calcified cyanobacteria and
a microburrowing ? metazoan were the most ubiquitous and abundant
elements; putative primitive cnidarian, spiculate sponges and various
problematica were also present. Several species of archaeocyaths were
obligate cryptobionts; infaunal deposit-feeding (?) worms and probable
boring sponges have been noted only in crypts. On a sub-zonal scale,
the vast majority of archaeocyath species appeared simultaneously in
both open surface and cryptic niches suggesting that Lower Cambrian
crypts were neither refuges for open surface inhabitants nor niches for
evolutionary innovations.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Cambrian +
Devonian; <b>Geography: </b>^The Devonian collections comprise the
nation&#039;s largest collection of Middle Devonian fossils from
Wisconsin. The largest suite of fossils is a unique collection from the
Taghanic Stage of Milwaukee County. The faunas are dominated by
brachiopods with significant numbers of trilobites, bryozoans, corals,
echinoderms and bivalves. Some of this material was described by
Blodgett (1988), Cleland (1907, 1911), Griesemer (1965), and Pohl
(1929a, 1929b). These localities are from quarries and temporary
excavations that are now filled and cannot be recollected. There are
384 drawers of Devonian fossils from 797 localities represented by
approximately 42,500 specimens. Of these localities, 360 are attributed
either wholly or in part to Gilbert O. Raasch and share the same
excellent documentation as his Cambrian collections. The Upper Devonian
collections were made from tunnel projects under Lake Michigan in the
early part of the century. These collections are especially significant
since this unit is not represented by outcrop, and correlative strata
in the subsurface of the Michigan Basin are important gas producers. *
Fossil preservation in these collections is very good, and the faunas,
which are in need of revision, provide outstanding possibilities for
taxonomic work. Interested professionals are encouraged to conduct
research in these collections. Hard copies of data are available on
request. [part of the paper]^1";

Innsbruck 20: 335-347.- <b>FC&#038;P 24-2</b>, p. 92, ID=3128^<b>Topic(s): </b>phylogeny; Porifera radiation; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Paleozoic L; <b>Geography: </b>^Sponges are primitive metazoan organisms which occur since the late Proterozoic. The oldest sponge remains (hexactinellids) are from a shallow marine carbonate facies of the late Sinian Shibantan Member (China). From the Tommotian (Sansha, China) protospongiid and rossellimorph hexactinellids were discovered in shallow marine silicified rocks. The middle part of this section consists of silty shales with entirely preserved hexactinellid sponges: Sanshadictya, Hyalosinica, Solactinella, Triticispongia, Hunanospongia. The hexactinellids typically are soft bottom dwellers, which sometimes grow on and form in situ spiculites (spicule mats). The sponges from the Chengjiang deposits of Atdabanian age, which show a rosselimorph spicule organization typical of the conservative hexactinelid groups, which inhabited the deep sea during most of the Phanerozoic, were also typical soft bottom dwellers. All sponge taxa (Leptomitella, Leptomitus, Paraleptomitella etc.) described from this locality we consider to be hexactinellids and not demosponges, as originally classified. The sponge communities of carbonate-dominated archaeocyathid mounds are completely different from the above described sponge mounds. The sponges from the archaeocyath mounds of the Flinders Ranges (S Australia) are characterized by Calcarea and demosponges (= modern type of the pharetronid Calcarea Gravestockia pharetroniensis., and many tetractinellid demosponges, Geodiida). Questionable is the
```

```
origin of four-rayed demosponge spicules found in some archaeocyaths.
The oldest ceractinomorph demosponges are documented from the middle
Cambrian (Vauxia - an aspicular sponge with keratose affinities, and
isolated sigmata microscleres). Sponge communities of the Early
Cambrian were highly developed, and already then they were
taxonomically strongly dependent on substrates and trophic
conditions.^1";

<b>Stratigraphy: </b>Cambrian - Devonian; <b>Geography: </b>^Late
Precambrian reefs, at a time of stromatolite and carbonate productivity
decline, were marked by calcimicrobial encrusters and cementers: soft
bodied metazoans played no identifiable role. This was largely
continued in the earliest Cambrian stage (Nemakit-Daldynian), a period
of radiation of many skeletal protostomes and deuterostomes, but a
period of restricted carbonate shelf production. Metazoan archaeocyath
reefs dominated the Tomotian-Toyonian, but vanished after only 10 Ma:
their demise is speculative but focuses on anoxia, cooling, phosphate
deposition, and regressions. The 65 Ma long Mid-Cambrian to late Middle
Ordovician (Llanvirn) is marked by sparse but increasing chlorophyte,
lithistid-pulchrilaminid, and bryozoan content, but most reefs were
calcimicrobial, especially in distal ramp and slope settings. Tabulate
and rugose corals, stromatoporoids, chlorophytes, rhodophytes (assisted
by calcimicrobes), and bryozoans of the late Llanvirn-Caradoc initiated
the expansion of mid-Paleozoic reefs, largest of the Phanerozoic. This
reef ecosystem collapsed in the late Devonian (Frasnian), never to
recover fully in the remaining Paleozoic: extended F/F mass extinction
over 10 Ma is related to anoxia, nutrient increase, cooling (steep CO2
decline, rising O2 with the arrival of vascular plants) and sea-level
drawdown as ocean shifted to an &#039;icehouse&#039; mode.^1";

(Pachyprocteria), Palaeacis and Smythina, and the rugose genera Combophyllum, and Baryphyllum, have morphologic characters that suggest they were capable of such self-directed movement. The rugose corals Gymnophyllum and Hadrophyllum, sensu stricto may have exhumed and righted themselves. No single morphological character is diagnostic for an automobile habit, but the following characters appear to be important indicators: 1) lack of an external attachment surface; 2) concentric skeletal accretion; 3)discoid corallum shape; 4) concavo-convex, plano-convex, and, less commonly, biconvex corallum profile; and 5) small, lightweight corallum. Additionally, the occurence of corallites on the base of the corallum (hypocorallites) is a good indicator of automobility in freeliving corals, but the character is so far known only in Procterodictyum. All known fossil automobile taxa appear to have inhabited relatively quiet environments
```

```
on muddy or silty, soft substrates.The earliest known automobile corals
were early Emsian (Devonian) Procterodictyum. Paleozoic automobile
corals were most abundant during Devonian time, with Procterodictyum,
Procteria (Granulodictyum), and Combophyllum distributed in a narrow
longitudinal band in the southern hemisphere on both sides of the Rheic
Ocean. Carboniferous and Permian automobile taxa (Palaeacis partim,
Smythina and Baryphyllum) were less diverse, but more cosmopolitan.
Throughout Paleozoic time, the vast majority of automobile corals was
confined to within 40 degrees of the paleoequator. However, additional
research will be required before coral automobility can be used to
constrain paleolatitude independently.^1";
s[4849] = "GUDO M. (2002).- Soft body reconstructions of Palaeozoic
corals: implications for the system of Anthozoa (Coelenterata).-
Lethaia 35, 4: 328-344.- <b>FC&#038;P 31-2</b>, p. 26,
ID=1664^<b>Topic(s): </b>soft tissues; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Paleozoic; <b>Geography:
</b>^The soft bodies and individual development sequences of the polyps
of Palaeozoic corals are reconstructed on the basis of the functional,
engineering and constructional morphology of recent Anthozoa. Four
types of body reconstruction can be distinguished by the arrangement of
mesenteries, the number of mesentery insertion zones and characteristic
septal insertion patterns: (1) serial insertion of single mesenteries
in four sectors, which has resulted in the serial insertion of septa,
(2) symmetrical insertion of single mesenteries in four sectors, which
has resulted in a symmetrical septal pattern or pseudo radial patterns,
(3) exponential insertion of paired mesenteries in four sectors, which
has resulted in septal bifurcation, and (4) exponential insertion of
paired mesenteries in six sectors, which has resulted in a radial
pattern. Suggestions for a constructional taxonomy are given on the
basis of the arrangement of mesenteries and on individual development
of reconstructed polyps. Accordingly, new superorders are introduced:
&#39;Seriales&#39; for the first body constructions and
&#39;Symmetricales&#39; for the second. The third body construction is
that of the Heterocorallia and the fourth that of the Hexacorallia.
Following a constructional taxonomy, new and stricter definitions are
given for the new and already known taxonomic categories of Rugosa,
Heterocorallia and Hexacorallia. A byproduct of this re-definition is
that several Palaeozoic corals represent the body reconstruction of the
Hexacorallia and should therefore be revised as Hexacorallia;
consequently, Hexacorallia must already have been present in the
Palaeozoic.^1";

genera; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>^The two major subclasses of
Palaeozoic corals, the Tabulata and the Rugosa, appear respectively in
the Lower and Middle Ordovician. Analyzed at the generic level, both
show similar patterns of peaks of extinction close to successive system
boundaries accompanied or followed by enhanced rates of
diversification. Prior to the final disappearance of both groups at the
end of the Permian, the most important extinction event occurs in the
late Givetian, followed by the loss of most remaining genera about the
Frasnian-Famennian boundary. Both subclasses survive into the
Carboniferous through a very small number of long ranging genera
together with the continued evolution of distinctive Rugosa, mainly
adapted to deeper water fine clastic environments. Although the Rugosa
```

```
eventually rediversify vigorously in the Lower Carboniferous the
Tabulata never regain their early-mid Palaeozoic prominence.
Coloniality and colonial integration appear to have little value to
overall in enhanced survivorship among Rugosa. Tabulate faunas are
dominated successively by massive coenenchymal, massive perforate
cerioid, and communicate fasciculate colony forms. A detailed analysis
of generic ranges from the late Frasnian to the early Tournaisian
reveals three extinction events among the rugose corals which can be
matched to those in other groups. Environmental pertubations of
eustatic and/or climatic origin are favoured as the principal causal
factors.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Paleozoic;
<b>Geography: </b>^Primary or secondary origin of the microlamellar
microstructures of many Palaeozoic corals, is an object of controversy.
They are especially frequent in Carboniferous corals (rugosans,
tabulates, and all known Heterocorallia). Architecture and
relationships of the microlamellar elements with fibrous
microstructures seem to demonstrate that they are primary and not
diagenetic. Futhermore some petrographic criteria indicate that they
are not secondary. Since it is probably primary, the lamellar
microstructure could be used in taxonomy. Nevertheless our knowledge of
the microstructure of rugose corals is too slight. Many studies on
microstructure must be done before using it broadly in the systematics
of Rugosa. Such studies should be done with the appropriate techniques,
scanning and ultrathin sections, and not with conventional thin
sections.^1";

started by A. Stuckenberg (Carboniferous and Permian of the European
Russia and Urals); these works are classical ones. A new stage began in
```

```
the thirties with the papers of E.D. Soshkina, T.A. Dobrolyubova
(Rugosa) and a little bit later with the papers of B.B. Chernyshev and
B.S. Sokolov (Tabulata). The works of these paleontologists stimulated
the study of Paleozoic corals in various aspects: that especially
became evident in the late fifties, when dozens of paleontologists
worked on this topic. At that time progress was achieved especially in
systematics and stratigraphy. Later on the number of specialists and
their quality decreased which had nothing to do with falling interest
in corals, but can be explained by a general decrease in the USSR for
research on paleontology and stratigraphy. That led to the fact that
only a few specialists now work on Paleozoic corals and this tendency
does not promise any positive changes in this respect.^1";
s[4857] = "WEBB G.E. (1993).- Phylogeny reconstruction: problems posed
by Paleozoic corals.- Courier Forschungsinstitut Senckenberg 164:
71-074. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International
Symposium on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P
22-2</b>, p. 11, ID=3439^<b>Topic(s): </b>phylogeny, cladistic
taxonomy; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Paleozoic; <b>Geography: </b>^Cladistic theory
provides a sound basis for phylogeny reconstruction of Paleozoic corals
because it: 1, forces evaluation of every morphologic character; 2,
bases relationship on shared morphologic &#34;novelties&#34; rather
than gross morphologic similarity; and 3, rejects a priori conclusions
on the taxonomic value of characters (i.e., &#34;specific level&#34;
and &#34;generic level&#34; characters). Despite the value of cladistic
theory, standard cladistic methodology is not an effective technique
for phylogeny reconstruction of Paleozoic corals. To operate properly,
cladistic methodology requires limited amounts of convergence and large
numbers of non-convergent morphologic characters. Paleozoic corals are
notable for convergence and parallel evolutionary trends and, in many
cases, offer few characters for analysis owing to simplicity of
morphology and phenotypic plasticity. These problems may be overcome in
the future by developing: 1, better taxonomic descriptions; 2, new,
untested morphologic characters; 3, better understanding of Paleozoic
coral biology; and 4, new cladistic techniques that make use of both
morphologic data and non-morphologic data, such as stratigraphic and
geographic distribution.^1";
s[4858] = "SCRUTTON C.T. (1997).- The Palaeozoic corals I: origins and
relationships.- Proc. Yorkshire Geol. Soc. 51, 3:177-208.- <b>FC&#038;P
26-2</b>, p. 63, ID=3742^<b>Topic(s): </b>phylogeny, taxonomy; corals;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Paleozoic;
<b>Geography: </b>^The status, origins and relationships of the various
groups of Palaeozoic corals are reviewed. Five orders are currently
recognized: Rugosa, Tabulata, Heterocorallia, Cothoniida and
Kilbuchophyllida, to which I add the Tabulaconida and Numidiaphyllida.
The Rugosa and Tabulata are considered to be broadly monophyletic
clades, and the Tabulata are confirmed as zoantharian corals.
Morphological features, particularly aspects of septal insertion in
both groups, are discussed as clues to their likely origins and
relationships. They are not considered to have had a skeletonized
common ancestor, but they may have arisen as separate skeletonization
events from the same broad group of anemones, represented by the living
Zoanthiniaria. The Rugosa are not considered to be ancestral to the
Scleractinia. The latter, together with the Permian Numidiaphyllida,
are considered to have evolved through skeletonization events among a
group of anemones derived from the Actiniaria &#47; Corallimorpharia, a
member of which also gave rise to the Kilbuchophyllida in the
Ordovician. The pattern of septal insertion in the Heterocorallia is
controversial and the relationship of these corals to contemporary
coral groups remains uncertain. The increasingly important record of
Cambrian coralomorphs is assessed, and considered to include several
genera of zoantharian corals. However, although similarities are
apparent, none is regarded as directly ancestral to the post-Cambrian
```

```
coral clades. The history of diversification and extinction of corals
through the Palaeozoic is briefly reviewed.^1";
s[4859] = "SCRUTTON C.T. (1998).- The Palaeozoic corals II: structure,
variation and palaeoecology.- Proc. Yorkshire Geol. Soc. 52, 1: 1-57.-
<b>FC&#038;P 27-1</b>, p. 61, ID=3777^<b>Topic(s): </b>structures,
variation, ecology; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Paleozoic; <b>Geography: </b>^Palaeozoic corals
faunas were dominated by two orders of Zoantharian corals, the Rugosa
and the Tabulata. Almost all rugose and tabulate corals developed an
epitheca or holotheca around the corallum and possessed small to minute
attachment scars. A limited number had an encrusting life style and
many others could facultatively encrust to some extent when settling by
chance on a hard substrate. However, most were effectively free living
on a soft substrate as mature coralla. A high percentage of rugose
corals were solitary and of the colonial genera few exhibited physical
integration of modules within the colony. In contrast, most of the
exclusively modular tabulate corals possessed some degree of
integration. Colony formation in tabulate corals was, with doubtful
exceptions, solely of non-parricidal increase, whereas both
non-parricidal and parricidal increase, the latter in a minor role,
occur in the Rugosa. The sources of variation in solitary and colonial
Palaeozoic corals are reviewed and data on growth rates, measured on
the basis of cyclomorphic variation expressed as density band couplets,
are assessed. Growth-form variation in solitary corals and its
relationship to stability on the substrate are explored. Growth
strategies in colonial corals are described and their adaptive success
under different environmental conditions is discussed. Colonial
growth-forms were a function of the interaction between growth strategy
and prevailing conditions during astogeny, although some species had
genetically constrained, relatively invariate growth-forms. Factors
controlling the distribution of Palaeozoic corals in the environment -
substrate and turbidity, water energy, depth, light, temperature and
variations in salinity and oxygenation - are reviewed. Palaeozoic coral
diversity was much lower than that of Recent hermatypic scleractinian
corals in comparable environments. Most Palaeozoic corals were adapted
to soft substrates in warm, shelf seas, and made a limited contribution
to reef frameworks. It is concluded that none of them developed a
symbiosis with algae in contrast to zooxanthellate scleractinian
corals.^1";

Hexactinellida (Porifera) im Palaeozoikum.- Geol. Palaeont. Mitt.
Innsbruck special volume 4: 1-55.- <b>FC&#038;P 25-2</b>, p. 39,
ID=3123^<b>Topic(s): </b>phylogeny; Porifera Hexactinellida;
<b>Systematics: </b>Porifera; Hexactinellida; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>^The Hexactinellida, first appearing
in the Late Proterozoic of China, are the earliest animals in
Earth&#39;s history, which can be definitely attributed to an extant
metazoan group. Already in the Middle Cambrian the hexactinellids show
remarkably high diversity. Beside many specialized extinct groups, such
as the Protospongiidae, the main groups of the recent Hexactinellida,
the sister groups Amphidiscophora and Hexasterophora, are known since
the Early Paleozoic. The large Paleozoic taxa, Reticulosa and
Brachiospongiidae, known since the Cambrian and Ordovician,
respectively, may have given rise to the recent Hexasterophora and
Amphidiscophora. First representatives of the Hexactinosa, important
sponges of the widely distributed Mesozoic spongiolithic facies and
common also in recent deep sea environments, are known since the
Devonian. A probably paraphyletic grouping, the
&#34;Rossellimorpha&#34;, stayed conservative in its skeletal
achitecture from the Early Cambrian until today, most of the time
apparently restricted to deep-sea habitats, similar to those of most
recent hexactinellids. During some periods of Earth&#39;s history,
specialized groups of the Reticulosa, e.g. the Dictyospongiidae,
developed the ability to live in shallow water under higher-energetic
conditions. The Late Palaeozic, especially Permian, was a time of
highly diversified spicular skeletal types within the Hexactinellida,
including &#34;lithistid&#34;-like frameworks with zygosis and also
groups with demospongioid spicule tracts. During the history of the
Hexactinellida, the main faunal extinction occurred at the end of the
Permian. However, no major extinction event is recorded at the Frasnian
&#47; Famennian boundary. The distribution of sponges and assemblages
of isolated sponge spicules, especially for Early Palaeozoic sediments,
gives important palecological indications. An evolutionary-ecological
evaluation of organismic groups expands the method of palecology. The
value of this concept for our understanding of e.g. taphonomic and
sedimentary processes is demonstrated by some examples on account of
Palaeozoic Porifera.^1";
s[4872] = "ELIAS R.J., MCAULEY R.J., MATTISON B.W. (1987).- Directional
orientations of solitary rugose corals.- Canadian Journal of Earth
Sciences 24, 4: 806-812.- <b>FC&#038;P 17-1</b>, p. 19,
ID=2117^<b>Topic(s): </b>growth orientation; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Paleozoic; <b>Geography:
</b>^Unattached solitary rugose corals lying parallel to bedding are
common in many Ordovician and younger Paleozoic units, but their
directional orientations have seldom been examined. Interpretations
based on occurrences in North American Upper Ordovician and Lower
Silurian strata provide a foundation for such studies. Distinct
directional patterns resulted from preferred orientation with respect
to water motion. They indicate transportation rather than biologic
orientation, if it can be shown that the corals were not preserved in
life position or were abraded to a significant degree before burial.
Transported, slightly curved specimens having trochoid to ceratoid form
were aligned parallel to currents, with the apex pointing upstream, and
```

```
(or) were rolled nearly perpendicular to currents or almost parallel to
crests of advancing waves, with the apex facing either way but directed
slightly upstream. Therefore, unimodal orientation patterns, bimodal
patterns with equal peaks that are opposite one another but slightly
skewed, and trimodal patterns that are a combination of these can be
used to determine flow directions. An apparently bimodal pattern with
nearly equal and directly opposite peaks has been observed in a case
involving mostly subcalceoloid corals. These individuals may have been
aligned parallel to currents or to the direction of wave progression,
with the apex facing either way. Random directional distributions do
not necessarily indicate low-energy environments. They could have
resulted from changes in flow direction during the time in which the
sampled stratigraphic interval was deposited or from the effects of
bioturbation on corals that were initially preferentially oriented.
Directional patterns of solitary rugose corals are of value in
paleoecology (recognition of transported assemblages) and basin
analysis (determination of paleocurrent directions). They may also
prove to be useful in making paleoenvironmental reconstructions (type
of water motion, nature of substrate) if the reasons for different
types of orientation patterns can be established with experimental work
and additional data from the geologic record.^1";

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Paleozoic; <b>Geography: </b>^The Scleractinia,
which are one of the most important builders of modern reefs, have been
considered to have first appeared in the Middle Triassic. Recently,
Paleozoic scleractiniamorphs have been reported from both the
Ordovician and the Permian, suggesting that the scleractinian-like body
plan was already established in the Paleozoic. Those Paleozoic
```

```
scleractiniamorphs are considered either unsuccessful skeletonized
offshoots (extinct experiments) or Paleozoic progenitors of the
post-Paleozoic Scleractinia. Permian scleractiniamorphs are
characterized by &#34;ancestral&#34; features and have no specific
morphologies that deny scleractinian affinities. Molecular
phylogenetics also indicate that extant scleractinians are monophyletic
and originated long before their Triassic appearance. A Paleozoic
origin for the Scleractinia is supported by morphological and molecular
phylogenetic data. On the other hand, there is no positive evidence to
show that different groups of scleractinians had separate soft-bodied
precursors. The Paleozoic scleractinians evolved within the framework
of their basic body plan, and a direct derivation of the Scleractinia
from the Rugosa is not probable. The Anthozoa are characterized by a
bilaterally symmetrical body plan, which is traditionally considered to
have been derived from other radially symmetrical Cnidaria. The problem
of the origin of scleractinian body plan may provide a key for
deciphering the early anthozoan radiation within the Bilateria. Other
examples of Paleozoic Scleractinia and scleractiniamorphs will be
found, probably in shallow-water reefal facies or deeper-water
communities, bridging the stratigraphic gaps in occurrence and
elucidating the origin of the Scleractinia and their body plan.^1";

<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>^Paleozoic stromatoporoids comprise a
distinct class of non-spiculate poriferans that are represented as
fossils by their basal skeleton. A revised terminology for the
description of these fossils is presented. Seven orders (Labechiida,
Clathrodictyida, Actinostromatida, Stromatoporellida, Stromatoporida,
Syringostromatida, Amphiporida) are recognized. The following are
recorded for each genus: (1) type species, catalogue number and
depository of the primary holotype; (2) synonyms and their type
species, (3) diagnosis; (4) stratigraphic range; (5) estimate of the
number of species assigned to the genus; (6) stratigraphic and
geographic distribution of the genus. Problems in definition and
recognition of the genus are briefly discussed in annotations. One
hundred and nine genera are considered valid, or doubtfully valid.
Fifty-three genera are placed in synonymy. An additional 14 genera are
considered to be of uncertain placement in the classification.^1";
s[4893] = "KERSHAW S., BRUNTON F.R. (1999).- Palaeozoic Stromatoporoid
taphonomy: ecologic and environmental significance.- Palaeogeography,
Palaeoclimatology, Palaeoecology 149: 313-328.- <b>FC&#038;P 28-2</b>,
p. 37, ID=4034^<b>Topic(s): </b>taphonomy, ecology; stroms;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>^Epibenthic marine organisms, such as
the aspiculate stromatoporoids, show a wide range of growth forms in
different settings across Palaeozoic carbonate banks and reefs making
them useful taphonomic tools in palaeoenvironment analysis. Three main
postmortem taphosignatures are discussed: (1) physical breakage and
bioerosion prior to burial are the main processes; (2) loss of
morphologic and taxonomic information due to postburial diagenesis; and
(3) minor localized reorientation during karstification. Hydrodynamic
behaviour of stromatoporoid clasts was similar to that of other
carbonate skeletal clasts in their rounding and sorting
characteristics. Although bioerosion and bioturbation did not play an
important role in Palaeozoic stromatoporoid taphofacies
characterization, a marked increase in bioerosion of stromatoporoids is
evident, beginning in certain Silurian (Wenlock) morphotypes and in
some Devonian rnorphotypes. Stromatoporoids offer various profiles to
shelf currents and seasonal storm surges, and apparently have different
skeletal strength (durability) depending on skeletal architecture.
Cyst-dominated skeletal architecture appears to have been resistant to
```

```
fragmentation. Latlaminae represent inherent zones of weakness that
appear to have enhanced equidimensional (breakage away from
latilaminae) to oblate (breakage along latilaminar surfaces) breakage.
Construction of lamina-pillar architecture, gives the visual impression
of varying robustness but this is supported by few data. Stromatoporoid
response to increasing hydrodynamic energies varies greatly from no
movement or simple overturning to severe fragmentation and size
sorting. Although such variation broadly reflects palaeogeographic
setting and thus periodic disturbance by tropical storms, familial and
generic skeletal traits greatly influenced taphofacies
characterization. These differences in modularity and ontogeny in the
stromatoporoid groups have hampered the development of generalized
taphofacies models. Taphofacies are not comparable between modern
coralgal reefs and Palaeozoic stromatoporoid-bearing reefs for the
following reasons: significant differences exist in the diversity of
observable growth strategies; probable significant differences in life
modes between these groups; and Palaeozoic microborers were fewer than
modern representatives and apparently less effective in stromatoporoid
taphofacies characterization than modern reef macrobioeroders are for
coral taphofacies development.^1";
s[4894] = "MISTIAEN B. (1994).- Skeletal density: implications for
development and extinction of Palaeozoic Stromatoporoids.- Courier
Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.)
Proceedings of the VI. International Symposium on Fossil Cnidaria and
Porifera, Vol. 2]: 319-327.- <b>FC&#038;P 23-1.1</b>, p. 23,
ID=4089^<b>Topic(s): </b>skeletal density; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Paleozoic;
<b>Geography: </b>^Palaeozoic Stromatoporoids present a large diversity
of skeletal density (S.D.). A computer process is used to calculate
this S.D.; the method is detailed. The first (Early Ordovician) and the
last (topmost Devonian) Palaeozoic Stromatoporoids have the lowest
S.D.; the Givetian and Frasnian ones present the highest S.D. The
variations in the S.D. correspond to differences in the amount of
calcium carbonate used by the Stromatoporoids to build their skeleton.
These are correlated with variations in paleoenvironments (differences
in water temperature and variation of PCO2). Palaeozoic Stromatoporoids
may be derived from pre-Ordovician non-calcified soft-bodied organisms
(Webby, 1979). During the Early Ordovician, they develop a thin cystose
skeleton. From the Ordovician to the Frasnian, they progressively erect
a thicker and thicker skeleton. From Famennian to topmost Devonian they
develop again a thin cystose skeleton. During and after the
Carboniferous they may have again been living as non-calcified
soft-bodied organisms.^1";

elements. Because microstructures are subject to extensive diagenetic
alteration, and classifications that have been based on them are
difficult to apply, they have not been used as diagnostic criteria in
the classification. The stromatoporoids are recognized as a class
within the phylum Porifera and divided into five orders. Within the
Labechiida, the families Labechiidae, Rosenellidae, Aulaceridae, and
Cliefdenellidae are recognized. The Lophiostromatidae are the only
family in the order Lophiostromatida. The Actinostromatida include the
Pseudolabechiidae, Actinostromatidae, and the Densastromatidae. Within
the Clathrodictyidae, the families Clathrodictyidae, Ecclimadictyidae,
Tienodictyidae, Diplostromatidae, and Amphiporidae are recognized. The
Stromatoporida includes the families Stromatoporidae,
Syringostromellidae, and Syringostromatidae. Eighty-seven genera are
recognized as valid and are distributed to the various families. Forty
```

microstructure de quelques Micheliniidae et Michelinimorphes (Tabulata
paleozoiques).- Bulletin du Museum national d&#039;histoire naturelle,
Paris, ser. 4, 7, C, 1: 13-63.- <b>FC&#038;P 14-2</b>, p. 37,
ID=0921^<b>Topic(s): </b>microstructures; Tabulata; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Paleozoic; <b>Geography:
</b>^The present study deals with the group of michelinioid Tabulate
corals having in common convex incomplete tabulae, they are namely:
Michelinia, Praemichelinia, Eumichelinia, Michelinopora,
Protomichelinia, Cystimichelinia, Holacanthopora, Beaumontia, Rhizopora
and Turnacipora nov. gen. Except for the lamellae in Praemichelinia
their microstructure has been poorly known with only few illustrations
given of the lamellar sclerenchyme within Michelinia and
Holacanthopora. Ultra-thin sections bring new light on the wall
structure of most of these Devonian to Late Permian genera. Michelinia
shows parallel undulating lamellae; Praemichelinia has its lamellae
diverging upwards; in Turnacipora the wall is composed of domed
micro-lamellae as is the case in Beaumontia. The presence of a fibrous
stereozone in Protomichelinia seems probable. The microstructure of
Michelinopora and Cystimichelinia remains unknown. A genus close to
Praemichelinia shows a lamellar wall still with the formation of fibres
in its median part. Finally a totally fibrous composition is recorded
in a Late Permian form. Concerning stratigraphy, forms having parallel
lamellae are not found beyond the Middle Carboniferous; forms showing
divergence are present up to the Late Permian whereas the microlamellar
michelinioids are good indicators of the Early Carboniferous. For the
research of evolutionary trends, such characters as inclination of
tabulae or presence of epitheca are revealed to be insignificant
whereas microstructural patterns suggest phylogenetic relations between
the principal michelinioid genera. The interest of microstructure in
generic definition of michelinioid Corals is underlined. At the same
time attention is drawn to problems arising by its introduction into
family definition and the profound eventual changes to be expected in
Tabulate corals&#039; systematic.^1";

464-468.- <b>FC&#038;P 31-2</b>, p. 13, ID=7119^<b>Topic(s):
</b>phylogeny; Cnidaria; <b>Systematics: </b>Cnidaria; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>^Recently, Oliver, Jr. W.A. (1996) and
Scrutton, C.T. (1997) published their important papers on the
classification of the Cnidaria as well as the origins and relationships
of Palaeozoic corals respectively. These papers have great value to us
in the systematics of Cnidaria and the origins and relationships of
various coral groups although these themes have been discussed for over
100 years. Integration of newly available global data of Cnidaria and
Palaeozoic corals makes possible biologically significant advances in
our understanding. The classification of Phylum Cnidaria recognizes
three classes: Hydrozoa, Scyphozoa, and Anthozoa. Corals and ture
anemones are anthozoans. They are referred to zoantharians. The Phylum
Cnidaria is represented in the geological record principally by the
corals. The two major Palaeozoic groups of corals have records from the
Early Ordovician (Tabulata) and Middle Ordovician (Rugosa) to the end
of Permian. The third major group (Scleractinia) ranges from Middle
Triassic to Holocene. The Rugosa and Tabulata may have arisen as
separate skeletonization events from some groups of anemones. None of
Cambrian coralomorphs is regarded as directly ancestral to the post
Cambrian coral clades. Scleractinia are considered to have evolved
through skeletonization events among a group of anemones. The Rugosa
are not considered to be ancestral to the Scleractinia. Some of the
Cambrian coralomorphs can be dismissed as cnidarians, others may be non
zoantharian, or even non anthozoan cnidarians. Some have been
reassigned to other phyla, such as algae, bryozoan or sponges. Among
them only a small number of genera are accepted as true zoantharian
corals. The scleactiniamorph corals were found in the Ordovician from
Scotland and northern Ireland as well as in the Permian from North
Africa and South China respectively. It is likely that these Palaeozoic
scleractiniamorph corals represent another small independent
skeletonized clades. They disappeared at the end Permian extinction.
The Palaeozoic corals were strongly affected by the mass extinction
events. The end Ordovician (O/S) event and the Late Devonian (F/F)
event distinctly reduced the diversity of Rugosa and Tabulata. Finally,
these two groups became extinct at the end of Permian. [original

Spatial competition among clonal organisms in extant and selected
Paleozoic reef communities.- Facies 42, 1: 1-24.- <b>FC&#038;P
29-1</b>, p. 49, ID=1507^<b>Topic(s): </b>reefs, spatial competition;
reefs ecology; <b>Systematics: </b>; <b>Stratigraphy: </b>Paleozoic;
<b>Geography: </b>^Occurrences of densely packed benthic organisms in
extant reefs are of two types: (1) live-live interactions, where two
living organisms interact, and (2) live-dead associations, where only
one is alive and uses the other as a substrate. The latter are common
in reef deposits due to biostratinomic feedback, i.e. dense skeletal
accumulations provide hard substrates for clonal recruitment, thus
facilitating greater frequency of live-dead encounters than in lower
biomass level-bottom communities dominated by solitary organisms.
Differentiating between these two types in ancient reefs is difficult,
often impossible. * Most live-live interactions among clones in extant
reef communities involve competition for space. Clonal spatial
competition is divisible into four types: (1) direct-aggressive:
encrusting overgrowth; (2) indirect-passive: depriving neighbors of
resources, chiefly sunlight, by growth above them; (3) stand-off:
avoidance of competition by organisms adopting positions that avoid or
```

```
minimize direct polyp &#47; zooid contact; and (4) overwhelming: one
clone &#47; species volumetrically or numerically overwhelms the other,
meeting minimal resistance. Despite class-order level differences in
taxa, our results indicate that extant analogs, based on the
arrangement and distortion of skeletons, are valuable for recognizing
live-live interactions in Silurian and Carboniferous reefs and
interpreting the types of spatial competition represented. * Comparison
of overhead (plan) views of live-live coral competition in Polynesian
reefs with vertical sections of Silurian and Carboniferous
sponge-dominated reefs and biostromes suggests that direct-aggressive
competition is more common among extant than among Paleozoic
reef-builders. Stand-offs showing clone margin distortion and
overwhelming with minor skeletal distortion are most common in our
fossil examples and probably relate to the dominance of these reefs by
sponges. Success by extant sponges in spatial competition is largely
due to allelochemical deterrence which may explain the predominance of
stand-off and overwhelming confrontations in fossil sponges rather than
tentacle-mesentery based direct aggression among extant corals and
bryozoans. [original abstract]^1";

sedimentology; reefs vs bioaccumulations; <b>Systematics: </b>;
<b>Stratigraphy: </b>Paleozoic; <b>Geography: </b>^One unresolved
conceptual problem in some Palaeozoic sedimentary strata is the
boundary between the concepts of &#039;shell concentration&#039; and
&#039;reef&#039;. In fact, numerous bioclastic strata are transitional
coquina-reef deposits, because either distinct frame-building skeletons
are not commonly preserved in growth position, or skeletal remains are
episodically encrusted by &#039;stabilizer&#039; (reef-like) organisms,
such as calcareous and problematic algae, encrusting microbes,
bryozoans, foraminifers and sponges. The term
&#039;parabiostrome&#039;, coined by Kershaw, can be used to describe
some stratiform bioclastic deposits formed through the growth and
destruction, by fair-weather wave and storm wave action, of meadows and
carpets bearing frame-building (archaeocyaths, bryozoans, corals,
stromatoporoids, etc.) and/or epibenthic, non-frame-building (e.g.
pelmatozoan echinoderms, spiculate sponges and many brachiopods)
organisms.This paper documents six Palaeozoic examples of stabilized
coquinas leading to (pseudo)reef frameworks. Some of them formed by
storm processes (generating reef soles, aborted reefs or being part of
mounds) on ramps and shelves and were consolidated by either encrusting
organisms or early diagenesic processes, whereas others,
bioclastic-dominated shoals in barrier shelves, were episodically
stabilized by encrusting organisms, indicating distinct episodes in
which shoals ceased their lateral migration.^1";

ID=7225^<b>Topic(s): </b>not alga; Chaetetida Solenopora;
<b>Systematics: </b>Porifera; Chaetetida; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>^For over 100 years the Ordovician
fossil Solenopora (Dybowski) has been widely considered to be a
calcified red alga. The type species Solenopora spongoides consists of
tubes with longitudinally flexuous walls, lobate-petalloid cross
sections 30-175µm across with septal projections and sporadic cross
partitions. This internal morphology is not characteristic of calcified
red algae but is consistent with the original interpretations of
Solenopora as a chaetetid and with subsequent recognition of chaetetids
as sponges. Solenopora is widely misidentified in Silurian and younger
rocks. Removal of Solenopora from the algae underscores the need to
comprehensively reassess the palaeoecological and phylogenetic
significance of numerous disparate Ordovician to Miocene fossils
currently classed as Solenoporaceans. [original abstract]^1";

s[4935] = "SCRUTTON C.T. (1996).- The scleractiniamorph coral Kilbuchophyllia clarksoni at Kilbucho.- Scottish Journal of Geology 32, 1: 91.- <b>FC&#038;P 25-2</b>, p. 44, ID=3087^<b>Topic(s): </b>scleractiniamorpha, new material ; Anthozoa Kilbuchophyllidae; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Ordovician Car; <b>Geography: </b>^The first well authenticated Palaeozoic examples of a scleractiniamorph coral were described by Scrutton &#038; Clarkson (1991). The material was collected from fossiliferous mid-Ordovician (Caradoc) silt-grade greywackes of the Kirkcolm Formation in Tract 2 (of the accretionary prism model) of the Northern Belt of the Southern Uplands at Kilbucho, near Biggar. Subsequently, further material became available (Scrutton 1993), including a new, small specimen from the greywackes at Kilbucho which demonstrated hexameral cyclic septal insertion with much greater clarity than any of the original material. The range of the type species, Kilbuchophyllia discoidea, was extended to further localities along strike to the southwest and a new species, K. clarksoni, was described. The new material from these additional localities, Wallace&#039;s Cast, Glenkip Burn, Snar Water and Duntercleuch, was all found in a poorly sorted, matrix-supported, quartz pebble conglomerate facies. However, despite extensive collecting no kilbuchophyllids had been found in the fossiliferous conglomerates underlying greywackes at Kilbucho. This note is to record the finding of a single specimen of K. clarksoni from the conglomerate facies at Kilbucho during a visit in August 1995, the first record of this species from any facies at that locality. This find provides further evidence to support the likelihood that throughout Tract 2, the kilbuchophyllids are occurring in fossiliferous conglomerate and greywacke obrution deposits at a single level in the Kirkcolm Formation (Clarkson et al. 1992). One further additional observation since the publication of Scrutton (1993) has been the rediscovery of the fossiliferous conglomerate localities in Glenkip Burn [NS 869174] and Snar Water [NS 859169]. Additional material of both species of Kilbuchophyllia was recovered from these localities, the original material having been collected in the last century during the survey by Peach and Horne (1899). The correlation of this level in the succession has contributed to a reassessment of the structure and history of the Northern Belt of the Southern Uplands shortly to be published (Armstrong et al. 1996).^1";

to assess the early (that is, Ordovician) history of stromatoporoid
genera using both cladistic and stratigraphical data. Only two
relatively independent and homogeneous stromatoporoid groups have been
recorded. The order Labechiida is the most diversified, with elements
first appearing in the Middle Ordovician. The group is divided into
four families based on differing morphological features and growth
form: the rosenellids with their simple (?more primitive), small to
large cysts, denticles, and encrusting, laminar to domical form; the
labechiids with rounded pillars formed by superposition of denticles,
and a trend in some to flatter, lamina-like cysts; the stylostromatids
(fam. nov.) with mamelon columns and development of composite,
blade-like pillars within columns; and the aulacerids with extended,
mamelon-like, cylindrical to branching forms. The massively thickened,
encrusting lophiostromatids may comprise a fifth group. The order
Clathrodictyida has only a few members, and these make then first
appearances in the Upper Ordovician; they differ from representatives
of the Labechiida in showing downwardly inflected pillars and common
astrorhizae. Given the distinctively different morphologies of the two
groups, it may be suggested that they represent separate lines of
descent from uncalcified sponge-like organisms. ^1";

```
the Ordovician. One stromatoporoid community is associated with the
reef facies; another is characterized by genera of columnar growth and
is presumed to have lived in deeper water on carbonate ramps. All
Ordovician stromatoporoid communities plot into paleolatitudes between
30 degrees north and thirty degrees south. The pulchrilaminids comprise
a family of doubtful affinity of large framebuilders that occur in the
late Early Ordovician of North and South America. The rest of the
labechiids first diversified in late Middle Ordovician and secondly in
Caradoc time. The initial radiation of the clathrodictyids occurred in
mid to late Caradoc with the appearance of Ecclimadictyon. Ordovician
stromatoporoid diversity peaked in early to mid Ashgill and fell
abruptly with the Hirnantian glaciations. Diversity curves for genera
and species are presented as &#34;normalized&#34; and &#34;range
through&#34; versions. The latter shows a steady increase in generic
diversity from late Middle Ordovician to mid Late Ordovician and a
sharp decline in the Hirnantian. The sensitivity of labechiids to
oceanic cooling is discussed in the light of the hypotheses of Stearn
(1987) and Nestor and Stock (2001). The relationship of the diversity
trends to sea level changes is also considered.^1";
s[4941] = "JULL R.K. (1976).- Septal development during hysteroontogeny
in the Ordovician tabulate coral Foerstephyllum.- Journal of
Paleontology 50, 3: 380-391.- <b>FC&#038;P 6-2</b>, p. 20,
ID=0152^<b>Topic(s): </b>blastogeny; Tabulata, Foerstephyllum;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>^Middle and Upper Ordovician
specimens of Foerstephyllum from a number of localities in eastern
North America were studied to determine the details of hysteroontogeny
and most particularly the nature of sepal development in the genus. The
increase is exclusively lateral in nature, most common in cericoid
rugose corals and in tabulate genera. The dividing wall appears
adjacent to the intercorallite wall or it appears to be formed by
splitting of the intercorallite wall. The holotypes of F. halli
(Nicholson), type species of the genus, and of F. magnificum (Okulitch)
are illustrated and commented upon. Closely spaced serial acetate peels
show that F. halli and forms comparable to F. magnificum lack an
ordered sequence of sepal development such as is characteristic of
rugose and scleractinian corals. Septa emerge in an apparently random
manner around the corallite. Corallites of a specimen of F. vacuum
(Foerste), however, show an early stage of development in which septa
possibly equivalent to the cardinal and alar septa are present.
Subsequent development in this specimen is more typical of other
representatives of the genus.Remarks: The used term
&#034;intercorallite wall&#034; does not coin-cide with the definition
of a corallite. According to Hill (1956: 247; in Moore R.C., Treatise
on Invertebrate Paleontology, Part F) a corallite means
&#034;exoskeleton formed by an individual coral polyp&#034;. Therefore,
it is proposed to use &#034;corallite wall&#034; only.^1";

life-history strategies of a late Ordovician halysitid coral.- Journal
of Paleontology 65, 2: 191-199.http:&#47;&#47;
www.jstor.org/pss/1305754.- <b>FC&#038;P 20-2</b>, p. 62,
ID=2956^<b>Topic(s): </b>growth mode, life strategies; Tabulata,
Halysitida; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Ordovician U; <b>Geography: </b>^The upper surface of the corallum
of Catenipora rubra was often at or just above the sediment-water
interface during life. The vertical growth rate was barely sufficient
to keep pace with background sedimentation and possible subsidence of
the corallum. Therefore, the colonies were in constant danger of being
covered by influxes of sediment, especially during storms. This was
compensated by the ability of polyps to respond to sedimentation events
and by certain aspects of colony growth. Rapid regeneration following
partial mortality involved budding of uninjured polyps and rejuvenation
of damaged individuals, in some cases accompanied by a type of axial
increase not previously known in tabulate corals. Rapid lateral
expansion was possible because small, &#34;immature&#34; polyps could
bud and grow in a reptant manner. Interconnected ranks of the
cateniform corallum served to dam shifting sediment at the periphery of
the colony. Lacunae within the colony were reservoirs for material that
breached peripheral ranks and for sediment that settled on the ranks
and was rejected by polyps or removed by passive flow. Polyps
comprising the colony were distributed over a large area of the
substrate surface, thereby decreasing the probability of complete
mortality during sedimentation events and increasing the probability
that a sufficient number of individuals would survive to ensure the
optimum regeneration. The corallum, anchored in the substrate and with
sediment filling the lacunae, provided a broad, stable base during
high-energy events. It remains to be established how widespread these
growth patterns and strategies were among other corals with cateniform
colonies, a form that appeared in many unrelated stocks. Most previous
workers emphasized physical strength when considering functional
morphology, following a tacit assumption that the corallum rose high
above the substrate and was therefore susceptible to breakage during
high-energy events. An understanding of the origin of cateniform
patterns and the phylogeny of these corals requires knowledge of their
modes of growth and life-history strategies, which were genetically as
well as environmentally controlled.^1";
s[4945] = "ELIAS R.J., LEE D.-J. (1993).- Microborings and growth in
Late Ordovician halysitids and other corals.- Journal of Paleontology
67, 6: 922-934.- <b>FC&#038;P 23-1.1</b>, p. 67, ID=4046^<b>Topic(s):
</b>borings; Tabulata, Halysitida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Ordovician U; <b>Geography:
</b>^Microborings in the Late Ordovician tabulate corals Catenipora
rubra (a halysitid) and Manipora amicarum (a cateniform nonhalysitid)
and in an epizoic solitary rugose coral differ from nearly all of those
previously reported in Paleozoic corals. These microborings were formed
within the coralla by endolithic algae and fungi located beneath living
polyps. Comparable structures in the Late Ordovician tabulate Quepora
lagglomeratiformis (a halysitid) represent algal microborings, not
spicules, and halysitids are corals, not sponges as suggested by
Kazmierczak (1989). Endolithic algae in cateniform tabulates relied
primarily on light entering through the outer walls of the ranks rather
than through the polyps; lacunae within coralla permitted appropriate
levels of light to reach many corallites. The direction of boring was
determined by corallum microstructure and possibly also by the
distribution of organic matter within the skeleton. There is an
apparent inverse correlation between boring activity and coral growth
rate. The location and relative abundance of pyritized microborings
within calcareous coralla can be established quantitatively and
objectively from electron microprobe determinations of weight percent
sulfur along appropriate traverse of the coral skeleton. The
```

```
distribution of such microborings in Catenipora rubra and Manipora
amicarum is comparable to algal banding in modern corals; this is the
first report of such banding in the interiors of Paleozoic corals.
Change in the intensity of boring within each corallum was evidently a
response to variation in the linear growth rate of the coral, or to
fluctuation in an environmental factor (perhaps light intensity) that
could control both algal activity and growth rate in these corals.
Change in the algal boring intensity and linear growth rate of the
coral was generally but not always seasonal and usually but not
invariably associated with changes in the density of coral skeleton
deposition. Cyclic bands of boring abundance maxima within fossil
colonial corals provide a measure of annual linear growth comparable to
the widely accepted method based on skeletal density bands. Algal bands
are more sporadically developed than density bands within and among
coralla, thus increasing in difficulty of interpretation. Fluctuations
in the abundance of algal microborings apparently provide a detailed
record of changes in the linear growth rate of colonies and individuals
within colonies. Combined analyses of microboring abundance and
skeletal desity will contribute significantly to our understanding of
the biological and environmental factors involved in endolithic
activity and coral growth.^1";
s[4946] = "DIXON J. (1976).- Corallite increase and a new corallite
type in Upper Ordovician Cateniform corals.- Journal of Paleontology

</b>Animalia; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>^The
Ordovician radiation of marine life was among the most substantial
pulses of diversification in Earth history and coincided in time with a
major increase in the global level of orogenic activity. To investigate
a possible causal link between these two patterns, the geographic
distributions of 6576 individual appearances of Ordovician genera
around the world were evaluated with respect to their proximity to
probable centers of orogeny (foreland basins). Results indicate that
these genera, which belonged to an array of higher taxa that
diversified in the Middle and Late Ordovician (trilobites, brachiopods,
bivalves, gastropods, monoplacophorans), were far more diverse in, and
adjacent to, foreland basins than they were in areas farther removed
from orogenic activity (carbonate platforms). This suggests an
association of orogeny with diversification at that time.^1";
s[4948] = "CARRERA M.G., RIGBY J.K. (1999).- Biogeography of Ordovician
Sponges.- Journal of Paleontology 73, 1: 26-37.- <b>FC&#038;P 28-1</b>,
p. 48, ID=3983^<b>Topic(s): </b>biogeography; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Ordovician; <b>Geography:
</b>^Sponges have an unrealized potential importance in biogeographic
analysis. Biogeographic patterns determined from our analysis of all
published data on distribution of Ordovician genera indicate Early
Ordovician sponge faunas have relatively low diversity and are
completely dominated by demosponges. Early Ordovician (Ibexian) faunas
are characterized by the widespread co-occurrence of Archaeoscyphia and
the problematic Calathium. This association is commonly found in
biohermal structures, Middle Ordovician faunas show an increase in
```

```
diversity, and two broad associations are differentiated: Appalachian
faunas (including Southern China and the Argentine Precordillera) and
Great Basin faunas. Late Ordovician faunas show important changes in
diversity and provincialism. Hexactinellid and calcareous sponges
became important and new demosponge families appeared. Four
Mohawkian-Cincinnatian associations are recognized here, including: 1)
Mid-continent faunas; 2) Baltic faunas; 3) New South Wales faunas; and
4) Western North American (California and Alaska) faunas. However, two
separate biogeographic associations are differentiated based on faunal
differences. These are a Pacific association (western North American
and New South Wales) and an Atlantic association (Midcontinent
Laurentia and Baltica). Distribution of sponge genera and migration
patterns are utilized to consider paleogeographic dispositions of the
different continental plates, climatic features, and oceanic currents.
Such an analysis points to close paleogeographic affinities between the
Argentine Precordillera and Laurentian Appalachian faunas. However,
significant endemicity and the occurrence of extra-Laurentian genera
suggest a relative isolation of the Precordillera terrane during the
Late Ibexian-Whiterockian. The study also shows a faunal migration from
the Appalachian region to South China during the Middle Ordovician and
the migration of faunas from Baltica to Laurentia in the Late
Ordovician. The occurrence of Laurentian migrants in New South Wales
during the Late Ordovician could be related to inferred oceanic current
circulation between these two areas, although other paleogeographic
features may be involved.^1";
s[4949] = "WEBBY B.D. (2002).- Patterns of Ordovician reef
development.- SEPM Special Publications 72 (Phanerozoic Reef Patterns):
129-179.- <b>FC&#038;P 33-1</b>, p. 42, ID=7198^<b>Topic(s):
</b>geohistory; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>^A review of factors that may have
influenced the major changes in Ordovician reef development is
presented against an earth-system background of profound global and
biotal change that includes a greenhouse climate, a sluggish, saline
oceanic state, high sea levels, progressive ventilation of surface
waters, intense episodes of volcanicity and orogeny, massive
diversification of biotas, and an apparently short, sharp,
end-Ordovician glaciation with accompanying extinction. Major controls
on reef growth are inferred to include: (1) under the existing high
levels of atmospheric carbon dioxide of the Early Ordovician,
higher-than-normal temperatures promoting microbial reefal communities
and cyanobacterial calcification processes - high temperatures may have
exceeded adaptive ranges of many metazoans (excepting sponges),
delaying their proliferation as reef builders; (2) sea-level
fluctuations and elevated sea-level highstands of the Early Ordovician
caused episodic drowning and influx of anoxic waters from an expanded
oxygen-minimum zone over platforms and archipelagos, limiting reefal
diversification to more rudimentary phases involving mainly microbial
growth; (3) lower sea-level highstands during the Middle Ordovician
restricted flooding to outer shelves, and consequently reef building
occurred only in peripheral parts of platform areas, hence the lower
abundances (only 18% of all preserved Ordovician reefs); (4) apparent
rise in levels of oxygenation of tropical surface waters to a peak near
the Middle-Late Ordovician boundary aided significantly the
colonization of the reef habitat by sessile, respiring metazoans; and
(5) elevated Late Ordovician sea-level highstands again causing
episodic drowning over platforms, but this time influxes of oceanic
waters had a limited, mainly regional, impact on reef development.
Diversification and spread of reefs continued through the Ashgillian
but, in the lead up to the end-Ordovician glaciation, late Ashgillian
(Hirnantian) reefs developed in only a few sites, though they retained
diverse biotas. [end-fragment of extensive summary]^1";

```

```
fauna after the Late Ordovician extinction.- Bulletin of the Tohoku
University Museum 1 [Proceedings of the 8th International Symposium on
Fossil Cnidaria and Porifera]: 333-341.- <b>FC&#038;P 30-2</b>, p. 33,
ID=1600^<b>Topic(s): </b>extinctions O/S; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Ordovician &#47;
Silurian; <b>Geography: </b>^The Late Ordovician extinction of
stromatoporids was a gradual rather than an abrupt process of decrease
in diversity throgh the Late Ordovician to Early Silurian transition. A
transformation of a labechiid-dominated Ordovician stromatoporoid fauna
into a clathrodictyid-dominated Early Silurian fauna embraced a wide
time interval, from beginning of the late Caradoc to the end of the
middle Llandovery (Aeronian). It roughly coincided with a supposed
global cooling, ore &#34;ice-house&#34; period in Earth history. During
this period the earliest labechiids with poorly calcified (probably
aragonitic) skeletons were replaced by more advanced labechiids and
clathrodictyids with well-calcified skeletons. The generic diversity of
stromatoporoids reached its lowest value in the early Rhuddanian with
representatives of only four genera, Clathrodictyon, Ecclimadictyon,
Pachystylostroma and Forolina. During the late Rhuddanian and early
Aeronian the earliest representatives of the families Actinostromatidae
(Plectostroma) and Atelodictyidae (Intexodictyon) were added,
respectively. Generic diversity abruptly increased in the late Aeronian
(reaching at least 12 genera) when the first representatives of the
Gerronostromatidae (Petridiostroma), Pseudolabechiidae (Pachystroma),
Stromatoporidae (Lineastroma) and Syringostromellidae
(Syringostromella) appeared. During the Telychain the generic diversity
of actinostromatids and stromatoporids increased further and the first
densastromatids (Densastroma) appeared. A comparatively long duration
of Late Ordovician extinction and Early Silurian recovery of the
stromatoporoid fauna is probably best explained by general global
cooling, including several glacial episodes in addition to the
well-known end-Ordovician (Hirnantian) ice age, unfavourable for
stromatoporoids as thermophilic organisms.^1";

banding; <b>Systematics: </b>Porifera Cnidaria; Stromatoporoidea
Anthozoa; <b>Stratigraphy: </b>Ordovician Silurian; <b>Geography:
</b>^Palaeozoic corals and stromatoporoids exhibit a variety of
internal banding phenomena, many of which have been commonly
interpreted as annual growth bands. We evaluate bands through analysis
of colonial corals and stromatoporoids from three stratigraphic
intervals: Upper Ordovician of Manitoba, Canada, and Llandovery –
Wenlock and Ludlow of Gotland, Sweden. Banding features are divided
into four categories: (1) absence of banding; (2) density banding
formed by variation in density or form of elements; (3)
growth-interruptions banding including growth cessation and
regeneration; and (4) postmortem banding caused by compaction or
diagenesis. For discrimination of band types, it is essential to
```

```
examine internal structures and skeletal margins in thin sections or
acetate peels. Species vary considerably in degree and type of banding;
each has a distinct pattern of variation. We propose criteria to
determine if banding is consistent with seasonally induced growth
variation: (1) consistency in band character and thicknes; (2)
continuity of skeletal growth; (3) marginal features; and (4) evidence
of diagenetic alteration. Density bands in tabulate and rugose corals
probably represent annual variations, but results for stromatoporoids
are more ambiguous; although stromatoporoids commonly show banding,
unequivocal density banding is poorly developed and growth interruption
generated most stromatoporoid banding. Cerioid rugose and tabulate
corals possess the thickest density bands; the thinnest bands are in
stromatoporoids and heliolitid tabulates.^1";
s[4959] = "YOUNG G.A., ELIAS R.J. (1997).- Patterns of variation in
Late Ordovician and Early Silurian tabulate corals.- Boletin de la Real

</b>variation patterns; Tabulata; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Ordovician U &#47; Silurian L;
<b>Geography: </b>^A large data set on latest Ordovician and earliest
Silurian tabulate corals from the East-central United States permits
recognition and explanation of trends in intracolony and intraspecies
variation. All common colonial coral species from this region were
analyzed; these represent the orders Heliolitida, Halysitida, and
Favositida. Comparison of patterns of intraspecific variation indicates
that the inherent variabilities of the orders are different, and that
certain types of variation tend to recur between species and orders.
The variation pattern of each species was produced by the combination
of structural and growth factors, working in concert with the
coral&#039;s response to a particular set of environmental conditions.
The development of external growth form was affected by environmental
factors such as sedimentation rate and substrate stability.
Interlocality variation within some species indicates that internal
morphology was also strongly linked to environment. Correlation of
internal characters with paleoenvironment probably reflects the control
exterted on their development by space constraints determined by
external corallum form. Assessment of the control of variation by
structural factors can permit a more valid definition of coral
species.^1";

Upper Ordovician and Silurian Favositidae (Tabulata) and its possible
use in stratigraphic correlation.- Palaeoworld 19, 3-4: 256-267.-
<b>FC&#038;P 36</b>, p. 77, ID=6482^<b>Topic(s): </b>wall structure;
Tabulata Favositidae; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Ordovician U - Silurian; <b>Geography: </b>^Based
on an analysis of the significant collections of Favositidae (tabulate
corals) from the Upper Ordovician-Lower Devonian of the Taimyr
Peninsula, Western Slope of the North Urals and the Tchernychev Uplift,
this paper focuses on the macro- and micro-structure of the corallite
wall. Seven structural types of the corallite wall have been
recognized; some of them seem to have a definite stratigraphic range.
The results contribute to the long-time discussion on the applicability
of skeletal structure for systematics of the Favositidae, its
evolutionary implications, and stratigraphic correlation. It has been
held that the skeletal structure of the fossilized remains of
Favositidae is inapplicable for such purposes because diagenetically,
it is secondary, being a product of mineral replacement of the primary
structure. In contrast, an assumption is made here that the
&#34;secondary&#34; skeletal macro- and micro-structure may reflect in
some way the &#34;primary&#34; skeleton. As a result, it is proposed
that some evidence of evolution of the Favositidae may be obtained by
evaluating the stratigraphic range of favositid representatives
possessing different types of structure of the corallite wall.

Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>^Colony growth form in
some Silurian heliolitid corals is analyzed by the measurement of their
shape in profile. Data are presented for seven species, Stelliporella
parvistella, Heliolites interstinctus, H. megastoma, H. daintreei, H.
spongodes, Propora tubulata, and Plasmopora scita from three localities
in Gotland, Sweden, and three localities in England. Intraspecific
growth-form variation is presented on triangle diagrams. These plots
allow variation to be compared between species present at each locality
```

```
and between localities for each species. Results indicate that the
overall potential for growth-form variation is genetically controlled
and that levels of response to environmental stimuli may differ
markedly between species. Stelliporella parvistella is a very plastic
species, the only one developing branching growth in addition to other
growth forms. Heliolites interstinctus is much less variable,
dominantly tabular, domal, and low bulbous in form, but demonstrates a
similar response. Propora tubulata has a tightly constrained bulbous
growth form that shows little variation between localities. The other
species are represented by few specimens, most of which parallel H.
interstinctus. The likely moderating influences of light levels,
substrate type, sedimentation rate, energy levels, and other variables
on growth-form variation and species range are considered. The main
environmental factor including ecophenotypic response is concluded to
be sedimentation rate. A close correlation between this factor and
growth form in S. parvistella indicates that form in this species is a
particularly sensitive indicator of sedimentation rate and substrate
conditions. No simple equations can be made between specific
environments and one particular growth form in these corals. [original

</b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>^Many specimens of Heliolites interstinctus from the Aymestry
Limestone (Ludlovian) of the Welsh Borderlands contain borings: the
most commonly associated coral, Favosites gothlandicus, does not. The
only fossil preserved intact in the now sediment filled borings is
Lingula sp., which occurs in life position in some 28 borings. It is
concluded that in some cases the corals were still alive when the
borings were occupied. It is inferred that Lingula was unlikely to have
made the borings and from the morphology of the borings themselves,
annelids, bivalves or cirripeds were the most likely borers. It is
concluded that Lingula occupied preformed sediment filled borings, in
some cases living symbiotically with the live Heliolites. It is
suggested that the structure of Heliolites was less resistant to boring
attack than that of Favosites. [original abstract.]^1";

The Silurian rugosan Stauria favosa ordinarily exhibits cerioid coralla with a characteristic cross-shaped axial structureand a typical pattern of parricidal increase. Quadripartite increase at the sites of the four protoseptais most common, whereas cases of tripartite increase are rare. Parental protosepta are transformedinto dividing walls, where the four protosepta first appear with a definitive polarity in offsetcorallites. Daughter corallites inherit metasepta as metasepta, and catasepta as catasepta, within thesame quadrants as those of the parents. Metasepta are inserted serially, following Kunth&#39;s rule, as ischaracteristic of rugosan protocallites. As each daughter corallite derived immediately from thesame parent is arranged with identical polarity, it grows equally and evenly both individually and asa group. Daughters thus form protosepta and metasepta under strict phylogenetic and developmentalconstrains. However, individual corallites grow and reproduce autonomously, by using all availableskeleton and space of the parent. Although each module cannot modify essential modes of division,flexibility of the system was via changes in the density and arrangement of corallites, and regulatingmodes of growth, in tandem with adjacent corallites within the corallum. It is probable thatregularity, due to constrains of several origins, as well as flexibility are typical of other rugosan16colonies and played an important role in growth dynamics between corallites and corallum.^1";
s[4974] = "YU CHANGMING, OEKENTORP K. (1983).- Electron microscopic study on the microstructure of the Silurian Ketophyllum djupviki Wedekind, 1927 (Rugosa).- N. Jb. Geol. Palaont. (1996).- Ecophenotypic variation in the early Silurian rugose coral Palaeocyclus porpita.- Proceedings of the Yorkshire Geological Society 05, 1: 1-8.- <b>FC&#038;P 25-2</b>, p. 45, ID=3088^<b>Topic(s): </b>variation; Rugosa, Palaeocyclus; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian L; <b>Geography: </b>^Palaeocyclus porpita (Linnaeus) is a highly distinctive and biostratigrapbically important early Silurian rugose coral, widespread in north-west Europe and with scattered records in North America. In eastern North America, Palaeocyclus rotuloides (Hall) occupies a similar biostratigraphical position, but differs from P.
```

```
porpita in possessing a thin or imperfectly developed epitheca with
septal ridges or exposed septal plates and a distinct profile to the
undersurface. The calicular surfaces of P. rotuloides and P. porpita
are essentially indistinguishable. The relationship between P. porpita
and P. rotuloides is resolved by material from the Coralliferous Group
of Dyfed, south-west Wales. Collections from siliciclastic horizons
have P. porpita type epitheca, whereas material from thin bioclastic
limestone beds has P. rotuloides type epitheca. P. rotuloides from
eastern North America also appears to be associated with thin
bioclastic limestones. It is suggested that these two forms were
ecomorphs of the same species, P. porpita, in which epithecal
development was influenced by the character of the substrate. The
stratigraphical and palaeoecological distribution of the species is
briefly reviewed.^1";

They were most common on carbonate shelves bordering peneplaned continents in low palaeolatitudes. They were rare in shelve seas with a high influx of coarse elastics. Stromatoporoids were absent from seas of the Malvinokaffric Realm and late Silurian evaporitic epicontinental basins (Michigan basin, Tunguska basin). High-energy carbonate shoal environments were optimal for Stromatoporoids, and there they often formed parts of organic buildups (bioherms, biostromes, banks). Their role in reef building increased during the Silurian. Near-shore low-energy environments (lagoons, mud flats, restricted shelf) were less favourable for Stromatoporoids, especially when their hydrochemical regime declined from normal marine. Stromatoporoids were typical of low-energy open shelf environment, but their taxonomic diversity and frequency decreased offshore. They lived in normal marine
```

```
conditions in warm water, at depth up to 70 m. They preferred agitated
water and a hard or semi-soft, stable bottom. Ecological
differentiation of Silurian stromatoporoid faunas was quite low.^1";

stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>^The Silurian was a
period of the most intensive diversification of the Palaeozoic
stromatoporoid fauna. By the end of this period all the main
phylogenetic branches of the Palaeozoic Stromatoporoids were formed.
Half of the orders (Stromatoporellida, Actinostromatida,
Stromatoporida) and most of the families originated in the Silurian.
The most rapid expansion in diversity took place in Wenlock time.
Progressive folding of the basal surface of the soft body, increasing
the skeleton secreting ability of the basal pinacoderm, was the most
general tendency in stromatoporoid evolution. The role of labechiids
decreased and that of clathrodictyids increased rapidly.
Stromatoporoids with regular continuous laminae (order
Stromatoporellida), with a loose skeleton lattice (order
Actinostromatida) and irregularly amalgamated structure (order
Stromatoporida) appeared in the early Silurian. Parallel evolution of
Stromatoporoids with different kinds of microreticulate microstructure
(ortho-, clino- and akosmoreticulate) was characteristic of the
Silurian.^1";

</b>Silurian; <b>Geography: </b>^Paleofavosites asper (d&#039;Orbigny)
is redescribed on the basis of the holotype and additional material
from its type area of the Welsh Borderland. The species shows
considerable variation, particularly in the form and location of
intercorallite pores, from colonies with pores, including a high
proportion of solenia, almost exclusively located in corallite angles
to those with up to 40% of pores within corallite walls. This species,
the type species of Paleofavosites Twenhofel 1914, includes variants
with the structural features considered characteristic of Mesofavosites
Sokolov 1951. We, therefore, regard Mesofavosites as a junior
subjective synonym of Paleofavosites. [original summary]^1";
s[4997] = "POWELL J.H. (1980).- Palaeoecology and taxonomy of some
Wenlock tabulate corals and stromatoporoids.- Leeds Inst. of Geol.
Sciences, unpublished Ph.D. thesis.- <b>FC&#038;P 9-1</b>, p. 25,
ID=5788^<b>Topic(s): </b>; Tabulata, stroms; <b>Systematics:
</b>Cnidaria Porifera; Tabulata Stromatoporoidea; <b>Stratigraphy:
</b>Silurian Wen; <b>Geography: </b>^The stratigraphy of the Wenlock
Series of the Welsh Borderlands is briefly reviewed and the application
of the standard East European coral biozones discussed. * The taxonomy
of some Wenlock tabulate and heliolitid corals from the Welsh
Borderlands and South Wales is revised. The taxa comprise 13 genera and
28 species including new species of Favosites (2), Thamnopora (1), and
Halysites (1), as well as species of Paleofavosites, Thecia, Angopora,
Coenites, Cladopora, Alveolites, Cystihalysites, Heliolites,
Plasmopora, and Propora. Observations are made on the concepts of some
genera particularly Paleofavosites, Angopora and Halysites. Some
Wenlock stromatoporoids are briefly described along with commensal
associations of Diplostroma yayorski and calcareous algae, Cornulites
and heliolitids, and chimney shaped burrows in Thecia. * Periodic zones
of skeletal thickening in favositids are shown to be related to levels
of increase in colonies, and the seasonal nature of periodic thickening
is discussed. Serial sections of Favosites have revealed pits at three
corallite junctions and confirm lateral increase in favositids. Wall
structure and septal spine development in the Halysitidae is revised
and their taxonomic significance outlined. * Poorly defined tabulate -
heliolitid coral associations have been established in the reef and
inter-reef facies of the Much Wenlock Limestone. The associations are
related to phases of reef development and location on or off-reef.
Growth rates and longevity in favositids are comparable with
Scleractinian corals. * Analysis of reefs within the sequentially
developed (inter-reef) facies of the Much Wenlock Limestone of Wenlock
Edge has shown that the reefs of the stratigraphically lower, clay-rich
facies are dominated by heliolitids, whereas the reefs of the uppermost
grainstone facies show a decrease in heliolitids with a marked increase
in favositids and stromatoporoids. This pattern is attributed to a
gradual shallowing through the deposition of the Limestone, but with
only the uppermost facies deposited within wave base. * Regional faunal
- facies variations in the Wenlock of the Welsh Borderlands and South
Wales indicate a high diversity focus in the Wenlock-Dudley area with a
decreasing diversity gradient towards deeper water and non-reef facies.
Local variations are apparent, such as the bryozoa dominated reef at
Usk. Comparison of Wenlock coral faunas between the Welsh Borderlands
and the Baltic province indicates few palaeozoogeographical links
between these areas.^1";

warmer, high-latitude climates; salinity-dense bottom waters; and
accompanying low diversity, planktic and nektic faunas. Periodic
removal of reef and bottom-level community habitats by tectophases and
relative sea-level falls appears to have stimulated reorganization and
evolution of invertebrate communities during subsequent transgressive
intervals. Latest Ordovician and early-middle Llandovery
metazoans-parazoans gradually reestablished shallow- and deeper-water
reef ecosystems. Evolutionary radiations of coral and stromatoporoid
faunas are evident in the upper Llandovery and lower Wenlock. Although
corals and stromatoporoids reached their Silurian acmes in the Wenlock,
stromatoporoids maintained similar diversities in the Ludlow. Numerous
coral species disappeared by the early Ludlow, in part coinciding with
the end-Wenlock extinctions of different planktic and benthic faunas.
Calcimicrobial communities and calcareous algae were important
constructors in many early-middle Llandovery reefs, are less
conspicuous in many late Llandovery-early Wenlock reefs, and were
volumetrically important reef constructors in many Late Silurian reefs.
Morphological innovations of selected Ludlow benthos and associated
lithofacies show a &#034;Devonian carbonate bank archetype&#034;, with
distinguishable forereef, reef, backreef, and lagoonal facies.
Partially reef-rimmed, late Ludlow, distally-steepened, carbonate banks
reflect a change in reef patterns from the patchiness that
characterized most Early Silurian flat-topped carbonate bank seascapes.
Wenlock and late Ludlow reef tracts were larger in areal extent than
modern reef tracts and were concentrated in subtropical and equatorial
climatic belts [See also: Brunton F. R., Copper P. &#038; Dixon O. A.,
1997, Silurian reef-building episodes. Proceedings 8th International
Coral Reef Sumposium 2: 1643-1650].^1";

<b>Geography: </b>^During his long career, James Hall named and
described over 250 species and several genera of fossil corals, mostly
of Middle Silurian to Middle Devonian age. Hall&#039;s principal coral
works were published in 1843, 1877, 1882-84, and (with G. B. Simpson)
```

```
1887. Sporadic work on corals continued to 1898, the year of his death.
In spite of shortcomings, his four main contributions provided the
taxonomic base for much of the later work on Helderberg, Onondaga and
Hamilton corals in New York and adjacent areas. Beginning in 1868,
George B. Simpson was one of Hall&#039;s many assistants. He began as
illustrator, became a describer of corals and bryozoans, and ultimately
co-author of the 1887 work. His own study of Paleozoic coral genera,
based on thin section analyses, began the post-Hall era of coral work
in eastern North America.^1";
s[5003] = "WEYER D. (1984).- Das Rugosa-Genus Duncanella Nicholson 1874
(Anthozoa, Silur-Devon).- Abhandlungen und Berichte für Naturkunde und
Vorgeschichte 12, 5: 29-52.- <b>FC&#038;P 13-2</b>, p. 38,
ID=0468^<b>Topic(s): </b>; Rugosa, Duncanella; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian Devonian;
<b>Geography: </b>^Studies on the morphology of the type species
Duncanella borealis Nicholson 1874, from the Waldron Shale (upper
Wenlockian) of Waldron (Indiana), result in a redefinition of the
genus, which is classified because of its aulos as a member of
Laccophy11inae, with probable synonym Petronella Birenheide 1965.
Distribution of Duncanella reaches from lower Wenlockian to upper
Eifelian throughout Europe, Asia, and North America. Additionally
described species are Duncanella? n.sp. A from the Kitaigorod horizon
(early Wenlockian) of Podolia, and Duncanella n.sp. B from the Haragan
formation (Lochkovian) of Oklahoma. Duncanella borealis occurs in
Wenlock limestones/shales near Dudley (England). * Missing apical wall
structures in Duncanella and some few similar genera (of
Laccophy11idae, Hapsiphy11idae, Plerophyllidae, Po1ycoeliidae) may be
explained by a special mode of asexual reproduction, well known from
several Scleractinian corals as gemmation by transverse fission.
Comparative materials of European Miocene Kionotrochus
(Cylindrophyl1ia) Yabe &#038; Eguchi 1937 are figured, with signs of
transverse fission. There was no proof for the adradosiid growth model
proposed by Plusquellec (1981). Records of a wall-free apex run from
Lower Silurian to Upper Permian (Wen1ockian-Dzhulfian). The curious
feature obviously is of no taxonomic use at the generic level, and some
taxa perhaps might become synonyms of identical parallel genera
provided with normally developed archaeothecate corallum tips (Gymnaxon
Birenheide &#038; Soto 1977 = Laccophyllum Simpson 1900;

```

```
Petraia; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian Devonian; <b>Geography: </b>^Morphology and systematic position of Petraia Muenster 1839 are unknown, not one of the five genosyntypes being sufficiently studied for generic determination. The revision proposed by Schindewolf in 1931 must be rejected because of serious errors concerning morphological observation and nomenclature. * The type species Petraia decussata Muenster 1839 is probably of Upper Devonian rather than of Upper Silurian age. A series of 14 syntypes (Berlin museum) has been found in Famennian clymeniid limestones at the locality Schubelhammer. Up to a future revision based on a lectotype to be selected and perhaps offering basic taxonomical alterations, the best way will be to retain the traditional idea of Petraia in the sense of Schindewolf, using one of his specimens (1931, text-figs. 5-9) as a provisional standard. * The coral fauna of the Upper Silurian &#34;orthoceratite limestone&#34; at the locality Elbersreuth includes species of several genera: Palaeocoyathus Foerste 1888, Petraia Muenster 1839 (sensu Schindewolf 1931), Sutherlandinia Weyer 1972, Laccophyllum Simpson 1900. The lectotype of Petraia radiata Muenster 1839, used by Schindewolf to define the genus Petraia, is a coral without contratingent minor septa, most probably belonging to Palaeocyathus. [original summary]^1";
s[5006] = "LAFUSTE J. (1983).- Disparite microstructurale entre Calceola Lamarck et Goniophyllum Dybowski (Tetracoralla, Devonien et Silurien).- C. R. Acad. ```

```
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^Literature data
indicate above average diversity of the Cyathaxonia fauna in the
Devonian period, both in absolute numbers of (sub)families and genera
per age and also with respect to taxonomic diversities as calculated
per Ma (106 years). The Emsian and Famennian faunas, although
represented by most numerous (sub)families and genera have less than
average diversities, due to their more than average durations, whereas
the shorter intervals of the Pragian and Givetian have the highest
values for diversity per Ma, and the Frasnian faunas the lowest
diversities, for both (sub)families and genera. The post-Givetian
crisis may have been responsible for the Frasnian minimum, although
limited temporal resolution of the analysis does not allow for a more
precise description of the Givetian/Frasnian transition. However,
&#34;silent taxa&#34; are extremely numerous in the Frasnian, i.e. taxa
which are present both prior to and after the Frasnian, but missing
from the Frasnian record itself indicating that the Famennian
Cyathaxonia fauna contains significant numbers of Lazarus and/or Elvis
taxa.^1";

Smithicyathus; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Fra; <b>Geography: </b>^The rugose coral genus
Smithicyathus is diagnosed in this paper as massive to phaceloid
phillipsastreid, with common horseshoe dissepiments and major septa
that are very short in the tabularium. Revised taxonomy of this genus
is based on analysis of over 20 numerical characters measured in
sections and/or extracted from the literature data. Species are
distinguished either by morphometric non-overlap in at least one, key
feature or by geographic-stratigraphic isolation. The earliest possible
representatives of the genus are known from the Eifelian of Angara (S.
? emendatus and S. ? russakovi). In the Upper Frasnian Smithicyathus is
represented by seven species; in western Euramerica occur S. cinctus
and S. mcleani sp.nov.; south-eastern Euramerican shelf area is with S.
lacunosus, S. cf. lacunosus, S. smithi, S. cf. smithi, and S.
lubliniensis, one probable species is recorded in Angara: S.?
belkovskiense. The genus did not survive the Frasnian-Famennian crisis.
Smithicyathus lived in tropical and sub-tropical shallow-marine
carbonate environments, with the possible exception of the northern
mid-latitudes species from Siberia. In the Holy Cross Mountains, S.
lacunosus and S. smithi show a preference for restricted-marine facies.
They may make up over 90% of all rugosan colonies collected in such
locations, whereas in the more open-marine settings they are rare both
in numbers and in proportion to other rugosan species.^1";

distribution as a test of Devonian palaeogeographic models.- Geological
Society Memoir 12 [McKerrow W. S. &#038; Scotese C. R. (eds):
Palaeozoic palaeogeography and biogeography]: 267-275.- <b>FC&#038;P
19-1.1</b>, p. 40, ID=2622^<b>Topic(s): </b>distribution database,
biogeography; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^A data bank, based on
stage by stage distributions of 420 rugose coral genera in 25 regions
of the world is analysed, mostly by means of Otsuka coefficients, to
test an Emsian reconstruction of the world proposed by Scotese.
Devonian rugose corals inhabited a narrower range of facies than some
other benthic groups, and even without regard to facies, provide a tool
for testing geographic reconstructions. Basin dwelling coral genera
typically have longer temporal and broader geographic ranges than
corals living in shallower environments, and are less suitable for
palaeogeographic studies. They are treated separately in this work. For
the most part, conclusions drawn from the analysis are either
consistent with, or positively supportive of, the Scotese
reconstruction. However, large but poorly known rugose coral faunas
from Mongolia and the Amur Basin are at about 60º N in the
reconstruction, and other well known coral faunas, from Altai-Sayan,
are at 45-50º N. In the light of known distributions of both modern
corals and Devonian southern hemisphere corals, in all recently
proposed palaeogeographic reconstructions, it is questionable that the
original latitude of any large northern hemisphere Devonian coral fauna
would have exceeded 45.^1";

Rugosa, Tabulophyllum; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^The predominantly
Middle Devonian and Frasnian coral genus Tabulophyllum is highly
characteristic of the cosmopolitan faunas of the latter part of the
Devonian System and approximately 99 species have been described from
all major areas of marine Devonian outcrop. At least 20 of these are
wrongly assigned and should be placed in Carboniferous or other
Devonian genera, and in addition the status of some of the remainder
must be regarded as possible synonyms due to the highly variable nature
of those species that are thoroughly known. In this study all
post-Frasnian corals are excluded from the genus, with the questionable
exception of one species from Czechoslovakia. * The genus has a
characteristic diagenetic lamellar wall structure in thin-section; its
septal structure is of very fine monacanthine trabeculae and
fibro-normal flanks in well preserved specimens. Long, complete tabulae
are typically marked by peripheral gutters, gracefully downcurved (as
seen in longitudinal section), while the characteristic lonsdaleoid
dissepimentarium is marked by large presepiments which interrupt the
septa in peripheral areas. Some Frasnian species show the development
of large individuals with a cardinal fossula and marked bilaterality.
This is most marked in species of the latest Frasnian, preceeding the
Frasnian-Famennian extinction event. Adaptation to substrate played an
important role in the success of Tabulophyllum species. Those
inhabiting soft, muddy substrates are commonly characterized by thin,
leaf-like expansions of the corallite through large presepiments, along
with a sharply pointed apex positioned within the substrate. Several
species were apparently adapted for a sandy (shifting?) substrate, with
```

```
the apical part of the skeleton filled by biogenic calcite. Species
living on a firm substrate have well developed talons and normal growth
above, forming a large base.^1";
s[5030] = "OLIVER W.A.jr, PEDDER A.E.H. (1994).- Crises in the Devonian
history of rugose corals.- Paleobiology 20, 2: 178-190.- <b>FC&#038;P

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>^Detailed analysis of the stratigraphic
ranges of Devonian rugose coral genera within the Old World and Eastern
Americas Realms gives new information on faunal extinctions and other
bioevents in both realms. Various origination and extinction metrics
are calculated from tabulations of occurrences in each stage. The most
significant faunal changes were near or at the ends of the Lochkovian
and Frasnian stages. The former marks the gradual transition from
dominance by Silurian families and genera to the characteristic
Devonian coral assemblages; the latter marks the virtual extinction of
the Devonian families and genera. Other coral events are related to the
two major changes. The data provide new bases for comparing the
histories of the two realms. Most of the events are recorded in both,
giving support to previous suggestions that the causes were worldwide.
The coral record shows an increase (probably episodic) in environmental
deterioration persisting through the Middle Devonian and culminating in
extinction at the end of the Frasnian. Eustatic sea level fluctuations
may have caused the precursor events and a bolide impact may have
caused the end-Frasnian extinction. ^1";

</b>^Czamockia is known by three specimens from the Upper Famennian
Clymenia and Wocklumeria genozones of the Holy Cross Mountains in
Poland and of the Tafilalt in Morocco. The redescription (based on
additional sectioning of both holotype and paratype) leads to a
classification within the phyletic line Neaxon &#62; Petraia &#62;
Famennelasma &#62; Czarnockia of the ahermatypic family Petraiidae
Koninck, 1872 (synonym Neaxoninae Hill, 1981). The more common ancestor
Famennelasma Weyer, 1973, which is found in the same Upper Famennian
time span from Poland through Germany and France to Morocco, differs in
the lack of dissepiments occurring only in the mature calice of
Czarnockia. * A redefinition (quite different from that proposed by
Schindewolf, 1931) for Petraia Munster, 1839 is included in order to
attain taxonomic stability of its family taxon by selection and
illustration of a lectotype of the true type species Petraia decussata
Munster, 1839 from the Upper Famennian (Clymenia genozone) of Upper
Franconia in Germany (anticipating a future more detailed revision of
that genus). * Another pleonophorous descendant from Neaxon is
Nicholsoniella Soshkina, 1952, with type species Nicholsoniella
baschkirica Soshkina, 1952, from the Upper Frasnian of the western
slope of the southern Ural Mountains in Russia. After reillustration of
its type series, this genus is grouped into a phyletic line Neaxon
&#62; Neosyringaxon &#62; Nicholsoniella. [original summary]^1";
s[5045] = "GUDO M., HUBMANN B. (2001).-&#039;Engineering
morphology&#034; of the rugosan Argutastrea quadrigemina: new views on
the reconstruction of soft body behaviour during parricidal budding.-
Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th
International Symposium on Fossil Cnidaria and Porifera]: 041-049.-

Argutastrea; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>^Two general types of budding can be
distinguished in massive colonies of Rugosa, Tabulata or Scleractinia:
extratentacular and intratentacular budding. A remarkable variation of
intratentacular budding, so called &#34;parricidal increase&#34;, is
studied in the rugose coral Argutastrea quadrigemina. Instead of
creating a new corallite, an existing one is divided into four new ones
by &#34;killing&#34; the mother corallite. * To understand the
character of this special kind of reproduction we reconstruct the
process by which fleshy soft parts divide into four new individuals. On
the basis of considerations of engineering morphology (i.e.,
constructional morphology) we present a model to explain the generation
of structures observable in skeletal tomography of Argutastrea
quadrigemina during the budding process. Our hypothetic soft body is a
polyp with distinct engineering and structural functional constraints:
it is supplied with single mesenteries (in contrast to scleractinian
corals!) which are added symmetrically in four sectors. Due to the
remarkably deep calyces and quite short septa our polyp has rather
short mesenteries. * Arrangements of mesenteries and positions of their
insertion imply that from each growth sector, the body wall of the
```

```
polyp increases until enough body mass is present to divide the
existing polyp into four new ones. Thus the new body walls are arranged
in a definite way as proposed by D&#39;Arcy Thompson for four bubbles
in close contact. [original abstract]^1";

of Calceola (Cnidaria, Calceolidae), with comments on the phylogeny of
Devonian operculate tetracorals.- Memoirs of the Association of
Australasian Palaeontologists 39: 159-176.ISSN 810-8889.- <b>FC&#038;P
36</b>, p. 71, ID=6472^<b>Topic(s): </b>morphology, ecology, phylogeny;
Rugosa Calceolidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^In Calceola sandalina
the full complement of counter major septa was established very low in
the calyx, extending from the counter septum across to the edge of the
counter face. At about mid-height of the calyx, a counter-lateral major
septum was generated on either side of and from the counter septum.
Serial minor septal insertion was initiated adjacent to the
counter-lateral septa at a slightly later stage and continued
throughout the subsequent ontogeny of the corallite, with minor septa
(schizosepta?) arising on the median side of major septa and
bifurcating from them. Alar fossulae are seen in the calyx of mature
corallites, on the counter side of a low ridge near the lateral
extremity of the inner surface of the counter face. Insertion of major
septa in the alar fossula has been observed rarely on the external
counter face of worn corallites. The median septum in the operculum of
C. sandalina is a compound structure which incorporates adjacent minor
septa. * In an Emsian(?) corallite of ?Chakeola sp. minor septa are
derived from major septa, new-minor septa being generated on the outer
side of major septa. This corallite also exhibits minor septa adjacent
to the K septum, thus casting doubt on Birenheide&#039;s generalisation
that the counter-lateral septa of C. sandalina are not separated from
the counter septum by minor septa. In the Emsian Chakeola whitehousei
minor septa are present adjacent to the counter septum of the
operculum. * The distal, anteriorly facing, projecting peg of the K
septum of the corallite articulated within the large socket in the
opercular K septum, and subsidiary grooves and plates on the socket and
septum further facilitated interlocking. Knobs and/or small lists are
developed along the posterior edge of the operculum, in the shelf
inside the counter edge; septal pegs developed by septa in the
corallite were accommodated within this shelf. The opercular septal
blades interlocked loosely between the anteriorly facing, distal parts
of septa of the corallite. * Rare opercula show one or more (abortive?)
attempts to overcome damage which led to displacement of the operculum
relative to the corallite, and rejuvenescence is exhibited to various
degrees in many opercula. One operculum was apparently broken (bitten?)
in half as a juvenile, but was reconstructed to reach a mature form.
Other specimens show epifauna, borings and bioerosion either on the
external surface of the operculum or on the external cardinal surface
of the corallite. &#039;Galls&#039; on the inner opercular surface are
interpreted as stereome deposited to seal off some type of internal
parasite. In C. sandalina, tubules containing tabulae are located just
inside the counter face, and may have served to house soft parts
associated with the operculum. Changes of opercular septal morphology
```

37-49.- <b>FC&#038;P 29-1</b>, p. 50, ID=7043^<b>Topic(s): </b>soft
body; Rugosa Calceola; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^The slipper-like
corallum of Calceola sandalina comprises the calyx and the lid. It was
generated by an anthozoan-like coral. Anthozoan polyps have a
barrel-like shape that is produced and maintained by the activity of
internal tethering elements and muscular structures in the body wall.
All these structures counteract the hydrodynamics of the gastrovascular
cavity* In this reconstruction of the soft parts of Calceola the
functional aspects pointed out by Richter (1929) will be reviewed and
revised and partially corrected. Calceola was reconstructed on the
basis of the model of rugose polyps. Consequently it consisted of
single mesenteries which were added in four sectors in a serial manner.
The lid was formed on the counter side and is explained as a bulge of
the basal parts of the soft body. The lid was connected coherently by
the mesenteries to the whole construction. It could be closed by
contraction of the mesenteries and opened by regeneration of the
hydraulic volume in the gastric cavity. As a mechanical consequence of
moving the lid a straight hinge was developed between the calyx and the
lid.The soft body of Calceola developed by quite simple structural
modifications of a rugose coral. The most important modification was
the bulging of the basal parts of the soft body on the counter side
which formed the lid. This bulge enlarged the surface for adhesion to
the substrate and might have been an advantage in survival as well. The
soft body generated its own substrate giving it the specific slipper
shape. This shape prevented Calceola from sinking into the soft or
muddy substrate by the principle of a snowshoe which enabled Calceola
to conquer new territories. The lid meant protection where enemies and
pollution were concerned.The slipper shape and the lid of Calceola
indicated a complex evolutionary pathway, but they evolved by simple
modifications of an ancestor with a round diameter. The slipper shape
is just a mechanical consequence of a flappable lid. [original English

monacanthine trabeculae, commonly flexed to varying degrees in a
vertical plane, small, globose dissepiments, and a broad, clearly
defined tabularium. The high degree of intraspecific variability
evident in large populations of many North American charactophyllid
species indicates that only the genera Charactophyllum Simpson,
Spinophyllum Wedekind, Temnophyllum Walther, Sinodisphyllum Sun,
Hunanophrentis Sun, Alaiophyllum Goryanov, Piceaphyllum Rozkowska,
Chostophyllum Pedder and Ceciliaphyllum McLean can be recognized within
the family, at least provisionally. It is clearly important for such
```

```
variability to be assessed in species from other regions, especially many relevant type species. Mictophyllum Lang &#038; Smith has commonly been regarded as a member of the Charactophyllidae, but restudy of the type species, M. nobile Lang &#038; Smith, indicates it is unrelated to that family. Its affinities lie with the kyphophyllid genus Tabulophyllum Fenton &#038; Fenton.^1";

These, and presumably the whole family, have species with an outer wall composed of laterally expanded septal bases coated by epitheca. The biogenic structure of this septotheca is shown in several best preserved individuals of Tabulophyllum traversensis collected from Givetian rocks in Michigan. The structure is fibrous, with calcitic fibers directed towards those of neighboring septa to form septotheca by lateral coalescence, with banding of magnesium providing a geochemical indicator of growth pattern. Diagenetic change of this structure progressively alters in to a septotheca with lamellar structure within septal bases, but with boundaries of remaining distinct. In T. traversensis., the lamellar wall structure thus is demonstrably diagenetic in origin. Similar lamellar structures occur in other species of Tabulophyllum, and in Smithiphyllum and Tarphyphyllum from Frasnian strata of Iowa. As yet, pristine biogenic structure is known in this family only in T. traversensis. A uniform style of diagenetic modification is envisaged for all genera of the Kyphophyllidae, although only the three have been studied to date. Additional data is needed prior to generalizing microstructure in other families and higher taxa of the Rugosa and Tabulata.^1";

</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^Understanding of the morphological variation and
defining characters of the abundant and ubiquitous dendroid
stromatoporoid genus Amphipora has been hindered by the loss of the
holotype specimen of the type species, A. ramosa (Phillips). In the
absence of the type, the boundaries of the genus could only be defined
vaguely, yet 12 genera of Amphipora-like fossils have been named to
constitute the family Amphiporidae Rukhin and about 175 species of
these genera have been described. Assemblages of amphiporids in a
single bed show a wide range of variation but are considered to be the
remains of a monospecific stand because a comparable range of variation
can be demonstrated along the length of single stems. Some highly
variable characters have been used to distinguish genera and species.
In particular, the expression of the axial canal, nature and presence
of peripheral membranes., thickness of skeletal elements, and density
of the skeletal network are shown to be of dubious value as criteria
for characterizing genera or species. A neotype for A. ramosa is
selected from collections made from the Chercombe Bridge Limestone at
Broadridge Wood quarry, Newton Abbot, Devon, and revised diagnoses of
the species and genus are formulated. The presence of distinct pillars
in the neotype and all examined specimens from Devon, shows that the
four genera whose distinctness from Amphipora was based on the presence
of this character, should be regarded as junior synonyms. Four other
genera are also placed in synonymy with Amphipora. The amphiporid
animal is reconstructed as a small cylindrical, branching, calcified
sponge in which the dermal membranes covering the vestibules were
locally calcified to form the peripheral membranes and vesicles.^1";

changes during growth history and their methodological consequences in
morphometrical analyses.- Lethaia 39, 4: 339-358.- <b>FC&#038;P 36</b>,
p. 34, ID=6400^<b>Topic(s): </b>morphometry; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^Eight Devonian stromatoporoids with clearly exposed
arrangements of latilaminae were subjected to detailed morphometrical
analyses. Distinctive sets of latilaminae were marked on photographs
taken from polished specimens, which allowed reconstruction of their
individual growth histories by presenting consecutive stages of their
growth. The growth forms measured above the sediment surface and the
overall shapes of the skeleton at a given time have proved to differ
distinctly between each other throughout the growth history of these
stromatoporoids. The morphometrical features of individual specimens
(both of their growth forms and of their whole skeletons) distinctly
changed throughout their development. Changing environmental factors
directly influenced the growth form above the sea floor, and each
specimen shows its own specific history of growth form changes.
Instead, overall shapes of the skeleton of most of the studied
specimens changed in a similar general manner resulting from growth
during sediment accumulation. Basing the palaeoenvironmental
considerations only on the stromatoporoids&#039; final shapes may thus
be very misleading. It is therefore suggested that the ascription of a
specimen to a particular morphometrical category should be based on the
mode of its growth history represented by a curve recording the V/B
changes (vertical height versus basal length) during consecutive growth
stages. Certain sedimentary processes have their direct reflection in
the mode of stromatoporoid growth, and are recorded by the attributes
of the shape profile (V/B), and burial ratio (BR) curves, which allows
deciphering such features as, for example, periodicity of sediment
supply, substrate consistency and tempo of sediment cementation. This
is particularly valuable when the deposits are recrystallized and the
sedimentary structures are not visible. The paper also tests the
applicability of the new definitions of the parameters describing the
stromatoporoid shape introduced recently by the author. [original
abstract]^1";

Biogeography]: 257-265.- <b>FC&#038;P 19-1.1</b>, p. 67,
ID=6820^<b>Topic(s): </b>biogeography; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^Stromatoporoids were a common component of shallow
carbonate environments of North America, Eurasia, and Australia during
the Devonian. They were least abundant during the Early Devonian. After
that time abundance increased, and remained high steadily through the
Frasnian. At the Frasnian-Famennian boundary the number of
stromatoporoids was greatly diminished, but they did not become extinct
until the end of the Devonian (at the end of the Strunian). The
geographic extent of stromatoporoids expanded and contracted
concurrently with increases and decreases in total population size.
Provincialism at the genus level prevailed during the Early Devonian,
with stromatoporoids inhabiting the Old World and Eastern Americas
Realms; none are known from the Eastern Americas during the Siegenian.
For the remainder of the Devonian stromatoporoids were cosmopolitan at
the genus level. The abundance of stromatoporoids varied directly with
eustatic sea level during the Devonian. Variations in depositional
conditions apparently controlled the local distribution of genera.

Schiefergebirge and a new species, R. cubiniensis from the Couvin area
of Belgium. Their external and internal characters and microstructures
are described in detail. The dominant morphological features they have
in common are cerioid and locally fasciculate corallites and tabulae
with an infundibuliform profile. The microstructure of the corallite
walls is characterized by an hitherto undescribed association of an
internal fibrous zone and a peripheral lamellar zone flanking a median
plate made of small granules and larger elements of stellate form. The
only microstructural variation between the three species lies in the
proportions of these components.^1";
s[5082] = "TOURNEUR F. (1988).- Mise au point sur le genre Trachypora
Milne-Edwards et Haime 1851 (Tabulata, Devonien).- Annales de la
Societe geologique de Belgique 110: 297-308.- <b>FC&#038;P 17-2</b>, p.
32, ID=2193^<b>Topic(s): </b>nomenclature; Tabulata, Trachypora;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^The genus Trachypora Milne-Edwards et Haime 1851 was
originally established for the species T. davidsoni Milne-Edwards et
Haime 1851, which is insufficiently known; therefore the use of this
generic name should be avoided. Most of the Devonian species of the Old
World assigned to this genus by subsequent authors belong very probably
to the genus Hillaepora Mironova 1960. The American Devonian species
are either members of the family Dendroporidae de Fromentel 1861, or
species of the genus Thamnoptychia Hall 1877. Consequently, the use of
the family name Trachyporidae Waagen et Wentzel 1886 should be
avoided.^1";
s[5083] = "LAFUSTE J., TOURNEUR F. (1991).- Biocristaux et elements
fonces de la muraille chez Thamnopora Steininger 1831 (Tabulata,
Devonien).- Annales de Paleontologie 77, 1: 3-20.- <b>FC&#038;P
20-2</b>, p. 31, ID=2891^<b>Topic(s): </b>microstructures; Tabulata,
Thamnopora; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>^In the axial part of Thamnopora
corallum, the wall is composed of a median lamina in large vertical
elements flanked by perpendicular fibers; in the middle part of the
corallum, the median lamina broadens out and becomes made of pennate
rods; in the cortical part of the corallum, the skeleton is entirely
fibrous. Biocrystals of the median lamina enclose dark granulae whose
dimensions and location are not hazardous. Interfaces of biocrystals
are strongly underlined (by organic matter ?) between the median lamina
and the fibers, but considerably less pronounced between rods and
fibers themselves. Microstructure of Tabulate corals must be studied in
various parts of the corallum. Thamnopora is a good example of
fibrization, a tendency which is a general feature of Tabulata. In its
axial part, the skeleton of Thamnopora is analogous to that of
Pachyfavosites . Problems of relations between
Pachyporidae-Thamnoporidae (with peripherically thickened skeleton) and
Favostidae (with walls of uniform thickness) are evocated.^1";
s[5084] = "SORAUF J.E., STEIN W.E.jr (1993).- Biological fabric and the
study of growth in the Devonian tabulate coral genera Lecfedites and
Favosites.- Courier Forschungsinstitut Senckenberg 164: 159-168. [P.
Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium
on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p.
15, ID=3450^<b>Topic(s): </b>biological fabric, growth study; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^Study of tabulate corals has been plagued by a lack
of consistently definable anatomical features. Conspicuously absent are
homologous point-for point correspondences between corallites.
Corallite size, growth patterns, colony form and polymorphism comprise
much of the basis for current systematics, but these commonly are only
informally descriptive. This study approaches corallite pattern and
```

```
growth from a numerical standpoint by means of &#34;biological
fabric&#34;. Biological fabric is defined as a morphological pattern in
which there are multiple subunits displaying complex relationships
between individuals and also between neighborhoods. In these patterns,
variability and position of subunits are parameters as important as
overall pattern means, or central tendencies. Measurements of corallite
sizes, shapes, relative locations, and orientations in colonies of the
genera Lecfedites and Favosites have been collected from transverse
sections using a microcomputer based videometric system. Methods have
been developed for consistent characterization of corallite fabric:
these are interpreted as variations in rates of skeletal growth and
budding. Regions of faster and slower growth and a dynamic
hummock-hollow behavior of the colony surface are seen in Lecfedites.
Measurable variability in corallite size and shape are interpreted in
terms of intracolony population structure. In contrast, species of the
genus Favosites studied tend to be homogeneous both at the level of
individuals and in larger regions of colonies. However, some areas of
more patterned budding are present and these are easily distinguished.
Further success in using the morpho-metric characterization of
biological fabric in the study of the Tabulata will lead to more
accurate definition of species and genera. ^1";
s[5085] = "MAY A. (1997).- Statistics on Thamnopora (Tabulata,
Devonian).- Boletin de la Real Sociedad Espanola de Historia Natural,
Seccion Geologica 91, 1/4: 217-230.- <b>FC&#038;P 26-2</b>, p. 15,
ID=3686^<b>Topic(s): </b>statistical analysis; Tabulata, Thamnopora;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>^Thamnopora is a ramose tabulate coral that was
abundant world-wide in the Devonian (Lochkovian to Frasnian). Its
simple morphology allows the testing of statistical methods. 312
descriptions of 148 species and subspecies of Thamnopora and
Gracilopora were assembled from 73 publications. Every description has
been entered into a data bank with the following morphological data:
growth of the corallites in the branches, septal elements, diameter of
branches, diameter of corallites in the central (resp. peripheral) part
of the branch, thickness of the walls in the central (resp. peripheral)
part of the branch, diameter and spacing of mural pores, and distance
between tabulae. Some morphological characters show interdependent
positive correlations, and peripheral corallite diameter is a good
indicator for the size of the polyp, which is at least partly
genetically controlled. It is not possible to discriminate between
Gracilopora and Thamnopora: therefore Gracilopora Tchudinova 1964 is a
junior synonym of Thamnopora Steininger 1831. Thamnopora shows a
phylogenetic increase in size. A cluster analysis performed with the
aim discriminating true species from synonyms failed.^1";
s[5086] = "YU CHANGMING, OEKENTORP K. (1997).- Morphogenesis, taxonomy
and microstructures of Beiliupora Yu &#038; Deng 1974 (Devonian,
Tabulata), with bearing on Devonian stratigraphy in Beiliu, Guangxi
(South China).- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 91, 1/4: 245-260.- <b>FC&#038;P 26-2</b>, p.
16, ID=3688^<b>Topic(s): </b>morphogenesis, taxonomy, microstructures;
Tabulata, Beiliupora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^Beiliupora Yu &#038;
Deng is a tabulate coral genus erected in 1974 with the monotypic
species Beiliupora beiliuensis Yu &#038; Deng in Wang, Yu &#038; Wu
1974 from the Lower Devonian, Emsian, Beiliu Formation in Beiliu,
Guangxi, South China. The present restudy based on the topotypic
material collected by Kl. Oekentorp during his visit to the type
locality in 1982 reveals that the coral is mainly characterized by its
peculiar colonial growth form, which is named here the
lattice-framework form. The branches grow to a certain level and extend
horizontally almost in all directions (never downwards). Subsequently,
they grow further in the vertical direction, either isolated or in
combination with another branch extending from the opposite direction.
```

```
The corallites radiate from the axial part of the cylindrical branch
extending upward to the surface of the branch at a sharp to rectangular
angle. All branches show continuous growth. The walls are
recristallized, e.g. the thickening of the walls at the calical
portions with fibrous structures are secondary caused by reorganization
of the crystals. Because of the peculiar colonial form, the genus is
best placed under a distinct family, regarding the well developed
polygonal to subrounded corallite walls, the mural pores, the more or
less complete tabulae and the transition from anormal type of septal
spines to squamulae. It is believed that family and genus are
reasonably placed in the Favositina. Forms of Beiliupora have a wide
distribution not only in Guangxi, South China, but also in Da Hinggan
Ling, Northeast China, and in Gansu province, Northwest China. They
have been assigned to Graciloporella Tchi 1982 and to Gracilopora
Tchudinova 1964; the former is believed to be synonymous with
Beiliupora. They all occur in Lower Devonian Emsian beds; commonly
within the so-called Zdimir-limestone. Some tabulate corals with small
corallites and peculiar colonial form described as species of
Gracilopora in the former Soviet Union Territory may be a form of
Beiliupora. A form occurring in the Zdimir-bearing limestone beds near
Oviedo, Spain, once recognized by Yu during a field-trip, might also be
referred to Beiliupora.^1";
s[5087] = "IVEN C., MISTIAEN B., TOURNEUR F. (1997).- New data on the
morphology and microstructure of the genus Caliapora Schlueter 1889
(Tabulata, Middle Devonian): systematic implications and reflections on
the function of squamulae.- Boletin de la Real Sociedad Espanola de
Historia Natural, Seccion Geologica 91, 1/4: 261-271.- <b>FC&#038;P
26-2</b>, p. 16, ID=3689^<b>Topic(s): </b>morphology, microstructures;
Tabulata, Caliapora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>^The examination of
exposed calices as well as of thin sections of coralla overgrown by
stromatoporoids has revealed that, in addition to the swallow-nest
shaped squamulae, pillars in the corners of the calices rising above
the colony surface and leaving large open gaps between them are
important characters of the genus Caliapora. This character corresponds
with the microstructure and the arrangement of growth bands delineating
former growth stages. The pillars are centres, from which the fibres
constituing the skeleton originate and rise steeply to the middle of
each wall. The function of the squamulae seems to have been to enlarge
the surface of the digestive and resorptive tissue of the polyp and to
improve the stability of the polyp, which is assumed to have been
necessary due to the large gaps between the pillars, which was probably
spanned by soft tissue. The family Caliaporidae Mironova 1984 is
regarded as valid and separate from the Favositidae as well as from the
Alveolitidae because of the peculiar characters described.^1";
s[5088] = "HLADIL J. (1998).- Evolution of intraspecific morphological
variability and its relationship to environment (Caliapora battersbyi,
Devonian).- Vestnik Ces. geol. ustavu 73, 1: 61-74.- <b>FC&#038;P
27-1</b>, p. 82, ID=3823^<b>Topic(s): </b>variability, phylogeny;
Tabulata, Caliapora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^Quantitative
evaluation of morphology including parameters of environment provided
these results: Morphological variability of the species decreased
slowly but continuously, beginning from the stage of its initial biotic
radiation. Episodes of increased variability corresponded to agitated
water and strokes of sedimentary clasts. Local maxima of variability
are correlated with the longevity of coral colonies. Surprisingly, the
changes of morphological variability are almost independent of the
changes of diversity of accompanying corallomorph fauna and flora.
Variability displayed negative correlation with direct biological
attack during the initial 3/5 of the Givetian history of the species.
Then a change arose and during the remaining tunes until the end of the
Givetian, the variability displayed a negative correlation with the
```

```
direct biological attack. The weakly positive correlation of
variability with the density of the populations has been documented.
Similar but not identical complexes of morphological features in
conjunction with a specific decrease/increase in variability were found
during several ecological crises during the Middle and Late Givetian (a
primary control by marine regressions on carbonate platforms). To
conclude, the study about C. battersbyi indicates that the
intraspecific morphological variability of tabulate corals is not only
dominantly controlled by energy of waves and quality of the sedimentary
substrate, as it would correspond to state-of-art of the discipline
before this study. The morphological variability reflects distinctively
also the ecological and evolutionary situations.^1";

</b>biogeography; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography: </b>^The evolution
of species assemblages of Tabulata corals in the Salair, Altai and West
Siberian Seas, which were located in Siberia in the Devonian Period, is
discussed. Three species assemblages are established in the Salair and
Altai Seas: Early Frasnian, Late Frasnian and Famennian. In the West
Siberian Sea only one specific assemblage has been found, namely Early
Frasnian. Tabulate assemblages in the Famennian consisted of solitary
species. Evolution of tabulate assemblages is discussed for the entire
Late Devonian. It is recognised that a major reconstitution of tabulate
species assemblages occurred across the Frasnian-Famennian boundary.
This reconstitution is expressed not only in a sharp change of
taxonomic composition, but also in the mass extinction of many groups
of corals and other organisms. Based on the analysis of
temporal-spatial distribution of tabulates it is concluded that seas in
Australia and Eurasia in the Frasnian could be treated as one
Australia-Eurasian paleobiogeographical province. [original summary]^1";

Halysitid corals in Devonian strata.- Alcheringa 04: 183-202.-
<b>FC&#038;P 11-1</b>, p. 52, ID=1779^<b>Topic(s): </b>review;
Tabulata, Halysitida; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^A review of reported
and new occurrences of &#039;Devonian&#039; halysitids indicate that
most are older than Devonian. Reports of Emsian halysitids from Chios
are best attributed to errors in the compilation of Bassler (1950). The
occurrences of halysitids in Quebec in strata considered Early Devonian
provide the only plausible examples of the existence of this family in
the Devonian. Thus, only Cystihalysites and Quepora appear to linger
into the Devonian. Five Australian occurrences, yielding seven taxa,
are described and interpreted as Silurian or older halysitids. All are
from allochtonous material in the Early Devonian of New South Wales and
include: Schedohalysites murramirra sp.nov., Halysites suesmilchi
Etheridge and an indeterminate specimen from the Mullamuddy Formation
near Mudgee; Schedohalysites sp. cf. S. ? chillagoensis from the
Sutchers Creek Formation, also near Mudgee; Quepora sp. indet. from the
Jesse Limestone at Limekilns; cf. S. orthopteraides (Etheridge) from
the Nubrigyn Formation near Stuart Town; and ? Halysites sp. indet.
from the Sharpeningstone Conglomerate near Bowning. The type material
of Schedohalysites ? chillagoensis (Etheridge) is redescribed and a
lectotype is selected. ^1";

the 5-6 Myrs long Frasnian (Late Devonian) metazoan reef episode had
```

```
relatively low diversity compared to middle Devonian highs (with over 200 genera of calcitic rugose and tabulate corals). Following an initial early rise after late Givetian coral and stromatoporoid extinctions, reefs expanded for the last time during mid-Frasnian sea-level highstands but declined markedly in the late Frasnian (rhenana-linguiformis conodont zones) below the Frasnian/Famennian (F/F) boundary. Globally metazoan reefs were wiped out by the end Frasnian: some Famennian reefs while partly retaining the structure of the underlying carbonate platform, were built by cyanobacterial consortia such as Rothpletzella, Girvanella and Epiphyton.During the Famennian, foraminifera with calcite walls became abundant for the first time in the Phanerozoic adding a new dimension to carbonate platforms. Colonial rugose corals (phacelloid, cerioid and thamnastraeoid modules) were absent in the early post-extinction phases up into the mid-Famennian and very rare and non-reefbuilding later, but solitary deep-water Lazarus corals survived locally. Coral-sponge reefs are unknown from the 21 Myr long Famennian, also a time of very low platform carbonate production. Rare small isolated stromatoporoid sponge and lithistid sponge patch reefs returned episodically during the Famennian in North America, western Europe, Australia, and China. The aragonitic stromatoporoids became extinct at the end of the Famennian. During a late Devonian tectonically very active collisional Caledonian mountain-building phase, oceanic and atmospheric cooling accompanied by sea-level lowstand systems, exposed most carbonate platforms accelerating coastal erosion and karsting. This increased the amount of clastics in the shelf-slope setting, in the last 1-3 Myrs prior to the F/F boundary often buring reefs. Immediately following there were protracted losses in practically all major tropical shelf marine invertebrates exceeded only by the end-Permian extinctions in severity. There is no apparent link between black organic-rich horizons and reef demise at, or close to, the F/F boundary. The F/F boundary not also (sic) marks the largest change from widespread flooded Early and mid-Paleozoic continental cratons to narrow distal shelves but also spikes the largest known global Paleozoic shift in atmospheric O2 enrichment and CO2 draw down. This threshold matched the rise of the first tropical rainforests and expansion of terrestrial biomes on the tropical central lowlands formerly occupied by carbonate platforms.^1";

Expanding during times of exceptional sea-level highstands and widespread epicontinental shallow seas, this 26 m.y. long acme of coral-sponge reef growth coincided with the warmest global temperatures known for the Phanerozoic, i.e. with a &#34;supergreenhouse&#34; climate mode well above Holocene interglacial norms. During the Middle Paleozoic, reefs were particularly abundant, occupying large, continental seaboard, carbonate platforms, and vast inland epicontinental seas. Examples of such &#34;extremes&#34; occurred mostly on passive margin settings, and extensively flooded continental
```

```
interiors, e.g. the 1700-3000km long tracts of the Western Canada
Sedimentary Basin, Canadian arctic (Innuitian platform), eastern
Laurentia &#034;Old Red Continent&#034; (linked United Kingdom to
Poland), eastern Russian Platform (northeast Laurussia), Ural &#34;Fold
Belt&#34; (eastern slopes of Urals), Siberia, northwest Africa, and
South China. Smaller scale reef belts between 700 and 1300km long were
constructed on isolated tectonic terranes facing Gondwana on the north
(Pyrenees, Afghanistan-Pakistan), Mongolia, Kolyma-Chukotka, and North
China. Large basins and flooded shelf areas, and the reefs featured
within them, were not persistently developed throughout the Middle
Paleozoic. They especially characterized the middle Emsian through
Givetian (late Early Devonian - Middle Devonian). The following
Frasnian (Late Devonian) showed more restricted and confined
distribution of coral - stromatoporoid reefs, and during the Famennian,
coral-stromatoporoid reefs &#34;crashed&#34; and were replaced by
calcimicrobial reefs and platforms. During the latter phases of the
Frasnian &#47; Famennian mass extinctions, such microbial reefs were
confined to relatively small areas, and metazoan reefs were nearly
entirely obliterated, being confined to rare stromatoporoid patch reefs
or lithistid mounds. Coral reefs were completely absent during the 21
m.y. long Famennian interval, and no real recovery of
&#34;keystone&#34; frame-building, colonial corals took place in reef
settings. The Famennian coincided with repeated glaciations, sharp
sea-surface cooling events, sea-level drawdowns, and concurrent,
matching stable isotope excursions. [original abstract]^1";

isotopes C; reefs extinctions; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fra/Fam; <b>Geography: </b>^Perturbations in the Upper
Devonian carbon cycle are evidenced by prominent variations in the
inorganic carbon isotope record. The decline of the Devonian
stromatoporoid - coral reef ecosystem is interpreted to be caused by
the ultimate consequences of these perturbations. The Frasnian is
characterized by a second order sealevel rise culminating in a maximum
sealevel highstand and maximum greenhouse conditions near the Frasnian
&#47; Famennian boundary. High sea-surface temperatures, a sluggish
oceanic circulation and low fertility may have stressed low latitude
shallow-water habitats. Superimposed transgressive - regressrve cycles
resulted in a maximum flooding of the epicontinental shelves, maximum
formation of warm saline deep waters and the spread of sub-pycnocline
anoxic waters onto the shallow water platforms. The latter resulted in
the deposition of organic rich sediments (Kellwasser Horizons) inducing
climatic cooling especially in high latitudes. Reduction of benthic
habitats, upwelling of sulfidic waters or toxic algal blooms represent
possible consequences of the transgressive pulses. The Devonian
stromatoporoid - coral ecosystem may have been highly stressed during
the Late Frasnian and superimposed transgressive pulses resulted in an
increase of ecological stress that may have been lethal especially for
low latitude shallow water ecosystems.^1";

<b>Geography: </b>^The microfacial and geochemical investigation of
seven profiles comprising the transition of reef to non-reef facies
showed that especially the Devonian biostromal reefs were highly
susceptible to any kind of change in the continental hinterland which
```

```
might have influenced the equilibrum of the reef habitat. As regards
the Devonian stromatoporoidal reefs, living conditions disimproved
during the Frasnian stage (doI&#946;/&#947;) leading to cyclic reef
growth mainly on the unprotected shelf platform of the Eifel/Ardennes.
One of the main factors controlling stromatoporoidal reef-growth turned
out to be the periodical blooming of microorganisms (e.g.
phytoplankton) which was triggered off by the periodical infux of
nutrients from the Old Red Continent. This led to a widespread
depletion of oxygen and light plus to an increased sedimentation of
organic matter in the reef habitat, thus inhibiting growth of reef
dwellers, causing latilaminae in stromatoporoids and also leading to
cyclic reef growth. A prolonged and more widespread event of this kind
finally terminated stromatoporoidal reef growth at the southern rim of
the Old Red Continent and resulted in widespread deposition of euxinic
sediments in Europe (Matagne-shales, doI&#948;). In further works light
should also be shed on the concurrent effects on associated platform
dwellers like corals, brachiopods and possibly conodonts. Investigation
of further Devonian profiles should render more spatial conclusions if
the obtained results were also valid at a larger scale.^1";
s[5111] = "MACHEL H.G., HUNTER I.G. (1994).- Facies Models for Middle
to Late Devonian Shallow-marine Carbonates, with Comparisons to Modern
Reefs: a Guide for Facies Analysis.- Facies 30: 155-176.- <b>FC&#038;P
23-1.1</b>, p. 89, ID=4205^<b>Topic(s): </b>facies, analysis; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>^Shallow marine tropical Devonian carbonates commonly were
deposited in two major geologic settings, i.e., shallow shelf with
shelf margin reef, and gently sloping ramp that grades into peritidal
to supratidal, in places evaporitic facies. The facies types within
these two settings can be grouped into a few distinct zones on the
basis of water energy, texture, amount of micrite, porosity, fossil
assemblages, and indicator fossils. These zones have been integrated
into a composite facies model for shallow marine, tropical Devonian
carbonates. The facies zones are easily recognizable in hand specimen
and core, and can be used for fast and accurate facies analysis. Some
facies recognizable in hand specimen or core do not easily fit into the
integrated model and represent facies of short-lived depositional
events, such as hurricanes or slump deposits, or spatially restricted
areas, such as channel fills. Such facies have to be interpreted on a
case-by-case basis by comparison to the surrounding facies and
depositional framework through time. Comparisons with Cenozoic reefs
reveal a number of similarities. In particular, large metazoans in both
Devonian and Cenozoic reefs display a range of growth forms that is not
species-specific. Furthermore, several metazoans display comparable
growth forms in equivalent facies zones. For exampie, dendroid
stromatoporoids, such as Stachyodes, and branching corals, such as
Porites porites, occur in equivalent facies zones.^1";

Eutrophication by decoupling of the marine biogeochemical cycles of C,
N, and P: A mechanism for Late Devonian mass extinction.- Geology 28,
5: 427-430.- <b>FC&#038;P 30-1</b>, p. 34, ID=7079^<b>Topic(s):
</b>extinctions; mass extinction; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography: </b>^The Late
Devonian mass extinction was unusually protracted and ecologically
selective, with preferential diversity losses among reef-building
organisms and tropical, shallow-water faunas in general. We have
investigated the link between the extinction&#039;s unique
characteristics and changes in biogeochemical cycling through analyses
of the &#948;13C and C:N:P atomic ratios of organic matter buried
across the Kellwasser Horizons in western New York State. Each horizon
is characterized by (1) a long-term, +4‰-5‰ excursion in &#948;13C, ~3‰
of which occurs within the horizon, and (2) a dramatic increase in the
burial ratios of C:N:P, from values of ~100:15:1 to an average of
~5000:170:1. On the basis of these results, we propose that (1)
increased efficiency of biolimiting nutrient recycling, resulting from
cyclic water column stratification and mixing, promoted eutrophication
during Kellwasser deposition in New York, and (2) the isotope
excursions represent the composite effect of long-term, global organic
C burial, and local changes in photosynthetic C isotope fractionation
related to nutrient availability. This eutrophication model forges a
mechanistic link between proposed Late Devonian climatic cooling and
the selective demise of taxa likely to have been narrowly adapted to
oligotrophic conditions. [original abstract]^1";
s[5118] = "McGHEE G.R.jr (2001).- The&#039;multiple impacts
hypothesis&#039; for mass extinction: a comparison of the Late Devonian
and the late Eocene.- Palaeogeography, Palaeoclimatology, Palaeoecology
176, 1-4: 47-58.- <b>FC&#038;P 31-1</b>, p. 72, ID=7110^<b>Topic(s):
</b>extinctions, multiple impacts; mass extinctions; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography:
</b>^Application of the lag-time multiple impacts hypothesis [Poag
```

```
1997b: Palaios 12: 582-590; Poag et al. 2001: Columbia Univ. Press] to
the Late Devonian leads to the prediction that the Frasnian-Famennian
pulsed extinctions were triggered by a rapid drop in global temperature
that followed an impact-produced anomalous warm interval, which
interrupted the global cooling trend from the Middle Devonian
greenhouse to the Early Carboniferous icehouse. In actualistic
comparison with the late Eocene, the lag-time multiple impacts
hypothesis would predict that a Frasnian interval of multiple impacts
should have occurred between 367.7 and 366.7 Ma. The fact that three
impacts (the Alamo, Siljan and Flynn Creek) do occur either within this
predicted interval, or close to it in time, is corroborative evidence
that the lag-time multiple impacts hypothesis may indeed provide the
causal mechanism for the Frasnian-Famennian mass extinction. Based on
the application of the lag-time multiple impacts hypothesis to the
Frasnian-Famennian mass extinction, it is here suggested that future
searches for evidence of impact events in the Late Devonian be
concentrated in strata that occur in the Frasnian transitans to Early
hassi zonal interval, and not in strata immediately below or above the
Frasnian-Famennian boundary. [original abstract]^1";
s[5119] = "JOACHIMSKI M.M., BUGGISCH W. (2002).- Conodont apatite
&#948;18O signatures indicate climatic cooling as a trigger of the Late
Devonian mass extinction.- Geology 30, 8: 711-714.- <b>FC&#038;P
31-2</b>, p. 56, ID=7135^<b>Topic(s): </b>mass extinctions;
paleotemperatures; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian
Fra/Fam; <b>Geography: </b>^The oxygen isotope composition of conodont
apatite from two Frasnian-Famennian boundary sections was measured in
order to reconstruct variations in marine paleotemperatures during the
late Frasnian extinction event. The measured conodont &#948;18O values
reveal two positive excursions with maximum amplitudes of +1‰ to +1.5‰
that parallel positive excursions in the carbonate carbon isotopic
composition. The +3‰ excursions in carbonate &#948;13C have been
interpreted as consequences of enhanced organic carbon burial rate
resulting in a decrease in atmospheric CO2 concentrations. Climatic
cooling as a potential consequence of lower atmospheric CO2
concentration is confirmed by the conodont &#948;18O records, which
translate into cooling of low latitude surface waters by 5-7°C.
Repeated cooling of the low latitudes during the late Frasnian had a
severe impact on the tropical shallow-water faunas that were probably
adapted to warm surface-water temperatures and severely affected during
the late Frasnian crisis. These prominent variations in ocean-water
temperatures were stressful to the tropical shallow-water fauna and
potentially culminated in low origination rates of new species, one of
the major factors of the decline in diversity during latest Frasnian.

s[5120] = "HOUSE M.R. (2002).- Strength, timing, setting, and cause of
mid-Palaeozoic extinctions.- Palaeogeography, Palaeoclimatology,
Palaeoecology 181, 1-3: 5-25.- <b>FC&#038;P 32-1</b>, p. 35,
ID=7148^<b>Topic(s): </b>extinctions; mass extinctions; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>^Much has been
written over the last 20 yr on the Upper Kellwasser Event
(Frasnian/Famennian or F/F boundary) as the major extinction event of
the Middle Palaeozoic (Devonian) and as the fifth largest extinction
event in the Phanerozoic; this opinion was based on analysis of family
range data. These views are misleading. A current analysis of family
extinction data, largely based on The Fossil Record 2, but updated in
some respects, supersedes the data base of Raup and Sepkoski (1982) and
shows that the Famennian has the highest total family extinction of
marine taxa, with the Givetian in second and Frasnian in third place.
If these new data are related to current (unreliable) estimated length
of stages, then the severest extinction rates are: first, the Givetian
at 14.2 family extinctions per Ma, secondly the Frasnian at 11.2 and
thirdly the Eifelian at 6.8. Many short-term &#039;events&#039; have
been named for the Devonian based on short-term distinctive sedimentary
```

```
and/or faunal perturbations. A review of these shows how they are often
transgression/regression couplets, many with an association of anoxia
and poor in benthos, or spreads of pelagic faunas, and some are phased
and complex. Evidence is presented to suggest that the transgressive
pulses correspond to warm temperatures which are terminated by cooling.
Possible links with orbitally forced patterns are considered. A common
explanation seems required, not just for the Kellwasser Event, but for
all these events. The relation of the family stage extinctions,
especially the Kacak, Taghanic, Kellwasser and Hangenberg Events, which
are of much more limited duration, is discussed particularly in
relation to new and more precise data of the extinction events known
within these stages. In the absence of detailed studies for many
groups, those that have been well documented may serve as a temporary
proxy for others. [original abstract]^1";

ID=7150^<b>Topic(s): </b>extinctions; mass extinctions; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian U; <b>Geography: </b>^Late Devonian
history is explained through event stratigraphy comprising a sequence
of 18 sea-level changes, catastrophic events and mass extinctions.
Generally rising sea level during the initial Frasnian Stage, beginning
with the Taghanic onlap and ending with a sea-level fall and major mass
extinction, was interrupted by several exceptionally rapid, very high
rises of sea level. These rises may be related to a series of comet
showers, as suggested by the coincidence of the Alamo Impact in Nevada
and the older Amonau Event in Germanv with two of the sea-level rises.
The sub-critical, off-platform marine Alamo Impact is demonstrated to
have produced greatly different effects in deep water from those
previously recorded on the carbonate platform. * The series of comet
showers, most notably those around the Frasnian-Famennian boundary,
evidenced by microtektites in widely separated regions, not only
produced the late Frasnian mass extinction, but also induced global
cooling. This cooling resulted in Southern Hemisphere glaciation.
Generally falling sea level during the later Famennian Stage was
interrupted by several warmer, interglacial episodes, evidenced by
glacio-eustatic rises. Another, less severe mass extinction occurred
during an abrupt sea-level fall near the end of the Famennian. This
glacio-eustatic fall is interpreted to have resulted from a severe,
terminal glacial episode. * Interpretation of Late Devonian history
suggests that impacts and comet showers coincided with sea-level rises,
whereas mass extinctions occurred during, not at the start of,
sea-level falls. [original abstract]^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fam
&#47; Carboniferous Tour; <b>Geography: </b>^Colonial species showing a
Heterocorallia-like septal pattern have been considered by Fedorowski
(1991) to belong not to the Rugosa, but to the Dividocorallia, a
subclass also including the Heterocorallia. Chinese and French colonial
species characterized by a Heterocorallia-like pattern of the major
septa, such as those assigned to Stylostrotion Chi by Fedorowski
(1991), are reassigned to the Rugosa under the name Heterostrotion Poty
&#038; Xu. The heterocorallian shape of the septa is considered to be
the result of a pinnate connection and not of a Heterocorallian septal
genesis. The corallites of Heterostrotion sometimes develop an aulos
and become identical to those of the genus Solenodendron. The two
genera also share increase patterns and septal carinae, suggesting a
close relationship, with Solenodendron evolving from Heterostrotion.^1";

Presence or absence of calices permits to divide the subclass into the orders Calyxcorallia and Heterocorallia respectively. Presence or absence of the dissepimentarium is a family level feature in the Calyxcorallia, whereas the microstructure of an external wall plays that role in the Heterocorallia. Primitive, caliculate Lower Devonian Rugosa were most probably ancestral to the Dividocorallia. This idea is supported by insertion of a single septum at the beginning of septogenesis in both subclasses. Deviation towards the Heterocorallia took place already during the Lower Devonian time, perhaps through neoteny.^1";

ID=4199^<b>Topic(s): </b>history; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian, Carboniferous; <b>Geography:
</b>^Analysis of the taxonomic composition, diversity and guild
structure of five &#34;typical&#34; reef and mud mound communities
ranging in age from Late Devonian to Early Carboniferous indicates that
each of these aspects of community organization changed dramatically in
relation to three extinction events. These events include a major or
mass extinction at the end of the Frasnian; reef communities were also
effected by less drastic end-Givetian and mid-late Famennian
extinctions of reef-building higher taxa. Peak Paleozoic generic
diversities for reef-building stromatoporoids and rugose corals
occurred in the Eifelian-Givetian; reef-building calcareous algal taxa
were long-ranging with peak diversity in the Devonian. These three
higher taxa dominated all reef-building guilds (Constructor, Binder,
Baffler) in the Frasnian and formed fossil reef communities with
balanced guild structures. The extinction of nearly all reef-building
stromatoporoids and rugose corals at the end of the Frasnian and the
survival of nearly all calcareous algae produced mid-late Famennian
reef communities dominated by the Binder Guild. Despite the survival of
most calcareous algae and tabulate corals, the mid-late Famennian
extinction of all remaining Paleozoic stromatoporoids and nearly all
shelf-dwelling Rugosa brought the already diminished Devonian
reef-building to a halt. These Devonian extinctions differ from mass
extinctions by the absence of a statistically significant drop in
taxonomic diversity and by their successional and cumulative effects on
reef communities. Tournaisian mud mounds contain communities markedly
different from the frame-building communities in Late Devonian and
Visean reefs. Mound-building biotas consist of an unusual association
dominated by erect, weakly skeletonized members of the Baffler Guild
(chiefly fenestrate Bryozoa; Pelmatozoa) and laterally expanded, mud
binding algae &#47; stromatolites and reptant Bryozoa. The initial
recovery to reefs with skeletal frameworks in the Visean was largely
due to the re-appearance of new species of abundant colonial rugose
corals (Constructor Guild) and fenestrate Bryozoa. This Frasnian-Visean
evolution in the taxonomic composition and structure of the
reef-building guilds is also expressed by abrupt changes in biofacies
and petrology of the reef limestones they produced. Thus
&#034;typical&#034; Frasnian reef limestones with balanced guild
structures are framestones-boundstones-bafflestones, Famennian reefs
are predominantly boundstones, Tournaisian mud mounds are bafflestones
and Visean reefs are bafflestones-framestones.^1";

Oekentorp (ed.): A. von Schouppe jubilee commemorative volume]:
119-239.- <b>FC&#038;P 9-2</b>, p. 14, ID=1790^<b>Topic(s):
</b>diagenesis, aragonite; Anthozoa; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Paleozoic U; <b>Geography:
</b>^Microstructures of Permian corals were investigated concerning
their primary structure. It could be shown that the microstructures of
the skeleton were affected by diagenetic processes causing secondary
textures and thickenings by cement precipitation veiling the original
septal structure. Signs indicating such structural changes are:
irregularity of the microtextural pattern, diversity of so-called
primary structures, unusual reduction or growth of grain size,
formation of frontal zones (&#34;Stirnzonen&#34;) as well as a
pseudolamellar and a zigzag-pattern. The diagenetic history of the
coral skeletons as well as the primary composition of the skeletal
carbonates are discussed: aragonit versus calcite. The nature of
present secondary textures, as formation of diagenetic processes and
corresponding recrystallizations in Triassic Scleractinia inevitably
lead to the conclusion that the primary skeleton in Permian Rugosa was
composed by aragonite.^1";

corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Paleozoic U; <b>Geography: </b>^La aplicacion de la microscopia de
catodoluminiscencia (CL) al estudio de la evolucion de los procesos
diageneticos que han afectado a diversos corales fosiles del
Palaeozoico superior (Viseense y Kasimoviense) ha puesto de manifiesto
su utilidad fundamentalmente en tres aspectos: - Identification de las
microestructuras originales de los corales. Microestructuras que son
irreconocibles con la microscopia conventional, son visibles con CL. Se
han podido reconocer como primarias las tres microestructuras
caracteristicas de los corales paleozoicos: fibronormal, trabecular y
microlamelar. - Diferenciacion de los procesos diageneticos
destructivos que han afectado a sus estructuras esqueleticas. La
microscopia CL permite reconocer claramente pel i culas de
micritizacion que con luz normal son dificilmente visibles. Asicomo
zonas recristalizadas de las estructuras esqueleticas que presentan una
luminiscencia caracteristica. - Reconocimiento de las generaciones de
cementos relacionadas con los corales. Se han diferenciado dos tipos de
secuencias de cementos, una rellenando cavidades internas y la otra
localizada en el caliz. Ambas reflejan el progresivo enterramiento de
los corales, desde ambientes de cementacion submarina hasta condiciones
de enterramiento relativamente profundo.^1";

s[5144] = "SORAUF J.E., WEBB G. (2003).- The origin and significance of
zigzag microstructure in late Paleozoic Lophophyllidium (Anthozoa,
Rugosa).- Journal of Paleontology 77, 19: 16-30. [19 ...].-
<b>FC&#038;P 32-2</b>, p. 61, ID=1394^<b>Topic(s): </b>zigzag
microstructure; Rugosa, microstructures; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Paleozoic U; <b>Geography: </b>^In late
Paleozoic solitary Rugosa, the zigzag microstructure as defined by
Schindewolf (1942) is related to presence of an elevated magnesium
content within biogenic calcite (internediate magnesian calcite, IMC)
and its subsequent loss during diagenesis by microdissolution and
neomorphism. This particular microstructure has been recognized with
certainty only in some Carboniferous and Permian rugose corals (e.g.
Lophophyllidium spp.). Septal and other skeletal microstructures in
those corals are dominantly (oblique) sloping-lamellar, which is also
interpreted as diagenetic in origin. Two directions of oblique lamellae
commonly occur in thickened skeletal elements, forming chevrons that
make up zigzag microstructure with its orientation determined by
presence of microdolomite blebs within skeletal calcite. Geochemical
studies of corals from the Mississippian Imo Formation of Arkansas, the
Pennsylvanian Buckhorn asphalt of Oklahoma and Pensylvanian Kendrick
Shale of Kentucky all indicate that magnesium content in skeletal
calcite of the corals was elevated, with a maximum in the neighbourhood
of six to eight percent CaCO3, thereby forming intermediate magnesium
calcite. Corals with this zigzag microstructure apparently only
occurred during the late Paleozoic interval of &#034;aragonite
seas&#034;; as a result, this diagenetic behaviour of rugose corals can
serve as a proxy for secular change in marine chemistry and/or
climate.^1";

</b>Paleozoic U - Mesozoic L; <b>Geography: </b>^Late Paleozoic and
early Mesozoic fusulinids, sponges, corals, spongiomorphs, brachiopods,
bryozoans and other tropical reef organisms of western North America
and the former Tethys region share remarkably close similarities over a
vast ocean that once separated the two regions. These relationships
were an anomaly to earlier workers, who assessed these faunas within
the paleogeographic context of Tethys and Pangaea. The nearly exclusive
occurrences of these faunas in exotic and displaced terranes of the
North America Cordillera, have fueled even greater discussions about
paleogeography. Several ideas explain the North American Tethyan
connection: 1) Long-range trans-Pacific dispersal of larvae, 2)
stepping stones, 3) beached funeral Viking ships, 4) staging posts and
Noah&#039;s arks, and 5) the Hispanic Corridor. Viable ideas need not
be mutually exclusive but must be tested against endemism, diversity
trends, and commonality of reef organisms in the former Tethys region
and in displaced terranes of western North America. Results must be
integrated with data on ecology, climate, sea level change, ocean
circulation, terrane movement and global circum-Pacific events in and
around the Pacific rim.^1";

</b>reefs; cryptic communities; <b>Systematics: </b>Porifera;
Chaetetida; <b>Stratigraphy: </b>Carboniferous U; <b>Geography:
</b>^Chaetetids, extinct demosponges, were common frame-builders in
small reef mounds during the Middle Carboniferous. Chaetetids from the
Coal City Limestone Member (Pawnee Limestone, Middle Pennsylvanian) in
Appanoose County, Iowa, contain the remains of a cryptic community
attached to the undersurfaces of the colonies. Identified coelobites
include the attached brachiopods Cooperina sp., Teguliferina sp.,
Heteralosia sp., and Composita sp.; the encrusting bryozoans
Fistulipora sp. and Metelipora sp.; the holdfasts of fenestrate/ramose
bryozoans; the worm Spirorbis sp.; the rugose coral Lophophyllidium
sp.; the foraminiferid Tetrataxis; and the boring traces Caulostrepsis
and Rogerella l Zapfella. Small echinoid plates and spines are
associated with some of these cavities suggesting that they may have
also lived there. Cross-cutting relationships reveal no clear pattern
of encrustation by these cryptic dwellers.^1";

Paleoecology of Upper Carboniferous Chaetetes - morphology, growth
style, and spatial distribution.- Courier Forschungsinstitut
Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI.
International Symposium on Fossil Cnidaria and Porifera, Vol. 2]:
365-372.- <b>FC&#038;P 23-1.1</b>, p. 24, ID=4093^<b>Topic(s):
</b>ecology; Chaetetida; <b>Systematics: </b>Porifera; Chaetetida;
<b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>^Chaetetes
growth styles correspond to the two most common species. Colonies
having a planar growth style and tabular or stacked-tabular columnar
morphology correspond to C. milleporaceus. Colonies having an axial
growth style and tabular, hemispherical, columnar, or massive to
branching compound columnar morphology correspond to C.favosus.
Colonies of different growth style do not co-occur; colonies of
different morphology do, to a limited extent. Both morphology and
growth style are poorly correlated with the major environmental
parameters of water depth, water energy, and sedimentation rate.
Chaetetes is infrequent in stratigraphic sections, but is commonly
abundant where present, dominating a low-diversity community and
forming biostromes. Four spatial distribution patterns can be
recognized: scattered small colonies, widely spaced (several m) large
compound columnar colonies, patches of colonies in living position, and
patches to continuous beds of colonies out of living position except
for the last generation. Chaetetes did not play a binding or encrusting
role, nor form reefs. It used a range of other organisms as substrate,
but with a generally weak attachment so that concurrent sedimentation
was necessary for the colony to remain in living position.^1";
s[5164] = "SUGIYAMA T. (1997).- New observations on some Carboniferous
Heterocorallia.- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 91, 1/4: 163-176.- <b>FC&#038;P 26-2</b>, p.
13, ID=3682^<b>Topic(s): </b>septal increase; Heterocorallia;
<b>Systematics: </b>Cnidaria; Heterocorallia; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>^Fedorowski (1991) proposed the
new Subclass Dividocorallia, divided into two orders, the Calyxcorallia
and Heterocorallia. Justification for the new subclass is based on a
unique method of septogenesis, observed in specimens from the Devonian
but not in Heterophyllia and Hexaphyllia, which have simple skeletal
elements. New observations on the septogenesis of Carboniferous
Heterocorallia by serial transverse sections have revealed that: 1)
both the corallite diameter and the number of septa ontogenetically
increased stage by stage; 2) all septa had equal potential for
bifurcation; 3) septal shifting and detachment frequently occurred
during corallite growth; 4) bifurcation began in the external wall.
This study casts doubt on the criteria used by some specialists for
establishing new taxa in the Heterocorallia.^1";

Two ducts are usually associated with each offset, one from each extremity where the offset wall meets that of the parent. The ducts may merge to form a tangentially elongate slit at higher levels in the dissepimentarium of the parent. The structures served to prolong gastric and nervous communication between parent and daughter polyp following budding. Ducts and slits are well developed in cerioid Lonsdaleia but are absent in fasciculate Lcnsdaleia, a distinction lending credence to the recognition of the former group of species as a distinct genus, Actinocaythus, within the Axophyllidae. In addition, less well developed ducts are present in at least some cerioid species of Lithostrotion, whereas they are absent from fasciculate species, supporting separation of the latter from Lithostrotion sensu stricto and their assignment to the genus Siphonodendron. The form and distribution of ducts also confirms polyphyly in Thysanophyllum. The separation of T. pseudovermiculare (as Dorlodotia}, without ducts, from Thysanophyllum sensu stricto, with weak ducts similar to those in some Lithostrotion. spp., is supported. Both are assigned to the Lithostrotionidae. T. praedictum has well developed ducts, however, which reinforce other evidence suggesting its removal from Thysanophyllum and classification in the Axophyllidae in close affinity with Actinocyathus.^1";

Their coloniality has been discussed, with the conclusion that the fasciculate corals basically acted on lateral increase and the cerioid on peripheral increase, and that although both of the polyps were similar to solitary corals and with no common tissue between each other in adults, the latter was obviously superior in connection between corallites, intensity of skeleton structure, utilization of all the available space and reduction in the surface area of the exposed skeleton. Also discussed are their axial features, by which most of the lithostrotionelloid genera are distinguished, such as the developed or undeveloped axial tabellae, the axial aulos, septal lamellae or radial carinae, the concentric trace of tabulae, the continuous or discontinuous axial structure, etc. The lithostrotionelloid corals described in the present paper were collected from the Lower Profusionella zone in Nandan, Northern Guangxi, containing 24 species and subspecies (including 7 new species and subspecies) within 5 genera, namely: Acrocyathus: A. pennsylvanicus (Shimer), A. hsujiulingi (Yoh), A. tingi (Chi), A. tingi proliferus subsp.nov., A. grechovkae (Degtyarev), A. yohi sp.nov.; Actinocyathus: A. lutugini (Fomichev), A. densiconus (de Groot); Lonsdaleia: L. cf. chutsingensis (Chi), L. huangi Chi; Petalaxis: P.

Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 14, ID=3446^<b>Topic(s): </b>paedomorphosis?; Rugosa, Siphonodendron; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>^The relationship of early species of Siphonodendron and the recently discovered Dorlodotia in Arundian (Lower Visean) limestones of northern England is examined. The discovery of coralla which possess the morphological characteristics of both genera suggests a closer relationship than has sometimes been supposed. The early ontogenetic stages of Dorlodotia are morphologically similar to adult Siphonodendron which suggests a possible phylogenetic relationship between these genera based on the theory of recapitulation. The stratigraphic distribution of Dorlodotia through the Chadian with Siphonodendron ranging from Arundian to Brigantian, suggests that reverse recapitulation has occurred as a result of the evolutionary process of paedomorphosis. Only a small change in the ontogeny of Dorlodotia is necessary to produce all of the morphological differences between it and Siphonodendron. A complete phylogeny of lithostrotionids from Chadian through to Brigantian can now be proposed.^1";
s[5175] = "POTY E. (1993).- Heterochronic processes in some Lower Carboniferous rugose corals.- Courier Forschungsinstitut Senckenberg 164: 141-152. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 14, ID=3448^<b>Topic(s): </b>heterochrony; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>^Some evolutionary trends in Lower Carboniferous rugose corals, such as changes in corallite diameter or number of septa, and loss or change of colonial increase, correspond to heterochronic processes. This is particularly suggested by lineages in four Visean genera: Siphonodendron, Lithostrotion, Diphyphyllum and Dorlodotia. The evolution giving rise to the genus Lithostrotion is the result of a neotenic process affecting fasciculate colonies of a species of Siphonodendron, probably for better adaptation to turbulent environments. The trends characterized by a decrease in corallite diameter and number of septa and dissepiments in Siphonodendron, Lithostrotion and Diphyphyllum correspond to progenetic processes. The trend characterized by an increase of these characters in Diphyphyllum is due to a hypermorphosis. The rise of Corphalia mosae from Dorlodotia briarti, mainly characterized by a decrease in size and number of septa and the loss of coloniality, corresponds to a progenetic process during a change in the environment.^1";
s[5176] = "NIIKAWA I. (1994).- The palaeobiogeography of Kueichouphyllum.- Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 215-222.-
<b>FC&#038;P 23-1.1</b>, p. 19, ID=4077^<b>Topic(s): </b>growth bands,
semi-daily?; Rugosa, growth bands; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>^An
elementary banding is described along the fibrous wall of Bothrophyllum
(?) proteum, a rugose coral from the Upper Carboniferous of the Bechar
Basin (Algeria). Observations in polarizing microscopy and with SEM
show a succession of alternate zones composed of fibre bundles, the
direction of which is perpendicular to the wall (the narrower F.P.
stria) and oblique (the wider P.O. stria). A couple of striae is about
60 µm wide and corresponds to one external minor banding. In analogy
with fine ridges described in living and fossil corals, minor bands are
supposed to be daily and elementary bands to be semi-daily (P.O.
diurnal and P.P. nocturnal). The mean annual growth rate is estimated
to be 23 mm.y-1. This rhythm is macroscopically found in a well marked
major banding. Elementary striae show a regular and sharp alternation
through the coral length. These growth increments represent the lowest
time units defined up to now in fossil corals. They will provide, in
relation with other growth markings in the same corals, a finer
definition of palaeoastronomical cycles and thereby new data on their
palaeogeophysical implications.^1";

The morphology of the calices strongly suggests that they have different taxonomic positions. Thus, their synonymy, suggested by Schindewolf (1942), is rejected. P. armatum, selected as type species for the genus by Hinde (1890) possesses six, not five leading major septa. Consequently, all taxa except Hexalasma Soshkina, 1928, and perhaps Pseudocryptophyllum Easton, 1944, are unrelated to Pentaphyllum. It is proposed to restrict the name Pentaphyllum to the lectotype. The well established Cryptophyllum Carruthers, 1919, which includes P. caryophyllatum is considered valid. In addition to a brief analysis of Lower Carboniferous corals included here in Cryptophyllum, a few specimens from the British Tournaisian are described and illustrated to show morphological variability of specimens from the same bed. Review of earlier studies on these types of corals, discussion on the difference between zaphrentoid and cryptophylloid early ontogeny and its bearing on taxonomy, and description of taxa, are also included.^1";
s[5187] = "RODRIGUEZ S., SOMERVILLE I.D. (2010).- Appearance of fasciculate rugose corals in the Visean and Serpukhovian: A review.- Palaeoworld 19, 3-4: 306-315.- <b>FC&#038;P 36</b>, p. 64,
```

```
ID=6457^<b>Topic(s): </b>colonial, ecology, phylogeny; Rugosa,
colonial; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Vise - Serp; <b>Geography: </b>^Appearances of new
fasciculate rugose corals are especially abundant in the
Visean-Serpukhovian interval. Fasciculate corals may have two different
origins. (1) Development of colonialism from solitary corals (e.g.,
Corwenia from Dibunophyllum); (2) morphological changes of the
established fasciculate taxa that produce new species or genera. Most
new fasciculates occur in shallow-water carbonate shelf environments,
but the first occurrence is not always easy to identify from published
data. One of the typical environments for their first occurrence during
the Visean was the top of microbial mud-mounds. The microbial mounds
perhaps have provided isolated areas of shallower water above the sea
bottom. These isolated elevated areas could have provided more
favourable environments where pioneer coral colonies may have evolved.
All Visean and Serpukhovian coral assemblages with new colonial corals
are dominated by phaceloid species. Consequently, the explanation
should be rejected that new colonial corals occur only in empty
ecological &#034;niches&#034;. Most of these assemblages also contain
solitary corals, including the ancestral &#034;parent species&#034;. *
All these observations pose new questions concerning the origin of the
fasciculate colonial forms in rugosans. There are evidences that single
specimens develop colonial forms as a response to environmental
factors. Development of colonialism is possible for single specimens of
some solitary genera. However, the capacity for developing persistent
colonial growth forms depends on multiple factors, including genetic
and environmental ones. [original abstract]^1";

history of research on Carboniferous and Permian corals, which began
with the first published record in 1683, may be divided arbitrarily
into three periods: 1) discovery in the 17th and 18th centuries, 2)
organization and definition in the 19th c., and 3) development and
application in the 20th c. Statistics on the volume of published
research, analyzed by decades since 1680, record a progressive increase
from decade 23 (1900-09) to decade 30 (1970-79), interrupted by two
major declines related to the two world wars. Research production
declined in the last two decades (1970-89) and will continue to decline
into the 21st c. Data on the geologic age, geography, and demography of
the research, and on the development of the main topics of research are
also presented.^1";
s[5204] = "SANDO W.J. (1997).- Late Paleozoic coral genera and
subgenera. State of the art, 1814-1994.- Boletin de la Real Sociedad
Espanola de Historia Natural, Seccion Geologica 91, 1/4: 061-071.-
<b>FC&#038;P 26-2</b>, p. 9, ID=3672^<b>Topic(s): </b>taxonomy genera;
corals genera; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous, Permian; <b>Geography: </b>^The production history
of 803 valid generic (including subgeneric) names for Carboniferous and
Permian corals published from 1814 to the end of 1994 is analyzed by
means of a computerized data base (GLIST) that includes 1.021 generic
names. Production of valid generic names was concentrated in western
Europe in the 19th century but shifted mainly to China, USSR/CIS, and
USA in the 20th century, where it increased significantly as a result
of government-funded paleontologic research in support of expanded
exploration for mineral and energy resources after World War II. More
than a fifth of the names were produced in China during the decade that
began in 1980. Production declined dramatically worldwide after 1989
during downsizing of the paleontologic workforce and a decline in
funding for coral research. Assessment of the number of currently
acceptable genera is practically impossible because of the subjective
nature of genera. Application of quality tests, based on knowledge of
the type material of type species and on opinions of generic synonymy,
reduces the number of valid names to approximately 300 to 450 that are
currently acceptable. More attention must be given to upgrading
knowledge of type material in order to provide a firmer foundation for
concepts of late Paleozoic biostratigraphy, phylogeny, and
biogeography. Chinese generic names pose a serious problem because they
constitute such a lage proportion of the total valid names and because
many Chinese names are of poor quality. The best solution to this
problem is upgrading of these names by the next generation of Chinese
specialists.^1";

Permophiles 31: 15.- <b>FC&#038;P 27-1</b>, p. 78, ID=3816^<b>Topic(s):
</b>dubious records; Rugosa, Heritschioides; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous U - Permian L;
<b>Geography: </b>Europe?^The colonial rugose coral Heritschioides Yabe
1950 is an index fossil for uppermost Pennsylvanian and Lower Permian
marine rocks of western USA plus western and Arctic Canada (Wilson 1980
and later reports by several authors). Kossovaya (1996, 1997) referred
to a Late Carboniferous coral from North Timan (NE European Arctic
Russia) as Heritschioides aff. H. carneyi Wilson 1982, but did not
describe or figure it. H. carneyi originally was described from the
Upper Pennsylvanian-Lower Permian McCloud Limestone of northern
California. This apparent intercontinental geographic range extension
of the genus may not be justified. I have corresponded with Kossovaya
(1995) and reviewed photographs of her thin sections of the North Timan
coral. The corallites are poorly preserved and somewhat crushed and the
short cardinal septum, an obligatory character for the Family
Heritschioidae Sando 1985, is not observable. The coral, therefore,
cannot be firmly referred to Heritschioides. Furthermore,
Kossovaya&#039;s coral is so unlike H. carneyi in numbers of septa and
lengths of minor septa that it cannot be placed in the same species
group (Wilson 1982: fig. 17) even if it did belong to the genus. Firm
identification of the North Timan coral awaits examination of better
preserved specimens. Until then, this range extension of such an
important index coral genus should be regarded with caution.^1";

<b>Geography: </b>^In terms of coral distribution in the Upper
Paleozoic, two major biogeographic provinces may be recognized:
```

```
Waagenophyllidae and Durhaminidae Provinces. The Waagenophyllidae
Province corresponds to the so-called Tethys, and is conceivable to
have been a tropical sea region stretching from east to west. On the
other hand, the Durhaminidae Province was situated further north, and
may have been probably subtropical. In contrast there was an Eurydesma
Province in the southern hemisphere, which was characterized by a
colder fauna almost lacking corals. Synopsis of the classification of
Waagenophyllidae and Durhaminidae, together with their phylogenetic
relations, are briefly presented.^1";
s[5217] = "SANDO W.J. (1983).- Revision of Lithostrotionella
(Coelenterata, Rugosa) from the Carboniferous and Permian.- US Geol.
Survey Prof. Pap. 1247: 1-52.- <b>FC&#038;P 12-2</b>, p. 29,
ID=6209^<b>Topic(s): </b>revision; Rugosa, Lithostrotionella;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Permian; <b>Geography: </b>^Species of predominantly
massive colonial rugose corals from the Carboniferous and Permian that
were referred previously to Lithostrotionella Yabe &#038; Hayasaka are
reassigned to the following genera: Acrocyathus d&#039;Orbigny
(including probable junior synonym Lithostrotionella Yabe &#038;
Hayasaka), Stelechophyllum Tolmachev (including junior synonym
Eolithostrotionella Zhizhina), Petalaxis Milne-Edwards &#038; Haime
(including junior synonym Hillia de Groot and Eastonoides Wilson &#038;
Langenheim), Aulostylus Sando, Kleopatvina McCutcheon &#038; Wilson,
Lonsdaleia McCoy (subgenus Actinocyathus d&#039;Orbigny), and
Thysanophyllum Nicholson &#038; Thomson. One of the species referred to
Cystolonsdaleia Fomichev is reassigned to Petalaxis. * Stelechophyllum
and Aulostylus are referred to the Family Lithostrotionidae
d&#039;Orbigny. A new Family, the Acrocyathidae, is created for the
genus Acrocyathus. Petalaxis is placed in the Family Petalaxidae
Fomichev, Thysanophyllum and Lonsdaleia are referred to the Family
Lonsdaleiidae Chapman, and Kleopatrina is assigned to the Family
Durhaminidae Minato &#038; Kato. * The principal 1ithostrotionelloid
genera are Stelechophyllum, Aulostylus, Acrocyathus, and Petalaxis.
Stelechophyllum ranges in age from Late Devonian(?) into the late
Visean and is represented in the Carboniferous by 15 nominal species
allocated to five species groups; the genus occurs in the USSR, USA,
Canada and Mexico. Aulostylus is represented by two middle Tournaisian
species in the USA and Canada and a possible species from the Visean of
China. Acrocyathus is represented by 14 nominal species (one new) from
the lower to upper Visean of the USSR, USA, Canada and China. Petalaxis
is represented by 41 nominal species (six new) allocated to five
species groups that range from the upper Visean into the Permian; the
genus occurs in the USSR, USA, Canada, Spain, Japan, and possibly China
and Spitzbergen. * Stelechophyllum may have been derived from
Endophyllum in the Devonian. Aulostylus, Acrocyathus and Petalaxis are
regarded as offshoots from the Stelechophyllum stock in the
Carboniferous. Lonsdaleia, Thysanophyllum and Kleopatrina do not seem
to be closely related to Stelechophyllum and its derivatives.
Hayasaka&#039;s type specimen of Lithostrotionella species from North
America are reassigned to Acrocyathus, Stelechophyllum, Petalaxis and
Aulostylus and are revised specifically. Three new species and two new
subspecies are based on specimens studied by Hayasaka. [original
summary]^1";

(Anthozoa, Rugosa) and its possible relatives and analogues.-
Palaeontology 52, 2: 297-322.- <b>FC&#038;P 36</b>, p. 56,
ID=6442^<b>Topic(s): </b>systematics; Rugosa Pentamplexus;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous, Permian; <b>Geography: </b>^Three ampleximorphic
taxa are revised and their most important characters are discussed in
terms of possible or apparent relationships. Re-interpretation of its
early ontogeny allows the assignment of Pentamplexus Schindewolf, 1940
to the family Polycoeliidae de Fromentel, 1861. Stereolasma variabilis
```

```
Vojnovsky-Krieger, 1934 is established as the type species of
Vojnovskytes gen. nov. It resembles the family Polycoeliidae in some
characters and the Antiphyllidae Ilina, 1970 or the Laccophyllidae
Grabau, 1928 in others. Thus, its family status is not established.
Revision of the type material of Fasciculophyllum tripus Schindewolf,
1952 allows its inclusion within the new genus Silesamplus, probably
related to the family Laccophyllidae Grabau, 1928. Amplexoid morphology
is further shown to be inadequate for the establishment of
relationships on the family or subfamily level. Early ontogeny is most
important in that respect, but biform vs normal morphology in the
tabularium and free vs contratingent development of minor septa must
also be considered, where appropriate.^1";

ID=7232^<b>Topic(s): </b>reefs ecology; algae phylloid; <b>Systematics:
</b>algae; <b>Stratigraphy: </b>Carboniferous Permian; <b>Geography:
</b>^The phylloid algal genera Eugonophyllum and Archaeolithophyllum
are common constituents of Virgilian and Wolfcampian reef limestones in
the Hueco Mountains of Texas. These algae form bioherms and biostromes
and are volumetrically important contributors to both the reef and
offreef sediment budget. Reefs constructed by phylloid algae have long
been considered as ecologically simple communities that lack dominant
framebuilding organisms. The previously accepted constructional
mechanism for reef formation has been inferred to be sediment baffling
and trapping, mainly by erect phylloid algae. This new, detailed
analysis of phylloid algal growth framework, however, clearly shows
that these algae were in fact capable of forming a rigid framework.
Phylloid algae, mostly Eugonophyllum, together with the problematicum
Tubiphytes and the red alga (?) Archaeolithoporella, formed complex,
multiple encrustations (both in vivo and post mortem) and were a
fundamental element of reef construction. Much of the micrite in these
reefs, often regarded as a sediment, has been identified as
microbialite; this microbialite is important in binding and stabilizing
the initial reef framework created by the phylloid algae. A dominant
ecological succession was identified from the Eugonophyllum
communities: (1) a pioneer community of phylloid algae would initially
stabilize the substrate; (2) this would enable an encrusting community
of mostly Tubiphytes, Archaeolithoporella, and microbialite to develop,
followed by (3) a climax community of larger calcisponges. In the
Archaeolithophyllum communities, the thalli were largely constratal
(organisms not substantially elevated above the substrate) and lacked
any obvious microbialite association. The resultant Archaeolithophyllum
communities therefore did not develop any significant depositional
relief and thus formed biostromes. [original abstract]^1";
s[5220] = "ROSS C.A., ROSS J.R.P. (1985).- Carboniferous and Early

Trachypsammia Gerth 1921 (Cnidaria, Permian): new data on the structure
and microstructure.- Courier Forschungsinstitut Senckenberg 164:
347-358. [P. Oekentorp-Kuster (ed.) Proceedings of the VI.
International Symposium on Fossil Cnidaria and Porifera, Vol. 1].-
<b>FC&#038;P 22-2</b>, p. 22, ID=3470^<b>Topic(s): </b>microstructures,
systematic position; Octocorallia (?), Trachypsammia; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>^The four Permian species hitherto assigned to the genus
Trachypsammia Gerth 1921 have been revised; they are from Timor, Xizang
(Tibet), and Sicily. They share the same morphological and
microstructural characters. Trachypsammia shows, from the center
towards the periphery, the following zones: 1) the lumen of the central
```

```
corallite; 2) a medullar zone, composed of radial fibres, with
trabeculae and centripetal growth; 3) an annular zone, composed of
trabeculae showing distal growth direction; 4) a canalicular zone, with
a network of vertical canals connected by horizontal tubules; 5) a
large cortical zone of numerous trabeculae with a serrate longitudinal
outline and a square cross-section, showing centrifugal growth,
arranged in vertical plates and surrounded by a fibrous stereoplasm
disposed into two layers. These trabeculae correspond to the
longitudinal flexuous files of granulae observed between the scattered
calices on the surface of the branches. These peculiarities emphasize
the affinities of Trachypsammia to the genus Palaeacis Haime in
Milne-Edwards 1857 and assignment to the family Palaeacidae Roemer
1883, in a somewhat indefinite position within the evolution of the
Cnidaria. The previously supposed affinities with Hexacorallia can be
rejected, those with Octocorallia are worked out.^1";

s[5229] = "WEYER D., ILYINA T.G. (1979).- Die permischen Rugosa-Genera
Pleramplexus und Pentamplexus.- Zeitschrift der geologischen
Wissenschaften 7, 11: 1315-1341.- <b>FC&#038;P 9-2</b>, p. 45,
ID=0351^<b>Topic(s): </b>; Rugosa, Pleramplexus; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>^Ampleximorphous Plerophyllidae are revised both morphologically
and taxonomically. Using the length of the cardinal septum as
diagnostic feature, two separate genera may be accepted: Paracaninia
Chi 1973 (Kasimovian - Dzhulfian), and Pentamplexus Schindewolf 1940
(Leonardian - Dorashamian). The former includes the subjective junior
synonyms Pleramplexus Schindewolf 1940, and Pseudobradyphyllum
Dobrolyubova 1940; its ancestor is Ufimia Stuckenberg 1895 (with
synonym Tachylasma Grabau 1922). The latter descends from Pentaphyllum
de Koninck 1872 (with synonyms Plerophyllum Hinde 1890, and
Cryptophyllum Carruthers 1919). The much enlarged record of assigned
species (24 valid names, nine species named in open nomenclature) is an
uncritical compilation without attempts to improve the present
unsatisfactory state of taxonomy at the specific level. The holotype of
Pentamplexus simulator Schindewolf 1940 (Leonardian of Timor Island) is
described. New topotypes of Paracaninia nikitini (Stuckenberg 1888),
Paracaninia variabilis (Soshkina 1941), and Pentamplexus leptoconicus
(Abich 1878) are figured (Gzhelian and Kazanian of Russian platform,
Baisalian of Armenia). Holotype illustrations of three probably middle
Permian Chinese species of Paracaninia (sinensis, kaoi, grabaui) are
reproduced from the generally inaccessible paper of Chi (1937), using
```

```
emendated identifications of protosepta. Paracaninia and Pentamplexus
are common members of Permian Rugosa communities of Cyathaxonia facies
type, with a wide regional distribution throughout the palaeotethys and
the boreal realm of Eurasia. These corals are typical Rugosa (four
points of septal insertion according to the law of Kunth, origin of new
septa from bipartition of old major septa). Orientation of septal
apparatus is indicated by biformous tabulae. Though originating each in
but one genus, both Paracaninia and Pentamplexus are polyphyletic taxa.

extinction of Permian Rugosa.- Geologos 2: 59-164.- <b>FC&#038;P
27-2</b>, p. 13, ID=3891^<b>Topic(s): </b>extinctions P/T; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>^The formation of Pangea resulted in an unique global
geography which in turn influenced the distribution, development and
exctinction pattern of the Rugosa. Free connection beteween the main
oceans existing up to the Gshelian allowed common roots to develop for
several Permian rugosa coral lineages. Two of those lineages,
represented by four large families (Kepingophyllidae - Waagenophyllidae
in the East and Durhaminidae - Hetitschioididae in the West) appeared
as early as the Bashkirian-Moskovian but were permanently restricted
geographically to become characteristic of two distinct faunal realms
which appeared near the end of the Carboniferous as a result of the
formation of Pangea. These realms were: (l)The
Cordilleran-Arctic-Uralian Realm, extending from the Ural Mountains
along the northern and western shelves of Pangea and including
carbonate oceanic platforms (future American accreted terranes),
located not far off shore in the Palaeopacific Ocean, (2) The Thetys
Realm, extending westward from China and Indochina to Tunisia. The
history of development and extinction of rugosa coral faunas in the two
realms was almost totally different in timing and faunal content.

phylogenetic relationship and implications for extinction patterns of
Rugosa.- Biotic and Geol. Develop. Paleo-Tethys in China 63-71.-
<b>FC&#038;P 28-2</b>, p. 21, ID=4018^<b>Topic(s): </b>extinction
patterns, extinctions P/T; Rugosa, Huayunophyllum; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian U; <b>Geography:
</b>^The Late Permian Rugosa were characterized by the presence of
Middle Permian holdovers, and some of them survived into the latest
Permian. The colonial waagenophyllid Waagenophyllum (Huayunophyllum,
with its simple axial structure and wide transverse tabulae, occurs as
```

```
high as the uppermost Permian. Huayunophyllum is treated as a cohesive
group at the supraspecific level, and its ancestor should be
Waagenophyllum (Liangshanophyllum). The morphological simplicity,
stress-resistant forms, would have enabled that group to survive the
end-Maokouan crisis into the latest Permian. Provisional strategies
might have been adopted by each Late Permian representative but only
within restricted phylogenetic constraints characteristic of the
Rugosa. However, the Rugosa became extinct just prior to the end of the
Permian, since extremely large-scale environmental deterioration far
exceeded their adaptive abilities. A new species of Huayunophyllum from
the upper part of the Middle Permian of Guangxi, China, is described
herein as Waagenophyllum (Huayunophyllum) taipingense.^1";
s[5234] = "FLUGEL H.W. (1970).- Die Entwicklung der rugosen Korallen im
hohen Perm.- Verh. Geol. B.-A. 1: 146-161.- <b>FC&#038;P 1-2</b>, p.
13, ID=4637^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Permian U; <b>Geography: </b>^During the
Upper Permian the evolution of the Rugosa shows a gradually
disappearance of the genera (tab 2) after a kind of evolution
characterized by the survival of the primitive forms. Firstly the
genera with the most complicate morphology die out, as for instance the
cerioid form with dissepiments (Wentzelella, Maoriphyllum e.g.) or with
dissepiments and presepiments (Polythecalis). The next step is the
extinction of the fasciculoid genera with dissepiments (Waagenophyllum,
Liangshanophyllum e.g.) and the forms with a septal columella
(Lophophyllidium). Therefore the highest faunas of the Permian
(Plerophyllum-fauna) comprise only solitary corals with a primitive
sceletal morphology (Ufimia, Plerophyllum, Pleramplexus, Cryptophyllum
e.g.) (tab 3). It is interesting that elements of this primitive
Plerophyllum-fauna occur firstly in the Lower- and Middle Devonian. But
in this time and also in the Carboniferous we find these genera only
locally in ecologic nishes, especially in sediments of deeper water.
Firstly in the Lower and Middle Permian forms of the Plerophyllum-fauna
appear worldwide besides the other rugose corals. The last named corals
disappear during the Upper Permian: In the Yabeina-zone we still know
some Rugosa from Greenland, China, Japan, Cambodga, New Zealand, Near
East and other localities however in the following Codonofusiella-zone
they appear only in Hungaria, Jugoslavia, Near East, China and
NE-Siberia. In the uppermost Permian time, the Palaeofusulina-zone, we
find only genera of the Plerophyllum-fauna and these forms only in the
central region of the Tethys between Iran and Nepal. The last 2 species
of Plerophyllum and Pleramplexus, die out in the lower part of Triassic
of Djulfa.^1";

Scleractiniamorpha; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>^Numidiaphyllum is one
of the Paleozoic scleractiniamorphs. The genusis characterized by a
poorly integrated, uniserial fasciculate form withan epithecate wall
and simple morphological traits. Parent corallites aredivided into
several daughter corallites using one mode of divisionamong several
theoretically possible alternatives. Bipartite increase ismost common,
followed by hexapartite and then tripartite increase.Daughter
corallites possess relatively large diameters from thebeginning, along
with a robust colonial pattern. This parricidal increasecaused the
morphologies of both parent and daughter corallites to begreatly
```

```
altered and to show high morphological variability. Forecological and
structural reasons, co-occurring daughter corallitesgenerally are equal
or subequal in size. Daughter corallites initiallyshow a bilateral
symmetry in both outline and septal arrangement duringthe course of
hystero-ontogeny. However, this symmetry results onlyfrom structural
necessity and is transitory. It is not homologous with thebilaterality
of body plans characteristic of anthozoan groups. Themorphological
simplicity, related parricidal reproduction, and resultingpoorly
integrated growth form as seen in Numidiaphyllum, all
suggestconservative features that could have resulted from
phylogeneticantiquity within the scleractiniamorph body plan. Those
generalizedfeatures are not themselves related to immediate
phylogeneticrelationships with any simply constructed rugosan group,
nor would they have been due to surrounding, stressful ecologic
conditions. They may have been phylogenetic-specific.^1";

recovery; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian U
&#47; Triassic L; <b>Geography: </b>^Late Permian stratigraphic reefs,
constructed by calcisponges and algae, survived into the latest Permian
in a few tropical refuges, indicating the continuation of favourable
conditions for reef formation. However, all kinds of reefs collapsed
prior to the large-scale biotic crisis of reef-dwelling and
level-bottom communities at the Permian-Triassic boundary. This
affected even the tropical refuges. Different elements of the
reef-forming biota showed distinct patterns of extinction. Whatever the
main causes of biotic decline, the reefs did not disappear at the very
end of the Permian catastrophically, but had already been strongly
affected by the extinction in the Midian (late Guadalupian). Reefs were
not developed until Anisian (Middle Triassic), and at that time
radiolarian bedded chert also began to be formed commonly in pelagic
environments, indicating global removal of the protracted inhibiting
conditions in the ocean. The main reef-builders and their role in reef
communities are similar in both Late Permian and Middle Triassic reefs.
However, the community structure was later modified by a change in
domination among components, such as Scleractinia which acquired algal
symbiosis and more efficient skeletal growth. Long-lasting unfavourable
marine environment on a global scale, rather than the severity of the
end-Permian extinction itself, hindered biotic recovery everywhere
during Early Triassic time despite the presence of Permian holdover
groups as potential organisms for reef-building. Both external
environmental and biological factors acted together in delaying
Triassic reef development. The end-Permian extinction resulted in the
restructuring of reef-forming biota in the Middle Triassic from Permian
survivors rather than the introduction of a new community.^1";

Permian-Triassic boundary interval as a model for forcing marine
ecosystem collapse by long-term atmospheric oxygen drop.- Geology 31,
11: 961-964.- <b>FC&#038;P 33-1</b>, p. 100, ID=7243^<b>Topic(s):
</b>extinctions; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian
&#47; Triassic; <b>Geography: </b>^Ecological traits of reefs across
the Permian-Triassic boundary interval coincide with a modeled decline
of atmospheric oxygen throughout the Permian Period. Selective
extinction and recovery patterns within the reef system are observed
both at the end of the middle Permian (end-Guadalupian) and at the
Permian-Triassic boundary. The end-Guadalupian event selectively
affected corals and broke down the cool-water carbonate factory.
Sponges, however, were largely unaffected and bloomed in reefs toward
the end of the Permian. The end-Permian total destruction of the
metazoan reef system only left behind poorly diverse microbial
communities. The temporal reef patterns are thus similar to spatial
patterns of modern benthic communities approaching oxygen minimum
zones. This observation suggests that a decline in oxygen
concentrations was at least partly involved in the destruction of
reefs, even where there is no direct evidence of oceanic anoxia.

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Triassic; <b>Geography:
</b>^A series of samples, mostly of compound and solitary coral
skeletons from Middle-Upper Triassic strata (San Cassiano strata) near
Cortina d&#039;Ampezzo (Dolomites, Italy) have been analyzed by X-ray
diffractometric and spectrophotometric method. * All the Triassic
samples appear entirely composed of aragonite, with a high strontium
content (7000-8000ppm) and absence of magnesium. The matrix is a
compact pelmicrite, entirely calcitic, with 2.04% of magnesium. * The
amount of strontium is roughly correspondent to the strontium
concentration in living corals. * Strontium concentration of
7000-8000ppm cannot be responsible for aragonite preservation under
subaerial conditions, at normal temperature and pressure, for more than
200 million years. The pelmicritic matrix cannot be interpreted as a
cause of inhibition of aragonite inversion to calcite. * Only the
highly developed fabric and texture of the skeleton and probable
occurrence of organic material can explain the long preservation of
both original skeletal tissue and mineralogical and chemical
composition. * A paleoclimatologic inference on the base of
aragonite/strontium ratio correspondent to warm water corals cannot be
attempted since cold and/or deep water corals analyzed in the present
study appear to have the same strontium content. Only the bahamitic
character of the matrix and the luxuriant fossil community of the
outcrops near Cortina may justify the supposition of a tropical
environment and certainly a warm and shallow water deposit.^1";

</b>^In living zooxanthellate corals, photosymbiosis explains increased
metabolism and accelerated skeletal growth, accounting for the success
of these corals in shallow-water tropical reefs. Mesozoic corals of the
order Scleractinia appeared in the geologic record during the Middle
```

```
Triassic, but it was not until the Late Triassic that these corals
became prominent reef builders - a change hypothesized to coincide with
the advent of photosymbiosis. There is considerable discussion,
however, concerning algal symbiosis and the timing of their
co-evolution with corals. Thus, the beginning of photosymbiosis in the
earliest corals of the Middle Triassic has not been established, nor
whether their paleoecology was similar to that of modern corals. Many
massive colonial reef-building corals lay down thick, discrete bands in
their skeletons that record annual growth. We discovered and illustrate
here growth bands in Middle Triassic corals from central Nevada, in
particular Ceriostella variabilis, whose skeletal structure and bands
are well-preserved in Middle Triassic biostromes of central Nevada. To
test the photosymbiosis hypothesis we studied colony growth forms in
these fossil corals and performed a quantitative analysis of the bands,
both in C. variabilis and in a morphologically similar living
zooxanthellate reef coral, Montastraea faveolata. Results of these
analyses revealed growth bands and colony shapes almost identical in
both living and fossil corals. These findings suggest that
photosymbiosis was present in Middle Triassic corals at a very early
stage in their Mesozoic history. Scleractinians were also likely
zooxanthellate from the onset of their Middle Triassic occurrence but
for unexplained reasons were not as efficient as modern corals in
building reefs. [original abstract]^1";
s[5255] = "STANLEY G.D.jr, SWART P. (1995).- Evolution of the
coral-zooxanthellae symbiosis during the Triassic: a geochemical
approach.- Paleobiology 21, 2: 179-199.- <b>FC&#038;P 24-2</b>, p. 90,

approach; coral-zooxanthellae symbiosis; <b>Systematics: </b>Cnidaria
algae; Anthozoa; <b>Stratigraphy: </b>Triassic; <b>Geography:
</b>^Scleractinian corals first appeared during Triassic time in
tropical shallow water environments. Controversy surrounds the
paleoecology of scleractinian corals of the Late Triassic. Were they
like their living counterparts, capable of supporting reefs, or had
they not yet coevolved the important association with zooxanthellae
that facilitated reef growth and construction? Indirect evidence
suggests that some Upper Triassic corals from the Tethys played
important constructional roles as reef builders within tropical
carbonate complexes of the Tethys. To evaluate this idea, we have
employed a geochemical approach based on isotope fractionation to
ascertain if Late Triassic corals once possessed zooxanlhellae. We have
determined evidence for the ancient presence of algal symbiosis in 13
species of Triassic scleractinians from reef complexes in Turkey and
northern Italy. In contrast, two higher latitude Jurassic species used
as a control group for isotope analysis, lacked isotopic indications of
symbiosis. These findings, together with stratigraphic and
paleoecologic criteria, support the contention that Late Triassic
scleractinian corals inhabiting shallow-water carbonate complexes of
the Tethys were predominantly zooxanthellate, like their living
counterparts from present day reefs. We view the zooxanthellate
condition in calcifying reef organisms as a necessary prerequisite for
constructional reef development. Our results emphasize the power of
stable isotope studies in helping to answer paleobiological
questions.^1";

research, cathodoluminescence; structures diagenesis; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Triassic;
<b>Geography: </b>^Triassic scleractinian corals from the Zlambach
Marls of Austria and the Cassian Formation of northern Italy, display
various diagenetic transitions, from unaltered orginal skeletal
aragonite to neomorphic calcite. Many neomorphosed specimens contain
calcitized aragonite needle &#34;ghost&#34; structures, whereas others
are either totally recrystallized or are in transition to coarse
neomorphic spar. In most samples, the relic microstructure is so
obliterated as to preclude taxonomic study. We applied
cathodoluminescence (CL) to thin sections of these diagenetically
altered corals. CL not only aided in understanding the process of
diagenetic replacement but also allowed original details of skeletal
structures to be distinguished even in some of the most recrystallized
specimens. The application was also successful with severely
recrystallized Triassic corals from Nevada. Diagenetic alteration
appears to have taken place by selective, preferential solubility of
aragonite (and later neomorphic calcite skeletal elements) over calcite
of the void cements. In carbonate material, Mn is the trace element
responsible for producing the characteristic red-orange luminosity on
CL where Fe may be a &#34;quencher&#34; affecting intensity. Mn and Fe
concentration gradients remain distinct in the void and pore-filling
cements of these corals and significant amounts are not incorporated
into the skeletal elements during neomorphic alteration. Our research
has direct application in taxonomy and systematic study of fossil
corals. It shows the utility of CL techniques in distinguishing lost
microstructure in a variety of scleractinians. CL is an important but
neglected tool in systematic study of diagenetically altered fossil
corals.^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Triassic;
<b>Geography: </b>^The early Carnian (Upper Triassic) phaceloid coral
originally described by Volz (1896) as Hexastraea fritschi, type
species of Quenstedtiphyllia Melnikova, 1975, reproduced asexually by
&#34;Taschenknospung&#34; (Pocket-budding), a process documented herein
for the first time. This type of budding is recognized only in the
Amphiastraeidae, a family thus far recorded only from
Jurassic-Cretaceous strata. Similar to amphiastraeids,
Quenstedtiphyllia fritschi (Volz, 1896) has separate calcification
centers and a mid-septal zone built of serially arranged trabeculae.
The most important discriminating characters of the new amphiastraeid
subfamily Quenstedtiphyllinae are one-zonalendotheca and radial
```

```
symmetry of the corallite in the adult stage (in contrast to two-zonal and bilateral symmetry in the adult stage in Amphiastraeinae). Quenstedtiphyllia fritschi shares several primitive skeletal characters (plesiomorphies) with representatives of Triassic Zardinophyllidae and, possibly, Paleozoic plerophylline rugosans: e.g. thick epithecal wall and strongly bilateral earlcy blastogenetic stages with the earliest corallite having on axial initial septum. To interpret the phylogenetic status of amphiastraeid corals, we performed two analyses using plerophylline rugosans and the solitary scleractinian Protoheterastraea, respectively, as the outgroups. The resulting phylogenetic hypotheses support grouping the Zardinophyllidae with the Amphiastraeidae in the clade Pachythecaliina (synapomorphy: presence of pachytheca). Taschenknopsung is considered an autapomorhy for the Amphiastraeidaw. This study is the first attempt to analyse the relationships of the Triassic corals cladistically.^1";

</b>microstructures, systematics, new taxa; stroms, Stromatowendtia;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Triassic; <b>Geography: </b>^The finding of ferroan calcite
pseudomorphs of spicules within the aragonitic basal stromatoporoid
skeleton of Stromatowendtia triassica n.gen. n.sp. indicate the
poriferan affinity of this Triassic form. A new Family, the
Stromatowendtidae, is erected for the unique combination of the
spicular skeleton and irregular aragonitic microstructure of the
secondary calcareous skeleton. On the basis of spicule type and
organization, together with the apparent absence of microscleres, the
new family is tentatively assigned to the Order Halichondrida. The
secondary calcareous skeleton is preserved in its original mineralogy
with a relatively high Sr content (7,000 - 8,000 ppm). The
microstructure is of irregular type like that of the living
sphinctozoan Vaceletia crypta (Vacelet). The biomineralization process
of the vertical elements, the pillars, occurred in sealed off spaces
delineated by phragmas, now observable as discontinuities or remains of
insoluble organic matrix. The incipient diagenesis of aragonitic
skeleton is minimal and of aggrading type. We recognized two cements
filling intraskeletal cavities: a primary marine isopachous cement
consisting of aragonite crystallites that grow on the skeletal tissue,
and a late cement of blocky anhedral ferroan calcite engulfing the
primary and/or the calcareous skeleton.^1";

```

```
Triassic reefs and reef biota. A survey of the distribution of the
reefs in time and space indicates the existence of Anisian buildups
(starting in the Pelsonian), and significantly restricted to the
southern part of Europe. Ladinian and Carnian reefs exhibit a larger
distribution pattern, including Europe, Asia and western North America
as well as Peru. Even broader is the distribution of Norian and
Rhaetian reefs, which are known from many parts of the Tethys but have
been studied in detail only in Europe, Central Asia and in western
North America. The exact age of many Triassic reefs is controversial
because of the strong facies control of reef biota. The composition of
the frame building fauna (especially calcisponges and corals) can only
differentiate an Anisian to Carnian time interval from a Late Upper
Triassic interval. The current state of research is characterized
geographically by strongly biased information (more than 75% of the
Triassic reefs studied in more detail are situated in the
Alpine-Mediterranean region and in the Cordilleran of western North
America). Information about the composition of the frame building and
binding communities as well as about facies types is generally good,
but there is a strong need for more study of the reef-dwelling
organisms and especially of the diagenetic history of reef carbonates.

40, ID=3603^<b>Topic(s): </b>reef biota; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Triassic; <b>Geography: </b>^The study of the
taxonomic composition of Triassic reef-building and reef-dwelling biota
reveals the existence of four major time-dependent biotic units
occurring in the Upper Anisian, Ladinian-Cordevolian, Tuvalian-Julian
(and Lower Norian?) and Norian-Rhaetian time intervals. Lower Triassic
reef organisms as well as undisputed Permian holdovers are missing. The
change in the biotic composition of Anisian to Ladinian-Cordevolian
reefs represents a gradual transition characterized by the replacement
of taxa whereas the change near the Carnian &#47; Norian boundary
corresponds to an extinction event of reef organisms. Anisian reefs are
characterized by Olangocoelia and sponges; corals and microbial crusts
are of no major importance. Ladinian and early Carnian (Cordevolian)
reefs are characterized by the abundance of sponges, significant
microbial contributions, occurrence of corals and frequency of
carbonate cement. The biotic composition of Middle and Late Camian
reefs is similar to that of Ladinian-Cordevolian but diversity is
higher. Norian and Rhaetian reef biota differ distinctly from Middle
Triassic and Carnian reef organisms in taxonomic composition, diversity
and importance of microproblematica different from Middle Triassic and
Carnian biota. Some Norian taxa show morphological similarities with
Upper Permian taxa indicating homologies or a survival of Late
Paleozoic taxa until late Triassic time.^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Triassic - Jurassic M;
<b>Geography: </b>^Recognizing extinction events and determining their
cause at the Triassic/Jurassic (T/J) transition and near the
Pliensbachian-Toarcian (Lower Jurassic) boundary is a field of growing
interest. We provide arguments for these events through a literature
based new evaluation of coral diversity from Triassic to Dogger and a
new palaeobiogeographical map. The T/J extinction of corals is clearly
related to the breakdown of reef environments. Origination curves show
that Hettangian (the lowest Jurassic stage) was not only a survival
phase but already rather a recovery phase. Post-extinction evolution of
reefs and their survival only in the northernmost margin of the Tethys
support the hothouse hypothesis for the T/J extinction event. During
Pliensbachian, many new taxa appear, but mostly solitary corals, not
really framebuilders. Many of these taxa do not occur anymore during
the following stages. The new increase in diversity is related to the
development of Bajocian (Middle Jurassic) reefs. [original abstract]^1";

up-to-date illustrated catalogue of coral genera is strongly felt among all those who are concerned with coral identification and classification. After much hesitation, we have decided to undertake this work with the hope of creating a useful standard reference in the relatively near future. To do so we intend to accumulate precise descriptions of each genus which will be condensed into a maximum of one or two pages. Diagnoses and illustrations will be followed by details of geographic distribution, age and related bibliographic references. The volume will present the generic descriptions in alphabetical order. When possible, a proposed systematic position for each genus will be indicated separately in an adjoining paragraph. * We count on the collaboration of all those who feel able and willing to propose a good overall summary of one or more genera, and as of now would appreciate suggestions for the treatment of individual genera. Each contribution will be signed by its author(s). Final editing is reserved for the organizers. English has been chosen as the language of publication. * Individual Technical Draft for Generic Treatment: (1) name (2) type species - locality, age and collection number(s) of the specimen(s) concerned in the description (3) diagnosis - detailed, including characteristic dimensions and septal layout (4) illustration(s) - preferably 3 oriented sections (transverse, radial &#038; tangential) in thin sections, peels or polished surfaces under adequate magnification; general form; highly magnified diagnostic details (5) distribution - I geographic (eventually map) and stratigraphic; main references (6) species - major forms and overall commentary (7) bibliography - main sources (8) systematics - supposed position with argumentation [original note, with minor layout changes]^1";

Proceedings of the 8th International Coral Reef Symposium Panama City
2: 1657-1662.- <b>FC&#038;P 27-2</b>, p. 61, ID=3928^<b>Topic(s):
</b>history; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Mesozoic; <b>Geography: </b>^The history of Early Mesozoic reefs is
recorded in the Tethys after the Permo-Triassic mass extinction. From
this time through the Paleogene, at least four stable reef ecosystems
are recognized. Each is preceded by mass extinctions of either first or
second-order importance and a perturbation phase characterized by an
eclipse of reefs. A recovery interval after the eclipse leads to a new
stable reef ecosystem. Following an early Triassic reef eclipse and a
middle to early Late Triassic recovery phase, a new ecosystem developed
toward the end of the Triassic. Following a small-scale Late Triassic
extinction zooxanthellate corals became dominant reef-builders. The
end-Triassic extinction abruptly terminated reefs and there followed an
early Jurassic eclipse interval and a Middle Jurassic recovery. This
led to coral-algal dominated ecosystems of the Jurassic. Following a
second-order mass extinction at the end of the Jurassic, a
coral-dominated ecosystem resumed. This was interrupted by a rudist
takeover later in the Cretaceous. The rudist-dominated ecosystem lasted
until near the end of the Cretaceous when a first-order mass extinction
disrupted reef ecosystems. This allowed surviving scleractinians to
reclaim reef ecosystems of the Genozoic. Important physical, chemical
and biological themes seem relevant throughout the Mesozoic history of
reefs.^1";

```

```
platy corals occur through most of the geological record of the
Scleractinia (late Triassic to Recent) but they have received almost no
detailed attention. Recent studies have suggested that they represent a
photoadaptive response by photosymbiotic corals to reduced illumination
in deeper and/or more turbid waters. As an informal working group, we
have aimed to establish (1) if this model applies more generally to the
geological record, and (2) if so, what implications this may have for
long-term stability of tropical marine ecosystems (e.g. role of
photosymbiosis). Here we discuss preliminary results compiled from our
own independent projects in 32 study areas ranging from late Jurassic
to mid Miocene age. We set out simple descriptive concepts of platy
corals and platy coral assemblages and provide other palaeoecological
and geological information that characterises these assemblages.
Sedimentological and palaeoecological evidence supports the
photoadaptive nature of platy coral assemblages (&#039;euphotic floor
model&#039;), and indicates their ecological functional stability since
the late Triassic. We recognise seven variants of such assemblages
according to the role of turbidity in different spatiotemporal
settings. Preliminary work so far has failed to reveal closely
comparable modern analogues.^1";
s[5304] = "LOSER H. (2002).- Verfahren einer von der Taxonomie
unabhängigen paläobiogeographischen Analyse post-paläozoischer
Korallen.- Mathematische Geologie 6: 15-43.- <b>FC&#038;P 33-2</b>, p.
32, ID=1162^<b>Topic(s): </b>biogeography, numerical approach;
Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Mesozoic Cenozoic; <b>Geography: </b>^Various unconventional
methods which are described in detail were used to analyse the
palaeobiogeography of post-palaeozoic corals. In view of the
complicated species concept in the group of organisms investigated,
traditional taxonomy was abandoned and operational taxonomical units
(OTUs) were derived exclusively from samples, using methods of
numerical taxonomy. The homogeneous units thus obtained are much more
likely representatives of species than the taxa were in the literature.
This method is practically a new approach not only to corals since
large scale palaeobiogeographical analyses covering a long time span
were up to now mainly based on data from the literature. The
distribution data thus obtained were tested by various methods to
discover invariant factors and patterns in the distribution of the
organisms. This mainly involves calculating the correlation of the
distribution of the OTUs with operational geographical units (OGUs),
stratigraphy, palaeo-latitude as well as palaeo-longitude. The
specificity of various correlation coefficients is discussed. Other
methods not used in this study are explained and their applicability
and reliability are discussed. The structures of the data and the
software used to record, process and estimate the data are briefly
described. The need for transparent data structures and evaluation
methods is pointed out.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Mesozoic
Cenozoic; <b>Geography: </b>^In this note we try to prove with some
examples taken from the post-paleozoic corals, that the mineralogic
transformations of the fossil madreporarian skeleton, consequently of
the diagenesis, plays a primordial role in the microstructures observed
under the light microscope. In fact, mineralogic analysis made upon
some triassic and cretaceous specimens have showed that, in certain
conditions, the skeletal elements of the Madreporaria can be entirely
or partially kept in aragonite. In the case where they are kept in
aragonite, the Corals we have studied, have the same fibrous structure
than the one of the living Madreporaria. But all the Madreporaria which
showed under the light microscope a fibro-lamellar or a
granulo-lamellar structure, are entirely or in part changed into
calcite. So, we can think that the microstructure of the fossil Corals
is subordinate to their state of preservation and that only the
mineralogic analysis of their skeleton allows to prove that the
microstructure observed is a primitive one.^1";

<b>Geography: </b>^Habitually considered as exclusively Paleozoic, the
Chaetetida group is particularly ignored, probably because the
difficulties posed by the study of its systematics. In none of the
treatises of paleontology are found the few representatives of this
group that have been described in post-Paleozoic beds. The present
work, which treats these Mesozoic and Cenozoic organisms successively
placed near the Alcyonaria, Tabulata and Bryozoa, shows that a good
number of them belong to the order Chaetetida, whose phylogenetic
duration, in consequence, is considerably extended. The author, first
of all, strives to specify the general characteristics, the methods of
study and the terminology concerning these organisms. He proposes next
a new definition of the Chaetetida and confirms their position
(Cnidaria, Hydrozoa). Then, after having searched to determine in what
should consist the diverse criteria of familial, generic and specific
rank, he proposes a new classification which recognizes nearly 40
post-paleozoic species, distributed in 3 families and 11 genera or
subgenera. A last chapter is devoted to doubtful organisms,
insufficiently characterized or which are preferably excluded from the

ID=6828^<b>Topic(s): </b>biology, phylogeny, taxonomy; Porifera
Demospongiae; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>Mesozoic - Recent; <b>Geography: </b>^Within the
demosponges in all main taxa, irregular spicules, the desmas are
observed. Therefore, the polyphyletic &#34;Lithistida&#34; Schmidt 1870
is eliminated. Desma-bearing demosponges are known since the Middle
Cambrian. The desma-types are differenciated by their axial symmetry.
In the present theory, the character desma probably evolved from a
regular tetraxonid calthrops through &#34;secondary&#34;
(intracellulary) silification within the scleroblast. This is indicated
by the ornamentation and zygomes (ends of these spicules) of this
special type of spicules. First the tetraxonid desmas (tetraclones)
evolved. Then a possible reduction of two calthrops rays to diactine
forms, like oxeas, and the reduction of three rays to monactine
spicules, like styles, took place. The monaxonid desmas (rhizoclones,
dicranoclones, dendroclones) are derived from &#34;normal&#34;
spicules, such as styles. The hypothesis is that the reduction of rays
of the calthrops first lead to normal monaxonid spicules, and monaxonid
desmas evolved by &#34;secondary&#34; silification. [initial part of
extensive summary]^1";

<b>Systematics: </b>Porifera; Hexactinellida; <b>Stratigraphy:
</b>Mesozoic - Recent; <b>Geography: </b>^The Hexactinellida (earliest
Cambrian - Recent) may be the best established monophylum within the
Porifera. They are the adelphotaxon (&#34;sister group&#34;) of the
Pinacophora (Demospongiae/Calcarea-taxon), from which they have evolved
separately at least since the earliest Cambrian. Because of the
syncytial organization of their soft tissues, Hexactinellida
fundamentally differ from all other sponges. Contrary to other current
phylogenetic assumptions, the closest relatives of the Demospongiae
within the Porifera probably are not the Hexactinellida but the
Calcarea. The siliceous spicules of Hexactinellida appear to have
evolved convergently to those of Demospongiae as a true functional and
constructive morphological homoplasy. Thus follows consequently the
conclusion that spicules do not belong to the poriferan basic pattern.
Spicules of rectilinear triaxial symmetry (basic type is the regular
hexactin), with an axial filament that is square in cross section,
represent a unique character within the Porifera. [initial fragment of

<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>^Defined
here as &#039;essentially in place calcareous deposits created by
sessile organisms&#039;, Organic Reefs are diverse and complex
structures with a long geological history. Their classification has
been the subject of fierce debate, often characterized by reliance on
subjective features such as wave-resistance and qualitative attempts to
discriminate between &#039;first&#039; and &#039;second class&#039;
reefs. In contrast, emphasis is here placed on the objective
characteristic of the type of sedimentary support, which largely
determines the sedimentary composition of the deposit. * Constructional
and depositional processes result in three principal sedimentary
components: matrix (M), essentially in place skeletons (S) and
cavity/cement (C), whose proportions can be represented on MSC
triangular plots. Separately or together, these components also provide
the structural support for the reef. On these compositional and
structural bases, three main categories of Organic Reef are recognized:
(1) Matrix-supported reefs (Agglutinated Microbial Reefs, Cluster
Reefs, Segment Reefs), (2) Skeleton-supported reefs (Frame Reefs), (3)
Cement-supported reefs (Cement Reefs). [initial part of extensive

</b>neritic, archibenthal; Porifera; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>Mesozoic Cenozoic; <b>Geography: </b>^The review
of the stratigraphic record, including excursions into Palaeozoic
lineages, concentrates on recognizable genera and families of
demosponges, relying chiefly on isolated spicules. Lithistid suborders
are reviewed with reference to de Laubenfels&#039; (1955) erroneous
treatment and to newer systematic accounts. 715 individual spicules,
including examples from living species for comparison, are illustrated
in 35 figures in systematic order. They are redrawn from various fully
quoted articles, including those in the Initial Reports of the Deep Sea
Drilling Project. The notes on fossil faunas, palaeoecology, and
palaeobiogeography elaborate on several aspects previously neglected or
widely scattered in the literature.^1";

<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Mesozoic Cenozoic;
<b>Geography: </b>^Sedimentary rocks characterized by siliceous sponges
occur during several time episodes in Earth history. The spongiolithic
facies culminates in the Late Jurassic. On the northern shelf of the
Tethys and in the adjacent North Atlantic basins, siliceous sponges
formed a discontinuous reef belt extending over more than 7000 km. The
scope of this study is the palaeoecological analysis of post-Palaeozoic
siliceous sponges in order to obtain a valuable tool for the
environmental and genetic interpretation of siliceous sponge-bearing
rocks. Methodically, the actualistic or uniformitarianistic concept was
applied to the group of siliceous sponges for the first time. The
knowledge of the biology and the ecology of recent siliceous sponges is
an improtant fundamental prerequisite for transforming the results to
the fossil record. The heterogeneous group of siliceous sponges belong
either to the desma-bearing demosponges (&#34;Lithistida&#34;) or to
the Hexactinellida. Both siliceous sponge groups differ fundamentally
in their biology (e.g., anatomy, reproduction, nutrition).
Consequently, they also differ remarkably in their ecologicals demands.
Ecologically important factors are bathymetry, substrate, water energy,
temperature, quantity and quality of food, sedimentation rate, settling
density, available space, space competition, water chemistry, and
reproduction rate. Usually, these factors do not work independently.
Their interaction determines the occurrence, spatial distribution and
the dominance of siliceous sponge groups. Most demosponges are active
filter feeders. Owing to the minute size of their ostia, bacteria are
```

```
their main food source. Demosponges are able to host bacteria to a great amount in their mesohyl. Most of these sponges can live either on the hosted bacteria itself or on the metabolic products of the bacteria. [part of very extensive summary]^1";

High- and low-density growth bands are identified in massive colonies. The denser part of each couplet is consistently the broader, in contrast with that of most shallow-water modern corals. This is interpreted as due to high local turbidity. The formation time for two sections is estimated with gross carbonate production of 2000 to 3300 g CaC03 m2 yr-1.^1";

Net-sedimentation rate obviously was the most important ecofactor regarding intensity of bioerosion as well as the organisms involved. Lower sedimentation rates favour dead-coral borers (Lithophaginae and Sipunculida &#47; Polychaeta) and strong bioerosion; increased sedimentation leads to dominance of live-coral borers (Gastrochaenidae) with relatively much reduced boring activity. Boring sponges (Clionidae) are the prominent macroborers in Neogene reefs; however, with grazing reef fish not yet evolved, they could become important only under special circumstances: in microbial-coral reefs, bacterial mats provided their nutrition and excluded competitors such as encrusters and dead-coral borers.^1";

```

```
having a fundamentally pennular perforate septal structure. This long
ignored pennular character is more or less obliterated in the slow
growth directions where predominance of horizontal tabuloid
dissepiments gives rise to a layered pattern. The way in which the
obliteration of pennular structure occurs introduces a new feature to
be taken into account in the classification of Mesozoic perforate
corals. The revision of Jurassic species using discriminant analysis
sketches evolutionary patterns through four stages: Bajocian (D.
dendroided), Bathonian (D. excelsa, D. pauciradiata and D. sp.),
Callovian (D. sp. 2 and sp. 3) and Oxfordian (D. racemosa). The
analysis of the colonial ontogeny (astogeny) permits a better
understanding of some ecological aspects particularly the role of two
factors: the bioerosion and the distance between the top of the colony
and the sea floor.^1";
s[5335] = "MORSCH S.M. (1994).- Mise au point sur les genres
Confusastrea d&#039;Orbigny et Complexastrea d&#039;Orbigny
(Scleractinia - Jurassique).- Annales de Paleontologie (Vert.-Invert.)
80, 4.- <b>FC&#038;P 23-2.1</b>, p. 51, ID=4391^<b>Topic(s):
</b>revision; Scleractinia, Confusastrea; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Jurassic; <b>Geography: </b>^The
revision of the specimen figured by Leymerie (1846) and appointed by
d&#039;Orbigny (1849) as the example of Complexastrea, as well as the
study of additional material belonging to the same species, permits to
give the diagnosis emended of this genus: Corallum plocoid appearing
subcerioid; septocostae compact, non confluent (sometimes subconfluent)
and composed of thick trabeculae probably with triangular teeth on
upper edge. Lateral surface with few opposite carinae; axial edge
entire. Vesiculoid endotheca. Budding is intracalicinal but
extracalicinal budding can be present too. The nomenclatural problem
concerning the type species of Complexastrea is resolved. The type
species is: Complexastrea subburgundiae d&#039;Orbigny (1850) and the
holotype is the specimen figured by Leymerie (1846, p. 252, pl. 10,
fig. 13) and named by him Astrea burgundiae. The following species are
not synonymous of Confusastrea subburgundiae: 1803 - &#034;Madrepore
petrifie&#8230;&#034; Faujas de St. Fond, p. 99, pl. 4 1830 - Astrea
burgundiae Blainville, p. 339 1834 - Astrea burgundiae Blainville, p.
373. The name Astrea burgundiae should be reserved to the specimen
figured by Faujas de St. Fond (1803). The study of thin sections of the
holotype of Agarida crassa, figured by Goldfuss and appointed by
d&#039;Orbigny as the exemple of Confusatrea, shows that this specimen
belongs to the genus Isastrea. Consequently Confusastrea is a senior
synonym of Isastrea. Astrea rustica Defrance would not be considered a
valid species because it was described from a not figured specimen and
of unknown age and origin, and on top of that is lost. Thus, Astrea
rustica could not be mentioned as type species of Complexastrea as it
was made by some authors.^1";

<b>Geography: </b>^A downward growth of the skeleton analogous to the
one observed in Chomatoseris is now recorded in Genabacia, a small
microsolenid colonial genus genus from the Bathonian of Western Europe.
As in Chomatoseris the author suggests for this genus the ability to
move independently; such an ability in the case of a colony, requires a
close coordination of polyps. Similar structural features were already
mentioned by the author within diverse taxonomic groups of solitary
corals, notably Chomatoseris (Dogger), Combophyllum (Devonian),
Micrabacia (Cretaceous-Recent). It is also the case with Fungia and
Cycloseris (Diaseris). This autonomous mobility enables these corals to
prosper in both very soft substrates and on mobile, high energy,
coarse, sandy bottoms - environments where sessile forms do not
thrive.^1";

système de gestion de base de données dans la détermination générique
approchée des coraux jurassiques. [using a database management system
in non exhaustive generic identification of Jurassic corals].- ... .-
<b>FC&#038;P 19-1.1</b>, p. 30, ID=6784^<b>Topic(s): </b>computer-aided
classification; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Jurassic; <b>Geography: </b>^The
database is a set of 405 cards. Each card corresponds to a genus with
17 characters, the present program allows a subset corresponding to the
characters selected by the user to be extracted from this database. *
It runs on an IBM PC compatible micro-computer with a dBase III+
compatible program. Each card comprises 18 fields. The first one for
the genus name, the 17 others for descriptive characters. Every
character-state is coded in the following way: A for an absent
character, P for a present one and AP for an ambiguous case. On
running, with the same codes A, P, and AP, the operator submits a
combination of 17 character-states corresponding to the specimens he
wants to identify. Then, the computer quickly displays or prints a list
of genera. A card (or a genus) is chosen if and only if all its fields
at the state A correspond to an A or an AP of the request and if all
its fields at the state P correspond to a P or an AP of the request.
The check-list obtained shows junior synonyms genera and old
comprehensive genera. This allows the omission of non reclassed species
to be avoided and this is a major advantage for a zoological group in
which generic assignments fluctuate so much. The program can be
optimized by adding cards and characters. It runs as a generator of
artificial classifications. The hierarchy of characters, inherent to
the so called natural classifications is avoided and for a group in
which fundamental characters are least conspicuous, the quality of
identification may only be improved.^1";

(Giurassico inferiore, Prealpi Bellunesi).- Annali dell&#039;Universita
di Ferrara, n.s., ser. Scienze della Terra 3, 4: 51-81.- <b>FC&#038;P
22-1</b>, p. 46, ID=3300^<b>Topic(s): </b>ecology; Porifera;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Jurassic L;
<b>Geography: </b>^[...] From this approach to the Porifer facies of
the Lower Jurassic, the occurence of the following taxa have been
suggested: 1) Demospongea, subcl. Ceractinomorpha and Tetractinomorpha;
2) Hexactinellida, ord. Lychniscosida; 3) Sclerospongea, ord.
Stromatoporida and Ceratoporellida; The taxa associations appear to
establish three kinds of Porifer communities: 1. Demospongea and
Exactinellida comm. (Calcaredel Misone, Calcari Selciferi a Poriferi
and Malga Agnerola facies); 2. Demospongea and Sclerospongea comm.
(Calcari Grigi of Grappa Mt.); 3. Inozoa comm. (Giallo Reale and
Calcari Gialli). The Demospongea and Exactinellida community from the
Cherty Limestone of the Vette Feltrine could represent a Porifer
meadow, while all the others have been referred to Porifer mud mounds.
Meadows and mounds should be placed on the external platform, belowe
the wave base. The setting depth has not been defined. On a
sedimentological basis, the Porifer Cherty Limestones bearing the
Demospongea-Hexactinellida community (Vette Feltrine) should correspond
a hundred meter-deeps. [fragment of extensive (!) summary]^1";

ID=3597^<b>Topic(s): </b>ecology, growth; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>^Reefs from the Late
Jurassic comprise various types of coral reefs, siliceous sponge reefs
and microbolite reefs. Upper Jurassic corals had a higher ratio of
heterotrophic versus autotrophic energy uptake than modern ones, which
explains their frequent occurrence in terrigenous settings. Coral
communities changed along a bathymetric gradient but sedimentation
exerted a stronger control on diversities than bathymetry. One coral
community was adapted to brackish waters. Reefal siliceous sponge
biostromes and sponge microbolite mud mounds generally occur below the
coral facies, and hexactinellid-dominated sponge communities generally
occur below a zone of mixed &#34;lithistid&#34;-hexactinellid growth.
This distribution mirrors differences in nutrient conditions, with
coral facies related to stable, moderately oligotrophic to mesotrophic
conditions whereas siliceous sponges could tolerate fluctuating levels
and hence may range from extremely oligotrophic to strongly mesotrophic
settings. This is due to the fact that hexactinellid sponges can
largely live on osmotrophy and &#34;lithistid&#34; sponges develop
deposits of living organic matter by hosting a huge mass of bacteria.
Microbolite crusts demand strongly reduced sedimentation and are
important framework contributors in many coral and sponge reefs.
Eutrophication or oxygen depletion may exclude reef fauna, giving rise
to pure microbolite reefs. Most Upper Jurassic reefs developed in ramp
settings. High-energy reefs contain little preserved framework, whereas
```

```
low-energy reefs may have excellently preserved framework and
pronounced relief whenever microbolite crusts provided stabilization.
Reefs in steepened slope settings are generally rich in microbolites
because of bypass possibilities for allochthonous sediment. Reef rimmed
shallow-water platforms did occur but only developed on preexisting
uplifts. Upper Jurassic sponge-microbolite mud mounds grew in
subhorizontal mid to outer ramp settings and reflect a delicate
equilibrium of massive and peloidal microbolite precipitation and
accumulation of allochthonous mud and fine allochems, determined by the
distance to shallow-water carbonate factories. Disturbances in this
equilibrium lead to the development of sponge biostromes or the
disappearance of sponge facies &#8230; [fragment of extensive summary]

controlling factors.- Profil 5: 1-45.- <b>FC&#038;P 23-1.1</b>, p. 88,
ID=4204^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>^Reefs occurred
widespread during the Late Jurassic, particularly along the northern
Tethyan shelf and the marginal basins of the young North Atlantic
Ocean. They thrived in a variety of settings such as on intrabasinal
tectonic and halokinetic uplifts, within lagoons or within
siliciclastic fan deltas. Most frequently they grew in homoclinal to
steepened ramp settings, where they occupied a wide bathymetric field
from the innermost, partly even hypohaline, part down to outer ramp
settings. Compositionally they comprise the end members &#039;coral
facies&#039;, &#039;siliceous sponges facies&#039; and &#039;microbial
facies&#039;, but transitions and successions are frequent. Microbial
crusts are important not only in the microbial facies where they build
thrombolitic reefs up to 30 meters thick but also within the siliceous
sponge and coral facies where they occur at variable quantities and are
largely responsible for constructing a positive relief. [part of

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic;
<b>Geography: </b>^In order to elucidate the control of local, regional
and global factors on occurrence, distribution and character of
Jurassic reefs, reefal settings of Mid and Late Jurassic age from
southwestern Germany, Iberia and Romania were compared in terms of
their sedimentological (including diagenetic), palaeoecological,
architectural, stratigraphic and sequential aspects. Upper Jurassic
reefs of southern Germany are dominated by siliceous sponge - microbial
cnist [...] automicritic to allomicritic mounds. During the Oxfordian
these form small to large buildups, whereas during the Kimmeridgian
they more frequently are but marginal parts of large grain-dominated
massive buildups. Diagenesis of sponge facies is largely governed by
```

```
the original composition and fabric of sediments. The latest
Kimmeridgian and Tithonian spongiolite development is locally
accompanied by coral facies, forming large reefs on spongiolitic
topographic elevations or, more frequently, small meadows and patch
reefs within bioclastic to oolitic shoal and apron sediments. New
biostratigraphic results indicate a narrower time gap between Swabian
and Franconian coral development than previously thought.
Palynostratigraphy and mineralostratigraphy partly allow good
stratigraphic resolution also in spongiolitic buildups, and even in
dolomitised massive limestones.[part of extensive summary]^1";

p. 96, ID=6513^<b>Topic(s): </b>; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Jurassic Cretaceous; <b>Geography:
</b>^Coral reefs are complex ecosystems. Their main producers - the
corals - are more primitive organisms. Nevertheless they create
complicated constructed skeletons presenting a wide range of shapes.
For half a billion years exist corals, for about 250 million years the
stony corals (Scleractinia) which colonize also today oceans. Changing
environmental conditions forced the sensible organisms to create again
and again new constructions resulting in a almost unlimited richness of
forms through time. Not much is known about the relationship between
the construction of the skeleton made of calcium carbonate and the
biology of the living animal, mainly for groups which lived in periods
long ago making classification and taxonomy difficult. This book will
be help to work with Mesozoic corals (without Triassic) and gives in
five large chapters (morphology; palaeoecology, diversity and
evolution; sampling and examination; systematics and list of common
genera; coral localities) insight in the most important aspects of a
difficult organism group. The book is based on lecture material and is
written for geology and biology students, as well for interested
amateurs and biologists or geologists who want to gain insight in this
invertebrate group. Much yet unpublished data on systematics, diversity
and taxonomy makes the book up to date and might be interesting also
for specialists. All drawn figures of the book are new; the majority of
fossil thin sections has been not published before. The numerous
illustrations of fossil corals have been selected from a pool of more
than 4000 scanned thin sections and peels - material from the whole
world, among them samples from countries as exotic as Iran, Jamaica,
Japan or Tanzania. [summary]^1";

sponge reefs; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Jurassic Cretaceous; <b>Geography: </b>^Investigations are based on
three different depositional areas in which siliceous sponges, mainly
with a rigid skeleton (hexactinellids and &#34;lithistids&#34;)
represent the prevailing faunal elements. Within these sedimentary
environments different forms of sponge bioconstructions developed,
which comprise bioherms, biostromes and sponge meadows. The mainly
flat-shaped &#34;lithistid&#34; biohermal assemblage of the
Kimmeridgian developed in a deeper lagoonal environment, poor in
water-derived nutrients. They gained bottom-derived nutrients and &#47;
or harbored autotrophic cyanobacteria. The dominating erect
hexactinellids of the other two depositional areas reflect sufficient
nutrient supply in the water body. They developed in a partly
restricted (Bajocian sponge biostromes) to open-marine (Lower Campanian
sponge meadows) environment. Densely populated bioherms, associated
with organic crusts developed under oligotrophic conditions to
guarantee appropriate nutrients and substrate for attachment. A
```

```
self-regulating biotic system developed, independent of the surrounding
environment. This state of self-organization was not reached by sponges
of biostromes and meadows. Sponge bioconstructions developed during
transgressions since nutrients are better available and provided in a
fine fraction, that can be metabolized by the organisms. Furthermore,
low energies were necessary for transferring sponge tissue to
automicrite. Different types of automicrite, aphanitic and peloidal
cements reflect differences in water energy and chemistry. Higher
energies and higher pH-values correspond to peloidal automicrites, low
energy and more alkaline water to aphanitic ones. This is reflected in
the state of preservation of sponges and the time of dissociation of
their skeletons. Geochemical analyses hint at an original
low-Mg-composition of those automicrites. Sulfur, organic carbon and
the DOP (degree of pyritization)-values show different
paleoredoxconditions during early diagenesis in the three environments
which correlate with the density of population in the
bioconstructions.^1";
s[5364] = "STOLARSKI J., RUSSO A. (2001).- Evolution of the
post-Triassic pachythecaliine corals.- Bulletin Biological Society of
Washington 10: 242-256.- <b>FC&#038;P 30-2</b>, p. 30,
ID=1705^<b>Topic(s): </b>phylogeny; Scleractinia, Pachythecaliinae;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Jurassic or younger; <b>Geography: </b>^Triassic pachythecaliines,
i.e., Zardinophyllids, and primitive amphiastreids, differ from the
coeval scleractinians in having pachythecal wall, septa developed
deeply in the calice, smooth septal faces, and two-by-two manners of
the protoseptal insertion. Among Jurassic and Cretaceous corals, only
amphiastreids have a thick, pachythecal wall (pachythecaliine
apomorphy)., whereas other supposed post-Triassic pachythecaliines,
i.e., carolastraeids, donacosmiliids, intersmiliids, and
heterocoeniids, share either only some morphological characters with
pachythecaliines, or their coralla are too badly preserved and no
diagnostic microstructural characters are recognizable. Review of
various Mesozoic taxa that previously have been linked with the
pachythecaliines, i.e., agatheliids (Agathelia, Stylohelia,
Bracthelia), Amphimeandra, Bodeurina, and Palaeohelia suggests that
their alleged &#34;pachythecaliine&#34; characters are either shared
with other scleractinians (trabecular peritheca of agathellids) or not
homologous with those in pachythecaliines (thick wall of Paleohelia).
Pseudoastraeopora, the only Cenozoic (Eocene) coral that originally was
classified as pachythecaliid, represents, most likely some distinct
acroporoid taxon. It is generally assumed that pachythecaliines become
extinct at the end of the Mesozoic era, and our review based on
presence/absence of apomoprhic characters corroborate this hypthesis.
However, we still need more arguments to falsify an alternative
hypothesis that some, and a few apomorhic pachythecaliine characters
could been lost in some lianeages that members are thus no longer
recognizable as pachythecaliine descendants.^1";

environments that often lack biostratigraphic index fossils. For that
reason many Cretaceous coral faunas are imprecisely dated or dated only
on the basis of comparisons with other coral faunas. Using a large
database on the taxonomy, stratigraphical and geographical distribution
of corals in the Cretaceous, a method is proposed that will make it
possible to specify the stratigraphical age of coral associations on
the basis of their specific composition. In this process the
stratigraphical range of the species (calculated before from well-dated
faunas) is summarized and a probable age of the association proposed.
The method does not only help to assess the biostratigraphical age of a
fauna, but may also indicate whether a fauna represents an original
composition or is a mixed association derived from reworked horizons or
olistoliths. The method can be applied to any other organism group,
provided that the essential data for a comparison are available.^1";

Corals and rudists in the late Cretaceous: a critique of the hypothesis
of competitive displacement.- Boletin de la Real Sociedad Espanola de
Historia Natural, Seccion Geologica 92, 1/4: 225-239.- <b>FC&#038;P
26-2</b>, p. 29, ID=3715^<b>Topic(s): </b>; corals, rudists;
<b>Systematics: </b>Cnidaria Mollusca; Anthozoa Bivalvia;
<b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>^The late
Cretaceous saw the sessile rudist bivalves reach maxima of adaptive
diversity and abundance on Tethyan carbonate platforms, yielding
extensive &#039;rudist formations&#039;. Meanwhile, reef frameworks
built by corals were of notably limited development, although diverse
associations of corals in tabular bedded units may accompany the rudist
formations. * The hypothesis of competitive displacement of
reef-building corals by rudists has sometimes been invoked to explain
these patterns. An alternative view is that they reflect passive faunal
replacement mediated by environmentally triggered extinctions, perhaps
together with changes in carbonate platform ecosystems. The hypothesis
of competition between contemporaneous organisms cannot be tested by
looking at patterns of biotic turnover alone, as such patterns are the
effects of many factors. What is needed is detailed palaeoecological
analysis of co-occurrences of the postulated competitors. * The
Santonian carbonate platform deposits of Sant Corneli in the southern
Central Pyrenees contain abundant and diverse corals, as well as
rudists. A spectrum of biotic assemblages, from coral-dominated to
rudist-dominated, is found to correspond with a sedimentary facies
gradient expressed both in vertical successions and in a lateral
zonation. The corals and rudists largely occupied different biotopes,
and even in mixed assemblages no evidence for competitive interference
between neighbors (e.g. overgrowth relationships) has been detected.
These observations imply little, if any, mutual interference between
members of the two groups, in the occupation of space, while inferred
nutritional differences between them allow us to reject trophic
overlap. * Similar distributional patterns reported for other
Cretaceous assemblages lead us to conclude that there was probably
little or no competition between rudists and corals, so undermining the
```

```
competitive displacement hypothesis. We further dispute the underlying
assumption that the rudists were occupying broadly the same kinds of
haitats that hosted coral reefs at other times; the rudists usually
thrived on flat to gently inclined mobile sediment surfaces, which we
argue would have been unfavourable sites for reef development.^1";

&#034;chaetetid&#034; Blastochaetetes irregularis (Michelin) is
redescribed. The presence of calcite pseudomorphs of long, thin style
spicules indicates poriferan affinities. Their type and arrangement is
characteristic of the Order Axinellida (Class Demospongia), but the
unique combination of spicule type and arrangement requires a new
genus, Stromatoaxinella, and family, Stromatoaxinellidae. The
distinction previously drawn between &#034;stromatoporoids&#034; and
&#034;chaetetids&#034; is artificial.^1";
s[5377] = "WILMSEN M. (2003).- Taxonomy, autecology and
palaeobiogeography of the middle Cretaceous genus Parkeria Carpenter,
1870 (spherical hydrozoan).- Journal of Systematic Palaeontology 1, 3:
161-186.- <b>FC&#038;P 34</b>, p. 107, ID=1379^<b>Topic(s):
</b>revision; Hydrozoa, Parkeria; <b>Systematics: </b>Cnidaria;
Hydrozoa; <b>Stratigraphy: </b>Cretaceous Alb - Cen; <b>Geography:
</b>^A revision of the poorly known, colonial, spherical hydrozoan
genus Parkeria Carpenter 1870 and its included species is presented.
Corresponding skeletal architecture and mode of accretion confirm the
suggestion that the genus belongs to the family Hydractiniidae Agassiz
1862. A previous classification of Parkeria and the Late Triassic
spherical hydrozoan genus Heterastridium Reuss 1865 within the family
Heterastridiidae Frech 1890 was based on external morphology only.
Considering the similarities of Heterastridium with representatives of
the family Milleporidae Fleming 1828, the Heterastridiidae may well be
redundant. Parkeria sphaerica Carter 1877, from the Late Albian &#47;
Early Cenomanian mainly of Europe, is characterised by an originally
aragonitic, spherical skeleton up to 70 mm in diameter formed by
concentric laminae and radiating pillars interlaced by stolonal tubes.
P. cf. sphaerica from Oman lacks the concentric internal fabric and
shows irregularly-formed skeletons; therefore, it is placed in the
species with reservation. P. provalei Parona 1909, from the Aptian of
Italy, is smaller (~20 mm), has larger skeletal interspaces and lacks
the strict incremental growth of P. sphaerica. The absence of external
attachment areas in Parkeria suggests a free-living mode of life. The
skeletons of P. sphaerica and P. provalei testify long-term uniform
centrifugal skeletal accretion. Contrary to previous assumptions, they
are not interpreted as floating (i.e. planktonic) colonies but as
&#039;benthic drifters&#039; that were constantly carried and drifted
across the sea-bottom by currents and/or waves. This mode of life,
where the zooids fed on benthic microorganisms, was aided by the
light-weight design of the skeletons, the cavities of which were
presumably filled with gas. Estimates of skeletaI-interskeletal ratios
and density calculations support the existence of weak buoyancy. The
```

```
genus shows a rather disjunct palaeobiogeographical distribution in
shallow seas of low to warm-temperate palaeolatitudes during the Aptian
and Late Albian &#47; Early Cenomanian.^1";

</b>stratigraphy; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous; <b>Geography:
</b>^Post-Palaeozoic coral genera are known to be long-lived.
Systematicmonographs define the stratigraphic distribution of the
genera in generalterms such as &#34;Jurassic&#34; or &#34;Early
Cretaceous&#34;. The usefulness of thecoral genera as dating aids is
restricted by imprecise data concerning their stratigraphic
distribution. More precise data could make it easier todate sediments
that contain only corals or other organisms not reallysuited as index
fossils.To assess the stratigraphic distribution of Cretaceous coral
genera, acomputer database containing records of species taken from
theliterature was analysed and compared with available type material
inmuseums and university collections worldwide. Cases where thespecimen
data did not agree with the stratigraphic distribution of agenus
reported in the literature were examined in detail and arediscussed
here.According to the literature a total of 705 coral genera
(subclassHexacorallia with the order Scleractinia; subclass
Octocorallia with theorders Alcyonacea, Coenothecalia, and Gorgonacae)
are known fromthe Cretaceous. Range data were determined for 394 of
them. Theremaining 311 genera were found to be synonyms, poorly
defined,invalid, or they simply did not occur in the Cretaceous. The
```

```
results ofthis study are restricted by the poor definition of many
genera so that itwas not possible to indicate their distribution
because theirmorphological characteristics were unknown and it was not
clear whatspecies had to be assigned to them.^1";

ID=1487^<b>Topic(s): </b>species index; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous;
<b>Geography: </b>^The Repertoire lists a total of 3,030 coral species
whose type localities are - as far as is known - of a Cretaceous age
and were established in the period between 1758 and 1999. The
Repertoire of Species is designed on the basis of the valuable work
published by Bernard Lathuiliere on the Jurassic corals (1989), but
some details have been modified (thus, the authors of genera are
indicated, papers published by one and the same author in the same year
are more clearly distinguished). The Repertoire lists all species under
the current genus and under the genus under which the species was
originally established (according to the literature published before
January, 1, 2000). Synonyms, both objective and subjective ones, are
generally not taken into account. All species are cited, whether they
are synonymous or not. Species which are described in the sense of a
subsequent author and used over a long time period are indicated.
Invalid species are cited according to their low number but are
indicated and invalid species names are cited without correction. Also
homonyms (genera and species) are cited as they are. The type locality
(or region, if no exact type locality is known), lithostratigraphy and
chronostratigraphy are indicated under the original genus. It is
indicated as correctly as possible. In some rare cases in which several
localities in various countries are indicated, no locality is cited.
Where the name of the locality (or of the formation) has changed since
it was first used in the literature, the old name is indicated in
brackets. An index is provided which cites the generic and specific
```

```
names; the specific name points to two entries when the original and
current genus differ. The reference list indicates all authors of taxa
cited; in a few cases where the exact source was not found, it has been
omitted. ^1";
s[5385] = "BARON-SZABO R.C. (2002).- Scleractinian corals of the
Cretaceous. A compilation of Cretaceous forms with descriptions,
illustrations and remarks on their taxonomic position.- published by
the author: 539 pp., 142 pls., 86 text-figs; Knoxville, Tennessee.
[review] - <b>FC&#038;P 32-1</b>, p. 28, ID=1730^<b>Topic(s): </b>;
Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>^This study is a
taxonomic review of the scleractinian coral genera of the Cretaceous
period. It deals with over 600 taxa, of which nearly 300 are discussed
in detail. It is the first extensive compilation of Cretaceous coral
genera since the Treatise works of Alloiteau (1952a, 1957) and Wells
(1956). A diagnosis is provided for each genus, as well as for each
higher levels taxonomic category, and issues concerning taxonomic
assignments are discussed in detail. The descriptions are accompanied
by illustrations (142 pls. And 86 text-figs.) of representatives of
each genus and, in many cases, include illustrations of the holotype or
a paratype of the type species. Also included is the first
comprehensive overview of the stratigraphical and geographical ranges
of each genus from Triassic to recent. A glossary and index to the
genera and approximately 2200 species are provided, and the following
new taxa are described: Columnocoenia elachia nom. nov.,
Turnsekophyllia cantabrica gen. nov., sp.nov., Rhipidastraea eliasovae
sp.nov., Cycloseris (?) wellsi sp.nov., and Comoseris aptiensis sp.nov.
A neotype is established for the type species of the genus Thecosmilia,
Thecosmilia trichotoma (Goldfuss, 1826).^1";

</b>calcitic skeleton; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>^It
has been generally thought that scleractinian corals form purely
aragonitic skeletons. We show that a well-preserved fossil coral,
Coelosmilia sp. from the Upper Cretaceous (about 70 million years ago),
has preserved skeletal structural features identical to those observed
in present-day scleractinians. However, the skeleton of Coelosmilia sp.
is entirely calcitic. Its fine-scale structure and chemistry indicate
that the calcite is primary and did not form from the diagenetic
alteration of aragonite. This result implies that corals, like other
groups of marine, calcium carbonate-producing organisms, can form
skeletons of different carbonate polymorphs.^1";

</b>; Scleractinia Felixigyra; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous L; <b>Geography: </b>^The
Early Cretaceous coral genus Felixigyra Prever 1909 is revised on the
basis of type material from Italy. Felixigyra has a
hydnophoroid-meandroid colony organisation with conical monticules
attached to each other. The very thick monticules are arranged in a way
that calicular centres become apparent. The septa are compact and
rhopaloid. The genus can be related to other genera of the Eugyridae
family, but differs from them by its particularly developed monticules.
It also shows certain resemblance to meandroid genera of the family
Trochoidomeandridae. Of the six species originally assigned to
Felixigyra only five are recognized, since the type of Felixigyra
crassa is too poorly preserved to give a diagnosis. The remaining five
species have almost no significant difference in calicular dimensions.
In addition to the Italian material, one sample from the Early
Cenomanian of Greece and one sample from the Early Albian of Mexico are
also assigned to the genus. Material assigned to Felixigyra after
Prever (1909) needs to be entirely reclassified to the genus
Eohydnophora. [original abstract]^1";

new coral, Blastozopsammia guerreroterion, from the Mid-Cretaceous
(upper Albian-lower Cenomanian) Mal Paso Formation of southwestern
Mexico is the earliest known and the first Mesozoic colonial member of
the Dendrophylliidae, an extant worldwide group. Blastozopsammia is
characterized by a ramose corallum produced by extratentacular budding,
dimorphic corallites, and branches with a continuous axial corallite
sheathed in an orderly arrangement of radially arrayed secondary
corallites and a robust layer of reticulate coenosteum. This growth
form is similar to that of many modern reef-building species of
Acropora Oken, 1815 and species of a nonreefal Petrophyllia Conrad,
1855 (=Archohelia Vaughan, 1919). Based on corallite configuration,
growth form and analogy with Acropora, Blastozopsammia had a relatively
high degree of colony integration and may have been zooxanthellate. The
combination of an axial corallite with radially arrayed secondary
corallites has been regarded as one of the morphological and ecological
pinnacles of coral evolution, yet it is rare among the Scleractinia.
This growth form has not been recognized in any Cenozoic
dendrophylliids. Blastozopsammia is an evolutionary enigma because no
ancestral lineage or closely related taxon has been identified.
However, the most likely origin of colonial Dendrophylliidae is
Jurassic or Early Cretaceous Actinacididae. [original abstract]^1";

(2004).- Extinction and recovery patterns of scleractinian corals at the Cretaceous-Tertiary boundary.- Palaeogeography, Palaeoclimatology, Palaeoecology 214, 3: 195-223.- <b>FC&#038;P 33-2</b>, p. 30, ID=1155^<b>Topic(s): </b>extinctions K/Pg; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous &#47; Paleocene; <b>Geography: </b>^The extinction and recovery of scleractinian corals at the Cretaceous-Tertiary (K-T) boundary was analyzed based on a global database of taxonomically revised late Campanian to Paleocene coral collections. In contrast to earlier statements, our results indicate that extinction rates of corals were only moderate in comparison to other marine invertebrates. We have calculated a 30% extinction rate for Maastrichtian coral genera occurring in more than one stratigraphic stage and more than one geographic region. Reverse rarefaction suggests that some 45% of all coral species became extinct. Photosymbiotic (zooxanthellate) corals were significantly more affected by the extinction than azooxanthellate corals; colonial forms were hit harder than solitary forms, and among colonial forms an elevated
```

```
integration of corallites raised extinction risk. Abundance, as
measured by the number of taxonomic occurrences, had apparently no
influence on survivorship, but a wide geographic distribution
significantly reduced extinction risk. As in bivalves and echinoids
neither species richness within genera nor larval type had an effect on
survivorship. An indistinct latitudinal gradient is visible in the
extinction, but this is exclusively due to a higher proportion of
extinction resistant azooxanthellate corals in higher-latitude
assemblages. No significant geographic hotspot could be recognized,
neither in overall extinction rates nor in the extinction of endemic
clades. More clades than previously recognized passed through the K–T
boundary only to become extinct within the Danian. These failed
survivors were apparently limited to regions outside the Americas.
Recovery as defined by the proportional increase of newly evolved
genera, was more rapid for 31 zooxanthellate corals than previously
assumed and less uniform geographically than the extinction. Although
newly evolved Danian azooxanthellate genera were significantly more
common than new zooxanthellate genera, the difference nearly
disappeared by the late Paleocene suggesting a more rapid recovery of
zooxanthellate corals in comparison to previous analyses. New Paleocene
genera were apparently concentrated in low latitudes, suggesting that
the tropics formed a source of evolutionary novelty in the recovery
phase.^1";
s[5405] = "BARON-SZABO R.C. (2006).- Corals of the K/T-boundary:
Scleractinian corals of the Suborders Astrocoeniina, Faviina,
Rhipidogyrina, and Amphiastraeina.- Journal of Systematic Palaeontology
2006, 4: 1-108.- <b>FC&#038;P 34</b>, p. 51, ID=1270^<b>Topic(s):
</b>extinctions K/Pg; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous &#47; Paleocene;
<b>Geography: </b>^This taxonomic review of the scleractinian corals of
the Maastrichtianand Paleocene period focuses on the scleractinian
suborders Astrocoeniina, Faviina, Rhipidogyrina and Amphiastraeina.
This, the first extensive compilation of coral species of the K/T
(Cretaceous/Tertiary) boundary, deals with more than 2500 records of
550 nominal taxa. In addition to the re-examination and re-evaluation
of described forms, this study also includes the first description of
the largest Maastrichtian coral assemblage known (consisting of about
4000 specimens from Jamaica), as well as new material from the
Campanian–Maastrichtian of Argentina, Lower Maastrichtian of Mexico
(Cerralvo), and the Paleocene of Austria (Kambühel–Kalke). A diagnosis
is provided for each species, as well as for each higher-level
taxonomic category and issues concerning taxonomic assignment are
discussed in detail. The descriptions are accompanied by illustrations
of representatives of each species and, in many cases, include
illustrations of type or original material. Also included is the first
comprehensive overview of the stratigraphical and geographical ranges
of each taxon. In the four suborders evaluated in this paper, 123 valid
species can be reliably documented as occurring in the Maastrichtian
and/or the Paleocene. The largest number of species is in the suborders
Faviina and Astrocoeniina. In the Faviina 62 valid species are known
from the Maastrichtian, of which 35 (56.5%) crossed the K/T-boundary,
while in the Paleocene 14 new species appeared. In the Astrocoeniina 18
valid species occurred in the Maastrichtian, eight of which (44.4%)
crossed the K/T-boundary and 16 new species appeared in the Paleocene.
Only eight species of Rhipidogyrina and five species of Amphiastraeina
occurred in the Maastrichtian and although two amphiastraeinid made it
into the Paleocene, only one of the rhipidogyrinids crossed the K/T
boundary. No new species of Amphiastraeina appeared in the Paleocene.
According to this revision on the genus level 44 out of the 65 genera
crossed the K/T-boundary, which is 67.7% (12 genera went extinct, 9
genera have their first occurrence in the Paleocene). In comparison to
previous estimates this result (generic extinction of around 32%)
represents the best estimation for scleractinian corals at present and
```

```
corresponds to recently reported results of other macroinvertebrate
groups after taxonomic revision (e.g. echinoids). ^1";

1987 [Wiedmann J. (ed.): Cretaceous of the Western Tethys]: 851-878;
Schweizerbart, Stuttgart.- <b>FC&#038;P 20-1.1</b>, p. 73,
ID=2860^<b>Topic(s): </b>ecological &#038; geographical comparison;
Porifera corallina; <b>Systematics: </b>Porifera; Corallina;
<b>Stratigraphy: </b>Cretaceous - Recent; <b>Geography: </b>^The
coralline sponges (chaetetids, stromatoporoids, sphinctozoans,
pharetronids) are sponges with a rigid calcareous basal skeleton.
Within modern oceans 3 communities are observed: 1. An Indopacific reef
community characterized by calcified demosponges like Acanthochaetetes,
Astrosclera, Stromatospongia, Merlia, and pharetronid calcarean sponges
(Murrayonida, Minchinellia). 2. A Mediterranean non-reefal community
characterized by pharetronids (e.g. Petrobiona) and the calcified
demosponge Merlia normani. 3. A Caribbean reef community characterized
by ceratoporellid &#47; agelasid calcified demosponges. From the
mid-Cretaceous comparable communities are known. Non-reefal subtropical
pharetronid communities are known from the Aptian of Faringdon
(England) and the Cenomanian of the Essener Gruensand (West Germany).
These sponge communities are characterized by sycettid sphinctozoans
(Barroisia, Thalamnopora), minchinellid pharetronids (Lymnorella), and
rarely by the calcified demosponge Neuropora. The Barremian &#47; Lower
Aptian coralline sponge communities from the Tethyan Realm (e.g.
Helvetic &#034;Schrattenkalk&#034;) are not comparable with the modem
ones. After the Middle Aptian (Gargasian) events new coralline sponge
communities occurred within the North Spanish Urgonian reef platforms,
e.g. the Acanthochaetetes community which has close taxonomic and
ecological relationship with the modern Pacific Acanthochaetetes
community. The genus Acanthochaetetes is first reported from the Albian
Mural Limestone in Arizona (USA). From a late Cenomanian hardground
(Liencres, Northern Spain) a deeper water sphinctozoan demosponge
community is described (Vaceletia &#47; Acanthochaetetes community)
```

```
which has also a close correspondence to some modern occurrences of
coralline sponges within deeper water environments of Indopacific
reefs. The extant Indopacific Acanthochaetetes &#47; Vaceletia
community and the Mediterranean coralline Calcarea community are relict
faunas (&#034;living fossil communities&#034;) from the mid-Cretaceous
Tethyan Ocean.^1";

25-1</b>, p. 44, ID=3041^<b>Topic(s): </b>revision; Scleractinia,
Actinacis; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Paleogene; <b>Geography: </b>^Twenty-seven Tertiary species
belonging to the cosmopolitan reef-building scleractinian genus
Actinacis, have been described in the literature. A detailed systematic
revision has been caried out for Italian and European species by thin
section measurements of material mostly sampled from several Italian
localities, by observation of some holotypes and topotypes and accurate
examination of the available literature. A combination of several
measured corallite morphologic characters and diagnostic features is
proposed as a reliable tool for species recognition. Results indicate
that only three species, of the twelve described for the Italian
Tertiary sites, actually belong to the genus Actinacis. Moreover, a
list of synonyms and a stratigraphic range chart of the established
species are proposed. An approximate taxonomic identification and
stratigraphic distribution are given for those species not included in
the systematic revision. Preliminary examination of the stratigraphic
and geographic distribution of Actinacis species suggests that: 1) the
Tertiary distribution of the genus ranges from the Late Paleocene to
the Late Oligocene (from Late Cuisian to Middle Chatian as concerns
Italy); 2) the highest species diversity occurred during the Middle
Eocene, when the genus consisted of a relatively large number of
geographically restricted species; 3) only two widespread species
survived the Eocene/Oligocene turnover and reached the Late Oligocene,
when the genus became globally extinct.^1";
s[5413] = "GILL G.A., RUSSO A. (1973).- Présence d&#039;une structure
septale de type &#034;Montlivaltide&#034; chez Trochosmilia,
Madréporaire Eocene.- Annales de Paléontologie 1973: 35-80.-
<b>FC&#038;P 2-1</b>, p. 20, ID=4733^<b>Topic(s): </b>septal
structures; Scleractinia, Trochosmilia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Eocene; <b>Geography: </b>^In the
Jurassic genera Montlivaltia, Stereophyllia and Thecosmilia and in
Cyclastraea spinosa of Cenomanian age, Gill (1970) and Gill and Lafuste
(1971) have recognized a common structure to the septa. This structural
pattern is characterized by trabeculae, rhombic in transverse section,
which compose a median part often thickened by laminar layers.
Described in the two above-mentioned works, this type of septa was
proposed as a basis for the superfamily Montlivaltioidae All. 1952
emend. Gill and Lafuste, 1971. The authors suggested as well that such
a septal scheme existed also from the Upper Cretaceous and onwards. A
collection of Eocene corals from Northern Italy permits the time upper
```

```
limit of this structure to be extended into the Tertiary due to its
discovery in Trochosmilia corniculum (Mich.) and other genera still
under study. The inventory of corals having a Montlivaltid septal type
is for the time being rather small and an elaboration of a detailed
classification within the superfamily is therefore premature.
Nevertheless, a comparison of characters of the aforementioned genera
emphasizes the distinction of two groups, one containing Montlivaltia,
Stereophyllia and Thecosmilia, the other Cyclastraea and Trochosmilia.
In the present work Trochosmilia corniculum (Mich.) from the Eocene of
Capo Mortola, province of Imperia (Northern Italy) is described. The
neotype, chosen by Alloiteau for the genus Trochosmilia is lost but a
thin section of it still exists permitting the identity of T.
corniculum from Italy to be confirmed. A complementary description of
the genotype Cyclastraea spinosa is given in order to demonstrate its
relationship with Trochosmilia.^1";

Acropora; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Eocene; <b>Geography: </b>^Acropora is the most diverse genus of
reef-building corals in the world today. It occurs in all three major
```

```
oceans; it is restricted to latitudes 31°N–31°S, where most coral reefs
occur, and reaches greatest diversity in the central Indo-Pacific. As
an exemplary genus, the long-term history of Acropora has implications
for the evolution and origins of present day biodiversity patterns of
reef corals and for predicting their response to future climate change.
Diversification of Acropora was thought to have occurred in the central
Indo-Pacific within the previous two million years. We examined Eocene
fossils from southern England and northern France and found evidence
that precursors of up to nine of 20 currently recognized Acropora
species groups existed 49–34 Myr, at palaeolatitudes far higher than
current limits, to 51°N. We propose that pre-existing diversity
contributed to later rapid speciation in this important functional
group of corals. [original abstract]^1";

<b>Geography: </b>^At the fourth International Symposium on Fossil
Cnidaria, held in Washington in August 1983, a small group of
attendants met informally to discuss ways of encouraging and
co-ordinating studies of Cainozoic (i.e. inclsing Recent) corals. * At
the moment, most Cainozoic coral work is concentrated on faunas of a
particular region and/or age, but it is also neccessary to balance this
with more work on the taxonomy of whole systematic groups like genera
and families, throughout their geographical and stratigraphical ranges.
* It was agreed that the group would especially try to encourage and
co-ordinate systematic work and that it should remain very informal.
Initially at least, Fossil Cnidaria [FC&P] (and possibly other existing
newsletters) will be used as means of circulating information to
participiants. * In due course it is aimed to devise and announce
projects for participation by post, and perhaps, eventually, to hold
workshops, e.g. in conjunction with the four-yearly Fossil Cnidarian
Meetings. [first fragment of a note; presented is also a circular for
gathering info on researchers and their study areas]^1";

Analysis from Fossils]: 181-229.- <b>FC&#038;P 25-2</b>, p. 72,
ID=3178^<b>Topic(s): </b>ecology, reefs; corals, coralline algae;
<b>Systematics: </b>Cnidaria algae; Anthozoa; <b>Stratigraphy:
</b>Cenozoic; <b>Geography: </b>^The value of quantitative surveys of
ancient reef slopes for palaeobathymetrie analysis is reviewed. Reefs
are selected for palaeobathymetrie analysis because they are
characterized by in situ preservation of benthic communities which are
often depth related. In addition, if the reef crest and slope are
preserved then ancient water depths can be measured. The zonation of
living reefs has been measured using semi-quantitative
phytosociological methods as well as a range of plot and plotless
techniques, but there is little agreement as to a single best method.
For this study a modified line intercept transect method is selected as
it may be used on both living reefs and on various types of outcrops of
fossil reefs. This method minimizes problems arising from outcrop
conditions, is faster than quadrat methods, can be used to assess
different frame-building taxa, matrix, cement and porosity along
ancient reef surfaces, and is also frequently used in studies of living
reefs. [first part of extensive summary]^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cenozoic; <b>Geography: </b>^Historically, the genus Culicia
(Anthozoa Scleractinia) was known (until Chevalier 1961) as beginning
in the Burdigalian of Basse-Provence (France). The study of new crops
in Aquitaine Basin as well as works in varied collections, show that
the species Culicia parasita (Michelin 1847) has been living in this
region since the Oligocene (Chattian), which is a noticeable extension
of the stratigraphical range of this genus. This species is here amply
illustrated, with specimens from each concerned stage, and
paleoecologic data are provided. Otherwise, a whole bibliographic
review of references concerning the genus Culicia, added to the new
collection made in the western France and Mediterranean Neogene, mainly
fills the classical stratigraphic hiatus recorded in the distribution
of this genus between the Middle Miocene of Eastern Atlantic and the
Pliocene-Quaternary of Australia; the question of possible phyletic
relations between fossil and extant Culicia species is set. A map of
biogeographic migration is proposed, including all the taxa of this
genus.^1";

Scleractinia; <b>Stratigraphy: </b>Cenozoic U; <b>Geography: </b>^New
morphometric methods for distinguishing morphologically similar species
of Recent colonial scleractinian corals involve the analysis of three
dimensional landmarks digitized on calical surfaces. Variables suitable
for multivariate statistical analysis are derived from the landmark
data by applying various geometrical techniques, including Bookstein
size and shape coordinates and generalized resistant fitting. Cluster
analyses of these variables and study of the relative positions of
replicates from the same colony on the resulting dendrograms are used
to recognize clusters of colonies representing morphospecies.
Comparisons with the results of genetic analyses on the same specimens
suggest that these morphospecies correspond closely with biological
species. Although slightly less effective, similar analyses of two
dimensional landmark data collected on thin sections of the same
specimens also distinguish species, and suggest that biological species
can be approximated in the fossil record. Multivariate statistical
analyses show that variables derived from two dimensional landmarks can
```

```
be used to trace the stratigraphic ranges of these fossil species. The
appropriate method for tracing ranges depends of the evenness of
sampling in different geologic horizons. Preliminary comparisons of
observed stratigraphic ranges determined by this approach with those
determined by cladistic analysis suggest that overall patterns in
evolutionary rates through geologic time are the same for both
approaches. Thus, nontraditional morphologic characters determined by
subsequent examination of morphometrically-defined species have
potential for providing sufficient resolution for phylogenetic
analysis.^1";

</b>revision; Scleractinia, Hydnophora; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cenozoic; <b>Geography: </b>^This
report presents a systematic revision of the Tertiary species of the
common reef-building coral Hydnophora. Major diagnostic characters of
various Tertiary genera that have been commonly confused with
Hydnophora (Leptoria,Monticulastraea, Staminocoenia, Michelottiphyllia
and Angeliphyllia) are defined and subsequently compared in order to
establish differences and synonymies. With the exception of Leptoria,
```

```
all other genera are considered synonyms of Hydnophora. * Forty-five Tertiary species ascribed to Hydnophora, or to synonymous genera, have been revised and type material analyzed. Collected material from Oligocène Italian localities and Miocene localities from Somalia and Pakistan has been also analyzed in order to provide a consistent taxonomy for distinguishing species within the genus, especially for the Mediterranean Tertiary. * According to this report, of the forty-five species of Hydnophora previously described, only twenty-one to be distinct. The Tertiary distribution of the genus, which started in the Late Paleocene, clearly shows that species richness increased significantly from Paleocene to Miocene. Originations of species were mostly concentrated during two time intervals, respectively the Chattian for the Mediterranean and theBurdigalian for the Eastern Tethys. As regards the Mediterranean, the genus developed only during Chattian time with five fully described species. The genus became extinct in both Caribbean and western-central Mediterranean regions at the end of the Oligocene and subsequently developed in eastern Tethys regions during the Miocene. * A new name is proposed for the only Paleocene species: Hydnophora gregoryi. reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The global decline of coral reefs
highlights the need to understand the mechanisms that regulate
community structure and sustain biodiversity in these systems. The
neutral theory, which assumes that individuals are demographically
identical regardless of species, seeks to explain ubiquitous features
of community structure and biodiversity patterns. Here we present a
test of neutral-theory predictions with the use of an extensive
species-level data set of Indo-Pacific coral communities. We show that
coral assemblages differ markedly from neutral-model predictions for
patterns of community similarity and the relative abundance of species.
Within local communities, neutral models do not fit relative abundance
distributions as well as the classical log-normal distribution.
Relative abundances of species across local communities also differ
markedly from neutral-theory predictions: coral communities exhibit
community similarity values that are far more variable, and lower on
average, than the neutral theory can produce. Empirical community
similarities deviate from the neutral model in a direction opposite to
that predicted in previous critiques of the neutral theory. Instead,
our results support spatio-temporal environmental stochasticity as a
major driver of diversity patterns on coral reefs. [supplementary info

ID=1323^<b>Topic(s): </b>biodiversity; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Ecological communities are influenced by processes operating at
multiple scales. Thus, a better understanding of how broad- as well as
local-scale processes affect species diversity and richness is
increasinglybecoming a central focus in modern community ecology. Here,
in astudy of unprecedented geographical scope, we show
significantregional and local variation in the species richness of
coral assemblagesacross an oceanic biodiversity gradient. The gradient
that we sampledextends 10.000 km eastwards from the world&#39;s richest
coral biodiversityhotspot in the central Indo-Pacific. Local richness
and the size ofregional species pools decline significantly across 15
islands spanningthe gradient. In addition, richness declines across
three adjacent habitats(reef slopes, crests and flats). In each
habitat, a highly consistent linearrelationship between local and
regional species richness indicates strongregional enrichment. Thus,
even on the most diverse coral reefs in theworld, local coral
assemblages are profoundly affected by regional-scaleprocesses.
Understanding these historical and biogeographicalinfluences is
essential for the effective management and preservation ofthese
endangered communities.^1";

KELLER N. (2000).- Paleotemperatures from deep-sea corals: Overcoming
&#39;vital effects&#39;.- Palaios 15, 5: 25-32.- <b>FC&#038;P 29-1</b>,
p. 54, ID=1500^<b>Topic(s): </b>paleotemperatures; Anthozoa;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Thirty-five azooxanthellate (non-photosynthetic)
corals belonging to 18 species were collected at sites ranging from the
Norwegian Sea to the Antarctic and of depths ranging from 10 to 5220m.
All specimens showed distinct, well-defined linear correlations between
carbonate oxygen and carbon isotopic composition, with slopes ranging
from 0,23 to 0,67 (mean 0,45 ± 0,9) and linear correlation r2 values
that averaged 0,89. These pronounced isotopic disequilibria have, to
date, rendered azooxanthellate corals unsuitable for use in
paleothermometry. Most, but not all, of the heaviest skeletal &#948;18O
values reached or approached equilibrium. If the isotopically-heavy
ends of the &#948;18O vs &#948;13C regression lines reliably
approximated isotopic equilibrium with seawater, these values could be
used to estimate the temperature of the water in which the coral grew.
The &#948;13C values of the heavy ends of each line, however, were
always depleted compared to carbon isotopic equilibrium with ambient
bicarbonate by varying amounts. * Despite the disequilibira, a reliable
method for obtaining paleotemperature data was obtained. It was found
that, if a &#948;18O vs &#948;13C regression line from an individual
coral could be generated, the &#948;18Oarag value corresponding to
&#948;13Carag = &#948;13Cwater and corrected for &#948;18Owater was a
linear function of temperature: &#948;18O = 0,25 T(°C) + 4.97.

A survey (255 m2) of the interactions between corals (Scleractinia) on a Caribbean reef (depth 10-30 m) indicated the outcome of 17-35% of the aggressive and defensive interactions to be unpredictable. Experiments on the reef (depth 7-13 m) with pairs of interacting corals - Madracis mirabilis (Duchassing et Michelotti), Agaricia agaricites (L.), Montastrea annularis (Ellis et Solander), Eusmilia fastigiata (Pallas) - showed that, after the initial contest through extracoelenteric digestion, there are at least two additional processes which can result in a reversal of dominance: interference by epifauna and sweeper tentacle development. Moreover, the impact of extracoelenteric digestion and the extent of sweeper tentacle development varied over the surface of the corals. Employing laboratory and field experiments to distinguish between the impact of extracoelenteric digestion, epifauna behaviour and sweeper tentacles, we show the three processes combined to explain the coral interaction process in toto. The outcome of the interaction process on the reef depends on numerous, partly unpredictable, variables, including mode of contact and effects of position. Consequently, patterns of community organization resulting from spatial competition will be slow to emerge and easily erased prematurely by disturbances.^1";
s[5458] = "GROTTOLI A.G., EAKIN C.M. (2007).- A review of modern coral &#948;18O and &#948;14C proxy records.- Earth-Science Reviews 81, 1-2: 67-91.- <b>FC&#038;P 35</b>, p. 106, ID=2437^<b>Topic(s): </b>stable isotopes, O, C; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^This paper is a review of published modern coral &#948;18O and &#948;14C isotopic records that are at least 30 and 20 years long, respectively. The data are presented to show basin-scale trends in both of these proxy records on decadal-to-centennial timescales. The goal was to qualitatively integrate the general inter-annual-to-centennial timescale variability revealed in these data, as well as the statistical and modeling output results that have been produced using these coral records. While many review papers typically include a representative subset of the data
```

```
available, this review aims to include as much of the available data as possible. In general, coral &#948;18O records show a long-term warming and/or freshening throughout the tropical oceans, and agree with the NOAA Extended Reconstruction Sea Surface Temperature 2 (ERSST) on decadal timescales. In the western Pacific, it is most likely a freshening of the seawater &#948;18O that dominates the signal. El Nino Southern Oscillation (ENSO) variability dominates most &#948;18O records either by varying local seawater temperature or salinity, depending on the regional oceanography/climatology. Outside of the Pacific, ENSO affects seawater temperature and salinity via atmospheric or oceanic teleconnections. Post-bomb coral &#948;14C records collectively show that the uptake of 14C has been greatest in gyre-water fed sites, followed in descending order by western boundary current areas, equatorial upwelling regions, and eastern tropical Pacific upwelling sites. These surface water &#948;14C values indicate the proportion of surface water and/or the residence time of water at the surface at a given location, and can be used to model water mass mixing rates. Such models have only begun to be run and show that the amount of eastern Pacific water entering the central South Pacific increases during El Ninos and that the Indonesian throughflow is supplied year-round by the North Pacific. Comparing ocean circulation models with coral &#948;14C-modelled circulation enables researchers to explore the mechanisms that drive seawater &#948;14C variability and fine-tune their models. In addition, our comparison between the rate of coral &#948;14C increase between 1960 and 1970 and total anthropogenic CO2 uptake rates show general agreement, demonstrating the value of coral records in understanding past carbon fluxes. Overall, coral &#948;18O and &#948;14C proxy records represent natural archives of seawater conditions and are critical for studying the natural variability in local and regional patterns within, and teleconnection patterns between, the tropics, extra-tropics, temperate, and Polar Regions on intra-annual-to-centennial timescales. Two natural chemical tracers, radon, and salinity, were used to calculate the exchange rate between surface sea water and reef interstitial waters. Dissolved radon concentrations are substantially higher in interstitial waters than in surface water. The degree of radon enrichment is quantitatively related to the time elapsed since interstitial water had equilibrated with the atmosphere. Residence time estimates are 1-40 days, with deeper wells having slower exchange. The average residence time for 1-m-deep wells was 2.1 days. A rainstorm-induced dilution of the salinity of Kaneohe Bay provides the second tracer. Samples of surface and reef interstitial waters following this salinity perturbation are used to calculate an average residence time of 2.6 days at a depth of 1m and 42 days at a depth of
```

```
2m. Three types of physical forces thought to cause exchange between
surface and interstitial water are considered by measurement of the
forcing functions and reef permeability. Hydraulic conductivities are
about 50 m/d, with lower values near the seaward side of the reef. Most
exchange seems to be caused by high-frequency, wave-driven oscillatory
pumping and by unidirectional hydraulic head gradients (of uncertain
origin) that are stable for at least 3-4 days. Wave-driven mixing is
probably more important shallower in the reef, whereas head-driven flow
may dominate deeper in the reef. Tidal pumping does not seem to
contribute to exchange. All methods indicate that exchange in the upper
part of Checker Reef is primarily through vertical exchange. The best
estimate for the residence time of water at a depth of 1m is 2 days.
Water at depths of 2-4m probably has a residence time of weeks to
months. ^1";

ID=4856^<b>Topic(s): </b>functional behavior; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Four species of Porites were selected from the Florida reef tract
for experimental studies designed to determine the functional
relationship of the polyp to the calcareous skeleton. Each species was
subjected to systematic sediment-shedding and cursory feeding and
calibrated current-flow experiments, crude lethal-limit studies of
their temperature and salinity tolerances, and time-marked growth
studies under laboratory conditions. At the end of these experiments
branches of Porites furcata Lamarck and P. divaricata Lesueur were
prepared for standard histological and petrographical observations. An
analysis of these results shows that Porites is neither truly colonial
nor truly polystomous; it possesses diagnostic characteristics of both
these types of organization and is therefore designated
quasi-polystomous. It is a colonial coral in which the polyps comprise
incomplete individuals with a common enteron; but they also have
distinct stomodea and tentacular rings which are capable of independent
action. Porites also possesses unique regenerative properties which
probably help it to survive adverse conditions. * Examples are given
from other Floridian reef corals from known environments of the
gradations in coloniality indicated by Wells (this volume). Thus
structurally linked colonial corals show behavioral responses which
range from solitary reactions in Mussa angulosa (Pallas) through
partial coordination in Porites to complete coordination in Diploria
and &#034;brain&#034; corals. Complete confidence as to the behavioral
nature of coloniality can only be ascertained from combining
histological and behavioral techniques with observations on skeletal
anatomy.^1";

<b>Geography: </b>^220 well-characterized coral specimens from 17
localities have been analised for Sr. 73 genera and subgenera, mostly
hermatypic scleractinians, are represented. For some genera, specimens
living in surface reef environments are compared with those from 18,3m
```

```
depth on the same reefs. Growth rates for some species have also been
measured at these depths at one of the sampling sites. Skeletal Sr for
a given genus decreases with increasing water temperature, a
relationship which previously eluded detection. Aragonite deposited by
corals living in the reef at depth of 18,3m contains more strontium
than the skeletal aragonite of the same coral genera from
shallow-water, surface environments. * Quantitative treatment of the
data for Acropora, one of the most abundant and widely distributed of
the reef-building corals, suggests that the observed Sr variations may
reflect variations in the rate of skeletal calcification, rather than
direct dependence upon temperature or water depth. There is evidence
for &#34;species effect&#34;, apparently unrelated to growth rate
differences, in that certain coral genera are consistently enriched or
depleted in skeletal Sr content relative to other genera living in the
same reef environments under identical ambient conditions. Temperature,
salinity, water depth, sea-water composition and/or other such
parameters may in part determine the levels of trace element
concentration in carbonate deposited by corals and other marine
invertebrates, but it would appear that these variables more directly
affect physiological processes which in turn control skeletal
chemistry.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Little is known about the magnesium content of the
skeletal aragonite deposited by the hermatypic reef-building,
scleratinian corals. Over 2000 corals specimens were analysed in an
attempt to determine the extent to which environmental and genetic
factors control magnesium uptake during skeletogenesis. Only three of
the 49 genera investigated show any evidence that skeletal magnesium
levels are temperature dependent, and even in these 3 cases,the
relationship is poorly defined.Calcification rate and water depth also
appear to exert no detectable influence. There is considerable
variability in skeletal magnesium content, even within a given genus,
but patterns linking Mg concentrations to taxonomic affinity suggest
that physiologic controls predominate in determining the quantity of
this element that can enter the aragonitic skeleton.^1";

reef-building Corals.- Geology 1974, 2, 3: 153-154.- <b>FC&#038;P
4-1</b>, p. 25, ID=5082^<b>Topic(s): </b>hermatypic, skeletal
plasticity; reef corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Reef corals are
remarkably variable in growth form and skeletal configuration. This
high degree of phenetic diversity has contributed greatly to the
success of the hermatypic scleractinians as widespread reef builders in
tropical oceans. Although phenetic variability or &#34;plasticity&#34;
is common, its cause remains obscure, because the species are
genetically stable. The extent of phenetic variability is surprising in
view of the morphologic simplicity of the animal itself. Carbon isotope
ratios have been used to determine changes in the relative proportions
of skeletal carbon in the form of carbonate derived from sea-water
bicarbonate and metabolic carbon dioxide sources. Increasing amounts of
respiratory CO2 incorporated into skeletal aragonite are attributed to
decreasing efficiency of metabolite excretion. Isotope data indicate
that zooxanthellae are effectively removing metabolic waste products
from the tissues of hermatypic scleractinians, and that, for these
corals, diffusion is not an important excretion mechanism. Ahermatypic
corals, however, depend on diffusion processes to eliminate metabolic
waste products. 13C/12C ratios indicate that, among the ahermatypes,
small changes in corallum geometry that result in greater coarctation
[?] of the polyps and (or) a decrease in the size of the polyp surface
exposed to sea water have a large effect on the isotopic composition of
the skeletal carbonate. These findings suggest that corals that do not
build reefs are restricted to small and relatively simple forms because
of serious difficulties in the metabolite excretion they would
encounter in more complex corallum geometries. In the case of the
hermatypes, however, the metabolite excretion problems that would limit
the range of possible skeletal configurations have been resolved by
zooxanthellae. The spectacular phenetic variability in reef corals is
thus achieved through a symbiotic association of the hermatypic corals
with zooxanthellae.^1";

<b>Geography: </b>^The objective of this study is to locate as closely
as possible the sites of strontium, magnesium, sodium, and potassium in
```

```
modern aragonitic corals, specifically whether these cations are
adsorbed, or are substituted in the carbonate lattice or are
incorporated in organic components. In addition to locating the sites
of each of these four elements we wanted to find out quantitatively how
much of each element occurs at each site. The experiments in this study
are based on the dissolution rate of aragonite in distilled water and
on the substitution of strontium and magnesium by calcium and sodium.
Special attention has been given to the occurrence of strontium,
magnesium, sodium and potassium in the organic components of the
corals. * The main site for strontium in the corals is in the aragonite
lattice. Twenty-five per cent of the total magnesium occurs in adsorbed
sites and in organic compounds. The rest of the magnesium may be
located in the aragonite lattice, but it is easily removed by repeated
leaching or by replacement with calcium ions. Another possibility is
that magnesium may occur in a dispersed mineral phase more soluble than
aragonite because magnesium was released at a higher Mg to Ca ratio
than is found in the solid coral; also because no local concentration
of magnesium could be detected with an electron microprobe. About 12%
of the total sodium is in adsorbed sites and is included in the organic
compounds. The rest of the sodium might be in the lattice replacing
calcium, but the low total exchange capacity is not enough to provide
the needed charge balance. Another possibility is that sodium is
located in a proposed mineral phase. Potassium is in adsorbed sites and
incorporated in the organic compounds to an extent greater than all the
other elements studied (30% of the total potassium), but again the
evidence suggests that the remaining potassium is in a proposed mineral
phase. * Calcite is detected on the surfaces of aragonite corals after
5 months in the substitution experiment. The change of aragonite to
calcite took place after the inhibitor magnesium was exchanged from the
surface sites and replaced by calcium. * The organic compounds in
corals contain small amounts of strontium, magnesium, sodium and
potassium. Strontium is preferentially enriched in the organic
compounds over magnesium.^1";

One component of this structural matrix is present transiently at the growth surface of the skeleton, and it consists of individual sheaths enveloping each forming aragonite crystals. These crystal sheaths, plus some small extracellular vesicles that are presumed to represent a precursor for the sheaths, are together implicated in the following hypotheses for coral calcification. * 1. The precipitation of calcium carbonate, and thereby skeletal accretion, occurs only within the crystal sheaths, i.e. within the terminal matrix compartments. * 2. The crystal sheaths have a role in crystal nucleation. * 3. The sheaths isolate and actively modify the space within these compartments, thereby controlling the rate of epitactic crystal growth subsequent to nucleation. * 4. The movement of calcium ions from seawater toward the skeleton is principally via a paracellular route. * 5. The matrix precursor vesicles, by analogy with vertebrate matrix vesicles, have a role in the transport of calcium and/or carbonate ions from the lateral extracellular spaces of the calicoblastic ectoderm to the growth surface of the skeleton. * 6. The synthesis of matrix precursor material by the calicoblast cells in enhanced in the presence of photosynthetic products translocated to the coral tissues from the zooxanthellae. diversity of soluble mineralizing matrices in some recent coral
skeletons compared with fine-scale growth structures of fibres.
Discussion of consequences for biomineralization and diagenesis.-
International Journal of Earth Sciences [Geol. Rundsch.] 88, 3:
582-592.- <b>FC&#038;P 28-1</b>, p. 46, ID=6926^<b>Topic(s): </b>coral
growth; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^In contrast to the
purely crystalline model of the coral fibre, a transversal zonation is
made visible within fibres by specific preparations (enzymatic or light
acidic etchings). This growth zonation that corresponds to the
successive positions of the secretory ectoderm during septal
development shows that crystallization of coral fibre is controlled not
only by an external organic coating of fibres, but also includes
intra-fibrous organic components. This results in a micron-scaled
internal structure of fibres, with a noticeable diversity depending on
species. In parallel, soluble matrices also exhibit significant
differences, although the global high content in acidic amino acids is
always observed. Gathering these two sets of data allows the current
ideas concerning structures and growth modalities of coral septa to be
discussed. Basically, the respective role of centres of calcification
and fibres during septal development appears clearly different from the
current ideas, resulting in significant change in interpretation of
coral structures, with concerns in both skeleton formation and
understanding of diagenetic processes. [original abstract]^1";
s[5491] = "VERON J.E.N. (2000).- Corals of the World.- Australian
Institute of Marine Science; 463 pp. + 429 pp. + 490 pp. [book, in 3

of Australia and the Indo-Pacific&#034;, first published in 1986 and
now considered a &#039;classic&#039;, is completely eclipsed by
&#039;Corals of the World&#039;. The book is one of the most
comprehensive, authoritative and spectacular productions ever given to
a group of marine organisms, the reef-building corals worldwide. *
Brief characteristics: (1) an extravaganza of colour and art - a
portrayal of the variety and the beauty of corals as never before -
over 3.000 underwater photographs including hundreds taken by the best
underwater photographers from around the world; (2) from reefs to
```

```
aquaria - a history of discovery - which comes first - the reefs or the
corals? - corals in aquaria: a path of interest and discovery; (3) 900
distribution maps - an atlas of information and explanation - one
hundred superb works of art reveal the beauty of microscopic dteail;
(4) what are species - the nature of species, how they vary according
to environment and how they change geographically; (5) encyclopaedic
information - one in ten species is new to science; there are several
new genera and a new family; this book is the outcome of comprehensive
taxonomic revisions of all reef-building corals - non-technical
summaries of the distinguishing features of all species, genera and
families - information about the colours, habitats and abundances of
all species - references to taxonomic detail and regional field guides
- chapters on &#039;what are species?&#039;, evolution, biogeography,
the fossil record, coral reefs, the structure of corals, reproduction
and the history of coral studies; (6) reproduction and dispersal - the
reproduction and dispersal mechanisms of corals - how reproduction and
dispersal relate to biogeographic and evolutionary issues; (7)
structure - a non-technical account of coral morphology - a glossary
explains all terminology; (8) geological history - an account of the
&#039;big picture&#039; of evolutionary change; (9) evolution - the
mechanisms which control the origin and evolutionary change in species
- an original concept of &#039;reticulate&#039; evolution which
integrates the information and observations presented throughout the
book.^1";
s[5492] = "FEINSTEIN N., CAIRNS S.D. (1998).- Learning from the
collector: a survey of azooxanthellate corals affixed by Xenophora
(Gastropoda: Xenophoridae), with an analysis and discussion of
attachment patterns.- Nautilus 112, 3: 73-83.- <b>FC&#038;P 29-1</b>,
p. 39, ID=7017^<b>Topic(s): </b>; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^All species
of the gastropod family Xenophoridae affix foreign objects to the upper
shell surface. Affixed objects may include bivalve shells, smaller
gastropod shells, shell fragments, and coral skeletons, as well as a
wide array of inorganic material. In deep water, Xenophora may serve as
useful proxy collectors of benthic organisms. Since 1842, coral
skeletons have been noted among the attached objects, but this
association has never been studied in detail. This paper surveys 227
Xenophora shells, comprising 8 species from 69 stations, for affixed
azooxanthellate corals. Five hundred and eighty-one coralla were found,
representing 74 coral species, 2 of which remain undescribed.
Twenty-four of the affixed coralla were alive at the time the Xenophora
hosts were collected; Xenophora not only collect the corals, but corals
can remain alive long after being affixed. Corals were found at 6 sites
where they had previously been unknown, and the geographic ranges of 29
species of coral were expanded as a result of specimens found on
Xenophora. * This paper has two sections. In the first, quantitative
observations were made on the orientation of affixed corals;
statistical analysis of these observations revealed non-random patterns
of attachment, based on orientation of both the long axis of the coral
and the coral calice. Qualitative observations suggest that species of
Xenophora favor corals of particular shapes. In the second section, the
speculations of previous authors regarding the ecological basis for
attachment behavior are summarized and new theories are discussed. Four
of these explanations suggest defensive adaptations, and the remaining
3 are functional support adaptations. Three of these hypotheses (armor,
tactile camouflage, and snow-shoeing) are proposed for the first rime
in this paper. [original abstract]^1";

ID=7244^<b>Topic(s): </b>mucus, energy carrier; corals; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Zooxanthellae, endosymbiontic algae of reef-building corals,
substantially contribute to the high gross primary production of coral
reefs, but corals exude up to half of the carbon assimilated by their
zooxanthellae as mucus. Here we show that released coral mucus
efficiently traps organic matter from the water column and rapidly
carries energy and nutrients to the reef lagoon sediment, which acts as
a biocatalytic mineralizing filter. In the Great Barrier Reef, the
dominant genus of hard corals, Acropora, exudes up to 4.8 litres of
mucus per square metre of reef area per day. Between 56% and 80% of
this mucus dissolves in the reef water, which is filtered through the
lagoon sands. Here, coral mucus is degraded at a turnover rate of at
least 7% per hour. Detached undissolved mucus traps suspended
particles, increasing its initial organic carbon and nitrogen content
by three orders of magnitude within 2 h. Tidal currents concentrate
these mucus aggregates into lagoon, where they rapidly settle. Coral
mucus provides light energy harvested by zooxanthellae and trapped
particles to the heterotrophic reef community, thereby establishing a
recycling loop that supports benthic life, while reducing loss of
energy and nutrients from the reef ecosystem. [original abstract]^1";
s[5495] = "OPRESKO D.M. (2004).- Revision of the Antipatharia
(Cnidaria: Anthozoa). Part IV. Aphanipathidae.- Zoologische
Mededelingen 78: 209-240.- <b>FC&#038;P 33-2</b>, p. 40,
ID=1184^<b>Topic(s): </b>systematics; Antipatharia; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^A new family of antipatharian corals, Aphanipathidae (Cnidaria:
Anthozoa: Antipatharia), is established for Aphanipathes sarothamnoides
Brook and related species. The family is characterized by tall, conical
to acicular to cylindrical spines, which can be smooth, papillose or
covered with small, conical tubercles, and by polyps that are 0.5–2.5
mm in transverse diameter and have small, subequal tentacles. The
family is divided into two subfamilies based on differencies in the
development of the polypar spines. In the Aphanipathinae the polypar
spines are subequal. Genera are recognized on the basis of
morphological features of the corallum. Aphanipathes Brook (type
species A. sarothamnoides Brook) has a sparsely to densely branched
corallum with straight, usually ascending, branchlets. Phanopathes gen.
nov. (type species Antipathes expansa Opresko &#038; Cairns) forms
fan-shaped colonies with short, bilateral branchlets. Pteridopathes,
gen. nov. (type species P. pinnata sp.nov.) has simple pinnules
arranged in two rows. Tetrapathes gen. nov. (type species Aphanipathes
alata Brook) has simple pinnules arranged in four rows, and
Asteriopathes gen. nov. (type species A. arachniformis sp.nov.) has
simple pinnules arranged in six or more rows. In the Acanthopathinae
the circumpolypar spines are considerably enlarged and the hypostomal
spines are usually reduced or absent. As in the Aphanipathinae, genera
are recognized on the basis of morphological features of the corallum.
Acanthopathes gen. nov. (type species Antipathes humilis Pourtales)
forms candelabra and flabellate colonies and has reduced hypostomal
spines. Rhipidopathes Milne Edwards and Haime (type species Antipathes
reticulata Esper), forms flabellate colonies and has hypostomal spines
that are not always reduced in size. Distichopathes gen. nov. (type
species D. disticha sp.nov.) has simple, straight pinnules arranged in
two rows, and Elatopathes gen. nov. (type species Antipathes abietina
Pourtales) has simple pinnules arranged in four or more rows.^1";

polyps elongated in the direction of the axis and having a transverse
diameter of 2 mm or more. Genera are recognized on the basis of
morphological features of the corallum. Schizopathes Brook (type
species S. crassa Brook) has a simple, pinnate corallum with a
hook-like holdfast for support in soft sediments. Bathypathes Brook
(type species B. patula Brook) is characterized by a simple pinnate
corallum and a flat discoidal basal plate for attaching to a solid
substrate. Parantipathes Brook (type species Antipathes larix Esper)
has a largely monopodial corallum with simple pinnules in six or more
rows. Taxipathes Brook (type species T. recta Brook) has a branched
corallum and simple pinnules in four to eight rows. Lillipathes gen.
nov. (type species Antipathes lilliei Totton) has simple pinnules in
four rows. Stauropathes, gen. nov. (type species S. staurocrada spec.
nov.) is branched with simple, bilateral, subopposite pinnules.
Abyssopathes, gen. nov. (type species Bathypathes lyra Brook) is
monopodial with two rows of simple, lateral pinnules and one (sometimes
multiple) row of simple or branched anterior pinnules.
Dendrobathypathes gen. nov. (type species D. grandis spec. nov.) has a
branched, planar corallum with two rows of subpinnulated primary
pinnules. Saropathes gen. nov. (type species Bathypathes scoparia
Totton) is monopodial to sparsely branched, with four rows of
subpinnulated primary pinnules.^1";

Anthozoa: Antipatharia) is revised. The family is characterized by
```

```
polyps 2mm or more in transverse diameter, six primary mesenteries, and no secondary mesenteries. The family is divided into three subfamilies: Cladopathinae Kinoshita, Hexapathinae subfam. nov. and Sibopathinae subfam. nov. The subfamily Cladopathinae is characterized by a branched pinnulate corallum with three or more rows of primary pinnules, some of which are subpinnulate. Included in the subfamily are the genera Cladopathes Brook (C. plumosa Brook, 1889), Chrysopathes gen. nov. (C. formosa spec. nov. and C. speciosa spec. nov.) and Trissopathes gen. nov. [T. pseudotristicha spec. nov., T. tetracrada spec. nov., and T. tristicha (van Pesch, 1914)]. The subfamily Hexapathinae is characterized by a monopodial or sparsely branched pinnulate corallum, with two rows of simple lateral primary pinnules and one or more rows of simple or subpinnulate anterior primary pinnules. Included in the subfamily are the genera Hexapathes Kinoshita, 1910 and Heliopathes gen. nov. Hexapathes contains the type species H. heterosticha Kinoshita, 1910, as well as H. australiensis spec. nov. Heliopathes contains the type species H. americana, spec. nov. and Antipathes heterorhodzos Cooper, 1909. The subfamily Sibopathinae van Pesch is defined by the absence of an actinopharynx. Species in the single genus Sibopathes [type species S. gephura van Pesch, 1914, and including S. macrospina Opresko, 1993] possess a branched corallum with four to six rows of simple pinnules. [original abstract]^1";

The family is characterized by small polyps, 1.5 mm or less in transverse diameter; small, conical, smooth spines, often distally directed (especially at the tips of the branchlets and/or pinnules); and by the tendency for the pinnules and branchlets to occur in subopposite pairs or to be arranged in verticils of three or four (rarely five) pinnules. In many species adjacent pinnules or branchlets fuse together or anastomose, resulting in the formation of cylindrical, reticulated worm runs along the stem or branches. Genera are established on the basis of morphological features of the corallum. Stylopathes gen. nov., includes the type species, Arachnopathes columnaris Duchassaing, and is characterized by a monopodial or very sparsely branched corallum. Triadopathes gen. nov. contains only the type species Parantipathes triadocrada Opresko, and has multiple, vertically directed, stem-like primary branches, arising primarily from the lower parts of the corallum. Tylopathes Brook contains the type species T. crispa Brook, and is characterized by a flagellate corallum with short, mostly bilateral branchlets.^1";

fractionation in marine aragonite of coralline sponges.- Geochimica et
Cosmochimica Acta 64, 10: 1695-1703.- <b>FC&#038;P 31-1</b>, p. 70,
ID=1646^<b>Topic(s): </b>oxygen isotopes; Porifera coralline sponges;
<b>Systematics: </b>Porifera; Corallina; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Oxygen isotope values of the extant Caribbean
coralline sponge Ceratoporella nicholsoni are compared with published
temperatures and &#948;18O of water calculated from salinities. The
measured values from aragonitic sponge skeletons have a mean offset of
1.0 ± 0.1‰ from calculated calcite equilibrium values
(&#945;_aragonite-calcite = 1.0010). This is in good agreement with
published values from synthetic aragonite. They further agree with
published near-equilibrium oxygen isotope values of temperate and cold
water molluscs and foraminifera extrapolated to the temperature range
of the coralline sponges. These results and the mode of skeleton
formation of Ceratoporella nicholsoni suggest that these sponges
precipitate aragonite close to isotopic equilibrium. * The temperature
dependence of oxygen isotopic fractionation between the aragonite of
Ceratoporella nicholsoni and water is only roughly constrained by the
available data, due to the narrow temperature range of the Caribbean
reef sites. However, as the data suggest oxygen isotopic equilibrium,
we can calculate a well constrained temperature equation combining
temperate and cold water equilibrium values from molluscs and
foraminifera with our sponge data: 103ln&#945;_aragonite-water =
(18.45±0.4)*103/T(K)-(32.54±1.5) and T (°C) =
(20.0±0.2)-(4.42±0.10)*(&#948;_a-&#948;_w); for 3°<T< 28°. [original

(Acanthochaetetes) wellsi (Demospongiae, Porifera).- Facies 34, 1:
193-208.- <b>FC&#038;P 25-1</b>, p. 46, ID=3055^<b>Topic(s):
</b>skeletogenesis; Porifera, Demospongiae, Spirastrella;
<b>Systematics: </b>Porifera; Demospongiae; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The modern hadromerid coralline sponge
Spirastrella (Acanthochaetetes) wellsi exhibits a unique secondary
high-Mg calcite (&#60; 19 mol % MgCO3) basal skeleton. The basal
skeleton is constructed of bundles of elongated crystals more or less
tangentially orientated. The initial formation of these crystals is
controlled by soluble highly acidic aspartic and glutamic-rich (40%)
macromolecules. The skeletal mineralization occurs in four different
loci: in the top of the calicles, at the tabulae, on collagenous anchor
fibres, and within closed spaces between the tabulae. The calicle walls
are formed on the uppermost top of the basal skeleton as a continous
process. Based on long term stainings with Ca2+-chelating fluorochroms
(calein, chlorotetracyclines) the growth rate of this sponge is
extremely low with ca. 50-100µm/a. The skeletal formation takes places
outside the sponge, within a narrow zone (300-500 mm) between the
basopinacoderm and the mature basal skeleton. The sponge produces
thread-like folded templates (&#039;spaghetti fibres&#039;) of 0,5-2 µm
```

```
size, the shape controlling insoluble organic matrix. These templates
become mineralized in a first step as MgCO3, then are stretched. A
soluble organic matrix is also secreted, and remains are included
inside the mineralized skeleton. This organic matrix consists of in a
complex mixture containing small very acidic proteins (5, 13, 31 KD;
40% Asp and Glu and therefore most probably Ca2+ -binding) and high
molecular weight glycoproteins among several other organic compounds.
The mature crystals arc high-Mg calcites. During calcification large
cells with large reserve granules (LCG) are always present in a tight
connection with the basopinacoderm. These cells form also the
collagenous anchor fibres. Primary tabulae are formed by a
non-collagenous organic sheet. Calcification happens only when LCG
cells are enriched on the organic sheet. Randomly oriented high-Mg
calcite crystals are growing on the collagenous anchor fibres. The same
type of the mineralization is observed within the spaces of the
tabulae. This particular case of mineralization is controlled by
decaying sponge tissue (ammonification). The d13C values are in
equilibrium with the ambient sea water and vary between +3.2 and
+2.8%O. The mode of mineralization of the basal skeleton can be
described as biologically induced resp. matrix mediated.^1";

tissue organization of Farrea occa has been examined by light
microscopy, transmission electron microscopy (TEM), and scanning
electron microscopy (SEM). It was found to agree closely with the
hexactinellid model established for Rhabdocalyptus dawsoni by Mackie
and Singla (1983) in consisting of a thin general syncytium
incorporating few discrete cellular components, several of which share
membrane continuity with the general syncytium by distinctive plug
junctions. The general syncytium, supported by a thin collagenous
```

```
mesolamella, is specialized regionally as dermal membrane, gastral
membrane, peripheral trabecular strands, and primary reticulum (R1) of
flagellated chambers. Extensions of the syncytium, which lack
mesolamella support, form the distinctive secondary reticulum (R2)
inside chambers and a newly discovered structure, the &#34;inner
membrane&#34;, which occupies the central region of flagellated
chambers. The choanosyncytia are enucleate networks of collar bodies
and stolons embedded in R1 and plugged into R1 and choanoblasts. The
discrete cell population consists of choanoblasts and archeocytes
located in the thin mesohyle space and plugged to syncytial elements,
cystencytes and vacuolar cells also located in the mesohyle bur lacking
plug connections, and granular cell emergent on R1 and apparently not
bearing plug connections. The status of scleroblast syncytia has not
been solved. Large populations of rod-shaped bacteria occupy the
mesohyle space; intraceilular ovoid bodies, possible symbiontic
prokaryotes, are common in R1 and R2. The previously unknown inner
membrane probably functions to control flagellar activity on a very
localized scale and to accumulate and release egesta in packages.^1";

</b>Recent; <b>Geography: </b>^The current data concerning Corallium
rubrum Linne 1758 allowed to identify a skeletal mineralization mode by
ectodermal secretion of independent units. These elements later
amalgamate by adjunction of calcitic cement. This growth process
extended to all Corallidae contrasts with the regular secretion of
fibro-crystals observed among the other Cnidarians. The analysis of
Corallium johnsoni Gray 1860 proves that this interpretation can not be
applied in every case. Indeed, the axial skeleton of this less common
Corallidae shows two successive mineralization stages: the first one,
brief and fibrous and the second one, most important, composed of
radial cylindrical units associated with groups of lamellar elements.^1";

sediment from coral branches than barrels with windows, and dead coral
produced more sediment than live coral. Tumbled dead coral produced a
gravel mode (2-4 mm) of fragmented barnacles and a sand mode (0.2 mm)
of coral. Tumbled live coral produced similar results but lacked
barnacles. Time series tests of 1-1000 min. showed that closed barrels
produced uncreasingly greater percentages of carbonate mud and
increasingly finer sand grain-size modes. Tumbling barrels with screen
windows yielded particles of unchanging size through the same
intervals. Natural sediment with broken coral branches contained coral
sand most abundantly between 0.125-0.250 mm, which is the same as
produce: by tumbling dead coral in barrels with screen windows. Strong
grain -size modes at 0.2 mm produced by sonification and tumbling of
live and dead coral and sealed and screen-window barrels support the
Sorby Principle of skeletal breakdown. (Original abstract)^1";

s[5526] = "SWART P.K. (1983).- Carbon and oxygen isotope fractionations in Scleractinian corals.- Earth Science Reviews 19: 51-80.- <b>FC&#038;P 13-1</b>, p. 23, ID=0400^<b>Topic(s): </b>stable isotopes, C O; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^The present theories on the fractionation of stable isotopes in scleractinian corals are critically discussed in the light of data available on primary productivity, respiration and stable isotope chemistry. These data support a model of fractionation in which the carbon and oxygen isotopes are decoupled. Calcification occurs from a reservoir of carbon dioxide derived from both organic and inorganic sources. Photosynthesis preferentially fixes 12C and thereby leaves behind 13C. Increases in the rate of photosynthesis therefore also enrich the carbon isotope ratio of the skeleton.From theoretical considerations, photosynthesis has little effect on the oxygen isotope ratio of the skeleton, a fact confirmed by available data. The process of respiration adds depleted carbon and oxygen to the calcification reservoirs. The varying correlations between carbon and oxygen isotopes seen in hermatypic corals are caused by changes in the relationship between photosynthesis and respiration at different geographical localities. The isotopic compositions in the skeletons of non-zooxanthellate corals, which show a consistent positive correlation, can also be explained by the above scenario. (Original summary)^1";

Porosity, compressive and bending strength, elastic modulus and resistance to abrasion were measured in the reef-inhabiting colonial dendrophylliids Tubastraea micranthus and T. aurea and in the acroporids Acropora palmata and A. cervicornis. Dendrophylliids are devoid of zooxanthellae, acroporids possess zooxanthellae and are well recognized reef-builders. The mechanical properties of T. micranthus colonies, collected in Philippine reefs, equal or even surpass those of the acroporids, which rank at the high-strength end of the porosity/strength continuum. Skeletal strength and colony form set out T. micranthus as a primary framework-builder (sensu Goreau 1963), corroborating field observations on Philippine reefs. Therefore the conventional affiliation of T. micranthus to the &#039;ahermatypic&#039; category (sensu Wells 1933) is not functionally correct. The respective data of T. aurea, however, show that this species has little significance as a reef-builder.^1";

morphology of coral shape and passive hydrodynamic self-righting in
recent Manicina areolata.- Senckenbergiana lethaea 82, 1: 125-130.-
<b>FC&#038;P 31-2</b>, p. 48, ID=1701^<b>Topic(s): </b>physiology;
Scleractinia, Manicina; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^The scleractinian
Manicina areolata is a common coral on Carribean hard and soft
substrata and was studied at Lee Stocking Island (Exuma Cays, Bahamas).
It is not only found in reefal areas but also in bioclastic sand with
seagrasses. The meandroid coralla typically grow to sizes of 2 to 10 cm
and are morphological variable. Growth form can vary from conical with
round to oval cross-section to turbinate forms with few meanders and
flat oval cross-section. The conical morphotype is usually attached to
hard substratum, while the turbinate morphotype tends to live
unattached, usually upright, in soft substatum. In infratidal areas,
both attached and unattached turbinate forms were found in close
vicinity, however, conical attached froms were rare.Habitats with sandy
softgrounds, where free-living turbinate morphotypes were common, were
influenced by strong tidal currents with concurrent danger of burial or
&#39;disorientation&#39; of the coralla. Therefore, strategies are
necessary for the coral to remain in the upright position. Besides a
high self-cleaning potential (Fabricius 1964), the colony shape itself
leads to passive cleaning and self-righting, which is achieved by the
flat-turbinate morphology of the corallum, with a concave side and a
flat to slightly convex opposite side, under high current speeds. The
concave side, and particularly the median lobes formed by many
meandroid coralla, are the critical morphological factors. Particularly
the grooves formed inbetween the lobes channel currents in a way that
scour underneath the coral and drag produced by the lobes act together
to allow passive self-righting.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The phylogenetic relationships of the
scleractinian genus Psammocora with the other genera traditionally
included in the family Siderastreidae and some Fungiidae are assessed
based on combined skeletal and molecular data. P. explanulata differs
from the other examined congeneric species (P. contigua, P. digitata,
P. nierstraszi, P. profundacella, P. superficialis, and P. stellata) in
possessing interstomatous septa between adult corallites, costae, and
```

```
in having continuous buttress-like structures joining septal faces
(i.e., fulturae) which typically occur in fungiids. These characters
are shared with Coscinaraea wellsi but not with the remainder of the
examined siderastreids (the congeneric C. columna, and Anomastraea
irregularis, Horastrea indica, Pseudosiderastrea tayamai, Siderastrea
savignyana) whose septa are interconnected by typical synapticulae.
Most of the examined species form septa with distinct transverse groups
of centers of calcification, a biomineralization pattern typical of the
Robusta clade. The observations on skeletal structures corroborate the
results of the ITS2 and 5.8S molecular phylogeny. C. wellsi and P.
explanulata are phylogenetically very close to each other and show
closer genetic affinity with the examined Fungiidae (Halomitra pileus,
Herpolitha limax, Fungia paumotensis, and Podabacia crustacea) than
with the other species in the genera Psammocora and Coscinaraea, or
with any other siderastreid. Our results show that neither Psammocora
nor Coscinaraea are monophyletic genera. The high genetic distances
between the species of Siderastreidae, especially between
Pseudosiderastrea tayamai and Siderastrea savignyana on one side and
the other genera on the other, suggest a deep divergence in the
phylogenetic structure of the family.^1";

Environmental controls on corallite morphology in the reef coral
Montastraea annularis.- Bulletin of Marine Science 80, 135/75 :
233-260.- <b>FC&#038;P 35</b>, p. 75, ID=2386^<b>Topic(s):
</b>variability; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Scleractinian reef-coral species display high phenotypic
plasticity in skeletal morphology. Understanding environmental and
physiologic controls on this variation is essential to explaining the
distribution and abundance of coral species as well as understanding
their susceptibility to pollution and global climate change. Here we
assess phenotypic plasticity in the corallite morphology of genetically
determined colonies of Montastraea annularis s.s. (Ellis and Solander,
1786) by analyzing the three-dimensional morphology of calical surfaces
and the two-dimensional corallite morphology represented in transverse
thin sections. Samples were collected along gradients of seawater depth
and coastal influence on the island of Curacao, Netherlands Antilles,
and additionally compared to M. annularis and two closely related
species, M. franksi (Gregory, 1895), and M. faveolata (Ellis and
Solander, 1786), collected from Panama. Significant phenotypic
plasticity was found between seawater depths and localities of Curacao,
as well as between the two geographic regions. Morphologic characters
associated with calical surfaces were significantly more plastic than
characters preserved in transverse thin sections. While characters
preserved in thin section were more successful at classifying the three
closely related species, characters associated with calical surfaces
provide a basis for interpreting the adaptive significance of the
observed differences between these three species. [original abstract]^1";

High resolution synchrotron radiation studies on natural and thermally
annealed scleractinian coral biominerals.- Journal of Applied
Crystallography 40, 1: 2-9.- <b>FC&#038;P 35</b>, p. 116,
ID=2453^<b>Topic(s): </b>aragonite, calcite; Scleractinia, mineralogy;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The structural phase transition from
aragonite to calcite in biogenic samples extracted from the skeletons
of selected scleractinian corals has been studied by synchrotron
radiation diffraction. Biogenic aragonite samples were extracted en
bloc without pulverization from two ecologically different
scleractinian taxa: Desmophyllum (deep-water, solitary and
azooxanthellate) and Favia (shallow water, colonial, zooxanthellate).
It was found that natural (not pulverized) samples contribute to narrow
Bragg peaks with ? d/d values as low as 1 x 10-3 which allows the
```

```
exploitation of the high resolution of synchrotron radiation
diffraction. A precise determination of the lattice parameters of
biogenic scleractinian coral aragonite shows the same type of changes
of the a, b, c lattice parameter ratios as that reported for aragonite
extracted from other invertebrates [Pokroy, Quintana, Caspi, Berner
&#038; Zolotoyabko (2004). Nat. Mater. 3, 900-902]. It is believed that
the crystal structure of biogenic samples is influenced by interactions
with organic molecules that are initially present in the
biomineralization hydrogel. The calcite phase obtained by annealing the
coral samples has a considerably different unit-cell volume and lattice
parameter ratio c/a as compared with reference geological calcite and
annealed synthetic aragonite. The internal strain in the calcite
structure obtained by thermal annealing of the biomineral samples is
about two times larger than that found in the natural aragonite
structure. This effect is observed despite slow heating and cooling of
the sample.^1";

<b>Stratigraphy: </b>Recent; <b>Geography: </b>^In Espers Werk &#34;Die
Pflanzenthiere&#34; (Bibliographie s. Grasshoff &#038; Scheer, 1991)
stellen die Steinkorallen mit 74 abgehandelten Arten einen gewichtigen
Teil dar. In Verbindung mit der Sammlung, die jetzt im
Senckenberg-Museum aufbewahrt wird, wurden diese Arten kritisch
ueberpruft. Zum grossen Teil waren sie anhand der guten Abbildungen
schon in der bisherigen Literatur unstrittig und klar identifiziert,
fur eine ganze Reihe jedoch erbrachte die jetzige Ueberpruefung erst
eine Klarung. Nur wenige, namlich 8 Arten, mussen auch heute noch als
nicht gedeutet oder aus anderen Grunden als nomina dubia gelten. Esper
stellte alle Steinkorallen zu der Gattung Madrepora. Wegen der durch
die Septen sternformig gekammerten Kelchoffnungen nannte er sie
&#34;Sternkorallen&#34;, ein Name, der spaeter kaum mehr benutzt und
ganzlich durch &#34;Steinkorallen&#34; ersetzt wurde. Wie auch bei
anderen der damaligen Gattungen (Esper nannte sie &#34;Geschlecht&#34;,
die Art nannte er &#34;Gattung&#34;) waren die Zuordnungen nicht immer
klar, zwei Steinkorallen-Arten behandelte Esper unter Millepora, und 5
von ihm zu Madrepora gestellten Arten sind keine Steinkorallen. Esper
hat in der Gattung Madrepora 72 Arten beschrieben und auf 100 Tafeln
abgebildet, zwei weitere Steinkorallen-Arten behandelt er unter
Millepora, namlich Millepora Nr. 5 und 11, hier im systematischen Teil
die Nr. [73] und [74]. Von diesen 74 Arten sind 25 Erstbeschreibungen,
davon sind nach heutiger Kenntnis neun Arten Synonyme und drei nomina
dubia. Funf Arten sind keine Steinkorallen, Espers Nummern 15, 30, 34,
45, und eine bei Esper ohne Nummer, hier Nr. [72]; insgesamt sind somit
in Espers Werk 69 Steinkorallen Arten (darunter eine fossile) behandelt
und auf 97 Tafeln in 121 Exemplaren abgebildet. [part of original
introduction]^1";

s[5542] = "BUDD A.F. (1993).- Variation within and among morphospecies of Montastraea.- Courier Forschungsinstitut Senckenberg 164: 241-254. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 18, ID=3459^<b>Topic(s): </b>variation; Scleractinia, Montastraea; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Morphometric data for two commonly known living &#34;species&#34; of Montastraea are reanalyzed using cluster and canonical discriminant analysis to search for morphologic discontinuities that could correspond with morphotypes recently recognized by neontologists on the basis of behavioral and electrophoretic evidence. The samples were collected at four environmentally distinct reef habitats near Discovery Bay, Jamaica. The characters consist of linear distances and counts made on several corallites within each colony. Despite the lack of polymodality in univariate histograms, the multivariate results show two distinct morphs in M. &#34;annularis&#34; and three in M. &#34;cavernosa&#34;. The character complexes which best distinguish these morphs are closely associated with corallite size and spacing and with number of septa, and are also found to vary among &#34;species&#34; and among habitats within morphs. When environmental variation is examined separately within each morph, patterns emerge which are more consistent with variation in environmental factors than those found in previous research, and thus offer added promise for the use of skeletal morphology in interpreting past environments. Patterns of environmental variation within morphs of the same &#34;species&#34; are similar, although different complexes may be involved within morphs of different &#34;species&#34;, due to differences in nutritional energetics. As shown using the Neogene species M. limbata as an example, similar patterns can be used to detect relative differences in sedimentation and light intensity among habitats.^1";
s[5543] = "HOEKSEMA B.W. (1993).- Phenotypic corallum variability in Recent mobile reef corals.- Courier Forschungsinstitut Senckenberg 164: 263-272. [P. Oekentorp-Kuster (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1].-
```

```
<b>FC&#038;P 22-2</b>, p. 19, ID=3461^<b>Topic(s): </b>variability,
mobile forms; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Among free-living reef
corals a distinction is made between those that are loose and
potentially mobile, and those that live partly buried in soft
substratum, here defined as &#34;semi-buried&#34;. A coral may become
loose by (1) detachment from its substratum or by clonopary; (2)
fragmentation by autotomy or traumatic breakage; (3) overgrowing its
substratum. Most reef corals programmed to become loose are able to
exhume and to right themselves, and to disperse over the bottom. The
phenotypic corallum variability of mobile species is related to their
(1) developmental history, (2) fission and fusion, and (3) habitat.
Environmental parameters that may affect corallum shape are (1) light
intensity, (2) sedimentation, and (3) turbulence; this may be reflected
in (1) corallum convexity, (2) thickness, (3) number of mouths, and (4)
coarseness of septocostal ornamentation. Some ecophenotypes may have
adaptive significance with regard to sediment-shedding and mobility.^1";

</b>feeding strategies; Scleractinia, Leptoseris; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^The organization of the zooxantellate scleractinian coral
Leptoseris fragilis was studied. The architecture of the corallite and
the histology of the polyparium were analysed for adaptations that
enable efficient capture and retention of suspended particles which
would increase energy supply. The data indicate that the gastrovascular
system of L. fragilis is not a blind but a flow-through system. Water
entering the coelenteron through the mouth leaves the body not only
through the mouth but also through microscopic pores (D 1-2 gm) which
are located near the crest of the sclerosepta in the oral epithelia.
Irrigation is achieved by flagellar and probably also by muscular
activity. This type of filtration enables L. fragilis, which lacks
tentacles, to utilize suspended organic material including bacteria.
The supposed suspension feeding in combination with effective
photoadaptations (presented in former communications) seems to be the
basis for the survival of L. fragilis in an extreme habitat (between
-95 and -145m) and for its successful competion with other
scleractinian species provided with larger catching surfaces, and with
other invertebrates depending on filter feeding.^1";

Gardineria; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^The basic architecture
(Bauplan) and microstructure of the skeleton of Recent Gardineria are
noticeably different from those of most other modern scleractinians.
The wall of the Gardineria skeleton is entirely epithecate
(non-trabecular), while in the majority of modern Scleractinia the
epitheca is either absent or added to the main wall which usually is of
```

```
trabecular nature. These different patterns of theca formation reflect significant anatomical differences in the peripheral parts of the polyp. The Bauplan of Gardineria pattern, exceptional in the modern scleractinian fauna, was widespread among early Mesozoic corals, particularly among the Triassic protoheterastraeids. Similar skeletons also occur in some late Palaeozoic rugosans (e.g., polycoeliids). Zardinophyllum zardini, an aberrant Triassic scleractinian coral, with a supposed rugosan septal insertion, supports the hypothesis of the rugosan origin of the Scleractinia. [original abstract]^1";
s[5548] = "SCHLICHTER D., CONRADY S., KAMPMANN H., KLUTER A., KRISCH H., KUHRAU M.L., ZSCHARNACK B., (1996).- Carbonate Production of Scleractinians in Dependence upon the Availability of Food and the Trophic Potential of Endolithic Algae.- Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ... .- <b>FC&#038;P 26-1</b>, p. 28, ID=3576^<b>Topic(s): </b>carbonate production; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^The nutrition and the growth of zooxanthellate, hermatypic Scleractinians in the Gulf of Aqaba was studied. Growth rates of entire colonies are species-specific and depend upon water depth. Annual skeletal mass increment correlates best with the seasonally changing light regime (photosynthesis by the zooxanthellae). The supply with particulate food (seston, sediment) during the year has no marked effect on carbonate production. Zooxanthellae of different origin (various species, different depths) showed photoadaptations toward light limitation. However, the zooxanthellae of two species studied showed no genetic heterogeneity (enzyme electrophoresis). Thus the different photosynthetic features base on phenotypic plasticity. Adaptations improving phototrophic and heterotrophic food supply were detected. The biomass, the pigmentation, the spectrum of assimilates and the productivity of endolitbic green algae was studied. The productivity is low and reaches 3-8% of that of the zooxanthellae under corresponding light coniditons. The utilization of endolithic photoassimilates by the coral&#039;s metabolism could be proven. Endolithic algae are - like zooxanthellae - involved in recycling processes within the reefal food web. Although the annual availability of light for scleractinians in the Gulf of Aqaba is considerably reduced in comparison to low latitude reefs, the corals show luxurious growth. Besides a multitude of other factors, the luxurious growth could speculatively be due to a lack of temperature stress.^1";
s[5549] = "GAUTRET P., CUIF J.-P., FREIWALD A. (1997).- Composition of Soluble Mineralizing Matrices in Zooxanthellate and Non-zooxanthellate Scleractinian Corals: Biochemical Assessment of Photosynthetic Metabolism through the Study of a Skeletal Feature.- Facies 36, 1: 189-194.- <b>FC&#038;P 26-1</b>, p. 84, ID=3656^<b>Topic(s): </b>mineralizing matrices; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Soluble organic matrices extracted from aragonitic skeletons produced by recent zooxanthellate and non-zooxanthellate scleractinian corals were studied after suitable hydrolyses, by FIPLC chromatographies allowing characterization of their amino acid and monasaccharide compositions. Clear compositional differences can be correlated with the symbiotic or non-symbiotic character in both proteic (via Asp, Glu, Ala and Ser) and glucidic phases of soluble matrices (via GalN, GlcN and Gal), providing new criteria to assess the impact of photosynthetic metabolism on skeletal features of scleractinian corals.^1";

```

```
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Morphological, histological and behavioral features indicate that
Mycedium elephantotus, a zooxanthellate scleractinian species without
tentacles, is well adapted for utilizing suspended organic matter for
nutrition. The colonies are composed of vertically growing fan-like
plates and can reach diameters of more than 1 m in depths below 20 m.
The external body surface is coated with a mucus layer (cuticle) which
enables the acquisition and accumulation of suspended organic material.
The mucus-entagled particles pass to the mouth openings by
gravitational transport assisted by water movement. In experiments the
corals were able to discriminate between suspended food and mineral
particles. Both types of particles were rapidly entangled in fine mucus
nets or filaments. Mineral particles were never ingested and instead
tumbled down the inclined skeletal plates. In contrast, food particles
were actively incorporated when the mucus filaments accidentally
touched the stomodaea during the downward gliding. The food-enriched
mucus filaments were either transported by ciliary activity into the
coelenteron or were sucked into the body cavities by decreasing
pressure in the coelenteron caused by contraciton of longitudinal,
mesenterial muscles. The discriminative reactions to mineral or food
particles are probably based on the release of different types of
mucus. Nematocysts are infrequent in the oral epidermis, indicating
that the capture of living prey plays a subordinate role in nutrition.
The mesenterial filaments, in contrast, are densely packed with large
nematocysts. Storage products were piled up within the tissues of
gastral pockets. The adaptations of Mycedium elephantotus for using
suspended food particles may explain the particularly high abundance of
this species between ca. 20 and 40 m depth on a steeply inclined
fore-reef slope in the Gulf of Aqaba (Red Sea). The evidence indicating
the importance of heterotrophic fueling to M. elephantotus is supported
by carbonate production rates which are, in contrast to that of many
other zooxanthellate scleractinian species, almost constant at depths
between 5 and 40 m and which are uneffected by varying light regimes
over the year, suggesting that the reduced phototrophic contribution by
the zooxanthellae is compensated by mucus suspension feeding.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^After introductory remarks on the
solitary coral genera Heterocyathus and Heteropsammia, commonly known
to be symbiotic with a sipunculan inhabiting a gastropod shell,
Heterocyathus japonicus is redescribed in detail. It occurs from Taiwan
to northern Honshu, Japan. It is the first of these symbiotic corals to
be found in association with an alternative partner, living specimens
of the large scaphopod Fissidentalium vernedei. The coral always
occupies the apical end of the shell, the part that protrudes from the
sediment. It is thus preserved from being buried and is maintained in
an upright position (the same advantages it also gets when its partner
is a sipunculan). On live F. vernedei, H. japonicus incrusts a
manganese rich black mineral coating that characterizes the exposed,
apical part of the shell. It is speculated about which factors may
cause coral larvae to associate with the partner (sipunculan squatting
a shell, scaphopod in its own shell).^1";

recent scleractinian corals: a key to palaeoenvironmental
reconstruction.- Geol. Rundschau 61, 2: 598-626.- <b>FC&#038;P 2-1</b>,
p. 14, ID=4712^<b>Topic(s): </b>sediment rejection; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^26 of the 59 living species of
scleractinian corals found in Western Atlantic and Caribbean waters,
less than 68 meters deep, and two fungiid genera from the Pacific, are
analysed in terms of their behaviour, sediment rejecting properties,
functional, morphology and distribution patterns. The contrasting
behaviour and Skeletal structure of the two solitary fungiids provides
evidence for the construction of a theoretical mechanical model which
is applied to the subsequent interpretation of the more complex
colonial reef corals from the Atlantic province. Regional distribution
patterns, growth forms and calical orientations of the Atlantic species
and their associated sediment types were noted in dives across
transects in extreme environments in the Caribbean. Representative
samples were then selected from the five functional ecological niches
in the Florida keys, and subjected to inundations of sized and painted
carbonate sand particles in the laboratory. The coral was filmed before
the sedimentary influx, on impact and during rejection. The skeletons
were then extracted and dissected to construct a mechanical model
compatible with their behavioural functions. There are four means of
sediment rejection: distension by the stomodeal up-take of water,
tentacular action, ciliary beat, and mucus entanglement. Differences in
sediment rejection are ascribed to two factors (1) variations in the
polyps distensional capacity, and (2) the geometry of the calice. A
theoretical model of characteristic scleractinian distribution patterns
on an Atlantic patch reef mirrors regional distribution patterns. The
sediment rejecting experiments are used as additional evidence for
interpreting other behavioural activities of greater consequence e.g.
food gathering and the removal of excrement. Theoretical models are
described for the relationship of calical form to polypal function and
calical orientation to distribution patterns on the corallum; and also
variations in growth form. Ecological distributions, in local patch
reef and regional occurrences, are outlined in terms of the recent
scleractinian corals of the Atlantic province. These models are tested
against some rugose and tabulate coral distributions in the Irish
Carboniferous.^1";

</b>^The calcification processes of the cool temperate coral
Balanophyllia regia have been studied during the settlement and
metamorphosis of planulae larvae into polyps. Ultrastructural studies
of the fully developed and settled post-larval stages have implicated
one of the gland cell types in the secretion of an organic matrix prior
to skeletal growth. Qualitative X-ray analytical studies using the
scanning transmission electrom microscope (STEM) have supported these
observations: calcium was detected in this organic substance after it
had been secreted into the 1-3µm wide space between the skeletogenic
epithelium and the substrate. Thirty-six hours later X-ray mapping of
this matrix showed that high levels of calcium were more easily
detected within crystal-like profiles than in the surrounding areas.

</b>^The morphometric and molecular boundaries between twelve
Psammocora (Cnidaria, Scleractinia) nominal species were addressed. The
type specimens of Psammocora haimiana Milne-Edwards &#038; Haime 1851,
P. togianensis Umbgrove 1940, P. folium Umbgrove 1939, P. digitata
Milne-Edwards &#038; Haime 1851, Maeandroseris australiae Rousseau
1854, P. samoensis Hoffmeister 1925, P. superficialis Gardiner 1898, P.
profundacella Gardiner 1898, P. nierstraszi van der Horst 1921, P.
verrilli Vaughan 1907, and P. albopicta Benzoni 2006, were analysed
together with specimens from museum collections, including those
depicted in widely cited taxonomic descriptions, and material collected
for this study in different parts of the Indo-Pacific. Morphometric
analyses of the dimensions of skeletal structures allowed the
identification of groups of specimens with similar morphologies.
Congruency between these groups and current species whose synonymies
and descriptions were found in recent taxonomic references was, hence,
investigated and the species revised. Finally, the phylogenetic
relationships of a representative subset of specimens were
reconstructed based on rDNA and COI, thus allowing a direct link
between morphologic and genetic information. Incongruence between type
of morphology and literature descriptions was evidenced for some widely
recognised species. Based on this integrated approach, five species
were unambiguously identified. [original abstract]^1";

(2010).- Skeletal growth, ultrastructure and composition of the
azooxanthellate scleractinian coral Balanophyllia regia.- Coral Reefs
```

```
29, 1: 175-189.- <b>FC&#038;P 36</b>, p. 84, ID=6492^<b>Topic(s):
</b>skeletal growth; Scleractinia Balanophyllia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^The biomineralization process and skeletal growth dynamics of
azooxanthellate corals are poorly known. Here, the growth rate of the
shallow-water dendrophyllid scleractinian coral Balanophyllia regia was
evaluated with calcein-labeling experiments that showed higher lateral
than vertical extension. The structure, mineralogy and trace element
composition of the skeleton were characterized at high spatial
resolution. The epitheca and basal floor had the same ultrastructural
organization as septa, indicating a common biological control over
their formation. In all of these aragonitic skeletal structures, two
main ultrastructural components were present: &#34;centers of
calcification&#34; (COC) also called rapid accretion deposits (RAD) and
&#34;fibers&#34; (thickening deposits, TD). Heterogeneity in the trace
element composition, i.e., the Sr/Ca and Mg/Ca ratios, was correlated
with the ultrastructural organization: magnesium was enriched by a
factor three in the rapid accretion deposits compared with the
thickening deposits. At the interface with the skeleton, the
skeletogenic tissue (calicoblastic epithelium) was characterized by
heterogeneity of cell types, with chromophile cells distributed in
clusters regularly spaced between calicoblasts. Cytoplasmic extensions
at the apical surface of the calicoblastic epithelium created a
three-dimensional organization that could be related to the skeletal
surface microarchitecture. Combined measurements of growth rate and
skeletal ultrastructural increments suggest that azooxanthellate
shallow-water corals produce well-defined daily growth steps. [original

skeletal growth; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^This paper presents the
results of an effort to label calcium carbonates formed by marine
organisms with stable isotopes to obtain information about the
biomineralization processes. The growing skeleton of the scleractinian
coral Porites porites was labeled three times with enhanced abundances
of 86Sr. The distribution of 86Sr in the skeleton was imaged with the
NanoSIMS ion microprobe with a spatial resolution of 200 nm and
combined with images of the skeletal ultra-structure. Importantly, the
distribution of the 86Sr label in the P. porites skeleton was found to
be strongly heterogeneous. This constrains the physical dimensions of
the hypothetical Extracellular Calcifying Fluid (ECF) reservoir at the
surface of the growing skeleton, which is implicit in most geochemical
models for coral biomineralization. These new experimental capabilities
allow for a much more detailed view of the growth dynamics for a wide
range of marine organisms that biomineralize carbonate structures.

They will therefore appreciate the value of this interactive key for identifying staghorn corals which has resulted from the first major review of the Acropora in over 100 years. * A simple step-by-step selection of characters will enable the user to identify any of the 113 species of Acropora. Over 2000 photographs, micrographs and illustrations in colour and black and white are included to guide the user. Additionally there is a photographic database of the type specimens of Acropora collected from museums around the world. The CD-ROM is complemented by the book, Staghorn Corals of the World: A Revision of the Genus Acropora, which synthesizes all we know about this genus. It is an essential tool for all reef workers and coral workers around the world.^1";
s[5575] = "GAUTRET P. (1999).- Matrices organiques intrasquelettiques des Scléractiniaires récifaux: Évolution diagénétique précoce de leurs caractéristiques biochimiques et conséquences pour les processus de cimentation. [in French, with English abstract].- Geobios 33, 1: 73-78.- <b>FC&#038;P 29-1</b>, p. 49, ID=7042^<b>Topic(s): </b>organic skeletal matrix; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Biochemical character and properties of intraskeletal organic matrices are studied in skeleton pieces from several growth zones sampled in a 25cm long living Porites core. In experimental conditions these organic matrices exhibit an inhibitory effect on CaCO3 precipitation which increases all along the 15-20 upper cm of the core. Parallelly relative amino acid compositions are more and more enriched in aspatic and glutamic acids from the surface to the base of the core, and molecular weights of glycoproteic compounds are comparable to those
```

```
of the uppermost living zone in all parts of the core except in the
base. From the combination of experimental results it is concluded the
the highest inhibiting efficiency of organic matrices is a consequence
of quantity, the copmposition (Asp concentration) of organic matrices,
and the preservation of high molecular weight assemblages. Consequences
for cementation processes in superficial zones of coral reefs are
examined. It is most probable that the diagenetic state of
intraskeletal organic matrices influences the development of cements
directly upon the surface of skeletal substrates, as well as the
formation of diagenetic aragonite overlaying biogenic aragonite within
skeletal structures. Conditions in reefal cryptic zones inhabited by
sponges are discussed as a comparison with photic zones where
scleractinian corals are located. [original abstract]^1";

diagenetic patterns of scleractinian skeletons: evidence at the scale
of colony lifetime.- Bulletin of the Tohoku University Museum 1
[Proceedings of the 8th International Symposium on Fossil Cnidaria and
Porifera]: 210-218.- <b>FC&#038;P 30-1</b>, p. 20, ID=7070^<b>Topic(s):
</b>microstructures, diagenesis; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^The earliest fine scale diagenetic changes in corals were
investigated by comparing microstructural and ultrastructural features
from the uppermost skeletal parts of living colonies with those
obtained from older parts of the same specimen. In addition to its
organic mineral duality, the initial heterogeneity of the scleractinian
skeleton is shown by the occurrence of a micron scale zonation within
crystal fibers, resulting from incremental growth during elementary
cycles of biomineralization and also by the presence of two basic
structural features, calcification centers and fibers, clearly
differentiated from each other. Within the species analyzed, micro and
ultrastructural data reveal additional fine scale diversity related to
taxonomy. At the time scale of colony life, the earliest processes of
diagenesis produce a thin fringe of syntaxial aragonite cements,
alteration of the incremental zonation of scleractinian fibers, and
also, preferential diagenesis within calcification centers. These early
modifications of coral skeletons are obviously controlled by the
biological ultrastructural characteristics of scleractinian taxa and
also suggest that early diagenesis does not necessarily imply drastic
change in environmental conditions. [original abstract]^1";

(2003).- XANES mapping of organic sulfate in three scleractinian coral
skeletons.- Geochimica et Cosmochimica Acta 67, 1: 75-83.- <b>FC&#038;P
33-1</b>, p. 69, ID=7216^<b>Topic(s): </b>skeletogenesis; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The presence and localization of organic
sulfate within coral skeletons are studied by using X-ray absorption
near edge structure spectroscopy (XANES) fluorescence. XANES spectra
are recorded from four reference sulfur-bearing organic molecules;
three amino acids (H-S-C bonds in cysteine; C-S-C bonds in methionine;
one disulfide bond C-S-S-C bonds in cystine) and a sulfated sugar
(C-SO_4 bonds in chondroitin sulfate). Spectral responses of three
coral skeletons show that the sulfated form is extremely dominant in
coral aragonite, and practically exclusive within both centres of
calcification and the surrounding fibrous tissues of coral septa.
Mapping of S-sulfate concentrations in centres and fibres gives us
direct evidence of high concentration of organic sulfate in centres of
calcification. Additionally, a banding pattern of S-sulfate is visible
in fibrous part of the coral septa, evidencing a biochemical zonation
that corresponds to the step-by-step growth of fibres. [original

</b>systematics, ecology; Scleractinia, Fungiidae; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^[Unlike the majority of other reef corals, most Fungiidae do not
remain attached to the bottom. Adult mushroom corals may be found on
several kinds of substrata; they live on sand, rubble, dead coral or
even on top of living coral. They can be found in environments where
many other corals cannot live, such as lagoons, reef bases and
terrigenous non-reefal bottoms. In the systematic part of this thesis,
a taxonomic revision is given with descriptions of the 40 species that
are presently classified with the Fungiidae (chapter 2.1). These
descriptions define the material used in the other chapters. The family
is divided into S1 genera, one of which, Fungia, is subdivided into
seven subgenera. Three species are new to science and one is renamed
because its name was already in use for another species. Furthermore,
an overview of the stratigraphic distributions is given for all
species. A tentative phylogenetic reconstruction down to the species
level is given. The fungiidae are the first scleractinian family for
which such an analysis has been undertaken. The cladogram that is
provided should be considered a working hypothesis and not a sound
basis for a completely revised classification. (fragment taken from
extensive summary)]^1";

p. 92, ID=3836^<b>Topic(s): </b>monograph; Scleractinia, Turbinoliidae;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^The monophyly of the Turbinoliidae is
based on the unique (with the Caryophylliina) character of having its
entire corallum invested with tissue, which is reflected in its
well-formed costae from base to calice and its characteristically deep
intercostal regions. All turbinoliids are solitary and free-living, and
thus the complete investiture of its corallum might facilitate movement
through or across a sandy substrate. The Turbinoliidae consists of 28
genera and 163 valid species, of which 22 genera and 49 species are
extant. The earliest known turbinoliid is from the Late Cretaceous
(Campanian) of Antarctica. All 28 genera are diagnosed and figured
herein. The stratigrapbic and geographic distributions are discussed
for each genus, and a list of species known for each genus, including
junior synonyms, is given. Two genera and two species are described as
new: Pleotrochus, P. zibrowii, Foveolocyathus, and Sphenotrochus
wellsi. Peponocyathus is restricted to those species having transverse
division, which requires the resurrection of Deltocyathoides Yabe and
Eguchi 1932, for those species that do not reproduce by transverse
```

```
division, and it also requires the synonym of Truncatocyathus Stolarski
1992. Tropidocyathus is divided into two genera, allowing the
resurrection of Cyathotrochus Bourne 1905. Oryzotrochus stephensoni
Wells 1959, is identified as a Turbinolia, which synonymizes
Oryzotrochus and extends the stratigraphic range of Turbinolia from the
Oligocene to Recent. [first part of extensive summary]^1";
s[5583] = "RIEGL B., BLOOMER J.P. (1995).- Tissue damage in
scleractinian and alcyonacean corals due to experimental exposure to
sedimentation.- Beiträge zur Paläontologie 20: 51-63.- <b>FC&#038;P
25-2</b>, p. 73, ID=3179^<b>Topic(s): </b>tissue damage; Scleractinia,
Octocorallia; <b>Systematics: </b>Cnidaria; Scleractinia Octocorallia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Four South African
scleractinian corals (Favia favus, Favites pentagona, Platygyra
daedalea and Gyrosmilia interruptd) and four alcyonacean corals
(Lobophytum depressum, Lobophytum venustum, Sinularia dura and
Sinularia leptoclados) were experimentally exposed to high
sedimentation conditions in the laboratory during a period of six
weeks. Experimental sedimentation corresponded to the highest measured
sedimentation levels on South African coral reefs, being 200 mg
cm~2h~l. Corals were monitored for tissue necroses and bleaching during
the course of the experiment and histological sections were prepared
after the termination of the experiment. During the experiment, tissue
necroses appeared earner and more frequently in alcyonacea than in
scleractinia. Histological sections showed degeneration and necroses of
epithelia and mucus-producing cells with accumulation of free mucous
material in the epithelia as well as loss of zooxanthellae, was
observed in three alcyonacea (Lobophytum depressum, Siniluaria dura,
Sinularia leptoclados). Not all parts of the alcyonacean colonies were
equally affected by tissue damage and bleaching. In particular,
elevated lobes and finger-like projections, which were never covered by
sediment for long periods, did not exhibit the same severe damage or
bleaching as flat parts of the colonies. Scleractinia did not suffer
the same amount of tissue damage as alcyonacea, no bleaching was
observed. Partial necroses and degeneration of epithelia as well as
changes in mucus producing cells were also observed in scleractinia.^1";

<b>Geography: </b>^Ratios of strontium to calcium have been analysed by
laser-ablation inductively coupled plasma-mass spectroscopy (LA-ICP-MS)
in a skeletal section of the sclerosponge Ceratoporella nicholsoni. The
growth period, representative of 3 yr, was stained in the skeleton with
a fluorochrome (calcein). Temperatures were recorded at 2 h intervals
within the shallow cryptic reef enclosure that the sclerosponge
inhabited on the northern coast of Jamaica, allowing the formulation of
a direct empirical relationship between Sr/Ca and temperature. To
verify this calibration, Sr/Ca ratios of two sclerosponges of the same
species from depths of 67m and 136m in Exuma Sound, Bahamas, were
```

```
analysed by LA-ICP-MS and compared to the temperatures from these
depths over a decade prior to collection. The result is an
independently verified, high-resolution empirical calibration for the
temperature sensitivity of Sr/Ca ratios in the aragonite skeleton of
sclerosponges from Jamaica and the Bahamas. The calibration is a first
for C. nicholsoni and indicates that the sclerosponges are more
sensitive temperature recorders than zooxanthellate corals. It
represents an important step in establishing skeletal geochemistry of
sclerosponges as a proxy of temperature in the upper 250m of the ocean.

</b>Porifera; Sphinctozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^A &#34;living fossil&#34; of the group Sphinctozoa has been
discovered in the Indian Ocean and in New Caledonia in a very cryptic
habitat of the outer slope of coral reefs. The living tissue is inside
a series of hemispherical chambers. The perforated chamber walls are
composed of aragonite and consist of a feltwork of microfibrills. In
the growing sponge, the skeleton of a new chamber appears first as an
organic matrix, which is the template for a later calcification. There
are no spicules. The histology, cytology and sexual reproduction are
compared to those of the recent Porifera. They are similar to those of
the Ceractinomorpha in the class Demospongea. * This study shows that
most fossil Sphinctozoa were relatives of Demosponges. They are
considered by the author as an order of the class Demospongea. These
sponges were devoid of spicules. Thus, the exclusion from the Porifera
of some fossil groups as Stromatopores or some Tabulates on the ground
of the absence of spicules is not valid. A new order Sphaerocoelida is
proposed for Cretaceous sponges which have the same structure, but
which have calcareous spicules and probably are homeomorphs of the
class Calcarea. A comparison is made between the 14 recent sponges
which possess a non-spicular calcareous skeleton. The large diversity
of both the skeleton and the living tissue of these sponges indicates
that their hypercalcification is an archaic character, which was
frequent in the past and which disappeared in most of the recent
sponges. [original abstract]^1";
s[5588] = "JAMES N.P., WRAY J.L., GINSBURG R.N. (1988).- Calcification
of Encrusting Aragonitic Algae (Peyssonneliaceae): Implications for the
Origin of Late Paleozoic Reefs and Cements.- Journal of sedimentary
Petrology 68, 2: 291-303.- <b>FC&#038;P 18-2</b>, p. 44,
ID=2501^<b>Topic(s): </b>calcification, cementation; Algae aragonitic;
<b>Systematics: </b>algae; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^Encrusting aragonite calcareous algae of the family
Peyssonneliaceae are the largest group of calcified red algae outside
the well-known Mg calcite Corallinaceae. They are distributed
worldwide, are most heavily calcified in temperate and tropical waters,
and grow as prone but arched sheets on soft mud substrates on hard rock
surfaces, as extensive bridge-like networks between corals in reefs,
and as concentric layers in nodules. Calcification is entirely
aragonitic, species-specific and both intracellular and extracellular
below the thallus as a hypobasal layer. The hypobasal layer develops
outside the tissue as an encrustation of small aragonite botryoids
attached to the lower surface between rhizoids, and on living plants it
may exceed in thickness of the thallus. Calcification ranges from
nonexistent in some cold-water forms, to thallus calcification only, to
both thallus and hypobasal calcification, to species in which the
```

```
thallus is noncalcified but there is a hypobasal layer of aragonite
botryoids. Although the confirmed fossil range of this family extends
only to the Early Cretaceous, striking similarities between these
aragonitic forms and some late Paleozoic phylloid algae suggest that
they may be closely related. Their ability to grow on soft mud
substrates and form structures composed of irregular arched sheets with
extensive pore space, as well as their brittle nature, so susceptible
to fragmentation, are all characteristics of mound-forming fossil
phylloid algae. The hypobasal layer of botryoidal aragonite, developed
while the plant is still growing, could easily act as a nucleation site
for further epitaxial submarine precipitation, thus explaining the
common association of Paleozoic phylloid algae and extensive
fossil-reef cements that resemble botryoidal aragonite. The presence of
hypobasal botryoidal aragonite on plants with noncalcified thallus
raises the possibility that some fossil-reef cements may be related to
now-vanished algae.^1";

ID=4536^<b>Topic(s): </b>reefs, ecology; reefs, Bryozoa;
<b>Systematics: </b>Bryozoa; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^In this paper, a preliminary concept on the interplay of local,
regional and global control factors of bryozoan diversity and
distribution pattern is introduced. Recent bryozoans from the
Philippines, New Zealand and the Gulf of Aqaba are compared to the
selected fossil specimens from the Oxfordian and Santonian. Reef
bryozoan skeletons are studied in order to separate local control
within the substrate-water interface from regional control. The latter
originate mainly from the transport function of the water column (e.g.
sediment load, wave energy, vagile predators). This is true especially
for erect (tree-like) and massive (multilaminar) bryozoans which are
subjected to the dynamics of the water body in the littoral area. This
regional control, affects simultaneously several structural and
substrate zones of a reef. Early life history of vertically growing
reef bryozoans reflect local control, while older zoarial structures
```

```
reflect the signals of regional influence. Three types of multiserial
nodular bryozoans are cited: self-overgrowing sheets
(&#039;S-Nodule&#039;, derived from &#039;S-Sheet&#039;),
circumlaterally budding colonies (&#039;C-Nodules&#039;), and fungiform

<b>Geography: </b>^The nervous system and its alterations in various
stages of development has been investigated in Cassiopea andromeda and
C. xamachana using immunocytological detection of RF-amide
(Arg-Phe-amide) related neuropeptides which are known to occur
generally in cnidarians. Immunoreactive neurons, visualized by
epifluorescence in whole-mount preparations, were found in ah1 stages
of development investigated so far (asexual buds, metamorphosing buds,
polyps, strobilae, ephyrae, and young medusae), except for bud analgen
developing at the parental polyps. Congruent results were obtained in
the two species, also with respect to non-specific immunostaining of
some ectodermal gland cells and nematocytes. Immunoreactive nerve nets
were observed in tentacles and the hypostome ofthe polyp stages, in the
manubrium and subumbrella ofthe ephyra, and also in the exumbrella of
the young medusa. Apicobasal tracts paralleling septal muscles of the
polyps calys were seen only during bud-to-polyp metamorphosis.
Condensations of anti-RF-amide positive nerve cells occurred in the
scyphistoma at the margin of the hypostome, and as a prominent nerve
ring below the tentacle bases, connecting the individual tentacular
nerve nets. Dense nerve cell populations were noticed next to the
rhopaha in ephyrae and in young medusae, a connecting circular tract at
the umbrellar magin was detectable only in the latter. An apparent lack
of anti-RF-amide positive neurons was recorded in the free-swimming
buds, and in some domains of both the polyp and the young medusa. We
suggest that the immunoreactive nerve elements in Cassiopea spp.
reported on here represent only a subset of neurons within a more
complex nervous system.^1";

(1974).- Observations on microstructure and biocrystallization in Coelenterates.- Biomineralization Research reports 7: 37-45.- <b>FC&#038;P 4-1</b>, p. 16, ID=4995^<b>Topic(s): </b>microstructures, biocrystallization; Cnidaria; <b>Systematics: </b>Cnidaria; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Study with the scanning electron microscope shows basic differences in microstructure between several groups of coelenterates. The present report deals with skeletal microstructure and microarchitecture in Millepora (Milleporina), Stylaster, Errina, and Distichopora (Stylasterina) among hydrozoans. In the octocorals (Anthozoa) details are presented of Tubipora, Heliopora, and the gorgonian Eunicea. * The aragonitic milleporines and stylasterines have similarities to the scleractinian skeleton and a similar ectodermal model of biocrystallization can be employed to explain observed skeletal characteristics. The three groups are unified by the presence of a spherulitic type of crystallization, although the consistency of the proteinaceous &#34;templating&#34; material is obviously different for different groups. * Those coelenterates with mesogloeal secretion of spicules or skeletal crystallites are all unified by needle-like crystallites of approximately the same size, each oriented with its long axis only slightly emergent from the surface of skeletal elements. The octocorals examined here each show such structure. Heliopora, in addition to this last has a different, more milleporine-like structure in the first-formed parts of its skeleton.^1";

and the first classification of Medusae.- Archives of Natural History
19, 3: 401-405.- <b>FC&#038;P 24-1</b>, p. 59, ID=4469^<b>Topic(s):
</b>classification; Medusae; <b>Systematics: </b>Cnidaria;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Francoise Peron
(1775-1810) and Charles-Alexander Lesueur (1778-1846) sailed with
Captain Nicolas Baudin on the great French expedition to Australia from
1800 to 1804. The results of their work were published in 1807 (Peron
1807), translated into English in 1809 and have been very well analyzed
recently by Wallace (1984) with the remark: &#34;Peron is a figure of
equal importance to James Cook&#34;. During and after the voyage Peron
and Lesueur became pioneers in the study of Medusae. At the beginning
of the nineteenth century, the jellyfish were still a puzzle to
scientists. Three species placed within the single genus Medusa without
specific names but numbered as follows: Medusa 1286, Medusa 1287,
Medusa 1288 were placed by Linnaeus (1746) among the Vermes. Medusa was
placed among the molluscs by Bruguiere (1791), and with the echinoderms
by Cuvier (1817) and Lamarck (1816). In 1799, Cuvier furthered the work
of Reaumur (1710) and separated the genus Rhizostomites using the shape
and number of mouths as characters. This last character was used by
Peron and Lesueur to produce their work and separate the groups of the
non-mouthed medusae and many-mouthed medusae. The structure of the
mouth was the only character used at that time. The work of Peron and
Lesueur was the first to show the diversity of the medusae with a
description of 122 species and 29 genera. Their work was first read to
the Academy of Sciences in 1808, and a table was published in the
Annales du Museum (Peron and Lesueur 1810). It consisted of very
specific descriptions which were made from the highly accurate Lesueur
drawings. However, neither the drawings, except for the first 14 plates
which were of some damaged animals (Lesueur 1815), nor most of the
manuscript notes of Peron were ever published. After the death of Peron
in 1810, this immense work did not stand up to critical review by
non-specialist scientists. However, in 1980, some 170 years later, the
text published in Annales du Museum d&#039;Histoire naturelle, Paris
(Peron and Lesueur 1809, 1810), the 96 plates painted by Lesueur and
the 400-page unpublished manuscript prepared by Peron were finally
brought together. Lesueur&#039;s plates and Peron&#039;s manuscript are
deposited in the Museum d&#039;Histoire naturelle at Le Havre (France)
with the reference numbers 70001 to 70062 and 68325 to 68839. At the
outset of the expedition neither Peron nor Lesueur were regarded as
zoologists; Peron was enrolled as a medical doctor and Lesueur as an
assistant gunner. As the jellyfishes were dominant in the catch in
quantity, diversity, coloration and bioluminescence, they became
attracted to them.^1";

</b>Porifera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Sponges
(Porifera) belong to the most common and in terms of their biomass
dominant sessile aquatic animals. The fact that sponges are important
sources of raw material is well known due to the world wide use of
Spongia officinalis, the bath sponge (order Dictyoceratida). Its
massive organic skeleton of spongine and the absence of spicules makes
this sponge suitable as a hygienic article. Bath sponges have been used
over centuries for cleaning wounds, for contraception and even as
implant after breast cancer operations (Arndt 1938). During Man&#039;s
history, many different types of medicine, mainly as powders, have been
made of dried sponges and used against all kinds of diseases. The
oldest pharmaceutical sponge utilisation was the ashes of burned bath
sponges, which because of its high iodine content has proven to be an
efficiacious medicine against diseases of the thyroid gland. [initial

<b>Geography: </b>^Total genomic DNA of the four freshwater sponge
species common in Belgium, Ephydatia fluviatilis, Ephydatia muelleri,
Spongilia lacustris and Eunapius fragilis was isolated and restricted
by the Eco RI endonuclease. Southern blot hybridization with a
radiolabelled E. fluviatilis homeobox (EfH-1) revealed hybridization
bands in the four species studied. Two restriction fragments of 2.2 kb
and 5.4 kb were identified in E. fluviatilis and E. muelleri DNAs
whereas in S. lacustris and Eunapius fragilis DNAs, only one fragment
of 2.3 kb was detected. Our results demonstrate the existence of
homeobox-containing genes in the four species. With Eco RI, no
differences were observed between E. fluviatilis and E. muelleri, nor
between S. lacustris and E. fragilis. It is suggested that S. lacustris
and E. fragilis might be taxonomically related to each other as closely
as are E. fluviatilis and E. muelleri. [original abstract]^1";

<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Recent?;
<b>Geography: </b>^The taxonomy of the Indo-Pacific sponge Spongia
mycofijiensis, order Dictyoceratida, was investigated with particular
regard to the appropriate genus assignment. This species, initially
collected in Fiji in 1987, was noted for the presence of its unusual
secondary metabolite chemistry. Since this time, there has been
discussion of two alternative assignments for the species, namely
Leiosella and Hyattella. Type specimens were studied from related
genera of the families Spongiidae and Thorectidae, including Spongia,
Leiosella, Hyattella, Coscinoderma, Lendenfeldia, Hippospongia,
Dactylospongia and Cacospongia. It was found that the skeleton compared
most closely to members of the genus Cacospongia, family Thorectidae (=
Irciniidae) and is therefore concluded that the species be reassigned
to this genus. [original abstract]^1";

bacterial symbiosis; Porifera; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Dense bush-like clumps
of several hundred individuals of a new species of Cladorhiza
(Demospongiae, Poecilosclerida) have been observed near methane sources
in mud volcanoes, 4718 to 4943m deep in the Barbados Trench. The sponge
tissue contains two main morphological types of extracellular symbiotic
bacteria: small rodshaped cells and larger coccoid cells with stacked
membranes. Stable carbon isotope values, the presence of MeDH and
ultrastructural observations all indicate that a least some of the
symbionts are methanotrophic. * Ultrastructural evidence of
intracellular digestion of the symbionts and the stable C and N values
suggest that the sponge obtains a significant portion of its nutrition
from the symbionts. Ultrastructure of the sponge embryo suggests direct
transmission through generations in brooded embryos. The sponge also
maintains a carnivorous feeding habit on tiny swimming prey, as do
other cladorhizids.^1";

ID=6916^<b>Topic(s): </b>biomineralization; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^The
different biomineralization processes of the two &#34;living
fossils&#34;, Astrosclera willeyana and &#34;Acanthochaetetes&#34;
wellsi were studied by epifluorescence microscopy, SEM, TEM, and
biochemical analyses.The basal skeleton of A. willeyana is made of
aragonite spherulites. These spherulites are built in the dermal layer
in large vesicle cells (LVC) in the early stages. After a releasing
event, the spherules fuse together by epitaxial growth. In &#34;A&#34;.
wellsi the basal skeleton is made of high Mg-calcite. It is constructed
of bundles of elongated, tangentially oriented crystals. The
biomineralization takes place in three different places in the
skeleton, the active zones are localized in the uppermost parts of the
skeleton. In both cases the mineralization is associated with highly
acidic mucus substances, rich in aspartic and glutamic acid which
control the biomineralization processes. The understanding of the
biomineralization processes in these two cases gives insight into the
formation of ancient reef constructors like the stromatoporoids and
chaetetids. [original abstract]^1";

&#038; Outlook&#039;. The theme of the Symposium, &#039;Origin &#038;
Outlook&#039; (held at the Queensland Museum, Brisbane, in June-July
1998), refers to the adage that scientific progress rests on the
```

```
knowledge of the past, and reflects the productive interaction between palaeontology, biology, chemistry, ecology, cytology, molecular biology and other disciplines as multidisciplinary approaches to the strange but innovative world of sponges. * The Proceedings volume contains 720 pages, comprising 4 invited papers, 67 peer-reviewed general papers, and an additional 72 &#039;Notes&#039; scattered throughout the volume (the latter consisting of other abstracts of papers and posters presented at the Symposium). The Proceedings volume contains information on all aspects of sponge sciences, encompassed a broad range of topics, including: the production of chemicals and the chemical ecology of sponge metabolites with pharmaceutical potential; commercial sponge fisheries and their human impacts; sponge cell behaviour and their immunological implications; the role of sponges as pollution indicators and their ecological interactions with other communities; the role of &#039;living fossil&#039; sponges in coral reef geomorphology; advances in the origins and relationships of Porifera as evidenced by molecular biology; recent discoveries in biodiversity, evolution, biogeography and palaeontology of the phylum; and the physiology, ultrastructure and interactions of sponges with symbiotic microbes. <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Siliceous and calcareous sponges commonly are
treated with acid to remove the spicules prior to embedding and cutting
for histological investigations. Histology of spiculated sponge tissue
represents a challenging problem in sponge histotechnology.
Furthermore, fluorescence in situ hybridization (FISH), a key method
for studying sponge-associated microbes, is not possible after acid
treatment. For a broad range of siliceous sponge species, we developed
and evaluated methods for embedding in paraffin, methylmethacrylate
resins, LR White resin and cryomatrix. Different methods for cutting
tissue blocks as well as mounting and staining sections also were
tested. Our aim was to enable histological investigations and FISH
without prior removal of the spicules. To obtain an overview of tissue
and skeleton arrangement, we recommend embedding tissue blocks with LR
White resin combined with en bloc staining techniques for large
specimens with thick and numerous spicules, but paraffin embedding and
subsequent staining for whole small specimens. For FISH on siliceous
sponges, we recommend Histocryl embedding if the spicule content is
high, but paraffin embedding if it is low. Classical histological
techniques are used for detailed tissue examinations. [original

<b>FC&#038;P 36</b>, p. 30, ID=6393^<b>Topic(s): </b>molecular studies;
Porifera Homoscleromorpha; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Sponges branch basally
in the metazoan phylogenetic tree and are believed to be composed of
four distinct lineages with still uncertain relationships. Indeed, some
molecular studies propose that Homoscleromorpha may be a fourth Sponge
lineage, distinct from Demospongiae in which they were traditionally
classified. They harbour many features that distinguish them from other
sponges and are more evocative of those of the eumetazoans. They are
notably the only sponges to possess a basement membrane with collagen
IV and specialized cell junctions, thus possessing true epithelia.
Among Homoscleromorphs, we have chosen Oscarella lobularis as a model
species. This common and easily accessible sponge is characterized by
relatively simple histology and cell composition, absence of skeleton,
and strongly pronounced epithelial structure. In this review, we
explore the specific features that make O. lobularis a promising
homoscleromorph sponge model for evolutionary and developmental
researches.^1";

</b>skeletal structures, diagenesis; Porifera, Pharetronida,
Petrobiona; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Petrobiona massiliana is a Recent pharetronid sponge
with a secondary basal skeleton composed of high Mg calcite. Petrobiona
is linked with the subclass Calcaronea. The basal skeleton is mainly
constructed of elongated spherulitic elements. The living tissue of the
sponge is restricted to the upper part of the calcareous skeleton,
except for narrow canals which penetrate the basal skeleton. The basal
skeleton grows within an extremely thin mucus layer between the
pinacoderm of the living sponge and the substrate or ontogenetically
older basal skeleton. This layer is called the &#34;extra-pinacodermal
mucus layer&#34;. The primary basal skeleton elements are called
&#34;sclerodermites&#34; or elongated cement-chips and grow within the
outer-pinacodermal space. The shape of the chips is influenced by the
upward movement of sponge tissue during growth. The spicular skeleton
of the sponge is partly entrapped by syn-vivo-formed cement-chips.
Chemistry of the spicules is nearly similar to the primary elements. An
early diagenetic neomorphic process alters the single Mg calcite
crystals of the spicules into polycrystalline, granular, or prismatic
structures. Within the oldest parts of the basal skeleton the entire
structure of the spicules is changed into diagenetic spherulites.
Stable isotope content (C13&#47; O18) of the primary cement-chips and
spicules are nearly similar. Cements of the basal skeleton differ only
in more positive O18 values, a typical diagenetic feature. Remarkable
are relatively high C13 values (+2,3). A strong vital effect (e.g. high
content of respirative CO2) is therefore not noticed. The basal
skeleton of Petrobiona was compared with another pharetronid species of
the Calcaronea group, Minchinella lamellosa. This particular sponge is
a true living fossil and is characterized by a rigid interior
choanosomal spicular skeleton. This second type of pharetronid basal
skeleton is constructed of spicules which are connected by high Mg
```

```
calcite cements, analogous to with the primary cement-chips of
Petrobiona. Chemical data as well as stable isotope content are
comparable with Petrobiona. [fragment of extensive original summary]^1";
s[5680] = "WEISSENFELS N. (1989).- Biologie und Mikroskopische Anatomie
der Suesswasserschwaemme (Spongillidae).- Gustav Fischer Verlag
(Stuttgart, New York); ISBN 3-437-30600-6; in German, English version
in preparation.- <b>FC&#038;P 18-2</b>, p. 48, ID=2514^<b>Topic(s):
</b>biology, anatomy; Porifera, Spongillidae; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^Well
illustrated (112 drawings and black and white photos) important new
contribution to sponge biology. The book represents on ca. 100 pages
the results of Prof. Weissenfels and co-workers investigations during
the last sixteen years on four European fresh water sponges (Ephydatia
fluviatilis (L.), E. muelleri (Lieberkohn), Spongilla lacustris (L.),
and Eunapius (Spongilla) fragills (Leidy) and therefore the current
knowledge of this group. Weissenfels&#039;s group was able to cultivate
fresh water sponges in aquaria, the species Ephydatia fluviatilis was
the main object of research. Important is, the new developed and used
SEM-preparation technique (critical point drying) to demonstrate the
outer shape of cells and other soft tissue characters beside well done
TEM micrographs. The author gives an extremly good overview on the
ontogenetic development of a young sponge hatching from a gemmule or
developed from an incubated parenchymella-larvae. All stages of tissue
development are figured with SEM, TEM, and LM micrographs and described
in simple but informative German, which allows not native speakers to
understand the main content. Beside the characteristics of tissue
structures different cell types, and ontogenetic development,
physiology aspects are described and help to understand e.g. how a
sponge feeds, how an injured sponge recreates, and how organic- and
mineralized skeletal elements are constructed. The problem of
individuality of a sponge is discussed. An ontogenetic
(&#034;phylogenetic&#034;) tree of sponge cells is given and allows a
short overview on the different sponge cell types and their function.
The book is made specially for biologists and students of biology. I
believe this book is good also for paleontologists, because it gives an
excellent overview on the anatomy, function morphology of certain
characters, the physiology of the excretions processes (function of the
pore- and channel system), and finally the formation of the
collagen/spongin- and spicule skeleton. The latter is very important
for paleontologists to understand more about sponge skeletons in
respect of taxonomy and phylogeny. Recommendation: necessary for all
scientists who are working on sponges and closely related organisms
like &#034;stromatoporoids&#034;, &#034;chaetetids&#034;,
&#034;sphinctozoans&#034; and &#034;archeocyathids&#034; and should be
available in every scientific library. [reviewed by Joachim Reitner]^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>^The long-term response of coral reefs to climate change depends on
the ability of reef-building coral symbioses to adapt or acclimatize to
warmer temperatures, but there has been no direct evidence that such a
response can occur. Here we show that corals containing unusual algal
symbionts that are thermally tolerant and commonly associated with
high-temperature environments are much more abundant on reefs that have
been severely affected by recent climate change. This adaptive shift in
symbiont communities indicates that these devastated reefs could be
more resistant to future thermal stress, resulting in significantly
longer extinction times for surviving corals than had been previously
assumed. [original abstract]^1";

According to calculations by Joan Kleypas of the US National Center for Atmosphere Research, increasing CO2 should already be making reefs grow more slowly. But exactly the opposite may be true on the Great Barrier Reef, according to a study of old coral skeletons by Dave Barnes of the Australian Institute of Marine Science. Calcification rates for the major reef-building genus Porites, he found, were 4 per
```

```
cent higher from 1930 to 1979 than for each of the three preceding
50-year periods, perhaps because rising ocean temperatures gave the
corals a growth boost. So what happened to the calcification problem?
In follow-up experiments in the laboratory, Barnes found a possible
explanation: as CO2 concentrations rise to levels approaching double
the pre-industrial norm, reef rocks release carbonate in a form known
as magnesian calcite. This has a buffering effect, shifting the acidity
of ocean water back towards its normal value and so stimulating
calcification. At about the same time, Robert Halley and his colleagues
with the US Geological Survey in St. Petersburg, Florida, used an
underwater chamber on an actual reef to monitor chemical responses to
raised CO2 levels. They observe the same buffering phenomenon. &#034;We
found it occurred at much less than a doubling of atmospheric CO2&#034;
he says. Many experts doubt this buffering mechanism will do much to
offset the expected decrease in calcification, though. Researchers led
by Chris Langdon of Columbia University saw no sign of buffering at
doubled CO2 levels in the Biosphere 2 experiments, for example. Halley
counters that this may simple be due to the oversimplified nature of
the Biosphere &#034;reef&#034;. For example, he notes, in natural reefs
the surf produces a soluble fine sediment that is absent in Biospere 2.
But even if buffering takes place, mixing by ocean currents will likely
overwhelm any locally produced effects on water chemistry, says
Kleypas. &#034;I think it might help some reefs in very calm, enclosed
areas,&#034; she says, &#034;but I don&#39;t think it&#39;s going to
operate on a large scale.&#034;]^1";

<b>Stratigraphy: </b>Holocene; <b>Geography: </b>^Elevations and ages
of drowned Acropora palmata reefs from the Caribbean-Atlantic region
document three catastrophic, metre-scale seal-level-rise events during
the last deglaciation. These catastrophic rises were synchronous with
(1) collapse of the Laurentide and Antarctic ice sheets, (2) dramatic
```

```
reorganization of ocean-atmosphere circulation, and (3) releases of
huge volumes of subglacial and proglacial meltwater. This correlation
suggests that release of stored meltwater periodically destabilized ice
sheets, causing them to collapse and send huge fleets of icebergs into
the Atlantic. Massive inputs of ice not only produced catastrophic
sea-level rise, drowning reefs and destabilizing other ice sheets, but
also rapidly reduced the elevation of the Laurentide ice sheet,
flipping atmospheric circulation patterns and forcing warm equatorial
waters into the frigid North Atlantic. Such dramatic evidence of
catastrophic climate and seal-level change during deglaciation has
potentially disastrous implications for the future, especially as the
stability of remaining ice sheets - such as in West Antarctica - is in
question. ^1";

database for storing information from a survey of the sublittoral
benthos of the Northern Ireland coast was developed in the Ulster
Museum during the period 1982-1985. The database included a thesaurus
of species names compiled with the intention of covering all marine
species known in the British Isles. This species dictionary was then
edited and published by the Marine Conservation Society, with
individual lists being checked by experts in each group. Code numbers
allocated to the species were used to store information on the species
present at each site surveyed. * These data have now been transferred
to a new database, programmed in Advanced Revelation. The relational
features of Advanced Revelation have been used to store a hierarchical
Linnaean taxonomy, enabling sorting of species in taxonomic order while
taking into account changing taxonomies. Special consideration has been
given to the coding of synonymous species names. Literature references
have been incorporated into the database and linked to the species
names. Specimens in the Ulster Museum collections and in the herbarium
of University College, Galway have been entered into the database.
Field sites have their own tables within the database, and specimen
records are linked to the details of the sites where they were
collected and the other species recorded at that site. Details of
photographs are also stored and linked to species, sites and specimens
where appropriate. [...] The Species Directory Marine Database is
described and the details of the structure of the database and the
validation routines discussed. A strategy for entering all species
names for the group Porifera, together with all citations of these
names in the literature and all specimens held in museums around the
world is presented. [excerpts from extensive summary; for full text see

s[5697] = "GUNKEL F., ZANKL H. (1996).- Effects of Different Substrate
Surface Roughness on Sessile Invertebrate Recruitment off Lee Stocking
Island, Exuma Cays, Bahamas - Preliminary Results.- Goettinger Arbeiten
zur Geologie und Palaontologie, Special Volume 2 [Reitner J.,
Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on
Biogenic Sedimentation I. Reef Evolution]: pp ... .- <b>FC&#038;P
26-1</b>, p. 24, ID=3566^<b>Topic(s): </b>benthos; sessile
invertebrates; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^The effects of different hard substrate surface
roughness on the early development of subtidal sessile invertebrate
communities were studied over a period of two years in a shallow tidal
channel (3m water depth) and a deeper platform edge habitat (27m) near
Lee Stocking Island, Exuma Cays, Bahamas. PVC-panels of different
surface roughness and panels of natural Key Largo Limestone were
```

```
deployed and collected after 6, 12 and 24 months of exposure. Sessile
invertebrates of nearly all major taxa also found in natural cryptic
habitats at each study site recruited on these panels (foraminifera,
sponges, hydrozoans, scleractinian corals, bryozoans, synascidian
tunicates, serpulid polychaetes and cirriped crustaceans). Recruited
communities showed clear variations between substrate roughness both in
mean number of species per panel and mean diversity with higher values
on rough surface PVC. A tendency towards community assimilation between
all substrate types from 12 to 24 months of recruitment was observed.
Recruitment on smooth surfaces may be a delayed convergence compared to
rough surfaces. This is likely to be the consequence of a much slower
development of bioorganic films by microbial activities due to low
potentials of adhesion on smooth substrates.^1";
s[5698] = "TREECK P.van, SCHUHMACHER H., PASTER M. (1996).- Grazing and
Bioerosion by Herbivorous Fishes - Key Processes Structuring Coral Reef
Communities.- Goettinger Arbeiten zur Geologie und Palaeontologie,

Global and Regional Controls on Biogenic Sedimentation I. Reef
Evolution]: pp ... .- <b>FC&#038;P 26-1</b>, p. 30,
ID=3580^<b>Topic(s): </b>reefs, coral reefs, bioerosion; grazing,
bioerosion; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Recolonization experiments were carried out in 10
and 20m depths within a fore reef area near Aqaba (Red Sea). Substrates
were exposed in different orientations towards light and in different
depths. Grazing by Diadema setosum was avoided by the experimental
design. The recolonization process of these substrates was heavily
affected by grazing herbivorous fish. Experimental substrates, made of
coral skeleton were measured before and after exposition. The loss of
material quantifies the impact of grazing. The rate of erosion varies
with orientation of the substrates and depths. Grazing fish belonged
mostly to families unsuspicious of being active bioeroders. Bioerosion
rates were compared with net carbonate production in the respective
area. A theoretical scenario of the impact of herbivorous fish on coral
reef communities is deduced. The study will present how grazing by
herbivorous fish is one of the major control factor structuring coral
reef communities.^1";

<b>Geography: </b>^Integrated electrochemical and biogenic deposition
of hard material in sea water provides an attractive substrate for many
hard bottom settlers. Brucite, aragonite and other minerals are
precipitated from the ambient seawater on a cathode of the shape
desired. The integration of direct-current phases and dead phases
permits the calcareous matter to be deposited by electrochemical
precipitation and by the secretion of sessile organisms. The physical
substrate is colonized by a highly diverse community of marine
organisms as they occur on natural hard substances in the sea. This
method is well suited for restoring damaged coral reefs and other
habitats which have been degraded by industrial activities or by the
exploitation of building materials in coastal areas.^1";

Factors controlling Holocene reef growth: an interdisciplinary
approach.- Facies 32: 145-188.- <b>FC&#038;P 24-2</b>, p. 105,
ID=4619^<b>Topic(s): </b>reef growth, limiting factors; reef growth;
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>global^This interim report deals with investigations on key factors
controlling reef growth by zoophysiologists, ecologists,
paleontologists and geologists. The different levels of emphasis are
the coral animal and the reef community. The main study area is the Red
Sea which reaches over 20° latitude up to the northernmost margin of
```

```
the global coral reef belt. Supplementary results on microborer ecology
are provided from the Bahamas. The desert enclosed Red Sea, not
influenced by land runoff and only minimally by anthropogenic (urban
and touristic) nutrient inputs, is predestined for a study on the
principal influence of light on calcification within bathymetrical and
latitudinal gradients. Hence, on the level of the zooxanthellate
scleractinian animal phototrophic and heterotrophic energy supply and
its bearing on calcification are being measured in different coral
species - in particular in Porites sp., one of the most important reef
builders. The growth of 15 zooxanthellate scleractinians in the Gulf of
Aqaba correlates with the annual light cycle. This correlation is
observable down to 40m depth. Other growth promoting factors seem to
have less influence on coral extension. [first part of extensive
summary]^1";

diagenesis; oxidation, diagenesis; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^A combination of field
and theoretical work is used to study controls on the saturation state
of aragonite inside a coral-reef framework. A closed-system
ion-speciation model is used to evaluate the effect of organic-matter
oxidation on the saturation state of aragonite. The aragonite
saturation state initially drops below 1 but becomes oversaturated
during sulfate reduction. The C:N ratio of the organic matter affects
the degree of oversaturation, with N-poor organic material resulting in
a system more corrosive to aragonite. Precipitation of sulfide as FeS
strongly affects the aragonite saturation state, and systems with much
FeS formation will have a stronger tendency to become oversaturated
with respect to aragonite. Both precipitation and dissolution of
aragonite are predicted at different stages of the organic reaction
pathway if the model system is maintained at aragonite saturation.
Field data from a coral-reef framework indicate that the system
maintains itself at aragonite saturation, and model-predicted changes
in dissolved calcium follow those observed in the interstitial waters
of the reef. Aragonite probably acts as a solid-phase buffer in
regulating the pH of interstitial waters. Because interstitial water in
the reef has a short residence time, the observed equilibration
suggests rapid kinetics.^1";

</b>^The coral-reef hypothesis of deglacial CO2 buildup in the
atmosphere can account for about one-half of the signal seen in ice
cores, assuming additional coral-reef growth releases 2 atmospheric
carbon masses (ACM). The carbonate dissolution signal on the deep sea
floor suggests titration of only 1 ACM. At least 4 ACM of CO2 must be
made available to satify the requirements of p CO2-increase, growth of
biosphere and of sedimentary carbon pool, carbonate dissolution on the
sea floor, and saturation of newly introduced meltwater. A drop in
ocean fertility is called for to provide the missing CO2. Such a drop
is evident in deep-sea cores from the western equatorial Pacific. CO2
buildup appears to occur as a step, near 13,500 years B.P. Dissolution
on the deep-sea floor begins near 11,000 years B.P. The difference of
2.500 years may describe a mixing lag due to meltwater input (the
&#34;Worthington Effect&#34;). [original summary]^1";

<b>FC&#038;P 36</b>, p. 100, ID=6522^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Quaternary; <b>Geography:
</b>^This book presents both state-of-the art knowledge from Recent
coral reefs (1.8 million to a few centuries old) gained since the
eighties, and introduces geologists, oceanographers and
environmentalists to sedimentological and paleoecological studies of an
ecosystem encompassing some of the world&#039;s richest biodiversity.
Scleractinian reefs first appeared about 300 million years ago. Today
coral reef systems provide some of the most sensitive gauges of
environmental change, expressing the complex interplay of chemical,
physical, geological and biological factors. The topics covered will
include the evolutionary history of reef systems and some of the main
reef builders since the Cenozoic, the effects of biological and
environmental forces on the zonation of reef systems and the
distribution of reef organisms and on reef community dynamics through
time, changes in the geometry, anatomy and stratigraphy of reef bodies
and systems in relation to changes in sea level and tectonics, the
distribution patterns of sedimentary (framework or detrital) facies in
relation to those of biological communities, the modes and rates of
reef accretion (progradation, aggradation versus backstepping; coral
growth versus reef growth), the hydrodynamic forces controlling water
circulation through reef structures and their relationship to early
diagenetic processes, the major diagenetic processes affecting reef
bodies through time (replacement and diddolution, dolomitization,
phosphatogenesis), and the record of climate change by both individual
coral colonies and reef systems over the Quaternary.^1";

thought to prevail: coral reefs.- The American Naturalist 148, 1:
138-159.- <b>FC&#038;P 29-1</b>, p. 65, ID=7048^<b>Topic(s):
</b>species richness; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^Much of the variance in species richness
of terrestrial organisms has been related to levels of available energy
(the species richness-energy hypothesis). In contrast, the global
patterns of coral diversity have been hypothesized to depend mainly on
disturbance and historical factors. In this study, we test several
general diversity hypotheses as they relate to hermatypic corals by
examining the relationships between coral generic richness at 130 sites
worldwide and descriptors of the environment that would be suggested by
the hypotheses. The best environmental predictors of diversity are mean
annual ocean temperature and an estimate of regional coral biomass,
which suggests that available energy limits regional generic richness.
In contrast, we found little evidence supporting other ecological
hypotheses, including the hypotheses that disturbance or invironmental
stability is an important control of diversity. We also investigated
historical hypotheses proposed to explain coral distributions. We found
a relationship between coral richness and up-current island density
that is consistent with vicariance models of speciation and theories of
coral dispersal. Using multiple regression, 71% of the variation in
coral generic richness could be statistically explained using a
combination of variables representing both ecological and historical
factors. Similar patterns exist for both coral species and reef fishes.

A redefinition of ecological groups in corals and other organisms.- Coral Reefs ..., 4: 1-9.- <b>FC&#038;P 14-1</b>, p. 45, ID=0957^<b>Topic(s): </b>zooxanthellate, hermatypic; reef builders; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^The term hermatypic, as widely used in the literature of extant and fossil Scleractinia, includes, by definition (Wells 1933), the confusing generalization of equating reef-building with containing zooxanthellae. In course of time the use of the term diverged into denoting organisms which are either reef-building (including calcareous Rhodophyta) or those that contain zooxanthellae (including soft Alcyonaria). The equation: reef-building corals harbour zooxanthellae and vice-versa, is invalidated by reviewing the various ecological categories of corals
```

```
such as: reef-building species without the support of zooxanthellae,
zooxanthellae-containing corals which inhabit but do not build reefs,
zooxanthellae-containing, non-reef-building corals beyond the
bathymetric and latitudinal limits of reefs, and framework-erecting
corals in deep waters without zooxanthellae. Former attempts to improve
the original definition of hermatypic are shown to be insufficient to
match the ecological diversity of corals. A strict terminological
separation of the properties zooxanthellae-containing, reef-building
and (more generally) framework-building is provided by the use of the
revised, respectively new terms zooxanthellate, hermatypic and
constructional (with the respective antonyms azooxanthellate,
ahermatypic and nonconstructional). This terminology also applies to
non-scleractinians.^1";
s[5728] = "PERRIN C. (2003).- Compositional heterogeneity and
microstructural diversity of coral skeletons: implications for taxonomy
and control on early diagenesis.- Coral Reefs 22, 2: 109-120.-
<b>FC&#038;P 33-2</b>, p. 12, ID=1103^<b>Topic(s): </b>coral skeletons,
mineralogy, taxonomy; coral skeletons; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Fine-skeletal
features of scleractinian skeletons were investigated in living
colonies, from ultra-thinsections and SEM preparations. In contrast to
what is commonly admitted, the coral fiber is a composite structure
differing markedly from a simple aragonite crystal unit. The
heterogeneity of coral fiber is shown by the occurrence of a
micron-scale zonation resulting from incremental growth during cycles
of biomineralization. In addition, high magnification SEM reveals that
a calcification center corresponds to a particular structural element
clearly differentiated from the surrounding fibers and defined by its
own crystal arrangement. The duality of this center &#47; fiber
arrangement corresponds to a general architecture of scleractinians,
resulting from similar processes of skeletogenesis. An additional
fine-scale diversity related to taxonomy is reflected by variations in
the geometry and crystallinity of centres and also in the strength and
regularity of fiber incremental zonation. These initial differences
both within the same colony and between distinct taxa would be
emphasized during diagenetic history, leading to differential
susceptibility of structural elements to diagenetic processes, and also
to specific behavior of distinct taxa in relation to diagenesis.^1";

Encyclopedia of Geology [Selley R. C., Cooks L. R. M. &#038; Plimer I.
R. (eds)]: vol. 2: 321-334.- <b>FC&#038;P 33-2</b>, p. 13,
ID=1107^<b>Topic(s): </b>; Anthozoa Cnidaria; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^This
paper is an entry to the Encyclopedia of Geology and gives an overview
on the actual knowledge of corals and related organisms.
&#034;Cnidarian Organization and Classification&#034;, &#034;Geological
History&#034;, &#034;Coral Structure and Taxonomy&#034;, and
&#034;Coral Ecology and Palaeoecology&#034; are the topics. In
&#034;Geological History&#034; the different groups are discussed,
their Precambrian origins and the Phanerozoic diversity, the latter
characterized by the main groups Hydrozoa, Scyphozoa and Anthozoa.
Organization, distinguishing features, origin and relationships are
treated in more detail - especially of the three main groups Tabulata,
Rugosa and Scleractinia. &#034;Coral structure and taxonomy&#034; deals
as well with problems of interpretation. Coral classification, Ecology
and Paleoecology are discussed with the Scleractinians first and in
comparison with those of the Rugosa and Tabulata. Instructive graphs -
for example life cycles, geological ranges of zoantharian corals,
relationship between septal insertion, and generalized ecological and
palaeoecological ranges of the three main groups - and representative
figures impart additional information. A glossary and selected
references for further reading complete this very informative
representation of &#034;Corals and other Cnidaria&#034;.^1";

<b>FC&#038;P 17-1</b>, p. 19, ID=2116^<b>Topic(s): </b>clonal growth,
algal symbiosis, reefs; Anthozoa; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^The occurrence of
zooxanthellae in Recent scleractlnian corals is strongly correlated
with their growth form, corallite size, and degree of morphological
integration of corallites. The great majority of zooxanthellate corals
are multiserial with small, highly integrated corallites, whereas most
corals lacking zooxanthellae are solitary or uniserial forms with
large, poorly integrated corallites. Beginning in the Jurassic, fossil
scleractinian faunas are morphologically similar to Recent faunas
dominated by zooxanthellate species, strongly implying that most
scleractinians contained zooxanthellae by that time. Evidence for
Siluro-Devonian tabulates and Triassic scleractinians is equivocal but
still suggests that rugosan corals lacked zooxanthellae. Most
populations of Recent zooxanthellate corals contribute to reef
formation, but many do not. Similarly, fossil corals interpreted to
contain zooxanthellae on morphological grounds did not always form
reefs. Recent reef formation depends upon a host of environmental
factors that have little to do with the possession of zooxanthellae per
se. Coral morphology should be a better predictor of the presence of
zooxanthellae in fossil corals than their association with reefs.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^A morphometrical method to quantify and characterize
coral corallites using Richardson Plots and Kaye&#039;s notion of
fractal dimensions is presented. A Jurassic coral species (Aplosmilia
spinosa) and five Recent coral species were compared using the
Box-Counting Method. This method enables the characterization of their
morphologies at calicular and septal levels by their fractal dimensions
(structural and textural). Moreover, it is possible to determine
differences between species of Montastraea and to tackle the high
phenotypic plasticity of Montastraea annularis. The use of fractal
dimensions versus conventional methods (e.g., measurements of linear
dimensions with a calliper, landmarks, Fourier analyses) to explore a
rugged boundary object is discussed. It appears that fractal methods
have the potential to considerably simplify the morphometrical and
statistical approaches, and be a valuable addition to methods based on
Euclidean geometry.^1";

However, biological factors, especially metabolism of symbiotic, hermatypic corals, are among the most important in the construction of coral reefs, despite the importance of geological, palaeoclimatic and hydrographic features. Of the different ways of feeding, the autotrophic one is the most effective for corals living in shallow waters. The intracellular cycling of metabolic products of host and symbiont uses the minimum of energy, leaving more energy available for growth, reproduction and production of calcium carbonate. Adaptation to different environmental factors by corals at different depths leads to the power of the hermatypic corals to compensate for oscillations of sea floor and relative sea level. Therefore, the biologic complex is the central point in understanding the origin of coral reefs. Because of the adaptational peculiarity of corals and their ability to compensate for environmental alterations, this proposal is called the coral reef theory of compensation. The model is valid for all reef types of all coral reef regions.^1";

The periodic occurrence of transgeneric highly variable specific units (spectra) in the fossil record poses nomenclatural and phylogenetic problems. A detailed example among Jurassic montlivaltiids is presented in this paper involving the genera Montlivaltia, Coenotheca, Thecosmilia, Latiphyllia and Complexastrea. These spectra are related to peculiar unstable nonreefal environments and are characterized by the dominance of young stages of the colonial growth (astogeny). The arising nomenclatural difficulties are solved by way of spectral nomenclature which allows naming morphological types, as well as taxonomic units and keeping some stability within the general frame of nominal taxa. Genera correspond to grades (solitary, thamnasterioid, phaceloid, meandroid, cerioid) rather than clades and the colonial structure is a labile character. Several alternative phylogenetic hypotheses are proposed, among which, some can renew our vision of this group and emphasize that the iterative production of generic level shapes is best explained by mean of heterochronic processes. It is suggested that testing of these hypotheses be extended to other families such as Microsolenidae, Stylophyllidae or Fungiidae.^1";

1 [Stanley G. D. jr (ed.): Paleobiology and Biology of Corals]:
249-291.- <b>FC&#038;P 25-2</b>, p. 46, ID=3133^<b>Topic(s): </b>stable
isotopes, C O; corals, zooxanthellate vs azooxanthellate;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^There is a fundamental ecologic differentiation
between zooxanthellate and non-zooxanthellate corals. This paper
reviews factors which govern the stable carbon and oxygen isotopic
composition of these groups of corals. Although the stable carbon and
oxygen isotope compositions of coral skeletons are strongly influenced
by environmental and physiological factors, the precise mechanisms
remain a matter of debate. In particular the oxygen isotopic
composition is known to be governed by the temperature and the oxygen
isotopic composition of the water and perhaps also by kinetic factors.
In contrast the carbon isotopic composition is controlled by a
combination of photosynthesis, respiration, autotrophy, heterotrophy,
and the isotopic composition of dissolved inorganic carbon. Using a
combination of carbon and oxygen isotopes it is possible to distinguish
zooxanthellate from non-zooxanthellate corals.^1";

Corals as Proxy Recorders of Volcanic Activity: Evidence from Banda
Api, Indonesia.- Palaios 11, 3: 286-292.- <b>FC&#038;P 25-2</b>, p. 36,
ID=3186^<b>Topic(s): </b>volcanism indicators; Anthozoa;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^Corals growing on the flanks of Banda Api,
Indonesia, contain records of volcanic activity which occurred in May,
1988. Ashfall killed portions of some massive coral colonies (Porties
lobata), resulting in the formation of death surfaces. These surfaces
were preferential sites for extensive bioerosion and incorporation of
volcanic ash into underlying skeletal pores. Subsequent coral
regeneration resulted in the preservation of death &#47; regrowth
surfaces overlying trapped volcanic ash. An orange-colored iron-rich
chemical precipitate is preserved in the skeletons of corals which
survived the volcanic event. These distinct orange bands are
contemporaneous with the death &#47; regrowth surfaces. The iron
banding is interpreted as being a product of hydrothermal activity
which accompanied volcanism X-radiographs of coral skeletons confirm
that the timing of formation of both the death surfaces and the orange
banding is coincident with the 1988 eruption. The features preserved in
these corals may be valuable proxy indicators of volcanic events in
analogous recent and ancient environments.^1";

</b>density banding; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^The historical development of
research on density banding and related features of cy-clomorphic
growth are briefly reviewed. Since the growth of interest in
sclerochronology in the early 1970&#039;s work on Recent and fossil
corals has proceeded quite separately. In Palaeozoic corals, it has
been the practice to study and illustrate density banding in acatate
peel or thin sections, whilst in Recent corals, X-radiography of thick
(±10mm) slices has been almost universally the rule. The problems
inherent in this latter practice are discussed. A study of the
structure of density banding in Recent and fossil corals underlines the
close similarity between these features in the two groups and supports
their interpretation as comparable in origin and temporal
significance.^1";

Proceedings of the VI. International Symposium on Fossil Cnidaria and
Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 16, ID=3453^<b>Topic(s):
</b>macrosymbiosis; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Symbiosis means living
together and encompasses various types of associations between
different species, ranging from parasitism through commensalism and
amensalism to mutualism. Instances of macrosymbiosis involving modern
zoantharian corals are numerous, especially in reefs, but only a small
proportion of these are likely to be preserved and recognizable in
fossil material. Sessile symbionts have the best potential for
fossilization and recognition. Fossil coral macro-symbioses can be
classified conveniently into encrusting, boring and intergrowth
categories. Trophic relationships between symbionts and the effects of
the symbionts on each others fitness are matters of speculation, but
data on obligacy, taxqnomic specificity, structural integration of
symbionts etc. are accessible in fossil material. A preliminary review
of coral macrosymbioses suggests that: (a) few symbioses are species
specific and obligate for both partners; (b) although some symbionts
show apparent adaptations for living in symbiosis, convincing examples
of coevolution have yet to be demonstrated; (c) symbioses peaked in
numbers during the Devonian, declined in the later Paleozoic, and
increased towards modern high levels from about the Miocene onwards;
(d) whereas encrusting and intergrowth symbioses predominated in the
Paleozoic, boring and intergrowth symbioses are commoner at the present
day.^1";
s[5771] = "POTTS D.C., BUDD A.F., GARTHWAITE R.L. (1993).- Soft tissue
vs. skeletal approaches to species recognition and phylogeny
reconstruction in corals.- Courier Forschungsinstitut Senckenberg 164:
221-231. [P. Oekentorp-Kuster (ed.) Proceedings of the VI.
International Symposium on Fossil Cnidaria and Porifera, Vol. 1].-
<b>FC&#038;P 22-2</b>, p. 17, ID=3457^<b>Topic(s): </b>classification;
corals classification; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Species of Caribbean Porites
were recognized independently in material collected from St. Croix and
Florida using live tissue, allozyme, and morphometric techniques.
Preliminary results suggest close correspondence between methods,
although more subgroups can be distinguished using live tissues and
allozymes. Although no morphometric differences separated three samples
of P. &#34;astreoides&#34;, differences in allele frequencies and
pigmentation suggest the existence of two species. Morphometric and
allele frequency differences both suggest that two species exist within
samples of P. &#34;divaricata&#34;. Both approaches also suggest that
corals collected as P. &#34;furcata&#34; from St. Croix and as P.
&#34;porites&#34; from Miami are the same species; P. &#34;furcata&#34;
and P. &#34;porites&#34; from St. Croix can be distinguished by both
techniques. Phylogenies constructed separately using the two approaches
also tend to agree. Incorporation of fossils into the analysis suggests
that two radiations may have occurred in the Caribbean since the
Eocene: (1) early to middle Miocene and (2) Pleistocene to early
Holocene. Extinctions appear concentrated between the late Pliocene and
early Holocene.^1";

s[5774] = "HUBBARD J.A.E.B. (1997).- Fundamental factors, material
properties and incipient diagenesis: a caveat case study of
scleractinian analogues for rugosan interpretation.- Boletin de la Real
Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4:
117-127.- <b>FC&#038;P 26-2</b>, p. 25, ID=3707^<b>Topic(s):
</b>taphonomy, diagenesis; Anthozoa; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^This paper is
concerned with the hypothesis that in overlooking the information which
can he derived from living corals we are in danger of ignoring data
which is critical to the proper interpretation of the highly sensitive
chemical signals currently beeing derived from them. This has
implications for the interpretation of both extant and extinct groups.
The fundamental feature which distinguishes this paper from the many
more sophisticated studies of living scleractinians and their more
recent geological records in the Pleistocene concerns the nature of the
material properties involved. It draws attention to the influential
role of the critical sizes of the individual components in relation to
their preparation and resultant geologic implications. The main
diagenetic contrasts in preservation appear to relate to the precise
timing of the sealing-off of the coralla from the surrounding migratory
fluids. Where an influx of clay mineral laden waters follows
immediately after a toxic event the likelihood of the preservation of
calical details is higher than normal. Thus clay rich horizons are
likely to contain the best preserved external features although
subsequent penetration of the seal may result in the complete
replacement of the internal fabric.^1";
s[5775] = "GUDO M., HUBMANN B. (1997).- Fremdkoerpereinschlusse in
fossilen Korallenskeletten aus Sicht der Konstruktionsmorphologie.-
Geol. Palaeont. Mitt. Innsbruck 22: 43-59.- <b>FC&#038;P 26-2</b>, p.
58, ID=3736^<b>Topic(s): </b>construction morphology; Anthozoa;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^The fossil records of rugose corals are rare of
swallowed bodies enclosed in the intratabular and intradissepimental
spaces. In the most well known examples of bodies enclosed in the
fossil skeletons they are probably swallowed through the gastrovascular
cavity of the polyp and then they were atrophied together with parts of
the basal soft body. These particles became an enclosed part of the
extracorporeal skeleton. Presupposing that living beings can be
understood as organismic constructions different functions performing
the hydraulic, machine-like, and energy conducing entities can be
explained. By analyzing anthozoan polyps some very important and
indispensible functions are realized. Retention of the hydraulic
filling by a valve like effect of the mouth tube, the ingestion of
large food particles and the ejection of swallowed objects through the
mouth tube are possible. Particles which get into the spaces between
the tethering mesenteries could not be ejected on the usual way back
through the pharynx. Getting rid of such swallowed particles is only
possible by atrophying the basal soft body where the swallowed body has
been deposited. Thereby the particle is enclosed in the extracorporeal
skeleton.^1";
s[5776] = "GATTUSO J.-P., FRANKIGNOULLE M., BOURGE L., ROMAINE S.,
BUDDEMEIER R.W., (1998).- Effect of calcium carbonate saturation of
seawater on coral calcification.- Global and Planetary Change 18:
37-46.- <b>FC&#038;P 27-1</b>, p. 49, ID=3805^<b>Topic(s):
</b>calcification; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^The carbonate chemistry of
seawater is usually not considered to be an important factor
influencing calcium-carbonate-precipitation by corals because surface
seawater is supersaturated with respect to aragonite. Recent reports,
however, suggest that it could play a major role in the evolution and
biogeography of recent corals. We investigated the calcification rates
of five colonies of the zooxanthellate coral Stylophora pistillata in
synthetic seawater using the alkalinity anomaly technique. Changes in
```

```
aragonite saturation from 98% to 585% were obtained by manipulating the
calcium concentration. The results show a nonlinear increase in
calcification rate as a function of aragonite saturation level.
Calcification increases nearly 3-fold when aragonite saturation
increases from 98% to 390%, i.e., close to the typical present
saturation state of tropical seawater. There is no further increase of
calcification at saturation values above this threshold. Preliminary
data suggest that another corals species, Acropora sp., displays a
similar behavior. These experimental results suggest: (1) that the rate
of calcification does not change significantly within the range of
saturation levels corresponding to the last glacial-interglacial cycle,
and (2) that it may decrease significantly in the future as a result of
the decrease in the saturation level due to anthropogenic release of
CO2 into the atmosphere. Experimental studies that control
environmental conditions and seawater composition provide unique
opportunities to unravel the response of corals to global environmental
changes.^1";

evolution.- Zhurnal obshchey biologii 56, 2: 200-209.- <b>FC&#038;P
27-2</b>, p. 58, ID=3922^<b>Topic(s): </b>extinctions; Anthozoa
phylogeny; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>; <b>Geography: </b>^In the evolution of corals the epochs of
flourishing alternated with crisis. During the crisis and the beginning
of the flourishing the evolution rates were maximal. At the time the
taxa of highest ranks emerged (families, suborders, orders).
Subsequently the evolution rates decreased and were minimal at the end
of the epochs of flourishing. 8 crises were established in coral
evolution: Postordovic, Postludlov, Serpukhovo-Bashkirian,
Lower-Triassic, Lower-Jurassic, Middle-Cretaceous, and Palaeocenic.
They differ in their significance and duration. The largest and longest
of them was the Lower-Triassic crisis. During it the most fundamental
taxonomic changes occurred. In the end of Palaeozoic the last clear
representatives of Tabulata and Rugosa disappeared, whereas 20 new
genera, 10 families, and 6 suborders of the Scleractinia order emerged
in the beginning of Middle Triassic. Small Permian solitary rugosae of
the family Plerophyllidae were the ancestors of Mesozoic
scleractinians. The second largest crisis was Famenian. By the
beginning of it the order Heliolitida disappeared, as well as some 30
families and 210 genera of other corals. By the beginning of Carbonic
200 new genera, 20 families, and three suborders of corals emerged. The
third largest crisis took place in Lower Jurassic. By the beginning of
it approximately 96% of Upper Triassic corals have disappeared, whereas
220 new genera, 22 families, and 3 to 5 new suborders emerged in the
end of Lower and in the Middle Jurassic. The epochs flourishing of and
crises of coral evolution were not dependent upon the degree of their
endemism.^1";

```

```
première partie de leur exposé à rappeler quelles sont les
caractéristiques essentielles, biotiques et abiotiques, des milieux
récifaux coralliens: nature des organismes constructeurs, morphologie
des récifs, classification des milieux coralliens, distribution et
conditions d&#039;existence des récifs à Madréporaires, tant fossiles
qu&#039;actuels. La seconde partie est consacrée à l&#039;examen de la
composition, de la répartition et de l&#039;importance des peuplements
malacologiques dans ces milieux, en envisageant successivement les
Mollusques commensaux ou parasites des Madréporaires hermatypiques, les
Mollusques du récif proprement dit, les Mollusques des substrats
meubles biogènes, les Mollusques des eaux récifales et périrécifales.^1";

zoantharian corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Genera of colonial
zoantharian corals have been more numerous than solitary genera through
most of Phanerozoic time even though colonial genera were a minority of
the Rugosa. Various forms of coralla represent widely different levels
of development in terms of both integration within colonies and
adaptive success, but the two are not necessarily correlated. Phaceloid
rugosans represent a low level of integration with no connection
between individuals other than skeletal; in contrast, coenosteoid
scleractinians represent a high level of integration with confluent
gastro-vascular cavities and coordinated skeleton building. But both
forms were very successful in terms of generic diversity and longevity,
whereas Paleozoic coenosteoid heliolitoidids were relatively
unsuccessful. The evolution of coloniality in zoantharian corals was
paralleled by the evolution of the coral-reef building habit. Paleozoic
corals built only small reefs, apparently because of slow growth,
relative instability, and failure to solve the problem of the disposal
of metabolic waste. Mesozoic to Recent corals developed porous
skeletons that are strong, stable, and rapidly built. In addition, they
have developed an algal symbiosis that has solved the waste problem and
increased the rate of CaCO3 deposition. These factors together have
made possible the surf-resistant oceanic reefs of late Mesozoic to
Recent time.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Many
peculiarities of growth and development in colonial metazoans are
related to the fact that a true colony is a clone, composed of
```

```
genetically identical individuals reproduced asexually from a single
founding individual. In fossil colonies the close relationship of
individuals may be difficult to prove, but it must be assumed for
analysis to be meaningful. Intercolony variation is due to the
interaction of genetic and environmental controls as in solitary
organisms. Intracolony variation may be very limited because of the
lack of genetic variation, but microenvironmental differences
(situation within colony) may cause enough individual variation to mask
the restrictive effect of genetic similarity. Study of the number of
major septa in some Devonian solitary and colonial rugose corals shows
significantly less variation within colonies than within
&#34;populations&#34; or species of colonial, or solitary forms.
Greater variation within some colonies may result from either genetic
or mechanical accidents. Septal number and diameter are closely
correlated in populations and species, but analyses of individuals
within colonies frequently show weak or no correlation. Available data
suggest: (1) that septal-number variation may be genetically limited in
rugose corals and (2) that the general assumption that number of septa
is a function of diameter may be in error.^1";

Coral Reefs.- Academic Press, New York and London; vol. 1: Geology 1.;
410 pp.- <b>FC&#038;P 3-1</b>, p. 21, ID=4861^<b>Topic(s): </b>coral
reefs, biology, geology; coral reefs; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^This first geology
volume is restricted to chapters dealing with the reefs of particular
areas;discussion of topics applicable to coral reefs throughout the
world is deferred to the second geology volume. Important additions of
our knowledge of corals reefs, particularly the spectacular results
that stemmed in recent years from work in the Marshall Islands -
seismic surveys and dredging at depths of 1460-3660m, as well as deep
borings - are discussed. This work not only provided proof of
Darwin&#039;s explanation of the origin of deep ocean atolls by
progressive subsidence of their foundations but also yielded important
conclusions on other aspects of the history of those reefs. Ladd
summarizes this work in his chapter on Bikini and Eniwetok Atolls. *
Ironically, the stimulus to the undertaking of these studies was the
desirability of surveys prior and subsequent to the testing of nuclear
explosive devices. The surveys were primarily to document the effects
of the explosions, but incidentally, during a few years of study, they
yielded far more definitive information on coral atolls than had the
total of all previous work. * Similar considerations prompted surveys
of Mururoa Atoll in the Tuamotu Achipelago, surveys which in turn
produced much new data on the reefs, only some of which can be
correlated with data on the atolls of the Marshall Islands. The reefs
of French Polynesia, including Mururoa Atoll, as well as those of New
Caledonia are described by Chevalier in Chapters 4 and 5. * As Stoddart
(Biol. Rev. 44, p. 437) has pointed out and as is briefly discussed by
Whitehouse in Chapter 6, Darwin&#039;s theory is not necessarily
applicable to barrier reefs on continental shelves or surrounding
&#034;high&#034; (continental) islands. Barrier reefs in particular
need further study in regard to the nature and geological history of
their foundations quite apart from work in other geological fields. *
Proposals to establish an air base on one of the islands in the Indian
Ocean initiated studies of the fauna of the islands involved, studies
which were widened to include most of the reefs in the ocean. The more
important features of these reefs are summarized by Stoddart in Chapter
2.[first part of extensive summary]^1";

(1974).- Flume studies on the stability of model corals as an aid to quantitative palaeoecology.- Palaeogeography, Palaeoclimatology, Palaeoecology 015: 1-27.- <b>FC&#038;P 3-2</b>, p. 30, ID=4912^<b>Topic(s): </b>stability, ecology; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Flume experiments were performed in order to investigate the movement, susceptibility to transport, and final orientation of model corals on various sediments under differing current conditions. Seven sets of models (giving a total of 50 models in all) were studied, first on a fixed bed of coarse sand (representing lithified conditions), then on a free bed of the same material (representing unlithified conditions). All movements of the models and their final orientations were recorded. The experiments began with a study of the relationship between a series of spherical caps (hemispheres) and right-spherical cones, and their competent velocities on a fixed bed. These results were then compared with a second series of models having an effective density believed to be analogous with that of Favosites gothlandicus (Lamarck), a species common in the Wenlock Limestone Formation, and found both in and out of its life position. * From these experiments, conclusions regarding the relative stability and susceptibility to transport of various growth forms were drawn. From the experimental evidence, spherical caps would generally be expected to return to their growth orientation, even after transportation, whereas it is unlikely that the conical forms would regain their growth orientation. These results and conclusions were extended by a study of composite models which indicated the manner in which coral colonies would move when subjected to transportation by an unidirectional current. These models demonstrated how the most stable orientation of these models was size-dependent. * The second group of experiments was carried out on an unlithified bed. Here, interference of the models with the current could be studied and also the resulting effect on the sediment. Scour hollows were developed owing to the intense vorticity generated around the higher models. This removal of sediment results in the undercutting of the model. Two possible situations could then arise. Firstly, the model was removed from the bed, this subsequently resulting in the removal of the previously produced sedimentary structures. Secondly, the models tipped forward into the upcurrent scour hollow and were buried, the associated sedimentary structures undergoing modification. * The relative hydrodynamic theory is included where this helps to clarify the results of the experiments. Finally, the relevance of the experiments to the colonial organisms of the Wenlock bioherms is discussed.^1";
s[5798] = "GVIRTZMAN G., FRIEDMAN G.M., MILLER D.S. (1973).- Control and distribution of uranium in coral reefs during diagenesis.- Journal of Sedimentary Petrology 43, 4: 985-997.- <b>FC&#038;P 3-2</b>, p. 32, ID=4918^<b>Topic(s): </b>reefs diagenesis, U; reefs, diagenesis; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^The concentration of about 2ppm of uranium in the aragonitic skeletons of modern scleractinian corals which we studied is a constant value, regardless of occurrence, anatomy or taxonomy. * The presence of cement of aragonite or high magnesian calcite usually raises the concentration of bulk samples to about 3ppm. Modern corals may contain up to 50% of cementing minerals. Organisms, such as corals and coralline algae, while secreting their skeleton, discriminate against the uptake of uranium, whereas the uptake of uranium by mineral
```

```
cements is less restrained. Aragonite cement contains about 3,6ppm and
high-magnesian calcite cement 2,6ppm uranium. * During leaching by
fresh water, the aragonite of the skeletons of corals dissolves out.
This creates hollow molds which fill with drusy low-magnesian calcite.
In emergent reefs from the shores of the Red Sea which display the
effects of progressive diagenesis this calcite is enriched in uranium
(3,9ppm) beyond that found in marine cements. Second-generation calcite
which fills original voids in the coral from the emergent reefs
contains a lower level of uranium concentration (1,3ppm). The level of
concentration of uranium in low-magnesian calcite of diagenetically
altered corals is a function of the availability of uranium in meteoric
waters. * In aragonite as well as in high- and low-magnesian calcite
uranium replaces calcium or occupies lattice vacancies in the crystal
lattice.^1";

Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^When pieces of the
staghorn coral Acropora acuminata are incubated with 14C-urea, the
label is incorporated into skeletal carbonate. Incorporation of this
label differs from that of H14CO3, suggesting urea is not immediately
hydrolysed to provide a further source of HCO3. The effects of certain
organic substrates upon calcification suggest the ornithine cycle is
involved. Citruline, an ornithine cycle intermediate, is found in high
concentrations in the tissues of hermatypic corals. Urea, allantoins,
NH3 and arginine are also present. These compounds are barely
detectable in zooxanthella or an ahermatypic coral. The allantoins may
be present as calcium salts. It is suggested that allantoins are the
medium by which Ca2+ and CO2 are transported to sites of calcification.
Hydrolysis of urea, formed by breakdown of allantoins, yields CO2 and
NH3. The NH3 may neutralise protons formed during precipitation of
CaCO3 and bring about their removal from sites of calcification. As
well as providing urea, the ornithine cycle may also be involved in the
removal of NH3 from sites of calcification.^1";

4/6: 229-273.- <b>FC&#038;P 8-2</b>, p. 52, ID=5735^<b>Topic(s): </b>;
Anthozoa Septodaearia; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Based on more than 6800
phosphatized, originally organic thecae and 12 specimens with partially
preserved soft parts, Septodaeum siluricum n.g., n.sp., a colony
building form ranging from early Ordovician through early Devonian is
described. * The phosphatized soft parts consist of a circular
stomodaeum, evenly subdivided by commonly 6 radial stomodaeal
mesenteries with strong retractor muscles on either side that also
operate a stomodaeal membrane spanning the intermesenterial spaces. The
peripheral zone is evenly subdivided by 3, 6, 7, or 8 radial complete
mesenteries with strong retractor muscles equally well developed on
both faces. Orally located intermesenterial spaces are separated from
the gastro-vascular cavity by an intermesenterial membrane that
represents an aboral-lateral extension of the stomodaeal wall and is
operated by retractor muscles of the complete mesenteries.
Intercommunication between intermesenterial spaces and gastrovascular
cavity is provided by fenestrae. The incomplete mesenteries are short
```

```
and may reach a total number of 32. The complete mesenteries are
inserted singly. Asexual reproduction is by means of lateral increase
and mesenterial budding. * Presence of stomodaeum in combination with
the mode of asexual reproduction characterizes the new taxon as a
representative of the Anthozoa. * The unusual anatomical configuration
of the complete mesenteries, the mode of their insertion, as well as
the possession of stomodaeal mesenteries, and stomodaeal and
intermesenterial membranes, unknown from other Anthozoa, necessitate
the placing of Septodaeum siluricum in a new subclass Septodaearia,
regarded as an ancient, separate phyletic line of the Anthozoa.

the rugose and tabulate corals.- Palaeoworld 19, 3-4: 389-400.-
<b>FC&#038;P 36</b>, p. 63, ID=6455^<b>Topic(s): </b>morphology,
phylogeny; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^At the family level, the
evolution in the compound rugose corals is usually characterized by the
progressive integration of corallites. This type of evolution
corresponds to paedomorphic processes in the astogeny of colonies: the
separation of the daughter polyp from the parent being progressively
delayed as compared to the development of the other characters. At the
end of the lineage, relations between mature polyps are similar to
those existing in the first stages of the increase in the ancestor. *
Tabulate corals are strictly colonial and usually have connections
between polyp cavities. They can develop colonies similar to those
known in the compound rugose corals (fasciculate or massive), but also
other forms (such as cateniform, ramose and coenenchymal). However, a
relative separation of growth habit exists between rugose and tabulate
corals from their radiation during the Ordovician. Besides the
differences in colony shapes, corallite diameters are generally larger
in the Rugosa than in Tabulata. * Several crises affected Palaeozoic
corals, and some of them caused the disappearance of major morphotypes.
After these crises, neither the surviving tabulate nor the rugose
corals gave rise to new taxa with these forms. The evolutionary
processes in post-crisis coral recovery correspond mainly to
heterochronic processes. These proceed within the limits of ontogenetic
(or astogenetic) variability and do not allow innovations such as a
type of colonial development that is not a usual type of increase
within a taxon. Therefore, the replacement of extinct habits by an
evolutionary convergence of taxa with other major habits does not occur
in Palaeozoic corals. These evolutionary processes probably differ from
those acting during an original evolutionary radiation. [original

Sektionsname &#34;Paläozoologie I&#34; mit dem Forschungsschwerpunkt
&#34;Fossile Nesseltiere&#34; innerhalb der Geologischen Abteilung des
Senckenberg-Instituts geht auf die in den späten sechziger Jahren
dieses [XX] Jahrhunderts durchgeführte Neuabgrenzung der Kompetenzen
für die verschiedenen Forschungssammlungen zurück; praktisch existiert
sie seit dem Arbeitsbeginn des Autors als DFG-Assistent in der
Geologischen Abteilung im August 1959 bei Dr. Wolfgang Struve, der als
Projektleiter verantwortlich zeichnete. Der &#34;Setzling&#34; zu
dieser Forschungsrichtung geht aber auf Rudolf Richter zurück: Durch
den Erwerb der Sammlung Wedekind im Jahre 1953, durch die Ausbeute der
Eifeler Richtschnitte und die von seinen Schülern durchgeführten
Neukartierungen der Eifeler Kalkmulden bereitete Rudolf Richter den
Boden für das Wachstum dieser damals neuen senckenbergischen Pflanze
vor. Nach nur vierzigjährigem Gedeihen ist ihr weiteres Schicksal
ungewi&#223;, denn im Frühjahr 1994 nahm der Verfasser seinen Abschied,
und es wird keinen Korallenspezialisten mehr in der Sektion geben.

s[5852] = "VASCONCELLOS A.C.de (1995).- Geometric morphometry and
fossil corals.- FC&P 24, 1: 50-53. [short note] - <b>FC&#038;P
24-1</b>, p. 50, ID=6861^<b>Topic(s): </b>morphometry; corals,
morphometry; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>; <b>Geography: </b>^Recently, two new approaches are being
considered by morphometricians concerning the investigation of problems
of form (Reyment 1991). They are Procrustes and Thin-Plate Spline
analyses. Both are the chief procedures of the geometric morphometry or
the &#034;new morphometrics&#034; (Rohlf &#038; Marcus 1993). Both
procedures are particularly interested in analyse the displacement of
specific points, namely landmarks, when comparing forms. Landmarks can
```

```
be summarized as specific points chosen for a group of organisms that will be compared from specimen to specimen. The displacement of &#034;homologous&#034; landmarks (not in a evolutionary sense) will be analysed and computed in an attempt to quantify transformations in form. [excerpt from a short note, introducing morphometric methods for corals]^1";
s[5853] = "VASCONCELLOS A.C.de (1998).- Geometric morphometry: an example using Lophophyllidium proliferum.- FC&P 27, 1: 33-41.- <b>FC&#038;P 27-1</b>, p. 33, ID=6915^<b>Topic(s): </b>morphometry; corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^The results presented by the analysis of the thin-plate splines has suggested that L. proliferum appears to have had a development centered mainly in two areas, (1) the counter quadrants and (2) its columella. After an initial moment, with enlargement of the corallite following symetrical growth rates (as suggested by W4 during early juvenile phase), subsequent stages contributed little energy to the development of the remaining regions of the corallite as a whole. That pattern explains clearly the bilateral symmetry of this specimen and when it was acquired. * Since most of the corals of L. proliferum type present a very similar pattern, the model of growth suggested here brings attention to two points, (1) the columella in lophophyllid corals seems to be a character of taxonomic value and worth further study, and (2) the counter accelaration, very often cited for these corals, seems to be closely related to the form of the columella. A survey of that accelaration among lophophyllids, in time and space, could possibly bring some new data to explain the great variability of the columellar structure in this lineage of simple solitary rugose corals. [conclusions of the paper]^1";
s[5854] = "anonymous (2000).- History of the International Association for the Study of Fossil Cnidaria and Porifera.- FC&P 29, 1: 15. [short note] - <b>FC&#038;P 29-1</b>, p. 15, ID=7011^<b>Topic(s): </b>IASFCP history; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Corals and sponges belong to the most important group of fossils - and of living animals as well - giving essential answers to lots of questions in paleontology, and especially geology, for example sedimentology. Constructing reefs - megalopoli of species - coral research played an important role in expanded geological mapping and exploration programs within the last fifty years. Especially in the former Soviet Union and in the USA fossil coral specialists &#34;became numerous enough to warrant formal and informal meetings for communication of current research. In the USSR, formal All-Union Symposia On Fossil Corals were organized on a four-year basis by Academician Boris S. Sokolov beginning in 1963 at Novosibirsk. In the USA, William A. Oliver Jr., organized topical sessions on corals for the Paleontological Society in 1965, leading to annual and other meetings of the Friends of the Corals, an informal group of North American specialists&#34; (Sando 1997). * To promote the transparency of coral research and its scientific results as well as to open the possibility for an international exchange of ideas and reprints first steps have been done to establish an International Association for the Study of Fossil Cnidaria. At that time the Eastern colleagues were under severe restrictions on travel outside the USSR and the Eastern-block. Therefore, and as proposed at the Second All-Union Symposium at Tallin in 1967, Sokolov started the organization of an International Symposium to include specialists from outside the &#34;Eastern-block&#34;, e.g. the communist sphere. Then, the Third All-Union Symposium in 1971 in Novosibirsk became at the same time the First International Symposium on Fossil Corals (And Some Other Coelenterata). * Until 1999 seven symposia have been held.^1";

```

```
Porifera]: 173-186.- <b>FC&#038;P 30-1</b>, p. 20, ID=7069^<b>Topic(s):
</b>diagenesis, metamorphism; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Disconnected
Devonian carbonate formations border many nappe and wedge units on the
exterior of the Late Carboniferous Variscan Orogen of central Europe.
Metamorphic gradient decreases sharply outwards, with disruptions by
some nappes. Alterations of the Devonian carbonates range from
amphibolite green schist facies to slight burial diagenesis, from inner
to outer belts of nappes, respectively. The evolution of carbonate
crystal fabrics (including ghosts and relic structures) correlates with
thermal alteration of organic matter, illite crystallinity, the
conodont alteration index and a leveling off of stable isotope amounts.
Bioclasts, mainly the fragments of walls of tabulate corals (genera
Thamnopora, Remesia, Alveolites, Scoliopora and Favosites), were
studied to determine their response to the maximum paleotemperature,
lithostatic pressure and oriented strain forming the host rocks.
Resistance of these fragments to alteration is almost as high as that
of low Mg calcite brachiopods or crinoid ossicles that have been
rapidly depleted in magnesium. Specific conditions, such as the
composition of sediment or early diagenesis of corals produce largely
interwoven paths of alteration, but regular changes can be understood
through analysis of large quantities of material. Eight typical crystal
fabric patterns, here introduced, provide standardized indicators of
differing maximum burial conditions. [original abstract]^1";
s[5856] = "KRASNOV Ye.V., KOSTINA Ye.Ye. (2000).- Corals and reefs in
ocean history. [in Russian, with English abstract].- Bulletin of the
Far Eastern Branch, Russian Academy of Sciences 1: 89-104;
Vladivostok.- <b>FC&#038;P 32-1</b>, p. 18, ID=7140^<b>Topic(s):
</b>reefs; corals, reefs; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^A review of experimental and
literature data is devoted to coral evolution and ecology. Anthozoa are
known from Vendian deposits (up to 700 million years ago) to recent
time. They adapted to depths from intertidal zone to abyssal area and
populated regions from tropical to polar zones. Coral fauna and flora
form different types of biorelief: bioherms, biostromes, reef massives.
Their metabolites are drawn into natural biogeochemical processes. It
is shown that solitary and colonial polyps have parallel evolution and
their geological history is subdivided into several important stages
fixed by the paleontological chronicle. [original abstract]^1";
s[5857] = "VASCONCELLOS A.C.de (2003).- Anthozoa.- FC&P 32, 2: 77-78.-
<b>FC&#038;P 32-2</b>, p. 77, ID=7163^<b>Topic(s): </b>taxonomy,
cladistic; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>; <b>Geography: </b>^This study attempts a
revision of the Rugosa at ordinal level using phylogenetic systematics.
Three major aims were (1) to test their monophyletic nature, (2) to
define at which hierarchical taxonomic level the characters commonly
used in rugose systematics were informative and (3) to formulate a
hypothesis to demonstrate the position of the Rugosa in the tree of
life. * To accomplish these goals a revision of the Orders
Cystiphyllida and Stauriida sensu Hill (1981) was performed. The
phylogenetic analysis was undertaken using the two orders of the Rugosa
as ingroup, and a combination of fossil corals and extant Anthozoa as
outgroup. A total of 126 characters were compiled of which 90 related
to biomineralised features and 36 related to &#34;soft tissues&#34;.
Two phylogenetic analyses were performed. The first analysis used
Alcyonaria as the prime outgroup yielding 6 trees that were merged into
a single tree after optimisation. The second analysis used Tabulaconus,
a Cambrian fossil coral, and yielded six trees. These trees were
combined into a single tree after optimisation being that tree accepted
as the most informative for the problem at hand. The Rugosa appeared as
a monophyletic group but eight of the sixteen sub-orders of the
Stauriida were dismissed. The Rugosa is the adelphotaxon of a group
formed by fossil corals and the Scleractinia with cyclic septal
```

```
insertion. The major implications for the Anthozoa were (1) the
subclass Zoantharia was dismissed and replaced by the subclass
Hexacorallia, (2) the subclass Alcyonaria was dismissed and has now the
status of a family within the Hexacorallia and (3) the time of origin
of the Anthozoa is accepted as Early Cambrian. A new classification for
the Anthozoa is provided. [full text of a short paleontological note;
possibly desription of a finished research project, concerning
systematics of the Anthozoa]^1";

[Proceedings of the 8th International Symposium on Fossil Cnidaria and
Porifera]: 164-172.- <b>FC&#038;P 30-1</b>, p. 20, ID=7068^<b>Topic(s):
</b>organic matrices; corals, sponges; <b>Systematics: </b>Cnidaria
Porifera; Anthozoa; <b>Stratigraphy: </b>; <b>Geography: </b>^Amino
acid compositions of organic matrices associated with modern demosponge
(Astrosclera and Ceratoporella) and coral (Solenastrea and Porites)
skeletons have been studied in different growth zones. Zones
investigated in extant coralla range in age from newly mineralized
areas in the uppermost parts to 3 or 4 hundred year old areas in their
deeper parts. Starting from distinct primary amino acid compositions in
living parts of sponge and coral skeletons, biochemical transformations
visibly affect organic matrices, especially with regard to variation in
aspartic acid concentrations. The influence of extracted organic
matrices on in vitro rates of CaCO3 precipitation was tested
experimentally. Both sponge and coral matrices proved to inhibit
mineral formation, with a strength that is closely correlated with
their amino acid compositions. During diagenesis there is first an
increase in aspartic acid concentration, correlated with a marked
efficiency of matrix to inhibit CaCO3 precipitation over 100 years at
the most, and second, a reverse tendency, leading to progressive loss
of both acidic amino acids and inhibitory strength. Timing of this
double stepped diagenetic pattern differs between sponges and corals,
and also varies among different species within each group according to
their initial biochemical features. [original abstract]^1";

</b>^The arguments advanced previously to include the Archaeo-cyatha
within the Phylum Porifera employed superficial morphological
similarities which do not correspond to the present state of knowledge.
Two major errors are frequently found in previous studies : 1) the
emphasis on the presence or absence of spicules as a definitive
argument, and 2) the direct comparison of fossilized skeletal
structures with living, soft tissue. Although the skeletal
microstructure of the Archaeocyatha is constant and does not correspond
to any known type of microstructure in calcified sponges, there is such
a great variety of microstructural types within calcified sponges that
it is conceivable to consider archaeocyathan microstructure as one of
their primitive forms. Recently some microgranules were discovered in
one species of Verticillites. Direct comparison between Verticillites
convexus (Sponge) and Korovinella sajanica (Archaeocyatha) attests a
great similarity of skeletal morphology, microstructure, and
morphogenesis.^1";

Archaeocyatha; <b>Systematics: </b>Porifera; Archaeocyatha;
<b>Stratigraphy: </b>; <b>Geography: </b>^A modular organization
confers many ecological advantages in reef-building settings, such as
indeterminate growth leading to larger size, greater powers of
regeneration, and an ability to encrust and gain secure attachment to
substrates. The Archaeocyatha, an early Cambrian group of calcified
sponges, were the first skeletal metazoans to develop a modular habit
and to be associated with reefs. Archaeocyaths show the predicted
ecological changes with the appearance of modularity. Supposed species
may be facultatively modular, with modular ecophenotypes always
dominating biohermal settings. However, only genera possessing porous
septa show any development of modularity, suggesting that an initially
well-integrated soft-tissue is a prerequisite for acquisition of the
habit. Increasing integration and simplification of the skeleton can be
correlated with an increase in soft-tissue flexibility. Even though
high integration, skeletally simple stromatoporoid-like forms developed
in irregulars, low integration, branching morphologies were by far the
most successful. Irregulars show a strongly progressive trend of
increasing modularity right up to the final extinction of the group.
This confirms the widespread adaptive significance of integration in
clonal organisms. Modular archaeocyaths survived beyond the extinction
of most solitary forms, suggesting a relative immunity to extinction
presumably on account of ecological response. The solitary nature of
many archaeocyaths explains many of their previously supposed
apomorphies. Modularity is an advanced condition in sponges and we
suggest that paedomorphosis facilitates its acquisition in
archaeocyaths. The widespread appearance of low integration modularlity
in different lineages of archaeocyaths is suggested to represent
adaptation to reef-building settings in areas of relatively high
turbulence, sedimentation rate and nutrient levels which may have
predominated in the early Cambrian.^1";

skeletal morphology and its paleobiological implications.- Paleobiology
18, 4: 464-480.- <b>FC&#038;P 22-1</b>, p. 50, ID=3421^<b>Topic(s):
</b>biomechanics; Archaeocyatha; <b>Systematics: </b>Porifera;
Archaeocyatha; <b>Stratigraphy: </b>; <b>Geography: </b>^A
biomechanical study of archaeocyathan (phylum Archaeocyatha) skeletal
construction was undertaken in order to compare its function with that
of poriferans. Flume experiments were conducted on three cylindrical,
brass models of regular archaeocyathans. Two of these, the
porous-septate and aporous-septate models (i.e., posessing septa either
with or without pores), represent an ontogenetic series; regular
archaeocyathans (phylum Regulares) typically exhibit a reduction in
septal porosity as they grow and many have aporous septa as adults. The
third model is aseptate and represents a morphology that is not found
in fossil record. All models exhibit passive entrainment of flow during
flume testing, a phenomenon on which modern sponges depend for
suspension feeding. Flow direction through the models is consistent
with predictions of the spongiomorph-affinity hypothesis. The three
models behave quite differently, however. The aseptate model is least
effective at passive entrainment. Although some fluid exits the top of
the central cavity (or osculum), a great deal of fluid is entrained out
the top of the intervallum and also leaks out the outer wall. Flow
induction from the oscula of the septate models is augmented when
compared to the aseptate model. The porous-septate model exhibits
slight leakage from the outer wall, and a dye-rich plume exits the top
of the intervallum. Alternatively, the aporous-septate model exhibits
no outer-wall leakage and no entrainment from the intervallum. These
differences in flow pattern between the porous- and aporous-septate
models suggest a hitherto unknown function for septa. Imperforate septa
prohibit the migration of fluid through the intervallum to the
low-pressure, downstream side where leakage occurs. The ontogenetic
shift in septal porosity, common to many archaeocyathan species, may be
a mechanism by which outer-wall leakage is avoided later in life.
Archaeocyathans would have encountered progressively higher ambient
current velocities as their height increased through growth. Outer-wall
leakage is not a problem at low velocities or small sizes, but leakage
becomes serious at higher velocities when tall, adult morphologies are
attained.^1";

Fluid movement in these models always proceeded from the outer wall to the central cavity, exiting through the opening of the central cavity. The performance of our models suggests that passive flow may have been an important factor in the lives of archaeocyathids. Furthermore, the size distribution of archaeocyathid fossils is consistent with the size distribution predicted by the model system for passive flow; that is, their height is inversely proportional to current velocity. Unhindered fluid movement requires that the central cavity be free of living tissue and that the pores not be occluded by tissue. Thus the location of living tissue must have been in and around the intervallum. Their large excurrent opening suggests that archaeocyathids utilized predominantly passive flow; in contrast, animals with constricted ex-current openings, such as sponges, utilize predominantly active, pumped flow. However, this distinction is incomplete since many sponges have large excurrent openings while some archaeocyathids have constricted excurrent openings. Thus, no functional discontinuity exists between sponges and archaeocyathids.^1";

ID=1549^<b>Topic(s): </b>ecology; Porifera, Calcispongiae;
<b>Systematics: </b>Porifera; Calcarea; <b>Stratigraphy: </b>;
<b>Geography: </b>^In Paleozoic calcisponge reefs calcisponges
(inozoans, thalamids, sclerosponges) occurred not only at more than 10m
but also at 0-10m water depth. In Permian and Middle and early Late
Triassic (Carnian) calcisponge reefs, calcisponges were dominat
reef-builders, being the most abundant at 0-10m deep part of the reefs.
In post-Carnian reefs, the 0-10m deep parts were occupied by
scleractinian corals, which won with calcisponges in the ecological
competition; that may account for the extinction of the dominant
reef-building calcisponges of Paleozoic and Middle - early Late
Triassic reefs. A statistic study of mine shows that all calcisponge
species of Permian and Middle - early Late Traissic reefs disappeared
at end-Carnian and all calcisponges species in late Late triassic
(Norian and Rhaetian) are new. The most striking evidences for the
shallow water occurrence of calcisponges in Paleozoic and Middle -
early Late Triassic reefs are (1) the association of calcareous algae
such as Archaeolithoporella, which should live in the shallow photic
```

```
zone, (2) the occurrence of the cemented framestones which lack
micritic matrix but have marine fibrous sparry cements, which indicates
the occurrence of wave action. By comparison with the occurrence of
scleractinian corals and calcisponges in modern reefs, I assume that
calcisponge bioliestones (bioliestone = bio+lie+stone; composed
overturned whole skeletons of main reef-building organisms) and
biorudstones (composed of the skeleton fragments of main reef-building
organisms) might have formed in a water depth 0-3m; cemented
calcisponge framestones (i. e., the calcisponge framestones with sparry
cements) formed in 3-10m; micritic calcisponge framestones formed in
10-20m; calcisponge bafflestone formed in 20-30m; calcisponge
prebafflestone formed in 30- 40m.^1";

growth-bands and paleoenvironmental proxies Sr/Ca and Mg/Ca in
hypercalcified sponge: A micro-laser induced breakdown spectroscopy
approach.- Spectrochimica Acta Part B: Atomic Spectroscopy 62, 12:
1537-1545.- <b>FC&#038;P 35</b>, p. 105, ID=2436^<b>Topic(s):
</b>sclerochronology; Chaetetida; <b>Systematics: </b>Porifera;
Chaetetida; <b>Stratigraphy: </b>; <b>Geography: </b>^Long classified
as coral hydrozoans, Chaetetids are now considered as a group of very
shallow marine hypercalcified sponges. As corals do, they grow by
adding calcium carbonate under their pellicular living body in such a
rhythmic and regular way that we suspect that sclerochronology is
possible, based on the hypothetical annual growth bands of their
skeleton. Regarding to its accurate lateral resolution of 5 µm by laser
shot, micro-LIBS study was chosen to check its potential for such
application. The LIBS apparatus is composed of a microscope coupled
with a 266 nm Nd-YAG laser, delivering a 4 mJ-power per shot, and an
ICCD camera. The acquisition of the spectra is made via the SE 200
spectrograph, on the large 190 nm to 1100 nm wavelength range. The
entire longitudinal thin section of the specimen was analysed from the
bottom to the top of the Ptychochaetetes section in a multi-elementary
cartography for Ca-Mg-Sr elements. Sodium and Barium were also detected
in trace amounts. The Mg/Ca concentrations are mainly between 400 and
600 mmol/mol considering an average value for each profile. This study
shows that during the Ptychochaetetes growth, an obvious time-dependent
```

```
heterogeneity in the chemical Mg/Ca and Sr/Ca composition can be
observed. These variations demonstrate the possible use of this method
for sclerochronological studies.^1";
s[5907] = "KERSHAW S., WEST R.R. (1991).- Chaetetid growth form and its
controlling factors.- Lethaia 24: 333-346.- <b>FC&#038;P 20-2</b>, p.
74, ID=2980^<b>Topic(s): </b>growth form, controlling factors;
Chaetetida; <b>Systematics: </b>Porifera; Chaetetida; <b>Stratigraphy:
</b>; <b>Geography: </b>^The skeleton begins as a laminar unit with
many callicules starting at the same time. Several styles of early
growth occur, but the profile remains simple. Similar morphologoes
develop to those of stromatoporoids, tabulates, colonial rugosans, etc.
and are primarily influenced by sedimentation and turbulence. Columnar
and branching chaetetids grew in quiet water; laminar and domical, in
water of higher energies. Encrusting forms grew in a wide range of
environments. No certain relationship can be demonstrated between
taxonomy and growth form.^1";

Proceedings of the VI. International Symposium on Fossil Cnidaria and
Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 20, ID=3466^<b>Topic(s):
</b>microstructures; Chaetetida; <b>Systematics: </b>Porifera;
Chaetetida; <b>Stratigraphy: </b>; <b>Geography: </b>^In the first part
of this paper, a review of three classical terms (&#34;water-jet&#34;,
&#34;penicillate&#34;, and &#34;trabecular&#34;) used in
microstructural analysis is presented. Examination of calcified fibrous
tissues encountered in living sponges: the &#34;water-jet&#34;
microstructure in a Merlia, and the &#34;penicillate&#34;
microstructure in a Ceratoporella is compared with a &#34;simple
trabecular&#34; structure (from a scleractinian coral) and leads us to
propose criteria for separating these different organizations of
skeletal tissues. Application of these criteria to different examples
of chaetetetid sponge skeletons ranging from Carboniferous to Recent,
allows us to modify the usual pattern of their distribution through
time. The synchronic changes observed in both mineralogic and
microstructural characters are clearly consistent with previous data
obtained by study of different &#34;spherulitic&#34; structures in
sponges. These results indicate that oceanic conditions inhibit or
promote the development of calcified nonspicular skeletons in
sponges.^1";
s[5910] = "STANTON R.J., LAMBERT L.L., WEBB G.E. (1997).- Positive
geotropic growth in Chaetetes.- Boletin de la Real Sociedad Espanola de
Historia Natural, Seccion Geologica 92, 1/4: 197-207.- <b>FC&#038;P
26-2</b>, p. 28, ID=3713^<b>Topic(s): </b>geotropic growth; Chaetetida;
<b>Systematics: </b>Porifera; Chaetetida; <b>Stratigraphy: </b>;
<b>Geography: </b>^Specimens of Chaetetes (Porifera) in living position
generally are oriented with growth directed upward and outward, away
from the substrate. This is documented by convex upward growth surfaces
denoted by tabulae and growth interruption surfaces, and by numerical
increase in tubules from the initial growth nucleus towards the outer
surface. Abundant Upper Carboniferous (Atokan) Chaetetes in the Hueco
Mountains of West Texas, USA grew predominantly in this orientation,
but many specimens grew downward, with the growth surface in contact
```

```
with the grainstone to packstone substrate. This growth habit is
documented by two types of evidence - tubules of some large specimens
in growth position grew only downward, or downward as well as upward
and laterally, and small, subspherical nodular specimens display
concentric growth without attachment surfaces, growth interruption
scars and overlapping, cross-cutting growth layers indicative of
sequential growth and rotation. Thus, that part of the Chaetetes in
contact with the substrate was not killed nor was skeletal accretion
interrupted. Growth to and against the substrate suggests either that
Chaetetes was capable of efficient organism-wide transport of
nutrients, oxygen, and metabolic waste, or that it possessed other
novel means of acquiring nutrients, such as heterotrophic symbiosis or
direct absorption of dissolved nutrients from substrate pore water.^1";

Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 399-409.-
<b>FC&#038;P 23-1.1</b>, p. 25, ID=4096^<b>Topic(s): </b>species
concept; Chaetetida; <b>Systematics: </b>Porifera; Chaetetida;
<b>Stratigraphy: </b>; <b>Geography: </b>^Skeletons of fossil coralline
demosponges of the order Chaetetida exhibit little morphological
variability. Differences in growth form are often obvious, but
microscopic features are few in number, though highly variable. This
skeletal conservatism is well illustrated by the, until now, number of
phyla into which chaetetids have been placed. Studies of Carboniferous
species, seven from North America and two from Europe, indicate that
the two most commonly used variables, tubule (calicle) diameter and
tubule (calicle) wall thickness, are not species specific.
Additionally, the cross-sectional areas of the tubules (calicles), a
more realistic parameter, also fails to discriminate between these
currently recognized species. Intraspecific variability of these
parameters is greater than interspecific varibility. No doubt some of
the observed variability is due to taphonomic (diagenetic) processes.
Perhaps some of the variability is linked to the clonality of these
simple invertebrates, a life style that has often been overlooked in
taxonomic, and other, studies. Available data strongly suggests that
perhaps a major amount of the variability noted is phenotypic
plasticity (ecophenotypic), resulting from the association between
Chaetetes and algal symbionts, and the resulting constrains of
latitudinal position and water turbidity. The drastic decrease,
possibly demise, of the genus Chaetetes at the end of the Westphalian
(Desmoinesian) may be related to the zooxanthellate association and
climate warming in the Stephanian (Missourian).^1";

corallina; <b>Systematics: </b>Porifera; Corallina; <b>Stratigraphy:
</b>; <b>Geography: </b>^Porifera with secondary calcareous skeletal
elements are observed within all main taxa of the Pinacophora (Calcarea
&#47; Demospongiae) except the Homosclerophorida. Within the
Hexactinellida, taxa with calcareous skeletons are missing. The
calcified sponges are normally called &#34;Sclerospongia, coralline
sponges, Pharetronida, Sphinctozoa, Chaetetida, and
Stromatoporida&#34;. These different skeletal types developed
independently several times. The ability to form secondary calcareous
skeletons is linked with the cytoplasmatic Ca2+ control and the Ca2+
detoxification which is a vital effect of the cell. The secondary
calcium salt skeletons are one possibility to eliminate the Ca-surplus,
and the calcareous skeletons thus are to be regarded as a metabolic end
product. The ability to form a calcareous skeleton is interpreted as a
symplesiomorphy within the Pinacophora and is part of their basic
pattern. It is a typical cryptotypic character which is developed in
certain pinacophoran taxa as autoapomorphies. [first fragment of
extensive summary]^1";

(eds)]: 322-340; Springer-Verlag, Berlin.- <b>FC&#038;P 21-1.1</b>, p.
61, ID=2814^<b>Topic(s): </b>non-spicular biomineralization; Porifera
Demospongiae; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>; <b>Geography: </b>^These sponges form calcareous
skeletons 1) by mineralization of a collagenous matrix (eg. Vaceletia,
Calcifibrosponoia); 2) through a secretory pinacoderm (eg.
Ceratooorella. Merlia); 3) intracellularly (eg. Astrosclera).
```

```
Mineralogy of the skeleton may be a response to water chemistry
changing in the Sandberg cycle. Microstructure of the calcareous
skeleton is likely to have taxonomic significance only at lower
taxonomic categories. The calcareous skeleton is thought to be a
passive response of the sponges to changing environmental conditions.
It can be produced &#034;with relative ease&#034; by these sponges.^1";

359-367.www.biolbull.org/cgi/content/abstract/193/3/359.- <b>FC&#038;P
26-2</b>, p. 54, ID=3732^<b>Topic(s): </b>polymorphism, molecular data;
Porifera Demospongiae; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>; <b>Geography: </b>^To test the competing
hypotheses of polyphyly and monophyly of &#034;sclerosponges,&#034;
sequences from the 5&#039; end of 28S ribosomal RNA were obtained for
Astrosclera willeyana, Acanthochaetetes wellsi, and six other
demosponge species. Phylogenetic relationships deduced from parsimony
and neighbor-joining analyses suggest that these sclerosponges belong
to two different orders of Demospongiae: Astrosclera willeyana, being
closely related to the Agelasidae, belongs to the Agelasida,
Acanthochaetetes wellsi, being closely related to the Spirastrellidae,
belongs to the Hadromerida. These results contradict the hypothesis
that sclerosponges are monophyletic and imply that a massive calcareous
skeleton has evolved independently in several lineages of sponges.^1";

(2001).- Coralline demosponges - a geobiological portrait.- Bulletin of
the Tohoku University Museum 1 [Proceedings of the 8th International
Symposium on Fossil Cnidaria and Porifera]: 219-235.- <b>FC&#038;P
30-1</b>, p. 20, ID=7071^<b>Topic(s): </b>skeletogenesis; Porifera
Demospongia corallina; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>; <b>Geography: </b>^The polyphyletic coralline
demosponges possess a calcareous basal skeleton of 4 major morphotypes.
Each has its own phylogenetic history, with different mechanisms of
formation. One extant taxon of each skeletal type has been
investigated, and its biochemical (e.g., intracrystalline organic
matrix proteins), geochemical (e.g., stable isotopes), and histological
properties described in detail. * The thalamid Vaceletia shows
similarities in its skeletal features to extinct archaeocyathid sponges
due to the presence of special Ca2 waste deposit chambers in the lower
part of the skeleton. In our opinion this type is phylogenetically the
most important one because it represents one possible evolutionary way
of Ca2 detoxification and illustrates one function of basic
biomineralization (Ca2 -detoxification). More sophisticated
biomineralization processes are developed in the agelasid
Ceratoporella, the &#34;chaetetid&#34; hadromerid sponge Spirastrella
(Acanthochaetetes) wellsi, and the &#34;stromatoporoid&#34; agelasid
Astrosclera willeyana. Each of these taxa shows a distinct process of
formation with a unique composition of its intracrystalline organic
matrix and geochemical features, here characterized in detail. A model
of phylogenetic relationships and grades of development is proposed. *
The first metazoans with CaCO3 biomineralization were the worm like
Cloudinidae from the late Sinian, which form a tube with a foliated
structure. However, the taphonomy controlled mode of basal skeleton
formation in Archaeocyatha and Vaceletidae is the most ancient type of
biologically controlled metazoan biomineralization. In general, basal
skeletons of coralline sponges represent the simplest biologically
controlled mineralization, intermediate between biologically induced
type (e.g., organomineralization) and the fully enzymatically
controlled mineralization of higher Metazoa. [original abstract]^1";

of the Heliolitida.- Palaeoworld 19, 3-4: 268-277.- <b>FC&#038;P
36</b>, p. 76, ID=6480^<b>Topic(s): </b>classification; Heliolitida;
<b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>;
<b>Geography: </b>^The concept of the sum of common features has been
used in order to compare the Heliolitida with the Tabulata and Rugosa
and determine the position of Heliolitida in the classification system
of Palaeozoic corals. Such morphological characters as the number of
septa, septa of the second order, epitheca, coenenchyme and
multiplicity by four have been considered. Coenenchyme is present in
many taxa and there are no more compelling reasons for the integration
of Heliolitida and Halysitida than for the integration of Heliolitida
with other taxa containing coenenchyme. The dynamics of some features
shows that the differences between three main groups of Palaeozoic
corals are within the limits of variation of relative organisms. A high
degree of similarity testifies to the close relationship of the
Heliolitida and the different qualitative and quantitative expression
of similar features testifies to their early divergence from a common
```

```
ancestor and subsequent independent evolution. Asto-phylogeny and
morphological homogeny of all Heliolitida confirm their evolution as a
separate, unitary group. Heliolitida is a monophyletic group of corals
that is equal to the Tabulata and Rugosa in rank. A common origin
requires that the orders should be united into one subclass
Paleosclerocoralla of the class Anthozoa. [original abstract]^1";

numbers; Heterocorallia; <b>Systematics: </b>Cnidaria; Heterocorallia;
<b>Stratigraphy: </b>; <b>Geography: </b>^Since the discovery of new
heterocoral with 3 septa, the septal variety of the different genera of
heterocorals has been clearly revealed. According to the developmental
model of the new septa, the heterocorals can be divided into two types,
one with fossula and the other without fossula. The fossula - bearing
type can be developed from the genus Triphyllia with 3 septa to the
genus Pentaphyllia with 5 septa and furtherly to the genus Fossaphyllia
of multisepta. The non-fossula type can be developed from the genus
Quadratiphyllia with 4 septa to the genus Hexaphyllia with 6 septa and
furtherly to the genus Heterophyllia with multisepta. Besides, the
family Crepidophylliidae with the aulos structure and the family
Longlinophylliidae with special wall structure have been found. This
paper has suggested a systematic classification of the known 19 genera
of the heterocoral, and placed the Heterocorallia as subclass of the
Anthozoa which is equivalent to the subclass Rugosa.^1";

monophyly; Porifera Hexactinellida; <b>Systematics: </b>Porifera;
Hexactinellida; <b>Stratigraphy: </b>; <b>Geography: </b>^Mostler
(1986) published a rich collection of Paleozoic hexactinellid spicules
from different localities of the world. We want to draw the attention
of spongiologists to this publication, because it has been practically
ignored so far (maybe due to the fact that they were published in a
geological journal). It can be shown that the main taxa of living
hexactinellid sponges (Hexasterophora and Amphidiscophora) can be
traced back even to the Cambrian. [...] The fact that Hexasterophora
and Amphidiscophora are very old in origin, and that they have been
developing independently at least since the early Paleozoic, of course
does not infer that the Hexactinellida are polyphyletic in origin. The
Hexactinellida are a well-established monophylum. [excerpts from the
short note]^1";

<b>Systematics: </b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^Several new types of conulariid septa are described.
They grew in adapertural direction with the growth of the animal,
supported mesenteries, and served for the attachment of longitudinal
muscles. One septal type indicates the presence of peristomial pits.
Cessation of septal growth, followed by the onset of new septal
portions, is interpreted to have been caused by processes linked with
strobilation. From observations made on skeletal structures, the
conulariid animal, a true scyphozoan, is reconstructed. Its relation to
the Scyphomedusae, in particular to test-bearing scyphopolyps, is
discussed. * Conical conulariid tests with a circular cross-section,
recovered from Silurian and early Devonian strata of New South Wales,
are placed in the new suborder Circonulariina. It comprises one new
family, two new subfamilies, four new genera, and five new species that
are described. [original summary]^1";

```

```
<b>Systematics: </b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>^The carbonate mineralogy of this calcified hydrozoan
family is controlled largely by phylogenetic rather than environmental
factors. X-ray diffraction analysis of 24 of 25 genera (almost the
entire family) indicate that the skeletons of most species analyzed (54
species in 20 genera) were aragonite; only 7 species in 4 genera were
calcite. In addition, several species contained coexisting polymorphs:
7 calcitic species with traces of aragonite; 1 aragonitic species with
traces of calcite and 2 species with variable percentages of both
polymorphs, which is dependent on the distance from the growing tip.
Mole % magnesium carbonate in the calcite ranged from 6.5 to 10.0, but
had no correlation to any known variable. Likewise, no correlation was
found between polymorph type and any morphological or environmental
variable, except for a generalized temperature effect, wherein genera
with calcitic coralla are restricted to water colder than 13°C;
aragonitic coralla occur at temperatures from -1.5 to 30°C. However,
there is a close correlation of the polymorph type to the generic
phylogeny of the family, according to the cladogram.^1";

Paläontologische Zeitschrift 51: 117-130.- <b>FC&#038;P 6-2</b>, p. 7,
ID=0114^<b>Topic(s): </b>growth bands; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Rugae
are more or less horizontal, fine ridges of the epitheca of corals.
Therefore, they are rare in modern scleractina who seldom have an
epitheca. Following the studies of Barnes (1972) the rugae are a sign
for the daily increment of the sceleton. Besides the rugae there are
also other zones of growth. They are shown by the radiography as an
alternation of dark and light bands. These zones of different density
are interpreted as a seasonal change of zones of different.thickness (?
and arrangement) of trabeculae. It seems possible that there is also a
monthly rhythm of the growth the causes of which are unknown. * In
rugosa there are rugae in solitary corallites as well as in colonial
coralla. The rugae of the cerioid specimen of &#34;Columniphyllum&#34;
sulcatum described by Quenstedt 1879 have a width up to 0,3mm. In spite
of this unusual width it seems probable that these rugae are also the
product of the daily increment. * The difficulties of interpretation,
identification and combination of rugae in determined time periods are
great handicaps for their use as &#034;geochronometric clocks&#034;.
But with more knowledge about the growth of recent corals in regard to
the diverse factors of the environment, the rugae would be a possible
important feature for palecologic evidences. [original abstract]^1";

coral skeletons.- Geologos 6: 89-109.- <b>FC&#038;P 33-1</b>, p. 51,
ID=1100^<b>Topic(s): </b>diagenesis; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Rugose
coral microstructure exhibits striking similarity to that in
Scleractinia. The main differencelies in the mineral composition:
calcitic in the former and aragonitic in the latter. Calcitic
skeletonsof the Rugosa are commonly better preserved than those in the
Scleractinia, and therefore some ofthem have been interpreted as
unaltered, a position rejected in this paper. The dual nature of
septa,which commonly consist of a primary trabecular septum and
secondary fibrous sheets, results indifferently expressed diagenetic
alteration in comparison of other structural elements.It has been
postulated that both early and advanced diagenesis may, in some
circumstances, bedistinguished in the Rugosa. In most instances the
early diagenetic features were destroyed by thepost-burial alterations.
Replacement and recrystallization are the most important processes
amongthe advanced chemical alterations. Both may either facilitate the
recognition of original macro- andmicrostructures or obscure them
Surface replacement by silica promotes perfect preservation ofshape and
inner morphology, whereas pervasive replacement my destroy both.
Selectedreplacement by hematite may help in exposing the trabecular
microstructure of septa, whereas deepreplacement may destroy the entire
morphology. Physical alteration, such as crushing and flatteningof
skeletons are always destructive. The result from compaction, and their
scale depends on skeletalmorphology and on the relationship between the
rate of infilling of intra-skeletal spaces and theaccumulation of
surrounding sediment.Pre-burial events, such as overgrowth and
```

```
penetration by borrowing organisms, their holdfasts orroots may aid in
the recognition of early diagenesis, but may also led to substantial
pre-or postburialskeletal alteration, resulting sometimes in total
destruction. This depends mostly on the pH ofpore fluids.^1";
s[5972] = "LIN YINGDANG, LIU PENGYU (1999).- The systematic position of
the solid column of Rugose corals.- Acta Palaeontologica Sinica 38, 2:
. [pp?].- <b>FC&#038;P 29-1</b>, p. 57, ID=1446^<b>Topic(s):
</b>structures columella; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>; <b>Geography: </b>^The systematic position of
the solid column of Rugosa has been a controversial issue for a long
time. The solid column consists of fibrous tissue and clearly differs
from the axial column or protoaxial column. Its axial structure has no
relationship with the cardinal septum or counter septum and inner ends
of the septa. It is an indepently developed structure in the rugose
coral. So, the Rugosa with solid column could constitute a new order -
Cyathaxoniida ord. nov. According to the unique fibrous tissue and the
shape of solid column, this order could be further subdivided into
three families: Cyathaxoniidae Edwards &#038; Haime, 1850,
Amygdalophyllidae Grabau, 1935, and Ekvasophyllidae Hill, 1981. There
are abundant solid column corals in Early Carboniferous of China. In
this paper, three genera (including 1 new genus) and five species
(including four new and 1 uncertain species) are described. They were
found from Datangian to Early Carboniferous in Qinghai and Yunnan
provinces. [original summary]^1";
s[5973] = "VASCONCELLOS A.C.de (2001).- Homoemorphy and levels of
generality in Rugose corals (Anthozoa, Rugosa).- Journal of Comparative
Biology 3, 1: 103-108.- <b>FC&#038;P 30-1</b>, p. 22,
ID=1545^<b>Topic(s): </b>homeomorphy; Rugosa, homeomorphy;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^Homeomorphy has been considered as one of the chief
problems in rugose systematics because it affects the whole form of the
organism, in contrast to homoplasy that acts only against some
features. However, it is observed in traditional rugose systematics
that all features used to diagnose forms are also usually employed to
define groups of different levels of universality. That practise leads
to a situation where many characters appear more than once in related
and unrelated groups causing a false feeling of homeomorphy as the main
process acting during the development of the Rugosa. In an attempt to
observe order in this group, it should be observed that characters of
higher generality be used to define lareger groups while those of lower
generalty be employed at lower levels of universality. Characters like
form of the coralla, in colonial forms, or corallite shape, in solitary
forms, are fitted to define groups immediately after the great group
Rugosa, that is, suborders or maybe families, but they cannot be used
at specific level since they are of higher order. The same can be said
of some skeletal elements like tabulae, dissepiments and axial
structure in general. The derived states of those characters can only
be used to define groups, in lower level of universality, after proved
to be synapomorphous among them. Using of non-biotic data, like
stratigraphy and biogeography, to test trees can just be accepted when
used a posteriori. An example of character distribution is presented
with some Carbonifeorus rugose corals from the Siphonodendron-group. ^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^Low-Mg calcite (LMC) and
high-Mg calcite (HMC) have been identified confidently as original
biominerals in different rugose corals. Devonian Tabulophyllum had a
LMC skeleton, whereas Pennsylvanian Lophophyllidium had a HMC skeleton.
Zigzag microstructure, a diagenetic microstructure in rugose corals,
may be related to early migration of Mg2+ ions during transformation of
HMC into LMC. Therefore, zigzag microstructure may indicate that the
original mineral was HMC even in specimens that subsequently converted
to LMC. Stratigraphically, corals with zigzag microstructure are
confined to the late Paleozoic, which is coincident with the
&#34;aragonite sea&#34; of P.A. Sandberg. Hence, fluctuating Mg/Ca
ratios may have directly controlled oscillations in marine carbonate
chemistry and the mineral composition of rugose corals so that HMC
skeletons (as indicated by zigzag microstructure) formed during
intervals with &#34;aragonite seas&#34; and LMC skeletons (e.g.,
Tabulophyllum) formed during intervals with &#034;calcite seas&#034;.

s[5976] = "GUDO M. (2002).- Structural-functional aspects in the
evolution of operculate corals (Rugosa).- Palaeontology 45, 4:
671-687.- <b>FC&#038;P 31-2</b>, p. 39, ID=1675^<b>Topic(s):
</b>constructional morphology; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Among the Rugosa
operculae were developed by only few genera. One is the slipper-shaped
Calceola and another is the pyramidal shaped Goniophyllum. On the basis
of biological and morphological knowledge of recent corals, the two
different bauplans of the soft bodies of Calceola and Goniophyllum have
been reconstructed. The soft body (i.e. the polyp) of a rugose coral is
thought to have all the basic structures of anthozoan polyps: a
barrel-like body shape, a flat oral disc with tentacles, and the mouth
from which the pharynx reaches inside the gastric cavity. Furthermore,
as in all Anthozoa, Rugosa had internal mesenteries that act as tensile
cords; during growth in diameter further mesenteries were inserted. In
contrast to all other Anthozoa, in the Rugosa new single mesenteries
were added in four insertion sectors. The bauplans of Calceola and
Goniophyllum differ in the pattern of mesentery insertion into these
four sectors. Calceola had a serial, insertion pattern and Goniphyllum
had a symmetrical insertion pattern. They are representatives of the
two different bauplans within the Rugosa. The lid corals are examples
of convergence evolved genera; Calceola as well as Goniphyllum
originated by quite simple modifications of the ancestral type. The
peculiar shapes, the operculae and especially the straight hingers
between the calyx and the lid(s) result only from mechanical necessity.
Under special conditions (such as high sedimentation rates) these
modifications of the corallum represent suitable tactics for
survival.^1";

The septa of Pilophyllia are clearly amplexoid, and are composed mainly of lamellar sclerenchyme in the proximal part of the corallum, but are characterized by development of trabeculae in the upper part. The outer part of the septa in the peripheral stereozone are thick and contiguous, containing stout rhabdacanth trabeculae invested with lamellar tissue. The septa grow suddenly thin beyond the stereozone, but still comprise rhabdacanth trabeculae that are developed upon the successive tabular floors. The clear boundary and evident difference between the juxtaposed and well-preserved lamellar and fibrous tissue as seen within the septa indicate that the idea of secondary origin of the lamellar structure of the skeleton is not tenable. * There are altogether 14 species and subspecies of the genus, among which, the three new ones, PilophyJlia simplex Chen, P. alternata Chen and P. densitabulata Chen are described here. Only three species occur in the Lower Silurian. A comparison of the various species show that a clear tendency existed for the fibrous structure, i.e. the trabeculae, to develop at the expense of lamellar structures at higher horizons (pI. II, fig. 1-4). Other evolutionary trends include thickening of the septa and increasing width of the stereozone. * On the basis of skeletal structures, Pilophyllia is attributed to Family Amplexidae, which is characterized by amplexoid septa and progressive development of fibrous skeletal structures. Two groups may be recognized in the family, a primary group dominated by the lamellar tissue of septa throughout, including Amplexoides, Lindstroemophyllum, probably also Zelophyllum and the Late Ordovician compound form Crenulites, in addition to the Carboniferous Amplexus and Bordenia, and an advanced group with a progressive development of trabeculae septa, including Pilophyllia and Protopilophyllum. The Devonian Siphonophrentis and Heterophrentis with complete septa may not be included in this family.^1";

```

```
this genus has a unique internal morphology most similar to Neaxon
Kullmann. Although the systematic relationships of small, aulate
solitary corals remain dubious, Trochophyllum is referred provisionally
to the family Petraiidae de Koninck. The genus is represented by the
type species, T. verneuilanum Milne-Edwards and Haime, and the informal
taxon T. sp. 1, which are known only from Tournaisian (early Osagean)
strata in Kentucky and Indiana, USA. Previously published records of
Trochophyllum outside the type locality of its type species are either
invalid or unconfirmable on present published information.
Trochophyllum is distinguished by a highly variable aulos that is
typically of the stereotheca-type, filled with stereoplasm at maturity;
axial tabulae absent or not preserved at maturity; cardinal septum
shortened in the calice; and minor septa developed only as
foundations.^1";

s[6000] = "WANG HONGZHEN, CHENG JIANQIANG (1990).- Microskeletal
structures of the genus Lophocarinophyllum with a discussion on the
family Lophophyllidiidae.- J. China Univ. Geosc., Earth Sci. 15, 3:
257-262. [in Chinese, with English summary].- <b>FC&#038;P 19-2.1</b>,
p. 33, ID=2751^<b>Topic(s): </b>microstructures; Rugosa,
Lophocarinophyllum; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Among the family
Lophophyllidiidae Moore et Jeffords 1945, Lophocarinophyllum Grabau
1922 possesses well developed septal flanges. The microskeletal
structures of the septa are either composed of distinct monacanth
trabeculae with clearly radiating needles, or of an axial zone of
irregular slender trabeculae with diverse needles and lateral zones
with subparallel needles or tufts. The flanges have slender trabeeulae
in the axial zone and parallel needles in the lateral zones, but no
regular trabeculae with radiating needles were observed. In several
specimens of Lophocarinophyllum acanthiseptum collected from the Upper
Carboniferous in the North China, weakly developed convex tabulae are
present. Thus it may be held that the genotype is possessed of tabulae,
and the genus Lophotabularia Shi, established on the presence of
tabulae, may better be considered as a synonym of Lophocarinophyllum.
So far 8 species of Lophocarinophyllum, L. acanthiseptum Grabau, L.
major Heritsch, L. yakovlevi Fomichev, L karpinski Fomichev, L. suetomi
Minato, L. lophophyllidium Liao et Xu and L abnome Shi may be
recognized, including the new species L. stereoseptum described herein.
In our revised classification of the rugose corals (Wang et al 1989),
10 genera were assigned to Lophophyllidiidae, but Lophophyllum was
tentatively included therein. Actually the latter genus (genotype L.
konincki) is a monozonal coral of zaphrentoidid affinity probably akin
```

```
to Claviphyllum and may therefore better be transferred to the family
Bradyphyllidae under the suborder Zaphrentitoidina. Thus the family
Lophophyllidiidae includes 8 genera: Lophophyllidium Milne-Edwards et
Haime, Sugiyamaella Yabe et Minato, Lophocarinophyllum Grabau,
Stereostylus Jeffords, Neostereostylus Lin, Tlmorphyllum Gerth,
Lophamplexus Moore et Jeffords and Paralophophyllidium Lin.^1";

164: 119-125. [P. Oekentorp-Kuster (ed.) Proceedings of the VI.
International Symposium on Fossil Cnidaria and Porifera, Vol. 1].-
<b>FC&#038;P 22-2</b>, p. 13, ID=3445^<b>Topic(s): </b>morphology,
taxonomic reliability; Rugosa, morphology; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Rugose
coral taxonomy is based on morphological features which vary in
reliability for taxonomic purposes. Microstructures are interpreted as
having a calcitic origin and only faintly altered by diagenesis. Thus
fibro-normal and trabecular septal structures as well as septal
dilations are important taxonomic features. The presence or absence and
type of holdfasts and genuine fossular structures reveals special modes
of life strategies and are also very important taxonomic signatures.
Biometry must be critically applied as intraspecific variation and is
dependent on various life strategies and ecological influence.^1";

apparatus of Rugosa.- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 91, 1/4: 037-052.- <b>FC&#038;P 26-2</b>, p.
8, ID=3670^<b>Topic(s): </b>structures, third order septa; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^Different types of &#34;third order&#34; septa are
fairly widely distributed among Rugosa in addition to major septa
(protosepta, metasepta) and minor septa (catasepta). The initial
standard septal apparatus of Middle Ordovician time included hyposepta,
which are recorded from 32 species of 12 suborders during lower
Caradocian to Serpukhovian and became steadily less abundant from the
Caradocian to their final disappearance in the late Palaeozoic.
Hyposepta (based on the Givetian Stereolasma rectum (Hall 1843) appear
as a very small third septal cycle (only active at the upper calicular
margin), intercalated between all major and minor septa, and best
discernible from special weaker septal furrows on the external
archaeotheca. The term diplosepta [based on the Ludlowian
Sutherlandinia petaloides (Ball &#038; Grove 1940] refers to major and
minor septa, which bifurcate at the periphery of the upper calice (but
always originate from only one septal furrow of the wall). This
specialization affects one (counter) or nearly all septa, and
characterizes mainly the Silurian-Devonian Ditoecholasmatinae and
Sutherlandiniinae, and some Lower Carboniferous pleonophorous taxa
(Cyathoclisia).^1";
s[6011] = "FALCES S. (1997).- Borings, embeddings and pathologies
against microstructure. New evidences on the nature of the
microstructural elements in rugose corals.- Boletin de la Real Sociedad
Espanola de Historia Natural, Seccion Geologica 92, 1/4: 99-116.-
<b>FC&#038;P 26-2</b>, p. 25, ID=3706^<b>Topic(s): </b>bioerosion vs
microstructures; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>; <b>Geography: </b>^The principal aim of the
present study has been to consider the moment of production of the
different skeletal anomalies (borings, embeddings and pathologies) for
```

```
obtaining an accurate datation of the affected microstructures. The use
of this textural cirterion has usually been accepted in those research
studies interested in the moment of production of the texture, such as
carbonate petrology and genesis of submarine cements. The material
studied in this report comes from the collections of solitary rugose
corals without dissepiments, from Upper Visean of Northwestern
Ossa-Morena region (Los Santos de Maimona and Guadiato Basin) except
some specimens supplied by Prof. J. Kullmann from the Emsian of
Bostanci at Istanbul (Turkey) which are totally recrystallized and
previously drilled as well. This study is based on the occurrence of
three kinds of evidences: Borings: Boring action penetrates and
dislodges coral structures, providing a source for dating, since boring
action must be posterior to these structures. Its study is based on the
analysis and the interpretation of morphology of borings, and also it
is completed with the description of their borders, and the different
alteration processes which occur in this areas. Embeddings and
pathologies: Both anomalies are contemporary with the
biocrystallization, generating borders with concordant microelements.
Description of complete diagenetic alterations in drilled speciments
and comparison with the described borders. The possibility of
describing rugose corals perforated and totally recrystallized (i.e.
with a previously well known microstructure) constitutes finally an
excellent reference for comparing the realized observation in the other
paragraphs.^1";
s[6012] = "NEUMAN B.E. (1997).- Evaluation of rugose coral potentials
as index fossils.- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 92, 1/4: 303-309.- <b>FC&#038;P 26-2</b>, p.
32, ID=3722^<b>Topic(s): </b>Rugosa as index fossils; Rugosa,
stratigraphy; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>; <b>Geography: </b>^Rugose corals were epifaunal benthos, most
profuse and diverse in carbonate perireefal and reefal environments.
Like modem scleractinian corals they were sensitive to several
ecological factors like water temperature, depth, salinity, bottom
conditions, nutrient supply and probably illumination. Rugose corals
showed highest diversity in subtropical and tropical realms. In cooler
realms their diversity was low and solitary lambelasmatid forms
dominated. At different times plate movements have brought the
continental plates with including shallow sea areas into different
climatic zones. This has often caused successions of different coral
provinces on the various plates. Areas with overlapping faunas between
these plates are often difficult to find. Rugose corals are mainly
useful for correlation on the stage level within the same confacies
belt as most species are comparatively short-ranging. Correlation based
on Baltoscandian rugose corals from Rawthyean - Hirnantian times
clearly indicates that very few species cross sharp lithofacial
boundaries. Morphologic trends observed in the succession of rugose
coral assemblages give valuable support to a more reliable
biostratigraphy. In order to improve the possibilities of using rugose
corals as biostratigraphical tools we need more detailed and uniform
taxonomic descriptions and more information about the strata where
these taxa are found. Regular workshop meetings where taxonomic
problems can be discussed by specialists are highly recommended.^1";
s[6013] = "GUDO M. (1997).- Konstruktionsmorphologische Rekonstruktion
rugoser Korallen.- Profil 11, 325-340.- <b>FC&#038;P 26-2</b>, p. 57,
ID=3734^<b>Topic(s): </b>constructional morphology; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^The rugose corals known from the Paleozoic era are
comparable to the skeletons of fossil and recent scleractinians. The
reconstruction of the rugose soft body is based on the assumption that
polyp-like organisms produced the skeletons of the rugosa. Analyzing
the construction of anthozoan polyps indicates a conception of a
general soft body for coral polyps. This soft body is characterized by
hydraulic filling, by tethering, and by internal mesenteries as well as
```

```
by tethering and fixing of a valve-like collapsible tube. Tentacles
could emerge between the mesenteries on the oral disc. The external
epithelian layers of the pedal disc are able to produce external
carbonate structures between the mesenteries. During the ontogenetic
growth of polyps, the installation of a new internal tethering
structure is necessary to preserve form and coherence of the whole
construction. Thereby new spaces between the mesenteries arise in which
new carbonate structures were produced. Therefore, the skeleton of a
coral polyp represents a kind of negative copy of the internal
construction of the soft body. Thus the fossil skeletons give some
valuable hints for the reconstruction of their soft bodies. The rugose
corals are reconstructed as polyp-like barrel-shaped constructions.
Their shape is determined by hydraulic filling and by the internal
tethering by single mesenteries. The given reconstruction of the
ontogenetic insertion of single mesenteries explains the pattern of the
septal insertion within only four sectors in the rugose skeletons. This
reconstruction is only valid for the general representation of the
rugosa. It is a testable approach to the reconstruction of the rugose
soft body, and it explains the pattern of septal insertion of the
rugose corals. The reconstruction presented here is not extended to the
very early ontogenetic stages of rugose polyps. Obviously, the model
should be modified to explain those groups of the rugosa which do not
show the general pattern of septal insertion in four sectors.^1";
s[6014] = "LIN Y., HUANG Z. (1996).- On genus Stylostrotion Chi and its
systematic position.- Acta Palaeontologica Sinica 35, 1: 84-87.-
<b>FC&#038;P 27-1</b>, p. 70, ID=3813^<b>Topic(s): </b>systematics;
Rugosa, Stylostrotion; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>; <b>Geography: </b>^After the establishment of
the genus Stylostrotion by Dr. Chi in 1935, many palaeontologists in
China and abroad have different opinions. As Chi described in diagnosis
of this genus: &#34;It has a distinct palicolumella&#34;, some
palaeontologists, such as S. Smith, D. Hill, Yu and Wang, regard it as
a synonym of the genus Siphondendron. However, J. Fedorowski
established a new subclass Dividocorallia (Palaeozoic Anthozoa) in
1991, holding a different opinion from Chi about this genus. He
indicated the inconstant number of major septa in quadrants, which are
similar to that of heterocoral, and so he established the new family
Stylostrotionidae, which belongs to the order Calyxcorallia under the
subclass Dividocorallia. Through examining the description and figures
of this genus in Chi&#39;s paper, the authors found that there are two
individual transverse sections in the type specimen (Pl. I, fig. 1a),
with a palicolumella-like structure at the center of the right one. In
fact, this is a structure caused by the connection of inner septa,
rather than a palicolumella; the left one also presents this
characteristic, with its septa in bunchwise arrangement, and each bunch
has a long septum prolonged to the center and conneced to others.
Hence, it may be concluded that this genus has no palicolumella and
bears no relationship with Siphonodendron. It is unavailable to
correlate the genus with Nemistium, Aulina, Diphyphyllum, and therefore
it is necessary for us to emend the diagnosis of the genus in this
paper. According to Fedorowski (1991), this genus is a kind of
heterocoral, and is regarded as a new Palaeozoic anthozoan. However,
the authors have a different opinion, since the heterocoral has a
specific structure, which is characterized by the never separated inner
ends of septa, the absence of minor septa and dissepiments, with some
boss, spines and ridges on the wall. While this genus has minor septa
and a dissepimentarium, with the inner ends of septa occassionally
separated, indicating that it is a typical Rugosa, instead of
heterocoral. In case this genus is placed in the heterocoral, it would
present a confusion between the Rugosa and the Heterocorallia.
Therefore the authors suggest that the family Stylostrotionidae
Fedorowski (1991) be placed under the suborder Stauriina of the Rugosa,
including Pseudopetraia Soshkina, Palaeophyllum Billings, Stylostrotion
```

s[6015] = "FEDOROWSKI J. (1997).- Remarks on the paleobiology of
Rugosa.- Geologos 2: 5-58.- <b>FC&#038;P 27-2</b>, p. 13,
ID=3890^<b>Topic(s): </b>biology; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^It is the
interpretation of anatomy, behaviour and general physiology of the
Rugosa.Variability in the suspected behaviour and general physiology of
the Rugosa is inferred from frequently appearing morphotypes in
solitary forms. This discussion is preceded by a review of important
skeletal and suspect soft features, supported mainly by external
characteristics of fossils. Existing skeletal data has led to the
proposal of an initial development of two pairs of mesenteries. They
are considered to be directive mesenteries by comparison to other
Anthozoa. Only the sclerosepta corresponding to these two pairs of
mesenteries are considered as protosepta. The cardinal fossula is
reconstructed as an important irrigation apparatus, leading to a
siphonoglyph above it, but not forming sufficient space to host
mesenteries earing gonades. Clear differences between the skeletal
morphology in juvenile and mature parts are discussed in detail using
several examples, beginning with reconstruction of earliest
skeletogenesis. Secretion of the attachment and first wall of the
aseptal cup is postulated as the initiation of the skeletogenesis of
the polyp.^1";
s[6016] = "OLIVER W.A.jr (1998).- Nomenclatural problems of
Breviphrentis Stumm 1949 and Contophrentis new genus (Devonian rugose
corals).- Journal of Paleontology 72, 5: 932-934.- <b>FC&#038;P
28-1</b>, p. 34, ID=3965^<b>Topic(s): </b>nomenclature; Rugosa,
Breviphrentis; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>; <b>Geography: </b>^Amplexus invaginatus Stumm, 1937, the type
species of Breviphrentis, is from Nevada; my redescnption (Oliver,
1993. p. 19-20) was based on the specimens collected by C.W. Memam that
were used by Stumm (1937), and Merriam (1940 and 1974) in their
descriptions. I concluded that most of the Merriam and Stumm material
represented two species, one a siphonophrentil and one from another
family (not named); I selected a lectotype from Stumm&#39;s (1937)
illustrated &#34;holotypes&#34; and identified it as belonging to the
siphonophrentid species (Oliver, 1993, p. 19-20). This had the apparent
effect of preserving Breviphrentis as a siphonophrentid and justifying
the assignment of the Eastern Americas species to that genus. * Later.
Dr. A.E.H. Pedder, Geological Survey of Canada, Calgary, collected a
large number of specimens from the type locality and horizon of
Amplexus invaginatus in Nevada. During a visit to Pedder&#39;s
laboratory (April, 1992), I was able to examine the prepared specimens
and agreed with his conclusion that the A. invaginatus lectotype
belonged to the population represented by his new collection and that
it was the non-siphonophrentid. Thus, Breviphrentis sensu stricto is
not a siphonophrentid and the Eastern Americas &#34;Breviphrentis&#34;
needs a new name. The purposes of this note are to clarify the status
of the Nevada Breviphrentis s.s. (see also Pedder, 1997) and to
establish Contophrentis new genus, for the EAR species. [taken from
introductory part of a short note]^1";

<b>Geography: </b>^A revision of Combophyllum osismorum M.E. &#038; H.,
type-species of Combophyllum, is given. This study was carried out on
the original material and on a large collection from the type-locality.
It was possible to state precisely the morphological, structural and
microstructural features of the species. The radiary elements of this
discoid coral are costo-septa of which the growth direction is chiefly
peripheric, distal and proximal. They are composed of trabeculae
arranged in a fan-shaped pattern. The stratigraphical position of the
species is accurately determined (lower part of the Middle Devonian). A
critical revision of the other known species of Combophyllum is
proposed.^1";
s[6030] = "COTTON G. (1973).- The rugose coral genera.- Elsevier
Scientific Publishing Co.; 358 pp., no illustr.- <b>FC&#038;P 3-1</b>,
p. 24, ID=4879^<b>Topic(s): </b>index of genera; Rugosa genera;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^[review by William A. Oliver jr] This book is in
three parts: an alphabetical listing of generic names with generic and
type species diagnoses (218pp), an identification key to the genera
(99pp), and a list of type species alphabetized by trivial name (11pp).
Remaining pages are occupied by a too brief preface, a reference list
and a short addendum. This is a reference book for the specialist -
neither more nor less. Generic listings are remarkably complete through
the 1971 literature. W.J. Sando and I have found only seven missing
genera, two missing spelling variants, and only one misspelled generic
name. Diagnoses range from three to 20 or more lines, and seem to be
good. Apparently they are based on original descriptions and published
revisions; sources are given. Subjective synonyms are separately
diagnosed and not necessarily noted as possible synonyms. This
represents good policy and makes the book more objective and useful. A
```

```
questionable procedure is that of proposing 11 new names for junior
homonyms that have been generally accepted as synonyms and not
previously renamed. This is consistent with the treatment of other
subjective synonyms but will cause trouble if later revisers decide
that the genera are not synonyms. Most of the names will find use only
in synonymies and other nomenclatural works. In any case, the new names
are easily found in the book as all were constructed by adding the
prefix &#034;Pro&#034; to the homonym. &#034;New names&#034; (pp 32-33)
for specimens originally described as &#034;Gen. I, Sp. I&#034; and
&#034;Gen. II, Sp. I&#034; by Kostic-Podgorska (1957) are unnecessary
and bad policy. These are new genera and species (with Cotton as
author) based on material that the original describer considered
inadequate.[part of extensive summary]^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^A new morphological term &#34;biform tabularium&#34;
is proposed for tabulae arranged in two systems corresponding to two
different groups of interseptal loculi (position I and II of
Sutherland, 1965). This feature, the variability of which is discussed,
occurs in several independent lines of Rugose corals and is known from
Upper Ordovician to Upper Permian times. The new genera Kaljolasma,
Kabakovitchiella, Sutherlandinia, and Pedderelasma are erected for some
species with a biform Tabularium. The revised family Cyathaxoniidae
contains Middle Ordovician to Upper Permian genera of five subfamilies
(Petraiinae, Ditoecholasmatinae, Cyathaxoniinae and two new ones,
Sutherlandiniinae, and Lophotichiinae). Sutherlandiniinae and
Ditoecholasmatiinae are characterized by curious split septa (cardinal,
counter, and two counter minor septa). The known definitions of the
genera Barrandeophyllum, Haptophyllum, Boolelasma, Petraiella, and
Lophotichium have been changed.^1";

species; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^G. Cotton has now published &#34;The Rugose Coral
Species&#34; listing some 10 000 species in about 1200 genera, with
2400 references. The primary purpose of this book is to serve as a
guide to where the original description of a Rugose Coral species is to
be found. * The first section lists alphabetically the species that
were originally referred or have subsequently been transferred to each
genus, the genera also being listed alphabetically. For each species,
the author, date of publication, page number, and horizons are given,
and when a species is transferred, the author who first transferred it
to the new genus. * In the second section all species are listed
alphabetically with the genus to which they were originally referred,
and the author and date. This makes it possible to trace the genus to
which a species was originally referred even when, as is very
frequently the case, only the genus to which it has subsequently been
transferred is mentioned. * The third section lists the References,
abbreviated in the manner of the World List of Scientific Periodicals,
4th Edition. [full text of a review]^1";

life history of solitary rugose corals.- Journal of Paleontology 56, 5:
```

```
1223-1229.- <b>FC&#038;P 12-2</b>, p. 33, ID=6212^<b>Topic(s):
</b>ontogeny; Rugosa, ontogeny; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>; <b>Geography: </b>^Coiled protocoralla of
solitary rugose corals from the Lower Mississippian (Lower
Carboniferous) of the United States continental interior suggest two
opposing life styles for their early life history. Specimens of
Cyathaxonia tantilia have a hollow, coiled protocorallum and represent
a coral with a pseudoplanktic brephic stage, as suggested by Sando
(1977). Amlexizaphrentis? sp. has planispiral or low spiral
protocoralla which are attached to fenestrate bryozoans and
consequently had a benthic post-larval habit. These alternative life
habits are important for the understanding of rugose coral ontogeny and
have significant biostratigraphic implications. [original abstract]^1";

the circumaxial skeleton in Rugosa (Anthozoa).- Lethaia 42, 2:
232-247.- <b>FC&#038;P 36</b>, p. 56, ID=6441^<b>Topic(s):
</b>structures axial; Rugosa, axial structures; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^An
elevated skeletal structure surrounding an empty axial area occurs in
many unrelated taxa within the Rugosa. This structure, commonly termed
the aulos, was first differentiated and described by Grabau in 1922.
Most terms introduced by that author for individual morpholypes have
not been accepted because the taxa he chose to illustrate the typical
development do not correspond to his diagnoses. The morphogenetic study
on some circumaxial structures in this paper points out differences in
their origin, their predicted role in the physiology of the coral
polyps. The study shows both the advantages and disadvantages of the
use of these circumaxial structures in taxonomy. In addition to the
term aulos, which was introduced by Smith in 1928, new terms i.e.
circulotheca and columnotheca are here introduced for the circumaxial
structures that also are newly proposed names, to allow distinguishing
them from true axial structures. [original abstract]^1";
s[6068] = "FEDOROWSKI J. (2010).- Does similarity in rugosan characters
and their functions indicate taxonomic relationship?.- Palaeoworld 19,
3-4: 374-381.- <b>FC&#038;P 36</b>, p. 58, ID=6444^<b>Topic(s):
</b>homologies, analogies; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Functional analysis
of changes in shape and arrangement of septa in the genera
Zaphrentites, Caninia, and Ufimia allows one to move slightly beyond
the usual boundaries of description and to ask why the arrangement in
Zaphrentites is permanent, but becomes radial in Caninia and bilateral
in Ufimia? This may be explained in terms of changing function and
biological role of major septa in the ontogeny.* The creation of open
space to accommodate strongly developed mesenteries is proposed as an
explanation for the shortening and radial arrangement of axially free
septa in mature Caninia, whereas the development of a slit on an oral
disc, increasing water flow through the gastro-vascular cavity, is
postulated for Ufimia. Both solutions point towards increased
effectiveness of feeding and oxygenation, necessary for the growing
organism. Such a conclusion negates the simple application of a given
arrangement of septa as an indicator of taxonomic relationship.

Palaeoworld 19, 3-4: 242-248.- <b>FC&#038;P 36</b>, p. 58,
ID=6445^<b>Topic(s): </b>taxonomic principles; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Precise
taxonomy is possible only when specimens are thoroughly investigated
and checked against well known types. This simple procedure is not
always followed and as a result, credible data are often lacking. *
Accuracy. To match his interpretation of calice morphology, Schindewolf
(1942, pl. 33, fig. 2a-d, text-fig. 89a-d) inaccurately oriented
transverse sections of Pentamplexus simulator Schindewolf, 1940. His
errors were in part corrected by Weyer and Ilina (1979), but they also
```

```
misidentified the counter protoseptum. Re-orientation of the original and two new thin sections allows that genus to be transferred to the family Polycoeliidae de Fromentel, 1860. * Manipulation: Schindewolf&#039;s (1942) manipulation of the data on Pentaphyllum De Koninck, 1872 and Cryptophyllum Carruthers, 1919 resulted in an incorrect diagnosis, which was followed by many students who introduced 49 species (Ilina, 1984). Despite its name and Schindewolf&#039;s (1942) description, the poorly preserved type of Pentaphyllum possesses six, instead of five, dominant septa in its calice. * Lack of attention to detail: Biform morphology in the tabularium is not always recognized and is commonly incorrectly described, despite its importance as a factor in water distribution within the gastro-vascular cavity and its diagnostic value for taxonomy. Failure to recognize that feature can lead to incorrect classification up to the family level.^1";
s[6070] = "WEYER D. (2008).- Revision des Ludwig/Kunth-Gesetzes zur Septeninsertion der Supraordo Rugosa (Anthozoa, Ordoviz-Perm). [Revision of the Ludwig/Kunth law of septal insertion in the superorder Rugosa (Anthozoa, Ordovician-Permian; in German with English summary].- Abhandlungen und Berichte für Naturkunde 30: 85-145.- <b>FC&#038;P 36</b>, p. 70, ID=6469^<b>Topic(s): </b>septal insertion patterns; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^The outstanding feature of the Rugosa, their ontogenetic mode of septal insertion, is redefined, based on a new morphogenetic nomenclature of septa. External furrows of the archaeotheca show septal increase either by bifurcation (schizosepta), or by intercalation (intrasepta). The primary phylogenetic radiation in the Late Ordovician comprises the two hitherto accepted orders characterized by schizosepta (metasepta, catasepta), the Stauriida (probably ancestral, with minor septa near antiseptum), and the Cystiphyllida (without antiseptal minor septa); but there exists an additional, completely neglected order Pholidophyllida as a sister group whose major and minor septa are intrasepta (here named addisepta and kalasepta). [original English summary]^1";

(1997).- Reconstruction of rugose corals - a constructional approach.- FC&P 26, 1: 9-16.- <b>FC&#038;P 26-1</b>, p. 9, ID=6874^<b>Topic(s): </b>constructional morphology; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^[the presented] model is qualified for a reconstruction of ontogeny of rugose corals from the early condition state with only six protosepta. However model is not sufficient to explain earlier phases of ontogeny. I must emphasize that the presented reconstruction is only valid for the generalized representations of the septal insertion mechanisms as described in paleontological textbooks and not for any special group of the tetracorallia. This model might possibly be modified to be valid for some special groups of rugose corals with only small modifications to adjust special situations. Furthermore it may also be applicable to describe and explain the limited capability of rugose corals to build coherent colonies and whole reef constructions as compared to those of madreporararian corals. [fragment of conclusions]^1";
s[6072] = "GUDO M. (2000).- A structural-functional approach to the soft bodies of rugose corals.- Organisms, genes and evolution [D.S.Peters &#038; M. Weingarten (eds): Proceedings 7th Intern. Senckenberg-Conference]: 219-240.- <b>FC&#038;P 29-1</b>, p. 51, ID=7044^<b>Topic(s): </b>constructional morphology, operculate corals; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^The study of generation and control of shape is an integral part of a constructional approach to organisms. If living beings are understood as organismic constructions, the determination of shape can be explained as being driven by hydraulic, mechanical and energy conducing entities. The recent Anthozoans such as the Actiniaria, Octocorallia, or Scleractinia, can be analyzed in such a manner that it leads to an understanding of their organisation and the
```

```
physical laws underlying it. * The most important principles that have
to be observed for a constructional approach of such organisms are
hydrostatic and hydrodynamic physical laws, the principles of
coherence, energy transformation and the mechanisms of muscular action,
including the antagonistic interaction necessary for the proper
functioning of all contractile elements (Gutmann 1991). A proper
understanding of these principles leads to the conclusion that no
structural transformation in individual development or evolution is
arbitrary or accidental (Gutmann &#038; Bonik 1981; Gutmann 1995;
Grashoff 1976; Peters &#038; Gutmann 1971; Schmidt-Kittler &#038; Vogel
1991). * The results of a constructional morphology of recent organisms
can be applied to analysis of the structural, organizational and
functional aspects of fossil organisms. Any anatomical reconstruction
of fossil and extinct organisms can only be performed in analogy to
that of recent relatives and has to refer to biological and
morphological knowledge. In this approach constructional morphology is
used as a principle of uniformitarism (Gudo 1997; Gutmann 1997) in
order to reconstruct the lost soft bodies of the fossil rugose corals.

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^All bauplans of the Anthozoa evolved independently
from each other. The ancestor is a so called gallertoid-coral, an
organism which bears a number of polyps, that have developed as closing
apparatusses for the openings of the internal canals. When inside these
polyps the gastric cavity enlarges, certain numbers of tissue pouches
was preserved to hold the polyp in shape. These pouches later formed
the mesenteries. The number of the initial developing pouches therefore
determined the number of mesenteries and accordingly the bauplan.

Heterocorallia; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>; <b>Geography: </b>^Detailed blastogenetic investigations using
serial acetate peels from Stylostrotion sudeticum Fedorowski 1991, a
representative of the controversial group Calyxcorallia, revealed that
offset formation in the youngest stages is close to some lateral
increase in rugose corals. The appearance of heterocoral symmetry in
later stages of blastogeny is a feature which would differentiate the
blastogeny of the Calyxcorallia from that of the Rugosa. Analysis of
the similarities and differences between the blastogeny of S.
sudeticum, the Rugosa and the Heterocorallia suggests that it is more
appropriate to regard the Calyxcorallia as a group within the Rugosa,
rather than grouping them with the Heterocorallia in a separate
subclass. However, the possibility cannot be excluded that the
Calyxcorallia was a transitional group from the Rugosa to the
Heterocorallia, as postulated by Fedorowski (1991).^1";
s[6079] = "JOHNSON G.A.L., NUDDS J.R. (1977).- Is the Columnariina
(Rugosa) wholely polyphyletic?.- FC&P 6, 1: 11-12.- <b>FC&#038;P
6-1</b>, p. 11, ID=5485^<b>Topic(s): </b>monophyly?; Rugosa,
Columnariina; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>; <b>Geography: </b>^Most workers on the Rugosa must have
experienced difficulty in assigning definite and exclusive
morphological characters to Suborder Columnariina. In Treatise F (p.
F296) a precise diagnosis gives no characters or combination of
characters that are not also present in other rugosan suborders. [ ]
The lack of unspecialised ancestors, rarety of solitary corals,
dominance of highly evolved compound coralla and the Devonian -
Carboniferous stratigraphical hiatus leads us to believe that the
Columnariina are entirely a polyphyletic group. * The suborder appears
to create confusion in the genetic taxonomy of the Rugosa as end stages
of many lineages have been placed in this group. * We suggest that it
would be an advancement to suppress this taxon, but this cannot be done
until the specialists in various groups of the Columnariina can
reallocate them within the remaining framework of rugosan
classification. * We intend to review the British Carboniferous
Columnariina and would welcome, through this newsletter, results of
research on other groups of Columnariina and suggestions as to their
true affinities. [initial and concluding fragments of the paper]^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>;
<b>Geography: </b>^The present paper discusses chiefly the
morphological characters, classification and Stratigraphical
significance of the fine structure in the septa of Cystiphyllida. In
addition to the discussion and emendation made of the definitions of
the known superfamily, families and subfamilies, here one new
superfamily, one new family and three new subfamilies have been
established.The author considers that the basic unit of the fine
structure in the septa of Cystiphyllida includes three forms:
spinal-tubular skeleton-clasts, lamellar tissue and lamellar
skeleton-clasts. Based on the septal fine structure, Cystiphyllida can
be devided into two superfamilies: Cystiphyllicae and Zonechyllicae.
The septa of Cystiphyllicae are made up of spinal-tubular
skeleton-clasts and lamellar tissue; this superfamily chiefly appeared
in Silurian. The septa of Zonophyllicae are only composed of lamellar
skeleton-clasts; most of members of the superfaraily occurred in
Devonian.^1";

SEM study, classification; Rugosa cystimorpha; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^SEM
study on the microskeletal structures of more than 10 cystiphyllid
genera has revealed that lamellar skeleton with fundamental unit
calcite flakes 15-35 µm in diameter and 1.5-2.5 µm in thickness is in
```

```
all cases dominant, while fibrous skeleton is mostly represented by
primitive types, by irregular granules some 2-3 µm in diameter and
brachycolumns 2-3 µm in diameter and 5-10 µm in length. These two kinds
of elements combine in various ways to form 4 types of septal spines or
trabeculae. They are (1) holacanth, tube-like and entirely lined with
lamellar flakes; (2) single rhabdacanth with axial granules enveloped
by peripheral flakes; (3) composite rhabdacanth comprising axial row of
clusters of rhabdacanths embedded in interstitial and enveloping
lamellar flakes, and (4) monacanth composed of parallel to subradial
brachycolumns or short needles. They are exemplified respectively by
Protocystiphyllum, Holmophyllum, Gyalophylloides and Tryplasma. Based
on these microstructures and megastructures we have recognized 50
genera of cystiphyllid corals grouped into 8 families. They are:
Primitophyllidae, Palaeocyclidae, Tryplasmatidae, Cystiphyllidae,
Mucophyllidae, Holmophyllidae, Goniophyllidae and Ketophyllidae.
Diagnoses of the families are given and briefly discussed, and genera
included in the families are named. Microstructures of some important
genera are indicated in the caption of plates. Stratigraphical and
geographical distribution in China and in the world are given in Table
1. Possible evolutionary and taxonomic relations are shown in the
figures. It is deemed that the two earliest appeared families,
Primitophyllidae and Mucophyllidae, came from different descent.
Palaeocyclidae and Tryplasmatidae were probably derived separately from
Primitophyllidae. A third branch is Cystiphyllidae, which underwent
radiating evolution to form the 4 families in the beginning of the
Silurian and became the major constituents of the group until the end
of Early Devonian, when most of the cystiphyllids died out.
Ketophyllidae may however represent another separate lineage directly
from Primitophyllidae.^1";

</b>phylogeny; Rugosa, Dividocorallia; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^Dividocorallia
Fedorowski 1991, the recently distinguished subclass of extinct
Devonian and Carboniferous Anthozoa, comprises two orders:
Heterocorallia Schindewolf 1941 and Calyxcorallia Fedorowski 1991. The
arrangement and development of septa are fundamental characters common
for the subclass. It has been postulated that only a single septum
appeared at the very beginning of septogenesis in both orders. This
common character of orders points on the Rugosa as the ancestral group
of the Dividocorallia.Presence (Calyxcorallia) or absence
(Heterocorallia) of calices is the basic distinguishing character of
the order-level. It can be traced back to the Lower Devonian, when the
oldest representatives of both orders occur. Pseudopetraia Soshkina
1951 represents Calyxcorallia whereas Tetraphyllia Yoh et al. 1984 is
the oldest known heterocoral. Symmetrical (Tetraphyllina Fedorowski
1991) versus asymmetrical (Heterocorallia) arrangement of septa allows
to distinguish suborders within the order Heterocorallia, whereas
morphogenesis and microstructure of the external wall are the basic
diagnostic characters of families of that order. The order
Calyxcorallia comprises families that are distinguishable by the form
of growth: solitary versus colonial. Majority of genera included in
```

and rugose corals demonstrate a broad environmental distribution; both
clades have a relatively high diversity of representatives which
live(d) at great depths. In order to determine the nature of
diversification of these deep-water forms the paleoenvironments of the
```

```
earliest Rugosa and representatives of extant deep-water scleractinian
families were determinded. Environmental patterns of the subsequent
diversification of the Rugosa and scleractinian suborder Caryophylliina
were also documented. The earliest reported Rugosa is Lambeophyllum
from the Chazyan Crown Point Limestone (Vermont, U.S.A.) which is
interpreted to have been deposited in a nearshore setting. Within five
million years of their initial appearance the rugosans expanded, at
relatively low diversities, offshore to the slope and deep-basin.
Nearly all representatives of families of extant scleractinians now
living in deep-water (>200&#039;) also first occur in an onshore
environment. The caryophylliids, the most specious deep-water coral
clade, first appeared in the Toarcian and soon after expanded across
the shelf. Thus, both rugose and scleractinian corals expand offshore
at relatively low diversities early in their histories. Throughout most
of the Mesozoic high diversities of caryophylliids occur in shelfal
settings. In the Tertiary high diversity patterns in the outer shelf
and slope are established.^1";

Palaeontologica Polonica 42, 3: 446-456.- <b>FC&#038;P 27-2</b>, p. 14,
ID=3892^<b>Topic(s): </b>phylogeny; Rugosa, Scleractinia;
<b>Systematics: </b>Cnidaria; Rugosa Scleractinia; <b>Stratigraphy:
</b>; <b>Geography: </b>^A critical review of two papers: (1) Dzik J.:
Early metazoan evolution and meaning of its fossil record. Evolutionary
Biology, 27, 1993 and (2) Stolarski J.: Gardineria - a scleractinian
living fossil. Acta Palaeont. Polonica, 41, 1997. An approach of Dzik
to the reconstruction of phylogeny and roots of Rugosa was questionned.
The inadequately known morphology and ontogeny of Cothonion, as well as
differences in the microstructure of the external wall and increase in
septa between that Middle Cambrian genus and the Rugosa, established by
Jell &#038; Jell (1976) eliminate it from potential ancestors of the
Rugosa. Its similarity to the Devonian genus Calceola is superficial
and those two cannot be compared as relatives. The operculate taxa
postulated by Dzik (1993) to be ancestors for all the Rugosa appeared
to being when all basic morphotypes of non-operculate Rugosa were
already flourishing. Thus, all phylogenetic conclusions by Dzik (1993)
were rejected. Stolarski (1996) in his study on the Recent Gardineria
attempted to prove a thesis of the rugosan origin of Scleractinia. The
long known similarity in morphology and microstructure of those two
Subclasses (or Orders) of the Anthozoa, as well as equally well known
differences between them, were briefly discussed in the critique to
show parallelism in the development rather than true relationships of
those taxa. An absence of the Rugosa from all latest Permian strata,
despite proper ecological conditions some of the. offer, speaks more
strongly against a direct relationship of those two large taxa than an
absence of Scleractinia from equally proper conditions existing in
Early Triassic.^1";

</b>^The study of the morphology of the rugose corals and the acception
of a solitary sexual polyp, as the stem form of the Anthozoa (B.
WERNER) lead to the conclusion that the stem form of the rugose corals
was a solitary sessil polyp without a base disc and with four or more
pairs of mesenteries from which two were directive pairs. Therefore it
seems correct to supply the name Rugosa by Tetracorallia Haeckel 1866.
The evolution of the Auloporida from such a stem form follows another
trend, which is characterised by the development of colonies. It seems
possible, that this trend was attended with the reduction and the lost
of the four mesenteries of the hypothetic stem form. Therefore it is
not sure, that the Auloporida belong to the Anthozoa.^1";

versus abiogenic calcium carbonate crystals.- Acta Palaeontologica
Polonica 50, 4: 847-865.http:&#47;&#47; www.a
pp.pan.pl/article/item/app50-847.html.- <b>FC&#038;P 34</b>, p. 105,
ID=1304^<b>Topic(s): </b>microstructures, biogenic vs abiogenic;
Scleractinia, skeletal microstructures; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>; <b>Geography: </b>^The mineral
phase of the aragonite skeletal fibers of extant scleractinians (Favia,
Goniastrea) examined with Atomic Force Microscope (AFM) consists
entirely of grains ca. 50-100 nm in diameter separated from each other
by spaces of a few nanometers. A similar pattern of nanograin
arrangement was observed in basal calcite skeleton of extant calcareous
sponges (Petrobiona) and aragonitic extant stylasterid coralla
(Adelopora). Aragonite fibers of the fossil scleractinians: Neogene
Paracyathus (Korytnica, Poland), Cretaceous Rennensismilia (Gosau,
Austria), Trochocyathus (Black Hills, South Dakota, USA), Jurassic
Isastraea (Ostromice, Poland), and unidentified Triassic tropiastraeid
(Alpe di Specie, Italy) are also nanogranular, though boundaries
between individual grains occasionally are not well resolved. On the
other hand, in diagenetically altered coralla (fibrous skeleton beside
aragonite bears distinct calcite signals) of the Triassic corals from
Alakir Cay, Turkey (Pachysolenia), a typical nanogranular pattern is
not recognizable. Also aragonite crystals produced synthetically in
sterile environment did not exhibit a nanogranular pattern.
Unexpectedly, nanograins were recognized in some crystals of sparry
calcite regarded as abiotically precipitated. Our findings support the
idea that nanogranular organization of calcium carbonate fibers is not,
per se, evidence of their biogenic versus abiogenic origin or their
aragonitic versus calcitic composition but rather, a feature of CaCO3
formed in an aqueous solution in the presence of organic molecules that
control nanograin formation. Consistent orientation of crystalographic
axes of polycrystalline skeletal fibers in extant or fossil coralla,
suggests that nanograins are monocrystalline and crystallographically
ordered (at least after deposition). A distinctly granular versus an
unresolvable pattern of nano-organization of CaCO3 fibers seems to
correspond, respectively, to an original versus a diagenetically
depleted amount of organic matter bounding a mineral phase; this is
consistent with qualitative and quantitative analyses of organic matter
content in extant and fossil skeletons^1";
s[6118] = "STANLEY G.D.jr (2003).- The evolution of modern corals and
their early history.- Earth-Science Reviews 60, 3-4: 195-225.-
<b>FC&#038;P 32-1</b>, p. 19, ID=1414^<b>Topic(s): </b>early phylogeny;
Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>; <b>Geography: </b>^Scleractinians are a group of
calcified anthozoan corals, many of which populate shallow-water
tropical to subtropical reefs. Most of these corals calcify rapidly and
```

```
their success on reefs is related to a symbiotic association with
zooxanthellae. These one-celled algal symbionts live in the endodermal
tissues of their coral host and are thought responsible for promoting
rapid calcification. The evolutionary significance of this symbiosis
and the implications it holds for explaining the success of corals is
of paramount importance. Scleractinia stands out as one of the few
orders of calcified metazoans that arose in Triassic time, long after a
greater proliferation of calcified metazoan orders in the Paleozoic.
The origin of this coral group, so important in reefs of today, has
remained an unsolved problem in paleontology. The idea that
Scleractinia evolved from older Paleozoic rugose corals that somehow
survived the Permian mass extinction persists among some schools of
thought. Paleozoic scleractiniamorphs also have been presented as
possible ancestors. The paleontological record shows the first
appearance of fossils currently classified within the order
Scleractinia to be in the Middle Triassic. These early Scleractinia
provide a picture of unexpectedly robust taxonomic diversity and high
colony integration. Results from molecular biology support a
polyphyletic evolution for living Scleractinia and the molecular clock,
calibrated against the fossil record, suggests that two major groups of
ancestors could extend back to late Paleozoic time. [first part of
extensive abstract]^1";
s[6119] = "STOLARSKI J., ZIBROWIUS H., LOESER H. (2001).- Antiquity of
the scleractinian-sipunculan symbiosis.- Acta Palaeontologica Polonica
46, 3: 309-330.- <b>FC&#038;P 30-2</b>, p. 30, ID=1586^<b>Topic(s):
</b>coral-sipunculan symbiosis; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography:
</b>^Extant corals symbiotic with sipunculans, i.e., the caryophylliid
Heterocyathus and the dendrophylliid Heteropsammia, develop corallum
modifications (in comparison with &#039;ordinary&#039; representatives
of these families) that seem to meet the needs of the coral&#039;s worm
partner. We distinguish two types of corallum modifications, designated
the monoporous and the polyporous types. In the adult monoporous type,
the shell inhabited by the sipunculan is usually overgrown only in part
by the coral base. There are two orifices: the main one and a smaller
pore in the upper part of the corallum. In the polyporous type the
shell inhabited by the sipunculan is entirely overgrown and the coral
produces a spiralled sipunculan housing. In addition to the main
orifice there are severalpores in the lower part of the corallum.
Heterocyathus priscus sp. n. from the Early Cretaceous (Albian) of
France is the oldest example of symbiosis, in which the monoporous-type
corallum was modified in the same way as in extant monoporous
Heterocyathus. We speculate that the monoporous type was ancestral, as
only this type is known to occur among Cretaceous corals. Morphological
similiarities between Heteropsammia and certain species of
Heterocyathus, such as the Pourtalés plan of septal arrangement and
skeleton porosity, may point to a close phylogenetic relationship.^1";
s[6120] = "CASTELLARO C., RIBAUD-LAURENTIA A., MUENCH P., MONTAGGIONI
I., RIOT S. (2000).- Image processing as a tool for reconstructing the
skeletal early evolution for branching scleractinian corals (Acropora
danai and Pocillopora verrucosa): preliminary results.- Géologie
Méditerrannéene 27, 3-4: 107-117.- <b>FC&#038;P 31-2</b>, p. 47,
ID=1699^<b>Topic(s): </b>image processing, ontogeny; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^For the first time, the early evolution of branching
corals skeleton (Acropora danai and Pocillopora verrucosa) has been
depicted using image processing technique. Several parameters have been
measured on digitized pictures of coral sections in order to
characterize the geometry, and its evolution with increasing age of
corallum, of intraskeletal cavities (fenestral pores).It has been
possible to describe precisely the mesostructure of corals and together
with the study of the microstructure, it has also been possible to link
evolution of the different measured geometrical parameters to biotic or
```

```
to abiotic (diagenetic) precipitation of aragonite. A biotic or abiotic
process both lead to a strengthening of basal parts of branches, it is
very difficult to identify the two types of aragonite. For this
purpose, it appears from this study that the hydraulic radius
(surface/perimeter ratio) may be one of the most useful parameters to
measure. The recognition of early marine diagenetic aragonite is only a
first step towards its quantification which will only be completed by
the use and the development of image processing technique.^1";
s[6121] = "STOLARSKI J., RONIEWICZ E. (2001).- Towards a new synthesis
of evolutionary relationships and classification of Scleractinia.-
Journal of Paleontology 75, 6: 1090-1108.- <b>FC&#038;P 30-2</b>, p.
29, ID=1704^<b>Topic(s): </b>phylogeny, classification; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^The focus of this paper is to provide an overview of
historical and modern accounts of scleractinian evolutionary
relationships and classification. Scleractinian evolutionary
relationships proposed in the 19th and beginning of the 20th centuries
were based mainly on skeletal data. More in-depth observations of the
coral skeleton showed that the gross-morphology could be highly
confusing. Profound differences in microstructural and
microarchitectural characters of e.g., Mesozoic microsolenine,
pachythecaline, stylophylline, and rhipidogyrine corals compared with
nominotypic representatives of higher-rank units in which they were
classified suggest their separate (?subordinal) taxonomic status.
Recent application of molecular techniques resulted in hypotheses of
evolutionary relationships that differed from traditional ones. The
emergence of new and promising research methods such as high-resolution
morphometrics, analysis of biochemical skeletal data, and refined
microstructural observations may still increase resolution of the
&#034;skeletal&#034; approach. Achieving a more reliable and
comprehensive scheme of evolutionary relationships and classification
framework for the Sclereactinia will require close co-operation between
coral biologists, ecologists, geologists, geochemists, and
paleontologists.^1";

Hierarchically structured scleractinian coral biocrystals.- Journal of
Structural Biology 161, 1: 74-82.PMID 17998166.- <b>FC&#038;P 35</b>,
p. 112, ID=2448^<b>Topic(s): </b>microstructures; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^Microscopic (AFM and FESEM) observations show that
scleractinian coral biomineral fibers in extant Desmophyllum and Favia,
and fossil Jurassic Isastrea are composed of nanocrystalline grains of
about 30-100 nm in size. In contrast to these findings, SR diffraction
data on the same coral materials exhibit narrow Bragg peaks suggesting
much larger crystallite size. These seemingly contradicting results of
microscopic and diffraction studies are reconciled within a new,
minute-scale model of scleractinian biomineral fibers. In this model,
nanocrystalline aragonite units are interconnected by mineral bridges
and form aggregates usually larger than 200 nm. Most likely, the size
of the aggregates is resulting from physiological biomineralization
cycles that control cellular secretion of ions and biopolymeric
species. Intercalation of biopolymers into crystal lattice may
influence consistently several structural parameters of the
scleractinian coral bio-aragonite in all studied samples: (i) the
lattice parameters and internal strains of the bio-aragonite are larger
than in mineral aragonite, (ii) lattice parameter elongations and
internal strains reveal directional anisotropy with respect to
crystallographic axes.^1";
s[6126] = "ZIBROWIUS H. (1988).- Mise au point sur les Scleractiniaires
comme indicateurs de profondeur (Cnidaria: Anthozoa). [review of the
Scleractians as depth indicators; in French, with English summary] .-
Geol. Mediterraneenne 15, 1: 27-47.- <b>FC&#038;P 19-1.1</b>, p. 55,
ID=2671^<b>Topic(s): </b>bathymetry; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography:
</b>^Before considering the use of fossil scleractinians as depth
indicators, their living counterparts are presented in their
morphological and ecological diversity. Jointly, the main environmental
factors conditioning their geographical and depth distribution are
pointed out. Intraspecific variation depending on environmental factors
makes taxonomy of the group more complicate. Taxonomy is yet far from
being satisfactory for many taxa, particularly to some areas. The terms
hermatypic - ahermatypic as currently used by biologists and
geologists, are not without ambiguities due to the original definition
(Wells 1933); they are discussed together with complementary terms,
which had been introduced in order to remedy to that ambiguity. In case
of precise taxonomy and well recorded ecology, reference to living
scleractinians permits extrapolation of paleoenvironments corresponding
to fossil assemblages. It is important to distinguish between shallow
water coral reefs of the tropical type and scleractlnian constructions
in deep water, characters useful for this distinction are indicated.
But the present contribution more specifically aims at demonstrating
the usefulness of non-reefal scleractinians as indicators of depth (and
temperature). According to Wells (1967), the depth (and temperature)
interval common to the taxa present in a fossil assemblage can be
estimated by reference to identical or related living forms. This
provides an approximation for the paleoenvironment under analysis. It
is essential to detect an eventual mixture of faunas issued from
significantly different depth levels in order to avoid the pitfall of
averaging incomparable data. At least for assemblages of a rather young
geological past, extrapolations can be remarkably precise (examples of
Pleistocene faunas from the Mediterranean). However, the more remote in
age the assemblages are, the less precise will be the results because
more and more taxons in common with the Recent drop out. Analysis of
```

```
morphofunctional adaptions, detached from any taxonomic basis, will
provide, at best, only general information on the type of the
environment (deep or shallow) and of the substrate (soft or hard,

molecular approach; Scleractinia, phylogeny; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography:
</b>^The evolutionary history of scleractinian corals, based on
morphological taxonomy and inferences from the fossil record, has been
poorly understood. Molecular techniques developed over the past ten
years are now bekg used to gain a new perspective on scleractinian
phylogeny. DNA sequences, mitochondrial genome structure, and
morphological characters support a basal position for the Anthozoa in
the phylum Cnidaria. Mitochondrial and nuclear DNA sequences suggest a
relatively derived position of the order Scleractinia within the class
Anthozoa. Mitochondrial and nuclear DNA sequences have provided a new
hypothesis for evolution within the Scleractinia that is different from
hypotheses based on morphological characters of extant and fossil taxa.
Groupings within the two major lineages defined by molecular data do
not correspond to morphological suborder groupings although groupings
of genera within families do correspond to traditional taxonomy. This
new molecular hypothesis suggests that the Scleractinia are represented
by two major lineages that diverged from each other before the
appearance of the scleractinian skeleton in the fossil record. This
divergence time supports the hypotheses that the Scleractinia are not
related to the Rugosa of the Paleozoic and that the scleractinian
skeleton has evolved more than once. These two major lineages may
represent two architectural strategies within the Scleractinia that
have led to their great morphological diversity.^1";

</b>variability; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>; <b>Geography: </b>^Patterns of morphological
variation in calice characteristics were investigated within a single
colony of Porites lutea Milne-Edwards &#038; Haime 1816 from the
Northern Red Sea. Hierarchical cluster analysis and canonical
discriminance analysis revealed four groups of calice morphs to occur
within this colony. The most clearly discriminating variables were
calice size and thickness of thecae, besides the thickness and length
of septa and the development of pali. The development and degree of
fusion within the ventral triplet as well as columella diameter had the
lowest correlation with the discriminant functions. The most stable
characters were the pattern of fusion within the ventral triplet and
the development of the columella. Corallites from the upper face of the
colony (vertical growth direction) were different from corallites on
the lateral face of the colony (horizontal growth direction). For the
identification of fossil Porites it is neccessary a) to obtian calices
from several regions of the specimen in order to give a sample of
corallite variability, b) It is neccessary to fully sample the pattern
of septal fusion in the ventral triplet, as this is a stable character
at a colony level.^1";

relationships among septal microstructures, and various indications
suggest that the widely used scheme proposed by Wells (1956) have to be
reexamined. The last decade of studies of biomineralization process
have demonstrated the leading role that specific macromolecules play
during the growth of calcareous biocrystals. These results make
possible a new microstructural approach, based on organo-mineral
relationships examined at the micronic scale. In addition, biochemical
informations obtained from extracted and purified macromolecules can be
studied by multivariat analysis, resulting in diagrams showing the
biochemical distances between species that can be compared to RNA &#47;
DNA based data. Thus, biochemically-based data provide us with
evolutionary-related criteria by which phylogenetic distances can be
asessed between the skeletal structures.^1";
s[6141] = "LOSER H. (1998).- Adelocoenia versus Pseudocoenia - some
rectifications.- FC&P 27,1: 29-32.- <b>FC&#038;P 27-1</b>, p. 29,
ID=3930^<b>Topic(s): </b>nomenclature; Scleractinia, Adelocoenia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^Colonial corals with small round calices,
rudimentary septa and no columella of the suborder Stylinida
(Scleractinia) are abundant in the Upper Jurassic and Cretaceous
(Berriasian-Cenomanian). Several very similar genera are known. Based
on Alloiteau (1948) and the type material available at that time, I
tried to clarify this problem (Loser 1994). I proposed the use of
Adelocoenia, instead of Pseudocoenia and Cyathophora. This proposal was
repeatedly discussed in this newsletter (Baron-Szabo &#038; Bertling
1995, 1996), as well as in Baron-Szabo &#038; Steuber (1996) and
Baron-Szabo (1997) but not accepted. * Generally, the IRZN
[International Code of Zoological Nomenclature] force[s] us to consider
genera and species in relation to their type species and type
specimens. Our personal opinion on a certain taxon may be interesting
but has no influence on its taxonomical status. This short note
provides some information on type species and types which were ignored
in my own work and in the previously mentioned discussions as well.^1";

the epithecate scleractinian corals.- Acta Palaeontologica Polonica 44,
2: 131-166.- <b>FC&#038;P 28-2</b>, p. 30, ID=4023^<b>Topic(s):
</b>epithecate corals, phylogeny; Scleractinia, epitheca;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^Adult stages of wall ontogeny of fossil and Recent
scleractinians show that epitheca was the prevailing type of wall in
Triassic and Jurassic corals. Since the Late Cretaceous the frequency
of epithecal walls during adult stages has decreased. In the ontology
of Recent epithecate corals, epitheca either persists from the
protocorallite to the adult stage, or is replaced in post-initial
stages by trabecular walls that are often accompanied by
extra-calicular skeletal elements. The former condition means that the
polyp initially lacks the edge zone, the latter condition means that
the edge zone develops later in coral ontogeny. Five principal patterns
in wall ontogeny of fossil and Recent Scleractinia are distinguished
and provide the framework for discrimination of the four main stages
(grades) of evolutionary development of the edge-zone. The trend of
increasing the edge-zone and reduction of the epitheca is particularly
well represented in the history of caryophylliine corals. We suggest
that the development of the edge-zone is an evolutionary response to
changing environment, mainly to increasing bioerosion in the Mesozoic
shallow-water environments. A glossary is given of microstructural and
skeletal terms used in this paper.^1";

leptocyathus as recent specimens and Favia speciosa, Premocyathus
compresus, Porites sp. and Goniopora sp. as fossil specimens. The
materials of the specimens were experimented with DTA under normal
pressure, and crystal structures of some of them were investigated by
means of X-rays. As a result of the experiments, the following can be
said: (1) Recent and Quaternary scleractinian corals are aragonite in
all of various species; (2) the aragonite in coral was inverted to
calcite lower temperature (about 310°-320°C) than that of inorganic
aragonite; (3) the DTA curves of the samples of recent and Alluvium
fossil coral showed exothermic peak in the neighborhood of 430°C. It is
supposed that some organic materials exist in the aragonitic
materials.^1";

<b>Geography: </b>^The ontogenetic development of a solitary
scleractinian coral, Flabellum distinctum Edwards &#038; Haime, has
been studied in serial thin section, with special attention being paid
to epithecal nature in relation to septal growth. The term
&#039;epitheca&#039; has been confusingly used for two different
skeletal structures: epitheca (sensu stricto) and marginotheca. The
latter is here newly proposed, &#039;epitheca&#039; is defined as a
calcareous investment developed on the outside of other skeletal
structures of a corallite. It can be distinguished from the
marginotheca in section by lacking a dark line (calcification centre)
and by being unrelated to the formation of septa,
&#039;marginotheca&#039; defines the outer margin of the main skeletal
structures of a corallite. It has a dark line which functionally
coincides with that of the eutheca. It is of primary origin, preceding
formation of septa and provides the origin of the septa. The
marginotheca is one of the more important and fundamental skeletal
structures for coral classification.^1";

</b>corals &#038; humans; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>; <b>Geography: </b>^It occurs to me
that it is desirable to establish clearly our relationship with any
group of animals, vertebrate or invertebrate, that we choose to study.
Are we to be master, servant or partner? For example, our relationship
with a member of the cat family is likely to be that of an inferior;
with the dog, Man has traditionally been the master; with most
reptiles, Man has maintained a precarious and uneasy relationship. When
we come to the invertebrates, however, the position is not so simple
and clear-cut. Some readers may think it merely frivolous to suggest
that Man could have any kind of a relationship with the coral polyps.
But I believe it is not only amusing but useful to look at the
Scleractinia to find some analogies with human organisation and
behaviour. [ ] The main lesson which Man could learn from the corals is
the importance of maintaining a balance between the individual and the
group (colony) and the environment. This is, after all, essential to
the success of most species. [first and last fragments of a short

s[6166] = "CUIF J.-P. (2010).- The converging results of
microstructural analysis and molecular phylogeny: Consequence for the
overall evolutionary scheme of post-Paleozoic corals and the concept of
Scleractinia.- Palaeoworld 19, 3-4: 357-367.- <b>FC&#038;P 36</b>, p.
89, ID=6498^<b>Topic(s): </b>phylogeny, systematics; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^During the last three decades, a series of
paleontological and biological results have brought considerable
changes to the long-standing question of a possible relationship
between the Paleozoic and modern corals. Microstructural descriptions
of samples from the alpine outcrops (Salzkammergut and Dolomites) along
with new specimens from Turkey have shown first that the classical
Wells&#039; schemes have to be re-examined. Accordingly, several
investigations based on molecular phylogeny have repeatedly led to the
conclusion that, at the family level, the taxonomy inherited from
Vaughan and Wells cannot be maintained. From an overall evolutionary
viewpoint, agreement also exists between microstructural analysis and
molecular phylogeny. A recently discovered Triassic family, the
Pachythecalids, exhibits highly unexpected skeletal features and
microstructures in both septa and walls. Additionally, structural
relationships between walls and septa demonstrate a particular mode of
growth, with ontogenic priority to the theca. Comparison of the
corallite microstructures suggests that most of the Triassic fauna can
be derived from this unique family by an evolutionary process during
which the septal system became progressively prevalent upon the wall.
This monophyly of the modern corals is also well supported by molecular
phylogeny. The present concept of Scleractinia has to be re-examined
because it cannot include neither Pachythecalids, probably related to
the Late Permian Polycoelids, nor some other post-Paleozoic corals,
including extant Guyniidae, with long recognized specific structural
patterns. [original abstract]^1";
s[6167] = "KITAHARA M.V., CAIRNS S.D., STOLARSKI J., BLAIR D., MILLER
D.J. (2010).- A Comprehensive Phylogenetic Analysis of the Scleractinia
(Cnidaria, Anthozoa) Based on Mitochondrial CO1 Sequence Data.- PLOS
ONE 5, 7: e11490.- <b>FC&#038;P 36</b>, p. 91, ID=6505^<b>Topic(s):
</b>phylogeny, molecular approach; Scleractinia, phylogeny;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^Background: Classical morphological taxonomy places
the approximately 1400 recognized species of Scleractinia (hard corals)
into 27 families, but many aspects of coral evolution remain unclear
despite the application of molecular phylogenetic methods. In part,
this may be a consequence of such studies focusing on the reef-building
(shallow water and zooxanthellate) Scleractinia, and largely ignoring
the large number of deep-sea species. To better understand broad
patterns of coral evolution, we generated molecular data for a broad
and representative range of deep sea scleractinians collected off New
Caledonia and Australia during the last decade, and conducted the most
comprehensive molecular phylogenetic analysis to date of the order
Scleractinia. Conclusions: There was a striking discrepancy between the
taxonomic validity of coral families consisting predominantly of
deep-sea or shallow-water species. Most families composed predominantly
of deep-sea azooxanthellate species were monophyletic in both maximum
likelihood and Bayesian analyses but, by contrast (and consistent with
previous studies), most families composed predominantly of
shallow-water zooxanthellate taxa were polyphyletic, although
Acroporidae, Poritidae, Pocilloporidae, and Fungiidae were exceptions
to this general pattern. One factor contributing to this inconsistency
may be the greater environmental stability of deep-sea environments,
effectively removing taxonomic &#034;noise&#034; contributed by
phenotypic plasticity. Our phylogenetic analyses imply that the most
basal extant scleractinians are azooxanthellate solitary corals from
deep-water, their divergence predating that of the robust and complex
```

```
corals. Deep-sea corals are likely to be critical to understanding anthozoan evolution and the origins of the Scleractinia. [abbreviated abstract]^1";
s[6168] = "ZLATARSKI V.N. (2008).- Need for a more integrative approach to scleractinian taxonomy.- Proceedings of the 11th International Coral Reef Symposium, Ft. Lauderdale, Florida, 7-11 July 2008; session 26. [conference abstract] - <b>FC&#038;P 36</b>, p. 109, ID=6541^<b>Topic(s): </b>integrative taxonomy; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography: </b>^The history of scleractinian taxonomy is divided into six periods: the original, purely typological, was based on scarce coralla material; the second, starting at the end of nineteenth century, originated with visiting natural habitat and established variability; the third commenced in the 1930s with detailed skeletal study; the fourth began in the 1950s with scuba access to coral habitat; the fifth began in the 1980s following fundamental discoveries in life history and molecular genetics; and the sixth started in 1995, when data from molecular genetics opened a new avenue for scleractinian megataxonomy, contradicting conventional gross-morphology taxonomy but resulting congruent with skeletal histology and ornamentation. Currently, there are four sources of scleractinian taxonomic information: morphology, paleobiology, developmental biology and molecular genetics. Taxonomy is important for understanding scleractinian biodiversity and reef conservation. However, the taxonomy is fragmented and the nomenclature tangled. The e-dimension benefits have not yet been realized and the New Taxonomy not yet arrived for scleractinians. Vision and teamwork are needed for a more integrative taxonomy. The Atlantic Scleractinia Initiative seeks to address the following points: massive sampling, study of the mesophotic habitat, collection access, analysis of phenotypic diversity, life history, geological history, molecular genetics, cyberinfrastructure and education of specialists. [original abstract]^1";
s[6169] = "ZLATARSKI V.N. (2010).- Palaeobiological perspectives on variability and taxonomy of scleractinian corals.- Palaeoworld 19, 3-4: 333-339.- <b>FC&#038;P 36</b>, p. 109, ID=6542^<b>Topic(s): </b>variaability, taxonomy; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography: </b>^Scleractinians are well known for their exceptional variability and difficult taxonomy. Until the end of the nineteenth century, these corals were studied outside their natural habitat. In situ investigation brought to attention their variability and led to description of formae and attempts to depart from the typological taxonomy. Studies commenced in 1950s of extant scleractinians of Jamaica, the South Pacific, Madagascar, the Red Sea, Cuba, and Australia demonstrated instances of coralla unclassifiable in the described species because they possess intermediate characters, and sometimes one corallum exhibits the characteristics of more than one species. Since 1984, discoveries about scleractinian life history and molecular data further challenged the conventional taxonomy. The coral holobiont is now being studied as a totality of the coral animal, its endosymbiotic zooxanthellae, and its associated community of microorganisms. Molecular genetics and studies of life history combined with morphological variability and variability in geological time are needed for scleractinian taxonomy. The input of palaeontologists with temporal aspect as well as an enormous amount of morphological data is invaluable, as demonstrated by several examples based on detailed morphological observations later supported by molecular and life history information. Efforts to resolve the variability vs. taxonomy dilemma for fossil scleractinians would benefit from further actuopalaeontological work: studies at all levels of biological organization, including ancient DNA and evolutionary genetics, the rich fossil record, fractals and RLQ analysis, palaeopathological research, sclerochronology, the ecology and skeletogenesis of extant deep sea corals. (2001).- Biomineralization and diagenesis in the Scleractinia: part 1, biomineralization.- Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 144-151.- <b>FC&#038;P 30-1</b>, p. 20, ID=7066^<b>Topic(s): </b>biomineralization; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography: </b>^Applying the organic matrix concept (Towe, 1972) to the study of coral skeletons leads to a series of results that considerably change our representation of the nature and fine scale organization of coral skeletal components. Since 1941, analogy between fibrous spherulites of inorganic origin and fibrous units that radiate from the &#34;centers of calcification&#34; has gained wide acceptance. Newer research greatly modifies this view, and organic control of fiber growth must be universally accepted. Specific preparations carried out on modern corals establish that the organic matrix concept explains all visible features in coral fibers, from overall morphology (with organic envelopes present), to control of longitudinal growth of fibers. Cyclic secretion of organic compounds leads to differential solubility between organic rich and organic depleted zones within these biocrystals at a micron scale, allowing very precise descriptions and comparison of development of various types of septa. * Since the 1940s, it has been commonly accepted that the role of &#34;centers of calcification&#34; is to provide a crystallographic substrate for further growth of aragonite skeletal fibers. Additionally, it is agreed that centers of calcification and septal microstructure have a very high taxonomic potential, but at the same time, they have also frequently been treated as formal descriptive concepts only. Physical chemical measurements (using non destructive methods) and evidence of microstructures obtained by an ultra light etching process complemented by specific biochemical staining allows demonstrating that centers of calcification are present in all species studied. They mostly contain very small, randomly oriented crystals that are always aragonitic, but no direct crystallographic link is seen between crystals from calcification centers and later coating layers of aragonite fibers. * All research areas involving coral skeletons are affected by these changing concepts of skeletogenesis. Thus, the biochemical study of macromolecular mineralizing matrices is important in the study both of coral phylogeny and environmental effects on coral calcification. Another major consequence of this &#34;organic and mineral&#34; concept of coral skeleton is to provide us with a new basis for studying the fossilization process. [original abstract]^1";

diagenesis in the Scleractinia: part 2, diagenesis.- Bulletin of the
Tohoku University Museum 1 [Proceedings of the 8th International
Symposium on Fossil Cnidaria and Porifera]: 152-163.- <b>FC&#038;P
30-1</b>, p. 20, ID=7067^<b>Topic(s): </b>diagenesis; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^Diagenesis in scleractinian corals depends on the
relative solubility of aragonite and calcite, the presence and
chemistry of pore fluids, and the amount, nature and configuration of
organic matrix macromolecules within skeleton. Concepts of skeletal
diagenesis have been largely based on mineralogic aspects ; thus we
recognize that neomorphism of scleractinian skeletal aragonite into
calcite results in obliteration of biogenic skeletal microstructure.
However, structure can be preserved as aragonitic material, due to
isolation, either by non permeable sediment or neomorphic calcite. In
calcitized fossil scleractinians, crystal boundaries are seen cutting
across biogenic features with resultant destruction of structure. Where
dissolution of aragonite and replacement by calcite occurs on a very
fine (µm) scale, aragonitic inclusions within calcite commonly outline
organic structures. Isolation also allows preservation of whole
specimens as aragonite, but fossils totally lacking neomorphic calcite
are seldom found, and it is unusual to find aragonitic skeleton with
preserved organic matrix within. * Concepts of diagenesis must take
into account consequences of biochemical diversity. Organic matrix
proteins play several roles in determining the end results of
diagenesis, due to their abundance in centers of calcification, their
presence in layers of abundant organic proteins within biocrystals and
forming protein envelopes around biocrystal clusters. Earliest
diagenesis of aragonite biocrystals begins in skeletal carbonate during
the life of the corals, resulting in fusion of aragonite fibers, and
loss of organic matter by microbial means or oxidation. There is a
common association of reduced sulfur with formerly organic rich areas
after breakdown of organic matter by microbes. Where organic material
is most abundant, in growth layers or at centers of calcification, its
early removal leads to modification of these structures or to
calcitization. Growth lamellae, both within and between aragonitic
fibers can be exaggerated by calcific neomorphism of aragonite enhanced
by early removal of organic matter. [original abstract]^1";
s[6180] = "STOLARSKI J. (2003).- Three-dimensional micro-and
nanostructural characteristics of the scleractinian coral skeleton: A
biocalcification proxy.- Acta Palaeontologica Polonica 48, 3: 497-530.-
<b>FC&#038;P 33-1</b>, p. 73, ID=7219^<b>Topic(s): </b>skeletogenesis;
Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>; <b>Geography: </b>^The contemporary
&#34;two-step model&#34; of growth of the scleractinian skeleton is
based mostly on transversely sectioned samples. According to this
model, many skeletal elements, e.g. septa are formed in two temporally
distinct phases represented by (1) &#34;centers of calcification&#34;
that are composed of homogenously distributed microcrystalline or/and
organic components and serve as scaffolding for the further growth of
(2) fibrous skeleton. Based on transverse and longitudinal sections and
histochemical staining techniques, I demonstrate herein that in extant
corals (i.e. Stephanocyathus, Flabellum, Desmophyllum,
&#34;Ceratotrochus&#34;, Galaxea, Platygyra), the entire septal
skeleton is composed of superimposed layers of mineral and
organic-enriched phases. These may be interrupted in some directions of
growth but in other directions there is continuity between &#34;centers
of calcification&#34; and &#34;fibers&#34;, making any distinction
between these two structures unclear. As an alternative to the
&#34;two-step model&#34;, a &#34;layered model&#34; of skeletal growth
is proposed, that explains the differences between &#34;centers of
calcification&#34; and &#34;fibers&#34; in terms of differential growth
dynamics between these regions. Instead of the traditional but
inadequate &#34;trabecular&#34; and &#34;centers of calcification&#34;
```

```
concepts, a distinction between deposits of the Rapid Accretion Front
(Draf); which in particular cases can be organized into Centers of
Rapid Accretion (CRA), and Thickening Deposits (TD) is proposed. In the
dRAF region, mineral components, ca. 50nm in diameter, seem to match
the size range of nodular structures recently interpreted as nascent
CaCO3 crystals. Remarkable regularity of the mineral/organic phase
alternations (microbanding) in the TD skeleton of zooxanthellate corals
and lack of such regular microbanding in azooxanthellate coralla is a
promising criterion for distinguishing these two ecological coral
groups on a skeletal basis, and one that could be applicable to
fossils. [original abstract]^1";

biodiversity; Scleractinia, Foraminifera; <b>Systematics: </b>Cnidaria
Foraminifera; Scleractinia; <b>Stratigraphy: </b>; <b>Geography:
</b>^The eastward decline in the diversity of Indo-Pacific
scleractinian corals and larger foraminifera is due primarily to the
shallowing of the thermocline and significant cooling of the Equatorial
Undercurrfent in the eastern Pacific. The coral larvae carried eastward
across the Pacific encounter temperatures below 18°C; which is lower
than the optimum for the long-term survival of reef-building corals.
This thermal barrier to dispersal of the Indo-Pacific fauna is
particularly effective in an area within 2000 km west of the Galapagos
Islands. Nevertheless, trend-surface analysis of faunal similarity
based on the probabilistic index of Raup and Crick (1979) suggests that
the modern scleractinian fauna of the eastern Pacific region exhibits a
high degree of similarity to that of the Indo-Pacific region. The newly
assembled data on the generic occurrence of larger foraminifera and the
results of the probabilistic analysis based on the method of Henderson
and Heron (1977) indicate that the observed diversity of a fauna
constituted, on average, 65% of the true diversity; the remaining 35%
can be viewed as a measure of the sampling bias. Last, the maximum
north-south range of a genus belonging to modern scleractinian corals
or larger foraminifera is 70 ±5° and its east-west range never exceeds
the distance that is four times the north-south range. The reason for a
correspondence between the maximum latitudinal and longitudinal ranges
of genera belonging to these two unrelated groups is believed to lie in
the similarity of their dispersal capabilities, which were largely
controlled by temperature.^1";

</b>thecal structures; Scleractinia, Caryophylliidae; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>; <b>Geography:
</b>^At the initial stage of ontogeny, in Caryophylliidae (Miocene
Caryophyllia salinaria, C. depauperata, Recent C.berteriana) and
Flabellidae (Miocene Flabellum roissyanum, Recent Javania cailleti),
wall and septa are formed simultaneously, and their trabecular
structure is coalesced (marginothecal wall). At subsequent juvenile
stage in Caryophylliidae the presence of the extensive exosarc enables
formation of costo-septa and, in consequence, formation of
trabeculotheca. Trabeculotheca consists of fragments of primordial wall
```

```
located between the costo-septa. The trabeculothecal segments vanish in the adult stage in the majority of corals when the septothecal wall is formed by thickening of the costo-septa. In others, however, marginotheca can be present troughout the whole ontogenetic sequence (C. salinaria). Most Flabellidae are characterized by limited expression of exosarc and the presence of marginothecal wall up to the adult stage. The origin of &#039;flabellid&#039; organization in Caryophylliina may result from a simple modification of ontogeny - extention of initial morphology to later ontogenetic stages. Such corals could develop several times, and the Flabellidae may be polyphyletic.^1";

Scleractinia, Rugosa; <b>Systematics: </b>Cnidaria; Scleractinia
Rugosa; <b>Stratigraphy: </b>; <b>Geography: </b>^The Mesozoic-Cenozoic
coral Order Scleractinia has been suggested to have originated or
evolved (1) by direct descent from the Paleozoic Order Rugosa or (2) by
the development of a skeleton in members of one of the anemone groups
that probably have existed throughout Phanerozoic time. In spite of
much work on the subject, advocates of the direct descent hypothesis
have failed to find convincing evidence of this relationship. Critical
points are:(1) Rugosan septal insertion is serial; Scleractinian
insertion is cyclic; no intermediate stages have been demonstrated.
Apparent intermediates are Scleractinia having bilateral cyclic
insertion or teratological Rugosa.(2) There is convincing evidence that
the skeletons of many Rugosa were calcitic and none are known to be or
to have been aragonitic. In contrast, the skeletons of all living
Scleractinia are aragonitic and there is evidence that fossil
Scleractinia were aragonitic also. The mineralogic difference is almost
certainly due to intrinsic biologic factors.(3) No early Triassic
corals of either group are known. This fact is not compelling (by
itself) but is important in connection with points 1 and 2, because,
given direct descent, both changes took place during this only stage in
history of the two groups in which there are no known corals. (Original
summary)^1";

All new species come from the Albian of Northern Spain. Murguithalamia
jugoensis n.gen., n.sp. was proved having pseudomorphs of originally
siliceous triaene megascleres. Vascothalamia arayaensis n.gen., n.sp.
was found having pseudomorphs of monaxone siliceous megascleres.
Considering these findings as well as the living &#34;sphinctozoan&#34;
Vaceletia crypta (Vacelet 1977) - it Is obvious that the demosponges
with a thalamid and aragonitic basal skeleton, and a trabecular
internal structure are polyphyletic. The taxa were attributed therefore
partly to the subclass Ceractinomorpha Levi 1973 (order Verticillitida
Termier et Termier 1977 with the families Verticillitidae Steinmann
1882, Vaceletiidae n. fam. and Stylothalamiidae n. fam.) and partly to
the subclass Tetractinomorpha Levi 1973 (order Murguiathalamida n. ordo
with the families Murguiathalamiidae n. fam. and Boikothalamildae n.
fam.).^1";

Phanerozoic Sphinctozoa of the Territory of the USSR.- Nauka, Moscow [
ISBN N 5-02-00223-3], 224 pp., 64 pls.- <b>FC&#038;P 20-1.1</b>, p. 82,
ID=2888^<b>Topic(s): </b>monograph; Porifera, Sphinctozoa;
<b>Systematics: </b>Porifera; Sphinctozoa; <b>Stratigraphy: </b>;
<b>Geography: </b>USSR^The monograph embracing all the information on
Sphinctozoa, a very important taxon in evolutionary and
biostratigraphical aspects, was created for the first time in the USSR.
The general part of the monograph includes the outlines devoted to the
problems of morphology, systematics, paleontology and the
stratigraphical significance of Sphinctozoa. The description of all the
species of Sphinctozoa known in the USSR (from the Carboniferous to the
Jurassic and from the Far Eastern USSR to the Crimea inclusively) is
given in another part of the monograph, which contains the regional
geological outlines. In some cases the revision of the higher taxa at
the level of &#34;genus&#34; - &#34;suborder&#34; is given. The
seperate chapter represents the materials related to the discussion on
the nature of Sphinctozoa among both the specialists from different
countries and the authors of this monograph. The book is richly
illustrated, includes textfigures and 65 plates, traces, the list of
references is complete.^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^Stromatoporoidea Nicholson
&#38; Murie (?Porifera, ?Demospongiae) are calcareous skeletal remains
of organisms present during the Palaeozoic to Mesozoic, comprising
sponge-like taxa with hypercalcified layered skeletons that were
important to reef-building. Earlier (Palaeozoic) forms lack spicules
but some of the later (Mesozoic) taxa have siliceous monaxonomic or
tetraxonic spicules in addition to calcitic basal skeletons, inferring
affinities to Demospongiae. &#39;Stromatoporoids&#39; has been used at
various levels (ordinal, class, and subphylum) within the phylum
Porifera, but also within other &#34;lower&#34; marine invertebrate
phyla at various times. The contemporary hypothesis is that these life
forms may represent a grade (not a clade) of poriferan construction,
although it is also recognized that there may be fundamental
differences between the Palaeozoic and Mesozoic stromatoporoid faunas,
such that this grade of skeletal construction may not be homologous,
and the taxon may be a completely artificial construct. Some
stromatoporoids have also been associated with the Calcarea and also
the &#039;sphinctozoan&#039; grade of construction. Only a brief
overview is provided although the stromatoporoids include about 110
genera in seven orders.^1";

</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>; <b>Geography:
</b>^The history of research on the &#034;true&#034; stromatoporoids, a
presumably monophyletic group of sponges that occurred from the
Ordovician through the Devonian, is examined in detail. Stromatoporoid
published research is summarized in five categories: quantity of
publication; biological affinities; systematics; skeletal
microstructure; and paleoecology. Quantity of publication is measured
from each of the 75 years. Moderate levels of publication in the late
1920s and 1930s declined in the early 1940s, and were reduced to zero
for four years due to the impact of World War II. Levels similar to
that of the 1930s returned in the 1950s, after which there was an
overall increase until the mid-1980s, when levels began a decrease that
persists today. The proportion of research on paleoecology has
increased as research on systematics decreased through time.
Post-Devonian forms assigned to the stromatoporoids are a polyphyletic
grouping of several apparently unrelated taxa, possibly representing
both Porifera and Cnidaria. Publications on the post-Devonian
&#034;stromatoporids&#034; amount to less than one-third that on the
true stromatoporoids during the same 75 years.^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^The ontogenetic changes
expressed in the earliest Amphipora-skeleton growth stages suggest that
the observed successions can be very different from those of common
stromatoporoids. The amphiporid organisms built first their bottom
```

```
discs or directly the complex first chambers (diameters ~0.2 mm), and
these structures were directly continued by upright growth of first
single tubes. The first occurrences of gradually developing amphiporid
skeleton fiber meshworks were concentrated in the zone of
metamorphosis, where the first tubes decayed. The attributes of adult
amphiporid stages (axial canal and sparsely perforated outer casings or
walls) developed with a little delay. The Amphipora stems increased
mainly during the first millimeters of their length (to ~1.5-2 mm), but
further increase of the stems (to ~3 or 5 mm) was a very slow process.
It can be suggested that amphiporids can be linked to very old
ancestors, somewhere around archaeocyaths or common metazoan sources at
~0.8 Ga.^1";

```

```
Phanerozoic (especially Palaeozoic) reef, and reef-related
environments, and may be used as tools for all scales of
palaeoenvironmental analysis. Palaeozoic stromatoporoid classification
uses the calcified skeleton, and although higher level taxa may be
convergent, genera and species are normally readily identifiable and
have palaeobiological utility. A hierarchical growth-form
classification of stromatoporoids comprises: Level 1 (outline forms:
laminar, tabular, domical, columnar, bulbous, defined with ratio
limits; and dendroid, expanding conical, digitate and irregular); Level
2 (ornament, as papillae, mamelons and protuberants, give an increasing
degree of disruption of the outline); and Level 3 (growth patterns of
smooth and ragged margins, enveloping and non-enveloping laminations,
coalescence and anastomosing). Inappropriate growth form terms in
current use are rejected especially massive and encrusting.
Stromatoporoid palaeobiology applied at local scale aids determination
of relative degree of contemporaneous turbulence and sedimentation;
community scale study of stromatoporoids promotes comparisons between
palaeoenvironments in reef and reef-related facies. Palaeozoic
stromatoporoids may aid regional and even global event recognition
including changes in ocean states. Major gaps in knowledge are growth
rates and whether stromatoporoids were photosensitive and &#47;or
photosymbiotic.^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^Modern coralline sponges
secrete a skeleton by means of a basal pinacoderm, intracellularly, or
inside the soft tissue on an organic matrix. The examination of
terminal growth surfaces of stromatoporoids indicates that soft tissue
in laminate and amalgamate forms occupied the upper galleries and that
the skeletal elements were secreted within soft tissue on an organic
matrix. The stromatoporellids and clathrodictyids secreted the skeleton
in modules that are homologous to the chambers of a sphinctozoan. In
stromatoporellids the module was bounded by a floor that formed the
upper layer of the tripartite lamina below and a roof that became the
lower layer of the next lamina; it further included the intervening
pillars. In clathrodictyids the module had only a roof and pillars and
the laminae are single layers.^1";

<b>Geography: </b>^Stromatoporoids are important in Lower Palaeozoic
reefs and related facies, and the palaeoecology of their external form
is studied here using examples from the Ordovician and Silurian of the
Oslo region, the Silurian of Gotland and the Devonian of Belgium. * A
new classification, of shape (bearing no relation to taxonomic schemes)
distinguishes laminar, domical, bulbous and dendroid shapes defined by
measurement of basal and vertical dimensions. Each has subdivisions,
most importantly being the distinction between smooth (enveloping) and
ragged (non-enveloping) latilaminae, interpreted to be a response to
sedimentation. * A parameterization scheme relates laminar, domical and
bulbous forms in a simple triangular display, in terms of basal,
vertical and diagonal extension. * Flume experiments on model
stromatoporoids, statistical analysis of field data and detailed hand
specimen and thin section studies show that: (1) laminar forms were
susceptible to sedimentation but were stable in high energy conditions.
In deep water they were possibly limited by low light intensity; (2)
domical forms were very stable and possessed a sediment shedding
capability; with laminar forms their shape has a strong taxonomic
component in some cases; (3) bulbous forms were unstable and generally
reflect quiet water conditions; complex bulbous forms are found in high
energy situations where they show overturning; (4) dendroid varieties
were delicate and well suited to environments with higher sedimentation
rates in areas of low turbulence. * Substrate composition and surface
shape were important factors in the distribution of stromatoporoid
morphotypes. Sandy substrates show susceptibility to scour around
stromatoporoids leading to burial of domical and bulbous forms in
environments of water flow, but low-profile laminar types were less
affected. Dendroid forms were infrequently affected by substantial
currents. Muddy substrates scoured less, and stromatoporoids were put
into transport more easily, but if partly buried in mud,
stromatoporoids were very stable. * The environments of stromatoporoids
were generally open marine, although in certain restricted conditions
examples show distinct morphological pecularities (irregularity and
extreme thinness) suggesting influence of other limiting factors, such
as salinity, food supply, temperature and water aeration.^1";

Kirkpatrick.- FC&P 13, 2: 28.- <b>FC&#038;P 13-2</b>, p. 28, ID=6369^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>; <b>Geography: </b>^Although I thought that I was reasonably well aquainted with the paleontological literature on stromatoporoids, one book containing extensive discussions on these organisms had escaped my notice until this summer. I knew by rumour that it existed but had not taken the time to verify its existence until, by accident, I came across it in the library. I recommend it to all stromatoporoid specialists as an essential part of the history of their science. * It is Randolph Kirkpatrick&#39;s book &#34;The Nummulosphere&#34; published by the author in three parts or volumes - the first two in 1913 and the third in 1917. Kirkpatrick will be remembered by stromatoporoid paleontologists for the beautiful work that he did describing Merlia normani, the sclerosponge from Porto Santo Island near Madeira. Kirkpatrick could see the structure of Nummulites in all the rocks he examined including limestones, sandstones, slates, metamorphic rocks, lavas, plutonic igneous rocks and meteorites. &#34;In the numerous igneous rocks that I have examined I have found them to be disguised (? colonial) foraminifera&#34; (vol. I, p. 52). He concluded that the whole crust of the Earth is composed of Nummulitic limestone changed in various ways and was therefore deposited out of an ocean. The reader of vol. III will find that the macrostructural features of stromatoporoids are produced inorganically like concretions in limestone and that both the structural elements and the gallery filling are composed of Nummulites, like most of the rest of the world. Kirkpatrick&#039;s viewpoints on stromatoporoids has &#34;matured&#34; from the first to third volumes for in the first volume he equates them with both Eozoon and nummulites as follows: &#34;I cannot find a single point of zoological difference between Eozoon canadense Dawson and Stromatopora concentrica Goldfuss. In both there are layers of Nummulite shells of the same structure and size&#34; (p. 26). He then proceeds to write about the stromatoporoid type of nummulite and we find that &#34;Jurassic Oolites and Chalk are probably mainly masses of Stromatoporoids, yet it is not possible to define the shapes of specimens, nor even of reefs&#34; (p. 27). * The book throws some light on Kirkpatrick&#39;s note in Nature (1912) stating that he had discovered spicules in stromatoporoids and they must therefore be sponges. No one since has been able to verify this observation. It appears that Randolph Kirkpatrick was capable of seeing structures in rocks that other scientists have missed. * Here is a book that illustrates and describes such stromatoporoid species as Stromatopora concentrica, Stromatoporella eifeliensis, Clathrodictyon striatellum, Idiostroma occulatum and discusses the Caunopora problem yet I have never seen it referenced in a synonymy - I wonder why. (2010).- Stromatoporoid biometrics using image analysis software: A first order approach.- Computers &#038; Geosciences 36, 4: 550-558.- <b>FC&#038;P 36</b>, p. 136, ID=6599^<b>Topic(s): </b>morphometry; stroms, biometry; <b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>; <b>Geography: </b>^Strommetric is a new image analysis computer program that performs morphometric measurements of stromatoporoid sponges. The program measures 15 features of skeletal elements (pillars and laminae) visible in both longitudinal and transverse thin sections. The software is implemented in C++, using the Open Computer Vision (OpenCV) library. The image analysis system distinguishes skeletal elements from sparry calcite using Otsu&#039;s method for image thresholding. More than 150 photos of thin sections were used as a test set, from which 36,159 measurements were obtained. The software provided about one hundred times more data than the current method applied until now. The data obtained are reproducible, even if the work is repeated by different workers. Thus the method makes the biometric studies of stromatoporoids objective.^1";
s[6269] = "STEARN C.W. (1993).- Petrostroma Stearn 1991, Pteridiostroma Stearn 1992 and Faciledictyon Lessovaya 1991.- FC&P 22, 2: 95-96.- <b>FC&#038;P 22-2</b>, p. 95, ID=6830^<b>Topic(s): </b>nomenclature; stroms; <b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>; <b>Geography: </b>^These three generic names
```

```
have been applied to the same taxon. They were proposed for
clathrodictyids with simple laminae and simple pillars confined to an
interlaminar space. Both authors realized that the discrepancy between
the type species of Simplexodictyon Bogoyavlenskaya and its diagnosis
required the establishment of a new genus to contain those species of
this genus that did not have double laminae. The type species that
Stearn used for Petrostroma (later corrected to Petridiostroma to
resolve the homonymy with Petrostroma Doderlein), P. simplex (Nestor),
is placed by Lessovaya (1991) in Faciledictyon. [&#8230;] Many journals
are now not available until months after the publications dates that
appear on their covers. This situation does not appear to be covered
satisfactorily by Chapter V of the Code of Zoological Nomenclature.

```

```
inherent factors, but arrangement of corallites within a colony could
be affected if environmental change induced a modified growth form.
Comparisons of internal and external characters during colony
development indicate how environmental and genetic factors determined
growth form. The results of these comparisons have implications for
understanding of colony integration, functional morphology, and
systematics. This study is based on serially sectioned coralla of the
cerioid tabulate Paleofavosites subelongus, from the uppermost
Ordovician to lowermost Silurian of the east-central United States.
Colony growth form resulted from changes in maximum growth angle of
marginal corallites, and in the shape of the growth surface. These
features were coordinated with corallite characters and were dependent
on variation in corallite growth. At the same time that a colony became
broader by expanding its maximum growth angle and developing a taller
growth surface, its corallites became larger, more new corallites were
initiated, and recently initiated corallites expanded more rapidly.
When a colony&#039;s maximum growth angle was reduced and the growth
surface became flatter, corallites also became smaller, fewer
corallites were initiated, and those corallites that were recently
initiated expanded slowly. Genetic constraint of growth is illustrated
by consistent patterns of initial colony growth, and by relationships
among characters of internal and external morphology. Frequent
small-scale variations in growth angle and growth surface height:width
during astogeny indicate fluctuating environmental factors.
Sedimentation and subsidence of the colony were probably the major
environmental controls on form. [original abstract]^1";

by various features, among them changes in the distribution of tabulae.
A method potentially useful in analysis of periodical environmental
changes is proposed herein. Measurement of spaces between tabulae in
tabulate corals and preparation of a histogram converted into a trend
curve may show relative periodical fluctuations of the environment.
Such an analysis, exemplified here on Givetian Pachyfavosites sp. from
the Avesnois (northern France), shows that this method may be used as a
tool for estimation of environmental changes.^1";

</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^^1";
s[6300] = "PANDOLFI J.M. (1989).- Phylogenetic analysis of the early
tabulate corals.- Palaeontology 32, 4: 745-764.- <b>FC&#038;P
19-1.1</b>, p. 52, ID=2666^<b>Topic(s): </b>early phylogeny; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Phylogenetic analysis of the extinct anthozoan clade
Tabulata yields new hypotheses concerning their pattern of
diversification in the Ordovician. Two separate phylogenetic analyses,
one based on primitive rugose corals as the outgroup (RUGSGRPS), and
the other based on Lichenaria as the ancestral tabulate coral
(LICHGRPS) yielded different phylogenies. The phylogenies generated are
broadly different from previously proposed phylogenies based on
possibly subjective morphological interpretations, and on
biostratigraphical and &#47; or biogeographical hypotheses alone.
Character analysis based on consistency index (a measure of homoplasy
of characters) yielded four suites of morphological characters: (1)
suites with a high consistency index (CI) that differentiate major
groups; (2) suites with a high CI that differentiate subgroups; (3)
suites with a low CI that differentiate major groups and (4) suites
with a low CI that differentiate subgroups. Therefore, CI does not
necessarily correspond with the potential for differentiating major
groups. The most useful characters in differentiating major groups of
Ordovician tabulates are architecture, wall thickness, mural pores,
```

```
microstructure, corallite shape, and coenenchyme, whereas those not
particularly useful in differentiating major groups are tabulae, septa,
rows of septal spines, columella, and stereozone. The phylogentic
analyses corroborate the taxonomic integrity of the presently defined
Auloporida, Favositida, Halysitida, Heliolitida and most Sarcinulida
and falsify the taxonomic integrity of the Chaetetida and the
Lichenariida. As presently defined the Halysitida should be separated
from Heliolitida.^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^SEM and ultra-thin section examination of the
fossilized &#34;polyps&#34;, corallite walls and tabulae in Late
Llandovery (Silurian, Aeronian) Favosites from the Jupiter Formation on
Anticosti Island reveal the following observations not previously
discovered or described: (1), the &#34;polyps&#34; have a very finely
radial and concentrically wrinkled surficial structure along the basal
portions, but not on the &#34;tentacles&#34;; (2), the &#34;polyps&#34;
are discrete and separate from the uppermost tabulae on which they
rest, and are not produced as modifications of the tabulae nor the
septal ridges; (3), the &#34;polyps&#34; occur only on top of the last
tabula, with no remnants remaining on or between abandoned tabulae
below; (4), the &#34;polyps&#34; consist of sparry calcite and are not
microlamellar like the walls or tabulae; (5), the walls and tabulae
consist of flattened microlamellae like those in Favosites
gothlandicus; (6), within the preserved &#34;polyps&#34; are small
yellow spherules (10-20µm), of possible cyanobacterial or algal origin.
Our tentative explanation for these remarkable structures is that they
reflect fortuitous burial and conservation which permitted early
infilling or saturation by aragonite or calcite of the soft tissues,
thereby preserving the 12-fold symmetry and morphology of the soft
polyps, which once rested on the tabulae.^1";
s[6305] = "HUBMANN B. (1997).- Astogenese von Catenipora micropora
```

```
(Whitfield 1882), Coelenterata, Tabulata.- Mitt. Ges.
Geol.-Bergbaustud. Osterr. 39/40: 15-28.- <b>FC&#038;P 26-1</b>, p. 65,
ID=3635^<b>Topic(s): </b>astogeny; Tabulata, Catenipora;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^The mode of growth of the adult corallum of
Catenipora micropora from the Llandoverian of NE-Iran (Shirgesht area)
is demonstrated. The investigation of intraspecific variabilities of
corallite geometries indicates, that intraserial variabilities
(variability within a &#34;plain&#34;) are not significant different
from interserial variabilities (variability in &#34;space&#34;).
Biometric data sets show the same variability of dimensions throughout
the entire adult part. Compared with younger parts of the colony the
older ones show a better defined data range. Size and geometry of the
ring shaped chains of corallites (lacunae) are interpreted as
genetically determined co-processes of all corallites (polyps) forming
a lacuna. This process is subordinated the simple polyp. The
investigation demonstrates that one section parallel and one vertical
to the growth direction of the corallum is sufficient for taxonomic
characterization.^1";
s[6306] = "SCRUTTON C.T. (1997).- Growth strategies and colonial form
in tabulate corals.- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 91, 1/4: 179-191.- <b>FC&#038;P 26-2</b>, p.
13, ID=3683^<b>Topic(s): </b>growth strategies, colony forms; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Adaptive strategies for colony development (growth
strategies) in tabulate corals can be viewed in terms of two
end-members, peripheral growth and medial growth. In peripheral growth,
new corallites are preferentially offset at the colony margin, whereas
in medial growth, new corallites are principally offset between
earlier, diverging corallites. Many tabulate coral species were
obligate followers of one or other strategy, whilst others could switch
or vary growth between the two strategies. Growth strategy was a factor
in recruitment success on different types of substrate. Colonial form
was a function of growth strategy, offset density and corallite growth
control, moderated during astogeny to a greater or lesser degree by
environmental factors, principally sediment mobility and rate of
substrate aggradation. A wide range of colonial growth-forms, with a
considerable area of overlap, could result from both strategies. The
interaction of growth strategy and environment is illustrated by two
contrasting examples from the Silurian. A deep water (>50-60m)
substrate, with no net sediment aggradation over a 15-20yr period, from
the Llandovery of County Mayo, Ireland, was dominated by tabulate
corals with a peripheral growth strategy and tabular to domal
growth-forms. This environment was probably close to the base of the
photic zone. Wenlock patch reefs in the Welsh Borderland of England
developed in water <30m depth. Here, different strategies and
growth-forms dominated the major phases of patch reef growth during
periods of continuous sea-floor colonization. Peripheral growth and
tabular form dominated in the initiation stage; a more even spread of
strategies and a shift to domal and bulbous growth-forms, together with
the highest percentage of halysitids occured in the reef core; and
medial growth dominated in the reef margin, with a wide range of
growth-forms including a significant percentage of nodular colonies.^1";

Porifera; <b>Systematics: </b>Cnidaria Porifera; Tabulata;
<b>Stratigraphy: </b>; <b>Geography: </b>^Une révolution a été
introduite dans l&#039;étude des organismes constructeurs par la
découverte dans les mers actuelles de Spongiaires à test hypercalcifié
parfois facultatif (Merlia) et qui peuvent être dépourvus de spicules.
Nous avons décidé de reprendre en détail la recherche de critères
permettant d&#039;en distinguer ou d&#039;en rapprocher certains
groupes constructeurs de position systématique mal établie, par exemple
les Trépostomes (rangés parmi les Ectoproctes Sténolèmes, Termier et
Termier 1976) et les Tabulés (rangés dans les Cnidaires). Nous pensons
devoir classer auprès des Chaetétoïdes non seulement plusieurs
Favositina à éléments de petites dimensions tels que Staphylopora Le
Maître 1956, Riphaeolites Yanet in Sokolov 1955 (pourvu de cf.
astrorhizes = rhodorhizes) mais aussi des formes plus classiques à
calices plus grands telles que Favosites aenigmaticum Porfiryev 1937
qui semble posséder des orthotriaenes. Les Théciidés, avec Thecia
Milne-Edwards et Haime 1849, paraissent devoir être apportés au même
ensemble. La texture fibreuse du test est chaetétoïde. La présence de
pores permettant le passage des fluides entre les tubes cloisonnés est
comparable aux prosopyles reliant entre eux les tubes radiaires du
sycon par exemple. * Les tubes de Syringoporacea ont une disposition
semblable à celle des astrotubes de Stromatopores de type Trupetostroma
par exemple. Cette assimilation pourrait expliquer la facilité de la
symbiose dite Caunopora entre les deux groupes. La présence de
planchers ou de plaquettes entre les tubes de certains Syringoporacés
indique d&#039;ailleurs l&#039;existence de tissus vivants
extracalicinaux, les calices pouvant alors avoir eu un rôle atrial. Les
baguettes calcitiques (épines) traversant le test fibro-lamellaire des
Syringoporidés, des Grabaulitidés (Auloporida p.p. de Stasinska), de
certains Favositidés et des Pleurodictyidés (Procteria et certains
Michelinia) suggèrent encore, chez ces Tabulés, une sorte de sécrétion
apparentée à celle des spicules des Spongiaires. [original short

Palaeontology 30, 3: 485-492.- <b>FC&#038;P 16-2</b>, p. 25,
ID=2056^<b>Topic(s): </b>systematic position; Tabulata, Favositida;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Although the favositids have been traditionally
interpreted as a group of Palaeozoic tabulate corals, there has been
persistent speculation, particularly over the last decade, that they
could be the massive basal skeletons of sponges and should be
transferred to the Porifera. Two recent papers, claiming respectively
the preservation of spicules and the fossilization of soft polyps,
strongly focus the dispute. Here, all the evidence relating to the
affinities of the favositids, including these recent claims, is
reviewed. It is concluded that this evidence strongly favors retention
of the favositids within the Tabulata and assignment of the Tabulata to
the Cnidaria Anthozoa.^1";

ID=2136^<b>Topic(s): </b>classification criteria; Tabulata, Favositida;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Of all the morphologic characters used in favositid
taxonomy, corallite size has most frequently been given more weight
than others because of its relative ease of measurement and because it
has been generally believed to be less variable. This study evaluates
the reliability of corallite size as a criterion by a statistical
```

```
treatment of several populations of favositids in the Upper Silurian
West Point Reef Complex in Gaspe, Quebec. Calculation of corallite
cross-sectional area was made feasible by computer-based image analysis
which provides a quick and accurate measure of size. The present study
shows that the mean of the largest 10 percent corallite areas in mature
parts of colonies with a minimum sample size of 100 corallites per
cross section is the best approximation available of mean adult
corallite size. It is suggested that intraspecific variability of
corallite size is often too large for this character to be used in
practice, probably due to phenotypic plasticity. The same may be true
of most other morphologic characters. In some cases, however, one or
two characters remain in variate within a species and can be used
diagnostically. The same characters may be extremely variable in other
species.^1";

Analysis of Genus Favosites.- Acta Palaeontologica Sinica 27, 4:
498-513.- <b>FC&#038;P 18-1</b>, p. 43, ID=2279^<b>Topic(s):
</b>numerical classification; Tabulata, Favositida; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^Since
tabulatomorph corals have been studied for more than a hundred years,
the related scholars have laid a good foundation for their
classification. Now it is essentially clear about the classification
above the genus level, but, there are still some problems about the
classification below the genus level, especially the species. The
obvious difficulty lies in the distinction of species with too little
difference and in the large number of synonyms, which cause some
confusions in classification. For instance, two specimens might have
been identified as different species or subspecies only because of the
very little difference between their individual sizes. Thus, there
would be an overflow of species names and it would become more and more
difficult to master and apply the criterion for species
identification.^1";
s[6334] = "KAZMIERCZAK J. (1991).- Further evidence for Poriferan
Affinities of Favositids.- In: Reitner J. &#038; Keupp H. (eds): Fossil
and Recent Sponges: 212-223; Springer.- <b>FC&#038;P 20-2</b>, p. 62,
ID=2954^<b>Topic(s): </b>as Porifera; Tabulata, Favositida;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^The new findings of spicule-bearing specimens of
typical favositids confirm previous suggestions of a sponge
(sclerosponge) nature of these common Palaeozoic fossils. Similar to
the calcareous skeletons of other modem and fossil sclerosponges
(coralline sponges), favositid fossils are basally excreted hard parts
of various demosponges and, as such carry little information about the
biological organization of the organisms producing them. The kinds of
spicules occurring in favositids, though generally monaxonid in
character, indicate that the forms assigned to Paleofavosites and
Favosites, which have ophirhabds and ?heloclones, are related to
choristid and/or sublithistid demosponges, whereas those assigned to
Mesofavosites, enclosing fusiform oxeas in their calcareous skeleton,
are related to monactinellid or ceractinellid demosponges. Further
examination of favositids is needed before new taxonomy of this
enormously splintered group can be established, which will take into
account its poriferan affiliation. Nevertheless, terms such as
&#034;corallum&#034;, &#034;corallites&#034;, &#034;colony&#034;,
&#034;coenosteum&#034;, and others stemming from the long-accepted
cnidarian attribution of the favositids should be abandoned. The
poriferan affinity of favositids requires also a considerable
reevaluation of their paleoecology, particularly concerning the role
they played in ancient communities. ^1";
s[6335] = "KAZMIERCZAK J. (1993).- Sclerite-bearing alveolitid
favositids from the Devonian of central Poland.- Paläontologische
Zeitschrift 67, 1-2: 27-44.- <b>FC&#038;P 22-2</b>, p. 84,
ID=3517^<b>Topic(s): </b>sclerites; Tabulata, Favositida;
```

```
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Calcitic and pyritic pseudomorphs of originally
siliceous monaxonic sclerites (predominantly heloclone-like monocrepid
desmas) have been found entrapped within calcareous skeletons of
alveolitid favositids identified as Squameoalveolites fornicatus
(Schlueter 1889) derived from Lower and Middle Devonian (Emsian and
Eifelian) deposits of central Poland. The sclerites are arranged in a
system of subvertical tracts forming a loose palisade along the midwall
of skeletal tubes. Poorly preserved remnants of such palisades
correspond to the so-called &#034;median line&#034; or &#034;median
suture&#034; of typical favositids. The finding supports the hypothesis
of poriferan affinity of favositid Tabulates and indicates that these
common Palaeozoic fossil cannot be longer classified as Cnidaria. They
should, on the basis of the sclerites, be regarded as remnants of
monaxial and &#47; or sublithistid demosponges, which - like the
members of modern and fossil demosponges called sclerosponges or
coralline sponges - had the ability to produce a basally secreted
calcareous skeleton in addition to siliceous sclerites.^1";
s[6336] = "KAZMIERCZAK J. (1994).- Confirmation of the poriferan status
of favositid tabulates.- Acta Palaeontologica Polonica 39, 3: 233-245.-
<b>FC&#038;P 24-1</b>, p. 65, ID=4483^<b>Topic(s): </b>as Porifera,
Lithistida; Tabulata, Favositida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^Reported are
findings of calcitic pseudomorphs of monaxonic sclerites (heloclones
and ophirhabds) occuring as highly ordered vertical tracts and
subhorizontal strands in the midwall of calcareous skeletal tubes of a
common Silurian favositid species, Favosites hisingeri, from Gotland.
The discovery ends conclusively the current controversy about the
nature of favositids and related tabulomorphs in favour of the
neglected early suggestion of Kirkpatrick (1911) that these fossils can
be basal calcareous secretions of siliceous sponges similar to those in
living Merlia normani. The type of sclerites found in F. hisingeri and
other favositids indicate that favositids are closely related to fossil
and extant sponges classified within the order Lithistida (class
Demospongia) as the so-called sublithistids.^1";
s[6337] = "FLUGEL H.W. (1973).- Zur Kenntnis von Asterosalpinx Sokolov
und anderer Sternstrukturen bei Favositinae (Tabulata).-
Paläontologische Zeitschrift 47, 1-2: 54-68.- <b>FC&#038;P 3-1</b>, p.
25, ID=4880^<b>Topic(s): </b>structures; Tabulata, Favositida;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^Starlike structures situated in the corners of the
corallites of Favosites are known from the Upper Silurian to
Lower-Middle Devonian. They have been described from Europe, Asia, and
Australia, by Etheridge, Frech, Tchernychev and others. Sokolov (1948,
1962) has named these structures Asterosalpinx, Antherosalpinx, and
Actinosalpinx. He was [of] the opinion that they are tubes and
commensales (Serpulidae) of Favosites. * The study of a specimen from
the Devonian of Karaburun (Anatolia) under both light microscope and
scanning electron microscope made it clear that Asterosalpinx cannot be
a tube. It is a node-like structure with a microstructure consisting of
two layers: a dark middle zone built up of homogenous calcite, probably
diagenetic, and a peripheral zone consisting of normal fibrous calcite.
These nodes are primary trabeculare structures built in the corners of
Favosites-like Tabulate corals. It seems necessary to erect a separate
Tabulate genus for forms exhibiting this feature. Therefore, Porfireus
(1937) genus Asteriophyllum should be reinstated.^1";

Tabulata, Favositida; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>; <b>Geography: </b>^Favosites asper
d&#039;Orbigny 1850 (described by Lonsdale 1839 as a minor variety of
Favosites alveolaris Goldfuss) was assigned to the genus Paleofavosites
Twenhofel as type species. Misinterpretations and lack of knowledge
about the type specimen always led to an erroneous synonymity with
Paleofavosites alveolaris (Goldfuss 1829). The present revision is
intended as a correct typisation and a new description of the holotype
of the type species. In this connection Paleofavosites alveolaris
(Goldfuss) and the major variety named by Lonsdale and until now in
synonymity with Paleofavosites alveolaris are described, and as a
result of this revision, the latter has to be placed to Paleofavosites
rugosus Sokolov 1951. [original summary; taken from FC&P 5, 1: 34]^1";
s[6342] = "STEL J.H., OEKENTORP K. (1976).- On the solenid growth habit
of Paleofavosites.- Geologie en Mijnbouw 55, 3/4: 163-174.-
<b>FC&#038;P 6-1</b>, p. 24, ID=5472^<b>Topic(s): </b>growth habit;
Tabulata, Favositida; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>; <b>Geography: </b>^The formation of the so
called &#34;solenia&#34;, which gives the colonies- of Multisolenia
Fritz 1937 the peculiar and striking appearance, is considered to be
the same as that of normal pores in favositoid corals. The solenia
occur in species of Multisolenia and related genera as well as in
Paleofavosites Twenhofel 1914, observed for example in the type
specimen of type species P. asper, e.g. in paleofavositoid forms with
corallites possessing only small diameters (less than 1mm). These small
measurements cause an adjoining of four corallites - instead of
normally three, where the diameters reach more than 1mm - and, based on
that arrangement, a crosswise, dumbbell-like connection of neighbouring
individuals by pores situated in the corallite corners. Therefore the
authors are of the opinion that Multisolenia and the related genera are
junior synonyms of Paleofavosites. [taken from FC&P 5, 1: 34]^1";
s[6343] = "OEKENTORP K. (1977).- Palaeofavosites Twenhofel in place of
Calamopora Goldfuss and the spelling of Palaeofavosites.- FC&P 6, 1:
13-14.- <b>FC&#038;P 6-1</b>, p. 13, ID=5489^<b>Topic(s):
</b>nomenclature; Tabulata, Favositida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^The decision to the
proposal forwarded by Oekentorp (1971, 1974) on &#34;Palaeofavosites
Twenhofel 1914 (Anthozoa, Tabulata): proposed validation under the
Plenary Powers&#34; has, in the meantime, been published by the
International Commission on Zoological Nomenclature in Opinion 1059.
According to this, the generic name Calamopora Goldfuss 1829, has been
```

```
abandoned in favour of Palaeofavosites Twenhofel 1914, and listed on
the Official Index of Rejected and Invalid Generic Names in Zoology
(under No. 2073). Palaeofavosites was included in the Official List of
Generic Names in Zoology (under No. 2028) as well as relating names of
species asper and alveolaris (No. 2576 and 2577 respectively). * Though
in this approval, the generic name Palaeofavosites was used in the
latinized writing and not in the original writing as given by Twenhofel
as Paleofavosites (see Caramanica 1975). The original citation in
question could not be traced at the time of publication. The writing
introduced by me in this approval was furthermore based on the -
correct - latinized form generally common in literature as e.g. Lang,
Smith &#038; Thomas (1940), Sokolov (1955), Hill &#038; Stumm (1956)
and Sokolov (1962) or Flügel (1970). According to the IRZN, however,
this was an unjustified emendation (article 33, see also article 32 a
(ii)). In accordance to this the correct mode of writing Paleofavosites
was to be continued (see Oekentorp 1976). But according to Opinion
1059, Palaeofavosites is firmly established again - based on sequently
unfortunate errors. Therefore, and to avoid any further confusion and
also considering the correctly latinized form of writing, it is
recommended that this writing should remain as Palaeofavosites. [full
text of a nomenclatorial note; originally accompanied by a list of
references]^1";

Favositidae.- Lethaia 9: 405-419.- <b>FC&#038;P 6-1</b>, p. 22,
ID=5492^<b>Topic(s): </b>; Tabulata, Favositida; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^The
opinion that the Favositidae are a group of the Madreporaria is based
on a paper by Edwards &#038; Haime 1849. These authors mentioned no
reason for their assumption. A critical review of the skeletal
material, microstructure and morphology shows that it is difficult to
compare this group with the true Madreporaria. On the other hand, the
discovery of the Sclerospongiae has shown that they are recent
organisms which are similar in their material and morphology to the
Favositidae. The only difference is the occurrence of wall pores in the
Favositidae and of astrorhizae in the Sclerospongiae. Like the primary
wall grooves of the upper edge of the walls of the Favositidae, which
are the primary stadium of the pores, the astrorhizae are initial
grooves on the surface of the Sclerospongiae. Therefore the formation
of the pores and of the astrorhizae is similar. If the Favositidae are
interpreted as Porifera, the wall grooves would analogically be the
impression of excurrent canals of the soft part on the surface of the
skeleton. The main difficulty in an interpretation of the Favositidae
as a new subphylum of the Porifera is that we are not yet informed
about the formation of the basal skeleton of the Sclerospongiae.

Stel (1985) drew attention to Copper&#39;s (1985) important paper on
&#34;fossilized polyps&#34;. In my opinion, they correctly emphasized
the importance of Copper&#039;s work while expressing some reluctance
to accept Copper&#039;s conclusions without further analysis. I would
disagree, however, with the Oekentorp and Stel assumption that prior to
Copper&#039;s work most Paleozoic coral workers had adopted the sponge
model of favositid relationships. I think instead that, with the
stimulus of the rediscovery of living sclerosponges, many students of
corals have had to reconsider some fundamental questions; and, in the
excitement of the moment, there have been more papers analyzing
possible sponge relationships than renewing arguments for coral or
cnidarian affinities. This is appropriate to the time and indicates the
fundamental importance of the question, but it does not suggest that a
new consensus had been achieved. [introductory remarks]^1";

<b>Geography: </b>^The next three papers concern palaeobiogeographical
aspects of the Devonian in Sibiria and arE especially based on Tabulate
corals - but also on Rugose corals - listed in a tabular form and on
additional maps.The following results can be given:Distribution of the
Devonian corals in the Sibirian seas and contiguous realms was
conditioned by palaeogeographic environ-ments. During the early
Devonian there were large geographical barriers between the seas of the
Altai-Sayan, Indigiro-Kolymian, and Mongolo-Okhotsk provinces that made
an exchange of coral species of adjacent seas difficult. These
conditioned sharp geographical differentiation of the faunas. In the
Indigiro-Kolymian province the Tabulate fauna was rather uniform.
Favositids predominated, e.g above all, the Fayosites soeialis group.
Alveolitids, and later on Striatopora, Gracilopora, etc. were abundant
as well as Sguameofayosites etc. On the other hand, Pleurodictyum is
the characteristic genus in the Mongolo-okhotian proyince but also
species of Fayosites different from those of the former proyince. Same
facts are noted for the Rugose corals: Taimyrophyllum characterizes the
Indigiro-Kolymian province, whereas Lindstroemia is a representa-£ive
of the Mongolo -Okhotian area.In the Middle Devonian, boundaries of the
proyinces became ob-literate. It resulted in the fact that the constant
content of fauna in different basins was more uniform. Faunal
integration continued up to the end of the Frasnian.^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>;
<b>Geography: </b>^[&#8230;] the structures discussed by Kazmierczak
represent extensive post-mortem infestation by endolithic organisms,
and the finding of these structures within specimens of the associated
fauna of brachiopods and trilobites from Baffin Island would provide
definitive proof. We welcome Kazmierczak&#039;s comments on the
intriguing problem of the convergent formation of calcareous skeletons
in sponges, and are equally eager to increase our understanding of
reef-building forms. However, we feel that the inclusion of favositid
and halysitid tabulates within the ranks of Porifera is unfounded on
the evidence available. [final conclusions of the note]^1";
s[6353] = "LEE D.-J., NOBLE J.P.A. (1990).- Colony development and
formation in halysitid corals.- Lethaia 23: 179-193.- <b>FC&#038;P
20-1.1</b>, p. 60, ID=2794^<b>Topic(s): </b>colony growth; Tabulata,
Halysitida; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>; <b>Geography: </b>^Modes of colony formation and their
relationship with colony morphology, size and substrate characteristics
in species of halysitid corals have been studied. Two distinctive modes
of colony formation in halysitids are proposed. In the monoplanulate
mode, represented by Catenipora simplex, the colony is developed from a
single protocorallite and colony formation is achieved by a combination
of asexual increase and intracolony fusions. In contrast, the
polyplanulate mode is demonstrated by C. escharoides, in which the
early colony formation is achieved primarily by fusions of many
&#34;incipient colonies&#34; of more than a single planulate origin and
of different generations. The latter mode has not previously been
described in tabulates and has significant implications for
coloniality, reproductive and life history characteristics,
histo-compatibility and adaptative ecology. The colony size and
morphology, and the distribution of halysitid species were primarily
determined by the modes of colony formation and the substrate
characteristics. Colonies of the monoplanulate mode, when developed on
soft substrates, exhibit a small and spherical morphology with isolated
distribution patterns, while those developed on hard substrates are
```

```
tabular and variable in size, depending on the availability of substrate. In colonies of the polyplanulate mode, on the other hand, the size of the colony is largely dependent on the frequency and timing of allograft fusion. They are characteristically found on soft substrates, often as dense monospecific thickets. The mode of colony formation in halysitids is probably species-specific and results in the adaption to substrates.^1";

First of all, hundreds of retrieval tables of the fossil-identification features of each taxonomic unit from the genus above are created, on the basis of the currently published 3 superorders, 10 orders, 15 suborders, 85 families, 15 subfamilies, and 476 genera of the subclass Tabulatomorpha in the world and 2 225 species found in China. Secondly, after the coding of the identification features, these tables are stored under a tree structure database system by applying dBASE-II, with each table corresponding to a database. Finally, according to the systematic taxonomy of tabulatomorphic corals, the automatic identification of an unknown specimen is progressively proceeded from a higher taxonomic unit to a lower unit until species. If the unit is from the genus above, the degree of membership is determined after the weighing of the features, with the highest degree indicating the belongingness of the unknown specimen to a specific unit. On the other hand, in case the unit is the species, a similarity coefficient is used to measure the similarity of an unknown specimen to each species of a specific genus based on the numerical taxonomy of the already known specimens of the genus, which redefines the species of the genus through scaling the features, weighing the features, determining the similarity coefficient between every two of the known specimens, and cluster analysis of all the known specimens. The best coefficicient shows the species decision of the unknown specimen. An identification example is given in this paper, with very satisfying result.^1";
s[6370] = "LIN BAOYU, LI YAOXI, DENG ZHANQIU, LI ZHIMING, XU SHOUYONG, TCHI YONGYI, JIN CHUNTAI, (1996).- Ultra-microskeletal Structures,

Classification, Evolution and its Use in Taxonomy of Tabulatomorph
Corals.- Geological Publishing House, Beijing: 125 pp., 56 pls, 34
textfigs.- <b>FC&#038;P 25-2</b>, p. 27, ID=3078^<b>Topic(s): </b>SEM
microstructures; tabulatomorpha; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>; <b>Geography: </b>^The present
monograph is based on the examination of 101 genera of tabulatomorph
corals (79 genera of Tabulata, 15 genera of Heliolitoidea and 7 genera
of Chaetetoidea). Data on skeletal microstructure were obtained from
thin sections and SEM observation. SEM photographs were all made from
lightly acetic acid-etched surfaces. Microskeletal structures of
Tabulatomorph corals, investigated by SEM, revealed three fundamental
kinds: 1, the crystal granules, with calcite granules; 2, the crystal
flakes, with calcite flakes and slabs and 3, the crystal fibrous, with
brachycolumns and needles. The three kinds of fundamental units
combined with each other in various ways to form seventeen types (or
patterns) of micro structure such as: I, the granular type; 2, the
double-comb type; 3, the com type; 4, the hemi-pinnate type; 5, the
pinnate type; 6, the fan-like type; 7, the fibro-lamellar type; 8, the
paratrabecular type; 9, the trabecular type; 10, the rhabdotrabecular
type; n, the eotrabecular type; 12, the parallelar lamellar type; 13,
the plicated lamellar type; 14, the V-shaped type; 15, the
&#034;A&#034;-shaped type; 16, the &#034;Y&#039;-shaped type and 17,
the zigzag type. The first type belongs to the crystal granular kind;
the second to the 12th ones belong to the fibrous kind and the 13th to
the 17th ones belong to the crystal flake kind. The crystal granular
kind of fundamental units of microstructure is the oldest one in the
three fundamental ones. It developed in the oldest tabulatomorph corals
such as in Lichenariida, Tetradiida and some Cambrian Auloporida. The
crystal flake and the crystal fibrous kinds are the younger ones. It
were very common in Upper Ordovician to Mesozoic tabulatomorph corals.
The use of microstructure in taxonomic studies of tabulatomorph corals
are very important. The different fundamental kinds are as the specific
character of Superorders, Orders, and the different microstructural
types (or patterns) to characterize families, genera have been quite
successful. This book is intended for palaeontologists, Geologists and
stratigraphers.^1";

```

```
corals is the degree of colony unity with respect to behavior,
physiology, and development of individual organs or organ complexes
within colonies. These are difficult to assess in fossils, but the
level of colony integration can be tested by analyzing ontogenies and
astogenies of two common Paleozoic tabulate coral groups, favositids
and heliolitids. Favositids have been previously interpreted as highly
integrated colonies, but results of the present examination suggest
that the level of colony integration in favositids was rather lower
than hitherto assumed. The ontogenies and astogenies in favositid
colonies are not correlatable; thus, the significance of ontogenetic
and astogenetic variations for systematic and phylogenetic resolution
in favositids is difficult to assess at present. In contrast,
astogenetic developmental sequences are recognized in heliolitids.
Ontogenies in heliolitids were subordinated to the astogeny of the
colony. This is closely related to the high degree of colony
integration with respect to behavior and physiology of individual
organs or organ complexes within colonies. Individual corallites were
well linked and coordinated so that the whole colony could have
functioned as a single individual. As a result, evolution in
heliolitids operated at the colony level and by heterochronic (and
other) modifications of astogenies rather than of ontogenies.^1";

</b>biometry, variability; Tabulata, Favositida, Heliolitida;
<b>Systematics: </b>Cnidaria; Tabulata Heliolitida; <b>Stratigraphy:
</b>; <b>Geography: </b>^Measurements of corallite size and spacing are
useful as species discriminators and as indicators of variability in
tabulate corals, but it must be recognized that these characters are
affected by corallite packing in massive colonies. A new, practical
method for corallite size measurement in favositids is based on an
aspect of their packing: polygonality. Corallites with six and more
sides are considered to be adults. They have virtually normal
size-frequency distributions on both dimetric and non-dimetric
transverse sections, making possible the use of basic statistics. The
method has been found to work consistently for many species, regardless
of corallite size or colony form. Comparisons between favositids and
heliolitids indicate that corallite size distribution is related to
packing and rates of offsetting. Differences in size distribution
between favositids and most heliolitids are due to colony design; rates
of corallite and tabularium expansion were constrained by physical
packing. The heliolitid coenenchyme permitted a greater flexibility of
growth strategy than the contiguous corallites of favositids.^1";

Tabellaephyllum, Michelinia et la distinction Tabulata-Rugosa.- Annales
de Paléontologie (Vert.-Invert.) 76, 1: 13-39.- <b>FC&#038;P
20-1.1</b>, p. 59, ID=2803^<b>Topic(s): </b>microstructures; Tabulata,
Rugosa; <b>Systematics: </b>Cnidaria; Tabulata Rugosa; <b>Stratigraphy:
</b>; <b>Geography: </b>^The genera Utaratuia (Rugosa), Tabellaephyllum
(Rugosa or Tabulata ?) and Michelinia pro parte (Tabulata) form a set
linked by synonymy. * Revision of the holotype of Utaratuia laevigata
Crickmay 1960 from the Hume Formation, early Givetian, Northwest
Territories, Canada, allows to establish the microlamellar constitution
of the wall, to confirm the fibrous constitution of the septal ridges
and their non trabecular structure. * The holotype of Tabellaephyllum
peculiaris Stumm 1948, possibly from the Escabrosa Limestone, Lower
Mississipian of SE Arizona, is a completely silicified specimen and its
microstructure remains unknown; mural pores on the centers of the faces
and at the angle between faces are described. * A comparative and
preliminary study of Michelinia expansa White 1883 from the type area
(Chouteau limestone, Sedalia, Missouri, Lower Mississippian) and from
the Western Interior Province (Redwall Limestone, Arizona Lower
Mississippian) shows that they seem to belong to two different species.
* The specimens from Missouri are completely silicified and their
precise generic attribution is impossible. Those of the WIP are
sometimes well preserved, the rnicrostructure of the wall is
microlamellar and they are to be assigned to Tumacipora Lafuste &#038;
Plusquellec 1985. A comparison of the different features of the
Tabulata and Rugosa shows that a lot of features are common and that
only the true mural pores do not exist in the Rugosa. The following
systematic attributions are proposed: Utaratuia is a Rugosa for the
same reason as pointed out by Jell and Hill, Tabellaephyllum peculiaris
is a michelinimorph Tabulata probably to be assigned to the genus
Tumacipora but to the species expansa.^1";
s[6378] = "OLIVER W.A.jr (1996).- Origins and relationships of
Paleozoic coral groups and the origin of the Scleractinia.-
Paleontological Society Papers 1 [Stanley G. D. jr (ed.): Paleobiology
and Biology of Corals]: 107-134.- <b>FC&#038;P 25-2</b>, p. 41,
ID=3125^<b>Topic(s): </b>phylogeny; Tabulata, Rugosa, Scleractinia;
<b>Systematics: </b>Cnidaria; Tabulata Rugosa Scleractinia;
<b>Stratigraphy: </b>; <b>Geography: </b>^Two major groups of corals
have essentially continuous records from the Early Ordovician
(Tabulata) and Middle Ordovician (Rugosa) to the end of the Permian. A
third major group, the living Scleractinia, range from Middle Triassic
to Holocene. Additional groups have shorter ranges within the
Paleozoic. The origins and relationships of these groups have been
discussed for over 100 years. Relations between the Rugosa and
Scleractinia have attracted the greatest interest because of their
morphologic similarities and the time sequence. Arguments involve the
significance of serial versus cyclic septal insertion, calcitic versus
aragonitic skeletal mineralogy, and the time gap between the last
rugosans and first scleractinians (there are no known Lower Triassic
corals). Discussions of relationships among the various Paleozoic
groups are commonly based on detailed morphological comparisons because
of their overlapping stratigraphic ranges. Recent work on the living
corals and anemones supports a closer relationship between groups than
is suggested by placing them in different orders or suborders. The
paleontological record of &#034;anemones&#034; is slight, but it is
reasonable to assume that one or more groups of skeletonless
zoantharians persisted through long parts of the Phanerozoic. It is
suggested that the major groups of zoantharian corals originated
through the development of skeletons in various anemone groups at
```

several different times.^1";
s[6379] = "SORAUF J.E. (1993).- The coral skeleton: analogy and
comparisons, Scleractinia, Rugosa and Tabulata.- Courier
Forschungsinstitut Senckenberg 164: 063-070. [P. Oekentorp-Kuster (ed.)
Proceedings of the VI. International Symposium on Fossil Cnidaria and
Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 11, ID=3438^<b>Topic(s):
</b>skeletal analogies; Tabulata, Rugosa, Scleractinia; <b>Systematics:
</b>Cnidaria; Tabulata Rugosa Scleractinia; <b>Stratigraphy: </b>;
<b>Geography: </b>^The analogy between modern scleractinian corals and
Paleozoic rugose and tabulate corals can add to understanding of their
skeletal structures and method of formation. It is based on
similarities in overall morphology of corallites, polyps, and in the
supposed formation of exoskeleton by polypal ectoderm utilizing organic
matric in all three groups. Skeletal structures in Paleozoic corals and
scleractinians suggest that a similar model for biocrystallization is
applicable for major portions of both groups. The scleractinian coral
skeleton is characterized by combinations of trabecular and fibrous
structures only. As there is no major variation in these two basic
skeletal structures in the Order Scleractinia, such variation is not
expected at the genus or species level in Paleozoic corals. A general
model for biocrystallization in most Rugosa and Tabulata can resemble
that for the scleractinians in all essential ways except mineralogy.
The origin of lamellar skeletal structures remains an enigma, as it is
not explained by this model for skeletogenesis. Mineralogy of Paleozoic
corals was calcitic, with a postulated MgCO3 content of 5 to 8 mol
percent.^1";

The reasoning about evolutionary transformations is based on engineering morphology, and includes the results of comparative anatomy and of molecular research. According to their evolutionary model, the specific metazoan multicellularity, which is different of that of fungi and plants, evolved in multinucleate heterotroph unicellular organisms by the deposit of gelatinous &#47; fibrous substance into the endoplasmatic reticulum. The multitude of cells, the syncytia, and the extracellular matrix with gelatinous properties and containing collagenous fibers, developed dependent of each other and simultaneously. The resulting ancestral metazoan, the ur-metazoan, was named &#039;gallertoid&#039; (German: Gallerte = gelatine) for the main feature of its body support, viz. the gelatinous &#47; fibrous material. By further internal differentiation of gallertoids several evolutionary lineages developed independently: Trichoplax, the Ctenophora, the Porifera, the Coelenterata, and the Bilateralia (= Coelomata), which soon split into two lines, the Notoneuralia and the Gastroneuralia. </b>phylogeny; Coelenterata polyps; <b>Systematics: </b>Cnidaria;
<b>Stratigraphy: </b>; <b>Geography: </b>^All anthozoan types apart of
the octocorallia are basically solitary polyps, some secondarily
developing polyp colonies; in all the inner gelatinous-fibrous mass is
largely reduced, forming a thin layer; the body motility is high, and
no internal skeletons are formed; rigid skeletons are external
productions (or, in Zoantharia, secondarily incorporated particles).
For engineering reasons, the body shape of solitary polyps without
(external) skeleton and of polyps with skeleton but single mesenteries
is restricted to a cylindrical form; only polyps with paired
mesenteries and skeleton, viz, scleractinia, are able to expand
laterally during growth. Apart of the Anthozoa, the evolutionary
lineage to the Tetrazoa, (the Scyphozoa, Hydrozoa, and Cubozoa),
characterized by alternating polyp/medusae generations, can be
explained as an offshoot of the ancestral gelatinoid coral. [excerpt

</b>experimental biology; Cnidaria; <b>Systematics: </b>Cnidaria;
<b>Stratigraphy: </b>; <b>Geography: </b>^This book is stated to be
&#34;the product of a summer course in which students were trained to
investigate the biology of coelenterates by using a variety of
experimental procedures&#34;. Neither this statement nor the title is
likely to attract the attention of paleontologists and even many
neontologists may &#34;put it off&#34;. This would be unfortunate,
because there is something of interest in this book for a variety of
specialists. The book consists of 25 papers in four sections - growth
```

```
and development, feeding and metabolism, endosymbiosis with algae, and
calcification. Hydroids were the most common subject of observation and
experimentation but scleractinian corals are the immediate subject of 7
papers, and 4 more papers report broad surveys that included corals.
The section on calcification begins with a general review paper and
proceeds to papers on sources of carbon, temperature effect on rate of
calcium-45 uptake, and organic matrices. These and a report on raising
planulae and newly settled polyps, will be the most useful for those
primarily interested in coral morphology and growth. Other papers
include many observations on behavior and natural history that will
inevitably make corals more understandable to those who are not
actively working with the living animals. [abstract by William A.

</b>Cnidaria; <b>Stratigraphy: </b>; <b>Geography: </b>^The
evolutionary history of cnidarian life cycles has been debated since
the 1880s, with different hypothesis favored even by current textbooks.
Contributing to the disagreement is the fact that the systematic
relationships of the four cnidarian classes have received relatively
little examination using modern systematic methods. Here we present
analyses of class-level relationships based on 18S ribosomal DNA (rDNA)
sequence, mitochondrial 16S rDNA sequence, mitochondrial genome
structure, and morphological characters. DNA sequences were aligned
using a repeatable parsimony-based approach incorporating a range of
alignment parameters. Analyses of individual data sets and of all data
combined are unanimous in grouping the classes possessing a medusa
stage, leaving the holobenthic Anthozoa basal within the phylum.

An extensive historical review of opinions about the affinities of these four groups is presented. The viewpoint that the solid skeletons are a convergent feature of diverse sponge lineages and hence express a stage of evolution rather than characterizing a monophyletic taxon is endorsed. Sponge faunas of the upper Paleozoic are claimed to fill the gap between mid-Paleozoic and Mesozoic stromatoporoids. Many features of corals and sponges are convergent and should not be the basis of definitions of taxonomic groups. Only spicules are reliable for determinations of affinitiy and phylogeny of sponges.^1";

Proceedings of an International Symposium, University of Camerino. Cambridge University Press: 113-124.- <b>FC&#038;P 20-2</b>, p. 75, ID=2804^<b>Topic(s): </b>reef builders?; sponges; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>; <b>Geography: </b>^Spicules reveal a polyphyletic origin for stromatoporoids, chaetetids, and sphinctozoans within the Demospongiae and Calcarea. Calcareous skeletons have been independently acquired and are easy to secrete through a limited number of biomineralization mechanisms. The calcareous skeletons are of little value in assessing evolutionary ancestry. These groups are regarded as grades, not reflecting systematic position but determined ecologically. Archaeocyaths inhabited soft substrates in unstable conditions and were unable to construct a reef framework. They gave rise to some sphinctozoan- and stromatoporoid-grade forms. Stromatoporoids and chaetetids are modular organisms with great plasticity of growth morphology. Their encrusting growth allowed them to build mid-Paleozoic reefs. Sphinctozoans are solitary or pseudomodular, small and fragile; they were dwellers and bafflers. Corals became dominant reef-builders of the Mesozoic and Tertiary presumably due to the acquisition of more porous skeletons and their faster calcification rates aided by zooxanthellae. Modular grades of sponges may be derived from solitary ones by paedomorphosis.^1";
s[6415] = "ZHURAVLEV A.Yu., DEBRENNE F., WOOD R.A. Porifera, flagellar vanes; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>; <b>Geography: </b>^Wing-shaped projections
(vanes) of the flagella of choanomeres are documented from the
hexactinellid sponge Aphrocallistes vastus. This observation completes
the report of such flagellar structures from the major taxa of the
Porifera: Demospongiae, Calcarea and Hexactinellida. It thus allows us
to assume flagellar vanes being an autapomorphy of the monophylum
Porifera. The wing-shaped flagellar vanes of sponge choanomeres often
have been compared with appendages of choanoflagellates, e.g. Codosiga,
but fundamental differences seem not to allow any homologization of
these structures. Only extensive comparative TEM studies on
well-fixated tissues, e.g. from fresh water sponges such as Ephydatia,
will settle this question.^1";

Porifera classification; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>; <b>Geography: </b>^The application of &#034;IdentifyIt&#034; from
Linnaeus II to create a visual sponge identification guide is explored.
A model for a field key using morphological characters with its various
states represented graphically is developed. Taxonomic characters that
can be easily and accurately represented and interpreted by an
inexperienced user are chosen. These characters include shape, surface,
oscule morphology and arrangement with a range of 3-15 character states
each. A graphic representation of the skeletal characteristics and/or
whole animal pictures, stored in the &#034;Species card&#034; mode of
Linnaeus II, will allow further corroboration of the identification
produced by the search from the &#034;IdentifyIt&#034; key. The graphic
capabilities and limitations of the current Linnaeus II software to
create and use a visual identification system are discussed. [original

</b>^When identifying a specimen, experts in systematics are able to
draw sound conclusions even in the presence of uncertain and incomplete
data. The purpose of this paper is to report on how expert system
technologies enable us to model taxonomic expertise and simulate some
of the experts&#039; reasoning skills. We emphasise the reasoning
strategies of SPONGIA, an expert system to help in the identification
of marine sponges. It has been implemented using the MILORD II language
for the construction of expert systems. We illustrate how the richness
of taxonomic knowledge has been represented by means on rules and
meta-rules. In addition, we show how the uncertainty handling and
deduction mechanisms make it possible to emulate complex identification
strategies such as those exhibited by experts in systematics. [original

inventory and documentation]: 81-88.- <b>FC&#038;P 25-2</b>, p. 29,
ID=3097^<b>Topic(s): </b>cladistics; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>; <b>Geography: </b>^A protocol is
proposed by which certain classes of characters may be selected for use
in phylogenetic reconstruction due to their overall better consistency
in phylogenies. Alternatively, they could receive additional weight as
opposed to classes that show an overall poor consistency and should be
down weighted. We recognized 16 classes of characters within previously
published data matrices of 17 poriferan phylogenies involving 221 OTUs
(Operational Taxonomic Units, = terminal taxa). Only five classes occur
in samples of large enough size that can allow discussion of observed
trends. The high consistency observed in choanosomal architecture
characters is possibly an artefact. Megascleres and microscleres show
opposing results and these are discussed with reference to function and
adaptation. In general, results are deemed preliminary because sample
sizes are too small for the majority of recognized classes of
characters, and different classes of characters may perform differently
in different taxa, a suspicion which calls for an even larger sample
base. [original abstract]^1";

56, ID=3733^<b>Topic(s): </b>phylogeny, molecular evidence; Porifera
phylogeny; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>;
<b>Geography: </b>^We sequenced 18S rRNA genes of a calcareous sponge,
Clathrina cerebrum, a demosponge, Axinella polypoides, and a zoanthid
cnidarian, Parazoanthus arinellae. Our phylogenetic analysis supports
the monophyly of kingdom Animalia and confirms that choanoflagellate
protozoans are their closest relatives. Sponges as a whole are
monophyletic, but possibly paraphyletic; demosponges and hexactinellids
form a monophyletic group of siliceous sponges. Our phylogenetic trees
support a monophyletic origin of the nervous systems in the immediate
common ancestor of Cnidaria and Ctenophora. They weakly suggest that
animals with a nervous system may be more closely related to clacareous
sponges than to siliceous sponges; the nervous system might have
originated in an early calcareous sponge. Our trees confirm that
Myxozoa and Placozoa are animals that arose by secondary loss of the
nervous system, but suggest that Myxozoa may be sisters of, rather than
derived from, Bilateria. Kingom Animalia is divided into four
subkingdoms: Radiata (Porifera, Cnidaria, Placozoa, Ctenophora),
Myxozoa, Mesozoa, and Bilateria. The 18S rRNA evolution in early
Bilateria followed by normal low rates for about 500 million years.^1";

theory to sponge functional morphology.- Indiana University,
Bloomington; unpublished M.Sc. thesis; 79 pp.- <b>FC&#038;P 27-1</b>,
p. 112, ID=3871^<b>Topic(s): </b>fluid transport theory; Porifera,
fluid transport theory; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>; <b>Geography: </b>^Certain extant sponges exhibit canal
architecture consistent with engineering fluid transport design theory
and this has been used to interpret functional morphology of putative
fossil sponges (stromatoporoids). Canal systems of two species of
modern sponges were impregnated with colored resins and canal diameters
were measured. Three functional models were tested: diffusion-based
transport; non-optimal bulk-flow transport; and optimal bulk-flow
(Murray&#039;s Law) transport. Optimal bulk-flow transport minimizes
the metabolic costs of moving fluid through the system and the
metabolic costs of maintaining the system. A diffusion-based transport
system, regulated by Pick&#039;s first law, would exhibit uniform
cross-sectional areas within the aquiferous modules. In this type of
system the sum of all canal diameters squared should therefore remain
constant. In non-optimally designed bulk-flow systems, governed by
Poiseuille&#039;s Law, flow is proportional to the fourth power of the
radius, and the diameters to the fourth power would sum to a constant.
Systems obeying Murray&#039;s Law would exhibit a cubic relationship
and the diameters to the third power would sum to a constant. For the
modern sponges statistical tests show that the diffusion-based
hypothesis can be rejected while both non-optimal and optimal bulk-flow
hypotheses are accepted. Murray&#039;s Law assumes an optimal design,
and morphology does not have to optimize a function to have adaptive
significance. If a putative fossil sponge conforms to Murray&#039;s
Law, then a sponge affinity is logical. However, if the architecture is
inconsistent with Murray&#039;s Law, a sponge affinity cannot be
rejected. [abstract condensed by C.W. Stearn]^1";

```

```
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>; <b>Geography: </b>^The two common calcium carbonate polymorphs, calcite and aragonite, have been alternatively predominant in both sediments (Sandberg 1983) and in skeletal carbonates (Wilkinson 1979), in partcular in those secreted by sponges (Cuif and Gautret 1991a). Changes in water chemistry and variations in temperature are often used to explain these oscillating global trends (Railsback and Anderson 1987). However, these parameters are not adequate to justify why, under the same diagenetic conditions, the skeletons of sponges and corals do not undergo the same mineralogical transformations, especially in Upper Triassic deposits. To interpret this anomaly it is necessary to take into account the peculiar feature of biogenic carbonates produced by the two taxa, the presence of an organic matrix closely linked to the mineral phase. This matrix, secreted during skeletogenesis, has two presumed functions: binding of calcium ions and orientation of crystal growth. Even after death and burial of the organisms, strong molecular interactions between the organic - mainly proteinaceous - and the inorganic phases will be maintained. The divergent diagenetic trends observed in sponge and coral skeletons could be partially induced by the biochemical differences in the organic matrix. [part of extensive summary]^1";

[short note] - <b>FC&#038;P 18-2</b>, p. 26, ID=6781^<b>Topic(s): </b>spicules; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>; <b>Geography: </b>^In some hexasterophoran taxa (the dictyonal Hexactinosa and Lychniscosa, and partly the lyssakine Euplectelliidae) the main parenchymalian spicules are fused into a siliceous basal skeleton. The resulting rigid skeletons are likely to be preserved as fossils, and thus the hexasterophoran hexactinellids are well-documented in the fossil record (e.g. in the Upper Jurassic of Swabia and in the Upper Cretaceous of Northern Germany). * In contrast no recent Amphidiscophora possess fused spicules, and so far we have no evidence of any fossil amphidiscophoran hexactinellids with rigid skeletons. For this reason, the fossil record of amphidiscophoran hexactinellids is extremely poor and mainly consists of isolated amphidiscs. [fragments of a short note]^1";

alkaloids and pyrroloquinoline alkaloids have been reported from 
sponges assigned to the genus Batzella. These sponges have been 
assigned to this genus because of their possession of a simple 
```

```
complement of thin strongyles in irregular plumoreticulate arrangement.
Cyclic guanidine alkaloids were first reported from an alleged
axinellid species from the Caribbean, Ptilocaulis aff. P. spiculifer,
and subsequently from a second Carribean specimen identified as
Ptilocaulis spiculifer and at the same time from a Red Sea
poecilosclerid, Hemimycale sp. Closely related compounds were described
from a Caribbean specimen identified as Batzella sp. and also from the
poecilosclerids Crambe crambe (Mediterranean) and Monanchora arbuscula
(Brazil). Isobatzellins (pyrroloquinoline alkaloids) were reported from
a black deep-water species from the Bahamas identified as Batzella sp.

follow the evolutionary pattern of level-bottom communities.- Geology
13: 46-49.- <b>FC&#038;P 15-1.2</b>, p. 43, ID=0774^<b>Topic(s):
</b>geohistory; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^There is a pervasive attitude that reefs were
isolated from the mainstream of evolution and that their history had
quite a different pattern from the level-bottom marine biota. However,
three striking similarities exist between the evolution of reefs and
other marine communities. (1) Reef composition and ecologic structure
were governed by the composition of the three Phanerozoic evolutionary
faunas. (2) Reefs were decimated by the major extinction events of the
geologic record. (3) Reefs conform to the pattern of level-bottom
community evolution. Intervals when reefs were absent were due either
to the absence of appropriate frame-building organisms in the biota
(for example in the Middle and Late Cambrian) or to the absence of
reefs following extinction events before frame-building organisms
re-evolved a reef-building mode of life.^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^PaleoTax is a Windows-based
```

```
relational database program to record, analyse, and output
palaeontological data. The program is taxon-based and handles
taxonomic, stratigraphic, and geographic data. Its structure is
relational and subdivided into literature, stratigraphy, geography,
sample material, taxonomy, and literature citations. It encompasses 39
tables and 254 data fields. Additional tables and fields can be added,
depending on the user&#039;s needs. The edit forms, which can also be
modified, are not part of the program. The main purposes of PaleoTax
are to record data obtained from the literature and to serve as an
information system. Once they have been recorded, data can be sorted
and searched for under various aspects. PaleoTax generates reports in
ASCII, RTF, and HTML for the most important tables, such as species,
genera, and localities, and can export the whole database as a large
catalogue in the form of the classic Fossilium Catalogus or as an
Internet application. Data analysis is an important part of PaleoTax: a
program interpreter provided with PaleoTax makes it easy for the user
to analyse the data and to display the results as graphs. The
analytical results can also be exported as ASCII files. [original

Discussion on Definition Method of Microstructural Units of
Invertebrate Skeletons.- Acta Palaeontologica Sinica 26, 1: 49-54.-
<b>FC&#038;P 17-2</b>, p. 26, ID=2177^<b>Topic(s): </b>skeletal
microstructures; invertebrates; <b>Systematics: </b>; <b>Stratigraphy:
</b>; <b>Geography: </b>^The use of microstructural characteristics of
calcareous skeletons is rapidly growing in invertebrate palaeontology
(Chen 1985). In the 19th century, the method was applied to some
zoological groups (i.e. Madreporaria), but it was only after the great
improvements given by Boggild and others that it has been generally
accepted. These works are founded on the definition of different basic
microstructural components, the arrangement of which provides various
kinds of skeletal tissues. This paper makes an attempt to show that a
relevant definition of these fundamental units requires progress in two
directions of observation. Firstly, it is now obvious that the basic
microstructural components (i.e. prisms, lamellae, etc.) may have
greatly different internal organizations related to the diverse taxa in
which they were observed. For instance, it is shown here that the so
called simple prisms of two lamellibranch genera (Pinna and Trigonia)
have very distinct structural features, which appear only in samples
treated with adequate preparative methods (enzymatic proteolysis, or
decalcification with fixative mixtures). Secondly, it also seems
necessary to bear in mind the general organization of the secretory
layer of the pallial edge, and its relations with the orientation of
the microstructural components. Some evidences are given in this way by
comparing the typical crossed-lamellar tissue of Acrosterigma and
Vepricardium, with the external layer of the Dosinia, which has long
been considered as some kind of prismatic composite.^1";

development of carbonate sediments and rocks.- Facies 18: 181-204.-
<b>FC&#038;P 17-2</b>, p. 38, ID=2201^<b>Topic(s): </b>carbonates;
carbonates; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Diagenetic sequences of many stages are known from various
carbonate rocks but the diagenetic spatial variations within a given
facies, outcrop, hand specimen or thin section are only gradually
rediscovered and taken into account in porosity studies. The variations
occur in various carbonate facies such as reefs, beachrocks,
shallow-water deposits, hardgrounds and concretions. Multiple parallel
diagenetic pathways branching in time are recognized in such cases. [
&#8230; ] Realization of spatial variations in porosity development
spoils fast and simple correlations, assessments, or predictions. The
synthesis of the detailed analytical information, however, provides a
route toward application of diagenetic complexities. [abridged

depositional events.- Earth-Science Reviews 86, 1-4: 106-144.-
<b>FC&#038;P 35</b>, p. 111, ID=2446^<b>Topic(s): </b>bioerosion;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^The development of coral reef framework and the preservational
character of both in-situ and rubble coral is strongly influenced by a
range of physical, chemical and biologically-mediated taphonomic
processes. These operate at, or just below, the reef framework-water
interface and can be defined as having either a constructive or
destructive effect upon primary reef framework (i.e., coral)
constituents. Constructional activities add additional calcium
carbonate to the primary framework structure via secondary framework
growth and early cementation. Destructive processes, which remove or
degrade primary (and secondary) framework carbonate, are associated
with the effects of either physical (mainly storm) disturbance or
biological erosion (termed bioerosion). Key bioeroding groups include
the grazing fish and echinoid groups, as well as the activities of an
array of infaunal borers. These include specific groups of sponges,
bivalves and worms (termed macroborers), as well as cyanobacteria,
chlorophytes, rhodophytes and fungi (termed microborers). The relative
importance of each process and the rates at which they operate vary
spatially across individual reef systems. In addition, many of these
processes leave distinctive signatures on, or in, the coral framework.
In some cases (e.g., calcareous encrusters) these are the skeletons of
the organisms themselves, whilst in other cases the organism may leave
behind a trace of their activity (e.g., macro- and microborers). These
represent useful palaeoenvironmental tools, firstly because they often
have good preservation potential and, secondly because the range and
extent of many of the individual species, groups and processes involved
exhibit reasonably well-constrained environment and/or depth-related
distributions. As a result these taphonomically important organisms or
processes can be used to delineate between reef environments in core or
outcrop, and to aid the interpretation of reef depositional processes
and &#039;events&#039;. This review summarises current understanding
regarding the distribution of these species/processes within
```

(1990).- Computer modeling the internal architecture of carbonate platforms.- Geology 18: 26-30.- <b>FC&#038;P 19-1.1</b>, p. 56, ID=2674^<b>Topic(s): </b>carbonate platforms; carbonate platforms; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>^A numerical computer model is described that calculates the internal architecture of carbonate platforms In response to varying values of carbonate production, subaerial and submarine erosion, sediment redeposition, and sea-level changes. The computer-generated sections closely resemble large-scale outcrops and interpreted seismic profiles through carbonate platform. Stillstand and transgressive sequences have prograding and downlapping platform geometries with lagoons developing in transgressive systems. Regressive sequences have downlapping clinoforms and erosional upper surfaces.
```

```
Glacioeustatic scale cycles have a major control on platform geometry
with erosional sequence boundaries developing during low stands and
platform drowning occurring during transgressive periods. Lowstand
downlapping wedges are minor features when compared with clastic
systems, and major progradation and downlap of slope deposits develop
with transgressions and flooding of platform tops. Carbonate erosion
rates are varied and have an important effect on the morphology of
floodback surfaces, which have a major control on platform top
production. The computer program contributes to the analysis of
carbonate systems in two ways: it gives a visual picture of the
quantitative effects of the many parameters controlling carbonate
geometries, and it aids quantitative analysis of the architectures and
time scales of ancient outcrop or seismic sequences.^1";

through Time: Importance of Tectonic and Biological Controls.- Facies
22: 159-168.- <b>FC&#038;P 19-2.1</b>, p. 38, ID=2760^<b>Topic(s):
</b>tectonism, geography; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>; <b>Geography: </b>^The evolution of reefs is controlled by
biological and global factors. The paper stresses the importance of the
tectonic and paleogeographical control. The evolution of reefs is
reflected by the changes in the composition of reef-building
communities during geological time, by changes in the mineralogical
composition of reef carbonates, and by changes in types, sizes and
tectonic settings of reefs. The composition of reef-building
communities is characterized by the development of new adaptive
patterns with decreasing diversity, by migration of reef-building
organisms to low-level communities, and by total or partial extinction
of reef organisms. Several changes in the composition of reef
carbonates (calcite, Mg-calcite, aragonite), strongly dependent on the
skeletal mineralogy of the reef organisms, are evident during Riphean
and Phanerozoic times. These changes coincide only roughly with the
long-time intervals recognized for the mineralogical composition of
non-reefal carbonates. Reef types started with the small organic
buildups of the Proterozoic and the Early Cambrian followed by the
differentiated reefs of the late Cambrian, the dome-shaped pinnacle
reefs and atolls of the Ordovician, and the strongly differentiated
reef-complexes of the Silurian and Devonian. The importance of bioherms
decreased during the Mesozoic and Caenozoic. Reef structures increased
in size during geological time from Precambrian and Cambrian (height -
elevation above off-reef basinal bottom: several meters) to Ordovician
(height several hundreds of meters), Devonian (more than 1000 meters)
to Caenozoic reefs (up to 2000 meters). Increase in thickness (of the
total reef structure) and elevation above sea bottom was connected with
an increase in the number of facies types. [abbreviated summary]^1";

<b>Geography: </b>^In rememberance of the death of Charles Darwin 100
years ago, a review is given on his coral reef research from the point
of view of present knowledge. Although during Darwin&#039;s time no one
was aware of the changing level of the glacial sea or of the important
function of the symbiontic zooxanthellae in the life of hermatypic
corals, his observations and considerations on the ecology of corals
and on the formation of coral reefs are relevant to this day. But of
course his ideas need new causal interpretations. The origin of the
different reef types can no longer be explained by subsidence only, but
by different modes biologists and geologists described during the
following century. To summarize all the many existing theories, the all
enclosing &#034;theory of compensation&#034; is put forward here in
honor of this great man.^1";

ID=3589^<b>Topic(s): </b>reefs, organomicrite; reefs organomicrite;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>^Data
obtained from Lower Cretaceous mud mounds provide evidence for organic
matrix mediated micrite production in place. Intracrystalline organic
macromolecules are typically enriched in Asp and Glu. Mineralization is
confined to non-living organic substrates (organomineralization of
Trichet &#038; Defarge 1995) originally derived from microbes, biofilms
and &#47; or metazoans. For seeding and epitaxial overgrowth organic
substrates and seed crystals need a persistent interaction with the
surrounding medium. Therefore, sedimentary starvation is required.
Sedimentary starvation is realized via protected space (semi-closed
cavities, interstitial pore space, sponge body container), via rapid
sealevel rise (TST-confined mud mounds), via rapid drop of sealevel
(emersion), and analogue episodes of low carbonate production
presumably controlled by eutrophism. Crystal growth also requires an
increased carbonate alkalinity. This is provided via sulfate reduction
```

```
on local scale and &#47; or via continental weathering in the
surrounding Paleozoic massifs. Genetically, mud mounds of the Soba Reef
Area correspond to organomicrite reefs. These reefs are opportunistic,
i.e. their occurrence within the photic zone indicates major crisis of
the stenotopic scleractinian coral &#47; calcareous algae community.
Mud mounds of the Soba Reef Area share some important features with
Albian &#47; Cenomanian hardgrounds (organomicrite related
lithification, dominance of active filter feeding organisms,
restriction of sediment supply) but hardgrounds were influenced by
stronger submarine dissolution and were exposed to relatively strong
current systems.^1";

ID=3624^<b>Topic(s): </b>growth modeling; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^Reef growth is the outcome of
a positive feedback between carbonate production and carbonate
stabilization. This basic game has been played by a variety of
organisms of many different taxa through the Phanerozoic. This
self-enhancing growth potential is cut back by a number of
environmental factors such as depth dependent growth potential, erosion
and sealevel changes. This basic concept is the backbone of our
computer-based reef model. It is cast into a mathematical form by a
Fisher equation adapted to the specifics of reef growth, such as
dependence of production rate on light and water depth, erosion and
redeposition. The solution of this equation is the reef topography
represented by reef height as a function of region and time. The
solutions can be represented as 3-d topography or vertical sections
thereof. The latter allow for sequence stratigraphic analysis.^1";

(1996).- The role of magnesium in the crystallization of calcite and
aragonite in a porous medium.- Journal of Sedimentary Research 66, 3:
482-491.- <b>FC&#038;P 26-1</b>, p. 48, ID=3626^<b>Topic(s):
</b>calcite, aragonite; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Morphological development of calcite crystals is
related to supersaturation conditions during growth. Crystallization of
calcium carbonate (calcite and aragonite) as well as Mg-calcite was
studied under controlled supersaturation conditions by the counter
diffusion of Ca2+ and CO32- ions through a porous transport medium (a
column of silica gel). Under our experimental conditions, where ion
transport is constrained to be diffusion controlled, nucleation and
growth take place under conditions of high supersaturation, the actual
threshold value of the supersaturation depending on the supersaturation
gradient. In the pure CaCO3 system, calcite grows at lower
supersaturation than aragonite. The calcite develops relatively simple
rhombohedra while the aragonite grows as spherulites. Presence of Mg2+
in the interstitial fluid inhibits nucleation, increasing the threshold
supersaturation at which crystallization begins. The resulting
Mg-calcite crystals show a range of morphologies depending on the Mg
content and the supersaturation at the point of crystallization. At
high values of supersaturation, up to 15 mol% MgCO3 is incorporated
into the calcite and the crystals form spheres. At lower
supersaturations, Mg content decreases and morphologies change
progressively through a well-defined and reproducible sequence from
spheres to dumbbell-like forms to wheat-sheaf-like bundles and
eventually single crystals with steep rhombohedral faces. The crystals
are compositionally zoned, showing both sector and oscillatory zoning.
The compositional evolution is related to the supersaturation and
interface roughness during crystal growth.^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^Marine organic reefs are
```

```
biological-paleobiological features; they are not
sedimentologic-stratigraphic features resulting from locally
over-thickened accumulations of sediment. The positive topographic
relief of reefs is due to the relatively rapid upward growth, skeletal
strength &#47; rigidity and high packing density of the clonal (or
gregarious) organisms comprising the reef framework. In modem, tropical
reefs, these features reach their acme at the relatively narrow,
shallow water crest marking the interface between the backreef lagoon
or reef flat and the forereef or seaward slope. In ancient reefs,
sediment commonly comprises a much greater volume of the reef than the
framework. However, it is the organisms, preserved either in their
original growth positions or in situ, that distinguish reefs from
accumulations of transported skeletal debris on level-bottom
substrates. Both modern and ancient reef communities have
characteristic taxonomic compositions, diversitites and guild
structures. It is the relative skeletal volume (or areal coverage) of
members of the constructor, baffler and binder guilds that controls the
reef-building prowess and in ancient reefs becomes the basis for their
classification as framestones, bafflestones and boundstones,
respectively.^1";
s[6525] = "GUDO M. (1997).- Ist Konstruktionsmorphologie ein
Aktualistisches Prinzip der Palaeontologie? .- Courier
Forschungsinstitut Senckenberg 201: 145-160.- <b>FC&#038;P 26-2</b>, p.
58, ID=3735^<b>Topic(s): </b>constructional morphology; <b>Systematics:
</b>; <b>Stratigraphy: </b>; <b>Geography: </b>^Constructional
Morphology was developed as a continuation of questions and methods
introduced in the concept of aktuopaleontology. The foundation of the
principle of &#34;Aktualismus&#34; or Uniformitarism is attributed to
Lyell (1830-1833), Gressly (1838) and Walther (1893). Using the present
conditions as a key to the past, Schaeffer (1962) developed the
principle of uniformitarism into the concept of aktuopaleontology by
drawing on several research methods such as ichnology, taphonomy,
functional morphology and facies reconstructions. Presupposing that
there is a difference in understanding functions in the environment and
the working of the whole organism, the group &#34;Kritische
Evlutionstheorie&#34; developed a new concept of organisms as hydraulic
energy conducing entities. Reconstructions can be performed for recent
as well as for fossil organisms; the analysis of fossil organisms makes
reference to constructional models developed for recent organism. Many
of the terms and concepts of the constructional theory of organisms are
based on ideas of Schaeffer. In this text it is demonstrated that
constructional morphology can be ssen as a continous development with
aktuopaleontology as its starting point. It is shown to be a principle
of uniformitarism. The soft body reconstruction of rugose corals is
given as an example, based on the generalized representation of rugose
skeleton ontogeny from Schindewolf (1950) and the constructional model
for recent anthozoans.^1";

biogeographic affinities of Fammenian rugose corals in the
Dzhungar-Hinggan Basin (Northern China).- Coral Research Bulletin 05:
239-246.- <b>FC&#038;P 27-1</b>, p. 77, ID=3790^<b>Topic(s):
</b>biostratigraphy, biogeography; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^In this study the
stratigraphic range and geographic distribution of Famennian solitary
rugose corals, not or poorly dissepimented, corresponding to the
Cyathaxonia-fauna and belonging to the Dzungar-Hinggan Basin (N China),
were analysed in detail. Coral fauna is well preserved in the
Hongguleleng (Hongguleleng area, North Xinjiang, NW China) Hongermiao
(Xuguit Qi area, Inner Mongolia, NE China) and Upper Daminshan (Sonid
Zuoqi-Abag Qi areas, Inner Mongolia, NE China) Formations. The studies
of the distributions of sixteen generic taxa known up to now in this
basin allows us to confirm the existence of endemic taxa (Honggulasma
and Hebukophyllum), significantly amplify the stratigraphic
distribution of Nicholsoniella and Caninia and to ratify for the rest
of the genera (Petraiella, Guerichiphyllum, Friedbergia, Gorizdronia,
Kozlowskinia, Nalivkinella, Ufimia, Cyathaxonia, Catactotoechus,
Metriophyllum, Syringaxon and Amplexus) a similar distribution to what
other Famennian basins in the rest of the world have. Besides, the
geographic distributions of these same taxa imply fairly strict
relations of the Dzungar-Hinggan Basin with the North East of Siberia
(Omolon Region), Urals and Eastern Europe (especially Poland), along
the North and West edges of the Proto-Thetys Ocean.^1";
s[6528] = "HLADIL J., CEJCHAN P., SEDLAK R. (1997).- Image analysis of
thin sections: Implication for calcite fabric of diagenetically changed
coral skeletons.- Coral Research Bulletin 05: 171-179.- <b>FC&#038;P
27-1</b>, p. 51, ID=3807^<b>Topic(s): </b>carbonates; carbonates
diagenesis; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Image analysis enables the detection, separation and
series-ordering of diagenetical stages. Early diagenetical growth of
fibral tufts was largely confirmed including the specific reactions
with ambit of the sclerenchyme. The regularly dominant &#34;tablet&#34;
[= short c-axis] crystal population are utterly assigned to late
diagenetical stages. Eventual early populations of &#34;tablet&#34;
calcite crystals are not satisfactory detected during our studies.
Nevertheless, the crystallization of the early tablets is theoretically
possible. The microenvironment of these domains has to be separated by
membranes and the survived tablet generation has to be marked by
solution-sutures on crystal margins. In previous studies on coral
microstructures, the late origin of tablet crystals has been either
supported (J. Sorauf) or refused (J. Lafuste). We can suggest a future
test of the potentially conflicting results: a comparison of ultra-thin
sections and image-analytic series based on thin sections (i.e. from
approximately the same place of the skeleton).^1";
s[6529] = "STEININGER F.F., MARONDE D. (1997).- Staedte unter Wasser -

figs.- <b>FC&#038;P 26-2</b>, p. 6, ID=3879^<b>Topic(s): </b>exhibition
catalogue; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Exhibition catalogue of the Senckenberg-Museum
(Frankfurt am Main) incorporating 25 contributions of German
reef-scientists compiled within the scope of the International Year of
the Reef 1997. This booklet is meant as a catalogue to the special
exhibition of the same name that can be visited until November 16, 1997
in the Senckenberg-Museum (Frankfurt am Main). It is about reefs, those
spectacular settlements below the sea-level, which were built for
example by corals, sponges and bivalves. It gives details on reefs and
their constructors during the &#34;Erdgeschichte&#34;. The first reefs
developed at least two billion years ago, so called stromatolite-reefs,
```

```
which are the most important reefal structures at that time. Other
types of fossil reefs and their constructors, for example coral reefs
of the Devonian Era or the fascinating rudist-reefs of the Cretaceaous,
are described. Information about excursions to several localities of
fossil reefs in Germany is given. Not only fossil reefs are considered,
living coral reefs and the role they play for mankind (fishery,
biological resources for pharmaceutical products, a.s.o.) are also
taken into account. Several contributions cover the endangerment of
recent reefs, caused by pollution of the oceans, the cut down of
tropical rain forests or excessive tourism and give advice for
travellers, visiting those areas, to save the &#34;marine
rainforests&#34;. The booklet presents the results of research-projects
within the scope of the development of reefs, promoted by the Deutsche
Forschungsgemeinschaft (DFG). Articles are written in colloquial German
and give an extensive information on the grand constructors below the
sea not only for Paleontologists or Geologists but especially for the
interested laymen. [translated from Natur und Museum 127, 9]^1";

ID=3996^<b>Topic(s): </b>aragonite - calcite epochs; carbonate
mineralogy, calcifying organisms; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^The primary mineralogy of
oolites and early marine carbonate cements led Sanberg (Nature 305:
19-22) to divide the Phanerozoic Eon into three intervals of
&#039;aragonite seas&#039; and two intervals of &#039;calcite
seas&#039;. Hardie (Geology 24: 279-283) has shown that these
oscillations, together with synchronous oscillations in the mineralogy
of marine potash evaporites, can be explained by secular shifts in the
Mg/Ca ratio of sea water driven by changes in the spreading rates along
mid-ocean ridges. The Hardie model also predicts that high Mg-calcite
```

```
should precipitate along with aragonite as it does in today&#039;s
aragonite sea. We have encountered oscillations in the carbonate
mineralogy of hypercalcifying organisms (ones that have produced mass
skeletons, large reefs, or voluminous bodies of sediment) that
correspond to Sandberg&#039;s aragonite seas and that are predicted by
the Hardie model. Particular groups of corals, sponges, and algae
appear to have been dominant reef builders only when favored by an
appropriate Mg/Ca ratio in sea water. [part of extensive summary]^1";

<b>Geography: </b>^The reef phenomenon is essentially a biological
phenomenon; therefore, it is important to emphasize its biological and
ecological aspects in terms of reef construction. However, the role of
organisms in the construction of a reef is manifold. Many organisms
play more than one role in the production of reef carbonate. They may
produce reef carbonates, either independently or by cooperation with
other groups of organisms. The ways in which organisms contribute to
reef construction can be classified as follows: 1. Framework
construction: Production of solid reef bodies with heavily calcified
colonies. 2. Consolidation: Cryptic reef organisms occur in cavities
and interstices. They encrust and bind reef colonies to consolidate the
reef framework. 3. Binding: Encrusting organisms overgrow and bind
blocks and debris together to form rigid reef carbonates. 4. Baffling:
Branching colonies can slow down water movement and allow sediments to
```

```
settle. 5. Stabilizing: Lamellar organisms may cover the debris or
loose sediments and would protect them, thus enabling their rapid
cementation to form rigid reef carbonate. 6. Biocementing: In a
protected environment, the colonization of microorganisms can produce
large quantities of micrite cement as metabolic byproducts, which would
fill the interstices and cement the debris and blocks into a solid reef
carbonate. 7. Forming reef carbonate contributors: In clear water
environment, microorganisms can immediately form important quantities
of self-supporting rigid micritic reef carbonates. 8. Contribution to
sedimentation: Their debris may become sediment The vast quantities of
blocks and debris produced by organisms that fill interstices of the
frameworks of reef bodies help to increase the reef volume. 9.
Co-building: Forming of reef carbonate by cooperation of several
different organisms.^1";

data; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Personal computers are increasingly used for scientific work. In
palaeontology they are employed mainly for building up data banks on
literature and localities, as well as on taxa with their morphological
characteristics. Compared with card files and lists, data banks offer
the following advantages: - They are not sorted according to a single
criterion but allow universal searching according to all criteria. -
They permit rapid access to information. - Several data banks can be
interlinked. The acquisition of data is mostly a time-consuming
process. In order to enable data banks to be exchanged without
difficulty and thus to obviate the need for other institutions having
to collect the same data all over again, colleagues are requested to
consider the problem of compatibility in their choice of computers and
data bank systems. Different computer systems and data formats have so
far hampered exchanges. We therefore suggest introducing a data
structure standard (especially for IBM compatible personal computers
under the operating system MS-DOS).^1";

reef-building.- Palaios 8: 526-543.- <b>FC&#038;P 23-2.1</b>, p. 69,
ID=4186^<b>Topic(s): </b>geohistory; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^The trophic structure of
modern tropical benthic communities, especially reefs, is profoundly
influenced by ambient nutrient levels and resultant predator
characteristics. In oligotrophic regimes the presence of abundant
specialist grazers promotes succession and yields climax-stage
communities. Such communities produce the classic &#34;framework&#34;
reef dominated by large, heavily calcified phototrophs and multiserial
mixotrophs. These primary producers bear many antipredator adaptations
and have a marked preference for hard-substrates. Increasing nutrient
levels favor a transition in the benthos from photo- and mixotrophs via
benthic algae to soft-substrate communities of solitary or uniserial
heterotrophs feeding on planktonic primary producers. Under such high
nutrient conditions, small heterotrophs are perpetually superior
competitors, thus maintaining assemblages which resemble pioneer
stages. Here, the history of Phanerozoic reef-building is reassessed
according to an analysis of trophic structure. Broad global patterns
may be largely explained by changes in nutrient availability. Differing
rates of oceanic circulation linked to climatic fluctuations and
sea-level changes determined the range of trophic regimes available in
shallow marine tropical habitats. Most Phanerozoic reefal buildups are
revealed as soft-substrate dwelling heterotrophic communities and as
such were not well-adapted to oligotrophic conditions: they were
trophically quite unlike modern coral reefs and had markedly different
```

```
environmental requirements. Prolonged phases when heavily calcified
multiserial metazoans, although available, did not form framework reefs
are postulated as times when few oligotrophic regimes were present in
tropical shallow seas, i.e., most of the early Carboniferous, Permian
and mid-late Cretaceous. Acquisition of mixotrophic nutrition allowed
invasion of previously inaccessible oligotrophic environments, but
current evidence suggests that photosymbiosis was not acquired by reef-
building organisms until the early to mid-Mesozoic onwards, with the
possible exception of the mid-Palaeozoic. This may have been in
response to increasing predation pressure and appears to have been
facilitated by the creation of extensive oligotrophic regimes. The
resilience of Tertiary scleractinian coral reefs to climatic
vicissitudes might be largely explained by the rise of anti-fouling
grazers, especially fish, during this time.^1";

(1993).- Microbial Carbonate crusts - a Key to the Enviromental
Analysis of Fossil Spongiolites? .- Facies 29: 41-54.- <b>FC&#038;P
23-1.1</b>, p. 88, ID=4203^<b>Topic(s): </b>carbonates microbial;
microbial crusts; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Morphological and geochemical comparisons between
modern cryptic microbialites from Lizard Island &#47; Great Barrier
Reef and fossil counterparts in the Upper Jurassic (Southern Germany,
Dobrogea &#47; Romania) and late Lower Cretaceous (Aptian &#47; Albian
from Cantabria &#47; Spain) spongiolitic environments show that there
are common factors controlling the crust formations mostly independent
of light despite of diverging (paleo) oceanographic positions as well
as relationships of competitors. Factors such as increased alkalinity,
oligotrophy, and reduced allochthonous deposition are of major
importance. Thrombolitic microbiolites are interpreted as biologically
induced and therefore calcified in isotopic equilibrium with the
surrounding sea water. Corresponding with shallowing upward cycles,
microbial mats which produce stromatolitic peloidal crusts become more
important. Different bio-markers are introduced for the first time
extracted and analyzed from spongiolitic limestones of lower
Kimmeridgian age from Southern Germany.^1";

s[6542] = "KERSHAW S. (1994).- Classification and geological
significance of biostromes.- Facies 31: 81-92.- <b>FC&#038;P 24-1</b>,
p. 87, ID=4450^<b>Topic(s): </b>classification of biostromes; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Biostrome and bioherm were described as terms by Cumings (1932),
and bioherm has become synonymous with reef because of the discrete
mound or lens shape in vertical section. The phrase &#34;reefs and
biostromes&#34; is common in the literature and emphasises that
biostromes are normally regarded explicitly as not reefal structures,
because of the lack of topographic relief and common absence of a
framework. However, the posifion adopted here is that bioherm and
biostrome are most usefully applied to simply describe the outline
shape of an organic accumulation, and not to denote any particular
inherent internal structural organisation. Furthermore, the view here
is that biostromes are most usefully considered as single organic
layers (i.e. beds). Observations of biostromes of numerous ages and
settings indicate that a considerable variety of internal structure
exists within the outline which defines biostrome. Often, the structure
comprises frameworks and dense clusters of in-place organisms and is
just as much &#34;reefal&#34; as similar constructions with a biohermal
shape. In other cases biostromes consist of beds of skeletal debris
consistent with the concept of biostrome used by many workers. These
```

```
differences demonstrate that classification of biostromes is needed in
order to allow comprehensive palaeoenvironmental analysis, and
highlight the long-standing problem of using &#039;reef&#039; to
describe organic buildups. For biostromes, autobiostrome,
autoparabiostrome, and parabiostrome are introduced to describe a
continuum from structures where the constructing organisms are mostly
in place (autobiostromes), to mostly debris of the structure
(parabiostromes), with autoparabiostrome as intermediate.
Allobiostrome, describes biostromes formed of material derived from
allochthonous sources, for example skeletal plankton sedimented onto
the sea bed. Most biostromes are of calcareous construction and their
composition is most adequately described by existing limestone
classification terminology.[part of extensive summary]^1";

identify porewater types during diagenesis. Changes in porewater
composition can be related to major geological events within southern
```

```
Israel. In particular, saline brines played an important role in late
(Pliocene-Pleistocene) dolomitization of these rocks. Diagenetic
carbonates included early siderite (d18OSMOW= +24.4 to +26.5‰; d13CPDB
= -1.1 to +0.8‰), late dolomite, ferroan dolomite and ankerite
(d18OSMOW = +18.4 to +25.8‰; d13CPDB = -2.1 to +0.2‰), and calcite
(d18OSMOW = +21.3 to +32.6‰; d13CPDB = -4.2 to +3.2‰). The petrographic
and isotopic results suggest that siderite formed early in the
diagenetic history at shallow depths. The dolomitic phases formed at
greater depths late in diagenesis. Crystallization of secondary calcite
spans early to late diagenesis, consistent with its large range in
isotopic values. A strong negative correlation exists between burial
depth (temperature) and the oxygen isotopic compositions of the
dolomitic cements. In addition, the d18O values of the dolomitic phases
in the northern Negev and Judea Mountains are in isotopic equilibrium
with present formation waters. This behaviour suggests that formation
of secondary dolomite post-dates the tectonic activity responsible for
the present relief of southern Israel (Upper Miocene to Pliocene) and
that the dolomite crystallized from present formation waters. Such is
not the case in the Central Negev. In that locality, present formation
waters have much lower salinities and d18O values, indicating invasion
of freshwater, and are out of isotopic equilibrium with secondary
dolomite. Recharge of the Inmar Formation by meteoric water in the
Central Negev occurred in the Pleistocene, and halted formation of
dolomite.^1";
s[6547] = "HUSSNER H. (1994).- Reefs, an elementary principle with many
complex realizations.- Beringeria 11: 1-99.- <b>FC&#038;P 24-1</b>, p.
85, ID=4521^<b>Topic(s): </b>feedback circuits; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>; <b>Geography: </b>^In this work reefs are
viewed as the result of self enhancing feedback circuits. Reef growth
comprises enhanced production of carbonate compared to the surroundings
and a better fixation of this carbonate as compared to the
surroundings. Moreover both of these elementary principles of
reef-growth enforce each other. This makes reefs different from
physically dominated sedimentary processes. In reefs biological
programs in multigeneration communities dominate the sedimentation
process, which demand and allow upward growth rather than isotropic
distribution. These principles are demonstrated in four case studies.

s[6548] = "COPPER P. (1994).- Paleoscene 14. Organisms and carbonate
substrates in marine environments.- Geoscience Canada 19, 3: 97-112.-
<b>FC&#038;P 24-2</b>, p. 36, ID=4532^<b>Topic(s): </b>benthos,
carbonates; organisms, carbonates; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^Carbonate substrates are
normally produced in situ by organisms that live above, at or below the
sediment-water interface; that is they represent a relatively
self-enclosed ecosystem. During the last 3.5 bilion years, there have
been major cyclical variations in the global carbonate sediment budget
in the oceans, and organisms have been, to a large extent, directly
responsible for these variations. At the substrate level, there is a
direct interplay between the planktic and nektic organisms that occupy
the watermass above, and the benthic organisms that utilize the
substrate as a food resource and domicile below though these
relationships depend more on grain size, nutrient in the sediment, pore
chemistry, and the general nature of the substrate (texture, fabric,
etc.) than it does on the mineralogical differences between the
siliciclastic or calcium carbonate composition of the sedimentary
grains. This synthesis is an attempt to look at both the macrocosmos
and microcosmos of organisms and the carbonate substrates they occupy.
It will exclude the reef and intertidal-subtidal microbial mat
environments, as well as terrestrial fresh water ecosystems. Trace
fossils will be treated only in passing because of their importance to
recognition of sediment cycling. Fossil organisms provide many clues to
the ancient marine environment, as their distribution is limited by
```

```
physico-chemical factors such as temperature light, substrate and
watermass chemistry (pH, Eh, solubles, salinity, etc.), gases
(oxidizing, reducing etc.) ambient physical energy, random or
predictable catastrophic effects (tides, storms, sea level change,
etc.), the nature of the substrate (hard, soft, mobile, static, smooth,
rough, grain size, etc.), and biological factors, such as their own
functional limitations and relationships to other organisms occupying
the substrate. [original introduction]^1";

(1994).- Reef metabolism and endo-upwelling in perspective.- Coral
Reefs 13, 4: 199-201.- <b>FC&#038;P 24-2</b>, p. 81,
ID=4563^<b>Topic(s): </b>endo-upwelling; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^Rougerie and Wauthy (1993)
have recently advanced the concept of endo-upwelling to explain high
rates of metabolism for oceanic coral reefs and atolls. The principal
hypothesis advanced in this and previous papers (Rougerie and Wauthy
1986, 1988; Rougerie et al 1992) is that geothermal heat deep within
the basalt and limestone underlying Pacific island reefs, stimulates
nutrient-rich Antarctic Intermediate Water at depths of several hundred
meters to flow upward through the reef structure. The emergence of this
nutrient-rich water in the shallow surface water of reefs is used to
explain high rates of carbon fixation, commonly measured on reef flats.
There are two problems with this hypothesis, one of a general nature,
and one that is specific to the data presented: (1) productivity on
reefs does not require a large supply of &#34;exotic&#34; nutrients and
(2) the data on nutrient concentration of interstitial water are easily
explained by the oxidation of organic matter within the reef structure
and sediments. [first fragment of a polemical short paper]^1";
s[6550] = "WAGNER P.J. (1995).- Stratigraphic tests of cladistic
hypotheses.- Paleobiology 21, 2: 153-178.- <b>FC&#038;P 24-2</b>, p.
81, ID=4564^<b>Topic(s): </b>cladistics, stratigraphic testing;
cladistics; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Cladograms predict the order in which fossil taxa appeared and,
thus, make predictions about general patterns in the stratigraphic
record. Inconsistencies between cladistic predictions and the observed
stratigraphic record reflect either inadequate sampling of a
clade&#39;s species, incomplete estimates of stratigraphic ranges, or
homoplasy producing an incorrect phylogenetic hypothesis. A method
presented in this paper attempts to separate the effects of homoplasy
from the effects of inadequate sampling. Sampling densities of
individual species are used to calculate confidence intervals on their
stratigraphic ranges. The method uses these confidence intervals to
test the order of branching predicted by a cladogram. The Lophospiridae
(&#34;Archaeogastropoda&#34;) of the Ordovician provide a useful test
group because the clade has a good fossil record and it produced
species over a long time. Confidence intervals reject several cladistic
hypotheses that postulate improbable &#34;ghost lineages&#34;. Other
hypotheses are acceptable only with explicit ancestor-descendant
relationships. The accepted cladogram is the shortest one that
stratigraphic data cannot reject. The results caution against
evaluating phylogenetic hypotheses of fossil taxa without considering
both stratigraphic data and the possible presence of ancestral species,
as both factors can affect interpretations of a clade&#39;s
evolutionary dynamics and its patterns of morphologic evolution.^1";

polygenetic spectrum of fine-grained carbonate buildups.- Facies 32:
1-70.- <b>FC&#038;P 24-2</b>, p. 103, ID=4616^<b>Topic(s): </b>mud
mounds, polygenetic; reefs, mud mounds; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^This research report contains
nine case studies (part II to X) dealing with Palaeozoic and Mesozoic
mud mounds, microbial reefs, and modern zones of active micrite
production, and two parts (I and XI) summarizing the major questions
and results. The formation of different types of in situ formed
micrites (automicrites) in close association with siliceous sponges is
documented in Devonian, Carboniferous, Triassic, Jurassic and
Cretaceous mounds and suggests a common origin with a modern facies
found within reef caves. Processes involved in the formation of
autochthonous micrites comprise: (i) calcifying mucus enriched in Asp
and Glu, this type presumably is linked to the formation of
stromatolites, thrombolites and massive fabrics; (ii) protein-rich
substances within confined spaces (e.g. microcavities) result in
peloidal pockets, peloidal coatings and peloidal stromatolites, and
(iii) decay of sponge soft tissues, presumably enriched with symbiotic
bacteria, lead to the micropeloidal preservation of parts of former
sponge bodies. As a consequence, there is strong evidence that the
primary production of micrite in place represents the initial cause for
buildup development. The mode of precipitation corresponds to
biologically-induced, matrix-mediated mineralization which results in
high-Mg-calcites, isotopically balanced with inorganic cements or
equilibrium skeletal carbonates, respectively. If distinct automicritic
fabrics are absent, the source or origin of micrite remains
questionable. However, the co-occurring identifiable components are
inadequate, by quantity and physiology, to explain the enhanced
accumulation of fine-grained calcium carbonate. The stromatolite reefs
from the Permian Zechstein Basin are regarded as reminiscent of
ancestral (Precambrian) reef facies, considered the precursor of
automicrite &#47; sponge buildups. Automicrite &#47; sponge buildups
represent the basic Phanerozoic reef type. Analogous facies are still
present within modern cryptic reef habitats, where the biocalcifying
carbonate factory is restricted in space.^1";

With the adoption of Atomic Time, the rotation rate can now be measured with unprecedented precision and independently of planetary or lunar motions. Information from earlier observations is also being recovered more accurately: independent analyses and new data from ancient eclipse observations have increased confidence in the controversial results obtained earlier. Perhaps the most outstanding development is the tentative measurement of the mean rotation rate in the remote geological past, made possible by the study of periodicities in the skeletal growth of fossil organisms. The improved data have exposed new geophysical problems and accentuated earlier ones. An unexplained acceleration of the Earth&#039;s rotation is confirmed by the re-examination of ancient eclipse records. In addition, Darwin&#039;s theory of tidal friction now has the arbitrariness of its time-scale replaced by data from modern astronomical observations so that, in spite of various theoretical refinements, it leads to the unacceptable prediction of a catastrophic period in the history of the Earth-Moon system in the mid-Precambrian. Information from the study of fossil growth increments can make a vital contribution in both these problems. The palaeontological data have been gathered mainly from corals and bivalves, although several other groups with accretionary skeletons provide a few figures and are potentially useful. The unexpected cosmogonic applications of these data have stimulated research into the physiological and particularly the ecological factors controlling incremental growth in these organisms, especially the bivalves. The main problems center on the recording accuracy and the definition of the growth increments. The difficulty of eliminating irregular interference and of recovering geophysically useful measurements from the fossil record is discussed and we have tried to assess the reliability of the information already derived from this source.^1";

```

```
the views of zoologists and paleontologists specializing in the study
of metazoan colonies. Contents include expanded versions of papers from
the symposium on animal colonies held at the November 1971 meeting of
the Geological Society of America and the Paleontological Society, as
well as additional commentary and papers of a review nature which
provide an overall perspective. The contributors examine the basic
nature of metazoan colonies, review much of the existing literature,
and offer new morphologic data from both fossil and modern animals. The
papers present new information on the development and function of key
groups of living and fossil colonial animals. New descriptive data
permit evaluation of the concept of coloniality as applied to the
Porifera, Coelenterata, Bryozoa and Hemichordata (Class Graptolithina).
The fossil records of these phyla are used to document the evolution of
the colonial habit. The text is extensively illustrated with 140 line
drawings and over 200 photographs. [from publishers notice]^1";
s[6563] = "LAPORTE L.F. (1974).- Reefs in Time and Space.- SEPM Special
Publication 18; 256 pp.- <b>FC&#038;P 3-1</b>, p. 14,
ID=4844^<b>Topic(s): </b>history; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^This is a series of generally
excellent papers on several aspects of living and fossil reefs.
&#34;Articles by Bloom, Purdy, and Goreau and Land emphasize the
significance of Pleistocene events in determining present day reef
geometry&#34;. Purdy&#39;s long paper (68pp) is especially notable in
challenging some aspects of &#34;Darwinian&#34; theory on reef origin.
He argues that &#34;many, if not most, of the shape attributes of
modern reefs are fundamentally karst-induced rather than
growth-induced&#34;, and provides a wealth of experimental and
observational data to support his conclusions. The paper by Heckel
(65pp) is a thorough and excellent review of reefs and &#34;reefs&#34;
through geologic time. He discusses terminology and reef classification
with emphasis on differentiating between description and
interpretation. After a system by system review of &#34;reefs&#34; in
the geologic record and of the major biological contributors to these
structures, he discusses modern analogs and origins. The papers by
Krebs and by Bosellini and Rossi summarize their studies of classic
ancient reef complexes of central Europe. Matthews reviews and analyzes
the complexities of diagenesis in recent and ancient &#34;reefs&#34;.
Contents of the symposium are as follows: * Geomorphology of Reef
Complexes, by Arthur L. Bloom; * Reef configurations: Cause and effect,
by Edward G. Purdy; * Fore-Reef morphology and depositional processes,
North Jamaica, by Thomas F. Goreau and Lynton S. Land; * Carbonate
Buildups in the Geologic Record: a Review, by Philip H. Heckel; *
Devonian Carbonate Complexes of Central Europe, by Wolfgang Krebs; *
Triassic Carbonate Buildups of the Dolomites, Northern Italy, by
Alfonso Bosellini and Daniele Rossi; * A Process Approach to Diagenesis
of Reefs and Reef Associated Limestones, by R.K. Matthews.^1";

Centre Rech. Pau SNPA 7, 1: 171-176.- <b>FC&#038;P 3-1</b>, p. 17,
ID=4852^<b>Topic(s): </b>cementation; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^Dans les récifs on peut
observer deux sortes de cimentation: sous-marine et subaérienne. * Dans
```

```
la cimentation sous-marine des récifs, l&#039;aragonite et la calcite
magnésienne oblitèrent progressivement les pores existants. Quand le pH
devient élevé (approximativement 9,0-10,0) les grains de quartz, dans
les récifs, sont remplacés par le CaCO3 qui précipite aussi sous forme
de ciment. Une telle augmentation du pH est un processus biologique. *
Dans la cimentation subaérienne, l&#039;aragonite des cristaux est
progressivement dissoute dans les récifs qui se trouvent au-dessus du
niveau de la mer. Cette dissolution continue jusqu&#039;à ce qu&#039;il
ne reste que des enveloppes micritiques . Les enveloppes micritiques
consistent originellement en calcite magnésienne mais elles deviennent
de la calcite peu magnésienne pendant la diagénèse subaérienne. La
dissolution de l&#039;aragonite crée une porosité et une perméabilité
extrêmement importante. La formation subséquente de la calcite sur les
enveloppes micritiques réduit les vides des pores secondaires.^1";

SEPM Special Publication 18 [Leo Laporte (ed.): Reef in Time and
Space]: 9-76.- <b>FC&#038;P 3-1</b>, p. 18, ID=4857^<b>Topic(s):
</b>reef morphologies, causes vs effects; reef morphologies;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>^It has
been generally assumed that the deep borings on Pacific atolls have
confirmed Darwin&#039;s theory of coral reef development which holds
that continued subsidence results in the successive appearance of
fringing reefs, barrier reefs and atolls. It is certainly true that the
considerable thicknesses of shallow water carbonates encountered in
these core holes necessitates subsidence; however it does not
necessarily follow that this subsidence has resulted in the genetic
succession of reef types advocated by Darwin. It is the purpose of the
present paper to enlarge on an alternate theory first presented by
MacNeil, and in so doing to demonstrate that many, if not most, of the
shape attributes of modern reefs are fundamentally karst-induced rather
than growth-induced. There can be little doubt that the carbonate
platforms beneath most modern reefs have suffered some degree of
subaerial exposure. This general inference is warranted by the apparent
thinness of Holocene shallow water carbonate deposits in conjunction
with the low stand of sea level during the Wisconsin glaciation. Thus
it seems logical to conclude that most modern reefs have developed on a
karst substrate. The occurrence of drowned sink holes a few hundred
feet deep on several modern carbonate platforms supports the same
conclusion and more importantly suggests a potential for the
development of considerable solution relief. * Experiments with
limestone blocks indicate the feasibility of solution development of
the diagnostic cross-section morphology of both barrier reefs and
atolls. Tropical karst landforms are suggestive of the same conclusion.
All that is apparently required is a large surface area of gently
dipping beds that is bordered on one or more sides by a relatively
steep slope. The dissolving action of meteoric water differentially
lowers the central area relative to that immediately adjacent to the
steep slopes and results in a partially or completely rimmed solution
basin. Subsequent rise in sea level permits coral colonization of both
the solution rim and the residual karst prominences within the basin.
The resulting barrier reef or atoll, with its satellite lagoon reefs,
is thus formed without recourse to a prior history of reef development.
The attributes of the reefs themselves support this interpretation.
Special pleas have been advanced for many of these, but all seem
related to the development of a karst solution basin. Thus, drowned
&#034;atolls&#034; reflect drowned karst topography; reef passes
originate as drainage breaches in the solution rim; faroes are a karst
product of breaching; peripheral limestone islands are exposures of the
```

```
fossil drainage divide; and spurs and grooves are expressions of
lapies. These karst-induced differences in relief are perpetuated, and
indeed accentuated, by reef growth, but reef growth per se has little
to do with the basic configuration.^1";

Sciences de la Terre 18, 3: 245-255 ; Nancy.- <b>FC&#038;P 3-2</b>, p.
35, ID=4925^<b>Topic(s): </b>reef morphologies, causes vs effects; reef
morphologies; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Bien que les principes généraux de la théorie de
Darwin sur le développement récifal soient acceptés, l&#039;auteur
suggère que la configuration actuelle des récifs est surtout
conditionnée par une morphologie karstique préexistante acquise par les
plates-formes carbonatées durant la glaciation pleistocene.
L&#039;expérimentation confirme la théorie selon laquelle une
plate-forme carbonatée exposée à la dissolution subaérienne se
modifiera, à l&#039;échelle régionale, pour donner une dépression
centrale limitée par un ressaut bordier. A une échelle plus locale, la
morphologie karstique est déterminée par le climat: les climats
tropicaux donnent une topographie de karst conique tandis que les
climats tempérés engendrent un paysage à dolines. Ces reliefs
karstiques submergés tous d&#039;une transgression ultérieure,
influencent la géométrie de nouveaux récifs; les barrières récifales
s&#039;installent sur les ressauts bordiers tandis que localement des
récifs de type &#34;patch&#34; se développent sur les parties hautes
des karsts coniques.^1";
s[6571] = "MONSEUR G., PEL J. (1974).- Reef environment and Stratiform
ore deposits (Essay of a synthesis of the relationship between them).-
In G.C. Amstutz &#038; A.J. Bernard (eds): Ores in sediments: 195-207;
Berlin.- <b>FC&#038;P 3-2</b>, p. 40, ID=4961^<b>Topic(s): </b>reefs vs
stratiform ore deposits; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>; <b>Geography: </b>^Comparative analysis of Givetian reef
complexes from Belgium and Aptian reef complexes from the Santander
province in Spain displays an identical sedimentary rhythm. The study
of the stratiform Reocin lead-zinc deposit, located in Aptian
dolostones from this Santander province, has disclosed genetic
relations between mineralization and location in the reef complex.
These relations are dependent on the sedimentary rhythm. This
observation affords a basis for comparing several stratiform deposits
of varying mineralogy and different ages, also associated with reef
complexes. Sedimentological analysis leads to an examination of other
deposits related with peri-reef facies and eventually to a conclusion
concerning the paleogeographical distribution of stratiform

</b>^Terms for subdivisions of species (variety, forma, mutant,
subspecies) have been applied by paleontologists for many years without
appreciable consistency. Commonly, a single taxon would be designated
as a &#34;variety&#34;, a &#34;subspecies&#34;, or a &#34;species&#34;
by workers with little regard for the rank assigned previously by
others. The current International Code of Zoological Nomenclature is
applicable to species-group taxa (i.e., species and subspecies), but it
definitely excludes from availability and from formal zoological
nomenclature (ICZN, Arts. 1, 15) those infrasubspecific taxa (i.e.,
varieties and formae) initially proposed after 1960. The essential
equivalency, for practical purposes, of taxa cited as
&#34;subspecies&#34;, &#34;formae&#34;, &#34;variety&#34;, etc. in
older publications was recognized in the Code (ICZN, Art. 45), however,
so that all these taxa proposed prior to 1961 (and otherwise available)
are to be regarded and cited as &#34;subspecies&#34;. It seems
undesirable and incorrect to cite available pre-1961 names as &#34;A-us
b-us var. c-us&#34; now rather than as &#34;A-us b-us subsp. c-us&#34;.
[ ] Objectively unavailable infrasubspecific taxa also cannot serve as
type species for genus-group taxa. Genus-group taxa based on such
&#34;type species&#34;, therefore, are unavailable. Removal from
consideration of a &#34;designated&#34; taxon having an unavailable
name, however, may originally fix as type species (e.g., by monotypy)
```

```
another taxon having an available name so that the genus-group name may
retain availability. [initial and final parts of a nomenclatorial

processus vitaux responsables de la formation des récifs (Fig. 1). Les
différences écologiques les plus importantes sur terre et en mer
résident dans la viscosité différente du milieu aérien dans lequel la
vie terrestre évolue, et du milieu aquatique abritant la vie
sous-marine. La viscosité aquatique a une multitude de conséquences
directes et indirectes: (1) inertie relative du transport de substances
dans le milieu aquatique et en particulier dans le sol; (2)
restrictions des surfaces réactives dans le sol aux deux phases solides
et fluides et restriction des modes possibles de réactions chimiques
dans le sol par l&#039;absence de la phase gazeuse; (3) importance
physique des mouvements de l&#039;eau souvent destructifs, limitant la
vie; (4) absorption rapide de la lumière dans la colonne d&#039;eau;
(4) possibilité de se maintenir en suspens dans l&#039;eau libre à peu
de frais énergétiques (vie planctonique). * Les conséquences de ces
quelques points (qui sont loin d&#039;être exhaustifs) se reflètent
dans la faible productivité relative du milieu aquatique et dans
l&#039;attrait vital du milieu terrestre dès que la quantité de
l&#039;eau transitant le système est suffisante. La différence de
productivité terre - mer peut atteindre trois ordres de grandeur.

Géologie et paléoécologie des récifs [J. Geister &#038; R. Herb (eds)]:
23.1-23.8.- <b>FC&#038;P 13-1</b>, p. 11, ID=6336^<b>Topic(s): </b>mud
mounds; mud mounds; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Mud-mounds are persistant carbonate build-ups
ranging at least from Early Cambrian to Cretaceous and probably Recent
times. Once interpreted as true ecological reefs built by
&#34;stromatactis organisms&#34;, by bryozoans, stromatoporoids, etc.,
the recognition of the volumetric abundance of constitutive mud led
many authors (Pray 1958; Lees 1964) to discard this interpretation. *
Beside their considerable sedimentological and (micro-)
palaeontological interest they are of great economic importance in
terms of oil and ore deposits (lead-zinc). Their accretion appears to
result from the superposition of sigmoidal muddy lenses eventually
separated by clay seams or grainstone tongues of variable importance.
This pattern may impart crude irregular bedding to the overall mound;
in cases, stratification may be emphasized by alignment of lamellar
organisms or of trains of fenestrae. Mud-mounds range from less than
metric to hectometric dimensions in thickness and diameter; they may
occur in fields of scattered mounds or coalesce laterally to form
larger kilometric banks. [initial parts of an introduction]^1";
s[6638] = "DULLO W.-C. (1984).- Carbonate diagenesis: selected examples
of Cenozoic and Mesozoic reefs.- Géologie et paléoécologie des récifs
[J. Geister &#038; R. Herb (eds)]: 27.1-27.18.- <b>FC&#038;P 13-1</b>,
p. 12, ID=6340^<b>Topic(s): </b>reefs diagenesis; reefs, diagenesis;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Diagenesis starts directly after the formation or genesis of any
skeletal grain. That means, for example, cementation occurs already in
living corals in those parts, wich are not more covered by the living
tissue. Most of the non-skeletal grains therefore are either the
products of primary diagenetic effects, like ooids, grapestones, or
micritized grains, or are reworked grains, already influenced by
diagenesis, like bio- or lithoclasts. Hence no carbonate rock exists on
earth, neglecting the age, which is not a product of diagenesis. *
Three main diagenetic environments can be distinguished: (1) submarine
diagenesis (marine phreatic) in shallow seas or in deeper parts of the
oceans; (2) vadose diagenesis under the influence of rain water; (3)
freshwater phreatic diagenesis below or in the water table. [first part
of an introduction]^1";

pétrolière.- Géologie et paléoécologie des récifs [J. Geister &#038; R.
Herb (eds)]: 31.1-31.16.- <b>FC&#038;P 13-1</b>, p. 12,
ID=6344^<b>Topic(s): </b>reefs hydrocarbons; reefs petroleum;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>^Les
récifs fossiles intéressent les géologues pétroliers depuis près de 100
ans. Ils représentent en effet des réservoirs prolifiques pour les
hydrocarbures et ont été parmi les premiers découverts (Cemsah en
Egypte par exemple). * Si certains récifs ont été aisés à découvrir,
soit en liaison avec des indices de surface, soit par leur situation
structurale élevée, d&#039;autres ne peuvent être décelés qu&#039;après
des études géologiques et géophysiques; et la difficulté même de ces
études laisse encore ouverte la porte à de nouvelles découvertes ou a
des extensions, même dans des bassins déjà explorés de façon intensive.
C&#039;est pourquoi l&#039;industrie pétrolière accorde une importance
particulière à la recherche sur les constructions récifales: modèles
dans l&#039;actuel, études paléo-écologiques de l&#039;environnement,
conditions de diagénèse, détection géophysique avec amélioration
continuelle des méthodes seismiques, utilisation faciologique des
diagraphies différées dans les sondages. [introductory fragments]^1";

plombo-zincifères.- Géologie et paléoécologie des récifs [J. Geister
&#038; R. Herb (eds)]: 32.1-32.16.- <b>FC&#038;P 13-1</b>, p. 12,
ID=6345^<b>Topic(s): </b>reefs mineralization Pb-Zn; reefs, Pb-Zn
minerals; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Un certain nombre de gisements Pb-Zn sont localisés dans des
formations récifales d&#039;âge et de nature différents. Parmi les plus
importants, citons: * dans le Cambrien de la plate-forme stable des
USA, le district du Missouri Sud-Est (biohermes à stromatolithes); *
dans le Dévonien du Canada, le district de Pine Point (barrière
récifale à stromatoporoïdes et polypiers); * dans le Carbonifère
d&#039;Irlande, les gisements de Tynagh et Silvermines (&#34;mud
mounds&#34; à stromatactis); * dans le Trias des Alpes orientales, les
gisements de Salafossa, Raibl, Bleiberg, Mezica (plate-forme carbonatée
ladino-carnienne interprétée par de nombreux auteurs comme un vaste
complexe récifal); * dans le Crétacé du Nord de l&#039;Espagne, le
district de Reocin (complexe urgonien à rudistes et polypiers). * Ces
exemples démontrent, en première analyse, l&#039;importance des
formations récifales en tant que roches encaissantes de concentrations
plombo-zincifères. Ils indiquent aussi une certaine variété des
organismes constructeurs et de la morphologie des appareils récifaux. *
Cependant, sans vouloir simplifier à l&#039;extrême, on peut dire
qu&#039;il n&#039;existe pas de relations étroites entre la
sédimentation récifale et la présence de minéralisations &#8230;

taphonomy; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Reefs are susceptible to multiple physical, chemical and
biological taphonomic processes. Bioerosion, in particular has
escalated through time and might be expected to have influenced the
taphonomy of reefs. The following biases can be predicted: (1) In the
absence of grain-reducing activities by reef biota (fish, echinoids,
and clionid sponges) abrasion on Paleozoic reefs would have been
dominated by physical processes and sediment grains may have been more
coarse. (2) Increased bioerosion since the Jurassic is such that modern
reefs are quickly reduced to rubble and sand leaving only the resilient
branching corals and thick coralline algae. By contrast, many
pre-Jurassic reefs commonly preserve intact, in situ frameworks that
include massive or laminar, often soft-sediment-dwelling, growth forms.
(3) After the appearance of reef fish in the Eocene, sediment
production and distribution within reef complexes is likely to have
increased markedly but this has not yet been fully elucidated. (4)
Escalation in rates of bioerosion from the Miocene onwards are such
that it can be expected that substantial aprons of reef-slope sediment
may not have been present on pre-Miocene reefs. [first part of

s[6645] = "FAGERSTROM J.A., WEST R.R. (2010).- Roles of clone-clone
interactions in building reef frameworks: principles and examples.-
Facies [on-line first].- <b>FC&#038;P 36</b>, p. 125,
ID=6575^<b>Topic(s): </b>reef frameworks, clonal organisms; reef
frameworks; <b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^In living and fossil reefs, rapid upward clone growth provides
positive topographic relief; the skeletal framework provides rigidity.
Clonal organisms have been the chief frame-builders during most of the
Phanerozoic; large clone size, growth habit, growth form, and
arrangement of these clones in the framework result from rapid growth
rates. Dense skeletal packing enhances rigidity and results in
live-live interactions between juxtaposed clones. These interactions
are both heterospecific and conspecific; the former mostly involve
spatial competition whereas the latter involve clone fusion,
self-overgrowth and fission. We describe three types of fusion: a)
inter-clone fusion of two or more clones, each from a separate
propagule; b) intra-clone fusion of parts of the same clone having its
origin from a single propagule; it includes recovery from partial clone
degradation and self-overgrowth; c) quasi-fusion between a live
bud/polyp/zooid and a dead part (stem; branch) of the same or a
different clone, i.e. a live-dead association. [original abstract]^1";

<b>FC&#038;P 14-1</b>, p. 71, ID=6627^<b>Topic(s): </b>phylogeny, tree
of life; systematics, phylogeny; <b>Systematics: </b>; <b>Stratigraphy:
</b>; <b>Geography: </b>^This is the first of three volumes. The books
describes the phylogenetic system of modern organisms. Fossil
organisms, as far as possible, are also included. The system of
organisms is quite new and certainly much more adequate to the natural
system than the old-fashioned one including two kingdoms of plants and
animals. All orders including most families are thoroughly described
and excellently illustrated by drawings. Latest scientific results are
included. The morphology, anatomy, cytology, embryology, ontogeny,
reproduction, life habitat, nutrition and behaviour, phylogeny and many
other things are reported. * About 100 pages are dealing with sponges
and about 200 with coelenterates. This important book represents a
treasure of information. It can be recommended to every biologist and
palaeontologist and should be available in every scientific library.

</b>biographical; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^On the 1st of December 1990. Jean Gabriel Lafuste
passed away in La Rochelle (France) [&#8230;] Jean Gabriel was a man of
principles - very many principles to which he arrived by his own
original thinking. From the very beginning he rejected the idea to
present a doctoral thesis. For him a person early in his career cannot
suggest a valuable thesis. It should then be postponed towards the end
of the career but by then most of the data is already published and
discussed. Consequently a thesis is rather a waste of time. Poor
Lafuste, he ran into considerable trouble because of this! On the other
hand he insisted on perfectly documented and illustrated short clear
notes which brought substantial new data. [&#8230;] Jean Gabriel has
revolutionized not only the study of tabulate corals by recognizing in
great detail a hierarchy of basic microstructural elements
(microlamellae, lamellae, fibres) with a typical disposition and a
transition in time characteristic of each genus, but also that of
rugose corals where he discovered microstructural analogy. He
contributed to microstructural comprehension in other groups of fossil
and Recent organisms such as Archaeocyatha, Sponges Stromatopora,
Bryozoans, Tentaculites and investigated also higher groups -
cephalopods, fish scales and others. [excerpts from an obituary]^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^John&#39;s first publications
(in 1930/32) were on scleractinian corals and these continued to be the
main focus of his research; over half of his 175+ publications over the
next 58 years addressed some aspect of scleractinian biology. He
published regularly on Cenozoic and Mesozoic Scleractinia throughout
his career, but not until 1950, coincident with his fieldwork at Arno
Atoll, did he seriously begin to publish on Recent Scleractinia. His
collaboration with T.W. Vaughan, on the &#34;The revision of the
suborders, families, and genera of the Scleractinia&#34; (1943a), is
perhaps his greatest contribution to coral biology. This monograph was
the first modern synthesis of the higher-level classification of the
Scleractinia (the next proceeding being that of Duncan in 1885) and is
the basic reference for most coral workers. The monograph includes not
only diagnoses and keys to all the scleractinian higher taxa, but a
summary of coral anatomy and morphology, reproduction, ecology,
distribution, and evolution, and an extensive bibliography. This
seminal work set the stage for Wells&#039; later account of the
Scleractinia in the &#34;Treatise on Invertebrate Paleontology&#34;
(1956d) and finally an updated list of all scleractinian generic and
subgeneric names and their type species (1986b, 1987b). [excerpt from
an obituary; attached is Wells&#039; portrait and a list of his
publications (1930-1988)]^1";

s[6670] = "FOOTE M. (1996).- On the probability of [finding] ancestors
in the fossil record.- Paleobiology 22, 2: 141-151.- <b>FC&#038;P
25-2</b>, p. 35, ID=6871^<b>Topic(s): </b>phylogeny, evolutionary
theory; phylogeny; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^Three homogeneous models of species origination and
extinction are used to assess the probability that ancestor-descendant
pairs are preserved in the fossil record. In the model of cladogenetic
budding, a species can persist after it branches and can therefore have
multiple direct descendants. In the bifurcation model, a species
branches to give rise to two distinct direct descendants, itself
terminating in the process. In the model of phyletic transformation, a
species gives rise to a single direct descendant without branching,
itself tenninating in the process. Assuming homogeneous preservation,
even under pessimistic assumptions regarding the completeness of the
fossil record, the probability of finding fossil ancestor-descendant
pairs is not negligible. [initial part of an abstract; for full text

```

```
stratigraphic ranges of taxa.- Paleobiology 22, 2: 121-140.-
<b>FC&#038;P 25-2</b>, p. 35, ID=6872^<b>Topic(s): </b>phylogeny,
evolution rate; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>^The incompleteness of the fossil record hinders the
inference of evolutionary rates and patterns. Here, we derive
relationships among true taxonomic durations, preservation probability,
and observed taxonomic ranges. We use these relationships to estimate
original distributions of taxonomic durations, preservation
probability, and completeness (proportion of taxa preserved), given
only the observed ranges. No data on occurrences within the ranges of
taxa are required. When preservation is random and the original
distribution of durations is exponential, the inference of durations,
preservabihty, and completeness is exact. However, reasonable
approximations are possible given non-exponential duration
distributions and temporal and taxonomic variation in preservabihty.
Thus, the approaches we describe have great potential in studies of
taphonomy, evolutionary rates and patterns, and genealogy. [first part
of an extensive abstract; for full text see http:&#47;&#47;

<b>Stratigraphy: </b>; <b>Geography: </b>^My interest and memory were
recently stirred by reading that Florence Bascom was the first woman to
earn a Ph.D. in geology from an American institution; this in 1893
(Geotimes, November 1996, p. 12). Not so: Cnidarologists should know
that the first was earned some five years earlier by a woman studying
Paleozoic (mostly Devonian) corals. Mary Emilee Holmes earned a Ph.D.
in paleontology from the University of Michigan in 1887 (Geotimes,
November 1986, p. 11) or 1888 (Arnold 1977, Geology v.5, p.493).
Holmes&#039; thesis, The Morphology of the Carinae upon the Septa of
Rugose Corals, was accepted by her Committee (Alexander Winchell and
others) on June 20, 1887, and published that same year in Boston by
Bradlee Whidden. According to Arnold, Holmes was the first woman Fellow
of the Geological Society of America, elected in May 1889 (Bascom
became the second woman Fellow in 1894). [full text of a short note]^1";

<b>Stratigraphy: </b>; <b>Geography: </b>^On the 22 of October 1998, in
the city Orel (Russia), during the lecture talking in the Orel
Pedagogic Institute, suddenly died famous palaeontologist, prominent
investigator of Rugose Corals from Middle Asia, Doctor of
Geological-Mineralogical Sciences, Professor Alexander Lavrusevich. *
Alexander was born at 18 January 1930 in Byelorussia. In 1941, on the
beginning of the war between Germany and USSR together with his parents
he was removed from Byelorussia to Tadjikistan. In 1948 he was entering
and in 1953 was graduating the Department of Geology of Tadjik State
University. After graduating from the University he worked in Tadjik
Geological Goverment Department. On 1957 he began studing of Rugose
Corals from Palaeozoic of Middle Asia. A.I. Lavrusevich reveal very big
diversity of Rugose Corals from South Thian Shan. He collected,
determited and described about 20000 patterns belonging to 250 species
and 100 generas of Upper Ordovician, Silurian and Lower Devonian Rugose
Corals from Central Tadjikistan. Alexander discovered and described 22
new genera of Rugose Corals: Amandaraia Lavrusevich, 1968; Chavsakia
Lavr., 1959; Cruciphyllum Lavr., 1976, Cystipaliphyllum Lavr., 1964;
Farabophyllum Lavr., 1971; Gissarophyllum Lavr., 1964;
Heterophrentoides Lavr., 1991; Isfaraia Lavr., 1991; Ketophylloides
Lavr., 1971; Maikotia Lavr., 1967 a.o. During 1966-1991 he worked in
the Department of Geology of Tadjik State University. At 1991 he was
leaving from Dushanbe to Orel and began to teach in the Orel Pedagogic
Institute. Alexander Lavrusevich authored 60 scientific papers, many of
them on corals. [original text]^1";

s[6692] = "ADACHI N., LIU J. &#038; EZAKI Y. (2012).- Early Ordovician
stromatoporoid Pulchrilamina spinosa from South China: geobiological
significance and implications for the Early development of
skeletal-dominated reefs.- Paleontological Research 16, 1: 59-69.-
<b>FC&#038;P</b> 37, 013, ID=7264^<b>Topic(s): </b>skeletal reefs;
<b>Systematics: </b>Porifera, Stromatoporoidea; <b>Stratigraphy:
</b>Ordovician L, Tremadocian-Floian; <b>Geography: </b>China S, Hubei
&#038; Guizhou^The thin, laminar to low domical, encrusting
stromatoporoid Pulchrilamina spinosa is reported from the
Tremadocian-Floian in Hubei and Guizhou provinces, South China. The
Chinese Pulchrilamina appeared earlier (late Tremadocian-early Floian)
than North American equivalents (early Floian), which possess large
domical forms and are the main framework-builders. Pulchrilamina
appeared much earlier than the observed diversification of other
stromatoporoids. These skeletal reef-builders thus provide excellent
clues for understanding the initial evolution of the stromatoporoids
and the subsequent development of the skeletal-dominated (especially
stromatoporoid - dominated) reefs that reached their first acme in the
late Middle-Late Ordovician.^1";
s[6693] = "ALLISON N., TUDHOPE A.W. &#038; EIMF (2012).- The skeletal
geochemistry of the sclerosponge Astrosclera willeyana: Implications
for biomineralisation processes and palaeoenvironmental
reconstruction.- Palaeogeography, Palaeoclimatology, Palaeoecology
313-314: 70-77.- <b>FC&#038;P</b> 37, 013, ID=7265^<b>Topic(s):
</b>sclerosponge skeleton, chemistry; <b>Systematics: </b>Porifera,
Astrosclera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>^To
investigate the controls on the geochemistry of aragonitic sclerosponge
skeletons, we used secondary ion mass spectrometry (SIMS) to analyse an
Astrosclera willeyana specimen. The high spatial resolution of SIMS
allows the independent analysis of the two key crystal structures in
the skeleton i.e. the fused spherulites (formed intracellularly and
fused together at the surface of the skeleton) and the epitaxial
backfill (deposited extracellularly at the base of the sponge tissue).
We analysed Sr/Ca, Mg/Ca and Ba/Ca across a short (~5mm) transect of
fused spherulites which represented several years growth. We observe
cyclical variations (with a length of 0.1 to 0.6 mm in both Sr/Ca and
Mg/Ca in some (but not all) sections of the transect. The observed
ranges of Sr/Ca and Mg/Ca over the presumed seasonal cycles are ~9.5 to
11.5 mmol mol-1 and 0.6 to 1.0 mmol mol-1 respectively. The annual
seawater temperature range at the study site is ~4.3&#176;C, so the
inferred temperature sensitivity of skeletal Sr/Ca and Mg/Ca is ~0.5
mmol mol-1&#176;C (or 5%&#176;C-1) and ~0.1 mmol mol-1&#176;C (or
13%&#176;C-1) respectively. This is higher than observed in most
previous sclerosponge studies or anticipated from studies of synthetic
aragonite. This indicates that the chemistry of the A. willeyana
skeleton is affected by one or more additional influences, besides
temperature, which are currently unresolved. The pH of the
precipitating fluid, estimated from skeletal &#948;11B, is ~8.1-8.2 for
both fused spherulites and epitaxial backfill. Epitaxial backfill
contains significantly higher Sr/Ca, Mg/Ca and B/Ca and significantly
lower Ba/Ca than the fused spherulites but Sr/Ca and Mg/Ca are
positively correlated by the same relationship in both skeletal
features. This suggests that the geochemistry of each feature is
predominantly controlled by a common process. This is unlikely to be
Rayleigh fractionation, which is indicated by negative correlations
between Sr and Mg in aragonite.^1";

```

```
compounds called sponge biomarkers.- Palaeontology 56, 5: 917-925.- <b>FC&#038;P</b> 37, 014, ID=7266^<b>Topic(s): </b>organic compounds, presumed sponge biomarkers; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Proterozoic, Cryogenian, Huqf Supergroup; <b>Geography: </b>Oman^Elevated concentrations of an organic compound, 24-isopropylcholestane, found in the Precambrian Huqf Supergroup of Oman may provide the oldest known sponge &#039;fossil&#039;. This evidence is of critical importance for a properly balanced understanding of the origin of animals. Several different pelagophyte (class Pelagophyceae part of the Stramenopiles within the Chromaveolata) algae are also capable of producing these exact compounds, and may similarly have done so in deep time. Modern marine algae are also reported to produce structural isomers that are compositionally identical to the sponge marker; they do this in copious quantities. Further, 24-isopropylcholestane can be produced by diagenetic alteration of compounds produced in large quantities by algae. It is also possible that contamination by petroleum derived lubricating oil used when coring while extracting these compounds from subsurface layers, has affected the data. All extinct organisms that may have produced this compounds are unavailable for analysis by the modern organic chemist and cannot be eliminated from the list of possible producers of the sponge marker. There are also significant uncertainties regarding the dating of the strata from which these ancient compounds are found. Although the compounds are widely reported as c. 751 Ma, they are younger than 645 Ma. It seems more likely that these compounds represent algal biochemical evolution at a time when algal burial occurred in great quantity with well known coeval algal fossils but no sponge fossils. The macroalgal biomass may have declined during the agronomic revolution at the base of the Cambrian Period owing to processing by metazoans, accounting for the comparative scarcity of these sponge markers in Phanerozoic sediments, after which time sponge spicules and body fossils become evident.^1";
s[6695] = "BOGOYAVLENSKAYA O.V. &#038; ELKIN Yu.A. (2011).- Klassifikacya paleozoyskikh i mezozyskikh gidroidnykh polipov i centry ikh vozniknoveniya [Classification of Paleozoic and Mesozoic hydroid polyps and their centers of origin; in Russian].- Litosfera 2011, 2: 13-30.- <b>FC&#038;P</b> 37, 015, ID=7267^<b>Topic(s): </b>stromatoporoids (as hydrozoans); <b>Systematics: </b>Stromatoporata; <b>Stratigraphy: </b>Paleozoic, Mesozoic; <b>Geography: </b>^In the paper are traced the development of some morphological features of Paleozoic and Mesozoic Stromatoporata (hydroid polyps). On the basis of evolution of astrorhizal elements is confirmed the status of this group in system of Hydrozoa . Paleozoic Stromatoporata and Mesozoic Sphaeractinoidea are equivalent representatives of class Hydrozoa, phylum Cnidaria. It is offered the new revised system of this group: 3 subclasses, 19 orders and 43 families are singled out. The 100 genera of Stromatoporata and Sphaeractinoidea are analyzed. Connections between Paleozoic Stromatoporata and Mesozoic Sphaeractinoidea hydroid polyps are considered. Morphology of a skeleton and progress of astrorhiza are analyzed. Relations of evolution of fossil hydroid polyps with maxima of tectonic-magmatic cycles are recognized. The centers of origin of fossil hydroids at the end of Baikal and the beginning Caledonian cycles have been connected with the Ural-Mongolian belt. Mesozoic Stromatoporata have been connected with the seas of Tethys ocean. For the determining of centers of origin and distribution is used the method of geohistorical biogeography.^1";
s[6696] = "BOTTING J.P. &#038; MUIR L.A. (2013).- Spicule structure and affinities of the Late Ordovician hexactinellid-like sponge Cyathophycus loydelli from the Llanfawr Mudstones Lagerst&#228;tte, Wales.- Lethaia 46, 4: 454-469.- <b>FC&#038;P</b> 37, 016, ID=7268^<b>Topic(s): </b>early sponges; <b>Systematics: </b>Porifera, ?Hexactinellida; <b>Stratigraphy: </b>Ordovician L, Sandbian;
```

```
<b>Geography: </b>UK, Wales^Exceptionally well-preserved specimens of
the reticulosan sponge Cyathophycus loydelli from the Sandbian (Late
Ordovician) Llanfawr Mudstones Formation of Llandrindod, Wales, UK,
have been examined using scanning electron microscopy (SEM). The
specimens include exquisitely detailed pyritized spicules, and granular
pyritization of surrounding soft tissues. Spicules frequently show
axial canals of diameter similar to those of modern siliceous sponges,
with hexagonal symmetry typical of modern demosponges rather than
hexactinellids. In one case, the axial filament is also preserved. The
largest spicules (ray diameter >20&#956;m) show a complex structure,
with a laminar external region similar to that of the extant
hexactinellid Monorhaphis. Some spicules preserve sub-micron detail of
the spicule surface, resembling the reticulate collagenous sheath of
Monorhaphis. The hexagonal symmetry of the canal confirms that at least
some Reticulosa are not crown-group hexactinellids, but stem-group
Hexactinellida or Demospongea, or stem-group Silicea. This suggests
that a square canal is a sufficient diagnostic feature of total-group
Hexactinellida, but that hexagonal canals were more widely distributed
among Early Silicea and were probably not restricted to demosponges.
Alternatively, comparison with the structure of modern verongiid fibres
suggests that these may be homologous with the outer layers of
Cyathophycus spicules, and Cyathophycus may instead be a stem-group
demosponge. The preserved detail of the surface layer shows that
pyritization can preserve certain material with extraordinarily fine
resolution.^1";

(2012).- An enigmatic, possibly chemosymbiotic, hexactinellid sponge
from the early Cambrian of South China.- Acta Palaeontologica Polonica
58, 3: 641-649.- <b>FC&#038;P</b> 37, 017, ID=7269^<b>Topic(s):
</b>chemosymbiotic (?) sponges, taxonomy; <b>Systematics: </b>Porifera,
Hexactinellida; <b>Stratigraphy: </b>Cambrian L, Tommotian-Atdabanian;
<b>Geography: </b>China S^Six specimens of a strongly curved,
cylindrical hexactinellid sponge have been recovered from the
Tommotian-Atdabanian Hetang Biota of South China, and are described as
Decumbispongia yuani gen. et sp. nov. The robust, thick-walled sponge
shows no evidence of an osculum or basal structures, and the body form
is inconsistent with an upright, filter-feeding life position.
Interpretations as a detritivore feeding by amoeboid extensions, or as
a facultative chemosynthetic symbiosis of sponge and bacteria are
considered. The latter interpretation is preferred due to the highly
constrained body shape, and the body form is interpreted from this
perspective. The species indicates that Cambrian sponges occupied at
least some autecological niches that appear to have been vacant since
that time.^1";

(2012).- Evidence for spicule homology in calcareous and siliceous
sponges: bimineralic spicules in Lenica sp. from the Early Cambrian of
South China.- Lethaia 45, 4: 463-475.- <b>FC&#038;P</b> 37, 017,
ID=7270^<b>Topic(s): </b>bimineralic sponge spicules, phylogeny;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Cambrian L, Hetang
biota; <b>Geography: </b>China S^The relationships of the extant sponge
classes, and the nature of the last common ancestor of all sponges, are
currently unclear. Early sponges preserved in the fossil record differ
greatly from extant taxa, and therefore information from the fossil
record is critical for testing hypotheses of sponge phylogenetic
relationships that are based on modern taxa. New specimens of the
enigmatic sponge Lenica sp., from the Early Cambrian Hetang Biota of
South China, exhibit an unusual spicule structure. Each spicule
consists of a siliceous core with an axial canal, an organic outer
layer and a middle layer interpreted to have been originally calcium
carbonate. This finding confirms previous work suggesting the existence
of bimineralic spicules in early sponges. Combined with data from
other early sponges, the new findings imply that the two fundamental
```

```
spicule structures of modern sponges were derived from a compound,
bimineralic precursor. Spicules are therefore homologous structures in
Calcarea and Silicea, and if sponges are paraphyletic with respect to
Eumetazoa, then spicules may also have been a primitive feature of
Metazoa.^1";

Stromatoporoid palaeoecology in the Frasnian (Upper Devonian) Belgian
platform, and its applications in interpretation of carbonate platform
environments.- Palaeontology 54, 4: 883-905.- <b>FC&#038;P</b> 37, 018,
ID=7271^<b>Topic(s): </b>stromatoporoids, ecology; <b>Systematics:
</b>Porifera, Stromatoporoidea; <b>Stratigraphy: </b>Devonian L,
Frasnian; <b>Geography: </b>Belgium, Ardennes^Stromatoporoid faunas in
the Frasnian of southern Belgium are abundant in the carbonate platform
environments present in this area. Stromatoporoids dominate the large
skeletal organisms and occur principally in biostromes. The
stromatoporoid assemblage is represented by a small number of taxa.
Stromatoporoid genera include Actinostroma, Amphipora, Atelodictyon,
Clathrocoilona, Salairella, Stachyodes, Stictostroma, Stromatopora and
Trupetostroma which are present in environments ranging from the outer,
outer intermediate, inner intermediate and inner zones and associated
biostromes. Most large skeletal stromatoporoids are low profile, which
reinforces the conclusions of previous studies that low-profile growth
forms were the most successful stromatoporoid forms. These low-profile
forms are likely to have been important sediment stabilisers that may
have led to expansion of the carbonate factory. Growth forms vary
between facies, indicating some degree of environmental control on
form, for example, laminar in the intermediate zone, bulbous and
domical in the inner and outer zones. Stromatoporoid taxa vary in
occurrence across the environmental gradient from shallow to deep.
There is some taxonomic control on growth forms, with some taxa showing
more variability than others in different environments.^1";
s[6700] = "DA SILVA A.-C., KERSHAW S. &#038; BOULVAIN F. (2011).-
Sedimentology and stromatoporoid palaeoecology of Frasnian (Upper
Devonian) carbonate mounds in southern Belgium.- Lethaia 44: 255-274.-
<b>FC&#038;P</b> 37, 018, ID=7272^<b>Topic(s): </b>carbonate mounds,
stromatoporoids, sedimentology, ecology; <b>Systematics: </b>Porifera,
Stromatoporoidea; <b>Stratigraphy: </b>Devonian L, Frasnian;
<b>Geography: </b>Belgium, Ardennes^Stromatoporoids are the most
abundant large skeletal organisms in middle Frasnian carbonate mound
environments of southern Belgium. They occur in environments ranging
from flank and off-mound, mound core, shallow mound and restricted
mound. A detailed log and comprehensive sampling of stromatoporoids in
a single section cutting through all middle Frasnian mound levels in La
Boverie-Rochefort Quarry, near Rochefort and Dinant reveals a
stromatoporoid assemblage comprising 10 genera, 472 samples, containing
an overall total of 3079 stromatoporoids (including complete and
fragmented specimens) have been studied. The following list gives
abundance using numbers of specimens and areas of total stromatoporoid
area on outcrop surfaces (% number, % area in cm2): Actinostroma (0.4,
9.2), Amphipora (15.5, 1.7), Atelodictyon (0.2, 4.4),
Clathrocoilona(0.3, 0.5), Euryamphipora (13.7, 0.7), Idiostroma (2,
1.9), Salairella (1.2, 9.6), branching Stachyodes (43.2, 59.1), laminar
Stachyodes australe (1.9, 1.3), Stictostroma (4.8, 13.1) and
Trupetostroma (0.2, 0.8), showing that Stachyodes is approximately half
of the total assemblage. Deeper environments contain more abundant low
profile forms, shallow water facies contain more domical and bulbous
forms, branching forms are ubiquitous. Low profile stromatoporoids are
likely to have been important sediment stabilizers that may have led to
expansion of the carbonate factory, and they may have therefore
contributed to the structural building of the mounds.
Stromatoporoid-coral intergrowths are observed in only Stictostroma
suggesting that there is a close biological relationship between them,
however, stromatoporoid skeletons in almost all cases appear to be
```

```
unaffected by the presence of intergrown corals, suggesting they were
commensals.^1";

111, ID=7274^<b>Topic(s): </b>corals, stromatoporoids, taxonomy, reefs;
<b>Systematics: </b>Cnidaria, Anthozoa, Porifera, Stromatoporoidea;
<b>Stratigraphy: </b>Devonian L, Pragian L; <b>Geography: </b>Spain N,
Cantabrian Zone^The oldest reefal episode in the Cantabrian Zone
(earliest Pragian) consists of small biostromal patch reefs, mainly
built by corals and stromatoporoids, and developed on a storm-dominated
ramp. Four outcrops provide the stratigraphic framework in which these
reef facies developed, and these permitted an interpretation of their
depositional setting in terms of a relatively distal or protected
shelf. We systematically describe three species of rugose corals, five
species of tabulate corals, and six species of stromatoporoids. This
fauna is allocated to three Pragian fossil associations. Association 1
is mainly composed of massive tabulate corals and stromatoporoids.
Association 2 contains dominant branching rugose and tabulate corals.
Finally, association 3 is represented by tiny massive tabulate corals.
Each association occurs at a specific location within a framework of
high-frequency deepening upward cycles, being related to a specific
depositional setting. This mode of occurrence suggests that their
development was tuned by relative base-level oscillations, forming
during rises that took the sea-bottom to relatively deep or sheltered
conditions, with rare reworking by storm-related currents. Finally, a
comparison of this reefal fauna with examples of similar age from
elsewhere is presented in order to explore their affinities.^1";
s[6703] = "FINKS R.M. (2010).- The Sponge Family Guadalupiidae in the
Texas Permian.- Journal of Paleontology 84, 5: 821-847.-
<b>FC&#038;P</b> 37, 020, ID=7275^<b>Topic(s): </b>taxonomy, new taxa;
<b>Systematics: </b>Porifera, Guadalupiidae; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>USA, Texas W^New and old species and
genera of the family Guadalupiidae (spherulitic hypercalcified
demosponges of the order Agelasida) are described or redescribed from
the West Texas Permian. The entire family is reviewed and observations
are made on the epibionts, growth patterns, functional morphology,
ecological relationships, morphologic variability, modular structure,
and evolutionary history of these largely reef-dwelling sponges. The
stratigraphic distribution of species is also noted; many are limited
and can define zones. The new genera Exovasa and Incisimura and the new
species Guadalupia auricula, G. cupulosa, G. ramescens, G. microcamera,
G. vasa, Cystothalamia megacysta, Lemonea simplex, Incisimura bella,
and Exovasa cystauletoides are described. Almost all previously
published taxa are redescribed and in some cases redefined. The
```

```
Guadalupiidae are unique among hypercalcified sponges in having a
modular thalamid layer (thalamidarium) covered on the exhalant surface
by a non-modular stromatoporoid-like layer (trabecularium).^1";

</b>microfossils, sponge-like; <b>Systematics: </b>?Porifera,
??Hexactinellida; <b>Stratigraphy: </b>Meso/Neoproterozoic, Lakhanda
Fm; <b>Geography: </b>Russia, Siberia SE, Maya River^New microfossils
of presumably sponge organization grade have been recorded in the
Meso-Neoproterozoic boundary beds of the Riphean Lakhanda Formation
(Maya River, Uchur-Maya Region, southeastern Siberia). Because of the
microscopic size, they remained invisible for a long time among
abundant green algae on the surface of individual acritarchs in
associations with nematode-like organisms and zygotes and suspensors of
fungal microfossils. The specimens were found during a reexamination of
the type material of Annulusia annulata Timofeev et Hermann, 1979,
fixed on biofilms. The biofilms have shown the presence of very small,
abundant, colonial organisms represented by aggregations of cells
tightly connected in a soft tissue structure. In morphological
characters, mode of life, occurrence of spicule-like structures,
symmetry of their body, with a central canal positioned at the apex and
interpreted here as an osculum, they are considered to be similar to
the sponges Demospongiae and Hexactinellida. The microfossils with a
syncytium and collagen-fibrous network (amorphous body) resemble the
sponge class Hexactinellida.^1";

key; <b>Systematics: </b>Porifera, Archaeocyatha; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>^The Archaeocyatha are a key group in
several of the many discrete disciplines that together make feasible a
valid history of the Earth: they are the oldest of the calcified
sponges, the first metazoans to build reefs (in association with
calcimicrobes), are characteristic fossils used for the biozonation of
the first, pre-trilobitic Cambrian stage (Tommotian). To date, a valid
key to their identification has not been available, so a tool for that
purpose has been devised: it was created using the software XPER2, and
is now available free, online. Published in English, the knowledge base
includes the 307 valid described genera identified by 120 descriptors
(85 morphological and ontogenetic, 8 stratigraphic and geographic and
27 taxonomic). A key to identification is supplemented by detailed
descriptive cards with images of type specimens of each genus and
details of their morphology that aid identification. [identification
key is available at http://www.infosyslab.fr/archaeocyatha]^1";
s[6706] = "KHROMYKH V.G. (2010).- Evolution of Stromatoporoidea in the
Ordovician-Silurian epicontinental basin of the Siberian Platform and
Taimyr.- Russian Geology and Geophysics 51: 684-693.- <b>FC&#038;P</b>
37, 22, ID=7278^<b>Topic(s): </b>stromatoporoids, phylogeny;
<b>Systematics: </b>Porifera, Stromatoporoidea; <b>Stratigraphy:
</b>Ordovician, Silurian; <b>Geography: </b>Russia, Siberian Platform,
Taimyr^The paper discusses the evolution of Stromatoporoidea in the
epicontinental sedimentary basin of the Siberian Platform and Taimyr
during the Ordovician and Silurian. Specimens of the oldest genus,
Priscastroma, were found in the middle of Middle Ordovician sediments.
This genus is represented by the species P. gemina Khrom., which has
two forms, A and B. Tracing the emergence of new genera over time, we
identified two distinct branches in stromatoporoid evolution. The
ancestor of the first branch is P. gemina f. A, which gave rise to the
genus Cystostroma. The latter is the ancestor of two subbranches with
```

```
predominant horizontal skeletal elements. The subbranches differ only
in tissue microstructure. The genera Stromatocerium, Dermatostroma, and
Aulacera display dense fibrous microstructure, whereas the genus
Rosenella and its descendants display dense microstructure. The genus
Lophiostroma, with a lamellar-fibrous tissue, may be a dead branch of
evolution. The ancestor of the second branch is P. gemina f. B, which
gave rise to the genus Labechia and its descendants. This branch has a
dense tissue, with predominant vertical skeletal elements. Ordovician
stromatoporoids from Siberia were compared with those from other basins
of the world. Comparison shows that all the Ordovician genera from the
epicontinental basin of the Siberian Platform and Taimyr originated
here. Thus, this basin was one of the centers of stromatoporoid
origin.^1";
s[6707] = "MAY A. &#038; RODRIGUEZ S. (2012).- Pragian (Lower Devonian)
stromatoporoids and rugose corals from Zujar (Sierra Morena, southern
Spain).- Geologica Belgica 15, 4: 226-235.- <b>FC&#038;P</b> 37, 022,
ID=7279^<b>Topic(s): </b>taxonomy, new taxa, reef biota, biogeography;
<b>Systematics: </b>Porifera, Stromatoporoidea, Cnidaria, Rugosa;
<b>Stratigraphy: </b>Devonian L, Pragian; <b>Geography: </b>Spain,
Obejo-Valsequillo-Puebla de la Reina Domain^The locality Zujar at the
boundary between the Badajoz and Cordoba provinces belongs to the
Obejo-Valsequillo-Puebla de la Reina Domain. Within the fossiliferous
reefal carbonates of Pragian age cropping out in Zujar, 10
stromatoporoid species and 7 rugose coral species are identified. The
new rugose coral species Martinophyllum miriamae n. sp. is described.
Hexagonaria soraufi Rodriguez Garcia, 1978 is a subspecies of
Martinophyllum ornatum Jell &#038; Pedder, 1969. The Pragian fauna of
Zujar is a typical fauna of the Old World Realm with remarkably close
relationships to Arctic Canada and Australia. Most species have been
recorded for the first time from Spain. No significant relationships to
the Eastern Americas Realm are visible. Remarkable is, that none of the
stromatoporoid species of Zujar is known from the famous Pragian reef
complex of Koneprusy in Bohemia, meanwhile the rugose coral fauna (e.g.
Joachimastraea barrandei Galle, Hladil &#038; May, 1999) shows some
relations. Some of the species found are ancestors of important
constructors of the Middle Devonian reef complexes, demonstrating that
the roots of the Givetian-Frasnian reef complexes reach down to the
Pragian.^1";

</b>Porifera, Stromatoporoidea; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Belgium, Ardennes^Previous studies of the
stromatoporoid palaeobiodiversity in the Devonian of the Ardennes are
revised. The data set used in this study consists of 3416 specimens of
180 species. The rarefaction method was employed in order to reduce
sampling bias in the diversity curves. The estimated stromatoporoid
diversity reached its plateau in the Eifelian (Couvin Formation) and in
the Givetian, and decreased during the Late Devonian.^1";
s[6715] = "WOLNIEWICZ P. (2012).- Same taxonomic name, different
species: a threat to stromatoporoid biodiversity research.- Geologica
Belgica 15, 4: 236-244.- <b>FC&#038;P</b> 37, 026, ID=7287^<b>Topic(s):
</b>taxonomy, biodiversity; <b>Systematics: </b>Porifera,
Stromatoporoidea; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Belgium, Ardennes, Poland, Holy Cross Mts^Taxonomic inconsistencies
between two published collections of Devonian stromatoporoids were
examined. The studied collections contain stromatoporoids sampled from
the Middle and Upper Devonian from the Ardennes (collection by
Lecompte) and the Holy Cross Mountains (collection by Kazmierczak). The
study was limited to stromatoporoid species that were assigned to the
order Stromatoporellida. At least eight species which were described
from the Devonian of both the Ardennes and the Holy Cross Mountains
should be revised: F. ruedemanni, H. crassum, H. porosum, H.
perseptatum, S. lensiforme, S. socialis, T. laceratum, T. pingue.
Specimens that were assigned to C. damnoniensis, C. spissa, H.
episcopale, H. schlueteri, P. cellulosum and S. huronense do not need
to be revised. The inconsistencies may severely influence the outcome
of palaeogeographic and biodiversity studies, since the error is not
distributed randomly among stratigraphic intervals and it affects
classification at the genus-level.^1";
s[6716] = "WOLNIEWICZ P. (2013).- The limited value of traditional
morphometric features in stromatoporoid taxonomy.- Palaeontology 56, 5:
947-959.- <b>FC&#038;P</b> 37, 027, ID=7288^<b>Topic(s): </b>taxonomy,
diagnostic features; <b>Systematics: </b>Porifera, Stromatoporoidea;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>^The morphological
variation of stromatoporoids, which are solitary organisms, is
partitioned into its presumably genetic and environmental components.
Potentially heritable, environmentally mediated and residual components
of morphological variability were estimated in a test set containing
Devonian stromatoporoids of the genus Gerronostromaria from southern
Poland using analysis of variance. The taxonomic importance of
traditional morphometric features is limited, because they are
dominated by the intra-skeletal component of variance. Conventional
metrics were therefore replaced by stereological and textural
quantities. Both stereological and textural features are dominated by
the inter-skeletal and inter-locality components of variation and thus
may be valuable in taxonomic and environmental studies of
stromatoporoids. Statistical analyses of these characters (principal
```

```
component analysis and cluster analysis) were performed. Of 13
characters considered most useful in taxonomic studies, only five have
been used previously in conventional species definitions.^1";

research on the Archaeocyaths.- Acta Palaeontologica Sinica 51, 2:
222-237.- <b>FC&#038;P</b> 37, 027, ID=7289^<b>Topic(s): </b>research
review; <b>Systematics: </b>Porifera, Archaeocyatha; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>China^Archaeocyatha (Porifera) were
an important group of marine sessile organisms during the Cambrian,
they evolved rapidly and were globally distributed during the Early
Cambrian. They are therefore important for biostratigraphic correlation
over large areas, nationally and internationally. In this paper we
review and discuss developments in classification and ideas of
relationships in the Class Archaeocyatha, particularly the work of
Debrenne et al. (2002). We highlight the need for a cladistic approach
in attempting to further clarify changing ideas about phylogenetic
relationships. In terms of biostratigraphy and palaeogeography, the
archaeocyaths of the Atdabanian, Botoman, and Toyonian Stages are
particularly useful for Early Cambrian stratigraphic correlation and
palaeobiogeographic analysis. We summarize the history and current
status of research on archeocyathan systematic, biostratigraphic, and
palaeogeographic distribution within China, as well as internationally,
and identify important foci of interest for further work - most notably
that they formed an important component of the Lower Cambrian carbonate
fauna of the Yangtze Platform.^1";

of parasitism in Devonian calcareous sponges (stromatoporoids).-
Parasitology 138, 1: 132-138.- <b>FC&#038;P</b> 37, 028,
ID=7291^<b>Topic(s): </b>endobionts, parasitism; <b>Systematics:
</b>Porifera, Stromatoporoidea, Torquaysalpinx; <b>Stratigraphy:
</b>Devonian M, Givetian; <b>Geography: </b>France, Ardennes, Mont
d&#039;Haurs section^* Introduction. Palaeozoic calcareous sponges
(stromatoporoids) are common bio-constructing fossils, they are
sometimes found in association with helicoidal structures of unknown
biological affinities. The interaction between the tube-forming
organisms has usually been classified as commensalism. ** Methods.
About 260 stromatoporoid skeletons from the Middle Devonian (Givetian)
of the Mont d&#039;Haurs section near Givet (Champagne-Ardenne, France)
were thin-sectioned and analysed under transmitted light. *** Results.
Approximately 10% of the examined stromatoporoids (mainly belonging to
the genera Actinostroma, Stromatopora and Stromatoporella) contain
tubes classified as Torquaysalpinx sp. The Torquaysalpinx organisms
penetrated the skeletons of stromatoporoids in vivo (as evidenced by
skeletal overgrowths), around the infesting organisms, growth bands are
bent down. **** Conclusion. Diminished growth rates around the
infesting organism demonstrate a negative influence on the host,
similar to that seen in the modern demosponge-polychaete association of
Verongia-Haplosyllis. This is demonstrated by changes in growth bands.
As in the above-mentioned association, the endosymbiont might have been
feeding directly upon the tissues of the host. The Torquaysalpinx
organisms were gaining habitat and possibly also food resources - for
them this interaction was clearly positive. This long-term association
can therefore be classified as parasitism. This is the first evidence
for parasitism in Palaeozoic sponges.^1";
s[6720] = "ARETZ M. (2010).- Habitats of colonial rugose corals: the
Mississippian of western Europe as example for a general
```

```
classification.- Lethaia 43: 558-572.- <b>FC&#038;P</b> 37, 029,
ID=7292^<b>Topic(s): </b>colonial corals, habitat classification;
<b>Systematics: </b>Cnidaria, Rugosa; <b>Stratigraphy:
</b>Carboniferous L; <b>Geography: </b>Europe W^Colonial rugose corals
are a major constituent of shallow-water marine benthic communities in
Mississippian times. The study of western European rugose coral
habitats from the base of the Tournaisian stage to the Serpukhovian
stage allows the recognition of four basic habitat types, which can be
divided into a total of 11 subtypes. The classification is mainly based
on field data, and thus rapidly applicable. Level-bottom communities in
which large colony distances are characteristic (type A) represent the
most basic community type, polyspecific (subtype A1) and monospecific
(subtype A2) subtypes occur. Reduced colony distances result in the
formation of coral meadows (type B), which either show homogenous coral
distribution (subtype B1) or the development of patches (subtype B2).
Coral biostromes (type C) represent a spectrum between hydrodynamically
controlled biostromes (nothing in place, subtype C1) and biologically
constructed and controlled biostromes (subtype C2). The bulk of the
biostromes represent mixtures of those two subtypes (subtype C3).
Colonial rugose corals are widely encountered in Mississippian bioherms
where they are dwellers (subtype D1), form capping beds (subtype D2),
support framework building along with other organisms (subtype D3) and
form coral framework (subtype D4). The latter is probably the most
uncommon of all subtypes in Mississippian times. The classification is
widely applicable to other groups.^1";
s[6721] = "ASHOURI A.R., ABBASI M.A. &#038; KHAKSAR K. (2010).-
Alborziphyllinae, a new Late Devonian Rugose corals subfamily.- Journal
of Sciences, Islamic Republic of Iran 21, 2: 131-136; Tehran.-
<b>FC&#038;P</b> 37, 030, ID=7293^<b>Topic(s): </b>taxonomy, new taxa;
<b>Systematics: </b>Cnidaria, Rugosa, Laccophyllidae, Alborziphyllinae;
<b>Stratigraphy: </b>Devonian L, Famennian, Khoshyeilagh Fm;
<b>Geography: </b>Iran, Alborz E^Members of the family Laccophyllidae
are small, solitary rugose corals with stratigraphic ranges from
Silurian to Permian. Among the laccophyllids, axial ends of major septa
are united in an aulos and dissepiments may be absent or present. Minor
septa can be contratingent and sometimes are small or in some genera
are absent. Septa and aulos may be thick or thin. In this study,
Famennian rugose corals of the Khoshyeilagh Formation in the north of
Meyghan village (35 km NE Shahrood, Eastern Alborz) have been
investigated for the first time. All the studied corals share their
common characteristics with family Laccophyllidae. Convincingly, based
on comparison of the presence of some key features among the collected
samples with characteristics of existed subfamilies of laccophyllids,
establishing a new subfamily can be essential. The Alborziphyllinae
(new subfamily) encompasses a Late Devonian laccophyllid lineage. The
new subfamily described here includes a new genus, Alborziphyllum and
two new species, Alborziphyllum ferdowsiense and Alborziphyllum
lonsdaleiforme.^1";
s[6722] = "BERKOWSKI B. (2012).- Life strategies and function of
dissepiments in rugose coral Catactotoechus instabilis from the Lower
Devonian of Morocco.- Acta Palaeontologica Polonica 57, 2: 391-400.-
<b>FC&#038;P</b> 37, 030, ID=7294^<b>Topic(s): </b>coral skeletons,
dissepiments, function; <b>Systematics: </b>Cnidaria, Rugosa;
<b>Stratigraphy: </b>Devonian L, Emsian; <b>Geography: </b>Morocco,
Anti-Atlas, Hamar Laghdad^This study focuses on the life strategies of
small, dissepimented rugose coral Catactotoechus instabilis
(representative of Cyathaxonia fauna) from the Emsian argillaceous
deposits of mud mounds of Hamar Laghdad (Anti-Atlas, Morocco). Numerous
constrictions and rejuvenescence phenomena as well as frequent
deflections of growth directions among the studied specimens suggest
unfavourable bottom conditions resulted from sliding down of the soft
sediment on the mound slopes. Dissepimental structures observed on
well-preserved calices and thin sections played an important role in
```

```
the life of the coral, supporting their successful recovery after
temporary burial within unstable soft sediment. The development of
lonsdaleoid dissepiments, apart from being biologically controlled, was
also strongly influenced by environmental factors. Such modifications
in lonsdaleoid dissepiments growth were observed in phases of
constrictions, rejuvenescence and deflections of growth, when their
development was significantly increased in comparison to phases of
their stable growth. Dissepiment morphology suggests that the process
of formation of lonsdaleoid dissepiments in Catactotoechus instabilis
is consistent with the hydraulic model.^1";
s[6723] = "BERKOWSKI B. &#038; KLUG C. (2012).- Lucky rugose corals on
crinoid stems: unusual examples of subepidermal epizoans from the
Devonian of Morocco.- Lethaia 45, 1: 24-33.- <b>FC&#038;P</b> 37, 136,
ID=7295^<b>Topic(s): </b>epibionts, subepidermal epizoans;
<b>Systematics: </b>Cnidaria, Rugosa, Echinodermata, Crinoidea;
<b>Stratigraphy: </b>Devonian L, Emsian; <b>Geography: </b>Morocco,
Anti-Atlas, Hamar Laghdad^In the fossil record, evidence for true
epizoans, i.e. living animals inhabiting other living host-animals, is
rather rare. A host reaction is usually needed to proof the syn
vivo-settling of the epizoan. Herein, we provide a first report of such
an epizoan biocoenosis from various strata of the Early Devonian of
Hamar Laghdad, the world-renowned Moroccan mud-mound locality. In this
case, solitary rugose corals settled as larvae on crinoid stems,
perhaps at a spot where the epidermis was missing for some reason
(injury, disease). Both the crinoid and the coral began to grow around
each other. By doing so, the affected crinoid columnals formed a
swelling, where ultimately only an opening slightly larger than the
coral orifice remained. We discuss both macroecological and small-scale
synecological aspects of this biocoenosis. The coral profited from its
elevated home because it reached into more rapid currents providing the
polyp with more food than at the densely populated seafloor, which was
probably covered by a coral-meadow around the mounds and hydrothermal
vents.^1";
s[6724] = "BERKOWSKI B. &#038; WEYER D. (2012).- Hamaraxonia, a new
pseudocolumellate genus of Middle Devonian deep-water Rugosa (Anthozoa)
from Morocco.- Geologica Belgica 15, 4: 245-253.- <b>FC&#038;P</b> 37,
031, ID=7296^<b>Topic(s): </b>taxonomy, new taxa, phylogenetic lineage;
<b>Systematics: </b>Cnidaria, Rugosa; <b>Stratigraphy: </b>Devonian M,
Eifelian M; <b>Geography: </b>Morocco, Anti-Atlas, Hamar Laghdad^The
monotypic genus Hamaraxonia gen. nov., with type species Hamaraxonia
africana sp. nov., is described, based on only four specimens, from the
middle Eifelian (top Costapolygnathus costatus Zone to basal Tortodus
australis Zone) of the Hamar Laghdad, Anti-Atlas, SE-Morocco. In its
prominent axial boss and dissepiments in maturity, the new genus is
unique among pre-Carboniferous ahermatypic Rugosa. It is classified
within the still polyphyletic subfamily Columnaxoniinae Weyer, 1980 of
the family Cyathaxoniidae Milne-Edwards &#038; Haime, 1850 (suborder
Cyathaxoniina Spasskiy, 1977). Possible ancestors will probably be
found among the neighbouring subfamily Laccophyllinae Grabau, 1928. For
the moment, a phylogenetic line: Laccophyllum Simpson, 1900 >
Hamarophyllum Berkowski, 2004 > gen. nov. pro Cyathaxonia hercynica
Roemer, 1855 (Weyer &#038; Zagora, 1990) > Hamaraxonia gen. nov. may be
proposed, pending further records from other regions and additional
intermediate taxa. The commonly used term columella (aseptal origin)
and the nearly forgotten term pseudocolumella (septal origin) are
redefined in the already morphogenetic sense of their authors
(Milne-Edwards &#038; Haime 1848) by selecting morpho-terminological
types: Cyathaxonia cornu Michelin, 1847 (late Tournaisian), and
Clisiophyllum keyserlingi M&#039;Coy, 1849 (middle/late Visean).^1";
s[6725] = "BLAKE P.R. (2010).- Devonian Corals of the Yarrol Province,
eastern-central Queensland.- Memoir of the Association of Australasian
Palaeontologists 38: 1-191.- <b>FC&#038;P</b> 37, 032,
ID=7297^<b>Topic(s): </b>taxonomy, new taxa, biogeography,
```

```
biostratigraphy; <b>Systematics: </b>Cnidaria, Rugosa, Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Australia, Queensland,
Yarrol Province^The Yarrol Province in eastern-central Queensland
contains rocks ranging from latest Silurian to Permian. Devonian corals
are locally abundant within the Yarrol Province, but their preservation
is typically poor compared to the well known Carboniferous coral faunas
of this Province and except for the Mount Etna coral fauna, the
Devonian corals have not been systematically described. Early and
Middle Devonian corals have been known from the Yarrol Province for a
long time, even though they have never been properly described. As a
result of this study it is now known that a fairly diverse Late
Devonian coral fauna is also present, and this is the first Late
Devonian coral fauna identified in Queensland. Overall, this study has
identified seventy-seven species of coral referable to forty-five
genera. Seventeen of the species are new: Tryplasma? careoseptum, T?
abyssum, Aphyllum simplexum, Cystiphylloides immanum, Breviphyllum
mirourum, Smithiphyllum petercollsi, S. finseni, Papiliophyllum jelli,
Disphyllum castellum, D. stupendum, Temnophyllum kroombitense, T.
stainesi, Squameofavosites craigileei, Alveolites murrayi, Heliolites
amplusa, H. comminus and Multithecopora tubus. Eighteen species have
been left in open nomenclature due to insufficient material or poor
preservation, and the remainder have been placed into forty-two
previously described species. The corals have been divided into six
faunas, with three faunas in the Early Devonian, two in the Middle
Devonian, and one in the Late Devonian. These are the Taragoola, Holly,
Armagh, Hopeful, Beschs and Kroombit faunas respectively. The Early
Devonian faunas share some of the common corals, such as Heliolites
daintreei, but do not show any strong affinities with other Early
Devonian coral faunas around Australia. The Middle Devonian Hopeful
Fauna contains only a small number of species. The Givetian Beschs
Fauna was diverse and many of the species are well known from eastern
Australia, though it has few colonial rugose corals compared to most
other Givetian faunas in Australia. The Kroombit Fauna is less diverse
than other described Late Devonian faunas in the Canning Basin of
Western Australia and Mostyn Vale Formation in New South Wales, and it
shares only a few species with them. The distribution of corals such as
Alveolites murrayi were very useful in mapping the Late Devonian rocks
of the Yarrol Province.^1";
s[6726] = "COEN-AUBERT M. (2011).- Reassignment to the Middle Devonian
of some rugose corals investigated by le Maitre (1934) in the Chalonnes
Formation from the Southeastern Armorican Massif (France).- Bulletin de
l&#039;Institut royal des Sciences naturelles de Belgique, Sciences de
la Terre 81: 27-53.- <b>FC&#038;P</b> 37, 033, ID=7298^<b>Topic(s):
</b>taxonomy, biostratigraphy; <b>Systematics: </b>Cnidaria, Rugosa;
<b>Stratigraphy: </b>Devonian M, Chalonnes Fm; <b>Geography:
</b>France, Armorican Massif SE^Nine taxa of rugose corals collected by
le Maitre (1934) and coming from the Chalonnes Formation of the
Southeastern Armorican Massif in France have been revised. They belong
to the genera StringophyllumWedekind, 1922, Sociophyllum Birenheide,
1962, Acanthophyllum Dybowski, 1873, Beugniesastraea Coen-Aubert, 1989
and Fasciphyllum Schl&#252;ter, 1885. Among this material,
Stringophyllum acanthicum (Frech, 1885), Sociophyllum elongatum
(Schl&#252;ter, 1881), Acanthophyllum vermiculare (Goldfuss, 1826) and
A. tortum (Tsien, 1969) occur close to the Eifelian-Givetian boundary,
on the south side of the Dinant Synclinorium in Belgium. Moreover, the
first three species have been defined in the Middle Devonian of the
Eifel Hills in Germany and they are observed in the Late Eifelian and
the Early Givetian of this area. For comparison, A. heterophyllum
(Milne-Edwards &#038; Haime, 1851) and Sociophyllum cf. elongatum
sampled by le Maitre (1934) in the Late Emsian Valet Formation from the
Southeastern Armorican Massif have also been investigated. The Belgian
material of Stringophyllum acanthicum is included in the systematic
description of this taxon.^1";

(2012).- Lower and Middle Famennian (Upper Devonian) rugose corals from
southern Belgium and northern France.- Geologica Belgica 15, 4:
273-283.- <b>FC&#038;P</b> 37, 035, ID=7303^<b>Topic(s): </b>mass
extinctions, recovery faunas; <b>Systematics: </b>Cnidaria, Rugosa;
<b>Stratigraphy: </b>Devonian U, Famennian L M; <b>Geography:
</b>Belgium S, France N^After the late Frasnian extinctions, the rugose
corals slowly recovered during the Lower and Middle Famennian (crepida
to marginifera conodont zones) in southern Belgium and northern France
(Avesnois) (Namur-Dinant Basin). Six genera represented by seven
species are recognized and described here, one species (Breviphrentis
superstes) is new. The rugose coral fauna described herein includes
small solitary forms belonging to the so-called Cyathaxonia fauna and
is similar or very close to those previously described within the same
stratigraphic interval in Australia, China and Germany. It also
contains a large species belonging to the genus Breviphrentis which was
considered as extinct since the end of the Givetian (Middle Devonian)
(&#034;Lazarus taxon&#034;). The tabulate corals from the Lower and
Middle Famennian of this area, mainly represented by auloporids, are
also briefly discussed. Rugosa only constituted a minor part of the
fauna after the end-Frasnian crisis in the Namur-Dinant Basin contrary
to the brachiopods, which were abundant and relatively diversified, and
no rugose corals have been recovered from the early Lower Famennian
(triangularis Zone). The first important Famennian coral radiation only
took place during the Latest Famennian (Strunian).^1";

The newly erected species are Heritschioides armstrongi n. sp., Pararachnastraea klamathensis n. sp., P. watkinsi n. sp., and P. kabyaiensis n. sp. These corals are associated with the fusulinids Millerella marblensis Thompson, 1944, Paramillerella Thompson, 1951, and Pseudostaffella Thompson, 1942, emend Groves, 1984, suggesting an early Atokan (Bashkirian) age. Both the coral and foraminiferal faunas bear a resemblance to those of similar age in the Brooks Range, Alaska, which could suggest geographic proximity between the two terranes at that time. These corals also represent the earliest known occurrence of the Family Durhamididae.^1";
s[6736] = "KIDO E. &#038; SUGIYAMA T. (2011).- Silurian rugose corals from the Kurosegawa Terrane, Southwest Japan, and their paleobiogeographic implications.- Bulletin of Geosciences 86, 1: 49-61.- <b>FC&#038;P</b> 37, 037, ID=7308^<b>Topic(s): </b>taxonomy, biostratigraphy, biogeography; <b>Systematics: </b>Cnidaria, Rugosa; <b>Stratigraphy: </b>Silurian, Gionyama Fm, Llandovery - Ludlow L; <b>Geography: </b>Japan, Kurosegawa Terrane^The Silurian to Devonian Gionyama Formation is assigned to the Kurosegawa Terrane in Southwest Japan. Abundant rugose corals in the Middle Member (late Llandovery to early Ludlow) of this formation represent 18 species belonging to 13 genera. These species are: Tryplasma sp. aff. T. ozakii, Tryplasma sp. A, Tryplasma sp. B, Cystiphyllum sp., Holmophyllum sp., Holmophyllum? sp., Labechiellata regularis, Rhizophyllum sp. A, Rhizophyllum sp. B, Neobrachyelasma japonica, Pseudamplexus sp., Amsdenoides sp., Amplexoides sp. aff. A. chaoi, Strombodes sp., Nanshanophyllum hamadai, N. gokasense, Shensiphyllum sp., and Ptychophyllum sp. The rugose corals from the Gionyama Formation include cosmopolitan genera that commonly occur in China, Kazakhstan, Siberia, Gotland, eastern Australia, and North America. Endemic genera, such as Nanshanophyllum and Shensiphyllum, which only occur in South China and Qaidam, are also present. Their stratigraphic ranges are restricted to the late Llandovery. The occurrences of these endemic genera may indicate a strong paleobiogeographic relation between the South China Block and &#034;Proto-Japan&#034; during the Silurian.^1";
s[6737] = "KOSSOVAYA O.L. &#038; KROPACHEVA G.S. (2013).- Extinction of Guadalupian rugose corals: an example of biotic response to the Kamura event (southern Primorye, Russia).- In: Gasiewicz A. &#038; Slowakiewicz M. (eds) Palaeozoic Climate Cycles: Their Evolutionary and Sedimentological Impact. Geological Society, London, Special Publication 376. First published online August 6, 2013, http://dx.doi.org/10.1144/SP376.13- <b>FC&#038;P</b> 37, 038, ID=7309^<b>Topic(s): </b>extinctions, ecology; <b>Systematics: </b>Cnidaria, Rugosa; <b>Stratigraphy: </b>Permian M; <b>Geography: </b>Russia, Russian Far East, Primorye S^Permian Rugosa of southern Primorye (Russian Far East) occur in a series of terranes of different tectonic origin. The taxonomical composition of Guadalupian (Wordian-Capitanian) rugose corals distributed in southern Primorye changed progressively in an ecological succession, starting with primitive persistent cosmopolitan taxa (assemblage I). This was replaced by assemblage II with a marked invasion of Peri-Gondwanian genera such as Timorphyllum and Verbeekiella, and, in the Late Capitanian, by typical Cathyasian colonial waagenophyllids (assemblage III). Subsequent communities have nearly no transitional forms. The latter assemblage was abruptly replaced by small fasciculate and solitary primitive forms (assemblage IV). Species peculiarities of assemblages of the Parafusulina stricta Zone and the specific
```

```
lithological features of coral-bearing deposits indicate a
palaeogeographical differentiation of terrane positions. The terranes
are of various origins: oceanic arcs, passive margin and guyot. The
extinction of massive colonial Rugosa in southern Primorye (western
Palaeo-Pacific) is identified as a biotic event that is recognizable in
Japan, and probably in Inner Mongolia. It also coincides with a general
reduction in coral diversity at the end of the Capitanian in China. The
present study of the taxonomical distribution of corals has enabled the
level of massive waagenophyllid extinction to be defined precisely and
to correlate it to a similar pattern in adjacent territories of the
Palaeo-Pacific below the Lopingian boundary. The diversity decrease
coincides with the last phase of the Kamura event, and the effects of
the Emeishan volcanism is correlated with a second positive shift in
&#948;13C (South China). The assumed cooling impacted on the fauna in
the western Palaeo-Pacific. The stepwise elimination of massive
colonial waagenophyllids and large fusulinids documented in the
southern Primorye at the end of the Capitanian is considered to be the
first step in the Permian-Triassic extinction, about 8 Myr prior to the
final Permian-Triassic (P-T) global event.^1";

<b>Geography: </b>China^Endophyllum are subfasciculate, cerioid or
aphroid corals. Corallites large, with septal stereozone broken up by
large irregular lonsdaleid dissepiments. Major septa long, attenuate,
and commonly convolute in the tabularium. Endophyllum is a cosmopolitan
genus in the Middle Devonian (Givetian) of Europe, Australia and Asia
including South China. Specimens referred to so-called
&#034;Endophyllum&#034; were reported from northern Xinjiang, NW China
(Cai 1983, Liao &#038; Cai 1987). However, they differ obviously from
the Endophyllum of Europe and South China in the morphology of their
epitheca, septa, dissepiments, tabulae and even in their minute
skeletal structures. The major septa of &#034;Endophyllum&#034; from
northern Xinjiang are not convolute in the tabularium. Its tabularium
is rather simple and the minute skeletal structures of the septum are
probably composed of composite rhabdacanth. We transfer the Xinjiang
materials to a new genus, Parendophyllum. Parendophyllum Liao &#038; Ma
2011 (type species: Parendophyllum stereoplasma Liao &#038; Ma 2011)
Diagnosis: corallum is cerioid, corallites are large, with a thick
septal stereozone and a large irregular lonsdaleoid dissepiments, Septa
of two orders, major septa are long but not convolute in tabularium,
Tabularium is rather simple and tabulae are convex or horizontal. The
minute skeletal structures of septum are composed of composite
rhabdacanth... [abridged]^1";
s[6740] = "NESTELL M.K. &#038; STEVENS C.H. (2013).- Mixed Tethyan and
McCloud Belt Rugose Corals and Fusulinids in an Upper Triassic
Conglomerate, Central Oregon.- Journal of Paleontology 87, 5: 909-921.-
<b>FC&#038;P</b> 37, 040, ID=7312^<b>Topic(s): </b>taxonomy,

</b>Cnidaria, Rugosa, Foraminifera; <b>Stratigraphy: </b>Carboniferous
- Permian ? Triassic; <b>Geography: </b>USA, Oregon, McCloud
```

```
Belt^Colonial rugose corals ranging in age from Carboniferous to Late
Triassic and Early Permian (Cisuralian) fusulinids have been recovered
from cobbles in a conglomerate in the Upper Triassic Brisbois Member of
the Vester Formation in the Izee terrane in central Oregon. Early
Permian (late Sakmarian or early Artinskian) fusulinids typical of
those present in the Coyote Butte Limestone in the nearby Grindstone
terrane (part of the allochthonous McCloud Belt) include
Eoparafusulina, Pseudofusulinella, Chalaroschwagerina, and Schwagerina.
The presence of these fusulinid genera and the Pennsylvanian coral
Heritschioides?, which is mostly restricted to the McCloud Belt,
suggest these particular cobbles were derived from limestone in that
belt. The Early Permian fusulinids Changmeia bostwicki new species and
Changmeia bigflatensis new species, and the Early Permian corals
Yokoyamaella? oregonensis new species and Yokoyamaella? sp. 1, all of
which have Tethyan affinities, occur rarely in other cobbles. The
presence of definitive fossils from the two different realms in a
conglomerate associated with beds containing Late Triassic ammonoids
indicates that by Late Triassic time a fragment of a Tethyan terrane
was close to or had been amalgamated with a terrane belonging to the
McCloud Belt.^1";

colonial; <b>Systematics: </b>Cnidaria, Rugosa, Geyerophyllidae;
<b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>^The family
Geyerophyllidae Minato, 1955 includes corals having clinotabulae,
lonsdaleoid dissepiments and a variable complex axial structure formed
as an extension of the cardinal septum. Included in the family are four
genera originally considered to have a colonial (fasciculate) growth
habit - Carniaphyllum Heritsch, Carinthiaphyllum Heritsch,
Lonsdaleoides Heritsch, and Darwasophyllum Pyzhyanov. More recent
studies and a review of the type specimens of Carniaphyllum,
Carinthiaphyllum and Lonsdaleoides have shown them to be solitary
corals with a gregarious growth habit. In its original description and
```

```
in all subsequent works, Darwasophyllum has consistently been referred
to as a fasciculate coral, but the presence of offsets has not been
illustrated in the genus and a colonial growth habit has not been
clearly demonstrated. Early Serpukhovian specimens of Darwasophyllum
from the Etherington Formation (Mississippian) in Canada were initially
regarded as fasciculate colonies with long, sub-parallel, closely
spaced corallites. When they were studied in detail by means of serial
sections, however, these corals were found to be solitary individuals
grouped into gregaria, without shared structures or offsets. Thus, true
colonies are unknown in the Geyerophyllidae and all genera described as
colonial in that family consist of gregarious, solitary corals.^1";
s[6744] = "RODRIGUEZ S., SOMERVILLE I.D., SAID I. &#038; COZAR P.
(2013).- An upper Visean (Asbian-Brigantian) and Serpukhovian coral
succession at Djebel Ouarkziz (Northern Tindouf Basin, Southern
Morocco).- Rivista Italiana di Paleontologia e Stratigrafia 119, 1:
3-17.- <b>FC&#038;P</b> 37, 042, ID=7316^<b>Topic(s): </b>corals,
stratigraphic succession; <b>Systematics: </b>Cnidaria, Rugosa;
<b>Stratigraphy: </b>Carboniferous L, Visean, Serpukhovian;
<b>Geography: </b>Morocco, Tindouf Basin^The Djebel Ouarkziz Formation,
located in the northern part of the Tindouf Basin, in western Algeria
and southern Morocco, is composed mainly of shales with interbedded
limestones, dolostones and sandstones. The limestone beds are
relatively thin, but are laterally persistent, and can be followed
along strike for tens of kilometres. We have identified 19 limestone
beds in three main sections; one logged along the road from Assa to
Zag, a second in the Tinguiz-Remz Valley, 15 km to the east, and a
third section 10 km west of the Assa-Zag road section. Rugose coral
assemblages are recorded in most limestone beds, but the
stratigraphically higher beds become more diverse However, many rugose
genera and species are persistent throughout much of the succession.
The oldest coral assemblages are Asbian in age and the youngest coral
assemblages indicate a Serpukhovian age, as confirmed by foraminiferal
biostratigraphy. The first appearance of rugose corals shows a
different pattern than that in northern Moroccan basins; some common
genera that first appear in the Asbian and lower Brigantian in northern
Morocco and Europe, appear much later, in the upper Brigantian or
Serpukhovian in the Djebel Ouarkziz. The genus Kizilia, which is rare
in the Upper Visean in northern Moroccan basins, is, however, abundant
in the Tindouf Basin. Interestingly, the occurrence of the genus
Lonsdaleia in the Serpukhovian from Djebel Ouarkziz poses a
palaeogeographic problem because of its absence in northern Moroccan
basins (except as transported elements in Serpukhovian conglomerates).
Similarly, Actinocyathus in the Serpukhovian in the Tindouf Basin is
not present north of the Anti-Atlas Mountains. A possible coral
migration route to the Tindouf Basin may be from the northeast via the
Bechar Basin in Algeria, similar to that already inferred for
foraminifers and calcareous algae.^1";

biostratigraphy, biogeography; <b>Systematics: </b>Cnidaria, Rugosa;
<b>Stratigraphy: </b>Carboniferous L/U; <b>Geography: </b>Morocco,
Tindouf Basin^A rich rugose coral assemblage has been recorded from a
biostrome at the top of the Djebel Ouarkziz Fm in the Tindouf Basin, S.
Morocco. It is composed of 10 genera and 14 species, of which 5 are
new. It represents essentially a Mississippian-type coral fauna but
with some evolved species. However, its age, as determined by
foraminifers and conodonts, is lower Bashkirian (Lower Pennsylvanian).
The presence of Mississippian-like corals in the Bashkirian indicates
that the epicontinental basins in northern Gondwana (Saharan basins)
were a refuge for coral faunas during the late Serpukhovian extinction
event. The persistence of the Mississippian assemblages in the
```

```
Bashkirian from northern Gondwana was probably due to a combination of
warm waters and tectonic stability. The coral assemblage from the
Tindouf biostrome is similar to those corals recorded from Ellesmere
Island, Arctic Canada and Novaya Zemlya, Arctic Russia where similar
tropical warm water conditions have been identified during the
Bashkirian in the northern hemisphere.^1";

coral assemblages from the Khenifra region of Central Morocco together
with data from foraminiferal / algal microfossils has established new
age dating of 5 localities within the Azrou-Khenifra Basin: Souk El Had
and Sidi Lamine, where corals occur mainly in biostromes protected by
oolitic shoals, Tabainout, where corals have been recorded in different
environments related to microbial mounds, Alhajra Almatkouba, where
corals occur in biostromal reworked beds and Tiouinine, where corals
occur in a well-structured, fringing reef. This study demonstrates the
presence of richer more diverse coral assemblages than previously
recorded, in a variety of environmental settings. These coral
assemblages strengthen correlations with the Adarouch area in the NE
part of the Azrou-Khenifra Basin. It is emphasized that in the upper
Visean there are close similarities with rugose coral assemblages in
other parts of the Western Palaeotethys including North Africa, SW
Spain and NW Europe, and that all belong to the same biogeographic
province. ^1";
s[6747] = "SOMERVILLE I.D., RODRIGUEZ S., SAID I. &#038; COZAR P.
(2012).- Mississippian coral assemblages from Tabainout mud-mound
complex, Khenifra area, Central Morocco.- Geologica Belgica 15, 4:
308-316.- <b>FC&#038;P</b> 37, 044, ID=7319^<b>Topic(s): </b>corals,
mud-mounds, ecology, biogeography; <b>Systematics: </b>Cnidaria,
Rugosa; <b>Stratigraphy: </b>Carboniferous L, Visean U; <b>Geography:
</b>Morocco, Azrou-Khenifra Basin^Analysis of Mississippian coral
assemblages from the Khenifra region of Central Morocco has
demonstrated the presence of a rich and diverse coral fauna. Rugose
coral assemblages from the Tabainout mud-mound complex comprise
abundant colonial and solitary taxa, particularly in the basal bedded
limestones, as well as the upper bedded flank and coquina capping beds.
The massive core facies with stromatactoid cavities in contrast has
rare solitary corals. The overlying shales, marls and limestone bands
which buried the mud-mound are dominated by small non-dissepimented
solitary rugosans. The age of the Tabainout mound based on foraminifers
is established as upper Visean (late Asbian-late Brigantian). The coral
assemblage strengthens correlations with the Adarouch area in the
northern part of the Azrou-Khenifra Basin where similar mud mounds
occur. These assemblages also show similarity with coeval coral faunas
from the Jerada mud-mounds (buildups) of NE Morocco and together
represent part of the same palaeobiogeographic province (Western
European Coral Province).^1";
s[6748] = "SORAUF J.E. &#038; KISSLING D.L. (2012).- Rugosans immured
in Silurian Paleofavosites, Brassfield Formation (Llandovery) of Ohio.-
Geologica Belgica 15, 4: 220-225.- <b>FC&#038;P</b> 37, 045,
ID=7320^<b>Topic(s): </b>corals, bioimmuration; <b>Systematics:
</b>Cnidaria, Rugosa, Tabulata; <b>Stratigraphy: </b>Silurian,
Llandovery, Brassfield Fm; <b>Geography: </b>USA, Ohio^The occurrence
of a solitary rugose coral, Streptelasma sp., anchored within colonial
skeleton of the tabulate coral Paleofavosites prolificus is here
reported. Numerous specimens of Streptelasma were found within three
coralla of this tabulate species among 55 collected from the uppermost
```

```
30 cm of the Lower Silurian (Llandovery) Brassfield Formation at
Fairborn, Ohio. These rugosans are largely immured in the favositid
coralla, and, as bioclaustrations, reveal important information on the
paleobiology of both species. However, the immuring of some
Streptelasma within Paleofavosites coralla was not complete during the
life of the rugosan, as calice openings of these are present at the
corallum surface. Complete immuration (or total overgrowth) indicates
that the rugosan no longer competed successfully for space, whether
entombment occurred after the death of the rugosan or was the cause of
its death is unknown. Streptelasma, in assuming an epibiotic lifestyle
probably benefited from the secure attachment to the larger, stable
colonial form of Paleofavosites prolificus and were able to exist
within this particular Brassfield facies interpreted to have been a
vigorous, current-swept environment. These high energy environments
would have been inimical to the small, light-weight rugosans living as
isolated corallites. The successful settling and growth of the rugosans
on the tabulate colonies reflects their higher status in an aggression
hierarchy. This interspecies interaction indicates an early Paleozoic
development of an aggression hierarchy of corals belonging to the
Rugosa and Tabulata (Phylum Cnidaria).^1";
s[6749] = "STEVENS C.H., FEDOROWSKI J. &#038; KAWAMURA T. (2012).- New
unusual skeletal structure in an Upper Carboniferous rugose coral,

120-125.- <b>FC&#038;P</b> 37, 046, ID=7321^<b>Topic(s): </b>corals,
skeletal structures, septal cysts; <b>Systematics: </b>Cnidaria,
Rugosa; <b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>Usa,
California, Klamath Mts^Unique among the Rugosa are specialized
cyst-like structures in corals from an upper Carboniferous limestone
within the Baird Formation in the Klamath Mountains, northern
California. These structures, here referred to as septal cysts, occur
mostly along the distal margins of the dark line extending along the
axes of the major septa as seen in transverse section. However, they
also commonly extend beyond the distal extent of those lines and may
interrupt the fibrous coating in the more proximal parts of some septa.
Their function is uncertain. Also present are small dissepiments which
form a ring around the distal margins of the minor septa. These
structures, however, do not appear to be related to the development of
those septa. Some other taxa, including corals from the Bashkirian of
Spain and the Kasimovian of Kansas, possess some specialized structures
similar to those in the California specimens suggesting at least a
remote relationship.^1";

characteristics in co-occurring Upper Ordovician species of the
tabulate Catenipora from southern Manitoba, Canada.- Lethaia 46, 1:
98-113.- <b>FC&#038;P</b> 37, 048, ID=7326^<b>Topic(s): </b>colonial
corals, growth parameters; <b>Systematics: </b>Cnidaria, Tabulata,
Catenipora; <b>Stratigraphy: </b>Ordovician U, Red River Fm;
<b>Geography: </b>Canada, Manitoba^Four species of the tabulate coral
Catenipora are present in the Selkirk Member of the Red River Formation
at Garson, Manitoba. They provide an opportunity to compare the growth
characteristics of multiple, co-occurring species that produced
cateniform coralla. Corallite increase, cyclomorphism and other growth
features show high variability within and/or among the species. A total
of five types of lateral increase and two types of axial increase are
recognized. Lateral increase accounts for over 80% of all occurrences
of corallite increase in each species, with the four species differing
significantly in the relative frequency of the various types of lateral
increase. The type of axial increase, megacorallites and agglutinated
patches of corallites that developed from normal, undamaged corallites
in C. foerstei are species specific. In all species, cyclic
```

```
fluctuations in the tabularial area of corallites are considered to be
annual, and the variable growth rates within colonies and species are
attributed to differences in astogenetic stages or environmental
conditions. Average annual vertical growth was positively correlated
with average tabularial area in C. foerstei, C. cf. robusta and C.
rubra. Catenipora cf. agglomeratiformis, however, which had the lowest
average tabularial area and greatest sensitivity to sediment influx,
had a high average growth rate comparable to that of C. rubra, which
had the largest average tabularial area. The formation of ranks or
lacunae by certain types of lateral increase seems to have been the
most effective strategy for maintaining and/or expanding the colony
growth surface in all four species, and was most common in C.cf.
agglomeratiformis. A reptant growth pattern, characterized by creeping
ranks, permitted effective recovery of damaged parts as well as quick
formation of new ranks or lacunae. The growth surface of these species
was situated near the sediment-water interface.^1";

</b>Cnidaria, Tabulata; <b>Stratigraphy: </b>Devonian L, Pragian;
<b>Geography: </b>Morocco, Hamar Laghdad^The Early Devonian (Pragian:
sulcatus to pireneae conodont zones) crinoid-coral biocoenosis from
Hamar Laghdad, Morocco contains fragments of crinoid stalks of various
taxa encrusted by spherical and ellipsoidal coralla of the tabulate
coral Hamarilopora minima. These corals were encrusting host crinoids
syn vivo, and this is evidenced by pluricolumnals exceeding 30 elements
overgrown from all sides. Most known to date crinoid-epibiont
associations display various types of reaction to the epibiont, such as
swellings and deformations. In the case discussed here, no clear
interaction is visible; therefore, this association can be classified
as paroecia. It can be inferred, however, that due to a change in
mechanical properties of the crinoid stalk (losing flexibility), the
epizoan influence on the host was negative, while the coral was
profiting from the elevated position over the seafloor and
nutrient-bearing water currents. It can be supposed that this
interaction was close to parasitism. No strict species-specific
relationship between the epizoan and the host was observed.^1";

Primary biogenic skeletal structures in Multithecopora (Tabulata,
Pennsylvanian).- Palaeogeography, Palaeoclimatology, Palaeoecology 386:
286-299.- <b>FC&#038;P</b> 37, 050, ID=7328^<b>Topic(s): </b>corals,
skeletal microstructure; <b>Systematics: </b>Cnidaria, Tabulata,
Multithecopora; <b>Stratigraphy: </b>Carboniferous U; <b>Geography:
</b>Spain^Corals are significant components of fossil marine
communities and important for paleoenvironmental reconstructions
throughout the Phanerozoic. Despite their abundance and diversity in
Paleozoic rocks, the presence, and criteria for the recognition of
primary, biogenic skeletal structures is highly controversial. The aim
of this study is a multilevel analysis of the diverse morphological
elements that form well-preserved specimens of the Carboniferous
Multithecopora tabulate coral skeleton. Results indicate that samples
are minimally altered by diagenesis, but most importantly that skeletal
structures are biogenic in nature, and similar to those of modern and
fossil carbonate-producing organisms. Nano- and microcrystals form a
complex framework of different domains of crystal morphologies that
comprise the bulk of the skeleton in Multithecopora. These domains are
thought to be the possible phenotypic response of the genotype of these
corals, and had a structural importance during the life of the
organism. Overall, this study sheds light for a better understanding on
the controversy that exists about the biogenic or abiogenic origin of
the Paleozoic coral microstructures.^1";

<b>Systematics: </b>Cnidaria, Tabulata; <b>Stratigraphy: </b>Devonian
M, Eifelian, Plabutsch Fm; <b>Geography: </b>Austria, Graz
Paleozoic^The Graz Palaeozoic, part of the Upper Austroalpine Variscan
sequence, represents a diversity hot spot of corals belonging to the
&#034;Austroalpine Coral Fauna&#034; (Hubmann 2002)... Among them, very
common are branches of thamnoporids which were named Pachypora
orthostachys by Penecke (1894: 607). Actually this tabulate belongs to
Thamnopora, but we do not comply with Kropfitsch &#038; Schouppe (1953)
that the species &#034;orthostachys&#034; is a younger synonym of Th.
reticulata (Blainville). However, detailed studies of surfaces of
Thamnopora orthostachys from two separate outcrops (Marmorbruch and
Fuchsenloch) yielded in several specimens concentrically wrinkled
structures at the bottom of some corallites... [named]
...&#034;pseudopercula&#034;. Pseudopercula ... are calcareous
membranes closing the apertures of certain corallites. Pseudopercula
occur preferentially at the basal parts of branches... The formation of
pseudopercula is therefore obviously a reaction of the thamnoporid
colonies to protect their tissue in stressed zones. The sealing of
portions of the colonies represents a strategy to preserve as much of
the soft body as possible under stress conditions. Logically, polyps
trapped under a close cover could not scavenge for food, but were able
to communicate over the pore system.^1";

MOTUS M.-A. (2013).- Growth characteristics of Protoheliolites
norvegicus (Tabulata; Upper Ordovician; Estonia).- Palaeontology 56, 4:
867-891.- <b>FC&#038;P</b> 37, 053, ID=7334^<b>Topic(s): </b>colonial
corals, growth characteristics, phylogeny; <b>Systematics:
</b>Cnidaria, Tabulata, Heliolitida; <b>Stratigraphy: </b>Ordovician U,
Katian; <b>Geography: </b>Estonia NW^Protoheliolites is an early
heliolitine coral characterized by closely spaced corallites separated
in places by sparse coenenchyme. Growth characteristics in the type
species, P. norvegicus, are revealed by detailed analysis based on
serial peels and thin sections of coralla from the uppermost Katian of
north-western Estonia. Colonies of this species had a strong ability to
recover from damage and partial mortality, resulting in various forms
of rejuvenation, regeneration, fusion and reorganization of corallites;
in some cases, this involved relatively large areas of undifferentiated
soft parts. The shells of commensal cornulitids became enclosed in host
coralla during colony growth. Coralla of P. norvegicus exhibit
distinctive growth cycles due to responses to seasonal changes. The
production of new corallites by coenenchymal increase usually occurred
in low-density bands, in which corallites generally display round to
subrounded transverse outlines. In high-density bands, the corallites
became crenulated, their wall thickness increased, septal development
was more pronounced, and the amount of coenenchyme increased. In
addition to these cyclomorphic changes, there were significant
astogenetic changes during growth. Compared with the early stage of
colony development, distinctive characteristics in the late astogenetic
stage include a decrease in the growth rate of the colony, better
coordination among corallites, maximum development of corallite
crenulations and septa in high-density bands, more numerous
coenenchymal tubules and a greater proportion of corallum area occupied
by coenenchyme. In general, the role of polyps in determining
```

```
morphological characteristics of individual corallites, such as
tabularium area, corallite crenulations and wall thickness, was
subordinate to the astogeny of the colony. Growth characteristics
including colony-wide coordination of polyp behaviour and subjugation
of individuals to restore the colony following damage suggest a strong
astogenetic control and high level of colony integration.
Protoheliolites probably arose from a heliolitine genus rather than
from a nonheliolitine group as some authors have proposed.^1";
s[6763] = "MOTUS M.-A. &#038; ZAYKA Y. (2012).- The oldest heliolitids
from the early Katian of the East Baltic region.- Geologiska
Foreningens Forhandlingar (GFF) 134, 3: 225-234.- <b>FC&#038;P</b> 37,
054, ID=7335^<b>Topic(s): </b>corals, taxonomy, early phylogeny;
<b>Systematics: </b>Cnidaria, Tabulata, Heliolitida; <b>Stratigraphy:
</b>Ordovician U, Katian; <b>Geography: </b>Estonia N, Russia NW^The
earliest heliolitids appeared more or less simultaneously in the Late
Ordovician shallow seas of different palaeocontinents. In this paper
the early Katian heliolitids, represented by the genus Protaraea, are
described from the East Baltic region (North Estonia and north-west
Russia) and discussed in detail for the first time. A new species
Protaraea procella n. sp. Motus is established and a neotype for
Protaraea diffluens (Eichwald) is designated. The new species shows a
wide intraspecific variability including variably oriented septal
trabeculae, which results in corallites commonly being poorly defined
or not apparent in transverse sections of coralla. P. procella has much
larger coralla than P. diffluens, with predominantly laminar growth
forms, whereas the latter species is usually encrusting, suggesting
that the two species were adapted to different palaeoenvironmental
conditions. The new data indicate that these heliolitids, together with
other tabulate corals, were already geographically dispersed in the
early Katian and thereby contribute to a better understanding of coral
diversification patterns in Baltica.^1";

But the lowest categories (species and genera) are established by him, first of all, on a regional material. Long-term study of heliolitids of Central Tajikistan and their comparison with heliolitids from other regions shows faunistical peculiarity of each region. Ambiguity of treatment of the same morphological features as a result takes place. The situation becomes complicated by parallelism of development between some taxa of the Heliolitida and wide variability of features of many species. Standardization of arrangement of coenenchyme because of parallelism of development results in occurrence of forms with a similar structure, but with a different genetic basis. So we can tell now that the main
```

It is mainly characterized by the following features: apical angle reaching up to 160&#176;, deep calices with numerous small spines roughly of the same size, setted in two rows or scattered on septal ridges which are wider than the interseptal furrows, no obvious cardinal ridge, tabulae scarce or missing. The species has been collected in the lowermost Emsian of the Givonne-Eislek Anticlinorium in Luxembourg. It is 1) the first record of the genus in the Devonian of Luxembourg and 2) in the autochtonous part (S.E. Laurussia) of the Ardenno-Rhenish Mountains and 3) very likely the first - or one of the two first - representative of the genus taking into account Gondwana and Laurussia.^1";
s[6780] = "SEILACHER A. &#038; THOMAS R.D.K. (2012).- Self-organization and emergent individuality of favositid corals adapted to live on soft substrates.- Lethaia 45, 1: 2-13.- <b>FC&#038;P</b> 37, 059, ID=7352^<b>Topic(s): </b>colonial corals, soft substrates; <b>Systematics: </b>Cnidaria, Tabulata, Favositida; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>^Secondary soft-bottom dwellers share the problem that their ancestors, attached to hard substrates, had lost their mobility. On soft substrates, only a limited number of alternative tricks are available to maintain sessile organisms in life position or to right them following disturbance. Consequently, convergent adaptations have emerged in unrelated members of this ecological guild. Those of favositid corals are of particular interest because, on account of their small polyps, they were always colonial. A comparative analysis of forms adopted by favositids on soft substrates shows that key elements of their adaptive paradigms could have been achieved by self-organization. This arose without centralized control by means of inherited reaction norms of individual polyps to local environmental conditions. The unique spiral growth habit of Favosites turbinatus Billings and its emergent individuality at the colony-level of organization are explained in these terms. &#034;Suicidal&#034; lids entombed altruistic marginal polyps, forming a secondary epitheca as the growing colony settled into the sediment. These lids also record the size and spacing of soft tentacles in this species.^1";
s[6781] = "WANG Guang-Xu &#038; DENG Zhan-Qiu (2010).- Application of cluster analysis to classification of cateniporids.- Acta Palaeontologica Sinica 49, 4: 478-486.- <b>FC&#038;P</b> 37, 059, ID=7353^<b>Topic(s): </b>fossil corals, numerical data, cluster analysis; <b>Systematics: </b>Cnidaria, Tabulata, Halysitida; <b>Stratigraphy: </b>; <b>Geography: </b>^^1";

(2012).- Tabulate corals from the Givetian and Frasnian of the southern region of the Holy Cross Mountains (Poland).- Special Papers in Palaeontology 87: 3-100.- <b>FC&#038;P</b> 37, 060, ID=7354^<b>Topic(s): </b>taxonomy, variability, new taxa; <b>Systematics: </b>Cnidaria, Tabulata; <b>Stratigraphy: </b>Devonian, Givetian, Frasnian; <b>Geography: </b>Poland, Holy Cross Mts^Givetian and Frasnian tabulate corals from the southern region of the Holy Cross Mountains, Poland, are described. Both Givetian and Frasnian tabulate faunas from the study region are dominated by alveolitids and comprise 52 species (Favositida: 40 species, Syringoporida: 6 species, Auloporida: 6 species). A new genus belonging to Syringoporida is proposed - Sapounofouskilites gen. nov. - and five new species are erected (Favositida: Striatopora sciuricauda sp. nov., Alveolites? obtortiformis sp. nov., Crassialveolites oliveri sp. nov., Roseoporella
```

```
heuvelmansi sp. nov.; and Auloporida: Aulopora slosarskii sp. nov.).
Study of the intracolonial variation in tabulates shows that minimal
and maximal corallite lumen diameters and pore diameters are the best
taxonomical discriminators for Alveolitidae and Coenitidae, while the
double wall thickness and tabulae spacing are less useful characters.
Moreover, alveolitids and coenitids show overall greater intracolonial
variation than, for example, heliolitids. The tabulate endobiont
Chaetosalpinx? plusquelleci isp. nov. is newly described. Study of
tabulate endobionts - that is, Chaetosalpinx? plusquelleci,
Helicosalpinx cf. asturiana Oekentorp and H. isp. - show that these
were parasites of tabulate corals. Givetian and Frasnian tabulate
faunas from the Kielce (southern) Region of the Holy Cross Mountains
are dominated by Alveolitidae.^1";
s[6783] = "ZAPALSKI M.K. &#038; BERKOWSKI B. (2012).- The oldest
species of ?Yavorskia (Tabulata) from the Upper Famennian of the Holy
Cross Mountains (Poland).- Acta Geologica Polonica 62, 2: 197-204.-
<b>FC&#038;P</b> 37, 060, ID=7355^<b>Topic(s): </b>taxonomy,
biogeography; <b>Systematics: </b>Cnidaria, Tabulata; <b>Stratigraphy:
</b>Devonian U, Famennian; <b>Geography: </b>Poland, Holy Cross Mts^A
single perfectly preserved colony of a tabulate coral assigned
tentatively to the genus Yavorskia Fomitchev, 1931, collected from
Upper Famennian beds (Palmatolepis expansa conodont Zone) in a trench
located north of the Kowala Quarry (Holy Cross Mts., central Poland) is
here described as a new species, ?Y. paszkowskii sp. nov. It differs
from other representatives of the genus in the lack of dissepimental
structures and in smaller corallite diameters, and may therefore
represent the ancestral taxon of this typically early Carboniferous
genus. Yavorskia tabulates were apparently migrating eastwards along
the southern margin of Laurussia and farther east and north towards
Siberia, as they appear in the Famennian in Europe and in the early
Carboniferous in the Altaides. Such a conclusion is consistent with
previous observations on Early-Middle Devonian Pleurodictyform tabulate
distribution.^1";
s[6784] = "ZAPALSKI M.K. &#038; DOHNALIK M. (2012).- Blastogeny in
tabulate corals: case studies using X-ray microtomography.- Lethaia 46,
2: 223-231.- <b>FC&#038;P</b> 37, 061, ID=7356^<b>Topic(s): </b>X-ray
microtomography, fossil corals; <b>Systematics: </b>Cnidaria, Tabulata;
<b>Stratigraphy: </b>Silurian, Devonian; <b>Geography: </b>^X-ray
microtomography (XMT) is a non-invasive and non-destructive method that
has often been used to study fossils. It allows serial sections to be
made as little as few micrometers apart, such a resolution is
unachievable for classical serial sectioning, moreover, in contrast to
the latter, the specimen is not destroyed. Microtomography can,
however, be applied only in cases where differences in X-ray absorption
between the skeleton and its infilling are great. We show that this
method may be also applied to tabulate corals. Case studies of
blastogeny are based on Silurian (Aulopora, Favosites) and Devonian
(Thamnopora) specimens from Poland. We show that the sequence of events
in the blastogeny of Aulopora sp. is different from that of
&#034;Aulopora serpens minor&#034; from the Devonian of the Holy Cross
Mountains and similar to auloporids from the Devonian of England.
Blastogeny in Favosites is very similar to that known from the related
genera Squameofavosites and Thamnopora. This suggests that members of
the genus Aulopora may be more diversified within the genus (as
presently understood) than genera within the Favositidae.^1";
s[6785] = "ZAPALSKI M.K. &#038; NOWINSKI A. (2011).- A new Silurian
Avicenia (Tabulata): taxonomy, growth pattern, and colony integration.-
Geodiversitas 33, 4: 541-551; Paris.- <b>FC&#038;P</b> 37, 061,
ID=7357^<b>Topic(s): </b>fossil corals, new species, blastogeny;
<b>Systematics: </b>Cnidaria, Tabulata, Heliolitida; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>Poland (glacial Baltic erratics)^A new
heliolitid tabulate coral Avicenia kocyani n. sp. is described from
Silurian erratic boulders from Pomerania (Poland). The new species has
```

```
higher intracolonial variation than other heliolitids. The growth
pattern in corallites of the new species is not correlated with the
growth pattern in coenenchymal tubes. This phenomenon is probably
caused by different gene expressions in corallites and common tissue.
Coenenchymal corals with a common skeleton, developed as polygonal
tubes may have two levels of colonial integration: lower, with
uncoordinated growth of corallites and common tissue (as for example in
Avicenia kocyani n. sp.) and higher, with a unified growth pattern
throughout the colony (as for example in Heliolites diligensis
Bondarenko, 1966). Heliolitids are known to show strong provincialism
during the Silurian. The discovery of Avicenia Leleshus, 1974 in Europe
(previously known only from Central Asia) shows that at least some of
them had a wider distribution than previously thought.^1";
s[6786] = "ZAPALSKI M.K., TRAMMER J. &#038; MISTIAEN B. (2012).-
Unusual growth pattern in the Frasnian alveolitids (Tabulata) from the
Holy Cross Mountains (Poland).- Palaeontology 55, 3: 697-706.-
<b>FC&#038;P</b> 37, 062, ID=7358^<b>Topic(s): </b>colonial corals,
growth patterns; <b>Systematics: </b>Cnidaria, Tabulata, Alveolitidae;
<b>Stratigraphy: </b>Devonian U, Frasnian L; <b>Geography: </b>Poland,
Holy Cross Mts^Growth periodicity is a phenomenon occurring in fossil
and modern corals. The most apparent feature is growth banding, and
environmental changes are broadly accepted as controls on this
phenomenon. If environment controls the growth, then all corallites
within a colony should repeat the same growth pattern, as individuals
are clones and must have shared the same environment. A study on
several species of Alveolitidae (Anthozoa, Tabulata) from the Late
Devonian (Early Frasnian) of the Holy Cross Mountains (Poland) shows
that the growth pattern varies between neighbouring individuals within
the same corallum. This contradicts observations of closely related
Favositida as demonstrated on Pachyfavosites sp. from the Givetian of
Avesnois, France, where neighbouring individuals repeat the same
pattern. Therefore, environmental control on growth rhythm in
Alveolitidae can be excluded, the causes of differences between
individuals remain unknown.^1";

```

```
the Caribbean.- Geology 39: 375-378.- <b>FC&#038;P</b> 37, 063,
ID=7361^<b>Topic(s): </b>free-living corals, biodiversity, temporal
trends; <b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy:
</b>Pliocene; <b>Geography: </b>Caribbean^Climate change is currently
having an impact on shallow-water corals, and global circulation models
predict that levels of pCO2 and temperature will rise within the next
century above anything recorded for at least the past 650 k.y. The
Pliocene Epoch is a recent, albeit imperfect, geologic analog for such
conditions in the Caribbean. Diverse communities of free-living
solitary and flabellomeandroid (FSFM) corals inhabited shallow
nearshore to deeper oligophotic habitats of the Pliocene. FSFM corals
were well suited to the low-angle depositional profiles, increased
productivity, increased sedimentation, and warmer temperatures of the
Pliocene. Origination rates of FSFM coral species between 8 and 4 Ma
are roughly double other zooxanthellate corals. FSFM corals underwent
abrupt extinction between 2 and 1 Ma, as environmental conditions
changed and suitable habitat was eliminated. The evolutionary
bottleneck of Pliocene-Pleistocene extinctions and relic steep-margined
Pleistocene topography may leave modern faunas vulnerable as we return
to Pliocene-like conditions.^1";
s[6790] = "KOLODZIEJ B., IVANOV M. &#038; IDAKIEVA V. (2012).- Prolific
development of pachythecaliines in Late Barremian, Bulgaria: coral
taxonomy and sedimentary environment.- Annales Societatis Geologorum
Poloniae 82: 291-330.- <b>FC&#038;P</b> 37, 064, ID=7362^<b>Topic(s):
</b>fossil corals, taxonomy, ecology; <b>Systematics: </b>Cnidaria,
Scleractinia, Pachythecaliina; <b>Stratigraphy: </b>Cretaceous L,
Barremian, Lovech Urgonian Gr, Emen Fm; <b>Geography: </b>Bulgaria
N-central^Diversified and abundant corals of the suborder
Pachythecaliina (order Hexanthiniaria) are described from Upper
Barremian, biostromal reefs of the Emen Formation, Lovech Urgonian
Group, north central Bulgaria. The corals are mostly of the phaceloid
growth form and represent 14 species (six new), 12 genera (three new),
belonging to five families. Pachythecaliines occur along, with the
small, monopleurid cylindrical rudist Mathesia darderi. The rudists
frequently are densely clustered, occur between coral branches or are
in contact with them. Other corals, with the exception of the phaceloid
Calamophylliopsis and other rudists, are rare. Non-laminated
microbialite crusts provided additional, structural support for
bioconstruction development. Microbialites (automicrites) can be
interpreted as a product of microbial activity, or alternatively, as a
result of carbonate precipitation, brought about by non-living organic
substrates (organomineralization s.s.). In addition to microbialites,
metazoans are encrusted by heterotrophic skeletal microorganisms, while
photophilic and oligotrophic microencrusters, usually common in other
coral-bearing limestones of the Emen Formation, are very rare. The
section at the Rusalya Quarry (NW of Veliko Tarnovo), about 42 m thick,
provides the sedimentary and environmental context for the reefal
biostromes. The vertical biotic and sedimentary succession displays a
general shallowing trend: from the outer carbonate platform with
bioclastic limestones containing small boundstone patches (corals, but
not pachythecaliines, Lithocodium aggregatum), to the inner platform
with rudist biostromes. The pachythecaliine-rich biostromes, 2.5 m
thick, were developed in a low-energy environment, referred to the
distal part of the rudist-dominated area of the platform. The
development of microbialites was facilitated by a low sedimentation
rate, and possibly by increased nutrient level. Only poorly diversified
and non-phaceloid pachythecaliines occur in other coral-rich limestones
and marls of the Urgonian complex in Bulgaria. The assemblage described
is the most remarkable, Early Cretaceous coral community worldwide,
with regard to pachythecaliines. Phaceloid pachythecaliines are only
more common in the Upper Jurassic rocks, being particularly diversified
in the Tithonian-Lower Berriasian &#352;tramberk Limestone (Czech
Republic) and its equivalent in the Polish Outer Carpathians. However,
```

```
their sedimentary context differs from that described for the corals of the Emen Formation.^1";
s[6791] = "LIAO Wei-Hua, JI Zhang-Sheng &#038; WU Gui-Chun (2012).- Late Jurassic scleractinian corals from Gerze, Northwestern Xizang (Tibet).- Acta Palaeontologica Sinica 51, 3: 290-307.- <b>FC&#038;P</b> 37, 065, ID=7363^<b>Topic(s): </b>fossil corals, taxonomy, biogeography; <b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>China, Tibet NW, Gerze^The described and illustrated scleractinian corals comprise 17 genera and 23 species, including one new species Stylosmilia xizangensis sp. nov. and six which are specifically indeterminable. Amongst them are: Heliocoenia aff. etalloni, H. bandukidzea, Heliocoenia orbignyi, Isastraea bernensis, Axosmilia sessilis, Cryptocoenia octosepta, genus Dermosmilia with D. laxata and D. cf. laxata, Thecosmilia trichotoma, Thamnasteria coquandi, Thamnasteria mettensis, Mitrodendron ogilvieae, Rhipidogyra flabellum, Isastraea rariseptata, Latiastraea pakongensis, Mitrodendron yilashanensis. Taken as a whole, this coral fauna indicates a Late Jurassic age. It bears a close relationship with those of Europe (Portugal, France, Germany, Switzerland, Poland, Czech, Romania, Ukraine and Greece), with Central South Asia (Azerbaijan, Georgia), and with parts of Gondwana (Madagascar and India).^1";
s[6792] = "LOPEZ-PEREZ R.A. (2008).- Fossil corals from the Gulf of California, M&#233;xico: still a depauperate fauna but it bears more species than previously thought.- Proceedings of the California Academy of Sciences 4, 59, 12: 503-519.- <b>FC&#038;P</b> 37, 065, ID=7364^<b>Topic(s): </b>fossil corals, taxonomy, ecology; <b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy: </b>Miocene, Pliocene, Pleistocene; <b>Geography: </b>Mexico, Gulf of California^A new collection of fossil hermatypic corals from the late Miocene Imperial Formation, the early Pliocene San Marcos Formation, the middle to late Pliocene Carmen Formation and the Pleistocene, Gulf of California, Mexico, has yielded four undescribed species Siderastrea sp., cf. Placosmilia sp., Favia sp. 1., and Favia sp. 2. Additionally, new occurrences of the previously described Pocillopora damicornis (Linnaeus 1758), Pocillopora verrucosa (Ellis and Solander 1786), Pocillopora meandrina Dana 1846, Gardineroseris planulata (Dana 1846), Pavona clavus (Dana 1846), Porites lobata Dana 1846, Diploria sarasotana Weisbord 1974 as well as Dichocoenia eminens Weisbord 1974, are reported. The fauna occurs either in low-angle ramps or flat lying terraces of variable extension. Most outcrops are small, and reminiscent of more extensive deposits usually deposited on open, exposed, high-energy environments. However, well reserved units deposited on protected embayments are also present. Except at Isla Coronados and La Ventana where multiple coral terraces occur, coral bearing units represent single spatio-temporal growth episodes. The present analysis shows that hermatypic coral fauna between late Miocene to late Pleistocene in the Gulf of California is still depauperate; nonetheless it bears many more species than previously thought.^1";
s[6793] = "LOPEZ-PEREZ R.A. Additionally, new occurrences of the previously described Pocillopora damicornis (Linnaeus, 1758), Pocillopora verrucosa (Ellis &#038; Solander, 1786), Pocillopora meandrina Dana, 1846, Gardineroseris planulata (Dana, 1846), Pavona
```

```
clavus (Dana, 1846), Porites lobata Dana, 1846, Diploria sarasotana
Weisbord, 1974, as well as Dichocoenia eminens Weisbord, 1974, are
reported. Morphometric analysis failed to distinguish between S.
californica Vaughan, 1917, and S. mendenhalli Vaughan, 1917, therefore
the former is synonymized with the latter. The fauna occurred either in
low-angle ramps or flat-lying terraces of variable extension. Most
outcrops were small, and reminiscent of more extensive deposits usually
formed in open, exposed, high-energy environments. However, well
preserved units deposited in protected embayments are also present.
Except at Isla Coronados and La Ventana where multiple coral terraces
occur, coral bearing units represent single spatiotemporal growth
episodes. The present analysis shows that the reef coral fauna between
late Miocene to late Pleistocene in the Gulf of California can be
considered depauperate when compared to the Caribbean fauna;
nonetheless, it bears many more species than previously thought.^1";

Neocoenia and Helladastraea from the Cretaceous of Greece.-
Palaeodiversity 4: 7-15.- <b>FC&#038;P</b> 37, 069,
ID=7371^<b>Topic(s): </b>fossil corals, taxonomy, revision;
<b>Systematics: </b>Cnidaria, Scleractinia, Neocoenia, Helladastraea;
<b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>Greece, Panourgias
(former Dremisa)^The two Cretaceous scleractinian coral genera
Neocoenia and Helladastraea are revised on the basis of the type
material of their respective type species. The type material of the
type species of both genera come from the Greek locality Panourgias
(former Dremisa) originally dated as Cenomanian in age. Regarding the
geological outcrop situation, this age is only valid for part of the
samples, which come from different coral bearing layers.Neocoenia is a
plocoid form closely related to Columastrea and probably a senior
synonym of Stephanaxophyllia. Helladastraea, originally established as
a subgenus of Aspidiscus and long-time considered a junior synonym of
this genus is indeed very closely related to this genus, but differs by
its conical monticules.^1";
s[6800] = "L&#214;SER H. (2012).- Revision of Actinastrea, the most
common Cretaceous coral genus.- Pal&#228;ontologische Zeitschrift 86,
1: 15-22.- <b>FC&#038;P</b> 37, 069, ID=7372^<b>Topic(s): </b>fossil
corals, taxonomy, revision; <b>Systematics: </b>Cnidaria, Scleractinia,
Actinastrea, Stelidioseris; <b>Stratigraphy: </b>Jurassic, Cretaceous;
<b>Geography: </b>^The very common and species rich Scleractinian genus
Actinastrea (family Actinastraeidae, suborder Archeocaeniina) is
revised on the basis of the type material of its type species and
additional material from the type locality. A lectotype is designated
for the type species. It was discovered that Jurassic to Early
Cretaceous corals currently assigned to Actinastrea do not fit into the
concept of this genus. These species belong to the genus Stelidioseris,
which is also revised on the basis of the type of the type species
including designating a lectotype. These two genera are distinguished
by various characteristics: septal external parts are swollen in
Actinastreabut not in Stelidioseris, the costae are confluent in
```

```
Stelidioseris, but not in Actinastrea, the coenosteum is granulated in
Actinastrea, but narrower than in Actinastrea and only with costae in
Stelidioseris. Actinastrea is restricted to the Late Cretaceous (Late
Turonian - Maastrichtian) whereas Stelidioseris originates in the
Jurassic and reaches into the Late Cretaceous, but is less common from
the Turonian on.^1";

s[6805] = "L&#214;SER H. (2012).- Intraspecific variation in the genus
Stelidioseris (family Actinastraeidae, suborder Archeocaeniina, order
Scleractinia; Jurassic-Cretaceous).- Geologica Belgica 15, 4: 382-387.-
<b>FC&#038;P</b> 37, 071, ID=7377^<b>Topic(s): </b>fossil corals,
taxonomy, morphometrics, statistical analysis; <b>Systematics:
</b>Cnidaria, Scleractinia, Stelidioseris; <b>Stratigraphy:
</b>Jurassic, Cretaceous; <b>Geography: </b>^The genus Stelidioseris (=
Actinastrea s.l.) is one of the most common genera in the Late Jurassic
and Early Cretaceous and has a high number of species. Species
separation is generally based on calicular dimensions, septal symmetry,
and septal number. To obtain better insight into intraspecific
variation and results for species separation, systematic measurements
of the corals were taken and statistically analysed. As a preliminary
study, ten type specimens were selected for analysis. In thin sections
a large number of calices (up to 200) were measured, including their
diameter, distance and the thickness of the wall and coenosteum. For
all values, the arithmetic mean, standard deviation and the coefficient
of variation were calculated. In Stelidioseris, the calicular diameter
is the character with the lowest variation. The distance of the
calicular centres, the thickness of the wall, and the number of calices
per a given area show a much higher variation and are therefore less
suitable for distinguishing samples within a population or species of
different faunas. It was found that about 70% of all values of the
lumen diameter fall in the first interval (range of the arithmetic mean
&#177; standard deviation). Hence, the first interval is a good
representation for most types of measured values in fossil corals. The
results are compared to traditional methods by remeasuring published
material. It is concluded that the application of systematic measuring
should be extended to other species rich coral genera.^1";
s[6806] = "L&#214;SER H. (2012).- Revision of the family
Amphiastraeidae from the Monti d&#039;Ocre area (Scleractinia; Early
Cretaceous).- Rivista italiana di paleontologia e stratigrafia 118, 3:

<b>Stratigraphy: </b>Jurassic L; <b>Geography: </b>Asia Central, Pamir
Mts^Four microstructural groups of corals representing the orders
Scleractinia and Hexanthiniaria are known in the Triassic and in the
Early Jurassic of the Tethys realm. In the south-eastern Pamir
Mountains, Lower Jurassic corals occur from the Hettangian to Toarcian
sediments. Hettangian?-Sinemurian and Sinemurian coral faunas discussed
in this paper come from the Gurumdy and Mynkhajir facies zones. Coral
associations are composed of classical Early Jurassic West European and
North African (Moroccan) taxa, accompanied by several genera previously
unknown in the West Tethys. After the end-Triassic extinction, the
Early Jurassic recovery faunas of the Pamir Mountains contain
Stylophyllopsis, Eocomoseris, a genus related to Elysastrea, and a
large number of Jurassic genera: Oppelismilia, Archaeosmilia,
Archaeosmiliopsis, Stylosmilia, Proaplophyllia, Cylismilia,
Intersmilia, Prodonacosmilia, Pachysmilia, Placophyllia and
Stephanastrea. More or less fragmented corals and complete skeletons
are found in detrital carbonate, oolitic, or micritic limestone facies.
Phaceloid growth forms prevail over solitary and massive ones.^1";

complex in the Dabrowa Tarnowska-Szczucin area (Polish Carpathian
Foreland).- Annales Societatis Geologorum Poloniae 82: 1-38.-
<b>FC&#038;P</b> 37, 077, ID=7389^<b>Topic(s): </b>fossil corals,
taxonomy, biostratigraphy, biogeography; <b>Systematics: </b>Cnidaria,
Scleractinia; <b>Stratigraphy: </b>Jurassic U, Tithonian, Swarzow Fm;
<b>Geography: </b>Poland, Carpathian Foreland^The studied corals have
been collected from cores of boreholes located in the central part of
the Polish Carpathian Foreland in the Dabrowa Tarnowska-Szczucin area.
The Jurassic complex in this area presents a continuous stratigraphic
section from the Upper Callovian to Tithonian, locally passing to the
Lower Cretaceous (Berriasian). Its thickness exceeds 1,100m in this
area. This complex is composed of marine, mainly shallow-water
deposits. The corals occur within the upper part of the Upper Jurassic
(Tithonian) deposits, almost entirely within the Swarzow Limestone
Formation (= coral-algal limestone formation). This occurrence marks
the northernmost extent of Tithonian shallow-water corals in Poland and
one of the northernmost in Europe. 42 coral species (among them 14 in
open nomenclature) were identified in deposits of this formation. They
include two new species: Complexastrea magna and Complexastrea
dabroviensis. All taxa, except one, belong to the order Scleractinia.
The described assemblage displays a Late Jurassic character. The
```

```
broader stratigraphic span is assigned to some species, which are quoted from the Middle Jurassic and some species lasted until the Early Cretaceous, Berriasian and/or Valanginian.^1";
s[6818] = "PANDEY D.K., F&#220;RSICH F.T., GAMEIL M. &#038; AYOUB-HANNAA W.S. (2011).- Aspidiscus cristatus (Lamarck) from the Cenomanian of Wadi Quseib, East Sinai, Egypt.- Journal of the Palaeontology Society of India 56: 29-37.- <b>FC&#038;P</b> 37, 077, ID=7390^<b>Topic(s): </b>fossil corals, taxonomy, ecology; <b>Systematics: </b>Cnidaria, Scleractinia, Aspidiscus; <b>Stratigraphy: </b>Cretaceous U, Cenomanian; <b>Geography: </b>Egypt, Sinai E^Aspidiscus cristatus (Lamarck) has been described and illustrated from three coral-bearing horizons of the Cenomanian sedimentary succession of Wadi Quseib, East Sinai, Egypt. The new specimens show well-preserved internal microarchitectures, which corroborate its assignment to family Latomeandridae Alloiteau, 1952. The stratigraphic range of Aspidiscus cristatus suggests that it can be used as index for the Middle to early Late Cenomanian. Based on the morphology of Aspidiscus cristatus and its consistent record, it is suggested here that the coral had a narrow facies range, being adapted to a free mode of life on soft, marly to argillaceous substrate, in low-energy environments subjected to high rates of sedimentation.^1";
s[6819] = "PERRIN C. (2012).- Paleobiogeography of scleractinian reef corals: Changing patterns during the Oligocene - Miocene climatic transition in the Mediterranean.- Earth-Science Reviews 111: 1-24.- <b>FC&#038;P</b> 37, 078, ID=7391^<b>Topic(s): </b>fossil reef corals, biogeography, temporal trends, numerical data; <b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy: </b>Oligocene, Miocene; <b>Geography: </b>Mediterranean^During the Oligocene-Miocene Greenhouse-to-Icehouse climatic transition, the biogeography of reef corals or zooxanthellate-like scleractinian corals was gradually changing from a pan-tropical Tethyan Province in the Eocene to three reef-coral Provinces of the Western Atlantic - Caribbean, Indo-Pacific and Mediterranean. Our REEFCORAL database encompasses update d and homogenized data on paleoenvironmental and systematics of scleractinian corals occurring in the Oligocene and Miocene outcrops from circum-Mediterranean regions, provided by most of relatively recently published data in the literature and by the study of published and unpublished collections of coral specimens from the same area, including the important collections housed at the MNHN (Paris) and our own collections. As there is no validated direct criterion for the identifi cation of the coral-zooxanthellate symbiosis in the fossil record, and considering the difficulty to use the biogeochemical approaches in the context of this study, the subjectivity of the morphological criteria and the relative recent age of the fossil corals we are dealing with, a uniformitarian approach has been used for inferring the symbiotic status of scleractinian genera in REEFCORAL. Among the 158 genera included in our database, 93 can be considered as zooxanthellate and 10 have a doubtful zooxanthellate status. This relatively exhaustive database was used to reconstruct the temporal and spatial distribution of scleractinian corals in the Mediterranean during the Oligocene - Miocene time in order to discuss the interplaying effects of the global cooling at that time, the reorganization of the Tethyan realm resulting from the African, Arabian and Eurasian plate collision and the emergence of the Alpine chains, driving the gradual northward movement of the whole region outside the tropical/subtropical belt. * It is shown that the structure of the Mediterranean z-coral Oligocene - Miocene paleobiodiversity was characterized by many geographically-restricted genera with a moderate to short stratigraphical range and a few long-ranging widespread genera. A major consequence of this structure is that the extinction pattern has proceeded through the preferential extinction of rare-occurrence genera through time. The potential rapid long-distance dispersal of most coral larvae compared to the size of the Oligocene -
```

```
Miocene Mediterranean, explains why no biogeographical sub provinces
can be distinguished for the z-coral fauna. On a local scale,
ecological processes tend to sort coral taxa by limiting z-coral
development to geographically restricted and discontinuous areas. This
accounts for the large amount of geographically-restricted taxa forming
the Mediterranean coral fauna. ** The interaction of plate-tectonics,
Alpine orogenesis and climate at local to subregional scales exerts
strong controls over the spatio-temporal distribution of z-coral
assemblages within the circum-Mediterranean realm. In particular, we
suggest that the richness and composition of the Eastern Atlantic coral
fauna are indirectly related to the opening and closure of the eastern
seaway connection with the Indian Ocean, which controlled the E-W
circulation of surface waters and hence the westwards dispersal of
pelagic larvae. At the scale of the whole region, the gradual regional
climatic change produced by the northwards migration of the entire
area, superimposed on the global cooling, appears in large part
responsible for the extinction pattern of z-corals through time in the
Mediterranean biogeographical Province.^1";
s[6820] = "RONIEWICZ E. (2011).- Early Norian (Triassic) corals from
the Northern Calcareous Alps, Austria, and the intra-Norian faunal
turnover.- Acta Palaeontologica Polonica 56, 2: 401-428.-
<b>FC&#038;P</b> 37, 079, ID=7392^<b>Topic(s): </b>fossil corals,
taxonomy, phylogeny; <b>Systematics: </b>Cnidaria, Scleractinia;
<b>Stratigraphy: </b>Triassic U, Norian; <b>Geography: </b>Austria, N
Calcareous Alps^The first description of early Norian coral fauna from
the Northern Calcareous Alps (Dachstein Plateau and Gosaukamm),
Austria, is presented: 31 scleractinian species from 24 genera
(including three corals not formally determined), and three
hexanthiniarian species belonging to two genera. The stratigraphical
position of the main part of the fauna discovered in the South
Dachstein Plateau at the Feisterscharte is determined by means of the
conodont Epigondolella quadrata (Lacian 1); single finds are from the
horizons with Epigondolella triangularis and Norigondolella navicula
(Lacian 3), and one close to the horizon with Epigondolella
cf.multidentata (Alaunian 1). Rare corals from the Gosaukamm are from
the Lacian 1 and Alaunian. Five species are described as new:
Retiophyllia vesicularis, Retiophyllia aranea, Margarosmilia adhios,
Hydrasmilia laciana; one new genus and species from the family
Coryphylliidae, Margarogyra hirsuta; one new genus and species,
Thamnasterites astreoides, cannot be assigned to a family. Two
hexanthiniarian species,Pachysolenia cylindrica and Pachydendron
microthallos, known exclusively from the Tethyan lower Norian,
represent stratigraphically valuable species. Aregularly porous coral
from the family Microsolenidae,Eocomoseris, which up to now has only
been known from the Jurassic and Cretaceous, is here identified from
the Triassic strata (originally described as Spongiomorpha
[Hexastylopsis] ramosa). Predominant taxa show solitary and phaceloid
(pseudocolonial) growth forms and an epithecal wall; pennules-bearing
corals are common. Carnian genera and genera typical of the Lacian and
Lacian-early Alaunian prevail; a hydrozoan genusCassianastraea has also
been encountered as well as a scleractiamorph coral, Furcophyllia
septafindens. The faunal composition contrasts with that of well known
late Norian-Rhaetian ones, the difference being observed not only at
the generic but also at the family level. The post-early Norian change
in coral spectrum documents the turnover of the coral fauna preceding
that at the Triassic/Jurassic boundary.^1";
s[6821] = "RONIEWICZ E. &#038; STANLEY G.D. jr (2013).- Upper Triassic
Corals from Nevada, Western North America, and the Implications for
Paleoecology and Paleogeography.- Journal of Paleontology 87, 5:
934-964.- <b>FC&#038;P</b> 37, 080, ID=7393^<b>Topic(s): </b>fossil
corals, taxonomy, biogeography, ecology; <b>Systematics: </b>Cnidaria,
Scleractinia; <b>Stratigraphy: </b>Triassic U; <b>Geography: </b>USA,
Nevada^Late Carnian-early Norian corals from the Luning and Osobb
```

```
formations in west-central Nevada represent an important Late Triassic
fauna for understanding the paleoecology and the paleogeography of the
eastern Panthalassa region during Late Triassic time. The corals occur
in bedded limestone representing biostromes and patch reefs and their
composition presages the important global changeover of faunas of the
intra-Norian interval. A taxonomic analysis of over 60 specimens
reveals a majority of colonial corals ranging from cerioid, astreoid
(i.e., cerioid-plocoid lacking walls), meandroid and thamnasterioid
types. Surprisingly, remnants of the original aragonite microstructure
remain in some specimens, allowing a better comparison with more remote
Tethyan corals. In total, 14 genera have been identified from Nevada
while two genera remain undetermined. The fauna is composed of species
considered typical of both the North American Cordillera and cratonal
South America. The following genera and species are new and endemic to
the Americas: Khytrastrea silberlingi and K. cuifiamorpha, Flexastrea
serialis, Nevadoseris punctata, Areaseris nevadaensis and a new genus
Minasteria (with Astrocoenia shastensis Smith, 1927 as type species).
Likewise are the new species: Margarogyra silberlingi and Curtoseris
dunlapcanyonae. Genera Meandrovolzeia, Margarogyra, Ceriostella,
Ampakabastraea, Retiophyllia, Distichomeandra, Curtoseris, Thamnasteria
and Astraeomorpha provide important links to the former Tethys
province. The revised coral fauna changes previous views of the close
taxonomic similarity with the Tethys, instead producing a
paleogeographic pattern emphasizing a much greater degree of endemism.
This pattern emphasizes the isolation of Nevada from the Tethys and the
similarities with some outboard terranes of the Cordillera.^1";
s[6822] = "SENTOKU E. &#038; EZAKI Y. (2012).- Constraints on the
formation of colonies of the extant azooxanthellate scleractinian coral
Dendrophyllia arbuscula.- Lethaia 45, 1: 62-70.- <b>FC&#038;P</b> 37,
179, ID=7394^<b>Topic(s): </b>corals, blastogeny; <b>Systematics:
</b>Cnidaria, Scleractinia, Dendrophyllia; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Scleractinia display a variety of growth forms,
whether zooxanthellate or azooxanthellate, as the consequence of the
combined effects of both intrinsic and extrinsic factors. New modules
arise in colonial corals through asexual reproduction, including
budding and division. The azooxanthellate, branching dendrophylliid
Dendrophyllia arbuscula van der Horst 1922, is a good species to
investigate intrinsic regularities in budding, because: (1) the lateral
corallites always occur in the vicinity of four primary septa,
excluding the two directive primary septa; (2) the two directive septa
in lateral corallites tend to be oriented almost perpendicular to the
growth orientation of parental corallites; (3) the lateral corallites
grow more-or-less diagonally upwards; and (4) these regularities are
retained from the axial to the derived lateral corallites during colony
growth. Accordingly, a colony of apparently complex dendroid corals is
formed according to certain universal rules that apply to successive
generations of corallites. The presence of two opposite sectors in
which budding does not occur seems to be common to other
azooxanthellate scleractinian families. Regularities, other than the
orientation of the directive septa, are also commonly found at least in
other azooxanthellate dendrophylliid genera. These regularities suggest
the presence of strict developmental constraints on the asexual
reproduction of the Scleractinia, both extant and extinct. These
regularities by azooxanthellate scleractinians, as one of the
representative colonial metazoan groups, provide us with fundamental
data with which we can understand how colonies are constructed.^1";
s[6823] = "SENTOKU E. &#038; EZAKI Y. (2012).- Regularity and polarity
in budding of the colonial scleractinian Dendrophyllia ehrenbergiana:
consequences of radio-bilateral symmetry of the scleractinian body

</b>Cnidaria, Scleractinia, Dendrophyllia; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>^Regularities and polarity in budding of the
```

```
azooxanthellate scleractinian Dendrophyllia ehrenbergiana were examined
with the aim of understanding the developmental constraints on the
formation of colonies. Its mode of budding, in light of the
orientations of directive septa of offsets and the inclination angle of
budding, is consistent with that of other dendrophyllids; however, the
offsets of D. ehrenbergiana only occur near the two primary septa on
the convex side of individual corallites, showing a plane of bilateral
symmetry with a distinct polarity. These regularities and polarity are
seen in the axial and its derived corallites throughout growth. Of
note, the polarity at individual corallites is clearly reflected in
subsequent colony growth by the branching pattern and corallite number.
These characteristics imply the presence of radio-bilateral symmetrical
constraints on the asexual reproduction of the Scleractinia and give us
invaluable clues to the understanding of shape-making mechanisms of
marine modular organisms.^1";
s[6824] = "SENTOKU E. &#038; EZAKI Y. (2012).- Regularity in budding
mode and resultant growth morphology of the azooxanthellate colonial
scleractinian Tubastraea coccinea.- Coral reefs 31, 1: 67-74.-
<b>FC&#038;P</b> 37, 082, ID=7396^<b>Topic(s): </b>corals, blastogeny;
<b>Systematics: </b>Cnidaria, Scleractinia, Tubastraea;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Scleractinia exhibit a
variety of growth forms, whether zooxanthellate or azooxanthellate,
according to factors that control asexual reproduction and ensuing
coral growth. The azooxanthellate branching scleractinian Dendrophyllia
arbuscula shows regular modes of budding in terms of the locations of
budding sites, the orientations of directive septa, and the inclination
angle of budding throughout colonial growth. This study reports that
such regularities are also found in the apparently different growth
form of the massive dendrophylliid Tubastraea coccinea, which shows the
following growth features: (1) the offsets (lateral corallites) always
occur near four primary septa, except the two directive primary septa,
meaning that the lateral corallites do not appear in the sectors of the
two directive septa; (2) the two directive septa in lateral corallites
tend to be oriented subperpendicular to the growth direction of the
parental corallites; (3) the lateral corallites grow approximately
diagonally upwards; and (4) these regularities are seen in the axial
and derived lateral corallites among all generations during colony
growth. Large differences in growth form are found between the
branching D. arbuscula and massive T. coccinea, irrespective of the
presence of specific regularities. It is likely that subtle
modifications of certain parameters (e.g., budding interval, branch
length, corallite size, and inclination angle of lateral corallites)
have a strong effect on the overall growth morphology. A precise
understanding of such regularities, which occur regardless of
generation or taxonomic position, would contribute to understanding the
&#034;shape-controlling mechanism&#034; of corals, which are an
archetypal modular organism.^1";
s[6825] = "SENTOKU E. &#038; EZAKI Y. (2012).- Regularity in budding
mode and resultant growth morphology of the azooxanthellate colonial
scleractinian Cyathelia axillaris: effective and adaptive ways of
utilizing habitat resources.- Paleontological Research 16, 3: 252-259.-
<b>FC&#038;P</b> 37, 083, ID=7397^<b>Topic(s): </b>corals, blastogeny;
<b>Systematics: </b>Cnidaria, Scleractinia, Cyathelia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>^Azooxanthellate coral species obtain
nutrients by themselves, retaining their colonial growth forms
independently of other species. This study examines the regularity of
budding in the bushy, azooxanthellate scleractinian oculinid Cyathelia
axillaris in order to identify the developmental constraints on colony
formation and the ecological significance of colonial forms. The
sympodial form of C. axillaris develops its bushy morphology by
repeated dichotomous branching without clear axial corallites. The
regularities in budding process are as follows: (1) in most cases, two
buds originate simultaneously on opposite sides of medially constricted
```

```
corallites near two parental second-order septa at individual distal
ends; (2) the two directive septa of lateral corallites are oriented
almost perpendicular to the directive septa of the immediate parental
corallites; (3) the lateral corallites grow more or less diagonally
upwards; and (4) these regularities remain valid from parental to
derived lateral corallites throughout growth. Thus, apparently complex,
threedimensional colonies with numerous offsets are formed according to
certain rules, irrespective of the generation of individual corallites.
The strict developmental constraints and the subtle modifications on
asexual reproduction greatly affect the colonial growth that is unique
to C. axillaris, for which the regularities in budding are effective
and adaptive ways of utilizing limited resources (i.e., growth spaces
and nutrients).^1";
s[6826] = "SENTOKU E. &#038; EZAKI Y. (2013).- Intrinsic constraints on
sympodial growth morphologies of azooxanthellate scleractinian coral
Dendrophyllia.- Plos One 8, 5; doi: 10.1371/journal.pone.0063790.-
<b>FC&#038;P</b> 37, 083, ID=7398^<b>Topic(s): </b>corals, blastogeny;
<b>Systematics: </b>Cnidaria, Scleractinia, Dendrophyllia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Background Asexual
increase occurs in virtually all colonial organisms. However, little is
known about the intrinsic mechanisms that control asexual reproduction
and the resultant morphologies of colonies. Scleractinian corals, both
symbiotic (zoaxanthellate) and non-symbiotic (azooxanthellate) corals
are known to form elaborate colonies. To better understand the growth
mechanisms that control species-specific type of colony in
azooxanthellate dendrophyllid scleractinian corals, we have studied
details of the budding pattern in the sympodial colonies of
Dendrophyllia boschmai and Dendrophyllia cribrosa. Principal Findings
Budding exhibits the following regularities: (1) the two directive
septa of offset corallites are oriented almost perpendicular to the
growth direction of parent corallites; (2) offsets generally occur in
either of the lateral primary septa that occur on one side of a
corallite; the individuals thus show a definite polarity with respect
to the directive septa, and only when branching dichotomously offsets
occur in both primary septa; (3) the lateral corallites grow
more-or-less diagonally upwards; and (4) the regularities and
polarities are maintained throughout growth. Given these regularities,
D. boschmai grows in a zigzag fashion by alternately budding on the
right and left sites. In contrast,D. cribrosa grows helically by
budding at a particular site. Conclusions / Significance The strict
constraints on budding regularities and shifts in budding sites
observed in the sympodial growth forms of corals greatly affect
resulting morphologies in azooxanthellate coral colonies. A precise
understanding of these intrinsic constraints leads to a fundamental
comprehension of colony-forming mechanisms in modular organisms.^1";

morphology, environmental variation; <b>Systematics: </b>Cnidaria,
Scleractinia, Manicina; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>USA, Florida S^Environmental variability exerts a substantial
control on massive, free-living, colonial corals such as Manicina
areolata, influencing their shape and size as well as other characters,
such as base morphology and colline complexity in meandroid forms. This
species is well adapted for life in shallow, wave-swept waters due to
its self-righting capabilities. Two different ecophenotypes of M.
areolata, as defined by overall shape and base morphology, are present
in two approximately coeval Pleistocene localities (PBA Quarry and
Holey Land Canal) in southern Florida. These differences reflect
adaptation to two depositional settings. Corallum size, shape, and oral
complexity allow clear differentiation between these two environments.
Greater corallum size, as primarily manifested by significantly greater
height, tends to accompany increased grain size. The basal area and
weight per cm2 of the coralla appear to be primary limiting factors in
M. areolata&#039;s growth by controlling the coral&#039;s ability to
self-right after overturning or causing sinking into less cohesive
substrates. Complexity of confluent corallites increases with
increasing size and colony volume. Thus, complexity of valley and
colline patterns on the oral surface increases as a function of base
area, so that collines developed on smaller, soft-substrate-inhabiting
colonies are characteristically less complex than are those of larger,
higher colonies. These complexities and variation in shape are
apparently related to environmental conditions, predominantly
substrate, water depth, and physical energy, resulting in recognizable
ecophenotypes.^1";

M. &#038; MEIBOM A. (2011).- The ancient evolutionary origins of
Scleractinia revealed by azooxanthellate corals.- BMC Evolutionary
```

```
Biology 11, 316: 1-10.- <b>FC&#038;P</b> 37, 086, ID=7402^<b>Topic(s):
</b>fossil &#038; living corals, phylogeny, molecular clocks;
<b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy:
</b>Paleozoic - Recent; <b>Geography: </b>^* Background. Scleractinian
corals are currently a focus of major interest because of their
ecological importance and the uncertain fate of coral reefs in the face
of increasing anthropogenic pressure. Despite this, remarkably little
is known about the evolutionary origins of corals. The Scleractinia
suddenly appear in the fossil record about 240 Ma, but the range of
morphological variation seen in these Middle Triassic fossils is
comparable to that of modern scleractinians, implying much earlier
origins that have so far remained elusive. A significant weakness in
reconstruction(s) of early coral evolution is that deep-sea corals have
been poorly represented in molecular phylogenetic analyses. ** Results.
By adding new data from a large and representative range of deep-water
species to existing molecular datasets and applying a relaxed molecular
clock, we show that two exclusively deep-sea families, the
Gardineriidae and Micrabaciidae, diverged prior to the Complexa/Robusta
coral split around 425 Ma, thereby pushing the evolutionary origin of
scleractinian corals deep into the Paleozoic. *** Conclusions. The
early divergence and distinctive morphologies of the extant gardineriid
and micrabaciid corals suggest a link with Ordovician
&#034;scleractiniamorph&#034; fossils that were previously assumed to
represent extinct anthozoan skeletonized lineages. Therefore,
scleractinian corals most likely evolved from Paleozoic soft-bodied
ancestors. Modern shallow-water Scleractinia, which are dependent on
symbionts, appear to have had several independent origins from
solitary, non-symbiotic precursors. The Scleractinia have survived
periods of massive climate change in the past, suggesting that as a
lineage they may be less vulnerable to future changes than often
assumed.^1";

ecology, history; <b>Systematics: </b>Cnidaria, Scleractinia;
<b>Stratigraphy: </b>Pleistocene - Recent; <b>Geography:
</b>Mediterranean E^Recent investigations of the Eastern Mediterranean
Sea carried out during the GECO cruise with RV Urania provided a
substantial number of new cold-water coral (CWC) records, including
branching and solitary scleractinian species. These new sites are
located along steep escarpments and on topographic highs along the
margins of Crete, Karpathos, and Rhodes. The majority of the corals
represent fossil occurrences, predominantly Late Pleistocene
assemblages. Our research documents that the Eastern Mediterranean
Basin has been colonized by CWC at favorable times during the Last
Glacial, in particular during the Younger Dryas.Schizocyathus fissilis
is reported for the first time for the Mediterranean, while the finding
of Ceratotrochus magnaghii represents the first record for the Eastern
Mediterranean. Various coral facies occur on the southerly island
slopes of Crete, Karpathos, and Rhodes, including hardgrounds and loose
skeletal sediments. Hardgrounds occur on steep topographies between ca.
500 and 1,700m, and can conveniently be subdivided as (1)
Neopycnodonte-Desmophyllum framestone, (2) Desmophyllum-Caryophyllia
framestone, (3) Madrepora-Lophelia rudstone, (4) Pelagic mudstone and
wackestone, and (5) Siliciclastic-carbonate conglomerate and breccia.
Unconsolidated skeletal sediments containing corals mainly occur on
gentler topographic situations between ca. 140 and 600m and can be
subdivided as: (A) Lophelia-Madrepora rubble, (B) Dendrophyllia rubble,
(C) Stenocyathus rubble, (D) Caryophyllia calveri rubble, and (E)
fine-grained sediment with octocoral axes. Many of these facies types
```

```
are also present in the western part of the Mediterranean and have
fossil representatives from the Pleistocene to the Recent. Radiocarbon
dating (AMS-14C) reveals Younger Dryas ages between 12.4 and 12.0 ka
cal BP for Lophelia pertusa and Madrepora oculata. Desmophyllum
dianthus occurs during the Last Glacial Maximum (21.8 ka cal BP) and
the Younger Dryas (11.7 ka cal BP), as well as during the Late Holocene
and subrecent times (4.4-0.6 ka cal BP). Caryophyllia sarsiae occurs
during the Late Glacial (15.5 ka cal BP), while Caryophyllia calveri
occurs during the Early Preboreal (10.8 ka cal BP). The ages for the
framework-constructing corals L. pertusa and M. oculata are coherent
with their temporal predominance during the Younger Dryas in other
parts of the Mediterranean.^1";
s[6832] = "TOKUDA Y. &#038; EZAKI Y. (2012).- Asexual reproduction of
Pliocene solitary scleractinian coral Truncatoflabellum: a
morphological and biometric study.- Journal of Paleontology 86, 2:
268-272.- <b>FC&#038;P</b> 37, 088, ID=7404^<b>Topic(s): </b>fossil
corals, reproduction patterns; <b>Systematics: </b>Cnidaria,
Scleractinia, Truncatoflabellum; <b>Stratigraphy: </b>Pliocene;
<b>Geography: </b>^Truncatoflabellum has been considered a free-living
genus that exhibits both sexual and asexual phases; divided lower
coralla (anthocauli) are specialized for asexual reproduction by
transverse division through a decalcification process, whereas the
upper coralla (anthocyathi) only undertake sexual reproduction, in a
life-cycle strategy that includes a distinct alternation of
generations. However, little evidence has been presented to support
this idea of its life cycle. We elucidate the life mode of
Truncatoflabellum by identifying key fossil characters (e.g., multiple
rejuvenations and decalcification records just beneath lateral spines)
and statistically analyzing the size distributions of over 500
individual coralla. Results of those morphological and biometric
analyses clearly indicate alternation of generations in the life cycle
of Truncatoflabellum.^1";
s[6833] = "TOKUDA Y. &#038; EZAKI Y. (2012).- Attachment structures in
Rhizotrochus (Scleractinia): macro- to microscopic traits and their
evolutionary significance.- Lethaia 46, 2: 232-244.- <b>FC&#038;P</b>
37, 089, ID=7405^<b>Topic(s): </b>corals, attachement structures,
phylogeny; <b>Systematics: </b>Cnidaria, Scleractinia, Rhizotrochus;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>^Marine sessile benthic
organisms living on hard substrates have evolved a variety of
attachment strategies. Rhizotrochus (Scleractinia, Flabellidae) is a
representative azooxanthellate solitary scleractinian coral with a wide
geographical distribution and unique attachment structures; it firmly
attaches to hard substrates using numerous tube-like rootlets, which
are extended from a corallum wall, whereas most sessile corals are
attached by stereome-reinforced structures at their corallite bases.
Detailed morphological and constructional traits of the rootlets
themselves, along with their evolutionary significance, have not yet
been fully resolved. Growth and developmental processes of spines in
Truncatoflabellum and rootlets in Rhizotrochus suggest that these
structures are homologous, as they both develop from the growth edges
of walls and are formed by transformation of wall structures and their
skeletal microstructures possess similar characteristics, such as
patterns of rapid accretion and thickening deposits. Taking molecular
phylogeny and fossil records of flabellids into
consideration,Rhizotrochus evolved from a common free-living ancestor
and invaded hard-substrate habitats by exploiting rootlets of spines
origin, which were adaptive for soft-substrate environments.^1";

(2010).- Unusually Preserved Metaconularia manni (Roy, 1935) from the Silurian of Iowa, and the Systematics of the Genus.- Journal of Paleontology 84, 1: 1-31.- <b>FC&#038;P</b> 37, 091, ID=7409^<b>Topic(s): </b>fossil scyphozoans, taxonomy, taphonomy, variation; <b>Systematics: </b>Cnidaria, Conulariina; <b>Stratigraphy: </b>Silurian L, Scotch Grove Fm; <b>Geography: </b>USA, Iowa^The Welton Member of the Scotch Grove Formation at Shaffton Quarry, near Camanche, Iowa, is about 427 Ma old and contains numerous metaconulariid specimens, many of which are preserved in apex-downward orientation. Some of these show an unusual, splayed, &#034;Maltese cross&#034; configuration. Apex-downward configurations suggest rapid burial, consistent with the soft part preservation known in other taxa from this locality. The abundance of Metaconularia at Shaffton Quarry, and of topotype specimens of M. aspersa, the generic type species, permits evaluation of the degree of individual and intracollectional variation in peridermal ornament. Variation within and among individuals precludes reliance on ornamental differences in species differentiation in most cases. In view of these results we assign all Shaffton specimens to Metaconularia manni (Roy, 1935), and revise Metaconularia based on its type material from Europe and other material from Europe and North America. An exploratory phylogenetic analysis highlights aspects of character distribution within the genus, but the small number of characters states and possible taphonomic influences upon them limit confidence in the clade topology. Subgroups within the genus are characterized by larger, discoidal papillae, and by strong transverse corrugation and sinuous rows of smaller papillae. The genus itself comprises those conulariids with an external ornamentation of simple, round, small papillae, paired internal septae along the midlines, and a thin periderm that was to some degree pliable during life.^1";

scyphozoans, taxonomy; <b>Systematics: </b>Cnidaria, Conulariina;
<b>Stratigraphy: </b>Ordovician U, Red River Fm; <b>Geography:
</b>Canada, Manitoba S^Six species of conulariids, assigned to four
genera, were recovered from the type locality of the Cat Head Member of
the Red River Formation in southern Manitoba, Canada. These are middle
Katian (Late Ordovician) in age. The most abundant conulariid species
from this locality, Conularia porcella, is new, and is represented by
21 specimens. Additionally, 28 three-dimensionally preserved
micromorphic conulariids, assigned to Eoconularia aff. loculata, were
recovered using acetic acid preparation from limestone samples of late
Katian (Late Ordovician) age. These samples had been collected from
Churchill, northern Manitoba, by the Geological Survey of Canada&#039;s
J.B. Tyrrell in 1894. These taxa are unusually abundant for
conulariids, which are normally represented by only a few specimens
from any given locality, and this abundance may be a reflection of the
exceptional preservation at these two localities.^1";

Asymmetry in an Ordovician conulariid cnidarian.- Lethaia 45, 3:
423-431.- <b>FC&#038;P</b> 37, 092, ID=7411^<b>Topic(s): </b>fossil
scyphozoans, asymmetry; <b>Systematics: </b>Cnidaria, Conulariina;
<b>Stratigraphy: </b>Ordovician; <b>Geography: </b>Czech Republic,
Drabov^Conulariids are fossils of the presumed polyps of an extinct
scyphozoan cnidarian group. Their cone-shaped skeletons normally show
perfect tetraradial symmetry. However, in the Ordovician species
Metaconularia anomala (Barrande 1867) from Drabov (Czech Republic),
tetraradial symmetry is compromised in three ways: (1) the skeleton
often shows torsion; (2) the four sides may vary in width at the same
level within one individual; and (3) one side may be deleted to give a
triradial skeleton. Almost 2000 specimens were studied in museum
collections. About 56% of analysed specimens are twisted in an
anticlockwise direction (sinistral) when viewed from the apex towards
the aperture, 28% show no torsion, 1% exhibit clockwise torsion
(dextral) and the remaining 15% cannot be classified. Maximum measured
torsion rate was 1.5&#176;/mm. A significant negative correlation
between torsion rate and length suggests that more highly torted
individuals may have survived less well. Almost 5% of individuals show
loss of one side for at least part of their lengths. Although many
individuals have four sides of equal width, in a significant proportion
the sides are of unequal width, up to a maximum / minimum side width
ratio of 2 (i.e. widest face twice the width of the narrowest). In the
absence of a satisfactory taphonomic model to explain the asymmetries,
they are regarded as mirroring asymmetries in the living conulariids,
with the strong preference for sinistral torsion interpreted as an
example of a fixed asymmetry that was genetically controlled and
heritable. It is speculated that the signalling protein Nodal as well
as Hox-like genes were involved in controlling the asymmetries
described in M. anomala.^1";
s[6840] = "SENDINO C., ZAGORSEK K. &#038; VYHLASOVA Z.D. (2011).- The

<b>Systematics: </b>Cnidaria, Conulariina; <b>Stratigraphy:
</b>Ordovician U; <b>Geography: </b>Czech Republic, Prague Basin^The
conulariids, an enigmatic fossil group believed to be of cnidarian
(scyphozoan) affinity, have four-sided, acutely pyramidal exoskeletons
terminated in apertural closures. To date, three main closure types
have been recognised in conulariids (plicated, triangular lappets, and
lobate lappets) but the first type is poorly illustrated in the
literature. Here we present the first photographic illustration of an
unequivocal plicated closure inMetaconularia? anomala, based on study
of the rich (1700+ specimens) material from the Upper Ordovician of the
```

```
Prague Basin. This closure is formed by inwardly folded, triangular
lappets centred on each of the four faces, with kite-shaped elements
centred on the four corners forming a webbing between the lappets.
Plicated closures were evidently rare in conulariids and restricted to
a few Ordovician species.^1";
s[6841] = "VAN ITEN H. &#038; SUDKAMP W.H. (2010).- Exceptionally
preserved conulariids and an edrioasteroid from the Hunsruck Slate
(Lower Devonian, SW Germany).- Palaeontology 53, 2: 403-414.-
<b>FC&#038;P</b> 37, 093, ID=7413^<b>Topic(s): </b>fossil scyphozoans;
<b>Systematics: </b>Cnidaria, Conulariina; <b>Stratigraphy:
</b>Devonian L, Emsian, Hunsruck Slate; <b>Geography: </b>Germany,
Bundenbach^Nineteen partial specimens of Conularia sp., together with
an articulated agelacrinitid edrioasteroid and several discinid
brachiopods, occur in close association with a probable biological
substrate on a small slab of silty Hunsruck Slate (Lower Devonian,
Emsian) from Bundenbach, Germany. Most of the conulariids occur in
V-like pairs or in a single cluster of 12 specimens arranged in a
fan-like radial pattern. Together with the edrioasteroid and (possibly)
brachiopods, the conulariids probably were attached to the substrate in
life and then were buried and possibly killed by a single influx of
silty mud. The apertural end of many of the conulariids is partially
covered by inwardly folded short lappets, which may have closed in
response to rapid (but gentle) burial. Rock matrix in the apertural
region of the peridermal cavity of nearly all of the conulariids
exhibits irregular, variably dense concentrations of pyrite. The
concentrations occur almost exclusively within the conulariids, where
they probably formed as a result of the decay of retracted conulariid
soft parts. Although the concentrations lack clearly defined anatomical
features that can be unambiguously homologized with particular
anatomical structures of any extant taxon, their form and distribution
within the conulariids are consistent with the hypothesis that
conulariids were polypoid scyphozoans.^1";
s[6842] = "VAN ITEN H., TOLLERTON V.P. jr, VER STRAETEN C.A., DE MORAES
LEME J., SIMOES M.G. &#038; RODRIGUES M.G. (2013).- Life mode of in

scyphozoans, life mode; <b>Systematics: </b>Cnidaria, Conulariina;
<b>Stratigraphy: </b>Devonian M, Givetian, Mount Marion Fm;
<b>Geography: </b>USA, New York^Exceptionally abundant specimens of
Conularia aff. desiderata Hall occur in multiple marine obrution
deposits, in a single sixth-order parasequence composed of argillaceous
and silty very fine sandstone, in the Otsego Member of the Mount Marion
Formation (Middle Devonian, Givetian) in eastern New York State, USA.
Associated fossils consist mostly of rhynchonelliform brachiopods but
also include bivalve molluscs, orthoconic nautiloids, linguliform
brachiopods and gastropods. Many of the brachiopods, bivalve molluscs
and conulariids have been buried in situ. Conulariids buried in situ
are oriented with their aperture facing obliquely upward and with their
long axis inclined at up to 87 degree to bedding. Most specimens are
solitary, but some occur in V-like pairs or in radial clusters
consisting of three specimens, with the component specimens being about
equally long or (less frequently) substantially different in length.
The compacted apical end of Conularia buried in situ generally rests
upon argillaceous sandstone. With one possible exception, none of the
examined specimens terminates in a schott (apical wall), and internal
schotts appear to be absent. The apical ends of specimens in V-like
pairs and radial clusters show no direct evidence of interconnection of
their periderms. The apical, middle or apertural region of some
inclined specimens abuts or is in close lateral proximity to a
recumbent conulariid or to one or more spiriferid brachiopods, some of
which have been buried in their original life orientation. The
azimuthal bearings of Conularia and nautiloid long axes and the
directions in which conulariids open are nonrandom, with conulariids
```

```
being preferentially aligned between 350 and 50 degree and with their
apertural end facing north-east, and nautiloids being preferentially
aligned between 30 and 70 degree. Otsego Member Conularia were erect or
semi-erect, epifaunal or partially infaunal animals, the apical end of
which rested upon very fine bottom sediment. The origin of V-like pairs
and radial clusters remains enigmatic, but it is probable that
production of schotts was not a regular feature of this animals life
history. Finally, conulariids and associated fauna were occasionally
smothered by distal storm deposits, under the influence of relatively
weak bottom currents.^1";

Redescription of Hexaconularia He and Yang, 1986 (Lower Cambrian, South
China): implications for the affinities of conulariid-like small shelly
fossils.- Palaeontology 53, 1: 191-199.- <b>FC&#038;P</b> 37, 095,
ID=7415^<b>Topic(s): </b>small shelly fossils, taxonomy, biology;
<b>Systematics: </b>Cnidaria? Conulariina?; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>China S^Hexaconularia, a Lower
Cambrian small shelly fossil (SSF) that has been allied with
conulariids and scyphozoan cnidarians, is redescribed and refigured. A
salient feature of this monospecific genus is the presence of distinct
apical and abapical regions. The apical region probably represents an
embryonic shell that apparently lacked a basal attachment structure.
Comparisons of this feature with the apical end of the smallest known
conulariids and with conulariids terminating in an apical wall (schott)
reveal substantial differences in structure and ornamentation.
Differences in apical anatomy between conulariids and Arthrochites,
possibly the nearest SSF relative of Hexaconularia, are also apparent.
Comparisons of Hexaconularia with Punctatus, an SSF taxon showing
distinct apical and abapical regions in both posthatching specimens and
prehatching embryos, suggest that the early development of
Hexaconularia was direct. These results have important implications for
hypotheses of a conulariid / scyphozoan affinity for Hexaconularia and
its possible SSF relatives, and they suggest that Hexaconularia-bearing
strata may yield prehatching embryos of this genus.^1";
s[6844] = "MUSCENTE A.D. &#038; ALLMON W.D. (2013).- Revision of the
Hydroid Plumalina Hall, 1858 in the Silurian and Devonian of New York.-
Journal of Paleontology 87, 4: 710-725.- <b>FC&#038;P</b> 37, 096,

</b>Cnidaria, Hydrozoa; <b>Stratigraphy: </b>Silurian, Wenlock,
Devonian, Givetian - Famennian; <b>Geography: </b>USA, New York^The
feather-shaped Plumalina Hall, 1858 is revised on the basis of new and
reexamined specimens from New York. Previously described from Givetian
through Famennian deposits, a single compression of P. tenera n. sp.
from the Rochester Shale extends the range into the Wenlock, and
provides new information regarding Plumalina&#039;s biology. We assess
the utility of morphologic characters in diagnoses of taxa, and present
the first quantitative analysis of fossil hydroids to distinguish P.
brevis n. sp. (Frasnian) from other Devonian species. * Plumalina has
been compared to plants, graptolites, and octocorals. Some
interpretations have proposed affinities among hydrozoans based on
colony form and the presence of putative polyp bases. Our analysis
shows that, like extant thecate hydrozoans, Plumalina had a delicate,
chitinous hydrocaulus with weakly articulated hydrocladia. An
assemblage of in situ specimens, steeply inclined relative to the
bedding plane in an Ithaca Formation (Frasnian Stage) turbidite,
indicates that Devonian species produced sessile, erect colonies
attached to a hard substrate, comparable to extant hydroids that feed
in currents. Morphometric comparisons between putative Plumalina polyp
bases and polyp bases of modern analogues reveal similarities to
hydroids in the superfamily Plumularioidea McCrady, 1859. Plumalina is
the most abundant fossil hydroid so far reported, and is pertinent to
interpretations of the hydrozoan record.^1";

Cretaceous sponge and coral faunas are reviewed and increased with new
discoveries. The largest new fauna described, from the very thin
Maastrichtian Miria Formation, an uncemented chalky marl, in the
Carnarvon Basin, Western Australia, includes a poriferan, Ventriculites
sp., the hydrozoans, Stylaster cretaceous sp. nov. and Astya nielseni
Wells, 1977 originally described from the Eocene of Tonga and the
scleractinian corals Smilotrochus carnarvonensis sp. nov., Conotrochus
giraliensis sp. nov., Parasmilia cyensis sp. nov., Palaeopsammia
cardabiaensis sp. nov., Flabellum miriaensis sp. nov., Ballanophyllia
acostae sp. nov., representatives of five genera left in open
nomenclature and Caryophyllia arcotensis (Forbes, 1846), originally
described from south India. The Santonian Gingin Chalk, in the northern
Perth Basin, Western Australia has yielded the scleractinian corals
Ceratotrochus ginginensis (Etheridge 1913), originally assigned to
Coelosmilia and Caryophyllia arcotensis (Forbes, 1846), holdfast
structures that probably supported octocorals and the poriferans,
Peronidella(?) globosa (Etheridge 1913) and Pachyteichisma corrugatus
sp. nov. Mckenziephyllia accordensis gen. et sp. nov. is described as
the first scleractinian coral (Faviidae) from the Eromanga Basin. It
```

```
comes from the Albian Allaru Formation in the Barcaldine district of
central Queensland. Purisiphonia clarkei Bowerbank, 1869 is noted from
the Aptian Wallumbilla Formation as the only known poriferan in the
Surat and Eromanga basins.^1";

<b>Systematics: </b>microbes, metazoans; <b>Stratigraphy:
</b>Ordovician L; <b>Geography: </b>^The Ordovician is a period when
novel reef ecosystems appeared along with new reef constructors and
skeletal-dominated reefs. The Lower Ordovician (late Tremadocian)
Fenhsiang Formation of the Three Gorges area in South China contains
the oldest known bryozoan reefs (lithistid sponge-bryozoan and
bryozoan-pelmatozoan reefs) alongside lithistid sponge-microbial reefs.
The latter are characterized by the dominance of microbialites that
encrusted and bound the frame-building sponges and inter-sponge
sediments. In contrast, the lithistid sponge-bryozoan and
bryozoan-pelmatozoan reefs are generally characterized by bryozoans
that encrusted the frame-building sponges or pelmatozoans and grew to
fill the inter-frameworks. These sponges and pelmatozoans did not
construct the rigid frameworks unaided; their association with
bryozoans enabled the development of small skeletal-dominated reefs
with rigid frameworks. Skeletal-dominated reefs, for which
frame-constructing and encrusting roles are conspicuous, were largely
unknown before the Early Ordovician. The appearance of skeletal
organisms (specifically colonial, encrusting bryozoans) enabled the
development of skeletal-dominated reefs, which were pioneers in the
rise of Middle-Late Ordovician reefs. The Early Ordovician
establishment of skeletal-dominated reefs at the earliest stages of the
Great Ordovician Biodiversification Event would have created novel
niches and biological interactions that further promoted the evolution
of reef-building and -dwelling organisms, as well as ensuing reef
ecosystems.^1";
s[6853] = "ADACHI N., EZAKI Y. &#038; LIU J. (2012).- The oldest
bryozoan reefs: a unique Early Ordovician skeletal framework
construction.- Lethaia 45, 1: 14-23.- <b>FC&#038;P</b> 37, 100,
ID=7425^<b>Topic(s): </b>reefs, ecological succession, temporal trends;
<b>Systematics: </b>bryozoans; <b>Stratigraphy: </b>Ordovician L;
<b>Geography: </b>China S, Three Gorges Area^The oldest bryozoan reefs
occur in the Lower Ordovician (late Tremadocian) Fenhsiang Formation of
the Three Gorges area, South China. These reefs show a unique type of
bryozoan (Nekhorosheviella) framework, and were constructed as follows:
```

```
the first stage involved colonization by lithistid sponges, which acted
as a baffler to trap sediments, providing bryozoans with a stable
substrate for attachment. The bryozoans then grew as an encruster on
the surfaces of sponges, showing a preferential downwards and lateral
growth within the sponge scaffolding to avoid biological and physical
disturbance. Finally, these biotic combinations among skeletal
organisms formed a rigid, three-dimensional skeletal framework. This
mode of bryozoan growth in association with lithistid sponges is
remarkable and unique in its growth direction, and the appearance of
such reefs, just prior to the widespread development of
skeletal-dominated reefs as part of the Great Ordovician
Biodiversification Event, provides an excellent example of the earliest
attempts by skeletal organisms to form frameworks by themselves. This
find significantly enhances our understanding of the initial stages of
skeletal-dominated reef evolution and the ensuing development of reefs
during the Middle-Late Ordovician.^1";
s[6854] = "ADACHI N., LIU J. &#038; EZAKI Y. (2013).- Early Ordovician
reefs in South China (Chenjiahe section, Hubei Province): deciphering
the early evolution of skeletal-dominated reefs.- Facies 59, 2:
451-466.- <b>FC&#038;P</b> 37, 100, ID=7426^<b>Topic(s): </b>bryozoan
reefs, reef structures, temporal trends; <b>Systematics: </b>bryozoans;
<b>Stratigraphy: </b>Ordovician L, Floian L; <b>Geography: </b>China S,
Hubei^The Lower Ordovician (late Tremadocian-early Floian) Fenhsiang
and the overlying Hunghuayuan Formations at the Chenjiahe section in
the Three Gorges area of Hubei Province, South China, include four
types of reef: microbe-dominated (lithistid sponge-stromatolite and
lithistid sponge-calcimicrobial) reefs, and skeletal-dominated
(lithistid sponge-bryozoan and bryozoan-pelmatozoan) reefs. The
microbe-dominated reefs are characterized by the dominance of microbial
sediments that encrusted and bound the surfaces of sponges to reinforce
the reef frameworks. In contrast, the skeletal-dominated reefs are
distinguished by bryozoans that encrusted frame-building sponges and
pelmatozoans, and that grew downward to fill the open spaces available
within the frameworks. A series of these reefs shows a temporal
succession in reef type, with a decline in the lithistid
sponge-stromatolite reefs and an increase in the lithistid sponges and
receptaculitids within the lithistid sponge-calcimicrobial reefs in the
Hunghuayuan Formation, the lithistid sponge-bryozoan reefs are common
in both the Fenhsiang and Hunghuayuan Formations. These features of the
Chenjiahe reefs are in marked contrast to other coeval reefs on the
Yangtze Platform and elsewhere. Skeletal-dominated reefs first
developed in the Three Gorges and adjacent areas, located on the
central part of the platform. Likewise, lithistid sponges and
receptaculitids first developed in the Three Gorges area and then
expanded their range. In contrast, stromatolites declined over time,
but remained abundant on a marginal part of the platform. The
spatial-temporal distributions of these reefs on the Yangtze Platform
reflect the initiation of the Great Ordovician Biodiversification Event
and its consequences, although influenced by local environmental
conditions. The Three Gorges area was a center for the development of
skeletal-dominated reefs, which were established earlier here than
elsewhere in the world. These reef types and their spatial-temporal
successions provide invaluable clues to the earliest evolution of
skeletal-dominated reefs and their ensuing development during the
Middle-Late Ordovician.^1";

<b>Geography: </b>Australia W, Canning Basin^The evolution and
architecture of a set of retreating Lower Frasnian patch reef outcrops
```

```
in the Canning Basin of Western Australia were evaluated, and their
depositional and stratigraphic contacts spatially recorded using
digital surveying tools. The geological data, together with
high-resolution digital elevation models, were assembled in
three-dimensional visualization and modelling software and subsequently
used for building two-dimensional surface models and three-dimensional
volumetric models. Numerical data on geometry and shape were extracted
from these models and used to quantitatively assess the retrogradation
motif of patch reef development. The development of the patch reefs
comprises three stages. During stages 1 and 2, the patch reefs
exhibited an overall retrogradational escarpment-type configuration
displayed by, on average, 60&#176; steep reef-margin walls that lacked
the support of coeval slope deposits. The subdivision between stages 1
and 2 is based on minor backstepping reducing less than 10% of the
platformtop area. The onset of stage 3 is recognized by stromatolite
development fringing reef-margin walls. During stage 3 an aggrading
accretionary reefmargin developed, comprising allochthonous and
autochthonous slope deposits. [abridged]^1";
s[6856] = "ALVARO J.J. &#038; DEBRENNE F. (2010).- The Great Atlasian
Reef Complex: An early Cambrian subtropical fringing belt that bordered
West Gondwana.- Palaeogeography, Palaeoclimatology, Palaeoecology 294,
3-4: 120-132.- <b>FC&#038;P</b> 37, 102, ID=7428^<b>Topic(s):
</b>archaeocyathan reefs, tectonics; <b>Systematics: </b>Porifera,
Archaeocyatha; <b>Stratigraphy: </b>Cambrian L; <b>Geography:
</b>Morocco, Atlas^The so-called Great Atlasian Reef Complex developed
during early Cambrian time throughout the Moroccan margin (Souss Basin)
of West Gondwana. According to the syndepositional tectonic activity
associated with its intracratonic Ediacaran-Cambrian rift, the great
reef complex can be subdivided into four major archaeocyathan-microbial
reef episodes: * (i) The Atdabanian episode is recorded by a
SW-NE-trending, 400km long barrier reef that extended across the
western Anti-Atlas. It was controlled by large-scale reactivation of an
inherited rifting branch, which resulted in the nucleation and growth
of linear reef complexes located along its margin. The interplay of
block tilting, sharp modifications in accommodation space, and relative
sea-level rise led to a composite retrogradational-aggradational reef
systems tract, characterized by archaeocyathan-microbial kalyptrate
complexes (Tiout Member and Amouslek Formation) that protected
stromatolite-dominated, back-barrier environments (lower member of the
Igoudine Formation). ** (ii) The western Anti-Atlas recorded an early
Botoman reactivation of the same rifting branch that triggered a
lateral migration of frame-building centres of carbonate productivity.
As a result, the involved grabens and half-grabens recorded the
development of fringing mound complexes (lower Issafen Formation).
These occupied some linear intra-platform, deeper depressions capped by
marls and shales, whereas laterally equivalent shallower environments
recorded the development of patch-reefs and bioherms. *** (iii) The
western Anti-Atlas subsequently recorded a late Botoman interval of
tectonic quiescence superimposed to a local interval of progradational
pulses. This favoured the nucleation of dispersed
archaeocyathan-microbial patch-reefs and bioherms. **** (iv) A distinct
palaeogeographic area is recognized in the southern High Atlas, where
the entire Atdabanian-Botoman interval recorded small-scale,
synsedimentary block tilting and high rates of volcaniclastic input. As
a result, this sector was characterized by the record of microbial and
archaeocyathan-microbial patch-reefs and bioherms, preferentially
developed on the uplifted parts of tilted blocks. * The end of reef
development and carbonate productivity in the Souss Basin is related to
the progradation of siliciclastic depositional systems (Toyonian
regression), considered to have caused the collapse of reef communities
throughout West Gondwana.^1";

Dyamics of a paleoecosystem reefs associated with oceanic change in
```

```
carbonate sedimentary regime and carbon cycling (Oxfordian, Swiss
Jura).- Palaios 26, 04: 197-211.- <b>FC&#038;P</b> 37, 103,
ID=7429^<b>Topic(s): </b>reefs, reefs dynamics, oceanic change;
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic U, Oxfordian;
<b>Geography: </b>Swiss Jura Mts^Herein we report an analysis of an
Oxfordian (Upper Jurassic) paleoreef located in the Swiss Jura
Mountains. The paleoreef is located in a Middle Oxfordian transitional
interval in which sedimentation switched from marl-dominated to
carbonate-dominated deposits. The paleoecosystem is composed of four
successive fossil communities characterized by microsolenid corals and
organisms that specialized in suspension feeding. Carbon isotopes
measured from echinoid spine carbonates exhibit a positive trend from
~1.0 &#8240; to 2.5 &#8240; in &#948;13C values from the base to the
top of the paleoreef. Comparison of &#948;13C curves with organic
matter and belemnites shows different patterns not compatible with a
global variation of the carbon cycle. Similar fossil assemblages and
stratigraphic sequences identical in age are found along the
continental margin of the Tethys-Atlantic Ocean. This
biolithostratigraphic succession corresponds to increasing &#948;13C
values of marine and biogenic carbonates, to the transition from
marl-dominated to carbonate-dominated deposits, and to the development
of carbonate platforms, which together suggest a change in the carbon
cycling regime within the Tethys-Atlantic Ocean system.^1";
s[6858] = "CHABLAIS J., MARTINI R., SAMANKASSOU E., ONOUE T. &#038;
SANO H. (2010).- Microfacies and depositional setting of the Upper
Triassic mid-oceanic atoll-type carbonates of the Sambosan Accretionary
Complex (southern Kyushu, Japan).- Facies 56, 2: 249-278.-
<b>FC&#038;P</b> 37, 104, ID=7430^<b>Topic(s): </b>reef carbonates,
reef ecology, mid-oceanic reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Triassic U, Carnian ? Rhaetian, Sambosan Accretionary Complex;
<b>Geography: </b>Japan, Kyushu S^The Upper Triassic shallow-water
limestones of the Sambosan Accretionary Complex are reconstructed as a
remnant of a mid-oceanic atoll-type build-up upon a seamount in the
Panthalassan Ocean. The Sambosan atoll-type carbonates and its pedestal
were accreted along with deep-water ribbon-chert and related siliceous
rocks to the eastern margin of Asia during the Late Jurassic to Early
Cretaceous. Studied limestones crop out in southern Kyushu Island,
southwest Japan. Although the prevailing and intense deformation during
the accretionary process prevents measurement of sections in
stratigraphic successions, and sedimentary structures are poorly
preserved, microfacies description and foraminifers analysis allow us
to speculate the depositional setting of the Sambosan limestones.
Seventeen microfacies are distinguished and several foraminifers of
Tethyan affinity are identified. Foraminifers indicate a Late Carnian
to Rhaetian age. The Tethyan affinity of the macro- and microfaunas
suggests that the Sambosan seamount was located presumably in a low- to
middle-latitudinal zone of the southern hemisphere during the Late
Triassic.^1";
s[6859] = "CHABLAIS J., ONOUE T. &#038; MARTINI R. (2010).- Upper
Triassic reef-limestone blocks of southwestern Japan: New data from a
Panthalassan seamount.- Palaeogeography, Palaeoclimatology,
Palaeoecology 293, 1/2: 206-222.- <b>FC&#038;P</b> 37, 104,
ID=7431^<b>Topic(s): </b>reefs, reef-derived blocks, reef
reconstructions; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic U,
Norian - Rhaetian, Sambosan Accretionary Complex ; <b>Geography:
</b>Japan, Shikoku W^Norian-Rhaetian reef-limestone outcrops belonging
to the Sambosan Accretionary Complex located near and within Inaba
Cave, western Shikoku Island (Japan), are described in detail for the
first time. This patch-reef complex is inferred to have formed within
an atoll-type carbonate system accumulated over a mid-oceanic seamount
surrounded by deep-water radiolarian cherts in the Panthalassic Ocean
during the Late Triassic. Because most Upper Triassic reef studies are
from the former Tethys Ocean, counterparts from the Panthalassic Ocean,
```

```
such as this study, are fundamental in resolving sedimentological,
palaeontological and palaeobiogeographical issues related to Late
Triassic reefs. The microfacies, palaeontology and palaeoecology of the
Inaba reef limestones were investigated. The reef-boundstone facies is
characterised by abundant coralline sponges that, in association with
microbial crusts, constitute the main framebuilders. Some phaceloid
and/or dendroid corals occur, but these groups are poorly represented,
as are algae. Microproblematica and foraminifers exhibit rich
associations, acting as secondary reef builders and/or reef dwellers.
The surrounding setting comprises biodetrital sponge-coral rudstone and
well-preserved megalodont rudstone-floatstone. The sedimentary contact
between reef and lagoon facies is observed for the first time within
Inaba Cave. Important similarities with the coeval Upper Triassic reefs
of the southern classic Peri-Tethys area and especially with the Omani
seamounts are recognised, suggesting a more southern-Hemisphere origin
for Upper Triassic Japanese reefs than predicted by previous reef
studies.^1";
s[6860] = "COPPER P. &#038; JIN J. (2012).- Early Silurian (Aeronian)
East Point Coral Patch Reefs of Anticosti Island, Eastern Canada: First
Reef Recovery from the Ordovician/Silurian Mass Extinction in Eastern
Laurentia.- Geosciences (MDPI) 2: 64-89; Basel.- <b>FC&#038;P</b> 37,
104, ID=7432^<b>Topic(s): </b>reefs, patch reef swarm, reef facies,
post-extinction reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Silurian L, Aeronian; <b>Geography: </b>Canada, Anticosti Island^An
extensive late Aeronian patch reef swarm outcrops for 60-70 km on
Anticosti Island, eastern Canada, located in the inner to mid-shelf
area of a prominent tropical carbonate platform of southeastern
Laurentia, at 20&#176;-25&#176; S paleolatitude of the southern typhoon
belt. This complex, described here for the first time, includes more
than 100 patch reefs, up to 60-80 m in diameter and 10 m high. Reefs
are exposed three-dimensionally on present-day tidal flats, as well as
inland along roads and rivers. Down the gentle 1&#176;-2&#176;
paleoslope, the reefs grade into coral-sponge biostromes, and westerly
they grade into inter-reef or deeper &#039;crinoidal meadow&#039;
facies. The reef builders were dominantly tabulate and rugose corals,
with lesser stromatoporoids. Other components include crinoids,
brachiopods, green algae (especially paleoporellids), and encrusting
cyanobacteria: reefs display some of the earliest known symbiotic
intergrowths of corals and stromatoporoids. Reefs were variably built
on a base of crinoidal grainstones, meadows of baffling tabulate
corals, brachiopod shells, or chlorophytes. These reefs mark an early
phase of reef recovery after a prominent reef gap of 5-6 million years
following the Ordovician/Silurian mass extinction events. The reefs
feature a maximal diversity of calcifying cyanobacteria, corals and
stromatoporoids, but low diversity of brachiopods, nautiloids and
crinoids. Following the North American Stratigraphic Code, we define
herein the Menier Formation, encompassing the lower two members of the
existing Jupiter Formation.^1";
s[6861] = "CORLETT H., JONES B. &#038; JIN Jisuo (2011).- Ecological
controls on Devonian stromatoporoid-dominated and coral-dominated reef
growth in the Mackenzie Basin, Northwest Territories, Canada.- Canadian
Journal of Earth Sciences 48, 12: 1543-1560.- <b>FC&#038;P</b> 37, 106,

Horn Plateau Fm; <b>Geography: </b>Canada, NW Territories, Mackenzie
Basin^The Horn Plateau Formation, composed of isolated reefs, is part
of the Devonian strata that formed in the Mackenzie Basin in the
Northwest Territories, Canada. The reefs stretch over a ~350 km
northeast-southwest trend and are dominated by tabulate and rugose
corals in the northeast, near exposed Canadian Shield rocks, and
stromatoporoids further out in the basin. Detailed facies analyses of
each reef type shows distinct differences in their biological makeup,
energy regimes, and carbonate sedimentation rates. Geochemical analyses
```

```
(stable isotopes and rare-earth elements) set against established
paleogeography in the Mackenzie Basin reveal that the coral-dominated
and stromatoporoid-dominated reefs grew under different ecological
conditions. Separations in the data imply that the coral-dominated
reefs grew in waters that were relatively enriched in nutrients and the
stromatoporoid-dominated reefs, further down the ramp, were in
oligotrophic conditions. With no current established method to directly
measure Paleozoic nutrient levels or to detect where they were sourced
from, it is unclear why the coral-dominated reefs experienced higher
nutrient levels. The paleogeography of the Mackenzie Basin could have
affected the apparent stratification of nutrients on the carbonate
ramp. Possible nutrient sources in the area are from coastal upwelling
from the open ocean northwest of the ramp, or locally sourced nutrients
from runoff on the adjacent exposed Canadian Shield rocks.^1";
s[6862] = "DENAYER J. &#038; ARETZ M. (2011).- Discovery of a
Mississippian Reef in Turkey: The Upper Visean
Microbial-Sponge-Bryozoan-Coral Bioherm From Kongul Yayla (Taurides, S
Turkey).- Turkish Journal of Earth Sciences 20, 2011: 1-?.-
<b>FC&#038;P</b> 37, 107, ID=7434^<b>Topic(s): </b>reefs,
bioconstructors, reef structures; <b>Systematics: </b>;
<b>Stratigraphy: </b>Carboniferous L, Visean, Asbian; <b>Geography:
</b>Turkey, Taurides central^For the first time, a Mississippian reef
is described from Turkey. This microbial-sponge-bryozoan-coral bioherm
has been discovered in the Central Taurides (South Turkey), at Kongul
Yayla located between Hadim and Taskent. The bioherm contains a rich
and diversified fauna: sponges and rugose corals are of particular
interest. The bioherm shows four main facies reflecting distinct growth
stages from the base to the top: (1) the basal bioclastic beds, (2) the
core facies formed of framestone comprising rugose corals, lithistid
sponges, fistuliporid bryozoans and microbial boundstone, (3) the crest
facies with large colonies of cerioid rugose corals and chaetetid
sponges, and (4) the bioclastic facies containing reworked material
from the bioherm in lateral and overlying positions to it. The entire
bioherm is topped by siltstones with thin bioclastic horizons, often
slumped.Siphonodendron pauciradiale and Lithostrotion maccoyanum are
the guide taxa for the RC7&#946; biozone and indicate an upper Asbian
age for the bioherm. The Kongul Yayla bioherm resembles most the
Cracoean reefs from northern England. It confirms the position of this
buildup type along the platform margins and edges in the Palaeotethyan
realm as seen in the British Isles, Belgium, southern France, southern
Spain and North Africa. Facies and the coral fauna argue for a European
affinity of the Anatolian terrane.^1";
s[6863] = "EZAKI Y., LIU J. &#038; ADACHI N. (2012).- Lower Triassic
stromatolites in Luodian County, Guizhou Province, South China:
evidence for the protracted devastation of the marine environments.-
Geobiology 10, 1: 48-59.- <b>FC&#038;P</b> 37, 108,
ID=7435^<b>Topic(s): </b>mass extinctions, reef crises, stromatolites;
<b>Systematics: </b>; <b>Stratigraphy: </b>Triassic L, Olenekian;
<b>Geography: </b>China S, Guizhou^Stromatolites are one of the oldest
and most intriguing organosedimentary deposits. In contrast to
stromatolites of the Precambrian to Early Ordovician, Phanerozoic
equivalents occurred episodically under specific conditions. A group of
previously undescribed stromatolites in composition occur in the Lower
Triassic (Olenekian) at the Dajiang section in the Luodian region of
Guizhou Province, South China. We described the textures of these
stromatolites with the aim of determining the genetic mechanisms and
revealing the nature of interactions between micro-organisms and marine
environments. Mesoscopic features show that the stromatolites consist
of several sets of stacked slices, and that they are embedded in
alternating beds of fine and coarse microsphere packstones that include
aggregates of microspheres, forming grapestones and lumps.
Microscopically, the stromatolites consist of spar- and
dolomite-infilled microspheres (average diameter, 100 &#956;m),
```

```
micrites, peloids, small-sized pyrite framboids (average diameter, 5.8
&#956;m) and fenestrae. Micrite-dominant intercalations accentuate
laminated textures at a mesoscopic level and are laterally continuous
with micrite-rich parts in surrounding interstromatolites, indicating
the simultaneous, widespread deposition of these layers. The
microspheres and associated micrites were the products of in situ
microbial activity, probably sulphate-reducing or anoxygenic
phototrophic bacteria, which led to the formation of these unusual
stromatolites. Even during a protracted period of harsh marine
conditions, the micrite-rich carpets were deposited intermittently on
the stromatolites and their surroundings under severely
anoxic/sulphidic conditions. The presence of Early Triassic
stromatolites and their subtle but important vertical variations in
texture provide a record of temporal changes in marine conditions
during geobiologically critical intervals.^1";
s[6864] = "FAGERSTROM J.A. &#038; WEST R.R. (2011).- Roles of
clone-clone interactions in building reef frameworks: principles and
examples.- Facies 57: 375-394.- <b>FC&#038;P</b> 37, 109,
ID=7436^<b>Topic(s): </b>reef frameworks, clonal organisms, biological
interactions; <b>Systematics: </b>; <b>Stratigraphy: </b>fossil &#038;
living; <b>Geography: </b>^In living and fossil reefs, rapid upward
clone growth provides positive topographic relief, the skeletal
framework provides rigidity. Clonal organisms have been the chief
frame-builders during most of the Phanerozoic, large clone size, growth
habit, growth form, and arrangement of these clones in the framework
result from rapid growth rates. Dense skeletal packing enhances
rigidity and results in live-live interactions between juxtaposed
clones. These interactions are both heterospecific and conspecific, the
former mostly involve spatial competition whereas the latter involve
clone fusion, self-overgrowth, and fission. We describe three types of
fusion: (a) inter-clone fusion of two or more clones, each from a
separate propagule, (b) intra-clone fusion of parts of the same clone
having its origin from a single propagule, it includes recovery from
partial clone degradation and self-overgrowth, (c) quasifusion between
a live bud/polyp/zooid and a dead part (stem, branch) of the same or a
different clone, i.e., a livedead association.^1";

RENEMA W. &#038; POTTS W.C. (2011).- The impact of the Mid-Pleistocene
Transition on the composition of submerged reefs of the Maui Nui
Complex, Hawaii.- Palaeogeography, Palaeoclimatology, Palaeoecology
299, 3-4: 493-506.- <b>FC&#038;P</b> 37, 110, ID=7437^<b>Topic(s):
</b>reefs, sea-level oscillations; <b>Systematics: </b>;
<b>Stratigraphy: </b>Pleistocene-mid, Maui Nui Complex; <b>Geography:
</b>USA, Hawaii^The submarine reef terraces (L1-L12) of the Maui Nui
Complex (MNC-the islands of Lanai, Molokai, Maui and Kahoolawe) in
Hawaii provide a unique opportunity to investigate the impact of
climate and sea level change on coral reef growth by examining changes
in reef development through the Mid-Pleistocene Transition (900-800
ka). We present an analysis of the biological and sedimentary
composition of the reefs that builds directly on recently published
chronological and morphological data. We define nine distinct limestone
facies and place them in a spatial and stratigraphic context within 12
reef terraces using ROV and submersible observations. These include
oolitic, two coral reef, two coralline algal nodule, algal crust,
hemi-pelagic mud, bioclastic and peloidal mud facies. These facies
characterise environments from high energy shallow water coral reef
crests to low energy non-reefal deep-water settings. Combining the
bottom observations and sedimentary facies data, we report a shift in
the observed sedimentary facies across the submerged reefs of the MNC
from dominant shallow coral reef facies on the deep reefs to coralline
algae dominated exposed outcrop morphology on the shallower reefs. We
argue that this shift is a reflection of the change in period and
amplitude of glacioeustatic sea level cycles (41 kyr and 60-70 m to 100
```

```
kyr and 120 m) during the Mid-Pleistocene Transition (MPT, ~800 ka),
coupled with a slowing in the subsidence rate of the complex. The
growth of stratigraphically thick coral reef units on the deep Pre-MPT
reefs was due to the rapid subsidence of the substrate and the shorter,
smaller amplitude sea level cycles allowing re-occupation and coral
growth on successive cycle low-stands. Longer, larger amplitude sea
level cycles after the MPT combined with greater vertical stability at
this time produced conditions conducive to deep-water coralline algae
growth which veneered the shallower terraces. Additionally, we compare
reef development both within the MNC, and between the MNC and Hawaii.
Finally we suggest that climatic forcings such as sea-surface
temperature and oceanographic currents may also have influenced the
distribution of coral species within the sample suite, e.g., the
disappearance of the Acropora genus from the Maui Nui Complex in the
Middle Pleistocene.^1";

fore reef limestones: a quantitative study (Iberg Reef, Harz Mts.,
Germany).- Palaeobiodiversity and Palaeoenvironments 93, 1 : 91-101.-
<b>FC&#038;P</b> 37, 111, ID=7438^<b>Topic(s): </b>reefs, reef facies,
diagenesis; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M U,
Iberg reef; <b>Geography: </b>Germany, Harz^Facies in a 238-m-long core
drilled through the fore reef of the Devonian (Givetian-Frasnian) Iberg
Reef is largely characterised by detrital deposits. Fibrous, early
marine cements are common. Stromatoporoids, corals, and crinoids are
the dominant reef-building taxa. Brachiopods, cephalopods, and
conodontophorids belong to the reef dwellers. Reef destroyers include
gastropods and rare echinoids. Quantitative analysis of abundance data
allows for dilineation of five facies including detritus-rich
grainstones- rudstones, cement- and detritus-rich
grainstones-rudstones, cement-rich rudstones, stromatoporoid rudstones,
and crinoid grainstones. Time-series analysis indicates cyclic
sedimentation that might have been related to mid-late Devonian
third-order sea-level variations. However, the long-term (mid-Devonian
to Early Carboniferous) development of the Iberg Reef including the
post-reef seamount stage was presumably controlled by subsidence.^1";
s[6867] = "GUIDO A., HEINDEL K., BIRGEL D., ROSSO A., MASTANDREA A.,
SANFILIPPO R., RUSSO F. &#038; PECKMANN J. (2013).- Pendant
bioconstructions cemented by microbial carbonate in submerged marine
caves (Holocene, SE Sicily).- Palaeogeography, Palaeoclimatology,
Palaeoecology 388: 166-180.- <b>FC&#038;P</b> 37, 112,
ID=7439^<b>Topic(s): </b>reefs, reef cavities, pendant
bioconstructions; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>Italy, Sicily SE^Unusual pendant bioconstructions
occur within two submerged caves in the Plemmirio Marine Protected
Area, south of Syracuse (SE Sicily). These cm- to dm-sized
bioconstructions project downward from the cave roofs. The main
framework builders are serpulids belonging to the genera Protula,
Semivermilia and Josephella. Encrusting bryozoans, corals, hydrozoans
and sponges are subordinately present, whereas bivalves and brachiopods
are overall rare. These faunal associations are characteristic of the
studied caves, but only in some places they form small bioconstructions
that are cemented by microbial carbonates made up by autochthonous,
peloidal to clotted peloidal and aphanitic micrite. The autochthonous
micrite stabilizes the pendant bioconstructions, herein referred to as
biostalactites. The microbial carbonate reveals high contents of
bacterial lipid biomarkers. Among the most abundant compounds are
mono-O-alkyl glycerol ethers (MAGEs) and branched fatty acids
(10-Me-C16:0; iso- and anteiso-C15:0 and -C17:0), interpreted as
biomarkers of sulfate-reducing bacteria. Other compounds preserved in
the autochthonous carbonates include lipids derived from marine zoo-
and phytoplankton (brassicasterol, dinosterol and monounsaturated
short-chain fatty acids), unspecified marine bacteria (saturated and
monounsaturated short-chain fatty acids) and land plants (long-chain
```

```
fatty acids, long-chain alcohols, stigmasterol, sitosterol and
campesterol). The observed lipid biomarker signatures are remarkably
similar to those of post-glacial reefal microbialites, where
microbialite formation in cavities of the coral framework was also
mediated by sulfate-reducing bacteria. In the submerged caves of
Plemmirio Marine Protected Area, serpulid colonies apparently occur
preferentially where freshwater is seeping through crevices in the
limestone. The consequent nutrification is believed to favor serpulid
aggregation and the growth of other skeletal (i.e., bryozoans and
corals) and soft-bodied organisms (i.e., sponges and ascidiae). The
resultant accumulation of biomass and its taphonomy provide niches for
sulfate-reducing bacteria, which induce carbonate precipitation
cementing and stabilizing the biostalactites. The finding of pendant,
cemented bioconstructions in the Mazzere and Granchi caves of the
Plemmirio Marine Protected Area reveals that sulfate-reducing bacteria
are involved in microbialite formation in various cryptic environments.
The formation of such peloidal to clotted peloidal microcrystalline
carbonates in cryptic ecosystems is a significant factor for the
stabilization of different kinds of bioconstructions, spanning from
small biostalactites to large reefs.^1";
s[6868] = "VAN HULTEN F.F.N. (2012).- Devono-carboniferous carbonate
platform systems of the Netherlands.- Geologica Belgica 15, 4:
284-296.- <b>FC&#038;P</b> 37, 113, ID=7440^<b>Topic(s): </b>reefs,
hydrocarbon traps; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian,
Carboniferous; <b>Geography: </b>Netherlands, deep subsurface^Large
Palaeozoic carbonate build-ups, globally important for hydrocarbon
exploitation, are generally not associated with the Netherlands or with
the larger Southern North Sea region. The last ten years, information
of new wells and seismic imaging have changed this perception. Recent
seismic interpretations have indicated massive reef like carbonate
platforms far below conventional petroleum exploration targets in the
Netherlands. Some of the platforms are very sizeable and comparison
with dimensions of Mississippian build-ups in the Caspian region or
Devonian reefs of Canada can be made. New well information, released
the last two years, dates the upper part of the platform as
Mississippian. Based on seismic interpretation, some platforms most
likely contain a Devonian core. UK petroleum exploration on the Mid
North Sea High also provides new insights into Devonian carbonate
build-ups. Due to the great depth of the Devono-Carboniferous strata in
most areas, it is unclear if these carbonate platform reservoirs are a
new petroleum exploration frontier or are situated below the economic
basement. For many years the same palaeogeographic map could be used
for North Western Europe for the Devonian and Mississippian time
interval. The new data requires a revised palaeogeography. The
following summary provides an overview.^1";
s[6869] = "KIESSLING W. (2010).- Reef expansion during the Triassic:
Spread of photosymbiosis balancing climatic cooling.- Palaeogeography,
Palaeoclimatology, Palaeoecology 290, 1-4: 11-19.- <b>FC&#038;P</b> 37,
114, ID=7441^<b>Topic(s): </b>reefs, photosymbiosis, climate cooling;
<b>Systematics: </b>; <b>Stratigraphy: </b>Triassic; <b>Geography:
</b>^The PaleoReefs Database indicates that reef abundance increased
profoundly during the Triassic period, from a pronounced low in the
Early Triassic to a major peak in the Norian. This expansion is also
evident when standardizing for sampling. Corresponding to the reef
expansion is a relative increase of scleractinian corals as reef
builders, whereas the contribution of hypercalcifying sponges and
microbes decreased during the Triassic. The numerical expansion of
corals is paralleled by a proportional increase of morphological
features that are suggestive of photosymbiosis, such that the Norian
reef boom might be explained by the spread of photosymbiosis in
corals.The geographical expansion of reefs was far less pronounced
especially concerning palaeolatitude. Late Triassic reef growth was
limited to more or less the same latitudinal range as modern reefs. As
```

```
oxygen isotope data and new modeling results indicate declining
temperatures and CO2 concentrations during the Late Triassic, the lack
of latitudinal expansion might be attributed to global cooling. Reef
development during the Triassic can thus be explained by the
evolutionary spread of photosymbiosis balancing the effects of climatic
cooling.^1";
s[6870] = "KIESSLING W. &#038; SIMPSON C. (2011).- On the potential for
ocean acidification to be a general cause of ancient reef crises.-
Global Change Biology 17: 56-67.- <b>FC&#038;P</b> 37, 114,
ID=7442^<b>Topic(s): </b>ocean acidification, reef crises;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Anthropogenic rise in the carbon dioxide concentration in the
atmosphere leads to global warming and acidification of the oceans.
Ocean acidification (OA) is harmful to many organisms but especially to
those that build massive skeletons of calcium carbonate, such as reef
corals. Here, we test the recent suggestion that OA leads not only to
declining calcification of reef corals and reduced growth rates of
reefs but may also have been a trigger of ancient reef crises and mass
extinctions in the sea.We analyse the fossil record of biogenic reefs
and marine organisms to (1) assess the timing and intensity of ancient
reef crises, (2) check which reef crises were concurrent with inferred
pulses of carbon dioxide concentrations and (3) evaluate the
correlation between reef crises and mass extinctions and their
selectivity in terms of inferred physiological buffering.We conclude
that four of five global metazoan reef crises in the last 500 Myr were
probably at least partially governed by OA and rapid global warming.
However, only two of the big five mass extinctions show geological
evidence of OA.^1";

Volcanism and reef development in the Devonian: A case study from the
Lahn syncline, Rheinisches Schiefergebirge (Germany).- Gondwana
Research 17: 264-280.- <b>FC&#038;P</b> 37, 115, ID=7443^<b>Topic(s):
</b>reefs, submarine volcanoes; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian, Givetian - Frasnian; <b>Geography: </b>Germany, Rhenish
Slate Mts, Lahn syncline^New data from the Rheinisches Schiefergebirge
in Germany offer insights into a complex marine basinal facies setting
on the southern shelf area of the Old Red Continent. This
interdisciplinary approach has the aim of providing a reconstruction of
depositional and palaeoecological conditions of volcanic island induced
reef growth during the Middle Devonian time. Devonian volcanic activity
culminated in a Givetian-Frasnian phase producing mainly
alkali-basaltic to basanitic melts. Some volcanic buildups reached sea
level and gave rise to the development of reefs during times of reduced
volcanic activity. Reef communities in the Lahn syncline were dominated
by corals and stromatoporoids. In terms of conodont stratigraphy they
began to flourish during the Middle varcus-subzone in the Givetian and
lasted until the Late falsiovalis-subzone in the Frasnian. A facies
model is presented for the entire area that clarifies the association
of volcanism and reef development.^1";
s[6872] = "KOSSOVAYA O., VACHARD D. &#038; IZART A. (2013).- Climatic
impact on the reef biota in the Cisuralian and Guadalupian (Permian),
East European Platform.- Geological Society, London, Special
Publication 376: 343-366.- <b>FC&#038;P</b> 37, 116,
ID=7444^<b>Topic(s): </b>reef biota, climate change; <b>Systematics:
</b>; <b>Stratigraphy: </b>Permian L M; <b>Geography: </b>Russia, East
European Platform^As important components of extinct as well as modern
reefs, the measurement of changes in the composition of reef biota is
crucial in order to evaluate the influence of extrinsic factors on the
marine communities. The dramatic abiotic changes in the eastern and
northern Pangea was mirrored by a gradual transition from a photozoan
to a heterozoan association and the appearance of cool- (temperate-)
water carbonates both in reef and carbonate ramp environments. Analyses
of large skeletal and microbiotic components as well as microfacies
```

```
succession were used for detailed explanation of reef structure,
especially for lesser-known heterozoan skeletal mounds. The youngest
skeletal mounds are recognized in the Roadian. The stable isotope data
demonstrated a negative oxygen shift between latest Sakmarian and late
early Artinskian coinciding with the end of P2 glaciation. The
multiplicative nature of the event included the series of successive
changes of extrinsic factors such as ice melting in interglacial
episodes, eustatic ocean level rise, change of oceanic circulation and
decrease of water temperature. The late Artinskian and subsequent
Kungurian climatic impacts in the Northern Hemisphere were irreversible
for the photozoan biota and prevented its further development. Roadian
(Guadalupian) bryonoderm extended skeletal mounds developed in rather
warm-water environments.^1";

Platy coral patch reefs from eastern Panthalassa (Nevada, USA): unique
reef construction in the Late Triassic.- Palaeogeography,
Palaeoclimatology, Palaeoecology 313-314: 41-58.- <b>FC&#038;P</b> 37,
117, ID=7448^<b>Topic(s): </b>reefs, platy corals; <b>Systematics:
</b>; <b>Stratigraphy: </b>Triassic U, Norian; <b>Geography: </b>USA,
Nevada^Upper Triassic (Lower Norian) reefal buildups near Mina, Nevada,
represent some of the earliest scleractinian coral reefs from eastern
Panthalassa. The small patch reefs (~ 20-40 m high and ~ 50-150 m wide,
obvious metre-scale elevation above the surrounding sediments) are from
the Luning Allochthon and grew on an inner to middle ramp or in a deep
lagoon. The Mina patch reefs were constructed by several different
coral ecomorpho- types (platy, tabular, domal/massive, and branching
corals) interpreted to have had zooxanthellate symbionts, and record
subtle coral zonation within the reefs. Based on modern coral
```

```
ecomorphotypes, platy to tabular corals at Mina grew in the lower
euphotic zone (stressed by low light conditions), and the massive or
domal corals inhabited shallower water (possibly above fair weather
wave base) and were stressed by wave energy. Unlike most other Late
Triassic reef ecosystems where phaceloid branching corals or calcareous
sponges constitute the principal bioconstructors, the platy to tabular
corals were the primary builders in the Mina patch reefs. The Mina
reefs are also unique because cryptic and cavernous internal
environments, epibionts, cryptobionts, and thick microbial crusts are
rare or absent. The combination of platy coral dominance with the lack
of epibionts/cryptobionts/microbial crusts suggests that the Norian
reefs from Mina, Nevada represent a unique form of scleractinian reef
construction from the Late Triassic.^1";

SENOWBARI-DARYAN B. &#038; MARTINI R. (2013).- Depth transect of an
Upper Triassic (Rhaetian) reef from Gosau, Austria: Microfacies and
community ecology.- Palaeogeography, Palaeoclimatology, Palaeoecology
376: 1-21.- <b>FC&#038;P</b> 37, 118, ID=7449^<b>Topic(s): </b>reefs,
bathymetry, ecology; <b>Systematics: </b>; <b>Stratigraphy:
</b>Triassic U, Rhaetian; <b>Geography: </b>Austria, Gosau^In the Late
Triassic (~235-201.3 Ma) scleractinian corals and hypercalcified
sponges built large, diverse reef ecosystems, the most famous of which
are the Dachstein reefs. This study presents a depth transect along an
Upper Triassic (lower Rhaetian) Dachstein reef from the Gosausee margin
of the Dachsteingebirge (Gosau, Austria). The Gosausee
microbial-sponge-coral reef is a complete barrier reef with an almost
continuous fore reef to lagoon transect preserved (a very rare
occurrence for the Triassic), and thus provides a window into depth
zonation of Dachstein-type reef facies and biotic succession. The
Gosausee reef facies exhibit strong depth control and five classic reef
facies or zones are identified: the fore reef, reef front, reef crest,
back reef, and lagoon facies. Thin, rare microbial fabrics and a high
abundance of fine-grained, mud-rich skeletal wackestones (transported
reef debris) characterize the deepest fore reef. As the reef shallows,
muddy sediments decrease in abundance and are replaced by microbial
fabrics, corals, and cements. Abundant sponges, microbial crusts, and
thick, marine cements typify the reef crest, whereas
microbialite-coated phaceloid corals are dominant in the back reef
facies. Heavily cemented oncoids or microbial-sponge bindstones are
characteristic of the lagoon. Based on their compositional and biotic
similarities, the Gosausee reef was likely part of the same barrier
reef systems as the source reef for the Gosaukamm reef breccia (one of
the classic Norian-Rhaetian Dachstein reefs). The reef zones of the
Gosausee margin can be used to interpret the depth or reef zone of less
well preserved reef fragments, can inform models of community ecology
and niche utilization in the Late Triassic, and highlight the need for
additional research into the environmental factors that controlled
biotic distribution in Upper Triassic reefs.^1";
s[6878] = "MARTINDALE R.C., ZONNEVELD J.-P. &#038; BOTTJER D.J.
(2010).- Microbial framework in Upper Triassic (Carnian) patch reefs
from Williston Lake, British Columbia, Canada.- Palaeogeography,
Palaeoclimatology, Palaeoecology 297, 3-4: 609-620.- <b>FC&#038;P</b>
37, 119, ID=7450^<b>Topic(s): </b>reefs, microbial framework;
<b>Systematics: </b>; <b>Stratigraphy: </b>Triassic U, Carnian;
<b>Geography: </b>Canada, British Columbia^The Upper Triassic (Carnian)
patch reefs from Pardonet Hill, British Columbia, Canada are the only
known Upper Triassic reefal buildups from the craton margin of
northwestern Pangaea. These buildups occur within the lower Baldonnel
Formation and are characterized by a moderately diverse assemblage of
corals, spongiomorphs, crinoids, echinoderms, bivalves, gastropods,
brachiopods, and microbialites. Despite the evidence that these
buildups had a rigid structure (e.g. brecciation and hardgrounds) and
relief above the seafloor (visible in outcrop), the exact nature and
```

```
extent of the framework has previously been undetermined. This study
focuses on the microfacies within these patch reefs and highlights the
importance of microbialites in the framework of these diminutive
buildups (~100m3 to 500m3). * The Pardonet Hill patch reefs were mapped
in outcrop to determine their structure, geometry, and the importance
of large metazoan framework builders. Samples of the reefal horizons
and surrounding strata were evaluated utilizing point count analyses of
organisms, cements, lithic grains, and microbial textures in thin
section. Quantitative analysis of the microfacies in concert with
traditional descriptions of reef construction and reef classification
allow a more thorough understanding of organism abundance and reef
structure. * Despite the presence of corals and spongiomorphs
throughout the outcrop, they very rarely form a true, intergrown
framework, except at the base of Patch Reef B. Instead, cemented
microbialites form a rigid framework in the core of some patch reefs.
Detailed examination of the microfacies and reef construction
demonstrates the importance of non-skeletal framework builders in the
structural fabric of these small buildups. Pardonet Hill Patch Reef B
is the first true reef with a microbial framework documented from the
Upper Triassic of North America. This microbial-coral framework bears a
striking similarity to some Triassic and Upper Jurassic coral-microbial
reefs from the Tethys, although the depositional environment of the
Pardonet Hill patch reefs is likely shallower and more energetic than
the Tethyan reefs.^1";

The shifting biogeography of reef corals during the Oxfordian (Late
Jurassic). A climatic control?.- Palaeogeography, Palaeoclimatology,
Palaeoecology 365-366: 136-153.- <b>FC&#038;P</b> 37, 120,
ID=7451^<b>Topic(s): </b>reefs, climatic change; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic U, Oxfordian; <b>Geography: </b>^Until
recently, the Jurassic was thought to have been a period characterised
by a predominantly warm and equable climate. During the Oxfordian (a
time span of six million years in the Late Jurassic) the distribution
of tropical coral reefs was limited to about 35&#176;N and near to
25&#176;S. However, in Middle Oxfordian time, coral reefs were abundant
only at higher latitudes and almost entirely missing near the equator.
During that time the area of maximum reef development had shifted
poleward to a belt lying between 20&#176;N and 35&#176;N, leaving
hardly any coral formations at the lower inner-tropical latitudes.
After demise towards the end of Middle Oxfordian time, the low-latitude
reefs recovered during the Late Oxfordian, accompanied by a southward
migration of reef corals in the northern hemisphere. As suggested by
stable isotope and palynological data, the faunal migration can be
correlated with a significant rise in seawater temperature during the
Middle Oxfordian.^1";
s[6880] = "MORROW J., HARRIES P.J. &#038; KRIVANEK J.G. (2011).- Reef
recovery following the Frasnian-Famennian (Late Devonian) mass
extinction: evidence from the Dugway Range, West-Central Utah.- Palaios
26: 607-622.- <b>FC&#038;P</b> 37, 120, ID=7452^<b>Topic(s): </b>reef
recovery, mass extinctions; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian U, Frasnian / Famennian; <b>Geography: </b>USA, Utah^The
temporally extensive late Middle through Late Devonian biotic crisis
involved at least three distinct peaks of elevated extinction intensity
during an interval spanning ,25 myr and resulted in the preferential
elimination of certain shallow-marine, warm-water taxa, especially
members of reef communities. By the end of the second peak, delimited
by the Frasnian-Famennian (F-F) boundary, the stromatoporoids, members
of the dominant constructor guild in mid-Paleozoic reefal ecosystems,
had ceased building reefs in most parts of the world. The northern
Dugway Range in west-central Utah, United States, however, represents
one of the few locations globally where stromatoporoids continued reef
building into the Famennian. Two measured sections there, which are
constrained biostratigraphically using conodonts, indicate that the
```

```
biohermal sequences occur within the middle Palmatolepis crepida
biozone and are early Famennian in age. The post-F-F extinction Dugway
reefal faunas are depauperate and dominated by labechiid and
stylostromid stromatoporoids, as is characteristic of other early
Famennian reefs. In this region, evidence for reefal development is
episodic, with stromatoporoid-bearing units interbedded with peloidal
and coated-grain carbonate units lacking evidence of reef construction.
The stromatoporoid survivors, although fairly minor constituents of
Frasnian reef communities, belong to long-ranging clades and may
represent so called extinction-resistant taxa that flourished, albeit
locally in Laurentia, following the F-F mass extinction.^1";

&#038; PAPAZZONI C.A. (2012).- Mesophotic coral buildups in a prodelta
setting (Late Eocene, southern Pyrenees, Spain): a mixed
carbonate-siliciclastic system.- Sedimentology 59: 766-794.-
<b>FC&#038;P</b> 37, 121, ID=7453^<b>Topic(s): </b>reefs, coral
buildups, carbonate-siliciclastic setting; <b>Systematics: </b>;
<b>Stratigraphy: </b>Eocene, Priabonian; <b>Geography: </b>Spain,
Pyrenees S^Lower Priabonian coral bioherms and biostromes, encased in
prodelta marls/clays, occur in the Ai&#180;nsa-Jaca piggyback basin, in
the South Central Pyrenean zone. Detailed mapping of lithofacies and
bounding surfaces onto photomosaics reveals the architecture of coral
buildups. Coral lithosomes occur either isolated or amalgamated in
larger buildups. Isolated lithosomes are 1 to 8m thick and a few
hundred metres wide; clay content within coral colonies is significant.
Stacked bioherms form low-relief buildups, commonly 20 to 30m thick,
locally up to 50m. These bioherms are progressively younger to the
west, following progradation of the deltaic complex. The lowermost
skeletal-rich beds consist of bryozoan floatstone with wackestone to
packstone matrix, in which planktonic foraminifera are abundant and
light-related organisms absent. Basal coral biostromes, and the base of
many bioherms, consist of platy-coral colonies &#8216;floating&#8217;
in a fine-grained matrix rich in branches of red algae. Corals with
domal or massive shape, locally mixed with branching corals and
phaceloid coral colonies, dominate buildup cores. These corals are
surrounded by matrix and lack organic framework. The matrix consists of
wackestone to packstone, locally floatstone, with conspicuous red algal
and coral fragments, along with bryozoans, planktonic and benthonic
foraminifera and locally sponges. Coral rudstone and skeletal
packstone, with wackestone to packstone matrix, also occur as wedges
abutting the buildup margins. Integrative analysis of rock textures,
skeletal components, buildup anatomy and facies architecture clearly
reveal that these coral buildups developed in a prodelta setting where
shifting of delta lobes or rainfall cycles episodically resulted in
water transparency that allowed zooxanthellate coral growth. The
bathymetric position of the buildups has been constrained from the
light-dependent communities and lithofacies distribution within the
buildups. The process-product analysis used here reinforces the
hypothesis that zooxanthellate corals thrived in mesophotic conditions
at least during the Late Eocene and until the Late Miocene. Comparative
analysis with some selected Upper Eocene coral buildups of the north
Mediterranean area show similarities in facies, components and
textures, and suggest that they also grew in relatively low light
(mesophotic) and low hydrodynamic conditions.^1";

studies of Cenozoic shallow-water, mixed carbonate-siliciclastic
```

```
depositional systems have focused on their sedimentology. To date,
however, comprehensive analyses of biotas and biofacies of Indo-West
Pacific reefs that developed in mixed carbonate-siliciclastic systems
are lacking. This study describes the palaeoenvironment and
biodiversity of a late Burdigalian patch reef that developed in a mixed
carbonate-siliciclastic depositional system. The studied exposure is
located at the northeast margin of the Kutai Basin near Bontang
(Indonesia), and is approximately 80m wide and 25m thick. Multi-taxon
analysis of the most abundant fossil groups, including larger benthic
foraminifera, corals, coralline algae, and bryozoans, aims to provide a
model for environmental interpretation that will allow comparison with
similar deposits of Indo-West Pacific region. Based on fossil content
and lithology, five different facies types have been distinguished:
foraminiferal packstone (FP), bioclastic packstone with foralgal
communities (BP), thin-platy coral sheetstone (CS), platy-tabular coral
platestone (CP), and shales (S). Among larger benthic foraminifera,
smaller and more robust forms dominate in the FP and BP facies, while
larger and flatter forms are the most abundant in the CS and CP facies.
Thin-platy corals are dominant in the CS facies and gradually change
into thicker platy-tabular forms in the CP facies. Assemblages and
growth forms of coralline algae show no major differences between the
facies types and are dominated by melobesioids and Sporolithon. The
majority of bryozoan species are encrusting and were found only in the
CS facies. Light-dependent organisms occurring in the reef indicate low
light conditions typical for mesophotic reefs. The relatively small
size of this reef complex and quite distinct vertical changes in the
facies types, combined with the high siliciclastic content in most of
the units, points to strong terrigenous input affecting water
transparency as the main factor controlling the reef growth.^1";
s[6883] = "OGAR V.V. (2012).- Carboniferous buildups in the Donets
Basin (Ukraine).- Geologica Belgica 15, 4: 340-349.- <b>FC&#038;P</b>
37, 123, ID=7455^<b>Topic(s): </b>biostromes, bioherms; <b>Systematics:
</b>; <b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>Ukraine,
Russia, Donets Basin^The Carboniferous (Mississippian and
Pennsylvanian) of the Donets Basin contains bioherms and biostromes in
several stratigraphic levels. The study of buildups of this region and
their comparison with other areas allows to suggest that the
composition of reef-building organisms changed during the
Carboniferous. Up to the late Visean, they were formed on a shallow
water carbonate platform, whereas younger bioconstructions are
restricted to distinctive limestone horizons of cyclothems. Visean
shallow-marine bioconstructions are represented by
Siphonodendron-biostromes which are typical for the Late Visean of many
areas of the Paleothetys. In the unstable conditions of the paralic
basin with frequent environmental changes bioconstructions formed
during transgressive phases. The late Serpukhovian buildups were
complex coral-chaetetid biostromes and bioherms. In Bashkirian times
appeared chaetetid and coral-chaetetid biostromes as well as algal
bioherms. In the early Moscovian coral and coral-chaetetid biostromes
were the most common. During the middle Moscovian dominated bioherms
probably of microbial origin, and at the end of Moscovian time
chaetetid biostromes were typical. At the earliest Gzhelian time
algae-sponge bioherms appeared in the Donets Basin.^1";

(2011).- Microbial carbonates and corals on the marginal French Jura
platform (Late Oxfordian, Molinges section).- Facies 57, 3: 469-492.-
<b>FC&#038;P</b> 37, 124, ID=7456^<b>Topic(s): </b>microbialites, coral
buildups, facies patterns; <b>Systematics: </b>; <b>Stratigraphy:
</b>Jurassic U, Oxfordian U; <b>Geography: </b>France, Jura Mts,
Molinges^Molinges was located on an Upper Jurassic ramp system of
low-energy regime that developed at the southern margin of the French
Jura platform. The sedimentary succession is characterized by the
transition from a mixed siliciclastic-carbonate to a carbonate
```

```
depositional setting that occurred during a long-term shallowing-upward
trend. The disappearance of siliciclastics is explained by a climatic
change, from humid and cold to drier and warmer conditions, previously
identified in Late Oxfordian adjacent basins. The base of the section
shows marl-limestone alternations of outer ramp. In its middle part,
the section displays oncolitic marls, coral-microbialite beds and
oncolitic limestones that deposited in a mid ramp position. Finally,
the upper section part is made of oolitic limestones of inner ramp. In
outer- to mid-ramp settings submitted to terrigenous inputs, the
stacking pattern of deposits and facies evolution allow the
identification of elementary, small-, medium-, and large-scale
sequences. Small amplitudes of sea-level variations probably controlled
rapid shifts of facies belts and reef window occurrences. In
small-scale sequences, the coral beds developed during periods of
sea-level rise. The decreasing rate of sea-level rise is marked by the
downramp shift of the oncolitic limestone belt that led to the demise
of coral-microbialite beds. These bioconstructions are mainly
represented by thin biostromes in which corals never reach great sizes.
The coral assemblages mainly include the genera Enallhelia,
Dimorpharaea, Thamnasteria, and some solitary forms (Montlivaltia and
Epistreptophyllum). They suggest relatively low-mesotrophic conditions
in marine waters during the edification of the primary framework.
Relatively cold water temperatures and periods of more elevated
nutrient contents are probably responsible of the reduced coral
development and the formation of a large amount of microbialites.^1";

Post-tectonic limitations on Early Devonian (Emsian) reef development
in the Gobi-Altai region, Mongolia.- Lethaia 45, 1: 46-61.-
<b>FC&#038;P</b> 37 number, 125, ID=7458^<b>Topic(s): </b>reefs,
community succession, reef suppression; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian L, Emsian, Chuluun Fm; <b>Geography:
</b>Mongolia, Gobi-Altay^This study investigates a Lower Devonian
(Emsian) carbonate sequence from the Chuluun Formation where it is
exposed in the Gobi-Altai region of southern Mongolia. Quantification
of abundance patterns across guild, morphotype and general taxonomic
levels was based on stratigraphical and thin-section analyses.
Comparison with other Emsian carbonate platforms allowed the factors
that influenced community development in the wake of a tectonic
perturbation to be determined. Our evidence reveals that potential
reef-building biotas preserved in the Chuluun Formation experienced
rapid colonization of a newly submerged carbonate platform following an
episode of tectonic uplift and the development of a coastal alluvial
fan. Although critical reef-building organisms were present, colonial
corals and stromatoporoids exhibited limited vertical growth and showed
no significant lateral expansion of individuals or biotic assemblages.
Nor did those taxa experience significant increases in abundance,
density, or size. We conclude that incomplete succession and the lack
of reef development occurred most likely because of an unsuitable
substrate, limited accommodation space and isolation that reduced
colonization potential.^1";

(Series 2) Cambrian archaeocyathan reefs of southern Labrador as a locus for skeletal carbonate production.- Lethaia 45, 3: 401-410.- <b>FC&#038;P</b> 37, 126, ID=7459^<b>Topic(s): </b>archaeocyathan bioherms, ecology; <b>Systematics: </b>Cnidaria, Archaeocyatha; <b>Stratigraphy: </b>Cambrian L, Series 2; <b>Geography: </b>Canada, Labrador S^Archaeocyathan reefs, the first reefs produced by animals, are prominent, global features of early Cambrian successions. However, microbialites - the dominant reef components of the Proterozoic - were still abundant in most archaeocyathan reefs. Although such reefs were a locus for carbonate production, it is unclear how much carbonate was produced skeletally. This analysis of well-known early Cambrian archaeocyathan patch reefs of the Forteau Formation, southern Labrador, demonstrates that skeletal carbonate was abundantly produced in these archaeocyathan reefs, although only about half was produced by archaeocyathans. Trilobites, echinoderms and brachiopods contributed substantially to the total carbonate budget, particularly in grainstone facies flanking the reefs. Through point count analysis of samples collected from the reef core and flanking grainstones, it can be demonstrated that skeletal material was most abundant in grainstone facies, where animals such as trilobites and echinoderms contributed significantly to carbonate production. In contrast, microbial fabrics were more abundant than skeletal fabrics in the reef core, although archaeocyathan material was more abundant than other skeletal debris. Similar to modern reefs, these reefs created a variety of habitats that allowed for the proliferation of skeletal organisms living on and around the reef, thereby promoting skeletal carbonate production through ecosystem engineering.^1";

This study uses palaeoecological data derived from a mid-Holocene age coral reef in the Wet Tropics region of Australia&#039;s Great Barrier Reef to develop a record of coral community composition and diversity, from a period that significantly pre-dates European settlement in the region. Major changes in catchment sediment and nutrient yields since European settlement have been documented, and thus the data presented provides a baseline against which to compare contemporary ecological datasets. Natural variations in coral assemblage composition, as preserved in core records, clearly occurred in this mid-Holocene reef and were associated with the reef shallowing to sea level as it accreted vertically. Comparisons between modern and mid-Holocene coral community data from equivalent water depths did not reveal marked shifts in coral community composition and diversity, suggesting the long-term persistence of a resilient coral assemblage over these time periods.^1";
s[6890] = "RODRIGUEZ S., SOMERVILLE I.D., SAID I. &#038; COZAR P. (2012).- Late Visean coral fringing reef at Tiouinine (Morocco): implications for the role of rugose corals as building organisms in the Mississippian.- Geological Journal 47, 5: 462-476.- <b>FC&#038;P</b> 37, 127, ID=7462^<b>Topic(s): </b>coral reefs, fringing reefs, rugosans; <b>Systematics: </b>Cnidaria, Rugosa; <b>Stratigraphy:
```

```
</b>Carboniferous L, Visean U; <b>Geography: </b>Morocco, Meseta^The
excellent exposure and preservation of a fringing reef located at
Tiouinine, near Khenifra (Central Moroccan Meseta) is a unique case in
the Mississippian which allows us to distinguish different facies belts
of a classical coral framework reef. The reefal facies rest on thin
basal siliciclastic rocks which rest unconformably on Ordovician
sandstones. There is a complete zonation from tidal deposits of the
inner shelf to reefal talus of the mid to outer shelf. Tidal deposits
occur in a narrow band and are composed of sandy packstones. There is a
transition to reef flat deposits composed of skeletal
packstone-grainstone with a patchy distribution of coral colonies.
There is also a transitional change to core reef facies that are
composed of fasciculate and massive corals reinforced by dasyclad algal
masses around the corals and microbial micropeloidal mudstone to
wackestone coating the corals and algae. The spaces between the corals
and algal masses are infilled by crinoidal and coral grainstone. The
dominant building organisms are rugose corals of the genera
Siphonodendron, Lithostrotion, Diphyphyllum and Tizraia, as well as
contributions from the tabulate genera Michelinia, Multithecopora and
Syringopora. The proximal reef talus is represented by skeletal
packstone and rudstone containing highly diverse bioclasts, with
corals, crinoids, foraminifers, gastropods and bivalves, as well as
large fragments of reworked coral colonies and some coral colonies in
growth position. These beds show erosive surfaces and amalgamation of
beds. A somewhat more distal reef talus is represented by well-bedded
marly limestones containing mainly crinoids and branches of fasciculate
corals. The existence of a well-preserved coral reef in the late Visean
contradicts the concept that rugose and tabulate corals did not build
reefs after the Late Devonian extinction.^1";

of Northwestern Luzon since 9.9 ka.- Palaeogeography,
Palaeoclimatology, Palaeoecology 292, 3-4: 465-473.- <b>FC&#038;P</b>
37, 128, ID=7463^<b>Topic(s): </b>sea-level changes, coral-reef growth,
tectonic correction; <b>Systematics: </b>; <b>Stratigraphy:
</b>Holocene; <b>Geography: </b>Philippines, Luzon NW^Coral reef growth
and relative sea-level record for the early mid-Holocene are
established from three boreholes drilled on a raised Holocene reef at
Currimao, northwestern Luzon, Philippines. Age control is provided by
230Th dates of 13 corals mostly in living position. The cores cover a
depth interval from 3.8m above to 26.7m below present mean sea level
(MSL) and consist of four lithofacies including (1) reef facies, (2)
bioclastic facies, (3) clayey facies and (4) tuffaceous facies. The
ages of dated corals vary from 6588 &#177; 27 ya at 1.4m below MSL to
9855 &#177; 42 ya at 22m below MSL. Results of this study indicate that
the reef started growing about 9.9 ka when the minimum sea level,
relative to the western Luzon coast, was about 27m below MSL after
tectonic correction. During 9.2-8.2 ka, reef accretion rate was as high
as 10-13m/ky. Coral reef developed to near paleo-sea level at about
6862 &#177; 28 ya and emerged due to tectonic uplift. The sea-level
curve of Currimao is generally similar to that of the Western Australia
coast but at least 8-11m higher than that of Tahiti from 10 to 8.5
ka.^1";
s[6892] = "SCHINDLER E. &#038; WEHRMANN A. (2011).- Genesis and
internal architecture of the Middle to Upper Devonian Gwirat Al Hyssan
reef-mound (Western Sahara).- Palaeogeography, Palaeoclimatology,
Palaeoecology 304: 184-193.- <b>FC&#038;P</b> 37, 129,
ID=7464^<b>Topic(s): </b>coral-reef mounds, genesis, structures;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M/U, Givetian /
Frasnian; <b>Geography: </b>Western Sahara, Tindouf Basin^On the
southern flanks of the Tindouf Basin (Western Sahara) reefal complexes
of various sizes were developed, mostly of Givetian age but possibly
reaching into the early Frasnian. Surrounding sedimentary rocks were
```

```
dominantly sandstones, siltstones and marls. The larger reef complexes
in the northeastern part of Western Sahara show three reef cycles
within the Givetian and lowermost Frasnian, interrupted by marly
sedimentation. Farther to the west, more isolated reef structures in
open shelf settings occur often showing smaller dimensions. The present
study focuses on one of these western reefal build-ups. Besides
large-scale reefs dominated by stromatoporoids (NE), several smaller
bioherms have been investigated, such as the Gwirat Al Hyssan reef
mound near Smara. Initial reef growth was of late Givetian age as
indicated by corals (e.g. Heliolites). The main reef builders were the
corals Alveolites, Thamnopora, Aulopora, Frechastraea, Phillipsastrea,
and, to a lesser degree, Heliolites, Scoliopora, and Roemerolites.
Stromatoporoids also contributed, but were less frequent. Chaetetids
(e.g. Rhaphidopora) acted as pioneer stabilizers on bare sediment
surfaces. Preservation in life position was frequently observed in both
groups of organisms. Crinoids are not rare, but only present as debris.
In distinct areas of the reef (depressions) concentrations of
brachiopods and small solitary corals occur. The reef-mound has a
present elevation of 17 m and measures about 370 m in diameter.
Vertical as well as horizontal zonation could be recognized in detail.
The initial reef growth started on a submarine shoal of siliciclastic
sediments, containing various trace fossils and sedimentary structures
such as cross-bedding and wave ripples, interference ripples suggest
generation in very shallow water. The initial reef-building organisms
were encrusting chaetetids, followed by platy Frechastraea colonies,
thamnoporids were also present. The overlying reef limestones consist
of different corals and, to a minor degree, stromatoporoids. The latter
are sparsely distributed vertically as well as horizontally, depending
on their position within the reef. Growth forms are more robust
(bulbous) towards higher hydrodynamic conditions at the southern reef
front. Reef growth is interrupted by debris limestones of thamnoporid
and crinoid bioclasts, intercalated with detrital platy
stromatoporoids. Generally, the debris was not transported over long
distances, as demonstrated by the presence of relatively large
fragments. This &#8216;debris phase&#8217; (early Frasnian) is overlain
by the last documented stage in reef development represented by medium-
to thin-bedded coral-rich limestones. The onset of the carbonate
production of the Gwirat Al Hyssan reef-mound is maybe related to the
global transgressive Givetian - Frasnian Boundary Event.^1";
s[6893] = "SHEN Jianwei, WEBB G.E. &#038; QING H. (2010).- Microbial
mounds prior to the Frasnian-Famennian mass extinctions, Hantang,
Guilin, South China.- Sedimentology 57: 1615-1639.- <b>FC&#038;P</b>
37, 130, ID=7465^<b>Topic(s): </b>microbial mounds, platform margin,
pre-extinction buildups; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian U, Frasnian U; <b>Geography: </b>China S, Guilin^Late
Frasnian mounds of the Yunghsien Formation, Guilin, South China,
developed as part of the Guilin platform, mostly in reef-flat and
platform margin settings. Microbial mounds in platform margin settings
at Hantang, about 10 km west of Guilin, contain Frasnian biota, such as
Stachyodes and Kuangxiastraea and, thus, occur below the
Frasnian-Famennian mass extinction boundary. Platform margin facies
were dominated by microbes, algae and receptaculitids. Massive corals
and stromatoporoids are not common and rarely show reef-building
functions as they did in Givetian time. The margin mounds are composed
of brachiopod-receptaculitid cementstone, and a variety of boundstones
that contain Rothpletzella, Renalcis, thrombolite and stromatolite.
Other microbial communities include Girvanella, Izhella, Ortonella and
Wetheredella. Solenoporoid algae are abundant locally. Zebra structures
and neptunian dykes are well-developed at some intervals. Pervasive
early cementation played an important role in lithification of the
microbial boundstones and rudstones. Frasnian reefs of many regions of
the world were constructed by stromatoporoids and corals, although a
shift to calcimicrobe-dominated frameworks occurred before the
```

```
Famennian. However, the exact ages of many Frasnian margin outcrops are
poorly constrained owing to difficulties dating shallow carbonate
facies. The Hantang mounds represent a microbe-dominated reef-building
community with rare skeletal reef builders, consistent with major Late
Devonian changes in reef composition, diversity and guild structure
occurring before the end of the Frasnian. A similar transition occurred
in the Canning Basin of Western Australia, but coeval successions in
North America, Western Europe and the northern Urals are either less
well-known or represent different bathymetric settings. The transition
in reef-building style below the Frasnian-Famennian boundary is
documented here in the two best exposed successions on two continents,
which may have been global. Set in the larger context of Late Devonian
and Mississippian microbial reef-building, the Hantang mounds help to
demonstrate that controls on microbial reef communities differed from
those on larger skeletal reef biota. Calcimicrobes replaced
stromatoporoids as major reef builders before the Frasnian-Famennian
extinction event, and increasing stromatoporoid diversity towards the
end of the Famennian did not result in a resurgence of skeletal reef
frameworks. Calcimicrobes dominated margin facies through the
Famennian, but declined near the Devonian-Carboniferous boundary.
Stromatolite and thrombolite facies, which occurred behind the mound
margin at Hantang, rose to dominate Mississippian shallow-water reef
frameworks with only a minor resurgence of the important Frasnian
calcimicrobe Renalcis in the Visean when well skeletonized organisms
(corals) also became volumetrically significant frame builders again.

facies; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L, Buchan
Gr; <b>Geography: </b>Australia SE, Gippsland^The Lower Devonian Rocky
Camp Member of the Murrindal Limestone, Buchan Group of southeastern
Australia consists of a series of carbonate mud-mounds and smaller
lagoonal bioherms. The Rocky Camp mound is the best exposed of the
mud-mounds and has many characteristics in common with Waulsortian
(Carboniferous) mounds. Detailed paleoecological and sedimentological
studies indicate that the mound initially accumulated in the photic
zone, in contrast to most of the previously recorded mud-mounds. Five
facies are present in the mud-mound: a Dasycladacean Wackestone Facies
at the base of the mound represents a moderate energy, shallow water
bank environment within the photic zone. A Crinoidal Wackestone Facies
was deposited in a laterally equivalent foreslope setting. A
Poriferan-Crinoidal Mudstone Facies developed in a quiet, deeper water,
lee-side mound setting associated with a minor relative sea-level rise.
A Stromatoporoid-Coralline Packstone Facies in the upper part of the
mound deposited in a high-energy, fair-weather wave base, mound-front
environment. The crest of the mound is represented by a
Crinoidal-Receptaculitid Packstone Facies indicative of a
moderate-energy mound-top environment in the photic zone, sheltered by
the mound-front stromatoporoid-coral communities. A mound flank facies
is present on the southern side of the mound and this consists of
high-energy crinoidal grainstones. Mud-mound deposition was terminated
by a transgression that deposited dark gray, fossil-poor marl of the
overlying Taravale Formation. The Rocky Camp mound appears to have
originated in shallow water photic zone conditions and grew into a
high-energy environment, with the mound being eventually colonized by
corals and stromatoporoids. The indications of a high-energy
environment during later mound growth (growth form of colonial
metazoans and grainstones of the flanking facies) suggest that the
micrite in the mound was autochthonous and implies the presence of an
energy damping mechanism (probably biological) at the mound surface.^1";

274, 1-2: 1-17.- <b>FC&#038;P</b> 37, 134, ID=7470^<b>Topic(s):
</b>microbialite-coral mounds; <b>Systematics: </b>; <b>Stratigraphy:
</b>Paleocene / Eocene; <b>Geography: </b>Tethys N, Slovenia^Upper
Thanetian microbialite-coral mounds from the Adriatic Carbonate
Platform (SW Slovenia) are described herein for the first time,
representing an important case study of extensively
microbially-cemented boundstones in the Early Paleogene. The mounds are
constructed primarily by microbialites associated to small-sized coral
colonies, forming metric bioconstructions in a mid-ramp setting. *
Detailed macroscopic and microscopic studies show that microbes are the
major framework builders, playing a prominent role in the stabilization
```

```
and growth of the mounds, with corals being the second most important
component. Microbial carbonates represent up to 70% of the mounds,
forming centimetric-thick crusts alternating with coral colonies. The
microbial nature of the crusts is demonstrated by their growth form and
internal microfabrics, showing accretionary, binding, and encrusting
growth fabrics, often with gravity-defying geometries. Thin sections
and polished slabs reveal a broad range of mesofabrics, with dense,
structureless micrite (leiolite), laminated crusts (stromatolites), and
clotted micritic masses (thrombolites). A first layer of
micro-encrusters, including leiolites and thrombolites, occurs in
cryptic habitats, whereas discontinuous stromatolites encrust the upper
surface of corals. A second encrustation, the major mound construction
phase, follows and is dominated by thrombolites, encrusting corals and
other micro-encrusters. This sequence represents the basic
constructional unit horizontally and vertically interlocked, in an
irregular pattern, to form the mounds. The processes, which favored the
deposition of these microbial carbonates, were mainly related to in
situ precipitation, with minor evidences for grain agglutination and
trapping processes. * Scleractinian corals comprise moderately
diversified community of small (centimetric) colonial, massive, platy
encrusting, and branching forms. Coral colonies are distributed
uniformly throughout the mounds without developing any ecological
zonation. These features indicate that coral development remained at
the pioneer stage throughout the mound growth. * The spatial
relationships between corals and microbialites, as well as the
characteristics of microbial crusts and coral colonies, indicate a
strong ecological competition between corals and microbes. A model for
the evolution of the trophic structures during the mound growth is
proposed, with changes in the paleoecology of the main bioconstructors
triggered by frequent environmental perturbations. Turbidity and
nutrient pressure, interpreted here as related to frequent recurrences
of wet phases during the warm, humid climate of the Uppermost
Thanetian, might have promoted temporary dominance of microbes over
corals, causing rapid environmentally-driven &#034;phase shifts&#034;
in the dominant biota.^1";

in the stable carbon isotopic composition of Porites corals at the
northern Gulf of Aqaba, Red Sea.- Palaeogeography, Palaeoclimatology,
Palaeoecology 381-382: 1-14.- <b>FC&#038;P</b> 37, 135,
ID=7472^<b>Topic(s): </b>stable C isotopes, corals, long-term record;
<b>Systematics: </b>Cnidaria, Scleractinia, Porites; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Red Sea, Gulf of Aqaba N^To study
long-term variations in surface ocean &#948;13C, we investigated coral
skeletal &#948;13C records of 20 colonies of the shallow-water coral
Porites spp. from the northern Gulf of Aqaba and the northern Red Sea.
The coral colonies represent different water depths, a wide range of
different periods (Last Interglacial, Holocene, the last centuries, the
last decades), and various growth rates. Records from modern and fossil
corals show irregular seasonal cycles, attributed mainly to the
seasonal cycle of light. No attenuation in the amplitude of the
seasonal skeletal &#948;13C cycle with depth is evident, and no
significant correlation between mean annual coral &#948;13C and water
depth was observed in the modern corals. The mean coral extension rates
show no clear relationship with mean skeletal &#948;13C values. The
average skeletal &#948;13C value of modern corals was -2.74 &#177;
0.49&#8240;, offset from both calcite and aragonite equilibrium values
by about 5.22&#8240; and 6.26&#8240;, respectively. Modern corals
```

```
reveal a clear trend toward lighter skeletal &#948;13C values since the
year 1974. At longer timescales, the skeletal &#948;13C values from
Last Interglacial and Holocene corals and from coral records extending
back to the mid- to late 18th century reveal much heavier &#948;13C
values compared to values from 1960 to the present. The trend toward
lighter skeletal &#948;13C values over the last decades can be
attributed to changes in the &#948;13C of the dissolved inorganic
carbon of the ambient seawater due to the addition of anthropogenically
derived CO2 (13C Suess effect) to the atmosphere. Other factors such as
the metabolic effects of corals may account for the modulation of
skeletal &#948;13C on shorter timescales. A centuries-long coral record
from the northern Red Sea reveals a magnitude of decrease in skeletal
&#948;13C comparable to global trends (1960-1990), whereas a
centuries-long coral record from the northern Gulf of Aqaba indicates a
larger decrease over the same period, probably due to local effects. In
conclusion, the combined carbon isotope records obtained from Porites
spp. corals from the northern Red Sea seem to be suited to provide
information on long-term world-wide changes in atmospheric CO2.^1";

SCHR&#214;DER S. (2012).- Coral-crinoid biocoenosis and resulting trace
fossils from the Middle Devonian of the Eifel synclines (Rhenish
Massif, Germany).- Journal of Paleontology 86, 2: 282-301.-
<b>FC&#038;P</b> 37, 137, ID=7473^<b>Topic(s): </b>biotic interactions,
commensalism, corals, crinoids; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian M, Givetian; <b>Geography: </b>Germany, Rhenish Slate Mts,
Eifel synclines^Fossil echinoderms are a rich source of information
concerning biotic interactions. In this study we analyzed the premortem
encrustation of the highly specialized Middle Devonian rugose corals
Aspasmophyllum crinophilum and ?&#034;Adradosia&#034; sp. on camerate
crinoid stems. Aspasmophyllum infested living crinoid stems by
sclerenchymal outgrowth that formed a skeletal ring but
?&#034;Adradosia&#034; sp. encrusted the stems rapidly, without
building a ring. These coral-crinoid biocoenoses indicate a settlement
advantage for the rugose corals within densely populated communities of
the lower Givetian. The corals could be interpreted as large
epizoozoans that benefited as secondary tierers reaching relatively
high tiering levels. It also suggests the ability for the affected
crinoids to repel the coral by overgrowing the corallite with a local
increased stereomic growth. Because the crinoid axial canals are not
penetrated, the corals cannot be considered as predators or parasites
of crinoids. Therefore, the described biocoenosis is interpreted as
commensalism. The species A. crinophilum is redescribed, and a neotype
is defined, because of the loss of the initial types. Two types of
ichnofossils can be attributed to the premortem encrustation of both
corals. They are described as Ostiocavichnus n. ichnogen. and are
attributed to the stereomic response of the infested hosts. These
swellings are characterized as either elliptical (Ostiocavichnus ovalis
n. ichnogen. n. ichnosp. due to the assumed reaction of A. crinophilum)
or subcircular concavities (O. rotundatus n. ichnogen. n. ichnosp. due
to the reaction of ?&#034;Adradosia sp.&#034;).^1";

(2013).- Evidence for shallow-water &#039;Upper Kellwasser&#039; anoxia
in the Frasnian-Famennian reefs of Alberta, Canada.- Lethaia 46, 3:
355-368.- <b>FC&#038;P</b> 37, 138, ID=7474^<b>Topic(s): </b>causes of
extinctions, shallow-water anoxia; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian U, Frasnian / Famennian; <b>Geography:
</b>Canada, Alberta^The Frasnian-Famennian extinction witnessed the
global devastation of both level-bottom and reef communities in low
latitudes. Marine extinctions in offshore level-bottom communities are
associated with two widespread, transgressive, anoxic &#039;Kellwasser
Events&#039; that support an anoxia-extinction link. Typical Kellwasser
facies of bituminous limestones and shales are not obviously recorded
in shallow-water settings, and thus, it is unclear whether anoxia
```

```
played a role in reef losses. We evaluate geochemical, petrographic and
facies evidence for oxygen restriction from an extremely shallow-water
carbonate platform in Alberta. Sequence stratigraphy places the
Frasnian-Famennian boundary at a sequence boundary that tops a
laminated mudstone and interrupts carbonate platform deposition. Two
transgressive pulses have been identified, one of which is associated
with the second, major transgression of T-R cycle IId of the Devonian
eustatic sea-level curve. Geochemical proxies indicate that these
transgressions were accompanied by influx of dysoxic or anoxic waters.
Organic carbon and U enrichment in the Frasnian, particularly just
below the Frasnian-Famennian boundary, points to episodic dysoxic
conditions that probably persisted into the basal Famennian and were
coincidental with the global Upper Kellwasser Event. This study
provides the first evidence for the smoking gun of an anoxia-driven
extinction in very shallow waters, implicating this potent killer in
the demise of the Devonian reefs.^1";

&#038; STRASSER A. (2012).- Corals on the slope (Aptian, Maestrat
Basin, Spain).- Cretaceous Research 37: 43-64.- <b>FC&#038;P</b> 37,
138, ID=7475^<b>Topic(s): </b>non-reefal corals, marly setting;
<b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy:
</b>Cretaceous L, Aptian; <b>Geography: </b>Spain E, Maestrat Basin^The
term &#034;reef&#034; has been frequently misused when applied to
fossil coral communities. Our popular but biased view of coral
community structure based on the idyllic picture of recent tropical
reefs has failed to recognize that, in many fossil examples,
alternative states of community structure with no or limited framework
may occur. The Aptian colonial scleractinians analysed in the western
Maestrat Basin (eastern Spain) constitute an example of
non-reef-building coral populations, which thrived in marly slope
settings. These corals developed within the photic zone but below the
storm wave-base. All colonies are found well-preserved in life
position. They are mostly decimetres in size and mainly occur isolated
giving rise to a continuous and uniform (dominated by domal and massive
forms) unbound growth fabric with a low to medium degree of development
(coral skeletal volume = 5-20%). Occasionally, however, colonies
growing on top of each other forming small metre-sized bioherms are
also present. A total of 21 species were identified. Coral diversity in
each sample location varies between three and nine species. These
numbers of species are comparable with those exhibited by coeval coral
assemblages from other basins of the Tethys, but are comparatively low
when compared with diversities exhibited by many Recent and fossil
coral communities. The corals studied apparently found optimal
ecological conditions for their development on the marly slopes of the
western Maestrat Basin. This is primarily expressed in the unusually
large dimensions (up to 2.3m in width) of some of the coral colonies
when compared to other Cretaceous occurrences, and in the persistence
and resilience of the coral populations. The observed coral genera and
species (suborders Archeocaeniina, Faviina, Fungiina and Microsolenina)
are very common in the time interval between the Barremian and the
Early Albian and most of them have been reported from several other
localities in the western and central Tethyan realm. In addition, the
coral-bearing levels also contain the poorly known and exotic genera
Agrostyliastraea and Procladocora. There are no significant differences
at species level or in community structure between the Early and Late
Aptian faunas investigated. Therefore, the coral communities as well as
the environmental conditions controlling them would have been
relatively stable during the time intervals when these corals
flourished. An important palaeoecological implication is that
comparatively low species diversities and the absence of reef
frameworks do not necessarily imply unfavourable environmental
conditions for coral growth. Furthermore, this study may serve as an
example for the analysis of other level-bottom coral communities
```

```
displaying a loose growth fabric.^1";
s[6904] = "CHOW N. &#038; WENDTE J. (2011).- Palaeosols and palaeokarst
beneath subaerial unconformities in an Upper Devonian isolated reef
complex (Judy Creek), Swan Hills Formation, west-central Alberta,
Canada.- Sedimentology 58: 960-993.- <b>FC&#038;P</b> 37, 140,
ID=7476^<b>Topic(s): </b>paleosols, truncated reefs; <b>Systematics:
</b>Devonian U, Frasnian, Swan Hills Fm; <b>Stratigraphy: </b>Devonian
U, Frasnian, Swan Hills Fm; <b>Geography: </b>Canada, Alberta^The
isolated Judy Creek reef complex in the Lower Frasnian Swan Hills
Formation in west-central Alberta, Canada, contains two subaerial
unconformities, R0.5 and R4, which formed as a consequence of relative
sea-level falls of at least regional scale. Deposits beneath these
unconformities have distinctive palaeosol and palaeokarst features.
Comparison of the R0.5 and R4 profiles indicates that the major
intrinsic controls on the development and modification of the profiles
are parent-material lithology, particularly the prior degree of
induration and particle size, the low topographic relief at the top of
the reef interior, and limited vegetation of the exposed reef top due
to unfavourable growth conditions and geographic isolation. In addition
to climate, the major extrinsic controls are the extent of relative
sea-level fall, and the degree of shoreface erosion during the ensuing
marine transgression. This study highlights the complex interplay of
mainly physical and chemical processes influencing the formation of
subaerial unconformities in carbonate environments during the Devonian.
[abridged]^1";
s[6905] = "CHUKI Hongo &#038; HAJIME Kayanne (2010).- Holocene
sea-level record from corals: Reliability of paleodepth indicators at
Ishigaki Island, Ryukyu Islands, Japan.- Palaeogeography,
Palaeoclimatology, Palaeoecology 287, 1-4: 143-151.- <b>FC&#038;P</b>
37, 140, ID=7477^<b>Topic(s): </b>sea-level records, corals data;
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>Japan, Ryukyu Islands^Holocene sea-level change provides direct
evidence of the melting of ice sheets; however, our understanding of
the timing and course of such change is limited by a lack of
information regarding environmental condition of corals. For example,
Holocene sea-level curves are compiled based on water depths estimated
from the occurrence of a small number of coral species, as species
identification is difficult work. The error associated with this method
of estimating sea level exceeds &#177;2.5m. In addition, there
generally occurs a difference in the living-water depth of corals
between high-energy reefs and low- to moderate-energy reefs. This
difference in living-water depth also results in an error in
reconstructed sea-level curves. In the present study, we analyzed drill
core and recorded the vertical distribution of corals at the
high-energy Ibaruma reef and low- to moderate-energy Fukido reef,
Ishigaki Island, Ryukyu Islands, Japan. Analyses of corymbose Acropora
(A. digitifera), massive Goniastrea (G. retiformis), massive
Pocillopora (P. verrucosa), massive Platygyra (P. ryukyuensis), and
other corals enables the accurate reconstruction of a sea-level curve
because these species are distributed in a narrow range, with a
weighted mean (MW) error of between &#177;0.5 and &#177;2.5m. These
observation data from Ibaruma and Fukido reefs can be used to
reconstruct Holocene sea-level curves based on drill core data from
Ibaruma reef; however, the two reefs yield contrasting sea-level
curves: the curve reconstructed based on data from Fukido reef is
several meters deeper than that reconstructed based on data from
Ibaruma reef. This discrepancy reflects the different energy levels of
the two reefs (high-energy at Ibaruma reef and low- to moderate-energy
at Fukido reef). Therefore, the accurate reconstruction of a Holocene
sea-level curve requires the identification of species from drill core
and observations of the vertical distribution of species at the
present-day reef at a location close to the drilling site. The Holocene
sea-level curve reconstructed based on drill core data from Ibaruma
```

```
reef reveals a rapid sea-level rise of approximately 7.5m kyr-1 between
8000 and 6000 cal. years BP. The rate of sea-level rise decreased from
7.5 to 3.5m kyr-1 between 6000 and 5000 cal. years BP. A mid-Holocene
highstand occurred at around 5000 cal. years BP, at a level of
approximately 3 &#177; 2.5m above the present mean sea level. The
increase in ocean volume corresponding to this sea-level rise indicates
that melting of the Antarctic ice sheet continued beyond 6000 cal.
years BP, as most of the Northern Hemisphere ice sheets had melted by
6000 cal. years BP, resulting in sea levels similar to those of the
present day.^1";
s[6906] = "COPP I.A. (2011).- Late Devonian (Famennian) facies of the
outer Lennard Shelf, Canning Basin, Western Australia - a preliminary
study.- Geological Survey of Western Australia Record 2011, 5: 1-11;
Perth.- <b>FC&#038;P</b> 37, 141, ID=7478^<b>Topic(s): </b>subsurface
reef complex, sequence stratigraphy; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian U, Famennian; <b>Geography: </b>Australia
W, Canning Basin, Lennard Shelf^A robust sequence stratigraphic
interpretation of the Late Devonian succession over the outer Lennard
Shelf requires a thorough review and integration of petroleum and
mineral core, Geological Survey of Western Australia outcrop data,
Geoscience Australia subsurface interpretations, and recently acquired
3D seismic. The subsurface Late Famennian platform evolution of the
outer Lennard Shelf includes features and sequence boundaries that have
not been recognised in outcrop. The reef extinction event is poorly
cored and equivocal on well logs, and requires high-resolution
biostratigraphy and seismic correlations to be fully resolved. Where
identified, it is commonly within an interval with a spiky gamma-ray
well log motif that is distinct from its equivalent outcrop response.
In the Blina oilfield, a locally developed ramp system briefly replaced
a reef-rimmed platform during a widespread backstepping transgressive
event of Famennian 2A sequence (postera-expansa conodont zone). This
backstepping event has not been recognized in outcrop, but would lie
within Nullara Sequence 2. A possible paleokarst zone in Janpam North 1
indicates karsting may be associated with the Famennian 2A/2B sequence
boundary (expansa conodont zone), but its outcrop equivalent has
similarly not been recognized. Silty carbonates of the &#039;inner
platform&#039; facies dominate Famennian sequence 2B
(expansa-praesulcata conodont zone) of the outer Lennard Shelf, but are
unlike the Nullara Limestone back-reef facies in outcrop.
Paleotopography may have been an important control on the extent of
inner platform development on the Lennard Shelf.^1";
s[6907] = "COZAR P., VACHARD D., SOMERVILLE I.D., MEDINA-VAREA P.,

during the Serpukhovian (Carboniferous) mass extinctions in the
northwestern Gondwana platform.- Palaeogeography, Palaeoclimatology,
Palaeoecology 394: 12-28.- <b>FC&#038;P</b> 37, 142,
ID=7479^<b>Topic(s): </b>mass extinctions, marine refuges;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous, Serpukhovian,
Bashkirian; <b>Geography: </b>Morocco - Algeria, Tindouf Basin^Several
macrofaunas and microfossils of the Carboniferous Saharan basins have
longer stratigraphic ranges than those of other basins in the western
Palaeotethys realm, particularly in the Tindouf Basin
(Morocco-Algeria). Foraminifers are particularly abundant and diverse
in the Serpukhovian and basal Bashkirian compared to coeval basins, and
some taxa have longer ranges than in the neighbouring Reggan and Bechar
basins, although this effect is more marked compared to the western
Palaeotethyan assemblages in Europe. Several rugose coral species are
recorded from the early Bashkirian that previously were considered to
have disappeared in the Serpukhovian. The Tindouf Basin, as one of the
most western Saharan basins in North Africa, shows the greatest
stratigraphic ranges of taxa which diminish eastwards. Evidence for a
mass extinction event during the Serpukhovian in the Tindouf Basin has
not been clearly recognized, although a possible influence of
```

```
glaciation is observed in the faunal diversity. Eustatic sea-level
changes were experienced in Tindouf with the cyclic pattern of
sedimentation, but warm water ocean currents from the palaeoequator
were able to maintain tropical conditions on the platform. Tectonics in
the area, led to emerging land masses and barriers, and created a
partly isolated basin in this sector of the western part of the Sahara
Platform in northern Gondwana. The combination of those factors
controlled the environmental conditions in the area, allowing the
persistence of the fauna for longer stratigraphic ranges than its
equivalent counterparts in the western Palaeotethys.^1";

(2012).- Magnetic susceptibility and its relationship with
paleoenvironments, diagenesis and remagnetization: examples from the
Devonian carbonates of Belgium.- Studia Geophysica et Geodaetica 56:
677-704; Prague.- <b>FC&#038;P</b> issue number, page,
ID=****^<b>Topic(s): </b>magnetic susceptibility, carbonates,
isothermal remanent magnetization (IRM) acquisition curves, diagenesis;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Belgium, Villers &#038; Tailfer sections^To better understand the
origin of the initial magnetic susceptibility (&#967;in) signal in
carbonate sequences, a rock magnetic investigation that includes
analysis of acquisition curves of the isothermal remanent magnetization
(IRM) and hysteresis parameters, was undertaken on Devonian carbonates
from the Villers and Tailfer sections, Belgium. Both sections are
divided into a lower unit, dominated by biostromal and external ramp
facies (biostromal unit) and an upper unit, only consisting of lagoonal
facies (lagoonal unit). The variations in &#967;in signal are mainly
driven by magnetite variation, mostly pseudosingle-domain (PSD)
magnetite. Clay minerals, pyrite, hematite and obviously calcite and
dolomite are also present but their contribution to the &#967;in
pattern is not significant. There is a correlation between detrital
proxies (Zr, Rb, Al2O3, TiO2) and &#967;in for the Tailfer biostromal
unit and the entire Villers section. The pervasive presence of
fine-grained magnetite is interpreted as related to remagnetization. In
absence of external fluids, the iron released during the smectite to
illite transition remains in situ. In those situations &#967;in may
reflect an inherited primary synsedimentary signal. In the lagoonal
unit of the Tailfer section, remagnetization appears to have obscured
the original detrital information prompting the need for an evaluation
of the composition of the susceptibility signal for individual case
studies.^1";
s[6909] = "DASSIE E.P., LEMLEY G.M. &#038; LINSLEY B.K. (2013).- The
Suess effect in Fiji coral &#948;13C and its potential as a tracer of
anthropogenic CO2 uptake.- Palaeogeography, Palaeoclimatology,
Palaeoecology 370: 30-40.- <b>FC&#038;P</b> 37, 144,
ID=7481^<b>Topic(s): </b>coral &#948;13C, anthropogenic CO2;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Pacific, Fiji Islands^In the context of increasing anthropogenic
CO2 emissions, determining the rate of oceanic CO2 uptake is of high
interest. Centennial-scale changes in &#948;13C of the surface water
dissolved inorganic carbon (DIC) reservoir have been shown to be
influenced by the carbon isotopic composition of atmospheric CO2.
However, the availability of direct oceanic &#948;13C measurements is
limited and methods for reconstructing past &#948;13C variability of
the oceanic DIC are needed. Geochemical reconstructions of DIC
variability can help in understanding how the ocean has reacted to
historical changes in the carbon cycle. This study explores the
potential of using temporal variations in &#948;13C measured in five
Fijian Porites corals for reconstructing oceanic &#948;13C variability.
A centennial-scale decreasing &#948;13C trend is observed in these Fiji
corals. Other studies have linked similar decreasing &#948;13C trends
to anthropogenic changes in the atmospheric carbon reservoir (the
&#034;13C Suess effect&#034;). We conclude that solar irradiance is the
```

```
factor influencing the &#948;13C cycle on a seasonal scale, however it
is not responsible for the centennial-scale decreasing &#948;13C trend.
In addition, variations in skeletal extension rate are not found to
account for centennial-scale &#948;13C variability in these corals.
Rather, we found that water depth at which a Fijian Porites colony
calcifies influences both &#948;13C and extension rate mean values. The
water depth-&#948;13C relationship induces a dampening effect on the
centennial-scale decreasing &#948;13C trend. We removed this
&#034;water depth effect&#034; from the &#948;13C composite, resulting
in a truer representation of &#948;13C variability of the Fiji surface
water DIC (&#948;13CFiji-DIC). The centennial-scale trend in this Fiji
coral composite &#948;13CFiji-DIC time-series shares similarities with
atmospheric &#948;13CCO2, implicating the 13C Suess effect as the
source of the this coral &#948;13C trend. Additionally, our study finds
that the &#948;13C variability between the atmosphere and the ocean in
this region is not synchronous; the coral &#948;13C response is delayed
by ~10 years. This agrees with the previously established model of
isotopic disequilibrium between atmospheric &#948;13CCO2 and oceanic
surface water DIC.^1";
s[6910] = "DELONG K.L., FLANNERY J.A., MAUPIN C.R., POORE R.Z. &#038;
QUINN T.M. (2011).- A coral Sr/Ca calibration and replication study of
two massive corals from the Gulf of Mexico.- Palaeogeography,
Palaeoclimatology, Palaeoecology 307, 1-4: 117-128.- <b>FC&#038;P</b>
37, 145, ID=7482^<b>Topic(s): </b>coral skeletons, Sr/Ca ratios;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Caribbean, Gulf of Mexico^This study examined the variations in the
ratio of strontium-to-calcium (Sr/Ca) for two Atlantic corals
(Montastraea faveolata and Siderastrea siderea) from the Dry Tortugas
National Park (centered on 24.7&#176;N, 82.8&#176;W) in the Gulf of
Mexico. Cores from coral colonies in close proximity (10s of meters)
and with the same environmental conditions (i.e., depth and water
chemistry) were micro-sampled with approximately monthly resolution and
the resulting Sr/Ca variations were calibrated with local sea surface
temperature (SST) records. Replication tests for coral Sr/Ca variations
found high agreement between intra-colony variations and between
individual colonies of S. siderea (a single M. faveolata colony was
sampled). Regression analysis of monthly variations in coral Sr/Ca and
local SST revealed significant correlation on monthly and inter-annual
timescales. Verification of the calibration on different timescales
found coral Sr/Ca-SST reconstructions in S. siderea were more accurate
than those from M. faveolata, especially on inter-annual timescales.
Sr/Ca-SST calibration equations for the two species are significantly
different (cf., Sr/Ca = -0.042 SST + 10.070, S. siderea; Sr/Ca = -0.027
SST + 9.893, M. faveolata). Mean linear extension for M. faveolata is
approximately twice that of S. siderea (4.63, 4.31, and 8.31 mm year-1,
A1, F1, and B3, respectively); however, seasonal Sr/Ca variability in
M. faveolata is less than S. siderea (0.323, 0.353, and 0.254 mmol
mol-1, A1, F1, and B3, respectively). The reduced slope for M.
faveolata is attributed to physical sampling issues associated with
complex time-skeletal structure of M. faveolata, i.e., a sampling
effect, and not a growth effect since the faster growing M. faveolata
has the reduced Sr/Ca variability.^1";

indication; <b>Systematics: </b>Cnidaria, Scleractinia, Porites;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>New
Caledonia^Coral-based climate reconstructions are typically based on a
single record and this lack of replication leads to questions in
regards to chronology accuracy and reliability of the inclusive
geochemical variations to record climate viability. Here we present two
```

```
multi-century coral Sr/Ca records recovered from a Porites lutea colony
offshore of Am&#233;d&#233;e Island, New Caledonia
(22&#176;28.8&#039;S, 166&#176;27.9&#039;E). The chronology was
developed by cross dating the coral Sr/Ca time series and verifying the
chronology with high precision absolute 230Th dating. We identify
chronological discrepancies of -2.3 and +3.7 years century-1 for
reconstructions based on a single core with uncertainty increasing
after ~250 years. We assess the impact of Porites skeletal architecture
on coral geochemistry by characterizing centimeter-scale architectural
structures with respect to sampling. Optimal sampling paths are those
on the slab surface parallel to the growth direction of individual
corallites along the central axis of an actively extending corallite
fan. Coral Sr/Ca time series extracted from optimal skeletal structures
are highly reproducible with a mean absolute difference of 0.021 mmol
mol-1 or 0.39 &#176;C for monthly determinations. Suboptimal skeletal
architecture is characterized by corallites extending through the slab
surface, and the coral Sr/Ca determinations derived from suboptimal
paths tend to produce a warm bias that varies between +0.04 and +2.30
&#176;C. Disorganized skeletal architecture is characterized by small,
terminating, or unclear corallite fans that produce a cold bias of
-0.11 to -2.45 &#176;C in coral Sr/Ca determinations. These problematic
architecture types also produce biases in coral &#948;18O
determinations, but to a lesser extent. We assess the impact of
sampling a coral colony along paths that vary from vertical to
horizontal in large and small Porites colonies with extension rates >6
mm year-1 and we determine there is no significant difference in the
coral Sr/Ca records.^1";
s[6912] = "DENAYER J. &#038; POTY E. (2010).- Facies and Palaeoecology
of the upper Member of the Aisemont formation (Late Frasnian, S.
Belgium): an unusual episode within the Late Frasnian crisis.-
Geologica Belgica 13, 3: 197-212.- <b>FC&#038;P</b> 37, 147,
ID=7484^<b>Topic(s): </b>coral limestones, ecology; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian U, Frasnian U, Aisemont Fm;
<b>Geography: </b>Belgium, Ardennes^The upper member of the Aisemont
Formation - also known as the &#034;second biostrome&#034; - is the
last significant Upper Frasnian carbonate unit in the northern part of
the Namur-Dinant Basin (Southern Belgium). It consists of bioclastic
limestone, often dolomitized, with numerous oncoids and corals. Despite
its local name, the member is not a biostrome because only one thin bed
is constructed by corals. It is mainly composed of limestone with
numerous oncoids and a rich fauna of opportunistic organisms
(bryozoans, brachiopods, gastropods, sponges, etc.) where
Phillipsastrea and Frechastraea are the dominant coral taxa, associated
with Alveolites. Ragged colonies of corals, as well as multi-encrusted
bodies, show that the sea floor was soft and the rate of sedimentation
was seasonal. These factors were unfavourable to common reef builders
(stromatoporoids), thus the occurrence of one bed constructed by corals
is a remarkable event that corresponds to the colonization of a hard
ground defining the base of a falling stage systems tract. This
confirms the model of the Aisemont sequence (third-order
transgression-regression cycle). The abundant development of microbial
structures in the member (oncoids) and in its lateral equivalent in
stromatolites and thrombolites of the Petit-Mont Member (Les Valisettes
Formation) in the Philippeville Anticlinorium is interpreted as an
evidence of the environmental deterioration corresponding to the Late
Frasnian Crisis.^1";

shells of Cornulites celatus n. sp. occur commonly within host coralla
```

```
of Propora conferta Milne-Edwards and Haime, 1851, sensu lato, from the
Laframboise Member of the Ellis Bay Formation (Ashgill: Upper
Ordovician) at Pointe Laframboise on western Anticosti Island. Examples
have also been found at the same locality in the tabulate corals
Paleofavosites sp., Acidolites arctatus Dixon, 1986, and A. compactus
Dixon, 1986, and the stromatoporoid Ecclimadictyon sp., but not in
other associated tabulate coral species. Growth interference between
the shells and their hosts indicates a commensal relationship. C.
celatus apparently had a more limited paleoenvironmental range than its
principal coral host species, which occurs abundantly elsewhere on the
island without its endobiotic partner. The diagnosis of Cornulites is
emended to include forms having a two-layered shell wall with a
distinctive outer layer consistently preserved as prismatic calcite.
This new species extends the known stratigraphic range of cornulitids
in commensal relationships with corals and stromatoporoids from the
Silurian back to the Upper Ordovician.^1";

<b>Geography: </b>Western Sahara, Morocco^Devonian bryozoans from North
Africa are scarcely known. The present study is devoted to the
investigation of bryozoan fauna and microfacies of a Middle Devonian
reef complex in Western Sahara, Morocco. In total, 26 bryozoan species
were identified. Two genera with two species are new. The studied fauna
shows relations to the Middle Devonian of Holy Cross Mountains, Poland
and Rhenish Massif, Germany, as well as to the Middle Devonian of North
America.^1";
s[6915] = "ERNST A. &#038; MAY A. (2012).- Bryozoan Fauna from the
Lower Devonian (Middle Lochkovian) of Sierra de Guadarrama, Spain.-
Journal of Paleontology 86, 1: 60-80.- <b>FC&#038;P</b> 37, 148,
ID=7487^<b>Topic(s): </b>taxonomy, ecology; <b>Systematics:
</b>Bryozoa; <b>Stratigraphy: </b>Devonian L, Lochkovian M;
<b>Geography: </b>Spain, Sierra de Guadarrama^A bryozoan fauna
containing 11 species is described from the Lower Devonian (middle
Lochkovian) of Arroyo del Agua, Sierra de Guadarrama, Guadalajara,
Spain. One genus containing one species is new: rhabdomesine
cryptostome Fehlerpora insolita n. gen., n. sp. Six additional new
species are described: three cystoporates: Cystiramus gracilis n. sp.,
Fistuliramus guadarramaensis n. sp., and Fistuliphragma tenuis n. sp.;
and three trepostomes: Eridotrypella hispanica n. sp., Boardmanella
dubia n. sp., and Leptotrypella inesae n. sp. Four further trepostome
species were identified: Leioclema incompositum Duncan, 1939, Minussina
spinosoformis Astrova, 1964b, Leptotrypella verisimilis Astrova, 1970,
and Leptotrypella vulgata Astrova, 1964b. The association is
distributed over three different sedimentary environments. The
high-energy one representing accumulation of debris from
bryozoan-coral-pelmatozoan thickets contains eight species dominated by
erect branched forms (six species). Tabulate corals are present,
especially branches which most likely belong to Subcladopora? abnormis
(Mironova, 1974). The environment with moderate to low wave influence
contains only two bryozoan species, one erect branched and one
encrusting. The third setting represents bryozoan thickets in situ
situated in deeper water, the most tranquil environment characterized
by four bryozoan species, dominated by three erect forms. Fenestrate
bryozoans are absent from the two higher energy environments, whereas
the bryozoan thickets in deeper water contain rare unidentified
fragments of fenestrates. The bryozoan fauna shows distinct relations
to the Lower Devonian (Lochkovian) of Ukraine, one species is known
from the Middle Devonian of U.S.A.^1";
s[6916] = "ERNST A., MAY A. &#038; MARKS S. (2012).- Bryozoans, corals,
```

```
and microfacies of Lower Eifelian (Middle Devonian) limestones at
Kierspe, Germany.- Facies 58: 727-758.- <b>FC&#038;P</b> 37, 149,
ID=7488^<b>Topic(s): </b>bryozoans, corals, taxonomy, environments,
biogeography; <b>Systematics: </b>Bryozoa, Cnidaria, Anthozoa;
<b>Stratigraphy: </b>Devonian M, Eifelian L; <b>Geography: </b>Germany,
Sauerland^The Lower Eifelian Meinerzhagener Korallenkalk (= upper
Cultrijugatus Beds) at Kierspe, Sauerland, contains a rich reefal
fauna. Eight bryozoan species are described, two of them are new: the
cystoporate Fistuliporella kierspensis n. sp. and the trepostome
Leptotrypella sophiae n. sp. The bryozoans from the Meinerzhagener
Korallenkalk show distinct similarities to the Lower-Middle Devonian of
Spain (Santa Luc&#237;a Formation, Emsian-Eifelian), and to the Middle
Devonian (Eifelian) of Transcaucasia. The coral fauna comprises five
tabulate corals and one rugose coral that document a paleobiogeographic
relationship between Central and Eastern Europe and Central Asia. The
associated fauna is represented by brachiopods, ostracods, and
echinoderms. The studied limestones also commonly contain calcimicrobes
represented by three species. The faunal and microfacial
characteristics indicate a shallow marine depositional environment just
above the storm wave base, with a supposed depth of 20 m, within the
photic zone. The nutrient regime was at least a mesotrophic. The upper
boundary of the Cultrijugatus Beds coincides with the Chotec-Event that
strongly affected brachiopods, whereas corals and bryozoans were
insensitive to this event.^1";
s[6917] = "FRANKE C. (2010).- Marine Fauna der Wiltz-Schichten

Mulden-Gruppe (Luxemburg, Deutschland): Teil 1.- Ferrantia 58: 5-63;
Luxembourg.- <b>FC&#038;P</b> 37, 151, ID=7489^<b>Topic(s):
</b>fossils, benthic fauna, flora, shallow-marine setting;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L, Emsian;
<b>Geography: </b>Luxembourg, Germany, Wiltz Beds^A multitude of new
finds permit a fundamental revision of the fossil contents of he Wiltz
layers. For this purpose, approx. 5,700 proofs of finds were evaluated.
Due to the numerous finds, the study will be published in several
parts. It turns out that the species-diversity is very much greater
than assumed to date. The presence of many of genera and species known
from other sedimentation areas have now been proved for the
Wiltz-layers in the Wiltz-basin and Daleiden Synclinal Group. This
publication includes plant fossils, Rhaphidopora sp. cf. Rhaphidopora
lonsdalei, Cornulites sp. and Pterygotoidea fam. et gen. et sp. indet.
The trilobite Leonaspis grafi n. sp. is redescribed. Finally, the area
examined can be defined as an extensive long-lived deposit region of a
shallow water situation extending from close to and far from the coast
of the Ardenno-Rhenish continental shelf with multifold faunistic
correspondences to other regions in the Variscan sea during the upper
Emsian.^1";
s[6918] = "GARBEROGLIO R.M. &#038; LASSO D.G. (2011).- Post-mortem and
symbiotic Sabellid and Serpulid-coral associations from the Lower
Cretaceous of Argentina.- Revista Brasileira de paleontologia 14, 3:
215-228.- <b>FC&#038;P</b> 37, 151, ID=7490^<b>Topic(s): </b>epibionts,
in vivo &#038; post mortem overgrowth, aanelids, corals;
<b>Systematics: </b>Annelida, Cnidaria, Anthozoa; <b>Stratigraphy:
</b>Cretaceous L, Hauterivian; <b>Geography: </b>Argentina, Neuquen
Basin^One morphotype of sabellids (Sabellida, Sabellidae) and two of
serpulids (Sabellida, Serpulidae), found as encrusters on scleractinian
ramose corals of the species Stereocaenia triboleti (Koby) and
Columastrea antiqua Gerth, from the Agrio Formation (early Hauterivian)
from Neuqu&#233;n Basin, Argentina, are described. The identified
morphotypes, Glomerula lombricus (Defrance), Mucroserpula mucroserpula
Regenhardt and Propomatoceros sulcicarinatus Ware, have been previously
recorded from the Early Cretaceous of the northern Tethys. Two
different type of sabellid and serpulid-coral associations have been
recognized. The first and more abundant association corresponds to
```

```
post-mortem encrustation on corals branches. The second one corresponds
to a symbiotic association between the serpulid P. sulcicarinatus and
both species of corals. The serpulid tubes are recorded parallel to the
coral branches reaching the upper tip of them and they were bioimmured
within the coral as they grew upwards. The studied symbiotic
relationship between serpulids and corals may be regarded as a
mutualism as both members probably benefited each other. This type of
association has similarities with recent cases of symbiosis between
serpulids and corals, but had no fossil record until now.^1";
s[6919] = "GATT M. &#038; DE ANGELI A. (2010).- A new coral-associated
decapod assemblage from the Upper Miocene (Messinian) Upper Coralline
Limestone of Malta (Central Mediterranean).- Palaeontology 53, 6:
1315-1348.- <b>FC&#038;P</b> 37, 152, ID=7491^<b>Topic(s): </b>coral
associated decapods; <b>Systematics: </b>Arthropoda, Decapoda;
<b>Stratigraphy: </b>Miocene, Messinian; <b>Geography:
</b>Mediterranean, Malta^A rich coral-associated decapod assemblage is
recorded from the &#039;Depiru Beds&#039; of the upper part of the
Upper Coralline Limestone (Messinian, Upper Miocene), from the island
of Malta. Nineteen species within 17 genera have been discovered, where
14 genera are new for Malta. Four new species are described, namely
Micippa annamariae sp. nov., Pilumnus scaber sp. nov., Panopeus
muelleri sp. nov. and Herbstia melitense sp. nov. Herbstia melitense
sp. nov. constitutes the first record of the genus from the fossil
record in the Mediterranean region. This discovery more than doubles
the number of known fossil decapod species from Malta. The fossil
bivalve Jouannetia (J.) semicaudata Des Moulins, 1830 and the extant
decapod Maja goltziana D&#039;Oliveira, 1888, are also recorded for the
first time from Malta. Other Neogene coral-associated decapod
assemblages are investigated and correlated with the new assemblage
from Malta. The migration of taxa between the Mediterranean region and
the Paratethys, particularly during the Lower Badenian (Langhian), is
evidenced by the strong affinity of the Maltese decapod assemblage with
that of the Middle Miocene Badenian assemblages from Hungary, Poland
and Ukraine. Upper Miocene, Messinian assemblages from Spain, Algeria
and Morocco are also similar to that from Malta.^1";

(2010).- Geochemistry and skeletal structure of Diploria strigosa,
implications for coral-based climate reconstruction.- Palaeogeography,
Palaeoclimatology, Palaeoecology 298, 3-4: 378-387.- <b>FC&#038;P</b>
37, 153, ID=7492^<b>Topic(s): </b>coral skeleton, geochemistry,
skeletal structure; <b>Systematics: </b>Cnidaria, Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Atlantic,
tropical^Geochemical tracers incorporated into the skeleton of
reef-building corals are ideal proxies for reconstructing environmental
parameters of ambient seawater such as temperature and salinity at
subseasonal resolution. However, validation concerns of these
environmental proxies due to the complex skeleton of some tropical
Atlantic corals have hindered such coral-based environmental
reconstructions in this region compared to the tropical Pacific. In
order to identify complications associated with the complex skeletal
architecture of the massive brain coral Diploria strigosa, we performed
microsampling experiments along and across individual skeletal
elements. We demonstrate that the mesoscale heterogeneity of Sr/Ca,
&#948;18O and &#948;13C is a systematic feature of D. strigosa and is
linked to different vital effects between skeletal elements. The thecal
wall is significantly depleted in Sr, 18O and 13C compared to the
adjacent septa and columella and differences between apparent
temperature signatures of several degrees are greater for Sr/Ca
suggesting that this temperature proxy is more sensitive to skeletal
mixing than &#948;18O. Parallel subseasonal microsampling experiments
performed along individual skeletal elements of a single corallite of a
D. strigosa coral which grew at a rate of 0.65 cm/year allow for
investigating potential biases associated with its complex skeletal
```

```
mesoarchitecture. Highest correlation between Sr/Ca and &#948;18O from
skeletal material retrieved from the centre of the thecal wall suggests
that microdrilling the theca provides the best environmental signal
compared to adjacent microsampling profiles. Moreover, based on
monthly-mean climatology, the temperature dependence of Sr/Ca for this
profile is comparable to previous calibrations published from faster
growing D. strigosa. Based on these results, we conclude that accurate
microsampling along the centre of the thecal wall of D. strigosa is a
prerequisite for generating robust climate reconstructions from its
skeleton.^1";
s[6921] = "GISCHLER E. (2010).- Indo-Pacific and Atlantic spurs and
grooves revisited: the possible effects of different Holocene sea-level
history, exposure, and reef accretion rate in the shallow fore reef.-
Facies 56, 2: 173-177.- <b>FC&#038;P</b> 37, 154, ID=7493^<b>Topic(s):
</b>reef morphology, spurs and grooves; <b>Systematics: </b>;
<b>Stratigraphy: </b>Holocene; <b>Geography: </b>^Shallow fore-reef
areas worldwide are usually characterized by spurs and grooves. A
comparison of examples from the three world oceans suggests that
Indo-Pacific spurs and grooves are shaped predominantly by erosion,
whereas western Atlantic spur and groove systems are largely a product
of constructive processes. I propose that this difference is caused by
regional differences in Holocene sea-level change, which controlled
exposure to waves and currents, and reef-accretion rates. The
transgressive-regressive sea-level curve in the Indo-Pacific realm,
i.e., the Mid-to-Late Holocene sea-level fall in these areas has
maintained high-energy conditions in the shallow fore reef. Higher
exposure to waves and currents favors erosion and leads to a dominance
of crustose coralline algae that have relatively slow growth rates. In
the western Atlantic, the transgressive Holocene sea level has caused
Mid-to-Late Holocene deepening and has maintained accommodation space
for reef accretion. Fast-growing acroporid corals thrive under lower
exposure and are more common than coralline algae. The fossil record of
the spur and groove system is rather poor, which is probably a
consequence of the need of excellent, three-dimensional outcrops for
identification.^1";
s[6922] = "GRETZ M., LATHUILIERE B., MARTINI R. &#038; BARTOLINI A.
(2013).- Hettangian corals of the Isle of Skye (Scotland): An
opportunity to better understand the palaeoenvironmental conditions
during the aftermath of the Triassic-Jurassic boundary crisis.-
Palaeogeography, Palaeoclimatology, Palaeoecology 376: 132-148.-
<b>FC&#038;P</b> 37, 154, ID=7494^<b>Topic(s): </b>corals, stable
isotopes, paleoenvironment; <b>Systematics: </b>Cnidaria, Scleractinia;
<b>Stratigraphy: </b>Jurassic L, Hettangian; <b>Geography:
</b>Scotland, Isle of Skye^At Ob Lusa (Isle of Skye, Scotland), six
distinct coral beds were observed in a modern outcrop where a
Hettangian succession is exposed. The coral associations are monogenic,
belonging to Lepidophyllia, a massive cerioid genus. The lowest bed has
relatively well-developed colonies that form small bioconstructions,
whereas the other beds have small and dispersed colonies that are
completely drowned in the matrix. Their morphology and size can vary,
but the general growth fabric is dominated by platy colonies. This type
of growth fabric is defined as a platestone. The most surprising
characteristic of these specimens, especially for the platy corals, is
their growth pattern; many samples do not exhibit the classical growth
polarity because they are bifacial. Geochemical analyses (&#948;18O,
&#948;13C) were conducted on oyster shells that were associated with
the corals. The results indicate that the mean palaeotemperature was
approximately 22 &#176;C. Sedimentological analysis revealed shallow
settings where the hydrodynamic energy and siliciclastic inputs
fluctuated. The general faunal assemblage of the outcrop had low
diversity and was mainly composed of allochthonous bioclasts. The
corals at Ob Lusa clearly did not live under ideal environmental
conditions for the development of corals.^1";

s[6923] = "GRIFFITHS N., M&#220;LLER W., JOHNSON K.G. &#038; AGUILERA
O.A. (2013).- Evaluation of the effect of diagenetic cements on element
/ Ca ratios in aragonitic Early Miocene (~16 Ma) Caribbean corals:
Implications for &#8216;deep-time&#8217; palaeo-environmental
reconstructions.- Palaeogeography, Palaeoclimatology, Palaeoecology
369: 185-200.- <b>FC&#038;P</b> 37, 155, ID=7495^<b>Topic(s):
</b>corals, skeletal geochemistry, temperature proxies; <b>Systematics:
</b>Cnidaria, Scleractinia; <b>Stratigraphy: </b>Miocene, Recent;
<b>Geography: </b>^Early Miocene corals (Siderastrea conferta and
Montastraea limbata) from the Paraguana Peninsula, Venezuela and a
modern coral (S. radians) from Bermuda were examined in order to
quantitatively assess the effect of skeletal preservation on element /
Ca proxies used for palaeo-environmental reconstructions. The
biostratigraphic age (Burdigalian) of the corals was confirmed via Sr
isotope stratigraphy to 16.5 &#177; 0.4 Ma. Light and scanning electron
microscopy revealed the presence of aragonite and calcite cements in
both fossil and modern corals, but brucite cements were found only in
the modern coral. Cement distribution is very heterogeneous, resulting
in zones of excellent preservation juxtaposed with less well preserved
regions in both modern and fossil coral. Oil-filled pore spaces were
noted in the fossil specimens. Targeted LA-ICPMS depth profile analyses
showed significant differences in Sr/Ca, Mg/Ca, B/Ca, Ba/Ca and U/Ca in
aragonite and calcite cements compared to primary skeletal aragonite.
Increased Sr/Ca and decreased Mg/Ca ratios were found in aragonite
cements compared to skeletal aragonite, whereas in calcite cements
these trends were reversed. B/Ca ratios were lower in both aragonite
and calcite cements compared to primary aragonite. Estimates of the
effect of 1% contamination by aragonite cements on coral Sr/Ca, Mg/Ca,
B/Ca and U/Ca palaeo-sea-surface-temperature reconstructions for the
fossil corals produced anomalies of -1.2&#176;C, -0.2&#176;C,
+0.3&#176;C and -0.1&#176;C respectively. Similar percentage calcite
cement contamination produced temperature anomalies of +1.7&#176;C,
+2.7&#176;C, +0.3&#176;C and -0.1&#176;C. Because of both highly
elevated and depleted Ba/Ca signatures in aragonite and calcite cements
respectively, care has to be exercised when reconstructing past flood
or upwelling events from fossil corals. When using targeted
spatially-resolved analysis, well-preserved early Miocene corals may
overall yield reliable &#8216;deep-time&#8217; palaeo-proxy information
in much the same way as commonly utilised Holo/Pleistocene corals.^1";
s[6924] = "HARRIES P.J. &#038; SORAUF J.E. (2010).- Epi- and endobionts
on and in free-living colonies of Manicina areolata (Cnidaria,
Scleractinia): a comparison of two Pleistocene communities from
southern Florida.- Palaios 25, 6: 400-414.- <b>FC&#038;P</b> 37, 156,
ID=7496^<b>Topic(s): </b>epi- and endobionts of corals; <b>Systematics:
</b>; <b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>USA, Florida
SE^The epi- and endobiont communities (EEBCs) found within an
exquisitely preserved collection of 48 Manicina areolata specimens from
two Pleistocene localities in southeastern Florida, United States, were
examined in detail. The EEBCs include a broad taxonomic spectrum of
encrusting and boring organisms, but differ markedly between the two
localities. Specimens from the Canal locality generally show an equable
distribution of EEBCs, with serpulids, spirorbids, and/or chamids
numerically dominant and chamids dominating in average area, whereas
the Palm Beach Aggregates (PBA) coralla have a much less even
distribution of EEBC constituents and lithophagids numerically and
spatially dominate virtually all bases. Given the relative proximity of
the two localities and inferred distance from the Pleistocene
shoreline, it seems unlikely that any of the EEBC components would have
been substantially less available in one locality as compared to the
other. Therefore, we favor an explanation focused on sedimentologic
differences between the two areas. The Canal environment was shelly,
carbonate mud, in contrast to the shelly, coarser-grained siliciclastic
sediment present at PBA. The substrate at the Canal site was relatively
```

```
soft, which resulted in corallum basal morphology commencing with a
prominent apical cone, whereas the substrate at the PBA site was firmer
and this support produced much flatter bases as well as allowing for a
substantially greater number of lithophagid bivalves to bore into the
coralla.^1";

WESTPHAL H. (2010).- Formation of deglacial microbialites in coral
reefs off Tahiti (IODP 310) involving sulfate-reducing bacteria.-
Palaios 25, 10: 618-635.- <b>FC&#038;P</b> 37, 157,
ID=7497^<b>Topic(s): </b>coral reefs, microbialites, sulfate-reducing
bacteria; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>Pacific, Tahiti^During IODP Expedition 310 (Tahiti
Sea Level), drowned Pleistocene-Holocene barrier-reef terraces were
drilled on the slope of the volcanic island. The deglacial reef
succession typically consists of a coral framework encrusted by
coralline algae and later by microbialites; the latter make up
&#8804;80% of the rock volume. Lipid biomarkers were analyzed in order
to identify organisms involved in reef-microbialite formation at
Tahiti, as the genesis of deglacial microbialites and the conditions
favoring their formation are not fully understood. Sterols plus
saturated and monounsaturated short-chain fatty acids predominantly
derived from both marine primary producers (algae) and bacteria
comprise 44 wt% of all lipids on average, whereas long-chain fatty
acids and long-chain alcohols derived from higher land plants represent
an average of only 24 wt%. Bacterially derived mono-O-alkyl glycerol
ethers (MAGEs) and branched fatty acids (10-Me-C16:0; iso- and
anteiso-C15:0 and -C17:0) are exceptionally abundant in the microbial
carbonates (average, 19 wt%) and represent biomarkers of
intermediate-to-high specificity for sulfate-reducing bacteria. Both
are relatively enriched in 13C compared to eukaryotic lipids. No lipid
biomarkers indicative of cyanobacteria were preserved in the
microbialites. The abundances of Al, Si, Fe, Mn, Ba, pyroxene,
plagioclase, and magnetite reflect strong terrigenous influx with
Tahitian basalt as the major source. Chemical weathering of the basalt
most likely elevated nutrient levels in the reefs and this
fertilization led to an increase in primary production and organic
matter formation, boosting heterotrophic sulfate reduction. Based on
the observed biomarker patterns, sulfate-reducing bacteria were
apparently involved in the formation of microbialites in the coral
reefs off Tahiti during the last deglaciation.^1";

D. &#038; HALFAR J. (2010).- Rapid 20th century warming in the
Caribbean and impact of remote forcing on climate in the northern
tropical Atlantic as recorded in a Guadeloupe coral.- Palaeogeography,
Palaeoclimatology, Palaeoecology 296, 1-2: 111-124.- <b>FC&#038;P</b>
37, 158, ID=7498^<b>Topic(s): </b>coral skeleton, &#948;18O and Sr/Ca
time series, temperature proxies; <b>Systematics: </b>Cnidaria,
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Caribbean,
Guadeloupe^We have generated 104-year long (1895-1999) monthly
&#948;18O and Sr/Ca time series from a fast-growing Diploria strigosa
coral core drilled off Guadeloupe Island, Lesser Antilles. Coral Sr/Ca
reliably records interannual to decadal surface air temperature (SAT)
variations in the region and shows a pronounced warming of
approximately 1.5&#176;C since 1950, with the strongest warming
(1.2&#176;C) occurring since 1975. This warming is also evident in SAT
measured at Guadeloupe, which ends in 1951. Thus, our Sr/Ca series
extends the air temperature record by 56 years. We find that the past
few decades are the warmest years over the entire period of record. The
accelerated warming since 1950 is accompanied by a pronounced decrease
in regional precipitation. This dampens the warming signal indicated by
coral &#948;18O, which is too low (only 0.7-0.8&#176;C since 1951).
Consistently, &#948;18Osw estimated from the coral proxies also shows a
strong decrease since 1950. Our data suggest an inverse relationship
```

```
between SAT and precipitation (i.e. warmer and drier) for the latter
half of the 20th century with the strongest trends since the mid-1970s.
This is consistent with recent observational and model data, which
report that while over the tropical oceans rainfall has increased due
to an increase in sea surface temperatures, precipitation over land
regions is reduced. A continuation of this warming and drying trend
over Caribbean land regions would have severe societal consequences,
especially in the context of anthropogenic warming. * The El Nino
Southern-Oscillation (ENSO) and the North Atlantic Oscillation (NAO)
are the two major climate modes affecting large-scale SST variability
in the northern tropical Atlantic. Both Sr/Ca and &#948;18O show a
close relationship to ENSO and the NAO. A quantitative comparison
between extremes in mean March-May coral &#948;18O and the Nino3 and
NAO indices imply that climate variability in the northern tropical
Atlantic is mainly forced by tropical Pacific and North Atlantic
variability. Spectral analysis suggests that the relative importance of
ENSO and the NAO is frequency dependent, with ENSO dominating at
interannual, and the NAO dominating at interdecadal time scales.^1";

Devonian rugose coral &#039;Amplexus&#039; and its relation to
submarine fluid seepage.- Palaeogeography, Palaeoclimatology,
Palaeoecology 386: 180-193.- <b>FC&#038;P</b> 37, 159,
ID=7499^<b>Topic(s): </b>corals, submarine seepage; <b>Systematics:
</b>Cnidaria, Rugosa, Amplexus; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Morocco, Anti-Atlas^The rugose coral
&#039;Amplexus&#039; occurs frequently in the sedimentary cover of the
Devonian submarine volcanic intrusion in the eastern Anti-Atlas,
southern Morocco. This study elucidates the palaeoecology of
&#039;Amplexus&#039;, which forms very rich and mostly monospecific,
spot assemblages within the Lower and Middle Devonian carbonates.
Geological and isotopic evidences show that these associations
developed at hydrothermal vents and at a cold seep site. The
assemblages are always spatially associated with micritic carbonate
bodies, occurring within bedded, hemipelagic deposits. The
&#039;Amplexus&#039; corals preferred locations in the close proximity
of submarine hydrothermal fluid seepage, but they generally avoided
places with the most elevated temperatures. The corals colonised also a
hydrocarbon seep, probably only in its terminal phase of development,
when the fluid flow was still at least periodically active. This was
only possible as a result of the corals following a calice-in-calice
growth, developed due to the environmental toxicity, which facilitated
selective survival of larvae that settled in the shelter of empty
calices. The &#039;Amplexus&#039; corals appear to have constituted
ecological opportunists, thriving in the nutrient-rich, venting- and
seepage-affected areas that were hostile for other benthic organisms.
It can be suspected that the unusual, extremely simplified morphology
of &#039;Amplexus&#039; made it particularly well adapted to living in
environments typified by harsh and unstable conditions.^1";
s[6928] = "JAKUBOWICZ M., BERKOWSKI B. &#038; BELKA Z. (2013).- Cryptic
coral-crinoid &#034;hanging gardens&#034; from the Middle Devonian of
southern Morocco.- Geology: online since 13 December 2013 as doi
10.1130/G35217.1- <b>FC&#038;P</b> 37, 159, ID=7500^<b>Topic(s):
</b>mud-mounds cavities, cryptic organisms, corals, crinoids;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M; <b>Geography:
</b>Morocco, Hamar Laghdad^An unusual and exceptionally well preserved
cryptic community of cnidarians, crinoids, sponges, and microbes
developed in a submarine cavity of Middle Devonian age in the Hamar
Laghdad area (Morocco). The biota encrusted the cavity roof and grew
predominantly in an upside-down position, forming spectacular
&#034;hanging gardens&#034;. The investigated assemblage differs
strikingly from both its Paleozoic and modern analogues; it constitutes
one of a very few known examples of fossil cryptic assemblages
developed in relatively deep water settings, and is the first report of
```

```
a cryptic paleoecosystem dominated by rugose corals. The results
support the view that during the middle Paleozoic there was no distinct
polarization between open-surface and cryptic faunas in deep-water
environments, but keen competition for space already existed in
Devonian cryptic assemblages. The regional species pool seems to have
been the main determinant of the ecological succession and structure of
this cryptic community.^1";

(2013).- Upper Devonian shoal-water delta integrated with cyclic
back-reef facies off the Mowanbini Archipelago (Canning Basin), Western
Australia.- Facies 59, 4: 991-1009.- <b>FC&#038;P</b> 37, 160,
ID=7501^<b>Topic(s): </b>reef - siliciclastics interaction;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian U, Frasnian;
<b>Geography: </b>Australia W, Canning Basin^The Oscar Range in Western
Australia&#039;s Canning Basin exhibits folded Proterozoic, quartzite,
quartzite conglomerate, phyllite, and metavolcanic rocks that survive
with positive relief. Facies of the Pillara Limestone were deposited
around this relief during Late Devonian (Frasnian) time. A segment of
the Great Devonian Barrier Reef with a linear reef margin strikes
parallel to the outer paleoislands in the Mowanbini Archipelago. A more
sheltered strait separates inner islands from the cratonic Devonian
mainland on the Kimberley Block. Large fandeltas emanated from the
craton, but locally small shoalwater deltas prograded from a drainage
basin on one of the larger paleoislands in the Oscar Range. That island
is expressed today by local topography exhumed from beneath a cover of
former Devonian, Carboniferous, and Permian strata. The Devonian
shoal-water delta rests unconformably on tilted Proterozoic phyllite
and incorporates abundant phyllitic debris accumulated under fluvial to
shoreface conditions. Some quartzite pebbles and hydrothermal quartz
were derived from a source more than a kilometer away. Rare gastropods
and stromatoporoid fragments in the deltaic sediments were abraded from
the adjacent reef margin. The clast-supported conglomerate in the
exposed shoal-water delta is mapped over a distance of 130 m to within
15 m of the inner reef margin, exposed nearby on steeply dipping
phyllite. A cyclic succession of mixed clastic and carbonate
parasequences, 31.5 m in thickness, follows above a disconformity
surface on the delta-top facies. The overall succession represents a
minor fall in relative sea level associated with erosion of delta
facies and a major transgression characterized by a retrograde
parasequence stacking pattern. The succession shifts through
siliciclastic-rich shoreface to intertidal distal back-reef facies,
ending with a subtidal, siliciclastic-poor proximal back-reef facies.
The study demonstrates how variability in sedimentary cycles is
influenced by local paleogeographic constraints in an island system
dominated by quartzite highlands and phyllite lowlands.^1";

HERGREAVES S. &#038; NUDDS J. (2012).- High resolution biostratigraphy
of the Tournaisian-Visean boundary interval in the North Staffordshire
Basin and correlation with the South Wales-Mendip Shelf.- Bulletin of
Geosciences 87, 3: 497-541.- <b>FC&#038;P</b> 37, 161,
ID=7502^<b>Topic(s): </b>biostratigraphy, sequence stratigraphy;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous L, Tournaisian
/ Visean; <b>Geography: </b>England, N Staffordshire Basin^A study of
three carbonate sections in the North Staffordshire Basin and two in
the South Wales-Mendip Shelf yielded so far the richest foraminiferal
associations at the Tournaisian-Visean boundary in Western Europe
enabling a very good correlation with the stratotype area in South
China. The biostratigraphic study was refined by sedimentological and
gamma-spectrometrical data in order to define and calibrate the high
resolution biostratigraphy across the boundary interval. The study
illustrates the cryptic entry of the stratigraphically important
species of the Chadian index genus Eoparastaffella which is abundant in
photozoan facies. Across the Tournaisian-Visean boundary, changes in
```

```
the character of the foraminiferal associations reflect the gradual
change from heterozoan dominated late Tournaisian ramps to Visean
photozoan dominated platforms. The combined application of
biostratigraphic and sedimentological methods and gamma ray
manifestation of the mid Avonian sequence boundaries have proved useful
in the identification of the Tournaisian-Visean boundary in
Carboniferous successions on either side of the Wales-Brabant Massif
and has widespread applicability for successions of a similar age
across Western Europe.^1";

Late Chadian-Early Arundian high-resolution biostratigraphy in the
Ogmore-by-Sea section (South Wales-Mendip shelf) and the mid-Avonian
unconformity.- Journal of the Geological Society, London
http://dx.doi.org/10.1144/jgs2013-023- <b>FC&#038;P</b> 37, 162,
ID=7503^<b>Topic(s): </b>high-resolution biostratigraphy;
<b>Systematics: </b>Foraminifera; <b>Stratigraphy: </b>Carboniferous,
Chadian-Arundian; <b>Geography: </b>United Kingdom, South Wales -
Mendip^The study of the foraminiferal fauna in the Ogmore section in
south Wales produced a detailed late Chadian-early Arundian
biostratigraphy and sequence stratigraphy with a higher resolution than
in the Arundian stratotype in Hobbyhorse Bay. The earliest Visean (late
Chadian) pedogenic horizon close to the Gully Oolite and Caswell Bay
Mudstone boundary (MFZ9) corresponds to the mid-Avonian unconformity.
The entry of primitive archaediscids of MFZ10 within the Caswell Bay
Mudstone is followed by more advanced archaediscids of MFZ11 at the
base of the High Tor Limestone. The mid-Avonian unconformity at the
Chadian-Arundian boundary is not confined to the London-Brabant Massif,
but is also present in central Europe, the East European Platform, the
Urals, west Siberia and probably also in Kuzbass and North America. The
global extent of the the mid-Avonian unconformity suggests that it is a
consequence of early to mid-Visean glacioeustacy.^1";

example from Puerto Rico.- Palaeogeography, Palaeoclimatology,
Palaeoecology 307, 1-4: 90-97.- <b>FC&#038;P</b> 37, 163,
ID=7506^<b>Topic(s): </b>coral skeletons, &#948;18O anomalies, tropical
cyclones; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Atlantic, Puerto Rico^Complimenting modern records of
tropical cyclone activity with longer historical and
paleoclimatological records would increase our understanding of natural
tropical cyclone variability on decadal to centennial time scales.
Tropical cyclones produce large amounts of precipitation with
significantly lower &#948;18O values than normal precipitation, and
hence may be geochemically identifiable as negative &#948;18O anomalies
in marine carbonate &#948;18O records. This study investigates the
usefulness of coral skeletal &#948;18O as a means of reconstructing
past tropical cyclone events. Isotopic modeling of rainfall mixing with
seawater shows that detecting an isotopic signal from a tropical
cyclone in a coral requires a salinity of ~33 psu at the time of coral
growth, but this threshold is dependent on the isotopic composition of
both fresh and saline end-members. A comparison between coral &#948;18O
and historical records of tropical cyclone activity, river discharge,
and precipitation from multiple sites in Puerto Rico shows that
tropical cyclones are not distinguishable in the coral record from
normal rainfall using this approach at these sites.^1";

corals skeletons; <b>Systematics: </b>chlorophytes, fungi, microbes;
<b>Stratigraphy: </b>Cretaceous L; <b>Geography: </b>Romania^A
spectacularly preserved assemblage of microbial euendoliths,
penetrating into skeletons of growing scleractinian corals, has been
recognized in Early Aptian (Early Cretaceous) reef limestone of the
Rarau Mountains (East Carpathians, NE Romania). Microboring
euendolithic filaments were found in five coral colonies of the
suborder Microsolenina. They remained in part well-preserved, often
impregnated with iron oxides, which made them visible even in strongly
recrystallized parts of coral skeletons. Filaments of a wide range of
sizes (2-40&#956;m in diameter) were concentrated within medium parts
of coral septa, oriented along the septa in the direction of the coral
growth. The larger filaments were tubular, occurring in bundles and
branched into finer, often tapering branches. Their behaviour and
organization were quite similar to the modern euendolithic siphonalean
chlorophyte Ostreobium. Filament diameters exceeded those reported for
the modern species, but covered a similarly wide size range. Narrower
frequently branching filaments, 4-8&#956;m in diameter, resemble distal
branching patterns of modern Ostreobium quekettii. Some very thin
filaments (ca. 1-2&#956;m) observed within skeleton or inside the large
```

```
tubular filaments, sometimes associated with globular swellings, may
represent euendolithic fungi. The recrystallization of coral skeleton
had limited effect on preservation of euendoliths due to their
impregnation with iron oxides; microbial euendoliths were subjected to
different taphonomic changes.^1";
s[6937] = "KRONE R., PASTER M. &#038; SCHUHMACHER H. (2011).- Effect of
the surgeonfish Ctenochaetus striatus (Acanthuridae) on the processes
of sediment transport and deposition on a coral reef in the Red Sea.-
Facies 57, 2: 215-221.- <b>FC&#038;P</b> 37, 165, ID=7509^<b>Topic(s):
</b>coral reefs, reef sweepers; <b>Systematics: </b>surgeonfish;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Red Sea^Excessive
sedimentation is a major threat to coral reefs. It can damage or kill
reef-building corals and can prevent the successful settlement of their
planktonie larvae. The surgeonfish Ctenochaetus striatus feeds on rocky
surfaces by sweeping loose material into its mouth with its flexible,
broom-like teeth. In addition, it grasps and removes hard substrates
with the aid of its special palate structure. It then transports
sediment matter off the reef by defecating the ingested material
outside the rocky zone of the reef. We analyzed 150 feces samples of
six individuals, differentiating between (1) ingested by sweeping and
(2) ingested by scraping, and compared their content with inorganic
land-derived and marine sediments trapped at the feeding area.
Projections based on fish densities, defecation rates, and quantities
as well as composition of sediments collected by traps on the same reef
site suggest that C. striatus removes at least 18% of the inorganic
sediment sinking onto the reef crest. The eroded share in the exported
matter is about 13%. This finding points to a hitherto not verified
role of C. striatus as a reef sweeper and reef scraper, whereby the
first function is by far dominating. [original abstract; Wrzolek]

s[6938] = "KRUZIC P., SRSEN P. &#038; BENKOVIC L. (2012).- The impact
of seawater temperature on coral growth parameters of the colonial
coral Cladocora caespitosa (Anthozoa, Scleractinia) in the eastern
Adriatic Sea.- Facies 58, 4: 477-491.- <b>FC&#038;P</b> 37, 166,
ID=7510^<b>Topic(s): </b>coral growth, seawater temperature;
<b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>Adriatic Sea^The scleractinian coral
Cladocora caespitosa deserves a special place among the major carbonate
bioconstructors of the Mediterranean Sea. Annual coral skeleton growth,
coral calcification, and skeleton density of the colonial coral C.
caespitosa taken from 25 locations in the eastern Adriatic Sea were
analyzed and compared with annual sea surface temperatures (SST). The
growth rates of the coral C. caespitosa from the 25 stations in the
Adriatic Sea ranged from 1.92 to 4.19 mm per year, with higher growth
rates of the investigated corallites in the southern part of the
Adriatic Sea. These growth rates are similar to those measured in other
areas of the Mediterranean Sea. The correlation between coral growth
and sea temperatures in the Adriatic Sea is seen as follows: an
X-radiograph analysis of coral growth in C. caespitosa colonies that
are over 60 years old showed that higher growth rates of this coral
coincided with a warmer period in the Mediterranean Sea. A positive
significant correlation exists between corallite growth rates and SST
and coral calcification and SST. A negative correlation exists between
coral density and SST. Coral growth rates also showed a correlation
with higher eutrophication caused by nearby fish farms, along with a
greater depth of the investigated colonies and high bottom currents.^1";

corals are potential geochemical archives that record oceanographic
parameters, such as bottom water temperature in the deep sea. In this
study, the three solitary scleractinian species,Caryophyllia cyathus,
Desmophyllum cristagalli and Stenocyathus vermiformis, were sampled
from upper bathyal 500m water depths in the southern Faial Channel
(Azores archipelago). The stable carbon isotope (&#948;13C) and oxygen
isotope (&#948;18O) compositions of the corals were analysed and
related to their skeletal architecture. Background data, including data
from high-resolution temperature logs and on the ambient seawater
isotopic composition, were compared with &#948;18O-based temperature
reconstructions to test the suitability of these cold-water corals as
geochemical archives and to explore the role of vital effects on
skeletal geochemistry. Although all of the corals experienced identical
and near-stable salinities and temperatures, the stable isotopic
signatures vary within and among species. Both &#948;13C and &#948;18O
values fluctuate in relation to growth bandings and are therefore most
likely dependent on calcification rates and associated kinetic vital
effects. The studied specimens are 13C depleted with respect to
equilibrium with ambient seawater, indicating significant uptake of
respired CO2 by their skeletons. Skeletal &#948;18O values vary by up
to 3.6&#8240; among the growth bands of one of the coral specimens,
translating into an unrealistic reconstructed temperature amplitude of
~16 &#176;C. This contrasts with the minute intra-annual amplitude of
the stable temperature regime (annual mean 12.30 &#177; 0.25 &#176;C).
Nevertheless, &#948;13C vs. &#948;18O regression lines can be used to
deduce ambient temperatures by applying the lines technique (Smith et
al., 2000; Palaios 15: 25-32), which yields temperatures that coincide
with the measured maximum temperature range in the case of D.
cristagalli and for most C. cyathus samples, but deviate by 2.95
&#176;C from the measured annual mean in the case of the S. vermiformis
specimen.^1";

```

```
potential ocean acidification event (the Triassic-Jurassic boundary)
using the presence of corals and coral reefs in the fossil record.-
Palaeogeography, Palaeoclimatology, Palaeoecology 350-352: 114-123.-
<b>FC&#038;P</b> 37, 169, ID=7515^<b>Topic(s): </b>ocean acidification,
carbonate crisis, mass extinction; <b>Systematics: </b>;
<b>Stratigraphy: </b>Triassic / Jurassic; <b>Geography: </b>^Ocean
acidification associated with emplacement of the Central Atlantic
Magmatic Province (CAMP) has been hypothesized as a kill mechanism for
the end-Triassic mass extinction, but few direct proxies for ancient
ocean acidity are available. This paper describes a new proxy that uses
the presence of fossil corals and coral reefs to determine aragonite
saturation state (&#937;Arag). Modern scleractinian corals struggle to
biomineralize a skeleton below an &#937;Arag of 2 and modern shallow
water coral reefs are typically only found in areas with source water
of &#937;Arag >3, so when corals or coral reefs are preserved in the
fossil record, these ocean saturation states can be inferred.
Atmospheric pCO2 reconstructions are combined with the coral &#937;Arag
limitations to calculate the total dissolved inorganic carbon (DIC) in
the Late Triassic ocean, which is a measure of the buffering capacity
or ocean sensitivity to acidification. Once DIC is known, the severity
of an acidification due to a carbon dioxide injection can be
determined, for example the Triassic-Jurassic (T-J) event. Our results
suggest that if Late Triassic DIC values were low to moderate
(2000-3000 &#956;mol/kg), the T-J pCO2 increases would have depressed
saturation state to the point where coral biomineralization would have
been extremely challenging (&#937;Arag &#060;2), resulting in the
observed coral and coral reef gap in the fossil record. While the
average pCO2 elevations recorded in stomatal and pedogenic proxies are
not sufficient to cause complete carbonate undersaturation, modeled
scenarios for CAMP-related T-J pCO2 increases (within error of
pedogenic pCO2 proxies) suggest that aragonite undersaturation is
plausible and in extreme cases calcite undersaturation is achievable.
Thus, a short but extreme acidification event could occur and would
satisfactorily explain the significant extinction of calcareous
organisms, the Early Hettangian coral gap, and the T-J carbonate
crisis.^1";

MANNING C. &#038; YOUNG J. (2011).- A re-assessment of age dating of
fossiliferous limestones in eastern Sabah, Borneo: Implications for
understanding the origins of the Indo-Pacific marine biodiversity
hotspot.- Palaeogeography, Palaeoclimatology, Palaeoecology 305, 1-4:
28-42.- <b>FC&#038;P</b> 37, 171, ID=7518^<b>Topic(s): </b>diversity
hotspot, stratigraphy; <b>Systematics: </b>; <b>Stratigraphy:
</b>Oligocene; <b>Geography: </b>Borneo, Sabah E^On the basis of a
combined larger benthic foraminifera, nannofossil and strontium isotope
dating programme we confidently re-assign muddy carbonate deposits from
the Lower Kinabatangan River Area of Borneo to the Oligocene rather
than the Early Miocene. High-diversity, coral-rich (>50 species)
deposits are here tightly constrained to predominately at, or just
after, the Early to Late Oligocene boundary (Larger benthic
foraminifera zone - Te1, Nannofossil zone - NP24, Sr isotope ages -
28.8-27.6 Ma). This new dating potentially pushes back the start of the
Indo-West Pacific Centre of Marine Diversity, at least for corals,
about 5 million years earlier than previous data indicated. Our new
data supports maintaining separation of the muddy carbonates
(previously defined as the Lower Kinabatangan Limestones: Haile &#038;
Wong, 1965) from nearby crystalline limestones of the Gomantong
Limestone Formation dated here as Early Miocene (Larger benthic
foraminifera zone - Te5/earliest Tf1, Sr isotope age - 21.0 Ma). This
apparently punctuated development of shallow marine carbonates is seen
at several locations in northern Borneo; an area underlain by oceanic
crust and long dominated by very deep marine sedimentation (Hutchison,
2005). The opportunistic formation of clastic-influenced coastal and
isolated biohermal carbonates is both an important palaeontological
data point and a geological marker of changing basin settings. The new
data on the first shallow marine deposits in a long established deep
marine location, and evidence for unconformities, has important
implications for the regional tectonic model, in an area of hydrocarbon
exploration.^1";

(2012).- Brachiopods and Their Auloporid Epibionts in the Devonian of
Boulonnais (France): Comparison with Other Associations Globally.- In:
Earth and Life - International Year of Planet Earth 2012: 159-188.-
<b>FC&#038;P</b> 37, 172, ID=7519^<b>Topic(s): </b>brachiopods,
auloporids, epibionts; <b>Systematics: </b>Brachiopoda, Cnidaria,
Auloporida; <b>Stratigraphy: </b>Devonian U, Frasnian; <b>Geography:
</b>France, Boulonnais^From research undertaken on brachiopods
encrusted by auloporids at two intervals in the Frasnian (Beaulieu and
Ferques Formations) of Boulonnais (France), we conclude that the most
important factors influencing encrustation were usually (in decreasing
order): size of the host, morphology, feeding currents, shell
orientation in vivo and shell ornament. Shell structure (punctate or
impunctate) seems not to have influenced the rate of encrustation. In
the cases discussed, most but not all auloporids encrusted their hosts
in vivo. The most favourable environments for development of both
brachiopods and epibionts seem to have been hard bottoms and thin
limestone beds alternating with argillaceous beds. The influence of
environmental (sedimentologic) conditions is difficult to precisely
specify in terms of the development of encrustation, but seems to have
```

```
played an important role.^1";

(2011).- Gzhelian-Asselian Palaeoaplysina-microencruster reef community
in the Taishaku and Akiyoshi limestones, SW Japan: Implications for
Late Paleozoic reef evolution on mid-Panthalassan atolls.-
Palaeogeography, Palaeoclimatology, Palaeoecology 310, 3-4: 378-392.-
<b>FC&#038;P</b> 37, 172, ID=7520^<b>Topic(s): </b>reef communities;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous - Permian,
Gzhelian - Asselian, Akiyoshi Limestone; <b>Geography: </b>Japan SW^A
Palaeoaplysina-microencruster reef community is recognized in the
Gzhelian-Asselian interval of the Taishaku and Akiyoshi limestones in
SW Japan, which represent accreted Panthalassan atoll carbonates. In a
reef-core area of the atoll, the alga Palaeoaplysina acted as a
framebuilder and was associated with various binders (e.g., Tubiphytes,
Archaeolithoporella, cystoporate bryozoans, and microbialites) and
sediment-bafflers such as fenestrate and cryptostomate bryozoans and
phylloid algae. In a subtidal environment of the back-reef area,
Palaeoaplysina and phylloid algae flourished as sediment-bafflers. A
microbial community, includingTubiphytes and sessile foraminifers, was
predominant in a very shallow, peritidal environment of the back-reef
area. * Palaeoaplysina was distributed mainly along the northern margin
of Pangea and is regarded as a boreal element. During Gzhelian-Asselian
time, its distribution extended to the tropical or subtropical
Panthalassa Ocean due to global cooling. On the Akiyoshi atolls, the
Palaeoaplysina-microencruster community was succeeded by a
sponge-microencruster community in the late Early Permian. The timing
of this biotic turnover is similar to that of a change in climate from
icehouse to greenhouse conditions, and coincides with superplume
activity beneath the mid-Panthalassa Ocean.^1";

J.-A. &#038; DRUFFEL E. (2013).- Regional calibration of coral-based
climate reconstructions from Palau, West Pacific Warm Pool (WPWP).-
Palaeogeography, Palaeoclimatology, Palaeoecology 386: 308-320.-
<b>FC&#038;P</b> 37, 173, ID=7521^<b>Topic(s): </b>coral skeletons,
stable elements, trace elements, climate reconstruction;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Pacific, West Pacific warm pool, Palau^Stable isotopic and trace
element records from corals collected within the West Pacific Warm Pool
(WPWP) are well suited to examine interannual to decadal climate
variability associated with the El Nino-Southern Oscillation (ENSO)
phenomenon. The most commonly used climate recorder in corals is
&#948;18O (&#948;18OCRL), a parameter subject to multiple regional and
local environmental influences. Location-specific calibration of
&#948;18OCRL is a necessary first step for developing long-term
paleoceanographic reconstructions. Here we present four new coral
&#948;18O stratigraphies from the Republic of Palau (7.5&#176;N
134.5&#176;E), and compare our records with instrumental measurements
for the period 1950-2008. We also compare our results with a previously
published coral record from Palau. We employ a new sea surface salinity
(SSS) product and validate its utility for coral-based paleoclimate
calibrations. We not only examine differences among the records but
also identify strong and regionally coherent environmental signals. We
find that SSS variability is the dominant influence on &#948;18OCRL in
Palau, while sea surface temperature (SST) is of secondary importance.
Our results show that time-averaging multiple &#948;18OCRL records into
a single composite series produce greater correlations with
instrumental data and indices than individual stratigraphies alone. Our
results are consistent with observations of a strengthening of the
hydrological cycle in the WPWP region over the past 50 years, though
the magnitudes of long term linear trends differ among the different
Palau &#948;18OCRL records. Interannual and interdecadal variabilities
between the Palau &#948;18OCRL records are more consistent than the
long term linear trends. Monthly Palauan &#948;18OCRL anomalies capture
```

```
strong El Nino events with high fidelity over the calibration period.
This study provides constraints for future paleoenvironmental
investigations in Palau using longer coral records.^1";
s[6950] = "PAS D., DA SILVA A.-C., CORNET P., BULTYNCK P.,
K&#214;NIGSHOF P. &#038; BOULVAIN F. (2012).- Sedimentary development
of a continuous Middle Devonian to Mississippian section from the
fore-reef fringe of the Brilon Reef Complex (Rheinisches
Schiefergebirge, Germany).- Facies 59, 4: 969-990.- <b>FC&#038;P</b>
37, 174, ID=7522^<b>Topic(s): </b>fore-reef sediments, Brilon reef
complex; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M,
Givetian - Carboniferous, Visean; <b>Geography: </b>Rhenish Slate Mts,
Brilon Reef Complex^The Brilon-reef complex is one of the biggest
Devonian carbonate buildups (~80 km2) of the Rheinisches
Schiefergebirge. The Burgberg section is located in the southeastern
fore-reef area of the Brilon Reef Complex and exposes a succession of
strata (117 m thick), which extends from the Middle Givetian (middle
varcus conodont Zone) to the Visean (bilineatus conodont Zone). Field
and microfacies observations led to the definition of nine microfacies
that are integrated into a sedimentary model divided into off-reef,
intermediate fore-reef, and proximal fore-reef sedimentary domains
(SD). The off-reef domain (SD1) is the most distal setting observed and
is characterized by fine-grained sediments, dominated by pelagic biota
and the local occurrence of gravity-flow deposits. The intermediate
fore-reef (SD2) is characterized by a mixture of biota and sediments
coming from both deeper-water and shallow-water sources and is
influenced by storm and gravity-flow currents. In this domain, Renalcis
moundlike structures developed locally. Finally, the proximal fore-reef
(SD3) corresponds to the most proximal setting that is strongly
influenced by gravity-flow currents derived from the Brilon Reef
Complex. The temporal evolution of microfacies in the fore-reef setting
of the Burgberg section show five main paleoenvironmental trends
influenced by the onset, general development, and demise/drowning of
the Brilon Reef Complex. Fore-reef to off-reef lithologies and their
temporal changes are from the base to the top of the section: (U1) -
finegrained sediments with large reef debris, corresponding to the
initial development of the reef building upon submarine volcaniclastic
deposits during the Middle Givetian (middle varcus Zone) and first
export of reef debris in the fore-reef setting, (U2) - high increase of
reef-derived material in the fore-reef area, corresponding to a
significant progradation of the reef from the Middle Givetian to the
Early Frasnian (maximum extension of the Brilon Reef Complex to the
south, disparilis to the falsiovalis conodont biozones), (U3) -
progressive decrease of shallow-water derived material and increase of
fine-grained sediments and deep-water biota into the fore-reef setting,
corresponding to the stepwise withdrawal of the reef influence, from
the Middle to the Late Frasnian (jamieae conodont Zone), (U4) -
development of a submarine rise characterized by nodular and
cephalopod-bearing limestones extending from the Late Frasnian to the
Late Famennian corresponding to the demise and drowning of the Brilon
Reef Complex as a result of the Late Frasnian Kellwasser events (upper
rhenana and triangularis conodont biozones), (U5) - significant
deepening of the Burgberg area starting in the Late Famennian, directly
followed by an aggrading trend marked by pelagic shales overlying the
nodular limestone deposits.^1";

establish the bio- and chronostratigraphic position of several levels
```

```
of the Silurian-Devonian succession of Bolivia, with respect to the
International Time Scale, additional Silurian and Devonian localities
belonging to the Eastern Cordillera and the Interandean Zone areas have
been recently revised and sampled, both for macrofossils and
palynomorphs. Specifically, the localities are Nunumayani, and Muruhuta
from the late Silurian-early Devonian time interval. Correlations with
other fossiliferous localities are discussed, namely Huacallani and
Rumicorral. A new outcrop yielding Middle Devonian tabulate corals at
Pisacavina is described, its faunal content is described, and compared
with the historical coral collection. As a result, it appears clearly
that the Silurian-Devonian Bolivian fauna needs a thorough revision, as
well as the selection of stratigraphically significant macrofossils.
Besides macrofossils, the analysis of palynomorph assemblages is
significant in establishment of both intra-Bolivian and international
correlations before any reliable biogeographic reconstruction is done.
This paper records the first discovery of a plant of the genus
Protolepidodendron from the Devonian of Bolivia. An ostracod assemblage
from Pisacavina is described, illustrated, and discussed for the first
time, it suggests an Early Devonian or an Eifelian age. Newly described
taxa include the coral Parastriatopora boliviana sp. nov., and the
chonetoidean brachiopods Sanjuanetes glemareci sp. nov., and
Kentronetes giae sp. nov.^1";
s[6952] = "SANFILIPPO R., ROSSO A., BASSO D., VIOLANTI D., DI GERONIMO
I., DI GERONIMO R., BENZONI F. &#038; ROBBA E. (2011).- Cobbles
colonization pattern from a tsunami-affected coastal area (SW Thailand,
Andaman Sea).- Facies 57, 1: 1-13.- <b>FC&#038;P</b> 37, 176,
ID=7524^<b>Topic(s): </b>cobble communities, settlement patterns;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent, post 2004 tsunami;
<b>Geography: </b>Indian Ocean, Andaman Islands^We studied the
sclerobiont community associated with organogenic and lithic cobbles
from soft bottoms in the Khao Lak coastal area (Andaman Sea) that was
damaged by the 2004 tsunami. The 15 cobbles examined originate from
grab and hand sampling carried out in the years 2006 and 2007 in the
depth range of 4.6-15.2 m. A rich endo- and epibenthos was identified,
mainly consisting of algae, foraminifers, sponges, cnidarians,
polychaetes, bryozoans and bivalves. Associations on each examined
cobble show similarities in composition and structure being
characterized by a few dominant groups. Differences were noted in the
degree and pattern of colonization, distinguishing for each cobble an
upward and a downward side at the time of sampling. The mean total
coverage is 15.09% being higher on the upper sides (17.4%) compared to
the lower sides (12.8%). Calcareous algae, bivalves and sponges prevail
on upper sides, while bryozoans prevail on lower sides. The
sclerobionts distribution allowed to infer the orientation of cobbles
on the seafloor during colonization. Major colonization values,
exceeding 30% coverage, were observed on organogenic cobbles located in
the proximity of reefs or collected from below 12 m of water depth.
Conversely, cobbles from the shallowest stations result poorly
colonized, independently of their composition. The water turbidity and
wave motion as a possible cause of the observed distributions were
discussed. The Khao Lak cobble community seems to be largely unaffected
by the tsunami event, as suggested by the estimated biodiversity,
abundance and coverage of sclerobionts.^1";
s[6953] = "SANTOS A., MAYORAL E., BAARLI B.G., DA SILVA C., CACHAO M.
&#038; JOHNSON M.E. (2012).- Symbiotic association of a pyrgomatid
barnacle with a coral from a volcanic middle Miocene shoreline (Porto
Santo, Madeira Archipelago, Portugal).- Palaeontology 55, 1: 173-182.-
<b>FC&#038;P</b> 37, 177, ID=7525^<b>Topic(s): </b>bioclaustration,

<b>Geography: </b>Atlantic, Madeira Archipelago^The bioclaustration of
the pyrgomatid barnacle Ceratoconcha aff. costata within the carbonate
skeleton of a colonial hermatypical coral (Tarbellastrea reussiana) is
described from a middle Miocene basaltic rocky palaeoshore on a small
```

```
north-eastern Atlantic islet of Porto Santo (Madeira Archipelago,
Portugal). The resulting structure is named as a new trace fossil
Imbutichnus igen. nov., characterized by a small, funnel-like cavity, a
circular to oval cross-section, with a nearly cylindrical shape in the
upper part and a conical shape towards the base. Imbutichnus costatum
isp. nov. is defined as a bioclaustration structure produced by the
overgrowth of a pyrgomatid barnacle by a coral. From an ethologic point
of view, Imbutichnus is attributed to the Impedichnia category. In
terms of palaeoecology, it is interpreted as the result of a parasitic
relationship. This is also the oldest record of pyrgomatid barnacles in
the eastern Atlantic and clearly demonstrates that the Miocene
palaeogeographic range of Ceratoconcha was much wider than previously
assumed.^1";
s[6954] = "SCHNEIDER S., BERNING B., BITNER M.A., CARRIOL R.-P.,

parautochthonous shallow marine fauna from the Late Burdigalian (early
Ottnangian) of Gurlarn (Lower Bavaria, SE Germany): Macrofaunal
inventory and paleoecology.- Neues Jahrbuch f&#252;r Geologie und
Pal&#228;ontologie, Abhandlungen 254, 1/2: 63-103.- <b>FC&#038;P</b>
37, 177, ID=7526^<b>Topic(s): </b>macrofossils, parautochthonous,
taxonomy, ecology; <b>Systematics: </b>; <b>Stratigraphy: </b>Miocene,
Burdigalian, U; <b>Geography: </b>Germany, Lower Bavaria^This paper
describes and illustrates a diverse parautochthonous macrofauna from a
single Upper Burdigalian (lower Ottnangian) horizon at Gurlarn in Lower
Bavaria (SE Germany). In total, 80 different taxa are recorded in
specific or open nomenclature; some 50% of these taxa are bryozoans,
followed by bivalves (16 taxa), cirripedes (7 taxa), echinoderms,
corals (5 taxa each), brachiopods, fish (4 taxa each), serpulids, and
gastropods (3 taxa each). The presence of additional organisms was
documented by actualistic comparison based on indirect evidence such as
drillholes, bite marks, and specialized growth forms of bryozoan
colonies. Analysis of aut- and synecological indicators suggests that
the fauna thrived in a near-shore shallow marine setting at a water
depth of 5-20 m. Based on particular faunal elements and overall faunal
composition we hypothesize that the environment is characterized by
three distinct but interfingering habitats, i.e. (1) rocky slopes and
boulders, (2) seagrass meadows, and (3) bryozoan meadows. Because
similar, albeit less well-preserved, faunas occur at several localities
along the northern coast of the early Ottnangian Molasse Sea, the
parautochthonous assemblage from Gurlarn provides an excellent example
for the structure of these typical biota.^1";
s[6955] = "SENOWBARI-DARYAN B., STANLEY G.D. jr &#038; ONOUE T.
(2012).- Upper Triassic (Carnian) reef biota from the Sambosan
Accretionary Complex, Kyushu, Japan.- Facies 58, 4: 671-684.-
<b>FC&#038;P</b> 37, 178, ID=7527^<b>Topic(s): </b>reef biota,
calcified sponges, algae, problematica; <b>Systematics: </b>;
<b>Stratigraphy: </b>Triassic U, Carnian, Sambosan Accretionary
Complex; <b>Geography: </b>Japan, Kyushu^Calcified sponges, algae, and
reef problematica are abundant yet poorly known from the Triassic of
Japan. They are abundant in shallow-water carbonate, redeposited blocks
ofthe Sambosan Accretionary Complex, Konose Group, and southern Kyushu.
Based on study of thin-sections from reef limestone exposed along the
Kuma River, some important organisms and reef microfacies are
described, which seem typical of Upper Triassic reef complexes. The
most abundant reef organisms are hypercalcified sponges, including
sphinctozoans, inozoans and chaetetids, followed by cyanophycean algae
(including &#034;Tubiphytes&#034;-like organisms), and solenoporacean
red algae. Loose sponge spicules in one thin-section also indicate the
occurrence of rare hexactinellid sponges. Chambered demosponges
described from the Konose carbonate rocks include Solenolmia manon
manon (M&#252;nster), Colospongia sp., Jablonskyia andrusovi
(Jablonsky), several unidentified chambered sponges as well as the
inozoid Permocorynella sp. 1 and Permocorynella sp. 2. Also present are
```

```
chaetetid sponges and solenoporacean red algae belonging to
Parachaetetes cassianus (Fl&#252;gel) and Parachaetetes? sp. or
Solenopora? sp. Especially abundant in thin-sections are cyanophyceans
and &#034;Tubiphytes&#034;-like organisms. Among the organisms is
Cladogirvanella Ott and Hedstroemia sp. The composition ofthe biota and
presence of typical problematic organisms increases our knowledge of
shallow-water Upper Triassic carbonate rocks in a remote setting in
western Panthalassa. The composition of the biota indicates a mostly
Carnian age. Most comparable organisms are known from both the
northeastern and southern Tethys.^1";

<b>Geography: </b>Morocco S, Tindouf Basin^The northern flank of the
Tindouf Syncline in southern Morocco exhibits a continuous, well
exposed Carboniferous succession with limestones of late Asbian to
early Bashkirian age containing rich and diverse foraminiferal and
rugose coral assemblages. Analysis of these assemblages provides new
data on the relatively poorly known Saharan basins. * The
palaeobiogeographical relationship of the Tindouf Basin with other
Palaeotethyan basins is complex. Although there is a predominance of
cosmopolitan taxa for the Palaeotethys, it is recognized that there was
an influence of basins from NW Europe, such as the UK and Ireland. Some
taxa are recorded in both NW Europe and Tindouf without any
characteristic contributions from intermediate basins in northern
Morocco. The neighbouring Bechar Basin in Algeria presents distinct
assemblages. The bulk of the data analyzed suggest that this sector of
the western Palaeotethys can be subdivided into four
palaeobiogeographical subprovinces: the Atlantic subprovince (UK,
Ireland, N. France and Belgium), the Mediterranean subprovince
(Pyrenees, Montagne Noire, Betic Cordillera, Rif - N. Morocco, and
Balearic Islands), and the Saharan subprovince (Bechar, Reganne,
Ahnet-Mouydir and Tindouf). In between, mobile belts of mixed faunal
assemblage characteristics are observed (e.g., SW Spain and Central
Meseta) forming the West peri-Gondwanan subprovince. ** Analysis of the
Tindouf Basin faunas shows that, as in other Saharan basins, there is a
high diversity and abundance of foraminiferal taxa, with a higher
proportion of survivors and longer stratigraphic ranges, features also
mirrored by rugose corals. This emphasizes the longevity of the
carbonate platform in a tropical setting, where periodic transgressions
introduced new assemblages, and oceanic currents are interpreted as one
of the main controlling factors for the distribution of the taxa in
these subprovinces. Moreover, not only were water temperatures on the
platform higher, but also tectonic stability greater. It is considered
that the effects of the first phases of the Gondwanan glaciation were
minimal on the Tindouf faunas.^1";

to excel as mentors to us. All showed remarkable determination and love
for paleontological research, and inspired their students and
colleagues to understand details of structure and systematic positions
of fossil corals and sponges. Each of these individual mentors was the
subject of a presentation by a former student at the 11th International
Symposium on Fossil Corals and Sponges in Liege, Belgium, thus,
somewhat broader coverage of each is provided in the abstracts volume
of the meeting.^1";
s[6958] = "SPENGLER A.E. &#038; READ J.F. (2010).- Sequence development
on a sediment-starved, low accommodation epeiric carbonate ramp:
Silurian Wabash Platform, USA mid-continent during icehouse to
greenhouse transition.- Sedimentary Geology 224: 84-115.-
<b>FC&#038;P</b> 37, 181, ID=7530^<b>Topic(s): </b>carbonata platform,
sequence development, icehouse-greenhouse transition; <b>Systematics:
</b>; <b>Stratigraphy: </b>Ordovician / Silurian; <b>Geography:
</b>USA, Wabash Platform^Twelve cored wells through the Silurian
section of the Wabash Platform, Indiana, U.S.A., and 2 non-cored
basinal wells with cuttings, were studied to define the sequence
stratigraphy of a sediment-starved ramp within a low-latitude epeiric
sea during the latest Ordovician icehouse to Silurian greenhouse
transition. The Wabash Platform (approximately 200,000 km2 area) was
bounded to the north by the Michigan Basin, to the east by the
Appalachian foreland basin, and passed to the southwest into the
Vincennes Basin, which was open to the ocean. Facies developed include:
platform-fringing buildups (stromatactis wackestone core,
stromatoporoid skeletal wackestone caps and crinoidal
rudstone/packstone flank facies), and non-buildup crinoid
grainstone-packstone sheets (shoals), skeletal wackestone (variably
cherty, between fair weather and storm wave base, deep lagoon and deep
ramp) and carbonate mudstone (clean to argillaceous, sub-storm wave
base, deep lagoon and deep ramp/basin). The eleven sequences, 2 m to 30
m thick and 1 to 4 m.y. durations (average ~ 2.5 m.y.), generally can
be correlated to global sea-level cycles. The lower three sequences are
disconformity-bounded (reflecting moderate ice sheets) but the others
are relatively conformable. The most easily mapped regional surfaces
are the transgressive surfaces, because the correlative conformities
are cryptic. The wide well spacing prevented mapping of lowstand system
tracts. The transgressive systems tracts are upward-deepening,
upward-fining carbonate units, that become more argillaceous and silty
upward. The highstand systems tracts are upward-coarsening carbonate
mudstone to wackestone-packstone and rare grainstone. Barrier bank
complexes and isolated buildups aggraded during deposition of the upper
4 sequences to form a discontinuous raised rim (~ 40 m relief) to the
ramp while the interior of the platform remained sediment starved.
Subsidence rates in the basin were very low (0.6 to 1.2 cm/k.y.), but
the low platform accumulation rates (0.2 cm/k.y. to 0.8 cm/k.y.)
prevented the seafloor from building to sea level in all but the lower
three sequences and later over barrier banks (accumulation rates 2
cm/k.y.). Parasequence development in high-accommodation settings
elsewhere in the Silurian in North America records transition from
moderate ice-sheets to an ice-free world. This is weakly expressed on
the Wabash Platform due to the dominantly deeper subtidal setting. The
remarkably low sedimentation rates resulted from the epeiric sea being
isolated from the open ocean, and they likely are typical of the large
epeiric seas of the Paleozoic.^1";

<b>FC&#038;P</b> 37, 184, ID=7532^<b>Topic(s): </b>calcareous algae,
case of homonymy; <b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician
M U; <b>Geography: </b>^Tetradium Dana, 1846 (type species: Tetradium
fibratum Safford, 1856), a common Middle and Upper Ordovician fossil,
is a calcareous filamentous florideophyte alga (Phylum Rhodophyta)
(Steele-Petrovich, 2009a, 2009b), and not a tabulate coral or a
chaetetid sponge, as traditionally classified. This makes it a later
homonym of Tetradium Loureiro, 1790 (see Farr et al., 1979), a Recent
tree. It will be substituted by Prismostylus Okulitch 1935. A new
specific classification of the genus Prismostylus Okulitch (and
possibly other closely related genera) would have to be based probably
on tube morphology. Family and Order names that are based on the
illegitimate genus Tetradium (i.e., Tetradiidae Nicholson, 1879 and
Tetradiida Okulitch, 1936, respectively), which would normally become
Tetradiaceae and Tetradiales in botanical tradition, must be replaced
also (ICBN, Rec. 16B, Art. 18.3). Therefore, the replacement names
selected here are Family Prismostylaceae and Order Prismostylales. The
type species is Prismostylus columnaris (Hall), 1847, as designated by
Okulitch (1935) when the genus was defined.^1";

Permian fossil groups in western USA and northern Mexico and their
relevance to interpretation of paleotectonic features along the
southwestern margin of Laurentia.- Palaeogeography, Palaeoclimatology,
Palaeoecology 288, 1-4: 103-107.- <b>FC&#038;P</b> 37, 184,
ID=7533^<b>Topic(s): </b>fossil groups, biogeography; <b>Systematics:
</b>corals, fusulinids; <b>Stratigraphy: </b>Permian L; <b>Geography:
</b>USA SW, Mexico N^Three species groups, including two groups of
corals and one of fusulinids, delineate the zone of favorable marine
environments for these animals along the shelves bordering southwestern
Laurentia during the Cisuralian (Early Permian). The three species
groups are: the coral Protowentzelella group of late Asselian to early
Sakmarian age, the fusulinid Eoparafusulina linearis group of late
Sakmarian age, and the coral Pararachnastraea illipahensis group of
late Artinskian to Kungurian age. Occurrences of these three species
groups clearly outline most of the major paleotectonic features that
were present along the southwestern margin of the Laurentian shelf at
that time. The paucity of data in Mexico, however, leaves open the
question of large-scale displacement on the Mojave-Sonora megashear, a
feature proposed to cut across northern Mexico and southwestern USA,
although the data presented here could be construed to suggest lack of
significant displacement in post-Pennsylvanian time.^1";

ZEMAN A. &#038; STEJSKAL M. (2012).- Blackened bioclasts and bituminous
impregnations in the Koneprusy Limestone (Lower Devonian), the
Barrandian area, Czech Republic: implications for basin analysis.-
Facies 58: 759-777.- <b>FC&#038;P</b> 37, 185, ID=7534^<b>Topic(s):
</b>blackened bioclasts, bitumen; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian carbonates, Variscan Orogeny;
<b>Geography: </b>Czech Republic, Barrandian^Carbonate reef talus
facies of the Koneprusy Limestone (Pragian, Lower Devonian, Barrandian)
locally exhibit widespread impregnation by organic matter resulting in
a partial to complete blackening of the limestones. Two contrasting
types of impregnation are recognized: blackening of individual
carbonate fossils and bioclastic layers within the limestone originated
very early during diagenesis. The blackening is due to finely dispersed
organic matter and possibly some iron sulphides and clay minerals that
selectively adhered to the outer layers of corals, bryozoans, and
crinoid fragments, leaving other fossils unaltered. These darkened
fossils are similar to black pebbles - i.e., reworked, dark to black
limestone clasts and bioclasts that are known to occur exclusively in
shallow-water zones of both ancient and modern carbonates. The
alteration of fossil fragments may have taken place in very
shallow-water environments, possibly those of saline and reducing
```

```
back-reef lagoons or supratidal/intertidal zones, with organic matter
being derived from decayed algae and microbes, or early vascular
terrestrial plant material. Following the coloration, the blackened
fossils were removed from their original position by waves or storms
and transported into relatively deeper-water reef slope settings to
form graded, &#8220;salt-and-pepper&#8221;-colored bioclastic beds. The
presence of blackened fossils in the carbonate succession may point to
episodic emergence and indicates a vanished vegetated siliciclastic
hinterland that may once have existed to the west or south from the
present-day erosive edge of the Barrandian Devonian strata. Subvertical
veins cutting the Koneprusy Limestone and filled with black solid
bitumen and blackened calcite resulted from a subsequent but
substantially later diagenetic event, which is a testament of aqueous
and petroleum fluid migration through the succession during deeper
burial. Microthermometric characteristics of the aqueous inclusions
embedded in vein calcite indicate that the veins were precipitated by
brines of low to moderate salinity (0.5-9.5 wt% NaCl equiv.) with
temperatures in the range of 87-116 &#176;C. The bitumen in the veins
is epi-impsonite (Rr = 0.70-1.90%), which is interpreted as degraded
petroleum residuum that experienced thermal alteration at around 120
&#176;C. The AFT modeling combined with fluid inclusion
microthermometry and wider geological considerations indicate that the
veins originated during the Variscan orogeny, most probably upon deep
burial of the Lower Paleozoic strata in Carboniferous time.^1";
s[6963] = "SURLYK F. &#038; S&#216;RENSEN A.M. (2010).- An early
Campanian rocky shore at Iv&#246; Klack, southern Sweden.- Cretaceous
Research 31, 6: 567-576.- <b>FC&#038;P</b> 37, 186,
ID=7535^<b>Topic(s): </b>rocky shore, morphology, fossils ;
<b>Systematics: </b>; <b>Stratigraphy: </b>Cretaceous U, Campanian;
<b>Geography: </b>Sweden S, Kristianstad Basin^Well-exposed, ancient
rocky shores are rare and the associated shelly faunas are normally
strongly worn and fragmented due to erosion during both sea-level rise
and fall. An early Campanian rocky shore with a rich fauna is preserved
at Iv&#246; Klack in the Kristianstad Basin, southern Sweden. Iv&#246;
Klack is situated on the small, hilly island of Iv&#246; situated in
lake Iv&#246;sj&#246;n with a lake level about 6 m above present-day
sea level. The rocky shore was formed during a major late early
Campanian transgression caused by a sea-level rise up to about 100m
above present sea level. An archipelago was formed along the northern
basin margin during the transgression with numerous small islands and
peninsulas. The steep palaeo-coast at Iv&#246; Klack consists of gneiss
overlain in the lower part by more than 30m of kaolin in places
containing large boulders of gneiss with a kaolinized outer crust. The
kaolin wedges out upslope and is absent above 30-35 m above lake level.
The kaolin is overlain by up to 5m of muddy quartz sand with highly
angular grains, representing a residue of the kaolin formed during
transgressive wave and current reworking. The steep gneiss coast was
rapidly transgressed by the sea in the latest early Campanian and at
least 25m of onlapping coarse-grained skeletal sand, gravel and whole
fossils were deposited on the clean gneiss surface during the
Belemnellocamax mammilatus belemnite biozone. Large boulders of gneiss
are common in the carbonates and formed distinct boulder beds at some
levels but these are now quarried away. The top 6m of the preserved
carbonate succession are free of boulders. The rocky surface is fairly
even on a large scale, but highly irregular in detail with numerous
metre-sized hummocks and boulders formed during terrestrial weathering
and kaolinization. The lowest part of the shore is developed as a
bench, topped by a sub-horizontal irregular platform, 20-30 m wide,
with large hummocks and rounded boulders. The platform passes upwards
into a steep boulder-strewn slope. A well-developed glauconitized
hardground with Thalassinoides burrows and several incipient
hardgrounds occur in the carbonates draping the bench and lower part of
the platform. They dip gently outwards and probably represent a kind of
```

```
beach rock. A highly diverse benthic fauna with more than 200
shell-bearing species lived between, below and on the hummocks and
boulders. It comprises bivalves, brachiopods, polychaetes, gastropods,
echinoids, asteroids, bryozoans and is dominated by large oysters and
includes the northernmost Late Cretaceous rudists and hermatypic
corals. The remaining benthic invertebrate groups are represented by
only a few species each. The non-benthic invertebrate fauna comprises
four belemnite species and one rare ammonite species. The lower
Campanian carbonates of the small basin have yielded an unusually
diverse vertebrate fauna totalling more than 60 species, including
mosasaurs, plesiosaurs, crocodiles, turtles, birds, and as many as 44
species of sharks and rays. Iv&#246; Klack thus provides information on
virtually all trophic levels in the rocky shore ecosystem and
represents the most diverse rocky shore fauna known from the geological
record. This paper aims at providing the framework for a series of
papers on the palaeoecology of the main benthic faunal groups.^1";

Heliolitida; <b>Stratigraphy: </b>Ordovician L, Katian; <b>Geography:
```

```
</b>Estonia NW^A diverse early endobiotic coral symbiont assemblage has been detected within heliolitid tabulate corals of Katian age from northwestern Estonia. This assemblage indicates that the earliest endobiotic coral symbiont communities were not restricted to North America. The symbiotic endobiont assemblage comprises abundant Cornulites aff. celatus and rare Conchicolites hosholmensis and Chaetosalpinx sp. The cornulitids are the earliest known symbiotic endobionts of this group. The symbiotic endobionts presumably occurred in certain hosts only and preferred Protoheliolites dubius over Propora speciosa. This record indicates that early endobiotic cornulitids were more diverse than previously thought and appeared in large numbers in the Katian. It is possible that the appearance of abundant skeletal symbiotic coral endobionts may coincide with the Global Ordovician Biodiversification Event, supporting the hypothesis of escape from increased predation.^1";
s[6968] = "VINN O. &#038; WILSON M.A. (2010).- Endosymbiotic Cornulites in the Sheinwoodian (Early Silurian) stromatoporoids of Saaremaa, Estonia.- Neues Jahrbuch f&#252;r Geologie und Pal&#228;ontologie Abhandlungen 257, 1: 13-22.- <b>FC&#038;P</b> 37, 190, ID=7540^<b>Topic(s): </b>endosymbiosis, stromatoporoids, cornulitids; <b>Systematics: </b>Porifera, Stromatoporoidea, Cornulitida; <b>Stratigraphy: </b>Silurian, Sheinwoodian; <b>Geography: </b>Estonia, Saaremaa^The new endosymbiotic cornulitid Cornulites stromatoporoides n. sp. is described here from the Sheinwoodian stromatoporoids of Saaremaa, Estonia. This new species represents the earliest record of cornulitid endosymbiosis, probably reflecting increased pressure by boring and durophagous predators on worms with mineral tubes in the Silurian. In lower Sheinwoodian open shelf marls, 30% of stromatoporoids are infested by C. stromatoporoides n. sp., 77 % of stromatoporoids in upper Sheinwoodian shoal limestones also had this endosymbiotic relationship. C. stromatoporoides n. sp. has thus far only been found as an endosymbiont in stromatoporoids. There is a range of one to six, averaging 2.4, endosymbiotic C. stromatoporoides n. sp. specimens (syn vivo) per infested stromatoporoid in the lower Sheinwoodian. Large stromatoporoids contain more Cornulites endosymbionts than smaller stromatoporoids.^1";
s[6969] = "VODRAZKA R., SKLENAR J., CECH S., LAURIN J. &#038; HRADECKA L. (2009).- Phosphatic intraclasts in shallow-water hemipelagic strata: a source of palaeoecological, taphonomic and biostratigraphic data (Upper Turonian, Bohemian Cretaceous Basin).- Cretaceous Research 30: 204-222.- <b>FC&#038;P</b> 37, 191, ID=7541^<b>Topic(s): </b>phosphatic lag, fossils, burial, diagenesis, exhumation; <b>Systematics: </b>; <b>Stratigraphy: </b>Cretaceous U, Turonian; <b>Geography: </b>Czech Republic, Bohemian Cretaceous Basin, Byckovice^A prominent phosphatic lag exposed in the Upper Turonian hemipelagic strata near Byckovice, Bohemian Cretaceous Basin, yields an enormous accumulation of diversified, phosphatized and unphosphatized fauna. Taphonomic, palaeoecological and sedimentological data suggest that the phosphatic lag records a complex history of burial, mineralization and exhumation of sediment and fossils. Three main stages can be distinguished in the formation of the lag: (1) deposition of a hemipelagic marlstone or limestone inhabited by a diversified, softground fauna, then (2) intense phosphatization, winnowing of unconsolidated sediment and exhumation of the phosphates due to a combined effect of elevated bottom shear stress and bioturbation, and (3) resumption of hemipelagic deposition and establishment of a new assemblage dominated by sponges attaching to the exhumed phosphatic intraclasts. The occurrence of sponges inhabiting phosphatic intraclasts is unique in both fossil and recent ecosystems. One of these sponges, a poorly known hexactinellid Laocoetis cretacea (Rauff) is therefore described in detail. Biostratigraphic data suggest that the lag represents the uppermost Subprionocyclus neptuni Zone and lowermost Mytiloides scupini Zone. Well-log correlation with coeval, orbitally tuned strata further

<b>FC&#038;P</b> 37, 192, ID=7542^<b>Topic(s): </b>bioerosion,
coral-sponge reef; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic
M, Callovian, Matmor Fm; <b>Geography: </b>Israel S^The Matmor
Formation (Middle Jurassic, Callovian, 165-161 mya) in southern Israel
contains abundant coral-sponge patch reefs and large crinoids which
have been extensively bioeroded by bivalves, worms, barnacles,
phoronids, and others producing eight ichnospecies. It is significant
for the evolutionary history of bioerosion because this is the first
equatorial Middle Jurassic boring ichnofauna to be documented. When
compared to contemporaneous ichnofaunas, this assemblage is of average
diversity and abundance but has only rare sponge borings and contains
abundant specimens of Oichnus paraboloides as shallow pits on crinoid
stems. The Matmor Formation surprisingly lacks carbonate hardgrounds,
which are otherwise abundant in subtropical and temperate
equivalents.^1";
s[6971] = "YU Kefu, ZHAO Jianxin, ROFF G., LYBOLT M., FENG Yuexing,
CLARK T. &#038; LI Shu (2012).- High-precision U-series ages of
transported coral blocks on Heron Reef (southern Great Barrier Reef)
and storm activity during the past century.- Palaeogeography,
Palaeoclimatology, Palaeoecology 337-338: 23-36.- <b>FC&#038;P</b> 37,
192, ID=7543^<b>Topic(s): </b>coral blocks, radiometric dating, storm
frequency; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Great Barrier Reef, Heron Island^Transported coral
blocks scattered on reef flats have previously been identified as
useful proxies for past storm occurrences. High-precision TIMS U-series
dating and detailed field observations of 110 coral samples collected
from 102 individual transported coral colonies (coral blocks) and 4
transported sections of reef matrix (reef blocks) from the northern
side of Heron Reef (southern Great Barrier Reef) indicate that: (1) the
youngest age of corals attached to reef blocks may represent the age of
possible past storm occurrence, providing a proxy for historical storm
reconstruction; (2) most ages of dated storm-transported coral and reef
blocks match well relatively with known cyclone and storm events,
further supporting that they are good indicators of past storm events;
and (3) age distribution and relative probability frequency analysis of
the dated coral and reef blocks suggest that there have been eight
broad periods of storm occurrence since 1900 AD (1904-1909, 1914-1916,
1935-1941, 1945-1960, 1965-1967, 1976-1977, 1983-1988 and 2001-2007),
roughly showing decadal variations. The coral-based storm
reconstruction therefore extended the database of past storm
occurrences around Heron Reef area. These findings suggest that coral
reefs in the southern Great Barrier Reef are frequently influenced by
periods of high storm activity, and show strong resilience to natural
disturbances over the past century. Additionally, our results show for
the first time that the blue skeletal coral Heliopora coerulea (order:
Helioporacae) has U concentrations of only 0.12 to 0.30 ppm, ~5-10%
that of common reef building corals with white skeletons (Order:
Scleractinia), which may be a unique chemical signature of the only
living species of the Helioporidae family.^1";

of mid Paleocene-early Eocene coral communities: How to survive during
rapid global warming.- Palaeogeography, Palaeoclimatology,
Palaeoecology 317-318: 48-65.- <b>FC&#038;P</b> 37, 193,
ID=7545^<b>Topic(s): </b>coral communities, diversity trends, global
warming; <b>Systematics: </b>Cnidaria, Scleractinia; <b>Stratigraphy:
</b>Paleocene - Eocene; <b>Geography: </b>^Today, diverse communities
of zooxanthellate corals thrive, but do not build reef, under a wide
range of environmental conditions. In these settings they inhabit
natural bottom communities, sometimes forming patch-reefs, coral
carpets and knobs. Episodes in the fossil record, characterized by
limited coral-reef development but widespread occurrence of
coral-bearing carbonates, may represent the fossil analogs of these
non-reef building, zooxanthellate coral communities. If so, the study
of these corals could have valuable implications for paleoenvironmental
reconstructions. Here we focus on the evolution of early Paleogene
corals as a fossil example of coral communities mainly composed by
zooxanthellate corals (or likely zooxanthellate), commonly occurring
within carbonate biofacies and with relatively high diversity but with
a limited bioconstructional potential as testified by the reduced
record of coral reefs. We correlate changes of bioconstructional
potential and community compositions of these fossil corals with the
main ecological / environmental conditions at that time. The early
Paleogene greenhouse climate was characterized by relatively short
pulses of warming with the most prominent occurring at the Paleocene -
Eocene boundary (PETM event), associated with high weathering rates,
nutrient fluxes, and pCO2 levels. A synthesis of coral occurrences
integrated with our data from the Adriatic Carbonate Platform (SW
Slovenia) and the Minervois region (SW France), provides evidence for
temporal changes in the reef-building capacity of corals associated
with a shift in community composition toward forms adapted to tolerate
deteriorating sea-water conditions. During the middle Paleocene
coral-algal patch reefs and barrier reefs occurred from shallow-water
settings, locally with reef-crest structures. A first shift can be
traced from middle Paleocene to late Paleocene, with small coral-algal
patch reefs and coral-bearing mounds development in shallow to
intermediate water depths. In these mounds corals were highly
subordinated as bioconstructors to other groups tolerant to higher
levels of trophic resources (calcareous red algae, encrusting
foraminifera, microbes, and sponges). A second shift occurred at the
onset of the early Eocene with a further reduction of coral
framework-building capacity. These coral communities mainly formed
knobs in shallow-water, turbid settings associated with abundant
foraminiferal deposits. We suggest that environmental conditions other
than high temperature determined a combination of interrelated
stressors that limited the coral-reef construction. A continuous
enhancement of sediment load / nutrients combined with geochemical
changes of ocean waters likely displaced corals as the main
bioconstructors during the late Paleocene-early Eocene times.
Nonetheless, these conditions did not affect the capacity of some
corals to colonize the substrate, maintain biodiversity, and act as
locally important carbonate-sediment producers, suggesting broad
environmental tolerance limits of various species of corals. The
implications of this study include clues as to how both ancient and

modern zooxanthellate corals could respond to changing climate.^1";
s[6974] = "ZAPALSKI M.K. (2011).- Is absence of proof a proof of
absence? Comments on commensalism.- Palaeogeography, Palaeoclimatology,
Palaeoecology 302: 484-488.- <b>FC&#038;P</b> 37, 195,
ID=7546^<b>Topic(s): </b>biotic interactions, commensalism;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography:
</b>^Commensalism in the narrow sense can be understood as an
interaction strictly neutral for one organism and positive for the
other. Neutral interaction is the absence of interaction and as such it
cannot be proven (the proof of absence cannot be made) and consequently
it can be regarded as a concept unfit for empirical science. In the
broad sense it is often understood as a weak (positive or negative)
interaction on one hand and positive on the other. This approach also
seems imperfect, as weak interactions should be regarded rather as
mutualism or parasitism, respectively. The borders between interactions
(commensalism/parasitism and commensalism / mutualism) are difficult to
define, hence commensalism should rather be considered as a theoretical
interval within the continuum of interactions. Detection of
commensalism in recent associations is rather difficult, while in the
fossil record it seems impossible. Commensalism as a null hypothesis in
paleoecology cannot be retained, as the possibility of making a type II
error is very high. The terms &#034;paroecia&#034; and
&#034;endoecia&#034; seem to be more useful to use in cases when a
particular ecological relationship is difficult to prove.^1";
s[6975] = "ZAPALSKI M.K. (2014).- Evidence of photosymbiosis in
Palaeozoic tabulate corals.- Proceedings Royal Society B 22 281: 1775
20132663. doi: 10.1098/rspb.2013.2633 (online since December 2013)-
<b>FC&#038;P</b> 37, 195, ID=7547^<b>Topic(s): </b>coral skeletons,
photosymbiosis, stable isotopes C &#038; O; <b>Systematics:
</b>Cnidaria, Scleractinia, Tabulata; <b>Stratigraphy: </b>Phanerozoic,
post-Silurian; <b>Geography: </b>^Coral reefs form the most diverse of
all marine ecosystems on the Earth. Corals are among their main
components and owe their bioconstructing abilities to a symbiosis with
algae (Symbiodinium). The coral-algae symbiosis had been traced back to
the Triassic (ca 240 Ma). Modern reef-building corals (Scleractinia)
appeared after the Permian-Triassic crisis; in the Palaeozoic, some of
the main reef constructors were extinct tabulate corals. The calcium
carbonate secreted by extant photosymbiotic corals bears characteristic
isotope (C and O) signatures. The analysis of tabulate corals belonging
to four orders (Favositida, Heliolitida, Syringoporida and Auloporida)
from Silurian to Permian strata of Europe and Africa shows these
characteristic carbon and oxygen stable isotope signatures. The
&#948;18O to &#948;13C ratios in recent photosymbiotic scleractinians
are very similar to those of Palaeozoic tabulates, thus providing
strong evidence of such symbioses as early as the Middle Silurian (ca
430 Ma). Corals in Palaeozoic reefs used the same cellular mechanisms
for carbonate secretion as recent reefs, and thus contributed to reef
formation. [electronic supplementary material at
