Island, Arctic Canada.- Journal of Paleontology 64: 493-510.-
<b>FC&#038;P 19-2.1</b>, p. 42, ID=2779^<b>Topic(s): </b>reef facies,
allochthonous; stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>Canada, Arctic^The
fauna is a mixture of genera that characterize Ludlovian-Gedinnian
rocks (Actinodictyon, Parallelostroma, Syringostromella) and those that
characterize Emsian-Eifelian rocks (Atopostroma, Anostylostroma,
Habrostroma, Syringostroma). The new genus Belemnostroma (type species
B. hastatum) is established for stromatoporoids with the basic
structure of Anostylostroma but penetrated by large rodlike
mega-pillars. New species of Gerronostroma (G. franklinense. G. nivale)
Actinodictyon (A. venustum), and Syringostroma (S. praecox) are
described. Species with long coenosteles are excluded from Stromatopora
on the basis that they are not cogeneric with the type species and many
species assigned to Ferestromatopora should be reassigned to
Stromatopora.^1";
s[2028] = "STEARN C.W., SHAH D.H. (1990).- Devonian (Givetian-Frasnian)
stromatoporoids from the subsurface of Saskatchewan, Canada.- Canadian
```

```
Journal of Earth Sciences 27: 1746-1756.- <b>FC&#038;P 20-1.1</b>, p.
79, ID=2880^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography:
</b>Canada, Saskatchewan^The lower Duperow beds (Frasnian) contain 11
species most of which occur in the upper Cairn and Peechee units of
Alberta. The Souris River Formation contains 2 species and the
underlying Dawson Bay Formation (Givetian) contains 7 species. No new
species are named but the generic assignments of several species are
changed and widening of species concepts places the following species
in synonymy: Anostylostroma intermedium Klovan, Hammatostroma nodosum
Klovan, Hermatostroma maillieuxi (Lecompte) of Fischbuch, Parallelopora
cf. P. dartingtonensis (Carter) of Stearn, Trupetostroma cervimontanum
Stearn, Clathrocoilona abeona Yavorsky of Fischbuch, Stromatopora
mikkwaensis Stearn, Ferestromatopora dubia (Lecompte) of Klovan,
Arctostroma ignotum Yavorsky, These revisions greatly reduce the
apparent endemism of western Canadian stromatoporoid faunas and
indicate the wide distribution of species of the Cairn-Flume interval
from the Northwest Territories to Iowa.^1";
s[2029] = "KLAPPER G., OLIVER W.A.jr (1995).- The Detroit River Group
is Middle Devonian: Discussion on &#034;Early Devonian age of the
Detroit River Group, inferred from Arctic stromatoporoids&#034;.-
Canadadian Journal of Earth Sciences 32: 1070-1073.- <b>FC&#038;P
25-1</b>, p. 30, ID=3004^<b>Topic(s): </b>stratigraphy; stratigraphy;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Devonian M; <b>Geography: </b>USA^In their paper on the age of the
Detroit River Group, the authors, Prosh E. G. and Stearn C. W., suggest
that the occurrence of two to four species of stromatoporoids in the
Detroit River, which are also known to occur in well-dated Lower
Devonian Arctic formations, outweighs the evidence of conodonts and
goniatites that is currently used to date the Detroit River as mostly,
or entirely, Middle Devonian. The conodont and goniatite evidence is
much stronger than indicated by the authors and too strong to be set
aside in response to their new data. Correlation difficulties are
attributable to the known endemism of the eastern North American Early
and Middle Devonian faunas and to environmental differences.^1";
s[2030] = "PROSH E.C., STEARN C.W. (1996).- Stromatoporoids from the
Emsian (Lower Devonian) of Arctic Canada.- Bulletins of American
Paleontology 109, 349: 66 pp.- <b>FC&#038;P 25-1</b>, p. 48,
ID=3058^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian Ems; <b>Geography:
</b>Canada, Arctic^Early Devonian limestones of Ellesmere, Bathurst and
smaller islands between them in the Canadian Arctic Archipelago contain
a diverse fauna of stromatoporoid sponges. This fauna provides the best
evidence in North America of the early recovery phase of this
reef-building group from a diversity low at the Silurian/Devonian
boundary, a recovery that led to its diversity peak in Givetian time.
Stromatoporoids from the lower member of the Blue Fiord Formation
locally form large reefal masses. Well preserved stromatoporoids also
occur less abundantly: 1. in the top of the underlying Bids Formation,
2. in the upper member of the Blue Fiord Formation, 3. in the
Disappointment Bay Formation, which is correlative of the upper Blue
Fiord, and 4. in the overlying Bird Fiord Formation and a correlative
unnamed formation both of which span the Lower/Middle Devonian
boundary. The stratigraphic distribution of these stromatoporoids can
be accurately determined according to conodont biostratigraphy as
spanning the dehiscens to partitus (Emsian to basal Eifelian) conodont
zones. Common occurrences of Stromatoporella perannulata, Stictostroma
gorriense, Habrostroma proxilaminatum, and Parallelopora campbelli in
the arctic fauna and southern Ontario and the adjacent United States,
indicate that the Detroit River Group is of similar Emsian age, and
that the Eastern Americas realm was open to migration from the Arctic.
Similarity of species with the Emsian faunas of Russia, Australia and
China suggests the cosmopolitan and equatorial distribution of
```

```
stromatoporoids in Emsian time and opens possibilities for using the
group in correlation. The fauna is therefore important in establishing
both the evolution of the order and also its geographic distribution in
Early Devonian time. Twenty-five species (assigned to 22 genera) are
described. The species concept used is a broad one and the range of
variations in each taxon is documented. New species described are:
Gerronostroma septentrionalis, Anostylostroma anfractum,
Pseudoactinodictyon conglutinatum, Stictostroma? nunavutense,
Clathrocoilona vexata, Stromatopora hensoni. The morphologic limits of
the following genera are considered in the description of species:
Plectostroma, Aculatostroma and Atelodictyon, Clathrocoilona,
Salairella and Syringostromella. The range of Trupetostroma is extended
downward into Emsian strata.^1";
s[2031] = "STEARN C.W. (1996).- Stromatoporoids from the Devonian
(Eifelian to lowest Frasnian) of Manitoba, Canada.- Journal of
Paleontology 70: 196-217.- <b>FC&#038;P 25-1</b>, p. 49,
ID=3059^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian Eif - Fra;
<b>Geography: </b>Canada, Manitoba^Twenty-two taxa of stromatoporoids
are described from the outcrop belt of the Elm Point, Winnipegosis,
Dawson Bay and Souris River formations in Manitoba. The Elm Point
Formation contaks a fauna of stromatoporellids of Eifelian age that is
characterized by the new species, Stromatoporella manitobaensis. The
Winnipegosis stromatoporoids are dolomitized but the widespread species
Actinostroma tyrrelli, Taleastroma logansportense and the new species
Trupetostroma imbrex can be recognized in this Givetian assemblage. The
Dawson Bay fauna is characterized by the appearance of the dendroid
forms, Stachyodes and Dendrostroma and species of Hermatostroma,
Trupetostroma and Parallelopora. A species of Actinostroma comparable
to A. filitextum is the most abundant stromatoporqid in the Dawson Bay
Formation. The Souris River fauna, referred to as the Arctostroma
contextum assemblage, is widespread at the Givetian-Frasnian boundary.
Elements occur elsewhere in western Canada in the Beaverhill Lake,
Waterways, lower Duperow and lower Fairholme units. Stromatoporoids in
these four assemblages are relatively restricted in their stratigraphic
occurrence and sufficiently widespread in their distribution to be
useful in correlation.^1";
s[2032] = "PROSH E.C. (1995).- Reply: Early Devonian age of the Detroit
River Group, inferred from Arctic stromatoporoids.- Canadian Journal of
Earth Sciences 32: 1073-1077.- <b>FC&#038;P 25-2</b>, p. 42,
ID=3127^<b>Topic(s): </b>biostratigraphy; stroms, stratigraphy;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>USA^The biostratigraphic review of G.
Klapper and W. A. Oliver jr, discussers, will assist interested readers
in weighing the evidence between their Eifelian date and the older
Emsian age proposed for the Detroit River Group by C. W. Steran and
myself in our original paper. Two important points emerge from their
review: Detroit River - Onondaga faunas are very endemic; the conodont
data do not immediately relate to the standard zonation, so some
interpretation is necessary. The Detroit River Group of Ontario is
mostly Lower Devonian. The Edgecliff and Nedrow members of the Onondaga
Limestone of New York are also Lower Devonian. Stromatoporoids in
common between the lower Detroit River Group and the Arctic Blue Fiord
Formation provide the Early Devonian date.^1";
s[2033] = "STEARN C.W. (1997).- Biostratigraphy of the Devonian reef
facies of Western and arctic Canada based on stromatoporoids.- Boletin

</b>Canada W, Arctic^Although stromatoporoids have been considered
inadequate for biostratigraphy, in western and arctic Canada ten
assemblages characterized by species with short ranges and wide
```

```
geographic distribution can be distinguished in the Devonian System.
Carbonate facies in the Arctic Islands and mainland of the Northwest
Territories contain stromatoporoids of Early Devonian and early Middle
Devonian ages. The reef facies of the Western Canada Sedimentary Basin
contains assemblages ranging from late Eifelian to middle Famennian in
age. (1) The earliest Devonian rocks in the Arctic are characterized by
species of Parallelostroma, (2) The lower Blue Fiord fauna of dehiscens
to grombergi zone stromatoporoids is distinguished by new species of
Gerronostroma and Stictostroma, and Stromatoporella perannulata. (3)
The upper Blue Fiord assemblage of inversus to partitus age has
Plectostroma salairicum and new species of Stromatopora and
Anostylostroma. (4) the late Eifelian assemblage of the Elm Point
Limestone in Manitoba is characterized by a new species of
Stromatoporella and Stictostroma cf S. foraminosum. (5) The early
Givetian (lower varcus Zone) assemblage is widespread in western Canada
and easily recognized by the presence of Neosyringostroma
logansportense and Actinostroma tyrrelli. (6) The middle Givetian
assemblage is a transitional fauna present in the Dawson Bay Formation
of: Manitoba. (7) Rocks of late Givetian and earliest Frasnian age
contain the Arctostroma contextum assemblage, widespread in the
Beaverhill Lake Group. (8) The mid-Frasnian fauna is characterized by
&#034;Ferestromatopora&#034; parksi. (9) Late Frasnian faunas found in
the Rocky Mountains and the Great Slave Lake areas can be characterized
as the Trupetostroma saintjeani assemblage. (10) The youngest
assemblage is found in mid-Famennian reefs and is identified by the
presence of Labechia palliseri and Stylodictyon sinense. Nearly all
these ten assemblages contain species that are valuable for correlation
within North America and assemblages 1, 2, 3, 5, 7, and 10 have species
that have potential for intercontinental correlation of the reefal
facies across the equatorial belt of Devonian time inhabited by
stromatoporoids.^1";

Idlewild Member of the Lithographic City Formation of North-central
Iowa.- University of Alabama, Tuscaloosa, unpublished M.Sc. thesis of
Department of Geology; 149 pp.- <b>FC&#038;P 27-1</b>, p. 109,
ID=3865^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian U; <b>Geography:
</b>USA, Iowa^Sixty-five specimens belonging to 13 genera and 22
species were collected to determine if their shapes were the result of
environmental or genetic factors. Many were collected from a single
bedding plane and are assumed to have been exposed to the same
environmental conditions. Domical and bulbous shapes predominate. Some
species exhibit a wide range of shapes; others, a narrow range.
Stromatoporoids from the same bedding plane did not grow to the same
shape. The relative importance of genetic disposition and environmental
factors in determining growth form cannot be determined from this
study. [condensed from abstract by C. W. Stearn]^1";
s[2035] = "STEARN C.W. (1998).- Devonian Stromatoporoid fauna of the
Bent Horn oilfield, Cameron Island, Northwest Territories.- Canadian
Journal of Earth Sciences 35: 16-22.- <b>FC&#038;P 27-1</b>, p. 110,
ID=3868^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Canada, NW Territories^The reservoir reef carbonates at the Bent
Horn Field have been referred to as the Blue Fiord Formation but they
are younger than the type Blue Fiord of Ellesmere Island. The top of
these carbonates, from which the Stromatoporoid fauna is described, is
dated by conodonts as of Eifelian age. They are the same unit that has
also been called the Unnamed Formation. Fourteen taxa of
stromatoporoids, none of them described as new, are identified from
cores. Five species are common to the fauna of the Unnamed Formation of
surface exposures on Bathurst and Truro islands. The ranges of the
three species from the fauna of the typical Blue Fiord of Emsian age
are extended into the Unnamed Formation. A synthesis of the
```

```
paleontological evidence suggests that the top of the reservoir is
basal Eifelian age. The recognition of Pseudoactinodictyon, cf. P.
stearni and Simplexodictyon vermiforme at Bent Horn suggests
paleogeographic connections to the Great Lakes and Yukon stromatoporoid
faunas of this age.^1";
s[2036] = "PROSH E.C., STEARN C.W. (1993).- Early Devonian age of the
Detroit River Group, inferred from Arctic stromatoporoids.- Canadian
Journal of Earth Sciences 30: 2465-2474.- <b>FC&#038;P 23-1.1</b>, p.
80, ID=4181^<b>Topic(s): </b>biostratigraphy; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian L;
<b>Geography: </b>USA^The group has traditionally been considered
mostly or entirely of Middle Devonian age but much of the fauna is
endemic. Four Detroit River Group stromatoporoid species are recognized
in the fauna of the Emsian Blue Fiord Formation in Ellesmere Island and
two other species show close relationships. The Emsian faunas of the
Arctic are accurately dated by conodonts and indicate a serotinus age
for the Amherstburg Formation and a serotinus to patulus age for the
Lucas Formation. This is the first direct species-level correlation of
a Detroit River Group &#034;endemic&#034; to a globally dateable level
and the first regional application of stromatoporoid biostratigraphy in
North America.^1";

Utah]: 43-53, 2 appendices, 8 plates.- <b>FC&#038;P 36</b>, p. 120,
ID=6563^<b>Topic(s): </b>strom buildups; strom buildups;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>USA, Great Basin^Devonian carbonates in
the Basin and Range Province of western Utah and eastern Nevada form
part of a large, carbonate-dominated depositional complex that occupied
the western margin of the mid-Paleozoic North American craton. These
Devonian carbonates are generally continuous with and coeval with
hydrocarbon reservoirs in the Alberta foreland basin of Canada. This
stratigraphic association and the production of modest amounts of oil
from the Devonian in Nevada raise the possibility that the
carbonate-reef play concepts that have been successful in Canada could
be applied to the Devonian of the Basin and Range. For this review
paper, we collected descriptions of more than 100 measured outcrop
sections in the literature and oil-industry data from about 45 wells,
and integrated the descriptions with published sequence stratigraphic
frameworks for the Middle and Upper Devonian. We assigned the
carbonates to eight depositional environments, ranging from supratidal
to deep subtidal, and correlated the measured sections across four
cross sections. Paleogeographic maps based on limited age control
suggest that two populations of stromatoporoid buildups occur: a
shelf-edge group that is probably not prospective for hydrocarbons, and
a middle-shelf group that may be prospective. However, the Basin and
Range buildups are smaller and less numerous than those in Canada, lack
structural control and internal biofacies zonation, and are mud
supported. From the hydrocarbon exploration perspective, carbonate
buildup distribution is probably less important than timing and
development of fracture porosity. [original abstract]^1";

microstructure de Favosites cylindrica Michelin 1847, espece-type de
Ohiopora n.gen. (Tabulata, Devonien).- Canadian Journal of Earth
Sciences 24: 1465-1477.- <b>FC&#038;P 17-1</b>, p. 25,
ID=2135^<b>Topic(s): </b>microstructures; Tabulata, Ohiopora;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian
Ems Eif; <b>Geography: </b>USA, Ohio^The holotype of Favosites
cylindrica Michelin 1847 is a fragment of a corallum completely
silicified and poorly preserved. Some specimens, regarded as topotypic
(Falls of the Ohio), allow a detailed study of internal characters,
wall, pores, and tabulae. Development of horizontal ridges results from
folding of the wall. The abundance of these ridges is generally
associated with the final stage of growth of the corallum. In
ultra-thin sections with polished faces (LFP thin sections), parts of
the skeleton not affected by silification show the microstructural
features of the wall. The median &#34;dark line&#34; is composed of
granules, sometimes elongated; the stereozone is made of lamellae
approximately parallel to the intramural coenozone. A biometric study
of the so-called &#34;topotypic&#34; specimens and of the holotype of
F. cylindrica shows the conspecifity of all this material. A new genus,
Ohiopora, is proposed for F. cylindrica. The new genus is very close to
Michelinia sensu stricto, from which it probably derived but from which
it may be distinguished by the presence of horizontal ridges, which
form an original feature within the Tabulata. Several old species may
be assigned to the new genus, and probably all are synonymous with O.
cylindrica. Occurrence: Emsian?, lower and &#34;middle&#34; Eifelian.
Ohiopora is endemic of eastern North American Province.^1";

mounds; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian U;
<b>Geography: </b>Canada, Alberta^The upper Peechee Member of the
Ancient Wall reef complex that is well exposed on the southeast margin
of Mount Haultain represents the end of the first main depositional
cycle of this complex. The uppermost part forms a 15-30m thick
carbonate sequence that extends basin-ward over deeper water fore-reef
detritus and is divisible into three distinct layers: the lower two
consist mainly of stromatoropoid and coral bioherms and biostromes and
associated calcarenites and calcilutites; the uppermost consists of
five small micrite and wacke-stone bioherms 7,5 - 22 m long and 4 - 6 m
high; three of these grew around and on top of a 30 m wide
stromato-poroid-coral biostrome. Frame-building organisms in- clude
laminar and hemispherical colonies of Phillipsastrea, renalcid algae
(often associated with smali fenestral cavities), encrusting oaloareous
algae (Sphaerocodium). and laminar stromatoporoids. Renalcid
encrustations of micrites and wackestones on the ver-tical sides and
undersides of bioherms indicate that early submarine cementation was
also significant in forming these rigid structures. The bioherms formed
during deepening water conditions with agitation and bioerosion too
gentle to apron them with detritus but sufficient to fragment and
disorient fragile skeletal elements. The sharp contacts and the lack of
inter-fingering with basin strata indicate that the bioherms were
drowned before burial by basin calcareous shales. (Original summary)^1";

Microbial carbonate as indicator of environmental change and biotic
crises in carbonate systems: examples from the Late Devonian, Alberta
Basin, Canada.- Palaeogeography, Palaeoclimatology, Palaeoecology 181,
1-3: 127-151.- <b>FC&#038;P 32-1</b>, p. 37, ID=1742^<b>Topic(s):
</b>carbonates; carbonates ecology; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian U; <b>Geography: </b>Canada,
Alberta^Microbial precipitation of calcium carbonate has played a vital
role in the development of carbonate platforms since their initiation
in the Proterozoic. We report here the varied roles that microbial
carbonates played in Late Devonian carbonate platforms in the Alberta
basin, Canada. We recognize microbial carbonates as important
contributors within the carbonate system during times of major
environmental change including transgressive events in platform
environments and the recovery interval following the Frasnian-Famennian
mass extinction. Detailed sequence stratigraphic analysis of two
isolated platforms in the Canadian Rockies was used to document their
evolution from a regional ramp to isolated platforms with phases of
progradation, aggradation and backstepping, and renewed progradation
related to rates of second-order and third-order sea-level change and
basin infill. The carbonate system was reorganized following
annihilation of many carbonate-producing biota during the
Frasnian-Famennian mass extinction. Microbial carbonates figure
prominently in both Frasnian platform development and the Famennian
recovery of the carbonate system following the Frasnian-Famennian mass
extinction. [...] Microbial carbonates occur at important sequence
stratigraphic and paleoecologic horizons indicating changes in sea
level, nutrient supply, and biotic assemblages. These examples indicate
that microbial carbonates can be important indicators of environmental
and ecological change within carbonate systems. [first and last part of

M; <b>Geography: </b>Canada, Quebec^Early and Middle Devonian fossils
from the Sainte-Helene Island diatreme breccias are critically reviewed
and analyzed stratigraphically. They include marine benthic faunas of
Helderberg, Oriskany, Schoharie, Onondaga, and Hamilton ages.
Brachiopods are the most abundant fossils; significant corals are also
present and are discussed for the first time. These diatreme faunas
from the Montreal region significantly augment the lithofacies -
paleogeographic data known for the first part of North America. For the
first time, attention is paid to the lithologies in which the
Sainte-Helene Island faunas are embedded, as clues to the regional
relations of these rock types. The absence of Silurian specimens is
ascribed to nondeposition similar to that known in the Albany, New
York, region to the south. The presence of marine, Hamilton age rocks
and fossils at Montreal shows that the Acadian Orogeny and uplift into
the nonmarine environment did not affect the area until at least some
time in the Hamilton.^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Canada W^Most Devonian reef and platform carbonates
in the Western Canada Sedimentary Basin (WCSB) are pervasively replaced
by grey matrix dolomite. The following parameters of these dolomites
have been investigated: textures, spatial relationships to facies and
structure, relationships to limestone diagenesis and stylolitization,
stable isotopes, trace elements, 87Sr/86Sr-ratios, associated sulfates,
recrystallization, fluid inclusions. The data presently available
suggest that most grey matrix dolomites in the WCSB are &#034;burial
dolomites&#034; that formed during burial at depths of about 300 to
1500m. Pervasive matrix dolomitization appears to have been a
basin-wide phenomenon, and the dolomitizing solutions probably were
diagenetically altered Devonian seawater. The &#034;mechanisms&#034;
and directions of dolomitizing fluid flows are presently unknown and
under further investigation. ^1";

carbonates (250-430m thick) of the eastern Great Basin were deposited
along a low energy, westward-thickening, distally steepened ramp. Four
third-order sequences can be correlated across the ramp-to-basin
transition and are composed of meter-scale, upward-shallowing carbonate
cycles (or parasequences). Peritidal cycles (shallow subtidal facies
capped by tidal-flat laminites) constitute 90% of all measured cycles
and are present across the entire ramp. The peritidal cycles are
regressive- and transgressive-prone (upward-deepening followed by
upward-shallowing facies trends). Approximately 80% of the peritidal
cycle caps show evidence of prolonged subaerial exposure including
sediment-filled dissolution cavities, horizontal to vertical
desiccation cracks, rubble and karst breccias, and pedogenic
alteration; locally these features are present down to 2 m below the
cycle caps. Subtidal cycles (capped by shallow subtidal facies) are
present along the middle-outer ramp and ramp margin and indicate
incomplete shallowing. Submerged subtidal cycles (64% of all subtidal
cycles) are composed of deeper subtidal facies overlain by shallow
subtidal facies. Exposed subtidal cycles are composed of deeper
subtidal facies overlain by shallow subtidal facies that are capped by
features indicative of prolonged subaerial exposure (dissolution
cavities and brecciation). Average peritidal and subtidal cycle
durations are between approximately 50 and 130 k.y. (fourth- to
fifth-order). [part of extensive summary]^1";
s[2062] = "KLOVAN J.E. (1974).- Development of Western Canadian
Devonian reefs and comparison with Holocene Analogues.- Bulletin of the
American Association of Petroleum Geologists 58, 5: 787-799.-
<b>FC&#038;P 3-2</b>, p. 39, ID=4956^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Canada W^The complex interplay of basin geometry and tectonic
history, subsidence rate, weather conditions, and postdepositional
history is the factor determining the ultimate morphology of a reef
tract, individual reefs comprising the tract, and the lithologic
variations within the reefs. Although the effects of these influences
usually can be documented in studies of recent reefs, their
determination in fossil settings is commonly obscure. This may preclude
the use of recent reefs as explicit analogues of ancient ones. The
applicability and limitations of such comparisons with references to
some Devonian reefs of western Canada and various Holocene structures
indicate that the variety of reef tracts available for study allows the
various causal influences to be isolated to a first order of
approximation.^1";
s[2063] = "HRISKEVICH M.E. (1967).- Middle Devonian reefs of the
Rainbow Region of northwestern Canada exploration and exploitation.-
Proceedings of the VIIth World Petroleum Congress: 733-763.-
<b>FC&#038;P 4-1</b>, p. 32, ID=5102^<b>Topic(s): </b>reefs,
exploration &#038; exploitation; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Canada NW^At least
three separate pulses of reef growth occurred in northwestern Canada
during Middle Devonian time. These are, in order of decreasing age, Keg
River (Rainbow Member), Sulphur Point and Slave Point reefs. Isopachous
and facies maps illustrate that in the western part of the region, in
northeastern British Columbia, the distribution of Keg River (Rainbow
Member) reefs determined to a considerable degree, the extent and
configuration of younger (Sulphur Point and Slave Point) reefs. In the
eastern part, no direct relationship is apparent. Examples illustrate
that seismic exploration for reefs must be adapted to specific geologic
```

```
conditions obtaining in the particular part of the basin being
explored. * During the two years ending March 31, 1967, exploratory and
development drilling has confirmed recoverable reserves of more than a
billion barrels of oil in Rainbow reefs of northwestern Alberta.
Substantial reserves of gas have been discovered in Middle Devonian
reefs in British Columbia. The new system of proration to market demand
adopted by Alberta has allowed this substantial reserve to be developed
with only those wells needed to broadly define the reserves in each
pool. Continuous year-round exploitation has been carried out in a
remote environment by employing extensive stock-piling during winter
months and by placing heavy reliance on air support. Rainbow crude
started to market on March 18, 1966, approximately one year after
discovery. Mathematical model studies of the discovery reservoir
confirm that primary recovery will be 57 per cent of the oil-in-place.
Maximum recovery of 96 per cent should be achieved by using a
downward-moving miscible blanket. A processing plant is under
construction to recover L.P.G., sweetened solution gas and compress
these fluids for injection for pressure maintenance.^1";

coral latitudinal diversity gradients (western interior United States):
Testing the limits of high resolution diversity data.- Journal of
Paleontology 71, 5: 780-791.- <b>FC&#038;P 27-2</b>, p. 48,
ID=3904^<b>Topic(s): </b>paleolatitudes; corals; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>USA interior W^Analysis of high resolution diversity
data for Mississippian corals in the estern interior United States
yielded mild latitudinal diversity gradients despite the small
geographic area covered by samples and a large influence on diversity
patterns by geographic sampling intensity (sample bias). Three
competing plate tectonic reconstructions were tested using the
diversity patterns. Although none could be forcefully rejected, one
reconstruction proved less consistent with diversity patterns than the
other two and additional coral diversity data from farther north in
Canada would better discriminate the two equivalent reconstructions.
Despite the relatively high sampling intensity represented by the
analyzed database, diversity patterns were greatly affected by sample
abundance and distribution. Hence, some effort at recognizing and
accounting for sample bias should be undertaken in any study of
latitudinal diversity gradients. Small-scale geographic lumping of
sample localities had only small effects on geographic diversity
patterns. However, large-scale (e.g., regional) geographic lumping of
diversity data may not yield latitudinally sensitive diversity
patterns. Temporal changes in coral diversity in this region reflect
changes in eustacy, local tectonism, and terrigenous sediment flux, far
more than they do shifting latitude. Highest regional diversity
occurred during the interval when the studied region occupied the
highest latitude. Therefore, diversity data from different regions may
not be comparable, in terms of latitudinal inference. Small-scale
stratigraphic lumping of the data caused a nearly complete loss of the
latitudinal diversity patterns apparent prior to lumping. Hence, the
narrowest possible stratigraphic resolution should be maintained in
analyzing latitudinal diversity gradients.^1";

well-preserved specimens of the new orchocladine anthaspidellid genus
and species, Virgaspongia ichnata, the rhizomorine haplistiid,
Haplistion sphaericum Finks 1960, and various root tufts, and the new
hexactinellid species Steioderma hadra are reported from the Brentwood
Member of the Morrowan Bloyd Formation from the Sulphur City
quadrangle, in the Ozark Mountains of northwestern Arkansas.
Virgaspongia is a subcylindrical branched or unbranched sponge that
lacks a spongocoel and has a dendroclone-based skeleton in which trabs
diverge upward and outward from an axial region. It is abundant here
but is one of only a few anthaspidellid genera known from the
Pennsylvanian. This is the first record of Haplistion from
Pennsylvanian rocks of Arkansas, although the genus is widespread in
upper Paleozoic rocks. The new hexactinellid species, Stioderma hadra,
also documents the first occurrence of that genus from Arkansas and in
Morrowan rocks. Only fragments were recovered but the swollen grotesque
spicules, of several sizes, that make the fused dermal layer and outer
sponge wall are distinctive, particularly where combined with an inner
layer(?) or root tuft of monaxons of various sizes. Two different root
tufts and one demosponge wall fragment(?) also occur in the
collection.^1";

```
Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>USA,
Oklahoma, Arkansas^The Upper Chesterian Pitkin Formation of the Ozark
Dome region contains a large and diverse, yet highly endemic, coral
fauna consisting of 10 genera of rugose corals and three of tabulate
corals. Coral distribution within the formation is affected by
stratigraphic, paleoecologic, and possibly paleogeographic controls.
Although it is impossible at this time to fully evaluate the importance
of stratigraphic controls on the coral distribution, the occurrence of
two types of carbonate bioherms within the formation provides
substantial paleoecologic control on the distribution of certain
corals. Despite the high endemism and facies restriction, the coral
fauna has proven to be biostratigraphically sensitive, correlating with
middle and upper Chesterian coral zones in the Western Interior
Province of North America. Among the Pitkin corals herein described are
the new genera: Lesliella n.gen. (L. amplexa n.sp., type species) and
Parvaxon n.gen. (P. minutum n.sp., type species). Other newly described
species are: Amplexizaphrentis browni n.sp., Barytichisma clubinei
n.sp., B. ozarkana n.sp., and Leonardophyllum arkansanum n.sp., which
represents the first reported occurrence of the genus in strata below
the Pennsylvanian boundary.^1";

12, ID=3678^<b>Topic(s): </b>variability; Rugosa, Petalaxis;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous M; <b>Geography: </b>USA, Oklahoma^A new species of
the genus Petalaxis occurs in strata of early Pennsylvanian Morrowan
age in northeastern Oklahoma, in the Branneroceras branneri ammonoid
zone, which correlate with the lower G2 interval in Western Europe. It
occurs in a quiet, offshore carbonate mudstone environment in which the
colonies are all in growth positions. Large colonies are grouped into
widely separated clusters in and on the top surface of a widely
distributed carbonate mudstone interval. With the slow influx of mud
new spats of Petalaxis settled immediately on muddy surfaces partly
covering the large Petalaxis n.sp. A colonies. In this adverse
environment the new colonies survived for varying spans of time. They
range in size from less than 2cm up to 16cm. Those over 5cm in diameter
can be identified with certainly as being the same species as the large
underlying colonies. Even those less than 2cm in diameter must be the
same species in that no corals are found in the extensive barren spaces
separating the underlying clusters of Petalaxis colonies. If a shale
containing tiny Petalaxis colonies occurred at the same horizon in a
locality separated even a short distance from a limestone containing
large colonies of Petalaxis then the two groups of specimens would
almost certainly be classified as different species. Such a conclusion
would not necessarily be justified.^1";

damage in rugose corals, Pella Formation (Mississippian, Iowa, USA).-
Palaeoworld 19, 3-4: 325-332.- <b>FC&#038;P 36</b>, p. 69,
ID=6468^<b>Topic(s): </b>skeletal repair; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous; <b>Geography:
</b>USA, Iowa^Little is known about predation on rugose corals or the
repair of damage to rugose coral skeletons. Here we describe a
population of the solitary rugose coral Amplexizaphrentis spinulosa
(Milne-Edwards and Haime, 1851) from the Late Mississippian Pella
Formation in Keokuk County, Iowa, USA wherein ~30% of 135 specimens
experienced sublethal damage resulting from compression apparently
inflicted by fish or other large predators. Many corals were able to
repair severe damage and re-establish a relatively normal morphology
despite the loss of parts of the wall. Healed damage includes: (1)
chips to the edge of the calice, (2) punctures in the wall, (3) lost
sections of wall, (4) re-cemented sections of wall, some at odd angles,
(5) changes in growth direction, and (6) rejuvenescence. Multiple
episodes of damage and repair occurred in 5% of samples. More severe
damage on the cardinal side in almost one-half of damaged samples may
reflect structural weakness at the cardinal fossula relative to the
counter side, but septa were broken in all positions in many samples.
The pattern of alignment and preservation of broken plates in the
calice suggests that soft tissues were better attached to the skeleton
in a band relatively far above the calice floor. Better musculature
also may have occurred in the same band. Where parts of the wall were
broken free from septa that remained fixed at their axial ends, new
wall was deposited as stereoplasm against and enveloping the adaxial
ends of the original septa. Lost lengths of septa were replaced by
```

```
adaxial growth. New septa were commonly contorted, presumably owing to
deformation of surviving soft tissues that had lost structural support.
Broken septa were generally healed, commonly with poor alignment. The
high survival rate, even following multiple attacks, suggests that the
soft tissues of the coral polyps were robust. The rarity of changes in
growth direction following attacks suggests that the corals may have
been more capable of righting themselves and re-establishing an optimum
growth orientation than has commonly been suggested for solitary
Rugosa. [original abstract]^1";

<b>FC&#038;P 30-1</b>, p. 20, ID=7072^<b>Topic(s): </b>diagenesis,
microstructures; Rugosa Lophophyllidium; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>USA,
Oklahoma^A rugose coral (Lophophyllidium sp.) from the Buckhorn Asphalt
of Oklahoma provides new information on the mineralogy and
microstructure of rugose corals. The Buckhorn Asphalt is an asphalt
impregnated interval of mixed marine carbonate and siliciclastic
sediments in the Deese Group (Upper Carboniferous) of central Oklahoma,
USA. Buckhorn strata are renowned for their well preserved aragonite
molluscan fauna. The Lophophyllidium specimen is slightly compressed
and interseptal spaces contain little cement. X ray diffraction
indicates that the coral is calcite. Septa contain medial &#34;dark
lines&#34; flanked by stereoplasm that contains prominent laminae,
possibly growth laminae, that have been diagenetically enhanced and
form part of the chevron structure of secondary zigzag microstructure.
Dissolution zones occur along septal margins. Microprobe minor element
maps (Mg, Sr, Fe, and S) demonstrate highly variable Mg values in the
dissolution zones, as much as 2-3 times Mg enriched, as compared to the
rest of the coral, which has a relatively uniform, lower Mg content.
Magnesium is mostly present in secondary microdolomite crystals, which
disrupt the primary fibrous microstructure, but which are aligned along
lineations defined by zigzag alteration. Strontium levels are low and
uniform; Fe and S are largely confined to asphalt. Partial dissolution
and occurrence of microdolomite crystals suggests that the skeleton was
originally metastable low intermediate Mg calcite. Magnesium in the
microdolomite was apparently derived from the coral itself by a process
of microdissolution reprecipitation in a relatively closed system.
Zigzag microstructure presumably formed during this very early
neomorphism and may be directly related to the mobilization of Mg from
the unstable precursor Mg calcite. [original abstract]^1";

(1993).- Skeletal microstructure and the mode of attachment in Palaeacis species (Anthozoa: Tabulata) from the Mississippian and Pennsylvanian of northeastern Oklahoma and northwestern Arkansas.- Journal of Paleontology 67, 2: 167-178.- <b>FC&#038;P 22-1</b>, p. 37, ID=3394^<b>Topic(s): </b>microstructures, attachment mode; Tabulata, Palaeacis; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>USA, Oklahoma, Arkansas^Three species of Paleozoic coral Palaeacis are described from northeastern Oklahoma and northwestern Arkansas. Included are the Chesterian species P. carinata Girty and P. snideri nom. nov., a replacement name for the junior homonym P. cuneata Snider, and the Desmoinesian? species P. erecta n.sp. Coralla of each species exhibit two types of microstructure that characterize two skeletal zones. The outer skeletal zone is composed of numerous parallel trabeculae, mostly between 0,2 and 0,3mm in diameter, that lie perpendicular to, and have their accretionary surfaces on, the exterior surface of the corallum. Trabeculae are closely spaced laterally and are not organized into rows except uncommonly on the distal portion of some coralla. Where trabeculae coalesce into parallel rows, ornamentation on the corallum exterior consists of parallel ridges or rows of small nodes. Where trabeculae are irregularly arranged, external ornamentation consists of irregularly disposed nodes. The inner skeletal zone consists of radially fibrous stereoplasm arranged into discrete septal spines that coalesce into irregularly developed septal ridges in each calice. In P. erecta, septal spines merge into continuous [zone] of fibro-normal stereoplasm in some places. On the basis of microstructure, corallum morphology, and external ornamentation P. carinata and P. snideri can be allied with P. axinoides Smyth and P. robusta Webb. P. erecta falls within the same group on the basis of microstructure and ornament, but has a unique corallum morphology. Two distinct types of skeletal attachment occur in these Palaeacis species. Palaeacis carinata and P. snideri exhibit an encrusting attachment surface that results in a prostrate growth habit wherein smaller substrates were entirely engulfed, producing free-living coralla. Palaeacis erecta exhibits a small, circular attachment surface and an erect growth habit wherein most skeletal accretion occurs perpendicular to, and away from, the substrate. The substrate is not engulfed and the corallum remains attached and sessile throughout astogeny. Palaeacis erecta, to date, the only Palaeacis species known to possess this erects, sessile growth form.^1";
s[2100] = "WEBB G.E. (1993).- A Lower Pennsylvanian encrusting tabulate coral from a rocky shore environment developed on the Mississippian-Pennsylvanian unconformity surface in northwestern Arkansas.- Journal of Paleontology 67, 6: 1064-1068.- <b>FC&#038;P 23-2.1</b>, p. 43, ID=4239^<b>Topic(s): </b>rocky shore dwellers; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Carboniferous U?; <b>Geography: </b>USA, Arkansas^Paleozoic corals are very rare in rocky shore settings. The only Paleozoic encrusting coral so far reported from this environment is Favosites sp. from Ordovician rocky shore deposits in Manitoba, Canada (Johnson and Baarli
```

```
1987). Reading and Poole (1961) reported corals and brachiopods that
occur between, and &#34;coating&#34;, boulders from a Silurian rocky
shore in England, but it appears that the corals and brachiopods only
occur in the sediment enveloping the boulders, not as encrusters on the
surfaces of the boulders. One reason for the sparse record of Paleozoic
corals in rocky shore settings is the scarcity of described Paleozoic
rocky shore deposits themselves. Johnson (1988) found only 20 examples
of Paleozoic rocky shores in a compilation of references on ancient
rocky shores from the literature. The paucity of described ancient
rocky shores has been attributed to the prevalence in the past of
epicontinental seas with little relict upon which to develop rocky
shores and with higher wave attenuation farther from shore (Boucot
1981; Harland and Pickerill 1984). Johnson (1988) concluded that the
major reason for the rarity of ancient rocky shores in the literature
is the difficulty with which they are recognized and studied, owing to
the relatively poor exposure of most unconformity surfaces. The rocky
shore environment was also probably hostile to many Paleozoic coral
genera. Recent scleractinian corals may serve as analogues because they
are also not very abundant in rocky shore settings despite their great
abundance in similar shallow-water, high-wave-energy reefal
environments. Turbidity and relative substrate stability may be
important limiting factors for corals in rocky shore environments. Many
corals are known to be highly sensitive to sediment in the water
column. Substrate stability (Wilson 1987) and the scouring effects of
sand in high-energy environments (Palmer and Palmer 1977) also have
been shown to affect the abundance and diversity of organisms
encrusting cobbles and boulders. The purpose of this note is to
describe a Lower Pennsylvanian encrusting coral, possibly Michelinia
scopulosa Moore and Jeffords 1945, from transgressive rocky shore
deposits at the base of the Cane Hill Member of the Morrowan Hale
Formation in northwestern Arkansas. Illustrated specimens are deposited
in the Oklahoma Museum of Natural History (OU).^1";

Palaeacis from the Pennsylvanian of the Ardmore Basin, Oklahoma? .-
Journal of Paleontology 68, 2: 223-233.- <b>FC&#038;P 23-2.1</b>, p.
43, ID=4240^<b>Topic(s): </b>benthic auto-mobility; Tabulata,
Palaeacis; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Carboniferous U; <b>Geography: </b>USA, Oklahoma^The enigmatic
tabulate genus Palaeacis is composed primarily of species with
wedge-shaped coralla. Palaeacis walcotti Moore and Jeffords 1945, P.
kingi Jeffords 1955, and P. cf. P. walcotti, described below from the
Morrowan (Pennsylvanian) Golf Course Formation of the Ardmore Basin,
south-central Oklahoma, represent a distinctive morphogroup
characterized by a discoid corallum. Discoid Palaeacis ranges from the
Morrowan to the Missourian and, so far, is known only from the
mid-continent region of North America. The discoid shape, combined with
concentric skeletal accretion, large corallite diameters, complex
calice floors, and porous skeleton suggest, based on comparisons with
the functional morphology of recent scleractinians, that these corals
were well suited to an auto-mobile (vagile) life strategy, much as are
many Recent fungiid corals. Discoid Palaeacis inhabited environments
with muddy or sandy, unconsolidated substrates and was associated with
low-diversity, non-encrusting faunas. This association is consistent
with an auto-mobile life strategy. Auto-mobility in Palaeacis would
represent the first such reported occurrence in the Tabulata, and the
first in Paleozoic colonial corals of all types.^1";

stratigraphic significance of Guadalupian (middle Permian) solitary
corals, Sverdrup Basin, Arctic Canada.- Canadian Society of Petroleum
Geologists, Memoir 19: 427-436.- <b>FC&#038;P 32-1</b>, p. 25,
ID=1727^<b>Topic(s): </b>biogeography, biostratigraphy; Rugosa,
biogeography; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Permian M; <b>Geography: </b>Canada, Arctic^The sparse rugose coral
fauna of the Degerböls and Trold Fiord formations consists exclusively
of nondissepimental, solitary taxa and includes the youngest Permian
corals in the Sverdrup Basin. Similar faunas occur in the youngest
coral-bearing deposits elsewhere in the northern parts of the
Cordilleran-Arctic-Uralian (CAU) Realm - in Alaska, East Greenland, the
Svalbard Archipelago, the Central European Basin and the East European
Platform. These assemblages occupy a separate biogeographic province,
here named the Calophyllum Province. In comparison to the CAU faunas,
Guadalupian faunas in the Tethys Realm are much richer and contain
abundant, diversified colonial taxa as well. The solitary,
nondissepimental corals of the Tethys Realm show much greater diversity
than those in the CAU Realm and survived almost until the end of the
Permian. On the family and genus level, there is a fairly close
relationship between the nondissepimental solitary corals of the two
realms. This did not result, however, from direct faunal exchange
during the Permian, but reflects common roots for these corals and
widespread faunal dispersion prior to Permian establishment of the
realms.^1";

(Tolkien reefs) associated with subaqueous evaporites, Canadian Arctic:
a record of syn-tectonic to post-tectonic reciprocal uplift and
subsidence.- SEPM Special Publication 78 (Permo-Carboniferous carbonate
platforms and reefs): 133-153.- <b>FC&#038;P 33-1</b>, p. 81,
ID=7229^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Permian Ass; <b>Geography: </b>Canada,
Arctic^Twenty-six reef-mounds of Early Permian (Middle or Late
Asselian) age crop out along the north shore of Greely Fiord on
west-central Ellesmere Island, Canadian Arctic Archipelago. Each reef
was attributed the name of a character from J.R.R. Tolkien&#39;s
&#34;The Lord of the Rings&#34;. The reefs interfinger with evaporites
in the upper part of the Mount Bayley Formation, immediately below the
Tanquary Formation. The reefs grew at the northern margin of a large
depression of the Sverdrup Basin referred to as the Fosheim-Hamilton
sub-basin, which is separated from the main Sverdrup Basin by the
Elmerson high, an elongated structure of probable compressional origin.
The Tolkien reefs range from 50m to over 130m in thickness and between
50m and 500m in width and length. The buildups have a massive core
around which are wrapped a series of well-defined, variably steep beds
(flanks), many of which display a sharp erosional base. Facies of the
core and inner flank comprise: bryozoan-Tubiphytes-stromatactoid
(sponge) boundstone; bryozoan cementstone; bryozoan
mudstone-wackestone; and bryozoan (fusulinacean) packstone-grainstone.
Facies of the outer flank include: algal boundstone; and
fusulinid-algal grainstone-rudstone. Facies that occur both in the
inner and outer flanks include carbonate breccia and moldic
dolomicrite. The Tolkien Reefs of west-central Ellesmere Island
recorded the transition from an evaporite-dominated succession (Mount
Bayley Formation) to an evaporite-free succession (Tanquary Formation).
```

```
The reefs grew south of a major structural element - the Elmerson high
- through the complex interplay between high-order to low-order
relative sea-level fluctuations driven by tectonics, glacio-eustasy,
and evaporative drawdown. The Tolkien Reefs recorded the rapid
transition between a long episode of differential, and in part
fault-controlled, syntectonic subsidence and a long period of slower,
regional post-tectonic passive subsidence. While the former can be
associated with a pulse of compressional tectonics that affected many
areas of the Sverdrup Basin, the latter represents a phase of tectonic
quiescence. [original abstract]^1";

hexactinellid sponge from the Cretaceous of Devon Island, Canadian High
Arctic.- Canadian Journal of Earth Sciences 44: 1235-1242.-
<b>FC&#038;P 35</b>, p. 45, ID=2326^<b>Topic(s): </b>new taxa; Porifera
Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>Canada, Arctic^Over
20 specimens of the new genus and species Nunavutospongia irregulara,
an irregular stump-like to columnar, or fan- to blade-shaped,
hexactinosid hexactinellid sponge, have been recovered from exposures
of the Upper Cretaceous upper Kanguk Formation on Devon Island, Nunavut
Territory, in the Canadian High Arctic. The species and genus are
characterized by dermal surfaces with prominent radial, irregularly
vertical, rib-like flanges that have a single linear series of
separated oscula perforating their rounded crests. The thin, but
persistent dermal layer of fused hexactine-based spicules has rays
thicker than those of the similarly fused endosomal, quadrangularly
arranged, hexactines of the principal skeleton. Ostia of coarse
exhalant canals, and finer inhalant canals, are extensively and
uniformly developed, but irregularly placed, in the dermal layer. A
```

```
thin, less prominent, gastral layer of thickened spicules lines the
short, internally tapered spongocoel openings. The skeleton exposed in
the commonly upward-arcuate base of each sponge has a radiate structure
that does not have significant ostia. The new genus is tentatively
included in the Family Cribrospongiidae Roemer, 1864, within the Order
Hexactinosa Schrammen, 1903. The specimens were found in unconsolidated
fine-grained glauconitic sediments along with other fossils such as
fish teeth, bird bones, lingulids, coprolites, and wood. The
sedimentology, stratigraphic context, and co-occurrence with fossil
wood suggest that these sponges inhabited the neritic zone. As such,
they would have been subject to polar light regimes, because
paleogeographic reconstructions indicate that Devon Island was above
the Arctic Circle during the Late Cretaceous. The distribution of the
specimens suggests that they were solitary sponges that used their
arcuate bases to colonize sandy substrates or biotic debris. ^1";

new fossil hydroid is reported as an organic impression on a calcareous
gastropod steinkern from the Prairie Bluff Chalk (Maastrichtian),
Oktibbeha County, Mississippi. This is the first such hydroid reported
from the Upper Cretaceous of the Atlantic Coastal Plain. The fossil
organism consists of anastomosing hydrorhizae forming a holdfast, a
fascicled hydrocaulus, and elongated, crenulated and ribbed
hydrothecae. The fossil is unlike other Mesozoic hydroids that have
been reported from Europe and North America; it is described as
Mesodendrium oktibbehaensis gen. et sp.nov. and tentatively referred to
an extant family, the Campanulariidae (Calyptoblastina). The complete
preservation of the holdfast, hydrocaulus and hydrothecae suggests that
this hydroid lived inside gastropod shells. In analogy with Recent
symbiotic hydroids inhabiting mollusc shells, the new specimen
described here possibly represents the oldest known example of a
symbiotic relationship between hydroids and hermit crabs.^1";

Scleractinia; <b>Stratigraphy: </b>Cretaceous U, Paleogene;
<b>Geography: </b>Greenland W^Localities and deposits in north-west
Nugssuaq yielding fossil corals of the order Scleractinia are
described. The age of the corals is Campanian?, Maastrichtian and Lower
Paleocene (Danian), on the basis of other marine fossils. 22 species
are considered; 7 are described as new and are indigenous, 2 are
possibly North American forms, 3 are known from Europe, and 10 are
identifiable only to generic level. The following genera and subgenera
are represented: Haimesiastraea (Haimesiastraea), H. (Peruviastrea)?,
Astrangia (Coenangia)?, Oculina, Caryophyllia, Trochocyathus,
Paracyathus, Stephanocyathus (Stephanocyathus), Desmophyllum?,
Lophelia?, Parasmilia, Flabellum, Balanophyllia, and Dendrophyllia. In
addition, two new genera are described: Kangiliacyathus and
Faksephyllia. Certain Danian corals from Scandinavia are also revised.
In a survey of habitats, the lithology of the coral localities is
considered together with bathymetric and thermal ranges known for
scleractinian genera and species from other parts of the world. Depth
and temperature of the Campanian and Maastrichtian seas in Greenland
cannot be estimated with any accuracy. The Lower and UpperDanian seas
```

```
were generally rather shallow. There is little evidence on which to
judge the Danian climate. Two species were perhaps hermatypic (no reef
structures have been found). The remaining scleractinians are presumed
to have been ahermatypic. A non-reef coral association has been found.
Lower Danian rather sparsely populated polytypic coral thickets show
signs of continual disturbance from water turbulence. The approximate
depth of formation of these thickets appears to have been 80m. or
shallower, which appears to be less than is usual for coral structures
of this type. Some Lower Paleocene species provide conclusive evidence
of a direct connection between the Danian seas of West Greenland and of
Scandinavia.^1";

Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Cenozoic; <b>Geography: </b>USA E coast^Extensive low-lying marine
deposits border the southeastern United States Atlantic Coastal Plain.
Some units are fossiliferous and contain corals as isolated fragments
in sediments of a detrital character. These corals are subject to
alteration processes such that suites of related samples must be
examined to determine the suitability of these coral samples for
reliable uranium-series dating. With the exception of those from one
location, most samples appear to have remained closed systems with
respect to the isotopes of uranium and thorium throughout their
geologic history. Extraneous 230Th has been detected in some of the
corals due to incorporation of some detrital materials into their
skeletons. For these samples, different methods are applied to correct
for the initial 230Th contamination. Continued sampling and analyses
have resulted in 55 individual uranium-thorium determinations. ^1";

ecological zonation; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Pleistocene; <b>Geography: </b>Kenya^Ecological succession on small
patch reef structures can be studied by employing the concept of
ecological stratification. The component coral of a patch are divided
into two basic categories, the B or C horizons (or strata). The former
category represents the initial colonizers (or pioneers) on a soft
substrate, and the latter the subsequent colonizers. The potential
exists for studying the later stages of successions by finely
subdividing the C horizon. Detailed mapping of vertical sections
through patch reefs in the Pleistocene reef limestones of the Kenya
coast provided stratification analyses in a variety of back-reef
environments. Massive Porites proved to be the commonest B horizon
coral throughout the region studied, and clearly was of fundamental
importance in patch reef formation. Massive faviids and mussids were
less frequent early colonizers. The most important C horizon corals
were encrusting Montipora (in more open water areas), encrusting
Cyphastrea (in quieter, deeper water areas), and tiny domes and patches
of massive Favia. Many coral may be much more specialized in their
habitat requirements than has previously been recognized. The principal
coral type within the back-reef patches of the Kenya Pleistocene reef
consistently adopt distinctive three-dimensional growth forms within
either B or C horizons, and it is argued that they must have
partitioned at least part of the available habitat space. Ecological
stratification is a useful tool for determining the nature and extent
of habitat resource partitioning by scleractinian corals. [original

the Devonian &#34;récifs rouges&#34; of Belgium and the Silurian mounds
of the Quebec Appalachians, we propose that deposition of the red
stromatactis limestone facies of Cambrian-Devonian carbonate mounds was
controlled by sponges and that the red color and stromatactis result
from early diagenesis within a few meters below the substrate-water
interface in the deep-marine environment. The common presence of sponge
body fossils, as well as various stages of sponge preservation, ranging
from easily delineated to indiscernible bodies, in the Belgian
```

```
&#34;récifs rouges&#34; support the conclusion that a large part of the red finely crystalline limestone originated from early cementation of sponge communities or spicule-rich organic mats derived from degradation of sponge communities. The role of bacteria and other microbes, although widely advocated as the main primary builders of carbonate mounds, is difficult to assess. Microbial communities may have contributed to mound accretion as primary builders and/or mud producers, but their presence cannot be documented. We suggest that they may have acted as agents for concurrent sponge petrefaction and early cementation (biodiagenesis) during the sulfate-reduction phase under alkaline pH and anoxic conditions. We interpret stromatactis as a spar body that resulted from early marine cementation of a cavity network created by excavation of uncemented material in partly indurated, decaying sponges and spicule-rich organic mats derived from degradation of sponge communities through circulation of interstitial water in the uppermost few meters of the sediments. This cavity network was connected to sea floor and flushed by oxic waters that changed the diagenetic environment from anoxic to oxic, converting amorphous iron sulfide to hematite and giving the facies its red color. Recognition of the dominant role of sponge communities in the construction of red stromatactis limestone mounds of the Cambrian-Devonian time interval has important implications for the geological record. This community was the main deep-water mound-building community during this time, but it is difficult to recognize because of its variable but often poor preservation.^1";

The oldest stromatoporoid in this community, Pseudostylodictyon lamottense (Seely), occurs in the Day Point Formation, the lowest in the group. Just above the base of the succeeding Crown Point Formation three species of Labechia [L. eatoni (Seely), L. cf. L. pustulosa (Safford) and L. prima n.sp.] and one species of Pachystylostroma (P. goodsellense n.sp.) appear. By late Crown Point time the fauna has attained a diversity of nine species including a new species of Labechia (L. valcourensis) and three new species of Pachystylostroma (P. vallum, P. pollicellum, and P. champlainensis). * The first stromatoporoids had denticled laminae and large irregular cysts. This genus (Pseudostyiodictyon) appears to have
```

```
given rise to forms with clearly differentiated laminae and cysts and
superposed denticles (Pachystylostroma) and to forms which combine
cysts and round pillars (Labechia). Solid pillars were formed by the
superposition of denticles and hollow pillars through the superposition
of erupted denticles. However the state of preservation may also
determine whether pillars are expressed as solid rods, hollow tubes or
columns of spar without walls.^1";
s[2142] = "LAUB R.S. (1983).- An annotated list of New York Silurian
corals.- FC&P 12, 1: 4-11.- <b>FC&#038;P 12-1</b>, p. 4,
ID=6171^<b>Topic(s): </b>taxonomy, annotated list of taxa; corals;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>USA, New York^Following is a list of the coral
species known or supposed to occur in the Silurian rocks of New York.
It represents part of a paper discussing the status of New York
Silurian coral biostratigraphy, to be included in the field guides for
the Fourth International Symposium on Fossil Cnidaria. The full paper
will include the stratigraphic distributions of each species. This list
is offered here in the hope that it may prove useful to specialists who
do not obtain the field guide. * The name next to each marginal number
is that which seems most correct or useful in light of our current
knowledge of the available specimens. Indented beneath each name are
citations of references to New York Silurian material believed to
pertain to that species. For brevity, only the first page of each
reference, and no indication of illustrations, is given. As indicated,
many of the reports are tentative identifications kindly provided by
William A. Oliver, Jr. (U.S. Geological Survey, Washington, D.C.),
based upon his own as-yet unpublished work. * Where known, the
catalogue numbers of the specimens on which each reference was based
are given following each citation. The prefixes attached to these
catalogue numbers indicate the following repository institutions: *
AMNH American Museum of Natural History, New York, New York; * NYSM New
York State Museum, Albany, New York; * USNM United States National
Museum of Natural History, Washington, D.C.; * YPM Peabody Museum of
Natural History, Yale University, New Haven, Connecticut. [introductory
part of a paper]^1";

biostratigraphy of the Devonian of New York and adjacent areas.-
Devonian biostratigraphy of New York [Oliver W. A. Jr. &#038; Klapper
G. (eds); Subcomission on Devonian stratigraphy; Washington, D.C.]:
97-105.- <b>FC&#038;P 13-1</b>, p. 38, ID=0462^<b>Topic(s):
</b>biostratigraphy; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>USA, New York^Rugose
corals are of little value for intercontinental correlations but are
useful for correlation within basins or biogeographic provinces. In
Devonian rocks of the northern Appalachian Basin (New York and adjacent
areas), 12 stratigraphically useful rugose coral assemblages are
recognized. These assemblages vary in the degree to which they are
controlled by facies and in the amount of time that they represent
(resolving power), but some are widespread and are more useful
stratigraphically than other fossils for correlations within the basin
or province.^1";
s[2149] = "SORAUF J.E. (2001).- External morphology and paleobiology of
Heliophyllum halli (Zoantharia, Rugosa), from the Middle Devonian
Hamilton Group of New York State.- Journal of Paleontology 75, 1:
24-33.- <b>FC&#038;P 30-2</b>, p. 19, ID=1539^<b>Topic(s):
</b>morphology, biology; Rugosa, Heliophyllum; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian M; <b>Geography:
</b>USA, New York^Heliophyllum halli contains variable, mostly solitary
rugose corals. Specimens reported here come from shaly beds of the
Middle Devonian Hamilton Group in New York State. Early recognition of
morphotype variation led James Hall to establish numerous species in
the H. halli group that were later interpreted by John Wells in terms
of varying life history. Life on unstable and/or soft substrates was
facilitated for these corals by talons, root-like structures that
allowed larval settling and post-larval development on hard particles
such as echinoderm or shell debris. Variation in subsequent growth
history is reflected in corallum shape and change in diameter. Straight
growth axes reflect partial burial accompanied by vertical growth,
while growth axis curvature resulted from unequal settling into
substrate or alternatively, life at the surface of substrate, with
sharp bends (geniculations) reflecting major changes in growth
orientation. Decrease in diameter resulted from environmental stress,
with greatest effects on the peripheral portion of the calice. Other
major reactions to increased burial rate (through sinking or increased
sedimentation) are epithecal secretion to form an outer wall for
isolation of itself from surrounding sediment or decrease in polyp size
as shown by terminal shrinking of the corallum diameter, at times
nearly to zero. Yonge&#039;s (1940) summary of observations on living
coral polyps suggests that the living H. halli was nonzooxanthellate,
```

```
with an efficient system of feeding that utilized its multitude of
tentacles without the help of cilia, which thus were able to generate
currents to promote efficient sediment cleansing. Sediment shedding
would also have been aided by polypal distension (swelling) above a
reflexed calical margin.^1";
s[2150] = "OLIVER W.A.jr (2001).- Anomalous occurrence of a colonial
rugose coral (Cnidaria; Anthozoa; Rugosa), in the Devonian Black Shale,
Central New York.- Bulletin Biological Society of Washington 10:

</b>ecology; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>USA, New York^A hand
sized specimen of a colonial rugose coral, Prismatophyllum foetidum,
new species, was collected from black shale of the Middle Devonian
Union Springs Formation in Onandagan County, New York. The coral could
not have grown in the black, fetid, mud environment indicated by the
shale and it most likely originated in the Seneca Member of the
Onandaga Limestone that uncomformably underlies the Union Springs. If
so, it is only the second specimen of colonial rugosan known from the
Seneca. The new specimen is congeneric, but clearly not conspecific
with the previously known specimen.^1";
s[2151] = "OLIVER W.A.jr, SORAUF J.E. (2002).- The genus Heliophyllum
(Anthozoa, Rugosa) in the Upper Middle Devonian (Givetian) of New
York.- Bulletins of American Paleontology 362: 1-72.- <b>FC&#038;P
31-2</b>, p. 40, ID=1678^<b>Topic(s): </b>; Rugosa, Heliophyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Giv; <b>Geography: </b>USA, New York^Specimens of the genus
Heliophyllum are among the most common components of the upper Middle
Devonian coral fauna (Givetian; Hamilton Group and Tully Limestone) in
New York State. Although these corals are abundant and widespread,
examination of large numbers of specimens indicate that most of them
belong in a single, variable species, H. halli Milne-Edwards and Haime,
including both solitary and colonial forms. This study has resulted in
the recognition of four subspecies of H. halli, the solitary H. halli
halli, and three colonial subspecies, H. halli confluens (Hall), H.
halli bellonense n. subsp., and H. halli joshuense n. subsp. The three
colonial subspecies occur in restricted stratigraphic positions, each
in a coral bed in which it is associated and intergrades with solitary
H. halli halli.Two additional species of Heliophyllum are recognized in
the Hamilton, the small solitary H. cribellum n.sp. and the dendroid
branching H. delicatum Oliver and Sorauf. The former has been found
only in the Centerfield Limestone, lower Ludlowville Formation; the
latter is limited to the lower Deep Run Shale, Moscow
Formation.Heliophyllum halli flourished in muddy but well-oxygenated
parts of the Hamilton sea floor because basal, rootlike structures
(talons) and shape adaptations helped keep the living polyp from being
overwhelmed by the mud. Septal carinae are thought to have helped
anchor the polyps in their calices, perhaps making it easier for them
to remove any sediments that accumulated on the oral
surface.Heliophyllum cribellum is common in the Centerfield Limestone,
which represents a more calcareous, relatively stable sea floor, while
H. delicatum seems to have adapted to a more muddy, subsiding sea floor
by fast upward growth. However, both species were associated with
solitary H. halli halli, a further indication of the great adaptability
of the species. ^1";

(Devonian Rugose corals) from New York and Ohio.- Journal of
Paleontology 68, 6: 1183-1201.- <b>FC&#038;P 24-1</b>, p. 62,
ID=4477^<b>Topic(s): </b>branching; Rugosa, Heliophyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>USA, New York, Ohio^Solitary species of Heliophyllum
are the most common form of the genus but branching and massive
colonies do occur, especially in Middle Devonian strata of eastern
North America. Heliophyllum delicatum n.sp. offsets laterally and has a
dendroid, broad bushy growth form. The species is known only from
western and west-central New York and appears to be limited to the
lower part of the Deep Run Shale Member of the Moscow Formation (middle
Givetian); specimens are common within this restricted geographic and
stratigraphic range. The skeleton of H. delicatum was poorly designed
for the common coral environments of the Devonian, but seems to have
```

```
been well adapted to muddy, carbonate-poor conditions where its thin
skeletal elements required less calcium carbonate and its unsupported
branches were not subject to vigorous water movement. Heliophyllum
stewarti n.sp. is based on a single specimen from the Tenmile Creek
Dolomite (middle Givetian) in northwestern Ohio. The colony is
phaceloid but each branch is an astreoid cluster without walls between
individual corallites. In addition, the apparent protocorallite is
turbinate with a larger diameter than any of the ceratoid offsets
although offset lengths are several times that of the protocorallite.^1";

```

```
analysis of two contemporaneous species of the stromatoporoid
Habrostroma from the Lower Devonian of New York.- Bulletin of the
Tohoku University Museum 1 [Proceedings of the 8th International
Symposium on Fossil Cnidaria and Porifera]: 279-284.- <b>FC&#038;P
30-2</b>, p. 33, ID=1601^<b>Topic(s): </b>morphometry, multivariate
analysis; stroms, morphometry; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>USA, New York^Two species of Habrostroma dominate the
stromatoporoid fauna of the Manlius and Coeymans Formations (Lower
Devonian, Lochkovian) of New York. In the past, Stock has discriminated
between these two species on the basis of localized, cystlike
microlaminae within the skeleton. Those with more than 37% of the
skeleton containing the cystlike microlaminae were placed in
Habrostroma microporum, whereas those with less than 34% of the
skeleton containing the cystlike microlaminae were placed in H.
centrotum. All other skeletal structures typically used in
stromatoporoid species identification failed to yield consistent
differences among species examined. However, Stock was uncomfortable
with this classification, so a statistical analysis was carried out to
confirm the earlier decisions. Measurements of nine morphologies from
103 specimens of Habrostroma were subjected to a hierarchical cluster
analysis. Using the average linkage between groups, two distinct
clusters were revealed. Group assignments made from the cluster
analysis were saved and entered into a canonical discriminant analysis
along with the nine morphological variables. An overall Wilk&#39;s
lambda was calculated, and is statistical significant at alpha <.001.
The hit rate for classifying group one was 95.5%, while that of group
two was 98%, and the total hit rate was 97.09%. The morphological
variable contributing the most to the classification of the two groups
was the percentage of the skeleton occupied by cystlike microlaminae,
the criterion regarded most important in Stock&#39;s earlier studies;
the second-best classifier was laminar thickness. Both morphological
variables were statistical significant at alpha=.01. The statistics
confirm that there are two species, H. centrotum, and H. consimile.^1";

krekovi (Yavorsky). Although previously reported from the Coeymans,
Coenostelodictyon jewetti (Girty) was not found. Species
identifications were based on qualitative traditional methods,
supplemented by statistics. The assemblage bears affinities with
Lochkovian faunas in Virginia and the Canadian Arctic.^1";
s[2167] = "BRETT C.E., COTTRELL J.F. (1982).- Substrate specificity in
the Devonian tabulate coral Pleurodictyum.- Lethaia 15: 247-262.-
<b>FC&#038;P 12-1</b>, p. 39, ID=1919^<b>Topic(s): </b>ecology;
Tabulata, Pleurodictyum; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>USA, New York^The
tabulate coral Pleurodictyum americanum Roemer has been cited as an
example of a host-specific organism occurring exclusively on the shells
of gastropods, particularly Palaeozygopleura hamiltoniae (Hall).
Examination of over 1600 specimens of P. americanum from the Middle
Devonian Hamilton Group of western New York reveals additional
complexities which require reinterpretation. While substrate
selectivity for Palaeozygopleura shells is evident in all 42
subsamples, a variety of other substrates were also utilized by
Pleurodictyum including corals, brachiopods, other molluscs and
pebbles. Recent scleractinian corals inhabitating soft bottoms show
similar substrate preference, selecting for the tubes of live
serpulids, or gastropod shells (invariably with a secondary sipunculid
host), but also occasionally settling on unoccupied shells or pebbles.
Shell surfaces of P. hamiltoniae, preserved as external molds on the
Pleurodiatywn epitheca, exhibit encrustations by worm tubes and
bryozoans as well as borings and mechanical shell damage, suggesting
that these were not the shells of live gastropods. However, the
invariant aperture-downward orientation and the high degree of
selectivity of P. americanum strongly suggests that the shells were
occupied by secondary hosts. ^1";

Mutvei&#039;s solution: an ideal agent for resolving microgrowth
structures of biogenic carbonates.- Palaeogeography, Palaeoclimatology,
Palaeoecology 228, 1-2: 149-166.- <b>FC&#038;P 34</b>, p. 24,
ID=7252^<b>Topic(s): </b>carbonates biogenic; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>^Accretionary hard parts of
many organisms provide excellent archives of past climate and
environmental conditions or life history traits. Variable growth rates
function as environmental and physiological proxies, and growth
increments as calendars. Recognition of growth structures is thus a
prime necessity for sclerochronological studies. Here we present a new,
handy, easy-to-use and time-efficient technique that resolves annual
and sub-annual growth structures in skeletons of a wide range of
different organisms. Mutvei&#039;s solution simultaneously etches
biogenic carbonates and calcium phosphates, fixates the soluble and
insoluble organic matrices and fibers, and stains mucopolysaccharides.
It produces a filigreed three-dimensional relief of etch-resistant
ridges (growth lines) and etched depressions (growth increments) and
stains skeletal growth structures in shadings of blue. Growth lines
stand out as crisp, darker-blue stained lines. Reflected optical light
microscopy (axial and oblique illumination) and scanning electron
microscopy can be used to analyze the microgrowth structures. We
demonstrate the use of the technique on hard tissues of various marine
and freshwater bivalves, a coral, a sclerosponge, a barnacle,
gastropods, a cephalopod, a fish otolith and a whale&#039;s ear bone.
This technique may be of interest for paleoclimatologists, geochemists
and biologists. It can significantly expand the use of biogenic hard
parts as environmental and physiological indicators because it reveals
microgrowth structures of biogenic skeletons that potentially form on a
periodic basis and thus function as calendars.^1";

corals in the Oriskany Sands (Lower Devonian) of New York.- Bulletin
New York State Museum 481: 265-287.- <b>FC&#038;P 24-1</b>, p. 66,
ID=4485^<b>Topic(s): </b>ecology; Tabulata, Favositida; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>USA, New York^Corals are rare in quartz sandstones of any age, and
are particularly rare in the medium - to coarse grained quartz
sandstone facies of Pragian age in the Appalachians. The occurrence of
well-preserved specimens of Favosites (&#34;Emmonsia&#34;) spp. in the
Oriskany Sandstone in a local area of central New York provides the
opportunity to re-analyze the Oriskany depositional environment and
comment on the meaning of &#34;Emmonsia&#34; The preservation and
details of occurrence of the corals suggest that they essentially grew
where found. They were moved and, in many cases, overturned, but lived
in the turbulent, nearshore depositional environment of the sandstone.
It is concluded herein that &#34;Emmonsia&#34; is a morphologic stage
in the development of many lineages of Favosites. However, the
near-restriction of the morphology to the biogeographic Eastern
Americas Realm indicates a more complex history. Either Eastern
American and Old World Favosites were genetically different, or
intrinsic or extrinsic factors caused the &#34;Emmonsia&#34; morphology
to be preferentially expressed in the American biogeographic area.
Favosites (&#34;Emmonsia&#34;) alternata n.sp. with two morphologic
variants (forms A and B) and F. (&#34;E.&#34;) congesta n.sp. are
described.^1";

</b>distribution; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Permian L; <b>Geography: </b>Pangea W &#47; NW^The
Pangaean landmass separated Cisuralian (Early Permian) colonial rugose
coral faunas into the Tethyan Realm, characterized by the exclusive
development of Kepingophyllidae Wu and Zhou, 1982, and Waagenophyllidae
Wang, 1950, and the Cordilleran-Arctic-Uralian (CAU) Realm,
characterized by Durhaminidae Minato and Kato, 1965, and Kleopatrinidae
fam. nov. Both realms also contain Lithostrotionidae d&#039;Orbigny,
1852, and Petalaxidae Fomichev, 1953. Within the four families in the
CAU Realm we recognize 20 genera, of which four are new (Sandolasma,
Cordillerastraea, Iskutella, and Shastalasma), and 156 species, of
which 14 are new (Sandolasma elegans, S.? cooperi, S. stonei,
Pararachnastraea lyallensis, P. wilsoni, Cordillerastraea complexa,
Iskutella gunningi, I. stikinensis, Heintzella borealis,
Protowentzelella columellata, Kleopatrina grinnellensis, Permastraea
buttensis, Tschussovskenia dilata, and Lytvophyllum sustutense).
Twenty-three previously described corals are unassigned because of
insufficient data. [first part of extensive summary]^1";
s[2181] = "STEVENS C.H. (2009).- New occurrences of Permian corals from
the McCloud Belt in western North America.- Palaeontologia Electronica
12, 2: 6A: 16./palaeo-electronica.org/2009_2/175/index.html.-
<b>FC&#038;P 36</b>, p. 66, ID=6462^<b>Topic(s): </b>new records;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>USA W^Previously unreported Permian
rugose corals from several terranes considered part of the McCloud Belt
are herein described and figured. These include two species from the
Eastern Klamath terrane, one of which is described as new; four species
from the Central Belt of the Northern Sierra Nevada, with two
additional species thought to have been derived from that terrane; four
species from the Bilk Creek terrane; and two species from the Harper
Ranch subterrane of the Quesnel terrane, one of which is described as
new. * Permian species of Lytvophyllum? and Cystolonsdaleia are now
reported from almost all parts of the dispersed McCloud Belt, and
Heterocaninia? is now known from the Bilk Creek terrane in addition to
the Eastern Klamath terrane. These newly reported occurrences
strengthen the interpretation that these terranes were closely
associated during Early Permian time. None of these genera, however,
occur anywhere along the Pangaean margin of North America. *
Conversely, Protowentzelella and Tschussovskenia, which are abundantly
represented in Lower Permian rocks all along the western and northern
margins of cratonal North America, are rare in rocks of the McCloud
Belt. These faunal differences suggest that the terranes of the McCloud
Belt lay far out in the Paleopacific Ocean, far west of cratonal North
America during the Early Permian so that faunal exchange was minimal.^1";
s[2182] = "STEVENS C.H. (2010).- New Early Permian colonial rugose
corals from the central Cordilleran miogeocline, USA.- Journal of
Paleontology 84, 3: 529-537.- <b>FC&#038;P 36</b>, p. 68,

<b>Geography: </b>USA W^Three species groups, including two groups of
corals and one of fusulinids, delineate the zone of favorable marine
environments for these animals along the shelves bordering southwestern
Laurentia during the Cisuralian (Early Permian). The three species
groups are: the coral Protowentzelella group of late Asselian to early
Sakmarian age, the fusulinid Eoparafusulina linearis group of late
Sakmarian age, and the coral Pararachnastraea illipahensis group of
late Artinskian to Kungurian age. Occurrences of these three species
groups clearly outline most of the major paleotectonic features that
were present along the southwestern margin of the Laurentian shelf at
that time. The paucity of data in Mexico, however, leaves open the
question of large-scale displacement on the Mojave-Sonora megashear, a
feature proposed to cut across northern Mexico and southwestern USA,
although the data presented here could be construed to suggest lack of
significant displacement in post-Pennsylvanian time.^1";

affinities and paleogeography of Stromatomorpha Smith, a distinctive
Upper Triassic reef-adapted demosponge.- Journal of Paleontology 83, 5:
783-793.- <b>FC&#038;P 36</b>, p. 40, ID=6409^<b>Topic(s):
</b>systematics; Porifera Demospongiae; <b>Systematics: </b>Porifera;
Demospongiae; <b>Stratigraphy: </b>Triassic Nor; <b>Geography: </b>USA
W^Stromatomorpha californica Smith is a massive, calcified, tropical to
subtropical organism of the Late Triassic that produced small
biostromes and contributed in building some reefs. It comes from the
displaced terranes of Cordilleran North America (Eastern Klamath
terrane, Alexander terrane, and Wrangellia). This shallow-water
organism formed small laminar masses and sometimes patch reefs. It was
first referred to the order Spongiomorphidae but was considered to be a
coral. Other affinities that have been proposed include hydrozoan,
stomatoporoid, sclerosponge, and chambered sponge. Part of the problem
was diagenesis that resulted in dissolution of the siliceous spicules
and/or replaced them with calcite. Well-preserved dendroclone spicules
found during study of newly discovered specimens necessitate an
assignment of Stromatomorpha californica to the demosponge order
Orchocladina Rauff. Restudy of examples from the Northern Calcareous
Alps extends the distribution of this species to the Tethys, where it
was an important secondary framework builder in Upper Triassic
(Norian-Rhaetian) reef complexes. Revisions of Stromatomorpha
```

```
    californica produce much wider pantropical distribution, mirroring
    paleogeographic patterns revealed for other tropical Triassic taxa.
    Review of Liassic material from the Jurassic of Morocco, previously
    assigned to Stromatomorpha californica Smith var. columnaris Le Maitre,
    cannot be sustained. Species previously included in Stromatomorpha are:
    S. stylifera Frech (type species, Rhaetian), S. actinostromoides Boiko
    (Norian), S. californica Smith (Norian), S. oncescui Balters
    (Ladinian-Carnian), S. pamirica Boiko (Norian), S. rhaetica Kuhn
    (Rhaetian), S. stromatoporoides Frech, and S. tenuiramosa Boiko
    (Norian). Stromatomorpha rhaetica Kuhn described from the Rhaetian of
    Vorarlberg, Austria shows no major difference from S. californica. An
    example described as S. oncescui Balters from the Ladinian-Carnian of
    the Rarau Mountains, Romania, is very similar to S. californica in
    exhibiting similar spicule types. However, because of the greater
    distance between individual pillars, horizontal layers, and the older
    age, S. oncescui is retained as a separate species. The net-like and
    regular skeleton of Spongiomorpha sanpozanensis Yabe and Sugiyama, from
    the Upper Triassic of Sambosan (Tosa, Japan), suggests a closer
    alliance with Stromatomorpha, and this taxon possibly could be the same
    as S. californica.^1";

<b>FC&#038;P 33-1</b>, p. 94, ID=7240^<b>Topic(s): </b>bryozoan mounds;
reefs; <b>Systematics: </b>Bryozoa; <b>Stratigraphy: </b>Ordovician U;
<b>Geography: </b>USA, Vermont^The stratigraphy of the Day Point
Formation (Middle-Upper Ordovician Chazy Group) is complex, and shows
lateral changes in lithology that produce sequences that are unique at
different localities around the Champlain Valley. This unit contains
bryozoan mounds or reefs built by Batostoma and Champlainopora species.
In the lower portion of the formation, the bryozoan mounds and
non-mound layers are often found on top of quartzose sand beds, or
within the sand. In contrast, no sand is found in the upper Day Point,
yet the bryozoan mounds also flourish. The Day Point Formation bryozoan
reefs, especially the one exposed on Garden Island, NY are the
geologically oldest in North America. They were built mostly by
encrusting Batostoma chazyensis and branching Champlainopora
chazyensis, in differing vertical and lateral relationships, that had
frame-building, sediment-binding, and sediment-forming roles. Nine
additional bryozoan species which are taxonomically updated herein,
functioned as minor accessories in the sedimentology of these
build-ups. Six lithofacies that represent various lagoonal, bar &#47;
shoal, and subtidal environments are recognized in the Day Point. These
include: (1) highly bioturbated sandstone with symmetrical and
bifurcating ripples; (2) bioturbated, brachiopod-rich wackestone; (3)
planar crossbedded, interlayered sandstone and sandy packstone; (4)
interlayered sandstone and shale grading into sand and limestone
layers; (5) grainstone, which at some localities, contains bryozoan
mounds, and at other localities, thin non-mound sheet-like layers, and
planar-laminated and cross-bedded packstone; (6 ) fine-grained
calcareous sandstone with planar and herringbone cross-bedding, which
in places contains small bryozoan mounds. This study has revealed more
laterally discontinuous sand units in the lower portion of the Day
Point Formation than noted by previous studies. There are repeated
sequences of sandstone units succeeded by deeper water (subtidal, open
shelf) carbonates in the Day Point, which we interpret to be a series
of transgressive cycles. We hypothesize that sedimentation of the sand
stopped as a result of a rise in sea level within each cycle. The
deeper water induced the accumulation of carbonate sediments, causing
the water depth to decrease and allowed sand to accumulate again.
Hydraulic variations may explain both the lithologic sequences and the
faunal relationships observed in mounds within the Day Point Formation.
The Day Point mounds are significantly different from Middle Ordovician
bryozoan reefs described elsewhere in the Appalachians. They are older,
contain a less diverse bryozoan fauna, and are smaller than bryozoan
reefs in the Holston, Rockdell, and Carters Limestones. They are more
similar in structure and composition to Middle Ordovician bryozoan
mounds in Pennsylvania, Virginia, and Oklahoma, and indeed also
resemble living Bahamian bryozoan reefs. [original abstract]^1";

<b>Geography: </b>USA, Vermont^Marine diagenetic calcite with both a
calcitic (low-to-intermediate Mg) and aragonitic origin was examined
from the middle Ordovician buildups of the Chazy Group in Vermont. All
marine phases have elevated Sr (up to 1800 ppm) compared with that
observed from marine precipitates in other middle Ordovician units.
Stromatoporoids (labechiids) which were originally aragonitic, have
higher Sr values than phases with an original calcite mineralogy
(trilobites, marine cement). Additional evidence supporting precursor
mineralogy interpretations includes elevated Mg values (up to 3.6 mole%
MgCO3) and the presence of microdolomite in interpreted calcitic
phases. Originally aragonitic precipitates have lower Mg values and
most significantly lack microdolomite. This study demonstrates the
presence of elevated Sr values in marine precipitates that formed
during a period when calcite, not aragonite, was the dominant
physiochemically precipitated calcium carbonate mineralogy that formed
from sea water. Elevated Sr is attributable to at least a partially
open system diagenetic stabilization of biogenic aragonite.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician M; <b>Geography:
</b>USA, Vermont^Fossiliferous mounds of carbonate muds are a
distinctive facies in middle Chazy Group (Crown Point Formation) at
Isle La Motte, Lake Champlain. The mounds are surrounded by bedded
calcarenite of spar cemented pelmatozoan debris. Channels which cut
into the mounds during mound growth are filled with the same
calcarenite. The mud free intermound rocks and the mound biota suggest
agitated, normal marine shallow-water environments. The principal
lime-secreting organisms within the mounds are stromatoporoids,
calcareous algae, tabulate corals, sponges and bryozoans. Each mound is
dominated in terms of biomass by one of three groups: stromatoporoids,
calcareous algae and bryozoans. Most of the mound biota first appear at
the base of the Crown Point Formation. In the lower Crown Point
Formation, the organisms increase in number and species. Both changes
in the biota are related to periods of shallowing of the Chazy Sea
which are also reflected in the character of the carbonate sands.^1";

Ptenophyllidae; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Silurian Devonian; <b>Geography: </b>America, ENA^A morphologic
sequence of ptenophyllid corals in Upper Silurian (Pridolian) and Lower
Devonian (Lochkovian) strata in New York and the central Appalachian
Mountains poses problems in the recognition, definition and naming of
genera. Ptenophyllids occur in the fine-grained, stromatiporoidal
limestone facies that crosses the system boundary. Specimens of
Embolophyllum are especially common in the Pridolian but
morphologically similar forms occur in the Lochkovian. Embolophyllum
generally has complete septa but, near the Pridolian-Lochkovian
boundary, ptenophyllids with peripherally incomplete septa are common
and, above the boundary, many specimens have a broad dissepimentarium
that entirely lacks septa. Using conventional morphological criteria,
the transitional morphotype might be referred to Dubrovia and the
younger from to Spongophylyloides. I consider it more likely that, in
the Appalachians, the three forms bear ancestor-descendant
relationship, and that biologically, the younger two should not be
assigned to the established genera they resemble. However, naming new
genera that can only be recognized locally is equally unsatisfactory
and there seems to be no way to suggest the postulated relationship in
Linnéan terms. The overall pattern is similar to what might be expected
from reticulate evolution.^1";

</b>endemites, phylogeny; Rugosa, endemites; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>America, ENA^Several families of rugosans, endemic to the Devonian
Eastern Americas Realm, are well enough known to justify an analysis of
both family- and genus-level relationships. Cladistic methods are used
to test ideas on evolution within three recently monographed families
with varied results. The analyses are most valuable in providing
justification for, or raising questions about, the results of earlier
studies. Genera of the Zaphrentidae and Craspedophyllidae are analyzed
both separately and as one unit because the families are considered to
be closely related. Several outgroups were tried; most successful was
the genus Phaulactis which has been mentioned elsewhere as a possible
zaphrentid ancestor. Results of the analyses are compatible with
earlier studies based on conventional, &#34;Simpsonian&#34; methods,
and support a near relationship between the two EAR families. Cladistic
analysis of the Siphonophrentidae is less satisfactory. No outgroup is
evident so a hypothetical &#34;primitive&#34; siphonophrentid, based on
conventional ideas of morphologic trends, is substituted. The value of
the analysis is in the questions raised about the importance of some of
the characters used. A discussion of family relationships is based on
comparative morphology, known stratigraphic ranges, and apparent
trends. Cladistic analysis at this level is impractical because of the
paucity of data and the lack of any general agreement on rugosan
classification at the family level.^1";

<b>Stratigraphy: </b>Devonian; <b>Geography: </b>America, ENA^Several
models showing possible evolutionary relationships of the genera of two
small families of Early and Middle Devonian rugose corals are analyzed.
Cladograms based on parsimonious character transpositions disagree with
what is evident in the paleontologic record and are rejected. Those
based on the record, using character state polarization where the
record is not clear, are more satisfactory even though much less
parsimonious. The apparent failure of cladistic methods in this
analysis reflects the low number of available morphologic characters
and the number of these characters that are convergent. This is a
common problem in fossil invertebrates, and it is suggested that the
principal value of cladistics in such groups is to force a more
rigorous consideration of the characters on which taxa are based.^1";

21, ID=1126^<b>Topic(s): </b>biostratigraphy, biogeography; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>Canada, Nova Scotia^The Upper part
of the Windsor Group, Nova Scotia, includes limestone members which are
of great value for local lithostratigraphic correlation. Three of them,
the Ryan Brook, the Herbert River and the Kennetcook Limestone, contain
rugose corals. The Ryan Brook Limestone Member has yielded only one
species of Siphonodendron, suggesting a possible Upper Viséan age. The
Herbert River Limestone Member marks the base of the upper part of the
Windsor Group. It is locally rich in Rugosa and yielded species
belonging to Siphonodendron, Nemistium, Lonsdaleia, Axophyllum,
Dibunophyllum, Koninckophyllum, a colonial Koninckophyllum and
Palastraea. Most of the corals were collected in boulders in the Mahone
Bay area, SW Nova Scotia. These taxa indicate Brigantian age, as
previously suggested by foraminifera, and are similar to those known in
Ireland, suggesting close relations between Nova Scotia and the
Irish-North England basin. The Kennetcook Limestone Member is at the
top of the Windsor Group. It contains only solitary corals belonging to
Amplexizaphrentis and Turbinatocaninia. This fauna, rich in specimens
but poorly diversified, is known in the Serpukhovian of the Russian
platform.^1";

This bed appears to have formed as a result of the destruction of a coral thicket by one or more severe storms over a relatively short period of time. The coralla surfaces were &#34;sand-blasted&#34; during the storm(s) and smoothed. The shattered thicket was then subjected to bioerosion for an estimated period of 25-30 years, before being buried relatively quickly by an influx of sediment, possibly by a migrating sand wave. The coral grew upon and was in turn grown upon by a variety of encrusting organisms including barnacles, bryozoans and oysters. The coral bed is continuous with both overlying and underlying assemblages allowing reconstruction of its paleoenvironmental setting and history. Fossil Septastrea crassa thickets preserved elsewhere display different patterns of physical wear and bioerosion, indicating that this coral bed experienced a different mode of formation.^1";
s[2226] = "NEWTON C.R., MULLINS H.T., GARDULSKI A.F., HINE A.C., DIX G.R. (1987).- Coral mounds on the West Florida slope: unanswered questions regarding the development of deep-water banks.- Palaios 02: 359-367.- <b>FC&#038;P 23-2.1</b>, p. 66, ID=4430^<b>Topic(s): </b>coral mounds; coral mounds, Lophelia; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>USA, Florida^Late Pleistocene deep-water coral mounds of 10-15m relief occur in a 20km linear zone parallel to the 500m isobath along the West Florida carbonate-ramp slope. These relict mounds were constructed by the densely calcified, ahermatypic framework builder, Lophelia prolifera, and provided habitats for a host of associated invertebrates, including epizoans, epifaunal commensal organisms, nestlers and crevice dwellers, and macroendoliths. Scleractinian diversity and taxonomic composition are congruent with those of other
```

```
Lophelia buildups in the North Atlantic, particularly buildups in the
eastern Atlantic. The scleractinians also retain primary mineralogic,
isotopic, and trace-element geochemical signatures, indicating
relatively little diagenetic alteration, despite &#34;dead&#34;
(>40,000 years b.p.) radiocarbon ages. The small but rapidly expanding
global data base on deep-water coral mounds has magnified two key
questions concerning the ecologic and environmental controls on mound
nucleation, growth, and death. First, what are the principal ecologic
controls on dominance within communities of deep-water framework
builders? Second, why are there so many relict and so few living
deep-water mounds in the modern ocean? Ecological and paleoecological
investigation of these questions would elucidate much about the
dynamics of deep-water mound growth.^1";

s[2228] = "SORAUF J.E. (2010).- Colonial form, free-living corals, and
macroborers from the Pleistocene of South Florida.- Palaeoworld 19,
3-4: 426-434.- <b>FC&#038;P 36</b>, p. 106, ID=6537^<b>Topic(s):
</b>morphology, ecology; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>USA,
Florida^Study of corallum shape in free-living colonies of Manicina,
Siderastrea and Solenastraea collected from the Pleistocene Bermont
formation in southern Florida indicates that they were mobile, either
self-righting (Manicina), or rotatory (Siderastrea and Solenastraea),
with colony forms that are the result of movement during growth. In
rotatory corals, growth of a radial and centrifugal nature away from
the corallum center indicates that rolling was frequent enough to
maintain the health of individual corallites along the skeleton&#039;s
entire spherical surface, as postulated previously by several authors.
Post mortem sponge boring and boring of sipunculid worms and the
bivalves Lithophaga and Gastrochaena during the life of these colonies
were common. Colonization by barnacles during the life of some colonies
also occurred, but they were generally overgrown. Boring of rotatory
coralla decreased the mass of the skeleton and probably increased the
ease and frequency of rolling of round colonies. The presence of these
rotatory coralla strongly suggests that the lower Bermont sediments
accumulated on and around shallow banks populated by numerous
free-living corals and some fixed corals such as branching Porites,
along with a diverse molluscan assemblage indicative of a Thalassia
(turtle grass) community. The Pleistocene Bermont Formation also
contains numerous well-preserved colonies of Manicina areolata,
indicative of deposition in shallow subtidal environments with abundant
sea grass. This species was well-suited to life in this environment,
and to overturning by current action, as it has the capacity to right
itself after overturning, either biologically or hydrodynamically or
both. The Bermont specimens of Manicina all (100%) possess a flat or
slightly concave base, typical of self-righting forms. Colonies
collected in the Bermont Formation show several types of macroborers,
sponges, sipunculid worms, but above all, the bivalve genera Lithophaga
and Gastrochaena as well as epibionts, bryozoans and serpulid worms.
Manicina is associated stratigraphically with rotatory colonies of
```

```
Siderastrea radians, but the two have not been found within the same lamina. However, the two, taken together, provide strong indications of depositional environments on banks populated by sea grasses and associated fauna. [original abstract]^1";

Fifty-one of the species are in the order Scleractinia and one in the order Milleporina. Five new species are proposed, and these are Diploria sarasotana, Thysanus floridanus, Dichocoenia caloosahatcheensis, Dichocoenia eminens, and Isophyllia? desotoensis. The salient characters of the several formations are depicted, and their ages, as determined by both biogeologic and radiometric dating, are analyzed and compared.^1";
s[2234] = "CUNNINGHAM K.J., RIGBY J.K., WACKER M.A., CURRAN H.A. (2007).- First documentation of tidal-channel sponge biostromes (upper Pleistocene, southeastern Florida).- Geology 35, 5: 475-478.- <b>FC&#038;P 35</b>, p. 41, ID=2318^<b>Topic(s): </b>biostromes; Porifera, biostromes; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>USA, Florida^Sponges are not a common principal component of Cenozoic reefs and are more typically dominant in deep-water and/or cold-water localities. Here we report the discovery of extensive upper Pleistocene shallow-marine, tropical sponge biostromes from the Miami Limestone of southeastern Florida built by a new ceractinomorph demosponge. These upright, barrel- to vase-shaped sponges occur in monospecific aggregations constructed within the tidal channels of an oolitic tidal-bar belt similar to modern examples on the Great Bahama Bank. The biostromes appear to have a ribbon-like geometry, with densely spaced sponges populating a paleochannel along a 3.5 km extent in the most lengthy biostrome. These are very large (as high as 2m and 1.8m in diameter), particularly
```

```
well-preserved calcified sponges with walls as hard as concrete. Quartz
grains are the most common particles agglutinated in the structure of
the sponge walls. Where exposed, sediment fill between the sponges is
commonly a highly burrowed or cross-bedded ooid-bearing grainstone and,
locally, quartz sand. It is postulated that the dense, localized
distribution of these particular sponges was due to a slight edge over
competitors for food or energy supply and space in a stressed
environment of tidal-influenced salinity and nutrient changes, strong
currents, and frequently shifting submarine sand dunes. To our
knowledge, this represents the first documentation of sponge biostromes
composed of very large upright sponges within high-energy tidal
channels between ooid shoals. The remarkably well-preserved
accumulations provide an alternative example of sponge reefs for
comparative paleoenvironmental studies.^1";
s[2235] = "GREENSTEIN B.J., PANDOLFI J.M. (2003).- Taphonomic
alteration of reef corals; effects of reef environment and coral growth
form. II. The Florida Keys.- Palaios 18, 6: 495-509.- <b>FC&#038;P
33-1</b>, p. 86, ID=7233^<b>Topic(s): </b>hermatypic, taphonomy; reef
corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Holocene; <b>Geography: </b>USA, Florida^In a companion study to
earlier work in the Indo-Pacific [Pandolfi &#038; Greenstein 1997],
taphonomic alteration in reef-coral death assemblages was assessed in
four distinct reef habitats ranging from 2-30m water depth in the
Florida Keys reef tract. Physical and biological taphonomic attributes
measured from coral specimens showed great variability with respect to
reef environment. Physico-chemical degradation (abrasion and
dissolution) was greatest in reef-crest and patch-reef environments.
With the exception of encrusting foraminifera, coverage by epi- and
endobionts was higher in deep-reef environments (20m and 30m).
Variability in dissolution and abrasion is likely the result of the
different energy regimes present in the reef habitats examined.
Variability in biological attributes results from a combination of
increased residence time of coral skeletons on substrates in deep-reef
environments, higher overall coral skeletal densities of corals
inhabiting deep reef environments, and increased nutrient availability
in the deep reefs sampled. Clear gradients in the degree of taphonomic
alteration of reef corals with reef habitat indicate the utility of
corals as taphofacies indicators in ancient reef settings. In contrast
to shallow-water reefs on the Great Barrier Reef, taphonomic alteration
of corals in the Florida Keys was equitable across growth forms.

s[2236] = "SWART P.K., DODGE R.E., HUDSON H.J. (1996).- A 240-Year
Stable Oxygen and Carbon Isotopic Record in a Coral from South Florida:
Implications for the Prediction of Precipitation in Southern Florida.-
Palaios 11: 362-375.- <b>FC&#038;P 26-1</b>, p. 59,
ID=3630^<b>Topic(s): </b>stable isotopes, C O; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>USA, Florida^This study reports on the
&#948;18O and &#948;13C composition of the skeleton from a 240-year-old
specimen of Montastraea faveolata growing in Biscayne National Park,
South Florida. Annual variations in the &#948;18O of the skeleton
deposited during the summer months show a bimodal correlation with
summer rainfall. During wetter years, the &#948;18O of the coral
skeleton and the amount of precipitation during the summer months are
inversely correlated (r = - 0. 7) reflecting dilution of the seawater
by meteoric water lower in &#948;18O. During years in which summer
rainfall is less than normal, increases in precipitation are positively
correlated with skeletal &#948;18O (r = +0. 6) reflecting the input of
freshwater from the Everglades higher in &#948;18O. Based on this
correlation the &#948;18O record of the coral skeleton suggests that
the 19th and 18th centuries have been relatively dry compared to the
20th century. Carbon isotopic compositions of the skeleton are
positively correlated with &#948;18O with the minimum in &#948;13C
```

```
occurring several months after the minimum in &#948;18O. Since the mid
1930s there has been a decrease in &#948;13C of the skeleton.
Explanations for this trend may be (1) it reflects the increased input
of carbon derived from the destruction of terrestrial ecosystems, (2)
it is part of a long-term decrease in &#948;13C associated with
increased addition of fossil fuel-derived CO2.^1";
s[2237] = "GHIOLD J., ENOS P. (1982).- Carbonate production of the
coral Diploria labyrinthiformis in South Florida patch reefs.- Marine
Geol. 45: 281-296.- <b>FC&#038;P 11-1</b>, p. 57, ID=6132^<b>Topic(s):
</b>Scleractinia; carbonate production; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>USA,
Florida^Average annual production of CaCO3 (aragonite) by the
hermatypic coral Diploria labyrinthiformis in the Florida reef tract is
11.8 ±0.3 kg/m2 of reef space occupied by the coral. Annual production
was estimated from a population of 271 Diploria colonies measured in
situ. The mass produced annually is the volume of annual growth times
the skeletal density. Cores of 31 Diplopia colonies were slabbed and
X-rayed to reveal annual growth bands. The mean vertical growth rate is
0.35 - 0.06 cm/yr for skeletal density bands representing up to 24
years of growth. The annual volume of growth is approximated by a
simple geometric shell whose thickness is determined by the horizontal
and vertical growth rates of the colony. Horizontal growth rates are
estimated from the ratio of the two lateral axes to the vertical axis.
Bulk density determined by dry weight/volume of 9 cyclindrical cores is
1.64 ± 0.13 g/cm3. Productivity of 11.8 kg/m2/yr for area occupied by
the coral does not vary appreciably among a nearshore patch reef and
two outer-shelf patch reefs. For comparison, production rates for 244
Porites astreoides near Key West, Florida, is 14 ± 3.3 kg/m2/yr for
area occupied by the coral. The 271 colonies of D. labyrinthiformis
potentially produce sediment which, if spread evenly, would accumulate
at a rate of 0.026 m/103 yr for 9008 m3 of reef surveyed. Potential
vertical accretion by all corals for the patch reef surveyed is
estimated at 2.2 to 6.6 m/103 yr. [original summary]^1";
s[2238] = "PARKINSON R.W. (1989).- Decelerating Holocene Sea-level Rise
and its Influence on Southwest Florida Coastal Evolution: A
Transgressive &#47; Regressive Stratigraphy.- Journal of sedimentary
Petrology 59, 6: 960-972.- <b>FC&#038;P 19-1.1</b>, p. 58,
ID=2678^<b>Topic(s): </b>eustacy, mangrove coast history;
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>USA, Florida^The Ten Thousand Islands (TTI) are a myriad of
low-relief mangrove islands that lie along the low energy, subtropical
southwest Florida coast. The region has been subjected to a relative
rise in Holocene sea level, which has continuously decelerated to its
present rate. Data derived from surface and subsurface sampling
indicate that the Holocene sediment package of the TTI area consists of
two sediment sequences. The lower sequence is transgressive and was
generated as coastal salt marsh and &#47; or terrestrial environments
[which] were submerged and replaced by a shallow coastal marine
setting. The upper sediment sequence consists primarily of 1) biogenic
shallowing upwards sequences or 2) thickened mangrove peat layers,
reflecting island emergence and shoreline stabilization, respectively.
Island emergence compartmentalized the area, further reducing wave and
current energy and promoting the infilling of the protected bays
through deposition of organic-rich shelly mudstone and wackestone.
Based on coastal stratigraphy and 14C dates, the formation of this
transgressive &#47; regressive sediment sequence is directly related to
changing rates of Holocene sea-level rise, reported to have occurred
between 3,500 and 3,200 YBP. Continued regressive sedimentation could
eventually generate a 5-10 m thick transgressive &#47; regressive
sediment couplet, with an aerial extent of over 300 km2, in roughly
10,000 years. This externally forced sediment couplet compares
remarkably well to individual small scale transgressive &#47;
regressive cycles which repeat tens to hundreds of times throughout the
```

```
geologic record (see James 1984). The results of this study thus
support the allocyclic mechanism as a viable working hypothesis for the
generation of these small scale rock cycles.^1";
s[2239] = "TOSCANO M.A., LUNDBERG J. (1998).- Early Holocene sea-level
record from submerged fossil reefs on the southeast Florida margin.-
Geology 26, 3: 255-258.- <b>FC&#038;P 27-1</b>, p. 121,
ID=3880^<b>Topic(s): </b>reef outliers, geochronometry, eustacy; reef
outliers; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>USA, Florida^Massive fossil (outlier) reefs are
preserved seaward of the modem shelf and reef tract along the southeast
Florida margin. Thermal ionization mass-spectrometric (TMS) U-Th dating
of 16 pristine Acropora palmata and head corals cored from two
transects document early Holocene reef growth from 8.9 to 5.0 ka, from
approximately -13.5 to -7 m MSL (mean sea level). These samples fill a
gap in the Florida Keys sea-level database and clarify the timing of a
significant decrease in the rate of sea-level rise. A portion of this
interval, represented by a gap in the Caribbean record of A. palmata
reefs, has been interpreted as reef drowning during an inferred
catastrophic sea-level rise event of >45 mm/yr, or 6.5 m rise between
7.6 and 7.2 ka, attributed to West Antarctic Ice Sheet instability and
changes in marine ice extent between 8 and 7 ka. Continuous in situ
shallow-water reef growth in Florida during this interval precludes the
occurrence of exceedingly rapid rates of sea-level rise and is
consistent with the North Atlantic record of deglaciation from 9 to 7
ka. Gaps in the early Holocene sea-level records for Florida and the
Caribbean are thus more likely to be artifacts of limited sampling
and/or core coverage, and not necessarily a result of drowning.^1";

Anthozoa; <b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>USA,
Nevada^Numerous Early Cambrian corals or &#34;coralomorphs&#34;, as
they are often classified, are recorded from North America, Australia,
and Siberia. A new Early Cambrian coral, Harklessia yuenglingensis
n.gen. et sp., is found in conjunction with archaeocyathan-microbial
reef in Esmeralda County, southwestern Nevada. The coral-bearing reefs
are within quartzic, trilobite-rich packstone beds in the upper portion
of the Harkless Formation (Bonnia-Olenellus Zone). Coralla are
constructed by subpolygonal to polygonal, cerioid, close-packed
corallite tubes. Coralla average 12cm in height by 18cm in diameter
with individual corallite tubes ranging from 1.2 to 3.2mm in diameter.
Corallites are greater than 25mm in length. Septa and tabulae are not
present. Many of the Early Cambrian corals previously described have
attributes of the class Anthozoa and subclass Zoantharia, with some
specific similarities to tabulate corals. Harklessia yuenglinggenis is
placed confidently within the class Anthozoa, subclass Zoantharia
because its morphological characteristics indicate an affinity to true
corals, but whether H. yuenglingernis is a tabulate coral remains
uncertain.^1";
s[2246] = "TYNAN M. (1981).- Microfossils from the Lower Cambrian
Campito and Poleta Formation, White Inyo Mountains, California.- US
Geol. Surv. Open File Report 81-743 [Second International Symposium on
the Cambrian System, Golden, Colorado]: 231.- <b>FC&#038;P 11-1</b>, p.
56, ID=6130^<b>Topic(s): </b>; paleontology; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Cambrian L; <b>Geography:
</b>USA, California^[the author proposed a new order of Zoantharia for
&#034;septate tubes&#034; which are interpreted as solitary corallites
of a maximum diameter of 1mm for 5mm in length; septal insertion
pattern is said bilateral and cyclic as in scleractinian corals, but
the corallites apparently lack any axial structures, tabulae,
dissepiments, septal groves, counter cardinal septum and so it is
highly dubious if they constitute &#034;the oldest occurrence of stony
corals from the United States&#034;]^1";
s[2247] = "TYNAN M.C. (1983).- Coral-like microfossils from the Lower
Cambrian of California.- Journal of Paleontology 57, 6: 1188-1211.-
<b>FC&#038;P 13-1</b>, p. 23, ID=0401^<b>Topic(s): </b>microfossils,
new order; microfossils coral - like; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>USA,
California^A distinctive group of longitudinally septate, bilaterally
symmetrical, phosphatic, tubular microfossil, the Paiutiida n.ord.,
have been discovered to occur in archaeocyathid-bearing carbonate units
of the Lower Cambrian Campito and Poleta formations, White Mountains,
Inyo County, California. Possible anthozoan affinity is suggested for
the organisms that once occupied these coral-like microfossils. The
```

```
tubules are solitary, commonly cylindrical, and rarely exceed a maximum
of 1 mm in diameter, or 5 mm in length. A thin epitheca-like layer may
be present, and the exterior tubule surface is smooth or weakly
annulate. The tubule wall is 0.02-0.05 mm thick and composed of
fluorapatite. Tubules are characterized by the presence of Although
fundamental compositional and structural differences in skeletal
morphology exist among the several Cambrian coral-like groups, and
between the later evolved skeleton-secreting anthozoan orders, the
basic coral architectural plan is recognizable. It is suggested that
all of the groups stem from a common Precambrian ancestral form, but
that each arose iteratively from later evolved anemone stocks. Thus,
fossils assigned to the new order Paiutiida are included in the
subphylum Cnidaria, and questionably assigned to the class Anthozoa.
Subclass-level assignment remains uncertain due to the unique
compositional and morphological characteristics of the paiutiid
skeleton.Paiutitubulites variabilis n.gen., n.sp., and P. durhami n.sp.
arecharacterized by the presence of well-developed secondary
septa(secondary as defined herein); Cambrptubulites trisepta
n.gen.,n.sp. and specimens assigned to the genus lack secondary
septa.These genera and forms questionably assigned to them are
characterized by the absence or weak development of septal grooves.,
which isa diagnostic feature of the Paiutitubulitidae n.fam. The
Paiutitubulitidae is defined to exclude problematical tubules:-
displaying a septa! arrangement pattern that is convergent upon that of
cnidarian groups that appear to display tetrameral symmetry.These
problematical specimens are considered as a separate species,and
familial-level classification is uncertain pending furtherstudy,
although assignment to the Paiutiida is unquestioned.(Original summary)

Cnidaria, Tabuloconus; <b>Systematics: </b>Cnidaria; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>USA, Alaska^Numerous specimens of
Tabuloconus Handfield. 1969, have been collected in carbonate buildups
within the Adams Argillite (Early Cambrian, Tatonduk area, Alaska). The
wall structure of this form has been investigated, along with
contemporaneous archaeocyathids and algae, through the use of polished
ultra-thin sections (2-3 µm thick) and scanning electron microscopy.
The results of this microstructural comparison indicate that despite
diagenetic alteration Tabuloconus has a skeleton that is unlike any
presently known and is quite distinct from associated algae and
archaeocyathids. It is more elaborate than that found in the
archaeocyathids but has not reached the stage of complexity seen in the
primitive coral Cothonion Jell &#038; Jell, 1976. The presence of some
elongated units may represent an initial step towards the fibrous
skeleton typical of Paleozoic corals. This study shows that even though
```

```
diagenesis alters the original microstructure of calcareous skeletons, the resultant fabric and detailed structures can be useful in systematic descriptions. Tabuloconus is removed from the Gastroconidae Korda due to the presence of rudimentary septa and constitution of the tabularium. A number of species assigned to the genus Bacatocyathus Vologdin and included within the Archaeocyatha appear to be examples of Tabuloconus or very close relatives. An emended description of Tabuloconus kordae, the type species, is proposed.^1";

Middle Ordovician), northern Rocky Mountains of British Columbia.-
Geol. Surv. Canada Bull. 491: 78-93.- <b>FC&#038;P 27-1</b>, p. 69,
ID=3663^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>Canada,
British Columbia^All corals known from slope deposits of the Advance
Formation are solitary rugosans. Paliphyllum norfordi n.sp.,
represented by a single specimen, and Grewingkia burdenetisis n.sp.,
which is more common, are the only identifiable species. Diversity and
abundance are low compared with the taxonomically different coral fauna
in approximately coeval shelf deposits of the Johnson Spring Formation,
California. Grewingkia burdenensis is considered to be the ancestor of
Grewingkia robusta, a Late Ordovician species that was widely
distributed within the Red River-Stony Mountain Province of cratonic
North America. Paliphyllum norfordi is the earliest paliphyllid
worldwide, and the only rugosan with dissepiments known from the Middle
Ordovician of North America. It appears to be most similar to some
representatives of Paliphyllum in the Dolbor Formation (uppermost
Caradoc-lowermost Ashgill), Siberian Platform. Coralla of G.
burdenensis were subject to little current action or transportation.
This species generally lived freely on soft substrates; sediment
cohesion may have been low. In one stratigraphic interval, the presence
of specimens with attachment structures suggests that the substrate may
have been unfavourable for the coral&#039;s normal mode of life, or
that more objects suitable for attachment were available than usual.
The corallum of P. norfordi was subject to higher current energy and
possibly transportation, and &#47; or longer exposure before final
burial. This coral was overturned, possibly due to current activity or
substrate instability or both, and redirected its growth upward several
times during life. It is the earliest North American solitary rugosan
that had the ability to resume upward growth after being fully
overturned.^1";

Ordovician to Lowermost Silurian solitary rugose corals from the
Beaverfoot Formation, southern Rocky Mountains, British Columbia and
Alberta.- Contr. Canad. Paleont., Geol. Surv. Canada 379: 47-91.-
<b>FC&#038;P 17-2</b>, p. 27, ID=2181^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician U
- Silurian L; <b>Geography: </b>Canada, Rocky Mts^Salvadorea distincta
distincta (Wilson 1926), Salvadorea sp. 2 of Nelson 1981, Bighornia
patella (Wilson 1926), B. cf. B. bottei Nelson 1963, Grewingkia haysii
haysil (Meek 1865), and Deiracorallium prolongatum (Wilson 1926) are
present within the Upper Ordovician Bighornia-Thaerodonta Zone of the
Beaverfoot Formation. Bighornia wilsonae sp.nov., is recognized from
the Montoya Group (Second Value Dolomite) of New Mexico and Texas, and
the Red River Formation (Selkirk Member) of southern Manitoba.
Paleoecological analyses suggest that Grewingkia haysii haysii and
Deiracorallium prolongatum inhabited higher energy environments than
Salvadorea distincta distincta and Bighornia patella, but all taxa
probably lived in close proximity. The Beaverfoot Formation accumulated
within the Red River - Stony Mountain Solitary Coral Province. Solitary
rugosan species in the Bighornia-Thaerodonta Zone represent an
&#34;epicontinental&#34; assemblage, and all occur in the Hudson Bay
Basin. The absence of &#34;continental margin&#34; taxa could indicate
that the formation was deposited some distance from the edge of the
continent, or could reflect environmental factors or geographic
barriers. The lowest occurrence of solitary Rugosa defines the base of
the Bighornia-Thaerodonta Zone in the Beaverfoot Formation (Whisky
Trail Member). Elsewhere such Salvadorea-dominated coral assemblages
first appear in Maysvillian to middle Richmondian strata. The zone has
been traced to 420 feet (128 m) above the base of the Beaverfoot at
Akutlak Creek; its top is probably Richmondian but could be Gamachian.
Solitary Rugosa in the thick, combined &#34;poorly fossiliferous
interval&#34; and Eostropheodonta Zone of the Beaverfoot Formation are
completely different from those of the underlying Bighornia-Thaerodonta
Zone. Rhegmaphyllum could be Upper Ordovician (Richmondian, Gamachian)
to Lower Silurian (Lower Llandovery). Dinophyllum could be Lower to
Middle Llandovery. Streptelasma is also present.^1";

reefs; <b>Systematics: </b>Porifera Cyanophyta; Sphinctozoa;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>USA, Alaska Alexander
terrane^Upper Silurian (Ludlovian) limestones from the Heceta Formation
of southeastern Alaska (Alexander terrane) contain skeletal
stromatolite reefs and stromatolite mud mounds that were colonized by
sphinctozoa sponges. Internal growth cavities, synsedimentary marine
cements, and stromatolite debris flows in slope deposits indicate that
theses reefs grew with relief at the seaward margin of the carbonate
platform. The biotas under study have evolutionary significance because
they contain the earliest widespread reef-building sphinctozoans and
represent a previously unrecognized stage in the evolution of
Phanerozoic microbial-metazoan (predominantly poriferan) reefs. On the
basis of the presence of Silurian stromatolite-sphinctozoan deposits in
southeastern Alaska, southwestern and west-central Alaska, and the
Urals, this study also establishes a Late Silurian palaeobiogeographic
connection between the Alexander terrane, cratonic northwestern North
America, and the Uralian region.^1";

associations in Silurian microbial reefs.- Palaios 18, 3: 225-235.-
<b>FC&#038;P 33-1</b>, p. 99, ID=7242^<b>Topic(s): </b>ecology,
parasitism?; sponges; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>USA, Alaska, Russia^Microbial
boundstones from Alaska and Russia yield new insights into the
paleoecology of Silurian biotas that inhabited stromatolite reefs.
These high-energy reefs were built along the Uralian Seaway in the Late
Silurian by a diverse suite of microorganisms in association with
accessory metazoans, predominantly sphinctozoan sponges. Within the
stromatolite framework, three species of small, solitary, sphinctozoans
(aphrosalpingids) encrusted a variety of hard substrates, mostly
skeletal remains but also microbial laminae and cavity surfaces.
Fossils encrusted by the sponges include the problematic hydroid
Fistulella, possible stromatoporoids (re-crystallized), crinoids, the
possible cyanobacterium Ludlovia, corals, and unidentifiable shelly
debris. In addition to the ubiquitous microbial laminae, the sponges,
Fistulella, and ?stromatoporoids were less commonly encrusted by
Ludlovia, Renalcis, or crinoids. Well-developed attachment surfaces,
including enlarged holdfasts, allowed the sponges to achieve stability
on the seafloor after larvae settled randomly on available hard
surfaces. A greater incidence of sponge encrustations on Fistulella
than on other organisms indicates that some of the sponges may have
enjoyed a commensalistic relationship while attached as juveniles to a
living substrate. The sponges orientation on Fistulella in the sediment
suggests that the relationship between the two taxa may have become
parasitic, whereby the weight of the sponges caused Fistulella to
collapse into the muddy substrate. Recognition of the intimate growth
relationships shared by Silurian sphinctozoans, Fistulella, and other
organisms expands the fossil record of encrusting sponges, identifies a
novel sponge-?hydroid association, and reveals organismal responses to
competition for space in mid-Paleozoic microbial reefs. [original

geomorphology; <b>Systematics: </b>; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>USA, Alaska Alexander terrane^Lower to Upper Silurian
(upper Llandovery-Ludlow) limestones belonging to the Heceta Formation
record several episodes of reef growth in the Alexander terrane of
southeastern Alaska. As the oldest carbonates of widespread
distribution in the region, the Heceta limestones represent the
earliest development of a shallow-marine platform within the Alexander
arc and the oldest foundation for reef evolution. The excellent
preservation of biostromes, fringing and barrier reefs, and a mud mound
in shelf, shelf margin, and slope deposits, respectively, contrasts
with the restricted occurrence of many marine sediments that originated
within other island arcs. Hence, these deposits provide important
insights into the dynamic processes, styles, and bathymetry associated
with reef growth in tectonically active oceanic islands. Massive
stromatoporoids, corals, and red algae are preserved in fragmental
rudstones and represent a fringing reef that formed at the seaward edge
of the incipient marine shelf. Accessory constituents in this reef
include crinoids and the cyanobacterium Girvanella. Small biostromes
were constructed by ramose corals and stromatoporoids on oncolitic
substrates in backreef or lagoonal environments. These buildups were
associated with low-diversity assemblages of brachiopods and with
gastropods, amphiporids, calcareous algae and cyanobacteria. Microbial
boundstones reflect the widespread encrustation of cyanobacteria and
calcified rnicroproblematica on shelly debris as stromatolitic mats
that resulted in the development of a stromatactoid-bearing mud mound
and a barrier reef complex. Epiphytaceans, other microbes, and
aphrosalpingid sponges were the primary framebuilders of the barrier
reefs. These buildups attained significant relief at the shelf margin
and shed detritus as slumped blocks and debris flows into deep-water
sites along the slope. The similarity of these
stromatolitic-aphrosalpingid reefs to those from Siluro-Devonian strata
of autochthonous southwestern Alaska suggests paleobiogeographic ties
of the Alexander terrane to cratonal North America during the
Silurian.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian
L; <b>Geography: </b>USA, Nevada^A range chart of some Early Devonian
conodont and graptolite taxa from central Nevada is presented. It is
based on the graphic correlation method of Shaw, and shows correlations
with the established zones for bachiopods and corals as well as
conodonts and graptolites. It indicates that the hesperius through
pesavis conodont zones established for western North America are
approximately equivalent to the Lochkovian of the Czechoslovakia
sequence, and the Pragian begins approximately with the sulcatus zone.
The chart also indicates that the zones based on different groups do
not coincide, are of very unequal duration, and that intervals of rapid
morphologic change correspond to intervals of higher diversity and
greater morphologic variation. Species have significantly different
longevities, generally those originating during time of greatest
morphologic variation being the shorter lived. The approximate duration
of the species studied is 2 to 10 m.y. * Use of the graphic correlation
method permits better correlation of shelf and basin faunas and
enhances the possibility for constructing accurate shelf margin
histories and for correlating provincial shelf faunas with those in
other parts of the world. [original summary]^1";

s[2294] = "PEDDER A.E.H., MURPHY M.A. (2004).- Emsian (Lower Devonian)
Rugose corals of Nevada: Reservoir of systematics and stratigraphic
ranges, and reassessment of faunal provincialism.- Journal of
Paleontology 78, 5: 838-863.- <b>FC&#038;P 33-2</b>, p. 20,
ID=1123^<b>Topic(s): </b>biostratigraphy, biogeography; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Ems; <b>Geography: </b>USA, Nevada^New collection from measured
sections provide much of the material for this study.
Holcocystis,Atopocaystis, and Stummelasma are erected as new genera.
Atopocastis mucronata andStummelasma sulfurense are new species;
Holocystis flexa (Stumm), Stummelasma lonense(Stumm), and S.
antelopense (Merriam) are new combinations. Revised coral ranges are
integratedwith the standard Nevada conodont zones and brachiopod-based
faunal intervals. A range chart for33 Rugosa emphasizes their value for
correlation in Icriodus, or brachiopod-poor biofacies of theGreat
Basin. It also shows that full recovery from the end Lochkovian/early
Pragian coral crisis inthe region was delayed until the start of the
middle Emsian gronbergi Zone. The recovery wasaccomphlished principally
by radiation of the Breviphyllidae and Papilophyllidae, and
byimmigration or cyathophyllid and other genera.Updated lists of Rugosa
genera present in the Great Basin, Mackenzie, and Appohimchi
provincesduring the Pragian and early Emsian (kindley-lenzi zones) and
middle to late Emsian (gronbergiserotinuszones) are given. Qualitative
and quantitative data, the latter as Otsuka Coefficients,indicate that
the Pragian Great Basin coral faunas can no longer be regarded as part
of a temporarywestward extension of the Eastern Americas Realm. Nor can
they be considered part of theMackenzie coral province. Genus
absence/presence data show that the Great Basin coral provincebegan
with a slow recovery of faunas after the late Lochkovian/early Pragian
coral crisis, and endedwith the arrival f typical Old World Realm
families, including the Ptenophyllidae andStringophyllidae, within the
early Eifelian, costatus Zone. During this time faunas of the
Mackenziecoral province were so distinct from those of the exotic
Alexander and Farewell terranes of Alaskaand British Columbia. The
duration of the Devonian Great basin coral province corresponds
closelyto the duration of a period of depressed seawater temperatures
postulated from the distribution ofgypidulinid brachiopods.^1";

```
Mackenzie (Lonely Bay, Nahanni, Headless and Hume formations). The
overlying Givetian carbonate complex of northeastern British Columbia
and southern District of Mackenzie (Presqu&#039;ile Barrier) has only
sparsely developed rugosans, but beds flanking the barrier (upper
Dunedin, Pine Point, Sulphur Point formations) locally develop more
diverse faunas of early-mid Givetian age. Downslope from the barrier
complex, numerous early-mid Givetian pinnacle reefs (upper Keg River,
Horn Plateau formations) bear particularly diverse and abundant rugose
coral assemblages. In the lower Mackenzie River valley of northern
District of Mackenzie a series of reefal complexes of mid-late Givetian
age (Ramparts Formation) carries significant rugosan faunas, especially
in platform and flanking beds.^1";
s[2301] = "PEDDER A.E.H. (2010).- Lower-Middle Devonian rugose coral
faunas of Nevada: Contribution to an understanding of the
&#034;barren&#034; E Zone and Chotec Event in the Great Basin.-
Bulletin of Geosciences 85, 1: 1-26.ISSN 1214-1119.- <b>FC&#038;P
36</b>, p. 62, ID=6454^<b>Topic(s): </b>biostratigraphy; corals;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian L
M; <b>Geography: </b>USA, Nevada^The &#34;lower Middle Devonian&#34;
part of a coral zonation proposed for the region in 1974 comprised in
ascending order D2 and D3 subzones and a &#34;barren&#34; E zone. In
terms of the conodont zonation currently employed in Nevada, the D2
subzone is Emsian gronbergi and inversus zones. The original
stratigraphic definition of the D3 subzone places it in the upper
Emsian serotinus Zone on Lone Mountain, whereas the coral index
defining the zone has been collected subsequently only from Eifelian
upper costatus Zone beds. The original stratigraphic definition of the
&#34;barren&#34; E zone places it in a lower part of the costatus Zone,
above an inferred depositional break. Thus, as defined on Lone
Mountain, the D3 subzone is slightly younger than the E zone. These
zones are not barren. Revised taxonomy and age determinations of
previously described species, coupled with new data from the southern
Sulphur Spring and northern Antelope ranges, have revealed four
successive coral assemblages ranging from serotinus to costatus Zone
age. Differences between the second and third of these assemblages are
particularly significant, and may be considered to represent a local
manifestation of the Chotec Event. A detailed review of the genus
Synaptophyllum shows it to be an Emsian endemic in the
Maghrebo-European Realm, not an early Eifelian endemic in the Eastern
Americas Realm. New taxa comprise a family, one genus and two species.
Romanophyllum paulyi gen. et sp.nov., which possibly represents one of
the last vestiges of the Pragian-Emsian Great Basin coral province, is
assigned to the Romanophyllidae fam. n. Xystriphyllum trojani sp.nov.
is described as an example of one of earliest ptenophyllid species to
return to the Great Basin after the absence of the family from the
region since late Lochkovian time.^1";
s[2302] = "PEDDER A.E.H. (2002).- New systematic and biostratigraphic
data concerning Breviphyllidae (Lower Devonian Rugosa) of Nevada.-
Coral Research Bulletin 7: 141-166. [Dieter Weyer&#039;s 65th birthday
commemorative volume; S. Schröder, H. Löser &#038; K. Oekentorp
(eds)].- <b>FC&#038;P 31-1</b>, p. 60, ID=1627^<b>Topic(s):
</b>biostratigraphy; Rugosa, Breviphrentis; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>USA, Nevada^Previous Lower to Middle Devonian coral biostratigraphy
for Nevada is reviewed. A reassessment of Merriam&#39;s 1974 Emsian
coral assemblages zones indicates that his D1 Subzone is longer ranging
than it was thought to be and his D3 Subzone is probably Middle
Devonian, costatus zone. Composition of the Breviphyllidae Taylor 1951
is revised to include Breviphyllum Stumm 1949, Breviphrentis Stumm
1949, Nevadophyllum Stumm 1937, Ogilviplasma Pedder 1978, Weyerides
gen. Nov., Bartineophyllum gen. nov., and possibly Baoshanophyllum Song
1974 and its probable synonym Puanophyllum Wang 1983. Breviphrentis
kirki, Nevadophyllum eximium, Weyerides salicensis, W. serus and
```

```
Bartineophyllum hassli are erected as new species. Ages of all the
formally described taxa are calibrated against standard conodont
zonations and the Nevada faunal intervals of Johnson (1977).^1";
s[2303] = "PEDDER A.E.H., MURPHY M.A. (2003).- The Papiliophyllidae
(Lower Devonian Rugosa): their systematics and reinterpreted
biostratigraphic value in Nevada.- Journal of Paleontology 77, 4:
601-624.- <b>FC&#038;P 33-1</b>, p. 60, ID=1386^<b>Topic(s):
</b>biostratigraphy; Rugosa, Papiliophyllidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>USA, Nevada^Field work has greatly increased the number of
well-dated papiliophyllid corals available from Nevada. The established
range of the family is expanded from Pragian and lower Emsian to
Pragian and almost the entire Emsian. Ranges of species are calibrated
against Johnson faunal intervals and a revised Pragian and lowermost
Emsian conodont zonation proposed by Murphy for Nevada. Study of all
reposited material has led to some revision of every member of the
family, Eurekaphyllum, previously imperfectly known from a single
specimen of vague stratigraphic origin, is shown to be a useful upper
Emsian index. Nine reported occurrences of the family in Europe and
Asia are re-examined and, except for a possible occurrence on Novaya
Zemlya, all are rejected. The three named genera of the family are
apparently endemic to the southwestern North American craton.
Papiliophyllum elegantulum asymmetricum new subspecies, P. murphyi new
species and Eurekaphyllum vescum new species are described by Pedder.

stratigraphy, Kakwa-Cecilia Lakes, British Columbia, Canada.- Notes et
Mémoires 10, Total, C.F.P. Paris, 80 pp.- <b>FC&#038;P 2-2</b>, p. 17,
ID=4806^<b>Topic(s): </b>stratigraphy; stratigraphy; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>Canada,
British Columbia^After 1968 field reconnaissance, a party spent three
weeks of summer 1969 in the General Kakwa area (British Columbia).
Northward shaling-out of Early Frasnian (Flume carbonates) was detailed
both sedimentologically and paleontologically. Field involvment of
these techniques secured appropriate faunal sampling which permitted
later detailed study of faunal assemblages during winter 1969-1970.
Strata herein studied cover this part of the Frasnian outcrop generally
known as the Flume member and stratigraphically correlate with the
Beaver Hill Lake - Waterways subsurface section, and northeastern
Alberta exposures. The four studied sections exhibit the shaling-out of
Southern carbonates deposited on a shallow open marine shelf. Tentative
build-ups were erected at the margins of the shelf amidst biostromal
banks. Stromatoporas were the major agents responsible for such
reefing. Northerly deepening conditions, or geographical changes in
current regimes, hindered both frame builders&#039; life and carbonate
deposition, favoring shales accumulation. Marine conditions were almost
the same along the horizontal slice of water for bottom dwellers such
as Brachiopods. An extremely rich Brachiopod fauna allows very detailed
correlations between sections spread over a 15 kilometer strip (coupled
with classical coral associations). Part II deals with paleontological
breakdown of the Flume section into five main faunal assemblages. The
quality of collected material is such that the three medial assemblages
are of uppermost value for correlating eastward into the Alberta Plain
subcrop, the well-described outcrop of Waterways, and subsurface of
Northwest Territories. Corals and Brachiopods correlations are extended
to United States. With the help of published Conodont and Cephalopod
evidence, relationship with European zones is tentatively established.
A reevaluation of the full Frasnian biostratigraphic zonation is
proposed in Appendix with emphasis on lower zones, namely DFR2
Ladogioides pax zone, DFR3 Atrypa scutiformis zone (gathering
assemblages II and III), and DFR4 Atrypa gregeri zone.^1";

<b>Geography: </b>USA, Utah^Epibionts Tolypammina ? sp. (Protozoa),
Eridopora sp. (Bryozoa), Petrocrania sp. (Brachiopoda), Spirorbis ? sp.
(Annelida), and Vermiforichnus sp. (Annelida) on the curved conical
coralla of Barytichisma sp. (Coelenterata) show a strong preference for
the concave side of the corallum and are more abundant on the upper
half of the corallum than on the lower half. This distribution helps
confirm Bernard&#039;s (1904) hypothesis that the corallum assumed a
living position lying on its side, after toppling from an early
attached upright growth position, and curved upward from the substrate
in order to maintain an optimum living position later in life. The
distribution also indicates that these epibionts inhabited the host
coralla mostly while the polyps were alive. Epibionts Thallophyta
(algae or fungi) and Bascomella sp. (Arthropoda) established themselves
on the host coralla later than the other epibionts and have a random
distribution with respect to the plane of curvature, indicating that
these organisms inhabited the hosts mainly after death of the polyps.^1";

Ch. favosus is confined to the later Atokan and Ch. milleporaceous to the earliest Desmoinesian in this area, although both taxa enjoy a far greater biozone. Both taxa are restricted further to a few, thin key beds, generally containing many individuals, within their local range. Microfacies and faunal analysis of the Chaetetes biostromes indicate deposition in normal marine waters somewhat below tidal range, at, or just below wave base. Similar rocks and faunal associations, however, occur in the absence of Chaetetes in rocks both below and above the Chaetetes-bearing sequence. Thus the environmental factor restricting Chaetetes distribution remains undetected. * Autoecological study of Chaetetes shows that it required a solid substrate and that it was capable of regeneration after being partially choked by fine -grained sediments. * It is suggested that Ch. favosus and Ch. milleporaceous may be environmentally differentiated forms of the same Mendelian species. Schoenophyllum; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Serp; <b>Geography: </b>Canada^Schoenophyllum has
been described as a columellate, fasciculate genus in which the
corallites bear slender lateral processes regarded as supporting
structures or as tubules connecting adjacent corallites. Recent
investigation of Serpukhovian specimens from the Etherington Formation
and its lateral equivalents in western Canada has shown these lateral
processes to be sub-horizontal to moderately elevated tubule-like
structures forming the initial stages of new offsets and commonly
containing tabulae. They locally reach and may interfere with the walls
of neighbouring corallites, but remain structurally distinct from them
and do not allow communication between parent and adjacent corallites.
The initial, tubule-like stage is followed by a steeply elevated to
vertical, sparsely septate stage in which the axial structure is
developed as a prolongation of the cardinal septum. The origin and
nature of the axial structure suggests assignment of Schoenophyllum to
the family Petalaxidae.^1";

Exceptional preservation of the sponge Fissispongia cloaca from the
Pennsylvanian Holder Formation, New Mexico.- Palaios 11:
559-570.http:&#47;&#47; www.jstor.org/pss/3515191.- <b>FC&#038;P
26-1</b>, p. 75, ID=3650^<b>Topic(s): </b>aragonite; Porifera,
Fissispongia; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Carboniferous U; <b>Geography: </b>USA, New Mexico^Exceptionally
preserved aragonitic demosponge material occurs within the Virgilian
Holder Formation, Sacramento Mountains, south-central New Mexico.
Fissispongia tortacloaca (King) is identified, a species previously
known only from completely calcified specimens. Standard optical
microscopy and SEM examination of broken surfaces of the F. tortacloaca
skeleton distinguishes between primary spherulites and a later
epitaxial overgrowth. F. tortacloaca biomineralization is readily
comparable to that of the modern agelasid demosponge Astrosclera
willeyana, thus confirming the demosponge affinity of this form.
Cathodoluminescence microscopy and back scatter SEM examination
identifies selective silicification and calcitization of the spherulite
centers. These diagenetic minerals affect the initial spherulite
biomineralization mimicking the original microstructural fabric.
Elemental composition of F. tortacloaca (Sr=7600ppm, S=1640ppm and
Mg=150ppm) is close to that of modern A. willeyana (Sr=10,000ppm,
S=1780ppm and Mg=320ppm). Sr concentration in F. tortacloaca indicates
that late Pennsylvanian seawater had slightly less Sr (7ppm) than
modern seawater. S is interpreted as having been incorporated into
sponge aragonite as SO4. The stable isotope composition of F.
tortacloaca d13C=+5.5%; d18O=-2.1‰) is compatible with other Virgilian
skeletal carbonates from the USA, but is about 1‰ heavier than A.
willeyana (d13C=+4.4‰; d18O=-0.8‰). The d18O composition of F.
tortacloaca indicates tropical to subtropical temperatures between
24-30ºC using Grossman and Ku&#039;s expression TºC=20.6-4.34
(d18O-sw): assuming the Pennsylvanian ocean had a d18O composition
similar to modern seawater with an 1.2‰ variation due to glacial ice
volume effects. [original abstract]^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>USA, Nevada^Rugose and tabulate corals from the Lower
Permian (Wolfcampian, Leonardian) Bird Spring Group in the Lee Canyon
section of the Spring Mountains, Clark County, Nevada, are referred to
eight genera and ten species. New taxa are Fomichevella nevadensis
n.sp., F. waltersi n.sp., Mccloudius parvus n.sp., and
Paraheritschioides richi n.sp. The fauna is most similar to the shelf
fauna in eastern Nevada, but there are significant similarities to
corals from the Antler Highland embayments of central Nevada and
southern Idaho and to faunas of the same age in northern California and
northern British Columbia. The paleogeography is interpreted as shallow
water near the east side of the mouth of a south-opening coastal sea,
bordered on the east by the continent and on the west by the Antler
Highland. Corals migrated south along the western shores of the Antler
Highland and mixed with the shelf fauna, perhaps with some corals
crossing from Tethys to the coast. The modern eastern Pacific tropical
coral faunas, which have several hermatypic coral genera and species
derived from the western Pacific in the Pleistocene, may occupy a
somewhat similar geography near the mouth of the modern Gulf of
California.^1";

<b>Geography: </b>USA, California^Examples of the &#34;hydrozoan&#34;
Radiotrabeculopora reticulata Fan, Rigby, and Zhang, 1991 have been
recently recovered from Lower Permian rocks in the Inyo Mountains,
Owens Valley area, of east-central California by G. Linder and C.
Stevens. That genus and species were originally described from the
Middle Permian (Leonardian-Lower Guadalupian) Maokou Formation from
western Hubei, China, by Fan et al. (1991). This is the first report of
the genus and species from North America. * The fossils were collected
from Unit 7 of the Owens Valley Group, US Geological Survey Map I-1932
(Stone et al., 1989). This unit represents a carbonate buildup composed
of wackestones, packstones, and grainstones that formed on an uplift
composed of an Upper Carboniferous-lowermost Permian deepwater
limestone sequence. Basinward, this unit lenses into rocks that
accumulated in deeper water. Fossils from Unit 7, in order of
abundance, include pelmatozoan parts, epimastoporid and phylloid algae,
and fusulinids. Tubiphytes Maslov, 1956, bryozoans, and the
&#034;hydrozoans&#034; are much less common, and brachiopods and corals
are rare. Algae are abundant throughout the section, becoming dominant
in the upper part, where they are associated with the
&#34;hydrozoans&#34;. [initial part of a short note]^1";

ID=1959^<b>Topic(s): </b>new taxa; Rugosa, Diffingiina; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>USA, Texas^Diffingiina subordo n., tentatively included in
Stauriida Verril, 1865, is characterized by the adaxial split of the
inner end of at least one (the cardinal) septum; the development of the
basal plate and the vertical position of the young corallite at the
beginning of its growth; the absence of the septal furrows; the
shortening of the counter septum at least during some part of the
neanic growth; the trabecular microstructure of septa; and the biform
tabularium. The attachment scars have once been illustrated for the
Rugosa, but they were recognized only in this paper. All taxa included
in the suborder are new, because their basic characteristics have not
been reported so far as present in the Rugosa. Two new families have
been established: the monotypic family Plerodiffiidae fam. n.,
containing only a single species Plerodiffia eaglebuttensis sp. n., and
the family Diffingiidae fam. n. subdivided into two subfamilies. In the
monotypic subfamily Diffingiinae subfam. n. seven new species have been
recognized. The presence of two opposite trends in the morphological
development suggests the possibility of further increase in the number
of genera within the subfamily. The subfamily Turgidiffiinae subfam. n.
contains two genera: Turgidiffia gen. n. with three new species and the
new genus and species left in the open nomenclature.^1";

County, northern California, are Lower Permian (Wolfcampian Series),
represent a composite thickness of at least 5.500 feet (about 1.700 m),
and contain rich invertebrate faunas including at least 49 species of
rugose and tabulate corals. 42 species in 17 genera of rugose corals
are described, including four new species. The general generic
composition is characteristic of the Durhaminid Coral Province known
from rocks in the Ural Mountains, Novaya Zemlya, Spitzbergen, Arctic
North America, and western North America as far south as southern
California. Some genera appear to be endemic to western North America.
The corals did not form reefs but were randomly spaced on calcareous
bioclastic substrates in shallow waters of the Cordilleran
eugeosyncline near the Permian paleoequator in an area temporarily
lacking much volcanic sedimentation. [original summary] The tabulate
corals described here are: Bayhaium merriamorum, B. virginiae n.sp.,
Enigmalites roberti n.sp., Michelinia nelsoni n.sp., Neomultithecopora
sandoi n.sp., Syringopora mccutcheonae, S. multattenuata. Among the
Rugosa mostly new species are described; solitary corals (Aulophyllum,
Clisiophyllum, Gshelia, Heterocaninia); fasciculate corals (Durhamina,
Heritschioides, Mccloudius n.gen., Siphonodendron, Yatsengia); cerioid
corals (Bassius n.gen., Dillerium n.gen., Kleopatrina, Kl.
(Porfiriella), Langenheimia n.gen., Petalaxis, Traskina n.gen.);
cerioid-astreoid corals (Arachnastraea).^1";
s[2366] = "RIGBY J.K., SENOWBARI-DARYAN B. (1996).- Gigantospongia, new
genus, the largest known Permian sponge, Capitan Limestone, Guadalupe
Mountains, New Mexico.- Journal of Paleontology 70, 3:

ID=3052^<b>Topic(s): </b>new genus; Porifera Gigantospongia;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>USA, New Mexico^Several specimens of the large,
discoidal, new inozoid genus and species, Gigantospongia discoforma,
have been discovered in the Upper Permian, Upper Capitan Limestone in
the northern Guadalupe Mountains of New Mexico, near Carlsbad Caverns.
The holotype is nearly 2.5m across, as exposed, and ranges from 8-20mm
thick, with numerous canals transverse and parallel to the principal
plane. These canals are approximately 1mm in diameter and separated by
tracts 1-2mm thick. Thickened dermal and gastral layers, each
approximately 1mm thick, occur at tops and bases of both the holotype
and associated paratypes in the &#34;Sponge Window&#34; exposures of
Bat Cave Draw, and in specimens from Chinaberry and Hackberry Draws.
Inverted Lemonea conica Senowbari-Daryan, 1990, is apparently attached
to the base, and appears to have grown inverted in a void formed or
capped by the tabular inozoid. Well-preserved specimens of
Amblysiphonella also appear inverted, as do examples of Lemonea
cylindrica (Girty, 1908), a new species of Lemonea, and Guadalupia
explanata (King, 1943), which occur between the holotype and an
underlying paratype. All appear coated with Archaeolithoporella crusts.
Microstructure of the inozoan skeleton is obscured by diagenesis.

ID=3091^<b>Topic(s): </b>ecology; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>USA, Texas, New
Mexico^The Permian Capitan reef was a predominantly heterotrophic
ecosystem strongly differentiated into open surface and cryptic
communities. Unlike modern phototrophic coralgal reefs, most of the
preservable epibenthos was housed within the cryptos and zonation
developed only in the shallow parts of the reef. Contrary to
established opinion, most sphinctozoan sponges did not grow upright to
form a baffling framework but rather were pendent cryptobionts, as were
nodular bryozoans and rare solitary rugose corals and crinoids. Indeed,
many members of the cryptos were obligate cryptobionts. Much of the
Middle Capitan reef framework was constructed by a scaffolding of large
frondose bryozoans, with the subsidiary platy sphinctozoan Guadalupia
zitteliana. Bathymetrically shallow areas of both the Middle and Upper
Capitan reef, however, were characterized by platy sponges. In parts of
the Upper Capitan, some platy sponges (Gigantospongia discoforma)
reached up to 2 m in diameter and formed the ceilings of huge cavities
which supported an extensive cryptos. In the absence of destructive
forces (both biotic and physical) prevalent on modem reefs, the
relatively fragile Capitan reef remained intact after the death of the
constructing organisms. Rigidity was imparted to this community by a
postmortem encrustation of Tubiphytes and Archaeolithoporella, together
with microbial micrite. The resultant cavernous framework was partially
infilled with sediment and preserved by synsedimentary intergrowth of
aragonitic botryoids and Archaeolithoporella. Extensive cement
precipitation was favoured by a number of factors including deep
anoxia, which generated upwelling waters with elevated alkalinity.
Although the accumulation rate of the Capitan may have been comparable
to that of modern coralgal reefs, both the trophic structure and
relative contributions of iriorganic and organic carbonate were
profoundly different.^1";
s[2370] = "NOE S.U. (1996).- Late-Stage Reef Evolution of the Permian
Reef Complex: Shelf Margin and Outer-Shelf Development of the Tansill
Formation (Late Permian), Northern Guadalupe Mountains, New Mexico,
USA.- Goettinger Arbeiten zur Geologie und Palaeontologie, Special
Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and
Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp
???.- <b>FC&#038;P 26-1</b>, p. 42, ID=3609^<b>Topic(s): </b>geology;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian Guad;
<b>Geography: </b>USA, New Mexico^The outer-shelf of the Tansill
Formation (Late Guadalupian; Kazanian) in the northern Guadalupe
Mountains (Permian Reef Complex, New Mexico, USA), located between the
peritidal pisolitic shelf crest and the submerged shelf margin, is
characterized by a patch reef facies in the seaward part and a
peritidal island facies in its landward part. These isolated buildups
represent the youngest Permian bioconstructions of SW-North America
which formed before the onset of the salinity crisis in the Delaware
Basin during latest Permian (Ochoan evaporites). Three types of patch
reefs were observed: 1) wave resistant calcisponge &#47; algal &#47;
cement reefs of a modified Capitan reef facies located next to the
```

```
shelf margin, 2) partially wave resistant reef mounds scattered across the seaward part of the outer-shelf, and 3) non-wave resistant skeletal mounds restricted to the landward part of the outer-shelf. After the demise of the underlying shelf margin reef rim (&#34;Capitan Reef&#34;) which was caused by a regional relative sealevel drop, increasing salinity in the adjacent Delaware Basin prevented a new formation of a continuous reef rim. Instead, the site of reef building shifted landward onto the shallow outer-shelf, where on-shelf currents and aperiodic precipitation were responsible for effective mixing of water masses and lowering of hyper salinity. Distribution of those patch reefs in space and time documents a progradational pattern reflecting the general shallowing-upward trend and continuous salinity increase during latest Guadalupian.^1";
s[2371] = "WEIDLICH O. (1996).- Comparative Analysis of Late Permian Reefal Limestones From the Capitan Reef (New Mexico, USA) and the Oman Mountains.- Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. The communities correspond to sponge reefs, algal cement reefs, phylloid algal reefs, and probably rugose coral reefs. The carbonate budget (the percentage of macro-reefbuilders, micro-framework, internal sediment, and marine-phreatic cements on the base of field-derived acetate sheets) is characteristic for the different case studies. The quantitative data from the Capitan reef point to dominance of low-growing organisms and marine phreatic cements. The communities from the Oman Mountains are rich in sediment. Taphonomic processes including breakdown of reefbuilders by waves or bioerosion were less important than constructional processes.^1";
s[2372] = "WEIDLICH O., FAGERSTROM J.A. (1998).- Evolution of the Upper Capitan-Massive (Permian), Guadalupe Mountains, New Mexico.- Brigham Young University, Geology Studies 43: 167-187.- <b>FC&#038;P 27-2</b>, p. 79, ID=3948^<b>Topic(s): </b>reef complexes, geohistory; reef complexes; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian; <b>Geography: </b>USA, New Mexico^A photo-transect of the seaward reef tract and six subvertically arranged reef maps covering about 13 m2 of outcrop surface provide digitized images and quantitative data for the interpretation of the evolution of the upper Capitan-massive near Whites City, New Mexico. The seaward reef front consists of a sequence from a phylloid algal sub-community to varied sponge-algal/cement reef sub-communities to a Tubiphytes-dominated reef. Progradational geometries suggested by seaward-shifting of facies boundaries are especially apparent in the Gigantospongia zone due to basinward extension of sheet-like inozoans sheltering elongate cavities. The unit above is characterized by a gradual disintegration of the framework as evidenced by an increase in platform sediment and decrease in framework. In the youngest Tubiphytes-dominated reef stage, only small incrusting reefbuilders constructed the framework, while macro-reefbuilders decreased significantly. Sponge-algal/cement reef sub-communities are the dominant element of the reef front. A quantitative analysis of digitized maps from this sub-community indicates that macro-reefbuilders, chiefly calcareous sponges (1-7%) and phylloid algae (0-3%) formed only a minor part of the framework. Post-mortem biostratonomic processes caused local skeletal breakage and fragment alignment. The most important reef element with an areal cover of 57-96% is the micro-framework, a consortium of low-growing organisms (e.g., Tubiphytes or Archaeolithoporelld) and synsedimetnary, marine-phreatic cements. Open reef cavities were either filled with early diagenetic cements (0-22%) or internal sediment (0-38%) of
```

```
different origins including reef-derived wacke/packstones,
platform-derived grainstones, and/or brownish quartz-rich sediments.
The grainstones locally yield the fusulinid Codonofusiella paradoxica
indicative of an Upper Yates or Lower Tansill age.^1";
s[2373] = "FAGERSTROM J.A., WEIDLICH O. (1999).- Strengths and
Weaknesses of the Reef Guild Concept and Quantitative Data: Application
to the Upper Capitan-Massive Community (Permian), Guadalupe Mountains,
New Mexico-Texas.- Facies 40, 1: 131-156.- <b>FC&#038;P 28-1</b>, p.
63, ID=4005^<b>Topic(s): </b>guild concept; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Permian; <b>Geography: </b>USA, New Mexico,
Texas^Analyses of large acetate sheet tracings, close-up photos and 105
sub-horizontal quadrat surfaces at four localities near the base of the
Guadalupe Mountains Escarpment indicate that the biotic framework of
the upper Capitan reef was built by about 35 species: one codiacean
(Eugonophyllum sp.), 17 calcisponges, 9 bryozoans, one richthofenid
brachiopod, some crinoids (known only from columns), 4 Problematics and
microbes. This widespread fossil community included members of the
Constructor, Baffler and Binder Guilds. A re-evaluation of the Guild
Concept (Fagerstrom 1987, 1991) highlights the validity of the
functional roles of the Constructor and Binder Guilds for reef
construction. Members of the Baffler Guild, however, need to be revised
and an interpretation of microbial micrite and cryptic biota remains
controversial. Open surface phylloid algal and cryptic sponge-bryozoan
dominated sub-communities were of only local importance. The upper
Capitan-massive differs from its Permian counterparts in the low
diversity and areal cover of the frame-building biota, low micrite
content and abundant micro-frameworks, i.e. intergrown small sponges,
Problematica and syndepositional cements (botryoidal and isopachous,
fibrous calcite). [part of extensive aummary]^1";
s[2374] = "HUNT D.W., FITCHEN W.M., KOSA E. (2003).- Syndepositional
deformation of the Permian Capitan reef carbonate platform, Guadalupe
Mountains, New Mexico, USA.- Sedimentary Geology 154, 3-4: 89-126.-
<b>FC&#038;P 33-1</b>, p. 87, ID=7234^<b>Topic(s): </b>reef carbonates,
syndepositional faults; reef carbonates; <b>Systematics: </b>;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>USA, Texas^The average
rate of fault displacement (0.021 m/ka) and the maximum rates of fault
propagation (0.088-0.123 m/ka) were normally less than the platform
accumulation rates (0.053-0.336 m/ka). Thus, the faults were normally
blind and rarely broke the platform top so that slumps and fault-scarp
degradation breccias are rare. The fault zones were substantially
modified by diagenesis during platform development. They are up to 9m
wide, taper both up and downward, have irregular margins and complex
fills mainly of sedimentary origin. Their margins and fill were subject
to extensive modification by karstic(?) &#47; mixing zone dissolution,
gravitational collapse and dolomitising fluids. Consequently, tectonic
fabrics and kinematic indicators are rare. Preserved tectonic fabrics
consistently indicate a normal and reverse dip-slip sense of movement.
Previously, these faults were mistaken for &#34;neptunian&#34; dykes
and fissures, so that the Seven Rivers and Yates 1-2 HFS shelf
stratigraphy has been miscorrelated across them. It is apparent that
the stratal relationships exposed in the Guadalupe Mountains do not
simply preserve the original depositional morphology of the
Capitan-equivalent shelf. The subsidence history, stratigraphy and
development of the platform succession is more complex than previously
thought. The study has important implications for many aspects of the
Capitan system, including: (i) shelf-reef correlations, (ii) the
controls on platform architecture and development, (iii) Capitan reef
palaeobathymetry, (iv) diagenesis, and (v) the amplitude of sea-level
changes affecting the platforms stratigraphic development. [final part

Triassic strata of the lower Baldonnel Formation at Pardonet Hill in
northeastern British Columbia, Canada. These small buildups (~100 to
500 m3) have planar bases and broadly convex tops. These mounds are
interpreted as small patch reefs composed of packstone, bioclastic
floatstone &#47; rudstone and carbonate breccia intercalated with mixed
siliciclastic carbonate sediments deposited in a shallow subtidal
setting (i.e. above fairweather wave base). Amalgamated hummocky
cross-stratified to current ripple-laminated, quartz-dominated
sandstone beds and numerous sharp-based, normally graded bioclastic
(commonly encrinitic) packstone &#47; grainstone-quartz-sandstone
couplets characterize inter-reef lithologies. Conodont biostratigraphy
indicates that the Pardonet Hill patch reefs occur within strata dated
as earliest Upper Carnian (lower nodosus zone). The Pardonet Hill patch
reefs originated and developed during an interval of regional sea level
lowstand. Strata within which these patch reefs occur represent the
westernmost migration of the Triassic shoreline in western Canada.
Disappearance of coral reefs in the study area may have been affected
by rapid marine transgression and failure of reef faunas to recolonize
the new shore zone further to the east. The Pardonet Hill locality
occurred on the western margin of the North American craton during the
Triassic. Prior to their discovery reef-like structures dominated by
corals in the western Panthalassa were limited to allochthonous
terranes (now part of the Cordillera). The Pardonet Hill patch reefs
occur at approximately 30° Triassic paleolatitude. In modern settings,
this is at the extreme latitudinal margin of subtropical zooxanthellate
reef development. The presence of benthic faunas characteristic of
low-paleolatitude settings on the northwestern coast of Pangea has
significant implications in paleotectonic and paleoenvironmental
reconstructions.^1";

ID=2669^<b>Topic(s): </b>taxonomy, biogeography; corals spongiomorphs;
<b>Systematics: </b>Cnidaria Porifera; Anthozoa; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>USA, Oregon Wallowa
terrane^Twenty-one species of corals and three species of spongiomoprhs
occur in a series of richly fossiliferous, molluscan-dominated beds
with silicified bioclasts in the Upper Triassic Martin Bridge Limestone
of Hells Canyon, Oregon. Two of these, Maeandrostylis grandiseptus and
Recticostastraea wallowaensis are new species. Recticostastraea is
designated as a new genus. The Fauna is early Norian and occurs in the
island arc Wallowa terrane, one of many tectonostratigraphic terranes
in western North America. Like other examples, it appears to have
developed independently of the North American craton and to have links
with Wrangellia. The fossil corals and spongiomorphs are
para-autochthonous, occurring in a series of tempestite beds. They are
```

```
interpreted to have inhabited a shallow-water carbonate platform that
developed around a tropical island arc following cessation of volcanic
activity. The corals and spongiomoprhs are associated with abundant
gastropods and a diverse epifaunal suspension-feeding bivalve fauna.
Relative to the corals, branching spongiomorphs, Spongiomorpha ramosa,
are more abundant and occur with relatively common branching, sheet to
plate-like, colonial corals. Solitary corals are relatively rare. The
associated bedded limestone includes a variety of shallow-water
microfacies but throughout the Hells Canyon sequence, reef structure is
absent. Together, the 24 coral and spongiomorph taxa show mixed
paleogeographic affinities with Upper Triassic faunas known only from
alpine regions of the western Tethys (five species), the Pamir
Mountains, USSR (two species), and the island of Timor (one species).
Five additional species are pan-Thethyan and exceptionally
cosmopolitan, but 11 species (45,8 %) occur only in displaced terranes.
Of these, a significant component (six species) is endemic to the
Wallowa terrane. At least four Hells Canyon taxa, previously thought
endemic to North American terranes, have recently been reported from
the high-latitude Koryak terrane of northeastern USSR, a displaced
tropical volcanic terrane of the northwestern Pacific. For Triassic
corals, this is the first example of a clear link between western
Pacific and eastern Pacific terranes. Less similarity exists with the
Wrangell Mountains, Alaska, where identical age lower Norian silicified
corals and spongiomorphs are known.^1";

<b>Systematics: </b>Porifera; Sphinctozoa; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>USA, Oregon^Two Upper Triassic
sphinctozoan sponges of the family Sebargasiidae were recovered from
silicified residues collected in Hells Canyon, Oregon. These sponges
are Amblysiphonella cf A. steinmanni (Haas), known from the Tethys
region and Colospongia whaleni n.sp., an endemic species. The latter
sponge was placed in the superfamily Porata by Seilacher (1962). The
presence of well-preserved cribrate plates in this sponge, in addition
to pores of the chamber walls, is a unique condition never before
reported in any porate sphinctozoans. Aporate counterparts known
primarily from the Triassic Alps have similar cribrate plates but lack
the pores in the chamber walls. The sponges from Hells Canyon are
associated with abundant bivalves and corals of marked Tethyan
affinities and come from a displaced terrane known as the Wallowa
Terrane. It was a tropical island arc suspected to have paleogeographic
relationships with Wrangellia, however these sponges have not yet been
found in any other Cordilleran terrane.^1";

<b>Systematics: </b>Cnidaria; <b>Stratigraphy: </b>Triassic M;
<b>Geography: </b>USA, Nevada^We described three scleractinian corals
and one species of hydrozoan from the New Pass Range, central Nevada,
which together constitute the oldest Triassic cnidarian assemblage from
North America. They occur in carbonate rocks tentatively correlated
with the Augusta Mountain Formation, Star Peak Group. At generic and
higher levels, these cnidarians seem representative of early Mesozoic
Tethyan faunas and carbonate lithofacies, but they indicate some
endemism. Although the original aragonitic skeletons and microstructure
are destroyed by recrystallisation, the corals still yield important
details allowing their correct taxonomic assignment. They contain the
minitrabecular cerioid coral, Ceriostella variabilis new genus and
species, the thick-trabecular, thamnasteroid coral Mesomorpha
newpassensis new species, and an undeterminable cuifastreid coral
tentatively assigned to Cuifastraea. The discovery of Mesomorpha marks
the first occurrence of this genus outside the Jurassic and Cretaceous
seas. Also discovered is a remarkably coral-like hydrozoan,
Cassianastraea reussi (Laube), already known from the Carnian stage of
the western Tethys. This is the first occurrence of this species
outside the western Tethys.^1";

The first Upper Triassic silicified hypercalcified sponges from the
Alexander Terrane, Gravina Island and Keku Strait, southeast Alaska.-
Journal of Paleontology 82, 2: 344-350.- <b>FC&#038;P 35</b>, p. 47,
ID=2329^<b>Topic(s): </b>hypercalcified, taxonomy biogeography;
Porifera hypercalcified; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>USA, Alaska^This paper describes the
first silicified Upper Triassic (Early Norian) hypercalcified sponges
known from the Alexander terrane, southeast Alaska. Sponges consist of
five taxa from the Cornwallis Limestone of Keku Strait, southeast
Alaska: Amblysiphonella Steinmann, Parauvanella Senowbari-Daryan and Di
Stefano, Nevadathalamia cylindrica (Seilacher), N. minima n.sp., and
Stellispongia (S. cf. subsphaerica Dieci, Antonacci, and Zardini). The
```

```
hypercalcified sponges of the Alexander terrane as described in this
paper provide paleogeographic linkage with other far-flung terranes of
western North America, namely the Western Great Basin of Nevada,
Stikinia of the Yukon, as well as the Antimonio terrane of northwestern
Mexico. In addition, Parauvanella cf. ferdowensis is known from the
Upper Triassic Nayband Formation, Iran. Finally Stellispongia cf.
subsphaerica is known from the Upper Carnian Cassian Formation of the
Dolomite Alps. Sponges (particularly hypercalcified inozoans,
sphinctozoans, chaetetids, and sponge-like organisms) are known
worldwide from many Upper Triassic reef and nonreef sites. Although
Upper Triassic deposits within the Cordilleran terranes and cratonal
North America do not typically contain reeflike buildups,
hypercalcifying sponge-like organisms were noted as occurring as part
of the intricate paleoecological structure within a biostrome along the
western shoreline of Gravina Island, southeast Alaska (southern
Alexander terrane). This is in contrast to Keku Strait, southeast
Alaska (central Alexander terrane), where hypercalcified sponges were
identified from limestone beds within nonreef deposits.^1";

upper Triassic patch reefs in the Yukon (Canada).- Palaios 01:
590-600.- <b>FC&#038;P 23-2.1</b>, p. 67, ID=4432^<b>Topic(s):
</b>reefs, morphology; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>Canada, Yukon Territory^Upper
Triassic patch reefs in the southern Yukon include tabular reefs, about
30m thick, and semicircular and elongate reefs, over 100m thick. The
```

```
tabular reefs consist predominantly of framework built by small
calcareous sponges, spongiomorphs, and corals; they are designated as
framework buildups, analogous, in a genetic sense, to modern coral
reefs. On the other hand, framework is a minor component of the
semicircular and elongate reefs, which consist predominantly of
skeletal sediment. The skeletal sediment of these reefs is interpreted
as a local accumulation of small and disarticulated organisms produced
independently of reef framework. Consequently, sediment producers,
rather than framebuilding fossils, are inferred to have been the
primary builders of these structures, designated as sediment buildups
genetically analogous to modern algal bioherms. The sediment buildups
in the Yukon are similar to upper Rhaetian patch reefs in Austria.
However, the origin of the Austrian reefs has been attributed to
framebuilding fossils and sediment producers have not been identified
as important reef builders.^1";

<b>Stratigraphy: </b>Triassic U; <b>Geography: </b>Canada, British
Columbia^Massive Upper Triassic (Norian) reef limestone at Eaglenest
Mountain, Takla Group, British Columbia, contains a wide variety of
shallow-water fossils in two different carbonate units. A sponge-coral
facies contains the sponges Fanthalamia astoma (Seilacher, 1962),
Fanthalamia multicanalis new species, Cinnabaria expansa (Seilacher,
1962), and Cinnabaria? sp. Cinnabaria expansa is a widely distributed
North American terrane species which, along with F. astoma, was
previously known from the Luning Formation of Nevada. Also included is
the &#34;disjectoporoid&#34;, Pamiropora sonorensis Stanley, 1994, and
a massive spongiomorph, Spongiomorpha tenuis Smith, 1927, previously
endemic to the Eastern Klamath terrane of California. Colonial corals
include: Retiophyllia quesneliana new species, Chondrocoenia waltheri
(Frech, 1890), Crassistella cf. juvavica (Frech, 1890), Distichomeandra
cf. austriaca (Frech, 1890), and Alpinophyllia flexuosa Roniewicz,
1989. A limestone conglomerate overlying these beds is dominated almost
exclusively by the planktonic hydrozoan, Heterastridium conglobatum
Reuss, 1865. A problematic taxon Lovcenipora cf. chaetetiformis Vinassa
de Regny, 1915, is reported for the first time outside Timor and the
Tethys. The faunas provide a first glimpse into the reef biota of the
Quesnel terrane. They contain taxa previously known from the distant
Tethys but also include endemics from other inboard terranes. [original

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic
Sine; <b>Geography: </b>Canada, British Columbia^A very early Jurassic
(Sinemurian) coral reef is described from Telkwa Range (British
Columbia, Canada). The 48 m thick bioherm is dominated by large
dendroid/phaceloid corals, mainly Phacelostylophyllum rugosum, also
known from the Upper Triassic of Italy. The reef seems to be the first
Jurassic reef after the end-Triassic mass extinction which profoundly
affected reef ecosystems.^1";
s[2395] = "STANLEY G.D.jr, BEAUVAIS L. (1994).- Corals from an Early
Jurassic coral reef in British Columbia: refuge on an oceanic island
reef.- Lethaia 27: 35-47.- <b>FC&#038;P 24-1</b>, p. 72,
ID=4501^<b>Topic(s): </b>taxonomy, biogeography; corals;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic
Sine; <b>Geography: </b>Canada, British Columbia^An Early Jurassic
(Sinemurian) reef in the Telkwa Range, British Columbia, Canada, yields
coral species previously known from Morocco, Great Britain, Italy,
Peru, and Chile. The principal constructional coral,
Phacelostylophyllum rugosum (Laube), known from the Upper Triassic
Dolomite Alps in northern Italy, is a holdover species. This coral
survived the mass extinctions of the end-Triassic without leaving any
other Jurassic records outside Canada. Other corals from the Telkwa
reef include Stylophyllopsis victoriae (Duncan) and Actinastraea minima
Beauvais known from Jurassic rocks of the Tethys. Closely related
corals, Phacelostylophyllum chocolatensis (Wells) and Actinastraea
plana (Duncan), are from southern Peru. The paleogeographic occurrence
of the Canadian reef in the volcanic terrane of Stikinia supports the
contention that volcanic islands in distant outposts of the ancient
Pacific served as refugia. In the aftermath of the end-Triassic reef
decimation affecting the Tethys, corals and reef building activities
continued on ancient islands of the ancestral Pacific. The Hispanic
Corridor, connecting the western Tethys with the western Pacific, may
have played an important role during Sinemurian time.^1";

Lower Albian Sequence Stratigraphy and Coral Buildups: Glen Rose
Formation, Texas.- SEPM Special Publications 87 [R.W. Scott (ed.):
Cretaceous rudists and carbonate platforms: environmental feedback]:
181-191. ISBN 9781565761278.- <b>FC&#038;P 35</b>, p. 114,
ID=2451^<b>Topic(s): </b>sequence stratigraphy, coral reefs; sequence
stratigraphy; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Cretaceous Alb; <b>Geography: </b>USA, Texas^The Glen Rose
Formation of the Comanchean Series represents the second circum-Gulf
carbonate shelf that extended from Florida to Mexico. The Glen Rose
comprises limestone, dolomite, and thin interbeds of marl and
calcareous shale that overlie the Hensel Sandstone and underlie the
Fredericksburg Group in Texas. The Glen Rose is here formally divided
into Lower and Upper, mappable members separated at the top of the
regionally persistent Corbula Marker, and a boundary stratotype section
is designated. The age of the Glen Rose Formation ranges from latest
Aptian to near the end of the Early Albian, from approximately 113.3 Ma
to 108.0 Ma, and encompasses four ammonite zones. Three local
assemblage zones facilitate correlation of Glen Rose outcrops in Texas.
```

```
The Salenia texana Credner Assemblage Zone spans a marl, 3 to 4 m
thick, with a diverse shelf biota in the upper part of the Lower
Member. The Corbula Range Zone is at the top of the Lower Member. The
Loriola rosana Cooke Assemblage Zone is in the middle part of the Upper
Member. The Glen Rose together with the underlying Hensel Sandstone
comprise at least five medium-scale depositional cycles separated by
transgressive disconformities. Two types of biotic accumulations are
well developed in the Lower Glen Rose Member, coral-rudist assemblages
and caprinid- dominated assemblages. Coral-rudist biostromes crop out
at the Narrows of the Blanco River and had no bathymetric relief and do
not qualify as reefs. Colonial corals are common and are part of a
Tethyan fauna; toucasiids and other mollusks comprise a diverse
assemblage. Coral diversity is underestimated because of incomplete
preservation and sampling. These biostromes are overlain by grainstone
capped by a subaerial contact that serves as a sequence boundary
between cycles one and two. The younger caprinid bioherms at Pipe Creek
have up to 10 m of depositional relief. The bioherm facies grade
landward into shoreface grainstone and seaward into shelf wackestone.
The caprinid species, Coalcomana ramosa, dominates this low-diversity
assemblage and is endemic to the Caribbean Province. The bioherm facies
are overlain by dolomitic, stromatolitic facies with dinosaur tracks.
The contact with the overlying Salenia Zone is a sequence boundary
between cycles two and three. Two more long-term cycles may be
identified in the Upper Glen Rose Member. The coral-rudist biostromes
and the caprinid bioherms formed paleocommunities on the landward ramp
of the interior marine shelf. The coral-rudist biostromes developed
below normal wave base but above storm wave base and shoaled above wave
base and were subaerially exposed. The caprinid bioherms formed on a
ramp and grew into the zone of normal wave action in mainly normal
marine salinities.^1";

Porifera Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Cretaceous Sant; <b>Geography: </b>USA,
California^The new farreid hexactinellid sponge Hormathospongia
dictyota new genus and new species, is described from the upper
Santonian Dobbins Shale Member of the Forbes Formation of the Upper
Cretaceous Great Valley Sequence from the west side of the Sacramento
Valley, northwest of Sacramento. The relatively simple skeleton is
composed of quadrangularly arranged hexactines with overlapping rays,
an arrangement strikingly similar to the skeletal structure of early
Paleozoic reticulosid hexactinellid. However, the California Cretaceous
sponges clearly show those spicules embedded in siliceous beams that
are united to form a solid dictyonal skeletal framework of only a
single layer of regular mesh. Such an occurrence and stratigraphic
relationships suggests that the dictyonine sponges had their origin
from the simply spiculed reticulosid hexactinellids rather than from
the more complex dictyosponges.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Cretaceous L; <b>Geography:
</b>USA, Texas^Biohermal buildups, or &#34;patch reefs&#34;, have
become an important play type in Maverick County in southwest Texas.
Their primary method of discovery is by 3-D seismic analysis. The
bioherms produce mainly gas and condensate. The porous biohermal
section and associated facies are >70 feet thick and consist from the
base upward of (1) burrowed, mud-dominated lime packstone that
increases in grain content upward and includes fragmented and whole
requienid rudists, (2) mud-rich lime packstone containing abundant
whole requienids, stromatoporoids, corals, and a few caprinid rudists,
(3) lime boundstone (bafflestone and bindstone) consisting of
requienids, stromatoporoids, corals, Chondrodonta, rare caprinids,
echinoid and mollusk fragments, and binding stromatoporoids and
Lithocodium, and (4) coarse-grained lime grainstone (rudstone) that has
the same components as the boundstone. The biohermal section has an
average porosity of 9.2% and an average permeability of 2.9md. The
bioherms are found in the highstand systems tract of the lower Glen
Rose high-frequency sequence (third-order-sequence 7 of Kerans and
Loucks, 2003) within the longer term Glen Rose composite highstand
sequence. It is anticipated that in this setting, strings of
subparallel isolated buildups will be encountered rather than a
continuous barrier that would be associated with a late highstand
prograding system at the shelf margin. [original abstract]^1";

Octocorallia; <b>Stratigraphy: </b>Eocene; <b>Geography: </b>USA,
Texas^The geologic history of the Octocorallia is poorly known. A
fossil record extends back to the Cretaceous, and doubtful or
problematic octocoral-like fossils have been reported as far back as
the Pre-Cambrian. * However, the record is sparce because the organisms
are largely of soft tissue which is not preserved, because the spicules
or stem fragments of calcite are easily overlooked unless they are
being particularly sought, and because the full range of taxa within
the subclass can not be recognized on the basis of the limited material
that can be found as fossils.n * The octocoral collection from the
Stone City Formation, consisting of 35 stem fragments and holdfasts,
belong to the order Gorgonacea. They represent the fifth reported
occurrence of octocorals in the Tertiary strata of the Gulf Coast, the
second reported occurrence in the Texas Tertiary, and the first certain
reported fossil occurrence of the family Gorgoniidae. * In addition to
studying the octocoral fossils along the Gulf Coast, a stratigraphic
```

```
distribution chart is being prepared for the octocorals on a global
basis. If any Newsletter readers have found octocoral fragments in
their collections of other fossil materials, I would be happy to try
and provide them with a taxonomic identification in exchange for
locality and stratigraphic information. I would also appreciate any
information on published or unpublished literature concerning this
topic - especially as octocorals may be mentioned as ancillary remarks
in a paper with a different major subject. [full text of s short

Pliocene coral thicket from North Carolina: an example of temporal
change in community structure and function.- Journal of Paleontology
60, 6: 1159-1176.- <b>FC&#038;P 16-1</b>, p. 71, ID=2006^<b>Topic(s):
</b>ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Pliocene; <b>Geography: </b>USA, California^A two meter
stratigraphic interval within the Chowan River Formation of North
Carolina contains a thicket of branching coral, Septastrea crassa
(Holmes), associated with a diverse macrofaunal assemblage. The thicket
modified a local shelf habitat by providing protection and feeding
opportunities for certain vagrant epifaunal species. Faunal adjustments
wrought by the thicket and thicket growth represent autogenic
succession. Coral growth rates and preservation suggest a time span of
about 100-300 years for thicket development. Bottom shoaling,
associated with a eustatic regression, caused movement of a depth
controlled environmental gradient during thicket growth. As the habitat
changed, a plane bottom macrofaunal assemblage replaced the thicket
assemblage by reordering abundances of intergradational species and
introducing a few new species. Faunal density, diversity, trophic
structure and modes of life of component species were altered during
replacement. Observed temporal community changes are best explained as
gradual faunal adjustments along a shelf stress gradient. Short term
allogenic or autogenic events may temporarily perturb gradual changes.
Changes associated with the thicket development are interpreted as a
brief autogenic perturbation of long term community replacement.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>America
W, Cache Creek terrane^Conodonts, radiolarians, foraminiferids, and
corals provide constraints on the geology and tectonics of the Nechako
region. They also support the notion that the Cache Creek Terrane is
allochthonous with respect to the North American craton. The 117
conodont collections, assigned to 20 faunas, range in age from
Bashkirian (Late Carboniferous) to Norian (Late Triassic); 70
radiolarian collections representing 12 zones range from Gzhelian (Late
Carboniferous) to Toarcian (Early Jurassic); 335 collections assigned
to 11 fusulinacean assemblages (with associated foram-algal
associations) range from Bashkirian to Wordian (Middle Permian); and
two coral faunas are of Bashkirian and Wardian age. The fossils
document a long but sporadic history of sedimentary events within the
Cache Creek Complex that included two major carbonate buildups in the
Late Carboniferous (Pope limestone) and Middle Permian (Copley
limestone), punctuated by intervening Early Permian deepening; basaltic
eruptions during the mid Carboniferous and mid Permian; the onset of
oceanic chert sedimentation close to the Carboniferous-Permian boundary
```

```
and its persistence through the Late Triassic (Sowchea succession);
latest Permian and Early Triassic mixed clastics and volcanics (Kloch
Lake succession); Middle and Late Triassic reworking of carbonates
(Whitefish limestone), including cavity fill in older limestones
(Necoslie breccia), and fine-grained clastic sedimentation extending
into the Early Jurassic (Tezzeron succession). Tethyan, eastern
Pacific, and (or) low-latitude biogeographic attributes of the faunas
are noted in the Gzhelian (fusulines); Artinskian (conodonts,
fusulines), Wordian (fusulines, corals, conodonts), and Ladinian
(conodonts, radiolarians). The Cache Creek Terrane lay far to the west
of the North American continent during these times. [original

paleontology; <b>Systematics: </b>Cnidaria Porifera; Anthozoa;
<b>Stratigraphy: </b>Triassic U; <b>Geography: </b>Mexico, Sonora^A
diverse Upper Triassic tropical marine fauna from northwestern Sonora,
Mexico, includes 31 taxa of tropical invertebrates including
scleractinian corals, spongiomorphs, disjectoporoids,
&#34;hydrozoans&#34;, thalamid and nonthalamid sponges, spiriferid and
terebratulid brachiopods, gastropods, bivalves, coleoids, and anomuran
microcoprolites. They occur within the late Karnian to Norian part of
the Antimonio Formation (Antimonio terrane), which is juxtaposed
against a fragmented portion of the North American craton. Most of the
fauna is also known from the Tethys region. Sixteen Sonoran taxa
co-occur in the western Tethys and five have never been known outside
this region. Four additional taxa (one identified only at genus level)
are geographically widespread. Some taxa occur in displaced terranes of
North America, especially in west-central Nevada (Luning Formation). A
weak link exists with the California Eastern Klamath terrane but
stronger ties exist with Peru. Among Sonoran sponges, Nevadathalamia
polystoma was previously recognized only from the Luning Formation,
western Nevada. Sponges Cinnabaria expansa, Nevadathalamia cylindrica,
and a coral, Astraeomorpha sonorensis n.sp., are also known from
Nevada. The corals Distichomeandra austriaca, Chondrocoenia waltheri,
Pamiroseris rectilamellosa, and Alpinophyllia flexuosa co-occur in
central Europe. Two new taxa, a spongiomorph hydrozoan,
Stromatoporidium lamellatum n.sp., and a disjectoporoid, Pamiropora
sonorensis n.sp., have distinct affinities with the Tethys. The
geographically widespread North American brachiopod, Spondylospira
lewesensis, and Pseudorhaetina antimoniensis n.gen. and sp. are among
the Sonoran fauna. The Sonoran coleoid (aulacocerid) Dictyoconites
(Dictyoconites) cf. D. reticulation occurs in the Tethys realm and
Calliconites cf. C drakei is comparable with a species from the Eastern
Klamath terrane. Calliconites milleri n.sp. is the first occurrence of
the genus outside Sicily. The bivalves Myophorigonia jaworskii, M.
salasi, and Palaeocardita peruviana are known from Sonora and Peru.
Eight gastropod taxa include Guidonia cf. G. intermedia and G. cf. G.
parvula, both previously known from Peru, and Eucycloscala subbisertus
from the western Tethys. The gastropods are unlike those already known
from other North American terranes.^1";
s[2420] = "GOODWIN D.H., STANLEY G.D.jr (1997).- Norian sponge and
coral biostromes in the Antimonio formation, Northwestern Sonora,
Mexico.- Revista mexicana de Ciencias Geologicas 14, 2: 160-166.-

diverse marine invertebrate fauna has previously been documented from
the Norian carbonate interval of the Antimonio terrane. However, little
research has been aimed at understanding its paleoecology fine scale
stratigraphy, and depositional environments. Preliminary field work by
the authors represents the first attempt of the present paper have
documented four sedimentary rock types: (1) argillites and mudstones,
(2) lime-cemented sandstones, (3) sandy limestones, and (4) massive
limestone. Each of these lithofacies contains distinct associated
biofacies. The coincidence of lithofacies and biofacies indicates that
these biostromes were dominated by physical processes which, to a large
extent, controlled their biological development. In addition to the
similarity of faunal components of these biostromes of Sonora with the
```

```
Luning Formation in west-central Nevada, the paleoecological patterns
and biotic structure are also remarkable coincident. This observation
suggests that the relationship of the Antimonio Formation to units
farther north in the United States requires more investigation.^1";

</b>Cnidaria Mollusca; Anthozoa Bivalvia; <b>Stratigraphy:
</b>Cretaceous U; <b>Geography: </b>Mexico^In the Cardenas Formation
(central Mexico),a 175 m thick sedimentary sequence of Maastrichtian
age was analyzed with respect to its palaeontology and sedimentology. A
wide variety of lithological and palaeontological features characterize
this sequence comprising unfossiliferous and fossil-bearing sand-and
siltstones, and diverse rudist and coral -rudist associations in
carbonate or mixed carbonate&#47; clastic lithologies. A total of 24
rudist and coral-rudist associations are exposed in the investigated
section, which are grouped into 5 limestone units. Radiolitid
assemblages, coral -rudist reefs, coral-dominated reefs, and
hippuritid-dominated reefs are present. The stacking pattern of these
reef intervals indicates a general transgressive trend through the
entire section. Smaller-scale facies trends could be distinguished
within each limestone unit, comprising deepening-upward sequences,
defined by a shoreface -calcareous algae -radiolitid-marl facies
transition, and shallowing-upward sequences defined by a hippuritid
-actaeonellid -coral/rudist facies transition. This cyclic
sedimentation pattern is obscured by an episodic input of clastic
sediments derived from the uplifting Sierra Madre Oriental, which in
turn triggered either the development or decline of reefs.^1";

landward shift of facies in an Upper Campanian ? to Maastrichtian
transgressive-regressive cycle. The succession consists of 2-30-m-thick
```

```
rhythms comprising a lower volcanoclastic siltstone/sandstone devision; a middle volcanoclastic siltstone/limestone with abundant corals or the rudist Antillocaprina trellata; and an upper division of rudist rudstones and floatstones. The lower division consists of either bioturbated sandy siltstones with lignite and abundant gastropods and infaunal bivalves (lower rhythms in the Guinea Corn Formation),or interbedded volcanoclastic siltstones and normally graded sandstones. The rudist limestones are parallel-bedded and consist of high abundance mono-to paucispecific assemblages. The boundary between the middle and upper parts of rhythms contains a concentration of oncoids with coral nuclei and a mantle of microbial laminates, red algae and serpulids. Four coral assemblages are recognised based on diversity and coral morphology. The Paracycloseris-?Dasmosmilia assemblage occurs in the lower division of the rhythms and is interpreted as a soft-substrate assemblage that was adapted to elevated nutrient levels. The Ovalastrea-Actinacis, Actinacis-Multicolumnastrea and Actinacis-Calamophyllia-Gyrodendron assemblages occur in the middle parts of the rhythms and consist of bedded rudstones, rudstone mounds and rarer platestones, pillarstones and mixstones. Polyparia arrangements, colony morphology and low diversity suggest the Ovalastrea.Actinacis and Actinacis-Multicolumnastrea assemblages were adapted to high sedimentatin rates. The more diverse Actinacis-Calamonphyllia-Gyrodendron assemblage is interpreted to have grown under more optimum conditions (low sedimentation rates and high light intensities). Rudists are classified on their growth orientation (elevator, clinger, recumber) and on their communal relationships (isolated or clustered). The cluster elevator Biradiolites mooretownensis occurs in the lower division of rhythms and the recumbent A. stellata occurs in the middle part of rhythms. The upper part of rhythms contains abundant rudists including isolated elevators (Antillocaprina occidentalis), cluster elevators (Bournonia sp., Biradiolites jamaicensis, Thyrastylon spp. And Chiapasella radiolitiformis) and clingers (Plagioptychus spp.), with the topmost part contains large recumbent Titanosarcolites.^1";

<b>Stratigraphy: </b>Cretaceous Maas; <b>Geography: </b>Mexico^A
detailed taxonomical description of scleractinian corals from the
Maastrichtian of Mexico (Cardenas Formation) is given for the first
time. The coral association comprises 16 taxa which belong to 9
families: Dictuophyllia conferticostata (Vaughan), Cladocora
jamaicaensis Vaughan, Cladocora gracilis (d&#039;Orbigny), Antiguastrea
cellulosa Duncan), Multicolumnastraea cyathiformis (Duncan),
Placocoenia major Felix, Siderastrea vancouverensis Vaughan,
Siderastrea adkinsi (Wells), Goniopora sp., Actinacis haueri Reuss,
Actinacis parvistella Oppenheim, Actinhelia elegans (Goldfuss),
Meandrophyllia oceani (de Fromentel), Dermosmiliopsis orbignyi
Alloiteau, Trochoseris aperta Duncan, and Cyathoseris formosa
d&#039;Achiardi. The corals described herein were collected from mixed
coral-rudist and coral-dominated assemblages in the Arroyo de la
Atarjea, and one unnamed riverbed which lithologically correspond to
the Arroyo de la Atarjea section, both of which belong to the upper
member of the Cardenas Formation. On the genus level, 94% of the
Mexican fauna corresponds to the Maastrichtian coral assemblages of
Jamaica. Moreover, the Cardenas fauna shows close affinities to both
Upper Cretaceous coral associations of central Europe and the
Caribbean, as well as to Lower Tertiary faunas of Central America and
the Caribbean. On the species level, 68.8% of the Cardenas corals are
known from Lower Tertiary strata of Central America, the Caribbean,
South America, Asia, European &#47; Mediterranean region, and/or
southeastern parts of the USA.^1";
s[2433] = "LOSER H. (2006).- Taxonomy, stratigraphic distribution and
palaeobiogeography of the Early Cretaceous coral genus Holocystis.-
Revista Mexicana de ciencias geologicas 23, 3: 288-301.- <b>FC&#038;P
35</b>, p. 75, ID=2387^<b>Topic(s): </b>revision; Scleractinia,
Holocystis; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous L; <b>Geography: </b>Mexico, Sonora^The
Early Cretaceous Scleractinian coral genus Holocystis Lonsdale, 1849 -
first reported for southern England and for a long time believed to be
restricted to this region - is easy to recognise but it is also rare.
Abundant material from the Late Barremian to Early Albian found in
Sonora (Mexico) as well as the available type material and additional
material from Europe and East Africa allowed a systematic revision.
Five species are distinguished. One of them - Holocystis nomikosi - is
described as a new species. Three species previously described for
other genera were assigned to the genus Holocystis and two species
formerly assigned to Holocystis were found to belong to other genera.
Two genera (Tetracoenia and Nowakocoenia) are considered junior
synonyms of Holocystis. The stratigraphic extent of the genus was
limited to the range from the Barremian to the Early Albian. Holocystis
is not a common coral genus but occurred in a large geographic area
comprising the central Tethys, the Caribbean, and even the eastern to
south-eastern Tethys. It is restricted to sediments with a certain
terrigenous input.^1";
s[2434] = "LOSER H. (2006).- Barremian corals from San Antonio Texcala,
Puebla, Mexico - a review of the type material of Felix 1891.- Boletin
del Instituto Geologico de Mexico 114: 1-68 (CD-ROM).- <b>FC&#038;P
35</b>, p. 76, ID=2388^<b>Topic(s): </b>type material, Felix
collection; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Barr; <b>Geography: </b>Mexico,
Puebla^The Barremian coral fauna from San Antonio Texcala described by
the German palaeontologist Johannes Felix is revised. The material is
completely recrystallized; therefore, it was not possible to study the
internal structures. Studies were exclusively confined to the coral
```

```
surface. The original type locality of the material was not located in
the field. Corals found in the outcrops at the presumed type locality
area differ in their preservation and taxonomic composition. The nearby
localities of the San Juan Raya Formation yielded corals different from
those of San Antonio Texcala. The only material available for a
revision is therefore the collection material at the Leipzig University
(Germany). Forty-two species are assigned to 26 genera, six species
more than described by Felix. Most species belong to the suborders
Stylinina, Faviina, and Microsolenina, the most common genera are
Cryptocoenia and Polyphylloseris. The suborders Archeocaeniina,
Amphiastraeina, and Rhipidogyrina, which are usually common in the
Early Cretaceous, are conspicuous by their complete absence from the
fauna of San Antonio Texcala. Stratigraphically, the fauna shows
affinities with faunas between the very Late Jurassic and the
Campanian, though the closest correlation is with early Aptian
associations. Palaeobiogeographic relationships are slight and exist
mainly with Barremian-Aptian faunas of the central Tethys, the
Caribbean, and even Asian and Boreal provinces.^1";

Scleractinian fauna from Jamaica (Hauterivian, Benbow Inlier).- Journal
of Paleontology 83, 3: 333-349.- <b>FC&#038;P 36</b>, p. 98,
ID=6518^<b>Topic(s): </b>; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous Haut; <b>Geography:
</b>Jamaica^From the oldest Cretaceous marine sediments of Jamaica, the
Copper Limestone within the Devils Racecourse Formation (Benbow Inlier,
Clarendon Block), the oldest known coral fauna of the Caribbean is
described. The small but diverse fauna encompasses 18 species in 17
genera of the suborders Amphiastraeina, Archeocaeniina, Heterocoeniina,
Faviina, Fungiina, Microsolenina, and Stylinina. The fauna contains the
first representatives of the suborder Amphiastraeina in the Caribbean
and the Americas. One genus of the family Amphiastreidae,
Monoaulastrea, and three species - Monoaulastrea rawi, Latusastrea
rubrolineata, Camptodocis corralesi - are described as new. The
preoccupied coral genus Floria is replaced by the new name Floriastrea.
The new fauna shows relationships to faunas from the late Berriasian to
late Albian. Most species are shared with the Hauterivian faunas from
Georgia in the central Tethys and the Paris Basin in the Boreal, but
also with younger faunas such as the Barremian of Central Mexico, the
early Aptian of Greece and the early Albian of the Bisbee Basin
(Northern Mexico). [original abstract]^1";

ID=7217^<b>Topic(s): </b>distribution, research history; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous; <b>Geography: </b>Mexico^An extensive, detailed
compilation of known occurrences and described species of Cretaceous
scleractinian corals in the country of Mexico, based on published
scientific literature, is presented for the first time. Cretaceous
corals have been reported from more than 170 localities in more than
200 published studies dating from at least as early as 1839.
Unfortunately, relatively few of these 200 publications actually
described coral species; the entire research history on Mexican
Cretaceous coral systematic paleontology is contained in only 16
studies. A total of 116 coral species have been described from these
occurrences, inclusive of unnamed coral species and with previously
suggested synonymies taken into consideration. Overall the coral
occurrences span nearly the entire Cretaceous Period, from the
Berriasian through the Maastrichtian, but at least 60 percent of them
are from the Early Cretaceous. Furthermore, the vast majority (about 90
percent) of the total number of Mexican Cretaceous coral species are
known from the Early Cretaceous. Based on these data, it seems likely
that many of the Cretaceous corals of Mexico are still unknown. The
detailed review of the literature on Mexican Cretaceous corals [is]
presented in this study establishing a modern foundation for future
investigations of the paleobiography and systematic paleontology of the
members of this significant group of reef-building organisms. [original

```

```
deposition in the Jurassic, included deep - and shallow water marine
carbonates (Late Jurassic to Late Cretaceous) - and concluded with
terrigenous detritus from the deformation of the Sierra Madre Oriental
(Eocene). Rudist fringed shallow water carbonate platforms attained
their maximum areal extent and facies contrast with the surrounding
carbonate basins in the Albian-Cenomanian. The resultant lithofacies
are: (1) a suite of platform carbonates; (2) dark, cherty, pelagic,
basinal limestones; (3) basin-margin carbonates consisting of
platform-derived breccias and bioclastic rocks interlayered with
pelagic limestones. Scale and relief of the Mexican platforms compare
with those of the Capitan reef and the Bahama Banks. Steep-sided,
high-relief platforms provide optimum conditions for basin-margin
debris accumulations, but the necessary and sufficient combination of
conditions for debris accumulation and for platform development is
unsolved.^1";

<b>Geography: </b>Mexico, Baja California^Worm reeflets described here
are composed of parallel and straight, curved, or bifurcated tubes,
which are up to 10 cm long and have an average diameter of 1.4 mm.
Their walls are composed of microgranular calcite and are
multilamellar. The reef-builders settled on soft bottoms within the
tidal or uppermost zone. They tolerated high water turbulence and a
certain rate of sedimentation. Dead parts of the reef were recolonized
by a new population. The reefs stabilized the sediment, produced
biogenic debris, and offered new ecological niches for endo- and
epilithic organisms. They mark a regional ecological event at the
Oligocene &#47; Miocene boundary. Diplochaetetes mexicanus as well D.
longitubus demonstrate close relationships to a modern skeletal-forming
polychaete worm, Dodecaria. Diplochaetetes is definitly not a
sclerosponge and demonstrates a convergence with the chaetetid basal
skeletons of sponges and favositid corals. ^1";

Group of Jamaica.- Cainozoic Research 3 (1-2): 83-107.- <b>FC&#038;P
33-2</b>, p. 38, ID=1177^<b>Topic(s): </b>reef corals; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Eocene
- Miocene; <b>Geography: </b>Jamaica^Sedimentary rocks of the White
Limestone Group of Jamaica were deposited in the range of shallow to
deep-water marine settings from the Middle Eocene to Middle Miocene.
Horizons rich in scleractinian corals occur throughout this lithologic
unit. The present study, using large, new collections (>2.000
specimens) and museum specimens, recognises 98 scleractinian species in
42 genera in the White Limestone Group. Thirty-six of these species
have not been previously described in the literature. From the Middle
to Upper Eocene, eleven species are reported from the Troy Formation,
twelve from the upper Middle Eocene Swanswick Formation and eleven
species from the Late Eocene Somerset Formation. In the Moneague
Formation, fifty-two species are recorded from the lower part of the
Upper Oligocene succession in units formerly mapped as the Browns Town
Formation. Also, in the uppermost Oligocene of the Moneague Formation,
sixty-four coral species are reported from rocks formerly mapped as the
Newport Formation. An additional fifteen species are reported from the
Early Miocene portions of the Montpelier Formation. In addition to
scleractinian corals, a stony octocoral species (Parapolytremacis sp.)
is found in the Upper Oligocene of the Moneague Formation, and at least
two species of Millepora (class Hydrozoa) are recorded from the Eocene
and Oligocene portions of the White Limestone Group. Coral assemblages
from the Eocene of the White Limestone group are largely dominated by
scattered, thinly branched and free-living corals, while Late Oligocene
assemblages contain a diverse group of large massive, plate-shaped and
branched corals in a system of patch reefs and coral carpets. The Early
```

```
Miocene assemblages represent a possible deeper fore-reef community
transported into deep water sediments in a olistostromic block. The
total number of species found exceeds that known from any other single
region or lithologic unit in the Caribbean Eocene through Miocene.^1";

</b>numerical taxonomy; Scleractinia, Stephanocoenia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Neogene; <b>Geography:
</b>Dominican Republic^Multivariate statistical procedures are used to
distinguish species in the reef-coral genus Stephanocoenia through a
continuous Neogene sequence (five-million year time interval) in the
Cibao Valley of the Northern Dominican Republic. This genus is the only
member of the family Astrocoeniidae that occurs in the sequence. The
material consists of 56 colonies (17 of which are measured) from 24
localities in four river sections, the most important being Rio Gurabo
and Rio Cana. Ten characters are measured on each of 10 corallites per
colony. The data are analyzed using cluster and canonical discriminant
analysis to group colonies into clusters representing species.
Identical measurements on modern colonies collected near Discovery Bay,
Jamaica are included for comparison. Two fossil species are defined in
the analysis, one of which is new (Stephanocoenia duncani, n.sp.). Both
species are significantly distinct from the single modern species (S.
intersepta) that is the sole living representative of the genus. Study
of collections from other reef localities shows that both fossil
species occur only during Neogene time and only at a limited number of
localities. Patterns within each species are traced up a composite
stratigraphic section using nonparametric statistical analyses. One of
the two fossil species (S. spongiformis) is found to remain stable
through time, whereas the other (S. duncani) changes its morphology in
a direction approaching the cluster for the modern species. Further
study of patterns of variation within the one modern and two fossil
clusters shows that intraspecific variation is unusually complicated in
this genus. The clusters overlap, and colonies within each cluster
differ widely. Variation between populations within the modern species
occurs in the same characters as those which distinguish the modern
species from the fossil species converging with it (S. duncani).
However, these two species form a morphologic continuum that cannot be
explained by environment alone. Therefore, they may represent two
gradually intergrading chronospecies within one lineage. [part of
extensive summary]^1";

</b>Panama^Caribbean reefs underwent significant biotic change during
```

```
the Late Oligocene and Early Miocene. This was a critical time in the
evolution of the modern Caribbean fauna characterized by increasing
endemism resulting from regional extinction of lineages that survive in
the modern Indo-Pacific. An understanding of the dynamics and potential
causes of the Oligocene/Miocene transition, however, is hampered by the
relative lack of well-preserved Oligocene to early Miocene coral faunas
in the Caribbean. Here we examine new exposures in the Culebra
Formation of Panama that contain a well-preserved coral fauna of Early
Miocene age. Taxonomic, stratigraphic, and paleoecologic study of the
Culebra Formation exposed along the Gaillard Cut of the Panama Canal
allows us to infer the paleoenvironments and reef coral communities
from the Panama Canal Basin during this critical interval. The Culebra
Formation consists of a deepening upward sequence with shallow-lagoon
sediments at the base, overlain by fringing reef facies in the middle
of the section, and open-shelf to bathyal facies at the top of the
section. We recovered 31 species of reef corals from a combination of
new and old collections. Comparison of our collections with other Late
Oligocene to Middle Miocene reef coral assemblages confirms that there
was a major faunal turnover after deposition of the Upper Oligocene
Antigua Formation. This turnover consisted of a large number of
extinctions followed by an increased rate of first occurrences so that
regional diversity did not change appreciably. Improved stratigraphic
resolution at this and other Caribbean localities is required to
understand fully the dynamics of change during the Oligocene&#47;
Miocene transition.^1";
s[2452] = "FOSTER A.B. (1986).- Neogene Paleontology in the Northern
Dominican Republic. 3. The Family Poritidae (Anthozoa: Scleractinia).-
Bulletins of American Paleontology 90, 325: 1-123.- <b>FC&#038;P
15-2</b>, p. 37, ID=6747^<b>Topic(s): </b>; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Neogene; <b>Geography: </b>Dominican Republic^Various multivariate
statistical procedures are used to distinguish species in the
reef-coral family Poritidae through a continuous Neogene sequence (5myr
time interval) in the Cibao Valley of the Northern Dominican Republic.
Some older (by approximately 10 myr) material from the same region is
also included in the analyses. The material consists of approximately
450 colonies (120 of which are measured) from 92 localities in four
river sections. The colonies are first sorted into three genera, and
approximately 30 characters measured on five calices per colony. The
data are analyzed using cluster and canonical discriminant analyses to
group the colonies into clusters representing species. Five species are
so defined in Porites and three in Goniopora. These groupings are then
used statistically to reclassify type specimens for 22 of the 25
described species of Neogene Caribbean poritids. Eight described
species are thereby synonymized with four previously-described species
in Porites and one new species of Porites, Porites convivatoris n.sp.,
is discovered. Five described species are synonymized with two
previously-described species in Goniopora. The stratigraphic range of
three species of Porites and three species of Goniopora is also shown
to extend back to the late Oligocene, thereby diminishing the
significance of any presumed early Miocene adaptive radiation. Only one
species was found to be endemic to the Dominican Republic and only one
confined to the northern Carribean. The rest are widely distributed
throughout the Carribean. Thus, the endemism previously believed common
during the Neogene is shown to be far less extensive. Evolutionary
trends within each species are preliminarily analyzed for various
characters using nonparametric statistical procedures. In general, the
results show that seven species experienced little or no evolutionary
change (= stasis) through the sequence. Slight increases in corallite
size are detected in two species, an increase in colony height in one
species, and a more rounded colony shape in one species. These trends
may be related to the general deepening of the environment; however,
little correlation is found between lithology and morphology within
```

```
species. Preliminary analyses of the relationship between intraspecific
variation and poritid abundance and diversity yield significant
results, suggesting that intraspecific trends may be environmental and
that future study of coral species associations may offer insight into
paleoenvironmental interpretations. * Statistical comparisons with the
Miocene Mediterranean show that no species co-occur in the two
provinces during the Neogene. Similarly, none of the studied Neogene
species of Porites resemble modern Carribean species of Porites,
signifying that all nine poritid species studied must have become
extinct and that the modern Carribean species of Porites radiated
during the late Pliocene or early Pleistocene. [original summary]^1";

clastic lagoonal succession.- Sedimentary Geology 144, 3-4: 291-306.-
<b>FC&#038;P 34</b>, p. 97, ID=1361^<b>Topic(s): </b>carbonates;
carbonates; <b>Systematics: </b>; <b>Stratigraphy: </b>Pleistocene;
<b>Geography: </b>Jamaica^The Port Morant Formation consists of a mixed
clastic-carbonatesedimentary sequence that was deposited as a lagoon
fill during theSangamonian interglacial. Ten sedimentary facies are
recognised andsequence stratigraphic analysis indicates the presence of
transgressiveand highstand systems tracts. The transgressive systems
tract consists ofa basal transgressive conglomerate (facies I),
crustose coralline algalbindstones-boundstones (II) and 2 m high
Solenastrea coral heads (III).The highstand systems tract is
represented by sediments of a braiddelta/fan-delta prograding into the
lagoon (IV and V), marine pebblysandstones deposited adjacent to
mangrove swamps (VII), more distalalgal mudstones (VIII), and
sheet-like (VI) and channelized (IX)conglomerates filling delta-top
distributary channels. A barrier and/orfringing reef is present (X),
but its relationship with the lagoon-fillsediments is obscure due to
poor exposure. Carbonates are restricted tothe transgressive systems
tract and the barrier/fringing reef(transgressive and/or highstand
systems tract). Two transgressive eventsare recog-nized, the
transgressive systems tract (facies I to III) andfacies VII, the latter
either a second sea-level rise or due to delta abandonment. A single
coral date from facies VII gave an age of 132 a7kyr. This indicates
that the upper transgressive event (facies VII)belongs to the early
highstand that has been recognized in isotopesubstage 5e. The lower
transgressive event (facies I to III) in the FortMorant Formation is
```

```
therefore either also of this age, or older.^1";

(1987).- Back-reef and fore-reef analogs in the Pleistocene of North Jamaica: implications for facies recognition and sediment flux in fossil reefs.- Palaios 02: 219-228.- <b>FC&#038;P 23-2.1</b>, p. 64, ID=4424^<b>Topic(s): </b>reefs, ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>Jamaica^The 125,000 y.b.p. (Sangamon) Falmouth Formation is an emergent fringing-reef complex exposed along the north coast of Jamaica. Q-mode cluster analysis using constituent composition of Falmouth Formation rocks collected near Discovery Bay was employed to differentiate two distinctive facies. These are a dense, well-lithified skeletal packstone containing abundant calcareous algae (Halimeda and coralline algae) and molluscs, and a poorly lithified skeletal grainstone composed primarily of sand-sized coral fragments and coralline algae with only minor amounts of Halimeda. The composition of sediments within these facies is comparable to the composition of back-reef and shallow (5-8m deep) fore-reef sediments of the Holocene Jamaican fringing-reef system. These results contradict the pervasive idea that sand-sized, reef-derived sediments are ineffective as environmental indicators owing to post-depositional transport away from the reef system. Petrographic and X-ray analyses of the mineralogy of Falmouth Formation limestones reveal that back-reef packstones retain much of their original aragonite and high-Mg calcite. In fore-reef grainstones, however, better soiling (increased permeability) results in dissolution and leaching of these metastable phases and reprecipitation of low-Mg calcite. Thus, variability in original sediment texture may create a preservational bias in the fossil record against the more permeable fore-reef deposits.^1";
s[2458] = "MANN P., TAYLOR F.W., BURKE K., KULSTAD R. (1984).- Subaerially exposed Holocene coral reef, Enriquillo Valley, Dominican Republic.- Bulletin geological Society of America 95: 1084-1092.- <b>FC&#038;P 14-1</b>, p. 67, ID=1081^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography: </b>Dominican Republic^An extremely well-preserved Holocene fringing coral reef occurs at an average elevation of 5 m below sea level around the margins of the central Enriquillo Valley, Dominican Republic. The reef records the latest marine incursion from the east into an 85-km-long, 12-km-wide tectonic depression and appears to represent a unique preservation. Excellent cross sections of the reef exposed in erosional gullies reveal e composition and zonation typical of modern Caribbean reefs that are found in offshore low-energy environments. Radiocarbon age determinations (2) indicate that reef growth coincided with sea-level rise following the last ice age (5,930 + 100 to 4,760 ± 90 yr B.P.). Deltaic deposition and possible vertical movements on active fault scarps dammed the eastern mouth of the valley and created Lago Enriquillo, the level of which was then rapidly lowered by evaporation in an arid climate to produce e saline lake ca. 40m below sea level. Stratigraphic studies of rocks along the valley edge and data from drill holes in the basin center indicate that there were
```

```
earlier post-Miocene marine incursions similar to that described here.^1";
s[2459] = "GUNTHER A. (1990).- Distribution and Bathymetric Zonation of Shell-boring Endoliths in Recent Reef and Shelf Environments: Cozumel, Yucatan (Mexico).- Facies 22: 233-262.- <b>FC&#038;P 19-2.1</b>, p. 37, ID=2758^<b>Topic(s): </b>endobionts boring; <b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Mexico, Cozumel^Pelecypod shells from bottom sediments of the shelf and upper slope off Cozumel (Mexico), at depths ranging from 1 to 47m, were studied with regard to the taxonomy, frequency and distribution of microboring produced by endolithic organisms. Scanning electron microscopy of plastic casts of the borings reveals the existence of 29 microboring types, distinguished on the base of shape, size, mode of branching, overall boring pattern and sporangia. The endoliths include cyanobacteria, chlorophycean algae, rhodophycean algae, fungi, sponges and several microborers of uncertain taxonomic affinities. Although most of the borings exhibit a wide bathymetrical range, a subdivision of the photic zone is indicated by the abundance and vertical distribution of some species. The upper part of the photic zone (1-30m) is characterized by higher species diversity, by the green algae Phaeophila engleri and Entocladia testarum, and by the abundance of the cyanobacteria Hyella gigas. Fungi occur at all depths but are more common in the lower photic zone (30-47m). The bathymetrical position of the boundary might be influenced by the vertical sampling distance. Generally, there is a good agreement with other bathymetrical patterns of recent endoliths, especially with those from the Puerto Rican carbonate shelf. There is no distinct difference in the frequency or taxonomic composition of shell-boring endoliths from reefs and interreef areas (platforms covered by bioclastic sands). Boring intensity, measured by point-counting of SEM photographs, is generally high; in 58% of the samples 60 to 99% of the outer shell surface is bored, predominantly by fungi and by the green alga Phaeophila engleri. Mean boring intensities show no relationship with water depths.^1";
s[2460] = "MUCKELBAUER G. (1990).- The Shelf of Cozumel, Mexico: Topography and Organisms.- Facies 23: 185-240.- <b>FC&#038;P 20-1.1</b>, p. 69, ID=2853^<b>Topic(s): </b>eustacy, shelf geomorphology; eustacy, terraces; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography: </b>Mexico, Yucatan^The Caribbean Island of Cozumel lies 18 km off the north-eastern coast of the Mexican Peninsula of Yucatan. A relatively narrow shelf is developed on both sides of the roughly NS striking island, whereby terraces and marked steps are evident. On the western shelf 3 terraces can be found at 5m, 10m and 20m below sea level. The shelf edge lies at approximately 20m. On the eastern side 5 distinct terraces are developed (3m, 10m, 20m, 30m and 50m) and the shelf edge lies about 50m deep. These terraces are interpreted as abrasion platforms of the rising sea level in the Holocene. In the W the insular slope drops almost vertically to a depth of about 400m. In the E it drops even further, with interruptions to over 1000m. The northern shelf area remains flat (20-30m) and ends at the Banco Arrowsmith, about 50km NNE of Cozumel. ```

```
<b>Stratigraphy: </b>Holocene; <b>Geography: </b>British Honduras^The distribution of Holocene sediment types on the British Honduras shelf is correlated broadly with bathymetry as a result of the modifications in water circulation and turbulence imposed by bathymétrie relief. Subsurface information demonstrates that this relief has been inherited in large part from an underlying, pre-Holocene limestone erosion surface. * On the northern shelf the relatively subdued pre-Holocene relief is symptomatic of temperate or doline karst; on the southern shelf the considerable relief on the same surface is suggestive of tropical or conical karst. This difference in offshore-relief expression is consistent with parallel changes in the mainland limestone topography and with differences in the presumably causal factor of rainfall distribution. In both karst regimes, however, solution morphology has been directed in its expression by underlying structure. * Significantly, Holocene carbonate sedimentation has accentuated the drowned topographic relief through an accelerated rate of carbonate deposition on the highs. Thus the climatically and structurally determined variations in karst topography not only control the distribution of Holocene sediments but also their three-dimensional geometry. The same relation should apply to the geologic record.^1";

The analysis here employs a large, comprehensive computer database on Mesozoic corals. The database is used to develop a uniform palaeogeographic framework for the comparisons (300 palaeo-provinces are distinguished worldwide for the Cretaceous), and a distance matrix cluster analysis of shared presence is performed on the data to correlate coral faunas both within and outside of the study area. The study is based entirely on coral material recently collected in the field and studied in museum collections. Of the 754 coral samples examined, a total of 160 species is identified from 54 sample locations. This large total number is in contrast to the low to moderate number of species found in each locality, with a maximum number of 28 species from one locality in northwestern Mexico. This demonstrates that coral distribution was controlled by regional (even local) factors. Outside of the sample
```

```
area, the coral faunas show a strong correlation to central Tethyan
faunas, with strongest affinities to that of the Iberian Peninsula, and
also to eastern Tethys and western Pacific faunas. This argues against
the commonly held concept of a distinct New World coral faunal realm,
and is explained by a west-to-east orientation of warm oceanic
connections and the close proximity of the land masses during the Early
Cretaceous.^1";

<b>Geography: </b>Argentina^Anthaspidellid sponges are reported from
the La Laja Formation in the Chica de Zonda Range in the Precordillera
Oriental, Argentina. These are generically unidentifiable fragments of
trabs and more or less well-defined dendroclone spicules. They occur as
skeletal elements in small transported fragments and are the only
Cambrian occurrence of anthaspidellids known thus far from South
America. Walcott (1920) proposed to include an array of dissociated
spicules, including triradiate prodiaenes, hexactines, and probable
monactine spicules, in the genus Kiwetinokia. Assemblages tentatively
identified as Kiwetinokia utahensis? Walcott, 1920, are reported from
the Estancia San Martin Formation, of latest Early Cambrian and early
Middle Cambrian age from San Isidro Gulch near Mendoza. Similar spicule
assemblages occur in the La Laja Formation from the Chica de Zonda
Range, in the Precordillera Oriental near San Juan, and in the Los
Sombreros Formation in the Tontal Range of the Precordillera
Occidental. Sclerites of the sponge-like Chancelloria eros Walcott,
1920, are described from the upper Lower to lower Middle Cambrian La
Laja Formation. Chancelloria sclerites are also reported here from
rocks of the Middle Cambrian Glossopleura Zone in the San Isidro
Formation in Empozada Gulch in the San Isidro area of the Precordillera
Austral, west of Mendoza, in Mendoza Province. Sponges and
chancelloriids from the Cambrian of Argentina are known basically from
dissociated skeletal elements. [original abstract]^1";
s[2469] = "MEHL D., LEHNERT O. (1997).- Cambro-Ordovician sponge
spicule assemblages in the Ordovician of the Argentine Precordillera
and paleoenvironmental ties.- N. Jb. Geol. Palaont. Abh. 204, 2:
221-246.- <b>FC&#038;P 26-2</b>, p. 75, ID=3763^<b>Topic(s):
</b>spicules, ecology; Porifera spicules; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>Cambrian, Ordovician; <b>Geography: </b>Argentina,
Precordillera^Well preserved silicified sponge spicule assemblages are
described from residues of conodont samples from Ordovician strata in
the Precordillera of western Argentina. The material has been recovered
from Cambrian olistoliths in the Los Sombreros Formation
(Llanvirn-Caradoc) and from autochthonous limestones of the San Juan,
Gualcamayo and Las Aguaditas formations. The poriferan taxa include
Polyactinellidae and Heteractinellidae (Calcarea) as well as
hexactinellid and demospongian spicules. Associations of exclusively
```

```
hexactine spicules are restricted to outer platform and slope deposits,
whereas on the shallow platform a relatively high diversity of
different types of polyactinellid and heteractinellid spicules may be
observed in the upper part the San Juan Formation. There, these
assemblages are related to reef-mound horizons and biostromes with
sponges, stromatoporoids, receptaculitids and some autrotrophic
organisms. The restriction of spicule associations to distinct
environments is discussed with respect to previous studies treating the
distribution of Early Paleozoic sponge faunas in different facies, and
3 different sponge biofacies zones for the Cambro-Ordovician platform
and slope settings in the Precordillera are described.^1";

&#47; Devonian; <b>Geography: </b>Argentina, Precordillera^Very few
coral species have been described to date from the Silurian and
Devonian rocks of Argentina . An important association of rugose and
tabulate corals was collected from the Silurian and Devonian
siliciclastic rocks in western Argentina . The coral assemblage was
recovered from the Pridolian and Lockovian transition in the Cerro del
Fuerte and Talacasto sections in the Argentine Precordillera. The
tabulate Argentinella argentina (Thomas) is described and figured,
building thick accumulations of gregarious colonies in a shallow, near
shore environment associated with a sea level fall in the base of the
Lochkovian. From the same levels an indeterminate favositid is also
described. In the subjacent Pridolian rocks the solitary rugose
Enterolasma sp. and a tabulate, pleurodictyform indet. were recovered
from fossil-rich beds associated with tempestites. This is the first
record of the genus Enterolasma and the Family Pleurodyictidae in South
America. [original abstract]^1";

</b>; <b>Stratigraphy: </b>Carboniferous Bashk; <b>Geography:
</b>Brazil, Amazon Basin^A vicariant model is proposed to evaluate the
distribution pattern of thirty-nine Bashkirian rugose coral genera
cited for both the Amazon basin and selected Western Laurasian regions.
Laurasian regions embrace the Western Interior, Eastern Interior and
Midcontinent region in the USA, part of the Mediterranean Province
```

```
(Northern Spain) and Donets basin in Europe; Amazon basin is included
in the Western Gondwana. The selected rugose coral genera were grouped
into seven suborders and a phylogenetic study was carried out in an
attempt to produce area cladograms. A reduced area cladogram was
produced using BPA (sensu Wiley 1988), which shows area relationships
and ancestor-groups distribution. The results attest to a close
relationship of the Amazone basin to the Midcontinent region. A
possible sea-way linking Western Laurasian regions during Early
Bashkirian is also suggested via the Canadian Arctic Archipelago.
Previous suggestions about a sea connection running from North Africa
to the Amazon basin is rejected. The biogeographic model proposed is in
agreement with that of Rodriguez et al. (1996) for the Bashkirian
interval.^1";

Neuquen^In this paper the scleractinian corals from Lajas Formation
outcrops (Lower Bajocian) - Neuquen Basin, western central Argentina -
are described. The Lajas Formation is mainly constituted by shore-face
arenaceous sediments, and not one of the studied outcrops presents a
reef facies. At the moment, this kind of facies is unknown in the
Argentinean Middle Jurassic. The coral fauna is comprised of 15 species
among which 6 are new ones. They are distributed in 11 genera, three of
which are new. The new taxa described are Araucanastrea mimiscula nov.
gen. nov. sp., Araucanastrea majuscula nov. gen. nov. sp., Garateastrea
bardanegrensis nov. gen. nov. sp., Kobyastraea louisae nov. sp.,
Neuquinosmilia gerthi nov. sp. and Mapucheastrea andina nov. gen. nov.
sp. The specimens possess a similar morphology to those having the same
age and belonging to the rich Tethys coral fauna, but the
microstructure observed in same species appears to be closer to that of
more ancient forms. However the exactness of the identification is
somehow limited by the parallelisms existing in scleractinian
systematics. This parallelism is originated by the determinations of
scleractinians founded only on well preserved microstructures, but
which are not observable in all specimens. It can too induce inaccuracy
in the paleobiogeographical reconstruction and in the phylogenetic
interpretations.^1";
s[2492] = "MORSCH S.M. (2001).- Scleractinian corals of the Neuquen
Basin (Lower Jurassic), Argentina.- Bulletin of the Tohoku University
Museum 1 [Proceedings of the 8th International Symposium on Fossil
Cnidaria and Porifera]: 320-332.- <b>FC&#038;P 30-1</b>, p. 21,
ID=7076^<b>Topic(s): </b>; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Jurassic L; <b>Geography:
</b>Argentina, Neuquen^Lower Jurassic scleractinians from the Neuquen
Basin (Argentina) are newly described. Inferred paleoenvironmental
conditions are based on coral life positions and sedimentology for
corals of the Puesto Araya and Piedra Pintada Formations. Coral bearing
levels are placed in a precise chronostratigraphic sequence according
to ammonoid faunas, which indicate a Pliensbachian age. These units
belong to the transgressive phase of a depositional sequence. In one
outcrop, coral bearing levels are classed as autobiostromes. In the
other outcrops, the corals do not form any biologically constructed
structures. Taxa are regarded as eight species, among which six are
noted for the first time in Argentina. Species are as follows:
Stylophyllopsis? sp. cf. S. victoriae, Phacelostylophyllum sp. cf. P.
peruvianum, Meandrostylis? jaworskii, Distichomeandra sp. cf. D.
austriaca, Retiophyllia? sp., Microphyllia sp. cf. M. flemingi,
Myriophyllum sp. and Goldfussastraea? toarciensis. Some specimens are
similar morphologically to those of the rich coral faunas of Tethys of
the same age, but others appear to be closer to older forms. However,
```

```
the exactness of identifications is limited by the state of
preservation of specimens, and somewhat, by differing diagnostic
criteria (microstructure vs macrostructure) used in the systematic
classification of Scleractinia. [original abstract]^1";
s[2493] = "BARON-SZABO R.C., CASADIO S., PARRAS A. (2004).- First
shallow water scleractinian coral reef from the Danian, northern
Patagonia, Argentina.- Ameghiniana, Suplemento 40, 4: 79R.-
<b>FC&#038;P 33-1</b>, p. 28, ID=7182^<b>Topic(s): </b>reefs, shallow
marine; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Dan; <b>Geography: </b>Argentina,
Patagonia^Hermatypic coral reefs have not been reported from the
earliest Paleocene with a few exceptions of the unverified records
(e.g. Paris Basin). On the other hand azooxanthellate coral reefs from
the early Paleocene of Greenland and Faxe, Denmark are well-documented.
We describe the first Danian hermatypic coral reef from the Roca
Formation at Lomita Baya, La Pampa, Argentina. The coral reef is
primarily formed by the colonial taxa Siderastrea adkinsi (Wells, 1934)
and Haimesastraea conferta Vaughan, 1900, and is distinctly dominated
by S. adkinsi (62%-88% in shallowest parts of the reef, 82%-100% in
adjacent areas). In the shallowest parts of the reef colonies of S.
adkinsi are massive-folious or encrusting, ranging between a few
centimeters to over 1m in diameter. Specimens of H. conferta are
distinctly smaller, generally knobby, and range between a few
millimeters and 15cm in diameter. Frequently, corals of the
&#039;rolling stone type&#039; occur which, in addition to the presence
of folious-encrusting morphotypes and the microfacies images, indicate
that the reef developed in a highly wave-agitated environment of 0-10m
depth. Sponges and coralline algae played an important role in the reef
frame. Other members of the coral reef community are the branching
coral Cladocora cf. C. gracilis (d&#039;Orbigny, 1850), the solitary
coral Sideroseris durhami Wells, 1945, the echinoid Micropsis desori
(Cotteau, 1856), which is an inhabitant of hard substrates, the
bivalves Acesta cf. A. latens (Feruglio, 1935), and Venericardia
iheringi (Böhm, 1903), as well as several species of warm water
gastropods. [ short communication, full text]^1";

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Paleocene; <b>Geography: </b>Argentina^A horizon
with large, massive corals in growth position was discovered in the
Paleocene, probably upper Danian, part of the Maastrichtian-Paleocene
Lefipán Formation of Chubut (Patagonia, Argentina). All corals belong
to one species, the cosmopolitan Haimesiastraea conferta Vaughan, which
survived the end-Cretaceous mass extinction. The occurrence of massive
corals at this site is exceptional both because of the siliciclastic
depositional regime and because of the high palaeolatitude setting. An
unusual autecology of this coral and strongly reduced sedimentation
rates, were probably the prerequisites for coral growth, but a link to
palaeoclimate is less likely.^1";

extraordinary position of the occurrences and the Pacific terranes are
discussed.^1";
s[2512] = "SENOWBARI-DARYAN B. (1994).- Mesozoic sponges of the Pucara
group, Peru.- Palaeontographica A233, 1-6: 57-74.- <b>FC&#038;P
24-1</b>, p. 75, ID=4508^<b>Topic(s): </b>; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Triassic U - Jurassic M;
<b>Geography: </b>Peru^The Pucara Group of central Peru represents
nearly 3,000 m of shallow-water carbonate deposition spanning from the
Late Triassic to Middle Jurassic in time. The Upper Triassic carbonate
rocks, the Chambara Formation, and the Jurassic units, the Aramachay
and Condorsinga Formations, exhibit distinctive associations of
sponges, which are described in this paper. From the Triassic
succession of Huanincocha near the Lake Junin in central Peru three
genera of inozoan sponges, including Eusiphonella, Corynella and
Peronidella and two genera of sphinctozoan sponges, Amblysiphonella and
Colospongia have been found. Amblysiphonella tubifera is described as a
new species. A specimen of Colospongia was observed in the field but
not collected. Jurassic sponges were collected from several localities
southeast of the town of Cerro de Pasco in central Peru. The
Carhuazcocha locality south of the town of Junin contains the most
diverse sponge fauna including the following described taxa:
Stellispongiella ? juninensis n.sp. Stellispongiella ? ramosa n.sp.
Stellispongiella ? minor n.sp. Trammeria dendroidea n.gen., n.sp.
Cornuaspongia longidepressa n.gen., n.sp. Cornuaspongia reticulata
n.gen., n.sp. Neither the Triassic nor the Jurassic sponge associations
of Peru, are known from other Triassic or Jurassic localities of the
world.^1";
s[2513] = "STANLEY G.D.jr (1994).- Early Mesozoic carbonate rocks of
the Pucara group in northern and central Peru.- Palaeontographica A233,
1-6: 1-32.- <b>FC&#038;P 24-1</b>, p. 58, ID=4468^<b>Topic(s):
</b>carbonates; carbonates fossils; <b>Systematics: </b>;
<b>Stratigraphy: </b>Triassic Jurassic; <b>Geography: </b>Peru^From
northern and central Peru 19 Triassic and Jurassic localities were
investigated. Measured sections and collection sites yielded abundant
and diverse groups of silicified fossils and carbonate microfacies from
the Pucara Group, a carbonate rock unit exceeding 2,000 m in thickness
which is well-exposed in the Peruvian Andes. Over eighty years of
geologic investigation on the stratigraphy, ore deposits, and
paleontology of the Pucara have resulted in biostratigraphic
classifications, recognition of depositional environments,
correlations, age and stratigraphic framework, but study of many fossil
groups has tagged behind. Fossils from previous investigations have not
been precisely located and age-diagnostic fossils are usually scarce in
the carbonate rock sequence of the Pucara. New fossils described from
the 19 localities have helped in refining dating and correlations. The
thick Pucara succession in Peru is important because relative to many
other regions of the world, it records a fairly complete history of
late Triassic to Early Jurassic rocks and fossils, including the
Triassic-Jurassic systematic boundary. It also includes an extensive
record of marine sedimentation along the Pacific Cordillera of South
America. Abundant and diverse marine fossils of the Pucara Group
include Upper Triassic (Norian) and Lower Jurassic (Hettangian -
Sinemurian) tropical, shallow-water sponges, corals, spongiomorphs,
calcareous sponges, gastropods, bivalves, ammonites, crinoids and
echinoderms. Conodonts also occur in the Late Triassic portion of the
sequence. Abundant shallow-water depositional environments, including
small-scale coral, sponge and oyster biostromes characterize the
sequence. The 19 localities and the measured sections described in this
```

```
paper are utilized by most authors in this volume [to] designate their
fossil material.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Jurassic M; <b>Geography: </b>Chile N^Five hermatypic coral genera
from the north Chilean Pre-Cordillera are presented; one of the species
is probably new. The coral limestones mark the beginning of a
transgression in the Bajocian. Except in boreal regions, the occurrence
of hermatypic corals is world-wide in this period and indicates a warm
and balanced climate. An unusual biogeographic phenomenon is the
abundance of meandroid forms in N-Chile. The following genera and
species are described: Actinastrea cf. ramulifera, A. pentagonalis, A.
ssp., Dendrastrea langrunensis, Isastrea richardsoni, Microphyllia cf.
pulchella, M. sp., Latomeandra sp.^1";
s[2516] = "SENOWBARI-DARYAN B., STANLEY G.D.jr (1994).- Lower Jurassic
marine carbonate deposits in Central Peru: Stratigraphy and
paleontology.- Palaeontographica A233, 1-6: 43-56.- <b>FC&#038;P
24-1</b>, p. 58, ID=4467^<b>Topic(s): </b>carbonates; carbonates
paleontology; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic L;
<b>Geography: </b>Peru^Field investigation of Lower Jurassic rocks of
central Peru belonging to the Condorsinga Formation near Manzanares,
yielded a rich variety of carbonate microfacies with diverse
invertebrate fossils including sponges, corals, brachiopods,
echinoderms, molluscs, foraminifers, serpulid tubes, microcoprolites of
crustaceans, and the probable crustacean trace fossils of
Thalassinoides. Organic constructional microfacies were lacking and
coarse to fine-grained, bedded carbonate rocks predominate. Locally
five biofacies were delineated: 1) coral wackestone with solitary and
colonial corals Stylophyllopsis, cf. S. victoriae, Stylophyllopsis sp.
and Hispaniastraea ramosa, 2) thalamid sponge pelleted wackestone,
characterized by large in situ &#34;Stylothalamia&#34;, 3) serpulid
wackestone with in situ clusters of tubes, 4) bioturbated bioclastic
pellet packstone, and 5) brachiopod packstone coquina. The microfacies
types, fauna and flora indicate the presence of a broad carbonate
platform (ramp) with much of the carbonate sediment deposited on the
outer slope. Based on the Manzanares section, this platform was
differentiated into subenvironments of low-energy, deeper water
protected and more open, fairly agitated environments. Reef structures
are absent The invertebrate fauna bear similarities with taxa known
from both the western Tethys and North America.^1";

</b>geology, geography; geography, Prototethys; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian, Carboniferous L; <b>Geography: </b>Asia,
Australia^More than 40 discrete crustal blocks (micro/mini continents,
minor &#34;suspect terranes&#34; excepted) delineated by ophiolite
belts, major geosutures, flysch wedges and radiolarites can be
identified in the Asia-Australia region. For the Palaeozoic, analysis
has suffered from inadequacy of longitudinal constraints; this has led
to important differences in models previously proposed for the
dispositions and motions of island arcs and continental fragments,
especially for pre-Permian reconstructions - the era of
&#34;Prototethys&#34; or the &#34;Prehercynian Ocean&#34;. The age of
suturing of successive blocks can be shown to decrease in a general way
from the Siberian Block towards the east, southeast and south.
Prototethys (and its successor, Tethys) and the northern margin of East
Gondwana changed markedly in configuration through Palaeozoic and early
Mesozoic times as block after block moved northwards and then sutured
with the enlarging Asian Block (Eurasian Block from Bashkirian times
onwards). It is against this background that preliminary results for
the biogeography of Devonian and Lower Carboniferous brachiopod faunas
are presented. Not all blocks have adequate faunas for useful analysis.
Those which do, show a greater level of provincialism, consistent with
greater dispersion of blocks relative to one another, than might have
```

```
been anticipated, especially if they are construed as having formed
part of a single land-mass with open seaways which should have
facilitated ease of interplay between shallow marine faunas.^1";

```

```
ID=3071^<b>Topic(s): </b>reefs, structure, diversity; reefs,
Archaeocyathan-microbe; <b>Systematics: </b>Porifera; Archaeocyatha;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>Russia, Siberia^The
oldest sponge reef is a small Early Cambrian bioherm at the base of the
Tomotian Stage (~535-540 Ma) in southeast Siberia. The mainly
archaeocyath construction may be a response to turbid conditions.
Cambrocyathellus bowls fused to create a rigid cavernous frame
colonized by cryptic Archaeolynthus and calcified microbes (Renalcis).
In addition to these constructors and binders, other reef guilds are
present: bafflers (other archaeocyaths, spiculate sponges, and
hyoliths) and dwellers (hyoliths, mollusks, and many others). This is
the oldest known reef possessing an open skeletal frame structure built
by animals and a mixed animal-autotroph composition. It provides a
blueprint for younger Phanerozoic reefs.^1";
s[2529] = "ZHURAVLEVA I.T. (1972).- Facial assemblages of
Archeocyathids of the Lower Cambrian (middle course of Lena River).- In
Problemy Biostratigrafii i Paleontologii nizhnego Kembriya Sibiri:
31-109; Izdat. Nauka, Moskva.- <b>FC&#038;P 2-2</b>, p. 25,
ID=4834^<b>Topic(s): </b>facies; Archaeocyatha assemblages;
<b>Systematics: </b>Porifera; Archaeocyatha; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>Russia, Siberia, Lena river^The
author studies the relationships between environmental facies and
archeocyathids assemblages during the development of the basin of Lena
River. She distinguishes the following facial types: (1) bioherms: a)
isolated bioherms; b) massive bioherms; (2) biostromes; (3)
taphostromes; (4) interbioherms: a) near the bioherms; b) far from the
bioherms. * Steps are recognized for the evolution of the Basin - 4
main conclusions: - one cannot speak of the diminution of the thickness
of the rocks at the East and an augmentation at the West, but only of
local variations; - migrations of the assemblages are observed towards
the East; - 3 main types of organic building are recognized (bioherms,
biostromes, taphostromes); - the differences of complexity of the
bioherms are not only due to their size or their duration but also to
the environmental conditions. * This article is the first important
attempt to point out the links between the different species of
Archeocyathids, and the types of the rocks including them. The
insurpassed experience of the author concerning the phylum
Archaeocyatha as well as the stratigraphy of Siberian platform make
this article a precious guide for further studies in other regions. It
shows clearly that Archaeocyathids are not only good biostratigraphical
markers, but could be used for ecology and biogeography.^1";

One of the poles has a double cross-like structure, consisting of two sets of four bands each. The bands of the upper set radiat at 90° from each other; those of the lower set also radiate at about right angles from each other, but the set is rotated 45° in respect to the upper set. Although there is a resemblance to the cross-like arrangements of cells in pregastrulation spiralian eggs, in particular those of annelids, the combined evidence favors an interpretation of the bands as incipient tentacles of a cnidarian actinula larva. The embryos occur with one of the first assemblages of shelly fossils in norhtern Siberia, that of the Angustiochrea lata zone. The co-occurring shelly fossils, anabaritids, probably also represent the phylum Cnidaria, but because their tubes have a consistent triradial symmetry, the connection with the tetraradially symmetrical embryos is problematic. The size of the embryos suggests that they are nonplanktotrophic, and the presence of actinula-like features suggests the lack of a free planula stage.^1";

</b>Cnidaria Bryozoa; Anthozoa; <b>Stratigraphy: </b>Ordovician
Silurian; <b>Geography: </b>Russia, Siberia, Verkhoyan^Presented is
extensive paleontological and stratigraphical research on Ordovician
and Silurian of the southern Verchoyan region. A biostratigraphic
scheme is presented including faunistic reasons for the definition of
horizons and subhorizons as well as an interregional correlation.
Palecological investigations reveals three main stages in the
development of fossil communities. Corals and Bryozoans from this
region are, for the first time, monographically dealt with. * Described
are numerous representatives of tabulate and rugose corals of the
following genera: (*) Tabulata - Nyctopora, Eocatenipora, Catenipora,
Halysites, Cystihalysites, Agetolites, Paleofavosites, Priscosolenia,
Multisolenia, Mesosolenia, Mesofavosites, Favosites (Favosites),
F.(Sapporipora), Gephuropora, Parastriatopora, Syringopora,
Fletcheriella, Cyrtophyllum, Sibiriolites; (*) Rugosa - Streptelasma,
Crassilasma, Dinophyllum, Tungussophyllum, Holophragma, Miculiella,
Ptychophyllum, Cyathactis, Neocystiphyllum, Palaeophyllum,
Entelophyllum, Strombodes, Tryplasma, Ketophyllum, Dentilasma,
Diplochone, Cyatiphyllum, Kymocystis, Holmophyllum, Nipponophyllum,
Yassia.^1";
s[2547] = "KHROMYKH V.G. (2010).- Evolution of Stromatoporoidea in the
Ordovician-Silurian epicontinental basin of the Siberian Platform and
Taimyr.- Russian Geology and Geophysics 51: 684-693.- <b>FC&#038;P
36</b>, p. 33, ID=6398^<b>Topic(s): </b>phylogeny; stroms;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Ordovician Silurian; <b>Geography: </b>Russia, Siberian
Platform^Stromatoporoids were collected from 29 measured sections from
along the Khakoma, Moiero, Moilerokan, Bugarikata, Yuktali,
Bol&#39;shaya, and Parmaya Rivers. This paper does not include
descriptions of the stromatoporoids, but rather notes the stratigraphic
occurrence and evolutionary relationships of the genera present. The
author notes that correlation of strata at the Siberian localities with
the new Ordovician stages is &#34;fairly tentative&#34; (p. 687). The
emergence of new genera is noted by stage: * Darriwilian: Priscastroma,
Cystostroma; * Sandbian: Stromatocerium, Rosenella, Lophiostroma,
Pachystylostroma, Labechia; * Katian: Aulacera, Nestoridictyon,
Stratodictyon, Stelodictyon, Ecclimadictyon, Dermatostroma,
Taymyrostroma; * Hirnantian: Clathrodictyon; * Aeronian: Clavidictyon,
Plectostroma, Mamellolabechia; * Telychian: Stromatopora, Vikingia,
```

```
Parallelopora, Neobeatricea, Yabeodictyon, Yavorskiina; * Sheinwoodian: Plexodictyon, Parallelostroma; * Gorstian: Hermatostromella. The author concludes that Ordovician stromatoporoid genera emerging in this basin indicate that the basin was one of the global centers of stromatoporoid origination.^1";

```

```
1950-1960, were clearly different from all rugosa known before, but
material was too insufficient to establish new taxa. During the
following years additional material could be collected which now gave
new insights concerning the skeletal structure. Diagnoses of the new
taxa are given. Tetrafossularia Ivanovskij gen. nov. (Densiphyllidae),
type species Triplophyllum tetrafossulum Ivanovskij 1962; diagnosis:
solitary corals with distinct fossulae between each of the protosepta;
distribution: lower - middle Llandoverian (Siberian Platform);
Cereoelasma Ivanovskij gen. nov. (Cyathophylloididae), type species
Cereoelasma sibirica sp.nov.; diagnosis: corallum cerioid, septa short,
tabulae complete and incomplete, dissepiments sporadical or forming a
narrow dissepimentarium, sometimes lonsdaleoid dissepiments may be
developed; distribution Wenlockian (Gotland, Podolia, Siberian
Platform); Aphroelasma Ivanovskij gen. nov. (Phillipsastreidae), type
species Frechastraea russakovi Spasskiy et Kravtsov 1975; diagnosis:
aphroid Phillipsastreidae with short ripidacanth septa, small globose
tabulae, one row of horseshoe-dissepiments is developed; distribution:
Devonian, Emsian (Yakutia and Canada).^1";

Symposium, Brisbane [1998?]; poster. [poster] - <b>FC&#038;P 28-1</b>,
p. 51, ID=6927^<b>Topic(s): </b>spiculae; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Russia,
Baikal^Sponges are beside diatoms, because of their wide spatial
distribution in geological time, the only endemic species for
paleostratigraphy in Lake Baikal. This poster presents first attempts
in this field. * For a sure identification of species of baikalian
sponges it is necessary to know the architectonics of their skeletons
and the form of their spicules The difficulty: in Lake Baikal bottom
sediments is that we have only isolated skeleton spicules. Therefore to
identify the spicules in the sediments we compared photos of skeleton
architectonics in recent sponges, their spicules and spicules of the
sediments. It has been found that some species of baikalian sponges can
be easily identified by their typical morphological and morphometric
pecularities of their spicules (B. robusta, B. recta, Rezinkovia sp.,
Swartschewskia sp.). The spicules of such species as B. intermedia, B.
bacilifera, B tenera, gen. Lubomirskia, are more variable, therefore
the identification of these species by spicules is done with less
trustworthiness degree. The use of this method has given a possibility
to identify species composition of spongiofauna of Holocene-Pleistocene
deposits of underwater Akademicheskiy Ridge in Lake Baikal.^1";

</b>biodiversity; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>; <b>Geography: </b>Russia, Siberia^Biodiversity
of Devonian tabulatomorph corals of the Salair, West-Siberian, Taimyr,
and Central-Siberian seas has been investigated for years. The data
obtained demonstrate it significant variability. We have tentatively
recognized periods of great and small biodiversity as well as
borderlines at which the taxonomic diversity of tabulatomorphs either
increased or decreased drastically. It is shown that in the Salair sea,
tabulatomorphs were the most diverse during the Lochkovian, Emsian, and
Givetian. The same stages are observed in the Altai sea, although the
dynamics of tabulatomoph biodiversity was not so well-pronounced in the
Lochkovian or Givetian. Biodiversity was little variable in the
West-Siberian, Taimyr, and Central Siberian seas. In all Siberian seas,
it reached its minimum in the Famennian. This was related to a change
in the composition of predominant corals, when Thamnoporina and
Alveolitina became extinct and gave way to Syringoporidae and
Auloporidae. Of favositids, Micheliniidae and Cleistoporidae were of
the greatest abundance.^1";

Geological Magazine 133: 429-444.- <b>FC&#038;P 25-2</b>, p. 62,
ID=3090^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>Mongolia, Zavkhan
Basin^The Neoproterozoic-Cambrian succession in the Zavkhan Basin of
western Mongolia preserves Early Cambrian bioconstructions of
Nemakit-Daldynian to Botomian age. As elsewhere (Siberia, Morocco), the
older bioconstructions (upper Tsagan-Oloom to lower Bayan-Gol
Formations = Namakyt-Daldynian) were purely calcimicrobial; in the
upper Bayan-Gol Formation (?Tommotian), spectacular calcimicrobial
&#34;patch-reefs&#34; are present. In contrast, the Salaany-Gol
Formation bioherms (late Atdabanian-early Botomian) are varied and well
developped and included archaeocyaths and other metazoans as
bioconstructors together with calcimicrobes. Three types of
bioconstructions are recognized : 1) Gordonophyton-Razumovskia crusts
supporting a cryptic community of corallomorphs, cribricyaths and
archaeocyaths; 2) radiocyathan - archaeocyath bioherms; the abundant
and diverse archaeocyath fauna served a binding function, while
calcimicrobes were relatively minor; 3) calcimicrobial bioherms
including layered fabric of intergrown erect bushes and rafts of
calcimicrobes with associated oligotypic archaeocyaths and bioclastic
debris. Comparisons with coeval bioconstructions of the Gondwana
margins are made; among them, the Zavkhan Basin archaeocyathan -
radiocyathan bioherms represent the moderate to high-energy spectrum

Stromatoporoidea; <b>Stratigraphy: </b>Ordovician - Devonian;
<b>Geography: </b>Mongolia^Presented are descriptions of all taxa from
genus to order levels of stromatoporoids, tabulates, heliolitids and
rugosans from Ordovician, Silurian &#038; Devonian deposits of
Mongolia. Described are 23 orders, 82 families and 179 fossil genera.
All major groups are supplied by short note of systematical position,
morphology, ecology, biogeography and stratigraphic distribution. Each
genus is with one illustrated species, and with a list of its other
species recorded from Mongolia. The book contains also an index of
latin names of taxa.^1";

<b>Systematics: </b>Cnidaria; Tabulata Rugosa; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Dzhungaro-Balkhash province^In this
monograph, a review of the Devonian stratigraphy of the Near-Balkhash
and Djungarian Alatau is followed by a description of Tabulates and
Tetracorals of that period. The analysis of corals rendered possible
the division of the Djungaro-Balkhash Province into two
paleobiogeographical regions, each having characteristic and
correspondent complexes of genera and species. On the basis of the
study of corals, the Early and Middle Devonian are subdivided each into
three parts. The relationship of the Djungaro-Balkhash Province with
adjacent territories is presented. The book is of interest to
stratigraphers, paleontologists and geologists working in Kazakhstan
and Central Asia.^1";

</b>ecological interactions; Porifera; <b>Systematics: </b>Porifera;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Russia, Baikal^The
composition of invertebrate communities inhabiting Baikalian sponges
was studied. All the sponges examined were inhabited by invertebrates.
Their number varied from 80 to 280 individuals per 100 cm3 of sponge,
the biomass was found to be from 200 to 1020 mg per 100 cm3 of sponge.
Twelve taxa: Turbellaria, Hirudinea, Nematoda, Oligochaeta, Polychaeta,
Copepoda, Ostracoda, Isopoda, Amphipoda, Trichoptera, Chironomidae,
Mollusca were found. There are two distinctive sets of species within
the sponge consortia, which we designate as &#034;specific&#034; and
&#034;non-specific&#034; ones. The latter differs in sponges sampled in
different parts of the lake. The specific set consists of species,
which are typical of all the sponge species sampled in different parts
of the lake. The interaction between the sponges and the inhabiting
invertebrates includes topic and trophic links. For most of
sponge-dwelling invertebrates their interaction with the sponge is most
likely to be as proto-cooperation (non-obligate co-existence), and for
some species like Brandtia parasitica and Acanthocyclops spongicola as
mutualism (obligate co-existence). [original abstract]^1";

Investigations on the endemic freshwater Porifera of Lake Baikal
(Lubormirskiidae): status and perspectives.- Terra Nostra 2000, 9:
49-59.- <b>FC&#038;P 30-2</b>, p. 36, ID=1605^<b>Topic(s):
</b>freshwater, taxonomy; Porifera, freshwater; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Russia,
Baikal^The endemic Porifera of Lake Baikal constituting the family
Lubomirskiidae are comparably well investigated, but still there are
many &#34;white spots&#34;. This group is unique in its adaptation,
both with respect to nutrition and reproductive strategies and also
regarding its synecological significance. Particularly the genus
Baikalospongia exhibits remarkable flexibility of its endosymbiontic
relations, from autotrophic eucaryotes in the littoral to
methanotrophic bacteria at thermal vents, and the role of these
different symbiontic strategies are poorly investigated. So far, only
one genetic analysis of Baikal sponges has been published, and the
resulting phylogenetic tree rises more questions than answers. To
clarify the phylogenetic relationships within the Lubomirskiidae,
further genetic sequencing as well as intensive palaeoecological
research of fossil spicule assemblages from drilling cores are
necessary. First investigations of oxygene isotopes on spicules from
recent Lubomirskiidae show the perspectives for a broader use of
freshwater sponge spicules as a paleoclimatological indicator in limnic
sediments.^1";

<b>Stratigraphy: </b>Recent; <b>Geography: </b>Russia, Baikal^During a
9-day excursion at the beginning of September 1993 to Lake Baikal
(Sibiria) several samples of the endemic Baikal-sponges
(Lubomirskiidae) Swartschewskia papyracea, Lubomirskia baicalensis, and
Baikalospongia cf. bacillifera were collected and afterwards examined
at histological and ultrastructural level. Special interest was focused
on the morphology of choanocyte chambers and choanocytes, embryonal
stages, larvae, spicules, and the contact between the substrate and the
sponge. All choanocytes of the examined lubomirskiid species showed
similar morphological patterns. The flagellum is located in a little
pit and the kinetosome anchored with microtubules. In September
Baikalospongia contained allready fully developed parenchymellae, while
Swartschewskia exhibited cleavage stages and Lubomirskia large oocytes
only. Between sponge and substrate a biofilm-layer was detected.^1";

Cambrian anemones with preserved soft tissue from the Chengjiang
biota.- Lethaia 38, 3: 193-203.- <b>FC&#038;P 34</b>, p. 97,
ID=1359^<b>Topic(s): </b>soft tissues; Anthozoa Anemones;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Cambrian;
<b>Geography: </b>China, Chengjiang^The group Cnidaria includes
&#039;jellyfish&#039;, soft-bodied anemone and anemone-like forms and
calcified corals. These diploblastic organisms have a fossil record
extending back to the earliest metazoans of the Neoproterozoic; however
certain cnidarians of the subclass Zoantharia, characterized by
soft-bodied anemone-like forms, are absent or poorly represented in the
fossil record. Despite the paucity of fossils, it is thought that
calcification by soft anemone-like animals was responsible for
producing the skeleton that allowed the preservation of the first
corals. We report discovery of an abundant assemblage of in situ
soft-bodied polyps with tissues. They are preserved in exquisite detail
and come from the well-known Lower Cambrian Chengjiang biota of Yunnan,
China. The soft-bodied polyps display a simple anatomy that is
comparable to some extant anemones of the order Actinaria. The new
fossils are assigned to Archisaccophyllia kunmingensis n.gen. et n.sp.
Their simple and conservative form suggests that these fossils may
represent some kind of ancestral rootstock. The preserved life
assemblage provides a unique snapshot of Lower Cambrian anemone life
and provides clues for relationships with extant actiniarians as well
as calcified corals.^1";
s[2663] = "JIAN HAN J., KUBOTA S., UCHIDA H., STANLEY G.D.jr, YAO X.,
SHU D., LI Y., YASUI K. (2010).- Tiny sea anemone from the Lower
Cambrian of China.- PLOS ONE 5, 10: e13276.- <b>FC&#038;P 36</b>, p.
78, ID=6485^<b>Topic(s): </b>; corals anemones; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Cambrian L; <b>Geography:
</b>China S^Abundant fossils from the Ediacaran and Cambrian showing
cnidarian grade grossly suggest that cnidarian diversification occurred
earlier than that of other eumetazoans. However, fossils of possible
soft-bodied polyps are scanty and modern corals are dated back only to
the Middle Triassic, although molecular phylogenetic results support
the idea that anthozoans represent the first major branch of the
Cnidaria. Because of difficulties in taxonomic assignments owing to
imperfect preservation of fossil cnidarian candidates, little is known
about forms ancestral to those of living groups. * We have analyzed the
soft-bodied polypoid microfossils Eolympia pediculata gen. et sp.nov.
from the lowest Cambrian Kuanchuanpu Formation in southern China by
scanning electron microscopy and computer-aided microtomography after
isolating fossils from sedimentary rocks by acetic acid maceration. The
fossils, about a half mm in body size, are preserved with 18
mesenteries including directives bilaterally arranged, 18 tentacles and
a stalk-like pedicle. The pedicle suggests a sexual life cycle, while
asexual reproduction by transverse fission also is inferred by
circumferential grooves on the body column. * The features found in the
present fossils fall within the morphological spectrum of modern
Hexacorallia excluding Ceriantharia, and thus Eolympia pediculata could
be a stem member for this group. The fossils also demonstrate that
basic features characterizing modern hexacorallians such as bilateral
symmetry and the reproductive system, have deep roots in the Early
Cambrian. [original abstract]^1";

At least 11 genera and 20 species have been found, forming the second most diversified metazoan group in Chengjiang. A majority of the sponges belong to the Demospongea with a broad spectrum of morphological variation and sizes. - They were embedded in the mudstone layers of the lower part of the Yuanshan Member. This member is the unit representing the upper part of the Chiungchussu Formation. Stratigraphically the fossils in our study range in a narrow interval dated as the lowest Eoredlichia Zone in the trilobite sequence. [fragment of extensive summary]^1";
s[2680] = "CHEN JUNYUAN, HOU XIANGUANG, LI GUOXIANG (1990).- New Lower Cambrian Demosponges - Quadrolaminiella gen. nov. from Chengjiang, Yunann.- Acta Palaeontologica Sinica 29, 4: 402-414.- <b>FC&#038;P 20-1.1</b>, p. 70, ID=2855^<b>Topic(s): </b>; Porifera Demospongiae; <b>Systematics: </b>Porifera; Demospongiae; <b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>China, Chengjiang^Although isolated spicules of sponges are known, virtually in all continents with greatly abundant Lower Cambrian rocks, the preservation of verified articulate skeletons is extremely rare in the past records. The Chengjiang Lagerstatten is of special importance in fossil sponge studies for the record of its older age and the excellent preservation. Because of the biased preservation, the knowledge of Lower Cambrian sponges has been heavily dependent on the isolated spicules which are largely known as isolated stauractines, and which have led to assumption by various authors that sponges in Early Cambrian had a limited diversity, consisting largely of Hexactinellid protosponges with a few rare demosponges. On the contrary, a supported evidence from Chengjiang Lagerstatte suggest that the sponges, particularly Demospongea in the Early Cambrian Chiungchussu stage underwent very rapid diversification which led to many indefinite morphologic types, with an evolutionary complexity which might stand comparison with those of the Middle Cambrian Burgess Shale. The striking similarity of the sponge fauna between the Chengjiang Lagerstatten and the Burgess Shale suggest that sponges have retarded their evolutionary pace from the Chiungchussu stage for at least a period of 30 Ma. Among the demosponges, Leptomitus has a simple and thin double-layered skeleton and stratigraphic lowest occurrence which have led to assumption as the central stock of the Demospongea. Fossil evidences indicate that many elements of demosponges have adopted from Leptomitus a virtually unchanged pattern of double-layered skeleton. None of multiple-layered skeletons have been known among the Cambrian sponges apart from the present new genus Quadrolaminiella. This new form is characterized by a unique four-layered and double-netted skeleton. The outer net consists of the
```

```
1st (outermost) and the 2nd layers of oxeas, which extend parallel and
vertical to the length of the sponges respectively; inner net formed by
the 3rd and 4th layers, extending upward diagonally clockwise and
counter clockwise respectively. Quadrolaminiella migth have derived
from Leptomitus as if it had development a thicker skeleton with an
additional inner net. All the specimens available for the present
studies were collected from Quarries M3 and CF5 on the W and NW slopes
of the Maotian hill, about five km SE of Chengjiang. They were embedded
in the mudstone layers in the lower part of the Yuanshan Member, a unit
representing the upper part of the Chingchussu Formation.
Biostratigraphically the specimens under study range within a narrow
interval dated as the lower Eoredlichia zone. [fragment of extensive
original summary]^1";

(2005).- Hexactinellid Sponges from the Early Cambrian Black Shale of
South Anhui, China.- Journal of Paleontology 79, 6: 1043-1051.-
<b>FC&#038;P 34</b>, p. 25, ID=1219^<b>Topic(s): </b>taxonomy; Porifera
Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>China, Anhui^Three
new and one completely preserved species of hexactinellid sponges are
described from Early Cambrian black shales of South Anhui, China. The
sponges occur in the middle part of the Huangboling Formation, which is
assigned to the early Canglangpuian based on trilobite biostratigraphy.
Metaxyspongia skelidata n.gen. and sp. and Hexatractiella dongzhiensis
n.sp. are subcylindrical thin-walled Protospongiidae. Ratcliffespongia
multiforamina n.sp. is assigned to the Hintzespongiidae. With these new
sponges, the first occurrences of the Protospongiidae and
Hintzespongiidae, and of Hexatractiella Mehl, 1996, can be traced back
to the Early Cambrian. Solactiniella cf. plumata Steiner et al., 1993,
with irregular rossellimorph skeletal architecture and regular spicular
organization, is found here associated with the above species. Thus,
the Anhui assemblage can be considered as intermediate between
Atdabanian shallow-water communities of hexactinellids with irregular
skeletons and the Middle Cambrian deepwater sponge facies characterized
by regularly organized Hexactinellida.^1";

from Chengjiang, Yunnan, China.- Acta Palaeontologica Sinica 26, 3:
257-270.- <b>FC&#038;P 17-1</b>, p. 37, ID=2149^<b>Topic(s):
</b>taxonomy, stratigraphy, biogeography; Hydrozoa; <b>Systematics:
</b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>Cambrian L; <b>Geography:
</b>China, Yunnan, Chengjiang^This paper presents a preliminary report
on the highly diversified and beautifully preserved medusoid fossils
recently discovered from the Lowermost Cambrian Yuanshan Member of the
Chiungchussu Formation at Mt. Maotian-shan, Chengjiang County, eastern
Yunnan, southwestern China. The specimens are moulds and casts of
medusa body impressions, which were compressed into very thin discs or
completely flattened into films between the bedding planes of shales
and mudstones. They are accompanied by abundant and varied, soft-bodied
and also shelly metazoans including sponges, annelids, brachiopods,
gastropods, hyolithids, bradoriids, trilobites and other arthropods,
etc. in the same assemblage, i.e. the Chengjiang fauna. The rock
sequence of this fauna is marked by the Parabadiella Zone just at the
bottom and bracketed within the lower part of the succeeding
Eoredlichia-Wutingaspis Zone. These two trilobite zones represent the
very early Cambrian Chiungchussu Stage, which was immediately predated
by the Precambrian-Cambrian transition of the Meishucun Stage. * The
medusoid fossils constitute a prominent part of the Chengjiang fauna.
Four new genera and species are described here, including the hydrozoan
Heliomedusa orienta gen. et sp.nov., the chondrophoran Rotadiscus
grandis gen. et sp.nov. and the scyphozoan Stellostomites eumorphus
gen. et sp.nov. and Yunnannomedusa eleganta gen. et sp.nov. * The
medusae in the Chengjiang fauna represent the genuine medusoid fossils
first discovered in China and the only known medusae occurring in the
basal Cambrian of the world. The diversification of these new medusae
can be traced back to their ancestors in the latest Precambrian
Ediacara fauna in South Australia, providing remarkable evidence for a
continuous metazoan evolution across the crucial Precambrian
(Proterozoic) - Cambrian (Phanerozoic) boundary [fragment of extensive
summary].^1";

Soft-bodied anemone and gelatinous fossils (Cnidaria &#47; Ctenophora)
from the Lower Cambrian, Chengjiang biota, Yunnan Province, China.-
Geological Society of America, Abstracts with Programs 37, 7: 486.
[abstract] - <b>FC&#038;P 34</b>, p. 104, ID=1371^<b>Topic(s): </b>ex
Chengjiang biota; Cnidaria, Ctenophora; <b>Systematics: </b>Ctenophora;
<b>Stratigraphy: </b>Cambrian L; <b>Geography: </b>China, Yunnan^The
celebrated Early Cambrian Chengjiang biota of southwestern China has
yielded some exquisite and extraordinary fossils. These fossils have
provided important and unparalleled insights into the biology,
taxonomic diversity and nature of the Cambrian explosion. While
arthropods and other hard-shelled fossils are well known, considerable
soft-bodied components of this biota also have been discovered. Among
these newly discovered taxa are a whole assemblage of in situ anemones
preserved on the bedding surface, replete with attachment disc, column,
tentacles and crown. Also found are an abundance of possible hydroids
on the bedding planes. Extremely fragile gelatinous taxa belonging to
the phyla Cnidaria and Ctenophora are present as well. Pelagic taxa
among the gelatinous biota include a possible jellyfish-like
siphonophoran with tentacles and gonozooids and also several examples
of ctenophores. The ctenophores are the oldest yet known. They are
```

```
easily recognized as ctenophores because they still retain their eight
comb-rows, cilia plates and associated gelatinous soft tissues.
Compared to some other soft-bodied taxa, they are unique in preserving
details of the delicate soft tissues and gelatinous material of the
original living organisms. These fossils also provide valuable
information on anatomy and body organization, connecting these 530
million-year old organisms with their distant living relatives. The
striking degree of anatomical similarity at high taxonomic levels
between some of these Early Cambrian taxa and their extant
counterparts, hints at a much older origin in the late Precambrian for
the ancestors of these groups.^1";

Anhui^Abundant well-preserved large articulated sponge fossils and
isolated spicules have been reported from Early Cambrian Hetang
Formation, southern Anhui Province. This unique epifaunal fossil
assemblage dominated by articulated sponge fossils is called the Xidi
Sponge Fauna. The sponge fauna lived in a quiet oxygenic environment
below the storm wave base. Bloom of phytoplankton and rapid
sedimentation rate resulted in the deposition of the black shales.
Sufficient food supply, lack of other competitors, abundant ecological
niches, and demand for oxyen during early Cambrian were in favor of the
diversification and evolution of large sponges in the Early Cambrian.^1";
s[2687] = "DONG XIPING, KNOLL A.H. (1996).- Middle and Late Cambrian
sponge spicules from Hunan, China.- Journal of Paleontology 70, 2:
173-184.- <b>FC&#038;P 25-1</b>, p. 46, ID=3053^<b>Topic(s):
</b>spicules; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Cambrian M &#47; U; <b>Geography: </b>China, Hunan^Abundant and
well-preserved assemblages of disarticulated sponge spicules occur in
Middle and Late Cambrian platform carbonates of western Hunan, China.
Assemblages recovered from 11 stratigraphic horizons include
calcisponges, demosponges, and hexactinellids. Hexactinellida, in
particular, are both abundant and diverse in Upper Cambrian carbonates.
Comparison with spicule assemblages from Australia indicates that many
of these taxa have long stratigraphic ranges, limiting their use in
correlation. The morphological diversity of these spicules exceeds that
known for living siliceous sponges, supporting the observation that
during the Cambrian radiation, sponges, like other metazoans, evolved a
variety of architectural forms not observed in later periods. Like
conodonts, individual sponges can produce more than one spicule form;
thus, an &#34;apparatus genus&#34; concept based on multiple
cooccurring elements may eventually prove useful in the
biostratigraphic and paleobiologjcal interpretation of disarticulated
sponge spicules. Four distinctive forms are recognized as new taxa.
Australispongia sinensis new genus and species, Flosculus gracilis new
genus and species, Pinnatispongia bengtsoni new genus and species, and
Nabaviella paibiensis new species.^1";

</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Paleozoic; <b>Geography:
</b>China, Xinjiang^Northern Xinjiang is subordinate to Palaeozoic
Tianshan-Hinggan geosynclinal area. Coral faunas, especially those of
Palaeozoic. Are well-developed in many rock formations. The Ordovician
to Devonian tabulate corals from northern Xinjiang represent the
geosynclinal faunas in North China, which are different from the faunas
from South China in their assemblages and some structural features of
corallites. In general, wall and septal component of corallites from
geosynclinal faunas in North China are more varied than those of
corallites from platform faunas in South China. The species of tabulate
corals described in this paper amount to 58 species, including 21 new
ones, which belong to 28 genera (3 of them are new). Their geographical
and stratigraphical distributions are indicated, and features of some
tabulate corals from Northern Xinjiang are briefly discussed.^1";

<b>Geography: </b>Myanmar, China^The Paleozoic sequences of the
Padaukpin area of the Northern Shan States (Union of Myanmar)and the
Baoshan region in Western Yunnan (P.R. of China) are compared. They
show many similarities. A hiatus in sedimentation during the
Carboniferous is developed in both regions and is therefore of regional
importance. The Middle Devonian rugose coral fauna of both regions are
typical for the Old World Faunal Realm and especially corals from the
Padaukpin area (Northern Shan States), show strong affinities to the
Rhenish faunas from the German Eifel Mountains. While the &#034;pebbly
mudstones&#034; of Lower Permian age from the Baoshan region are
usually discussed in the literature as glaciomarine deposits, similar
strata in the Shan States are described as oligomictic conglomerate
facies at the base of the Thitsipin Limestone Formation.^1";

<b>Geography: </b>China, Guizhou^The latest Ordovician (Hirnantian)
rugose coral fauna from the Guanyinqiao Beds in Bije, Remhuai and
Shiqian districts of northern Guizhou are studied in detail, and some
genera and species are reviewed. 4 genera and 2 species of rugose
corals are reported from the Guanyinquiao Beds in northern Guizhou for
the first time, they are Axiphora, Bodophyllum, Dalmanophyllum,
Leolasma, Brachyelasma unicum (Neuman), and Grewingkia anguinea
(Scheffen). In the past, quite a number of rugosan taxa, including the
genera Borelasma, Kenophyllum and Ullernelasma, etc. had been
discovered in the Guanyinqiao Beds (He 1978, 1985). The present new
material thus further enrich the content of the latest Ordovician
(Hirnantian) rugosan fauna in the Upper Yangtze region and indicate the
close affinities of the late Ordovician rugosan faunas in the Yangtze
region to those of the Scandinavia and central Asia. Up to now, totally
39 species of 18 genera have been found from the Guanyinqiao Beds (tab.
1). Among them, 12 species of 10 genera of rugosan are described in
this paper, including Amplexobrachyelasma He et Chen gen. nov.,
Grewingkia densicolumna He et Chen sp.nov., Kenophyllum fossulatum He
et Chen sp.nov. and Leolasma qianbeiense He et Chen sp.nov.^1";
s[2740] = "HE XINYI, CHEN JIANQIANG (2004).- Late Ordovician mass
extinction of rugose corals in the Yangtze region. [in Chinese, with
English abstract].- Biotic Mass Extinction and Recovery of the
Paleozoic in South China [Rong Jiayu &#038; Fang Zhongjie (eds)]:
chapter 2, part 6, pp 167-183; Hefei Science and Technology Press.-
<b>FC&#038;P 33-1</b>, p. 57, ID=7172^<b>Topic(s): </b>extinctions O/S;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Ordovician U; <b>Geography: </b>China, Yangtze region^Two phases of
the latest Ordovician rugosan mass extinction are recognized based on
the study of rugose coral fauna from the Sanjushan Formation (middle
Ashgill) in the Lower Yangtze region and the Guanyinqiao Beds (late
Ashgill) in the Upper Yangtze region integrated with modification as
well as statistical analysis of range and distribution of the genera
```

```
and species. The first phase took place during the end of Rawtheyan
Stage. The Late Ordovician (middle Ashgill) rugosan fauna of Lower
Yangtze region contains 16 genera, among which 6 genera
(Cystocantrillia, Hillophyllum, Bowanophyllum, Parastreptelasma,
Favistina and streptelasmatid one new genus) (37.5%) became extinct in
the end of Rawtheyan Stage. The second phase happened during the latest
Himantian. The rugose coral fauna from the Guanyinqiao Beds of Upper
Yangtze region contains 15 genera, among which 9 genera
(Sinkiangolasma, Lambeophyllum, Kenophyllum, Borelasma, Salvadorea,
Ullernelasma, Siphonolasma, Pycnactoides, Bodophyllum) (60%) became
extinct. The present paper deals with the controlling factors of two
extinction events and their differences. The global sea-level decline
caused by the Southern Hemisphere glaciation of the Late Ordovician and
climatic deterioration are the main factors, which resulted in the
first phase of rugosan mass extinction during the end of Rawtheyan. In
the Lower Yangtze region, because of the beginning time of the first
phase of rugosan mass extinction was earlier than brachiopods and
graptolites, the authors concluded that the factors of the first phase
may be also connected with the Guanxian Orogeny. The second phase of
the extinction again related to a rise of global temperature and a
sharp rise of sea-level with oceanic water anoxia which caused the
demise of the shallow, bottom-living and cool &#47; cold water rugose
coral fauna at the late Himantian (latest Ashgill) and the earliest
Silurian. The two phases coincided with the start of the Gondwana
Supercontinental glaciation and its melting respectively. [original
abstract]^1";

ID=0221^<b>Topic(s): </b>new taxa; Rugosa, Tchingizophyllidae;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician;
<b>Geography: </b>Kazakhstan^The new genus Tchingizophyllum is
described from the Upper Ordovician (Upper Caradoc) of the Chingiz
ranges. Evolution of microstructure and morphology of the skeleton in
representatives of this genus are investigated. The older
representatives are related to Primitophyllum, whereas the younger ones
show relations to the Lower Silurian genera Cysticonophyllum
Zaprudskaya &#038; Ivanovskiy 1962, and Cantrillia Smith 1930. A close
genetic relationship between the genera Tchingizophyllum.
Cysticonophyllum and Cantrillia allows to combine them into the family
Tchingizophyllidae. The new species T. primitivum and T. perplexum,
both from the Upper Caradoc, and the new species Cantrillia orientalis
from the lower Upper Llandovery, as well as Cysticonophyllum
tchingizicum are described. Diagnosis of Tchingizophyllum: solitary,
conical to cylindrical. The wall consists of lamellar sclerenchyma with
fine holacanthic trabeculae; septal spines are sometimes developed.
Tabulae absent or rare, horizontal or deeply inclined. Elongated
dissepiments sometimes are developed at the wall.^1";

YOO and Yong II LEE, 1993. Original mineralogy of Ordovician
stromatoporoids. Carbonates and Evaporites, 8(2):224-229. In this paper
Chan and Yong claim to have shown that Ordovician stromatoporoids were
originally high-magnesium calcite, rather than the aragonite that
```

```
others have proposed (at least for labechiids). They called their
specimens Labechia regularis. * What is interesting is that the Korean
specimen they illustrated looks very much like Cliefdenella, with
relatively straight laminae and tubelike pillars. Cliefdenella is now
considered a sphinctozoan sponge. The end product of this is that they
apparently did not work with labechiids (or clathrodictyids), and the
most useful information we have is a new occurrence of Cliefdenella.

stromatoporoid skeletons.- Boletin de la Real Sociedad Espanola de
Historia Natural, Seccion Geologica 92, 1/4: 067-076.- <b>FC&#038;P
26-2</b>, p. 23, ID=3703^<b>Topic(s): </b>fluorite cements; stroms;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Ordovician M; <b>Geography: </b>Korea S^Fluorite crystals have been
found within the skeletons of a Middle Ordovician (Llanvirn)
stromatoporoid, Labechiella regularis (Yabe &#038; Sugiyama), from
peritidal carbonates of the Youngwol area, Southern Korea. Observation
of sedimentary and diagenetic characteristics indicates that the
carbonates were deposited and buried in an evaporitic, very shallow
water environment, with some dolomite also formed. Occurrence fluorite
is most common within the stromatoporoid skeletons. The fluorite occurs
in pillars, galleries, and within dolomitic sediment between the
latilaminae. In normal optical view, the pillars seem to exhibit a
tube-like structure. However, the &#34;walls of the tubes&#34; are
composed of fine-grained calcite crystals representing the earliest
stage of cementation, and appear to have a different refractive index
to the fluorite crystals occurring in the centre of the pillars.
Formation of the fluorite clearly postdates and may be related to the
dolomitization, consuming the magnesium ion and releasing the fluroide
to the reacting fluid. Diagenesis of the stromatoporoids does not
resemble the diagenesis of aragonitic (molluscan) or high-Mg calcitic
(echinoderm) skeletons. However, the selective occurrence in the
stromatoporoid is probably related to the textural or mineralogical
characteristics of the stromatoporoids.^1";

mineralogy; stroms ?; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Ordovician M; <b>Geography:
</b>Korea^Stromatoporoids in the Middle Ordovician Yeongheung Formation
show delicate reticulate structure of persistent laminae and
discontinuous pillars. Abundant microdolomite inclusions are found in
the stromatoporoid skeletons. Coexisting aragonite precursor grains,
such as those of gastropods and cephalopods, preserve no internal
microstructures due to extensive dissolution and subsequent filling by
low-magnesian calcite. Brachiopods (low-magnesian calcite precursor)
show well preserved skeletal microstructures but do not contain any
microdolomite inclusions. Stromatoporoids were not dissolved as
completely as original aragonitic shells but recrystallized more than
shells with low-magnesian calcite precursor. The similarity of the
stromatoporoid preservation pattern to that of echinoderm grains (high
magnesian-calcite prescursor) and the widespread occurrence of
microdolomite rhombs in the stromatoporoid skeletons indicate that the
Middle Ordovician stromatoporoids were originally composed of
high-magnesian calcite. [original abstract; Stock, 2000, states the
specimens described in the present paper are in fact sphinctozoan
sponge Cliefdenella]^1";

systems and settings in South China before the Late Ordovician mass
extinction.- Palaeogeography, Palaeoclimatology, Palaeoecology 205,
3-4: 235-254.- <b>FC&#038;P 33-1</b>, p. 89, ID=1193^<b>Topic(s):
</b>reef systems; reefs stroms; <b>Systematics: </b>; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>China S^Ordovician reefs of the South
China Block occur chiefly in three stratigraphic units: (1) the middle
Tremadoc Fenhsiang Formation and the upper part of the Lunshan
Formation; (2) the late Tremadoc Hunghuayuan Formation; and (3) the
middle Ashgill Xiazhen, Sanjushan and Daduhe Formations. The region
therefore records part of the Early Palaeozoic reef expansion episode
and permits a broader assessment of change in Ordovician reef facies.
During middle Tremadoc time, lithistid
sponge-bryozoan-Calathium-calcimicrobially dominated patch reefs of the
Fenhsiang Formation occur in the high-energy belt of the central
Yangtze Platform. Columnar nonskeletal stromatolites of the Lunshan
Formation (coeval with Fenhsiang Formation) occur on the southeastern
margin of the platform, where low diversity reef-attached organisms,
and the generally fine-grained character of the sediment, are
consistent with a depth below normal wave base. Calathium and lithistid
sponges were the principal reef builders of late Tremadoc reefs and
were widespread in the areas of Yichang (Hubei Province) and Dongzhi
(Anhui Province), from the platform centre to its margin settings.
Bryozoan reef builders occur only in the platform centre with a high
diversity of reef dwellers such as brachiopods, trilobites and
nautiloids. However, during the same time, at the platform margins,
microbes played an important part in reef building together with
Calathium and lithistid sponges. The middle-late Tremadoc lithistid
sponge-bryozoan-Calathium-microbial community was replaced by a middle
Ashgill coral-stromatoporoid community and shows that the succession of
community replacement during the Ordovician took a relatively long
time. Restricted by the black shales of the main part of the Yangtze
region, middle Ashgill reef complexes can be found only on the
northeast platform of Cathaysian Land, between the Yushan (Jiangxi) and
Changshan (Zhejiang) regions. Carbonate mudmounds are present on the
```

```
western margin of the Yangtze Platform. On the northeast platform of
Cathaysian Land, patch reefs (some higher relief) with talus and
biostromes of the Xiazhen Formation consist of high-diversity biotas of
corals, stromatoporoids, calcimicrobes, brachiopods and gastropods. The
Sanjushan Formation is age-equivalent to the Xiazhen Formation and
contains carbonate mudmounds that are composed of abundant calcareous
algae and calcimicrobia. Uplift forced a northward extension of
Cathaysian Land and caused a regional relative sea-level fall,
eliminating this reef complex prior to the first extinction event of
the Late Ordovician. The Daduhe Formation carbonate mudmounds occur in
the nearshore belt of Kangdian Land (western margin of the Yangtze
Platform) and are paraconformably overlain by the Hirnantian Nancheng
Formation. In total, the Ordovician reefs of south China show a range
of habitats and controls on growth and demise. [original abstract]^1";

(2003).- The distribution and features of reef in Tazhong Area of Tarim
Basin, Northwest China. [in Chinese].- Petroleum exploration and
development 30, 2: 33-36.- <b>FC&#038;P 33-1</b>, p. 97,
ID=7241^<b>Topic(s): </b>reefs, ecology, paleontology; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician U; <b>Geography:
</b>China, Tarim Basin^There are many different kinds of reef in
Tazhong Area of Tarim Basin, Northwest China in age of Medium-Upper
Ordovician. The main reef-building organisms are sponges, Calathium,
stromatoporoids, corals, Crytalgaes, bryozoans, blue-green algae,
chorophyte and rhodophyte in solenoporaceae. The reef can be divided
onto calcilutite mound, framework reef and baffle reef. The analyzing
on the reed encountered during the drilling shows that the calcitite
mound is mainly formed in continental shelf are mainly in the shelf and
the shelf margin. And by studying the sedimentary facies and the
features of seismic reflection in this area, it can be predicted that
reef with the distribution shapes of belt and discontinuous belt can be
found in the shelf margin area of Tazhong Uplift and in the middle area
of northern slope of Tazhong area. Especially, the areas at the west
end of No. 1 fracture of Tazhong in west Shutuoguole block, up to now
six anomaly reflection bodies have been found. Depending on the
characters of environment and features of interior reflection they are
very likely the reef mounds. It will have great effects on the oil and
gas exploration of this area in case of that more play would have been
processed. [original abstract]^1";

biogeographic affinity of the Middle-Late Ordovician and the Landovery
rugose corals in the Yangtze Region.- Acta Palaeontologica Sinica 43,
2: 179-191.- <b>FC&#038;P 33-1</b>, p. 55, ID=1115^<b>Topic(s):
</b>distribution, biogeography; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Ordovician Silurian; <b>Geography:
</b>China, Yangtze region^The Middle Ordovician - Llandovery rugose
corals are abundant in the Yangtze region, especially in the Early
Silurian. Altogether 123 genera of Rugosa, which contain 4 genera of
Middle Ordovician, 25 genera of Late Ordovician, and 94 genera of
Llandovery respectively, have been reported from this region, of which
30 genera first appeared in the Yangtze region and then dispersed to
Europe and North America and other adjacent regions. The following may
represent the earliest occurrence age of the referred genera:
Calostylis in the Middle Ordovician (Llandeilo) of southern Sichuan;
Aphyllum and Cantrillia in the middle Ashgill of western Zhejiang; the
streptelasmatids Briantelasma, Pycnactis and Tunguselasma in the late
Ruddanian of northeastern Guizhou; the columnariids Ceriaster, Stauria,
Amplexoides and Synamplexoides, and the cystiphyllids Maikottia,
Rhizophyllum among others in the Middle Llandovery of northeastern
Guizhou, South China. Based on these data, we may regard that the
Yangtze region may have been one of the origin centers for the
Ordovician and Silurian rugose corals. This paper deals with the Middle
Ordovician to Llandovery rugose coral faunas in the Yangtze region,
especially with their palaeobiogeographic affinities. The Middle
Ordovician Rugosa of this region are characterized by the calostylids
Calostylis and Yohophyllum. The Late Ordovician (mid-Ashgill) rugosan
fauna from the Sanjushan Formation of western Zhejiang Province
contains some Australian elements (Hillophyllum, Bozoanophyllum), while
the late Ashgill rugose fauna from the Guanyinqiao Bed in the Upper
Yangtze region shows a high degree of similarity to that of North
Europe, indicating that Yangtze and Europe have a close
palaeobiogeographic affinity with each other. The Llandovery rugose
fauna in the Yangtze region is much closer with that of Siberia,
Kazakhstan and Australia.^1";

ID=7180^<b>Topic(s): </b>; reef reconstruction; <b>Systematics: </b>;
<b>Stratigraphy: </b>Ordovician &#47; Silurian; <b>Geography:
</b>China, Yangtze platform^Carbonate sediments gradually developed
into beds rich in brachiopods and crinoids in the lower part of
Xiangshuyuan Formation, middle Rhuddanian. In the middle part of
Xiangshuyan Formation, biostromes, containing abundant and high
diversity benthic faunas such as corals, crinoids and brachiopods, show
beginnings of reconstruction of reef facies. Substantial reef recovery
occurred in the upper part of Xiangshuyuan Formation, lower Aeronian,
as small patch reefs and biostromes. During the late Aeronian,
carbonate sediments, especially reefs and reef-related facies, expanded
on the upper Yangtze Platform, and radiation of reefs occurred in
Ningqiang Formation, upper Telychian. The long period of reef recovery,
```

```
taking several million years, remains difficult to explain, because
redistribution of any refugia faunas would be expected to take place
soon after the extinction. Reefs and reef-related facies subsequently
declined after Telychian time due to regional uplift of the major
portion of the Yangtze Platform. Carbonate facies are therefore
uncommon in South China during the rest of Silurian time. [last part of

Tadzhikistana. [new Silurian Heliolitida of Tajikistan; in Russian].-
Izvestiya Akademii Nauk Tadzhikskoy SSR, otdieleniye biologicheskikh
Nauk 71, 2: 49-54.- <b>FC&#038;P 9-1</b>, p. 48, ID=0289^<b>Topic(s):
</b>taxonomy; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Tajikistan^Four new
species of Heliolitidae are described from Silurian deposits of
Tadzhikistan and are assigned to the genera Thaumatolites Yanet in
Sokolov 1955, and ? Bogimbailites Bondarenko 1966. The new species are:
Th. cylindricus, Th. turkestanicus, Th. relictus and B. tangisaicus.
The diagnosis concerning Thaumatolites is amended and precisely
defined. Diagnosis (Thaumatolites): coralla small, pear-, boil-shaped
or cylindrical. Corallites either without own or with interrupted
walls. In the first case they are confined by coenenchymal vesicles
which sporadically show vertical orientation in the area of the
corallites though forming a corallite tube. In the second case the
walls appear interrupted or as an almost closed, compact line which
stands out against the remaining skeletal elements due to thickening.
Tabulae horizontally and only rarely emanating from each other.
Coenenchyne consisting of convex, frequently merging vesicles of
differente size and shape. Thorns my be recognized in the coenenchyme.
These are absent in corallites.^1";
s[2788] = "OSPANOVA N.K. (1979).- Novyj rod geliolitoidej i ego
znachenie dlja sistematiki.- Paleontologicheskiy Zhurnal 1979, 2:
16-22.- <b>FC&#038;P 9-1</b>, p. 49, ID=0291^<b>Topic(s):
</b>systematics; Heliolitida, Helioplasmolites; <b>Systematics:
</b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Asia^The new genus Helioplasmolites takes an intermediate position
between the Proporida and Heliolitida. During the initial growth stage
and locally as well as zonally it shows a proporid coenenchyme which is
replaced by a heliolitid coenenchyme during further growth of colony.
This indicates that the Heliolitida are derived from the Proporida and
not from the Protareida as was presumed before. New informations are
presented regarding morphology, phylogeny and systematics of the family
Plasmoporidae. The new species H. communicata from the Silurian (Lower
Wenlockian) of Central Asia (Zeravshan mountains) is described being
the type species of the new genus. Diagnosis of Helioplasmolites:
corallum semi-globular to bowl-shaped; corallites closely situated, in
places touching each other; connecting canals may develop between the
corallites; tabulae horizontal, bent or emanating from each other;
septal formations absent or thorn- or tubercle-shaped; around the
corallites there is an aureole consisting of 12 coenenchymal tubes,
polygonal in outline and differing in size; diaphragm horizontal,
oblique, conical or vesicular; during initial stage of colony and
locally, e.g. in some zones, there is a proporid (vesicular)
coenenchyme which leads to a typical heliolitid one during further
growth of the colony, showing zigzag-shaped, bent walls; walls of
coenenchyme and corallites thick.H. communicata Ospanova n.sp.:
corallum 30 to 150 mm; corallites rounded, 0.8 to 1.3 mm in diameter,
distance between corallites 0 to 1.0 mm; distance of tabulae 0.1 to 0.9
mm; thickness of wall 0.0? to 0.05 mm; between the corallites 1, rarely
2 to 3 rows of polygonal coenenchymal tubes of 0.1 to 0.6 mm in
diameter, arranged in an aureole of 12 coenenchymal tubes; distance of
their diaphragms 0.015 to 0.02 mm; the new species differs from H.
regularis (Dun, 1927), the diameter of which is also 0.8 to 1.3 mm, by
the greater numbers of connecting canals and a lesser development of
coenenchyme (H. regularis is found in the Silurian of New South Wales,
Australia).^1";

</b>China, Qinling^The Early Silurian rugose coral fauna of Tewo area,
West Qinling was first reported in 1990. Recently, the fauna has been
researched in detail, including 9 families, 13 genera and 18 species.
In this paper 11 genera and 12 species (of which 5 are new) are
described. They are: Brachyelasma sp., Paramplexoides sp.,
Kodonophyllum cf. leijiatunensis Ge et Yu, Eostauria minor (Chen),
```

```
Amplexoides chaoi (Grabau), Tryplasma cf. multitabulata Nikolaeva, T.
sp., Aphyphyllum tewoense sp.nov., Cystocantrillia silurica sp.nov.,
Cystiphyllum yiwaense sp.nov., Gyalophylloides simplex sp.nov., and
Pseudamplexus intermedius sp.nov. All the specimens are collected from
the upper member of Lalong Formation (M. Llandovery) in Tewo area, West
Qinling.This fauna may be correlated with the Leijiatun Formation (M.
Llandovery) of northeastern Guizhou, indicating the Early Silurian
rugosan fauna from West Qinling to be close to those of Yangtze region
in biogeographical affinity, and it may belong to the Yangtze Province.
[original summary]^1";
s[2804] = "CHEN JIANQIANG, HE XINYI (2004).- Early Silurian (
Llandovery) rugose coral recovery and radiation in the Upper Yangtze
region. [in Chinese, with English abstract].- Biotic Mass Extinction
and Recovery of the Paleozoic in South China [Rong Jiayu &#038; Fang
Zhongjie (eds)]: chapter 2, part 7, pp 185-205; Hefei Science and
Technology Press.- <b>FC&#038;P 33-1</b>, p. 48, ID=7170^<b>Topic(s):
</b>recovery, radiation, post O/S; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian Llan; <b>Geography:
</b>China, Yangtze region^Upper Yangtze region contains many complete
sections through the Upper Ordovician and Lower Silurian (Llandovery).
Three macroevolutionary stages, including survival interval (early and
middle Rhuddanian), recovery interval (late Rhuddanian to early
Aeronian), and radiation interval (mid-to late Aeronian), are
recognized based on rugose coral data, with the redefinition and
modification of some genera and statistical analysis of the range and
distribution of the rugosan genera, including rugose coral 44 genera,
assigned to 3 orders and 13 families from the Lower Silurian
(Llandovery) of the Upper Yangtze region. It is discussed that the
feature, pattern, and control factors of the macroevolutionary stages
and their fauna. The rugose coral fauna of the survival interval are
composed of 6 genera, assigned to 2 orders and 3 families, and are
characterized by a few survival and Lazarus genera. During the recovery
interval the rugose coral fauna are possessed of 15 genera from 3
orders and 8 families, and are dominated numerically by the small,
solitary Streptelasmatida (10 genera: 61%), with first appearing
abundance debutantes taxi and endemic forms. Forty-two rugose coral
genera are recorded from the radiation interval. Some genera in the
radiation interval extended up from the recovery interval, whereas many
genera occur first in the form of the debutantes taxa and radiation
taxa. One of the most striking differences between the recovery and
radiation interval is a rapid generic increase of the Cystiphyllida (13
genera; 31%), the Streptelasmatida (19 genera; 45%) and the
Columnariida (10 genera: 24%), with 14 new genera first appearing from
the radiation interval. In addition, the radiation interval is of many
colonial forms (12 genera: 29%)and occur the small reef composed of the
rugose corals, tabulate corals and stromatoporoids. It should be
emphasized that typical Silurian rugose corals are known to occur
during the recovery interval and the radiation interval in Yangtze
region. They include representatives of the crisis progenitor taxa,
debutantes taxa and radiation taxa. It is recognized that the beginning
of the 3 orders (Cystiphyllida, Streptelasmatida, Columnariida), with
differential recovery and radiation rates for each group, were
different respectively. In the recovery interval and radiation
interval, the beginning of Cystiphyllida and Streptelasmatida were
earlier than the order Columnariida. It is indicated that the
conditions of the ecological environments or ecosystem during the Early
Silurian were more adaptable for diversity of the Cystiphyllida and
Streptelasmatida which were more primitive rugose corals than the
Columnariida which was more advanced group with rapidly development
after Silurian. The debutantes taxa are subdivided into three kinds of
the endemic-debutantes, the emigrant-debutantes and the
immigrant-debutantes. [original abstract]^1";

The stratigraphic position of the lower part of the Xibiehe Formation is correlated by means of conodonts with the upper part of the Ancoradella ploeckensis Zone in the basal Ludfordian Stage (corresponds to mid-Ludlovian Epoch, ca. 421 Ma). Elongate in plan (610m x 200m), the exhumed diorite core rises 30m above the lowest elevations of surrounding Silurian strata. Paleoshores along the principal axis of the inlier delineate contrasting facies. Robust stromatoporoids are in growth position within silty limestones, some directly encrusting the unconformity surface of the sheltered southeast margin. A basal conglomerate of diorite cobbles and boulders characterizes the high-energy northwest margin. The depositional constraints and timing of transgressive facies associated with this continental paleoisland have implications for the eustatic and paleogeographic history of the parent Sino-Korean plate. Burial of the island corresponds to the beginning of a global rise in sea level that peaked in late Ludlovian time. Our interpretation of windward and leeward facies requires an approximate 90° clockwise rotation of the parent plate to accommodate the dominant pattern of low-latitude trade winds and storms. [original abstract; see also Rong J.-Y. et al. in Chinese Science Bulletin 46: 238-241)]^1";

The Bater Island (named herein) is 610 m x 200 m in size and is composed of Ordovician diorite. Limestone strata dating from the Ludlow epoch (about 420 Ma) surround the island and dip away from the igneous core in a radial pattern. The encrusting fossils occur on the sheltered (south and southeast) side of the island, whereas the north side was exposed to stronger wave activity based on a basal conglomerate unit composed of diorite boulders. This is the first record of an ancient island in China and the first report worldwide of stromatoporoids as members of a rocky shore community. The island clearly shows distinct windward and leeward deposits comparable to geologically younger islands from the Mesozoic and Cenozoic outside China. (original abstract)The taxa mentioned in the text are: unidentified species of Plexodictyon, Actinostromella slitensis, Hexastylostroma sp., Syringostromella sp., and Clathrodictyon? microstriatellum.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian Llan; <b>Geography:
</b>China S^Ningqiang Formation (late Telychian, Llandovery, Silurian)
characterized by nearly 3000 m of shales intercalated with carbonates,
is situated between Ningqiang (S. Shaanxi Province) to Guangyuan (N.
Sichuan Province) adjacent to the northwest margin of the Yangtze
Platform. The high diversity &#34;Xiushan Fauna&#34;, and abundant reef
development, illustrate a relatively warm and persistent shallow marine
environment in these early Silurian sediments. The sequence shows reef
radiation after recovery from the end of Ordovician mass extinction
events. Multiple horizons of reef-building occurred within a relative
short geological interval and resulted in more than 30 patch reefs up
to 2000 m in diameter and 1-50 m vertically, composed of abundant
fossils. Reef biota include frame-building corals, stromatoporoids,
bryozoans, and microbiolites, and reef-associated organisms such as
crinoids, brachiopods, trilobites, gastropods, nautiloids and
ostracods. Three reef-related biotic associations are recognized: a)
reefs dominated by framework with crinoids and microbiota; b)
crinoid-dominated facies. Seven representative reef examples illustrate
different morphologies and growth styles. A high terrigenous debris
input and shallow epicontinental ramp, which lacked obvious topographic
variation, were major controls which resulted in rather simple reefs;
sedimentation was apparently the main constrain on lateral and vertical
extension of reefs, and prevented large-scaled reef complexes
developing.^1";

Calceolidae; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Silurian Devonian; <b>Geography: </b>China^There are some peculiar
calceoloid corals appeared in the Siluro-Devonian. Corallum is
semicircular in transverse section and the calyx is with an operculum
of one or four plates of dense sclerenchyme. The nomenclature of actual
systematics is as follows (Weyer, 1996): Family Calceolidae King, 1846,
Subfamily Calceolinae King, 1846, Genus Rhizophyllum Lindstrom, 1866,
Genus Calceola Lamarck, 1799, Genus Goniophyllum Milne-Edwards &#038;
```

```
Haime, 1850. * Among these three genera, Goniophyllum is pyramidal in shape and has four plates of operculum. It is very easy to distinguish it from the two other. Rhizophyllum differs from Calceola in its lumen which is filled with numerous cystose dissepiments, but the latter is completely filled by sclerenchyme. * There exist also some differences on their geological ranges between Rhizophyllum and Calceola. The former appears from Llandovery (Lower Silurian) to Emsian (Lower Devonian) and the latter occurs only in the Lower and Middle Devonian. Moreover, Rhizophyllum has a global geographical distribution. It is found in Europe, Asia, North America and Australia (Hill, 1981), but Calceola is not known from North America up to now (Oliver, 1964). * Some geologists used to consider the genus Rhizophyllum as a typical Silurian coral. However, its real geological range is from Llandovery (Early Silurian) to Emsian (Early Devonian). [introductory part of the original summary]^1";

s[2836] = "LI YAOXI (1983).- Silurian and Devonian Tabulate coral
assemblages in the Beishan area, Gansu province. [in Chinese, with
English abstract].- Acta Palaeontologica Sinica 22, 1: 71-81.-
<b>FC&#038;P 12-2</b>, p. 37, ID=6225^<b>Topic(s): </b>zonation,
biogeography; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Silurian Devonian; <b>Geography: </b>China,
Gansu^Six Silurian and Devonian tabulate coral assemblages are
recognized in the so-called Beishan area which covers the vast
territory north to the Hexi Corridor and west to the Weak Stream in
Gansu Province. (1) Paleofavosites-Hexismia Assemblage (Lower Silurian
Xieshan Group); (2) Favosites-Multisolenia-Halysites Assemblage (Middle
Silurian Gongpoquan Group); (3) Hemithecia-Romingerella-Alveolites
Assemblage (Upper Silurian Salinhaolai Formation); (4)
Parastriatopora-Favosites-Squameofavosites Assemblage (Upper
Silurian-Lower Devonian Shuishishan Group); (5)
Neoyacutiopora-Squamites Assemblage (Late Lower Devonian Qinghegou
Formation); (6) Thamnopora-Parastriatopova Assemblage (Early Middle
Devonian Hazhu Formation). * The first two assemblages are distributed
in the southern Beishan while the other four are in the northern
Beishan. The genera Hemitheca, Romingerella, Rachopora, Crenulipora and
Squamites found in the northern Beishan are known to be restricted to a
belt extending from Kazakhstan, Beishan, Inner Mongolia to
Heilungjiang. In the southern Beishan, however, most genera are
cosmopolitan and similar in specific composition to those in the
Qilianshan. It seems that there exist two different biogeographic
provinces in this area, the Kazakhstan-Xingan Province in the North and
the Qinling-Qilian Province in the South. [original summary]^1";

```
<b>Geography: </b>China S^The paper summarizes the sequence and
distribution of the Devonian coral faunas in South China. Corals are
proliferated and very diversified in the shallow sea which, during
Devonian time, covered major parts of South China. They may roughly be
divided into two faunas, namely the western and the eastern fauna. In
the early Devonian they differ considerably from each other. The
western fauna mainly developed in the miogeosynclinal region of western
Yunnan, western Szechuan and West Tsingling. Regarding this fauna,
Tabulata are prevalent. Five rugose complexes are established ranging
from Upper Lochkovian to Zlichkovian (see Yu &#038; Liao 1978). The
eastern part of South China is characterized by a sedimentary
prevailing system of platform type (nearshore shallow water
enyironment). Corals, for the first time, appeared in the transgressive
marine carbonate deposits and continued to develop until the Late
Devonian. Both, Rugosa and Tabulata are abundant in this sequence. From
this type, rich in corals, the faunal sequence of the Lower and Middle
Devonian may be taken as a standard of reference. The following
[assemblages] are recognized in ascending order: the Nahkaoling fauna
(Upper Lochkovian &#47; Lower Pragian), the Yukiang fauna (Middle &#47;
Upper Pragian), and the Ertang fauna (Zlichovian); the Beiliu fauna of
the early Middle Devonian (Dalejan &#47; Eifelian) probably equivalent
to the Szepai and the Yingtang faunas, the Tungkangling fauna of the
late Middle Devonian (Givetian), and the Shetienchiao fauna of the
early Late Devonian (Frasnian). Representatives of the successive
faunas are listed in two tables, and their characteristic features are
briefly discussed.^1";

Arpishmebulaq Formation (Early Devonian, Lochkovian) of South Tianshan
in Xinjiang.- Acta Palaeontologica Sinica 43, 3: 366-376.- <b>FC&#038;P
33-2</b>, p. 19, ID=1120^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Lochk;
<b>Geography: </b>China, Xinjiang^The Arpishmebulaq Formation is
exposed at the eastern South Tienshan of Xinjiang and wasoriginally
proposed by E. Norin (1937, 1941), a Swedish geologist. It consists
mainly of limestonesand shales with a thickness about 400 m and yields
abundant corals, brachiopods, ostracods,stromatoporoids and conodonts.
Norin subdivided it into 6 divisions (A, B, C, D, E, F).There are some
different opinions about the geological age of the Arpihmebulaq
Formation:1. Norin &#47;1941) and Regnell (1941) first regarded most of
formations (division A to division E) ofLate Silurian age, while the
top part (division F) of possibly Early Devonian age;2. Zhang, Yu et al
(1959) as well as Hou, Wang and al. (1988) recognized it as of the
LowerDevonian;3. Wang (1988) and Wang (1990) considered it as belonging
to the Late Silurian;4. Liao and others (1990, 2001), Liao and Xia
(1996), Xia (1997), Deng (2001), Soto and Liao(1998, 1999, 2001)
believed that it (from division B to division F) would be the age of
lateLochkovian (Early Devonian) in the light of some index conodonts
Amydrotaxis praejohnsoni,Pandorinellina optima, Ozarkodina
remscheidensis remscheidensis.The rugose corals described and
illustrated comprise 17 species within 7 genera:
Cystiphylloidescorniculum (Regnell, 1941), C. cf. laticystis (Regnell,
1941, C. cf. macrocystis (Schlüter, 1889),Tryplasma cf.
tomtchumyshensis Zheltonogova, 1961, T. hercynica (Peetz, 1901), T.
aequabileLonsdale, 1845, Pseudotryplasma sp. A, Dubrovia sp. A., D. sp.
B, D. aff. dubroviensis,Salairophyllum cf. angustum (Zheltonogova,
1961, Neomphyma sp., Rhizophyllum hedini (Regnell,1941), R. cf. enorme
Etheridge, 1903, R. extensum Soto and Liao, 1998, R. sp. A, R. sp.
B.Among these rugose corals, Tryplasma cf. tomtchumyshensis, T.
hercynica and T. aequabile closelyresemble some Lower Devonian forms
from the Urals, Salair and Altay Mountains. Although genusRhizophyllum
is usually recorded from Silurian but R. cf. enorme is somewhat related
to R. enormefrom the Lower Devonian of eastern Australia, Salair, Altai
and the Urals. Dubrovia aff.dubroviensis and Salairophyllum cf.
angustum closely resemble their holotypes from the LowerDevonian of the
Salair, Russia respectively. Besides, the tabulate corals
Dictyofavositesmultitabulata Dubatolov, D. nagorskyi Mironova,
Favosites terrejaeensis Tchernychev andCladopora rectilineata Simpson
have also been recorded from the Lower Devonian of Salair.Taken as a
whole, they all indicate an Early Devonian age (Lochkovian), obviously
bearing a muchcloser relationship with those of Salair, Altay and the
Urals of Russia.^1";
s[2861] = "ZHANG YUBAO, SUN YUANLIN, LIU JIAOBO, HAN BAOFU (2004).- A
new species of Aphraxonia from the Upper Middle Devonian of the South
Tianshan Area, Xinjiang, China.- Acta Palaeontologica Sinica 41, 3:
118-123.- <b>FC&#038;P 33-1</b>, p. 65, ID=1137^<b>Topic(s): </b>new
taxa; Rugosa, Aphraxonia; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Giv; <b>Geography: </b>China,
Xinjiang^Aphraxonia, a rare Middle-Late Devonian rugosa coral genus
with columella structure, was previously only known from two
localities: Upper Devonian of Anatolia area, Turkey and the Qiziqiao
Formation (Givetian) of Hunan Province, China (Ünsalaner 1951; Jia et
al. 1977), including two species: Aphraxonia salaner and Aphramonia
zhuzhouensis (Jia). Aphraxonia zhuzhouensis (Jia) was originally
described by Jia (see Jia et al. 1977) under the genus Hunanamonia.
After comparing the main features of Aphraxonia Ünsalaner 1951 and
Hunanaxonia Jia 1977, Hill (1981) thought that [there are] no basic
differences between the two genera and, thus, she put Hunanaxonia under
```

```
the subjective synonyms Aphramonia Unsalaner 1951. In this paper, we
report a new species of the genus, namely Aphraxonia wuqiaensis
sp.nov., collected from the Middle Devonian of the South Tianshan area,
Xinjiang. This new species represents an intermediate form between
Aphraxonia taurensis Ünsalaner and Aphramonia zhuzhouensis (Jia) in the
internal morphological features. It is the first to confirm the
existence of Aphraxonia outside the Anatolia area of Turkey and Hunan
Province of China. This discovery demonstrates that Aphraxonia has wide
geographical distribution during the Middle to Late Devonian period
although it is rare in the fossil record. It also suggests that the
South Tianshan area had close biogeographical relationship with both
Turkey and Southern China during the Devonian. [first part of extensive
summary; numerous misspellings !]^1";

Yunnan^Eastern Yunnan, southwest China, especially the Panxi (Poshi)
area, has been one of the most important areas for the study of the
neritic Devonian in South China. Fossiliferous Devonian deposits in the
Panxi region have been well known for a long time. The Devonian in the
Panxi section is mainly composed of carbonate rocks, which contain
abundant benthic fossils (rugose corals, stromatoporoids and
brachiopods). Significant biostratigraphic works on these Devonian
rugose corals have been made by Wang Hong-zhen, who assigned them to 36
species in 19 genera, including 19 new species. He subdivided them into
7 horizons (in ascending order: G, C, K, E, T, P, D). The rugose corals
described and illustrated in this paper comprise 15 species within 14
genera: Cystiphylloides tungshanensis (Wang), Mesophyllum panxiense
(Yu, Liao Deng), Dendrostella trigemme, Neosyringaxon huaningense
sp.nov., Endophyllum panxiense sp.nov., Grypophyllum tenue Wedekind,
Disphyllum sp., Spinophyllum hejiazhaiense (Kong in Kong Huang),
Temnophyllum waltheri Yoh, Truncicarinum temeniophylloides (Wang),
Pseudozaphrentis cf. difficile Sun, Thamnophyllum sinense Yu, Liao
Deng, Mictophyllum intermedium Liao, Axophyllum vaughani longiseptatum
Wu Zhao, Axophyllum zhanyiense Wu Zhao. Among them, Grypophyllum tenue,
Temnophyllum waltheri, Thamnophyllum sinense, Cystiphylloides
tungshanensis and Spinophyllum hejiazhaiense, the species in the
Kutsing and Poshi Formations, as well as the genera Endophyllum and
Neosyringaxon are characteristic of the Givetian in South China, Russia
and Germany. Pseudozaphrentis difficile and Mictophyllum intermedium,
the former is from the upper part of the Itate Formation and the latter
is from the Zaijie Formation, usually recorded from the Frasnian of
South China. Dendrostella trigemme, from the Nanpanjiang Formation,is
commonly found in the upper Eifelian to lower Givetian. The overlying
strata yield Lower Carboniferous corals Axophyllum zhanyiense and
Axophyllum vaughani longiseptatum. Both species were originally
reported from the Lower Carboniferous of western Guizhou and eastern
Yunnan. The boundary between Carboniferous and Devonian in Panxi area
may be disconformable. [original abstract]^1";
s[2864] = "LIAO Wei-Hua (2003).- Devonian Biostratigraphy of Dushan,
Southern Guizhou and its coral Extinction events. [in Chinese, with
English abstract].- Acta Palaeontologica Sinica 42, 3: 417-427.-
<b>FC&#038;P 33-1</b>, p. 58, ID=1384^<b>Topic(s): </b>biostratigraphy,
extinctions; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
```

```
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>China, Guizhou^The shallow marine Devonian is well developed in Dushan, southern Guizhou and rich in fossil corals. The Devonian corals in Dushan flourished in a nearshore shallow water environment and all coral communities fall in the range of BA3 and BA4 (equivalent of the upper part of subtidal) in the Pedder and McLean&#039;s benthic assemblage scale. * On the basis of study of the Devonian rugose corals in Dushan section, 7 assemblages have been established. (1) Of which the Utaratuia-Sociophyllum Assemblage of Longdongshui Member is correlated with the coral assemblage of Hume Formation (Eifelian) from northwestern Canada. (2) The Columnaria-Dendrostella Assemblage from Tunshang Member may be correlated with the late Eifelian coral assemblages in Germany. (3) The Paramixogonaria-Jipaolasma Assemblage from Chipao Member together with the (4) Endophyllum-Sunophyllum-Argutastraea Assemblage from Chiwochai Member should be equivalent to European Givetian coral assemblages. (5) The Sinodisphyllum-Pseudozaphrentis-Mictophyllum Assemblage from Hejiazhai Member and the (6) Wapitiphyllum-Pseudozaphrentis-Disphyllum Assemblage from Lujiazhai Member are approximately equivalent to the Frasnian oral assemblages in northwestern Canada. (7) The Cystophrentis Assemblage in Kolaoho Formation should be approximately contemporaneous with the European Strunian (latest Famennian) coral assemblages. * Four-times bio-events have been found from the Devonian in Dushan recently. (I) The first occurred at the top of the Longdongshui Member, in which all of Favosites disappeared, it may be correlated with the mid-Eifelian event (Oliver and Pedder, 1994). (II) The second appeared at the top of Chiwochai Member, in which a lot of cystimorph corals and Stringocephalus died out, it is approximately equivalent to the end-Givetian event (Oliver and Pedder, 1994). (III) The third happened at the bed about 80m above the lower boundary of Yaoso Formation, a large number of shelly benthos, such as tentaculites, Atrypacea, the characteristic Devonian corals, stromatoporoids, bryozoans and reefs were killed, it should be equivalent to e F-F mass extinction (Kellwasser event in Germany). (IV) The fourth found near at the top of Kolaoho Formation, many Strunian (latest Devonian) fauna were replaced by the Tournaisian (earliest Carboniferous) taxa. It should be equivalent to the D-C extinction (Hangenberg event in Germany). [original summary]^1";
s[2865] = "RODRIGUEZ S., LIAO Wei-Hua (2003).- A restudy of Cystophrentis Yu, 1931 (Rugosa) from the uppermost Famennian (Strunian) of South China.- Geobios 36, 4: 407-419.- <b>FC&#038;P 32-2</b>, p. 59, ID=1387^<b>Topic(s): </b>revision; Rugosa, Cystophrentis; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>China S^The genus Cystophrentis, first described by Yü, 1931 occurs in South China, Tibet, Viet Nam and Armenia. Its geological age is Strunian (latest Fammenian). It forms the basis for the order Mesocorallia Yü, 1963, regarded as intermediate between the Rugosa and the Scleractinia based on the presence of metasepta between the counter septum and the counter-lateral septa. The genus Kailingophyllum Yu and Lin, 1984 was described as being similar to Cystophrentis, but the apparent differences between these genera are no more than ontogenetic variations. Consequently, Kailingophyllum is regarded here as a synonym of Cystophrentis. Three species from six localities in South China and Tibet are described: Cystophrentis kolaohoensis Yu, 1931; Cystophrentis simplex (Yu and Lin in Yu, Lin and Fan, 1984) and Cystophrentis grandis Kuang in [Jia et al., 1977]. Serial sections and external septal grooves of the corals studied show no insertion of metasepta between the counter septum and the counter-lateral septa in Cystophrentis. Thus there is no basis for the recognition of the order Mesocorallia Yü, 1963. [original abstract]^1";
s[2866] = "SOTO F., LIAO Wei-Hua (1998).- Rhizophyllum Lindström, 1866 (Rugosa) del Devonico inferior (Lochkoviense) en el SE de las Montanas de Tian-Shan (NO de China).- Revista Espanola de Paleontologia 13, 2: 197-206.- <b>FC&#038;P 30-2</b>, p. 20, ID=1566^<b>Topic(s): </b>;

Rugosa, Rhizophyllum; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Lochk; <b>Geography: </b>China,
Tien-Shan^En el presente trabajo se describen varias especies del
género Rhizophyllum Lindström, procedentes de la Formación
Arpishmebulaq (Lochkoviense), en el SE de las Montañas de Tian-Shan
(provincia de Xinjiang, NO de China). Las descripciones realizadas
comprenden cinco especies, de las cuales Rhizophyllum extensum se
propone como nueva, R. sp. A y R. sp. B son también, probablemente,
nuevas, pero la falta de material más abundante y mejor conservado hace
que las mantengamos, por el momento, en nomenclatura abierta. R. hedini
(Regnell) era conocida solo por su morfología externa y ahora se
describen por primera vez sus estructuras internas. Finalmente, R. cf.
enorme (Etheridge) no había sido citada nunca en China y su presencia
en el área de Arpishmebulaq confirma relaciones biogeográficas durante
el Lochkoviense con los Montes Urales, Salair, Asia Central (Altai) y
Este de Australia. [original abstract]^1";
s[2867] = "SOTO F., LIAO Wei-Hua (2001).- Corales rugosos
(Tryplamatidae, Mucophyllidae y Cystiphyllidae) de la Formacion
Arpishmebulaq (Lochkoviense) en el SE de las Montanas de Tian-Shan (NO
de China).- Revista Espanola de Paleontologia 16, 2: 255-268.-
<b>FC&#038;P 30-2</b>, p. 20, ID=1568^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Lochk; <b>Geography: </b>China, Tien-Shan^In the present paper seven
species of the rugose coral genera Tryplasma Lonsdale, 1845,
Pseudotryplasma Ivaniya, 1958 and Mesophyllum Schlüter, 1889 {subgenus
Mesophyllum (Cystiphylloides) Chapman, 1893, sensu Birenheide, 1974}
from the Arpishmebulaq Formation (Lochkovian) in the south east of the
Tian-Shan Mountains (Xinjiang province, NW China) are described. With
the exception of the species Mesophyllum (Cystiphylloides) corniculum
(Regnell, 1941) and M. (C.) cf. laticystis (Regnell, 1941), which are
known up to now only in the SE of the Tian-Shan Mountains (NW China),
the other described species/subspecies, Trylasma aequabile Lonsdale,
1845, T. hercynica (Peetz, 1901), T. cf. tomtchumyshensis Zheltonogova,
1961, Pseudotryplasma sp. A and Mesophyllum (Cystiphylloides)
macrocystis cf. macrocystis (Schlüter, 1889) have been recorded at
several localities, specially in the Russian Federation. Thus, the
geographical and stratigraphical distributions of the mentioned species
confirm strong biogeographical relationship during the Lochkovian age
with the Ural Mountains, Altay and Salair, as well as with NE China
(Jilin province). Also, such relationship, in a less degree, could have
existed among NW China (Tian-Shan Mountains) and Tadjikistan,
Kazakhstan, eastern Australia and E of North America (Nevada and
Yukon). This relationship was previously confirmed by the authors (Soto
y Liao, 1998, 1999) in relation to different taxa of rugose corals from
the same formation and locality.^1";

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Fam; <b>Geography: </b>China, Guangxi^The Famennian rugose
corals described in the present paper were collected from the Yishan
county of Guangxi, comprising 7 species in 6 genera, namely: Neaxon
cheilos Weyer 1984, N. longiseptatum sp.nov., Kielcephyllum guangxiense
sp.nov., Ufimia xiakouensis sp.nov., Prosmilia? yishanensis sp.nov.,
Yishanophyllum bellum gen. et sp.nov. and Zaphriphyllum sp. Although a
majority of the above-mentioned corals are new species, however, they
all bear obviously a much closer relationship with those of the Holy
Cross Mountains of Poland and the Thuringian Mountains of GDR. Since
the latest Devonian (Famennian) corals have rarely been reported in
China, a brief description of these fossils seems desirable.
[Kielcephyllum guangxiense ?] Corallite solitary, about 11-18 mm in
diameter. In adult stage, major septa long, extending to the centre,
numbering 24-30; minor septa short or rudimental; dissepiments variable
in cross section. In later stage, major septa withdrawing from the
centre, about half as long as the radius; cardinal septum shortened
with cardinal fossula clear. Tabulae incomplete and cystose,
dissepiments elongate or semiglobular. Remarks: Kielcephyllum cupulum
Rozkowska differs from the present new species in its wider peripheral
cystose [zone] and differentiated tabulae.^1";

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Prag; <b>Geography: </b>Tajikistan, Zeravshan Mts^The
colonial rugose corals of the Shishkat fauna (Pragian, Kshtut
Formation) from the Zeravshan Mountains are compiled and redescribed
according to current taxonomic standards. The fauna can be categorized
as a so-called &#039;Carlinastraea-Fauna&#039;, and a generally
comparable generic composition is recognized on a global scale. Some
Silurian relictual genera such as Maikottia or Pycnostylus are
recorded. Of the 15 taxa discussed, Australophyllum soghdianum sp.nov.
is described. All other specimens are assigned to known species or
discussed in the context of open nomenclature. The Shishkat-fauna is
clearly dominated by the Ptenophyllina (especially Carlinastraea and
Spongophyllum), and Ptenophyllidae (Australophyllum, Xystriphyllum and
in particular Lyrielasma). A remarkable occurrence of Vepresiphyllum
indicates a weak faunal relation to eastern Australia. All other taxa
show close affinities to coeval associations in the Urals, but
especially to those from the Turkestan Range and the south Fergana
Valley. The treatment of the Fasciphyllidae is supplemented by a short
rediscription of the Turkestan Fasciphyllum maikottaense Lavrusevich,
1972 because its type material is lost.^1";
s[2881] = "LIAO Wei-Hua, BIRENHEIDE R. (1989).- Rugose corals from the
Frasnian of Tushan Province Guizhou, South China.- Courier
Forschungsinstitut Senckenberg 110: 81-103.- <b>FC&#038;P 18-2</b>, p.
32, ID=2477^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>China,
Guizhou^The present paper deals with descriptions and illustrations of
12 species of 8 genera of the rugose coral family Cyathophyllidae,
subfamilies Columnariinae and Zaphrentinae sensu Birenheide 1978. Their
reference material is taken from collections of the localities
Lujiazhai and Balhupo, near the county town Tushan, Province Guizhou,
People&#039;s Republic of China. Geologically it was taken from beds of
the Lujiazhai Member of the Wangchengpo Formation. The Frasnian of the
Lujiazhai Member is concluded by means of brachiopods and the corals
described herein; its proof by means of conodonts is not yet executed.
The following two compound rugose coral species are new Wapitiphyllum
balhupoense n.sp., and Spongonaria frechi n.sp. The stratigraphical and
facial sequence of the Upper Devonian part of the Tushan Section are
described and illustrated. The relations between the Givetian and
Frasnian coral faunas of the Tushan section, as described by Liao
&#038; Birenhelde 1984, 1985, this paper, and that of the Rhenish Realm
are discussed by comparison of the respective genera and species.^1";
s[2882] = "GUO SHENGZHE (1989).- Early and Middle Devonian rugose
corals from Toudaoqiao district of Central Da Hinggan Ling (Mts.).-
Bulletin Shengyang Inst. Geol. Min. Res., Chin. Acad. Geol. Sci. 18:
25-36.- <b>FC&#038;P 20-1.1</b>, p. 54, ID=2821^<b>Topic(s): </b>;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian L M; <b>Geography: </b>China, Gt Khingan Mts^The Devonian
strata are widespread with numerous fossil corals in the central Da
Hinggan Ling (Mts.). In 1979, the author took a field trip in the
Toudaoqiao district, about 150 km south of Hailar City of Inner
Mongolia (see the locality map), and collected abundant fossil corals
and stromatoporoids from the Wunur formation. 16 genera with ...
species, including 1 new genus, 5 new species and 1 new subspecies, of
the Wunur formation studied in the present paper are as follows: -
```

```
Calceola sandalina weinaheensis (subsp.nov.), Cystiphylloides
robertense (Stumm), Siphonophrentis elongata (Rafinesque &#038;
Clifford), Briantelasma breviseptata (sp.nov.), Metriophyllum sp.
indet., Acanthophyllum 1 sp. indet., Leptoinophyllum sp., Grypophyllum
cf. carinatum (Soshkina), G. cf. graciliseptatum Pedder, Lyrielasma
chapmani Pedder, Hinganophyllum polygonalis (gen. et sp.nov.),
Fasciphyllum obesum (sp.nov.), Chalcidophyllum cf. recessum (Hill),
Exilifrons hinganesis (sp.nov.), Hexagonaria toudaoqiaoensis (sp.nov.),
Thamnophyllum cf. stachei Penecke, Glossophyllum sp.indet. Obviously,
the genetic group of the fauna is composed mainly of the common genera
of Eurasian continent added with some North American types and an
endemic genus, and the species is also a mixture of the European and
Australian species with the North American forms, except the endemic
one. The age of the coral fauna is considered to be early Middle
Devonian that may be correlated with the Heitai formation in eastern
Heilong-jiang province and with the Wendurobot formation of central
Inner Mongolia, and furthermore, may be corresponding to the
Shandin-Mamontov formations of Salair of USSR, with which together to
construct the Late Paleozoic folded belt in the southern margins of the
Siberian plate. A few beds of gray-yellow and gray-green siltstone
containing some small solitary corals is bound by fault with the Wunur
formation in the stratigraphic section. These corals are identified as
to be Neaxon curta (Pocta) which is very common in the Lower Devonian
(Lochkovian to Pragian stage) in our region. The new genera
Hinganophyllum and its type species H. polygonalis are described in the
English abstract.^1";
s[2883] = "GUO SHENGZHE (1990).- Frasnian-Famennian extinction and late
Devonian rugose corals from Great Xing&#039;an ranges, NE China.- Acta
Palaeontologica Sinica 29, 4: 427-446.- <b>FC&#038;P 20-1.1</b>, p. 54,
ID=2822^<b>Topic(s): </b>extinctions, F/F; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fra/Fam;
<b>Geography: </b>China, Gt Khingan Mts^Data on occurrences of Late
Devonian rugose corals suggest a major worldwide extinction of
platform- and reef-dwelling corals occurring near the end of Frasnian
time. The basin-dwelling corals, however, were virtually unaffected by
the Late Frasnian event. The Daminshan district in the central Great
Xing&#039;an Ranges of NE China is one of the very rare localities in
the world, where the Frasnian shallow-water corals and the Early
Famennian basinal corals were well-developed. The Frasnian sediments
called the Lower Daminshan Formation containing the corals Hexagonaria
zambinskiensis (Ivania), Temnophyllum rectum (Walther), T. densum
sp.nov., and Hinganastraea daminshanensis gen. nov., while in the
Famennian strata called the Upper Daminshan Formation, the corals are
small and solitary with thin and simple skeletal elements, reflecting a
semipelagic basinal enviroment, such as Petraiella sp.,
Barrandeophyllum zhaduenheense sp.nov., Guerichiphyllum daminshanense
(Guo), Friedbergia sinensis sp.nov., Amplexocarinia sp., Gorizdronia
simplex (Guo), G. minor sp.nov., Kozlowskinia sinensis sp.nov.,
Tabulophyllum tenuis sp.nov., Famennelasma sinensis sp.nov., etc. Their
age may be bounded by the associated ammonoids corresponding to the
Cheiloceras and Platyclymenia zones. The collisional suture between the
Sino-Korean and the Siberian plates extends roughly along the border
line of China with Mongolia, about 350 km south of the Daminshan
district. In the author&#039;s (1986) interpretation, the convergence
of the two paleoplates in Late Devonian, and so the orogenic movement
and volcanic activities caused by the collisional process might be the
direct reason of the Late Frasnian extinction in this region. Of
course, this requires further study on the stratigraphic sections to
find the iridium anomaly and determine the isotopes. [original summary]
The following new genera and species are described in the English
abstract: Barrandeophyllum zhaduenheense sp.nov., Friedbergia sinensis
sp.nov., Gorizdronia minor sp.nov., Kozlowskinia sinensis sp.nov.,
Tabulophyllum tenuis sp.nov., Temnophyllum densum sp.nov.,
```

```

The development and evolution of the tetracoral assemblages varies with changes in sedimentary environments and can be divided into two main stages. 1. From the Lianhuashan to Yujiang epochs (Pragian - early-middle Emsian), a shallow shelf environment without obvious facies differentiation developed and very similar tetracoral assemblages occur in different areas of the Guangxi Devonian. 2. In the second stage, post-Yujiang to Rongxian epoch (late Emsian - Famennian), a carbonate platform developed in Guangxi. With the accompanying differentiation of sedimentary environments, two distinct tetracoral communities developed. In the open platform facies the tetracoral faunas are characterized by dense phaceloid and massive colonies. Eight assemblage biozones can be distinguished, represented by Spongonaria, Breviseptophyllum, Disphyllum, Hexagonaria, etc. In the platform margin fades tetracorals are solitary or loose fasciculate colonies. Six assemblage biozones can be recognised, represented by taxa such as Grypophyllum, Stringo-phyllum, Temnophyllum, Sociophyllum, Neocolumnaria, etc. They form reefs in association with tabulates and stromatoporoids or algae.^1";
s[2889] = "YU CHANGMING (1994).- Distribution of rugose corals in Devonian reef complexes in South China.- Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 77-86.- <b>FC&#038;P 23-1.1</b>, p. 14, ID=4065^<b>Topic(s): </b>distribution within reefs; Rugosa, reef complexes; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Prag - Giv; <b>Geography: </b>China S^An attempt is made to determine the environments of the Pragian to Givetian rugose corals of the South China carbonate platform. Six different facies have been recognized in which Devonian rugose corals occur. Evidently most of the Devonian rugose corals in South China can be found in argillaceous limestones and marls containing terrigeneous material; this facies indicates a nearshore shelf or a protected open shelf environment. Late Emsian and Eifelian corals show a greater diversification of taxa and distribution than Pragian coral faunas. The maximal diversification of rugose corals was attained in Givetian time, corresponding with maximum reef development. There were no deep water corals in the Devonian sea of South China.^1";

```

```
</b>Devonian Ems; <b>Geography: </b>China, Qinling Mts^Aulacophyllum
and Hallia described in this paper were found in the Early Devonian
Emsian deposits in the western part of southern Qinling Range. These
rugose corals are recorded for the first time in China; but outside
this country more than 30 species of Aulacophyllum and about ten
species of Hallia, so far known to the writer, have been described
mainly from Onesquethawan stage in the central-eastern part of the USA,
occasionally from the Devonian in England, Germany and Spain of West
Europe, Sahara and Mauritania of N Africa, Ural, Russian platform and
Armenia of USSR, Northern Shan State of Burma and NSW of Australia. *
The Early Devonian Emsian deposits in this area may be compared with
the Onesquethanwan stage of the USA in the abundance of fossils.
Nevertheless, the coral-bearing beds are thought to be lower in
stratigraphic position than those at other places of the world.

Palaeontologica Sinica 49, 1: 29-43.- <b>FC&#038;P 36</b>, p. 73,
ID=6475^<b>Topic(s): </b>revision; Rugosa Heterophaulactis;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Ems; <b>Geography: </b>China, Guangxi^The Devonian rugose coral genus
Heterophaulactis from Lower Emsian Yujiang Formation in Guangxi,
previously not fully described, is thoroughly examined and described in
this paper. The main characteristics of this genus are also diagnosed.
Based on the characters displayed in the holotype and additional type
materials, the description of its type species, Heterophaulactis
semicrassa is made in detail with full illustrations. A new species of
this genus, Heterophaulactis yujiangense sp.nov. is erected with
detailed description and full illustration. The genus is compared with
other relevant genera in different aspects. It is interesting to note
that a number of genera from the Lower Devonian in western Qinling
mountainous region are of close affinity to Heterophaulactis. Some
species referred to those genera may be assigned to Heterophaulactis,
indicating that the distribution of Heterophaulactis is not restricted
in south China, but extended to northwest China. The family assignment
of Heterophaulactis is discussed and concluded that Heterophaulactis
may be derived from Silurian Pycnactis - Phaulactis evolutionary
lineage. The Subfamily Miroelasmatinae Cao 1983 is emended to include
Heterophaulactis and its relevant genera and the family assignment of
this subfamily is herein switched from Family Halliidae Chapman 1893 by
Cao et al. (1983) to Family Lykophyllidae Wedekind 1927. [original

been systematically described. There are 7 species of Rugosa including
one new species, 4 species of tabulatomorphic corals including 2 new
species. The three new species are Hunanaxonia xizangensis sp.nov.,
Pachycanalicula sparcula sp. Nov. and Paraheliolites zakangensis
sp.nov. The discovery of these corals in this area is beneficial for
more understanding the symbiotic assemblage, evolution of the corals
and their biogeography in Early Devonian. [original abstract]^1";
s[2901] = "MA X.P., SUN Y.L., HAO W.C., LIAO W.H. (2002).- Rugose
corals and brachiopods across the Frasnian-Famennian boundary in centre
Hunan, South China.- Acta Palaeontologica Polonica 47, 2: 373-396.-
<b>FC&#038;P 31-2</b>, p. 39, ID=1676^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria Brachiopoda; Rugosa; <b>Stratigraphy:
</b>Devonian Fra/Fam; <b>Geography: </b>China, Hunan^We present
taxonomic revision of rugose corals and brachiopods from several
Frasnian–Fammenian (F–F) boundary sections in central Hunan Province,
China. Diversity of shallow-water rugose corals gradually increased
during the Frasnian, but ended with sudden extinction near the end of
Frasnian. Ostracods were abundant during the Frasnian; their extinction
coincided with anoxic deposition of the end-Frasnian black shale
deposits. The early Famennian ostracod fauna is of low diversity. The
brachiopod fauna of the late Frasnian (Palmatolepis rhenana and Pa.
linguiformis zones) is dominated by atrypids, small-sized
cyrtospiriferids, and the rhynchonellid Hunanotoechia. All atrypids
disappeared before the F–F boundary with highest rates of extinction
below the boundary (probably low in the Pa. linguiformis Zone). The
Frasnian cyrtospiriferid fauna is also of low diversity and dominated
by small taxa. All but one of the cyrtospiriferid taxa crossed the F–F
boundary. The early Famennian post-extinction recovery brachiopod fauna
was the result of rapid radiation of new forms shortly after the
terminal Frasnian event. The early Famennian fauna is characterized by
diverse cyrtospiriferids, abundant Yunnanellina and productoids. Above
the early recovery fauna another fauna was recovered, with brachiopods
Hunanospirifer and Yunnanella and is correlated with the late or latest
Pa. crepida Zone. Sinalosia rugosa gen. et sp.nov. (Productida) is
erected. ^1";

Rugosa cystimorpha; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Ems Eif; <b>Geography: </b>China,
Gansu^In this work different species and subspecies of cystimorph
Rugose corals coming from the lower half of the Dangduo Formation
(Upper Emsian) and Lure Formation (Eifelian), Tewo District (Gansu
Province, Central China), are described in detail. Five taxa, Cayugaea
aff. gansuensis Cao, C. aff. cylindrica (Bulvanker), Mesophyllum
(Cystiphylloides) secundum ssp. A, M. (C.) secundum ssp. B and
Mesophyllum (Mesophyllum) aff. arrectum (Yu &#038; Cai) probably
correspond to new forms. Regarding the rest of the species and
subspecies, Mesophyllum (Cystiphylloides) fongi (Yoh), M. (C.)
caespitosum (Schlueter) and M. (C.) cf. macrocystis macrocystis
(Schlueter), the stratigraphical range in China is extended. The rest
of the species had been cited and described before by other authors
from the same district. Finally, on the basis of the analysis of the
stratigraphical and geographical distribution of the taxa studied, new
data are given which support the paleobiogeographical hypothesis
proposed by other authors. A relationship among Central China, NW
Canada, Europe and S China, during the Upper Emsian-Eifelian, is
shown.^1";

(Rugosa) from the Hongguleleng Formation (Devonian, Lower Famennian) at
the northwestern margin of Junggar Basin (Northern Xinjiang, NW
China).- Coral Research Bulletin 7: 209-220. [Dieter Weyer&#039;s 65th
birthday commemorative volume; S. Schröder, H. Löser &#038; K.
Oekentorp (eds)].- <b>FC&#038;P 31-1</b>, p. 34, ID=7105^<b>Topic(s):
</b>; Rugosa Laccophyllidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>China,
Xinjiang^The Famennian Laccophyllidae (rugose corals) described in the
present paper were collected in the Hongguleleng Formation, at Hoboksar
(northwestern margin of Junggar Basin, Northern Xinjiang Uygur
Autonomous Region, NW China). They are represented by six species,
referred to three genera, some of them are redescribed in this paper
after their original description in Liao &#038; Cai (1987). Neaxon
kullmanni and Guerichiphyllum hebukeense are new, Amplexocarinia
tenuiseptata Liao &#038; Cai 1987 is reassigned to the genus
Catactotoechus Hill 1954 and Guerichiphyllum sinense Liao &#038; Cai
1987 is described, refigured and its diagnosis amended. Finally,
Catactotoechus sp. A and C. sp. B are considered also as new, but the
scarcity of specimens does not allow the establishment of new species
at the present time. This rugose coral assemblage and, especially, the
presence of conodonts could be stratigraphically correlated with those
of the Lower Famennian from the Holy Cross Mountains in southern
Poland. The geographic distribution of the genera mentioned for the
Junggar Basin during the Famennian confirms a close relationship with
Inner Mongolia (Grand Khingan Mountains Range), Germany (Variscan
Thuringian Mountains), Western Australia (Canning Basin) and Poland
```

Rugosa, Ptenophyllidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Lochk; <b>Geography: </b>China,
Tien-Shan^En el presente trabajo se describen los corales rugosos
pertenecientes a la familia Ptenophyllidae de la Formación
Arpishmebulaq (Lochkoviense), en el SE de las Montañas de Tian-Shan
(provincia de Xinjiang, NO de China). Se han reconocido tres géneros y
cinco especies, de las que Dubrovia aff. dubroviensis Zheltonogova, D.
sp. A y D. sp. B son, probablemente, nuevas, pero se mantienen en
nomenclatura abierta dada la escasez de ejemplares, mientras que
Salairophyllum cf. angustum (Zheltonogova) y Neomphyma sp. se citan
también ahora por primera vez en esta región. La distribución
geográfica de estos taxones permite afirmar la existencia de relaciones
paleobiogeográficas durante el Devónico Inferior (Lochkoviense) entre
el SE de Tian-Shan y otras regiones asiáticas (Kazakhstan, parte E de
los Urales, Altai y Salair). Estas relaciones son apreciables asírnismo
con el E de Norte América (Nevada y Yukón). [original abstract]^1";

Tabulata, Pseudofavosites; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>China,
Xinjiang^Pseudofavosites (Tabulata), as one characteristic genus of the
Permian, was first reported by Gerth (1921) who described only one
species from Timor. Since then, Yakovlev (1939) and Sokolov (1955) have
described two species of the genus from the Lower Permian from the Ural
in the USSR. In recent years, Pseudofavosites has also been found in
the Carboniferous and Devonian of Guangxi and Xinjing. Lin Bao-yu, for
instance, described two species of the genus from the Carboniferous in
Guangxi. Six new species of Pseudofavosites: P. giganteus sp.nov., P.
kakesuensis sp.nov., P. longispinus sp.nov., P. transitorius sp.nov.,
P. barkolensis sp.nov. and P. rarus sp.nov. are described from the
Lower Devonian in Barkol of Xinjiang. They are preserved in bioclastic
limestone (Dananhu formation and Taheier-basitao formation). These
species are associated with other Tabulata (Squameofavosites,
Favosites, Steatothamnopora, Striatopora), Rugosa (Syringaxon,
Barrandeophyllum), brachiopods (Mucrospirifer), and trilobites
(Odontochile), indicating an early-middle Early Devonian age (Gedinnian
and Siegenian).^1";
s[2933] = "WANG BAOYU (1986).- The Devonian tabulate coral assemblages
of Northern Xinjiang with remarks on subdivision of the Lower Middle
Devonian.- Journal of Stratigraphy 01, 1: 34-40.- <b>FC&#038;P
15-2</b>, p. 36, ID=0723^<b>Topic(s): </b>assemblages; Tabulata,
communities; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>China, Xinjiang^During the past two
decades, a large number of Devonian tabulate corals were gathered from
many localities in northern Xinjiang. On the basis of study on these
corals, five Devonian coral assemblages of northern Xinjiang are
established as follows: Upper Devonian: Aulopora-Striatopora
Assemblage; Middle Devonian: Alveolites-Trachpora Assemblage,
Pachyfavosites polymorphus-Tyrganolites-Xinjiangolites Assemblage;
Lower Devonian: Squameofavosites-Placocoenites-Pseudofavosites
Assemblage, Aulocystis-Steatothamnopora-Pleurodictyum Assemblage. In
the light of the tabulate coral assemblages mentioned above, the author
suggests that the Lower Devonian of marine facies may be subdivided
into two parts, namely, the Utubulake (including Mengeer) and
Taheierbasitaw (or Asushan) Formations in the lower part; the Mongkelu,
Zuomubasitaw (or Tuoranggekuduke) and Dananhu Formations in the upper.
The Middle Devonian may be also subdivided into two parts, namely, the
Kulumudi (or Sawuershan), Altai, Wulusubasitaw (or Beitashan) and
Baixinde Formations in the lower part; the Zhifang Formation in the
```

```
upper. The author also suggests that the first occurrence of Pachyfavosites polymorphus, Tyrganolites, Xinjiangolites is considered as the beginning of the Middle Devonian.^1";

Chaetetids from Dushan, southern Guizhou. [in Chinese, with English
summary].- Acta Palaeontologica Sinica 18, 2: 131-160.- <b>FC&#038;P
8-2</b>, p. 44, ID=5718^<b>Topic(s): </b>; Tabulata, Chaetetida;
<b>Systematics: </b>Cnidaria Porifera; Tabulata Chaetetida;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>China, Guizhou^This
paper deals with the tabulate corals and chaetetids collected from the
Longdongshui Member of the Houershan Formation in Dushan of Guizhou.
The collections contain 19 genera and 30 species (including 12 new
species and 3 varieties) of tabulate corals, 2 genera and 2 species of
heliolitids and 2 genera and 4 species (including 2 new species) of
chaetetids. The new species are: Roemerolites dushanensis, R.
polymorphus, Parastriatopora jumuwanensis, P. jumuwanensis var. varia
(var.nov.), P. jumuwanensis var. thamnoporoidea (var.nov.), Thamnopora
tersa, T. longdongshuiensis, Gracilopora spina, Alveolites convolutus,
A. inconstans, Crassialveolites yunnanensis var. dushanensis
(var.nov.), Caliapora mixta, Placocoenites elasmatus, Aulopora mixta,
Syringoporella convexotabulata, Chaetetes raritabulatus and
Cyclochaetetes distortus. The tabulate corals, heliolitids and
chaetetids were found together with rugose corals (Utaratuia sinensis,
Sociophyllum minor and Breviseptophyllum kochanensis etc.) and
Brachiopods (Acrospirifer houershanensis, Eospiriferina lachrymosa,
Athyrinsina squameosaeformis, Acrospirifer fongi, Gypidula biplicata
and Kwangsia perfecta etc.). * Accordingly, the tabulate coral-bearing
deposits may be assignable to the early Middle Devonian stage,
approximately corresponding to the Eifelian stage in Europe. Based upon
the characteristic features of the tabulate corals and chaetetids, two
coral assemblages may be recognized in the Longdongshui Member of the
Houershan Formation, the upper assemblage is characterized by the
presence of Parastriatopora jumuwanensis, Favosites clarus and
Roemerolites dushanensis, while the lower assemblage is represented by
Pachyfavosites nilella, Favosites multiplicatus and Pachycanalicula
barrandei.^1";

Heliolitida from Alengchu of Northwestern Yunnan.- Bulletin Nanjing
Institute Geology and Palaeontology, Academia Sinica 7: 287-310.-
<b>FC&#038;P 15-2</b>, p. 35, ID=0720^<b>Topic(s): </b>; Tabulata,
Heliolitida; <b>Systematics: </b>Cnidaria; Tabulata Heliolitida;
<b>Stratigraphy: </b>Devonian L M; <b>Geography: </b>China, Yunnan^The
Lower and Middle Devonian marine deposits well developed in Alengchu of
Lijiang N.W. Yunnan contain tentaculites, conodonts, brachiopods and
corals. The tentaculites collected from there have been identified in
1975 by Mu Dao-cheng and the rugose corals in 1978 by Yu Chang-min and
Liao Wei-hua. Here described which are Tabulata and Heliolitida belong
to 14 genera and 35 species including 12 new species and 7 new
subspecies with their stratigraphical distribution given as follows.In
China, the Devonian sea may be generally outlined by two
paleobiogeographical districts, the North district and the South one.
The Lower Devonian marine strata with coral faunas including Tabulata
and Heliolitida are developed from West Sichuan, Northwest Yunnan,
Central Guangxi and West Qinling in the South, from East Junggar and
```

```
Central Da Hinggan Mountains in the North. Favositids, Thamnoporids,
Heliolitids are abundant in the above areas, chiefly containing
Favosites, Dictyofavosites, Squameofavosites, Pahcyfavosites,
Thamnopora, Striatopora, Cladopora, Parastriatopora, Heliolites and
Paraheliolites, among which Favosites, Dictyofavosites and
Squameofavosites are predominant. On the whole, the Lower Devonian
coral faunas with Tabulata and Heliolitida from either North and South
China bear a resemblance to those of Kazakstan and Kuznetsk Basin.^1";
s[2943] = "FENG Qi, GONG Yi-Ming &#038; RIDING R. (2010).- Mid-Late
Devonian calcified marine algae and cyanobacteria, South China.-
Journal of Paleontology 84, 4: 569-587.-  <b>FC&#038;P</b> 36, 125,
ID=6576^<b>Topic(s): </b>taxonomy, temporal patterns; <b>Systematics:
</b>calcified algae, Cyanobacteria; <b>Stratigraphy: </b>Devonian M U;
<b>Geography: </b>China S^Givetian, Frasnian and Famennian limestones
from southern China contain microfossils generally regarded as
calcified algae and cyanobacteria. These are present in 61 out of 253
sampled horizons in four sections from three widely spaced localities
in Guangxi and southern Guizhou. Three of the sections sampled are
Givetian- Frasnian-Famennian, one section is Frasnian-Famennian. They
include reef and non-reef carbonates of shallow marine platform facies.
The following taxa are identified with differing degrees of confidence,
and placed in algae, cyanobacteria or microproblematica. Algae:
Halysis, &#039;solenoporaceans&#039;, Vermiporella. Cyanobacteria:
Bevocastria, Girvanella, Hedstroemia, Subtifloria. Microproblematica:
?Chabakovia, Garwoodia, ?Issinella, Izhella, Paraepiphyton,
Rothpletzella, Shuguria, ?Stenophycus, Tharama, Wetheredella. As a
whole, the abundance of algae, cyanobacteria and microproblematica
increases by 34% from Givetian to Frasnian, and declines by 63% in the
Famennian. This secular pattern of marked Famennian decrease does not
support recognition of them as &#034;disaster forms&#034; in the
immediate aftermath of late Frasnian extinction. Nonetheless, their
survival into the Famennian could indicate tolerance of environmental
stress, independence of changes in food supply, morphologic plasticity,
and ability to occupy a range of habitats and depths. Uncertainties
concerning the affinities of the problematic taxa hinder assessment of
their significance.^1";

calcimicrobial (Renalcis) reef at Miaomen, Guilin, Guangxi, South
China.- Palaeogeography, Palaeoclimatology, Palaeoecology 204, 3-4:
373-394.- <b>FC&#038;P 33-1</b>, p. 98, ID=1198^<b>Topic(s): </b>reefs;
reefs; <b>Systematics: </b>Cyanophyta; <b>Stratigraphy: </b>Devonian
Fam; <b>Geography: </b>China, Guangxi^Famennian (Upper Devonian) reefs
represent a calcimicrobial and stromatolitic reef framework with a few
skeleton-dominated (stromatoporoid) examples after the skeletal
metazoans in reef ecosystems were impacted on a global scale by the
Frasnian-Famennian extinction event. Calcimicrobes, thrombolites,
stromatolites, and biologically induced cement formed the major part of
reef framework volume and contributed to rigidity of reefs. In this
study, one example of Famennian non-skeletal carbonate buildups at
Miaomen, Guilin, South China, has been documented in detail. Thick and
massive limestones in the platform margin facies show a lateral
transition to well-bedded fenestral and laminated limestone in the
```

```
back-reef facies southeastward and to well-bedded intraclastic grainstone, mudstone, and shale with lithoclasts and breccias in fore-reef slope facies northwestward. The Miaomen reef is almost exclusively constructed by calcimicrobes and cement. Major reef builders are Renalcis, Izhella, Paraepiphyton, Garwoodia, and a &#039;Keega&#039;-like microbe. Other reef builders are Wetheredella, Rivularia, Rothpletzella, Ortonella, and Girvanella. Some less common algae and calcimicrobes also occur in the Miaomen reef, including Parachaetetes, Solenopora, Tharama-like objects, and unidentifiable microbes. Cavities are well developed in the reef limestone. The Miaomen Renalcis reefs developed along leeward platform margin settings adjoined by intraplatform depressions and rimmed Famennian carbonate platforms along with stromatolite reefs, ooid shoals, brachiopod-shell shoals, nautiloid shoals, and previously described Renalcis-Epiphyton and Renalcis-cement reefs. Miaomen reefs demonstrate the significant roles of calcimicrobes and microbial carbonates in the development of Famennian carbonate systems in South China. Famennian microbial reefs in Guilin represent an interval of profound biotic change in the style and extent of carbonate buildups and in the composition of buildup communities and indicate important environmental and ecological changes within the carbonate system. Im tieferen Unterdevon finden sich noch verstarkt Relikte silurischer Gattungen und Arten (unter den Rugosa z.B. Schlotheimophyllum, Araeopoma, Pilophyllum, Ptychophyllum; unter den Tabulata Astrocenum, PachyporiL, Alcuolites), die aber gegen Ende des Unterdevons verschwunden sind.
```

```
Gleichzeitig treten aber neue Formen auf, die teils starken endemischen
Charakter besitzen und im Kazakhian (Upper Emsium) den grossten Anteil
der Fauna ausmachen. Favositidae spielen die bedeutendste Holle. Das
Dshungarskiy-Balkhash-Meeresbecken stellt somit im Unterdevon eine
selbstandige biogeographische Einheit dar. Die mit dem Ende des
Kazakhian erfolgende Regression fuhrt zu einem Aussterben der meisten
Korallen und Brachiopoden. Im Mitteldevon, insbesondere im Givetium,
wird die Isolierung Beckens beendet. Neue, teils kosmopolitische
Faunenvertreter erscheinen. Unter den Tabulata herrschen die
Thamnoporinae vor, aber auch Alveolitidae u.a. Ein Austausch mit
benachbarten Provinzen findet statt, so konnen Einwanderer aus
Westeuropa (z.B. Thamnopora cervicornis), aus der Mediterranean -, der
Uralo-Tienshan -, der Altai-Sayan-Provinz festgestellt werden.
Verbindungen nach Nordamerika und Australien fehlen. Im Oberdevon
schreitet die Transgression fort. Gleichzeitig aber tritt, vor allem im
Famennium, dem Hohepunkt der Transgression, eine Faunenverarmung ein.
Herrschen zunachst in Frasnium noch Alveolitidae vor, so finden sich im
Famennium in erster Linie Syringoporen und Auloporen, die zudem bereits
Anklange an die karbonischen Formen aufweisen. [fragment of extensive
summary]^1";

The F-F event killed most of the Devonian reefs, the characteristic Devonian corals, stromatoporoids, bryozoans, nearly all tentaculites, a few superfamilies of brachiopods, such as Atrypacea and Pentameracea and some important elements of goniatites, such as Manticoceras. * The end-Frasnian was a phase of mass extinction. A large number of shelly benthos were killed by the F-F event. Early and middle Famennian was the survival interval. The marine faunas were very rare at that time. The late Famennian was the recovery interval. There appeared to have many new taxa in the Strunian stage. It lacked a radiation interval in Late Devonian Famennian because another event (the D-C mass extinction) happened at the Devonian-Carboniferous boundary. * Several causes for the F-F mass extinction have been proposed by some geologists, which have been grouped into two broad types, terrestrial and extraterrestrial. The former is related to sea level changes, climate changes and anoxic water event. The latter is linked with some forms of meteorite impact. * A large-scale eustatic change of sea level and black shales representing an anoxic environment has been invoked to explain one of the causes for the F-F mass extinction. [original abstract; also reported in FC&#038;P 30, 2: 11 - similar, Chinese version of this paper: Liao Wei-Hua 2001, Biotic recovery from the Late Devonian F-F mass extinction event - this could not be confirmed by our bibliographic query in June 2013]^1";

Devonian community from Panxi in eastern Yunnan, with notes on fossil
counting in a quadrat.- Acta Palaeontologica Sinica 26, 1: 18-29.-
<b>FC&#038;P 16-2</b>, p. 19, ID=2042^<b>Topic(s): </b>biocoenoses;
fossils; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M;
<b>Geography: </b>China, Yunnan^This paper discusses the fossil
counting in a quadrat, with the recognition that it is appropriate and
effective to use the alternate fossil counting method for diverse
organisms which are individually different in size. From the
consumption of food resources in an ecosystem, a colonial form with
smaller individuals (e.g. bryozoans) may be equivalent to a larger
solitary form (e.g. solitary tetracorals). Application of this method
would precisely ascertain the relative importance of each population at
the same trophic level. By using the quadrat method and based on the
data from autecology and sedimentology, the authors have analysed the
structures of the PM (Parasociophyllum isactis - Microplasma fungi)
community from the Middle Devonian Huaning Formation of Panxi, Eastern
Yunnan and reconstructed the general features of the living community
(fig. 6). The PM community represents a living community dominated by
benthic suspension feeders. Including at least 28 populations, with the
dominant species Microplasma fongi (Yoh) and Cystiphylloides
kwangsiense Yoh, and rare species Stringocephalus obesus, Murchisonla,
etc. The PM community has a high diversity (D=3.795), a high dominance
(C=0.648) and a low equitability (E=0.286), at two trophic levels
(producer level and primary consumer level). The spatial distribution
of the community is characterized by a mosaic pattern with patch areas
of high biomass and high density enclosed in scattered areas of low
biomass and low density, on four levels in height. Probably the PM
living community was developed in the tropic zone and on the upper part
of a shallow-shelf (below the normal wave base).^1";
s[2960] = "YU CHANGMING, WU YI (1988).- Middle Devonian Facies Patterns
and Reef Development in South China.- Canadian Society of Petroleum

World], II: 649-658.- <b>FC&#038;P 18-2</b>, p. 46,
ID=2504^<b>Topic(s): </b>reef complexes, facies; reef complexes;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M; <b>Geography:
</b>China S^Middle Devonian rocks in Southern China exhibit a variety
of lithofacies and biotas. Three facies areas can be recognized,
including four facies zones or belts. The distribution of various
facies zones was only controlled by a basement fracture system but also
by syndepositional faults. The reefs range in age from late Emsian to
Eifelian and from Givetian to the end of Frasnian time. They are mainly
distributed along the northwest-trending Nandan-Yadu fault zone and
along the northeast-trending Yongfu-Tao-jiang fault zone. Some of the
Givetian reefs in Southern China are laterally differentiated into
fore-reef, reef-core and back-reef subfacies. In vertical section they
exhibit in ascending order repeated cycles of reef basement, reef,
dolomitized reef and biodetrital limestones. Hematite ore deposition
occurs preferentially in the transition zone between clastic rocks and
argillaceous limestone in the central part of the littoral facies area.
Siderite and its sister deposits typically occur in the transitional
terrane between the reef platform and depressional facies so they, too,
are related to the reef facies. The Devonian of South China was
deposited in an epicontinantal sea which onlapped paleo-landmasses. On
the east the epicontinental sea was bounded by the Cathaysian landmass,
on the north and northwest by the Jiangnan landmass and the Qianbei
landmass respectively, and on the west by the Kongdian landmass. These
paleo-landmasses were source areas for terrigenous material that was
transported, respectively, from east to west, from north and northwest

<b>Stratigraphy: </b>Devonian; <b>Geography: </b>China, Hunan^Devonian
reefs in Hunan were developed in the late Givetian and early Frasnian.
Most reefs have been discovered in the area of carbonate platform
facies and regarded as biostromes or patch reefs. Rare oil shows have
been found in these kinds of reefs. Some so-called &#34;reef
mounds&#34; have abundant oil shows, but they have been considered to
have developed only on a few elevated blocks in the area of
inter-platform depressional facies. Based on research on reef
distribution and characters of sedimentography and paleoecology, this
paper proposes that many so-called &#34;biostromes&#34; are not layered
but instead are narrow [structures] along the edges of platforms
[acting] as barrier reefs. Some &#34;reef mounds&#34; are only the
upper parts of barrier reefs, which extended towards the depressional
facies area and were broken by faults. If this is true, they will be
found along the edges of platforms and are not restricted within narrow
limits. Because these parts of the reefs are preserved in the black
shales and have fine oil shows, great attention should be paid to them
in oil exploration.^1";

[in English].- Jiangsu Science and Technology Press, Nanjing: 168 pp., 57 text-figs, 27 pls.- <b>FC&#038;P 29-1</b>, p. 13, ID=7009^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>China, Guilin^A professional volume contains rich data on Devonian reefs and reef complexes in Guilin, South China based on the result of as long term study under multidisciplinary principles of biology and geology, especially based on the result of paleobiologic study on many fossil groups, on the lithostratigraphic, biostratigraphic, sedimentology, microfacies analysis of carbonate rocks etc. It reveals that the region of present Guilin was covered by warm and shallow marine about 360 million years ago and was prosperous with the reef development. By the beginning of the geologic time interval approximately equivalent to the varcus conodont zone there started a record of carbonate deposition in Guilin. It was until the late Famennian and earliest Carbniferous that the reefs were intermittently developed along the margin of carbonate platform, and in places in the interior of platform. As a whole the marine Devonian form a megacycle mainly composed of the clastics at the base (pre-varcus zone), and of the carbonates at the above, where some hiatus of various scale caused by the bioevents and sedimentary events can be found. Some patch reefs, fringing reefs and algal mounds of smaller size occurred mainly in the earlier stage of the carbonate platform development in Givetian, whereas the barrier reefs along the margin of platform and rare patch reefs behind them were growing in the late developmental stage mainly in Frasnian, locally in Famennian. * Beside the first chapter in which the regional geology and the Devonian stratigraphy including the biostratigraphic framework and lithostratigraphic sequences are introduced, there are descriptions and records of the characteristics of various parts of the reef complexes and different facies types outcropped from place to place in Guilin. these contents occupying the length of three chapters are appended with many photos in plates and text-figures made from the outcrops or under the microscopy, the fifth chapter deals with the aspects of diagenesis and in the sixth chapter there is discussion of the sea-level changes affecting the Devonian sedimentation and reef development, the conclusive parts issued that the special mode of Devonian reef development in Guilin is distinct from the contemporaneous reef development in western part of North America, northwestern Australia and western Europe.^1";

They are mostly frame reefs, built mainly by stromatoporoids and tabulate corals. Some are the baffle reefs, built mainly by dendroid tabulate corals or algae. Four communities and an association are recognized in the reef complex. The Ilmenia-Crassialveolites community is characterized by small brachiopods and dendroid tabulate corals and occupied in the lower-turbulent shallow sea. The Thamnopora-Stringocephalus community consists of the dendroid tabulate corals and big brachiopods and develops in the open shallow sea. The Stromatopora-Alveolites community
```

```
is the very important reef-building community, characterized by the massive stromatoporoids and various corals. The blue-green algae community is the builder of the baffle reefs. The Cyclocyclicus-Clathrocoilona association is composed of the crinoids and thin-bed stromatoporoids and develops in bank facies. By the ecological analysis and comparison with the reefs in neighboring areas, the reef complex developed in a stable shallow marine environments, which was more suitable for growth of reef-building organisms. ```

```
</b>distribution, microstructures; Heterocorallia; <b>Systematics:
</b>Cnidaria; Heterocorallia; <b>Stratigraphy: </b>Devonian,
Carboniferous; <b>Geography: </b>China^China yields the most abundant
fossils of Heterocorallia in the world. However, so far only eight
genera have been established, namely, Tetraphyllia, Oligophylloides,
Pentaphyllia, Crepidophyllia, Longlinophyllia, Radiciphyllia,
Heterophyllia and Hexaphyllia. Among them, Oligophylloides, is only
found in Poland, Radiciphyllia only in Japan, while the others are all
discovered from China, and can be classified into 3 families, 6 genera
and 58 species. These Chinese taxa include not only the genera first
identified in Europe, for example, Heterophyllia and Hexaphyllia, but
also the endemic forms such as Tetraphyllia, Pentaphyllia,
Crepidophyllia and Longlinophyllia. In China, Tetraphyllia is found
from the Lower Devonian of Wenshan, Yunnan, while the others are
widespread in the strata of the Tatang Stage. The genus Hexaphyllia is
much more abundant than others and together with Yuanophyllum may be
regarded as zonal fossils for late Tatang Stage. It has been found that
the microstructures of the skeleton of Hexaphyllia are all made up of
fibrous elements, based on electron microscope observation of the
specimens of Hexaphyllia floriformis Wang et Ye from Majiaoba, Sichuan.
These microstructures resemble the septal structure of advanced forms
of Carboniferous tetracorals. The walls are made up of fibrous crystals
which are mainly composed of brachy-columns and needles, with rare
crystal-granules, nearly in parallel arrangement and are perpendicular
to the fibrolamellae. The fibrous elements in the septa are mainly
brachy-columns and crystal-granules, with rare needles; they are
arranged parallel to each other and are perpendicular to the mid-septal
face. The tabulae are also mainly made up of brachy-columns and
crystal-granules; they seem to be arranged in only one row and roughly
perpendicular to the surface of tabulae.^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fam
&#47; Carboniferous Tour; <b>Geography: </b>China, Hunan^Rugosa were
collected in four sections in Hunan, to determine precisely the
biozonation of Famennian to upper Tournaisian strata and to attempt
correlations with Western Europe. 29 species (including two new ones),
belonging to 16 genera (including three new ones), are described and
compared with Rugosa from equivalent levels in Europe. Their
stratigraphical distributions are documented. In systematics,
Eocaninophyllum nov. gen. has been created for Famennian species
previously assigned to Caninia, Parastelechophyllum nov. gen. for
Tournaisian species resembling Stelechophyllum, previously assigned to
Thysanophyllum, and Heterostrotion for Famennian to Visean species
assigned to Donophyllum or to Stylostrotion. It is shown that
Pseudoralinia is a junior synonym of Uralinia and is not close to
Cystophrentis. The fauna, which developed during the Strunian, is
totally different to that occurring at the same time in western Europe.
It includes genera which are not known outside southern and central
Asia, or in other levels than the Strunian, except one taxon
(Smithiphyllum), and do not allow correlations. The Tournaisian strata
yielded corals belonging to the Uralinia tangpakouensis and
Keyserlingophyllum Zones, including some genera which are known outside
China, or closely related to them. The base of the U. tangpakouensis
Zone is correlated with the base of the RC1?, Zone of Belgium. The base
```

```
of the Keyserlingophyllum Zone corresponds closely with the base of the
RC3 Zone.^1";

biogeography; <b>Systematics: </b>; <b>Stratigraphy: </b>Paleozoic U;
<b>Geography: </b>China, Baoshan Block^The Carboniferous and Permian of
the Baoshan block consist of three major depositional sequences: a
Lower Carboniferous carbonate sequence, a Lower Permian siliciclastic
sequence, and a Middle Permian carbonate sequence. These three
sequences were interrupted by two major regressive events: first, the
Namurian Uplift ranging in age from Serpukovian to Gzhelian, and
second, the Post-Sakmarian Regression occurring probably at Artinskian
time in the Baoshan block, although the precise time interval of the
latter event is still unclear. The Baoshan block is characterized by
warm-water, highly diverse and abundant faunas during the Early
Carboniferous, by cold-water and low diversity faunas during the Early
Permian, and by possibly warm-water but low diversity faunas during the
Middle Permian. The Sweetognathus bucaramangus conodont fauna
constrains the upper boundary of the diamictite-bearing siliciclastic
deposits (Dingjiazhai Formation) to the Sakmarian to early Artinskian,
as well as the eruption of the rifting basalts (Woniusi Formation) to,
at least, the post-early Artinskian. Paleozoogeographically,
affiliation of the faunas in the Baoshan block changed from Eurasian in
```

```
the Early Carboniferous, to Peri-Gondwanan in the Early Permian, and to
Marginal Cathaysian/Cimmerian in the Middle Permian. Cimmerian blocks
have more or less comparable geohistory to one another in the
Carboniferous and Permian. During the Middle Permian, the eastern
Cimmerian blocks such as Sibumasu (s.s), Baoshan, and Tengchong are not
far from the palaeoequator, but apparently more distant than the
western Cimmerian blocks based on the presence or absence of some index
taxa such as the fusulinaceans Eopolydiexodina and Neoschwagerina, and
the corals Thomasiphyllum and Wentzellophyllum persicum.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>China^The Carboniferous marine
deposits are generally known to be extensively widespread and fairly
well-developed in China. These deposits contain a great amount of
corals. During the past two decades, knowledge regarding the
Carboniferous corals of China has been increased considerably. In broad
outline, three faunal regions may be [distinguished], based on the
characteristics of Carbonifer ous coral fauna: the southern, northern
and northwestern faunal regions. In this paper, accounts are given of
the coral assemblages in each region, especially those in the southern
region with their stratigraphical implications.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Carboniferous U;
<b>Geography: </b>China, Xinjiang^From uppermost Carboniferous
deposits, the Kangkelin Formation, consisting of light grey
argillaceous limestone, a rich coral fauna is described of which 29
species and subspecies are belonging to ten genera. Among them one
Family (Kepingophyl1idae), three genera (Cardiaphyllum,
Paraduplophyllum, Anfractophyllum) and 20 species and subspecies are
new. * Two coral assemblages can be differentiated: the Cardiaphyllum
elegans assemblage below and the Kepingophyllum aksuense assemblage
above. These are contemporaneous in age with coral faunas in the Maping
Formation of northern Guangxi and western Guizhou, as well as with
those faunas from the Upper Chuanshan Formation of southern Jiangsu. *
This is proved by the occurrence of Lophocarinophyllum, Caninia,
Timania, Koninckocarinia and Kepingophyllum in the Kangkelin Formation
and the occurrence of characteristic fusulinids in addition. Regarding
the Upper Paleozoic biogeographic provinces, it seem unlikely that the
coral fauna of the Kangkelin Formation belongs either to the
Waagenophyllidae or to the Durhaminidae provinces. The Kepingophyllidae
province thus is established covering the western Guizhou, eastern
Jizang and southern Jiangsu areas as well as the Kalping area,
Xinjiang. It approximately corresponds to the Sakmarian in the Urals or
the Wolfcampian of North America. * Cardiaphyllum gen.nov. very closely
```

```
resembles Palaeosmilia in the character of the tabulae and can easily
be distinguished from the latter by its longer minor septa, the
concentric dissepiments, and the absence of keyhole fossula. It also
resembles Amandophyllum, but in the latter the cental column is
distinct and the character of the tabulae indistinct. The following
[species] belonging to the new genus are mentioned: Neokoninckophyllum
dunbari Ross &#038; Ross 1962, N. cooperi Ross &#038; Ross 1962, N.
deciense Ross &#038; Ross 1962, Koninckophyllum oklahomense Rowett
&#038; Sutherland 1964, and probably Dibunophyllum clari Felser 1937. *
Paraduplophyllum gen.nov. is similar to Duplophyllum with regard to the
longer minor septa. It can be distinguished from the latter by its
developing carinae and the incomplete tabulae. It also closely
resembles Asserculina, but in the latter the columella and fossula are
developed. * Anfractophyllum gen.nov. is similar to Szechuanophyllum in
the shape of the corallites and the character of the tabulae. The
difference between these two genera is the epitheca of the present
genus being generally suppressed, the septa being of three orders and
the cystose zone rather developed. * At first glance, the present genus
shows a similarity to Polythecalis, but differs from the latter in
presenting tertiary septa.^1";

Strata under discussion may be divided into three formations, namely the Liushugou, Qijagou and Aoertu Formations. * The Liushugou Formation is subdivided into two subformations. The lower one is made up of grey-greenish, medium-bedded to massive interbeds, intermediate-acid tuff and volcanic rocks and a few siliceous rocks, totalling 1131m in thickness. The upper one is composed of green, grey-violetish volcanic breccia and agglomerate, intercalated with a few andesitic porphyrite, with a thickness of 894m. The modified Qijiagou Formation, 189m thick, consists of carbonate and clastic rocks of normal littoral shallow water facies and contains abundant fusulinids, brachiopods, corals. In the present paper the volcanic and volcaniclastic rocks in the lower part of the Qijiagou Formation have been incorporated into the Liushugou Formation. Thus, the contact between the Qijiagou and Liushugou Formations is conformable. The Aoertu Formation is also subdivided into two subformations. The lower one consists chiefly of carbonate rocks intercalated with a low calcium-bearing clastic rocks 66m thick, containing brachiopods, corals, etc. The upper one is made up of the normal clastic rocks intercalated with a few carbonate rocks 175-228m thick, yielding gastropods, cephalopods and a few corals.^1";

The corals of the Gaolishan Formation occur in lenticular mudlimestone of littoral facies in Nanjing-Zhengjiang area and Caohu area. The majority of corals in this area is of Huanan type, and the minority is of European type. Besides, a quantity of them belongs to local type. * The tetracoralla from the Lower Carboniferous Jingling Formation is monotonic and undiversified, belonging to solitary Zweizoner. Pseudouralinia is a zone fossil of Jingling Formation. The corals of Gaolishan Formation differs from that of the Jingling Formation. Dreizoner begin to appear but in small quantity. In Hezhou period, the Early Carboniferous corals flourished, solitary, compound Dreizoner and
```

```
Zweizoner appeared in great number. Yuanophyllum kansuens - Aulina
carinata are assemblage zone fossils of Hezhou Formation. In late Early
Carboniferous Laohudong period fossils are rare. Aulophyllidae and
Palaeosmiliidae which flourished in Hezhou period largely vanished.
Lithostrotion mccoyanum is the zone fossil of Laohudong Formation. The
corals in Late Carboniferous Huanglong period is less flourishing than
that in Early Carboniferous. Main Early Carboniferous species
extinguished continuously. New elements such as Kionophyllum,
Fomitchevella, Wentzellophyllum and so on appeared. In Chuanshan period
developed solitary and compound Dreizoner corals with axial structure
and clinotabulae. Some species resemble to Permian species. The coral
group has a transitional nature of Carboniferous-Permian. (Original
summary) The new taxa are: Dingshanophyllum minglingense n.gen. et
n.sp., Chaohuphyllum anhuiense n.gen. et n.sp., Vesiculoamplexocarinia

Visean rugose coral communities in China.- J. Fac. Sci. Hokkaido Univ.
IV, 23, 3: 329-342.- <b>FC&#038;P 23-2.1</b>, p. 39,
ID=4234^<b>Topic(s): </b>biostratigraphy; coral communities;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous Vise; <b>Geography: </b>China^Within China six Early
Visean rugose coral communities are recognized, they are: 1) the
Siphonophyllia community, 2) the cool water Gangamophyllum community,
3) the Thysanophyllum community, 4) the Bothrophyllum-Zaphrentites
community, 5) the island Humboldtia community and 6) the cold water
Hapsiphyllum-Rhopalolasma community. In northwest China, the
Siphonophyllia community is distributed along the northern margin of
the Tarim-Qaidam Oldland. The Gangamophyllum community was widespread
north of the region occupied by the Siphonophyllia community, including
north Tianshan, central Tianshan and east Junggar. In South China there
were three rugose coral communities. The Thysanophyllum community
occurs on the margin of the Upper Yangtze Oldland. The
Bothrophyllum-Zaphrentites community was confined to the southern and
western part of the region occupied by the Thysanophyllum community.
```

```
These two communities merge into each other without a distinct
boundary. The Humboldtia community is found only in the Baoshan area.
The Hapsiphyllum-Rhopalolasma community is found in Xainza and Himalaya
of Tibet. The distribution of the six Early Visean rugose coral
communities was controlled by the palaeogeographical background. The
Gangamophyllum community occurs along the southern margin of the
Siberia Oldland, while the Siphonophyllia community is distributed
along the northern margin of Tarim-Qaidam Oldland. The
Hapsiphyllum-Rhopalolasma community is confined to the northern margin
of the Gondwana Oldland. In the wide southern and western margin of
Yangtze Oldland the distribution of the Thysanophyllum and the
Bothrophyllum-Zaphrentites communities was controlled by the
bathymetry. The Humboldtia community probably lived in island seas far
from the Yangtze Oldland.^1";

<b>FC&#038;P 10-2</b>, p. 61, ID=5883^<b>Topic(s): </b>geology;
geology, corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>China,
Sichuan^The region of northwestern Szechuan is in the western of the
line from Chengdu to Guangyuan which comprises the places of
Longmenshan, Songpan and Nanping. It is characterized by Lower
Carboniferous strata completely developed and by the distribution of
corals and faunas of different varieties in those places. Based on more
practical material, the writer studied the rules of coral distribution,
suggested an opinion to divide the Lower Carboniferous strata, and to
divide three coral zones from lower to upper according to these. Thus,
the writer emended the original terms of the Zongchanggou series and
subdivided these series into three different members as given below: *
3. Zongchanggou member - zone of Yuanophyllum and important member
Melanophyllum (Upper Visean); * 2. Majiaoba member - zone of
Pseudoouvalinia and important member Stelechophyllum (Upper
Tournasian); * 1. Changtanzi member - zone of Cystophrentis, and
important member Beichuanophyllum (Lower Tournasian). * In the paper
presented, the writer describes 17 genera (4 of which are new and 2 new
subgenera), 50 species (42 of which are new and 1 new subspecies, 2
species indet.) and establishes one new family. [original summary]^1";

s[3016] = "LIU ZUHAN, SU LINYAO (1992).- New materials of
Heterocorallia from Hunan with discussion on their structures.- Acta
Palaeontologica Sinica 31, 4: 472-482.- <b>FC&#038;P 22-1</b>, p. 36,
ID=3392^<b>Topic(s): </b>structures; Heterocorallia; <b>Systematics:
</b>Cnidaria; Heterocorallia; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>China, Hunan^Recently a wealth of perfect specimens
of Heterocorallia was collected from the dark grey limestone of the
Upper Datang Stage of the Lower Carboniferous in Central Hunan, China.
These specimens belong to four known genera: Hexaphyllia, Pentaphyllia,
Haptaphyllia, Heterophyllia, and two new genera. A series of sections
have been made. Based on detailed observation of these sections, some
revisionary views about the structures of Heterocorallia can be
proposed. Central tube: Yu C.-C. et al. (1978) first discovered and
named Crepidopbyllia as a sub-genus of Hexaphyllia with their inner
ends of six septa conjoined to form an aulos-like central tube. Among
the specimens from Central Hunan, the central tubes were also found in
some heterocorals with six or five septa, but they are very unstable,
and they could appear or disappear in a distance of several milimeters.
In the parts where they disappeared, the inner structures were the same
as those in Hexaphyllia or Pentaphyllia. The unstable central tubes
were formed by the splitting of the connected part of the septa.
Tabula: It is a controversial issue whether the tabulae of
Heterocorallia are convex upward or on the contrary, because it is very
difficult to determine the growth direction of the specimen. In the
collected specimens, an individual Hexaphyllia with a bud has been
discovered, so that it is very easy to confirm the growth direction. In
the longitudinal section of this specimen, tabulae ascend from the
center to the wall. In many longitudinal sections deviating from the
center, the tabulae between two septa are domical, but those between
the septum and wall ascend to the wall. For this reason, it is inferred
that the tabula of Heterocorallia is similar in form to an inclined
saddle ascending to the wall. Septum: Nearly all septa are complete,
and mostly even platelike. But in many of the specimens from Hunan the
septa are wavy in longitudinal direction or in both longitudinal and
transverse directions. Since the septa are usually thickened, mostly at
outer ends, many septa are sphenoid. The septa and their stereoplasma
stretch into the wall, forming clear limits with the peripheral
stereozone. These limits have been mistaken as the supports of the
septa. In a new species there are seven septa; one of them is
incomplete with a free outer end. This fact is contrary to the
inference that the septa were developed from the wall to the center.
Wall: The epitheca is clearly observed in the specimens from Hunan,
including all six genera. It is obvious that the wall consists of
tabula wall, peripheral stereozone and epitheca. The peripheral
stereozone is lamellar in both transverse and longitudinal sections.^1";

s[3039] = "GUO SHENGZHE (1985).- On the Early Carboniferous Corals from
Xieertala District of Nei Mongol (Inner Mongolia).- Bulletin Shengyang
Inst. Geol. Min. Res., Chin. Acad. Geol. Sci. 12: 68-73.- <b>FC&#038;P
16-2</b>, p. 18, ID=2039^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>China, Nei Mongol^The Xieertala Formation was
established on the western slope of Da Hingan-ling (Great Khingan) by
Hailar in 1976. Based mainly upon the determination of brachiopods, the
age of the formation has been recognized as Late Carboniferous, but the
coral fauna of the Xieertala Formation indicated that the age should be
Early Carboniferous. This coral fauna consists merely of very few small
solitary corals and its generic assemblage, such as Zaphrentites,
Zaphrentoides, Trochophyllum, Cyathaxonia and Amplexus etc., clearly
shows a Early Carboniferous feature, although its dominant species are
endemic. Whereas in West Europe the characteristic forms of the
Tournaisian corals are dominated by &#34;Zaphrentis&#34;, the Xieertala
coral fauna is comparable with the &#34;Zaphrentis&#34; konincki
subzone (Z2) of England except for disappearance of caniniid corals.
Our coral assemblage is also similar to some types of American
Mississippian corals, therefore the Xieertala Formation seems to be
able to compare with the Keoikuk Limestone or the New Providence Shale
of the Osagean Series of Mississippian in the United States.^1";

The lower is the Sanjiazhai Formation (equivalent to Aikuanian), consisting of siliceous clastic rocks, unfossiliferous and 34 m in thickness. The upper is the Longhuo Formation (equivalent to Tatangian), mainly composed of carbonate deposits, yielding abundant marine fossils and attaining a thickness of 188 m. This paper describes 22 genera and 25 species, among which 1 genus, 1 subgenus, 21 species and 1 subspecies are new. All coral specimens were collected from the Longhuo Formation of the Tatang stage in the Longhuo area. In this area, the coral fauna is outstandingly characteristic of the South China zoogeographical province. There have been found some genera such as Yuanophyllum, Kueichouphyllum and Neoclisiophyllum, which appear all over the Guizhou, and Guangxi regions, with occurrence of certain genera such as Siphonophyllia, Cyathaxonia, Palaeosmilia, Dibunophyllum, Carcinophyllum, Lithostrotion and Corwenia, which generally have a wide distribution in the West European - Tethyan coral [province], and a few coral elements either from the Ural - Arctic area such as Aulokoninckophyllum, Gangamophyllum, or from North America such as Vesikulophyllum. During the Early Carboniferous time the sea of the Longhuo area was connected with the European sea and possibly with the North American sea.^1";

```

```
Early Carboniferous corals from the Nalingala Formation of the Altai
area, northern Xinjiang. Here are described 9 genera, 11 new species
and 2 indeterminate species, namely, Zaphrentoides crassiseptatus
sp.nov., Amplexus regularis sp.nov., Paralleynia xinjiangensis sp.nov.,
Plerophyllum bilamellatum sp.nov., P. sp., Pleramplexus nalingalaensls
sp.nov., P. multitabulatus sp.nov., P. raritabulatus sp.nov.,
Pentaphyllum elegantum sp.nov., P. sp., Cryptophyllum xinjiangense
sp.nov., Cyathaxonia altaiensis sp.nov., and Endamplexus xinjiangensis
sp.nov. They are especially rich in the middle and upper parts of the
Nalingala Formation. This coral fauna is characterized by the corals
which are all in simple forms, small, cornuted-conical and ceratoid
with very thickened septa but no dissepiments. The occurrence of the
ammonoids Goniatites, Epicanites, Prolecanites and Stenopronolites in
the Nalingala Formation also lends support to such a conclusion.
Therefore, the palaeoecological conditions of this coral fauna belong
to offshore water rather than to warm water of low energy, and are
prevailing in the transitional area from foreslope to organic
(ecologic) reef. [part of extesive summary]^1";
s[3050] = "WANG ZHIGEN, ZHAO JIAMING (1989).- Carboniferous corals in
Huize, Yunnan.- Acta Palaeontologica Sinica 28, 1: 79-97.- <b>FC&#038;P
18-2</b>, p. 34, ID=2481^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous; <b>Geography:
</b>China, Yunnan^The Carboniferous corals described were collected
from two sections in the Huize County, Yunnan. At these sections are
exposed the Upper Carboniferous Maping Formation with Axolithophyllum
sp., the Upper Carboniferous Weining Formation with Amygdalophylloides
kionophylloides sp.nov., A. aepitabulatus sp.nov. and A. stenotabulatus
sp.nov., the Lower Carboniferous Shangssu Member with Corwenia magna Wu
et Zhao, Arachnolasma leptaxia sp.nov., A. multitabulata sp.nov.,
Axophylloides huixensis gen. et sp.nov., A. varium (Fan), Durhamina
yunnanensis sp.nov., Syringopora honanesis Lin, Kueichowpora distans
sp.nov. and Chaetetes, accounting for 11,2 % of the total genera. * The
corals from Huize, Yunnan, obviously belong to two groups. In the first
group, since both Rugosa and Tabulata occur, and the rugose corals have
tabulae or tabellae ascending towards the median plate, this group can
be roughly correlated with the Yuanophyllum zone of the Zhimenqiao
Formation of Hunan, the Zhongchangou Member of Sichuan, and the
Shangssu Member of Guizhou. In the second group, there are only two
genera and four species of Rugosa, but it can be easily made out that
this group had entered into the Late Carboniferous facies. According to
the structural morphology of these corals, they are regarded as then
living in a warm neritic environment, but of some mud and low
turbulence. [fragment of extensive summary]^1";

s[3059] = "WANG XIANGDONG (1992).- Early Carboniferous Rugose Corals of
Baoshan District, Western Yunnan &#47; China.- PhD Thesis [University?
unpublished?]: 172 pp.- <b>FC&#038;P 22-1</b>, p. 33,
ID=3388^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>China,
Yunnan^[unpublished?] Based on materials from four sections of the
Lower Carboniferous in Baoshan District, Yunnan, it is suggested that
the Tournaisian-Visean boundary in the study area was drawn at the base
of the Gnathodus taxanus Zone in the Shihuadong Formation. The large
solitary rugosans, i.e., Keyserlingophyllum, Siphonophyllum, in the
formation, occur above the conodont Zone. In light of rugosan types and
sedimentological features, three Visean rugosan biofacies are
recognized as follows: I - the deeper water and soft substratum
biofacies characterized by small cornute solitary rugosans, II - the
shallow water and hard substrate biofacies characterized by solitary
rugosans with dissepiments, and III - the shallow water and mobile
substrate biofacies characterized by large solitary rugosans with
lonsdaleoid dissepiments. Meanwhile, the Lower Carboniferous rugose
corals in the area are grouped into 7 assemblages, they are: I.
Zaphrentites parallelus-Saleelasma hadrotheca Assemblage, II. I to III
interval Zone, III. Lophophyllum-Siphonophyllum sp.-Parazaphriphyllum
cf. P. cylindricum Assemblage, IV. Cyathoclisia
arachnolasmoidea-Siphonophyllia cylindrica-Kueichouphyllum sinense
Assemblage, V. Palaeosmilia murchisoni-Caninophyllum tomiense
Assemblage, VI. Dibunophyllum-Diphyphyllum carinatum Assemblage, VII.
Commutia exoletus-Sychnoelasma affossularis Assemblage. Among them, the
first assemblage is attributed to Tournaisian and the latter six belong
to Visean. Cladistical analysis is applied for discussing the
relationships among all genera of Antiphyllinae and two genera
(Neozaphrentis and Longiclava) of Hapsiphyllinae. Polarities of 7
character states are determined by ontogenetic criteria. The results
show that the subfamilly Antiphyllinae should be revised and might
contain the following 10 genera: Actinophrentis Ivanovskiy, Longiclava
Easton, Neozaphrentis Grove, Fasciculophyllum Thomson, Rotiphyllum
Hudson, Falsiamplexus Fedorowski, Lytvolasma Soshkina, Monophyllum
Fomichev, Bradyphyllum Grabau, Claviphyllum Hudson. A detailed
taxonomical study on 72 species (13 new) of 38 genera is undertaken.
Furthermore, intrapopulation variations of 4 new rugose species, (e.g.
Commutia exoletus sp.nov., Pentaphyllum amoebum sp.nov., Ufimia
```

```
baoshanica sp.nov., Neozaphrentis sphenoidale sp.nov.) are dealt with.
It is suggested that the scarcity of small corallites in the four
fossil populations is due to biases in sampling and in taphonomy,
variations in some characters are caused by differently-oriented
sections, and some discontinous variation (e. g., diameters of
Pentaphyllum amoebum sp.nov.) are due to paleoecological factors.^1";

Formation of the early Lower Carboniferous in Shidian County, Western
Yunnan.- Bulletin Chinese Academy geological Sciences 27-28: 155-173.-
<b>FC&#038;P 23-1.1</b>, p. 65, ID=4142^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous L; <b>Geography: </b>China, Yunnan^The rugose corals
dealt with in the present paper were collected from the Xiangshan
Formation of the early Lower Carboniferous in Shidian County, western
Yunnan. The early Lower Carboniferous strata, are called the Xiangshan
Formation, it may be subdivided into two members: Upper and Lower. In
this paper 12 genera, 15 species and 3 indetermined species (including
2 new genera and 12 new species) are described. They may be divided
into two rugose coral assemblages as follows: Lower assemblage:
Rotiphyllum yudongense - Commutia crassoseptata - Antikinkaidia typica
assemblage, including Rotiphyllum yudongense (sp.nov.), R. dilatatum
(sp.nov.), R. crassoseptatum (sp.nov.), Commutia crassoseptata
(sp.nov.), Antikinkaidia typica (sp.nov.), A. sp., Parametriophyllum
symmetricum (gen. et sp.nov.), Pentaphyllum crassosseptatum (sp.nov.),
Shidianophyllum staurum (gen. et sp.nov.), Tachylasma sp. The fossil
corals of this assemblage are simple, small in size and conical in
shape, without dissepiments. They are not in intergrowth with compound
rugose corals and genus Cystophrentis has not been found. The coral
fauna possibly lived in the deep and calm sea water. It differs from
that of South China, but closely resembles that of Europe. The coral
fauna belongs to the Gattendorfia Zone and the lower part of the
Cystophrentis Zone. Upper assemblage: Thuriantha sinensis - Tachylasma
shidianense assemblage, containing Tachylasma shidianense (sp.nov.),
Thuriantha sinensis (sp.nov.), Fasciculophyllum omaliusi (Edwards
&#038; Haime), Caninia cornucopiae Michelin, Sychnoelasma konincki
(Edwards &#038; Haime). The upper assemblage belongs to the upper part
of the Cystophrentis Zone. The description of the new genera is given
as follows: Genus Shidianophyllum Z.J. Wang (gen. nov.) Type species:
Shidianophyllum staurum Z.J. Wang (gen. et sp.nov.) [fragment of
extensive summary]^1";

s[3064] = "ZHAO JIAMING, LIANG XlANG-YUAN (1994).- A phaceloid colonial rugose coral from Late Carboniferous Taiyuan Formation of Henan.- Acta Palaeontologica Sinica 33, 5: 593-603.- <b>FC&#038;P 24-1</b>, p. 64, ID=4481^<b>Topic(s): </b>new taxa; Rugosa, Ccrocyathus; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>China, Henan^The genus Ccrocyathus [sic!] discovered in the Taiyuan Formation (Late Carboniferous) of Jiyuan, Henan, China, is a large phaceloid colonial corallum measuring 80cm in height and 40 x 25cm in diameter, in coexistence with the fusulinids Pseudofusulina, Quasifusulina and Rugosofusulina. In this genus, one phaceloid colonial species, C. proliferus (Hall) (in Sando 1983), is distributed in the Lower Carboniferous (Visean) of USA. The present specimen was cut in 22 transverse sections and 14 longitutinal sections. It is found that the corallites grew densely in the lower part (approximately in the early and middle stages), with their skeletons thickened on sides. Based on the development of septa and axis, 2 stages of the corallites may be recognized in descending order as follows: Stage I : Corallites measuring 1.0-4.0mm in diameter; major septa shortened; minor septa undeveloped; stereocolumella small, usually forming platform (text-fig. 4). Stage II: corallites measuring 4.1-9.0mm in diameter; major septa prolonged but not extending to the center; minor septa developed; stereocolumella enlarged with carina to form an irregular shape (text-fig. 5). Increase of Ccrocyathus jiyuanensis sp.nov. occurring frequently, usually with buds put forth from external walls or propagated from lonsdaleoid dissepimentarium. It must be pointed out that the axis of the present species is usually composed of a counter septum extending to the center to form a simple axial plate, but sometimes it is in coexistence with the upturned edges of tabulae to form a pseudosyncolumella. The phaceloid colonial coral lived in a beachy, slightly turbulent and shallow-water ecological environment with a slightly higher energy. ^1";

Characters exhibiting a wide range of variation are: size and shape of corallites, number of septa, diameter of aulos and the timing of its appearance, number of septa connected to the inner wall, and the septal arrangement in each growth quadrant. Combinations of these variable characters result in corallites that are each uniquely different. Variations of those characters are partly due to stressed environments, such as unstable, muddy substrates resulting in corallite rejuvenescence and redirection. [original abstract]^1";

The Yanguanian coral geographic subprovince is subdivided into Northern coral region (N China coral region) and Tethys coral region (S China coral region). The N China coral region can be further classified into Xingan coral subregion and Zhungeer coral subregion, where the former is represented by the coral Ankhelasma, Homalophyllites and the latter by the Kassinella, Hebukephyllum. The S China coral region can be subdivided in to Huanan coral subregion characterized by the coral Cystophrentis, Pseudouralinia and the western coral subregion containing Beichuanophyllum, Siphonophyllia and Humboldtia. The Datangian geographic subprovince is subdivided into Tethys coral region (Kueichouphyllum-Yuanophyllum region). The Kueichouphyllum-Yuanophyllum region can be classified into N Tienshan-central Jilin coral region characterised by the coral Yuanophyllum, Gangamophyllum, Siphonophyllia and southern coral subregion yielding Kueichouphyllum, Yuanophyllum. The southern Tibet coral region is classified into Gangdesi-Nianqingtanggula coral subregion containing the Rhopalolasma, Mirusophyllum and the Himalaya coral subregion with the coral Longiclave, Cumminsia. We think that the first appearance of the caninoid coral of China suggests the beginning of the Yanguanian stage.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous, Permian; <b>Geography: </b>China, Yunnan, Gondwana
&#47; Cathaysia^West Yunnan, Southwest China, is composed of several
allochthonous continental blocks. The Changning-Menglian Belt contains
a continuous rugose coral succession ranging from Early Carboniferous
to Middle Permian. The succession is dominated by such Eurasian and
Cathaysian taxa as Siphonodendron, Fomichevella, Lublinophyllum,
Sestrophyllum?, Caninella, and Nephelophyllum,thus, the
Changning-Menglian Belt belongs to the Cathaysian province. However,
the successions of coral faunas in the Baoshan and Tengchong blocks are
similar of the Cimmerian blocks. The similarities, contrary to those
observed in the Changning-Menglian Belt are: 1) an affinity with the
Eurasian forms during the Early Carboniferous, 2) absence of Late
Carboniferous faunas, 3) very low diversity of faunas during the Early
Permian, and 4) presence of massive forms during the Middle Permian.
Thus, it is clear, based on corals faunas, that the boundary between
Gondwana and Cathaysia existed along the Lancangjiang suture and the
Kejie-Nandinghe fault, the boundary between the Baoshan block and the
Changning-Menglian Belt in West Yunnan. ^1";

From 1983 to 1984, the writers made a systematical study of the fossil corals between Upper Carboniferous Triticites zone and Lower Permian Misellina claudiae zone in Yishan, Guangxi. A total of 51 genera with 97 species (Table 1) are recorded in this area, among which 13 new species are described. The 5 coral assemblage-zones were established based on the Carboniferous-Permian boundary coral fauna in the Manaoshan-Wuguiling section. The present paper deals with these coral zones in order to make correlations with other regions both at home and abroad. The five coral assemblage-zones described are: 1. Paracarruthersella-Carinthiaphyllum carnicum (Pa-Ca) assemblage-zone, 2. Pseudocarniaphyllum-Pseudozaphrentoides mapingensis-Antheria polygonalis (Ps-Pm-A) assemblage-zone, 3. Chusenophyllwn-Polythecalis nephyelophylloides-Nephelophyllum yunnanense (Ch-Pn-N) assemblage zone, 4. Szechuanophyllwn-Polythecalloidea pulchra (Sz-Pp) assemblage zone, 5. Yatsengia yishanensis-Wentzellophyllum kueichowense (Y-Wk) assemblage-zone. The new species described are: Gshelia yishanensis sp.nov., Petalaxis difformis sp.nov., P. guiensis sp.nov., P. wuguilingensis sp.nov., Polythecalis nephelophylloides sp.nov., P. variformis sp.nov., P. typica sp.nov., P. crassiseptata sp.nov., Parapolythecalis raredentata sp.nov., Wentzellophyllum epicharis sp.nov., W. wuguilingense sp.nov., Yatsengia yishanensis sp.nov., Sinopora manaoshanensis sp.nov.^1";

Late Palaeozoic corals of Tibet (Xizang) and West Yunnan, Southwest
China: successions and palaeobiogeography.- Palaeogeography,
Palaeoclimatology, Palaeoecology 191, 3-4: 385-397.- <b>FC&#038;P
33-1</b>, p. 19, ID=7169^<b>Topic(s): </b>biostratigraphy,
biogeography; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Carboniferous Permian; <b>Geography: </b>China,
Tibet, Yunnan^A dynamic pattern of coral faunal provincialism in the
Carboniferous to Permian sequence is preserved in Tibet-West Yunnan.
During the Early Carboniferous, an undifferentiated Eurasian province
was present, containing the Kueichouphyllum,
Keyserlingophyllum-Siphonophyllia, and Cyathaxonia faunas, that reflect
major environmental differences relative to previous interpretations.
During the Late Carboniferous-Early Permian, the Indoralian province
and the Cathaysian province can be distinguished. The former is
recognised by an absence of Late Carboniferous-Asselian corals and by
the presence of the Sakmarian-Artinskian Cyathaxonia fauna. The latter
contains the Late Carboniferous and Early Permian compound corals
Nephelophyllum and Kepingophyllum. As many blocks drifted northward
beginning in the late Early Permian, the Indoralian province had
evolved into two discrete provinces: the Himalayan and Cimmerian
provinces. The Himalayan province as a relic of the Indoralian province
was in the northern margin of Gondwanaland. The Cimmerian province
between the Himalayan and the Cathaysian provinces consists of the
present tectonic blocks: Lhasa, Qiangtang, Tengchong, and Baoshan in
Tibet and West Yunnan. It is characterised by Roadian non-dissepimental
solitary corals and Wordian-Capitanian compound Waagenophyllidae, as
well as some endemic Cimmerian taxa such as Thomasiphyllum and
Wentzellophyllum persicum. The Cathaysian province is dominated by
Szechuanophyllum and Ipciphyllum. During the Late Permian, the
Himalayan province and the Cathaysian province can be recognised. The
former contains only small solitary corals, referred to as the
Lytvolasma fauna, and the latter is identified by Liangshanophyllum, a
fasciculate waagenophyllid. [original abstract]^1";

corals from Batang and Yidun, western Szechuan.- Acta Palaeontologica
Sinica 18, 1: 25-38.- <b>FC&#038;P 8-2</b>, p. 42, ID=0341^<b>Topic(s):
</b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous, Permian; <b>Geography: </b>China, Sichuan^The
present paper deals with the rugose corals found from the latest Lower
Carboniferous Xuchika formation and the late Lower Permian Bingfeng
formation in Batang and Yidun, western Szechuan. The Xuchika formation
contains Hiroshimaphyllum, Ozakiphyllum, Amygadalophyllidium and
Ramiphyllum with Hiroshimaphyllum as the leading form. It deserves to
be mentioned that Hiroshimaphyllum was previously recorded only from
the early Namurian in southwestern Japan, but unseen in this country.
The Bingfeng formation yields a coral fauna of western Tethys called
Iranophyllum-Ipciphyllum fauna, which, so far as known, includes
Wentzelel1a, Wentzelellites, Wentzelloides (Wentzelloides), W.
(Multimurinus), Waagenophyllum, Yokoyamaella (Yakoyamaella),
Praewentzelella, Thomasiphyllum and Laophyllum. Both the faunas are,
however, quite different in assemblage from those in the
contemporaneous deposits in southwest and southeast China. It seems
that the distributional pattern of the two faunas must have something
to do with the geotectonic condition. The range of the Hiroshimaphyllum
fauna is more or less controlled by the eugeosynclinal factor, whereas
```

```
the distribution of the Iranophyllum-Ipciphyllum seems to be restricted
by the fold belts. * 9 genera and 11 species are described; two genera
- Ramiphyllum and Batangophyllum - as well as six species are
recognized as new ones. [part of extensive summary]^1";

Diversity patterns of Carboniferous and Permian rugose corals in South
China.- Geological Journal 41, 3-4: 329-343.- <b>FC&#038;P 34</b>, p.
40, ID=1244^<b>Topic(s): </b>diversity patterns; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous, Permian; <b>Geography: </b>China S^The diversity and
changing patterns of rugose corals in theCarboniferous and Permian of
South China are analysed by statistical analyses of 45 families, 284
genera, and 1979 species from 14 consecutive time intervals. The
ancestors of Carboniferous rugose corals originated early and underwent
preliminary radiation in the late Famennian, but were eliminated by the
Hangenberg global regressive event, which marks the
Devonian–Carboniferous boundary. Radiation of typical Carboniferous
rugose corals began in the late Tournaisian, when they were represented
by an abundance of columellate taxa such as Kueichouphyllum and a
significant diversification of Keyserlingophyllum. A decrease in the
diversity of rugose genera occurred in the Serpukhovian, followed by a
change in the composition of the rugose coral assemblages at the
Mid-Carboniferous Serpukhovian–Bashkirian boundary, where large
dissepimented taxa with complex axial structures disappeared. In the
Bashkirian the Serpukhovian taxa were replaced by compound rugosan taxa
of the Geyerophyllidae, Kepingophyllidae and Waagenophyllidae. This
compositional change was associated with a global regressive event,
recognized in South China by the absence of upper Serpukhovian strata
in many places and by several erosional surfaces in carbonate sequences
in the Lower Yangtze region. This regressive event was probably caused
by an episode of glaciation in Gondwana. Subsequent transgression
occurred in South China during the early Bashkirian, where a wide,
uniform shallow-water platform developed in South China, on which were
deposited tidal-flat dolostone and pure limestone containing compound
rugose corals. Another change in the rugose coral assemblages, at the
Sakmarian-Artinskian boundary, resulted in the absence from the
Artinskian of representatives of typical Pennsylvanian and Early
Permian families such as the Bothrophyllidae, Lithostrotionidae,
```

```
Cyathopsidae, and Petalaxidae. Families uniquely typical of the
Permian, characterized by Waagenophyllidae and Kepingophyllidae,
dominate post-Sakmarian strata. This faunal change may be related to a
major, worldwide regression, recognized at the end of the Sakmarian.
Extinction of rugose corals at the end of the Permian occurred in two
phases in South China. The first phase occurred at the end of the
Capitanian and eliminated 47% of the families and 45% of the genera.
Extrusion of the Omeishan Basalt, which is widely distributed in the
western part of South China, and/or a global regression at the end of
the Guadalupian could be the principal causes of this first phase of
mass extinction. The second phase, which occurred at the end of the
Changhsingian and is the largest extinction event in Earth&#039;s
history, eliminated all remaining rugose corals.^1";

Rugosa; <b>Stratigraphy: </b>Carboniferous ? Permian; <b>Geography:
</b>China, Fujian^The Huanglung Formation exposed in Quanxia, Ninghua
Country, SW Fujian is composed of continuously deposited marine
carbonate rocks which contain abundant fossil corals with 27 genera and
59 species and subspecies, and can be grouped into two assemblages and
two subassemblages in ascending order as follows: - 1. Yinophyllum
crassum Assemblage. [...] Besides, Yinophyllum crassum gen. et sp.nov.
[it] is characterized by naotic septa and the thickened, curved
```

```
columella, sometimes with a few axial tabellae, also some
non-dissepimented solitary corals are also found in the assemblage,
such as Lophophyllidium sp., Bradyphyllum sp., etc. The assemblage is
associated with the fusulinid Profusulinella. - 2.
Protoivanovia-Arachnastraea Assemblage. (1) Protoivanovia
quanxiaensis-Koninckocarinia minor Subassemblage. [...] It is dominated
by the caninid corals and dreizoner corals developing lonsdaleoid
dissepiments. Both of the index fossils are prosperous and
characteristic, for example, Protoivanovia quanxiaensis sp.nov. is a
kind of aphroid compound corals with a simple columella. Besides, the
dreizoner corals developing lonsdaleoid dissepiments include
Actinocyathus similis (Dobr.), A. sinensis (Wu et Zhao), Acrocyathus
baijingensis (H. D. Wang), Dorlodotia subcaespitosa (Meek),
Kionophyllum dibunum Chi, K. ovatum Wu et Zhao, K. sp., Koninckocarinia
cf. yishanensis Wu, K. minor sp.nov., K. sp., Petalasis wyomingensis
Sando, etc. The caninid corals are characterized by the appearance of
Pseudozaphrentoides nosovi (Fom.), P. chuanshanensis X. Yu, Caninella
sp., Caninia brockleyensis minor X. Yu, C. lipoensis (Chi), C.
lipoensis chuanshanensis X. Yu, C. simpliseptata Chi, C. wangi sp.nov.,
C. sp., Fomichevella holtedahli (Herit.), F. sinensis X. Yu, F.
stuckenbergi (Fom.), Haplolasma lingwuensis (Lee et Yu), H. juddiformis
regularis (Gorskiy), H. extensa (Gorskiy), Pseudotimania cf. mosquensis
(Dobr.), etc. The fusulinids in the subassemblage are Fusulinella,
Fusiella. This fauna is obviously equivalent to the lower part of the
Fusulina-Fusulinella Zone in age. (2) Arachnastraea
exquisita-Fomichevella aff. hoeli Subassemblage. [...] It is
characterized by the fasciculate and asteroid compound coralla,
including such important components as Arachnastraea manchurica Yabe et
Hayasaka, A. exquisita sp.nov., Fomichevella campophylloides Yan et
Chen, F. aff. hoeli (Holt.), F. holtedahli (Herit.), F. sinensis X. Yu,
F. stuckenbergi (Fom.), F. sp., Opiphyllum fomichevi Kozyreva and
Crataniophyllum ninghuaense sp.nov., among which the last one is a
quasi-colonial coral, while the genus Arachnastraea is a kind of
asteroid compound (or thamnasteroid in part) coral developing
plate-columella and distributed widely in the Soviet Union, Spain and
China as an index fossil for the late Moscovian. Taking into account
the shared fusulinids Fusulina, Beedeina, etc., the subassemblage can
be compared to the upper part of the Fusulina-Fusulinella Zone.

s[3117] = "LUO JINDING, XU HANQIU (1990).- Rugose coral fauna of late
Carboniferous and early Early Permian in Fujian.- Acta Palaeontologica
Sinica 29, 6: 668-693.- <b>FC&#038;P 20-1.1</b>, p. 56,
ID=2826^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous U &#47; Permian L;
<b>Geography: </b>China, Fujian^The Chuanshan Formation widespread in
western Fujian is composed of continuously deposited carbonate rocks
and contains very abundant fossils. [&#8230;] The rugose corals
comprise 83 species and subspecies in 38 genera, including 2 new
genera, Paraantheria and Pseudobothrophyllum, 10 new species and 1 new
subject [?]. Based on the obvious evolutionary phases, they can be
grouped into three assemblages and two subassemblages in ascending
order as follows: 1. Nephelophyllum Assemblage. [&#8230;] The common
elements are Nephelophyllum, Caninia, Haplolasma, Arctophyllum,
Timania, Orygmophyllum, Pseudozaphrentoides, Caninophyllum,
Fomichevella, Lytvophyllum, etc. Among them, the solitary corals with
dissepiments, complete and domed or flat tabulae without axial
structures are prominent, which are commonly called the
&#34;Carboniferous type&#34;. But the occurrence of the massive rugose
coral genus Nephelophyllum reveals an evolutionary trend from typical
Carboniferous to Permian form. This assemblage is associated with the
fusulinids Montiparus and Triticites. 2. Anfractophyllum-Kepingophyllum
Assemblage. The first appearance of Kepingophyllum marks the beginning
of this zone. It is sensibly different from the underlying
```

```
Nephelophyllum Assemblage in the emergence of a great number of new
types, such as the advanced Kepingophyllidae, which possess massive
compound, tertiary septa, brambly [?] or septal thecae, more or less
cystose dissepiments, clinotabulae, inclining tabulae towards the
centre, and complex axial structure. The significant elements include
Kepingophyllum simplex Wu et Chow, K. ninghuaense sp.nov.,
Monsteraphyllum yunnanense Wu et Kong, Anfractophyllum fujianense
sp.nov., Ivanovia? elegans sp.nov., Paraantheria multiseptata gen. et
sp.nov., Pseudobothrophyllum fujianense gen. et sp.nov.,
Pseudocarniaphyllum sp., Chuanshanophyllum sp., among which
Anfractophyllum appeared in the upper part of this assemblage.
Therefore, this assemblage can be subdivided into two parts, i.e. the
Kepingophyllum Subassemblage below and the Anfractophyllum
Subassemblage above. The fusulinids in the assemblage are
Pseudoschwagerina, Sphaeroschwagerina, etc. 3. Wentzellophyllum volzi
Assemblage. The first appearance of the zonal species is regarded as
the beginning of this zone, which is coincident with the lower limit of
the Gaodian Stage. The principal elements are Wentzellophyllum volzi
(Yabe et Hayasaka), Yatsengia asiatica Huang, Pseudohuangia tsengi
(Zhao et Chen), etc. mainly the massive and fasciculate compound
corals, in addition to some small non-dissepimented solitary corals and
the tabulate Protomichelinia. [abridged abstract]^1";

figs, 36 tabs, 73 pls; Hunan Science &#038; Technology Press.-
<b>FC&#038;P 33-1</b>, p. 50, ID=7207^<b>Topic(s): </b>biogeography;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Permian; <b>Geography: </b>China, Tibet^This
monograph includes the following 8 parts (besides the introduction):
(1) stratigraphical regionalization and description of section (2) the
sequences and assemblage zones of the Rugose corals (3) characteristics
and distinction of Rugose Corals in the Palaeotethyan Neritic facies,
Slope facies and Gondwanan facies (4) composition of carbon and oxygen
isotopes of corals skeleton in Palaeotethyan neritic, Slope, and
Gondwanan facies (5) biogeographical Regions of the rugose corals. *
According to the characters of assemblage and distribution of the much
rugose corals in Late Palaeozoic, the authors have divided into the
China biogeographical Region of the Boreal Realm, the Palaethethysan
Realm and the Gondwanan Realm in China. (a) The China Region of the
Boreal biogeographical Realm; The rugose corals dominated North America
in type, most of them are solitary corals of no dissepiments. (b) The
China Region of the Palaeotethysan biogeographical Realm; It occupied
the richly solitary and compound corals, with dissepiments, and some
reef building corals appear usually in this Realm. (c) The China Region
of the Gondwanan biogeographical Realm; The rugose corals are small
solitary, their dissepiments absent. But during the Late Middle Permian
(Maokouan age), the Indian Plate gradually shifted northwards into the
Palaeotethysan Realm where sediments were received, when the rugose
coral fauna, adapted to the warm water environment, is predominated by
```

```
the Suborder Wentelellina. (6) The affinities of some rugose corals.
The authors have made a systematic research on the affinity of some
rugose coral genera and have solved the problems of their origin, the
evolution and the interrelationship of some rugose corals genera,
revising their taxonomic position. (7) Restatement on the
classification of Wentelellina (8) Description of corals. The monograph
describes totally 38 family (3 new family), 149 genera (12 new genera
and 3 new subgenera), 338 species [64 new species and 2 subspecies (1
new)] and 6 non-determinable species. Among of them, 12 [new?] genera,
including 2 new genera are the small solitary without dissepiments
being adapted to the cold-water environment by the sea of the north
margin of the Gondwanaland, and 5 genera, including 1 new genus, belong
to the slope facies of the Palaeotethys. The 73 plates of fossils and
53 text-figures show the affinity and the characters of growth in
various stages of some genera and species. [part of original
introduction]^1";

</b>diversity, extinctions; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Permian; <b>Geography: </b>China^Coral
diversity and extinction patterns in the Permian of China are revealed
through stastistical analyses of 56 coral families, 263 genera and 2100
species from five consecutive time intervals. The highest coral
diversity in the Chuanshanian, with 753 species, 167 genera and 39
families. In contrast, the lowest diversity is in the Changsibgian.
With only 68 species, 20 genera and 10 families. Two decreases in
diversity can be recognized during the Permian. The first occurred at
the end of the Maokouan (end-Guadalupian) and is marked by the loss of
75,6% of coral families, 77,8% of coral genera and 82,2% of coral
species. The second major diversity drop took place at the end of the
Changsingian, when all rugose and tabulate corals became extinct. The
extinction at the end of the Guadalupian in Pangea may be related to
the middle Permian global regression of the Omeishan basalt. A
triple-zoned palaeobiogeographical pattern is well preserved by coral
diversity.^1";
s[3140] = "WANG XIANGDONG, SUGIYAMA T. (2002).- Permian coral faunas of
the eastern Cimmerian Continent and their biogeographical
implications.- Journal of Asian Earth Sciences 20: 589-597.-
<b>FC&#038;P 32-2</b>, p. 63, ID=1398^<b>Topic(s): </b>biogeography;
corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>Cimmeria E^Because of a depositional
hiatus, Late Carboniferous corals are unkown from the eastern Cimmerian
Continent. Early Permian (Asselian to Artinskian) corals are
characterized by non-dissepimented solitary forms, and the absence of
Kepingophyllidae and Waagenophyllidae, forms common in the Cathaysian
biotic province. Roadian faunas in most areas of the eastern Cimmerian
Continent are dominated by small solitary corals. These faunas are
quite different from those of the Cathaysian area, where abundant large
```

```
solitary and compound corals occur. By the Wordian, into the
Capitanian, large solitary and massive Waagenophyllidae, with a
Cathasian aspect, were well developed and widespread in the Cimmerian
Continent. However, some endemic taxa, like Thomasiphyllum, also occur.
Late Permian corals consist only of Cathyasian elements. Therefore,
paleobiogeographically, the coral faunas in the eastern Cimmerian
Continent reveal the following changes: 1) a Peri-Gondwana affinity
during the Early Permian to early Middle Permian, (2) an endemic
Cimmerian-Cathaysian affinity during the Late Middle Permian, and (3) a
true Cathaysian fauna during the Late Permian. These changes may be
related to the rifting of the Cimmerian Continent from Gondwana in the
Late Early Permian and its subsequent northward drift.^1";

preliminary study of plate-shaped hydrozoans from Upper Permian reefs
in Huaying Mountains, Sichuan, China.- Acta Palaeontologica Sinica 33,
1: 106-117.- <b>FC&#038;P 23-2.1</b>, p. 53, ID=4397^<b>Topic(s):
</b>reefs; Hydrozoa, reefs; <b>Systematics: </b>Cnidaria; Hydrozoa;
<b>Stratigraphy: </b>Permian Chang; <b>Geography: </b>China,
Sichuan^Since 1983, numerous Upper Permian reefs have been discovered
in the Huaying Mountains, Central Sichuan, which are similar in
textures, structures and developing process, with such main
reef-building organisms as calcareous sponges, hydrozoans and
bryozoans, and encrusting organisms such as Archaeolithoporella and
Tubiphytes. Associated in great amounts with the reef building
organisms are reef dwelling organisms, such as brachiopods,
foraminifers, gastropods, crinoids, ostrocods and various calcareous
algae. In sedimentological and palaeontological characteristics of
these reefs, the Upper Permian reefs developed in central Sichuan
represent the typical organic reefs in South China. All of these reefs
occurred in the Upper Permian Changhsing Formation which is overlain by
the Lower Triassic Feixianguan Formation. The tops of the reefs are
covered with tidal flat deposits attaining about 1-7 m in thickness and
made up of micritic dolomites accompanied by some evaporitic remnants
in which specialized ostracods and stromatolites can be found. It is
not very clear whether the tidal flat deposits belong to Triassic or to
Permian. The decline of the Permian reefs corresponds to the mass
extinction of various Permian organisms across the Permo-Triassic
boundary, and therefore the reefs in this area can be regarded as the
latest Palaeozoic reefs in the world. Here described are abundant
&#034;plate-shaped hydrozoans&#034; found in these reefs over the past
several years, with two new genera and three new species which are
placed in the family Palaeoaplysilidae Chuvashov 1973 and included
tentatively in the class Hydrozoa. [original summary] The following new
taxa are described: Pseudopalaeoplysina huayingensis sp.nov.,
Phragmorpha asiatica gen. et sp.nov., Cnidopora tuberculosa gen. et
sp.nov.^1";

Cnidaria; Hydrozoa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>China^Of late years, a number of fossil sponges have been obtained
from different localities in the provinces of Sichuan, Guizhou and
Jiangsu. Among them the Permian calcareous sponges preponderate in
number over others. Some of them described in this paper include six
genera and seven species. They are as follows: Sollasia aff. ostiolata
Steinmann (Batang, Sichuan), Waagenella muliensis sp.nov., Cystauletes
ribuzuoensis sp.nov., Coelociadia cf. spinosa (Muli, Sichuan),
Cryptocolia sp. (Mianning, Sichuan), Heliospongia sp. (Wuxian, Jiangsu)
and Heliospongia? houchangensis sp.nov. (Ziyun, Guizhou). * These forms
belong to the classes Calcispongea and Demospongea respectively. They
are collected from the Maokou Formation (P12) Southwest China except
Sollasia aff. ostiolata Steinmann from the Bingfeng Formation (P12),
and they may be compared with those from Carboniferous-Permian strata
of the Tethysian area of Eurasia. * Here a fragment of hydroid
collected from the Late Triassic Jieza Formation in Ylishu of Qunghai
is also described. This form belongs to the order Sphaeactinoida and is
designated under the name Ellipsactinia qinghaiensis sp.nov. [original
summary]^1";

(Rugose coral) from the Chihsia Formation of Lower Permian, Southern
Anhui.- Acta Palaeontologica Sinica 22, 5: 510-516.- <b>FC&#038;P
13-1</b>, p. 31, ID=0438^<b>Topic(s): </b>; Rugosa, Chusenophyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian L;
<b>Geography: </b>China, Anhui^The Lower Permian Chihsia Formation is
well-developed in southern Anhui. In the upper part of the formation a
considerable number of Chusenophullum occurred which may be regarded as
a guide fossil since it is confined to a certain horizon.
Chusenophyllum is characterized morphologically by the entire vanishing
of thecae, while Polythecalis is characterized by a partly vanishing of
thecae and Wentzellophyllum by well-developed thecae. It seems that
Polythecalis has evolved from Wentzellophyllum, and Chusenophyllum from
Polythecalis through a gradual vanishing of the thecae. According to
the lithological characters and the coral assemblage, the Chihsia
Formation in southern Anhui may be divided into two zones and two
subzones: 2. Polythecalis zone a. Chusenophyllum subzone b.
Polythecalis yangzeensis subzone 1. Wentzellophyllum volzi zone. In
addition eight new species of Chusenophyllum are described and
illustrated: Ch. chaoxianense, multiseptatum, anhuiense,
pingdingshanense, chaohuense, guichiense, intermedium and annulatum.

Intraspecific variation in Kepingophyllum aksuense Wu et Zhou from the
Lower Permian of Kelping, Xinjiang, Northwest China.- Acta
Palaeontologica Sinica 43, 4: 579-585.- <b>FC&#038;P 33-2</b>, p. 24,
ID=1136^<b>Topic(s): </b>variation, numerical analysis; Rugosa,
Kepingophyllidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Permian L; <b>Geography: </b>China, Xinjiang^After
a detailed observation in a large number of thin sections of
Kepingophyllum aksuense from Lower Permian of Kelping area, Xinjiang,
we found that there are strong variations in corallites of colony. The
characters exhibiting high variability include: shape of corallites,
width ratio of tabularium to dissepimentarium, septal length, shape of
tabulae, the number of septa, and the ratio of septal number to
diameter. The shape of corallites is greatly different in transverse
section. The [corallites] are commonly hexagon and some pentagon, and
even triangle. The statistical analysis shows the ratio of tabularium
to dissepimentarium has a random distribution. This abnormal
distribution may be caused by unstable development of lonsdaleoid
dissepimentariums. Major and minor septa are measured in the length and
indicate a good linable relation between them. In longitudinal
sections, shapes of tabulae can be differentiated into three kinds: the
concave complete tabulae, incomplete tabulae, and clinotabulae. About
200 corallites are measured in number of septa to show a distribution
pattern that the number 14-16 takes the majority. Eighty corallites are
measured for theratio of septal number to diameter. The distribution
pattern shows that data points are surprisingly scattered away from the
curve and the R value is only 0.3923. In addition, in longitudinal
section there exists a periodic increase that probably shows a kind of
seasonal variation, represented by alternative arrangement of large and
small vesicular dissepiments. The comparison between the present and
type specimens indicates a less difference in variability.^1";

Permian rugose coral faunas of Inner Mongolia-Northeast China and
Japan: Paleobiogeographical implications.- Journal of Asian Earth
Sciences 26: 369-379.- <b>FC&#038;P 34</b>, p. 39, ID=1243^<b>Topic(s):
</b>biogeography; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>China, Japan^The faunal
characteristics, successions and geographical distribution of the
Permian rugose corals in Inner Mongolia-Northeast China and Japan are
reviewed using current coral taxonomy and the recently revised Permian
global time scale. The co-occurrences of Cathaysian compound corals,
abundant non-dissepimented solitary corals, and endemic corals indicate
```

```
that Inner Mongolia and Northeast Chinare present an independent
biogeographical entity, quite separate from South China and the
Japanese terranes. However, the common occurrence in South China of
Permian taxa such as Wentzellophyllum, Lonsdaleiastraea, Yatsengia,
Ipciphyllum, and Waagenophyllum indicates, in a broad sense, a Tethyan
affinity for the Akiyoshi and Mino terranes in Japan. Rocks from the
Asselian to the Artinskian in the South Kitakami Terrane of Japan
contain eleven large dissepimented solitary and compound genera,
including Huangia, Iranophyllum, Laophyllum, Polythecalis,
Sestrophyllum, Wentzelella, Wentzellophyllum and Yatsengia. These
genera are all typical of, and common in, South China, but are absent
from coeval strata in Northeast China. Middle Permian rocks in the
South Kitakami Terrane also contain rugose corals that are abundant in
South China, in some cases the same species, such as Parawentzelella
regularis, Waagenophyllum indicum, Waagenophyllum virgalense and
Yatsengia kiangsuensis. Thus, the coral faunas from the South Kitakami
Terrane indicate a close paleobiogeographical affinity with those from
South China, which is consistent with the paleobiogeography based on
ammonoids and bivalves.^1";
s[3159] = "WANG XIANGDONG, SUGIYAMA T. (2001).- Middle Permian rugose
corals from Laibin, Guangxi, South China.- Journal of Paleontology 75,
4: 758-782.- <b>FC&#038;P 30-2</b>, p. 24, ID=1397^<b>Topic(s): </b>;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Permian M; <b>Geography: </b>China, Guangxi^The Middle Permian
Chihsia and Maokou formations in Labin, central Guangxi, South China
contain 19 rugose coral species; of these taxa, Lophocarinophyllum
sandoi, Asserculinia solida, and Innixiphyllum wuae are new.
Innixiphyllum represents a new genus characterized by contratingent
minor septa. Ten species are reviewed and described in detail, and the
diagnoses of three of these species, Allotropiophyllum heteroseptatum
(Grabau 1928), Lophocarinophyllum taihuense (Yan &#038; Chen 1982), and
Ipciphyllum regulare (Wu 1963), are emended. The morphological
variation and ontogenetic changes of the solitary, nondissepimented
species are particularly emphasized. Six additional taxa are described
and illustrated but are left in open nomenclature. The corals from
Labin are typically Tethyan. Four biostratigraphic assemblages are
recognized: an assemblage of massive corals in the Upper Chihsia
Formation represented by Polythecalis longliensis; an assemblage of
small solitary and nondissepimented corals in the lower Maokou
Formation, dominated by species of Allotropiophyllum, Innixiphyllum and
Lophocarinophyllum; an assemblage of mixed massive colonial and small
solitary corals in the middle Maokou Formation, characterized by
Ipciphyllum regulare; and an assemblage of solitary nondissepimented
corals in the uppermost Maokou Formation, characterized by Ufimia
elongata. These assemblages correspond well to those from other areas
of South China. In Labin, only two rugose taxa, Amphicarinia sp. and
Paracaninia minor, occur in the basal part of the Wuchiaping Formation
of Lopingian age.^1";

Guangxi^The Asselian corals described in this paper were collected in
1984 by Zhou Zuren and others during their investigation of the
Carboniferous-Permian boundary in Nandan County, the Zhuang Autonomous
Region of Guanxi. Those identified here as Notophyllum liuzhaiense gen.
et sp.nov., Liuzhaiphyllum intermedium gen. et sp.nov. Thomasiphyllum?
sp. and Bayhaium nandanense sp.nov. were found in association with the
Asselian ammonoids and fusulinids. All of these fossils occur in the
carbonate blocks of the debris flow, which derived probably from the
foreslope of the Carbonate platform, 6 m in thickness at the quarry,
1.2 km southwest of the Liuzhai Town. In 1982, the author defined two
paleogeographical regions of corals in the Sakmarian all over the
world, the Durhaminidae region which is distributed in North America,
Soviet Union and Spitsbergen and the Kepingophyllidae region which is
limited within the Tethys only. Since no typical elements of the
Kepingophyllidae have been found in the present coral fauna so far, it
is difficult to define the exact age of the described corals. Of
interest is the discovery of the specimens of the genus Bayhaium which
was proposed in 1959 by Langenheim et McCutcheon. Since then, about
five species of the genus have been described by different authors,
including the American species found in the Wolfcampanian of California
(Langenheim et McCutcheon 1959; Wilson 1982), and two other species
which also have been identified by Ding et Yu in 1983 from the lower
part of the Permian in southern Shaanxi, China. These seem to indicate
that the age of the present coral fauna could be recognized as the
earliest Permian. However, the presence of the associated Asselian
ammonoids is something noticeable which can be taken as an evidence to
put them in the Asselian age [part of original summary].^1";

<b>Stratigraphy: </b>Permian L; <b>Geography: </b>China, Guizhou,
Hunan^The ecological-environment differentiation of the Early Permian
rugose corals in Southern Guizhou and Central Hunan is very obvious.
According to quantitative analysis of the rugose corals of different
facies in some major stages of the Early Permian, the
ecological-environment differentiation of these corals is discussed as
the following: (1) In turbulent shallow marine on platform margin,
massive compound rugose corals dominated. (2) In tranquil shallow
marine on platform margin, solitary rugose corals of trizone type,
aphroid and thamnasterioid compound corals dominated, but massive
compound corals decreased. In this environment, the diversity of rugose
corals is the largest. The elements of these corals usually occurred in
this environment. (3) In basin sedimentary area, only non-dissepimented
rugose corals occurred. These studies will provide some important
paleontological evidences for the sedimentology and paleogeography of
future.^1";

<b>Geography: </b>China, Shaanxi^Microskeletal structures of the Late
Permian rugose corals of Zhengan, Southern Shaanxi, investigated by SEM
and optical microscope, are revealed as follows: 1. Their septal
structures may be divided into two types: a trabeculate type and a
non-trabeculate type; with two types of septal thickening, one formed
by the clustered arrangement of minor trabeculae; the other by thick
trabeculae with carinae on both sides of septa completely constituted
by fascicles, not extending as part of the trabeculae. 2. The walls of
both solitary and fasciculate compound corals are composed of parallel
needles or brachycolumns. Two types of intercorallite walls exist in
the massive corals, in one type, an obvious dark-line formed by
irregular granules or needles present in the central part of the
intercorallite wall. The other form is composed of densely interlocked
trabeculae of septal outer ends from neighbouring corallites. 3.
Lateral structures and columellar walls of the corals consist of
parallel needles or brachycolumns.^1";

Permian coral reef and colonial rugose corals in Northwest Hunan, South
China.- Facies 39, 1: 35-65.- <b>FC&#038;P 27-2</b>, p. 52,
ID=3946^<b>Topic(s): </b>coral reefs; coral reef; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian U; <b>Geography:
</b>China, Hunan^The roles of Permian colonial corals in forming
organic reefs have not been adequately assessed, although they are
common fossils in the Permian strata. It is now known that colonial
corals were important contributors to reef framework during the middle
and -late Permian such as those in South China, northeast Japan, Oman
and Thailand. A coral reef occurs in Kanjia-ping, Cili County, Hunan,
South China. It is formed by erect and unscathed colonie of
Waagenophyllum growing on top of one another in situ to form a baffle
and framework. Palaeontological data of the Cili coral reef indicates a
middle to late Changhsing age (Late Permian), corresponding to the
Palaeofusulina zone. The coral reef exposure extends along the inner
platform margin striking in E-S direction for nearly 4 km laterally and
generally 35 to 57 m thick. The Cili coral reef exhibits a lateral
differentiation into three main reef facies; reef core facies,
fore-reef facies, and marginal slope facies. The major reef-core facies
is well exposed in Shenxian-wan and Guanyin-an sections where it rests
on the marginal slope facies. Colonial corals are dispersed and
preserved in non-living position w eastward. Sponges become major
stabilizing organisms in the eastern part of Changhsing limestone
outcrop in Kanjia-ping, but no real sponge reefs were formed. Coral
reefs at Cili County in Hunan are different distinctly from calcisponge
reefs in South China in their palaeogeography, lithofacies development,
organic constituents, palaeoecology and diagenesis. The Cili coral reef
also shows differences in age, depositional facies association, reef
organisms and diageneisis from coral reefs in South Kitakami of Japan,
Horat Plateau of Thailand, and Saih Hatat of Oman. Although some sponge
reefs and mounds can reach up to the unconformable Permian/Triassic
boundary, coral reef at Kanjia-ping, Cili County, is the latest Permian
reef known. This reef appears to had been formed in a palaeoenvironment
that is different from that of the sponge reefs and provides an example
of new and unique Permian reef type in South China, and could helps us
to: 1) understand the significance of colonial corals in Permian
carbonate buildups; 2) evaluate the importance of coral community
evolution prior to the collapse of reef ecosystems at the
Permian/Triassic boundary; 3) better understand the effects of the
biotic extinction events in Palaeotethys realm; 4) look for
environmental factors that may have controlled reefs through time and
```

```
space, and 5) provide valuable data for the study of Permian
palaeoclimate and global evolutionary changes of Permian reefs and reef
community.^1";
s[3174] = "EZAKI Y. (1994).- Patterns and palaeoenvironmental
implications of end-Permian extinction of Rugosa in South China.-
Palaeogeography, Palaeoclimatology, Palaeoecology 107: 165-177.-
<b>FC&#038;P 23-1.1</b>, p. 59, ID=4126^<b>Topic(s): </b>extinctions
P/T; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Permian U; <b>Geography: </b>China S^Late Permian rugose corals are
undoubtedly the last phylogenetic representatives of the Rugosa. These
corals are widely, though sporadically, distributed, notably in South
China. The Late Permian corals of South China decrease markedly in
diversity and are represented by surviving genera from the Maokouan,
showing common patterns of disappearance, morphologically and
phylogenetically. Colonial Wentzelellinae mostly disappeared by the end
of the Maokouan, followed by solitary Wentzelellinae and later
Waagenophyllinae having simple morpholgies. Non-dissepimented solitary
corals and fasciculate Waagenophyllinae, though morphologically simple,
are common during the Late Permian, ranging up to the latest Permian.
Permian Rugosa apparently show two terminal patterns, suggesting
environmental differences. One pattern is terminated with a progressive
reduction, leaving only non-dissepimented solitary corals as survivors,
and the other pattern is distinguished by the disappearance of the
platform-dwelling colonial corals at the end of Permian. The general
trend, characterized by later disappearance of the simpler corals,
reflects progressively adverse changes in the marine environment. The
persistence and disappearance of a latest Permian Waagenophyllum fauna
suggests that the regional continuation of favorable environments
followed by the onset abrupt and severe, though tempoary, enviromental
changes for coral growth. The causes of rugosan extinction are not
necessarily attributed to factors characteristic of the latest Permian
time, and the extinction was individually stepwise, each different
disappearance event correlating with, and possibly caused by variable
factors, such as sea-level fluctuations and volcanic activity. Multiple
interactions of individual factors on a local and global scale affected
each faunal component, resulting in selection of corals that culminates
in the regional, and finally global, disappearance of Rugosa.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>China S^Scleractinian corals are the
most important constituents of modern coralgal reefs. For many years,
it as thought that they first appeared in the Middle Triassic and
subsequently underwent explosive radiation. However, abundant
scleractinian-like corals within ancestral morphological traits have
recently been recovered from the Middle Permian sponge reefs in China,
which not only confirms a role in Permian reef ecology but also
suggests a possible Palaeozoic origin for the group. Two species of a
new Permian scleractiniamorph genus from China are described herein as
Houchangocyathus wangi gen. et sp.nov. and Houchangocyathus yaoi gen.
et sp.nov. Putative Palaeozoic Scleractinia may have evolved over a
substantial time interval and diverged into stem lineages by the end of
the Permian. These forms evolved within both the rigid framework of
their basic body plan and the morphological constraints characteristic
of each lineage. The Middle Permian development of calcisponges reefs
was closely related to habitat expansion, which would have provided an
ideal dwelling for scleractinian-like corals and enhanced their chances
of fossilization. Such scleractiniamorphs disappeared at the
end-Permian extinction, but may have survived as progenitors of
Triassic Scleractinia.^1";

Tabulata; <b>Stratigraphy: </b>Permian; <b>Geography: </b>China^The
present article deals with the following contents: (1) For the Lower
Permian Tabulata two distinct zoogeographical provinces in China - the
South China and North China provinces are recognized. In the South
China province, the tabulate coral fauna comprises Tetraporinus,
Thamnopora, Sinopora, Protomichelinia Michelinia, Cystomichelinia and
abundant Hayasakaia. This tabulate coral fauna marks an independent
zoogeographical province. In the North China province, Tabulata are
few, lacking the typical South China genera Hayasakaia and
Cystomichelinia. (2) In the Lower Permian two major tabulate zones and
three tabulate subzones are establised in descending order as follows:
Maokou Limestone 2. Zone of Protomichelinia multitabulata Yabe et
Hayasaka. Chihsia Limestone 1. Zone of Hayasakaia (3) Subzone of
```

```
Protomichelinia microstoma (Yabe et Hayasaka)-Protomichelinia siyangensis (Reed) (2) Subzone of Hayasakaia elegantula (Yabe et Hayasaka)-Tetraporinus nankingensis (Yoh) (1) Subzone of Hayasakaia syringoporoides (Yoh).^1";

S^Inozoans are described from patch reefs on the carbonate platform of
eastern Sichuan, from the uppermost Permian Laolongdong reefs in the
Changxing Formation (Kazanian-Tatarian) at Beipei, northwest of
Chongqing, and from the Middle to Uppper Permian reefs from the Maokou
(Kungurian), Wujiaping (Ufimian), and Changxing Formation at Xiangbo,
Longlin County, in northwestern Guangxi. Classification of inozoans,
particularly late Paleozoic ones, is still in a state of flux, but
genera recognized to date can be keyed using the general nature of the
spongocoel, canals, and growth form. New genera described are
Intratubospongia, Grossotubenella, Cavusonella, and Radicanalospongia.
The new species described are Stellispongia radiata, S. minor,
Peronidella beipeiensis, P. regulara, P. parva, Intratubospongia
typica, I. tenuiperforata, I. multisiphonata, I. minima,
Grossotubenella parallela, Cavusonella cavema, and Radicanalospongia
normala. A Corynella that is not identifiable to species and a
sphinctozoan-like inozoan (?) sp. A that has a fibrous-appearing
internal skeleton but is poorly preserved are also described. Inozoans
and other sponges are major frame-builders in the Permian reefs of
South China and our fauna is one of the most diverse late Paleozoic
assemblages described to date.^1";
s[3202] = "YANG Z.-Y., LIU Z.-H. (2003).- Inozoan, Major Reef
frame-building organisms in Late Permian, Hunan. [in Chinese, with
English abstract].- Oil &#038; Gas Geology 24, 1: 70-74.- <b>FC&#038;P
33-1</b>, p. 104, ID=7247^<b>Topic(s): </b>reef sponges; Porifera
Inozoa; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Permian U;
<b>Geography: </b>China, Hunan^The late Permian reefs are distributed
in Chengxian, Guiyang and Chenxi Counties in southern Hunan province.
Reefs in Bangxian and Guiyang are patch reefs developed along Chengru
shallow sea. Reefs in Chenxi are bioherms, undeveloped patch reefs. The
reefs in both sites occur in the late Permian Changxing Formation. A
lot of samples of fossils and rocks have been collected while surveying
8 reef composite sections in southern Hunan. We find that the most
important frame-building organisms are calcisponges, just as other
Permian reefs in southern China. By systematically researching
Inozoans, one of the important frame-building calcisponges, it is
thought that the water system and fibres might be important evidence in
classification. Twelve species and 8 genera of Inozoans including one
new species, one comparative species and one undefined species are
found, and some species are newly classified. [original abstract]^1";

lithological characters and faunas of three Gondwana-related
```

```
regions,namely the Baoshan area of West Yunnan, western and southern
Thailand, and southern SydneyBasin, is here introduced. During Asselian
and Sakmarian time, these three regions are very similar14not only in
lithology that is characterized by marine glacio-origin diamictites but
also in faunas thatare mainly composed of cold water brachiopods and
small nondissepimental corals. Started fromArtinskian, differences on
lithology and faunal characters occur among these three regions.
Warmwater faunas such as fusulinid Pseudofusulina and conodont
Sweetognathus, and carbonatedeposition are present in the Baoshan area
during the Artinskian. A warm water fusulinidMonodiexodina fauna occurs
in Western Thailand during the Kungurian. These two regionspossibly
located in relatively northern area comparing to the Sydney Basin due
to rifting fromGondwanaland and drafting northward closing to the
Tethyan continent. And more later time,during the Roadian to Capitanian
or even Wuchiapingian, particular Cimmerian mixed fauna andcomplete
carbonate sequence dominated in the Baoshan block and western and
southern Thailand.In the contrast, southern Sydney Basin continued to
be characterized by siliciclastics and cold-waterbrachiopods, bivalves,
and small nondissepimental corals during the Middle Permian.^1";
s[3206] = "YANG WANRONG, LI XU (1995).- Permian reef types and
controlling factors of reef formation in South China.- Acta
Palaeontologica Sinica 34, 1: 67-75.- <b>FC&#038;P 25-1</b>, p. 35,
ID=3019^<b>Topic(s): </b>reefs, typology, ecology; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>China S^In South China, the Permian is a period of maximal marine
transgression in Late Paleozoic and the best reef-formation since
Middle Devonian. There are two major Permian reef-formation cycles, the
Maokouan and the Changhsingian. In the Changhsingian, reefs are better
developed and common in occurrence, mainly occurring in Guizhou,
Guangxi, eastern Sichuan, Hunan, western Hubei and the Lower Yangtze
Region. Based on the reef-forming origin, composition and texture,
abundance of reef-forming organisms and reef rock types, with reference
to the classification of Dunham (1962), the Permian reef in South China
are of the premagmatic origin and may be divided into 4 types: (1)
Organic reefs; (2) Bioherms; (3) Lime-mud mounds; and (4) Stratigraphic
reefs. The Changhsingian reefs in Cili of Hunan are the largest Permian
organic reefs in China, which are entirely built of corals
(Waagenophyllum) and preserved with original growing conditions in situ
(ecological reef), with clumpy branching corals closely woven together.
There are many types of Permian reefs developed in South China. Their
growth, development and disappearance were controlled not only by
internal biological factors, but also by external factors such as
tectogenesis (especially fault-block movement), paleogeography,
paleoenvironments, transgression-regression and eustatic changes. The
bioherms and stratigraphic reefs formed on platforms are especially
sensitive to sea-level changes. Since the reef growing rate is
sometimes in accordance and sometimes in discordance with the rise of
sea-level, the vertical distribution of reefs shows multicyclic and
rhythmic characteristics in stratigraphic sequence.^1";

<b>Stratigraphy: </b>Permian; <b>Geography: </b>China, Yunnan^Recent
progress in the study of Permian stratigraphy in western Yunnan,
southwest China, is reviewed with particular references to the
Tengchong and Baoshan blocks and the Changning-Menglian Belt. Where
confusion or controversy exists in stratigraphical nomenclature and/or
dating, we attempt to clarify the situation based on our recent field
observations and newly obtained research results. The Perrnina within
the Changning-Menglian Belt embraces different stratigraphie
successions, suggesting different tectonic settings, ranging from
passive margin and active margin, to oceanic basin and seamounts.
Permo-Carboniferous faunas in the carbonate sequences of the
Changning-Menglian Belt are of typical Cathaysian affinity, as
demonstrated by abundant fusulinaceans and compound rugose corals. The
Permian stratigraphy and faunas of the Tengchong and Baoshan blocks are
markedly different from those of the Changning-Menglian Belt. The
Baoshan Block lacks Upper Carboniferous deposits, and its subsequent
Lower Permian sequence consists predominantly of siliciclastic strata
yielding cool-water faunas and possibly glaciogenic diamictites,
overlain by thick balsaltic lava and volcaniclastics of probably rift
origin. The upper part of the Permian in the Baoshan Block is
characterized by carbonates containing mixed Cathaysian and Gondwana
faunas. The Tengchong Block has a similar evolutionary history to the
Baoshan Block, but completely lacks volcanic rocks. [original
abstract]^1";

```

```
<b>Geography: </b>China, Hunan^Various fossil communities on different places indicated a shallow marine with various depositonal environments developed in Hunan during the Qixia Period of Middle Permian. The Stigmaria and Skolithos communities indicated the environments of seamarsh (or littoral depression) and supratidal respectively. The Pycnostroma community meant a very shallow turbulent environment, including the intertidal zone and very shallow subtidal zone. The Orthotetina community was characteristic of the nearshore subtidal environment with soft-mud substratum. The Lophophyllidium community occupied the underturbulent subtidal environment, suffered occasionally by storm turbulence; and the Wentzellophyllum community showed the clear subturbulent subtidal environment, where compound rugose corals were broken and overthrown frequently by storms. The trace-fossil Zoophycos community developed in a clear and relatively turbulent subtidal environment, which was very suitable for flourishing of benthic organisms. * In the Sangzhi-Shimen, Chenxi-Huaihua and Dongkou-Xinhua areas, the Stigmaria community developed well at the beginning of Qixia Period, indicating environments of seamarsh or littoral depression. Then the Orthotetina and Zoophycos communities dominated, meaning a relatively restricted sea near the old land. In Liangyuan-Liuyang, the Skolithos and Pycnostroma communities at the beginning of Qixia Peroid proved a wide tidal flat zone or very shallow subtidal zone. In Shaoyang-Leiyang, the Skolithos and Pycnostroma communities were never found, the Lophophyllidium and Zoophycos communities supported an evidence of the area far away from the old land and the environements being more restricted. * Based on distributions of the various communities, five paleogeographic units could be divided in Qixia Peroid; the Sangzhi-Shimen littoral-shallow sea, Chenxi-Huaihua littoral-shallow sea, Dongkou-Xinhua littoral-shallow sea, Lianyuan-Liuyang open shallow sea and Shaoyang-Leiyang restricted shallow sea. The reefs of Qixia Period, composed of the sponges of Pronidella community and firstly discovered from Shuangshouting to Xiandong of Lianyuan, Central Hunan, was located on the margin of the Lianyuan-Liuyang open shallow sea. [original abstract]^1";
s[3215] = "WU Y.-S., FAN J.-S., JIN Y.-G. (2003).- Emergence of the Late Permian Changhsingian reefs at the end of the Permian. [in Chinese, with English abstract].- Acta Geologica Sinica 77, 3: 289-296.- <b>FC&#038;P 33-1</b>, p. 103, ID=7246^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian Chang; <b>Geography: </b>China, Guizhou^Dolostones occur on the top of the reef core, reef front and back reef sequences of the Upper Permian. The Changhsingian reef in Ziyun County, Guizhou Province, southwestern China. Comprehensive study on them reveals that these dolostones are of the supratidal sabkha genesis: (1) all have &#948;18O values higher than those of their precursor limestones, (2) all have Sr and Fe contents similar to those of know typical supratidal sabkha evaporative finely crystalline dolostones from a well in the Ordos Basin, Shaanxi-Gansu-Ningxia provinces,China, (3) all are composed of finely crystalline euhedral-subhedral dolomite, (4) all occur on the top of reef core, reef front and back reef, (5) algal laminated structure, bird-eyes, mudcracks and crustose limonite occur in the reef front and back reef. These features indicate that this reef was once emerged at the terminal Permian. The emergence of the Changhsingian reefs at the terminal Permian might be caused by sea-level drop. This inference is in agreement with the sedimentary environmental changes in China and North Italy. The Cadore Basin in North Italy changed from a mid-shelf environment to a meteoric phreatic diagenetic environment at the end of the Permian. During the Permian-Triassic transition, the water depth of the Lower Yangtze Basin changed from more than 1000m (below the carconate compensation depth) to less than 1000m (near the carbonate compensation depth). The sea-level drop indicated by evidence from not only reefs but also non-reef deposits might be one aspect of the
```

?microbialite carbonate crust at the Permian-Triassic boundary in South
China, and its palaeoenvironmental significance.- Palaeogeography,
Palaeoclimatology, Palaeoecology 146, 1-4: 1-18.- <b>FC&#038;P
27-2</b>, p. 10, ID=6918^<b>Topic(s): </b>carbonates microbial;
microbialite crusts; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian
&#47; Triassic; <b>Geography: </b>China, Sichuan^A 1m thick carbonate
crust, layered and commonly domal, caps crinoidal limestones on reef
complexes of the top Permian Changxing Formation in the Huaying
Mountains, eastern Sichuan, China. The crust&#039;s stratigraphic level
lies at a sharp change in facies, and is overlain by poorly
fossiliferous laminated micrites and shales of the Lower Triassic
Feixianguan Formation. The crust therefore appears to coincide with the
end-Permian extinction event, although the dating of the strata is
currently imprecise. The crust is composed mostly of digitate
carbonate, locally thrombolitic, with remnant lobate fabric, and
resembles microbialites, but is mostly recrystallised and a microbial
origin is unconfirmed. It is enclosed in micrite with pyrite crystals,
ostracode and other shell debris. The crust is absent from interreef
areas. Previous interpretations of karstification and calcrete
formation are not upheld, and the facies were deposited under water.
Overlying sediments are low energy, with abundant ferroan calcite and
pyrite, reflecting anoxia associated with rising sea level. Various
interpretations of the crust are possible: (1) it was organic, and
microbia grew preferentially on topographic highs of reef tops; (2)
microbia were a disaster biota in the absence of grazers; (3) microbia
took advantage of favourable conditions for calcification, associated
with a rapidly rising environmental-CO2 content during the Late
Permian; (4) the crust was an inorganic precipitate associated with
CO2-rich water. Microbial crusts are rare after the Cambrian, but
whether this crust is organic or not, its presence in these strata
reinforces the view that oceanic-atmospheric conditions in the
Permian-Triassic boundary interval were unusual. [original abstract;

hexactinellid sponge mounds from the Upper Triassic of northern Sichuan
(China).- Palaeogeography, Palaeoclimatology, Palaeoecology 76: 17-29.-
<b>FC&#038;P 19-1.1</b>, p. 63, ID=2697^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>Porifera; Hexactinellida; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>China, Sichuan^A belt of Upper
Triassic (Carnian) sponge mounds was discovered in northern Sichuan in
the transition zone between a shallow shelf sea in the SE (Chuan-Dian
Shelf) and a deeper marine trough (Ganzi-Aba Trough) in the NW.
Individual sponge mounds are up to 60 m high and 150 m wide and
interfinger laterally with dark shales. Main framebuilders of the
mounds are Lychniscosa and Lyssacinosa, accompanied by (much rare)
```

```
Hexactinosa, Lithistida, annelid worms, occasional crinoids and
Bryozoa. The reef-dwelling fauna consists of brachiopods, ostracods,
foraminifera, pelecypods, gastropods and ammonites. Typical shallow
water reef builders (scleractinian corals) and calcareous algae are
lacking or extremely rare (coralline sponges). This supports the
interpretation of the mounds as buildups in deeper water of several
tens up to one hundred meters. The sponge mounds of northern Sichuan
are thus an equivalent of similar buildups of late Jurassic age in
central and western Europe. They provide the first well-established
record of Lychniscosa in the Triassic and their first reported
pre-Tertiary occurrence outside of Europe.^1";

Furcophyllia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Triassic M; <b>Geography: </b>Tajikistan,
Pamirs^Furcophyllia is an unusual coral with septa regularly splitting
into branching sets called septal brooms. This pattern of septal
apparatus is so alien to scleractinians, that, despite a trabecular
microstructure of septa resembling that of the Scleractinia, the genus
was originally ascribed to a rare group of corals informally referred
to as sleractiniamorphs, previously known from the Ordovician and
Permian. Genus Furcophyllia emerged together with corals of several
groups, after the post-Permian crisis diversification of skeletonized
anthozoans, some of them markedly differing in their skeletal features
from typical Scleractinia. So far, the genus was represented by middle
Carnian Furcophyllia septafindens from the Dolomites, in the Southern
Alps. Here, we report Furcophyllia shaitanica sp.nov. from limestone
boulders found in the volcano-clastic deposits of the upper Ladinian
Shajtan suite of the South Eastern Pamirs. A new species of
Furcophyllia signifies that the genus was a faunal element widely
distributed in the Tethys.^1";

<b>Stratigraphy: </b>Triassic M; <b>Geography: </b>China SW^From the
lower Upper Anisian (Middle Triassic) of Bangtoupo in the vicinity of
Qingyan, Guizhou Province, SW-China, three sponge taxa are described.
Two taxa of large lyssacinosan sponges, Hexactinoderma? cf. roemeri
(Rauff 1937) and Lyssacinosa gen. et sp. indet. A, lived on soft
substrate. These fossil sponges are calcified, but in parts relics of
their spicules and their spicular skeleton are preserved. One specimen
of Hexactinoderma? cf. roemeri is an usual twinned sponge. Hartmanina?
bangtoupoensis n.sp., a new sclerosponge species (Demospongia), on the
other hand, was attached to (secondary) hard substrates. Its variable
growth form largely depends on the size of the substrate. In spite of
their rarity in the fossil associations preserved at Bangtoupo, sponges
had some ecological importance as substrates for the attachement of
other invertebrates. [original abstract]^1";

Scleractinia; <b>Stratigraphy: </b>Mesozoic; <b>Geography: </b>China
SW^Here are the supplemental notes on the Mesozoic corals from the Mts.
Hengduan in Southwest China. Altogether, twenty-five species and
fifteen genera of scleractinian corals (including eleven new species
and one new genus) as listed below: Pinacophyllum cf. parallelum Frech,
Sichuanophyllia sichuanensis (gen. et sp.nov.), S. sp., Pachysolenia ?
sp., Volzeia aff. badiotica Cuif, Astraeomorpha minima sp.nov.,
Distichophyllia decora sp.nov., D. cf. norica Cuif, Paradistichophyllum
delicatum sp.nov., P. cf. dichotomum Melnikova, Craspedophyllia
spinifera sp.nov., Procyclolites elongatus sp.nov., Margarophyllia
persticta sp.nov., M. aff. capitata (Muenster), M. sp., Omphalophyllia
cf gracilia (Muenster), Thamnotropis megaxis sp.nov., Beneckastraea
medialis sp.nov., B. ruida sp.nov., B. multigranulata sp.nov.,
Montlivaltia aff. deqenensis Deng &#038; Zhang, M. sp. 1, M. sp. 2,
Plesiocunnolites aff. ellipticus subcircularis (Oppenheim), P. sp.
Except the two forms of Plesiocunnolites collected from the possible
Upper Cretaceous in the Markam of eastern Xizang, all the above-stated
corals were found from the Upper Triassic deposits in western Sichuan
and northern Yunnan. In general respects they are similar to those of
the Alps and Turkey. [part of extensive summary]^1";

the genera Actinastrea, Caryophyllia, Discocyathus, Dungulia,
Epistreptophyllum, Isastrea, Microsmilia, Montlivaltia, Prothetmos,
Thamnasteria and Trochocyathus are described and particularly depicted.
Four species, Isastrea deriyingensis (? Upper Triassic), Dungulia minor
(Tithonian), Discocyathus petaliformis and D. ellipticus (both Lower
Cretaceous) are described as new. The fauna is compared to those of
Spiti and Kachchh (India) and Portugal.^1";
s[3248] = "LIAO Wei-Hua, XIA JINBAO (1993).- Mesozoic and Early
Cenozoic scleractinian corals from Tibet.- Courier Forschungsinstitut
Senckenberg 164: 205-210. [P. Oekentorp-Kuster (ed.) Proceedings of the
VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 1].-
<b>FC&#038;P 22-2</b>, p. 17, ID=3455^<b>Topic(s): </b>taxonomy;
Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Mesozoic Paleogene; <b>Geography: </b>China, Tibet^The Mesozoic and
Early Cenozoic marine strata of Tibet are very rich in scleractinian
corals. The fossil Scleractinia on which the present study is based
include 108 genera comprising 221 species, some of which are new. The
occurrences indicate strong palaeogeographical relations between the
Tibetian and the other Tethyan scleractinian corals. The Triassic
strata are widespread in Tibet, especially in the Hengduanshan Mts. and
in the Himalayas. The marine Jurassic strata of Tibet have been well
known, except for those east of the Lancang Jiang River area. The Early
Cretaceous corals have been found in the area south of the Nagqu-Ngari
highway and the area west of the Qinghai-Tibet highway. The marine
Upper Cretaceous beds are only distributed in the Himalayan Mts. of S
Tibet. The Early Tertiary (Palaeocene and Eocene) marine strata are
also restricted to the Himalayas of S Tibet. The highest marine strata
in Tibet are known to be of Middle Eocene age. It seems that in Tibet
the history of marine sedimentation came to an end during post-Eocene
time. After the Middle Eocene, the sea withdrew completely from the
Himalayas, although the tremendous uplift forming the Tibetian Plateau
did not occur until the Pliocene epoch. Based on the scleractinian
corals occurring in the stratigraphic sequence, 11 scleractinian
assemblages of Mesozoic and Early Cenozoic from Tibet are recognized.^1";
s[3249] = "YANG T.-T., WANG C.-Y. (????).- Stromatoporoids and
```

```
Hydrozoans from the Mt. Everest Area.- Nanking Inst. Geol. Paleont.,
Chinese Acad. Science.- <b>FC&#038;P 5-2</b>, p. 13,
ID=5459^<b>Topic(s): </b>taxonomy; stroms, Hydrozoa; <b>Systematics:
</b>Porifera Cnidaria; Stromatoporoidea Hydrozoa; <b>Stratigraphy:
</b>Triassic - Paleogene; <b>Geography: </b>China, Tibet, Himalaya^Four
species of stromatoporoids belonging to three genera are recognized:
Actinostromina cf. grossa (Germovsek), Actinostromaria taenia Yang and
Wang, sp.nov., A. tibetensis Yang and Wang sp.nov., Stromatoporina?
stromatoporiforma Yang and Wang sp.nov. Five species of hydrozoans
belonging to three genera are also present: Ptychochaetes cf. globosus
Koechlin, Spongiomorpha robusta Yang and Wang sp.nov., Spongiomorpha
(Heptastylopsis) cf. ramosa Frech, Bauneia irregularia Yang and Wu,
sp.nov., B. gangbaensis Yang and Wu sp.nov. Among these the geological
age of S. cf ramosa collected from Chue-Tsung-Pei Shan, Ting-Jih Hsein
is Late Triassic, B. gangbaensis from Ho Shan, Gang-Ba Hsien, Eocene;
the remainder of the fauna all from Hsi-Mu-TiHsi Shan, Ting Jih Hsien -
although mostly new species are considered by us to be Late Jurassic
because A. grossa was first described from the Upper Jurassic of
Yugoslavia and P. globosus from the Upper Jurassic of Germany. Other
areas of Late Jurassic strata along the Mediterranean coast, in the
Middle and Far East also have stromatoporoids similar to those of the
Mt Everest Area. Occurrences of the genus Spongiomorpha from several
localities show its geological range to be Late Triassic to Late
Jurassic. S. ramosa reported from the Alps and Alaska occurs in Late
Noric rocks and the specimens reported here should come from Late
Triassic or late Noric rocks. The genus Bauneia occurs commonly in
Mesozoic strata. However, B. gangbaensis from Ho Shan occurs with the
Eocene forams Orbitolites, Nummulites and Fasciolites indicating an age
range of Mesozoic to Eocene. The geographic distribution of these
fossils indicates that during Jurassic and Triassic time the Mt Everest
Sea was closely related to basins in the areas mentioned above.
Depositional environments and conditions support the presence of a
Tethys Sea. [abstract translated and abridged by C. Fong]^1";

Biostromes (coral and sponge) are tabular bodies 15-17m thick, 5-10km long in outcrop. Bioherms are lenticular or mound-like bodies composed of massive limestones and dolomites containing numerous entire fossil shells. Reef complexes are made up of a combination of bioherms and their erosion products, differing in age, visible dimensions, nature of their relations to the enclosing rocks, assemblage of reef-building organisms, and so forth. In Middle Callovian time, shallow water conditions of marine sedimentation were dominant, with weakly differentiated submarine relief. In Late Callovian time the basin became differentiated and the Karasan reef formed, the position of which marks the facies change of the Late Callovian. Change in facies of Lower Callovian rocks takes place to the south. In Late Callovian time, the zone of reef formation shifted still farther to the south.^1";
s[3263] = "LIAO Wei-Hua, XIA JINBAO (1985).- Upper Jurassic and Lower Cretaceous Scleractinia from Bangoin district of Northern Xizang (Tibet).- Memoir Nanjing Institute Geology 21: 119-174.- <b>FC&#038;P 14-2</b>, p. 33, ID=0950^<b>Topic(s): </b>; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Jurassic U, Cretaceous L; <b>Geography: </b>China, Tibet^Late Jurassic was a period of extensive reef-building, especially in the Tethys. In Xizang, there are a lot of such species as Actinastrea ramulifera (Etallon), Cryptocoenia tabulata Koby, C. octoseptata (Etallon), Epistreptophyllum giganteum Roniewicz, E. cf. densum Roniewicz, Heliocoenia bandukdzeae Babaev, Kobyastrea tenuis Roniewicz, Latiastrea foulassensis Beauvais, Pseudocoenia decipiens (Etallon), P. hexaphyllia (d&#039;Orbigny), Stylina parcicosta Koby and Stylosmilia michelini Edwards et Haime. The fauna, as a whole, shows close affinities to those of the Late Jurassic in Portugal, France, W.Germany, Switzerland, Poland, Romania, Yugoslavia as well as the Caucasus of USSR. Thus the fossil-bearing bed may be Late Oxfordian-Early Kimmeridgian in age. * The Lower Cretaceous may be subdivided in ascending order into the Xarqung Group (Berriasian to Hauterivian) and the Bangoin Group (Barremian to Cenomanian). The corals described in this paper were collected from the lower part of Xarqung Group and the upper part of Bangoin Group respectively. Those from the Xarqung Group appear to bear, to some extent, a Jurassic aspect. Among them Montlivaltia continued to develop slowly, and some old forms still survived, such as Montlivaltia cf. gigas Fromentel and M. caryophyllata Lamouroux. Besides, a few new elements such as Leptoria (DictuophyIlia) collignoni Alloiteau, Placotrochus cf. texanus
```

```
(Vaughan), Stylina cf. regularia Fromentel, S. parvistella Volz, etc.,
are also present in this group. The latter group contains Eohydnophora
tosaensis Yabe et Eguchi, Blothrocyathus harrisi Wells, Pleurcora
crassa (Reuss), Agathelia asperella Reuss, Preverastraea iseli (Prever)
and some new species, bearing a close relationship with those from
France, Poland, Yugoslavia, Japan as well as Texas of USA. [extracted

reconstruction of past precipitation records using coral skeletal Sr/Ca
and &#948;18O data.- Earth and Planetary Science Letters 237, 3-4:
370-386.- <b>FC&#038;P 34</b>, p. 101, ID=1366^<b>Topic(s):
</b>ecology; fossil precipitation records; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>China, Taiwan^Coupled records of &#948;18O and Sr/Ca
in Porites coral have been used to derive hydrological conditions by
removing the Sr/Ca-inferred temperature component from the &#948;18O
signal. Nanwan, a semi-enclosed bay in southern Taiwan, provides an
opportunity to demonstrate the feasibility of quantitatively
reconstruction past precipitation history. Recurrence of seawater
&#948;18O offsets between wet and dry seasons in the early 1990s is
well correlated with the precipitation record. Even though the
hydrological signal only accounts for 20% of the total annual coral
&#948;18O variation of ca. 1‰, offsets can be found in the residual
&#948;18O of modern corals after removing the thermal effect, which
contributes to the other 80%. The observation timing and amplitude of
the seasonal seawater &#948;18O offsets in Nanwan and their correlation
with precipitation are reproduced by hydrological models. In the
mid-Holocene, the seasonal anomaly of residual &#948;18O was twice of
the modern value based on the 9-yr Sr/Ca- &#948;18O data recorded in a
6.73-ka Porites coral. Hydrological models suggest an annual rainfall
of 1800-3000 mm/yr at the window during mid-Holocene, 20% higher than
that of the average of 30yr modern instrumental records of 1500-2500mm,
consistent with the qualitative pollen record from lake sediments. The
seasonal decrease of residual &#948;18O in 5 of 9 yr was earlier than
the increase of the coral Sr/Ca-inferred temperature, which implies
that these rainy seasons probably occurred from the early-mid spring to
midsummer, earlier than that from late spring to late summer today. The
driving force may be related to the changes of solar insolation and the
East Asian monsoon. It [is] cautioned that the variation of
hydrographic conditions impose restrictions on a precise calculation of
the amount of paleo-precipitation. The dynamic nature of local
tectonics, monsoons and water circulation should be further addressed
to precisely quantify precipitation over the past 10,000yr from coral
geochemical records.^1";
s[3284] = "WALLACE C.C., DAI C.-F. (1997).- Scleractinia of Taiwan
(IV): Review of the Coral Genus Acropora from Taiwan.- Zoological
Studies 36, 4: 288-324.- <b>FC&#038;P 27-1</b>, p. 100,
ID=3850^<b>Topic(s): </b>taxonomy, new taxa; Scleractinia, Acropora;
```

```
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Recent; <b>Geography: </b>China, Taiwan^The coral genus Acropora is
reviewed from Taiwan for the first time. Forty species belonging to the
coral genus Acropora occurring in waters of Taiwan are briefly
described and illustrated. The Acropora fauna of Taiwan is seen to come
from an essentially Pacific Ocean or broad Indo-Pacific fauna: all 40
species found also occur on the Pacific coast of Australia; 2 species
(Acropora verweyi and A. azurea) are not found in the central
Indo-Pacific (Indonesian) region, although A. verweyi is also found in
the western Indian Ocean. The dominant species in the Taiwan Straits,
Acropora formosa, occurs in extensive polymorphic populations, which
invite further exploration of species boundaries within this species in
this locality. The 40 species of Acropora herein recorded from Taiwan
show an 89% similarity in species composition compared with 49 species
recorded from islands in the Capricorn group of SE Australia, which is
at a similar latitude south. The Acropora fauna of Taiwan is seen to be
less diverse compared with 74 species recorded from Japan to the north,
67 species recorded from the Philippines to the south; 83 species
recorded from Indonesia, and 51 species recorded from the South China
Sea. This variation is possibly due to differences in sampling effort
and species interpretation; however, differences in the areas of reef
available for colonization, and fewer types of reef habitat within
Taiwanese waters, would also imply that many species recorded from
those other localities will not be found in Taiwan.^1";

Chinese scientists have gotten outstanding achievement in the classification, microstructure and septal evolution of the heterocoral. After we found a kind of heterocoral with 3 septa, the septal variety of the different genera and the developmental model of the septa have been clearly revealed. The heterocoral can be divided into two series, one with fossula and another without fossula. The geologic age of the heterocoral should be from the Early Devonian to the Late Carboniferous in mainland China. In our country most of the heterocoral are found at the Datang stage of Early Carboniferous and they frequently associate with the elements of the rugose coral in the Yuanophyllum zone, so the heterocoral is an important fossil group in classifying the lower Carboniferous of China.^1";

sequence stratigraphy; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fra/Fam; <b>Geography: </b>China S, Ardennes^The
sedimentological evolution of the Frasnian-Famennian transitional
strata in South China and southern Belgium has been investigated. A
similar trend in the deepening and shallowing of the sedimentation
environment occurs in the two palaeogeographically distinct areas. The
stratigraphic succession has been subdivided into depositional
sequences. A general deepening occurs in the Palmatolepis rhenana
conodont zone. During the most rapid rise in sea level, a transgressive
systems tract formed. This transgressive systems tract is followed by a
highstand systems tract in the late P. rhenana zone. A major sequence
boundary within the latter zone is indicated by an unconformity in
intraplatform and platform areas and by a conformity in the basinal
area. The uppermost sediments within the late rhenana zone correspond
to a lowstand systems tract. A rapid flooding took place near the base
of the Palmatolepis linguiformis zone and dark shales and limestones
formed. A second sequence boundary coincides with or is very close to
the Frasnian-Famennian boundary (base P. triangularis zone). The global
extinction event at the Frasnian-Famennian boundary coincides with an
important eustatic fall in sea level. The proposed stratigraphic
subdivision should allow worldwide correlations of shallow and deep
water deposits.^1";

```
</b>China, Guangxi,, Ardennes^In the Etaoucun area (Guanxi, South
China), a well developed and continuous section is exposed at the
Devono-Carboniferous boundary, in a platform environment context. The
following formations have been sampled.- The Dongchium Formation (upper
Famennian) consists of thick, bird-eyes limesotne, they are azoic
except in the uppermost part in which several Leperditidae Ostracod
bearing beds have been observed and one reefal level recognised for the
first tune.- The Etaoucun Formation (uppermost Famennian = Strunian)
consists of grey and dark thick bedded limestone; many reefal levels
are present (with a lot of Stromatoporoids and Tabulate corals but few
Rugose corals). The other groups are usually very poorly represented
and slightly diversified (Brachiopods, Ostracods, &#8230;); however,
Gastropods are abundant, but often very badly preserved in dolomitized
beds; Foraminifera are also very common and allow some good
biostratigraphical zonation.The D/C boundary is located about two
meters below the top of this formation. The lower part of the overlying
Zaoyunling Formation (Lower Carboniferous), beginning with the
Shanyeshan Member, mainly consists of thin bedded, dark limestones;
they contain a more open marine fauna with very diversified Ostracods,
few Brachiopods and also Foraminifera.This Chinese fauna is compared
with the fauna of the Strunian stratotype in Etroeungt (Avesnois, North
of France), where precise bed to bed sampling has been done; Except
Foraminifera, which allow some correlations, the other bentic groups
present very few taxa in common; this support the endemism of the
Strunian faunas, already underlined by some authors.^1";

Asian corals.- Mem. Geol. Soc. 12 [McKerrow W.S. &#038; Scotese C.R.
(eds): Palaeozoic Palaeogeography and Biogeography]: 175-179.-
<b>FC&#038;P 19-2.1</b>, p. 23, ID=2734^<b>Topic(s): </b>biogeography;
Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Paleozoic; <b>Geography: </b>Asia E^In East Asia the oldest
tabulate and rugose corals appeared in the Early and Middle Ordovician.
All rugose corals and most tabulate corals appear to have become
extinct at the end of the Permian. The Ordovician corals of North China
were most closely related to the Americo-Siberian region, but those of
South China occupied an independent province. The Silurian corals of
Junggar, Hinggan, Mongolia, Altai and Tuva are genera characteristic of
the Uralian-Cordilleran region. The South China fauna had a close
affinity to that of the East Australia in the Early Silurian, but was
more akin to that of the Urals and Central Asia in the Middle and Late
Silurian. During the Early and Middle Devonian, there were 5
```

```
biogeographic provinces in East Asia, all belonging to the Old World
Realm: (1) Arctic province; (2) Junggar-Hinggan province; (3)
Uralo-Tian Shan province; (4) Palaeotethyan province and (5) South Chin
province. In East Asia, two distinctive zoogeographic provinces are
fairly clearly defined: a southern province, with occurrence of
Kueichouphyllum and a northern province with occurrences of
Gangamophyllum during the Early Carboniferous. In addition, during the
Early Permian, an Uralo-Arctic province was dominated by Durhaminidae
and a Tethyan province by Waagenophyllidae.^1";

Australian &#034;Siphonodendron&#034; (Anthozoa, Rugosa): ecological
and geographical influence on taxonomy.- Geologos 14, 1: 3-17.-
<b>FC&#038;P 36</b>, p. 54, ID=6438^<b>Topic(s): </b>biogeography;
Rugosa Siphonodendron; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>China,
Australia^Normal marine salinity is the main limiting factor for the
Subclass Rugosa. Water depth and temperature are less critical.
Individual characteristics of specimens and some characteristics of
species are, however, excellent environmental indicators. Being
distributed exclusively by larvae, Rugosa required free distribution by
means of marine currents, as well as midway areas suitable for
settlement and metamorphosis of the larvae. Not distance but rather
geography and midway environments are therefore the limiting factors
for their distribution, relationships and stratigraphic value.
Siphonodendron and Siphonodendron-like (&#034;Siphonodendron&#034;)
corals are discussed as examples of morphological similarity, but not
necessarily representing a phylogenetic relationship. The known
homeomorphy of European and western North American Siphonodendron taxa
(Fedorowski &#038; Bamber 2007) may be extended on the European, some
southern Chinese and all south-eastern Australian Siphonodendron-like
corals, but only the Chinese and SE Australian forms may be truly
related. The latter relationship would extend the boundaries of the
Early Carboniferous Australian rugose coral province. The Late
```

```
Tournaisian age of the earliest Australian &#034;siphonodendrons&#034;
indicates an ancestry of the coral fauna within the province (SE
Australia and S China). A mechanism for north-westward migration of
this fauna, from SE Australia to S China, is not clear.^1";

Precambrian-Cambrian boundary interval.- Facies 49, 1: 351-372.-
<b>FC&#038;P 33-1</b>, p. 75, ID=7221^<b>Topic(s): </b>; Porifera;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Precambrian &#47;
Cambrian; <b>Geography: </b>India, Lesser Himalaya^A study of fossils
in thin sections of a sample from the uppermost Krol E Member in the
Mussoorie Hills of the Lesser Himalaya, India, proves the existence of
morphologically differentiated calcified sponges within the
Precambrian-Cambrian boundary time interval. The sponges described as
Mussooriella kroli n.gen. n.sp. and Maldeotainia composita n.gen. n.sp.
indicate the presence of different organization grades at the
Precambrian-Cambrian interval. Mussooriella had a calcareous skeleton
consisting of skeletal elements composed of an inner laminated part and
a distinct peripheral layer with knobs. Maldeotainia is characterized
by a stromato-poroid-grade growth pattern following a thalamid-grade
pattern. The stromatoporoid grade part of the skeleton is very similar
to skeletal elements common in labechiid Ordovician and younger
stromatoporoids. Maldeotainia also shows criteria of Early Cambrian
fossils originally described as stromatoporoids and later excluded from
this group and transferred to archaeocyathids. These similarities point
to an Early Cambrian age of the fossil - bearing horizon in the topmost
Krol E member. Growth cavities within crypts indicate that the sponges
might have contributed to the formation of small metazoan reef-like
structures. Although the study is based on limited material, and many
interpretations are still tentative, a thorough documentation of the
preliminary results seems reliable considering the high potential of
fossils of the upper Krol Formation as an important source in the
understanding of early metazoan differentiation. [original abstract]^1";
s[3345] = "FONTAINE H. (1997).- Paleontology of Thailand, the fossil
corals.- FC&P 26, 2: 43-46. [short note] - <b>FC&#038;P 26-2</b>, p.

p. 44, ID=7202^<b>Topic(s): </b>; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>fossil; <b>Geography:
</b>Thailand^Fossil corals are widespread in Thailand. They belong to
many geological intervals, from Ordovician to Quarternary. They have
been studied actively during the last 20 years. They are better known,
even though some research still needs to be carried out; for instances,
Triassic corals, which occur in abundance at many localities of
Thailand, remain inadequately known. Carboniferous, Permian and
Triassic corals are widespread in Thailand. Devonian and Jurassic
corals are in abundance in restricted areas. Ordovician and Silurian
corals are rare and remain poorly known. Cretaceous corals are
completely absent. In Thailand, the study of corals is the study of
long history. One can observe living corals as well as many groups of
fossil corals. Corals provide important information on past
environments and help to reconstruct paleogeography; they also provide
information on the ages of the rocks in which they are included. In
this paper, two Devonian localities are mentioned for the first time;
they were discovered in January 2002. [original abstract]^1";

diversity in limestones of Thailand: a cornucopia of information about
the history of life.- Siam Society Natural History, Bulletin 53, 1:
33-70.- <b>FC&#038;P 34</b>, p. 94, ID=1353^<b>Topic(s):
</b>carbonates; carbonates fossils; <b>Systematics: </b>;
<b>Stratigraphy: </b>Phanerozoic; <b>Geography: </b>Thailand^In
Thailand, fossils are common and diverse. They come from
bothterrestrial and marine environments. The belong to many time
periods beginning with the Cambrian, thus spanning more than 500
millionyears (the Phanerozoic eon). This rich past emerges from
extensive published data and is still very interesting to explore. This
publication concerns only fossils included in limestones deposited in
the seas of the past. Limestone is widespread in Thailand and of
various ages. Marine floras (algae) and faunas are in abundance at many
limestone exposures and their skeletons are an important component of
the limestone. They give deep-time perspective on the evolution of the
life in the seas of the past.The limestones of Thailand are not
restricted to the widespread visible on the land. They have been found
by hydrocarbon exploration at varied depths and in different areas.
Permian limestone has been reached by wells under the Khorat Plateau
and its extent has been determined by seismic interpretation; it is
widespread (for instance, see Mouret, 1994).This publication is
concerned only with limestones exposed at ground surface. Limestone is
a general term for diverse types of rocks, deposited in different
environments. Before describing their biodiversity, we discuss the
origin of the limestones of Thailand.^1";

In Tertiary basins throughout most of East Asia, CCOP [Coordinating
Committee for Geoscience Programmes in East and Southeast Asia] decided
in 1973 to investigate the pre-Tertiary series which had already
generated some interest in China and which were rather incompletely
known in large areas of the CCOP region. Accordingly, it included in
its programme of work a critical review of the current knowledge on the
pre-Tertiary oil and gas potential of East Asia. In 1974, A. Bonnet
started the &#34;CCOP pre-Tertiary Programme&#34;; his work is
```

```
continued by H. Fontaine. Very rapidly, interesting results on
stratigraphy were obtained in areas easily accessible and previously
investigated by geologists. The sedimentary rocks of these areas
contained few macrofossils, and for example, Carboniferous
microfossils, were poorly known and difficult to study in the past.
Hence, the first fieldwork led to many new palaeontologlcal and
stratigraphical discoveries, especially in remote areas. Ten years of
geological research with CCOP is indeed an adventure. Many fossils have
been discovered and provided new data to stratigraphy and
paleogeography. Results of the studies have been published regularly,
giving the impression of plainly logical development of knowledge.
[review by Kl. Oekentorp] Almost every article in this book refers to
fossil corals and related groups. In the following - however - only the
most important articles are mentioned here, this means only those
dealing with systematic aspects.^1";

Spiti-Kinnaur, Himachal Himalaya, India.- Facies 15: 35-52.-
<b>FC&#038;P 15-2</b>, p. 41, ID=0734^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>India, Himalaya^The Silurian sequence in Spiti and Kinnaur was
studied at Takche, Gechang, Muth-Shian, Leo and Manchap. At all these
localities the sequence commences with an intertidal - near-shore
argillo-arenaceous succession. The overlying part at Takche comprises
arenaceous dolomite, calcareous sandstone and dolomite. It sporadically
contains rugose and tabulate corals deposited in a shallow undathem
near the shore. The succession at Gechang is more calcareous and in
some parts rich in corals; stromatoporoids occur locally. Here
bioclastic wacke/packstones and framestones formed a buildup which was
possibly formed in a lagoon. The Muth-Shian area is characterized by
bioclastic mudstones, bioclastic wacke/packstones and framestones. Reef
builders are corals, stromatoporoids and solenoporoids. These sediments
seen to be lateral equivalent of the coastal arenaceous sequence
exposed at Baldar and may represent a fringe reef.^1";

s[3368] = "SCHRODER S. (2004).- Devonian rugose corals from the
Karakorum Mountains (Northern Pakistan).- Rivista Italiana di
Paleontologia e Stratigrafia 110, 3: 605-641.- <b>FC&#038;P 33-2</b>,
p. 22, ID=1131^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>Pakistan,
Karakorum Mts^The Karakorum Block is regarded as a microplate of
&#34;Gondwanan&#34; origin and was part of the Cimmerian continent
(&#34;Mega Lhasa&#34;) which rifted away from the northern margin of
Gondwana during the Late Palaeozoic/Early Mesozoic. From the Northern
Karakorum Range (Yarkhun and Karambar River Valleys: structurally
belonging to the Northern Sedimentary Belt) an Upper Givetian to Lower
Frasnian rugose coral fauna of the Shogram Formation is described. The
fauna is dominated by cosmopolitan genera such as Hexagonaria,
Disphyllum, Macgeea and the Temnophyllum/Spinophyllum group, generally
showing a geographically wide distribution, although being absent from
the Eastern Americas Realm in the Upper Givetian/Lower Frasnian.
Therefore its components are of little use for biogeographical
deductions at sub-realm level, and in explaining the relation between
the Karakorum Range and other Cimmerian crustal blocks. A remarkable
exception is the first record of the genus Pseudopexiphyllum outside of
Turkey, indicating a connection to the western part of the
Cimmerides.On species level, the coral fauna of the Shogram Formation
is characterized by the development of a diverse and rather unique
fauna including about 35 taxa, that differs from the faunas known from
neighbouring crustal blocks. So far, faunistic links to the Central
Iranian Microcontinent (Yazd-, and Tabas-Block), the northwest Iranian
Plate (Elburz), Central Pamir, the Lhasa Block and Western Qiangtang
are not clear, and although each of these fragments are believed to be
closely connected they were apparently not in direct contact during the
Devonian. However, the Karakorum fauna is remarkably close to one known
from the Helmand Block in Afghanistan, showing a very similar generic
composition that includes numerous morphologically closely related,
although not identical species. Accordingly, the restricted faunal
exchange led to the development of new taxa. Distribution of the new
species of Spinophyllum, Pseudopexiphyllum and Pseudozaphrentis is
limited to the Karakorum Mountains. Reasons for this individual
faunistic development and the missing faunal exchange are unexplained,
but suggest that some kind of active faunal barrier must have existed
during the Devonian, which led to the development of the specific
Karakorum fauna. With the exception of Phillipsastrea orientalis Smith,
1930, which is elsewhere only known from the Burmese Devonian, the
occurrence of some other species suggest a connection to regions which
are regarded as biogeographically unrelated. A weak relation to central
European faunas is indicated by the occurrence of characteristic
species of Macgeea and Hexagonaria known from the Ardennesand the Holy
Cross Mountains. More unusual are the faunistic affinities to the
Altai-Sayan region shown by the surprising occurrences of species of
Spinophyllum and siphonophrentid corals morphologically very close to
those known from the Altai Mtns. and Kazakhstan.^1";

</b>Thailand^Carboniferous fossils have been collected from limestone
lenses which intercalated with basic to intermediate volcaniclastic
sediments in an area of central Thailand east of Lam Narai. They
consist of calcispherids, algae, foraminifers and corals; they mainly
indicate a Late Moscovian (Miatchkovian) age, locally extending to
early Kasimovian. They bring interesting new information showing that
the stratigraphic range of the sedimentary rocks of that area extends
in continuity from Middle Carboniferous to the top of Middle Permian.
[original summary; the taxa are: an undeterminated Micheliniid genus,
Multithecopora sp., Caninia sp., Bothrophyllum aff. conicum Trautschold
1879, Bothrophyllum sp., Amygdalophyllum sp., and Petalaxis siamensis
Fontaine, 1994]^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Carboniferous;
<b>Geography: </b>Thailand^Since 1980, many Carboniferous localities
have been found in Northeast Thailand (Northeast of Loei and southwest
of Phetchabun); some of them have yielded corals. In 1988 and 1989, new
Carboniferous sections have been discovered as well as new scattered
outcrops, especially in the new area west of Petchabun (Noen Maprang
area). A summary of our knowledge on the Carboniferous corals of
Thailand will show that several different coral assemblages have been
indentified. This result is important because Carboniferous corals,
which were almost unknown in Thailand ten years ago, indicate the
presence of a shelf with shallow and warm sea water around the Khorat
Plateau during the whole Carboniferous. Elsewhere in Thailand, no
Carboniferous coral has been found yet.^1";

ecology; Chaetetida; <b>Systematics: </b>Porifera; Chaetetida;
<b>Stratigraphy: </b>Carboniferous Mos; <b>Geography: </b>India,
Himalaya^The &#034;Fenestella shales&#034; are a mid-Carboniferous
marker unit which has long been described from classic localities of
the NW Himalaya (Kashmir, Spiti). Correlative shaly units have recently
been traced in central Nepal and as far as South Tibet, where they
yielded varied brachiopod assemblages indicative of Bashkirian age. * A
second distinct interval of black shales, characterized by the
abundance of chaetetids and directly underlying the widespread
Gondwanan diamictites, has been dated as Moscovian in Spiti and
represents the youngest fossiliferous horizon hitherto identified in
the Upper Carboniferous of the Tethys Himalaya. The &#034;Chaetetid
shales&#034; are recognized also in Manang, whereas in South Tibet the
stratigraphic framework still needs improved definition. These major
fossiliferous black shale units, marking repeated transgressive events
in the middle part of the Himalayan rift sequence, have not only major
stratigraphic significance but also represent a fundamental landmark in
palaeogeographic and palaeoclimatic reconstructions of Northern
Gondwana. With the onset of continental rifting, arid tropical climates
```

```
at the close of the Tournaisian were replaced by temperate humid
conditions in the Visean-Serpukhovian, when diamictites were deposited
in South Tibet. After this first cooling stage, the &#034;Fenestella
shales&#034; mark a widespread transgression at the very beginning of
the Late Carboniferous, coupled with reduced tectonic activity and
temperate to temperate-warm climates. After renewed tectonic activity
during a second cooling episode, marked by local deposition of
diamictites in central Nepal, the &#034;Chaetetid shales&#034;
represent another major transgression in the Moscovian, shortly
preceding the final and most intense cooling event marked by deposition
of glacio-marine diamictites in the whole Tethys Himalaya from Kashmir
to South Tibet during the latest Carboniferous &#47; earliest Permian.
Two fossiliferous horizons containing very similar brachiopod faunas of
early Late Carboniferous age have recently been found also in North
Karakorum, at lower southern latitudes, where climatic conditions
always remained temperate and there is no trace of Upper Palaeozoic
glacial deposits or ice-rafted debris. [original abstract]^1";

</b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>Malaysia^In Malaysia,
Carboniferous corals are few in number; usually scattered in the
sediments and commonly represented by assemblages, which are not rich
and diverse. The corals are commonly reworked; broken specimens and
small fragments prevail. They do not build reefs at all. In contrary to
other areas, the Kuantan area is relatively rich in corals. A peculiar
Carboniferous coral fauna collected from four limestone hills i.e.
Bukit Tenggek, Bukit Sagu, Bukit Charas and Bukit Panching in the
Kuantan area has been studied. Systematic descriptions are given for
the seclected corals. In order to give better information on
stratigraphy, associated algae and foraminifera have also been
identified. The Kuantan fauna is not very diverse, but it is very
interesting, even from an international point of view, because it
belongs to the boundary between Lower and Middle Carboniferous, to a
```

```
horizon of contention. Hexaphyllia is common, at least locally. Other
corals belong to Fomichevella, Amygdalophyllum, Dibunophyllum and
Axophyllum; such a fauna has not been found so far in other parts of
Southeast Asia. Among the foraminifera, the important taxa are
Howchinia, Monotaxinoides, Bradyina cribrostomata, Eastaffella
mosquensis, Janichewskina and Archaediscus karreri.^1";

synthesis is provided of the many papers published on the Carboniferous
of northeast Thailand since 1960, which have been restricted to
localities north of latitude 17°10&#039;N. In addition, new data are
provided on Carboniferous localities recently discovered south of
latitude 17°10&#039;N. All stages of the Carboniferous are represented
in northeast Thailand and their exposures are delimited in this paper.
In northeast Thailand Carboniferous rocks are widely exposed in an area
where Loei and Wang Saphung are the main towns, an area 20-40km wide
and 140km long. In parts of this area, they are overlain by Permian
strata (mainly limestone) in the core of a syncline. Middle-Upper
Devonian limestone, shale and chert occur occasionally in the central
and northern parts of the area. They are less widely distributed than
the Carboniferous rocks but are obvious features because the limestone
```

```
forms karstic hills and the chert outcrops are prominent. An important
development of shale during the Middle-Upper Carboniferous has favoured
differential erosion so that today these rocks are distributed commonly
in flat areas with paddy fields; the shale concealed under a few meters
of earth. Their discovery has been due to farmers digging ponds at
several places.^1";

<b>Stratigraphy: </b>Permian; <b>Geography: </b>Thailand
peninsular^[The Permian limestones of Peninsular Thailand range in age
from the upper Lower Permian to Dzhulfian (Wuchiapingian). They are
poor in many kinds of fossils at their base. Diverse fossils with
corals become quite widespread at their top, especially in
Murgabian-Midian horizons. In this conclusion, the corals are taken
into account as well as the associated fossils for the sake of
certainty and clarity. All the fossils focus on the same facts, which
are important for paleogeography.1. Tabulata are widespread, but belong
only to Sinopora at many localities. Rugosa are more interesting, but
they are not actually diverse, even in younger Permian beds where they
may be in abundance to a certain extent. They do not build reefs but
are scattered. They do not include the well known genera of Central and
Northeastern Thailand such as Ipciphyllum or Pseudohunagia. On the
other hand, Paraipciphyllum is a common genus of Peninsular Thailand
whereas it is rare elsewhere in Thailand. This genus had been described
for the first time in China (Wu, 1963).]^1";

ID=3001^<b>Topic(s): </b>geography; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>Thailand^The Permian corals found in Chom Bung area belong to an
aberrant fauna when compared to those of central and eastern Thailand.
They are similar to other faunas known to the south in Peninsular
Thailand. Chom Bung is 115 km westsouthwest of Bangkok as the crow
flies and this town belongs to the extreme north of Peninsular
Thailand. It is surrounded by a flat land where limestone hills are
scattered. Limestone is bedded and massive, commonly dolomitised. It
belongs to the &#34;Ratburi Limestone&#34; as shown by the following
study of the corals. In the past, it yielded a few Murghabian
foraminifers at Khao Chom Phon, a hill within the town of Chom Bung
(Fontaine and Suteethorn 1988, p. 34-35). Recently, much more abundant
fossils (foraminifers, Tabulata, solitary and massive Rugosa,
bryozoans, brachiopods, gastropods and crinoids) have been found at
other hills 5 to 10 km from Chom Bung: Khao Lan 5.5 km to the south,
Khao Pak Kwang 10 km to the northeast, and Khao Kwak 9 km to
north-northeast. The fauna is very interesting because of strong
affinities with the fossils found to the south in Peninsular Thailand
which is part of a distinctive biogeographic unit (Fontaine et al.
1994). It is different from the faunas known in central, eastern and
northeastern Thailand.^1";
s[3415] = "FONTAINE H., SUTEETHORN V. (1992).- Permian corals of
Southeast Asia and the bearing of a recent discovery of Lower Permian
corals in northeast Thailand.- National Conference on Geologic

```

```
<b>FC&#038;P 22-1</b>, p. 29, ID=3366^<b>Topic(s): </b>; Anthozoa;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>Thailand^Permian corals have been mentioned in many
papers concerning the geology of Southeast Asia; they are much more
diverse and prolific than what is known in Australia during Permian.
Even Timor or Peninsular Thailand where coral faunas are somewhat
restricted are richer than Australia. Accordingly, the impression may
be that coral reefs are common and geographically widespread in
Southeast Asia from bottom to top of Permian sections. This is not
actually correct although not entirely wrong. The aim of this paper is
to access what we currently know. Lower Permian corals have been poorly
known in Southeast Asia up to now. Therefore, the recent discovery of
these corals in northeast Thailand is an important result which cannot
be ignored by this paper.^1";

(1997).- The Permian of East Thailand: Biostratigraphy, corals,
discussion about the division of the Permian.- [journal?] The
International Conference on Stratigraphy and Tectonic Evolution of
Southeast Asia and the South Pacific Bangkok, 19-24 August, Thailand.-
<b>FC&#038;P 27-1</b>, p. 49, ID=3804^<b>Topic(s): </b>biostratigraphy;
biostratigraphy; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>Thailand E^Permian
limestones are common in a large area of East Thailand near the
Cambodian border; they are studied in this paper. They are clearly
divided into two areas where they show different ages: Roadian with
Cancellina and Neoschwagerina simplex (= Kubergandian-Early Murgabian)
to the west and Capitanian with Yabeina and Lepidolina (= Midian) to
the east. Corals are in abundance in the Capitanian limestones; they
consist of rare Tabulata (Sinopora), solitary Rugosa (Tachylasma,
Khmerophyllum Lophocarinophyllum, Paracaninia), fasciculate and massive
Rugosa (Waagenophyllum and Multimurinus). They are described in this
paper and a new species is established: Multimurinus makkaensis. These
corals from east Thailand as well as those previously found in west
Cambodia are clearly different from the corals collected from the
Murgabian (sensu Leven 1981) of central Thailand and of other areas of
Southeast Asia. They raise the problem of the Murgabian-Midian boundary
and more generally of the Permian division.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>Thailand^Permian corals are common in Thailand. They have been
observed at more than one hundred localities. They are prolific in many
areas where they are associated with diverse faunas and abundant algae.
They may locally form reefs. However, their stratigraphic distribution
is not uniform. The variation of the coral fauna composition provides
information on Permian paleogeography.^1";
s[3418] = "FONTAINE H., SATTAYARAK N., SUTEETHORN V. (1994).- Permian
corals of Thailand.- CCOP Technical Bulletin 24: i-vi + 1-171, 19
figs., 3 tabls., 31 pls.- <b>FC&#038;P 23-2.1</b>, p. 35,
ID=4230^<b>Topic(s): </b>; Anthozoa; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>Thailand^Permian corals are present at many localities distributed
all over Thailand. They are locally prolific and diverse. Accordingly,
they are very important fossils of this country. Even though their
number has fluctuated with time, they are found in beds ranging from
Early to Late Permian. Their assemblages change with depositional
environment. In quiet and confined environments, assemblages are poor
and restricted to solitary Rugosa without dissepiments. In more
favourable environments, assemblages are luxuriant with high diversity.
Moreover, Permian corals clearly show two biogeographic provinces. In
Peninsular Thailand, they are different from those of central Thailand;
they share this characteristic with fusulinids. A halt to the dispersal
```

```
of many corals and fusulinids into Peninsular Thailand is obvious. In
Thailand, Permian corals went on the wane a long time before the
closure of Permian; their decline was rapid during Late Permian. They
are no more diverse in Dzhulfian limestones and are poorly known in
Dorashamian limestones. In the past, Permian limestones of Thailand
were called &#034;Ratburi Limestone&#034; (Brown et al. 1951) or were
included in &#034;Ratburi Group&#034; (Javanaphet 1969 in the
Geological Map of Thailand of scale 1:1,000,000). No type section was
designated. Bunopas (1981) limited the &#034;Ratburi Group&#034; to
limestone and interbedded shale exposed in Peninsular Thailand; he
proposed several names for other Permian limestones, with an important
name: &#034;Saraburi Limestone&#034; for the limestone exposures of
central Thailand and Loei-Wang Saphung-Pha Nok Khao region. Local names
for different limestone outcrops will be discussed in the next chapter.
Recent studies show that the Ratburi Limestone of Peninsular Thailand
is actually Permian and Triassic in age (Fontaine et al. 1993).
Saraburi Limestone is restricted to Permian. Accordingly, Ratburi
Limestone and Saraburi Limestone belong to two different
paleogeographic units as indicated by their coral and fusulinid
assemblages as well as by their stratigraphic ranges (Fontaine et al.
1992 and 1993). [part of introduction].^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>Thailand NE^A very fossiliferous limestone is exposed
at Khao Tham Yai; it is thick and ranges from Murghabian to the top of
the Midian. Fossils are diverse and in abundance. The fusulinacean
genus Lepidolina occurs at the top of the limestones; it has a
palaeogeographic meaning. Photographs of the main fossils are provided
in this paper [including Ipciphyllum subelegans Minato &#038; Kato, I.
phadaengense Fontaine, 1992, Multimurinus fontainei Kato &#038; Ezaki,
1986, M. cf. frechi Volz, M. sp.,]. In the valley east of Khao Tham
Yai, a clastic sequence with predominant scale has yielded recently
some fusulinaceans. Farther to the east, Khao Pa Khi limestone is very
poor in fossils; its age was doubtful because of an apparent absence of
fusulinaceans. Other samples have been collected recently; they bring
new information suggesting a Permian age, but still with a slight
doubt. The occurrence of a fault appears probable between Khao Tham Yai
and Khao Pa Khi. South of the Khao Tham Yai - Khao Pa Khi area along
the Lomsak - Chumphae Highway, other limestone outcrops contain
characteristic fossils, in particular common Codonfusiella. [original

(2002).- Permian of Southeast Asia: an overview.- Journal of Asian Earth Sciences 20, 6: 567-588.- <b>FC&#038;P 31-2</b>, p. 27, ID=7126^<b>Topic(s): </b>geology; geology; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian; <b>Geography: </b>Asia SE^Permian rocks are widely distributes throughout Southeast Asia. Because of the tropic-equatorial climate the rocks are commonly deeply weathered and covered by dense vegetation over much of the region. Elsewhere, Permian rocks are well exposed and easy to access, particularly where limestone outcrops have weathered to form spectacular, castellated, tower Karst. Many limestone outcrops, containing abundant fusulinaceans, were early recognized to be of Permian age, but many outcrops without fusulinaceans, erroneously assigned to the Permian, were found subsequently to be of Triassic age, and more careful studies have established the Permian age of rocks of other lithologies. It is now recognized that different depositional environments are represented by the Permian deposits in various parts of the region. Massive limestones, widespread throughout the region, represent extensive carbonate platforms; local occurrences of thick bedded cherts indicate deposition in deep marine environment, coal, bauxite and clastic sediments with vertebrate remains in the North Vietnam and Laos indicate deposition in a continental environment, and pebbly mudstones in Myanmar, Peninsular Thailand, northwest Malaysia and Sumatra, are considered to have been formed in a glacial environment. Volcanic rocks are absent in northwest Peninsular Malaysia and Peninsular Thailand, but are extensively developed in North Vietnam, Sumatra, the eastern Malay Peninsula and Timor. Fossils, representing many fossil groups, are often prolifc in Permian sediments, with fiasulinaceans, for example, occurring in astronomical numbers in many limestone outcrops. Age-diagnostic fossils demonstrate that the whole of Permian is represented in different areas of Southeast Asia. Fossil faunal and floral assemblages have been used to establish climatic and environments of deposition, to define distinct crustal blocks and to provide the basis for reconstructing the palaeogeography during Permian times. [original abstract]^1";
s[3431] = "FONTAINE H., SALYAPONGSE S., NGUYEN DUCTIEN, VACHARD D. (2002).- Permian fossils recently collected from limestones of Nan area, North Thailand.- The Symposium on Geology of Thailand, 26-31 August 2002, Bangkok: 46-57.- <b>FC&#038;P 31-2</b>, p. 43, ID=7134^<b>Topic(s): </b>geology, fossils; geology, paleontology; <b>Systematics: </b>; <b>Stratigraphy: </b>Permian; <b>Geography: </b>Thailand N^Permian limestones are exposed in Nan area at several localities: they are less widespread than what was thought in the past. They belong mainly to Middle Permian; at an important hill, the occurrence of the Midian has been strongly evidenced and an unexpected fauna including Lepidolina has been found. The lower Part of Lower Permian (Asselian - Sakmarian) is entirely unkown in Nan area. The upper part of Lower Permian (Artinskian - Kungurian) has been evidenced at a single locality. Late Permian shale (Wuchiapinhian) is exposed locally north of Nan. The presence of Upper Permian limestone is possible. Fossils are locally in abundance, they show mainly Cathaysian affinities. * Nan region is a remote and mountainous area of northern Thailand where an impressive number of new roads has been built during the last few years. These new constructions have allowed an actually new geological research because of many road-cuts reaching the bedrock. Permian exposures consist of shale and limestone. * The studied localities are limestone hills north of Nan as well as south of Nan. At a locality, limestone is restricted to a small lens in shale. [original abstract]^1";

<b>Stratigraphy: </b>Permian; <b>Geography: </b>Malaysia peninsular^A
limestone which has been uncovered during the extension of an oil palm
plantation appears to be an important deposit. It is rich in relatively
well preserved fossils although it out crops only 500m from a granite.
The fossils are diverse and consist of common Tubiphytes, a few algae,
calcispherids, smaller forarninifers, abundant fusulinaceans (including
Levenella, Pamirina, Brevaxina, Chalaroschwagerina, Leeina, Toriyamaia,
Laosella), calcareous sponges, a few bryozoans, brachiopods, bivalves,
rare gastropods, ostracods and crinoids. They indicate a Late
Cisuralian age (Yahtashian-Bolorian) and appear to belong to three
biozones. The rocks of the area were previously considered to be Early
Carboniferous in age. [initial part of extensive summary]^1";

(1993).- Triassic coral buildups observed in the Chaiburi Formation,
near Phatthalung, Peninsular Thailand.- Ann. Rep., Inst. Geosci., Univ.
Tsukuba 19: 27-31.- <b>FC&#038;P 24-1</b>, p. 82, ID=4514^<b>Topic(s):
</b>coral reefs, geology; coral reefs; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Triassic; <b>Geography:
</b>Thailand^Light colored carbonate rocks extensively crop out in the
southern part of Peninsular Thailand. Their distribution further
extends to the south and crosses the national border of Thailand and
Malaysia. These rocks are mostly limestones intercalated with dolomite
beds in the lower part and constitute many isolated hills surrounded by
steep cliffs with spectacular pinnacles at their tops or with flat tops
of which elevation is 50 to 300m above sea level. Thailand geologists
assigned these limestones to the Permian Ratburi Limestone, but Igo el
al. (1988) reported the occurrence of lower Middle Triassic conodonts
in one of the limestone hills, Khao Chiak, about 5km west of the
Phatthalung city area. More recently, Sashida &#038; Igo (1992) added
new data of geochronology based on radiolarian biostratigraphy.
Recently, one of the authors, Ampornmaha (1993, MS) has studied
extensively the geology of the Phatthalung area and newly designated
the Chaiburi Formation for these limestones. She further subdivided
this carbonate formation into the Phukhaothong Dolomite Member, Chiak
Limestone Member, and Phanomwang Limestone Member in ascending order.
This formation attains a total thickness of more than 400m. According
to her biostratigraphic reconnaissance, this formation ranges from
Dienerian to early Carnian in age, but the lower part of this formation
probably grades into the Upper Permian. She also studied microfacies of
these carbonate rocks and clarified their depositional environments.
The microfacies of the Chaiburi corresponds with Facies 3 and 4 of
Standard Facies Belts proposed by Wilson (1975). During our field
survey in 1990 and 1991, we found coral buildups in the basal part of
the Phanomwang Limestone Member exposed in a quarry of Phanom Wang
about 9km north of Phatthalung. Triassic coral buildups have not been
fully known in calcareous facies of southeastern Asia. Fontaine &#038;
Gafoer (1989) reported the presence of reefal limestone in the
Sibaganding Limestone exposed near Lake Toba, northern Sumatra, but
they did not document any details of this limestone. We describe the
coral buildups observed in the Phanomwang and discuss their geologic
significance in this paper.^1";

sedimentology; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic U;
<b>Geography: </b>Indonesia, Sulawesi^An Upper Triassic (Upper
Norian-Rhaetian) carbonate complex, composed of open marine to reefal
deposits, has been investigated for the first time in Eastern Sulawesi.
The age is based on the occurrence of benthic foraminifera, and also of
the Upper Sevatian to Rhaetian conodont Misikella posthernsteini Kozur
and Mock. Palynological assemblages contain Upper Triassic-Lower
Jurassic palynomorphs. The scleractinian coral Retiophyllia seranica
and the chaetetid sponge Blastochaetetes intabulata, together with
Solenoporacean algae, are the main framebuilders of the reefal facies.
* The entire carbonate series, composed of conodont bearing limestones,
reefal deposits, and intertidal/supratidal cryptalgal laminites, shows
a general regressive trend from a marginal to an inner platform
environment. The relationship between microfaunal distribution and
sequence analysis is discussed. * The Upper Triassic foraminifers and
palynomorphs of Eastern Sulawesi show affinities to microfaunas of the
Australian-Indonesian southern Tethyan domain, and the general
organisation of the platform should be investigated through further
studies from Banda Sea dredgings. [original abstract]^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic; <b>Geography:
</b>Thailand, Myanmar^The Jurassic of Thailand has provided corals
belonging to the three main parts of the Jurassic; Lower, Middle and
Upper Jurassic. Nevertheless, these species which have been found in
Thailand display generally a long stratigraphic range and cannot give
any accurate stage indication without the help of associated fauna and
flora. As in Sumatra, the Scleractinia do not form true reefal buildups
in Thailand; they may be considered as an adapted fauna, dependent of
the very specific food offered by the abundance of microorganisms
occurring in the muddy environments in which they lived scattered
(Beauvais et al. 1985). The true reef builders are, in fact,
microorganisms (bacteria and microalgae) producing a biobuilt micrite.
Even in Ban Phu Kloe Khi (Burma) where metric colonies of Scleractinia
in life position have been found, we cannot speak of &#34;reef
limestone&#34; in the classic sense of the term, the limestone being
there undisputably of microbial origin also. [original introduction] 22
genera and 5 new species are described.^1";

corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Paleogene; <b>Geography: </b>Asia SE^Two contrasting major patterns
can be discerned: a Paleogene one in which diversity, endemicity and
origination rates of corals in SE Asia were low, and a post-Paleogene
one which is effectively the opposite. The change coincides with
tectonic events, especially the collision of Australia with SE Asia.
During the paleogene, the marine region between the continental margins
of SE Asia and Australia was about 3000 km wide and, compared with the
```

```
post-Neogene, there were few shallow water areas suitable for z-corals.
A much more extensive, but now largely inaccessible area of shallow
water carbonates existed in the mid-Pacific (on the Darwin
Rise/Superswell) especially during the Eocene. However, the z-coral
faunas of both regions appear to have been low diversity outposts of
the very much richer faunas of Europe, eastern Tethys and the western
Indian Ocean margins. The modern high diversity pattern in SE Asia and
the Indo-West Pacific center began to emerge around the earliest
Neogene with an apparent regional radiation of corals. However,
detailed studies are revealing that relicts, and migrations of taxa
into the region were both as qualitatively important as originations
within the region. Local originations derived, at least in part, from
these antecedent elements. The geographical complexity of the region
since the neogene favoured all three processes. Although increased
habitat heterogeneity and potential allopatric speciation amongst
fragmented shallow water areas, would have been enhanced in the last 10
Ma by the effects of glacio-eustasy and increased climatic fluctuation.
Our fossil patterns show that a Centre of Origin model (Table 1) is
completely inapplicable to Paleogene corals of the SE Asian region,
since there was only a small non-endemic fauna here. In fact, it is
misleading to think of it as a &#039;centre&#039; of any kind during
this time. This contrasts with the neogene onwards, which superficially
accords with a Centre of Origin model, though the combined patterns
from a range of different studies show that a more appropriate model
requires a combination of all three of the possibilities in Table 1. A
longer-term perspective suggests that the above contrast in Paleogene
and post-Paleogene patterns represents a cyclical sequence which has
occurred at least twice before with strong coral developments in the
late Triassic and late Jurassic in SE Asia, coincident with times when
rifted Gondwanan blocks docked against the Asian continent in the
tropics. Thus plate tectonic processes rather than intrinsic
evolutionary processes (like Centres of Origin, competitive
displacement, etc.) have been a major control on regional diversity
patterns of z-corals, and presumably also numerous other shallow marine
organisms.^1";

<b>Systematics: </b>Porifera Monera; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Indonesia, Satonda^The small crater lake of the
Island Satonda is characterized by highly alkaline conditions as a
whole probably due to an intense sulfate reduction in the deep anoxic
water body. Some portions of the highly alkaline water is penetrating
through the uppermost pycnocline and increases the alkalinity in the
upper oxic water body (alkalinity pump). The upper water body is beside
its slightly increased alkalinity (4-5 meq/l) characterized by a
decreased salinity (32 ‰). This special hydrochemical situation let to
a very specific and endemic development of the biota. Cyanobacteria and
heterotrophic microbes exhibit large diversities in contrast to just
one sponge taxon (Suberites/Polmastia n.sp.). Common are cyanobacteria
of the taxa Pleurocapsa, Phormidium, Calothrix, Spirulina, Microcoleus
```

```
and Microcystacea.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Indonesia, Satonda^The Satonda crater lake is up to now the only
known &#34;marine&#34; lake with an increased alkalinity compared to
seawater. Therefore, the lake contains a decreased amount of Ca2+. Its
pH values about 8.5-8.6. The lake was originally filled with
freshwater, which is evident from peat deposits (3,150 14C-yrs BP).
Shortly after the lake was rapidly filled with seawater and a marine
fauna had established. Large input of organic matter has caused an
intense oxygen consumption and, as a result, the bottom water of the
lake became anaerobic. Thus, an intense sulfate reduction occurred
producing high amounts of bicarbonate ions. The lake became stratified
into three water bodies with various salinities separated by two
pycnoclines. The surface water body is oxygenated and exhibits brackish
conditions. The algae/microbialite reefs exhibit a vertical development
which started with a serpulid framework, followed by loose crusts of
the calcified red alga Peyssonnelia and thalli of the green alga
Cladophoropsis calcified by cyanobacteria (microstromatolites). The top
calcified layer is formed by a network of Lithoporella, Peyssonnelia
and microbialites. On the top layer the living reef community is
located.^1";

fringing reefs in a muddy environment, South Thailand.- J. sediment.
Res. A 64, 4: 752-764.- <b>FC&#038;P 24-1</b>, p. 92,
ID=4529^<b>Topic(s): </b>reef complexes, reef growth &#038; structure;
reef complexes, muddy environment; <b>Systematics: </b>;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Thailand S^Most fringing
reefs of the SE coast of Phuket, Thailand, have wide (up to 300m)
intertidal reef flats and narrow (2-5m) reef fronts that abut the muddy
forereef only a few meters deep. These reefs prograde by splitting,
toppling, and regeneration of reef-front massive corals, notably
Porites lutea. Splitting of massive corals is greatly aided by the
boring action of Upogebia sp. shrimps and by planes of weakness
developed within the colony skeleton by nestling bivalves. The large
size of toppled blocks ensures that some of the uppermost polyps are
viable above the soupy forereef sediment surface. Cores indicate that
the reefs are essentially tabular features consisting of mainly massive
reef-front corals grown on muddy foundations that have
shallowing-upwards sediment characteristics. 14C ages and leveling data
of fossil former reef-front corals exposed on the reef flat suggest
that reef growth started in the mid-Holocene when sea level was at
least 0.8m higher than now. Since then, the rate of lateral reef
progradation has averaged 40 mm/yr. The preservation potential of these
reefs is low because of the combination of a lack of organic or
inorganic binding of the corals into a rigid frame, and the
unconsolidated nature of the underlying sediments.^1";

Sedimentary rocks of the Loei Region, Northeast Thailand: 165 pp., 15
figs, 1 tab, 30 pls; Bangkok. ISBN 9789749674512.- <b>FC&#038;P 34</b>,
p. 94, ID=1354^<b>Topic(s): </b>research history; geology;
<b>Systematics: </b>; <b>Stratigraphy: </b>; <b>Geography: </b>Thailand
NE^In the 1950s, the Department of Mineral Resources was very active in
the geologic reconnaissance of the diverse mineral deposits of Thailand
(Brown et al., 1951), but it was also interested to extend the
investigation to other geologic problems. For instance, it was eager to
find good sections of sedimentary rocks, to study their fossils, and
then, to distinguish biozones easy to correlate with the rocks of other
countries (Sethaput, 1956). An important programme started in Loei
Province and was carried out by M. Veeraburus, D. Bunnak and A.
Hongnusothi, with the cooperation of Japanese paleontologists (T.
Kobayashi, H. Igo, T. Hamada, J. Iwai, J. Yanagida). K. Pitakpaivan
(1966) studied fusulines from calcareous shale of Wang Saphung area as
well as from other localities of Thailand; he became the first Thai
paleontologist. Near Wang Saphung, Middle-Upper Carboniferous and
Permian fossils were collected in fair quantity. They were diverse and
consisted of trilobites, foraminifera, conodonts, brachiopods, and
ammonoids. They were described in many publications; see the references
of this publication. Permian plant imprints were discovered in Loei
area. In 1980 in Loei region, information on rocks older than Middle
Carboniferous was very poor. Fossils, supposed to be Devonian in age,
```

```
had been mentioned as early as 1925, but at a single locality, without
good identification and description. New research was needed; it was
undertaken under an agreement between the Department of Mineral
Resources and CCOP. New results were obtained during the first
fieldwork carried out with the cooperation of Mr. N. Nakornsri and Mrs.
B. Sektheera; they were published in CCOP Newsletter in 1981. Devonian
and Lower Carboniferous fossils had been discovered at a few
localities. Outside of the Wang Saphung area, other parts of the Loei
region appeared as also very rich in fossils and very interesting, but
they remained poorly known. Some geologists became enthusiastic for new
investigations, especially Dr. V. Suteethorn and Mr. W. Tantiweanit.
New field work led to many new discoveries of fossiliferous localities.
Later on, Mr. S. Salyapongse was happy to be involved in this research
and was eager to extend it. Dr. D. Vachard of the University of Lille
(France) has been very helpful in the identification of the
Carboniferous and Permian microfossils. Dr. B. Mistiaen and Dr. D.
Brice of the University of the University Federation of Lille are
presently studying Devonian samples collected from the Loei region and
consisting of stromatoporoids, Tabulata and some brachiopods. The study
of this publication corresponds to the programme proposed in 1956 by
Mr. V. Sethaput.^1";

(2005).- Silurian rugose corals from the Gionyama Formation, Gokasecho, Miyazaki Prefecture, Southwest Japan.- Fukuoka University Science Reports 35, 1: 11-29.- <b>FC&#038;P 33-2</b>, p. 17, ID=1094^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Japan SW^The Gionyama Formation, a unit of Silurian and Devonian rocks, is exposed in the Gokase-cho, Miyazaki Prefecture, and assigned to the Kurosegawa Terrane in Southwest Japan. Two localities from the G2 Member of the Gionyama Formation contain an abundant rugose corals fauna consisting of 17 species in 12 genera. These are: Tryplasma sp. A, T. sp. B, T. sp. C, Cystiphyllum sp., Holmophyllum sp. A, H. sp. B, Labechiellata regularis, Rhizophyllum sp. A, R. sp. B, Neobrachyelasma sp. aff. N. balchascicum, Pseudamplexus sp., Amsdenoidessp., Amplexoides sp., Strombodes sp., Nanshanophyllum sp. aff., N. typicum, N. sp. aff. N. mirandum and Ptychophyllum sp. The following genera are reported for the first time from this member: Cystiphyllum, Holmophyllum, Rhizophyllum, Neobrachyelasma, Pseudamplexus, Amsdenoides, Amplexoides, Strombodes, Nanshanophyllum and Ptychophyllum. In addition, Neobrachyelasma, Strombodes and Ptychophyllum are previously unknown from the Silurian of Japan. Of these genera in the G2 Member of the Gionyama Formation, eight commonly occur in the Upper Llandovery sequence in the Ningqiang – Guangyuan depression in the northern part of South China. In China, Nanshanophyllum indicates a middle to late Telychian age. Therefore the coral fauna from the G2 Member can be inferred to indicate a Late Llandovery age. Also, this is the second report of the co-occurrence of Neobrachyelasma and Nanshanophyllum, which previously was know only from the Ningqiang – Guangyuan depression. Neobrachyelasma is also known from Kazakhstan and the Altay area, and Nanshanophyllum has been reported from the Hunan Province in South China, Gansu Province in Qidam, Australia and Canada. Thus, the similarities of the coral faunas between the Gionyama Formation and these areas should be considered in any paleobiogeographic reconstruction of the Kurosegawa Terrane.^1";

```

```
found in the Akiyoshi Limestone Group, Southwest Japan.- Bulletin
Akiyoshi-Dai Museum of Natural History 20: 1-17.- <b>FC&#038;P
15-1.2</b>, p. 42, ID=0770^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>algae Porifera; Chaetetida; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>Japan^This paper deals with the
detailed reconstruction of a reef framework newly found in the upper
part of the Millerella yowarensis Zone of the Akiyoshi Limestone Group.
The reef framework, developed on a calc-arenitic sedimentary mound,
consists mainly of chaetetids, calcareous algae and rugose corals with
minor amount of encrusting foraminifers, bryozoans and annelid worms.
Chaetetes, the most dominant group of organisms in this framework,
played an important role as a framebuilder and a sediment trapper.
However, hard mass is indispensable for the growth of Chaetetes. In
relation with this problem, calcareous algae played as a sediment
binder at an early stage of the framework-growth. And then the soft
bottom became consolidated, providing the best condition for the growth
of Chaetetes. After the growth of Chaetetes rigid framework for the
organic reef was formed. (Original summary)^1";
s[3520] = "WEST R.R., NAGAI K., SUGIYAMA T. (2001).- Chaetetid

organisms underlying (substrate) and overlying (cover) chaetetids on
polished vertrical slabs from the Pseudostaffela antiqua and Millerella
yowarensis zones of the Akiyoshi Limestone Group are here recorded. A
total of six slabs have been examined. Two slabs were of encrusting
chaetetid algal framestone, and two of algal bindstone; one of each
lithology was from each biostratigraphic zone. The remaining two slabs,
both from the back reef slope, were of algal chaetetid boundstone from
the P. antiqua Zone.Slabs of encrusting chaetetid algal framestone were
collected from the reef crest and those of algal bindstone from the
reef flat. The facies and environment from which we have the most data
over the greatest area, are the algal chaetetid boundstones from the
bacck reef slope. Algal bindstone from the reef flat was next and the
encrusting chaetetid algal framestone from the reef crest was least
represented. Using reference grid, five by five centimeters, transects
at one centimeter intervals were made parallel to the inferred
direction of chatetid growth, i.e. as near as possible to the direction
paralleling the long dimension of the chaetetid tubules. Where
transects crossed a chaetetid mass, the substrate of that chaetetid and
what covering the chaetetid mass was recorded. The greatest diversity
in subtrate and cover occurred in the back reef slope environment. In
all polished surfaces examined, algal/microbial mats are the dominant
chaetetid substrate, and also covering strata, irrespective of reef
environment or limestone facie. These results suggest that from upper
Serpukhovian into middle Bashkirian time (the interval reflected by the
two foraminiferal zones noted above), algal/microbial mats overgrew
chaetetid sponges, but the mats also provided a suitable substrate for
subsequent chaetetid sponge colonization and growth. Although
competitive interactions are posible, it is more reasonable to suggest
that algal/microbial overgrowth occurred as part of all the sponge
tissue died as a result of disease or injury. Additionally,
algal/microbial mats, as binding agent of unconsolidated sediment,
produced a stable surface for chaetetid colonization. ^1";

A detailed correlation of the lower part of this limestone is given by the foraminiferal assemblage. Among the heterocorallian limestones, the CL3 to CL5 Zones are corelative with the upper Visean (V3b and V3c), and the CL6 Zone with the lower Namurian (E1) in Western Europe. Based on the morphological characteristics, the heterocorallian genera from the Akiyoshi Limestone are divided into two groups. One of the groups, which contains Hexaphyllia, Heterophyllia, and Pentaphyllia, is presumed to have had a living habit of attaching, to other organisms or hard objects by cementing tips of the hollow spines. The other group, containing Radiciphyllia, has had a sessile habit on the substratum by cementing talon-like attachments.^1";

It is characterized by the following points: 1) a large-sized corallite, 2) a large number of septa in two
```

```
orders, which have the trabecular microstructure, 3) conical tabulae,
4) a wide dissepimentarium with the regular dissepimental rows, and 5)
a tendency of change in axial structure of several types throughout
corallite ontogeny. * Carcinophyllum enorme (Ozawa) is also a compound
rugosan with the dendroid form. It is characterized by the following
characters: 1) a medium-sized corallite, 2) a large number of septa in
two orders, which have stout trabecular microstructure, 3) septa
dilated in both peripheral and inside ends, 4) dense tabulae of nearly
horizontal direction, 5) extremely thick stereozone with large
lonsdaleoid dissepiments, and 6) carcinophylloid axial structure. *
Nagatophyllum satoi and Carcinophyllum enorme generally form composite
colonies. [original summary]^1";
s[3536] = "IGO H., ADACHI S. (2001).- Carboniferous corals from the
Ichinotani Formation, Fukuji, Hisa Massif, central Japan.- Bulletin of
the Tohoku University Museum 1 [Proceedings of the 8th International
Symposium on Fossil Cnidaria and Porifera]: 311-319.- <b>FC&#038;P
30-1</b>, p. 11, ID=7056^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous; <b>Geography:
</b>Japan^The Ichionotani Formation exposed in the Fukuji area of
central Japan, yields abundant corals from various levels. The
formation is subdivided into lower, middle, and upper members, and its
geologic age is well controlled by fusulinacean biostratigraphy and is
of Late Early to Late Carboniferous age. The basal part of the Lower
member (late Visean to Serpukhovian) contains a prolific coral fauna,
including Heterocanina, Kueichouphyllum, Arachnolasma, Yuanophyllum,
Koninckophyllum, Lithostrotion, Siphonodendron, Dibunophyllum and
others. Neokoninckophyllum, Lonsdaleia, and Axophyllum are also above
those, still part of the lower member but dated just above the
Mid-Carboniferous boundary, yield Cladochonus and Cyathaxonia. The
middle member (early to middle Moscovian) yields Amplexocarinia,
Dorlodotia, Kionophyllum, and other taxa below, in the lower part, and
Ivanovia (s.l.), Fomichevella, Pseudozaphrentoides, and
Dibunophylloides above, characteristic of the upper. The lower part of
the upper member (late Moscovian) yields abundant Dibunophylloides and
Fomichevella, both of which occurred earlier, in the middle member. The
middle and upper parts of the upper member (Kasimovian to Gzhelien)
include two distinct coral faunas: Carinthiaphyllum and
Koninckocarinia, associated with a dendroid type of Chaetetes (B) in
the middle; and notably abundant Bothrophyllum in the upper part. The
uppermost part of the member yields Sestrophyllum. Coral faunas in the
Ichinotani (except the Onimaru-type fauna of the lower member) have not
been found in other Carboniferous sections in Japan. [original

Numerous auloporidid corals are found in many types of boundstones distributed in the reef core facies of the Akiyoshi organic reef complex in this area. The auloporidid corals usually adhere to the main reef builders or rarely to the hard substrate. The present corals are apparently divided into two forms, form A and B. The form A grows up to be a shrub-like dendroid corallum. The form B, on the other hand, reveals an encrusting corallum. These two forms, however, have the same characteristics in their corallites, such as the size of corallite, the microstructure and thickness of wall, the shape of tabulae (horizontal to convex and complete), the presence of short spinose ridges, and the absence of mural pores and connecting tubes. Furthermore, these two forms have a similarity in their young growth form, in which the corallites closely contact with each other and encrust on the surface of other organic skeletons. It is obvious from the above that these two forms represent two morphological varieties in the growth form and belong to one and the same species. Two forms of auloporidid corals are respectively found in the different types of boundstones built up under the different environments. The form A discriminated by shrub-like dendroid corallum occurs in the framestone and the bafflestone, which are mainly constructed by rugose corals. The form B characterized by encrusting corallum occurs in the framestone and the bindstone, which consist of encrusting reef-builders, such as calcareous algae and chaetetids. Accordingly, it might be stated that the two variant growth forms are recognized as the ecophenotypes in the same species of auloporidid corals. Two growth forms of the present corals show some resemblances to those of the several genera among the different families of the Order Auloporida. The convex and complete tabulae of the Minamidai species are different from those of the other genera among the Carboniferous auloporidid corals. As the result of this
```

```
study, it can be stated that the variant growth form must be taken into
consideration to classify the auloporidid corals.^1";

</b>Carboniferous; <b>Geography: </b>Japan^Tournaisian faunas of Japan
possesss certain elements colsely related to stratigraphically
equivalent faunas of Australia, the USSR, the United States, and
```

```
northern China. Upper Visean coral faunas show strong resemblance to
corals of the same age from southern China and are of the
Kueichouphyllutn province of HILL (1948). Corals of the Japanese
Silesian include both Tethyan and Boreal elements as well as many
endemic forms, but fusulinids appear to be similar to those of the
Boreal fauna of the Urals, Moscow basin, northern China, and Korea.
Volcanic rocks are dominant in the Japanese Tournaisian. There are also
Lower and Middle Carboniferous granites, the former dated by Rb-Sr as
339-332 m.y.B.P. Angular unconformities are present at the base of
Tournaisian and upper Visean deposits, and a paraconformity is present
between the upper Visean and Silesian deposits. From paleomagnetic
studies, the Japanese Islands are inferred to have shifted from north
to south during the time span ranging from Early Carconiferous until
Early Permian, and thereafter have moved generally northward. (Original
summary)^1";

</b>reefs, ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Carboniferous; <b>Geography: </b>Japan, Akiyoshi lst^The Akiyoshi
Limestone Group (Lower Carboniferous to upper Middle Permian) is a huge
exotic limestone mass containing abundant reef-building shallow marine
fossils and resting on a basement composed of basaltic lava and
volcaniclastic rock. Tectonic, sedimentologic, and paleoecologic
characteristics of the limestone sequence indicate that it represents
an organic reef complex developed on top of an oceanic seamount. Rugose
corals are among the important reef-builders and are mainly distributed
on the outer side of the reef complex. They present various growth
forms in response to habitat differences in a well defined reef facies
zonation^1";

</b>diagenesis, late mineralization; reefs, Akiyoshi lst;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous, Cretaceous;
<b>Geography: </b>Japan^Abundant euhedral of quartz were found in the
reef limestone from seven localities in the Akiyoshi Limestone area.
Quartz crystals occurred in an grainstone has an average length of
0.261 mm and width of 0.121 mm, and the average ratio between length
and width is 2.149, which means the quartz crystallized in elongate
shape under ahydrothermal environment. The quartz crystals have
different size distributions and inside structures among their host
limestone textures. Large crystals grew up in trabecula tissue of reef
building organisms, such as rugose corals and chaetetids, and small
ones in micritic matrix of coated grains. It might depend on density of
fine clucks and solubility to the hydrothermal liquid in each host
limestone texture. Quartz usually has solid calcite inclusions as
inside layers. These solid inclusions are come from remains of host
calcite tissues which unsolved during crystallization in hydrothermal
liquid. Mineralogical identification of inside layers of quartz was
done by the laser Raman microprobe. Homogenization temperatures of
primary fluid inclusions in quartz veins (from 150–220 °C.) and a
calcite vein (169,5 °C) talked that the origin of these euhedral
crystals of quartz came from a hydrothermal activity which possibly
occurred in Late Cretaceous after the intrusion of quartz porphyry in
the Akiyoshi Limestone area.^1";

limestone; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic Nor;
<b>Geography: </b>Japan^Microfacies of the Early to Middle Norian
reefal limestone of the Sambosan Accretionary Complex (SAC) at Kamase
locality, southwest Japan, are classified into seven major facies types
in stratigraphic order: peloidal grainstone-packstone, unfossiliferous
lime-mudstone, tubular problematica-rich wackestone, sponge-coral
floatstone, sponge bafflestone, coral rudstone, and peloidal-bioclastic
packstone-grainstone. The SAC records patch reef development on a
mid-oceanic seamount in the Panthalassa Ocean. Because most examples of
Triassic reefs come from the former Tethys, counterparts such as those
from the SAC are pivotal in resolving paleogeographic issues as well as
clarifying the depositional patterns between the eastern Tethys and
adjacent western Pacific (Panthalassa). We also reveal that the primary
stratigraphy of the reefal limestone was disrupted by submarine
landslides of the seamount in an open-ocean realm during the late
Middle to Late Jurassic time. [original abstract]^1";

Cnidaria, Porifera; <b>Systematics: </b>Cnidaria Porifera;
<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Japan SW^Cnidarian
and poriferan fossils were reported from the Torinosu-type limestones
in the middlemember of the Ikenoue Formation, Kurosegawa Terrane,
westeren Kii Peninsula, Southwest Japan.They include 16 species
belonging to 13 genera (nine Scleractinia, one Spongiomorphida,
oneSclerospongia, and two Stromatoporoidea). The recorded cnidarian and
poriferan fauna shows LateJurassic in age, and the age estimation is
consistent with the radiolarian chronostratigraphic data ofthe
fine-grained clastic rocks enclosing the Torinosu-type limestones.
Field observations suggestthat the Torinosu-type limestone bodies were
originally formed as laterally discontinuous carbonatemounds in shallow
```

```
marine environment, and they were broken in part into blocks and
transporteddownwards. Torinosu-type limestones associated with
fine-grained clastic rocks are widelydistributed in the Tithonian to
Berriasian strata of both the Kurosegawa and Southern Chichibuterranes
in the western Kii Peninsula. It has been discussed that shallow marine
carbonateenvironment was formed as a result of uplift of the fore-arc
basin caused by collision of seamounts.Furthermore, thrust movement of
the Kurosegawa nappe over the Southern Chichibu Terraneaccummulated
thick olistostrome on the fore-arc basin during the middle Oxfordian
toKimmeridgian, resulting in the formation of shallow marine
environment.^1";

Jurassic-lowermost Cretaceous reef limestone (Torinosu Limestone,
Southwest Japan).- Facies 50, 2: 217-227.- <b>FC&#038;P 34</b>, p. 91,
ID=1339^<b>Topic(s): </b>reefs encrusters, microencrusters; reefs
encrusters; <b>Systematics: </b>Monera; <b>Stratigraphy: </b>Jurassic
&#47; Cretaceous; <b>Geography: </b>Japan^Tethyan microencrusters and
microbial crusts, most of them previously unknown in Japanese Mesozoic
biotas, are present in the uppermost Jurassic–lowermost Cretaceous
Torinosu Limestone distributed in southwestern Japan. They construct
reefal facies together with reef-forming metazoans. Bacinella
irregularis and Lithocodium aggregatum are quantitatively most
important, while subordinate constituents include Thaumatoporella
parvovesiculifera, Koskinobullina socialis, Iberopora bodeuri,
Girvanella sp. and Tubiphytes morronensis. They are especially common
in the shallow-water reefal facies, but appear micritic in outcrops.
Microencrusters and microbial crusts can only be recognized in thin
sections, and they grow around the reef building metazoans and form
bindstone. Each microencruster exhibits some specific spatial
distribution associated with its paleoecology. Similarities with the
taxonomic composition of the upper Jurassic Tethyan microencruster
association imply that the community extended geographically at least
to the Tethyan gateway where the Japanese Island Arc was located.

p. 42, ID=1194^<b>Topic(s): </b>freshwater; Porifera; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>Japan^Fossils of spongillid sponges, Eunapius fragilis and
Ephydatia muelleri occur in the MiddlePleistocene Tsumori Formation in
Mashiki-machi, Kumamoto Prefecture, Japan. This is the 2nd record of
Eunapius fragilis and Ephydatia muelleri from the Pleistocene in Japan.
The Tsumori Formation consists of a lacustrine sediment which contains
fossils of diatoms, plant fragments, sponges, molluscs, insects, and
fish. The fossil sponges occur in the lower part of the Tsumori
Formation that is subdivided into the lower and upper parts with
lithological characters. The fossils are found on the surface of plant
fragments and in massive mudstone. Those occurrences suggest that the
sponges were rapidly deposited after death of the sponge. If the
habitat of the sponges have not changed over time, the fossil sponges
from the lower part of the Tsumori Formation is inferred to have been
formed in shallow lake with waters of high mineral and organic
contents.^1";

stratigraphy; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Pleistocene; <b>Geography: </b>Japan, Ryukyu Isls^Sedimentological
investigations were conducted on Pleistocene reef-complex deposits of
the Ryukyu Group, recovered in 30 drill cores from Ie-jima, off Motobu
Peninsula, the Ryukyu Islands, southwestern Japan. Four depositional
units are identified by lithologic changes and numbered sequentially
from the base upwards. Unit 1, the lowest unit, commonly begins with
marine conglomerate or coral limestone, both of which grade upward into
detrital limestone containing abundant larger foraminiferal tests
(Operculina spp. and Amphistegina spp.). Units 2 and 3 are composed of
```

```
shallow-water coral limestone overlain by deep-water detrital and
rhodolith limestones. Unit 4, unconformably overlying Unit 3 at
elevations exceeding 50m, consists of coral limestone grading upward
into detrital limestone rich in coral rubble. These units clearly
display a deepening-upward stratigraphic succession. Calcareous
nannofossil biostratigraphy indicates that Unit 1 mostly correlates
with the Early Pleistocene between 0.85 Ma and 1.65 Ma and that Units 2
to 4 range in age from 0.41 Ma to 0.85 Ma. Thick deposits of carbonates
and siliciclastics (Unit 1) formed in response to tectonic subsidence
of this area before 0.85 Ma. Subsequently, reefal and shelf carbonates
(Units 2 to 4) accumulated in response to glacioeustatic sea-level
changes. The change is likely to be related to the Mid-Pleistocene
Transition (MPT). The MPT at the Ryukyus is marked by increased
amplitude of sea-level changes and a subsequnet enhanced mode of
coral-reef deposition. [original abstract]^1";

</b>Pleistocene Recent; <b>Geography: </b>Japan^Numa coral bed of
Tateyama city is famous for Japanese Geologists, because of its well
studied fossil corals and known as only one Pleistocene reef formation
in Honsyu. Since July 1969 we have often chances to study the
localities and obtained several fossil and recent specimens of corals.
Some 100 species of corals were known to occur there, judging from the
growth form, especially abundant Echinophyllia, Pectinia and other thin
explanate delicate forms it belongs evidently [to] calm inland bay
facies. Among them following two species of southern form were
discovered as first fossil occurrence. Palauphyllia hataii is a
Lobophyllid coral and its distribution is now restricted in the
tropical or subtropical sea (Loc. Palau Islands, Pracer Islands and
Ogasawara Islands). Koseleya sp. is similar to Moseleya latistellata of
the Great Barrier Reef, but much smaller in size and much larger than
M. minor Ma (nom. nud.). Echinophyllia, Acropora, Caulastrea are
illustrated here as fossil. Several ahermatypic corals thriving the
continental shelf of Chiba pref. were listed here for the future study
of fossil corals of the younger cenozoic formations of Kwanto district,
and others.^1";

```

```
Anthozoa; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Japan, Ryukyu
Isls^Investigations were conducted on bathymetry, reef biota and
sediments on the Hirota Reef, Tane-ga-shima, North Ryukyus, near the
northern limit for coral-reef formation. A bathymetric profile from
shore to the reef edge was depicted along an approximately 420-m
transect on the Hirota Coast of this island. A total of 20 quadrats (1m
× 1m) were analyzed along the profile at 10- or 20-m intervals to
clarify distribution of macrobenthos inhabiting the reef. The Hirota
Reef is divided into four geomorphologic zones according to their
depth, gradient, surface roughness, substrate and characteristic
macrobenthos. They are, from shore to offshore, shallow lagoon, seaward
reef flat, reef edge and reef slope. The shallow lagoon comprises a
shoreward depression (~160m wide on the transect) with a sand/gravel
bottom that inclines gently toward offshore, and a seaward patch zone
(~70m wide). The patches (<2m high) are covered with fleshy algae,
coralline algae and hermatypic corals. The seaward reef flat (~190m
wide) is a flat plane that is constructed by biogenic carbonates and is
covered with turf algae, with hermatypic corals scattered. Although the
seaward reef flat of the Hirota Reef cannot be differentiated into
different geomorphologic zones, similar seaward reef flat areas in the
Central and South Ryukyus can be clearly subdivided into inner reef
flat, reef crest and outer reef flat. This difference may be attributed
to a lower reef growth rate and/or the later reef formation of the
Hirota Reef in Holocene time than the southern examples. The coral
fauna on the Hirota Reef is delineated by low diversity and
characterized by taxa typical of high-latitude, non-reefal communities.
The algal flora consists of tropical to subtropical species associated
with warm-temperate species. These faunal and floral characteristics
may be related largely to lower water temperature in Tane-ga-shima than
those in typical coral-reef regions. [original abstract]^1";

MUTTI M. (2006).- Introductory perspective on the COREF project.-
Island Arc 15, 4: 393-406.- <b>FC&#038;P 34</b>, p. 83,
ID=1322^<b>Topic(s): </b>reefs, ecology, geohistory; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Quaternary; <b>Geography:
</b>Japan, Ryukyu Islands^Coral reefs are tropic to subtropic, coastal
ecosystems comprising very diverse organisms. Late Quaternary reef
deposits are fossil archives of environmental, tectonic and eustatic
variations that can be used to reconstruct the paleoclimatic and
paleoceanographic history of the tropic surface oceans. Reefs located
at the latitudinal limits of coral-reef ecosystems (i.e. those at
coral-reef fronts) are particularly sensitive to environmental changes
- especially those associated with glacial-interglacial changes in
climate and sealevel. We propose a land and ocean scientific drilling
campaign in the Ryukyu Islands (the Ryukyus) in the northwestern
Pacific Ocean to investigate the dynamic response of the corals and
coral-reef ecosystems in this region to Late Quaternary climate and
sealevel change. Such a drilling campaign, which we call the COREF
(coral-reef front) Project, will allow the following three major
questions to be evaluated: (i) what are the nature, magnitude and
driving mechanisms of coral-reef front migration in the Ryukyus? (ii)
what is the ecosystem response of coral reefs in the Ryukyus to
Quaternary climate changes? (iii) what is the role of coral reefs in
the global carbon cycle? Subsidiary objectives include: (i) the timing
of coral-reef initiation in the Ryukyus and its causes; (ii) the
position of the Kuroshio current during glacial periods and its effects
on coral-reef formation; and (iii) early carbonate diagenetic responses
as a function of compounded variations in climate, eustacy and
depositional mineralogies (subtropic aragonitic to warm-temperate
calcitic). The geographic, climatic and oceanographic settings of the
Ryukyu Islands provide an ideal natural laboratory to address each of
these research questions. [original abstract]^1";
```

```
s[3609] = "SASAKI K., OMURA A., MIWA A., TSUJI Y., MATSUDA H., NAKAMORI
T., IRYU Y., YAMADA T., SATO Y., NAKAGAWA H. (2006).- 230Th/234U and
14C dating of a lowstand coral reef beneath the insular shelf off Irabu
Island, Ryukyus, southwestern Japan.- Island Arc 15, 4: 455-467.-
<b>FC&#038;P 34</b>, p. 91, ID=1338^<b>Topic(s): </b>reefs,
geochronometry; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Holocene; <b>Geography: </b>Japan, Ryukyu Isls^High-resolution
seismic reflection profiles delineated the distribution of mound-shaped
reflections, which were interpreted as reefs, beneath the insular shelf
western off Irabu Island, Ryukyus, southwestern Japan. A sediment core
through one of the mounded structures was recovered from the sea floor
at a depth of -118.2m by offshore drilling and was dated by radiometric
methods. The lithology and coral fauna of the core indicate that the
mounded structure was composed of coral-algal boundstone suggesting a
small-scaled coral reef. High-precision a-spectrometric 230Th/234U
dating coupled with calibrated accelerator mass spectrometric 14C ages
of corals obtained reliable ages of this reef ranging from 22.18 ± 0.63
to 30.47 ± 0.98 ka. This proves that such a submerged reef was formed
during the lowstand stage of marine oxygen isotope stages 3-2. The
existence of low-Mg calcite in the aragonitic coral skeleton of 22.18 ±
0.63 ka provides evidence that the reef had once been exposed by
lowering of the relative sealevel to at least -126m during the last
glacial maximum in the study area. There is no room for doubt that a
coral reef grew during the last glacial period on the shelf off Irabu
Island of Ryukyus in the subtropical region of western Pacific.

different islands exhibit two contrasting trends along reef flats: a
shoreward decrease on Ishigaki and Tane-ga-shima Islands and a
shoreward increase on Kudaka Island. A total of 25, 24 and 13
foraminiferal taxa were identified in Ishigaki, Kudaka and
Tane-ga-shima Islands, respectively. Baculogypsina sphaerulata,
Neorotalia calcar and Amphistegina spp. were dominant (i.e. >3% of
foraminiferal assemblages) in the three islands. Calcarina gaudichaudii
and Calcarina hispida were common on Ishigaki and Kudaka Islands but
were absent on Tane-ga-shima Island. Larger foraminiferal assemblages
from three different reef-flat environments on Ishigaki Island can be
distinguished, whereas those from the three environments on Kudaka and
Tane-ga-shima Islands are similar in composition. These latitudinal
changes in larger foraminiferal assemblages in reef sediments may
possibly be caused by variations in the topography of reef flats,
distributions and standing crops of living foraminifers on reef flats,
and the northern limit of some calcarinid species in the northern
Ryukyus. [end-fragment of extensive abstract]^1";

(2003).- Holocene sea-level change and tectonic uplift deduced from
raised reef terrace, Kikai-jima, Ryukyu Islands, Japan.- Sedimentary
Geology 159, 1-2: 5-25.- <b>FC&#038;P 34</b>, p. 92,
ID=1346^<b>Topic(s): </b>reefs, eustacy, tectonic uplift; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Holocene; <b>Geography:
</b>Japan, Ryukyu Isls^Kikai-jima (Kikai Island) is surrounded by four
Holocene raised coral reef terraces, which are thought to be an
offlapping sequence of reef deposits caused by combined effects of
seismic uplift and Holocene sea-level change. Many studies in this
region have investigated Holocene sea-level changes and reef growth,
but there are relatively few in which reliable sea-level indicators are
given. We have found that Pocillopora verrucosa, one of the most
```

```
abundant coral species on the upper-reef slopes of fringing reefs in
the Ryukyus, has its peak abundance at a depth of 1.5m. Therefore, this
species is considered ideal for the analysis of relative sea-level
change and can be used as a dipstick for the Holocene reef deposits in
this area. Based on the distribution of P verrucosa on the four
Holocene raised terraces, we calculate relative paleo-mean sea levels
to be 10.8-11.1 and 8.5-8.9 m for Terrace I, 5.0-5.3 m for Terrace II,
4.0-4.3 m for Terrace III and 1.9-2.5 m for Terrace IV. These results,
combined with hitherto known and newly measured radiometric dates (103
total), clearly show that the four terraces formed in response to
repeated seismic uplifts at 6.3, 4.1, 3.1 and 1.4 ka, and that sea
level was higher than present between 7.0 and 6.3 ka. [original

s[3612] = "YAMANO H., KAYANNE H., YONEKURA N. (2001).- Anatomy of a
modern coral reef flat : A recorder of storms and uplift in the late
Holocene.- Journal of Sedimentary Research 71, 2: 295-304.-
<b>FC&#038;P 30-1</b>, p. 31, ID=1555^<b>Topic(s): </b>reefs, storms,
eustacy; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Holocene;
<b>Geography: </b>Japan^Cores from the Kabira Reef, Ishigaki Island,
southwest Japan, reveal the internal structure and temporal changes in
sedimentary process of a complete coral reef flat. The reef crest
caught up with sea level at about 4000 yr BP. Since then, it expanded
oceanward and the reef pavemant has grown landward. The backreef
structure is composed of bioclasts derived from the reef framework. Of
all the bioclasts, corals and coralline algae are most abundant. Coral
fragments coarser than - 3,0 ø have dominated the backreef sediments
since 2000 yr BP. Benthic foraminiferal tests first occurred at about
4000 yr BP, and their abundance increased significantly starting around
2000 yr BP. Shallowing of the reef crest is also indicated by the
presence of the shallow-water benthic Foraminfera Baculogypsina
sphaerulata tests after 2000 yr BP. The date 2000 yr BP is coincident
with tectonic uplift at Kabira Reef (Kawana 1989). We consider this
uplift to have caused a relative sea-level fall that aided the
deposition of coral fragments transported from the reef pavement by
storms. The relative sea-level fall also caused subaerial exposure of
the reef crest during low tides and the transition of reef-building
organisms from corals to shallow-water species of benthic Foraminifera,
resulting in a change noticeable in the constituents of backreef
sediments. The results of this study suggest that the coral reef flat,
and especially the backreef, can be a faithful recorder of relative
sea-level changes.^1";

</b>reefs intra-oceanic; reefs, oceanic settings; <b>Systematics:
</b>Monera; <b>Stratigraphy: </b>Carboniferous, Permian; <b>Geography:
</b>Japan, Panthalassa^This contribution emphasizes the significant
rock-building role of microbial encrusting organisms including
Tubiphytes, filamentous cyanobacteria (mainly Girvanella and
Ortonella), and Archaeolithoporella in the Carboniferous to Permian
buildups that formed on seamounts in the Panthalassa ocean. The
description concentrates on the paleontological characters of these
microbes and the petrographic properties of the microbial bindstones
and related cryptomicrobial fabrics. Comparisons of major rock-building
biotas in the Carboniferous-Permian Panthalassan buildups and Parigean
reefs are briefly discussed. The Lower Carboniferous (Visean) to upper
Middle Permian (Murgabian) limestone units and the upper Lower to upper
Middle Permian (Artinskian to Murgabian) limestone units in southwest
Japan were examined. All these limestone units are underlain by oceanic
island-type basalts and are totally free from terrigenous materials.
The limestones are lying in disrupted accretionary terranes of Japan
and are regarded as relicts of oceanic buildups upon seamounts in the
Panthalassan open-ocean realm. [first fragment of extensive summary]^1";

</b>reefs; reefs; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>Cambrian M; <b>Geography: </b>Iran N^Middle and
Late Cambrian reefs were built mainly by cyanobacterial communities. A
few reefs with a metazoan as well as an algal component, however, are
known from this interval. A Middle Cambrian reef formed primarily by
spicular demosponges is described here from the Mila Formation in the
```

```
Elburz Mountains, northern Iran. The reef is enclosed within calcareous
grainstones which contain terminal Middle Cambrian (late Mayan)
trilobites. The Mila Formation reef was constructed by sponges of the
family Anthaspidellidae and bacterial (algal?) sheaths, and is the
earliest metazoan reef to be documented from the interval after the
demise of archaeocyath sponges. The reefal community is typical of
subsequent reefal communities of Early-Middle Ordovician age. The
Ordovician examples differ only by the incorporation of additional
metazoan elements.^1";

mounds; Porifera, reefs; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Cambrian M - U; <b>Geography: </b>Iran N^Middle to Upper Cambrian
sponge mounds occur in shallow marine carbonates, (the Mila Formation)
of the southern Elburz Mountains, northern Iran. The mounds are up to
6m thick, with a 30m diameter, and have low, rigid frameworks formed by
a single species of the demosponge genus Rankenella and microbial
micrite. The mound bearing unit mainly consists of coarse grained
crinoidal grainstone, less than 70m in thickness, and includes
brachiopod shell beds and oncoids. Cross stratified and lenticular
grainstone units indicate shoaling. During the development of the
carbonate shoal, water energy increased and the shoal was cut off from
terrigenous influx. Stabilization by brachiopods or early lithification
may have provided favorable substrates for sponge colonization. The
sponges probably adapted to a clear, strong water flow, which provided
an effective nutrient supply, thus inhabiting the environment
previously occupied by archaeocyaths. These Iranian mounds represent
the oldest reef building by a non archaeocyath sponge community (Hamdi
et al., 1995). Middle to Late Cambrian reef building in other
localities generally is by microbial thrombolites and stromatolites.
Although the Iranian mound community is very simple, it is regarded as
an ancestor of Early Ordovician sponge microbial reefs. [original

and Kerman regions; de Lapparent collection) and central Iran (Soh
region, Zahedi collection), fourteen species are described. From
Silurian, one species is attributed to Araeopoma (first citation
outside the type-area: Gotland) and on to Axolasma. Ten are Devonian
and have been yielded by the same stratigraphic level which is Lower to
Middle Frasnian in age (Brachiopod zone 6 of Brice 1977). They are: two
Disphyllum species (one is Disphyllum caespitosum tricyclicum von
Schouppé, 1965); two Hexagonaria species also found in Afghanistan; One
species of Cystihexagonaria with, where septal thickening is
noticeable, large monacanths of Hexagonaria- type; two Macgeea species;
Temnophyllum lapparenti nov. sp.; Sinodisphyllum sp. and Peneckiella ?
cf. cylindricum (Yoh, 1937). From Carboniferous, Sinophyllia cylindrica
and from Permian Polytehcalis cf. denticulatus are also included.
Affinies of the Devonian corals are with those of Afghanistan and
Chitral. ^1";

Devonian corals of the Adapazari area, NW Turkey.- Senckenbergiana
lethaea 68 1/4: 263-303.- <b>FC&#038;P 17-1</b>, p. 25,
ID=2134^<b>Topic(s): </b>biostratigraphy; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian M; <b>Geography:
</b>Turkey NW^As an introduction to the geology of the Devonian of the
area of the town of Adapazari, NW Turkey, the geological position of
the Alabalik Member at the base of the Yilanli Formation is outlined by
reference to its type section (O. Kaya). At its type locality the
Alabalik Member contains a relatively well-preserved fauna of rugose
and tabulate corals which are described herein for the first time (R.
Birenheide). The majority of the 16 currently recognized species are
conspecific with described taxa or comparable with such species, of
which the bulk of occurrences have been recorded from the Middle
Eifelian of Eurasia and N Africa; therefore the Alabalik Member is very
probably of the same age. The following species are new: Xystriphyllum
kayai n.sp., Dohmophyllum bulbosum n.sp., Favosites dorotheae n.sp.,
Mariusilites osmanicus n.sp., Mesolites interruptus n.sp. and
Heliolites asiaeminoris n.sp.^1";

(Esfahan Province, central Iran).- Annales de la Societe geologique du
Nord 8 (2eme serie): 67-71.- <b>FC&#038;P 30-1</b>, p. 26,
```

```
ID=1536^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>Iran^Three
rugose coral species are described from collections made in the two
biostromes of Kuh-e-Kaftar section n°2, at Chariseh, Esfahan province,
central Iran: Disphyllum sp. 1, Hexagonaria cf. magna (Fenton &#038;
Fenton, 1924), sensu Brice, 1971 and Temnophyllum lapparenti Rohart,
1999. This coral level is an interesting stratigraphic marker since it
also occurs in eastern Iran and in Afghanistan with the same coral
species and with brachiopods characteristic of the 6th Brachiopods Zone
of Brice (1977), as here. In central Iran, Hexagonaria cf. magna was
formerly found in the Soh area (Rohart 1999) but without associate
fauna. The age is lower to middle Frasnian according to the
brachiopods; according to the conodonts, it is inside the interval
&#034;middle to late Frasnian (jamieae Zone to rhenana Zone)&#034;
(Ghomalian 1998).^1";
s[3644] = "GHODS P. (1982).- Rugose Korallen des Givetium und Frasnium
im Elburz-Gebirge (Nord-Iran).- Diss. Univ. Hamburg 171 pp., 11 figs.;
Hamburg. [German, English summary].- <b>FC&#038;P 16-1</b>, p. 59,
ID=1960^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography: </b>Iran,
Elburz^Givetian and Frasnian corals (Rugosa) of four sections from the
Devonian Khoshyeilagh-Formation in North-Iran (Elburz) were
palaeontologically studied. 16 genera and 25 species were
systematically described. 12 species belong to the Givetian and 10
species to the Frasnian. Three species indicate upper Givetian to lower
Frasnian range. By these species definite Givetian was identified and
definite Frasnian was confirmed in the Khoshyeilagh-Formation. Eifelian
age could not be identified because none of the examined sections
delivered any definite Eifelian coral. The Devonian corals manifest an
evolution from lower Givetian to upper Frasnian in the Elburz. The
sections were correlated according to the biostratigraphic and
lithological facts. Ontogenetic studies demonstrate that species within
one genus have similar ontogenetic development. Studies of phylogenetic
evolution indicate that species within one genus (f. ex. Disphyllum,
Heliophyllum) derive from each other or replace one another. Ecological
circumstances permit relatively good conditions for the evolution of
Devonian corals in the shelf-region. [original summary]Described are
the following species: Disphyllum caespitosum, D. cf. geinitzi, D.
virgatum, D. lazutkini, D. caespitosun caespitosum, D. hsianghsienense
kostetskae, Ceratophyllum dohmi, Charactophyllum nanum, Heliophyllum
halli, H. shinnery, H. aiense, Temnophyllum cf. richardsoni, T. cf.
difficile, Columnaria sulcata, Donia laxa, Hexagonaria cf. philomena,
H. cf. hexagona, Macgeea cf. proteus, M. cf. bathycalyx kasimiri,
Stringophyllum cf. inflatum, Thamnophyllum caespitosum, Spongophyllum
imperfectum, Aulacophyllum vesiculatum, Tabulophyllum gracile,
Scenophyllum sp.^1";

<b>Geography: </b>Afghanistan^Volume 1 is largely stratigraphic but its
6th part includes a summary of the biostratigraphy of the 28
stromatoporoid taxons that occur in these sections. Volume 2 is devoted
to the stromatoporoids and discusses their stratigraphic distribution
in Afghanistan and the relationship of the fauna to other Frasnian and
Givetian faunas. In the systematic section species of the following
genera are described and figured: Actinostroma (5), Atelodictyon (4),
Bifariostroma (1), Anostylostroma? (1), Pseudostictostroma (1),
Clathrodictyon (1), Clathrocoilona (2), Stictostroma (3),
Stromatoporella (1), Gerronostroma (1), Atopostroma (1), Stromatopora
(2), Salairella (1), Taleastroma (3), Habrostroma (2), Hermatostroma
(3), Stachyodes (3), Euryamphipora (1), Labechia (1). Only two of the
species are new (Atelodictyon dewalense, Hermatostroma afghanense).
Most genera are discussed at length and several are placed in
synonymy.^1";
s[3651] = "MISTIAEN B. (1999).- On some Devonian (Frasnian)
stromatoporoids from Kerman province, eastern Iran.- Annales de la
Societe geologique du Nord 7 (2eme serie): 33-44.- <b>FC&#038;P
30-1</b>, p. 33, ID=1521^<b>Topic(s): </b>; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian Fra;
<b>Geography: </b>Iran^The present study is based on material
consisting of twenty or so stromatoporoid pecimens collected by de
Lapparent at the beginning of the seventies in Kerman Province (Bidu
```

```
River and Ab-Bid sections) in east-central Iran. Although
stromatoporoids have been noted several times in the Devonian of Iran,
until now, no systematic studies have been published. However,
Actinostroma stellulatum Nicholson 1886a was identified from the Tabas
area by Flügel (1961) and Amphipora sp, was cited from the Kerman area
by Wendt et al.(1997). The following stromatoporoid species have been
recognized and are here described: Actinostroma filitextum Lecompte,
1951, A. sp., Stictostroma saginatum (Lecompte, 1951), S. brylkini
(Yavorsky, 1955), Clathrocoilona cf. inconstans Stearn, 1962, C. sp.,
Dendrostroma sp., Hermatoporella cf. pertabulata (Zukalova, 1971),
Habrostroma dubia (Lecompte, 1952), H. sp., Stachyodes costulata
Lecompte, 1952, and Stachyodes australe (Wray, 1967). This
stromatoporoid fauna clearly shows very close relations with the
Frasnian Afghan stromatoporoid fauna recognized by Mistiaen (1985) in
the Central Mountains and in the Axial zone, and more generally with
the well-known very cosmopolitan Frasnian stromatoporoid fauna of the
Old World Realm (Brice et al. 1999).^1";

microproblematica; <b>Systematics: </b>algae; <b>Stratigraphy:
</b>Carboniferous Vise - Serp; <b>Geography: </b>Turkey NW^The
taxonomic revision of the carbonate microbiota of the limestone lenses
intercalated into the Carboniferous siliciclastic series of Balia-Maden
(Turkey) shows that most lenses are early or middle Brigantian in age
(latest Visean), only a single lens being of younger age (late
Serpukhovian). Calcareous microbiota are abundant in the Balia-Maden
lenses carbonates. Microfacies analysis shows the dominance of shallow
water environments. The Brigantian assemblage is accurately
illustrated. The new foraminiferal taxon Cribrospira baliamadeni nov.
sp. is morphologically similar to type-material of Cribrospira panderi
von Moller, but has a porous wall with wider pores, almost keriothecal.
C. baliamadeni nov. sp. corresponds to the misinterpreted Bradyina and
Janischewskina of the previous literature on Balia-Maden lenses. These
limestones show a great diversity of algosponges (carbonate
microproblematica). Among them, (1) small, atypical Fasciella
previously confused with Eosigmoilina; (2) an abundant form described
for the first time, Frustulata reticulata nov. sp.; and (3) typical
Falsocalcifolium punctatum (Maslov), important for the biostratigraphic
implications, are also mentioned. The single Serpukhovian lens consists
of a grainstone and contains the age-sensitive alga Archaeolithophyllum
johnsoni Racz, and the foraminifers Monotaxinoides gracilis and
Janischewskina sp. [original abstract]^1";

<b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Egypt,
Sinai^The Lower Carboniferous (Visean) succession of the Um Bogma
Formation at Gabal Nukhul, west-central Sinai is subdivided into lower,
middle and upper members. Integrating field observations and
microfacies analysis led to the recognition of six microfacies as
follows: wackestone/packstone, packstone/grainstone, grainstone,
bafflestone, calcareous quartz arenite and paleokarst breccia. The
paleokarst breccia is the first record to indicate an Early
Carboniferous karstification in the Gabal Nukhul area. During the Early
Carboniferous (Visean) marine transgression, the lower member of Um
Bogma Formation was deposited in intertidal to shallow subtidal
environments. A marked drop in sea level and/or synsedimentary block
faulting (uplifting) let to subaerial exposure of the lower member and
followed by karstification process (paleokarst surface). The middle
member was deposited in an open platform environment followed by
shallow subtidal facies of the upper member. The uniform stacking
pattern of the middle and upper member&#039;s facies implies a
characteristically regressive trend throughout the studied area. The
abundance of oolitic deposits together with chlorozoan assemblage
within the Um Bogma Formation indicates that the Lower Carboniferous
sediments of Sinai were deposited in the lower subtropics region.^1";

Sinai^The study of Carboniferous successions in the Um Bogma and Abu
Durba areas of west-central Sinai yielded 70 species of brachiopods,
corals, bryozoans, molluscs and trace fossils, 10 which are new to
Sinai. The distribution of these fossils suggests the presence of three
macrofaunal biostratigraphic units within distinctive lithofacies: a
Middle-early Late Visean coral/brachiopod assemblage in the Um Bogma
formation, a Serpukhovian-Bashkirian brachiopod/trace fossil assemblage
in the Abu Thora Formation and an Early Moscovian brachiopod/bryozoan
assemblage in the Abu Durba Formation. The fossil Associations indicate
that the Carboniferous sequence of Sinai was deposited in a subtropical
epicontinental sea inferred to have covered a greater area in northern
Africa. The palaeoecological conditions and the palaeobiogeographic
relations of this macrofauna to the Carboniferous Palaeothethys Realm
are discussed. [the following corals of the Um Bogma formation are
figured (pl. 4): Clisiophyllum garwoodi (Salee 1913), Amplexizaphrentis
enniskilleni (Edwards &#038; Haime 1851), A. palmatus (Easton 1944) and

Reefal Blocks (Hawasina Compelx, Oman Mountains): Implications for Reef
Degradation.- Facies 35: 133-142.- <b>FC&#038;P 25-2</b>, p. 46,
ID=3134^<b>Topic(s): </b>bioerosion; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian U; <b>Geography:
</b>Oman, Oman Mts^Rugose corals are known from allochthonous Late
Permian reefal blocks of the Al Jil and Ba&#039;id Formation (Hawasina
Complex), Oman Mountains. In contrast to many Late Permian Rugosa found
elsewhere in the Tethys, they occurred in sponge reefs and contributed
to reef construction. The waagenophyllid warm water coral fauna is
moderately diverse comprising cerioid, thamnasterioid, and fasciculate
taxa. In contrast to sponges, chaetetids, and low-growing reefbuilders,
```

```
the corals secreted diagenetically stable, most probably Mg-calcitic
skeletons. Borings in coral skeletons are consequently well preserved
providing important data for the interpretation of reef destructive
processes. Thin-section analysis revealed three taxa of infaunal borers
including Entobia Bronn 1837, uncertain thallophyte borings, and
borings of unknown bioeroders. Macroborers were more important than
microborers, because of the dominance of clionid sponges. Good evidence
exists also for the occurrence of two types of undetermined grazers
which destroyed the coral surfaces. The amount and distribution of
bioerosion is variable among different coral taxa. The fasciculate
coral Praewentzelella regulare Fluegel 1995 was the favorate substrate.
Up to 33% of the calices were bored. Dendroid and compound corals were
bored subordinately. Bioerosion of these colonies does not exceed 2%.
There is good evidence for substrate preference amongst the borers.
Major controlling factors affecting borer distribution are believed to
be variations of skeletal density and gross morphology. The borer
assemblage could not limit reef accretion significantly. Factors
controlling boring activity might have been quality of substrate,
sedimentation rate, rapid incrustation of substrates, and competition
for food with reef constructors including sponges, chaetetids, and
rugose corals.^1";

</b>extinctions P/T; Rugosa, Pentaphyllum; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian U; <b>Geography:
</b>Iran^Solitary rugose corals (plerophyllids) are known to have
flourished in the Upper Permian in the Abadeh and Julfa regions of
Iran. They are phylogenetically one of the last representatives of
Rugosa. Among them, of special interest are the two small-sized and
simply constructed species (Pentaphyllum breviseptum and P. minimum).
Morphological changes during ontogeny, intraspecific variability, and
their comparisons with those of other species, suggest that both
species are phylogenetically related to P. leptoconicum from which they
were independently derived. During the Late Permian, both Pentaphyllum
breviseptum and P. minimum followed an adaptive strategy:
paedomorphosis, in order to survive under unfavourable conditions. The
heterochronic change and the resultant variability closely interacted
with palaeoecological conditions. Each species showed different
morphological modifications within the inherited phylogenetic
constraint characteristic of Rugosa. No further improvements finally
appeared to combine &#34;adaptation&#34; to the prevailing,
unfavourable environments. The latest Permian rugose corals failed to
break through the phylogenetic constraint, resulting in their
extinction.^1";

Transcaucasus^At the end of the Permian, many Palaeozoic organisms,
including the Rugosa, became extinct. The marine Upper Permian yields
```

```
relict groups within Rugosa. The Abadeh and Julfa regions, Iran and
Transcaucasus in the West Tethys are the important case areas for
elucidating the end Permian extinction patterns of Rugosa. Permian
Rugosa in those areas showed distinct disappearance patterns
morphologically and taxonomically. The disappearance of Yatsengia and
Wentzelellinae was succeeded by that of Waagenophyllinae, and
Plerophyllidae were last to disappear. Each event boundary is marked by
changes in sedimentary conditions and is associated with prominent
biofacies changes in fusulinids, smaller foraminifers and so on, some
of which were global and coeval. The disappearance pattern of corals in
Iran and the Transcaucasus was sequential in abundance and composition,
owing to successive selection caused by progressively more adverse,
local habitat changes under pelagic to littoral [conditions]. However,
similar faunal successions appeared in different places and synchronous
geological events, such as sea-level changes and volcanism, were
prevailing over areas. Not only single and/or local environmental
conditions, but global factors having multiple interactions could
produce such characteristic faunal successions.^1";

Perm Afghanistans.- FC&P 13, 2: 30.- <b>FC&#038;P 13-2</b>, p. 30,
ID=6371^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>Afghanistan^Olaf Otto Dillmann arbeitet im Rahmen einer
Dissertation an der Untersuchung permischer Rugosa aus Afghanistan. Das
zu untersuchende Material stammt aus dem Mittelperm Ost-Afghanistans.
Es handelt sich um eine Aufsammlung von Prof. G. Mennesier, Amiens. *
Im folgenden soll ein kurzer Zwischenbericht uber den Stand der
bisherigen Arbeit gegeben werden. Die Untersuchung beschrankt sich auf
kolonial auftretende Rugosa. Dabei handelt es sich ausnahmslos um
Formen aus der Familie der Waagenophyllidae. So konnten bislang mit
Sicherheit folgende Arten festgestellt werden: (1) Unterfamilie
Wentzelellinae - Lonsdaleiastraea typica Gerth, L. cf. vinassai Gerth,
Wentzelella (Wentzelella) wynnei (Waagen &#038; Wentzel), Wentzelella
(Szechuanophyllum) szechuanensis Huang, W. (S.) kitakamiensis Yabe
&#038; Minato, Wentzelloides (Battambangina) frechi (Volz), W.
(Multimurinus) n.sp., Polythecalis chinensis (Girty); Arten der Gattung
Wentzellophyllum Hudson sind ebenfalls vertreten. Ihre artliche
Zuordnung steht jedoch noch aus. * Bemerkenswert aber ist, dass die
Gattung Wentzelloides Yabe &#038; Minato ausserhalb Ost- und
Sudostasiens erstmals nachgewiesen wurde. Auffallend ist auch der hohe
Anteil dieser in der Literatur nur wenig beschriebenen Gattung in der
zu bearbeitenden Fauna. (2) Unterfamilie Waagenophyllinae - Ipciphyllum
flexuosum (Huang), Paraipciphyllum n.sp., Yokoyamaella (Yokoyamaella)
tertioseptata (Yokoyama), ? Yokoyamaella (Maoriphyllum) sp.
[preliminary note]^1";

Iran, West Tethys.- J. Fac. Sci. Hokkaido Univ. 23, 1: 53-146.-
<b>FC&#038;P 20-2</b>, p. 50, ID=2920^<b>Topic(s): </b>; Rugosa,
Tabulata; <b>Systematics: </b>Cnidaria; Rugosa Tabulata;
<b>Stratigraphy: </b>Permian M U; <b>Geography: </b>Iran^This paper
mainly concerns the systematic palaeontology of some Middle to Upper
Permian corals from the Abadeh and Julfa regions, Iran. The fauna
consists of 35 species of 15 genera belonging to eight families. Two
different kinds of faunas are clearly to distinguish. One is from the
```

```
Middle Permian and is characterised by such typically Tethyan elements
as waagenophyilids and by several species of Ufimia and micheliniids.
It is followed by an Upper Permian fauna, terminal phylogenetic
representatives of the Rugosa, composed mostly of solitary corals
(Pentaphyllum). The Permian fauna corresponds well to that of the
Transcaucasus, USSR, reported by Iljina (1962, 1965a). Many of the
Middle Permian corals are known from South China, whereas Upper Permian
corals indicate high endemism. Each species of Pentaphyllum shows a
wide range of morphological variation, phylogenetically irrespective of
Scleractinia. Inter- and intraspecific variability as well as
ontogenetic changes are especially documented to clarify the
distinctness of each species. Tabulata mentioned are: a species of
Sinopora (S. asiatica) and some species of the genus Protomicheilnia
(P. microstoma, P. favositoides, P. laosensis, P. allata, and P.
sp.).^1";
s[3694] = "FLUGEL H.W. (1972).- Die palaeozoischen Korallenfaunen
Ost-Irans 2. Rugosa und Tabulata der Jamal-Formation (Darwasian?,
Perm).- Jahrb. Geol. B.-A. 115: 49-102.- <b>FC&#038;P 2-1</b>, p. 16,
ID=4716^<b>Topic(s): </b>; Rugosa, Tabulata; <b>Systematics:
</b>Cnidaria; Rugosa Tabulata; <b>Stratigraphy: </b>Permian Darwasian
?; <b>Geography: </b>Iran E^The coral-fauna of the Jamal-formation of
Eastern Iran can be subdivided in a &#034;Cyathaxonia&#034;-fauna and a
&#034;Waagenophy1lum&#034;-fauna. The first mentioned faunal-type
occurs in the lower Jamal-Formation, the last type in the upper
Jamal-Formation (faunal-list Table 1). The age of the Cyathaxonia-fauna
is probably the Pseudofusulina-or the lower Parafusulina-Zone, the age
of the Waagenophyllum-fauna is the Parafusulina-Zone and perhaps the
Neoschwagerina-zone. The environment of the Cyathaxonia fauna was the
deeper part of a shallow water, probably 50 or 60m. under the sea
level, whereas the Waagenophy11um-fauna indicates a high wave energy
environment of a litoral zone.^1";
s[3695] = "WEIDLICH O., SENOWBARI-DARYAN B. (1996).- Late Permian
&#034;Sphinctozoans&#034; from reefal blocks of the Ba&#039;id area,
Oman Mountains.- Journal of paleontology 70, 1: 27-46.- <b>FC&#038;P
25-2</b>, p. 57, ID=3157^<b>Topic(s): </b>taxonomy, biogeography;
Porifera, Sphinctozoa; <b>Systematics: </b>Porifera; Sphinctozoa;
<b>Stratigraphy: </b>Permian U; <b>Geography: </b>Oman^Late Permian
reefal blocks exposed in the Ba&#039;id area of the Eastern Oman
Mountains yield a sphinctozoan assemblage that has not been studied
previously. The sphinctozoan fauna described here is the first report
of such an assemblage from the Arabian Peninsula. Approximately 70
samples were studied with respect to systematic paleontology, as well
as frequency of taxa based on presence &#47; absence lists. The
Sphinctozoans include 14 genera and 25 species. One genus
(Rahbahthalamia) and five species (Amblysiphonella omanica, Salzburgia?
irregularis, Welteria? hawasinensis, Thaumastocoelia? irregularis, and
Girtyocoelia gracilis) are described as new. Amblysiphonella Steinmann
(1882), Colospongia Laube (1865), and Sollasia Steinmann (1882) have
the highest species diversity. On a generic level, Sollasia,
Amblysiphonella, and Parauvanella Senowbari-Daryan and Di Stefano
(1988) occur most frequently in the investigated samples. The described
fauna exhibits close relationships to sphinctozoan faunas known from
the Middle and Late Permian of China and Tunisia.^1";
s[3696] = "WEIDLICH O., BERNECKER M., FLUGEL E. (1993).- Combined
Quantitative Analyses and Microfacies Studies of Andes Reefs: An
Integrated Approach to Upper Permian and Upper Triassic Reef Carbonates
(Sultanate of Oman).- Facies 28: 115-144.- <b>FC&#038;P 22-1</b>, p.
54, ID=3430^<b>Topic(s): </b>reef complexes, geomorphology,
microfacies; reef complexes; <b>Systematics: </b>; <b>Stratigraphy:
</b>Permian Triassic; <b>Geography: </b>Oman^The Internal architecture
of Upper Permian calcisponge reefs, Upper Triassic coral thickets, and
Upper Triassic coral reef communities of the Oman Mountains have been
investigated. In order to gain comparable data sets, investigations
```

```
were carried out at different scales comprising quantitative data from
outcrops and descriptions from thin-section. Methods of quantitative
outcrop investigations were modified with reference to standard
investigations techniques used in the study of communities of modern
reefs. Data evaluation comprises mapping of reef fabric in natural
scale on plastic sheets in the field. Data calculation was carried out
utilizing the digitized image analysis system Vidas. Measurement
parameter are the total detrital framework coverage, coverage of reef
builder taxa, mean diameter of taxa, and mean distance. In addition,
measured plastic sheets were printed for paleoecological
interpretation. Thin-section analysis reveal microfacies types,
sedimentological criteria and taxonomic inventory of reef organisms.
Based on quantitative field data five Upper Permian and four Upper
Triassic communities were differentiated. Late Permian communities are
represented by a (1) Low-diversity sphinctozoan community, (2)
Radiotrabeculopora Archaeolithoporella community, (3) Cerioid coral
community, (4) Solitary coral community, and (5) Waagenophyllid coral
community. Upper Triassic communities comprise (1) Diverse coral
community, (2) coral Spongiostromata community, (3) Solenporacean
dendroid coral community, and (4) Crinoid community. The synthesis of
both quantitative field data (plot technique with quadrats as sampling
units) and the study of thin sections (microfacies analysis, taxonomy)
is believed to result in data sets which could be used in comparative
reef research with a higher degree of reliability than up to now.^1";
s[3697] = "BERNECKER M., WEIDLICH O. (1994).- Attempted Reconstruction
of Permian and Triassic Skeletonization from Reefbuilders (Oman,
Turkey): Quantitative Assessment with Digital Image Analysis.-
Abhandlungen der Geologischen Bundesanstalt 50: 31-56.- <b>FC&#038;P
23-1.1</b>, p. 59, ID=4124^<b>Topic(s): </b>reef builders,
skeletonization; reef builders; <b>Systematics: </b>; <b>Stratigraphy:
</b>Permian Triassic; <b>Geography: </b>Oman, Turkey^Upper Permian and
Upper Triassic reefbuilders from different tectonic units of the Oman
Mountains and Turkey were analyzed quantitatively with respect to
skeletonization (skeleton in area percent) and skeletal mass (skeleton
in g/cm3). Data were derived from thin-sections using the digital image
analysis system &#39;Vidas&#39;. The quantitative data were combined
with taxonomy, description of gross morphology and microfacies analysis
in order to understand the influences of diagenesis in the different
sizes and orientations of thin-sections. The investigated skeletons
exhibit a wide range of preservation, ranging from unaltered to
recrystallized with relic structures. Reefbuilders studied were
&#34;sphinctozoans&#34;, &#34;inozoans&#34;, &#34;chaetetids&#34;,
rugose corals, scleractinians, and hydrozoans. The measured parameters
vary considerably for higher taxa (e.g., skeletonization of
sphinctozoan sponges is 21-54%) as well as for species (e.g., the
Skeletonization of the sphinctozoan Alpinothalamia bavarica is 29-51%).
The variation is regarded to be triggered by three main factors: a)
differences in morphotypes, b) intraspecific variability, and c)
variation of skeletal elements within the colony. Well-skeletonized and
weakly skeletonized higher taxa were observed in the mean
skeletonization and the mean skeletal mass. These data help refine the
guild concept proposed by Fagerstrom (1987). The quantitative
assessment of the skeletonization and skeletal mass may provide data
for the discussion about paleoproductivity of reefbuilders and the
sedimentary net budget of ancient reefs.^1";
s[3698] = "WEIDLICH O., BERNECKER M. (2003).- Supersequence and
composite sequence carbonate platform growth: Permian and Triassic
outcrop data of the Arabian platform and Neo-Tethys.- Sedimentary
Geology 158, 1-2: 87-116.- <b>FC&#038;P 32-2</b>, p. 72,
ID=7161^<b>Topic(s): </b>carbonates; carbonates; <b>Systematics: </b>;
<b>Stratigraphy: </b>Permian Triassic; <b>Geography: </b>Arabian
Platform, Neotethys^Correlation of maximum flooding surfaces with
published data suggests that supersequences P1, P2, and Tr4 can be
```

```
traced across the Arabian platform into the Neo-Tethys basins, while
supersequences P3, P4, and Tr1-Tr3 resulted from local tectonic events
at the margin of the Arabian platform (Hulw half-graben). The presented
sea level curve corresponds therefore to the Tethyan sea level curve
during the Cisuralian and Guadalupian, but differs significantly during
the Lopingian, as a result of the dispersal of Pangea. The Middle and
Upper Triassic sea level curve from Oman is again in good correlation
with published data. The Permian and Triassic sequence architecture on
the Arabian plate and adjacent Neo-Tethys was predominantly triggered
by the global warming after the Permian-Carboniferous glaciation, the
initial rifting of Neo-Tethys, and subordinately by eustatic sea level
changes. [end-fragment of extensive abstract]^1";

carbonate platform in the Hawasina Basin: The Late Triassic Jebel Kawr
of Oman.- Palaeogeography, Palaeoclimatology, Palaeoecology 252, 1-2:
270-280.- <b>FC&#038;P 35</b>, p. 93, ID=2414^<b>Topic(s):
</b>carbonates; carbonates; <b>Systematics: </b>; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>Oman^In the oceanic realm of the
southern Tethys, carbonate production of isolated platforms ceased
after the end-Permian mass extinction and did not recover until the
Late Triassic. The Misfah Formation (MF) at Jebel Kawr in the Oman
Mountains is interpreted as a relic of such an isolated Late Triassic
platform of the Hawasina Ocean, a part of the Neo-Tethys. Correlation
of three sections at Jebel Kawr points to a sequence attached to
Arabian platform. The shallow-water carbonates of Jebel Kawr comprise a
platform rim reef facies and bedded inner-platform facies characterized
by stacked high-frequency cycles with subtidal to intertidal carbonate
sequences. The depositional profile of this Late Triassic isolated
platform evolved during Carnian and Norian time from a low-relief phase
with volcaniclastic interruptions, followed by a carbonate bank stage
with a shallow subtidal to peritidal interior and marginal oolite
shoals. In the Norian vertical accumulation caused an increase of the
platform height and developed a relief along the margins that
progressively increased through the aggrading reef stage.^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic U;
<b>Geography: </b>Oman^The Upper Triassic reefal limestones of the Oman
Mountains were investigated with respect to their microfacies,
palaeontology and community structure. The reef fauna described and
figured for the first time occurs in parautochthonous slope deposits of
the Arabian platform (Sumeini Group) and in allochthonous reefal blocks
(&#039;Oman Exotics&#039;, Hawasina Complex). The &#039;Oman
Exotics&#039; are tectonically dislocated blocks, derived from isolated
carbonate platforms on seamounts in the Hawaska bask or in the South
Tethys Sea. The lithofacies and fauna of these blocks comprise a cyclic
platform facies with megalodonts, reef and reef debris facies. The
reefal limestones are dated as Norian/Rhaetian by benthic foramkiferal
associations (Costifera, Siculocosta, Galeanelld) and typical
encrusting organisms (Alpinophragmium, Microtubus). Some small
&#039;Oman Exotics&#039;are of Carnian age. The shallow-marine
organisms include scleractkian corals of different growth forms,
&#039;sphinctozoans&#039;, &#039;inozoans&#039;chaetetids,
spongiomorphiids, disjectoporids and solenoporacean algae as the main
reef builders, various encrusters like microbes, foraminifers, sponges
and many different problematical organisms for the stabilisation of the
reef framework and a group of dwellers including benthic foraminifers,
gastropods, bivalves and a few dasycladacean algae. The reef
communities are characterized by the coverage of organisms and
```

Triassic reefs and reefal buildups are lacking in Alborz and in the
Zagros Mountains (in northern and in southwestern Iran respectively)
but some small-scaled Norian-Rhaetian reefs and reef mounds occur in
central and eastern Iran, belonging to the central Iranian plate as a
part of the Cimmerian Continent. These reefs or bioconstructions are
embedded within the Nayband Formation, a mixed siliciclastic-carbonate
unit almost 2,800m thick, in the type locality in the Tabas area. Most
```

```
of the buildups have a biostromal geometry, biohermal constructions are
rare. A large number of reef organisms was found in the Iranian reefs
and is also known from other Norian-Rhaetian reefs of the western
Tethys. However, some organisms seem to be endemic and are not known
from other localities. Based on the relative abundance of reef
organisms, reefs within the Nayband Formation may be characterized as
sponge dominated reefs (sponge reefs), coral-dominated reefs (coral
reefs), or sponge-coral or coral-sponge reefs. In comparison with other
Norian-Rhaetian reefs, the Iranian reefs are differentiated by their
different organisms (especially foraminifera and microproblematica) and
by encrustations represented mainly by small brachiopods and worm
tubes. Reefs within the Naband Formation were formed on carbonate ramps
in subtidal depths below the wave base.^1";
s[3709] = "PANDEY D.K., FURSICH F.T. (2003).- Jurassic corals of

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic Toar - Baj; <b>Geography: </b>Iran,
Alborz Mts^Nineteen taxa of scleractinian corals are described and
figures from the Toarcian-Lower Bajocian part of the Shemshak Formation
of the Alborz Mountains. Dominant taxa are Isastrea, Microsolena,
Trigerastraea, Periseris, and Collignoastraea. Most of these corals
occur near the top of the formation (lower Bajocian), close to the top
of a large-scale shallowing cycle. Scattered specimens are found in
transgressive lags of small-scaled parasequences in the Toarcian part
of the succession. Corals are very rare in the Shemshak Formation with
the exception of Rian, NE of Semnan, where strongly reduced
sedimentation rate facilitated the establishment of coral meadows and a
patch reef in mixed carbonate-siliciclastic setting on the crest of a
tilted fault block.^1";

s[3714] = "EL-ASA&#039;AD G.M.A. (1989).- Callovian Colonial Corals
from the Tuwaiq Mountain Limestone of Saudi Arabia.- Palaeontology 32,
3: 675-684.- <b>FC&#038;P 19-1.1</b>, p. 53, ID=2668^<b>Topic(s): </b>;
Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic Call; <b>Geography: </b>Saudi Arabia^The
earliest development of coral-bearing strata in Central Saudi Arabia
took place during deposition of the Tuwaiq Mountain Limestone (upper
Middle-Upper Callovian). It does not appear to constitute a major
barrier reef, but rather a series of isolated corals and coral
bioherms; coral heads (20-50 cm in diameter) are scattered in life
position within an extensive sheet of pure limestone (20-40 m thick)
stretching for more than 1000 km along strike in Central Saudi Arabia.
This sheet could be described as an extensive biostrome. A striking
feature of the Tuwaiq Mountain Limestone coral fauna is the low
diversity of species that persisted throughout the development of the
formation. These species are: Meandraraea gazaensis Alloiteau &#038;
Farag, Ovalastraea caryophylloides Goldfuss, Trigerastraea collignoni
(Alloiteau), Columnocoenia lamberti Alloiteau and Brachthelia sp. A
possible explanation for the low diversity of the fauna is inimical
ecological conditions or palaeobiogeographical barriers which could
have prevented the historical accumulation of species from neighbouring
areas. Similar factors are responsible also for the endemism of the
Jurassic Arabian fauna including ammonites, foraminifers, algae,
ostracods, nautiloids, brachiopods and echinoids.^1";
s[3715] = "GILL G.A. (1993).- Free pennulae within Dendraraea sp.
(scleractinian coral) from the Callovian of southern Israel.- Courier

Porifera, Vol. 1].- <b>FC&#038;P 22-2</b>, p. 16, ID=3454^<b>Topic(s):
</b>pennulae; Scleractinia, Dendraraea; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Jurassic Call; <b>Geography:
</b>Israel^Specimens of the Jurassic branching coral Dendraraea,
collected from Middle and Late Callovian beds at Hamakhtesh Hagadol
(Negev, Israel), commonly have free pennulae. The pennulae differ from
each other in size and outline according to the space available for
their growth. Their elevated rims are continuous all around, and bear
numerous, uniform marginal teeth. The space between the pennular rim
and the central trabecula remains equal all around. Such a degree of
individuality is uncommon among pennular corals which mostly developed
menianae (long balconies) by the fusion of the inner and outer flanks
of each pennula to those in front and behind. The global formation of
free pennulae within Dendraraea was apparently due to the trabecular
growth at right angles to the long axis of the branch.^1";

</b>structures; Scleractinia, Montlivaltia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Jurassic M;
<b>Geography: </b>Afghanistan^A study of several Jurassic solitary
Corals from Afghanistan led us to a detailed examination od structural
features in Montlivaltia. The septa were found to consist of two
distinct components: an axial structure formed by fibrous trabeculae
rhombic in transverse section, and laminar layers which thicken
secondarily the axial structure on both sides. The same sort of
architecture for several genera is deduced from Koby&#039;s work and is
confirmed in Stereophyllia All., Thecosmilia M.-E. &#038; H. and
Cyclastraea All. The septal structure of recent Fungia seems to be
closer to the aforementioned structure than to those of typical
Mesozoic Fungidae. The authors believe that corals having a
&#34;Montlivaltia-type&#34; septal composition should be introduced as
such in the classification (Superfamily Montlivaltioidae Alloiteau 1952
emend.). This group seems to had been widely spread geographically and
```

```
over long periods of time. The presence of clear microstructure in
specimens from different parts of the world allows us to deny the
existence in Montlivaltia of an axis of divergence for the trabeculae
as described in earlier works. An ecological interpretation for
Chomatoseris and Montlivaltia is proposed as well. ^1";

&#034;D&#034; reservoir in Qatar.- Journal of Petroleum Geology 24, 3:
243-264.- <b>FC&#038;P 31-1</b>, p. 70, ID=1645^<b>Topic(s): </b>reefs,
sedimentology, facies; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Jurassic U; <b>Geography: </b>Qatar^Deposition of the Arab
Formation on the Arabian Plate followed a eustatic sea-level high
during the Oxfordian that deposited the open-marine shelfal carbonates
of the Hanifa and Jubaila Formations. Oolite/peloidal shoals and local
coral-algal stromatoporoid banks were subsequently deposited on the
platform margin. These acted as barriers and led to the differentiation
of intrashelf basins from open-marine (Tethyan) waters to the east.
During the subsequent Kimmeridgian lowstand, gypsum wedges were laid
down in the intrashelf basins. Slight changes in water depth, which
exposed or flooded these barriers, are believed to be responsible for
the cyclic nature of the Arab Formation sediments. Arab Formation
cycles show a 4th order frequency but have thicknesses more typical of
3rd order Vail-type sequences. This is probably explained by the 4th
order flooding events merely topping-up pre-existing accommodation
space of tens of metres water depth in the intrashelf basin. Diagenesis
associated with movement of hypersaline brines may have been
responsible for the development of widespread dissolution porosity and
dolomitization. The laminated, organic-rich, bituminous lime mudstones
of the Hanifa/Jubaila Formations are the probable source of oil in the
Arab Formation in Qatar. The main reservoir types are oolitic-peloidal
grainstones and dolomitized limestones. [original abstract]^1";

Scleractinian corals from Lower Cretaceous deposits north of Esfahan
(Central Iran).- Facies 48, 1: 199-216.- <b>FC&#038;P 33-2</b>, p. 25,
ID=1140^<b>Topic(s): </b>; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous L; <b>Geography:
</b>Iran^A new section through Cretaceous deposits was discovered 1 km
west of the Dizlu village(approximately 40 km north of Esfahan, central
Iran). Lithologically, the section distinctly differsfrom all other
sections exposed in neighboring localities. A scleractinian coral fauna
(Upper Aptian-Upper Albian), collected from a reefal limestone, is
described in detail. The following taxa werefound: Actinastrea aff.
pseudominima (Koby), Columactinastraea sp., Eugyra cotteaui
(d&#039;Orbigny),Pseudomyriophyllia turnsekae Baron-Szabo, Montlivaltia
sp., Paraclausastrea pulchra Morycowa,Placocoenia robusta Oppenheim,
Columnocoenia ksiazkiewiczi Morycowa, Stylina micropora26Koby,
Felixigyra deangelisi Prever, Cyathophora haysensis Wells, Diploastraea
harrisi Wells,Morphastrea cf. ludovicina (Michelin), Meandrophyllia
meandroides (Koby), Eocomoseris raueniLöser, Fungiastrea crespoi
(Felix), Latiastraea cf. kaufmanni (Koby), Kobya aff.
crassolamellosaGregory. The coral association of the Esfahan region is
dominated by forms that are known to becosmopolitan and
semicosmopolitan in the Lower Cretaceous. It was found that over 40% of
thecoral fauna had previously been reported from both Lower and Upper
Cretaceous strata. A similarpattern has been recognized for other
reefal associations (e.g. Albian of Greece and UpperBarremian-Middle
Albian of Mexico). In contrast, coral assemblages which developed in
rather softbottom environments have a significantly smaller percentage
(15-20%) of taxa extending into theUpper Cretaceous and show closer
affinities to Upper Jurassic and Lower Cretaceous faunas.^1";

Revue de Paléobiologie 24, 2: 515-532.ISSN 1661-5468.- <b>FC&#038;P
34</b>, p. 57, ID=1279^<b>Topic(s): </b>ecology; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous U; <b>Geography: </b>United Arab Emirates, Oman^The
Upper Cretaceous (Campanian-Maastrichtian) rocks that areexposed et
several localities in the United Arab Emirates and theSultanate of Oman
are rich in macro- as well as microfossils. Solitarycorals are found in
these outcrops, associated with colonial corals,rudists, gastropods,
pelycopods and echinoids. Nineteen species ofsolitary corals were
identified from Jabal Buhays, Al Faiyah rangeMountains (United Arab
Emirates), Jabal El Rawdah and JabalHuwayyah (Sultanate of Oman). Of
these nineteen species ten speciesare described from the Qalah
Formation (Upper Campanian) of JabalHuwayyah and ten species are
described from the Simsima Formation(Upper Campanian-Masstrichtian) of
Jabal Buhays and Jabal El Rawdah where one species Cunnolites profundus
is common in the threelocalities. One species found in the Simsima
Formation belongs to thenew species Cunnolites trifurcata described
herein.Two morphotypes are observed in the studied solitary corals.
Trochoidmorphotypes prevailed during the deposition of the Qahlah
Formation,these lived on a hard substrate in a shallow marine
protectedenvironment. Hemispherical to dome-shaped morphotypes
belonging tocunnolitid corals prevailed during the deposition of the
SimsimaFormation. These are better adapted to a slightly higher
energyenvironment with terrestrial supply by having elevated corallites
whichaided them to lie freely on the soft substrates as well as to
freethemselves from the fine sands and silts. The absence of costosepta
atthe basal part of cunnolitid corals shows that they were immobile
during life.^1";

Ruqum, North Sinai, Egypt: taxonomy and adaptive morphotypes.- 7th
International Conference on the Geology of the Arab World, Cairo
University, February 2004. [abstract] - <b>FC&#038;P 36</b>, p. 90,
ID=6503^<b>Topic(s): </b>adaptive morphologies; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous Apt; <b>Geography: </b>Egypt, Sinai^Colonial and
solitary corals of variable morphotypes are abundant in the Aptian
rocks of Gabal Abu Ruqum, North Sinai. A taxonomic study on these
corals revealed the occurrence of 24 species 11 solitary and 13
colonial species. Six species are established as new: Trochosmilia
cretacea, Montlivaltia amini, Meandrastraea sinaiensis, Peplosmilia
gawadi, Acrosmilia egyptiaca and Epistreptophyllum manzourensis. The
solitary corals belong to genera Montlivaltia, Epistreptophyllum,
Ellipsosmilia, Paracycloseris, Acrosmilia and Rennensismilia. Ceratoid
and trochoid forms with a narrow base and a curved corallite dominate
in these corals. Most corallites are filled with fine sand grains or
clogged with large forams (mainly Orbitolina). Discoid solitary corals
are rare and are represented by Paracycloseris sp. The dominance of
ceratoid and trochoid forms in addition to the small-sized and curved
corallites reflects unfavorable conditions with high terrigenous
supply. On the other hand, colonial corals belong to the genera Eugyra,
Stylina, Thamnastrea, Fungiastrea, Leptoria, Actinastrea and
Ellipsocoenia. The colonial forms show a wide range of adaptation to
```

```
the soft substrate with much terrigenous influx. Most forms are
hemispherical to mushroom shaped with wide bases for stability. These
forms usually have a long peduncle or are usually elevated above the
substrate to avoid being buried by sand and mud. Only two species
[Eugyra (P.) rariseptata and Leptoria sp.] have encrusting morphotypes.

rudist and stromatoporoid associations of Central Oman (Arabian
peninsula).- Facies 32: 189-202.- <b>FC&#038;P 24-2</b>, p. 107,
ID=6866^<b>Topic(s): </b>sedimentology, sclerochronology; rudists,
stroms; <b>Systematics: </b>Mollusca Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>Oman^Rudist and
stromatoporid associations of the Campanian from Central Oman are
nearly monospecific. They are dominated by Durania aff. nicholasi,
Vaccinites vesiculosus, Torreites milanovici or phaceloid and massive
stromatoporids. Several other rudist genera play a secondary role. The
thickness of the associations is rarely more than one metre. Solitary
corals do not occur in the associations. Colonial corals are less
common, although they are up to 1m high and show considerable
diversity. There are no binders. The reef structure indicates variable
hydrodynamic conditions. They are always associated with very shallow
water. The pure Durania aff. nicholasi patches with large colonial
corals and Torreites milanovici are presumably the most rigid
structures. The near monospecific associations of Vaccinites
vesiculosus are widely distributed. Although mostly preserved in situ,
strong currents, presumably caused by tropical storms, have repeatedly
impaired and interrupted growth. The specific growth characteristics of
the shell of some rudists, especially the radiolitids, enable an
estimation of the individual lifespan. Frameworks of approximately 1m
thickness probably developed in ± 100 years. The sediments of the
complete sections are predominantly bioclastic. [original abstract]^1";

Global and Regional Controls on Biogenic Sedimentation I. Reef
Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 34, ID=3590^<b>Topic(s):
</b>reefs rudist; rudist reefs; <b>Systematics: </b>Mollusca;
<b>Stratigraphy: </b>Cretaceous Camp; <b>Geography: </b>Oman^Complete
in situ rudist associations are preserved in the Campanian of Central
Oman. They developed during a transgression onto the Arabian Plateau.
Microfacial analysis reveals that vigorously turbulent conditions
prevailed throughout the Lower Campanian. The development and
preservation of in situ rudist associations are obviously rare events.
As a rule, turbulence prevents the development of such structures. The
absence of vast rudist reefs is not a consequence of an inherent
inability of rudists to build reefs, but can be attributed to
exogenous, abiotic factors. The associations investigated here
inhabited restrictive shallow-marine environment. Rapid growth of a few
rudists has been verified. Vertically growing rudist associations of
5-8 in situ generations represent a period of only 100-200 years.^1";

Early Campanian rudists in a siliciclastic-calcareous setting (Pontid
Mts., North-Central Turkey).- Geobios. Memoire Special 22: 385-401.-
<b>FC&#038;P 28-1</b>, p. 45, ID=3978^<b>Topic(s): </b>growth rates;
rudists, growth rates; <b>Systematics: </b>Mollusca; <b>Stratigraphy:
</b>Cretaceous Camp; <b>Geography: </b>Turkey, Pontides^Rudist
communities that developed on the southern slope of the Pontid magmatic
arc during the late Cretaceous thrived in a tectonically unstable
setting, and in environments that were strongly influenced by
siliciclastic sedimentation. Strontium isotope stratigraphy indicates
an early Campanian age of the investigated association at Hobek Tepe,
near Amasya. Stable isotope analyses of: sclerochronological profiles
of several shells of the three dominating hippuritid species yielded
```

```
cyclic variations of &#948;18O that delineate seasonal variations in
palaeotemperature. This allowed for the determination of individual
life spans, skeletal growth rates and the reconstruction of the living
growth fabric. Annual vertical shell growth of 35-40mm was maintained
by cylindrical morphotypes of Vaccinites ultimus during several
successive years, while adult annual shell accretion of conical
morphotypes was only 27 to 30mm. Vertical growth of the co-occurring
Yvaniella alpani was considerably slower and rarely exceeded 10mm/year.
Differential growth rates of the two most abundant species, and
morphological characters of Yvaniella which indicate that skeletal
growth capacity was similar to sediment accumulation, allowed for a
consistent reconstruction of the original growth fabric. CaCO3
production of the rudist communities amounted to 20 kg x year-1 x m-2
and contributed significantly to the sedimentary budget. Large-scale
formation of fine-grained calcareous sediments by bioeroders occurred
only in environments of less rapid burial, indicated by associations of
slowly-growing geniculate rudist morphotypes and patellate corals. The
implications of these results for the distribution of rudists and
corals in Cretaceous shallow-marine environments are discussed.^1";
s[3735] = "SCHUSTER F. (2002).- Scleractinian corals from the Oligocene
of the Qom Formation (Esfahan-Sirjan fore-arc basin, Iran).- Courier
Forschungsinstitut Senckenberg 239: 5-55.- <b>FC&#038;P 33-2</b>, p.
36, ID=1174^<b>Topic(s): </b>; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Oligocene;
<b>Geography: </b>Iran^Sixtyone scleractinian species of 39 genera are
described from the section of Abadeh, central Iran. Nine of these
species and one genus are new. The section comprises sedimentary rocks
of the Qom Formation located on the Iranian Plate (Esfahan-Sirjan
fore-arc basin). The age of the section ranges from latest Rupelian to
Chattian (late Early to Late Oligocene) based on planktonic and larger
foraminifers. The coral fauna belongs to three different assemblages:
1) a solitary coral assemblage, 2) a Leptoseris-Stylophora assemblage
of a low light environment, and 3) a Poritid-Faviidae assemblage
forming patch reefs. This study presents a detailed description of a
previously unknown Oligocene coral record from this region. The study
area is located palaeogeographically between the well known coral
occurrences of the Mediterranean Tethys and the coral bearing Nari
Series of Sind, Pakistan and eastwards following Indopacific
localities, and is therefore of prime importance for
palaeobiogeographical reconstructions. Comparisons at the species level
show that the coral fauna from central Iran represents a mixture of
Mediterranean Tethyan and Indopacific elements. Nevertheless, the
majority of the species are unknown from the Mediterranean Tethys
indicating a beginning of faunal separation despite an open Tethyan
Seaway which still connected both regions during this time.^1";
s[3736] = "GAMEIL M., ALY M.F. (2001).- Paleontological studies on some
Oligocene colonial corals from Gabal Hafit, (Al Ain Area, UAE).-
M.E.R.C. Ain Shams University, Earth Sci. Ser. 15: 61-78.- <b>FC&#038;P
31-2</b>, p. 15, ID=1278^<b>Topic(s): </b>; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Oligocene; <b>Geography: </b>United Arab Emirates^A highly
fossiliferous Lower Oligocene (Rupelian) section is well exposed on the
flanks of Gabal Hafit anticline near Al Ain City, United Arab Emirates.
The section contains different kinds of macro- and microfossils. Corals
are the most abundant faunal element in that area and are represented
by colonial and solitary forms where colonial forms dominate. Colonial
corals are the main target of the present work and are studied here for
the first time. The present work focuses on the taxonomic and
stratigraphie aspect of these colonial corals. The study includes the
identification and description of 21 species of which two species are
believed to be new. These are Tarbellastraea hqfitensis and
Siderastraea osmani. The paleoecologic aspect of the studied faunas and
their relation to other Tethyan faunas are also discussed. [original

s[3737] = "SCHUSTER F., WIELANDT U. (1999).- Oligocene and Early Miocene coral faunas from Iran: palaeoecology and palaeobiogeography.- International Journal of Earth Sciences 88, 3: 571-581.- <b>FC&#038;P 29-1</b>, p. 64, ID=7026^<b>Topic(s): </b>ecology, biogeography; corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Oligocene Miocene L; <b>Geography: </b>Iran^Oligocene and Early Miocene coral assemblages from three sections of central Iran are investigated with respect to their palaeoecological and palaeobiogeographic implications. These corals are compared with faunas from the Mediterranean Tethys and the Indopacific. Associated larger foraminifers are used for biostratigraphy and to support the palaeoecological interpretation. The studied sections are situated in the foreland basins of the Iranian Plate which is structured into a fore-arc and a back-arc basin separated by a volcanic arc. The coral assemblages from Abadeh indicate a shallowing-upward trend. Infrequently distributed solitary corals at the base of the section indicate a turbid environment. Above, a distinct horizon characterised by a Leptoseris-Stylophora assemblage associated with lepidocyclinids and planktonic foraminifers is interpreted as maximum flooding surface. Small patch reefs with a Porites-Faviidae assemblage are a common feature of Late Oligocene to Early Miocene coral occurrences and indicate water depths of less than 20m. The diversity of the coral faunas shows marked differences. Oligocene corals from the Esfahan-Sirjan fore-arc basin comprise more than 45 species of 32 genera and occur in a wide range of environments. Early Miocene corals from the Qom back-arc basin are less frequent, show a lower diversity (13 genera with 15 species) and occur in single horizons or small patch reefs. [original abstract]^1";

Scleractinia; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>Egypt, Sinai^The nature and distribution of syntaxial cements in
Scleractinian corals and their growth in optical continuity with the
skeletal carbonate fibres combined with simultaneous recrystallization
allow a comparison with similar structures in Palaeozoic corals. Marked
thickenings of the septa are due to cementation fabric, as syntaxial
cements for instance. Moreover, these are also the cause of the
development of pseudoskeletal elements, as for example the
stereoplasmatic cones in the case of Cystimorpha. These studies of
diagenesis of scleractinians from the Pleistocene of the Sinai
Peninsula led to an analysis of the elements Ca, Sr, Mg, Na, Si, and Al
in the skeletal carbonate as well as in syntaxial cements. The amount
and distribution of these elements enable the indentification and
delimitation of organic and diagenetic carbonates, if no
recrystallization has taken place. The results of the investigation
demonstrate again that mere observation and graphic description of
microstructures is not sufficient. Rather, the diversity of hitherto
described microstructural units necessitates an interpretation which
takes into account the diagenesis of the fossil. This leads to the
conclusion that while the skeletal architecture of Paleozoic corals has
in most cases been preserved, the microstructure may have suffered
recrystallization. [an English version of this paper has been published
in &#039;Memoir 8 of the Association of Australasian
Palaeontologists&#039; = Oekentorp 1989]^1";

Deposition in Accretionary Prism Setttings: Early Miocene Coral
Limestones and Corals of the Makran Mountain Range in Southern Iran.-
Facies 31: 141-178.- <b>FC&#038;P 24-1</b>, p. 90, ID=4524^<b>Topic(s):
</b>reefs, accretionary prism setting; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Miocene Aquit Burd; <b>Geography: </b>Iran,
Makran^The regional mapping of the Makran mountain range on behalf of
the Geological Survey of Iran represents a unique coverage: the entire
area of the mountain range was compiled in a unified progamme. During
this mapping, Miocene limestones containing rich coral and
foraminiferal faunas were recorded over a strike length of several
hundred kilometres, as minor developments within thick neritic clastic
sequences which in turn overlie great thicknesses of Eocene-Miocene
flysch. These limestones include rigid bioconstructional frameworks,
loosely compacted coralline assemblages and foraminiferal calcarenites:
they include in situ reefal deposits and material redeposited quite
close to their original site of depositions. Most are Burdigalian, as
shown by the benthonic position foraminifera, but some are Aquitanian.
The geotectonic setting was an accretionary prism in a zone of plate
convergence. The limestones and enclosing clastic sediments comprise an
intensely folded, reverse-faulted and locally dislocated sequence, the
duplex structure being the result of a major Late Miocene-Pliocene
episode of regional deformation. This concentration of the intense
tectonic deformation in a late major episode requires a different model
for this zone of plate convergence to the model widely applied to such
zones. The possible controls on limestone deposition are discussed:
tectonic uplift and shallowing of the sea, climatic warming and
eustatic factors. Depositional features of reefal formations in the
late Jurassic of the Caucasus, the Pliocene-Recent of Halmahera, and
the early Miocene of SE France are discussed in comparison with the
Makran model.[part of extensive summary]^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Oman^Corals living in the coastal waters of southern
Oman experience the influence of the seasonally reversing Asian monsoon
system. The objective of the research reported here is to assess the
potential for using the skeletal chemistry of these corals to
investigate past variability in the monsoon climate. To this end,
20-year long, monthly resolution geochemical records are presented for
cores from two massive Porites corals, located 20 km apart near Marbat
on the Arabian Sea coast of southern Oman. We consider four aspects of
skeletal chemistry: oxygen and carbon isotopic composition, barium
content and the nature and occurrence of annual fluorescent bands
within the coral skeletons. Coral skeletal &#948;18O documents
variations in sea surface temperature which have regional and
basin-wide significance. In particular, the &#948;18O of coral skeleton
precipitated during the period of the NE monsoon is strongly correlated
with annual rainfall anomalies in India, whilst that precipitated
during the period of the SW monsoon appears to provide information on
variability in the strength of coastal upwelling. The stable carbon
isotope composition and barium content of these particular corals
display strong annual cycles, but do not appear to directly record
interannual climatic oceanographic variability. It is concluded that
corals on the coast of southern Oman have great potential to provide
high-resolution, century-long records of oceanographic and climatic
variability associated with the operation of the monsoon climate
system.^1";

Stromatoporoidea; <b>Stratigraphy: </b>Ordovician; <b>Geography:
</b>Australia^Webby describes the distribution of Ordovician
stromatoporoids on pages 69 and 70. The earliest assemblages are
labechiids best represented in the middle Ordovician of Tasmania which
show affinities with Chazyan and Blackriveran forms of Laurentia. Late
Darriwilian faunas from New South Wales show relationships to north
China and Korea. The diverse labechiid fauna of earliest Eastonian
(mid-Caradoc) age includes species with relationships to Tasmania,
Malaysia, north China, Mongolia, Tuva and Siberia. Clathrodictyids
first appearing in late Caradoc rocks also have Asian connections but
appear about the same time in Australia, east Canada, and north
China.The most diverse Ordovician faunas occur in early Ashgill rocks.
Aulacera is common in late Ordovician rocks in Tasmania, the Siberian
platform, Urals, Novaya Zemlya, etc. but not in New South Wales. The
affinities of island-arc assemblages from New South Wales are closest
to SE Asia and China. The affinities of the Tasmanian shelf fauna is
dominantly Asian, but at least twice had influxes of North American
stocks.^1";

Biostratigraphic review of the Silurian tabulate corals and chaetetids
of Australia.- Historical Biology 15, 1-2: 41-60.- <b>FC&#038;P
31-1</b>, p. 60, ID=1625^<b>Topic(s): </b>stratigraphy; Tabulata,
Chaetetida; <b>Systematics: </b>Cnidaria Porifera; Tabulata Chaetetida;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Australia^The
biostratigraphic distribution of the Silurian Tabulata and Chaetetida
of Australia can informally be described in terms of four successive
coral assemblages. * The earliest Bridge Creek Assemblage
(Rhuddanian-Aeronian) contains abundant halysitids and is not
geographically widespread. Species of this assemblage tend to be
holdovers from Late Ordovician faunas. * A major radiation event
occurred at the time of the Quarry Creek Assemblage (Telychian-early
Sheinwoodian), involving favositids, heliolitids, halysitids, and other
groups. This may indicate the onset of conditions favourable to corals
over widespread areas of eastern Australia. * The late
Sheinwoodian-earliest Gorstian Dripstone Assemblage is characterised by
a continued expansion in the number of species of favositids, the
appearance of auloporids, and a contraction in the number of species of
sarcinulids, multisoleniids, and halysitids. * Favositids continued to
dominate the youngest Hatton&#039;s Corner Assemblage
(Gorstian-Pridoli), but halysitids almost became extinct by the end of
the Ludlow. * Faunas of Pridoli age are neither abundant nor well
studied, but appear to be reduced continuations of earlier faunas. A
number of tabulate taxa are identified as possibly useful
biostratigraphic indicators in Silurian sequences. [original

s[3757] = "ZHEN YONGYI (1998).- Biogeographic and biostratigraphic
perspectives for Australian Devonian rugose corals.- Acta
Palaeontologica Sinica 37, 3: 359-379.- <b>FC&#038;P 27-2</b>, p. 50,
ID=3906^<b>Topic(s): </b>biogeography, biostratigraphy; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Australia^The highly diverse Early Devonian rugose
corals characterized by the occurrences of Carlinastraea,
Martinophyllum and Pradisphyllum of the late Lochkovian-Pragian faunas
and of Chalcidophyllum. Macgeea and Protomacgeea of the Emsian faunas
are widely distributed in eastern Australia, and exhibit a high ratio
of newly evolved generic taxa. Philipsastreids and endophyllids made
their first appearance in the Pragian and became common in the Emsian.
The earliest elements of the stringophyllids occur in the various rock
units of Emsian age. While in the other provinces of the Old World
Realm, these three families are recorded mainly from the Middle or even
Upper Devonian. This pattern of distribution suggests that many of the
common genera belonging to these families originated in eastern
Australia during the Early Devonian. Middle Devonian rugosan faunas of
eastern Australia are characterized by endemic Sanidophyllum and
Blysmatophyllum. The Eifelian faunas seem to exhibit gradational
changes from the earlier faunas. In contrast to a strong northwestwards
dispersal from eastern Australia to south China and other provinces of
the Old World Realm during the Early Devonian, the diverse Givetian
faunas of Australia were less provincial, and exhibit a major influx of
elements from south China, central Asia, Europe, northwestern Canada
and other provinces of the Old World Realm. The Upper Devonian of
eastern Australia is dominated by red-beds and associated facts of
non-marine depositional setting with only rare records of rugose
corals. Western Australian Frasnian faunas consist of both shelf and
basin dwelling forms and show a long diversity and a strongly
cosmoplitan nature.^1";
s[3758] = "DARGAN G.M. (2000).- Regressional episodes and diversity
patterns of Australian Devonian tabulate corals.- Records of the
Western Australian Museum, Supplement 58: 273-277.- <b>FC&#038;P
33-2</b>, p. 15, ID=1112^<b>Topic(s): </b>diversity patterns; Tabulata,
diversity; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Australia^Biostratigraphical
distribution of Australian Devonian tabulate corals appears to be
influenced by episodes of transgression and regression both locally and
world wide. Decrease in species diversity can be related to local
regressive phases. Examination of contemporaneous sequences unaffected
by regression is needed before a strong cause and effect relationship
can be established.^1";
s[3759] = "HILL D., JELL J.S. (1970).- The Tabulate Coral Families
Syringolitidae Hinde, Roemeriidae Pocta, Neoroemeriidae Radugin and
Chonostegitidae Lecompte, and Australian species of Roemeripora
Kraicz.- Roy. Soc. of Victoria Proc. 83, 2: 171-190.- <b>FC&#038;P
1-2</b>, p. 14, ID=4644^<b>Topic(s): </b>taxonomy; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian L
M; <b>Geography: </b>Australia^The genera Roemeria E. &#038; H.,
Roemeripora Kraicz (and its possible synonym Vaughanites Paul 1937, non
Woodring 1928), Roemerolites Dubatolov, Armalites Chudinova,
Pseudoroemeripora Koksharskaya, and Bayhaium Langenheim &#038;
McCutcheon are considered to have syringoporid affinities and to form a
family Roemeriidae Pocta. The three Australian Lower or early Middle
Devonian species Michelinia progenitor Chapman, Syringopora thomii
Chapman and Roemeria ocellata Hill are revised, transferred to
Roemeripora, and considered probably synonymous. Pseudoroemeria
Chekhovich and Syringoporinus Sokolov are possibly better grouped with
Troedssonites Sokolov than in the Roemeriidae. Neoroemeria Radugin and
Thecostegites E. &#038; H. have syringoporid affinities and are grouped
in the family Neoroemeriidae while Chonostegites E. &#038; H., also
with syringoporid affinities, is considered the sole member of its
```

```
family Chonostegitidae Lecompte. Haimeophyllum Billings is shown to be
a synonym of Chonostegites. Gorskyites Sokolov, Neosyringopora Sokolov
and Roemeripora wimani Heritsch form a group of Upper Carboniferous and
Permian Tabulates that appears to deserve syringoporid subfamily
status. Syringolites Hinde is considered more closely related to
Favosites than to Syringopora, and is treated herein as the only genus
in the family Syringolitidae Hinde of the Favositoidea.^1";
s[3760] = "WOOD R., OPPENHEIMER C. (2000).- Spur and groove morphology
from a Late Devonian reef.- Sedimentary Geology 133, 3-4: 185-193.-
<b>FC&#038;P 30-1</b>, p. 9, ID=7052^<b>Topic(s): </b>reefs morphology;
reefs, morphology; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian
U; <b>Geography: </b>Australia^Spur and groove structures form on the
windward side of modern coral reefs in response to wave action.
Hitherto, no examples have been confirmed in the Palaeozoic record. We
confirm here ancient spur and groove morphology from the Teichert
Hills, an exhumed platform atoll from the Upper Devonian (Frasnian)
reef complex of the Canning Basin, Western Australia. Oriented growth
of the reef-building metazoans (laminar tabulate corals and
stromatoporoid sponges) proves an organic and constructional origin for
the spurs. Grooves acted as sediment traps that filled with coarse
bioclastic sand and winnowed brachiopods derived from the back reef and
reef flat. Geometry and style of ancient spurs and grooves may provide
indications of ancient synoptic hydrodynamic regimes: on the basis of
the relationship between modern coral reef spur orientation and
incoming wave direction, these ancient spurs are inferred to have
formed normal to refracted waves. The presence of these structures
offers unequivocal evidence for the active growth of mid-Palaeozoic
reefs in wave-dominated hydrodynamic regimes, and demonstrates that
reef-building biota can show a common morphological response to wave
energy independent of taxonomic position. [original abstract]^1";

&#038; J.R. Laurie (eds)]: 167-257.- <b>FC&#038;P 31-1</b>, p. 75,
ID=7113^<b>Topic(s): </b>biogeography; biogeography; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Australia^[Stromatoporoid faunas are described by Webby and Zhen on
pages 196 to 198. They discuss whether stromatoporoids were restricted
to latitudes 40°N and 35°S as suggested by Heckel &#038; Witzke or show
a wider spread (60°N to 45°S) as supported by Stock. Several
Pragian-Emsian genera found in eastern Australia show affinities with
the Kuznetsk basin, Siberia and the Tien Shan, Altai moutnains,
Uzbekistan, Salair, arctic Canada, and south China. The Eifelian record
of north Queensland is linked to the Urals and the early Devonian of
the Czech republic and the Reefton occurrences of New Zealand,
Givetian-Frasnian faunas of Queensland and western Australian basins
are much more cosmopolitan and have many species in common with
European faunas. The dramatic reduction in diversity at the
Frasnian-Famennian boundary led to a relict fauna of labechiids,
stromatoporellids and stromatoporids.]^1";
s[3762] = "PISERA A., BITNER M.A. (2007).- The sponge genus Brachiaster
(Pachastrellidae, Demospongiae) and its first known fossil
representative, from the late Eocene of southwestern Australia.-
Alcheringa 31, 4: 365-373.- <b>FC&#038;P 36</b>, p. 39,
ID=6406^<b>Topic(s): </b>; Demospongiae Brachiaster; <b>Systematics:
</b>Porifera; Demospongiae; <b>Stratigraphy: </b>Eocene; <b>Geography:
</b>Australia^The pachastrellid genus Brachiaster Wilson
(Pachastrellidae, Demospongiae, Porifera) has had until now no known
fossil representatives. Here we describe its first known fossil
representative from the late Eocene of southwestern Western Australia,
assigned to Brachiaster claudelevii sp.nov. Brachiaster claudelevii has
well-developed axial canals in the mesotriders, which points to it
```

```
being intermediate in character between the typical tetraxial desmas of
lithistids, and tetraxial spicules of non-lithistid demosponges. This
further supports the position of Brachiaster among the Pachastrellidae.
The geographic and bathymetric distribution of the extant and newly
described fossil representatives of Brachiaster indicates that the
Eocene sponge described here is important in understanding the
evolution of Indo-West Pacific sponges because it points to a long
evolutionary history and complex biogeographic distribution of this
lineage of pachastrellid sponges. [original abstract]^1";

28: 171-240.- <b>FC&#038;P 15-2</b>, p. 40, ID=0729^<b>Topic(s):
</b>new taxa; Octocorallia; <b>Systematics: </b>Cnidaria; Octocorallia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia^This paper
presents a taxonomic treatment of four Australian collections of
octocorals belonging to the orders Stolonifera, Telestacea, and
Alcyonacea. The four collections are located in the Australian Museum,
Sydney, the Department of Fisheries, Adelaide, the National Museum of
Victoria, Melbourne, and the Fisheries Laboratory, Queensland Fisheries
Service, Mourilyan Harbour, Queensland. The material contains 67
species, 20 being found in Australian waters for the first time.
Forty-five are known species, but nine of these are more or less
completely redescribed. Twenty-two species are new, including eight new
species of Capnella. A key to the species of this genus is given.^1";
s[3765] = "CAIRNS S.D. (2004).- The Azooxanthellate Scleractinia
(Coelenterata: Anthozoa) of Australia.- Records of the Australian
Museum 56, 3: 259-329.- <b>FC&#038;P 33-2</b>, p. 26,
ID=1142^<b>Topic(s): </b>azooxanthellate; Scleractinia,
Azooxanthellate; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia^A total of 237
species of azooxanthellate Scleractinia are reported for the Australian
region, including seamounts off the eastern coast. Two new genera
(Lissotrochus and Stolarskicyathus) and15 new species are described:
Crispatotrochus gregarius, Paracyathus darwinensis,Stephanocyathus
imperialis, Trochocyathus wellsi, Conocyathus formosus,Dunocyathus
wallaceae,Foveolocyathus parkeri, Idiotrochus alatus, Lissotrochus
curvatus, Sphenotrochus cuneolus,Placotrochides cylindrica, P. minuta,
Stolarskicyathus pocilliformis, Balanophyllia spongiosa, andNotophyllia
hecki. Also, one new combination is proposed: Petrophyllia rediviva.
Each speciesaccount includes an annotated synonymy for all Australian
records as well as reference toextralimital accounts of significance,
the type locality, and deposition of the type. Tabular keys areprovided
for the Australian species of Culicia and all species of Conocyathus
and Placotrochides. Adiscussion of previous studies of Australian
azooxanthellate corals is given in narrative and tabularform. This
study was based on approximately 5500 previously unreported specimens
collected from500 localities, as well as a re-examination of most of
the types and previously reported specimensfrom the Australian region.
Fifty-six species are recorded as new to Australia; 183 state
rangeextensions are listed; and 96 worldwide bathymetric range
extensions are noted. In order tocharacterize the Australian fauna, all
703 known azooxanthellate species were tabulated as tocoloniality,
method of attachment, and depth range: 187 species are colonial, 516
solitary; 373 areattached, 265 free, and 54 transversely dividing; and
200-1000 m is the most common depth range.Compared to all
```

```
azooxanthellate species, those from Australia have a slightly higher
percentage ofspecies that are solitary and unattached (or transversely
dividing), due to a disproportionate numberof species in the families
Flabellidae and Turbinoliidae. Bathymetrically they are typical of
theworldwide fauna. Sixty-seven species are endemic to the Australian
region. Both UPGMA clusteranalysis and MDS ordination reveal two main
regions: a northern tropical region and a southernwarm temperate
region, consistent with zonation patterns of shallow-water marine
invertebrates.^1";

high-energy platform reef: One Tree Reef, Southern Great Barrier Reef.-
Journal of Sedimentary Petrology 53, 4: 1133-1149.- <b>FC&#038;P
13-1</b>, p. 26, ID=0407^<b>Topic(s): </b>reefs, cementation; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Australia^Three major framework facies (algal pavement, coral
heads, and branching corals) identified within the Holocene section of
One Tree Reef shows varying degrees of cementation. The widest
distribution and greatest variety of submarine cements occur within
those facies or subfacies that have extensive encrustation by coralline
algae; these are found beneath the windward margin and within the patch
reef drilled. Both Mg calcite and aragonite cements exhibit diverse
fabrics and textures. Mg calcite is the dominant cement and is present
as both an interskeletal and intraskeletal infill, whereas aragonite
cement is exclusively intraskeletal. Interskeletal cements are
relatively uncommon and are only developed within those facies or
subfacies whose particular style of framework construction is capable
of trapping significant quantities of fine-grained internal
sediment.Lithified crusts, with either a laminated or columnar
morphology, are a prominent cavity infill within many of the reef
framework facies. Although direct evidence is lacking at this stage,
```

```
the morphology and other features of these crusts probably indicate
some form of organic influence during their formation. Peloids, which
are the major component of the lithified crusts as well as many other
cavity infillings, are considered to be a particular form of Mg calcite
micrite and to have nucleated within the interstitial waters of the
reef. Microcrystalline rim cements around the peloids have often
cemented them into a coherent mass that resembles detrital lime
mudstones. (Original summary)^1";

Press, Boca Raton, Florida, 356 pp. ISBN/ISSN: 84930833X.- <b>FC&#038;P
30-1</b>, p. 24, ID=1547^<b>Topic(s): </b>reefs, oceanography; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Australia^Demonstrating the relevance and need of science in
planning the future of the Great Barrier Reef and coral reefs
worldwide, Oceanographic Processes of Coral Reefs: Physical and
Biological Links in the Great Barrier Reef emphasizes
multi-disciplinary processes - physical and biological links - that
have emerged as the dominant forces shaping and controlling the
ecosystem. The book draws heavily on data from coral reefs in
Australia, Indonesia, Thailand, and the Philippines. Oceanographic
Processes of Coral Reefs: Physical and Biological Links in the Great
Barrier Reef covers: * Climate and global change * Coastal oceanography
* Wetlands ecology * Estuaries * Marine biology * Land use management
in the tropics * Fisheries management * Coral Reef ecological modeling
* Biodiversity and the human impact. Explore how the ecosystem responds
to both physical and biological stimuli, and how they interact.
Understand processes imperative to create sustainable design strategies
Comprehend the connectivity of biotopes - land, mangroves, seagrass,
and corals Discover the relationship between managing marine resources
and managing adjoining land use Learn how fish behavior and migration
patterns control fisheries.^1";
s[3771] = "BEAMEN R., LARCOMBE P., CARTER R.M. (1994).- New evidence
for the Holocene sea-level high from the inner shelf, Central Great
Barrier Reef, Australia.- J. sediment. Res. A, 64, 4: 881-885.-
<b>FC&#038;P 24-1</b>, p. 83, ID=4516^<b>Topic(s): </b>reefs, eustacy,
geochronometry; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Holocene; <b>Geography: </b>Australia^Radiocarbon dates from fossil
oyster beds of intertidal origin on Magnetic Island, north Queensland
indicate that the local Holocene maximum of relative sea level was
attained no later than 5660 ±50 B.P. (conventional uncorrected age) and
remained at 1.6-1.7m above modern levels until 4040 ± 50 B.P. Given the
tectonic stability of the area, this implies that eustatic sea level
remained at its Holocene peak for at least ca. 1600 yr. The new
high-precision sea-level data indicate sea levels 1-5m higher than
those of the same age inferred from buried mangrove deposits on the
inner shelf in north Queensland. Uncertainties in deriving relative sea
level from such mangrove deposits may be a significant source of error
in worldwide attempts to distinguish the eustatic and crustal warping
components of relative sea-level change, especially in the tropics.^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Australasia^The occurrence of approximately 100
rugose coral genera has been confirmed in the Devonian carbonate
dominated successions of Australasia. Their temporal distribution shows
that the largest faunal turnovers were in the Pragian and Givetian,
with profound extinction events at or near the ends of the Emsian,
Givetian and Frasnian. The evolutionary innovation and diversification
of the Early Devonian rugose corals of eastern Australia are
characterized by a high turnover rate in the late Lochkovian-Pragian
and strong dynamism of radiation from late Pragian to medial Emsian,
implying considerable dispersal to South China, central Asia and
Europe.After a high intensity of origination in the Pragian, maximum
diversity was reached in the Emsian. Phillipsastreids and endophyllids
appeared late in the Pragian and became common in the Emsian;
stringocephalids appeared in the Emsian. As elements of these families
are recorded mainly from the Middle, or even Upper Devonian of other
provinces of the Old World Realm, it appears that they may have
originated in eastern Australia during the Early Devonian.Following a
marked decrease in generic richness in the Eifelian, faunal diversity
reached another high peak in the early mid-Givetian as a result of
immigration of coral genera, probably from South China, central Asia,
Europe and northwestern Canada in the Old World Realm.^1";

hexactinellid sponges. They occur within the Ediacara Member of the
Rawnsley Quartzite (Pound Subgroup) from several locations in the
Flinders Ranges. The new genus, Palaeophragmodictya, is characterized
by disc-shaped impressions preserving characteristic spicular networks
and is reconstructed as a convex sponge with a peripheral frill and an
oscular disc at the apex.^1";
s[3779] = "SAVARESE M., MOUNT J.F., SORAUF J.E. (1993).- Paleobiologic
and paleoenvironmental context of coral-bearing Early Cambrian reefs:
Implications for Phanerozoic reef develoment.- Geology 21: 917-920.-
<b>FC&#038;P 23-1.1</b>, p. 91, ID=4210^<b>Topic(s): </b>reefs,
biology, ecology; reefs, Archaeocyatha corallimorpha; <b>Systematics:
</b>Porifera; Archaeocyatha; <b>Stratigraphy: </b>Cambrian L;
<b>Geography: </b>Australia S^Early Cambrian corals from South
Australia have been found within fossil reefs of unusual biological and
paleoecological composition. The framework of these reefs is composed
of a diverse assemblage of calcareous sponges (e.g., archaeocyaths and
sphinctozoans), calcimicrobes, and at least two species of coral-like
organisms, one of which is first reported herein and bears similarities
to younger Palaeozoic tabulate corals. Complex growth interactions
occur among these organisms, suggesting that space was a limiting
factor in Early Cambrian reef ecosystems, as it is today in modern
scleractinian reefs. In striking contrast to most Early Cambrian
archaeocyath-calcimicrobe reefs, these South Australian reefs
flourished within energetic, mixed siliciclastic-carbonate
shallow-marine environments along the margins of arid, coarse-grained,
sea-marginal alluvial fans. The implications of these coral-bearing
reefs are multifold. First, their existence not only extends the range
of tabulatelike corals to the Botomian (middle Early Cambrian), but it
adds an additional clade of participants to the Early Cambrian metazoan
radiation event. Second, the existence of Botomian-aged skeletonized
colonial cnidarians necessitates an earliest Cambrian or Neoproterozoic
ancestor for the group. Third, the presence of tabulatelike corals and
their involvement in reef building prior to the Toyonian extinction
(late Early Cambrian) challenges hypotheses (e.g., lack of a suitable
reef builder after the extinction of archaeocyaths until the
Ordovician) used to explain the paucity of Middle and Late Cambrian
reefs worldwide. The presence of these corals on sea-marginal fans
contradicts the perception that early reefs were restricted to
low-energy, predominantly carbonate subtidal environments.^1";

Bedford R., W.R. and J. or by subsequent designation. The aim of this
new volume is to give a modern approach of Monocyathina, Dokidocyathina
and Ajacicyathina (i.e. regular atabulate Archaeocyatha) present into
the whole material collected on Ajax Mine area. The most up-to-date
results of anatomic and systematic studies are used and carried further
on distinction between wall-canals and simple pores, porous and non
porous septa (in connexion with stirrup-pores) are taken into
consideration for the definition of new taxa.^1";

The oldest tabulate coral and the associated Archaeocyatha, Lower
Cambrian, Flinders Ranges, South Australia.- Geobios 24, 6: 697-718.-
<b>FC&#038;P 21-1.1</b>, p. 51, ID=3257^<b>Topic(s): </b>; Tabulata,
Flindersipora; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Cambrian L; <b>Geography: </b>Australia S, Flinders Ranges^The
oldest known tabulate, Flindersipora bowmani Lafuste gen. et sp.nov.
from the Flinders Ranges of South Australia is described for the first
time. The new genus presents all morphological and structural
characteristics of Tabulata: cerioid shape, septal ridges, tabulae,
wall pores. Its microstructure is nevertheless new, formed by
&#34;platelets&#34;. Specimens have been found associated with
archaeocyaths and calcified cyanobacteria in Lower Cambrian shelf
margin buildups in the Oraparinna Shale and Moorowie Formation in two
different localities: Ten Miles Creek where they are associated with
solitary archaeocyaths, and Moorowie Mine, where they built complex
bioconstructions associated with colonial archaeocyaths. The
archaeocyaths, comprising 11 species indicate a middle Botomian age.
One species Robertocyathus brenti Debrenne is new. The buildups were
among the last to flourish prior to widespread regression in the Early
Cambrian in South Australia. With this discorvery, the present opinions
on the phylogeny of Tabulate Corals must be modified. In comparison
with some Cambrian or even Ordovician forms which have been supposed to
have affinities with corals, Flindersipora has a less rudimentary
morphology and could not be said more primitive than these previously
known genera. Because of its advanced favositid architectural type
Flindersipora reinforce the idea that the origin of Tabulata is very
ancient and must be looked for in the Precambrian.^1";

<b>Stratigraphy: </b>Cambrian M; <b>Geography: </b>Australia, Georgina
Basin^A rich assemblage of poriferan spicules and sclerites of the
Chancelloriidae has been found in Mid Cambrian phosphatic sediments of
the Georgina Basin. The hexactinellid spicules are especially diverse,
```

```
and contain several new types. These include pulvinusactins (nom. nov.)
and follipinules, strongly inflated triaxons which probably formed an
armouring dermal layer in Thoracospongia, and cometiasters which may be
the first Cambrian evidence of the Hexasterophora. Demosponge spicules,
especially triaenes, are moderately diverse. Polyactine spicules with
central canals are interpreted as proto-aster megascleres, which may
have evolved into aster microscleres. Calcarean, heteractinellid
spicules are also common. These features suggest an early Cambrian
diversification of the Porifera. The systematic position of the
Chancelloriidae is still controversial.^1";

reef: Canning Basin, Western Australia.- Palaeontology 43, 4: 671-703.-
```

```
<b>FC&#038;P 30-1</b>, p. 23, ID=1503^<b>Topic(s): </b>reefs, ecology;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fra;
<b>Geography: </b>Australia, Canning Basin^Back-reef ecologies within
the celebrated mixed carbonate-siliciclastic Late Devonian (late
Frasnian) Pillara Limestone of Windjana Gorge, in the Canning Basin,
Western Australia, are re-interpreted as being dominated by microbial
communities. Proposed microbialites are expressed as weakly-laminated,
fenestral micrite, that show unsupported primary voids, peloidal
textures, disseminated bioclastic debris, and traces of microfilaments.
These grew as either extensive free-standing mounds or columns, often
intergrown with encrusting metazoans, or thick post-mortem
encrustations upon skeletal benthos. In some cases, microbial
encrustations are inferred to have developed in protected cavities
formed by progressive burial of the reef. The calcimicrobe Shuguria
also shows a preferentially cryptic habit, encrusting either primary
cavities formed by skeletal benthos, microbialite, or the ceilings of
mm-sized fenestrae within microbialite. A further calcimicrobe,
Rothpletzella, formed columns up to 0.3m high in areas enriched by very
coarse siliciclastic sediment. * Stromatoporoid sponges with a diverse
range of morphologies also formed in situ growth fabrics. Monospecific
thickets of closely-aggregating dendroid stromatoporoid sponges
(Stachyodes costulata), and platy-laminar forms (?Hermatostroma spp.)
were common, as were remarkably large stromatoporoids (Actinostroma
spp.) that grew as isolated individuals up to 5m in diameter. Such
sponges showed impressive powers of regeneration from partial
mortality, and individual clones may have been capable of substantial
longevities of up to 500 years. Actinostroma spp. showed highly complex
growth forms including platy-multicolumnar (A. windjanicum), and a
hitherto undescribed inferred whorl-forming foliaceous morphology
(Actinostroma sp.) reminiscent of the modern photosymbiotic coral
Acropora palmata. These complex morphologies formed abundant primary
cavities, previously thought to be only rarely developed in association
with stromatoporoids. [original abstract]^1";
s[3793] = "WOOD R.A. (2000).- Novel paleoecology of a postextinction
reef: Famennian (Late Devonian) of the Canning basin, northwestern
Australia.- Geology 28, 11: 987-990.- <b>FC&#038;P 30-1</b>, p. 37,
ID=1504^<b>Topic(s): </b>reefs, post-extinction reefs; reefs ecology;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fam; <b>Geography:
</b>Australia W^Reefs are supposed to be particularly susceptible to
mass-extinction events, and to survive only as low-diversity, remnant
communities dominated by holdover or disaster taxa. Famennian (Late
Devonian) reefs exposed in the Windjana Limestone of the Canning Basin,
northwestern Australia, demonstrate, however, that a novel reef ecology
was established in the immediate aftermath of the Frasnian-Famennian
mass extinction. Here diverse calcimicrobes (including Rothpletzella
spp., Shuguria spp., Ortonella and Girvanella) together with bryozoans,
brachiopods and stromatoporoid, sphinctozoan, and lithistid sponges
grew as complex framework intergrowths in previously undocumented
morphological forms, forming spectacular elevated laminar to platy
structures up to 3 m in diameter and 0.35 m thick. At least 15
morphospecies of lithistids are now identified, where only two were
previously documented. These communities show no substantial reduction
in biodiversity compared to Frasnian counterparts, nor any change in
tiering or loss of complex ecological interactions. These observations
suggest that where stable carbonate platforms persisted after
mass-extinction events, reef-building could continue. More important,
they demonstrate that no protracted interval of time was necessarily
required either for recovery to ecological stability or for completely
new ecologies to assemble. Such studies highlight the need to document
ecosystem recovery after mass-extinction events using detailed
paleoecological analyses in addition to simple compilations of global
biodiversity changes.^1";

s[3795] = "HURLEY N.F., VOO R.van der (1990).- Magnetostratigraphy,
Late Devonian iridium anomaly, and impact hypotheses.- Geology 18:
291-294.- <b>FC&#038;P 20-1.1</b>, p. 67, ID=2848^<b>Topic(s):
</b>extinctions; iridium anomaly; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography: </b>Australia,
Canning Basin^Paleomagnetism, sedimentology, and fine-scale
stratigraphy have been integrated to explain the origin of an iridium
anomaly in the Late Devonian of Western Australia. Thermal
demagnetization experiments were carried out on 93 specimens of
marginal-slope limestone from the northern Canning Basin. Samples are
from a condensed sequence of deep-water (> 100 m) Frutexites
microstromatolites. Frutexites is a shrublike cyanobacterial organism
that probably precipitated hematite, or a metastable precursor, from
sea water. When plotted within the microstratigraphic framework for the
study area, the observed characteristic directions from the sampled
interval (14.5 cm thick) are in five discrete, layer-parallel, normal-
and reversed-polarity zones. The measured northeast-southwest
declinations and shallow inclinations probably record Late Devonian
magnetostratigraphy on a centimetre scale. The Frutexites bed studied
here occurs close to the Frasnian &#47; Famennian (Late Devonian)
boundary, a time of mass extinction of a wide variety of marine
organisms throughout the world. Anomalously high iridium concentrations
observed in the Frutexites bed have suggested to some authors that the
mass extinction was caused by meteorite impact. This study concludes
that iridium, which is present over the span of five layer-parallel
magnetic reversals, was concentrated over a long period of time by
biologic processes. Thus, the Canning Basin iridium anomaly may be
unrelated to meteorite impact. ^1";

Platform-margin collapse during Famennian reef evolution, Canning
Basin, Western Australia.- Geology 23, 8: 691-694.- <b>FC&#038;P
25-1</b>, p. 52, ID=3065^<b>Topic(s): </b>reefs, margin collapse;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fam;
<b>Geography: </b>Australia, Canning Basin^Sedimentological
investigations of well-exposed slope strata in the Upper Devonian reef
complexes of the northern Canning Basin lead to a
sequence-stratigraphic interpretation that differs from others based on
predictive models in which coarse carbonate debris deposits are
regarded as lowstand deposits. In the upper Frasnian-Famennian Napier
Range slope succession, we recognize an important phase of
platform-margin collapse during a sea-level highstand in the middle
Famennian. At this time the reef-rimmed margin was rapidly prograding,
and the platform was producing carbonat grams (notably ooids and
peloids) that were beeing transported by turbidity currents to the
slope and basin floor. Periodic collapse of the platform margin led to
deposition on the slope of allochthonous blocks of reefal limestone and
channelized debris-flow units, intercalated with the ooid-peloidal
turbidites and quartzo-feldspathic sandstones. Collapse of the
early-cemented margin was probably triggered by gravitational
instability caused by oversteepening during rapid progradation and/or
tectonic activity, with falling blocks initiating some of the debris
flows.^1";
s[3797] = "PAUL J. (1996).- Stromatolites of the Canning Basin (Upper

</b>; <b>Stratigraphy: </b>Devonian U; <b>Geography: </b>Australia,
Canning Basin^In the Canning Basin of Western Australia stromatolites
are very abundant in marine sediments overlying Frasnian reefs. There
are stratiform and columnar types in beds of some meters thickness as
well as small bioherms of the same size. They are associated with
normal marine fossils like sponges, corals, crinoids, brachiopods,
ammonoids, and conodonts. Growth rates of stromatolite beds were very
low. Stromatolite bearing beds are preferentially red probably due to
the presence of hematite indicating oxidizing conditions as a
consequence of low productivity. Crinoidal fastholds are very common at
the surface and within stromatolites. They prove a very early
lithification as they need a hardground for settling. The
synsedimentary lithification may be the reason for the preservation of
the stromatolites as their potential of fossilization is usually
realtively low.^1";
s[3798] = "WOOD R.A. (1998).- Novel reef fabrics from the Devonian
Canning Basin, Western Australia.- Sedimentary Geology 121: 149-156.-
<b>FC&#038;P 28-1</b>, p. 57, ID=4000^<b>Topic(s): </b>reef fabrics;
reef fabrics; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fra;
<b>Geography: </b>Australia, Canning Basin^Large cement-filled cavities
(0.2 to 1.5 m wide) are well developed in slope-margin sediments of the
spectacular Upper Devonian (Frasnian) reefs of the Canning Basin,
Western Australia, where they account for up to 50% of the primary
porosity. These are here interpreted as primary reef framework cavities
formed beneath a variety of domal, tabular, or laminar stromatoporoid
sponges. Of particular note are those created by unusual, very thin (2
to 8 mm) laminar stromatoporoids (mainly Stachyodes australe), that
formed arching hollow domes up to 0.3 m in height and 1.5 m in diameter
over the sediment surface to enclose flat-based cavities. The free
undersurface of these stromatoporoids often supported a hitherto
unrecognized cryptic community, dominated by pendant growth of the
putative calcified cyanobacterium Renalcis, with rare intergrown
lithistid sponges and spiny atrypid brachiopods. The uneven growth
surface of the cryptos imparts an irregular stromatactis-like texture
to the upper surface of the remaining cavity, which is filled by early
marine, finely banded fibrous cements (mainly radiaxial calcite)
embedded with often multiple generations of geopetal cement containing
peloids and ostracod debris. This ecology yields the tabular
stromatoporoid-Renalcis fabric described ubiquitously from the Canning
Basin reef complex. Such unusual reef fabrics are a consequence of the
ecology of shallow-water marine mid-Palaeozoic reefs which were quite
unlike that of modern coral reefs. The frequent preservation of
relatively delicate, in situ communities was due to (1) rapid and
pervasive early cementation, (2) growth under non-energetic conditions,
and (3) the relative insignificance of bioeroders associated with reefs
at this time.^1";

<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Australia, Canning
Basin^The Devonian reef belt of the Canning Basin is one of the best
exposed and best preserved ancient reef complexes of the world. The
reefs crop out over about 350 km in a 1.5 to 50km wide zone along the
northern margin of the Canning Basin. This zone, called the Lennard
```

```
Shelf is bounded on the north by the Precambrian rocks of the Kimberley
Block and to the south by the deep Fitzroy Trough. A marginal fault
(Pinnacle Fault) with a throw of about 6000 m displaces the Fitzroy
Trough from the Lennard Shelf. * As a result of block faulting
preceding the beginning of reef growth in Middle Devonian times a
relief of locally up to 1000m was formed. The reefs were established on
this rugged topography along the coasts of the Kimberley Block and also
surrounded offshore islands. It is thought that they once also flanked
the shores of the Kimberley Basin to the west and north over a distance
of another 1000km. Thus the &#34;Great Devonian Barrier Reef&#34; as it
was called by Teichert (1943) in analogy to the modern Great Barrier
Reef is quite an appropriate term. [extracted from an introduction]^1";

proximal reef-slope communities within the Windjana Limestone, Canning
Basin, north-western Australia, show that, notwithstanding the loss of
large metazoans, novel ecologies were established in this setting by a
rich biota of survivor and progenitor taxa. Diverse calcimicrobes,
together with algae, crinoid, bryozoans, brachiopods and abundant
sponges (stromatoporoids, inozoans, sphinctozoans, lithistids and
hexactinellids) formed a reef framework of either elevated platy
structures up to 4m in diameter and 0.35m thick, or mounds up to 15m in
diameter. This framework was dominated by a complex intergrowth of
calcimicrobes where Rothpletzella formed the primary framework,
Ortonella and Girvanella were secondary encrusters, and Shuguria spp.
occupied small crypts 2-30mm in diameter. Contiguous columnar
stromatolites up to 50mm in height and 1m in width grew upwards from
substrate sheltered beneath large sheltered primary cavities; based on
minimum growth rates of 50-100 µm/year these are estimated to have been
500-1000 years old. The elevated platy community is inferred to have
grown in conditions of episodic siliciclastic sediment input; the reef
mounds grew during either episodes, or in localized areas, of low
sedimentation. At least 14 species of spicular sponges are now
identified from the Windjana Limestone where only two were previously
documented. These fore-slope reef communities exposed in Windjana Gorge
flourished in high energy carbonate environments dominated by coated
grain sediments and, where rapid, early lithification was pervasive. *
Such observations demonstrate that no protracted interval of time was
```

```
necessarily required for post-extinction &#039;recovery&#039; in
regions where some reef-building taxa survived and suitable carbonate
habitats persisted or returned. Moreover, they show that new ecologies,
rather than remnants of the pre-extinction community, could be
established rapidly. The reef-slope communities of the Windjana
Limestone offer little evidence to support the ideas of resurgence or
invasion of taxa from deeper waters after the Frasnian &#47; Famennian
extinction event. Indeed, there is evidence to suggest that similar
microbial-sponge communities were already established in margin and
reef slope communities in the latest Frasnian. As such, the most
dramatic ecological changes caused by the extinction occurred in
back-reef communities, [original abstract]^1";
s[3804] = "WEBB G., JELL J.S. (2002).- A new species of Palaeacis from
Western Australia.- Coral Research Bulletin 7: 221-227. [Dieter
Weyer&#039;s 65th birthday commemorative volume; S. Schröder, H. Löser
&#038; K. Oekentorp (eds)].- <b>FC&#038;P 31-1</b>, p. 34,
ID=7106^<b>Topic(s): </b>new species; Tabulata Palaeacis;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Carboniferous Vise; <b>Geography: </b>Australia W^Palaeacis
irregularis n.sp. is described from the middle to lowermost upper
Visean Utting Calcarenite from the Bonaparte Basin of Western
Australia. The species is characterised by: 1) wedge-shaped corallum;
2) occurrence of all corallites within a single plane; 3) divergence of
mature corallites away from each other so as to end up as isolated
tubes; and 4) sessile, attached or free-living habits. Palaeacis
irregularis n.sp. does not bear close affinities to any described
Palaeacis species from the Lower Carboniferous of eastern Australia,
although it conceivably could be derived from the P. cuneiformis group,
which occurs in eastern Australia. Regardless, the difference between
P. irregularis and relatively well known forms in eastern Australia
supports the palaeobiogeographic distinction of the two regions.

microbialites; <b>Systematics: </b>Monera; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Australia W^Lake Thetis is a small saline lake with
an increased alkalinity and abundant domal microbialites. These
microbialites exhibit a rough stromatolitic structure. The recent
growth results mainly from calcifying Entophysalis-biofilms which are
forming a more or less laminated crust. Within the deeper parts of the
Entophysalis-biofilm the outer basophilic polysaccharide envelopes
contain abundant heterotrophic bacteria. Calcification events exactly
start at these points. The older, subfossil portions of the
microbialites are characterized by plumosely arranged
Scytonema-filaments which are enclosed by fibrous aragonite. Within
small cryptic primary and secondary cavities clearly laminated
organomicrites are lining the cavity walls. The formation of this type
of &#34;microstromatolites&#34; is related to organic films, which
contain no active microbes. These organic films are composed of
degraded organic material (polysaccharides, proteins etc.) acting as
matrices and templates for nucleation and growth of organomicrites and
fibrous aragonite crystals.^1";

```

```
211-250.- <b>FC&#038;P 31-2</b>, p. 58, ID=1716^<b>Topic(s):
</b>taxonomy; fossils; <b>Systematics: </b>; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>Australia, New South Wales^Diverse
shallow water assemblages dominated by brachiopods, molluscs, sponges
and stromatoporoids, and a tabulate coral, in the Wahringa Limestone
Member (Darriwilian-Gisbornian), and Yuranigh Limestone Member
(Gisbornian, or early Late Ordovician) of the Fairbridge Volcanics, are
documented from the northern Molong Volcanic Belt in central N.S.W. New
species described include Billingsaria spissa, Shlyginia printhiensis
and Sowerbyites? wahringaensis. Elements of the Wahringa Limestone
Member assemblage such as Labechia banksi, Labechiella regularis, and
Maclurites cf. M. florentinensis are biogeographically significant in
displaying strong similarities with contemporaneous Tasmanian faunas.
The brachiopods Ishimia and Shlyginia from the Yuranigh Limestone
Member are recognised for the first time outside Kazakhstan and
Sibumasu. The presence of the brachiopod Anoptambonites in
allochthonous limestone breccia within the lower Fairbridge Volcanics
provides evidence of a regionally significant hiatus of 10-15 Ma
duration separating this unit from the underlying Hensleigh Siltstone,
of Early Ordovician (Bendigonian) age. The sponge Archaeoscyphia?, from
allochthonous limestones in the latter formation, is the oldest
macrofossil yet described from the Lachlan Fold Belt in central N.S.W.

s[3827] = "WEBBY B.D., ZHEN Y.Y., PERCIVAL I.G. (1997).- Ordovician
coral- and sponge-bearing associations: distribution and significance
in volcanic island shelf to slope habitats, Eastern Australia.- Boletin
de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92,
1/4: 163-175.- <b>FC&#038;P 26-2</b>, p. 27, ID=3710^<b>Topic(s):
</b>biocoenoses; coral &#038; sponge associations; <b>Systematics:
</b>; <b>Stratigraphy: </b>Ordovician; <b>Geography: </b>Australia, New
South Wales^The Cliefden Caves area of central New South Wales has a
well preserved Late Ordovician sedimentary succession that formed in an
offshore, near-equatorial, volcanic island setting. Initially fringing
deposits (the Fossil Hill Limestone) accumulated, with occurrences of
corals such as Tetradium cribriforme, Nyctopora, Bajgolia?, Dualites,
Hillophyllum, and stromatoporoids like Cystistroma, Rosenella and
Stratodictyon. These were particularly characteristic of the
shoal-type, mid-shelf T. cribriforme biofacies, and were contributors
to a number of bioherms and biostromes. The succeeding, massive
Belubula Limestone accumulated mainly in shallow lagoonal phases of the
planated island with only sparse heliolitine corals, Aulopora,
Bajgolia?, the stromatoporoids Cystostroma and Alleynodictyon? and the
sphinctozoan sponge Belubulaia. The overlying deeper platform
carbonates of the Vandon Limestone have a more diverse fauna with T.
cribriforme, numerous heliolitines, Palaeophyllum, the sphinctozoan
Cliefdenella, and stromatoporoids (Ecclimadictyon, Clathrodictyon), but
no indubitable &#034;reefs&#034;. Deep water assemblages of the
overlying Malongulli Formation include reworked and in situ siliceous
sponge associations. Limestone breccias include; (1) clasts with corals
(Favistina and favositids) and rare silicified sphinctozoans, presumed
to be derived from the adjacent shallow platform; and (2) clasts eroded
from the slopes, with a diverse assemblage of demosponges,
```

```
hexactinellids and discrete spicules. The in situ Malongulli assemblage
occupied a lower slope &#47; basin position, and includes undescribed
hexactinellids and abundant spicules. A striking onshore-offshore
faunal differentiation exists, with (1) the corals and stromatoporoids,
most diversified and abundant in the mid-shelf island settings above
wave base, (2) the sphinctozoans, rare constituents of lagoonal to
subtidal &#034;level bottom&#034; carbonate platform habitats, (3) the
demosponges, most common and diversified in the upper slope, and (4)
the hexactinellids, well represented in both upper and lower slope
&#47; basin habitats.^1";
s[3828] = "PICKETT J.W., PERCIVAL I.G. (2001).- Ordovician faunas and
biostratigraphy in the Gunningbland area, central New South Wales,
Australia.- Alcheringa 25, 1: 9-52.- <b>FC&#038;P 31-2</b>, p. 30,
ID=7127^<b>Topic(s): </b>geology, fossils; geology, paleontology;
<b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician; <b>Geography:
</b>Australia, New South Wales^The Billabong Creek Formation and
overlying Gunningbland Formation within the Northparkes Group in the
Gunningbland area, 28km west of Parkes, range in age from late
Darriwilian (late Middle Ordovician) to late Eastonian (middle Late
Ordovician). These strata provide the most complete sequence through
this interval in the central Lachlan Orogen in New South Wales. A
biostratigraphic zonation spanning the Darriwilian to Gisbornian is
proposed, employing conodonts and corals. This supplements the existing
coral &#47; stromatoporoid, brachiopod and trilobite faunal assemblages
defining Eastonian and Bolindian shelly fossil zones. The Pygodus
anserinus Zone (late Darriwilian) in the basal Billabong Creek
Formation is succeeded by the Foerstephyllum-Billingsaria-Stratodictyon
Assemblage-Zone (of Gisbornian age) in the middle Billabong Creek
Formation. A further five Assemblage-Zones extending through the
Eastonian succession are formally defined to replace the existing
shelly fossil &#039;faunas&#039;. New coral species described are
Billingsaria domica, Eofletcheria subcerioidea, Foerstephyllum
nelungaloo, and ?Paleoalveolites explanatus; a possible new species of
the conodont Eoplacognathus is described, but not formally named.

from the Quinton Formation, Broken River Province, northeast
Queensland.- Memoirs Association Australasian Palaeontologists 21:
1-65.- <b>FC&#038;P 29-1</b>, p. 57, ID=1447^<b>Topic(s): </b>taxonomy;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Silurian Llan; <b>Geography: </b>Australia, Queensland^Three late
Llandovery rugose coral faunas are described from allochthonous
limestones near the base of the Quinton Formation in the north of the
Graveyard Creek Subprovince, northeast Queensland. The limestones occur
within predominantly siliciclastic turbiditic sediments, and consist of
large slumped blocks, calcirudites and calcarenites. These were
probably derived from contemporaneous shallow marine areas along the
unstable northern margin of a small, rapidly subsiding basin, which
developed during the Early Silurian in a probably extensional tectonic
setting.Twenty-three species referable to 17 genera are descibed,
including the new taxa: Aphyphyllum leprostylum sp.nov.; Dentilasma
benestratum sp.nov.; Holmophyllum hadrakainum sp.nov.; Plektelasma
eurybykane gen et sp.nov. (Streptelasmatidae); Spinocarina vitilia gen.
et sp.nov. (Palyphyllidae); Amplexoides grayense sp.nov.; Amplistela
speciosa gen. et sp.nov. (Arachnophyllidae); and Burota compluvium gen.
et sp.nov. (Burotidae fam nov.). Other genera recorded include
Tryplasma, Stortophyllum, Rhizophyllum, Cystiphyllum (Cystiphyllum),
Palaeophyllum?, Pycnostylus, Lindstroemophyllum ?, Grewingkia and
Cyathactia. The faunas are endemic at the specific level, but have some
generic links with faunas of central and southern New South Wales,
southern China and to a lesser extent, the Siberian Platform. Age
interpreations from the faunas are consistent with associated conodont,
graptolite and trilobite age deteminations of Telychian (late
Llandovery).^1";
s[3833] = "STRUSZ D.L., MUNSON T.J. (1997).- Coral assemblages in the
Silurian of Eastern Australia: a rugosan perspective.- Boletin de la

311-323.- <b>FC&#038;P 26-2</b>, p. 32, ID=3723^<b>Topic(s):
</b>biostratigraphy; Rugosa assemblages; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Australia
E^Four successive coal assemblages can be recognized in the Silurian of
Eastern Australia. The Bridge Creek Assemblage (Rhuddanian-Aeronian) is
of limited extent, characterized by species of C. (Cystiphyllum),
Grewingkia and Calostylis as well as numerous halysitids and
Pseudoplasmopora. The earliest arachnophyllids and species of
Ptychophyllum occur in the widespread Quarry Creek Assemblage
(Telychian-early Sheinwoodian), in which there is greater rugosan and
halysitid diversity. The late Sheinwoodian-earliest Gorstian Dripstone
Assemblage is mainly characterized by changes in the tabulate fauna,
but is also notable for the appearance of Entelophyllum, Holmophyllia,
and Zenophila. The Gorstian-Pridoli Hattous Corner Assemblage is a
diversification of older faunas (except the halysitids), and is
characterized by such rugosans as Phaulactis shearsbyi, Aphyllum
lonsdalei, as well as Idiophyllum patulum and species of
Toquimaphyllum.^1";

species, is a Silurian and Devonian favositid. It is characterized by
distant groups of tabulae developed at the same level throughout the
corallum and by pores which are confined to these levels. The genus is
endemic to eastern Australia. Two new species, H. fascitabulata from
the lower Gedinnian of New South Wales and H. spinosa from the Emsian
of north Queensland, are referred to it.^1";
s[3844] = "TROTTER J.A., TALENT J.A. (2005).- Early Devonian
(mid-Lochkovian) brachiopod, coral and conodont faunas from Manildra,
New South Wales, Australia.- Palaeontographica 273, 1-2:
1-54.http:&#47;&#47; hdl.handle.net/1959.14/32268.- <b>FC&#038;P
34</b>, p. 39, ID=1242^<b>Topic(s): </b>; paleontology; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian Lochk;
<b>Geography: </b>Australia, New South Wales^New data are provided for
assessing the sedimentary context, palaeoecology and biogeographic
affinities of the brachiopod, coral and conodont faunas from Manildra.
The deeper-water Maradana Shale shallows upwards into the shallow
marine, brachiopod-dominated Garra Limestone The latter is
characterised by angular, poorly sorted allochemical constituents, high
mud contents, and encrusting algal mats of Girvanella, all implying
low-energy conditions with limited post-mortem transport. This is
supported by the relatively low degree of valve disarticulation of the
silicified brachiopod assemblages. The sedimentological data accord
with a shallow (photic zone), open marine environment, with moderate to
low-energy conditions of a protected zone within a carbonate platform
or shelf-margin. The Garra Limestone is terminated by an influx of
clastics and volcaniclastics, the Mandagery Park Formation (redefined).
The 55 species of brachiopods from the Garra Limestone at Manildra are
referred to 36 genera including two new rhynchonellid genera,
Protodorsisinus and Discamella, with type species P. similis sp nov.
```

```
and D troparvis sp, nov. respectively. A new species of the cemented
strophomenid, Colletostracia, is described but not named. None of the
coral and conodont taxa documented appear to be new. [end-fragment of
extensive abstract]^1";
s[3845] = "ZHEN YONGYI (1996).- Succession of coral associations during
a Givetian transgressive-regressive cycle in Queensland.- Acta
Palaeontologica Polonica 41, 1: 59-88.www.a
pp.pan.pl/article/item/app41-059.html.- <b>FC&#038;P 25-2</b>, p. 59,
ID=3158^<b>Topic(s): </b>ecology, succession; coral associations;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian
Giv; <b>Geography: </b>Australia, Queensland^The small solitary coral
dominated, Grypophyllum-Chostophyllum association, a pioneer coral
community, is widely distributed at the base of the Givetian Burdekin
Formation of north Queensland in the mixed arkose-carbonate sediments.
It is succeeded by fasciculate coral dominated, Dendrostella trigemne
association, which is mainly associated with wackestone or bioclastic
calcirudite of inner shelf, lagoonal or protected environments. The
Australophyllum-Sanidophyllum association, Blysmatophyllum-Iowaphyllum
schlueteri association, and Spongophyllum association, all dominated by
in situ, large massive coral colonies, formed biostromal deposits on
the margins of the basin. They developed in nearshore envrironments
during the maximum flooding in the region. The Aphyllum
salmoni-Stringophyllum (Neospongophyllum) bipartitum association
indicates relatively deeper, mid-outer shelf environments connected
with maximum flooding in the depocentre and least terrigenous influx.
The massive coral dominated Endophyllum columna-Stringophyllum
(Stringophyllum) isactis association, developed in the initial
regressive phase, forms a distinctive biostromal unit at the top of the
Burdekin Formation. The Lekanophyllum association developed at the base
of the Cultivation Gully Formation in a very shallow nearshore
environmentwith a large terrigenous influx as a result of the basin
wide, relatively rapid regression. It is characterised by the abundant
occurrence of solitary corals and large sized, cerioid Endophyllum
columna, which often formed micro-atolls. Rugose corals were better
adapted than stromatoporoids to survive of mud inllux. [original
abstract]^1";

interval (?)]^1";
s[3853] = "WRIGHT A.J. (2000).- A new Early Devonian operculate
tetracoral genus from eastern Australia.- Records of the Western
Australian Museum, Supplement 58: 21-35.- <b>FC&#038;P 30-2</b>, p. 21,
ID=1573^<b>Topic(s): </b>new taxa; Rugosa, Calceolidae, Chakeola;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian L;
<b>Geography: </b>Australia E^Chakeola, a solitary latest Lochkovian to
late Emsian (Early Devonian) new genus of the operculate tetracoral
family Calceolidae, is characterized by: opercular septa that are
present from adjacent to the median septum to the lateral extremities
of the operculum; a lack of rootlets on the counter face of the
corallite; a weak counter opercular face in mature specimens; and
eccentric growth increments on the external opercular surface. The type
species, C. johnsoni new species, is described from latest Lochkovian
(pesavis Zone), early Pragian (sulcatus Zone) and late Pragian
(pireneae Zone) strata of the Garra Formation, Wellington, NSW. C.
whitehousei new species is described from the Ukalunda Beds (perbonus
Zone, mid-Emsian), near Ukalunda, Queensland. Specifically
indeterminate occurrences of the genus from the Mudgee district in New
South Wales are in: the Taylors Hill Formation (?kindlei Zone, late
Pragian); the Sutchers Creek Formation (serotinus Zone, late Emsian);
and possibly the Mullamuddy Formation (sulcatus Zone, early Pragian).
Rhizophyllum calceoloides from the Tabberabbera Formation (Emsian),
Victoria also belongs to this new genus. Calceola sinensis and Calceola
sandalina acuminata from Emsian strata in northern Vietnam are also
assigned to this genus.Chakeola thus ranges from the latest Lochkovian
(pesavis Zone) to the late Emsian serotinus Zone; it presumably arose
from Rhizophyllum or a related form, and probably gave rise to Calceola
in the Emsian in eastern Australia or SE Asia. The occurrence of the
genus in eastern Australia and Vietnam provides further evidence of
faunal exchange during the Early Devonian. This study concludes that
features of the exterior and interior surfaces of the opercula of
genera of the Calceolidae are diagnostic at the generic level.^1";

Devonian) and possibly Eifelian (Middle Devonian) strata. The subfamily assigment is based on a close similarity to Macgeea touti Pedder, which appears to be ancestral to F. climax. Silicified specimens show F. climax to be a polymorphic fasciculate form which undergoes up to three phases of parricidal peripheral increase. When basal structures are preserved, F. climax is mostly found attached to various types of fossil skeletons which offered a firm substrate above the muddy sea floor by sheaths of skeletal material. Calcareous specimens show a well -defined vertical series of horseshoe dissepiments outside which are horizontally disposed ranks which consist alternately of mostly horseshoe dissepiments and flat dissepiments. Outside this zone normal dissepiments are developed which are proximally and ourwardly inclined. This outermost array of skeletal material often spreads down the side of the colony over the wall of the trunk, demonstrating the presence of a highly extensile edge zone and everted calyx. Polymorphism is manifest in the diameter and number of septa developed in each of the several generations within a colony. [original summary]^1";

s[3860] = "ADACHI N., EZAKI Y., PICKETT J.W. (2006).- Marked
accumulation patterns characteristic of Lower Devonian stromatoporoid
bindstone: Palaeoecological interactions between skeletal organisms and
microbes.- Palaeogeography, Palaeoclimatology, Palaeoecology 231, 3-4:
331-346.- <b>FC&#038;P 34</b>, p. 26, ID=1220^<b>Topic(s): </b>reefs,
ecology; stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>Australia, New South
Wales^The growth history of stromatoporoid bindstones is as follows: 1)
the laminar stromatoporoid &#034;Aculatostroma&#034; first grew
laterally, thereby stabilizing bioclastic sediments; 2) the
stromatoporoid growths were partly or totally interrupted in relation
to deteriorating habitat conditions, where micritization (leiolites
with microborings), and encrustation by thrombolites occurred in
succession. However, somewhat ameliorated conditions enabled
Syringodictyon to temporarily dominate; 3) surviving parts of
&#034;Aculatostroma&#034; again spread vertically and laterally upon
the recovery of optimum conditions and; 4) the ceilings of cryptic
spaces produced within &#034;Aculatostroma&#034; are affected by
micritization (leiolites) and then encrustation of thrombolites.
Repeated accumulations at various scales indicate antagonistic
interrelationships within skeletal organisms and between skeletal
organisms and microbes within their habitable ranges. These
accumulation patterns thus provide invaluable clues for biotic
interactions between skeletal frameworks and microbes, biological
successions in accordance with microenvironmental changes, and
resultant depositional sequences of bindstones. [last part of extensive

<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>Australia, New South
Wales^Holacanthopora clarkei sp.nov. is described from late Early
Devonian beds of the Mount Frome Limestone, near Mudgee, New South
Wales, Australia. The species and genus are referred here to the
Micheliniidae (Favositoidea, Tabulata). Difficulties encountered in
comparing genera of this family, as a result of mode of preservation
and uncertainty concerning the significance of the various growth
forms, are discussed.^1";
s[3868] = "POHLER S.M.L. (2001).- Paleoecology, biostratigraphy and
paleogeography of Favositidae (Tabulata) from the Emsian to Middle
Devonian Tamworth Group (New South Wales, Australia).- Senckenbergiana
lethaea [Palaeobiodiversity and Palaeoenvironments] 81, 1: 91-109.-
<b>FC&#038;P 30-2</b>, p. 25, ID=1579^<b>Topic(s): </b>ecology,
stratigraphy; Tabulata, Favositida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Devonian L M; <b>Geography:
</b>Australia, Tamworth Belt^Different species and species groups of
the family Favositidae from the Emsian and Middle Devonian limestones
of the Tamworth Group (N.S.W., Australia) were investigated with regard
to their paleoecology, biostratigraphy and paleogeography. The Emsian
Sulcor Limestone Member yielded Favosites sp. aff. F. basalticus
(Goldfuss), Favosites sp. aff. F. salebrosus Ehteridge, Favosites
stellaris Chernyshev, Squameofavosites nitidus (Chapman), Sq. bryani
(Jones), Pachyfavosites rariporus Dubatolov, and P. tumulosus Yanet.
The Middle Devonian Moore Creed Limestone Member yielded Favosites ex
gr. goldfussi d&#039;Orbigny, exclusively. In the Emsian limestones
favositids occur in different lithofacies, but mostly in stratified
biostromes, bedded nodular limestones and Amphipora limestones. In the
Middle Devonian favositids are found in nodular and lumpy limestones
which occur at the base and at the top of some successions. A
relationship between sediment composition and the septal apparatus
could be detected in F. ex gr. goldfussi. The favositid faunas from
Tamworth display faunal ties to eastern Australia and various regions
of Asia. Most striking is the similarity to faunas from the southern
Tien Shan region. Complex provincial affinities and high diversities
are displayed by Emsian favositids, whereas Middle Devonian faunas are
of low diversity and consist of cosmopolitan species.^1";
s[3869] = "PICKETT J.W., RIGBY J.K. (1983).- Sponges from the Early
Devonian Garra Formation, New South Wales.- Journal of Paleontology 57,

at Reefton, New Zealand: guilds, origin and paleogeographic
significance.- Lethaia 35, 1: 35-50.- <b>FC&#038;P 31-1</b>, p. 71,
ID=1651^<b>Topic(s): </b>reefs, guild structure; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian L; <b>Geography: </b>New
Zealand^Study of 35 systematically collected and 10 semi-random samples
(about 100 cm2 each) from one outcrop of the Lankey Limestone (Emsian)
near Reefton, New Zealand, indicates that it is a reef framestone built
by tabulate (4? spp.) and clonal rugose (one sp.) corals, two species
of stromatoporoids, a few bryozoans (2? spp.) and crinoids. The guild
structure of the reef community and data on skeletal orientation and
growth direction further indicate that there was relatively minor
biostratinomic alteration of the original community. Skeletons are
```

```
either in growth position or tipped, toppled, or even overturned, but
they have remained in situ. Other clone-rich Lankey Limestones outcrops
in the Reefton area support the notion of an upper shelf reef system
and stratigraphic and sedimentologic data suggest that it was located
near the Gondwana margin at a paleolatitude of about 35°S. (original
abstract). The stromatoporoid species identified are Anostylostroma
(now Stictostroma) clarum and Stromatopora hupschii. The first is shown
in an outcrop photograph.^1";
s[3871] = "POHLER S.M.L. (1998).- Devonian Carbonate Buildup Facies in
an Intra-oceanic Island Arc (Tamworth Belt, New South-Waltes,
Australia).- Facies 39, 1: 1-34.- <b>FC&#038;P 27-2</b>, p. 75,
ID=3944^<b>Topic(s): </b>reefs intra-oceanic; reefs, intra-oceanic;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L M; <b>Geography:
</b>Australia, Tamworth Belt^Biohermal and biostromal buildups were
investigated in late Early and Middle Devonian carbonate complexes of
the Tamworth Belt. The buildup types and subtypes were studied in three
regions (Yarramanbully, Sulcor and, Wyaralong&#039;) to clarify their
paleo-environmental position. Two stages of development are recognized:
Incipient bioherms and bioherms. Incipient bioherms are carbonate
buildups with organisms which commonly form true bioherms. They
dominate the sediment with small growth forms but are not prolific
enough to build large bio-frameworks. Small nodular and globular
stromatoporoids characterize the incipient bioherms and are interpreted
as stunted growth forms. In one location (,Wyaralong&#039;) the coarse
stromatoporoid calcarenite represents a fore-reef facies, at Sulcor a
shallow subtidal setting with moderate water energy can be deduced. The
bioherms can be sub-divided into stromatoporoid-,
stromatoporoid-Stachyodes-, and stromatoporoid-rugose coral bioherms.
Their variable composition probably reflects growth and deposition in
different zones of a reef complex and/or different proximity to areas
of denundation indicated by high siliciclastic input. In the Tamworth
region true bioherms occur only in the Moore Creek Limestone Member
(Middle Devonian), and not in older carbonate successions. Biostromes
are sub-divided into (1) incipient biostromes with
stromatoporoid-heliolitid biostromes and alveolitid biostromes; (2)
aggregate biostromes with Amphipora and Stachyodes biostromes; (3)
stratified biostromes; (4) mixed aggregate/stratified biostromes. The
different types of biostromes are not limited to specific
time-intervals, but rather to environmental conditions. (1) Incipient
biostromes are characterized by laminar stromatoporoids and tabualte
corals. Their forms are interpreted as initial layers of skeletons
which were hampered by adverse conditions in growth. The
stromatoporoid-heliolitid incipient biostrome (Eifelian Moore Creek Ls.
Mbr., Yarramanbully) is characterized by abundance of dislodged
laminar, ragged and tabular colonies associated with small globular and
nodular heliolitids. An unstable substrate may have caused the growth
disruptions. Decreasing grain-size of skeletal debris andincreasing
mud-content suggests deposition on a bathymetric gradient with
deepening to the south. The alveolitid incipient biostrome (Eifelian
Morre Creek Ls. Mbr., Wyaralong&#039;) is composed of nodular limestone
with laminar alveolitids, stromatoporoids and Sphaerocodium.^1";
s[3872] = "PICKETT J.W., OCH D.J., LEITCH E.C. (2009).- Devonian marine
invertebrate fossils from the Port Macquarie Block, New South Wales.-

stratigraphy, biogeography; paleontology; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian Ems - Giv; <b>Geography: </b>Australia,
New South Wales^Two assemblages of rugose and tabulate corals, with
accessory stromatoporoids and chaetetids, are described from the
Touchwood and Mile Road Formations of the Wauchope - Port Macquarie
district of northeastern New South Wales. Both assemblages are derived
from allochthonous limestone clasts, except that the Mile Road fauna is
```

```
accompanied at the same level by branching tabulate corals occurring in
the matrix, indicating probable contemporaneity. The fauna from the
Touchwood Formation indicates an Early Devonian (Emsian) age.
Macrofossils from the Mile Road Formation indicate a broad Middle
Devonian, probably Givetian age; conodonts accompanying the coral
assemblage yield a precise age in the upper part of the early Givetian
varcus Zone. Geographic affinities of the assemblages are typically
eastern Australian, so that if terranes are represented in the block,
these were not remote. Stratigraphic and structural relationships of
the units are discussed. The name Mile Road Formation is formally
defined. [listed, and mostly illustrated fossils, are: Chaetetes sp.,
Coenostroma sp., Endophyllum cf. columna Hill, Acanthophyllum sp.,
Xystriphyllum cf. mitchelli minus Parker, Phillipsastrea cf. maculosa

s[3873] = "WEBB G.E. (2000).- The palaeobiogeography of eastern
Australian Lower Carboniferous corals.- Historical Biology 15, 1-2:
91-119.- <b>FC&#038;P 31-1</b>, p. 62, ID=1631^<b>Topic(s):
</b>biogeography; corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Australia
E^Eastern Australian Lower Carboniferous (EALC) corals are
characterized by high endemism, with endemism indices of 50 in the
Tournaisian and 44 in the Visean. The most closely related coral faunas
occur in the Akiyoshi and Kitakami Terranes of Japan. Less robust
faunal linkages exist with southeast Asia, south China, northern
Siberia and Kazakhstan, suggesting east to north Tethyan linkages on
most tectonic reconstructions. Amygdalophyllum appears to have
originated in the eastern Australian-Japanese region and then migrated
throughout the Palaeotethys during the late Tournaisian and early
Visean. Eastern Australian taxa that lacked such a widespread
distribution during the Tournaisian did not spread throughout the
Palaeotethys during the Visean. EALC coral distributions can be
explained by a palaeobiogeographical model wherein: 1) shallow-water
coral faunas were largely depleted following the Frasnian/Famennian
extinction event; 2) dispersal occurred during the late Famennian to
early Tournaisian from an oceanic centre to the northeast, in western
Panthalassa; 3) eastern Australian coral faunas were isolated from the
north by the prevailing southerly current direction and possible
coastal upwelling in northernmost Australia and New Guinea, and from
the south by cooler high latitudes; 4) endemic taxa arose by vicariance
subsequent to geographic isolation. * Sampling of EALC corals is
incomplete owing to the restriction of most taxa to shallow carbonate
facies, which have very limited geographic and stratigraphic
distributions. Hence, EALC coral diversity is probably controlled
largely by sample density. Better sampling will be required before
coral data can be used to independently constrain EALC palaeolatitude,
but the limited incidence of coral-bearing facies may preclude a
definitive analysis. * High EALC coral endemism is puzzling in light of
the apparently cosmopolitan nature of co-occurring shallow benthos.
Hence, either EALC corals were particularly subject to genetic
isolation for ecological and/or other reasons, or other EALC
invertebrates may prove to have higher levels of endemism than has been
assumed. Increased emphasis on detailed reconstruction of phylogenies,
and the recognition of homoplasy, in particular, in other EALC benthic
invertebrates suggest that they may be less cosmopolitan than is
currently accepted. [original abstract]^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous Tour; <b>Geography: </b>Australia, New South Wales^A
detailed geological map of the Slaughterhouse Creek area, near
Gravesend, New South Wales, Australia, is presented, and the
Tournaisian and earliest Visean age of the marine formations
established using conodonts. A sequence of six informal coral
assemblages is described, all of Late Tournaisian age. The new tabulate
coral genus Spinuliplena is described, and two new species. The type
horizon of the long doubtful genus Cionodendron Benson &#038; Smith has
been identified, and most Australian fasciculate species previously
referred to Lithostrotion are transferred to it. The cerioid
Roemeripora is reported from the Australian Carboniferous for the first
time.^1";

ID=1348^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>Monera;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Australia,
Queensland^Small (> 30m diameter, ~ 9m thick) reefs in the Gudman
Formation of Queensland, Australia are the oldest known Mississippian
reefs, occurring very near the Devonian-Carboniferous boundary
following Late Devonian extinction events. They occur in high-energy,
shallow, oolitic grainstones and consist of &#62; 70% microbialite and
bound detritus on the basis of point-count analysis. Skeletal
organisms, including potential frame-building rugose and tabulate
corals, ramose bryozoans, crinoids, and algae, occur in growth position
but account for only 4.4% of sampled framework. The microbial framework
was syndepositionally rigid on the basis of: (1) vertical and
overhanging relief in a high-energy setting, (2) export of framework
intraclasts, (3) hard-substrate-encrusting organisms, (4) abundant
hard-rock borings, and (5) neptunian dikes. Unusually for Mississippian
reefs, stromatolites make up a large part of the framework (~ 32%), but
more typical thrombolites are equally abundant. Interfingering of
skeletal organisms and microbialites suggests that they grew in well
oxygenated, normal marine waters and that microbial biofilms competed
effectively with skeletal organisms for available substrate. Abundant
and diverse co-occurring skeletal flora and fauna are inconsistent with
interpretations of Gudman stromatolites as post-extinction
```

```
&#034;disaster taxa&#034;. Hence, Gudman reefs are stromatolite-rich
examples of a larger class of microbialite-dominated Phanerozoic reefs
that occurred with abundant skeletal metazoans in normal marine
settings. [original abstract]^1";
s[3881] = "WEBB G.E. (1998).- Earliest known Carboniferous
shallow-water reefs, Gudman Formation (Tn1b), Queensland, Australia:
Implications for Late Devonian reef collapse and recovery.- Geology 26,
10: 951-954.- <b>FC&#038;P 27-2</b>, p. 78, ID=3947^<b>Topic(s):
</b>reefs, recovery; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Carboniferous Tour; <b>Geography: </b>Australia, Queensland^The
Phanerozoic history of reefs extensively has been considered a direct
reflection of the history of skeletal reef-building organisms. However,
such a relationship does not characterize global mid-Paleozoic reef
history. The extinction of most reef-building stromatoporoids and
corals at the Fransian-Famennian boundary correlates with the collapse
of North American and European stromatoporoid-dominated reefs, but
Western Australian, Russian, and Chinese reefs were much less severely
affected until the late Famennian, when algae, calcimicrobes, and
nonskeletal microbialites (i.e., stromatolites, thrombolites) declined
globally. Additionally, reef recovery was more rapid than previously
thought. Small, early Tournaisian (Tn1b) shallow-water reefs in the
Gudman Formation of eastern-central Queensland substantially reduce the
duration of the &#34;reefless lag time&#34; following Late Devonian
reef decline, essentially confining it to the Strunian. Gudman reefs
are dominated by microbialite, but contain a diverse, although
volumetrically insignificant, skeletal fauna and flora, including large
colonial corals, bryozoans, crinoids, brachiopods, and calcareous
algae. Hence, mid-Paleozoic reef collapse and recovery reflect an
amalgam of more-or-less independent histories of skeletal organisms,
calcimicrobes, and nonskeletal microbialites, in response to regional
and global environmental parameters, a better understanding of
mid-Paleozoic reef history will require detailed local- and
regional-scale studies to isolate global from nonglobal signals.^1";
s[3882] = "WEBB G.E. (1999).- Youngest Early Carboniferous (Late
Visean) Shallow-Water Patch Reefs in Eastern Australia (Rockhampton
Group, Queensland): Combining Quantitative Micro- and Macro-Scale
Data.- Facies 41, 1: 111-139.- <b>FC&#038;P 28-2</b>, p. 48,
ID=4042^<b>Topic(s): </b>reefs, patch reefs; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography:
</b>Australia, Queensland^Although skeletal organisms have received
most of the emphasis in studies on Phanerozoic reef history, the roles
of non-skeletal (non-enzymatic) carbonates (e.g., synsedimentary
cements, automicrite, microbialite, etc.) in reef framework
construction are becoming increasingly better understood. One problem
in understanding the role of non-enzymatic carbonates in reef
construction has been the difficulty in recognizing them in reef
facies. Whereas skeletal organisms commonly can be recognized and
documented in the field, non-enzymatic carbonates may be recognizable
only in thin section. This paper describes the application of a new
sampling technique that allows the quantitative comparison of skeletal
macrofauna and flora with associated non-enzymatic carbonates and other
microfaunal/microfloral constituents. The technique involves the point
counting of thin sections made from small diameter cores that are
systematically recovered from grids and line transects that cover a
reasonable area (m2) of reef facies. [part of extensive summary]^1";

organisation de type tetracoralliaire chez Trachypsammia (Tabulate,
Permien).- Lethaia 25, 4: 429-437.- <b>FC&#038;P 22-2</b>, p. 85,
ID=3478^<b>Topic(s): </b>tetracoral septal arrangement; Tabulata,
Trachypsammia; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>Timor^A rugosan pattern of the septal
ridges, formerly described in Kerforneidictyum and Palaeacis, is
pointed out in Trachypsammia monoseptata (Permian of Timor) for which
```

```
only the &#039;Median septum&#039; had been observed. T. monoseptata
exhibits a strong cardinal ridge in dorsal or internal position, just
opposite a shorter counter ridge, thus creating a plane of bilateral
symmetry. The ridges assumed to be alar can be identified by their
proximal ends being in contact with the &#039;Median septum&#039;. The
major ridges (proto- and metaridges) are obvious, the minor ones show
only their very proximal ends. T. monoseptata could be a calicinal
young stage of T. dendroides. T dendroides (Permian of Timor) shows a
plane of bilateral symmetry, the cardinal ridge is stronger and longer
than the others, the counter shorter, the alar ridges can be identified
in tranverse sections, major and minor ridges are well developed; the
number of ridges is often 32. In T. xizangenis (Permian of Tibet) only
the bilateral symmetry is known, while there are no data for T.
mediterranea (Permian of Sicily). The systematic affinities between
Palaeacis and Trachypsammia pointed out on the basis of microstructural
data are also supported by the septal ridges pattern. Do Palaeacis,
Trachypsammia and other form a special division of Tabulate corals?
That is the question.^1";

diagenetic history of Timorphyllum wanneri (Rugosa), Permian, Timor,
Indonesia.- Memoirs Association Australasian Palaeontologists 01 [J.
Roberts &#038; P.A. Jell (eds): Dorothy Hill Jubilee Memoir]: 275-288.-
<b>FC&#038;P 13-1</b>, p. 27, ID=0408^<b>Topic(s): </b>microstructures,
diagenesis; Rugosa, Timorphyllum; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Permian; <b>Geography: </b>Timor^Study of
structures in septa, wall and tabulae within specimens of Timorphyllum
from Basleo, Timor, indicates that preservation is excellent. Skeletal
structures are original rather than relic, as they are formed by
present crystal boundaries rather than being inherited from
pre-existing crystal fabrics or compositional changes. Scanning
electron micrographs of the corals show little or no modification
either of the septal trabeculae or of biogenic carbonate generally, and
also indicate several generations of cement. Early cementation by
coating skeletal calcite with drusy epitaxial calcite took place
shortly after burial, and only sporadic and incomplete deposition of
blocky cement took place later, perhaps due to insufficient burial to
develop the necessary pressure solution to provide sufficient
carbonate.^1";
s[3885] = "FEDOROWSKI J. (1986).- Permian rugose corals from Timor
(Remarks on Schouppe &#038; Stacul&#039;s collections and publications
from 1955 and 1959).- Palaeontographica A161 (4-6): 173-226.-
<b>FC&#038;P 15-1.2</b>, p. 29, ID=0805^<b>Topic(s): </b>revision;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Permian; <b>Geography: </b>Timor^The original thin sections of
Schouppe &#038; Stacul (1955, 1959) formed a basis for the
reinterpretation of majority of genera and families discussed by those
authors. The following new taxa were introduced: Asserculiniidae n.
fam. with two subfamilies: Asserculiniinae n. subfam. and
Duplocariniinae n. subfam. with Duplocarinia n.gen. and D. timorica
n.sp.; Wannerophyllidae n. fam. with Productiophyllum n.gen.;
Lophbillidium n.subgen. of the genus Lophophyllidium Grabau 1928. The
ontogeny and morphology of the axial structure make one possible to
introduce a new concept of the genus Verbeekiella Penecke 1908 and the
family Verbeekiellidae Schouppe &#038; Stacul 1955. The genus
Basleophyllum Schouppe &#038; Stacul 1959 was transferred to
Polycoeliidae de Fromentel 1861. The generic name Duplophyllum Koker
1924 and Paralleynia Soshkina 1936 were discussed on a basis of their
type species. These type morphologies were compared to those of the
species described by Schouppe &#038; Stacul (1959). Some of these
species may belong to new, unrelated genera. Formal generic names were
not introduced because of incompleteness of the specimens restudied.^1";
s[3886] = "FEDOROWSKI J. (2004).- Considerations on most Rugosa and
Dividocorallia from de Groot&#39;s (1963) collection.- Scripta
```

```
Geologica 127: 71-311.- <b>FC&#038;P 33-1</b>, p. 52,
ID=1114^<b>Topic(s): </b>revision; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian; <b>Geography:
</b>Timor^Rugose corals reinvestigated herein constitute the main part
of the collection described by de Groot(1963). The taxonomy proposed
herein differs in several instances from that accepted originally byde
Groot. Some changes, such as Petalaxis for Lithostrotionella and
Calophyllum instead ofPolycoelia, were already introduced in de
Groot&#39;s unpublished catalogue. Others were introduced inorder to
match the recent advances in rugose coral systematics. Most systematic
changes werebased on new microstructural, diagenetic and
hystero-ontogenetic studies. These are described indetail for
individual species and briefly discussed in the concluding
considerations. Trabecularmicrostructure of septa and its diagenetic
alteration was documented for most species. Presence oftwo kinds of
intercorallite walls (partition and dividing walls) was documented on
the basis of theirdifference in microstructure. This was especially
important for the genus Petalaxis, allowing proofof a distinction
between species representing its nominative subgenus and that
distinguished by deGroot as Hillia. A new name Degrootia was proposed
for Hillia, is preoccupied by a lepidopterian.Two genera, one new
(Arctocorallium gen. nov.), represented by two species, were
transferred tothe Calyxcorallia (Dividocorallia), the order and
subclass not distinguished by de Groot. Both thosespecies were
investigated and documented in particular detail, especially their
hystero-ontogeny.The restudied material allowed proof of a distinction
between Calyxcorallia and the Rugosa in theinsertion of major septa.
Also, an uncertain status of minor-like septa that may replace the
majorsepta was demonstrated. Both those determination are based on the
hystero-ontogeny.^1";
s[3887] = "SORAUF J.E., FREIWALD A. (2002).- Skeletal structure in the
rugosan genus Calophyllum from Permian strata of Timor: Comparison with
the living deep water coral Lophelia pertusa.- Coral Research Bulletin
7: 191-207. [Dieter Weyer&#039;s 65th birthday commemorative volume; S.
Schröder, H. Löser &#038; K. Oekentorp (eds)].- <b>FC&#038;P 31-1</b>,
p. 34, ID=7104^<b>Topic(s): </b>structures septa; Rugosa Calophyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>Timor^Skeletal structures within several species of
Calophyllum reflect generic microstructure and its diagenesis, and also
impact our understanding of diagenetic modification in other Permian
corals from Timor. Most of these microstructural features of the septa,
axial dark line, stereome coating, arcuate growth fronts (stirne), and
tabulae (boden) are well-developed. There has been some controversy
regarding their origin, whether biogenic or diagenetic. However, they
closely resemble skeletal structures in Lophelia pertusa (collected
live) from deep cold waters, here from the Norwegian Shelf in the
Atlantic Ocean. This occurrence, along with the nature and timing of
microbial infestations in each, indicates the biogenic nature of
identical structures in Permian and living corals. The two groups of
corals have much in common in their morphology, living environment and
nonzooxanthellate nature (apparently), but no phylogenetic relationship
between these genera of Paleozoic and modern corals is here postulated.

```

```
history; Rugosa Tabulata; <b>Systematics: </b>Cnidaria; Rugosa
Tabulata; <b>Stratigraphy: </b>Permian; <b>Geography: </b>Timor^The
modern history of collection and study of corals in the Perminan strata
of Timor began in 1911, with a German expedition (J. Wanner, leader)
and a Dutch expedition (H. Molengraaff, leader) to collect Permian and
Triassic fossils in the colony of Netherlands Timor, and with a survey
by the Swiss geologist F. Weber the same year in Portuguese Timor, the
eastern portion of the island. Later expeditions led by Jonker (1916)
and Brouwer (1937), both of the Netherlands, greatly increased already
huge collections of fossils and additionally, understanding of the
island&#039;s geology. Monographic studies of these coral collections
by Gerth (1921), Koker (1924), Schindewolf (1942), Hehenwarter (1951)
and Schouppe &#038; Stacul (1955, 1959) have much enhanced the
systematic value of these fossil corals, both Rugosa and Tabulata.
Locality information and maps containing collecting localities are
somewhat scattered (Wanner 1931, Burck 1923, Marez Oyens 1940, Van
Bemmelen 1949), but are summarized here. A list of all valid species
names (109 Rugosa, 25 Tabulata) is appended to this paper, with type
localities and horizon. Serious problems of nomenclature are avoided in
this paper by accepting genus names used in Hill (1981), modified by
later systematic studies, such as that of Fedorowski (1986), but some
unknown number of names in the list of species are to be synonymized,
especially since 31 of them are based on a single specimen (e.g.
Niermann 1975). The biostratigraphy of these faunas is uncertain, in
great part due to the greatest number of corals having been collected
from a tectonic melange sequence in the Baun to Basleo structural
region, and additionally because of the purchase of huge numbers of
fossils from the indigenous people of Timor, with accompanying
uncertainties regarding locality and horizon data. The coral fauna of
Permian age from Timor needs serious restudy to insure its
stratigraphic and palaeontologic value, but future study will require
new field collection of specimens from relatively complete
stratigraphic sequences in the northern &#039;Fatu&#039; belt of
outcrops. The huge numbers of individuals of some coral species provide
great opportunities for understanding population structure in the
faunas. [original abstract]^1";
s[3890] = "LAFUSTE J., TOURNEUR F. (1991).- Distribution of the
tabulate coral genus Mirandella Tchudinova 1986 in the Early Permian.-

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Permian
Art; <b>Geography: </b>Australia, Tasmania^The genus Mirandella
Tchudinova 1986 (Tabulate, Cnidaria) is emended and a new species, M.
greeni, described from the Artinskian of Tasmania. The microstructure
of the genus, observed in ultra-thin sectims, is very distinctive, with
a dark undulating lamina, surrounded by fibers locally arranged in
tufts. The presence of a typical reticulate tissue, along with other
morphological features, allows the assignment of the genus to the
family Pyrgiidae De Fromentel 1861; a microstructural evolution from
mostly&#039;lamellar&#039; forms in the Lower Carboniferous to entirely
fibrous ones in the Permian can be observed in this family,
corroborating a general trend in the Tabulata. The genus Mirandella is
present in Lower Permian strata of Kamtchatka, Prekolyma, Australia,
Tasmania and New Zealand. Such a geographical distribution suggests
that the genus was well adapted to rather&#039;cold&#039; waters.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Triassic Carn; <b>Geography: </b>Timor E^Four scleractinian coral
taxa are deseribed from limestones within a sandstone-shale sequence
correlated with the Late Triassic Babulu Formation, Manatuto township,
on the northern coast of Timor-Leste (East Timor). The coral fauna
consists of three phaceloid taxa, Paravolzeia timorica gen. et sp.nov.,
Craspedophyllia ramosa sp.nov., Margarosmilia confluens (Muenster), and
a generically indeterminate solitary taxon attributed to the family
Margarophylliidae. All four corals are related at various taxonomic
levels to Carnian faunas from the Dolomites of northern Italy.
Previously, only Norian coral faunas were known from the Triassic of
Timor. The fauna exhibits both similarities to and differences from
Carnian faunas of the Dolomites and helps confirm palaeogeographie
affinities with the westem Tethys, although during Late Triassic time
Timor lay in the distant southeastern portal of the Tethys. Despite
isolation from the western Tethys, the presence of two species found
also in the Dolomites indicates that larval dispersal occurred between
the two areas.^1";

Uplift Rate of Coral Reef Terraces in the Area of Kupang, West Timor:
Preliminary Results.- Palaeogeography, Palaeoclimatology, Palaeoecology
068: 259-272.- <b>FC&#038;P 18-1</b>, p. 48, ID=2290^<b>Topic(s):
</b>neotectonics terraces; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Pleistocene; <b>Geography: </b>Timor W^A Th/U date
of 152,000 years obtained from the prominent fifth step, at 44 m
elevation, of a flight of 7 well defined raised reef terraces at Cape
Namosain, 5 km west of Kupang, allows inference of a preliminary mean
uplift rate of 0.3 mm/yr since the last interglacial. Such a slow
uplift rate is supported by the observation of numerous large modern
reef platforms and of very limited mid-Holocene emergence - if any -
throughout the region. Subject, to confirmation through further dating,
this suggests the existence of a more rapid uplift zone in central West
Timor, by contrast with the area of Kupang to the west and of northern
East Timor and Atauro Island to the east, possibly in relation with the
NW-SE seismic tear zone which has been recently pointed out within the
subducting plate north of West Timor. One of the main interests in the
terraces of Cape Namosain, apart from its neotectonic aspect, resides
in the fact that there may be an opportunity to define the 180,000 year
old paleo-sea level (terrace VIII of Huon Peninsula): based on the
geomorphological interpretation of the series, it could correspond here
to the fourth or the sixth terrace. Field investigation and dating in
that regard are currently in progress. Another Th/U date of 124,000
years, obtained on the lowest emerged terrace (7 m above low tide) in
the southeast of the nearby island of Semau, indicates that this second
area has been uplifting little during the last 125,000 years. This,
together with the observation of tilts and other structural features,
leads to the conclusion that the area to the southwest of Kupang is
affected by differential uplifts and block-faulting.^1";

Evidence of high sea level during isotope stage 5c in Queensland,
Australia.- Quaternary Research 24, 1: 103-114.- <b>FC&#038;P 14-2</b>,
p. 17, ID=6693^<b>Topic(s): </b>reefs, sea level changes; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Pleistocene; <b>Geography:
</b>Australia, Queensland^Thirty-nine species of scleractinian corals
have been recovered from under a high dune on the western (mainland)
side of North Stradbroke Island, eastern Australia. The corals are
associated with thin intertidal sediments and their good condition
implies burial in situ and preservation in a saturated zone. Most
likely this occurred as the coast prograded and a large dune advanced
into the littoral zone, burying intertidal sediments and coral. The
species assemblage indicates a sheltered environment but one open to
the ocean without wide fluctuations in salinity. Three species yielded
a mean 230Th/234U age of 105,000 yr B.P. which is significantly younger
than the nearest Pleistocene corals at Evans Head, New South Wales. The
corals provide evidence of a sea stand near present sea level during
isotope Stage 5c, which is considerably higher than previously
suggested for this period. Their good condition implies that the
overlying parabolic dune is of comparable age and formed during that
high stand of sea level. Also, the isotope age provides a maximum
period for the development of giant podzols in the podzol
chronosequences on coastal dunes in southern Queensland. [original

s[3897] = "SINCLAIR D.J. (2005).- Non-river flood barium signals in the
skeletons of corals from coastal Queensland, Australia.- Earth and
Planetary Science Letters 237, 3-4: 354-369.- <b>FC&#038;P 34</b>, p.
103, ID=1367^<b>Topic(s): </b>geochemistry; Anthozoa chemistry;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Australia, Queensland^Two corals from coastal
Queensland (Cow and Calf Islands, andOrpheus Island) have been analysed
for a suite of trace elements bylaser-ablation ICP-MS (LA-ICP-MS).
Barium signals in these twocorals are `anomalous&#39; in comparison
with Ba behaviour seen in othernear-shore corals from this region. The
two corals display large sharppeaks in spring which do not correlate
with markers of river discharge(Y/Ca and fluorescence). This Ba pattern
contrasts with `normal`behaviour - characterised here by the patterns
previously published fortwo other coastal Queensland corals (King Reef
and Pandora Reef),which display Ba peaks in summer associated with
flooding of nearbyrivers [see: Sinclair &#038; McCulloch 2004 Corals
record low mobilebarium concentrations in the Burdekin River during the
1974 flood:evidence for limited Ba supply to rivers? 3xPalaeo 214].
Similarities areobserved between the anomalous Ba in the Queensland
corals and otherpublished patterns of Ba behaviour in corals from South
Africa and theArabian Sea. This non river-flood Ba behaviour is
characterized bylarge sharp spikes of Ba which are resistant to
oxidative cleaning andform a continuous horizon within the corals.
Curiously, not all coralsfrom a region display anomalous Ba behaviour
despite being in similarenvironment. The timing of anomalous Ba is
consistent within a coral,but may vary from one location to the next.
Anomalous Ba spikes aretoo large to be caused by Ba-rich upwelling, and
no singleenvironmental forcing function seems to be able to account
their timing.This combination of observations argues against an
exogenous abioticsource for the anomalous Ba signal; instead, it may
result from abiological event triggered by a combination of
environmentalparameters. Three hypotheses are presented, and critically
tested againstthe observations: barite inclusion following
phytoplankton blooms,decaying blooms of the blue-green algae
Trichodesmium, andphysiological perturbations associated coral mass
spawning. None ofthe tree hypotheses are fully consistent with all of
the observations and it is concluded that no satisfactory explanation
currently exist for theanomalous Ba spikes.^1";

Age accuracy and resolution of Quaternary corals used as proxies for
sea level.- Earth and Planetary Science Letters 253, 1-2: 37-49.-
<b>FC&#038;P 35</b>, p. 97, ID=2421^<b>Topic(s): </b>eustacy;
geochemistry Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Quaternary; <b>Geography: </b>Papua New Guinea^The
accuracy of global eustatic sea level curves measured from raised
Quaternary reefs, using radiometric ages of corals at known height, may
be limited by time-averaging, which effects the variation in coral age
at given height. Time-averaging was assessed in uplifted Holocene reef
sequences from the Huon Peninsula, Papua New Guinea, using radiocarbon
dating of coral skeletons in both horizontal transects and vertical
sequences. Calibrated 2delta age ranges varied from 800 to 1060 years
along horizontal transects, but weighted mean ages calculated from
15-18 dates per horizon were accurate to a resolution within 154-214
yr. Approximately 40% of the variability in age estimate resulted from
internal variability inherent to 14C estimates, and 60% was due to
time-averaging. The accuracy of age estimates of sea level change in
studies using single dated corals as proxies for sea level is probably
within 1000 yr of actual age, but can be resolved to over 250yr if
supported by dates from analysis of a statistical population of corals
at each stratigraphic interval. The range of time-averaging among reef
corals was much less than for shelly benthos. Ecological time-averaging
dominated over sedimentological time averaging for reef corals,
```

```
opposite to patterns reported from shelly benthos in siliciclastic environments.^1";

(1999).- Stromatoporoid palaeoecology and systematics from the Middle Devonian Fanning River Group, north Queensland.- Memoirs of the Queensland Museum 43, 2: 463-551.- <b>FC&#038;P 28-2</b>, p. 36, ID=4032^<b>Topic(s): </b>ecology, systematics; stroms Devonian M; <b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>; <b>Geography: </b>Australia, Queensland^Thirty-five Stromatoporoid taxa are described from the Givetian lower Fanning River Group, Burdekin Subprovince. Ten faunal communities are recognized based on the study and distribution of Stromatoporoid and selected molluscan taxa and the distribution of tabulate and rugose corals: Burdikenia, Modiomorpha, Stachyodes costulata-Syringopora, Hermatostroma maculatum-Gerronostroma hendersoni, Clathrocoilona spissa-Aulopora, Ferestromatopora heideckeri-Amphipora ramosa-Stringocephalus, Coenostroma-Hermatostroma episcopate, Amphipora pervesiculata, Endophyttum and cephalopod communities. Analysis of Stromatoporoid shape demonstrates the influence of both genetic and ecologic factors. Zonation of skeletal shape, apparent for both biostromal and biohermal complexes, indicates that strong ecologic influences dominated. Substrate type, sedimentation rate and water depth were important controls. Most taxa display a range of shape. Complex overgrowth phenomena between Stromatoporoid taxa, tabulate corals, chaetetids, and algae produced compound skeletons that are most common within nearshore biostroms, and are interpreted to indicate stress imposed by repeated lethal depositional events or by seasonal variations in salinity. Intergrowth of stromatoporoids with tabulate corals Syringoporellal sp., and Syringopora sp., a number of rugose coals, and a ?vermetid are documented. Syringoporellal sp. is more common in stromatoporoids with irregular skeletal architecture. For Syringoporellal sp. an even distribution of corallites within the host, skeletal response to corallite occurrence, and the absence of micritic envelopes suggests a symbiotic relationship with both the coral and the Stromatoporoid accreting at the same rate and maintaining an even growth surface. Six new species of Stromatoporoid are described comprising Gerronostroma hendersoni, Trupetostroma zheni, Euryamphipora merlini, Ferestromatopora heideckeri, Coenostroma budekinense, and Coenostroma wyatti. Biogeographic affinities of the fauna are strongly with the Old World Realm with species level affinities with Guangxi, Poland and Belgium.^1";

ID=3739^<b>Topic(s): </b>benthos, geography; paleontology;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Ems; <b>Geography:
</b>Algeria, Ougarta^The benthic faunas (corals, crinoids, brachiopods
and trilobites) identified in the Lower and Middle Devonian formations
of the Ougarta area (western Sahara, Algeria) are used in order to
depict the timing and the magnitude of fauna migrations through the
Rheic Ocean. Our data show the Rheic Ocean had already started its
closure phase at the beginning of the Devonian. In upper Emsian time it
was no longer wide enough to prevent the migration of benthic
organisms. Indeed, by late Emsian, number of genera and species are
common both to the Laurussian and Gondwanan margins of the Rheic Ocean.
A new paleobiogeographic entity: the Maghrebo-European realm is
defined. It includes the more restricted Ibarmahian Domain and North
Gondwana Province.^1";

Zonation of a Carboniferous Carbonate Ramp: Upper Visean of Bechar
Basin, Western Algeria.- Facies 35, 1: 59-80.- <b>FC&#038;P 26-1</b>,
p. 89, ID=3658^<b>Topic(s): </b>reef facies, ecological zonation; reef
facies; <b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous;
<b>Geography: </b>Algeria^Following the demise of the
Stromatoporoid-coral reef community in Late Frasnian time, Lower
Carboniferous carbonate shelf profiles possessed a ramp geometry, with
major organic buildups represented by mud-rich mounds. Microfacies
petrography of the exceptionally well-preserved Upper Visean (Lower
Carboniferous) carbonate ramp of the Bechar Basin, Algerian Sahara, may
well contribute significantly to our understanding of the
paleoecological zonation of Carboniferous non-rimmed platforms, and of
the still enigmatic mounds commonly referred to as Waulsortian banks or
mounds. Facies are grouped into two broad groups: (a) a mound facies
group which comprises sponge wackestone-bafflestone, sponge-fenestellid
bafflestone-wackestone, crinoid wackestone-packstone, and bedded flanks
of intraclastic wackestone-packstone, all four facies composing the
actual mud-rich mounds, and (b) a supramound facies group composed of
coral-microbial framestone, crinoid packstone-grainstone,
algal-foraminiferal grainstone and oolite grainstone. Calcareous algae
are important bathymetric indicators and are used to delineate three
bathymetric zones based on light penetration: the aphotic zone, which
contains no calcareous algae; the dysphotic zone, where there is little
ambient light, and which is characterized by the presence of red algae
(Fasciella, Ungdarella, Stacheia, Epistacheoides) and absence of green
algae; and the euphotic zone, which receives the full spectrum of
sunlight, and is characterized by the occurrence of both green algae
(Koninckopora, Kamaenella, Kamaena, Palaeoberesella, Calcisphaera,
Anthracoporellopsis, Issinella, Exvotahsella) and red algae.
Integration of algal zonation, distribution of the other biota, and
recurrence of distinct assemblages, enable recognition of seven
depth-related benthic assemblages. Together with the physical
properties of the facies, the benthic assemblages were used to define
seven bathymetric zones, from upper to lower ramp: (1) algal assemblage
(upper ramp); (2) crinoid-ramose bryozoan assemblage (mid-ramp); and
(3) productid brachiopod assemblage, (4) colonial rugose
coral-microbial encruster assemblage, (5) crinoid-fenestellid
assemblage, (6) sponge-fenestellid, and (7) sponge assemblage (lower
```

```
ramp). The vertical zonation of the mud-rich mounds and associated
facies differ from that reported from the classical Upper
Toumaisian-Lower Visean Waulsortian moundbearing successions.^1";

Carboniferous stratigraphy and depositional environments in the Ahnet
Mouydir area (Algerian Sahara) by Wendt et al. (Facies 55, 3:
443-472).- Facies 56, 3: 471-476.- <b>FC&#038;P 36</b>, p. 128,
ID=6583^<b>Topic(s): </b>stratigraphy, ecology; geology;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous; <b>Geography:
</b>Algeria, Sahara^The attribution of a Bashkirian age to the Berga
Limestone and the proposed Late Visean-Serpukhovian hiatus is not
supported by the data and discussion presented herein. This also sheds
some doubts on the existence of a lower Bashkirian transgression in
entire North Africa. Wendt et al. (2009) have questioned the
stratigraphic extension of some commonly used groups and organisms, but
all data except the three samples containing D. noduliferus of Wendt et
al. (2009) point to a Visean-Serpukhovian age. However, the
Reggane-Ahnet data in combination to the Spanish data indicate that the
first entry of D. noduliferus was possibly during the uppermost (?)
Serpukhovian. and thus it is of limited use for defining the base of
the Pennsylvanian. This may help to elucidate the confusion at this
stratigraphic level, north of the Hoggar as well as on a global
perspective. [original conclusions]^1";

</b>Porifera; <b>Stratigraphy: </b>Permian U; <b>Geography:
</b>Tunisia^Fossil sponge faunas from Upper Permian reefs and
inter-reef rocks in the Djebel Tebaga area of southern Tunisia include
the most varied and abundant Late Paleozoic inozoid fauna known. The
inozoid sponge part of that assemblage, plus minor demosponge and
hexactinellid sponges, are described from the numerous localities and
collections. The Djebel Tebaga area of southern Tunisia includes the
only outcrop of marine Upper Permian strata in the entire African
continent and was in the western part of the classic Tethyan belt. The
sponges described here were collected, in large part, weathered out
from ????sures of sandy carbonates, marls, and bioclastic limestones
```

```
and are commonly associated with moderately large bioherms of which the
sponges were the most important reef builders. [...] Seventy species
are described of which fifty-four are new. Also included in the
description are new examples of the demosponge Heliospongia finksi
Termier and Termier, 1977a, and a fragmental brachiospongid
hexactinellid. * Possible relationships of the Inozoida with the
Paleozoic Heteractinida and Sphinctozoa are discussed. The latter are
possible stem-groups from which the Inozoida may have developed during
the Carboniferous. * The Inozoida were encrusters, frame builders, and
bafflers for some of the bioherms in Djebel Tebaga. They produced
moderately complicated community sequences, even on a small,
hand-sample scale. Such sequences of encrustation, diagenesis, and
preservation are described. Many hand samples show at least five
generations of encrustation of sphinctoxoans, inozoans, sclerosponges
and algae. [excerpts from extensive summary]^1";

Africa (Tanzania, Kenya; Late Valanginian-Aptian) and revision of the
Dietrich collection (Berlin, Germany).- Palaeontographica 285, 1/3:
23-75, 5 pls.- <b>FC&#038;P 36</b>, p. 93, ID=6508^<b>Topic(s):
</b>geology; corals, geology; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Cretaceous L; <b>Geography: </b>Tanzania^The
extensive vertebrate excavations of the Late Jurassic to Early
Cretaceous around the Tendaguru hill in Tanzania in the early 20th
century also yielded significant invertebrate faunas. The corals were
first described by Dietrich (1926) and his work conformed to a
remarkably high standard for his time. Since then, progress in
examination methods and other criteria of coral classification has made
a modern revision necessary. In addition, the stratigraphy of the coral
bearing sediments has greatly improved over the past ten years,
allowing a better palaeobiogeographic analysis. The present paper gives
an introduction to the research history, discusses the various
denominations of the lithostratigraphical units exposed in the
Tendaguru area, and explains the progress of the stratigraphy of these
units. Using both the original material described by Dietrich, as well
as collection material that he did not describe, the corals of the
Cretaceous are described and illustrated using new thin sections.
Several corals from the Early Cretaceous of Kenya are also included.
The Jurassic corals from the Tendaguru area have not been examined. In
total, 15 species from the Late Valanginian to Early Aptian unit and 31
species from the Late Aptian are described. Two genera described by
Dietrich that were largely forgotten and many species established by
him that were not precisely interpreted in later literature are revised
here. Camptodocis replaces Actinareopsis Roniewicz, 1968, and
Metaulastrea corresponds to the concept of Amphiaulastrea Geyer, 1955,
which is considered a junior synonym of Pleurostylina and should no
longer be used. Together, these revisions place the Cretaceous corals
of the Tendaguru area in a modern taxonomic and palaeobiogeographic
```

(1996).- Paleocene Coral Reefs and Related Facies Associations, Kharga Oasis, Western Desert, Egypt.- Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 32, ID=3586^<b>Topic(s): </b>coral reefs, post extinction reefs; coral reefs complex; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Paleocene; <b>Geography: </b>Egypt, Western Desert^The primary objective of this study is to document the development of corals and coral reefs during the early Paleogene in south-western Egypt. Corals have been known from this geological period since the expedition of Gerhard Rohlfs at the end of the last century. The interest in early Paleogene corals is also caused by the Cretaceous &#47; Paleogene boundary event which drastically affected reef building organisms. After a recovery period of several minion years, scleractinian corals began to take over the dominant role of reef constructors, a situation which has continued until today. In addition, the sedimentology and paleoecology of the limestones of the Paleocene Abu Tartar Carbonate Platform were studied. An attempt has been made to reconstruct the depositional history of this carbonate platform. The Abu Tartur Plateau is located west of El-Kharga (Kharga Oasis). It is covered by Early to Late Paleocene limestones.^1";

Facies analysis and biostratigraphy of the Auradu Limestone Formation
in the Berbera-Sheikh area, northwestern Somalia.- Geologica Romana 29:
213-235.- <b>FC&#038;P 23-2.1</b>, p. 70, ID=4438^<b>Topic(s):
</b>reefs, stratigraphy; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Paleogene; <b>Geography: </b>Somalia^The main stratigraphic and
sedimentological features of the Auradu Limestone Formation [Tertiary
&#47; Paleogene] in NW Somalia, close to its type area, are outlined.
The present study of the depositional and diagenetic characteristics,
associated with the investigation of the fossil assemblages and their
biostratigraphy and paleoecology, allows to focus on some significant
features useful for a better definition of the paleoenvironmental
setting and the stratigraphic evolution of the formation in its
westernmost outcrop area. Biostratigraphic evidence gathered from the
larger foraminiferal assemblages [and coral assemblages] allows a
correlation of the lower Paleogene faunal associations of Somalia with
the existing peri-Mediterranean biozonations, thus extending their
validity to the Horn of Africa, with implications for the dating of
neighbouring formations of the Arabic peninsula.^1";

sediments of the northwestern Gulf of Suez, Egypt.- Courier
Forschungsinstitut Senckenberg 239: 57-81.- <b>FC&#038;P 33-2</b>, p.
37, ID=1175^<b>Topic(s): </b>; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Miocene L;
<b>Geography: </b>Egypt, Suez Gulf^Early Miocene corals from the
northwestern Gulf of Suez area (Eastern Desert, Egypt) grew on a
shallow epicontinental shelf flooded by the Burdigalian transgression.
Acropora layers and isolated massive Tarbellastraea colonies associated
with abundant corallinacean red algae (rhodolith and marl facies) and
green algae (Halimeda) lived in a very shallow, lagoonal-like
environment. Some small patch reefs were formed. The lack of a suitable
substratum and the high sedimentation rate are considered the main
reasons for the relatively low diversity (24 species/16 genera) of the
Burdigalian coral fauna from this region. Global climatic cooling
during this time favoured the development of temperate water carbonates
and hindered the formation of more extensive coral reef structures. The
described corals most probably were the predecessors of Middle Miocene
coral faunas from the Red Sea coast which built large fringing reefs
during the Langhian when the sea advanced from the Mediterranean Tethys
to the Red Sea. This is shown by the presence of several identical or
similar species (e.g., Tarbellastraea reussiana, Favites neglecta)
described from these Langhian reefs. Generally, the described corals
show a Mediterranean Tethyan affinity and are comparable to coral
faunas from the Aquitaine Basin, central Iran, and Turkey.^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Miocene;
<b>Geography: </b>Egypt^The reef limestones, of Langhian (Middle
Miocene) age; were formed during regressive-transgressive episodes.
They were subdivided into four main depositional facies: 1) fore-reef,
made up of bioclastic marly limestone with broken skeletons and debris,
2) reef-core, constructed of a framework exclusively of branched
colonies of Porites sp. coated by micrite submarine cements, 3)
back-reef, consisted of friable limestone, rich in shell hash with
flodded Heterostegina praecostata and, 4) beach and nearshore, made up
of fossiliferous cros-bedded pebbly sandstone. The complete leaching
and alteration of the original aragonitic slceractinian corals
microstructure, and the cements into low Mg-calcite mosaic by fresh
water in the subaerial environment, is the main diagenetic process
which affected the reef. Micrite is the most important constituent in
the reef-core sedimentes (40-70 %) and all over the sequence in
general.^1";

corals biogeography; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Malvinokaffric
Realm^Corals are extremely rare in Silurian to Middle Devonian rocks of
central and South America and in southern Africa and none are reported
from Antarctica, the areas that constituted the Malvinokaffric Realm.
Most workers have interpreted the realm as one characterized by cold
water; this is in accordance with its high latitude during the
Silurian-Devonian and is the most likely explanation of the dearth of
corals. It is also noted that the known Malvinokaffric marine shelly
faunas are found in shales and siltstones whereas the rich coral faunas
of the other realms occur in limestones and calcareous shales. However,
in the other realms corals do also occur in shales and siltstones and
the inhospitality of the Malvinokaffric sedimentary facies is not an
adequate explanation for the scarcity of corals.^1";

biogeography; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Devonian M; <b>Geography: </b>Morocco,
Anti-Atlas^Paleobiogeographic distribution of rugose corals essentially
depends on ocean current systems. Sea level fluctuations can cause
migration between formerly isolated realms. The facies analysis of
Middle Devonian sequences of the eastern Anti-Atlas (Morocco) reavels
at least three T-R-cycles. Linked with the aggradational stacking,
shallow marine, coral bearing reefal carbonates appear upon a carbonate
ramp. Several immigration-pulses of Eastern American faunal elements
into the Moroccan coral faunas are related to these transgressive
events. Migration routes apparently are via Western Africa into Central

corals in an ancient hydrothermal vent community, Devonian, Morocco.-
Acta Geologica Polonica 55, 1: 1-7.- <b>FC&#038;P 33-2</b>, p. 15,
ID=1111^<b>Topic(s): </b>thermophyly; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Morocco, Anti-Atlas^Living corals are remarkably broad in their
thermal and bathymetric ranges. But corals that could tolerate
abnormally high temperatures (higher than 40°C) are unknown both in the
living communities and in the fossil record. Here we report the
discovery of small thermophilic rugose corals in the Devonian vent
community of southeastern Morocco. These organisms were adapted to
conditions prevailing within chimney conduits of a hydrothermal system
that developed on the roofof a submarine volcanic high. The coral
larvae followed a calice-in-calice settlement and growth strategy to
survive the contact with thermal fluids. This adaptation was not
related to taxonomy and characteristic of all coral taxa present in the
vents. Monospecific coral population was identified in several Emsian
vents whereas the coral fauna of the single Givetian vent was more
diverse and included four species. The entry of different rugose coral
species into the hot vents resulted from atrophic relation to ostracods
flourishing in the chimneys.^1";
s[3984] = "BERKOWSKI B. (2006).- Vent and mound rugose coral
associations from the Middle Devonian of Hamar Laghdad (Anti-Atlas,
Morocco).- Geobios 39, 2: 155-170.- <b>FC&#038;P 34</b>, p. 28,
ID=1223^<b>Topic(s): </b>vent &#038; mound corals; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian M;
<b>Geography: </b>Morocco, Anti-Atlas^Peculiar associations of small,
solitary, deep-water rugose corals are described from the Middle
Devonian buildups situated in the easternmost part of Hamar Laghdad
area of southern Morocco. The most of them are monospecific and consist
of simplified taxon &#34;Amplexus&#34; florescens but one is
polyspecific and composed of specimens belonging to four different
species representing three families. These rugosan associations form
isolated nest-like aggregations where numerous densely packed specimens
are arranged mostly in life position. The polyspecific and two
monospecific associations are interpreted as growing in close proximity
to venting fields. They reveal a unique &#34;calice-in-calice&#34;
recolonization pattern expressed by successive settlement of juvenile
specimens in the calice of dead individuals. This pattern was
presumably a consequence of selective survival of coral larvae settling
in extreme vent habitats. Although, the &#34;calice-in-calice&#34;
pattern is common in both, mono- and polyspecific associations, there
are differences expressed in the character of larval attachments and
various types of the calice fillings. The trophic interaction between
corals and ostracods is discussed (Fossil Cnidaria &#038; Porifera 34:
29). Additionally, associations of &#34;Amplexus&#34; florescens, not
displaying &#034;calice-in-calice&#034; pattern of growth have been
found within the mound where polyspecific association occurs. These are
interpreted as growing away from venting fields. Comparisons of
Amplexus-type coral faunas with the other North African and European
corals allow the classification of these ampleximorph rugosan taxa as
characteristic biotic components of the Middle Devonian mound
environments influenced by venting activity. Two new genera and
species, Weyeraia prima and Vesiculolasma erfoudi, are introduced.^1";

maroccana is described from cephalopod limestones of the middle/upper
Clymenia genozone (level with Gonioclymenia) in the Tafilalt district
of the Anti Atlas region. The small collection of seven syntypes
demonstrates a surprising intraspecific variation visible only after
intensive serial sectioning of all subtabular and calicular parts of
```

```
the skeleton. This is the first record of the rare genus from a second
area outside the type occurrence in the Wocklumeria genozone of the
Polish Holy Cross Mountains. As a member of the phyletic line Neaxon
&#062; Petraia &#062; Famennelasma &#062; Czarnockia, the taxon should
be found cosmopolitically in the psychrospheric Cyathaxonia facies of
Upper Famennian times. ^1";
s[3989] = "PEDDER A.E.H. (1999).- Paleogeographic Implications of a
Devonian (Givetian, Lower Varcus Subzone) Rugose Coral Fauna from the
Ma&#039;der Basin (Morocco).- Abhandlungen der Geologischen
Bundesanstalt 54: 385-434.- <b>FC&#038;P 28-2</b>, p. 19,
ID=4015^<b>Topic(s): </b>biogeography; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Giv; <b>Geography:
</b>Morocco, Ma&#039;ader^A probably deep, or moderately deep, photic
zone coral fauna of early Givetian age is examined from Jbel Ou Driss.
The genera Zonophyllum, Lekanophyllwn, Siphonophrentis, Heliophyllum
and Spinophyllum are reviewed and the new species Zonophyllum
maderense, Z. pegoconus, Lekanophyllum hollardi and Stringophyllum
coenaubertae are erected. Otsuka coefficients have been calculated to
determine similarities between the genus composition of the Rugosa of
the Ma&#039;der basin and those of 15 other regions. Very high OC
values are obtained from comparisons with the northern Spain - Pyrenees
- Vendee and northern Vosges - Saar - Moravia regions. All these
regions were likely situated on the Gondwana side of the Rheic
paleo-ocean. A lesser, but nevertheless high OC value between the
Ma&#039;der basin and the Rhenohercynian zone indicates that the Rheic
paleo-ocean was narrow. Comparison with the Appalachian belt gives a
considerably lower OC value, and no more than 17% of the Ma&#039;der
basin Rugosa had an Eastern Americas Realm ancestry. In Givetian time,
coral migration from the EAR had ceased or was greatly reduced, and
transport of coral larvae was likely in a southwest direction through
the narrow Rheic paleo-ocean. Similarities decrease eastwards from the
Ma&#039;der basin along northern Gondwana to eastern Australia. The
Baoshan-Luxi microplate was likely attached or close to Gondwana in
Givetian time, at a longitude between the northern Pakistan part of the
Indian shield and western Australia. The OC value between the
Ma&#039;der basin and the Altay-Sayan collage suggests that the
allochthons carrying Givetian Rugosa were not accreted to the Angaran
shield in Givetian time, and were likely situated at <40° latitude.^1";
s[3990] = "BERKOWSKI B. (2008).- Emsian deep-water Rugosa assemblages
of Hamar Laghdad (Devonian, Anti-Atlas, Morocco).- Palaeontographica
A284, 1-3: 17-68.- <b>FC&#038;P 36</b>, p. 50, ID=6431^<b>Topic(s):
</b>deep water; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Ems; <b>Geography: </b>Morocco,
Anti-Atlas^Four types of assemblages composed of small, mostly
undissepimented, deep-water Rugosa corals, are described from
argillaceous sediments of the Amerboh Group (upper Emsian) in the area
of Hamar Laghdad (eastern Anti-Atlas, Morocco). During that time the
sea-bottom of studied area was extremely diversified due to prior
formation of numerous, up to 20-50 in high, closely spaced mud mounds.
The formation of mud mounds was caused by earlier hydrothermal
activity, which ended temporarily by the end of inversus conodont Zone
time. Since that time elevated mud mounds and especially depressed
spaces between the mounds were continuously buried by argillaceous
sediments of the Amerboh Group. The process of burial has been finished
by the end of the Emsian. These extremely diversified bottom
morphologies created exclusive environments where exceptional
assemblages of deep-water Rugosa corals developed. Four assemblages of
Rugosa corals are distinguished from each other not only in species
content and richness, but also in different types of life strategies in
response to various environmental conditions. The richest assemblage
(A) comprising of 15 species belonging to 10 genera, settled directly
on the already lithified slopes of mud mounds. Assemblage (B) occurring
in the same time, in depressed areas between the mounds, is composed of
```

```
nine species belonging to seven genera. Subsequent assemblages, (C) on
the slopes, and (D) distanced from the mud mounds, developed within
soft marly argillaceous deposits are less diversified and are composed
of three species belonging to three genera and two species belonging to
two genera respectively. These data show that the slopes of mud mounds
acted as isolated &#034;oases&#034; with exclusively favourable
environmental conditions for corals, and were surrounded by deep-water
environments, unfavourable even for a relatively tolerant Laccophyllid
fauna. Four new genera: Erfoudia n.gen., Marocaxon n.gen., Berberia
n.gen., Pentacyathus n.gen. and 16 new species: Enterolasma pachytheca
n.sp., Sutherlandinia anna n.sp., Boolelasma magnum n.sp., Syringaxon
exiguus n.sp., Syringaxon firmipes n.sp., Schindewolfia concors n.sp.,
Schindewolfia solida n.sp., Schindewolfia tenera n.sp., Catactotoechus
instabilis n.sp., Erfoudia eisenmanni n.sp., Marocaxon subcylindricus
n.sp., Marocaxon laticalix n.sp., Berberia kesskessi n.sp.,
Pentacyathus arduus n.sp., Pentacyathus tenuis n.sp., Pentacyathus
variabilis n.sp. are described.^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Ems?; <b>Geography: </b>Morocco, Anti-Atlas^Unique monospecific
assemblages of small, solitary, undissepimented rugose corals are
described from the Devonian deep-sea hydrothermal venting systems of
the Hamar Laghdad (Anti-Atlas, Morocco). Assemblages of numerous
rugosans (coral meadows) have been found around the outlets of venting
channels irregularly forked within the Emsian mud mounds. Majority of
rugose corals, which settled around vents, reveal a bizarre pattern of
growth called here &#34;calice-in-calice&#34;. The phenomenon of
&#34;calice-in-calice&#34; growth is related to selective survival of
coral larvae i.e. it is postulated that the larvae, which settle within
the calices of extinct individuals were more successful in their
development. They probably use empty calices as shelters against the
physical (hot or poisoning fluids) or biological (predators) factors.
The presence of numerous carapaces of ostracods within the calices of
extinct rugosans suggests a strong trophic relation between corals and
ostracods, which lived around hydrothermal vents. New genus and species
Hamarophyllum belkai is proposed. [original abstract]^1";

F. (2004).- Révision de Crenulipora difformis Le Maitre, 1956,
(Tabulata, Dévonien du Nord Gondwana): morphologie, structure et
microstructure.- Revue de Paléontologie 23, 1: 181-208.- <b>FC&#038;P
34</b>, p. 47, ID=1260^<b>Topic(s): </b>revision; Tabulata,
Crenuliopora; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Morocco^A revision of Crenulipora
difformis Le Maitre, 1956, type species of the genus, is presented and
its attribution to a new subfamily of Favositids is proposed. The
revision includes the examination of type specimens and numerous
topotypes. The geographical and stratigraphical data areas follows:
Morocco, Hamar Laghdad, top of the Kess-Kess Formation and basis of
Amerboh, Upper Emsian. A revised diagnosis of the genus is given and
the type species described herein in detail; its variations are
extremely important and unusual in Tabulata. The main features of
C.difformis are: more or less flat branches, calices bearing from 12
(usual) to only a few rows of spines showing a bilateral or axial
symmetry, operculum frequent, wall sinuous in transverse sections,
without peripheral thickening, spiny, tabulae numerous or not, very
often &#34;forked&#34;, some vertical, pores of P1 and P2 type.
Microlamellar microstructure. An accurate biometric analysis allows to
recognize two opposite forms, one called &#34;weak&#34; and the other
&#34;strong&#34; with between a group of &#34;composite&#34; specimens,
but no new taxonomic units have been defined. The genus is recorded in
Ougarta (Algeria), Armorican Massif (France) and probably in the
Cantabrian Mountains (Spain).^1";
s[3995] = "LAFUSTE J., PLUSQUELLEC Y., SOTO F. (1993).- Coexistence de
lamelles et de microlamelles dans le sclerenchyme de
&#034;Ligulodictyum&#034; Plusquellec 1973 (Tabulata, Devonien du
Nord-Gondwana).- Courier Forschungsinstitut Senckenberg 164: 329-337.

Symposium on Fossil Cnidaria and Porifera, Vol. 1].- <b>FC&#038;P
22-2</b>, p. 21, ID=3468^<b>Topic(s): </b>microstructures; Tabulata,
Ligulodictyum; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Gondwana N^The pleurodictymorph genus
Ligulodictyum Plusquellec 1973, from the late Gedinnian - Early
Siegenian of the Armorican massive shows an entirely fibrous
microstructure. Specimens -with a very similar morphology - from the
Gedinnian of Mauritania (Pleurodictyum mauretanicum Le Maitre 1959)
Morocco and Spain and from the Siegenian and Upper Emsian of Morocco
show trabeculae often embedded in abundant stereoplasm. The
microstructure of the stereoplasm, studied by ultra-thin sections with
polished sides (LFP), exhibits two types of biocrystals: 1) standard
lamellae in the proximal part of the basal plate, and 2) microlamellae
with different size and shape in the middle and distal parts. This
change of lamellar to microlamellar microstructures is a new finding.
In some specimens - especially from Asturias - intercalations of
fibrous layers in the microlamellar stereoplasm are described. The
discovery of stereoplasm in the mauretanicum group probably will
require the splitting of the genus Ligulodictyum. The change of
lamellar to microlamellar microstructures proves that genera which
solely differ by their microstructure, e.g. Michelinia and Turnacipora,
```

```
may represent evolutionary stages of the same lineage and belong to the
same family.^1";

ecology; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian Ems; <b>Geography: </b>Morocco,
Anti-Atlas^Four families of tabulate corals are abundant in the Hmar
Lakhdad Formation: auloporids, dendroporids and striatoporids are very
frequent in the micritic mounds (named &#34;kess-kess&#34;), and
favositids are rather common in the argilaceous limestones overlying
the mounds. Statistical analysis of tabulate coral distribution shows
an evident lateral variation. The western part of the mound range is
characterized by a facies with Bainbridgia, the central part by a
facies with tubular auloporids and ornate dendroporids, and the eastern
part by a facies with tubular auloporids. Striatoporids and auloporids,
fairly abundant in the western part, are present in all the kess-kess.
Each facies corresponds with a part of the range limited by two normal
faults. Tabulate coral distribution was probably controlled by
synsedimentary tectonics, affecting the three blocks of Hmar Lakhdad.
Building corals are absent and only bacterian structures
(microstromatolites) can be observed in all kess-kess. So the mound
cementation was probably controlled by bacterian activity. [original

<b>Systematics: </b>Cnidaria Porifera; Tabulata Rugosa Chaetetida;
<b>Stratigraphy: </b>Devonian Giv?Fra; <b>Geography: </b>Morocco,
Semara^The paper describes the three tabulate coral species Caliapora
robusta (Pradácová, 1938), Pachyfavosites tumulosus Janet, 1965 and
Thamnopora major (Radugin, 1938), the rugose coral Phillipsastrea ex
gr. irregularis (Webster &#038; Fenton in Fenton &#038; Fenton, 1924)
and the chaetetid Rhaphidopora crinalis (Schlüter, 1880). The specimens
are described for the first time from Givetian and probably Frasnian
strata of Semara area (Morocco, former Spanish Sahara). The material is
stored in the Museo Geominero in Madrid. The tabulate corals and the
chaetetid demonstrate close biogeographic relationships to Central and
Eastern Europe as well as to Western Siberia. The fauna does not show
any special influence of the Eastern Americas Realm. [original

<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>Morocco, Anti-Atlas^Spectacular conical Early devonian carbonate
buildups up to 55 m high that crop out in the eastern Anti-Atlas of
southern Morocco are microbially mediated carbonate mud mounds that
were surfaced by soft-bottom communities dominated by small tabulate
corals. They formed on the Hamar Laghdad elevation, which was created
by a submarine volcanic eruption, and were associated with a network of
synsedimentary radial and tangential faults that originated by uplift
of the intrusive laccolithic body underlying the Kess-Kess Formation.
These faults served as conduits for the migration of hydrothermal
fluids to the sea floor. Most mounds developed over cross-points of
radial and tangential faults. Vents were episodically active until the
Famenian, but extensive vent carbonate production occurred only during
the Emsian. Preliminary geochemical results document that mud-mound
carbonates and calcite cements in neptunian dikes precipitated from
brines comprising a mixture of hydrothermal fluids and seawater. In
addition, carbon isotope compositions (d13C as low as -18‰PDB) suggest
a contribution from thermogenic methane derived presumably from
underlying basaltic intrusives. Aerobic bacterial oxidation of methane
is favored as the main process driving carbonate precipitation in, and
rapid lithification of, the mounds.^1";

Signatures of Hydrocarbon Venting in a Middle Devonian Carbonate Mound
(Bollard Mound) at the Hamar Laghdad (Antiatlas, Morocco).- Facies 40,
1: 281-296.- <b>FC&#038;P 28-1</b>, p. 67, ID=4009^<b>Topic(s):
</b>reefs, carbonate mounds; carbonate mounds; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Morocco, Hamar
Laghdad^The Middle Devonian Hollard Mud Mound is situated in the
eastern Hamar Laghdad, which is a small mountain range in the Tafilalt
in SE Morocco. In contrast to the well known Lower Devonian Kess-Kess
mounds, the Hollard Mound is of Middle Devonian age. The facies in the
core of this mud mound differs from that of the other parts of the
mound, and exhibits signatures of ancient hydrocarbon venting. The
carbonate phases of the core facies are derived from the oxidation of
vent fluids and consist of clotted micrite, a cryptocrystalline
carbonate associated with spheres of uncertain origin, and a calcitic
rim cement (rim cement B). These vent carbonates show &#948;13C values
```

```
in the range of -11 to -20 PDB indicating that some of their carbon is
derived from isotopically light hydrocarbons. Fossiliferous micrite has
been affected by hydrocarbon venting int he proximity of the vent site,
which is indicated by intermediate &#948;13C values between vent
carbonates and not affected sediments. Bivalves occur in dense
populations within the core facies. They form autochthonous shell
accumulations and are almost exclusively articulated. It is likely that
these bivalves were dependent on chemosynthesis similar to their
counterparts at modern vents. The vent deposits also exhibit an unusual
prasinophyte assemblage, which might have been linked to the specific
nutrient availability at the vent site. The ancient vent site is
characterized by an enhanced carbonate precipitation and rapid
lithification. The latter is corroborated by the three-dimensional
preservation of phytoplankton (prasinophytes and acritarchs) and the
occurrence of stromatactoid pores. An early phase of carbonate
corrosion predating the formation of vent carbonates affected the
fossiliferous micrite of the core facies and is thought to be related
to a phase of H2S-rich venting.^1";

<b>Geography: </b>Morocco^A new genus of rugose coral, Tizraia, has
```

```
been recorded in the Tizra and Akerchi formations of the Adarouch area
(Brigantian, Central Meseta, Morocco). The new genus is characterized
by incomplete, mesa-shaped tabulae, absence of axial structure and
presence of well developed lonsdaleoid dissepiments, as well as
parricidal increase. It evolved from Diphyphyllum by the development of
lonsdaleoid dissepiments. Only the type species, Tizraia berkhlii gen.
nov. et sp.nov. is included with certainty in the new genus, but an
additional species represented by one single specimen is tentatively
described under this generic name. Tizraia has also been recorded in
the Djerada Basin (Eastern Morocco) and may be present in Ireland. It
has high biostratigraphic value as an Upper Brigantian (Upper Viséan)
index taxon.^1";
s[4007] = "ARETZ M. (2010).- Rugose corals from the upper Visean
(Carboniferous) of the Jerada Massif (NE Morocco): taxonomy,
biostratigraphy, facies and palaeobiogeography.- Paläontologische
Zeitschrift 84, 3: 323-344.- <b>FC&#038;P 36</b>, p. 48,
ID=6428^<b>Topic(s): </b>ecology, biogeography; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Vise;
<b>Geography: </b>Morocco NE^The Visean succession of the Jerada Massif
contains a relatively diverse rugose coral fauna, which comprises 12
genera. Only two of these (Siphonodendron and Lithostrotion) are
reported to include more than one species. Most taxa show distinctive
facies dependencies. Small solitary corals are found in shaly
environments of the Oued Es-Sassi Formation. On the northern flank a
coral patch reef formed on an oolitic shoal in the Koudiat Es-Senn
Formation. Its core mainly consists of Lithostrotion vorticale
colonies, whereas in its surroundings literally hundreds of specimens
of Siphonophyllia samsonensis occur. Associated with these dominant
taxa occur colonial and further large solitary taxa (Palaeosmilia,
Dibunophyllum). Tizraia and Pareynia are restricted to
microbial-dominated buildup facies. Their presence might be strongly
controlled by the development of this buildup type, because further
occurrences in Algeria. Morocco, and Belgium are all in the same
facies. The coral fauna at Jerada is a typical Late Visean assemblage
for the Western European Province. The Eastern Moroccan Meseta may be
an important pathway within the province for the connection between the
Central Saharan basins and NW Europe. The biostratigraphic ages of the
coral fauna partly contradict ages based on carbonate microfossils: the
coral ages are slightly older and typical Brigantian coral taxa are
absent.^1";
s[4008] = "ARETZ M., HERBIG H.-G. (2010).- Corals from the Upper Viséan
of the southern Azrou-Khenifra Basin (Carboniferous, Central Moroccan
Meseta).- Palaeoworld 19, 3-4: 294-305.- <b>FC&#038;P 36</b>, p. 49,
ID=6430^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography:
</b>Morocco, Meseta^This is the first taxonomic treatment of coral
faunas from upper Viséan shallow-water limestones of the southern
Azrou-Khenifra Basin (eastern central Morocco). Corals recovered during
reconnaissance work represent 8 genera and 11 species of rugose corals,
1 heterocoral species, and 3 tabulate coral taxa. The fauna is
tentatively attributed to the late Asbian. Siphonodendron scaleberense
is described from Northern Africa for the first time. Facies
differentiations clearly control the coral distribution in the
stratotype of the Bou-Rifi Formation near Sidi-Lamine. In the Tabainout
Ridge, the massive build-up facies is almost devoid of corals except
for specialised forms such as ?Sutherlandia. Bioclastic and oncolitic
limestone facies below and above the build-up facies contain coral
faunas, which differ in their compositions. The fauna of the
Azrou-Khenifra Basin is part of the West European-North African faunal
province.^1";

extensive abstract]^1";
s[4011] = "ARETZ M., HERBIG H.-G. (2008).- Microbial-sponge and
microbial-metazoan buildups in the Late Viséan basin-fill sequence of
the Jerada Massif (Carboniferous, NE Morocco).- Geological Journal 43,
2-3 [M. Aretz, H.-G. Herbig et I. Somerville (eds): From Platform to
Basin, Proceedings of the Carboniferous Conference, Cologne 2006]:
307-336.- <b>FC&#038;P 36</b>, p. 112, ID=6547^<b>Topic(s): </b>reefs,
microbial-sponge buildups; reefs; <b>Systematics: </b>Monera Porifera;
<b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Morocco
NE^Three distinctive Late Viséan buildup intervals are differentiated
on the southern limb of the Jerada Synclinorium. The oldest buildups
(BI-1) are preserved as olistoliths in the Oued El Koriche Formation
(Fm). They were located on a southern platform prior to reworking. The
younger Koudiat Es-Senn Fm contains two autochthonous buildup intervals
(BI-2 to BI-3). BI-1 and BI-2 buildups are large microbial-sponge
buildups, BI-3 are small microbial-metazoan buildups in the capping bed
succession above BI-2. All buildups are characterized by a rigid
non-skeletal microbial framework. Growth of the largest BI-2 buildups
started in aphotic to dysphotic conditions in a water depth
significantly less than 100m and continued into agitated shallow-water.
Smaller BI-2 buildups and all BI-3 buildups are encased in grainy
shallow-water carbonates. In contrast to a mostly homogeneous
microbial-sponge facies below, the uppermost part of the BI-2 buildups
and all BI-3 buildups consist of heterogeneous boundstones with
differing frame builders. BI-1 to BI-3 buildups represent different
stages within a Viséan basin-fill sequence. Carbonate sedimentation
ended with the deposition of peritidal oncolitic floatstones below the
unconformably overlying Namurian shales. The Jerada buildups have many
features commonly associated with &#039;reefs&#039;. Comparison with
contemporaneous buildups shows considerable similarities to buildups
from Algeria, the Eastern Moroccan Anti-Atlas and the British Isles.

s[4012] = "FLUGEL E., HERBIG H.-G. (1988).- Microfacies of
Carboniferous Limestone Clasts from the Rif Paleozoic (Morocco): A
Contribution to the Paleogeography of the Western Mediterranean
Carboniferous Paleotethys.- Facies 19: 271-300.- <b>FC&#038;P 18-2</b>,
```

```
p. 43, ID=2499^<b>Topic(s): </b>carbonates microfacies; <b>Systematics:
</b>; <b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>Morocco,
Rif^Post-lower Serpukhovian conglomerates with abundant limestone
clasts are intercalated within the Carboniferous flysch succession of
the Ghomarides (internal zone of the Rif, northern Morocco). They are
restricted to two ghomaridic nappes (Beni Hozmar, Akaili; Fig. 1). No
limestone-bearing conglomerates are known from the third nappe (Kuhdiat
Tizian). 83.4% of the limestone clasts derived from shallow-shelf
environments and adjoining proximal slope environments of late Visean
(V3b &#947;) to early Serpukhovian (Namurian E1-E2) age. Microfacies
types of the inner shelf lagoon and of restricted shelf environments
dominate. They indicate a complicated mosaic facies pattern (Fig. 2).
16.6% of the limestone clasts derived from distal slope environments
and deep, open marine environments. They are of unknown age except for
one Upper Devonian pebble from around the transition do IIa &#47;
doII&#946;. All are supposedly of late Middle Devonian and Late
Devonian age. Their sedimentology as well as the age and the
microfacies of the limestone clasts indicate that the conglomerates of
the Ghomarides are homologous to the Marbella Formation of the
Malaguides (Betic Cordillera, Southern Spain). The conglomerate of
Binifaillet (Minorca, Balearic Islands) is also similar. The source
area of the conglomerates was the not any more existent Betico-Rifean
Block south of the Malaguide-Ghomaride flysch trough. Owing to their
facies development in Devonian and Carboniferous times, the nappes of
the Ghomarides and the Malaguides can be arranged in a successively
more distal position towards the source: nappe of Beni Hozmar - nappe
of Kuhdiat Tizian - nappe of Akaili + Malaguides (Fig. 4). Minorca,
which received its flysch sediments from the north, seems to be
influenced only episodically by conglomerate inputs from the south.

<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Morocco^A
quantitative study of the Upper Jurassic coral associations of Cape
Ghir (Atlantic High Atlas, Morocco) revealed highly diverse coral
assemblages characterizing three reef environments, each of them
dominated by one of the following genera: Dimorpharaea, Microsolena,
and Stylina. A fourth assemblage is characterized by nerinean
gastropods and stromatoporoids. Combined GPS surveys, 3D
representation, and facies distribution studies permitted to understand
the geometry of this coral reef within a particular tectonic setting.
The reef became installed on top of a tilted block of Jurassic age
subsequently folded into an east-west-trending anticline near the
village of Tighert, exhibiting a 5 to 10° northward dip of its northern
flank near the lighthouse of Cape Ghir. We suggest that the different
fossil assemblages encountered in the field belong to one and the same
fossil reef tract (within a unique facies model). The previously
reported hypothesis of two successive reef horizons representing
different biochrons is abandoned.^1";

A fourth assemblage is characterized by nerinean gastropods and stromatoporoids. Combined GPS surveys, 3D representation, and facies distribution studies permitted to understand the geometry of this coral reef within a particular tectonic setting. The reef became installed on top of a tilted block of Jurassic age subsequently folded into an east-west-trending anticline near the village of Tighert, exhibiting a 5 to 10° northward dip of its northern flank near the lighthouse of Cape Ghir. We suggest that the different fossil assemblages encountered in the field belong to one and the same fossil reef tract (within a unique facies model). The previously reported hypothesis of two successive reef horizons representing different biochrons is abandoned.^1";

ID=3066^<b>Topic(s): </b>reefs, patch reefs; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Miocene U; <b>Geography: </b>Morocco^The
reef outcrop of Aghram Amallal (South-East of Fes) belongs to the reef
formations of the south side of the South Rifan Corridor. It is
presented like a horizontally allongated lense (approximately 60m
lenght; 3 to 6m thickness). The bioconstruction is almost exclusively
assured by the Tarbellastraea genera. The developed colonial
morphologies are varied and their spatiotemporal distribution has
allowed to establish morphological zonations. The study of different
distinguished morphological zonations, the investigation of the
accompanying fauna and flora as well as the analysis of the inter and
intracolonial sediment let appear a rythmicity of the bioconstruction
and the sedimentation. This rythmicity is summoned by two
&#34;regressive&#34; sequences that are separated by a positive
fluctuation of the sea level. The environmental conditions seem to
```

```
characterize a &#34;back reef&#34; set, and permit to assimilate the
studied reef to a &#34;Patch&#34; that would integrate itself to an
important marine platform. This later would develop in front of Ei
Aderj faults.^1";
s[4030] = "EL HAMZAOUI O., LACKHEM H. (1996).- Analyse paleoecologique
des affleurements recifaux du Miocene terminal a Boumeriem (region de
Tazouta; Sud-Est de Fes; Maroc).- Notes et Mem. Serv. geol. Maroc 387:
45-56.- <b>FC&#038;P 27-1</b>, p. 114, ID=3873^<b>Topic(s): </b>reefs,
ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Miocene U;
<b>Geography: </b>Morocco^The reef outcrops of Boumeriem (north east of
Tazouta) belong to the later Miocene reef formations of the South Rifan
Trench. They are represented in the form of more or less elongated
lenses, and display a vertical repartition on three successive levels.
The reef constructions are essentially built by Porites and
Tarbellastraea; Palaeoplesiastraea is much less abundant. The
developped colonial morphologies, whether they are massive or branched,
are very much varied. The spatio-temporal distribution of these
different types of colonies has allowed to establish morphological
zonations into these reef outcrops. The study of the different
distinguished morphological zonations, the analysis of the
intercolonial sediment and the examination of the accompanying fauna
and flora allow to make a certain number of paleoecological deductions.
Generally, the environmental conditions seem to characterize a
&#34;back reef&#34;environment frequently situated near the &#34;reef
crest&#34;. The analysis of the vertical succession of the different
sets let appear the clearly rhythmic character of the reef construction
and of the sediment. This kind of rhythm is summoned by four
&#34;regressive&#34; sequences, having each a few meters and all tend
to be sandy. The reappearance, at the end of each of these sequences,
of the reef conditions would display a positive fluctuation of sea
level.^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Morocco, Spain^The tabulate coral faunas of the
Moniello-Santa Lucia Formations (upper Emsian-lower Eifelian,
Cantabrian Mountains, NW Spain) and the &#034;recif coralligene de
Ouihalane&#034; (Tafilalt, Morocco, assigned by le Maitre 1947, to the
Eifelian) are compared in a quest for increased understanding of
relationships among the various Devonian outcrops in Morocco, and
between provinces of the Maghrebo-European realm. The Devonian of the
Asturian-Leonese Domain, in the Cantabrian Mountains (NW Spain) is
characterized by alternation of detrital and carbonate units,
principally with benthic fauna, deposited on a shallow marine platform.
Reef episodes of differing importance were developed in some of the
carbonate successions. The first of these, upper Emsian in age, is not
very important but some genera of tabulate corals (especially
Crenuliopora and Schlueterichonus) simply paleobiogeographic affinity
of this region with north Africa (Fernandez-Martinez &#038; Tourneur,
1995). Gondwana biogeographic patterns. [first part and conclusion of
extensive summary]^1";
s[4036] = "OEKENTORP K., TONG-DZUY THANH (1996).- Remarks on the genera
Striatoporella and &#034;Riphaeolites&#034; (Devonian Tabulata).- N.
Jb. Geol. Palaont, Mh. 1996, 5: 293-308.- <b>FC&#038;P 25-1</b>, p. 36,
ID=3021^<b>Topic(s): </b>taxonomy; Tabulata, Striatoporella;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian
Ems Eif; <b>Geography: </b>Morocco, Spain^Restudy of Mesofavosites
schouppei Potthast &#038; Oekentorp 1988 (Emsian-Eifelian boundary in
SE Morrocco) and of Pachyfavosites pseudoseptatus Oekentorp 1975
(Emsian of Asturias/N Spain) shows that M. schouppei has to be assigned
to Striatoporella Rukhin 1938 because of the typical growth form, the
peripheral thickenings of the walls and the development of spines, P.
pseudoseptatus has been assigned to Pachyfavosites on the basis of its
strikingly thick walls. Diagenetic processes may result in secondary
microstructures, for example the arrangement of carbonate fibers.
Therefore, wall thickness is useless as a diagnostic feature. In this
view, P. pseudoseptatus corresponds very well with other
representatives of the genus Riphaeolites.^1";
s[4037] = "GALLE A., MAREK L., VANNIER J., RACHEBOEUF P.R., REGNAULT S.
(1994).- Assemblage epibenthique a hyolithes, tabule Epizoaire et
ostracode Beyrichiacea du Devonien inferieur du Maroc et
d&#039;Espagne.- Revue de Paleobiologie 13, 2: 411-425. [in French,
with English abstract].- <b>FC&#038;P 24-2</b>, p. 86,
ID=4581^<b>Topic(s): </b>Tabulata, pseudoplanctic; biocoenoses;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>Morocco, Spain^Several Lower Devonian localities of Morocco (Middle
Atlas and coastal Meseta) yielded for the first time a hyolithid
(Pterygotheca sp.), an orthothecid (Orthotheca sp. A), an epizoan
tabulate coral Hyostragulum ometanum n.sp. and a beyrichiacean
ostracode (Gibba kandarensis n.sp.) together with rare bivalves,
cephalopod shells, abundant brachiopods and dacryoconarids. Only the
hyolithids, the new tabulate coral and the new ostracode species are
described herein. Specific commensal relationships between the
hyolithid Pterygotheca sp. and the epizoan tabulate coral Hyostragulum
ometanum n.sp. are demonstrated and compared with similar cases from
Bohemia and the Armoricain Massif (France). From a
palaeobiogeographical point of view, the genus Hyostragulum appears as
a typical north-Gondwanan genus. The genus Orthotheca occurs in both
Morocco (Orthotheca sp. A) and southern Spain (Orthotheca sp. B) like
the dimorphic beyrichiacean ostracode Gibba kandarensis n.sp. These new
data confirm the close faunal affinities previously described between
North Africa and southwestern Europa during the Lower Devonian. A lower
Emsian age is proposed for the fossiliferous beds of Spain and
Morocco.^1";
s[4038] = "PLUSQUELLEC Y., TOURNEUR F., LAFUSTE J. (1993).- Saouraepora
nouveau genre de Micheliniidae (Tabulata), du Devonien du Nord Gondwana
```

```
et du Carbonifere d&#039;Amerique du Nord.- Palaeontographica A227,
1-3: 1-86.- <b>FC&#038;P 23-2.1</b>, p. 47, ID=3521^<b>Topic(s):
</b>new taxa; Tabulata, Saouraepora; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Devonian, Carboniferous; <b>Geography:
</b>Gondwana, America N^The revision of the holotype and topotypes of
&#34;Dendropora&#34; (= Trachypora ?) gigantea Le Maitre 1952, brings
new data on the structure, the increase (lateral increase with apical
corner pore) and the microstructure of this tabulate coral. The new
genus Saouraepora - type species &#34;D.&#34; gigantea - is erected for
branching corallum with strongly thickened peripheral zone where
corallites are perpendicular to the surface, tabulae complete,
incomplete and convex, rounded calices with granular intercalicinal
platform, wall composed of upwards divergent lamellae, median dark
lamina only in axial zone and inner peripheral zone of branch. Several
species in open nomenclature and a new species - S. armoricana - are
described from Lower and Middle Devonian; Holacanthopora irregularis Le
Maitre 1957 is assigned to Saouraepora. The genus is represented in the
Carboniferous by Pachypora oklahomensis Snider 1915.The variability of
the genus is important, and brief review is given; its affinities with
Praemichelinia are undoubtedly established and possible relationship
with P. homofavosa are suggested; this interesting ramose species is
described in appendix. Between branching coralla the microstructure of
the wall prevents confusion with Parastriatopora (microlamellar) and
evolves from it. Biographic data show that Saouraepora evolves in the
North-Gondwana shelf during Lower and Middle Devonian and migrates to
North-America during Upper Devonian or Lower Carboniferous. In this
area the genus is located East of the Transcontinental arch.^1";
s[4039] = "WELLS J.W. (1982).- Fossil corals from the Midway Atoll.- US
Geol. Surv. prof. Pap. 680-G: 1-7; Washington.- <b>FC&#038;P 11-2</b>,
p. 44, ID=1876^<b>Topic(s): </b>; corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>fossil; <b>Geography: </b>Midway
Atoll^Fossil corals were recovered from the cores and cuttings of the
two drill holes made in Midway atoll in 1956. Reef-building
scleractinian corals were relatively continuous from near the surface
to a depth of 1,143 ft. Above 494 ft, six species representing five
genera were recognized, all identical with the living Hawaiian reef
fauna; the age range was Pliocene to Holocene. At and below 494 ft was
a poorly preserved surface reef fauna of Miocene age, represented by 10
genera and 13 species; this fauna was unlike that of similar age found
in the drill holes at Bikini and Enewetak (formerly Eniwetok).
[original summary]^1";

Palau Islands and its fossil representatives.- Bulletin Tohoku Univ.
Sci. Dept., ser. 2 (geol.), 46, 1: 1-9.- <b>FC&#038;P 5-2</b>, p. 13,
ID=5458^<b>Topic(s): </b>; Spongiae, Sclerospongiae; <b>Systematics:
</b>Porifera; Sclerospongiae; <b>Stratigraphy: </b>living &#038;
fossil; <b>Geography: </b>Palau Isls^The new genus and species
Tabulospongia horiguchii is described. It has a calcitic skeleton like
that of a ceriod tabulate coral. Siliceous megascleres and microscleres
are also part of the skeleton. The surface is marked by stellate
grooves of the excurrent system. Acanthochaetetes wellsi Hartman and
Goreau is removed from the genus Acanthochaetetes because, unlike the
fossil forms, it contains spicules and is placed in the new genus. Mori
believes that the presence of polyps in stromatoporoids is indicated by
the presence of oolites within the skeleton of a Parallelostroma
typicum from Gotland. The argument used is that a filter feeder could
not survive in an environment of this sort &#34;because it lacks
sufficient ability to remove the obstacles from the living tissue of
the skeleton. The fact that the stromatoporoid could survive in the
oolites environment may prove that it had polyps with tentacles like
other coelenterates because only the tentacles, possibly with
nematocysts could remove ooids falling down continuously on the
skeleton by wave action&#34;. He concludes that the stromatoporoids may
```

```
be hydrozoans or a phylum intermediate between the Porifera and the
Coelenterata.^1";

All available records of this biota in the Northwest Pacific (Japan and Sakhalin Island) are summarized in order to elucidate its stratigraphic distribution patterns and faunal changes, with special attention given to the biota of the Late Aptian-Early Albian.This carbonate platform biota flourished from the Berriasian to Early Albian interval in the Northwest Pacific, indicating that the Northwest Pacific clearly belonged to the Tethyan biotic realm at that time. A step-wise demise of the carbonate platform biota transpired in the latest Aptian to middle Albian interval. Mesogean key taxa (rudists and dasycladacean algae), some Mesogean indicators (hermatypic corals and stromatoporoids) and nerineacean gastropods disappeared at the Late Aptian to Early Albian transition. Following this event, other Mesogean indicators (orbitolinid foraminifers and calcareous red algae) and coated grains disappeared at the Early to middle Albian transition. There is no record of carbonate platform biota in the Northwest Pacific during the long interval between the Middle Albian and Paleocene. The step-wise demise of the carbonate platform biota in the latest Aptian-middle Albian interval strongly implies a &#34;vicariance event&#34;, which separated the North Pacific from the Tethyan biotic realm and established the North Pacific biotic province.^1";
s[4050] = "GROTSCH J., FLUGEL E. (1992).- Facies of sunken Early Cretaceous atoll reefs and their capping Late Albian drowning succession (Northwestern Pacific).- Facies 27: 153-174.- <b>FC&#038;P 22-1</b>, p. 52, ID=3425^<b>Topic(s): </b>reefs, submerged atolls; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>Pacific NW^Since first described in detail by Hamilton (1956), the causes and timing of the drowning of several hundred guyots in the northwestern Pacific is a puzzling question. Thus, the northwestern Pacific is one of the key areas in deciphering the demise of flat-topped platforms throughout the Earth&#039;s history. Based on older palaeontological data and the newly found shallow-water benthic foraminifera, the atoll reefs probably had a major period of vertical aggradation during the Barremian and the Aptian into the Late Albian depending on the stage of atoll development (type of guyot). New sedimentologic and stratigraphic data suggest a strong fall in sea level, leading to karstification and the formation of lowstand fringing reefs, prior to an even rapid rise of greater amplitude in the Late Albian Rotalipora appenninica zone ultimately causing drowning. After climate relaxation, a sea level rise led to the final formation of small barrier reefs, rimming the top of many guyots in the Japanese Group, the Wake Group and the Mid Pacific Mountains.
```

```
They can be interpreted as &#034;give-up&#034; structures indicating
final shallow-water carbonate production on top of the atoll during
drowning. The facies of the syn- and post-drowning sediments on the
guyot tops are strikingly similar even when vast distances apart. This
and the biostratigraphic data suggest a synchronous drowning of many
seamounts investigated up to now. Biotic composition and facies of the
final Albian reefs are very similar to Albian caprinid-dominated reefs
in the Caribbean region, indicating comparable environmental controls.
In the case of the northwestern Pacific guyots, the simultaneous demise
of reefs could be due to a short-term cooling event in the Late Albian,
connected with a strong regressive-transgressive cycle with an
amplitude of about 180m. This event is also known from the Tethys and
the Atlantic. Climatic disturbances triggering short-term cooling and
including a high amplitude regressive-transgressive sea level cycle,
might be responsible not only for the Late Albian event, but also
perhaps for other reef drownings throughout the Earth&#039;s history.^1";
s[4051] = "ROUGERIE F., FAGERSTROM J.A. (1994).- Cretaceous history of
Pacific Basin guyot reefs: a reappraisal based on geothermal
endo-upwelling.- Palaeogeography, Palaeoclimatology, Palaeoecology 112:
239-260.- <b>FC&#038;P 24-1</b>, p. 91, ID=4527^<b>Topic(s): </b>reefs,
guyot reefs; reefs, guyot reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Cretaceous; <b>Geography: </b>Pacific^The mid-Cretaceous histories
(origin, growth, death) of algal rudist stromatoporoid reef communities
located on many Pacific Basin guyots are complex and controversial.
These shallow water, tropical communities originated on volcanic
edifices extruded during the Barremian - Albian [interval], grew upward
during edifice subsidence &#47; transgression throughout the Aptian,
Albian and Cenomanian and several of them died almost synchronously
near the Cenomanian &#47; Turonian boundary. During their periods of
origin and growth, we postulate that the reef ecosystems received
dissolved oxygen by wave surge and nutrients by geothermal
endo-upwelling. By this process oceanic waters of intermediate depth
(approx. 500-1500m) were: (a) drawn into the weathered and fractured
volcanic summit and lower part of the older reef and driven upward
through the porous framework by the remnant geothermal gradient of the
volcanic foundation and (b) emerged at the reef surface to support the
high metabolism of the living community. * The death of most of the
reefs near the Cenomanian Turonian boundary approximately coincides
with the most intense oceanic anoxic event (OAE) in Pacific Ocean
history. During this OAE the chemistry of the endo-upwelled fluids
arriving at the reef surface changed from nutrient &#47; oxygen-rich to
dysoxic-anoxic toxic, and killed the community. Additionally, the
combination of foundation subsidence and global transgression reduced
aeration of interstitial reef waters by wave turbulence. The
post-mortem history of the guyot summits consisted of: (a) drowning to
prevent revival of the reef communities, (b) deposition of
Turonian-Cenozoic fossiliferous pelagic -sediments in the former atoll
lagoons and dead reef debris and (c) minor erosion (submarine;
karstification?) of the dead reef frameworks.^1";

reefs, geohistory; Scleractinia, reefs; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cenozoic; <b>Geography: </b>Pacific
E^Studies of hermatypic corals in the eastern Pacific have mainly
focusedon Recent species, and relatively few of these works have
studied fossilcorals. The purpose of the present contribution is to
provide acomprehensive synthesis on Cenozoic hermatypic coral studies
that will serve: a) to identify gaps in our understanding about the
Cenozoic evolution of eastern Pacific hermatypic fauna, and b) to be
used as a baseline for future work in the region. Our knowledge
regarding the eastern Pacific fossil coral fauna has increased
gradually since 1864. A total of 151 coral species including synonyms
have been recorded in the region. The species richness increases from
Paleocene to Oligocene followed by a loss of species towards the
Pleistocene, though to some extent biodiversity estimates are affected
by sampling intensity. Fossil bearing units are spatially restricted to
Washington-Seattle, south and central California, Gulf of California
and Chiapas, and there is a lack of outcrops in western Mexico and
Central America. In general, fossil coral studies have been sporadic,
incidental in nature, and restricted to species descriptions, faunal
lists and geographic affinities. The relative lack and nature of the
hermatypic fossil studies in the region have directly affected our
understanding about the origin of the modern eastern Pacific coral
fauna and its evolutionary history. Studies regarding to taxonomy and
systematics, and detailed spatio-temporal community dynamics, are
essential for understanding the evolution of the fauna.^1";

strata, subsurface Enewetak Atoll.- Journal of Sedimentary Petrology
56, 6: 743-762.- <b>FC&#038;P 16-1</b>, p. 73, ID=2011^<b>Topic(s):
</b>reefs diagenesis; reefs, diagenesis; <b>Systematics: </b>;
<b>Stratigraphy: </b>Miocene L; <b>Geography: </b>Enewetak
Atoll^Petrographic and stable isotopic data are consistent with
precipitation of radiaxial calcite in its present form directly from
seawater. Precipitation of radiaxial calcite after aragonite
dissolution indicates precipitation distinctly after deposition,
probably in a burial environment. Dissolution of aragonite by deep
marine water is suggested by: 1) abundant marine cement associated with
aragonite dissolution; 2) a lack of meteoric cements associated with
aragonite dissolution; and 3) no evidence of subaerial exposure in
Lower Miocene strata between 400 and 819 m. Modern Pacific Ocean water
```

```
is undersaturated with respect to aragonite at depths where aragonite
dissolution is observed (375-850 m). Tidal fluctuations and temperature
profiles indicate that Lower Miocene strata containing radiaxial
cementation are interpreted as having occurred in seawater
(undersaturated with respect to aragonite) circulating through the
atoll. Variations in magnesium concentration in Enewetak radiaxial
calcite may be the result of original heterogeneity or differential
loss of magnesium during later diagenesis in seawater. The first
alternative is preferred. Precipitation of radiaxial calcite at
different rates (at different degrees of saturation) could cause
variable magnesium concentrations. More deeply buried radiaxial calcite
may have precipitated more slowly in deeper, less supersaturated water,
resulting in lower magnesium concentrations. Likewise, slower rates of
precipitation may have resulted in organic infestations and lower
magnesium concentrations in inclusions-rich bands. Enewetak radiaxial
calcites suggest that two factors might be critical to development of
radiaxial fabric: 1) precipitation at fluctuating rates, and 2)
formation in waters undersaturated with respect to aragonite. [SECOND

Barrier Reef^Like many coral specialists [&#8230;] J.E.N. Veron thought
Australia&#39;s Great Barrier Reef was impervious to climate change.
&#34;Owned by a prosperous country and accorded the protection it
deserves, it would surely not go the way of the Amazon rain forest or
the parklands of Africa, but would endure forever. That is what I
thought once, but I think it no longer.&#34; This book is Veron&#39;s
Silent Spring for the world&#039;s coral reefs. * Veron presents the
geological history of the reef, the biology of coral reef ecosystems,
and a primer on what we know about climate change. He concludes that
the Great Barrier Reef and, indeed, most coral reefs will be dead from
mass bleaching and irreversible acidification within the coming century
unless greenhouse gas emissions are curbed. If we don&#039;t have the
political will to confront the plight of the world&#39;s reefs, he
argues, current processes already in motion will become unstoppable,
bringing on a mass extinction the world has not seen for 65 million
years.^1";

Pacific hurricanes on sub-rubble cryptic corals: the possible role of
cryptic organisms in maintenance of coral reef communities.- Journal of
Paleontology 61, 4: 663-675.- <b>FC&#038;P 16-2</b>, p. 29,
ID=2072^<b>Topic(s): </b>reefs cryptic corals, hurricane impact; reefs,
cryptic corals; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Pacific^The hermatypic
scleractinian cryptic coral biota living under mobile rubble in the
reef flat and back reef zones of a Fijian fringing reef was surveyed in
detail in August of 1984; only 138 days later the reef was struck by
the first of two sequential hurricanes (57 days apart). The sample
areas were re-studied in August 1985, thereby providing the first
detailed census of pre- and post-hurricane cryptic reef coral
populations, and allowing an assessment of hurricane impact on these
populations. The 61 cryptic species (60 corals and Millepora) show 88
percent commonality with the intertidal and shallow subtidal reef
surface coral population (68 species), and therefore are a good
representation of the surface biota. A major effect of the hurricanes
was a reduction of almost 50 percent in the number of boulders
sheltering cryptic coral. However, among boulders that retained coral
through the storms, there was only a five percent reduction in the mean
number of corals per boulder, signifying that damage to the surviving
```

```
population was minor. The composition of the surviving cryptic coral
population is essentially unchanged from its pre-hurricane state (there
are differences in absolute abundances), and the relative importance of
the species does not show marked change in most cases. Coral
morphologies show little change in their absolute and relative percent
abundances after the hurricanes. In contrast to what is normally seen
in reef surface habitats, therefore, coral colony form did not appear
to be an important determinant in survivability for those living under
boulders; primary selection by the storms seems to have been on boulder
form rather than cryptic coral form. Cryptic sub-rubble populations may
function as a preserve for elements of the pre-hurricane reef surface
community. For example, delicately-branching forms that are commonly
devastated in reef surface habitats during hurricanes may, in some
cases, be preserved in great numbers under boulders or in other cryptic
habitats. This provides a &#034;recruitment pool&#034; that can greatly
accelerate their recovery and re-establishment on the post-hurricane
reef surface, and dampen the potentially severe community dislocations
arising from intense competition for space in &#034;instantaneous&#034;
new reef substrate.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Philippines, Leyte^As part of a broader study
encompassing the palecologic significance of Recent Bryozoa in
different Philippine ecosystems, we have observed an association of
corals and bryozoans in Southern Leyte in the central part of the
archipelago. This association is non-reefal since strong currents
combined with migrating sand waves form an abrasive environment.
Moreover, typhoons are frequently encountered in the study area. Since
framebuilding is widely surpressed, the hermatypic coral association
shows a lowered diversity and is dominated by pioneering, high energy
resistant species. However, the bryozoans exhibit high diversity with a
dominance of spot form zoaria and sheets formed by species which have a
low competitive ability. The abrasion results in the total lack of
zoaria of the runner-type. Encrusting bryozoan species turned out to
react most sensitive to certain abiotic parameters which affect the
biological interactions. They apparently can be better utilized in
palecologic studies than erect species. The species Parasmittina
soulesi (Bryozoa, Ascophora) is newly described.^1";

Forschungsinstitut Senckenberg 201: 371-383.- <b>FC&#038;P 27-2</b>, p.
69, ID=3939^<b>Topic(s): </b>mineralization; biomineralization;
<b>Systematics: </b>Porifera; Corallina; <b>Stratigraphy: </b>Recent;
<b>Geography: </b>Pacific^Biomineralization of calcareous basal
skeletons in coralline sponges is a strongly phylogenetically
convergent character. However, the basic mineralization process is
ancestral and exhibits similarities with mineralization processes seen
in bacterial biofilms and organomineralization via controlled
taphonomy. The main biocalcification events in the phylogenetically
```

```
distinct taxa Vaceletia sp., Astrosclera willeyana, and Spirastrella (Acanthochaetetes) wellsi are discussed. Vaceletia, a demosponge with a thalamid basal skeleton, exhibits the most ancestral way to build a calcareous skeleton via controlled taphonomy. Archaeocyathids exhibit the same skeleton-forming mode as seen in Vaceletia. The stromatoporoid Astrosclera willeyana forms intracellularly egg-shaped aragonitic aster in a first step which grow together via an epitactical process. This mode of calcification is realized in many late Permian and Triassic coralline sponges with different phylogenetic origins. The chaetetid S. (Acanthochaetetes) wellsi, phylogenetically the most evolved coralline sponge taxon, forms its unique calcitic skeleton in extracellular acidic organic mucilages in the presence of collagen, In all cases the mineralization is controlled by acidic matrix proteins.^1";
s[4089] = "WORHEIDE G., GAUTRET P., REITNER J., BOHM F., JOACHIMSKI M.M., THIEL V., MICHAELIS W., MASSAULT M., (1997).- Basal skeletal formation, role and preservation of intracrystalline organic matrices, and isotopic record in the coralline sponge Astrosclera willeyana Lister 1900.- Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91, 1/4: 355-374.- <b>FC&#038;P 26-2</b>, p. 20, ID=3696^<b>Topic(s): </b>skeletogenesis; Porifera, Demospongiae, Astrosclera; <b>Systematics: </b>Porifera; Demospongiae; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia, Great Barrier Reef^A specimen of the coralline demosponge Astrosclera willeyana Lister with a 14C-age of approximately 400 years was collected in a small cave at Ribbon Reef No. 10 in the Northern Great Barrier Reef Composition and transformations of organic matrices, intimately linked to the Sr-aragonitic biominerals of the calcified skeleton, were examined by biochemical analyses. The matrices participate in the biomineralization process as long as the spherulites are growing and even during extracellular growth stages. Chromatographic analyses and biochemical characterization (molecular weight, amino acid, and monosaccaride composition) of the organic matrix from different growth layers of the skeleton show a stable composition of the insoluble organic matrix (IOM), but changing composition of the soluble organic matrix (SOM). The SOM in young skeletal parts exhibits high concentrations of aspartic and glutamic acid, which strongly decrease in the older parts of the skeleton. [first fragment of extensive summary]^1";

Scleractinia; <b>Stratigraphy: </b>Recent; <b>Geography: </b>New
Caledonia^Four species of solitary scleractinian corals were found to
be the hosts of one species of tube inhabiting tanaidacean off
southeastern New Caledonia (3 stations, depth 570-860 m). The tube is
attached to the outer side of the coral skeleton, its distal end being
near the calicular edge or bending over the edge into the calice. This
position suggests that the tanaidacean needs to keep close to the polyp
tissues for feeding. It also suggests immunity to the defense reactions
of the cnidarian host. The coral surface beneath the tube is altered:
superficially eroded or forming a very shallow groove, and of a chalky
white aspect that contrasts with the normally lustrous and shiny
surface. The erosion caused by the tanaidacean is thought to be
chemical. The new tanaidacean - scleractinian association closely
resembles that between the tubicolous polychaete Lumbrineris
flabellicola and various scieractinian species. * The tanaidacean
Bifida scleractinioides gen.nov., sp.nov., is placed in the family
```

```
Anathruridae, subfamily Leptognathiinae, based on peraeopodal structure
and armament. Within the subfamily Bifida gen.nov. is charaterized by
at least four cleft (bifid) terminal spines on the MX 1. Peraeopodal
setation indicates a probable closer relationship to Pseudoparatanais.

Sur la pente externe du récif barrière, les coraux sont peu abondants et disparaissent complètement entre 30 et 40 mètres. La faune du lagon est beaucoup plus riche. Comparaisons avec les autres îles récifales des Tuamotu. * Les Scléractiniaires jouent un rôle essentiel dans le peuplement des récifs et du lagon quoique sur la pente extérieure du récif barrière, on observe un faible recouvrement du substratum par ces organismes. Dans cette publication, est donné un aperçu sur leur répartition dans les différentes zones récifales: récif barrière, récifs frangeants, pinacles et fond du lagon. L&#039;étude systématique des espèces sera présentée dans un Mémoire sur les Scléractiniaires de Polynésie Française.^1";

A lamellar microstructure characterizes the calicle walls and spines. Increase in number of calicles occurs as intramural offsets. An epitheca with growth lines surrounds the entire sponge. * Living tissue is restricted to the space above the outermost tabulae and a thin layer lying above the calcareous skeleton. Siliceous spicules of two kinds, tylostyles and modified spirasters, are distributed in the living tissue but are not incorporated into the calcitic skeleton. Star shaped groups of exhalant canals converge upon central oscules on the sponge surface and leave astrorhizal patterns impressed into the calcareous skeleton below. * A new order, the Tabulospongida, of the class Sclerospongiae is proposed to receive the new Pacific species together with its Jurassic and Cretaceous forebears. Despite suggestive similarities between acanthochaetetids and favositids, a phylogenetic relationship between these two groups is considered unlikely on the basis of present evidence. * Sampling site: reefs of Rongerik Atoll, Guam.^1";

sphinctozoan coralline sponge colonies in shallow water caves of the
Osprey Reef (Coral Sea) and the Astrolabe Reefs (Fiji Islands).-
Goettinger Arbeiten zur Geologie und Palaeontologie, Special Volume 2
[Reitner J., Neuewiller F. &#038; Gunkel F. (eds): Global and Regional
Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???.-
<b>FC&#038;P 26-1</b>, p. 31, ID=3582^<b>Topic(s): </b>cavity dwellers;
Porifera, Sphinctozoa, Corallina; <b>Systematics: </b>Porifera;
Sphinctozoa Corallina; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Fiji Isls^Three new types of a Recent colonial sphinctozoan
coralline sponge are presented. All types show close relationships to
Vaceletia crypta, a non colonial form from Indo-Pacific reef caves. The
first two types were discovered in shallow water reef caves of the
Osprey Reef, which is located on the northern Queensland Plateau in the
Coral Sea. The sponges are common in these caves. The third type of a
colonial sphinctozoan was found only at three localities at the North
Astrolabe Reef and Great Astrolabe Reef of the Fiji Islands. The third
type shows similarities with a previously described deep water
variation of Vaceletia from New Caledonia.^1";

p. 90, ID=4525^<b>Topic(s): </b>calcification rate; Algae calcareous;
<b>Systematics: </b>algae; <b>Stratigraphy: </b>Recent; <b>Geography:
</b>Polynesia French, Moorea^On the northwestern part of Moorea Island,
calcification rates for 8 benthic species (Halimeda opuntia var
hederacea, H. opuntia var. opuntia, H. incrassata f. ovata, H.
discoidea, Amphiroa fragilissima, Porolithon onkodes, Hydrolithon
reinboldii and Padina tennis) were estimated using the total alkalinity
method during 24 hours cycles, spread in the course of a year. The
daily calcification rate vary largely within the taxa. Halimeda play a
major role in the carbonate budget and particularly in the sediment
deposition. The hourly rates vary over a 24-hours-cycle with a decrease
during the night period. Moreover, the calcification measurements
spread in the course of the year exhibit a strong seasonally in the
carbonate production. Lastly, the annual inorganic carbon budget shown
that these species play an essential role in the balance of the reef
calcification rates.^1";

Automicrites in a modern marine microbialite. Formation model via
organic matrices (Lizard Island, Great Barrier Reef, Australia).-
Bulletin de l&#039;Institut oceanographique, Monaco, special volume 14,
2: 237-263.- <b>FC&#038;P 25-1</b>, p. 31, ID=3007^<b>Topic(s):
</b>reefs microbialites; reefs, microbialites; <b>Systematics:
</b>Monera; <b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia,
Great Barrier Reef^Within shallow water caves of fringing reefs of
Lizard Island (Great Barrier Reef) indurated microbialites were
observed. These microbiahtes are formed under dark conditions and
therefore no phototrophic organisms are present. The microbiahtes are
composed of microcrystalhne high-Mg calcites (12-15 mol% MgCO3). They
```

```
exhibit mean values of &#948;13C +3.5 and &#948;18O - 1 which are close
to seawater equilibrium. Two main types of microbiahtes are observed, a
thrombolitic one with relatively high net growth and a hardground type
with reduced growth rates. They are associated with a filterfeeding
sessile benthic community which is dominated by coralline sponges. The
high-Mg calcitic micrite is mainly formed in place (automicrite =
organominerals). The accumulation of fine-grained biodetritus provides
only 15% of the total rock volume. Following types of automicrites are
recognized: a. mineralized microbes, b. spherical peloids, c. micrite
formed in microcavities, d. micrite formed within thrombolitic
structures, e. micrite formed within hardgrounds, and f. micrite
(micropeloidal) formed by decaying tissues (via ammonification). All
studied automicrites exhibit high amounts of Asp- and Glurich
macromolecules (soluble matrices) which are regarded as responsible for
crystal nucleation. The observed modem automicrites and the related
products are a key to understand the formation of widely distributed
fossil microbial buildups (&#034;mud mounds&#034;).^1";
s[4120] = "REITNER J. (1993).- Modern cryptic microbialite &#47;
metazoan facies of the Lizard Island Section (Great Barrier Reef;
Australia). Formation and concepts.- Facies 29: pp?.- <b>FC&#038;P
22-2</b>, p. 92, ID=3541^<b>Topic(s): </b>reefs cryptic microbialites;
reefs, cryptic facies; <b>Systematics: </b>Monera Animalia;
<b>Stratigraphy: </b>Recent; <b>Geography: </b>Australia, Great Barrier
Reef^From shallow water caves of fringing reefs related to continental
islands of the Lizard Island Section thrombolitic micritic
microbialites were obsered. The microbialites exhibit always a light
decreasing facies succession. The succession starts with a coralgal
community and ends with light independent microbial biofilms and
benthos (coralline sponges etc.). The sessile mineralized benthos
community is constructed of crustose foraminifera, serpulids, thecidean
brachiopods, bryozoans, and coralline sponges. The observed benthic
community is very similar to those one observed in cryptic habitats of
Aptian and Albian reefs of northern Spain. For longtime studies of the
microbialite formation and growth rates of coralline sponges the
specimens were stained in vivo, within their natural habitat with
histochemical fluorochromes and nonfluorescent agents. Main results are
a very slow growth of the microbialite and associated sponges
(50-100µm/y). Only few calcifying microbes are participators during
microbialite formation. Calcifying acidic organic macromolecules are
mainly reponsible for microbialite formation by cementing detrital
material. Fe/Mn-bacterial biofilms are responsible for strong corrosion
of the microbialite. Beside the corrosive activity of the
Fe/Mn-bacterial biofilms boring sponges (Aka, Cliona) are the main
destructors. Geochemically the observed microbialites are composed of
mainly high-Mg calcites and exhibit high positive d13C (+3 to +4)
values.^1";
