s[0] = "TOOMEY D.F. (ed.) (1981).- European Fossil Reef Models.- SEPM
Special Publications 30: 546 pp.- <b>FC&#038;P 12-2</b>, p. 44,
ID=6242^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>fossil; <b>Geography: </b>Europe^[excerpt from a
book review by J.A. Babcock]: &#034;There is another jewel in the
SEPM&#039;s crown of publications. European Fossil Reef Models is a
multifaceted gem of information about European carbonate buildups and
about the state of the art of European reef studies, all in English.
Diversity is the key word here. Contained within 546 pages (18 papers)
is an entire spectrum of scientific approaches and writing styles.
Contributions range in length from 8 pages (&#034;Upper Triassic coral
bioherms&#034;, Yugoslavia, by Car and others) to 70 pages (&#034;Upper
Triassic reef paleoecology&#034;, by Flügel). There are very specific
papers (&#034;Pore types in a Paleocene reef&#034;, Yugoslavia, by
Babic and Zypanic), and there are general summaries (&#034;Process
approach to reef recognition&#034;, by Longmann; and &#034;European
Devonian reefs&#034;, by Burchette). Although there is a bias towards
Upper Triassic paleoecologic studies (five contributions, most of them
by Erik Flügel and his students), there is good coverage of other parts
of the geologic column as well. The Silurian, Devonian, Paleocene,
Oligocene, and Recent are all represented by single papers, two papers
concentrate on the Upper Jurassic, and both the Permian and the
Cretaceous are covered by three papers each. If you are searching for
comprehensive review papers on &#034;European reefs&#034;, then this
volume will help. The contributions by Burchette (Devonian reefs), by
Flügel (Upper Triassic reefs) and by Frost (Oligocene reefs) are all
recommended. Silurian bioherms and biostromes are the subject of the
contribution by Riding. His excellent paper is well-balanced between
careful observations and interpretations. Car and others (Triassic
bioherms) have written one of the best short papers. The contribution
by Piller on the famous Steinplatte complex of northern Austria
presents new sedimentologic interpretations in a well-documented
manner. The monumental works by both Flügel (Upper Triassic reefs) and
Frost (Oligocene reefs) will be standards for years to come.&#034;^1";

rugose corals of the genus Lonsdaleia McCoy, 1849 (Lower
Carboniferous).- Bulletin de l&#039;Institut royal des Sciences
naturelles de Belgique, Sciences de la Terre 73: 109-135.- <b>FC&#038;P
32-2</b>, p. 51, ID=1393^<b>Topic(s): </b>parallel evolution; Rugosa,
Lonsdaleia; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
```

```
</b>Carboniferous L; <b>Geography: </b>Europe^Two lineages, both leading to cerioid and subcerioid species, can be discerned in the evolution of the genus Lonsdaleia McCoy, 1849: L. (Lonsadaleia) duplicata (Martin, 1809) gave rise to the subgenus Actinocyathus d&#039;Orbigny, 1849 (considered here as a subgenus of Lonsdaleia) at the beginning of the latest Viséan in northern Europe, and L. (Lonsdaleia) redondensis sp.nov. or a related species possibly evolved into L. (Serraphyllum) subgen. nov. near the Viséan/Serpukhovian transition in South France. Three new species of the genus Lonsdaleia are described from the uppermost Viséan and Serpukhovian of the Montagne Noire (South France), including two new species assigned to the subgenus L. (Serraphyllum). Two species of the subgenus L. ( Actinocayathus) are redescribed from the Serpukhovian of the Moscow Basin. Parallel evolution in Actinocyathus and Serraphyllum during the Serpukhovian is discussed.^1";
s[4] = "BODZIOCH A. (1993).- Sponges from the Epicontinental Triassic of Europe.- In Hagdorn H. &#038; Seilacher A. (eds) – Muschelkalk; Schoentaler Symposium 1991: 235-244.- <b>FC&#038;P 22-2</b>, p. 90, ID=3534^<b>Topic(s): </b>; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Triassic M; <b>Geography: </b>Europe, epicontinental^The knowledge about sponges from the epicontinental Triassic of Europe is not too extensive. This is mainly due to their sporadic occurrence and poor state of preservation. Until now, sponges were recorded only from few localities where they occur in various lithostratigraphical positions, but always within the Muschelkalk. From these localities, bodily preserved specimens, loose spicules and borings have been referred to hexactinellid sponges. However, the more exact systematical position is doubtful in most cases. During the last years, a lot of lyssacinosan sponges have been recorded for the first time both from well known and new localities. They were found in the lower Muschelkalk of Upper Silesia and of the Holy Cross Mts., where they occur locally in biohermal and biostromal accumulations. This material provides new information about Triassic sponges, which are presented here in their palaeontolgical, stratigraphical, and paleoecological contexts.^1";
s[5] = "BERTLING M. (1993).- Ecology and distribution of the Late Jurassic Scleractinian Thamnasteria concinna (Goldfuss) in Europe.- Palaeogeography, Palaeoclimatology, Palaeoecology 105: 311-335.- <b>FC&#038;P 23-1.1</b>, p. 73, ID=4160^<b>Topic(s): </b>distribution; Scleractinia, Thamnasteria; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Europe^The quantitative investigation of associations in northern Germany revealed Thamnasteria concinna as their main element, necessitating an evaluation of all data for the spatio-temporal distribution of this scleractinian. Autecological criteria and sedimentological data indicate an optimum fitness of the coral in turbulent environments with low net-sedimentation rate. In these facies, no conflicting aims existed for T. concinna in exploiting light or plankton and resisting adverse hydrodynamic conditions. The most important synecological parameters of the associations studied are dominance patterns and diversity as well as the structure of guilds. T. concinna mostly costituted the builder guild, occurring as an ubiquist, though dominant only in shallow water. As recorded in the study area, strong dominance of a few taxa and low diversity indexes are typical of immature communities in unstable environments. T. concinna was well adapted to varying environmental factors showing characteristics of an r-strategist, thus being more successful than other corals in stressful facies. The distribution pattern of T. concinna was not controlled by single environmental factors, but rather the oscillation of many of them. This seasonality is a typical feature of the temperate realm. T. concinna actually was important only in temperate regions of the Late Jurassic neritic sea or its borders with the Tethyan region. Further south, the coral was just one of the many members of the Tethyan reefs
```

```
where mature communities predominated. Because of sedimentological
restrictions, this pattern is most clearly visible in the Oxfordian,
whereas T. concinna was a negligible element of Tithonian reefs. Its
evolutionary decline is due to the concentration of reefs on the
(sub)tropican Tethyan region.^1";

Paleobiological Controls of Jurassic Spongiolites.- Goettinger Arbeiten
zur Geologie und Palaeontologie, Special Volume 2 [Reitner J.,
Neuewiller F. &#038; Gunkel F. (eds): Global and Regional Controls on
Biogenic Sedimentation I. Reef Evolution]: pp 209-214.- <b>FC&#038;P
26-1</b>, p. 35, ID=3594^<b>Topic(s): </b>spongiolites; spongiolites;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Jurassic;
<b>Geography: </b>Europe^Micro- and biofacies aspects as well as
biogeochemical data of Jurassic spongiolitic limestones from Spain,
Southern Germany and Romania allow to consider the following parameters
to have controlled the spongiolitic megafacies: 1) Pro- and regradation
of spongiolitic facies correlate with the sealevel development,
progradation characterizing transgressive phases. Consequently,
spongiolites are restricted to areas having had low sedimentation
rates. 2) Spongiolitic and coral facies were in competition during the
Jurassic. Factors, which favoured one boundstone type above the other
were a) the bathymetry and the dependent parameters hydrodynamics and
light intensity, and b) a constantly oligotrophic situation, which
favoured a dominance of coral reefs, while spongiolitic mud mounds
revealed certain tolerance to an episodically higher trophic level. 3)
The formation of microbialitic (automicritic) crusts can be traced to
heterotrophic activities, mainly with the aid of data from the
microfacies investigations, and isotopic and biogeochemical analyses
(Keupp et al. 1993). The spongiolithic facies was thus comparatively
more independent from photic conditions and could form in a wide
bathymetric range. 4) The spongiolitic facies, in which, conditioned by
the bathymetric and hydrodynamic situation, automicrites and
allochthonous mud deposition were continuously in competition
(Leinfelder &#038; Keupp 1995), reflect more-or-less the low energy
habitat, while the coral facies is characteristic of the high energy
level. 5) More-or-less cyclic successions within the spongiolitic
facies, which affected the Porifera and other benthic associations as
well as different types of microbialites (thrombolites, laminated
peloidal crusts, aphanitic automicrites), on the one hand were
controlled by hydrodynamic events and on the other by episodic oxygen
fluctuations. 6) The conservation of spongiolitic mounds presupposed
the formation of automicrites and the early diagenetic calcareous
lithification of siliceous sponges (&#034;Erhaltungsfenster&#034;),
which, besides the above mentioned environmental factors, depends on
the taxonomic composition of the sponge fauna, with regard to different
amounts of endosymbiontic bacteria (cf. Rehfeld, this volume).^1";

Mesozoic and Tertiary.- Palaeontology 18, 2: 255-274.- <b>FC&#038;P
4-2</b>, p. 65, ID=5310^<b>Topic(s): </b>symbiosis; hydroid-serpulid
symbiosis; <b>Systematics: </b>Cnidaria Annelida; Hydrozoa;
<b>Stratigraphy: </b>Mesozoic Cenozoic; <b>Geography: </b>Europe,
Middle East^Several species of Mesozoic and Tertiary serpulids from
Europe and the Middle East were infested by a colonial organism which
is preserved as the mould of a stolonal network with polyp chambers
buried in the peripheral zone of the calcareous tube. The polyp
chambers open to the outer surface of the tube through small, usually
semicircular apertures. The mould is the result of incorporation of the
organism into the worm tube during calcification by the serpulid: it is
not a boring. The organism is interpreted as a hydroid or group of
related hydroids which lived commensally or possibly mutualistically
with the serpulids. This hydroid-serpulid symbiosis is compared with
the living symbiosis between the hydroids of Proboscidactyla and
certain species of sabellid polychaetes. * The name of the fossil
symbiont is Protulophila gestroi Rovereto.^1";

Australian Mississippian shallow-water reefs: a comparison.-
Proceedings of the XVth International Congress on Carboniferous and
Permian Stratigraphy, Utrecht, the Netherlands (Wong, Th. E. (ed.): .-
<b>FC&#038;P 35</b>, p. 91, ID=2412^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>Europe, Australia^Shallow-water reefs were a common
element in the Mississippian successions of Western Europe and eastern
Australia. They formed in different palaeotectonic settings, the stable
southern shelf of Laurussia, near the collision zone of Armorica and
```

```
Gondwana, and in the fore-arc setting of eastern Australia. Reef
development in these areas responded to local and regional
tectono-sedimentary patterns, and, therefore, the timing was different
in the two regions. Shallow-water reefs occurred throughout almost the
entire Mississippian. Australian reefs already developed at the
Devonian/Carboniferous boundary, whereas European shallow-water reefs
did not appear until the early Visean. The lack of Tournaisian reefs in
Europe is only partly well constrained (unfavourable facies). Reef
development ended in Australia somewhat earlier than in Europe. The
youngest reefs formed on the southern shelf of Armorica. Reef
termination scenarios in all regions included combinations of sediment
influx, uplift, volcanism, and/or plate movements. Although individual
reef development differed, three major reef-forming fabrics can be
identified in both regions. Microbial communities were the most
important reef fabrics and entire reefs consisted only of microbial
framework. The second framework type consisted of microbial
communities, corals, lithistid sponges, and bryozoans of relatively
high diversity, but varying abundances. Coral-dominated facies, the
third major fabric type, only became volumetrically important in Visean
and Serpukhovian reefs, but, regardless, microbial fabrics were
generally essential for reef formation. A large number of reefs
consisted of a delicate balance of different reef builders, but a
unique Pangean reef community is not evident. The formation of Pangea
influenced reef formation in two ways. Firstly, the southward movement
of the Australian plate made reef formation impossible, and plate
collision and tectonic uplift terminated reef development in Europe.
Second, glacio-eustatic sea-level changes, a result of global climate
change and associated glaciation in Gondwana, greatly affected reefs in
inner shelf positions.^1";

Rugosa, Phillipsastreidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>Europe, Africa
N^Macgeea is a cosmopolitan genus of Devonian rugose corals that
includes numerous, generally highly variable, species. Because of its
wide skeletal variation and additional trabecular dilation it is
difficult to recognize taxonomically relevant characters and to
separate those from ecologically induced modifications. The high
variability is probably related to radiations following phases of sea
level rise and is connected to bioevents. Length of major septa in
ontogenetic stages allows a separation of different populations within
the Macgeea dubia species group. However, it remains questionable if
septal length is a reliable taxonomic character, indicating a
phylogenetic trend, or if it is subject to large individual
variability. By revising Macgeea dubia, we reveal its synonymy with
Macgeea heterophylloides sensu Birenheide. In addition, Macgeea recta
(type species of Pexiphyllum Walther 1929) is discussed as an
insufficiently defined taxon of problematic status. Macgeea
crassiseptata n.sp. is also described from the Late Givetian of
Morocco. The erection of the new pseudocolumellate genus Baculophyllum
with type species Pexiphyllum ultimum Walther 1929 requires a
comparison with Protomacgeea from Poland and Australia as well as a
phylogenetic discussion of the solitary Phillipsastreidae. The new
genus most probably belongs to a separate lineage of the Upper Devonian
Macgeea group but could also be considered as a descendant of the
Australian Lower Devonian columellate solitary phillipsastreid species
group, that has not yet been recorded from the Middle Devonian. Because
of large stratigraphic gaps between the occurrences of both genera,
preference is given to the interpretation of a development of
polychronomorph taxa (homeomorphic taxa living at a different time) not
belonging to a single lineage. This shows again the significance of
stratigraphic age when comparing similar-looking taxa, which should be
considered in any phylogenetic reconstruction.^1";

</b>Baltoscandia^Corals colonized the Palaeobaltic Sea in the middle
Caradoc. A century and a half of studies have produced many significant
results related to their taxonomy and other aspects. A summary of the
genus level taxonomic composition of the Baltoscandian rugose coral
assemblages and some aspects of their diversity dynamics are presented
by B. E. E. Neuman and D. Kaljo in Webby et al. (2004b). * Recent
advances in Baltic isotope studies gave rise to the idea of using
isotope data, together with biodiversity data, to investigate the role
of environmental changes in the evolution and diversification of
corals. The well-known diversity curves of Sepkoski (1995) show a
generalized pattern of diversity change. Regional curves are more
environmentally controlled and reveal details that can be correlated
with stable isotope data, sea level curves, etc. These links are
employed here for better understanding of the environmental background
of certain bioevents. Conclusions are also based partly on the
palaeoceanic and palaeoclimatic models suggested by Jeppsson (1990) and
revised by Munnecke et al. (2003) for the Silurian Period.
Morphological novelties are the essence of coral evolution in leading
to the appearance of new taxa. Usually, the time pattern of the latter
process correlates somewhat with environmental changes and this allows
biodiversity to be taken as a qualitative measure of possible
ecological influence. Some useful pointers to this influence can be
obtained via correlation of the coral diversity data with the late
Ordovician carbon isotope trends. [excerpts from an introduction]^1";

fossils; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>Europe, Central, erratics^Over many
years more than 60.000 silicified Ordovician erratic sponges from the
palaeocontinent Baltica have been collected in some areas in Northern
Europe. Especially in the Netherlands some hundred enthusiastic amateur
geologists have stored about 20.000 specimens in their private
collections or housed them in museums. However, appropriate literature
to identify them properly is not readily available. Either the
literature is too old to be loaned out by museums or institutes, or it
is inaccessible to the average amateur, due to both the scientific
level and the need to read foreign languages. The purpose of this
volume is first of all to provide a guide, a manual for Dutch (and
German) amateurs. This atlas also serves other purposes: It is also
meant to give an overview of the current knowledge of this subject at a
time that sponges are the subject of extensive research. Besides, there
is presently a concentration of knowledge, experience and availability
of the material. The third purpose is to draw the attention of sponge
specialists throughout the world to the extensive and varied sponge
assemblages from Baltica. It is remarkable that in the 19th century
German sponge specialists, such as Roemer, Rauff and von Zittel, were
leading the research and even examined American sponges. After that
generation only a few European palaeontologists continued these
investigations. Over the years American specialists dominated sponge
research. Perhaps as a result of this development Baltic sponges were
gradually left out of palaeontological focus. Perhaps this atlas will
stimulate renewed interest in these varied, sometimes wonderfully
preserved, erratic sponge assemblages. [from original English summary:

Lethaia 14: 169-188.- <b>FC&#038;P 11-1</b>, p. 58,
ID=6133^<b>Topic(s): </b>reefs, geohistory; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Ordovician M; <b>Geography: </b>Norway^The
Middle Ordovician reefs of Norway were the first to develop in the
western part of the Baltoscandian epicontinental sea and are the
earliest coral-stromatoporoid reefs so far reported in Europe. Small
patch reefs in the Steinvika Limestone, Langesund-Skien district,
consist mainly of algae, echinoderms, corals and stromatoporoids.
Bryozoans, molluscs, athropods and brachiopods are also present. The
reefs developed on pelmatozoan-rich substrates and are organically
zoned, consisting of a pioneer community of stemmed echinoderms and
sheet algae, a high-diversity intermediate community dominated by
fasciluate corals and a low diversity climax community of massive
corals and stromatoporoids. These communities are interpreted as the
seral stages of an autogenic ecological succession. Small patch reefs
are also present in the laterally equivalent Mjosa Limestone, Toten and
Nes-Hamar districts. These are organically very similar to those in the
Steinvika Limestone and developed in an identical way. A large complex,
consisting of several reefs, is also present in the Mjosa Limestone.
Unlike the reefs elsewhere, which developed with shallow inshore areas,
this complex developed at the outer edge of the inshore shelf. The
outstanding features of the complex is the main reef forming the
offshore limit which is totally dominated by stromatoporoids and lacks
a sequential development. This is due to the influence of the harsher
environment at the shelf edge. [original summary]^1";

</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Ordovician Ashg -
Silurian Prid; <b>Geography: </b>Estonia^Eighty-eight species of
Stromatoporoids have been described from all the regional stages of
Estonia from lower Ashgill to lower Pridoli. The ranges of the 26
genera are plotted in a large table (31). The distribution of these
genera in the various stages is briefly discussed. Labechiids are
relatively rare in the Ordovician rocks at the bottom of the sequence;
they are joined in younger Ordovician rocks by clathrodictyids. In the
Llandovery clathrodictyids make up 80 % of the fauna and labechiids are
next in abundance. Many new families appear in the Llandovery:
atelodictyids, actinostromatids, gerronostromatids and
pseudolabechiids. In the Wenlock beds occur the first densastromatids
and the first representatives of the orders Stromatoporida,
Stromatoporellida and Syringostromatida. The diversity maximum in
Estonia was reached in the Ludlow Stage. The richest Stromatoporoids
faunas are found in rocks deposited in high energy shoal
environments.^1";

</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Ordovician Silurian;
<b>Geography: </b>Estonia^Due to the favourable climatic and
shallow-water conditions in the Estonian part of the Baltic Basin,
tabulates played a significant role in the Late Ordovician and Silurian
faunal assemblages. In Estonia, the earliest tabulates are known from
```

```
the Late Caradoc. Lyopora tulaensis Sokolov, Saffordophyllum grande
Sokolov, Eoflecheria orvikui Sokolov, occur in the Vasalemma reef
facies of the Oandu Stage. At the beginning of the Late Ordovician, the
conditions for tabulates were unfavourable, therefore the fossils are
rare. Only one species, Catenipora obliqua (Fischer-Benzon) has been
recorded from the Nabala Stage. Diversification of the Late Ordovician
tabulate fauna began in the Vormsi Age with the appearance of the first
Paleofavosites - P. schmidti Sokolov and P. borealis Tshernyshev. The
most ancient heliolitids (Wormsipora, Esthonia, Protaraea) are also
known from the Vormsi Stage. Sarcinuliids and halysitids (Catenipora)
became common for the first time. During the Pirgu Age diversification
continued. The tetradiids (Cryptolichenaria multiplex Klaamann)
appeared for the first time in the Baltic area. The halysitid
Eocatenipora was widely distributed and early heliolitids were well
developed. The Late Ordovician favositids were blooming in the Porkuni
Age. The first records of Porkunites, Mesofavosites and Priscosolenia
are from the same age. The beginning of the Silurian was a time of
rapid diversification of Mesofavosites and Paleofavosites. [first part
of extensive summary]^1";

stromatoporoid and algal reefs were developed in the marginal part of
the gulf-like Baltic cratonic basin in Gotland, north and central
Estonia, and east to central Lihtuania. They are situated at different
stratigraphic levels from the middle Caradoc up to the lower Pridoli.
Their appearance coincided withn the transition of the Baltic Basin
from an epicontinental to pericontinental phase of development, and
with shifting from a temperate to the tropical climatic zone. Most of
these reefs had a flat or lenticular shape, as they grew in conditions
of relative tectonic and eustatic stillstand. Extensive progradation of
the reef belt took place during general regression of the basin at
these times. The role of stromatoporoids increased in frame building
towards the end of the Silurian. Shaol-barrier type reef tracts,
developed at different stratigraphic levels, were situated in the
middle part of a broad carbonate shelf (platform) on the SW margin of
the Baltic craton. This contrasts with Recent barrier reefs, usually
located at the shelf edge of eastern margins of continents.^1";

Silurian: 35-40.- <b>FC&#038;P 12-1</b>, p. 45, ID=6191^<b>Topic(s):
</b>coral reefs; coral reefs; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Baltic^In conclusion
it can be said that during the whole Wenlock and Ludlow reefs were
characteristic of the northern part of the Paleobaltic. They are
especially abundant on Gotland, where at least 9 levels with reefs of
different age have been preserved. Suggesting general regression of the
basin, they replaced regularly each other towards the South and
Southwest. The coincidence of the succession on Gotland and in Estonia
shows the presence of reef belts situated roughly parallel to the shore
line. This succession was partly interrupted at the end of the Wenlock
at the time of Silurian maximum regression (in Rootsikula time) when
reef formation took place only on Gotland (evidenced by buildups in the
uppermost Halla Beds, the Mulde and Klinteberg Beds). [original

</b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Sweden, Gotland^In the Silurian Hemse Group (Ludlovian) of Gotland,
Sweden, Lingula occurs in burrows in Heliolites interstinctus Linnaeus
and rarely in Densastroma podolicum (Yavorskiy). Statistical analysis
of patterns of burrow occupancy and mode of burrow construction
suggests that Lingula did not make the burrows, but occupied them after
they were abandoned by the burrowing organism. Lingula preferred to
occupy burrows in living Heliolites colonies, and was usually able to
keep the burrows open in spite of continued coral growth. The
relationship is interpreted as commensal, benefiting Lingula by
providing a solid substrate and perhaps nematocyst protection from
would-be predators. The virtual restriction of the relationship to
Heliolites is attributed to the open structure of the Heliolites
skeleton and its slow growth, as compared with the other available
colonial coral, Favosites.^1";

</b>Silurian U; <b>Geography: </b>Baltic E^[Heliolitids in the eastern
Baltic Silurian coral communities] Two coral communities from the
Ludlovian of the Ventspils boring (West Latvia) are discussed. The
older one is restricted to the Engure Formation. It contains two
species of heliolitid corals and Favosites gothlandicus, representing
probably the deep water Halysites laticatenatus-Favosites gothlandicus
community of Mulde and Hemse Marls of the Gotland area. The Dnestrites
community comes from the Mituva Formation, from the Andreaolepis hedei
Zone, mainly from an interregnum between that one and the Thelodus
sculptilis vertebrate zones, corresponding to the Uduvere Beds of the
Paadla Regional Stage. That community occupied the central part of the
inner shelf, the vicinity of shoal sedimentary barriers where the
organic buildups were developed. Six new species of heliolitid corals
are described: Heliolites subdecipiens, Pseudoplasmopora longisepta,
Saaremolites kurzemensis, Stelliporella baltica, Dnestrites ludlovicus
and D. incognitus. They are the first heliolitids in the East Baltic
Late Silurian coral communities.^1";

```

```
</b>Silurian; <b>Geography: </b>Sweden, Gotland^Fusiform calcitic
spicules occur abundantly in the Lower and Upper Visby beds and
sparsely in the basal Hoegklint Beds on the Island of Gotland in the
Baltic Sea. The stratigraphic interval spans the uppermost Llandoverian
to lowest Wenlockian. The spicules can be referred to the genus
Atractosella Hinde 1888, previously interpreted as a sponge. The new
species A. cataractaca is described on the basis of the Gotland
material. The spicules are built up of concentric layers, representing
stages of growth. The surface is usually covered with granula or small
thorns. The calcite shows good alignment of the c axes parallel to the
the spicule axis, but the direction may deviate up to ±8° between
opposing sides of the spicule. Occasional branched spicules are
interpreted as fused adjacent normal spicules. Two natural spicule
associations on a bedding surface show the organism to have had a
rounded outline and a diameter of a few centimeters. In all the
investigated characters, Atractosella is indistinguishable from a
modern soft coral of the family Alcyoniidae. It is interpreted as the
earliest known representative of the octocoral order Alcyonacea,
extending the range of this group from the Lower Jurassic to the Lower
Silurian. Mirmor andreae Lamont 1978, described originally as an
ostracoderm, is reinterpreted as a species of Atractosella. A.
cataraataca is common in fine-grained sediments and may have lived
attached to hard objects on soft bottoms. [original summary]^1";

</b>cladistic taxonomy; Rugosa Entelophyllidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Europe N^The construction of a character taxon matrix is
fundamental to cladistic analysis, and some of the methodological
issues involved in the making of such a data matrix are discussed.
Three aspects are emphasized: (1) character construction, (2) coding
procedure, and (3) the use of non morphological data. Characters used
in cladistic analyses are constructed, on the basis of observed
variation, in a manner that fits a specific taxonomic problem. In
rugose coral species, morphological variables are commonly continuous
and quantitative. There is a subtle interaction between observation of
variables and semantics of character naming, with non trivial
implications for parsimony analysis. Character coding can be approached
in several ways, and two contrasting methods of coding are considered:
(A) composite (multi state) coding, and (B) reductive
(absence/presence) coding. Skeletal morphology may be insufficient for
resolution of rugose coral phylogeny, suggesting the use of additional
sources of data. Methods of incorporation of stratigraphic information
in the data matrix pay little attention to the nature of the
sedimentary record, and a more rigorous evaluation of relationships
between stratigraphy and phylogeny is recommended. Examples are drawn
from a preliminary study applying cladistics to entelophyllid rugose
coral species from the Silurian of northern Europe. Consensus
cladograms from alternative search settings are here included to
illustrate effects of different approaches. Specific choice of
procedure affects homology assessment, character distribution, and tree
topology. If the data matrix is to be accessible to other workers, and
subject to testing, the construction of the data matrix must be made
explicit as far as possible. [original abstract]^1";

<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>Sweden, Gotland^Stromatoporoids in
argillaceous level-bottom limestones of the Upper Visby Beds in the
Silurian of Gotland, Sweden, show a variety of features of growth
forms, within a spectrum of coenosteal shapes from laminar through low
to high domical. Many coenostea show interdigitations of sediment in
their margins, attributable to intermittent sedimentation, while others
show abrupt changes in growth direction, which are the result of
movement, often leading to overturning. Stromatoporoids frequently
survived these agents and continued to grow, often resulting in
different morphotypes from those which would have been produced in the
absence of sedimentation and movement; serious problems of shape
identification and shape classification exist as a consequence.
Variations in the effects of sedimentation and movement are
recognizable in the specimens studied and the Stromatoporoids therefore
record a variety of events occurring at the sea bed during their
lives.^1";

storms shapes; sedimentology, stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Silurian Ludf; <b>Geography:
</b>Sweden, Gotland^The morphological range of stromatoporoids is
strongly related to depositional environment. In high energy
environments, characterized by packstones and grainstones, low profile
forms predominate, whereas in calmer settings, characterized by
wackestones and packstones, high profile stromatoporoids dominate. Four
rock units are recognized, representing two major facies: reeflike
limestones and detrital grainstones. Reeflike limestones comprise a
variety of lithologies including wackestones, packstones, boundstones,
and framestones. All units are shallow marine but the occurrence of
crystal silt may indicate a vadose situation on the top of the reeflike
facies. In the reeflike units hard substrates for stromatoporoid growth
were probably provided by microbial sedimentation. Sedimentation rates
were generally low although episodic high sedimentation occurred as
indicated by raggedness in stromatoporoid skeletons. The stromatoporoid
fauna is considered a low diversity assemblage dominated by
Parallelostroma typicum. Other species found are: Pycnodictyon densum,
Stromatopora venukovi, S. bekkeri, Petridiostroma convictum,
Ecclimadictyon robustum. &#034;Since measurements of skeletons were
made in the field, and due to limited amount of sampling, species
confined to certain shapes were not distinguished.&#034;^1";
s[88] = "KERSHAW S. (1994).- Cathodoluminenscence of Silurian
stromatoporoids from Gotland.- Courier Forschungsinstitut Senckenberg
172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International
Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 307-318.-
<b>FC&#038;P 23-1.1</b>, p. 22, ID=4088^<b>Topic(s): </b>research
methods, cathodoluminescence; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Sweden, Gotland^Cathodoluminescence (CL) response of
stromatoporoids from the Silurian of Gotland, Sweden, varies from none
to brightly luminescent. The greater contrast shown with CL can help
with identification of poorly preserved stromatoporoids. In normal
light, stromatoporoids show a range of alteration of skeletal structure
from apparently well preserved to strongly altered. In cross-polarized
light, skeletal elements are overprinted by large, bladed to irregular
calcite crystals, even in apparently well-preserved specimens, and
irrespective of microstructure, thereby demonstrating at least partial
alteration in all samples examined. The most common stromatoporoid
microstructure, termed compact, consists of irregularly arranged
micritic calcite crystals, which show a trend towards aggrading
neomorphism when altered; this is seen most clearly under CL. The CL
response in relatively well-preserved stromatoporoids with a compact
structure normally consists of a speckled mixture of micritic non-,
dull and bright luminescent crystals, also micritic in normal light.
This is probably close to its original texture, and earlier SEM studies
by others concur with this. Recent work shows that modern shells can
luminesce, and exhibit a range of CL response, even in different
individuals of the same species, reflecting minor variations in the
skeletal composition. Therefore, the variation of intensity of CL in
the speckling within stromatoporoid microstructure may indicate
original compositional variations, but in view of the partial
recrystallization of even well-preserved skeletons, separating CL
response of the original microstructure and that of diagenetic
alteration, is not practicable. However, in the present material, CL
response generally shows the same textural features as the normal light
view, and so the main advantage of its use is that these are more
clearly seen under CL. Stromatoporoids are normally more recrystallized
than brachiopods and rugose and tabulate corals (interpreted originally
Low Mg calcite), but better preserved than molluscs of originally
aragonitic composition. This has led to previous suggestions of a High
Mg calcite composition, but variation of state of preservation between
species in the same facies suggests variation in original skeletal
```

```
mineralogy; different stromatoporoid species probably secreted either
aragonite or High Mg calcite skeletons, with the possibility of varying
Mg concentrations.^1";
s[89] = "KERSHAW S., KEELING M. (1994).- Factors controlling the growth
of stromatoporoid biostromes in the Ludlow of Gotland, Sweden.-
Sedimentary Geology 89: 325-335.- <b>FC&#038;P 23-1.1</b>, p. 79,

<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Silurian Ludl; <b>Geography: </b>Sweden, Gotland^Lower Wenlock
bioherms grew during a relative sea-level fall, on substrates of
limited lateral extent and sediment accumulated around and on the reefs
as they grew. Middle Ludlow biostromes were determined by low levels of
clastic supply, laterally extensive suitable substrate, relatively
stable sea level and largely flat sea beds in shallow-water conditions.
The biostromes contain high and low profile forms and show differences
from upper Ludlow representatives of the same species which are low
profile only. Controls on growth may include: substrate consistency,
environmental energy, and closer adaptation by the same species between
middle and upper Ludlow times. Biostromes on Gotland may form when sea
level is stable and a dry climate ensures low clastic input.^1";
s[90] = "KERSHAW S. (1981).- Stromatoporoid growth form and taxonomy in
a Silurian biostrome, Gotland.- Journal of Paleontology 55, 6:
1284-1295.- <b>FC&#038;P 10-2</b>, p. 14, ID=6071^<b>Topic(s):
</b>growth forms; stroms, growth forms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Sweden, Gotland^A biostrome at Kuppen, in the middle Ludlow Hemse
Beds (Silurian) on Gotland, Sweden, is dominated by densely packed
laminar, domical and bulbous stromatoporoids to the exclusion of almost
all other organisms. Within the biostrome two contrasting growth forms
developed, growing together in the same environment. Clathrodictyon
mohicanum Nestor forms laminar to low domical shapes, while
Stromatopora bekkeri Nestor and Plectostroma scaniense Mori developed
higher domical and bulbous shapes. The interactions between
environmental factors and the genotype brought about the development of
characteristic shapes (phenotype) for each species. P. scaniense and C.
mohicanum show these and other morphotypes elsewhere on Gotland, while
S. bekkeri forms only higher domical shapes within the limits of its
known occurrence on Gotland. P. scaniense has the greatest potential
genotypic plasticity for shape variability and shows a sensitivity to
the environment not shared by the other two species. Variations in
environmental conditions and changes in selection pressures and
functional requirements of stromatoporoids appear to be responsible for
shape variations. Identifying genetic components of shape, and showing
how they relate to associated faunas and environments should make
interpretations of stromatoporoid morphology more meaningful. [original
abstract]^1";
s[91] = "NESTOR H. (1982).- Middle Silurian stromatoporoid succession.-
Akademiya Nauk Estonskoy SSR; D. Kaljo &#038; E. Klaamann (eds):
Ecostratigraphy of the East Baltic Silurian: 43-50.- <b>FC&#038;P
12-1</b>, p. 43, ID=6185^<b>Topic(s): </b>biozonation; stroms;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Silurian M; <b>Geography: </b>Baltic E^The present paper
distinguishes five successive stromatoporoid communities spread in the
shallow water sections of the Baltic Silurian Basin, in the
stratigraphical interval corresponding to the Wenlock Series by now
accepted correlations. In the ascending order they are: Stromatopora
impexa, Vikingia tenuis, Ecclimadictyon astrolaxum, Labechia conferta
and Parallelostroma tenellum Communities. However, there is a
possibility that the last community already belongs to the lowermost
Ludlow. Potentially these communities may serve as a basis for a zonal
stromatoporoid standard of the Baltic and adjacent regions. In the same
stratigraphical interval in deeper water, marginal areas of the
distribution of stromatoporoids, two communities are distinguished:
```

```
Densastroma pexisum and &#034;Pycnodictyon&#034; densum. [original

s[92] = "LUCZYNSKI P., SKOMPSKI S., KOZLOWSKI W. (2009).- Sedimentary
history of Upper Silurian biostromes of Podolia (Ukraine) based on
stromatoporoid morphometry.- Palaeogeography, Palaeoclimatology,
Palaeoecology 271, 3-4: 225-239.- <b>FC&#038;P 36</b>, p. 37,
ID=6403^<b>Topic(s): </b>sedimentology, stroms biostromes;
sedimentology, stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Silurian U; <b>Geography: </b>Ukraine, Podolia^The
sedimentary history of stromatoporoid biostromal accumulations
reflecting various depositional conditions (autoparabiostromes and
parabiostromes) is studied in two isochronous, Late Silurian carbonate
sections of the Malynivtsy Formation from Podolia (western Ukraine,
Kam&#039;janec&#039; Podil&#039;skyj area). This study focuses on
morphometrical analysis of massive stromatoporoids. Various
stromatoporoid attributes, such as growth form, volume, surface
character etc., are interpreted in terms of growth environments.
Attributes of redeposited specimens are also analysed in terms of their
susceptibility to exhumation and redeposition, and new criteria are
presented in this matter. The exposed facies succession, which can be
subdivided into three units: an oncolitic-fenestral complex and the
stromatoporoid-coral complexes that underlie and cover it, represents
the belt of shoals located at a considerable distance from shore, and
its transition to a narrow zone of back-shoal tidal flats. The facies
patterns proved to be strongly obscured by an intensive process of
onshore redeposition of material during high energy episodes. These
events caused exhumation and landward transport of stromatoporoids
inhabiting soft-sediment bottoms of outer shelf areas, which were
afterwards accumulated in parabiostromes in calm waters on lee side of
a zone of shoals. The main process governing the distribution of
redeposited stromatoporoids is fractional (weight) segregation. The
high energetic events had less effect on stromatoporoid-coral
autoparabiostromes that formed the zone of shoals, which were inhabited
by stromatoporoids better adapted to permanent wave action, but
nonetheless, they caused their partial reworking and depletion from
those forms that did not resist redeposition, on the one hand, and
supplementation by specimens derived from offshore areas, on the other.

s[93] = "KERSHAW S. (1987).- Stromatoporoid-coral intergrowths in a
Silurian biostrome.- Lethaia 20, 4: 371-380.- <b>FC&#038;P 17-1</b>, p.
40, ID=2161^<b>Topic(s): </b>symbiosis ?; stroms, Anthozoa,
intergrowth; <b>Systematics: </b>Porifera Cnidaria; Stromatoporoidea
Anthozoa; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Sweden,
Gotland^Four stromatoporoid species from a stromatoporoid biostrome in
the middle Ludlow Hemse Beds, Gotland, Sweden, show intergrowths with
syringoporid tabulate and rugose corals, and indicate close
relationships between particular coral and stromatoporoid species. The
stromatoporoid Clathrodictyon convictum always contains ?Syringopora
and this tabulate is rarely found in the other stromatoporoids. C.
convictum is also closely associated with Tryplasma flexuosum (rugosa)
while Petrozium pelagicum (rugosa) occurs only in the stromatoporoids
Plectostroma intermedium and Parallelostroma typicum. The
microstructure of ?Syringopora within the stromatoporoids is composed
of an inner lamellar layer and an outer radial layer of calcite
crystals. Diagenetic alteration has affected the microstructure which
differs from recently described Devonian forms having only a radial
layer. This shows variability in the structure of the tabulates within
stromatoporoids. Information is sparse on the range of such variation
and assessment of the relative importance of taxonomic,
palaeoenvironmental and diagenetic effects is not possible in the
present sample. No evidence is found to prove the precise nature of the
relationships; they were not parasitic but may have been mutually
symbiotic, or (most probably) commensal. The results suggest that the
```

```
corals selected the most suitable stromatoporoid species for their
requirements. Stromatoporoid morphology may have had an important
influence on the association, where corals are more abundantly
associated with those stromatoporoid species which adopted a high
profile. Overall the associations appear to have allowed the corals to
explore higher energy habitats otherwise unavailable to their delicate
branching structure.^1";
s[94] = "STEL J.H., De COO J.C.M. (1977).- The Silurian Upper Burgsvik
and Lower Hamra-Sundre beds, Gotland.- Scripta Geologica 044: 1-43.-
<b>FC&#038;P 8-1</b>, p. 50, ID=0214^<b>Topic(s): </b>geology; geology;
<b>Systematics: </b>Porifera Cnidaria; Stromatoporoidea Tabulata;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Sweden, Gotland^Five
facies are recognized in the Upper Burgsvik and Lower Hamra-Sundre Beds
on account of a lithological and paleobiological analysis : I)
siliciclastic. II) bioclastic, III) oolitic/pisolitic, IV)
oncolitic/biostromal, and V) crinoidal facies. The facies represent
five depositional environments : a beach, a fore-shore, a surf, a
shallow marine current, and an off-shore environment. The diversity and
colony shape of tabulates in facies IV is related to discrete physical
and biological factors. The succession of facies reflects a
transgressive sequence. Land was situated in the north-west.^1";
s[95] = "KLAAMANN E. (1977).- Ueber die silurischen
Tabulatenassoziationen Estlands und der Insel Gotland.- Academy of
Sciences Estonian SSR, chem. geol 26 (3): 203-210.- <b>FC&#038;P
7-1</b>, p. 23, ID=0183^<b>Topic(s): </b>assemblages; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>Baltoscandia^This paper compares the Silurian
Tabulate assooiations of the Baltio area with those of the island of
Gotland (Sweden). These faunas are of great importance for zonal
formations in the Baltic-Scandinavian area. During the Silurian time
the Tabulate corals lived in shallow and detritic facies (Kaljo 1970).
In the Silurian time a corresponding fauna with equivalent genera and
species is mostly found in Estonia as well as on the island of Gotland.
But some differences occur which are laid down in the following. During
the middle and late Llandovery Gotland lacks a coral fauna. Thereafter,
in the upper Llandovery two faunal associations exist: in Estonia the
Mesofavosites obliquus - Favosites favosus group. At the same time the
[gayosi.tes] stoermeri group is found on Gotland and in Norway. During
the Wenlockian time Estonia shows a restricted poor fauna, whereas on
Gotland the rich F. lichenarioides - Pachypora lamellicornis group is
typical. Prom the Hogklint or Jaani stage onwards both areas again show
similar development. With the beginning of the Ludlow a lagoon facies,
characterized by Parastriatopora commutabilis association, is found in
Estonia, whereas the former conditions continue on Gotland. A greater
unification is typical since the Hemse-Paadla stage. The F.
subgothlandicus group follows the F. effusus association. But in the
Baltic area the first one can be subdivided by Thecia swinderniana and
the younger Laceripora cribrosa. The Paadla-Hemse fauna is widespread;
species of this association are found in the Northern Ural, the
Sibirian platform, Central Asia and Podolia. Since the Upper Ludlow the
Tabulate corals are retrograde. In Estonia three different groups are
to be distinguished: the older F. forbesi - F. similis group, the F.
pseudoforbesi muratsiensis - Paleofavosites moribundus group and the
youngest F. pseudorprhcai ohesaarensis group. Because the upper two
groups are liiokinp on Gotland, it is concluded that the Silurian is
moro complete in Estonia: in the lower part as well as in the uppurmost
part.^1";

It can be demonstrated, that during early astogenetic growth the branching angle between offsetting corallites decreases rapidly from 165° to 100° averagely during later growth stages. This growth pattern resembles development of similar dichotomous branching uniserial bryozoans, e.g. Paleozoic Corynotrypa species or Mesozoic Stromatopora species.^1";
s[99] = "CALNER M., SANDSTROM O., MOTUS M.A. (2000).- Significance of a Halysitid-Heliolitid mud-facies autobiostrome from the Middle Silurian of Gotland, Sweden.- Palaios 15, 6: 511-523.- <b>FC&#038;P 31-2</b>, p. 52, ID=1591^<b>Topic(s): </b>reefs; Tabulata, reefs; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Sweden, Gotland^A low-diversity halysitid-heliolitid autobiostrome from the Late Wenlock Halla Formation at Blåhäll 1, Gotland, indicates a brief period of particular environmental conditions. The reef is 0.3-0.5 m thick, internally without bedding structures, and had a sheet-like distribution on a low-relief soft-bottom, in marginal platform, graptolitiferous strata (height-width ratio is 1:900 in outcrop). The dominating coral species building this mud-facies biostrome were the tabulates Stelliporella cf. parvostella and Halysites latitenatus. The rugose coral fauna is dominated by fixosessile and rhizosessile forms with well developed holdfasts, for example Dokophyllum elegantulum. Coral growth forms generally indicate high background sedimentation rates during the growth of the biostrome.Four successive stages of sea-.floor development are discussed: (1) a pre-biostrome stage, (2) a pioneering community stage, (3) a climax-community stage, and (4) a post-biostrome stage. Stratigraphically, these stages show an increased carbonate-siliciclastic ratio, a decreased phosphorus content, somewhat lighter d18 stable isotopes, and an increased rate of bioturbation. The climax-community stage coincides with a bloom(?) in paleocopid and metacopid ostracods.The biostrome differs from all other Wenlock-Ludlow reefs on Gotland in its geographic and stratigraphic isolation on the seaward slope of the carbonate platform. It was the first re-appearance of a reefal structure following the oceanic Mulde Event and associated eustasy. On a regional scale, this appearance coincide with an inferred high-stand systems tract and the onset of widespread reef growth in the basin indicating that, at least, basin-regional factors controlled reef growth.^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian
L; <b>Geography: </b>Sweden, Jamtland^The tabulate species of the
genera Paleofavosites, Favosites, Parastriatopora, Propora, Aulopora
and Catenipora recorded in Jämtland, Sweden, Scandinavian Caledonides,
are taxonomically revised. Biometrics is used for species definition.
The intraspecific variability is considered, and the analyses of type
material and other similar specimens from Estonia are included in the
taxonomical section. The neotype of Catenipora distans is illustrated
and remeasured together with two other specimens from the same
locality. Paleofavosites primus is synonymised with P. hystrix and
Favosites favosiformis is synonymised with F. favosus. Several species
are tentatively synonymized, what mostly demonstrates the problem of
typological species in Baltoscandia. The tabulates known from Jämtland
are also found in Estonia. The close relation of the development of
tabulate faunas in both areas is suggested. The stratigraphical
position of the Ede Formation at Ede, and the Berge Formation at Verkön
and Norderön is discussed, comparing the tabulate successions from
Jämtland and Estonia. The tabulate record from the Berge Formation
proves the Aeronian age of the unit. [original abstract]^1";

```

```
ID=4649^<b>Topic(s): </b>assemblages; Tabulata, assemblages;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>Baltic E^Five facies belts have been distinguished in
the Silurian of the East Baltic Area, which are tentatively referred to
as follows (from the shore towards the open sea): the lagoonal, the
shoaly, the detritic, the transitional and the off-sea facies. The
lagoonal facies is mainly represented in the Ludlovian and
characterized by ramose and cylindrical tabulate corals
(Parastriatopora, Laceripora); favositids occur extremely rarely and
represent casual immigrants from the shoaly facies. The majority of
Tabulata species of the East Baltic Silurian is restricted to the
shoaly facies. Within this facies we may distinguish a relatively
shallower part (reef region) and a deeper one (off-reef region); they
differ from each other by a different species content. In the process
of evolution of Tabulata, the shoaly facies was of the greatest
significance, and in the prochoresis likewise. In the detritic facies,
the significance of fasciculate forms increases, with eurifacial
species playing the predominant role. In the transitional facies, the
Tabulata occur sporadically and their assemblage may be regarded as a
considerably impoverished assemblage of the detritic facies. No
Tabulata have been found in the off-sea facies so far. ^1";
s[109] = "STEL J.H. (1979).- Environment and quantitative morphology of
some Silurian tabulates from Gotland.- Scripta Geologica 047: 1-75.-
<b>FC&#038;P 8-2</b>, p. 46, ID=5721^<b>Topic(s): </b>ecology,
morphometry; Tabulata, ecology, morphology; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Sweden, Gotland^An outline is given of reef development in Gotland,
Sweden, during the time when the Visby (Llandovery) and Hogklint
(Wenlock) Beds were deposited together with a sketch of the palaecology
in the time during which the Hemse and Hamra-Sundre (Ludlow) Beds were
formed. Variation is described in the tabulates Favosites hissingeri
Edwards &#038; Haime, F. obliquus (Sokolov), F. gothlandicus Lamarck,
F. forbesi Edwards &#038; Haime, Syringolites kunthianus (Lindstrom),
and Alveolites suborbicularis Lamarck. * In order to clarify
ecophenotypic variation of corallite size in tabulates, the corallite
area and three different corallite diameters were measured. Although
the corallite area is more related to the shape of the organism that
lived in a corallite, comparison of the several parameters revealed
that measuring of a corallite diameter can be applied in such species
from which ecophenotypic variation is known. However, the current
limitation of variability in corallite diameters within defined
morphospecies is often far too narrow, and does not allow for
ecophenotypic variation. As a consequence, the number of morphospecies
established since Sokolov (1950) is unrealistically large in the F.
forbesi group as well as in others. Variability in F. hissingeri is
influenced to a high degree by the environment. The characteristic
(genetically controlled?) pattern of larger corallites between smaller
ones in F. forbesi is hardly influenced by ecological factors.
Variation in thickness of the wall, in distance between the tabulae and
in intensity of the development of the septal structures is mainly
determined by the environment. [original summary]^1";

based on the research into the neotype and on the revision of
halysitids of the Gotland Silurian. The stratigraphic distribution is
limited to the Llandoverian stage of the Lower Silurian whence also the
finds made in Gotland (Lower Visby marl) and those of species
considered synonymous with Halysites catenularius (see the synonymies)
in other regions. The diagnostical characters of the species are as
follows: meshes outstretched, of varying shape; consist of corallites
of 1.3-1.5mm in width and 1.6-1.8mm in length. Mesocorallites mostly
rectangular, 0.5-0.6 x 0.75mm, the joints of meshes irregularly
triangular or polygonal. Corallite wall 0.15-0.2mm thick, consists of
uniform, finegrained calcium carbonate. Septa moderately developed,
constantly 12 in number. Tabules horizontal, slightly concave or
convex, placed at an interval of 0.4-0.7mm; mesocorallites are twice as
densely diaphragmed. A comparison of the quantitative characters of
Halysites catenularius and synonymous species are presented in a Table.

<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian U; <b>Geography:
</b>Baltoscandia^In the Baltic Sea, reef structures are common in the
Ordovician and Silurian sedimentary bedrock. Palaeozoic reef
development culminated in the Silurian when several successive reef
barriers developed. The present investigation has revealed new reef
structures in the upper Silurian sedimentary bedrock. Two new
biostromes, E1 and E2, have been found in the Ludlovian Eke Beds, east
of Gotland. The biostromes trend in a more or less east-west direction
and can be traced across the northern part of the Baltic Sea. In the
Pridolian, two reef-like barriers, named B5 and B6, occur at the
boundary to the Devonian. The lower barrier, B5, is found to the south
of the younger B6 barrier. This indicates that a transgression occurred
between the formation of the two barriers. A tentative reconstruction
of the Pridolian bay suggests that the coast shifted from a more
east-west direction in the Ludlovian to a more north-easterly to
south-westerly direction in the Pridolian. Bioherms are commonly
associated with the Eke biostromes and the upper Pridolian reef-like
barriers. The bioherms occur on the seaward side of the larger reef
structures, on the biohermal slope. Patch-reefs also occur on the
biohermal slope but they are more common on the landward (lagoonal)
side of the barriers. [original abstract]^1";

31-2</b>, p. 27, ID=1665^<b>Topic(s): </b>ecologic succession; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>Sweden, Gotland^Seismic reflection profiling east of Gotland has
given information on a succession of four reefal units in the lower
Ludlow stratal sequence ranging from the Klinteberg Formation to the
```

```
Hemse Group in the Gotland sequence. In this paper they are named the
Klinte Reef (Klinteberg Formation unit f), the Hammarudden Reef (Hemse
Group &#039;younger&#039; units a-c), the Östergarn Reef (Hemse Group
unit d) and the Millklint Reef (Hemse Group unit e). The reef units
form a mainly regressive succession with younger reefs resting on the
seaward slopes of older reefs. The reef succession is exposed on
Gotland and in the Baltic Sea east of Gotland, whereas towards the East
Baltic coast it is overlain by Pridoli sedimentary bedrock. Each reef
unit corresponds to a well-defined seismic unit with distinct facies
zonality ranging from lagoon via reef barrier and biohermal slope to
basin facies. The &#039;fore-reef&#039; facies is in this paper termed
biohermal slope to express its characteristic reefal features.
Reconstruction of the post-depositional tilting of the sequence
indicates lagoonal depths of up to 10m. The reef barriers developed at
depths of up to 20m and the biohermal slopes at between 10 and 55m. The
reef barrier and the biohermal slope are generally separated by a
debris fan of waste products from the reef, 1-2km wide. The reef
barriers are generally 1-3km wide, which is about the same width as
their lagoons. The biohermal slopes become successively wider towards
the upper part of reef succession, ranging from 5-9km at the Klinte
Reef to 15-18km at the Millklint Reef. Comparisons with the Gotland
sequence show that the reef barriers are biostromal stromatoporoid
reefs in a matrix of crinoid debris. The biostromes are of the Kuppen
type. The bioherms are of the Axelro and Hoburgen types. The bioherms
occur randomly on the seaward slope of the barriers. [original

limestones; <b>Systematics: </b>; <b>Stratigraphy: </b>Silurian;
```

```
<b>Geography: </b>Sweden, Gotland^Micritic limestone-marl alternations
make up the major part of the Silurian strata on Gotland (Sweden).
Their position on the stable Baltic Shield protected them from deep
burial and tectonic stress and allowed the preservation of early stages
of burial diagenesis, including lithification. In the micritic
limestones certain characteristics have been preserved (e.g., pitted
microspar crystals, sharp boundaries between microspar and components,
lack of deformation phenomena) that offer insights into their
formation. We suppose the formation of these micritic limestones and
limestone-marl alternations to be based on a rhythmic diagenesis within
an aragonite solution zone (ASZ) close below the sediment surface. The
micritic limestones are the product of a poikilotopic cementation of
carbonate muds which consisted of varying portions of aragonitic,
calcitic and terrigenous matter. Their microspar crystals show the
primary size and shape of the cements lithifying the original carbonate
mud. Dissolution of aragonite in the marls provided the carbonate for
the lithification of the limestones. By cementation, the limestone beds
evaded further compaction. The marls, which already underwent a volume
decrease by aragonite depletion, lacked cement and became more and more
compacted due to increasing sedimentary overburden. Although field
observations show that primary differences in material influence the
development of limestone-marl alternations they are not required for
their formation.^1";

Porifera, Vol. 2]: 141-146.- <b>FC&#038;P 23-1.1</b>, p. 17,
ID=4071^<b>Topic(s): </b>quantitative analysis; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Sweden,
Gotland^The Silurian (Wenlockian-Ludlovian) carbonate sequence of
Gotland includes numerous reef-like constructions formed on a warm,
shallow and open marine shelf. They were often exposed above sea-level
in their depositional time. The constituents of the reef-like
limestones were quantitatively analysed. The most important
reef-building organisms were stromatoporoids for all the investigated
limestones. However, the limestones in the upper part of the Gotland
sequence show stronger domination by stromatoporoids and higher
stromatoporoid density on the rock surfaces than the limestones in the
lower sequence show. The most important identifiable sediment producers
were echinoderms, with the exception of one example from the Hoglint
Formation in which calcareous algae dominated. The investigated
reef-like limestones vary as to stages of maturity. Only one of the
limestones (Holmhallar 1) can be strictly regarded as a reef limestone.
The other investigated limestones exhibit no or poorly developed
frameworks. Important conditions for the development of the Gotland
reefs were the formation of a stable bottom associated with karstic
processes, low sedimentation stress, and domination by stromatoporoids
as a condition for faunal capacity in constructing frameworks. This
last condition may have been dependent on the stages of global
evolution of the Palaeozoic reef community.^1";

s[141] = "ZAIKA Yu.V., KRUCHEK S.A. (2008).- Upper Devonian (Frasnian) corals (Anthozoa) of Belarus. Part 1: systematic composition, stratigraphic distribution, palaeoecology.- Lithosphere 2, 29: 49-60.- <b>FC&#038;P 36</b>, p. 82, ID=6489^<b>Topic(s): </b>taxonomy, biostratigraphy; corals; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>Belarus^The present paper describes the taxonomic composition, stratigraphic distribution and palaeoecology of Upper Devonian (Frasnian) Rugose and Tabulate corals (Anthozoa) of Belarus. Corals are widely distributed in carbonate rocks of the Pripyat Trough, Zhlobin Saddle and Orsha Depression, being especially abundant in the Buinovichi beds (Semiluki Formation, Middle Frasnian) and Ptich beds (Voronezh Formation, Upper Frasnian). * The following species have been recognized from the Semiluki Formation: Aulopora schelonica aseptata Zaika, subsp.nov., Thamnopora cervicornis (Blainv.), Th. polyforata (Schloth.), Th. reticulata (Blainv.), Th. tumefacta Lec., Gracilopora vermicularis
```

```
(McCoy). Scoliopora conferta albaruthenica Zaika, subsp.nov.,
Crassialveolties obtortus (Lec.), Cr. domrachevi (Sok.), Alveolites
suborbicularis lamellosa Lec., Planocoenites medius (Lec.), Disphyllum
pashiense (Soshk.), D. kostetskae (Soshk.), Thamnophyllum monozonatum
(Soshk.), Pterorrhiza multizonata (Reed) and Pt. berdensis (Soshk.).
Another association consisting of Peneckiella jevlanensis (Bulv.), P.
achanaiensis Soshk., P. szulczewskii Rózk., P. fascicularis (Soshk.),
Aulopora soshkinae Sok. and Aulocystis tikhyi Sok. is known from the
Voronezh Formation. * It may be supposed that the majority of species
mentioned above penetrated into Frasnian epicontinental basins of
Belarus during Middle and Late Frasnian time through the seas of the
Main and Central Devonian Fields, and, possibly, through the basin of
the Doniets-Dnieper depression. Two local subspecies of Aulopora
schelonica aseptata Zaika. subsp.nov. and Scoliopora conferta
albaruthenica Zaika. subsp.nov. are indicative of some isolation of
Frasnian faunas of the Pripyat Trough. * Different kinds of coral
biofacies are typical of the Buinovichi and Ptich beds. Coral
communities of Buinovichi time in the Pripyat Trough inhabited
hard-bottom upfolds and formed tabulate-stromatoporoid buildups like
biostromes and caliptras of several tens of centimetres thick. Ramose
tabulate and rugose corals populated soft-bottom depressions.
Coral-stromatoporoid buildups were much bigger in size in the Zhlobin
Saddle and Orsha Depression, which may suggest the more dissected
relief of the sea bottom as compared with that of the Pripyat Trough.
Also, massive cerioid colonies of unidentified rugose corals contribute
significantly to coral-stromatoporoid organogenic building in the Orsha
Depression. * Communities of fasciculate rugose corals and auloporoid
tabulates inhabited soft-bottom surfaces in the Pripyat Trough during
Ptich time. [original English summary]^1";

Rugosa; <b>Stratigraphy: </b>Carboniferous Vise Ser; <b>Geography:
</b>Russia, Moscow Basin^Actinocyathus floriformis and A. crassiconus
migrated to the Moscow Basin at the beginning of the Aleksin and
Mikhailov time (latest Visean) respectively. They gave rise to two
groups differing in some morphological characteristics, in patterns of
evolution and in ecological plasticity. In both groups the most
important evolutionary changes took place at the very beginning of the
Serpukhovian. The A. crassiconus group evolved in the open sea in the
south of the basin and in the current zone in the north-west as well.
It reached its acme at the beginning of the early Serpukhovian. The A.
floriformis group evolved in the open sea in the south only, but in the
early Serpukhovian it colonized a broad spectrum of habitats in the
west and north-west also and reached its acme at the end of the early
Serpukhovian. Intracolonial variability was typical for most species of
Actinocyathus and became especially high every time species dominated
in communities. Intraspecific variability could be represented either
by a few adaptive modifications with transitions between them or by
distinct adaptive norms. It cannot be recognized in species with high
intracolonial variability, those which are highly specialized or of low
abundance.^1";

Rugosa, Pseudobradyphyllum; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>Russia, Moscow
Basin^Pseudobradyphyllum Dobrolybova 1940 is a polycoeliacean genus and
a junior synonym of Paracaninia Chi 1937. Revision based on topotypes
and syntypes of the type species (Zaphrentis nikitini Stuckenberg 1888
from the basal Gzhelian stage of the Moscow basin) demonstrates all
essential features of Ufimia Stuckenberg 1895 (Plerophyllidae),
modified by an amplexoid trend. There are no affinities with
Bradyphyllum Grabau 1928 (Hapsiphyllidae). Due to intraspecific
variation, and if separated from their series of cross-sections cut
from one specimen, some sections might be identified as different
genera even of several families (Ufimia, Pentamplexus, Amplexocarinia,
Allotropiophyllum, Rotiphyllum, Bradyphyllum). [original summary]^1";

3: 283-317.- <b>FC&#038;P 36</b>, p. 55, ID=6440^<b>Topic(s): </b>new
taxa; Rugosa, Axiscavus Falsiamplexus; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous Bashk; <b>Geography:
</b>Ukraine, Donets Basin^Five species belonging to two genera:
Falsiamplexus Fedorowski, 1987 and Axisvacuus gen. nov. are described
in detail and their species content and relationships are discussed.
Both genera are perhaps related to Rotiphyllum and were probably
derived from it, but relationship of Falsiamplexus to Bradyphyllum
Grabau, 1928 cannot be excluded. The new genus Axisvacuus is
represented by four species, of which three are new: A. verus (type
species), A. extendus and A. semicirculatus. Stratigraphic ranges of
species described are compared to the western European and Russian
standards (Table 1). Some possible palaeogeographic implications of the
occurrence of Axisvacuus postumus (Smith, 1931) and Falsiamplexus
reductus Fedorowski, 1987 are briefly discussed.^1";
s[175] = "HECKER M.R. (2010).- Some aspects of evolution in the
Lonsdaleia (Actinocyathus) crassiconus species-group.- Palaeoworld 19,
3-4: 316-324.- <b>FC&#038;P 36</b>, p. 59, ID=6446^<b>Topic(s):
</b>phylogeny; Rugosa Lonsdaleia; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous Serp; <b>Geography: </b>Russia,
Moscow Basin^The Actinocyathus crassiconus species-group represents a
separate trend of evolution within the rugose subgenus Lonsdaleia
(Actinocyathus) (d&#039;Orbigny, 1849). It is distinguished by
consistently developed minor septa and by regular axial structures. In
the Moscow Basin, this species-group comprises seven species, A.
crassiconus (McCoy, 1849), A. lativesiculosus (Dobrolyubova, 1958), A.
sarytschevae (Dobrolyubova, 1958), A. subtilis (Dobrolyubova, 1958), A.
gorskyi (Dobrolyubova, 1958), Actinocyathus sp. A, and Actinocyathus
sp. B. It ranges from the Mikhailov horizon (Brigantian) to the Protva
horizon (lower upper Serpukhovian), and is especially characteristic of
the Tarusa horizon (lowermost Serpukhovian) in the north-western part
of the basin. Evolution in the group took place at the beginning of
Mikhailov time and in Tarusa time and showed three trends: (i) increase
in corallite size and number of septa; (ii) increase in number of septa
and tabularia diameter; and (iii) a wide range of variability in septal
number without important changes in tabularia diameter. Lonsdaleia
ornata Dobrolyubova, 1958, L. heckeri Dobrolyubova, 1958, and L.
longiseptata crassicolumellata Dobrolyubova, 1958 are synonymised with
Actinocyathus subtilis, and Lonsdaleia subcrassiconus subcrassiconus
Dobrolyubova, 1958 is with Actinocyathus gorskyi.^1";

```

```
</b>Carboniferous Bashk; <b>Geography: </b>Ukraine, Donets Basin^The
Bashkirian rugose coral fauna of the Donets Basin from the Homoceras,
Reticuloceras and Gastrioceras biozones is analysed in terms of modern
ammonoid, foraminiferal and conodont biostratigraphy. Comparison to the
Serpukhovian corals of the same area shows a drastic impoverishment in
the Homoceras biozone, culminating in the Reticuloceras biozone. Those
two biozones should be considered as the main period of turnover from
the Lower to the Upper Carboniferous rugosan faunas. The step by step
recovery and appearance of younger faunas began with, and was
accelerated during, the Gastrioceras biozone. The fauna of the Donets
Basin is distinctly different from that of the adjacent Voronezh, or
the Spanish and North African regions in both generic composition and
growth form. Except for a single species of the colonial Lytvophyllum?,
only solitary taxa of both dissepimental and non dissepimental types
occur in the Donets Basin. Many of these taxa are new and show
primitive characteristics of Upper Carboniferous taxa. The Donets Basin
represents environments differing from those in the areas mentioned
above and also was one of the main world centers for the appearance of
new rugose coral faunas following the Homoceras-Reticuloceras biozone
crisis. [original abstract]^1";
s[178] = "HECKER M. (2001).- Lower Carboniferous (Dinantian and
Serpukhovian) rugose coral zonation of the East European Platform and
Urals, and correlation with Western Europe.- Bulletin of the Tohoku
University Museum 1 [Proceedings of the 8th International Symposium on
Fossil Cnidaria and Porifera]: 298-310.- <b>FC&#038;P 30-1</b>, p. 21,
ID=7075^<b>Topic(s): </b>biozonation; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>Russia, Russian Platform^A sequence of nine rugose
coral zones (six assemblage zones and three interval zones) is proposed
for the Dinantian and Lower Serpukhovian of the East European Platform
and Urals. Two assemblage zones are recognized in the Tournaisian, the
Siphonophyllia-Conilophyllum and Uralinia-Cyathoclisia-Sychnoelasma
konincki zones, three in the Visean. the Haplolasma-Sychnoelasma
urbanowitschi, Acrocyathus-Dorlodotia and Palastraea-Actinocyathus
floriformis-Nemistium zones, and one in the lower Serpukhovian, the
Turbinatocaninia-Actinocyathus borealis-Paralithostrotion zone. They
correspond to the upper part of the Tn1b, to the Tn3, V1b-V2a,
V2b-V3b&#946;, V3c, and to the Pendleian-Arnsbergian respectively.
Interval zones correspond to the Tn2, V1a and V3b&#947;. All
litho-chronostratigraphic sigla are used in the sense of Conil et at.
(1990). * Rugose corals are usually considered important but endemic
index fossils, and are seldom used for long distance correlations.
Intraspecific variability is often overlooked, with the consequence of
the establishment of systematically invalid species. A regrouping of
these &#034;species&#034; puts a good tool for correlation at our
disposal. * The proposed zones can be correlated with the Lower
Carboniferous coral zones established in Great Britain, Belgium and
South China. Most of the genera, and even some species, upon which
zonations of Western Europe rely on, are observed in the Lower
Carboniferous of the Central Russia, Urals and Ukraine (Donets Basin).
Comparison of rugose faunas of Europe, Urals and South China shows that
communication existed between these areas in the Early Carboniferous,
and was especially intensive during the late Tournaisian and latest
Visean. [original abstract]^1";

<b>FC&#038;P 26-2</b>, p. 34, ID=3727^<b>Topic(s): </b>biostratigraphy;
coral assemblages; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Carboniferous U - Permian L; <b>Geography:
</b>Spitsbergen^Rugose coral assemblages from the Upper
Carboniferous-Lower Permian Wordickammen Formation of central
Spitsbergen are used in combination with microfaunal data and carbonate
facies analysis for biostratigraphic correlations and biofacies
interpretations. On the Nordfjordne Block in the West, an Upper
Carboniferous (late Moscovian) fauna was recovered from the lower part
of the Kapitol Member. This assemblage is characterised by abundant
cerioid colonies of Petalaxis, fasciculate colonies of Tschussovskenia
?, Profischerina ? and Fomichevella, as well as numerous chaetetid
demosponges. Many of the conical coralla are inverted and occur within
well-sorted, shallow-water, skeletal grainstones. In the upper beds of
the Kapitol Member solitary caniniids and bothrophyllids of Late
Carboniferous (Kasimovian-Gzhelian) age are dominant, including
Caninophyllum, Cornuphyllum, Gshelia, Amygdalophylloides,
Carinthiaphyllum, Fomichevella spp., and tabulate colonies (Roemeripora
and Syringopora). The overlying Tyrrellfjellet Member has only a few
corals near the base, where there is widespread development of
Palaeoaplysina bioherms, and rare Asselian representations of
Heintzella, Tschussovskenia and cerioid Kleopatrina are recorded. In
the Billefjorden Trough to the East, the Cadelfjellet Member
(equivalent to the Kapitol Member) has phylloid algal bioherms near the
base (Pyefjellet Beds) with large solitary rugose corals (Cornuphyllum
and &#039;Caninia&#039;) in packstones. These are succeeded by
concentrations of &#039;Caninia&#039; and Fomichevella in skeletal
packstones of Late Carboniferous (Kasimovian-Gzhelian) age, within the
otherwise sparsely fossiliferous micrites (Black Crag Beds). Skeletal
wackestones and packstones near the top of the Tyrrellfjellet Member
have abundant cerioid colonies (Kleopatrina (Kleopatrina), Stylastraea
and &#039;Thysanophyllum&#039;), together with solitary rugosans
(Bothrophyllum, Gshelia, Timania, Pseudotimania and Siedleckia) of
Early Permian (Sakmarian) age. Two main periods of cerioid development
are recognised in the corals of the Wordickammen Formation. The first
occurred in the late Moscovian (=Myachkovian of the Moscow Basin) with
a dominance of petalaxids, followed by a later event in the Sakmarian,
(age confirmed with fusulinacean and conodont data). The Upper
Carboniferous-Lower Permian rugose coral assemblages from central
Spitsbergen have strong affinities with those of the western part of
Russia (Urals, northern Timan, Moscow Basin) and the Sverdrup Basin,
Arctic Canada and in the late Moscovian form part of the Uralo-Arctic
Province. This province can be distinguished from the Mediterranean
Province to the south and the isolated coral faunas from California in
the west and Japan to he east. Later in the Early Permian the coral
faunas from Russia, Spitsbergen, Canada and the western USA form the
&#039;circum-Pangaea&#039; faunal realm.^1";

s[190] = "EZAKI Y., KAWAMURA T. (1992).- Carboniferous-Permian corals
from Skansen and Festningen, Central Spitzbergen: their faunal
characteristics.- In Nakamura K. (ed.): Investigations on the Upper
Carboniferous-Upper Permian Succession of West Spitsbergen 1989-1991;
Publ. Hokkaido Univ. Sapporo: 59-75.- <b>FC&#038;P 21-2</b>, p. 34,
ID=3312^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous, Permian; <b>Geography:
</b>Spitsbergen^Successive marine Carboniferous-Permian strata
containing fossil corals are widely distributed in Spitsbergen,
providing some of the best reference areas in the Boreal province.
Since Toula (1875) first described two species of rugose corals from
the Nordenfjorden, several palaeontological works have been published
(e.g., Holtedahl 1913; Heritsch 1993; Padget 1954; Fedorowski 1965,
1967, 1975; Tidten 1972; Birkenmajer &#038; Fedorowski 1980; Nowinski
1982). Among them, Heritsch (1939) first clarified the overall faunal
characteristics of the Carboniferous and Permian corals in Spitsbergen.
A series of studies by Fedorowski (e.g. 1965, 1967, 1975) mainly
focused on the Late Carboniferous to Early Permian from the Hornsund
and Bellsund areas. Tidten (1972) described the Carboniferous and
Permian Rugosa mainly from the Isfjorden. &#034;Middle to Late&#034;
Permian Corals of the Boreal province have not been fully described as
to their detailed lithostratigraphic and biostratigraphic data. This
report provides a brief account of the Carboniferous to Permian coral
fauna of the Nordenskioldbreen Formation at Skansen and the Permian
fauna of the Kapp Starostin Formation at Festningen in Central
Spitsbergen. Their faunal characteristics are also briefly discussed.
The Nordenskioldbreen Formation is overlain by the Gipshuken Formation.
The Kapp Starostin Formation represents the Uppermost Palaeozoic strata
observed in Spitsbergen. The Formation overlies the Gipshuken Formation
and is paraconformably overlain by the Lower Triassic Vardebukta
Formation. For a lithologic and stratigraphic explanation of the
Nordenskioldbreen and the Kapp Starostin Formation, see Nakamura et al.
(1987 1990) and in the preceding chapter of the volume mentioned and
edited by Nakamura.^1";

ID=4664^<b>Topic(s): </b>morphology, ontogeny; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous, Permian;
<b>Geography: </b>Spitsbergen^On the occasion of two stays in
Spitzbergen during the summers of 1960 and 1961, a rich fauna of Corals
from the Permo-Carboniferous deposits was collected. It was studied
with the aim of revising and completing previous explorations .From the
large amount of processed material, only those specimens were selected,
in which modern morphogenetic analysis had led to new results. This
analysis includes particularly: 1. the structure is the centre of the
corallite of those genera which have a constantly or temporarily
elongated counter septum, 2. the secondary thickening of the structural
elements (previously called &#034;stereoplasma&#034;), particularly
considering the reasons for their formation and their degeneration
during the course of the ontogeny and 3. the fossula development. The
results have been possible due to newly developed methods for thin
```

```
sections, etching and preparations. Thus, the additional knowledge,
presented in the systematics section, has led to a better
identification of the characteristics and to a more sophisticated
classification. The genus Sassendalia with the species S.
turgidiseptata as well as the species Pseudotimania latifossulata are
new. Furthermore, the following species are analysed: Bothrophyllum
conicum Trautschold 1879 sensu Dobroljubova 1937, B. conicum robustum
Dobroljubova 1940, B. pseudoconicum Dobroljubova 1937, Gshelia
rouilleri Stuckenberg 1888 sensu Dobroljubova 1940, Timania schmidti
Stuck. 1895, Pseudotimania mosquensis (Dobrolj. 1937), Caninophyllum
calophylloides (Holtedahl 1913), Yuanophyllum sp., Campophyllum kiaeri
Holtedahl 1913, Lithostrotion (Siphonodendron) affine (Martin 1809).^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian;
<b>Geography: </b>Spitsbergen^Field observations made in 1975
supplement existing data and make possible a new interpretation of
depositional environments of the upper Treskelodden beds. It is
demonstrated that the entire coral fauna in all &#034;Coral
Horizons&#034; represents re-deposited assemblages. Transportation in
some cases was sufficient to abrade and round individual colonies;
others were simply overturned from growth position. The upper
Treskelodden beds were deposited in very shallow marine environments
although some beds and parts of the studied area may have been
temporarily exposed above sea level. Environmental changes observed are
developed on a local scale only. Tectonic factors are interpreted
herein as causing the faunal and sedimentological variations observed
rather than the global climatological mechanisms suggested by earlier
workers. This interpretation is supported by the small scale and
character of the sedimentological variations observed.^1";

<b>Stratigraphy: </b>Permian U; <b>Geography: </b>Spitsbergen^Marine
Permian successions, containing various kinds of invertebrate fossils,
are distributed widely in Spitsbergen. The Kungurian to Tatarian Kapp
Starostin Formation is the uppermost Palaeozoic unit and is
characterized by a cold-water fauna dominated by brachiopods, bryozoans
and sponges. Non-dissepimented solitary Rugosa also occur, especially
in shallow-water carbonates. The coral fauna is entirely different in
composition and diversity from that of the underlying Nordenskioldbreen
Formation, which was deposited in tropical and &#47; or subtropical
conditions. However, similar cold-water faunas are commonly found in
contemporaneous formations in other present day Arctic regions such as
Greenland and the Canadian Arctic, belonging to the same faunal
province. Almost the same faunal succession appeared throughout this
province during a climatic cooling characteristic of the Arctic region.
The abundance of corals decreases upwards in the Kapp Starostin
Formation, showing a strong facies dependence on a local scale. The
cold-water, solitary Rugosa disappeared earlier than the other
level-bottom organisms, and the warm-water adapted Rugosa in the
Tethys. The fauna was primarily affected by a climatic cooling, but was
also diminished by various factors of sea-level, tectonic, geochemical
and biological origins on local and global scales.^1";

collection of solitary rugose corals collected from the Treskelodden
Formation of the Kruseryggen Hill, Hornsund area, south Spitsbergen,
consists of 30 specimens representing the Bothrophyllidae family with
the genera Bothrophyllum, Caninophyllum, Hornsundia, and Timania (5
species), and an indeterminate family with the genus Svalbardphyllum
(one species). These large, dissepimental forms, dating from the Early
Sakmarian (Tastubian), indicate a warm-water environment. The
lithology, the thickness of the succession, the reddish hue and the
abrasion of the fossils indicate that the area of the inner Hornsund
showed a relief that enabled considerable erosion of the elevated areas
and redeposition of the fossils at remote locations. The changing
morphology of this area during the Early Permian was probably
influenced by synsedimentary block tectonics. [original abstract]^1";

Formation in Spitsbergen: A sedimentary and faunal record of Late
Permian palaeoenvironments in an Arctic region.- Mem. Canadian Soc.
Petrol. Geol. 17: 647-655.- <b>FC&#038;P 24-1</b>, p. 56,
ID=4463^<b>Topic(s): </b>geology, paleontology; <b>Systematics: </b>;
<b>Stratigraphy: </b>Permian U; <b>Geography: </b>Spitsbergen^The Kapp
Starostin Formation is the uppermost Palaeozoic stratigraphic unit in
Spitsbergen, ranging from Kungurian to the Tatarian. It contains a cold
water adapted fauna dominated by brachiopods, bryozoans and sponges.
Four depositional facies are recognised in central Spitsbergen: 1) a
cold water carbonate facies on the shallow shelf; 2) a terrigenous sand
facies on the deep shelf; 3) a siliceous mud facies on the deep shelf
and slope; and 4) a black mud facies in the basin. The cold water
carbonates with a limited fauna contain rare non-skeletal carbonate
```

```
components and carbonate muds and were deposited on a shallow carbonate shelf. The siliceous mudstones, containing numerous sponge spicules, were deposited below normal wave base. At the same depth terrigenous sands with glauconite were distributed in places. The black mudstones are characterised by rare benthic fauna and less bioturbation, implying deposition in a stagnant Condition. The sequence of the Kapp Starostin Formation shows four cyclic facies successions, with several transgressive-regressive couplets from shallow carbonate facies to terrigenous sand, deep siliceous or basinal mud facies and vice versa. The whole sequence comprises one transgressive-regressive cycle commonly observed in the Arctic region. The organisms of the Kapp Starostin Formation vary in abundance and taxonomic diversity, showing a strong facies dependence. The faunal diversity decreases with increase in water depth and terrigenous sediment content. The Permian fauna shows strong faunal similarities in composition within Arctic and peri-Gondwana regions and flourished temporarily in a colder climate in the northern hemisphere. The fauna, however, disappeared in a tectonic framework established in the mid-Permian. Relative sea level fluctuations coupled with local and regional tectonism induced a marked variety of adverse conditions for the cold water organisms.^1";

During the Late Cretaceous and the Early Tertiary carbonate sedimentation prevailed. Locally small bryozoan mounds were formed during the Upper Maastrichtian. The bulk of bryozoan bioherms originated during Danian B to C. Coral communities and coral mounds are confined to the Danian C. About five coral limestone localities occur within the Danish-Polish Trough; Fakse is the most important one. Paleontological and sedimentological data of the coral limestones point to the interpretation of the coral reefs as &#034;cold- and deep-water coral bioherms&#034;. Important criteria are the (1) absence of algae, (2) low-diverse azooxanthellate coral community, (3) dominance of dendroid
```

```
growth forms in the corals, (5) occurrence of pelagic organisms
(globigerinid foraminifera, coccoliths) within the micrite of the mound
facies and intermound facies, (6) breakdown of framebuilders
predominantly by bioerosion instead of mechanical destruction, (7)
mound- or bank-like structure of the buildups, (8) occurrence at a high
paleolatitude. Three major facies types can be distinguished: (1)
bryozoan limestones, (2) transitional facies, and (3) coral limestones
which include five subfacies types defined by the predominating coral
taxa. Most coral mounds are composed of facies types 2 and 3.
Diagenesis is characterized by the formation of early marine-phreatic
fibrous and bladed cements and by late diagenetic meteoric-phreatic
dog-tooth cements and the replacement of calcite cements by quartz. The
mounds have an asymmetrical shape caused by unidirectional currents
from the south. The maximum length is 200 m, the height 30 m and the
width 80 m. The distribution of colonial corals within the mounds
indicates a zonation pattern. Framebuilders are represented only by
azooxanthellate organisms: Colonial scleractlnian corals, stylasterine
hydrozoans and octocorals. Scleractinian corals have dendroid and
arborescent growth forms, whereas hydrozoans and octocorals form
fan-like colonies. Strong bioerosion of the framebuilding organisms was
responsible for the breakdown of the skeletons; the bioclasts formed
the substrate for other framebuilders. The soft bottom between the
framebuilders was burrowed by bivalves and crustaceans. The comparison
with coral mounds occurring in the eastern Atlantic at similar
latitudes and in a position comparable with that of the Paleocene
Danish-Polish Trough suggests a paleo-depth between 100 and 300 m.^1";

Britain and their palaeobiogeographic significance.- Bulletin of the
Tohoku University Museum 1 [Proceedings of the 8th International
Symposium on Fossil Cnidaria and Porifera]: 245-253.- <b>FC&#038;P
30-1</b>, p. 21, ID=7073^<b>Topic(s): </b>biogeography; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician;
<b>Geography: </b>Britain^Ordovician Rugosa are abundant in Britain
(England, Scotland and Wales), but have not been comprehensively
studied recently. They were examined for this study from the viewpoint
of faunal composition and provincialism. The Craighead Limestone of the
Girvan area, Scotland, contains a fauna of Caradoc age that is marked
by the presence of Grewingkia and Streptelasma. However, Lambeophyllum,
Paliphyllum, Coelostylis, and Leolasma are conspicuously absent in
Scotland. When tabulate corals are also taken into account, the
Scottish fauna implies a possible North American affinity and
represents a warm water association. The English and Welsh faunas of
Ashgill age have been examined at several places, as follows: (1) the
Coniston Limestone in the Lake District, northern England; (2) the
Conway Castle Grit of Llandudno, as well as the Dolhir Limestone Member
of the Dolhir Formation, and the Glyn Limestone of the Glyn Formation,
in the Glyn Ceiriog area, North Wales; and (3) the Robeston Wathen
Limestone in Robeston Wathen and Whitland, South Wales. These English
and Welsh Ashgill faunas contain Bodophyllum, Grewingkia, Helicelasma,
Leolasma, Streptelasma, Rectigrewingkia, and Coelostylis. They show a
close affinity to faunas from other parts of the East Avalonia Terrane
and are also akin to those of Baltoscandia, which constituted the
palaeocontinent of Baltica. These two allied faunas may have been
strongly influenced by a relatively cold water environment. In
contrast, the Laurentian coral fauna differs in composition from the
fauna of Avalonia. These faunal differences apparently reflect
palaeoclimatic and palaeoceanographic variations, rather than
differences in age and terrane. Knowledge of the Late Ordovician rugose
corals of Britain, together with palaeoenvironmental studies, is
important for further elucidating faunal migration patterns in terms of
the palaeobiogeography of Laurentia, Avalonia and Baltica. [original

corals.- Monograph of the Palaeontographical Society 157 (620): 144
pp., 3 pls.- <b>FC&#038;P 33-2</b>, p. 23, ID=1135^<b>Topic(s):
</b>distribution, systematics, biogeography; Tabulata; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Ordovician; <b>Geography:
</b>Britain^Of the 13 families of tabulate corals represented in the
Ordovician successions of South and North Wales, Lake District,
Northwest Yorkshire, Cross Fell and Southwest Scotland, three
(Cryptolichenariidae, Lichenariidae, Paleoalveolitidae) are exclusive
to the Caradoc Series, being the oldest tabulate corals recorded from
Britain, five (Favositidae, Proheliolitidae, Proporidae,
Sibiriolitidae, Taeniolitidae) are exclusive to the Ashgill Series,
while the remaining five (Billingsariidae, Coccoserididae, Halysitidae,
Syringophyllidae, Tetradiidae) are represented in both the Caradoc and
Ashgill series. The total known fauna consists of 26 genera, of which
Elkanpora and Girvanopora are new. Of the 63 species and subspecies,
two are described under open nomenclature and 25 are new. The
palaeogeographical distribution of these tabulate corals was affected
by the separation of the Laurentia and Avalon palaeocontinents in
Caradoc and Ashgill times, the Iapetus Ocean acting as a barrier that
prevented the mixing of their coral faunas.^1";
s[240] = "SCRUTTON C.T., PARKES M.A. (1992).- The age and affinities of
the coral faunas from the lower Silurian rocks of the Charlestown
Inlier, County Mayo, Ireland.- Irish Journal of Earth Sciences 11:
191-196.- <b>FC&#038;P 22-1</b>, p. 29, ID=3132^<b>Topic(s):
</b>biostratigraphy; coral faunas; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Silurian L; <b>Geography:
</b>Ireland^The biostratigraphy and palaeobiogeography of the coral
faunas of the Lower Silurian succession in the Charlestown inlier,
County Mayo, are discussed. Coral faunas are restricted in the fine
sandstone lithology of the Cloonnamna Formation, but more common and
highly diversified in the Uggool Limestone Member at the base of the
formation. The fine sandstones contain the Palaeocyclus porpita -
Favosites multipora association, widespread in similar lithologies in
the circum-Iapetus area where it is dated as of late Telychian (Lower
Silurian) crenulata Biozone age. The Uggool Limestone Member contains
25 identifiable coral species together with 3 stromatoporoids, most
known only from one to three specimens. The fauna indicates an early
crenulata or possibly griestoniensis Biozone age and contains a mix of
species of Laurentian and Avalonian affinities.^1";

mode; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Britain^Growth-form
variation in two British Silurian species of Propora is illustrated
using the ternary diagram format of Young &#038; Scrutton (1991).
External form is related to an analysis of the internal distribution
and angle of growth of corallites and coenenchyme in these corals. The
two species are shown to possess quite distinct internal spatial
arrangements of corallites which are considered to be genetically
determined. Growth-form results from the interaction of these
determinative patterns and environmental factors, principally
sedimentation. Corallite growth vectors and resultant growth-form are
important taxonomic factors in these corals.^1";

Pseudodiscophyllum windermerensis gen. et sp.nov., from Cumbria,
```

```
represented by a well-preserved internal float (pneumatophore), is only
the fourth porpitoid reported from Silurian rocks world-wide and the
first to be found in any geological formation in England. Its circular
pneumatophore is more than 110mm in diameter. Because of the paucity of
hard parts, these animals are not common as fossils but may have been
important elements of the Palaeozoic oceanic plankton. Although the new
species is superficially similar to the Ordovician Discophyllum, there
are what appear to be fundamental differences. Similarities to species
of Paropsonema, from the Devonian and Silurian, are also probably
superficial. The wider relationships of these animals have long been
misinterpreted in the palaeontological literature. They are not
siphonophores. Correct understanding involves a complete
re-interpretation of various homologies and of the evolutionary history
of the group.^1";

dimetrism in some Favositid corals.- Acta Palaeontologica Polonica 25,
3-4: 477-491.- <b>FC&#038;P 11-1</b>, p. 50, ID=1776^<b>Topic(s):
</b>dimetrism, annual periodicity ?; Tabulata, Favositida;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian
Wen; <b>Geography: </b>Britain, Wenlock^Sporadic dimetrism in some
specimens of two English Wenlock favositid coral species, Favosites
multipora and Palaeofavosites rugosa, is investigated by serial
sectioning. The diametric appearance is found to be periodically
developed within a colony where it occurs and to be caused by
fluctuating rates of corallite increase. Peak increase corresponds in a
regular pattern to other periodic features in these corals. Zones of
close-spaced tabulae, thickened corallite walls and well-developed
septal spines form bands of denser growth occurring with an annual
periodicity and it is concluded that increase and, therefore,
diametrism is also seasonally controlled in these corals. Entraining
factors and the cause of modifications in the relative timing of peak
increase are discussed. Diametrism in these corals is considered to be
wholly of ecophenotypic origin and of no taxonomic significance.^1";
s[250] = "SCRUTTON C.T., McCURRY J.A. (1987).- The derivation,

(1995).- Mass mortalities on an Irish Silurian seafloor.- Journal of the Geological Society 152: 917-922.- <b>FC&#038;P 25-2</b>, p. 25, ID=6870^<b>Topic(s): </b>mass mortalities; benthic communities; <b>Systematics: </b>; <b>Stratigraphy: </b>Silurian Llan; <b>Geography: </b>Ireland W^Recurrent deep-water benthic communities, dominated by diverse tabulate corals, colonized soft substrates during the late Llandovery transgression in western Ireland. A number of autochthonous shelly assemblages dominated by brachiopods, corals and crinoids occur in the upper parts of the Kilbride Formation; the highest and most distal levels are dominated by in situ tabulate corals that are mantled by a thin layer of volcanic ash. Most of the coral colonies could cope with limited sedimentation: growth ceased after the volcaniclastic surge. This catastrophic mode of preservation permits an accurate analysis of an early stage of community development in deep-water benthos on a soft Llandovery seabed, periodically swept by volcaniclastic debris. The Kilbride faunas have implications for the palaeoenvironments and taphonomy of deep-water marine faunas associated with areas of active volcanism. [original abstract]^1";

Anthozoa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography:
</b>Ireland, Dublin Basin^Rugose coral assemblages from the late
Tournaisian and early Visean of the Dublin Basin appear to be strongly
influenced by water depth and lithofacies, associated with the
evolution of a carbonate ramp. This ramp later evolved into a
deep-water basin flanked by shallow-water platforms. Shallow-water
shelf assemblages in the late Tournaisian are characterised by
low-diversity non-dissepimented taxa. These pass up into high-diversity
assemblages dominated by large, dissepimented solitary rugose taxa
(Caninophyllum patulum, Cyathodisia modavensis, Siphonophyllia sp. A),
which colonised deeper-water slope settings on a carbonate ramp. In the
latest Tournaisian deep-water Waulsortian mudbank limestones supported
a sparse coral assemblage, but locally abundant caninioids with rare
Siphonophyllia cylindrica are recorded. An influx of terrigenous
sediment into the Basin during active tectonism, caused suppression of
carbonate sediment and only a low-diversity assemblage survived.
However, on the flanking shallow-water platforms an abundant
high-diversity rugose fauna (Sychnoelasma urbanowitschi, Axophyllum
simplex, Koninckophyllum cyathophylloides, Palaeosmilia murchisoni,
Carruthersella compacta) became established in the early Visean. Rugose
coral biozones can be recognised in the Basin similar to those in
Western Europe and compliment foraminiferal and conodont
biozonations.^1";

</b>Britain, Derbyshire^A comparison is made between recent and Lower
Carboniferous coral faunas from morphological and stratigraphical
aspects. The environment of recent corals is summarized and comparisons
and contrasts made of this environment with that of the Lower
Carboniferous, deduced from a study of Derbyshire rocks and fossils. It
is considered that the Lower Carboniferous corals lived in an
equatorial warm water marine environment developing mainly as patch
reefs, just below sea level, with an associated fauna. Outer barrier
reefs, knoll limestone, possibly controlled by abundant crinoid growth,
with or without algae and generally devoid of coral, separated the
coral patch reefs from the surrounding deeper water. Land areas would
be restricted to small, low islands lying to the south, the remnants of
an earlier more extensive St. Georges Land. The possibility that the
main Derbyshire limestone area subsided as a result of an ancient
volcanic platform, floundering, allowing the accumulation of over 2,500
feet of limestones, is investigated.^1";

algae; Anthozoa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography:
</b>Britain NW^Most carbonate buildups of Dinantian age are mud-mounds
lacking direct evidence of abundant framework organisms. This
contribution describes apparently unique structures containing abundant
frame-building organisms interpreted as true reefs. They occur in the
Red Hill Oolite, part of the Carboniferous Limestone succession in the
Furness area of northwest England. Reefs were initiated by the
attachment of numerous Syringopora colonies to a firm substrate.
Encrusting organisms, dominantly the supposed foraminifer Aphralysia,
colonised sediment and corallite surfaces leading to the development of
a rigid framework. Thrombolites also assisted in the establishment of
bindstone textures. During the later stages of reef growth. Syringopora
became less common and its place in the reef was taken by upright,
branching growths of solenporoid algae. Rapid sedimentation and
subsidence resulted in reefs with near vertical sides, but little
topographic expression on the sea-floor during growth. The occurrence
of these reefs cannot be attributed to any single environmental factor
but probably resulted from an unusual combination of favourable
circumstances. (Original summary)^1";

(1997).- Hexaphyllia: a spiny heterocoral from Lower Carboniferous reef limestones in Derbyshire, England.- Palaeontology 40, 4: 1031-1059.- <b>FC&#038;P 27-1</b>, p. 5, ID=3779^<b>Topic(s): </b>morphology; Heterocorallia, Hexaphyllia; <b>Systematics: </b>Cnidaria; Heterocorallia; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Britain, Derbyshire^Exceptionally well preserved and abundant corallites of Hexaphyllia are recorded from limestones of the Lower Carboniferous Castleton Reef Belt, north Derbyshire, UK. Details of corallite morphogenesis are presented and the growth attitude of corallites is determined. Tabulae curve down at their margins and fuse together to form the tabulotheca. Conversely, spines curve upward and point in the direction of corallite growth. Soft tissue reconstructions infer the presence of polyps sitting exposed upon and totally enclosing the distal tips of the corallites, with polyp lobes extending down their sides. Much of the corallite is therefore regarded as endoskeletal in origin. Rows of spines projecting from between the polyp lobes gave some degree of protection to the exposed polyps. Assemblages of corallites from different positions in the reef show notable differences in morphology. Variations in shape, wall thickness and tabulae spacing are attributed to contrasting growth rates at different positions within the reef. Examination of approximately 1300 corallites from two localities in the reef reveals the presence of a single species, Hexaphyllia marginata (Fleming), which shows considerable intraspecific variation. Systematic studies indicate that criteria used to distinguish Hexaphyllia: species in the past are invalid and that the majority of previously described taxa are junior synonyms of H. marginata. Heterocoral mode of life is discussed in the light of observations made on this species.^1";

s[277] = "ARETZ M., NUDDS J. (2005).- The coral Fauna of the
Holkerian/Asbian boundary stratotype section (Carboniferous) at Little
Asby Scar (Cumbria, England) and implications for the boundary.-
Stratigraphy 2005, 2: 167-190.- <b>FC&#038;P 35</b>, p. 48,
ID=2331^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography:
</b>Britain, Cumbria^Five coral assemblages from the Holkerian-Asbian
succession at the stratotype section at Little Asby Scar, Cumbria
(England) have been studied. The stratotype section is located near the
fault zone, and contact of the Potts Beck Limestone (earlier Asbian)
and the Knipe Scar Limestone (later Asbian) is tectonically
controlled.The coral fauna of the Limestone bed which defines the base
of the Asbian consists of a coral assemblage which does not contain any
coral taxa appearing in the Asbian. The first Dibunophyllum, the
traditional coral genus for the Asbian-Brigantian, is not known until
the overlying Knipe Scar Limestone. However, other coral taxa from the
Knipe Scar Limestone are typical of the later Asbian. No coral
assemblage can be doubtless assigned to the earlier Asbian. The coral
assemblages of the Little Asby Scar proved that the first appearance of
Siphonodendron junceum is in the upper Asbian.The distribution of other
important biostratigraphic groups, the foraminiferans and brachiopods,
support a relocation of the originally defined Holkerian-Asbian
boundary. However, the bases of the biozones of the two most abundant
groups, corals and foraminiferans, do not coincide; Asbian
foraminiferans appear earlier than Asbian corals.The attempt to
correlate the Little Asby Scar succession to the Belgian Namur-Dinant
basin and its standardized sedimentary sequences based on a simple
presence-absence comparison of corals and foraminiferans does not
result in a definite correlation.It is evident that the
Holkerian-Asbian boundary as originally defined is lithostratigraphic,
and that the absence of any biostratigraphic support prevents the use
of that level in a chronostratigraphic context. Therefore, after a
consensus on the criterion for the base of the Asbian, the stratotype
should be relocated to a better exposed section.^1";

Siphonodendron; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous L; <b>Geography: </b>Britain N^Fasciculate coralla of
the rugose coral, Siphonodendron martini (Milne-Edwards &#038; Haime),
preserved in life position in soft argillaceous shales within the
Arundian (Lower Carboniferous) Ash Fell Sandstone of Cumbria, northern
England, exhibit several peculiar features. Corallite diameter is
significantly reduced, with a corresponding decrease of the
dissepimentarium and in septal member; colony growth form tends towards
phaceloid with slender, parallel corallites devoid of lateral budding;
and finally, some corallites exhibit rejuvenescence, a feature
```

```
previously unknown in this genus. It is suggested that all of these
features are a result of an increase in clastic sedimentation in this
area. The introduction of large quantities of mud onto the coral
thicket would also lead to an imbalance in food supply and a reduction
in available light, the later inhibiting photosynthesis by endodermal
symbiotic algae. This in turn would inhibit the secretion of calcium
carbonate, leading to all of the morphological features observed.
Growth rate data, already published from this area, lend support to
this theory. The resulting stunted corallites are phenotypic
homeomorphs of the descendant species, Siphonodendron intermedium Poty,
S. irregulare (Phillips) and S. pauciradiale (M&#039;Coy), which appear
in the succeeding Holkerian and Asbian stages. This may help to explain
some of the long-held misconceptions surrounding the missing syntypes
of S. irregulare.^1";
s[281] = "SOMERVILLE I.D. (1997).- Rugose coral faunas from Upper
Visean (Asbian-Brigantian) buildups and adjacent platform limestones,
Kingscourt, Ireland.- Boletin de la Real Sociedad Espanola de Historia
Natural, Seccion Geologica 92, 1/4: 035-047.- <b>FC&#038;P 26-2</b>, p.
22, ID=3700^<b>Topic(s): </b>; rugose coral faunas; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Vise;
<b>Geography: </b>Ireland, Kingscourt^Detailed sampling from two
working quarries at Mokeeran and Ardagh, near Kingscourt have yielded
locally abundant Upper Visean coral faunas, with several rugose genera
and species new to Ireland. Pale grey, thickly bedded, crinoid-rich
platform limestones of late Asbian age at Mokeeran have produced 8
rugose coral genera and 16 species. Colonial corals predominate over
solitary rugosans by a ratio of 4:1, with most of the solitary corals
occurring within a darker, algal-rich limestone interval. Almost
two-thirds of all colonial specimens collected are either
Siphonodendron pauciradiale or Lithostrotion decipiens in approximately
equal proportions. In the coeval massive buildup (&#039;reef&#039;)
facies at Ardagh, in contrast, corals are sparse with rare Axophyllum,
Siphonophyllia, Siphonodendron and Lithostrotion within the >95 m thick
buildup. Several solitary genera (Siphonophyllia) are found in both
buildup and platform facies, but individual species are restricted to
one facies only. In the top 3m of the buildup at Ardagh, however,
abundant fasciculate colonial corals have been recovered including
Corwenia rugosa and &#039;Koninckophyllum&#039; cf. volgense which
establish a Brigantian age for the top of the buildup. Cerioid colonies
though are rare and suggest unfavourable conditions for colonization.
At Rathgillen Quarry, 10km to the South of Ardagh, bedded limestones
above a similar buildup at Cregg have yielded the Brigantian coral
Actinocyathus floriformis, which is its first reported occurrence in
the Kingscourt Outlier.^1";

ID=6460^<b>Topic(s): </b>new taxa; Rugosa Howthia; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Tour;
<b>Geography: </b>Ireland^A new genus and species of fasciculate rugose
coral, Howthia suttonensis Somerville and Rodriguez, has been recorded
from Howth peninsula, County Dublin, Ireland, in Waulsortian mud-mound
limestones of upper Tournaisian age. The new colonial genus is
characterized by having an axophyllid axial structure, steeply inclined
tabellae, and presence of interseptal and lonsdaleoid dissepiments. It
evolved probably from a solitary Axophyllum by the development of
peripheral offsets. This new taxon may have been an ecological pioneer
adapting to a specialised niche near the top of a large Waulsortian
mud-mound in shallower water than most Waulsortian settings and, as
such, may have provided a novel evolutionary opportunity. Howthia
suttonensis is associated with Amplexocarinia and an unusual form of
&#039;Fasciculophyllum&#039;, both of which display budding and
protocoloniality, as well as the fasciculate tabulate coral
Syringopora. [original abstract]^1";

Rugose coral biostromes in the late Viséan (Mississippian) of NW
Ireland: Bioevents on an extensive carbonate platform.-
Palaeogeography, Palaeoclimatology, Palaeoecology 292, 3-4: 488-506.-
<b>FC&#038;P 36</b>, p. 112, ID=6548^<b>Topic(s): </b>reefs biostromes;
coral biostromes; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Ireland
NW^The extensive upper Viséan (Asbian) platform carbonates in NW
Ireland (Bricklieve Limestone Fm, Glencar Limestone Fm and Dartry
Limestone Fm) contain distinctive rugose coral biostromes, which are
dominated by different species of the genus Siphonodendron. These are
in stratigraphic sequence: pauciradiale biostrome (oldest), martini
biostrome and several junceum biostromes (youngest). They represent
bioevents caused by special short-lasting ecological conditions and can
be used as approximately synchronous horizons to correlate within the
region. The pauciradiale biostrome is the thickest, laterally most
persistent and most variable in facies and biotic composition of all
biostromes. It formed on a tectonically influenced platform with a
landward-seaward zonation from northwest to southeast, mainly above
storm wave-base and below fair-weather wave-base. The northwestern
Streedagh facies is characterized by the presence of clusters of large
sheet-like colonies of S. pauciradiale. The intermediate
O&#039;Donnell&#039;s Rock facies is unique for the predominance of the
fasciculate genus Solenodendron. The southeastern Bricklieve facies
represents the amalgamation of autochthonous and allochthonous coral
debris and bioclastic debris with localized small patches of coral
boundstone. Mass occurrences of fasciculate rugose corals re-appear in
the martini biostrome. This biostrome developed in a shallower water
setting, just above fair-weather wave-base on a levelled carbonate
platform. The junceum biostromes are thinner, decimetre to some metres
thick, and less persistent. They formed in deeper water mostly below
storm wave-base, except for the composite 2nd junceum biostrome of the
Bricklieve Mountains, which records a period of shallowing. According
to facies and coral morphologies, which were compared with modern
scleractinian growth forms, sea-level variation exerted one of the
strong controls on the rise and decline of the biostromes. The
pauciradiale biostrome formed during an extended shallowing-upward
cycle in a depth interval leading to the climax of Siphonodendron
```

```
pauciradiale. The cycle ended with the development of the martini
biostrome in shallow water. Its demise is probably caused by drowning
during the late Asbian sea-level rise. During that time slice the
junceum biostromes flourished in deeper water on the platform. Coral
growth ceased almost completely after formation of the junceum
biostromes during the falling sea level of the latest Asbian.
Siliciclastic input and resulting turbidity, as well as turbulence
formed a complex cascade of ecological constraints. In addition to the
local tectonic influences, they combined to result in the
&#034;depth&#034; factor which controlled the distribution of
predominating coral populations and the succession of the different
biostromes in the Asbian of NW Ireland.^1";

Viséan carbonate platform rocks in the Carlow area, southeast Ireland.-
Geological Journal 40, 1: 35-64.- <b>FC&#038;P 33-2</b>, p. 10,
ID=1098^<b>Topic(s): </b>carbonates stratigraphy; stratigraphy,
carbonates; <b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous
Vise; <b>Geography: </b>Ireland^The stratigraphy of the upper Viséan
(Asbian to Brigantian) carbonate succession in southeast Ireland is
revised on the basis of seven quarry and two borehole sections. Six
lithological units have been distinguished, two units (units 1 and 2)
in the upper Asbian Ballyadams Formation, and four units (units 4 to 6)
in the Brigantian Clogrenan Formation (both formations are dated
precisely using foraminiferans, calcareous algae and rugose corals).
The boundary between the Ballyadams and Clogrenan formations is
redefined 19 m below the horizon proposed by the Geological Survey of
Ireland, and thus, lithological characteristics of both formations are
redescribed. The upper part of the Ballyadams Formation is
characterized by well-developed large-scale cyclicity, with common
subaerial exposure surfaces. Fine- to medium-grained thin-bedded
limestones with thin shales occur in the lower part of cycles, and
passing up into medium-grained pale grey massive limestones in the
upper part. The Clogrenan Formation is composed mainly of medium- to
coarse grained thick limestone beds with variable presence of shales;
but no large-scale cyclicity. There is a decrease in the number of
subaerial exposure surfaces towards the top of the formation and common
chert nodules; macrofauna occurs mostly concentrated in bands. The six
units recognized in the Carlow area are comparable with other units
described for the same time interval (Asbian-Brigantian) from south and
southwest Ireland, demonstrating the existence of a stable platform for
most parts of southern Ireland, controlled principally by
glacioeustatics.^1";

The mud mounds were deposited in a deeper shelf setting, water depth was about 200m. They consist of micrite and peloidal micrite. Mound builders are siliceous sponges and associated microbes. Carbonate forming the mounds was produced and accumulated in situ via microbial decomposition of sponge soft tissue. Stable isotope fractionation was in equilibrium with ambient seawater. Diagenetic processes changed the sponge images to a point that they are hard to recognize. Stromatactoid cavities were left, if calcification of sponges was incomplete. Radiaxial fibrous cements lining the cavities were precipitated almost synsedimentarily under marine phreatic conditions. During the transgressive part of the basin history the sponges grew continuously more important. This development finally resulted in the establishment of sponge-microbial mud mounds.^1";
s[294] = "STROGEN P., SOMERVILLE I.D., PICKARD N.A.H., JONES G.L.I. (1995).- Lower Carboniferous (Dinantian) stratigraphy and structure in the Kingscourt Outlier, Ireland.- Geological Journal 30: 1-23.- <b>FC&#038;P 24-1</b>, p. 59, ID=4448^<b>Topic(s): </b>biostratigraphy, facies; geology; <b>Systematics: </b>; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Ireland, Kingscourt^Logging of 55 recent boreholes, together with remapping, has resulted in a fundamental reassessment of the stratigraphy and sedimentology of the Dinantian Kingscourt Outlier. Despite the present isolated position of the outlier within the Longford-Down Massif, the Kingscourt rocks are an integral part of the Dublin Basin succession. The newly defined Ardagh Platform marks the most northerly limit to basinal sedimentation in the Dinantian Dublin Basin. The Courceyan is a typical but thinner, north Dublin Basin succession with two new formal units: the Rockfield Sandstone Member and the Kilbride Formation. The latter, a coarse-grained, well washed limestone of latest Courceyan to early Chadian (late Tournaisian) age is the shallow water equivalent of the Feltim Formation (Waulsortian facies), which is absent in the outlier.
```

```
The Courceyan interval in the north of the outlier is markedly
attenuated. In the succeeding Chadian-Brigantian interval basinal
facies predominate in the south, but on the Ardagh Platform an almost
complete coeval Visean shallow water sequence is found. A new platform
unit (Deer Park Formation) of latest Asbian to Brigantian age is
defined in the Ardagh area. The Dee Member (Chadian) is newly defined
for the lower part of the basinal Tober Colleen Formation and the
Altmush Shale Member is formally defined for the upper part of the
Loughshinny Formation. Two major structures dominate the Kingscourt
Outlier: the NE SW trending Moynalty Syncline in the south and the N-S
trending Kingscourt Fault. Both are Hercynian structures, but probably
represent reactivated Caledonide basement-controlled structures.
Dinantian syndepositional faulting is indicated in both the Courceyan
(&#039;Kingscourt Sag&#039;) and Chadian-Asbian. The latter period of
faulting in the Ardagh area separates platform facies in the north from
basinal facies to the south. In the late Asbian, platform facies with
carbonate build-ups prograded south into the basin as Ifar south as
Nobber, but in the latest Asbian to Brigantian, basinal facies extended
northwards over the collapsed platform margin. Foraminifers, corals and
conodonts are mentioned with the stratigraphic units.^1";

13, ID=4783^<b>Topic(s): </b>reefs, bathymetry; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Britain,
Derbyshire^In the Lower Carboniferous deposits of Castleton,
Derbyshire, well bedded &#039;shelf&#039; limestones, apparently of
shallow water origin, pass northwards into a marginal tract of poorly
bedded apron-reef limestones which dip at about 30° downwards and away
from the &#039;shelf&#039;. Geopetal infillings of shell cavities in
the apron-reef indicate only minor movement since deposition and the
observed dip must be due to deposition on a sloping sea floor. At
certain times this sea floor was colonised by stromatolitic algae and
corals such as Lithostrotion at the apron-reef crest where there was
minimum water depth, followed to progressively increasing depths by a
fauna dominated by the coral Michelinia, a fauna of small brachiopods,
bryozoa, molluscs, trilobites, and other organisms and a fauna
dominated by Pseudamussium. At other times crinoidal debris was the
dominant component of the apron-reef, when an alignment of crinoid
stems parallel to the dip of the slope occurred at low levels, but a
random orientation at the apron-reef crest. Other sediments on the
apron-reef are apparently devoid of macrofossils. Volcanic activity
occurred during the development of the apron-reef, and it is suggested
that uplift of the shelf area preceded the subaerial flow of a lava
tongue which reached and plunged down the apron-reef slope and into the
sea.^1";

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic; <b>Geography: </b>Britain^There are two
Jurassic localities which have become famous for the number of corals
ploughed up on certain fields over many years. One is Fairford,
Gloucestershire - Great Oolite, (Bathonian) and the other is Steeple
Ashton, Wiltshire - Corallian, (Oxfordian). [ ] There are, of course,
some disadvantages to ploughed field material. It is not in situ and
unless you are able to dig a trench, the stratigraphy remains
uncertain. The corals are subject to dispersal by farming activities
and damage by machinery. Also there is the possibility of intrusions,
that is, fossils from nearby exposures becoming mixed with the ploughed
up material. However, since the basic material of palaeontology is
often fragmentary and incomplete as many of you are well aware, I
suggest that ploughed fields can be rewarding, despite their drawbacks.

facies; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf;
<b>Geography: </b>Britain^This study documents the facies and fauna of
Late Jurassic (Middle Oxfordian) coral reefs in England.
Sedimentological and palaeoecological analysis of these reefs
distinguishes three generic reef types: (1) small reef patches and
thickets associated with siliciclastic deposits; (2) small reef patches
and thickets associated with siliciclastic-free bioclastic grainstones
and packstones; and (3) biostromal unites associated with deep water
facies. The depositional environments of these reef types are
discussed. Two coral assemblages are identified: (1) the microsolenid
assemblage; and (2) the Thamnasteria, Isastraea, Fungiastraea and
Thecosmilia assemblage (Thamnasteria assemblage). The Thamnasteria
```

```
assemblage developed in all shallow water environments in the study
area, regardless of local environmental conditions. The fauna is very
eurytopic, r-selected and can tolerate significant environmental
fluctuations on short temporal scales (sub-seasonal). The main control
on the development of the microsolenid assemblage was low light
intensity, low background sedimentation rates and low hydrodynamic
energy levels.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf; <b>Geography:
</b>Britain S^The Corallian Beds of southern England consist of 4
asymmetric, upward shallowing cycles. Each cycle is separated from the
next by a non-sequence, usually an erosion surface, which marks a
marine transgression. Transgression was the result of a sudden rise in
sea level, the period of rise being perhaps less than 7000 years. There
is evidence of the same non-sequences occurring elsewhere in Britain
and abroad, suggesting that the transgressions were the result of
world-wide, eustatic changes in sea level.^1";
s[309] = "TAYLOR P.D. (1988).- A probable thecate hydroid from the
Upper Cretaceous of southern England preserved by bioimmuration.-
Paläontologische Zeitschrift 62, 3-4: 167-174.- <b>FC&#038;P 18-1</b>,
p. 46, ID=2286^<b>Topic(s): </b>bioimmuration; Hydrozoa, Hydroidea;
<b>Systematics: </b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>Cretaceous
Sant; <b>Geography: </b>Britain S^An inferred thecate hydroid, moulded
on the attachment scar of the bivalve Pycnodonte vesiculare, is
described from the Santonian Chalk of Kent. The living hydroid was
evidently overgrown by the P. vesiculare shell and is preserved as a
bioimmuration. Eisenackiella thanetensis gen. et sp.nov. is
characterized by a hydrorhiza whose stolons bear hydrothecae
alternately to the left and right, and a hydrocaulus consisting of
several unbranched stems with alternating hydrothecae. The widely
spaced stolonal Hydrothecae have adnate proximal parts and erect distal
parts. Assignment to an extant hydroid family is difficult: whereas the
hydrorhiza resembles that of the family Lafoeidae, the hydrocaulus is
reminiscent of the family Sertulariidae.^1";

Pliocene skeletal carbonates from eastern England.- J. geol. Soc.
London 140: 377-385.- <b>FC&#038;P 12-2</b>, p. 41,
ID=6236^<b>Topic(s): </b>carbonate platforms; carbonate diagenesis;
<b>Systematics: </b>; <b>Stratigraphy: </b>Pliocene; <b>Geography:
</b>Britain E^The Crags of eastern England include marine skeletal
carbonates which were deposited and lithified under temperate
conditions. The Coralline Crag (Pliocene), in particular, exhibits a
variety of carbonate cement types which indicate exposure to meteoric
ground-waters during a regressive period. * The Coralline Crag has been
divided into an upper division of dominantly well sorted skeletal
calcarenites and calcirudites and a lower, poorly sorted silty
calcarenite division. &#039;Dogtooth&#039; spar cement and rudimentary
syntaxial cement overgrowths on echinoderm fragments are characteristic
of the sediments of the upper division, which has undergone extensive
aragonite dissolution. This division is consequently relatively evenly
cemented. In the underlying sediments aragonite dissolution has not
occurred and the sediments have remained largely uncemented, with
```

```
cement restricted to irregular patches where growth of intra- and
inter-particle equant spar has effectively eliminated porosity. In
contrast with the upper leached sediments, syntaxial echinoderm
overgrowths show a greater development but only where interference from
surrounding sediment and sparry cement was absent. The elongate shape
of the Coralline Crag outcrop may be the result of preferential
cementation of the upper, coarser, well sorted calcarenites originally
deposited as an elongate sediment body, possibly as an offshore
sandbank. [original summary]^1";

of England and France support early diversification of the coral genus
Acropora.- Journal of Paleontology 82, 2: 313-328.- <b>FC&#038;P
36</b>, p. 107, ID=6539^<b>Topic(s): </b>early diversification;
Scleractinia Acropora; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Eocene; <b>Geography: </b>Britain, France^Five new
species of the highly successful reef-building coral genus Acropora are
described from Eocene locations in England and France (Acropora
britannica, A. alvarezi, A. wilsonae, A. bartonensis, and A. proteacea)
and additional records are given for six fossil species (A. deformis,
A. anglica, A. solanderi, A. roemeri, A. lavandulina, and A. ornata),
based on re-examination of material in the collections of the Natural
History Museum, London. Specimens came from the Lutetian (49.0 to 41.3
Ma) of France, Bartonian (41.4 to 37.0 Ma) of England and France and
Priabonian (36.0–34.2 Ma) of England. Included are the earliest record
of a species with tabular or plate-like colonies similar to those in
the modern &#034;hyacinthus&#034; species group (A. proteacea n.sp.)
and the earliest records of simple hispidose forms (A. bartonensis
n.sp. and A. roemeri), similar to those in the modern
&#034;florida&#034; species group. The Priabonian material from
southern England (A. brittanica n.sp. and A. anglica) shows the
earliest occurrence of two sturdy species groups, the &#034;humilis
II&#034; and &#034;robusta&#034; groups respectively, which now occur
together on reef fronts throughout the modern Indo-Pacific. The new
descriptions and records contribute to evidence that the genus
diversified rapidly after its appearance in the fossil record. This
diversification may have contributed to the rapid speciation and
dispersal, observed in this genus during the Neogene, culminating in
its extraordinary dominance of modern Indo-Pacific reefs. [original

distribution of Archaeocyatha in Spain.- Courier Forschungsinstitut
Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI.
International Symposium on Fossil Cnidaria and Porifera, Vol. 2]:
341-354.- <b>FC&#038;P 23-1.1</b>, p. 23, ID=4091^<b>Topic(s):
</b>biogeography, biostratigraphy; Archaeocyatha; <b>Systematics:
</b>Porifera; Archaeocyatha; <b>Stratigraphy: </b>Cambrian L;
<b>Geography: </b>Spain^The biostratigraphy for the Lower Cambrian
succession in Spain as proposed by Perejon (1986) is here modified on
the basis of new observations. The finding of new outcrops of
unquestionable Lower Cambrian age in the Spanish Pyrenees (Gerona)
which bear a diverse and abundant archaeocyath assemblage (Abad 1987,
1989), the recently revised archaeocyath systematics, palaeogeography
and biostratigraphy and new data on Spanish palaeontology suggest a
revision of the biostratigraphic framework. This also allows new
observations to be made upon archaeocyath systematics, biostratigraphy
and palaeogeography. The Lower Ovetian Substage includes Capsulocyathus
and another 22 genera in Zone I; Robertocyathus, Tumulocyathus,
Sclerocyathus, Gordonifungia, Tumulifungia, Geocyathus, Spinosocyathus
and another 25 genera appear in Zone II; Echinocyathus and 21 further
genera appear in Zone HI. The Upper Ovetian Substage includes three
archaeocyath genera in Zone IV; five genera of wide stratigraphic range
appear in Zone V; Dictyofavus and another seven genera are presented in
Zone VI; and Anthomorpha, Porocoscinus, Prismocyathus and 19 further
genera appear in Zone VII. The Lower Marianian Substage includes eight
archaeocyath genera in Zone VIE; Mennericyathus, Densocyathus,
Chouberticyathus and another 18 genera occur in Zone IX.^1";

Estimating the exact age of the Archaeocyaths-containing Wojcieszów Limestone, has been a matter of dispute. Previously regarded as Cambrian, they were recognised as Silurian in 2000 (Skowronek &#038; Steffahn). After more than 120 years of controversies this finding finally proves Early Cambrian age of this unit. Introductory taxonomic studies have shown similarity between Myslow Archaeocyaths - represented, among others, by genera Dokidocyathella, Erismacoscinus, Afiacyathus, Leptosocyathus and Protopharetra - and those from the Doberlug syncline (Germany). This dating is of great importance for establishing the lithostratigraphic column of the Kaczawa Mountains and Cambrian palaeogeographic reconstructions.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Ordovician
Ashg; <b>Geography: </b>Ardennes, Brabant Massif^Carbonate facies are
not common in the Lower Paleozoic sections of Belgium. Limestones and
calcareous shales are only present in the Upper Ordovician Fosses
Formation in the Sambre-et-Meuse area, between the Brabant Massif and
the Ardenne. In these levels, dated as Ashgillian, numerous green
algae, as well as rugose and tabulate corals have been found. Their
presence was probably related to a general warming event in the
Ashgillian. However, it also indicates possible palaeotropical
conditions for the area of sedimentation, implying that the
Sambre-et-Meuse area was probably located in low latitudes during
latest Ordovician time. This is further evidence for the rapid drifting
of the East Avalonia terrane from Gondwana towards Baltica.^1";
s[353] = "YANET F.E. (1977).- Novoe o tabulatakh i gelioliToideakh
Ordovika zapadnogo sklona Urala. [new data on Ordovician Tabulata and

Mountains, Russia: A Review.- Facies 35, 1: 1-7.- <b>FC&#038;P
25-2</b>, p. 64, ID=3165^<b>Topic(s): </b>reefs, geology; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician U; <b>Geography:
</b>Russia, Urals^The Upper Ordovician reefs of the Urals were formed
at a subsiding shelf-margin during an early Late Ashgillian (Surya time
interval) regressive phase. Reefs of this age were studied in detail
from the western slope of the Northern, the Subpolar and the Polar
Urals with respect to lithofacies, biotic composition and
paleogeographical patterns. The thickness of the reefs varies between
100 and 500m. The backreef areas are characterized by lagoons with
increased salinity and sabkha development. Microbial associations and a
diverse algal flora (Cyanophyta, green and red algae and alga incertae
sedis) are the main constituents of reefal boundstones. Tabulate and
rugose corals, heliolitids, calcareous sponge-like fossils, bryozoans
and problematic hydroids were also part of the reef communities. Each
reef exhibits a characteristic framework-building association. Reef
development was terminated by a rapid and abrupt sea-level rise at the
end of the middle Upper Ashgillian connected with the global Late
Ordovician glaciation.^1";

(1997).- First articulated Silurian sponges from the Iberian Peninsula
(Spain and Portugal).- Journal of Paleontology 71, 4: 554-563.-
<b>FC&#038;P 27-1</b>, p. 105, ID=3855^<b>Topic(s): </b>taxonomy;
Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>Iberian Peninsula^The first-described articulated
Silurian sponges from Spain and Portugal include a moderate assemblage
of hexactinellids and a single monaxonid demosponge. The sponges were
collected from a thin layer at the top of the Cyrtograptus
lundgreni-Monograptus testis graptolite biozone, in a possible volcanic
ash of latest Homerian (Wenlock) age. The sponges are from southeastern
Portugal and southwestern Spain in the Ossa-Morena Zone of the
Hesperian Massif. The hexactinellid collection includes several
specimens of the new species, Protospongia iberica, and fragments of
Diagoniella species and Gabelia (?) sp. Specimens of the latter two
taxa are too small for species identification. Demosponges are
represented by a single described specimen of a probably new genus and
species preserved as a &#034;wreath&#034; of monaxon spicules. Dermal
and gastral layers are of very fine spicules developed over the
moderately coarse, aligned, principal body spicules.^1";

<b>Geography: </b>Czech Republic, Bohemian Massif^All stromatoporoid
```

```
species described by Pocta (1894) from the Silurian and Devonian of Bohemia have been revised. Very extensive newcollections of stromatoporoids are coming from quarries near the Bohemian village Koneprusy (ca. 30 km southwesterly of Prague). These stromatoporoids have been collected in the Koneprusy Limestone of Pragian age and the Acanthopyge Limestone of Eifelian to Lower Givetian age. The Koneprusy Limestone contains a large reef complex. Most of the Koneprusy Limestone succession including all stromatoporoids and the reef complex belong to the kindlei conodont zone (middle Pragian). The stromatoporoids and the other reef-building organisms show a clear dependence on the facies (resp. position within the reef complex). The stromatoporoid fauna of the Koneprusy Limestone contains 15 species, but only 7 of them have been described by Pocta (1894). The new species Stromatoporella anamariae n.sp. is described. The Pragian ofthe Barrandian was no refuge for the stromatoporoids of the Eastern Americas Realm. Biogeographically, all stromatoporoid faunas of Bohemia belong to the Old World Realm. Nevertheless, the stromatoporoid fauna of the Acanthopyge Limestone is much more cosmopolitic than the fauna of the Koneprusy Limestone. The stromatoporoid fauna of the Acanthopyge Limestone is composed of 19 species, all of which are known from other occurrences in Europe, Asia, or Australia - except of Actinostroma vastum Pocta, 1894 and Stromatoporella pertabulata preisleriensis n. ssp. The stromatoporoids of the Koneprusy Limestone frequently contain commensalic &#034;worm&#034;-like organisms and only rarely the new auloporoid tabulate coral Syringopora praehanshanensis n.sp. In the Acanthopyge Limestone the new species Syringopora hladili n.sp. and three other Syringopora species occur. Possible reasons for the scarcity of stromatoporoids and reefs in the Lower Devonian may be the water temperature, the lack of branching and encrusting stromatoporoids, and the scarcity of commensalic Syringopora corals.^1";

(1989).- Fauna from the limestones at the Frasnian &#47; Famennian
boundary at Mokra (Devonian, Moravia, Czechoslovakia).- Sbor. geol.
Ved, Paleont. 30: 61-84.- <b>FC&#038;P 18-1</b>, p. 33,
ID=2233^<b>Topic(s): </b>; fossils; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography:
</b>Czech Republic, Moravia^The reef-building fauna of the Mokra
section, extincted in the upper part of the conodont Palmatolepis
crepida Zone. Into the lower Famennian, penetrated namely less
diversified euryfacies species. The decrease in the diversity is being
associated with the Kellwasser eustatic and climatic events proved
today, from a general viewpoint, from the mid-levels of the
Palmatolepis gigas Zone up to its top (Walliser 1985, 1986) and
supposed up to the mid-levels of the Palrnatolepis triangularis Zone
(the so-called Crickites Event - Kalvoda 1986). In the Section, the
Frasnian &#47; Famennian boundary is restricted to the gap between the
intervals I and II. Under the gap, occur Scoliopora kaisini (Lecompte)
and the foraminifers Nanicella sp. - species so far found in Moravia
exclusively up to the upper limit of the conodont Palmatolepis gigas
Zone, while above the gap lower Famennian Labechia cumularis Yavorskiy
and Syringopora volkensis Tschernyshev appear already. The gap very
likely involves the current critical interval of the Frasnian &#47;
Famennian boundary corresponding to the lower third of the Palmatolepis
triangularis Zone. By contrast, the prominent lithologic change between
the Macocha and Lisen Formations (above int. IV) and extinction of
sessile benthos (by 3 to 5 cm lower in the section) do not lack a
biostratigraphic record - both the underlying and overlying levels
provide autochthonous conodonts of the upper part of the Palmatolepis
crepida Zone.^1";
s[385] = "MAY A. (1990).- Corals and other reef building organisms of
the higher Eifelian and lower Givetian (Devonian) from the northwestern
Sauerland (Rhenish Schiefergebirge).- Muenster University, Unpublished
thesis: 452 pp., 51 figs., 49 pls [in German with English summary].-

constructors; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Devonian Eif &#47; Giv; <b>Geography: </b>Germany,
Rhenish Mts^The Ihmert Formation is subdivided into Bergfeld-Member
(lower Upper Eifelian). Gruenewiese-Member (uppermost Eifelian). and
Dannenhoefer-Member (lowermost Givetian). The material has been
collected mostly in the coral limestones of the Gruenewiese-Member and
the Bredenbruch-Member (lower Lower Givetian) of the
Unterhonsel-Formation. From the Middle Eifelian to middle Lower
Givetian of the northwestern Sauerland (Eastern Rhenish
Schiefergebirge) 30 different tabulate corals and 21 different rugose
corals are described, as well as 21 species of stromatoporoids, 16 of
calcareous algae, and 2 of chaetetids. Only the tabulate coral
Squameoalveolites strigosus cusanorum n.ssp., the rugose coral
Smithiphyllum kloeckneri n.sp., and an unnamed calcareous red alga are
new. 5 tabulate corals, 3 rugose corals, 3 stromatoporoids, and 1
calcareous alga are described for the first time from Central and
Western Europe, but this fauna is in good accordance with the
reef-builder fauna of the Eifel Hills and Ardennes. Many species show
an important expansion of their known stratigraphical range. The most
Devonian reef-builders allow only rough stratigraphical
classifications. [first fragment of extensive summary]^1";

northwestern Sauerland (Eastern Rhenish Schiefergebirge) deposited
shallow marine carbonatic sediments of upper Eifelian to Givetian
(Middle Devonian) age contain numerous tabulate corals and rugose
corals, stromatoporoids, chaetetids, and calcareous algae. Their
investigation allows conclusions about the paleoecology and the
paleobiogeography.^1";
s[387] = "WEYER D., ZAGORA K. (1990).- Die ehemalige
Givet-Fossilfundstelle Buechenberg im Unterharz.- Hall. Jb. Geowiss.
15: 21-42. [in German, with English summary].- <b>FC&#038;P 20-2</b>,
p. 54, ID=2929^<b>Topic(s): </b>; paleontology; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian Giv;
<b>Geography: </b>Germany, Harz^Buechenberg fossils (Rugosa,
Trilobita), described by Roemer (1843 - 1855) come from locally
developed Greifenstein facies within the off-reef realm of the
Stringocephalus Limestone. Outcrops on the north flank of Buechenberg
anticline (north of Elbingerode) had arised and vanished in connection
with iron ore mining, and most fossils always had been collected from
loose debris material only. Conodonts indicate the varcus zone
(probably middle varcus at all) in accordance with old ammonoid records
(Koch 1896, Maenioceras terebratum zone) from nearby pelagic cephalopod
limestones. The trilobite fauna corresponds to the facially identical
Acanthopyge-Phaetonellus community of Bohemian Lower Eifelian.
Concomittantly occurs a tentaculitic association of
postotomari-bianulifera zones. Anthozoa bearing beds are differentiated
into Amplexus-limestone and Bainbridgia-limestone. (Original summary) *
The chapter Anthozoa contains figures of Amplexus? hercynicus Roemer
1855, Laccophyllum sp., Cyathaxonia? hercynica Roemer 1855, and
Bainbridgia alternans (Roemer 1850).^1";
s[388] = "MAY A., BECKER T. (1996).- Ein Korallen-Horizont im Unteren
Banderschiefer (hoechstes Mittel-Devon) von Hohenlimburg-Elsey im
Nordsauerland (Rheinisches Schiefergebirge).- Berliner
geowissenschaftliche Abhandlungen E18: 209-241.- <b>FC&#038;P 25-2</b>,
p. 38, ID=3122^<b>Topic(s): </b>biostratigraphy; coral horizon;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian
Giv; <b>Geography: </b>Germany, Rhenish Mts, Sauerland^Basinal shales
of the Lower Banderschiefer Formation (Upper Givetian, Pharciceras
Stufe) yielded for the first time in Hohenlimburg-Elsey (City of Hagen,
northern Rhenish Massiv) an allochthonous shallow-water fauna dominated
by corals. Among a total of twenty-four taxa the solitary Rugosa
Acanthophyllum concavum simplex and Macgeea multizonata as well as the
branching tabulates Alveolites (Alveolitella) polenowi and Scoliopora
denticulata are abundant. Other Rugosa, Tabulata, stromatoporoids,
brachiopods, crinoid ossicles and nautiloids occur as minor faunal
elements. M. multizonata, A. (Alv.) polenowi and &#034;Chaetetes&#034;
barrandei are recorded for the first time from Germany. The unusual
local lack of coarse crinoidal reef debris suggests as source a
subtidal coral garden which grew marginally on top of the drowned
Steltenberg Reef from where individual specimens were washed downslope
during storm events. The fauna combines Upper Givetian and Lower
Frasnian species and contributes to the understanding of coral
biostratigraphy at the Middle &#47; Upper Devonian transition.^1";

```

```
the Middle Devonian in the northwestern Sauerland includes two coral
limestone horizons, which contain a rich fauna of corals,
stromatoporoids, and calcareous algae. The Ihmert-Formation is
subdivided into three parts. The older coral limestone horizon is the
Gruenewiese-Member of the Ihmert-Formation (uppermost Eifelian), the
younger is in the Bredenbruch-Member of the Unterhonsel-Formation
(lower Lower Givetian). Conclusions about the environmental constraints
are drawn from the sedimentology and the fossil content of the coral
limestones. Predominant biostromes are built between storm wave base
and normal wave base. Only the few bioherms grew above the normal wave
base. These coral limestones were deposited in a tropical or
subtropical normal marine environment in the shallow euphotic zone.
Among the reef-builders epoecism is very frequent, and until now this
phenomenon has not been investigated in detail. Fragile rugose and
tabulate corals lived as commensals with stromatoporoids. Some other
aspects of paleoecology are concisely presented.^1";
s[390] = "MAY A. (1994).- Paleoecology and paleobiogeography of corals
and other reef-builders from the Middle Devonian of the Sauerland
(Germany).- Courier Forschungsinstitut Senckenberg 172
[Oekentorp-Kuester P. (ed.) Proceedings of the VI. International
Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 147-159.-
<b>FC&#038;P 23-1.1</b>, p. 17, ID=4072^<b>Topic(s): </b>ecology,
biogeography; ecology, biogeography; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Devonian Eif/Giv; <b>Geography:
</b>Germany, Rhenish Mts^In the NW Sauerland the coral limestone
horizons of the uppermost Eifelian and the Lower Givetian show a very
rich content of fossils: 28 tabulate coral species, 21 rugose coral
species, 21 stromatoporoid species, 2 chaetetid species, and 16
calcareous algae species were identified by the author. They generally
lived in a warm, normal marine environment in the shallow euphotic
zone. An analysis of the lagoonal Massenkalk sediments (upper Lower
Givetian to Frasnian) shows intertidal to subtidal cyclic
sedimentation. Herein several reef-builder associations can be
recognized. Their composition and distribution depend on water depth as
well as on the restriction of their environment. The Upper Eifelian and
Lower Givetian reef-builder fauna of the Sauerland corresponds to the
fauna of the Eifel Hills and the Ardennes, but a few of the Sauerland
species are up to now only known from occurrences east of it. The
&#034;Rhenohercynian Basin&#034; was a marginal sea, into which faunas
from the Asiatic part of the &#034;Old World Realm&#034; immigrated. A
marine connection to the &#034;Eastern Americas Realm&#034; was opened
in the Upper Givetian.^1";

(2002).- Toward an exact age of Middle Devonian Celechovice corals - Past problems in biostratigraphy and present solutions complemented by new magnetosuceptibility measurements.- Coral Research Bulletin 7: 065-071. [Dieter Weyer&#039;s 65th birthday commemorative volume; S. Schröder, H. Löser &#038; K. Oekentorp (eds)].- <b>FC&#038;P 31-1</b>, p. 33, ID=7100^<b>Topic(s): </b>biostratigraphy; coral fauna; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Devonian Giv; <b>Geography: </b>Czech Republic, Moravia, Celechovice^First discovery of the rich coral faunas of the Celechovice (Moravia) section was in the 1830s. This Celechovice section belonged to the classical outcrops which were visited by prominent geologists who first described the Devonian system. However, a mistaken identification of the brachiopod, &#034;Stringocephalus burtini&#034;, in a position below the coral horizon with Calceola sandalina presented a long-term biostratigraphic problem. Because of this identification, many paleontological papers pushed the age of this coral horizon to the Late Givetian. An opposite trend (i.e., to keep the age of the coral horizon close to the Eifelian/Givetian boundary) began with regional correlation of trilobites (Schizoproetus) in 1960s. This continued with revisions of thick-shelled brachiopods (&#034;Stringocephalus&#034; = Kaplex obesissimus Ficner &#038; Havlicek 1975) in the 1970s, and it culminated in 1990s, with numerous studies on trilobites, corals, conodonts, dacryoconarids and crinoids. In spite of these modern biostratigraphic data, the exact age of the coral horizon remained
```

```
unclear. It fluctuated within a wide range between the
Eifelian/Givetian and Lower/Middle Givetian boundaries.
Magnetosusceptibility stratigraphy allows the projection of the E/G
GSSP (Jbel Mech Irdane, Morocco) 5m below the base of the Celechovice
Upper Dark-colored Interval (abbrev. CUDI; beds 117-146), approximately
10m below the most productive, world-famous Celechovice &#034;Fossil
Korallen-Lagerstätte&#034;. According to the correlation of the
magnetics with the standard conodont zones, the age of the richest
Celechovice coral fauna is between the earliest Givetian hemiansatus
and Early varcus zones. [original summary]^1";

(Schlueter 1889), Coenites vermicularis (McCoy 1850), and Platyaxum
(Roseoporella) gradatum (Lecompte 1939) as well as the rugose corals
```

```
Cyathophyllum (Peripaedium) planum (Ludwig 1866), Acanthophyllum
heterophyllum (Milne-Edwards &#038; Haime 1851), and Mesophyllum
(Mesophyllum) cylindricum (Schlueter 1882) are described from the Upper
cultrijugatus Beds south of Kierspe, respectively west of Meinerzhagen.
Schistodictyon amygdaloides subvesiculosum, Alveolites (Alveolites)
intermedius, and Coenites vermicularis are found in the Eastern Rhenish
Massif for the first time. The coral limestones originated in a period
of reduced sediment supply within a tropical or subtropical, shallow
marine environment. The stratigraphical ranges of the investigated
reef-builders demonstrate, that the reef-builder fauna was not affected
perceptibly by the jugleri Event (= Chotec Event) of the Lower
Eifelian. Instead of this, the reef-builder fauna shows a remarkable
continuity within the whole Eifelian.^1";
s[402] = "MAY A. (1993).- Stratigraphie, Stromatoporen-Fauna und
Paloekologie von Korallenkalken aus dem Ober-Eifelium und
Unter-Givetium (Devon) des norwestlichen Sauerlandes (Rheinisches
Schiefergebirge.- Geol. Palaeont. Westf. 24: 5-93. [in German, with
English summary].- <b>FC&#038;P 23-1.1</b>, p. 83, ID=4190^<b>Topic(s):
</b>biostratigraphy, ecology; stratigraphy,, stroms, ecology;
<b>Systematics: </b>Cnidaria Porifera; Anthozoa Stromatoporoidea;
<b>Stratigraphy: </b>Devonian Eif &#47; Giv; <b>Geography: </b>Germany,
Rhenish Mts, Sauerland^The prevailing sandy-silty lower part of the
Middle Devonian in the northwestern Sauerland includes two coral
limestone horizons, which contain a rich stromatoporoid fauna besides
many corals (Tabulata and Rugosa) and calcareous algae. Bryozoans are
unimportant reef-builders. The entire fossil content is listed up and
concisely discussed. At first the lithostratigraphical subdivision, the
biostratigraphical classification, and the facies of the sequence are
discussed. The Ihmert-Formation is subdivided into Bergfeld-Member
(lower Upper Eifelian), Gruenewiese-Member (uppermost Eifelian), and
Dannenhoefer-Member (lowermost Givetian). 21 stromatoporoid species are
described from the coral limestone horizon of the Gruenewiese-Member
and the Bredenbruch-Member (lower Lower Givetian) of the
Unterhonsel-Formation. The classification of stromatoporoids by Stearn
(1980) is applied with minor modifications. Dendrostroma fibrosum
Galloway 1960, Trupetostroma dushanense Yang &#038; Dong 1963 and
Stachyodes (Stachyodes) dendroidea kuznetskensis (Yavorsky 1957) have
been found in Europe for the first time. 8 other stromatoporoids are
described from the Rhenish Massif for the first time as well.
Lectotypes are designated for Actinostroma dehornae densicolumnatum
Lecompte 1951, Stromatoporella solitaria Nicholson 1892 and Stachyodes
(Stachyodes) dendroidea kuznetskensis (Yavorsky 1957). Synthetostroma
Lecompte 1951 is considered as a subgenus of Clathrocoilona Yavorsky
1931. Clathrocoilona spissa (Lecompte 1951) is so similar to
Clathrocoilona solidula (Hall &#038; Whitfield 1873) from the Upper
Devonian of the U.S.A., that it is valued as a subspecies of solidula.
Probably the stromatoporoid skeleton consisted originally of
high-magnesian calcite, now less diagenetically altered than aragonite,
but more than calcite. Remarks to the biogeography of Devonian
stromatoporoids are given in this paper. Conclusions about the
environmental constraints are drawn from the sedimentology and the
fossil content of the coral limestones. The predominant biostromes are
built between the storm wave base and the normal wave base. Only the
few bioherms grew above the normal wave base. These coral limestones
are deposited in a tropical or subtropical normal marine environment in
the shallow euphotic zone. Among the reef-builders epoecism is very
frequent, and till now this phenomenon has not been investigated in
such an extensive Devonian material. Some other aspects of
palaeoecology are concisely presented.^1";

The ostracode shells were sealed in by skeletal tissue that was septal in origin (Heliolites) or they were roofed over by tabulae (Favosites). The foreign shell was near the axis of the polyp when trapped within the coral skeleton. Only ostracodes, not other rounded shells or sedimentary particles, were trapped in this way. Approximately one in 30 favositid corallites and one in 70 heliolitid corallites display this peculiar condition, where the ostracode shells seem to have been swallowed by the polyps. A probable scenario involves the injury of the mouth area and the trapping of the ostracodes. A high probability that the basal part of the polyp experienced a controlled penetration is the most striking part of the process.^1";

Heterocorallia; <b>Systematics: </b>Cnidaria; Heterocorallia;
<b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>Poland, Holy
Cross^Studies on the taxonomy and morphology of the Famennian
heterocoral Oligophylloides have placed great emphasis on the character
of the soft tissue, coloniality and distal development of the skeleton
with regard to the construction of the wall. Here, the existence of
soft tissue covering the entire skeleton of the colony is proposed.
Thirty-eight branching specimens have been found in addition to the
predominant single fragments of corallites; these should be regarded as
colonial with a well-developed branching form. It is here proposed that
the external wall grew not only at the distal end, and that its
thickening did not result from the overlapping of tabulae, but was
built independently of tabulae by the soft tissue covering the whole
skeleton of the colony. The following new characteristics of
Oligophylloides are described: a change in the position of septa,
so-called &#039;septal shifting&#039;, a rearrangement of the septal
apparatus; the occurrence of aulos-like structures; a groove
ornamentation on the external wall; and the granular microstructure of
the axial part of septa. A detailed study of Late Devonian
Oligophylloides corals shows that O. tenuicinctus Rozkowska and O.
pachythecus pentagonus Rozkowska are synonymous with O. pachythecus
Rozkowska. [original abstract]^1";

<b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>Poland, Holy
Cross^Coral growth in Heterocorallia is described and illustrated for
the first time. It has been studied in Oligophylloides pachythecus
Rozkowska 1969 from the Upper Famennian of the Swietokrzyskie (Holy
Cross) Mountains, Poland. One single offset at a time was formed
laterally with respect to the parent polyp. It did not inherit any
septa from the parent corallite forming its own, independent set of
septa. The young polyp was for a long time connected with the parent by
soft tissue being separated from its skeleton by a tabulotheca. The
theca and possibly all the other skeletal elements of the species
studied grew centrifugally. Evidence is presented that O. pachythecus
had a distal part of its corallite in the shape of a slender distal
cone with a set of septa protruding on top of the cone. [original

Plectodiscus discoideus (Rauff): a redescription of a chondrophorine
from the Early Devonian Hunsruck Slate, West Germany.- Paläontologische
Zeitschrift 57: 39-68.- <b>FC&#038;P 12-2</b>, p. 46,
ID=6247^<b>Topic(s): </b>taxonomy; Hydrozoa, Chondrophorina;
<b>Systematics: </b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>Devonian
L; <b>Geography: </b>Germany, Hunsruck^Additional specimens of a
&#034;by-the-wind sailor&#034; (vevellid hydrozoan) from the Hunsruck
Slate indicate that Palaeonectris Rauff is a subjective synonym of
Plectodiscus Ruedemann. Silurovelella Fisher is also judged to be a
synonym of Plectodiscus. The nature of the matrix and the degree of
decay and flexing of the pneumatophore disc affect preservation of
these fossils. The internal chitinoid gas-filled float structure of
Plectodiscus discoideus is often preserved as a concentrically
laminated, oval disc. After death of the organism, it was separated
from the soft tissues and before burial in the sediment, it may have
been transported by the wind and surface currents. Some new details are
added to the anatomy of P. discoideus (Rauff), and a new reconstruction
is presented. [original summary]^1";
s[419] = "HERGARTEN B. (1985).- Die Conularien des Rheinischen Devons.-
Senckenbergiana lethaea 66, 3/5: 269-297.- <b>FC&#038;P 14-2</b>, p.
47, ID=0906^<b>Topic(s): </b>taxonomy; Conulata; <b>Systematics:
</b>Cnidaria; Hydrozoa; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Germany, Rhenish Mts^The present paper is introduced by a survey of
the stratigraphic distribution of about 90% of the actually known
species of the Conulata as well as of the range of their genera. - In
the Rhenish Devonian of W.Germany, these invertebrate fossils are
extremely rare. All of the 18 species recorded till now belong to the
family Conulariidae. With the exception of the four conulariid species
of the Lower Devonian Hunsruck Shale, these taxa are revised
respectively described as new. - The Lower Devonian Conularia
subparallela G. Sandberger 1847 and the Middle Devonian species
Conularia gerolsteinensis Archiac &#038; Verneuil 1842 and Conularia
dencknanni n.sp. belong to the subfamily Conulariinae. The Middle
Devonian Paraconularia deflexicosta (G. Sandberger 1847) is placed
among the Paraconulariinae. The Lower Devonian species Climacoconus
imodevonicus n.sp. is attributed to the Ctenoconulariinae, with
reservation also the genus Holoconularia n.g. with the type species
Holoconularia hummeli (Kegel 1926), Holoconularia fimbriata (Walther
1903), and Holoconularia kiderleni n.sp. from the Lower Devonian and
with Holoconularia eifliensis (Steininger 1853), Holoconularia richteri
n.sp., Holoconularia geesensis n.sp., and Holoconularia? rospensis
n.sp. from the Middle Devonian; Holoconularia ornata (Archiac &#038;
Verneuil 1842) is the only Upper Devonian species.^1";

(Unter-Devon) [Conulariids of the Hunsrueckschiefer (Lower Devonian)].-
Senckenbergiana lethaea 74, 1/2: 273-290. [in German, with English
summary].- <b>FC&#038;P 23-2.1</b>, p. 63, ID=4422^<b>Topic(s):
</b>taxonomy; Conulata; <b>Systematics: </b>Cnidaria; Hydrozoa;
<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>Germany,
Hunsruck^The Conularia species from the Lower Devonian
Hunsrueckschiefer are reviewed based on new material. In addition to
the four species already known from the Hunsrueck region, five further
species are described as new, one also from the Hunsrueck (Conularia
hunsrueckiana) and four from the &#034;Hunsrueckschiefer&#034; of the
Eifel region (C. mayenensis, C. bausbergensis, C. bartelsi and
Sinusconularia blasii). The new genus Sinusconularia (Suborder
Circonulariina Bischoff 1978) is described. The species from the
typical Hunsrueck region, i.e. from the slate pits at Bundenbach and
Gemuenden, are assigned to the Lower Emsian substage. However,
according to Meyer (1986), for the species from the Eifel region, i.e.
from the slate pits at Mayen and Kehrig, a Siegenian age is adopted.
The evaluation of X-ray photographs is discussed with regard to the
&#034;Chordata theory&#034; held by Steul (1984).^1";

</b>new taxa; Rugosa, Neaxon; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>Germany,
Thuringia^From cephalopod limestones dated as upper Cheiloceras-Stufe
(lower marginifera zone) and quarried near Rodersdorf north-northeast
of Schleiz (northwestern border of Berga anticline), the new species
Neaxon cheilos is described, with discussions on stratigraphic
distribution of the genus Neaxon Kullmann 1965, and on taxonomy of the
subfamily Neaxoninae Hill 1981. The &#034;third order&#034; septa
regularly distributed between all major and minor septa in high
calicular regions of Neaxon regulus (R. Richter 1948) and Ufimia
tricyclica (Schindewolf 1942) seem similar to hyposepta, but differ in
their primary absence just as the most distal calicular margin. The new
morphological term meiosepta is proposed for these structures appearing
in a short distance below the upper calicular rim, functioning as
active septa in a small zone of the highest calice, and disappearing by
secondary incorporation into the thickening archaeothecal wall not far
from the distal margin.^1";

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Spain, Cantabrian Mts^Most rugose
corals from the Devonian of the Cantabrian Mountains (NW Spain) can be
dated in terms of conodont zones. * At present the base of the
Polygnathus costatus partitus Zone is accepted as being the
Lower-Middle Devonian boundary. In the Asturo-Leonese region of the
Cantabrian Mountains the equivalent to that boundary could be the base
of the Icriodus retrodepressus Zone. The rugose corals of the Moniello
and Santa Lucia Formations will be analyzed in relation to this
stratigraphic position. Recently, the Middle-Upper Devonian boundary
has been interpreted as being the base of the Lower Polygnathus
asymnetricus Zone, equivalent to the transition Ancyrodella
binodosa-Ancyrodella rotundiloba. The association of rugose corals from
the Candas and Portilla Formations are listed with respect to this
```

```
transition which is well established in the Cantabrian Mountains.

s[440] = "COEN-AUBERT M. (2004).- Two new species of Temnophyllids
(Rugosa) from the Upper Givetian of Belgium.- Bulletin de
l&#039;Institut royal des Sciences naturelles de Belgique, Sciences de
la Terre 74: 19–34.- <b>FC&#038;P 33-2</b>, p. 14, ID=1109^<b>Topic(s):
</b>new taxa; Rugosa, Temnophyllum; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Giv; <b>Geography:
</b>Ardennes^Temnophyllum delmeri n.sp., and T. ramosum n.sp. are
described in detail and come from theUpper Givetian of Belgium. On the
south side of the Dinant Synclinorium, T. delmeri is associatedwith
Sunophyllum beichuanense He, 1978 and Wapitiphyllum laxum (Gürich,
1896), at the top ofthe Mont d&#39;Haurs Formation. It is also present
in the Flohimont Member, the lower subdivision ofthe Fromelennes
Formation. At the base of the overlaying Moulin Boreux Member, there is
a levelof limestones rich in stringocephalids, diverse groups of
tabulate corals and in rugose coralsrepresented by W. laxum,
Temnophyllum ramosum, T. delmeri and locally Sunophyllumbeichuanense.
Nearly all these fossils disappear higher in the Moulin Boreux member.
The samesituation has been observed in the Philippeville Massif, on the
north side of the DinantSynclinorium and in the Vesdre Massif. As the
base of the Flohimont Member lies at the top of theLower Polygnathus
varcus Zone and as the major part of this lithographic unit belongs to
the P.ansatus Zone corresponding to the Middle P. varcus Zone, it is
quite possible that the Taghanicevent occurs in Belgium just above the
level of limestones with the last stringocephalids.^1";
s[441] = "PLUSQUELLEC Y. (2005).- Hadrophyllum asturicum n.sp., Rugosa

The framework of these investigations is provided by the recent revision of the lithostratigraphic units supervised by the Belgian Commission on Devonian Stratigraphy.^1";
s[453] = "GLINSKI A. (2001).- Tryplasma (Anthozoa, Rugosa) im Mittel-Devon der Eifel (Rheinisches Schiefergebirge, Deutschland).- Senckenbergiana lethaea 81, 1: 71-89.- <b>FC&#038;P 30-2</b>, p. 15, ID=1558^<b>Topic(s): </b>; Rugosa, Tryplasma ; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Germany, Rhenish Mts^The genus Tryplasma Lonsdale 1845 with the species Tryplasma rohrensis n.sp. (family Tryplasmatidae Etheridge 1907) has been recorded from the middle and western European Middle Devonian for the first time. Tryplasma is widely distributed in the lowermost part of the coral-rich Niederehe Subformation (Eifelian, Ahrdorf Formation) of the Eifel Mountains. From investigation of the trabecular microstructure of the new species Tryplasma rohrensis in view of its taxonomic value and related terminology, the hitherto preferred idea of &#034;rhabdacanths&#034; sensu Hill (1936) cannot be fully accepted and is instead contrasted with the concept of &#034;Primärseptum&#034; of some earlier authors. Microscopic analysis revealed identical acanthine characteristics in a species of the tabulate genus Syringocystis Deng 1966, thus suggesting a basic revision and reinterpretation of its systematic position. Syringocystis can clearly be compared with Tryplasma and so possibly classified as a rugose coral. The horizon with Tryplasma constitutes a sharp stratigraphical marker. Its horizontal distribution supports the isochronic correlation of the Niederehe reefal facies in the individual Eifel Synclines and, in addition, confirms the traditional dating of
```

```
the stratigraphic boundary layers of the Ahrdorf and Junkerberg
formations. There is no age relationship between the Antoniusbusch Reef
near Rohr and the Bouderath Reef (Hollerberg) in the eastern
Blankenheim Syncline, which belongs to the Nohn Formation. Regional
analysis of Tryplasma occurrences indicates many biostratigraphical
parallels between the Eifel region and the Russian Devonian provinces
in Europe and Asia as well as Middle Devonian areas in China and
Australia and points to certain paleogeographic connections.^1";
s[454] = "SCHRODER S. (2001).- Wenig bekannte rugose Korallen aus dem
Mittel- und Oberdevon der Aachener Mulde (Rheinisches

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian M
U; <b>Geography: </b>Germany, Aachen syncline^Some taxa of
insuffciently known rugose corals are described from the Upper Givetian
of Friesenrath and the Frasnian-Famennian boundary-beds near Werth in
the Aachen Syncline: Tabulophyllum aff. cylindricum Walther 1928,
Temnophyllum blacourti (Rohart 1988), Spinophyllum cf. spongiosum
(Schlüter 1889), Macgeea recta (Walther 1928), Hexagonaria? sp. W,
Frechastraea pentagona minima (Rózkowska 1953) and Frechastraea cf.
carinarta Scrutton 1968. Rugose corals are generally rare within this
stratigraphical interval and thus are important records for the Aachen
Syncline. In addition, clear faunistic relationships in regard to
faunas known from France (Ferques) and Belgium are recognizable.^1";
s[455] = "SCHRODER S., SALERNO C. (2001).- Korallenfauna und Fazies
givetischer Kalksteinabfolgen (Cürten-/Dreimühlen-Formation) der
Dollendorfer Mulde (Devon, Rheinisches Schiefergebirge &#47; Eifel).-
Senckenbergiana lethaea 81, 1: 111-133.- <b>FC&#038;P 30-2</b>, p. 18,
ID=1565^<b>Topic(s): </b>facies, shallow-marine; shallow marine facies;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Giv; <b>Geography: </b>Germany, Eifel^The descriptive terms
&#034;Leperditien-Kalke&#034; and &#034;Klotzige Bank-Kalke&#034; were
introduced by Kräusel (1953) during the reinvestigation of the
Dollendorfer Mulde and describe two lower Givetian limestone intervals,
each of about 15 to 20 m thickness. As none of those limestones yield
biostratigraphically relevant macrofaunas, the age of both deposits can
be estimated only approximately, considering the position of both
between the well correlated Cürten and Rodert Formations. Examination
of the sections revealed four facies types, characteristic for a
shallow marine, peritidal setting. The limestones are composed mainly
of calcisphere ostracode wackestones or peloidal
calcisphere-ostracod-packstones. Together with amphiporoid-floatstones
they indicate lagoonal and restricted environmental conditions.
Intercalated amphiporoid rudstones suggest temporarily more agitated
water conditions. Remarkable thrombolithic bindstones occur with a
partly stromatactoid fabric yielding cortoiods and Algae of the genus
Issinella Reitlinger 1954 and Jansaella Mamet &#038; Roux 1975.
Deposition of several stromatoporoid coral rudstone layers indicates a
greater water depth with more open marine influence.Eleven taxa of
rugose corals can be recognized. Most of those are related to small
trochoid zaphrentids or charactophyllids, which were able to survive in
the restricted conditions of a lagoonal environment. Common species are
Glossophyllum sp. cf. schouppei, Grypophyllum sp. and Sinodisphyllum
sp. Pseudozaphrentis intermissa n.sp. Schröder is described as a new
species.^1";

</b>Poland S^After the Frasnian-Famennian extinction the colonial
Rugosa disappeared almost entirely from the fossil record. New data
```

```javascript
indicate that during the Late Famennian radiation colonial Rugosa
evolved rapidly within isolated areas and became an important component
of coral assemblages of the southern Poland. The assemblages consist of
surviving taxa (Smithiphyllum aff. imperfectum and 4 Famennian species
of Scruttonia), homeomorphic taxa (2 species of Pseudoendophyllum) and
one new Famennian genus (Heterostrotion). The pattern of extinction and
recovery of colonial Rugosa seems to have followed the following rule:
survivors from the F-F crisis went extinct after the Famennian
radiation (the D-C extinction), and the homeomorphic species, as well
as new taxa, survived subsequent D-C extinction.^1";

Ferques, Boulonnais - France.- Biostatigraphie du Paléozoïque 7 [BRICE
D. et al. (eds)]: 231-296.- <b>FC&#038;P 16-1</b>, p. 20,
ID=1935^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography:
</b>France, Boulonnais^&#192; partir des récoltes banc par banc, 39
espèces parmi les plus communes sont décrites et figurées dont 9
nouvelles et 4 laissées en nomenclature ouverte.L&#039;étude historique
montre que 2 seulement avaiant déjà été citées dans le Boulonnais et
que la plupart des 47 noms anciens attribués aux rugueux boulonnais
jusqu&#039;ici (tableau 1) doivent être abandonnés. La repartition
stratigraphique est résumée dans le tableau 2. La série stratigraphique
qui a livré des rugueux s&#039;étend de la Zone à ensensis supérieure
(Givétien) à la Zone supérieure à asymmetricus (Frasnien). Les
Disphyllidés dominent tant en nombre d&#039;espèces qu&#039;en nombre
d&#039;individus. La plupart des formes possèdent une extension
stratigraphique limitée comparable à celle qu&#039;elles ont dans des
régions voisines. Au Givétien, quelques espèces sont communes avec le
Massif Schisteux Rhénan; au Frasnien, c&#039;est avec l&#039;Ardenne et
la Pologne que l&#039;on remarque les plus grandes affinités. Mais la
valeur de ces observations est limitée par la connaissance incomplète
que l&#039;on a des faunes coralliennes européennes spécialement au
Givétien et en Allemagne. La succession des faunes de rugueux, mise én
evidence par Galle (1985), en Moravie, se retrouve &#34;en gros&#34;
dans le Boulonnais au niveau générique mais les espèces typiques sont
différentes. La partie systématique décrit les 39 espèces suivantes
placées dans 22 genres en portant, chaque fois que cela est possible,
une attention particulière à la variation et à la structure fine :
Lythophyllum secundun secundum (Goldfuss 1826), L. secundun
conistructum (Quenstedt 1879), L. secundum pseudoseptatum (Schulz
1883), Mesophyllum cristatum (Schlueter 1882), Metrioplexus richteri
Glinski 1963, M. sp. cf. carinatus Rozkowska 1969, Catactotoechus
variabilis n.sp., Tabulophyllum smithi Tsien 1976, T. sylvaticum n.sp.,
T. vorticis n.sp., Acanthophyllum concavum (Walther 1928),
Ellesmerelasma ? sp. cf. diluvianum (Wedekind 1925), Stringophyllum
isactis (Frech 1886), Gaofengophyllum cf. longiseptatum (Bulvanker
1958), Columnaria ? sp. cf. junkerbergiana Glinski 1955, Disphyllum
rugosum (Wedekind 1922), D. pashiense (Soshkina 1939), D. lazutkini
(Ivaniya 1953), D. gradatum Tsien 1970, D. grabaui Tsien 1970,
Pseudohexagonaria amanshauseri (Glinski 1955), P. glinskii (Tsien
1977), Disphyllia wangi (Tsien 1977), D. hamoriensis (Tsien 1977), D.
periclada (Kraemer 1982), D. magnei n.sp., Aristophyllum lemaitreae
n.sp., Hexagonaria marmini (Milne-Edwards et Haime 1851), H. mirabilis
Moenke 1954, Hexagonaria mae Tsien 1977, H. mireillae n.sp.,
Cystohexagonaria defecta n.sp., Temnophyllum longiseptatum (Luette

Limestone from Resteigne, with B. parvistella (Schlueter 1882). In this
locality and at Pondrome, Sociophyllum elongatum (Schlueter 1881), S.
torosum (Schlueter 1881) and S. birenheidei n.sp. occur in the same
level. Four of these taxa characterize the Loogh Formation, at the base
of the Givetian from the Eifel Hills in Germany. The Couvinian species
Beugniesastraea varia (Schlueter 1889) is also described.^1";
s[487] = "BIRENHEIDE R. (1988).- Middle &#47; Upper Devonian boundary
coral stratigraphy in the Rhenish Mountains of W Germany.- Canadian
Society of Petroleum Geologists, Memoir 14 [McMillian N. J., Embry A.
F. &#038; Glass D. J. (eds): Devonian of the World], III: 141-145.-
<b>FC&#038;P 18-2</b>, p. 29, ID=2467^<b>Topic(s): </b>biostratigraphy;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Giv/Fra; <b>Geography: </b>Germany, Rhenish Mts^Since
investigations of Frech (1885, 1886), Paeckelmann (1913) and Walther
(1928), only sporadic work has been done on the coral faunas of the
Middle &#47; Upper Devonian boundary beds of the Rhenish Mountains.
Recent studies based on new material mainly collected by the author
yielded the following results: Whereas rugose corals of the upper
Givetian time-equivalent Kerpen, Buechel and Schwelm Formations are
relatively abundant and well known also at comparable stratigraphic
levels all over the world, they become rare in uppermost Givetian and
lowermost Frasnian beds. Such units are represented in W. Germany by
the Wallersheim Formation (Eifel hills), the &#034;Grenzschiefer&#034;
(Walheim, near Aachen), the &#034;Plattenkalk&#034; (Upper Bergisch
Land), and the &#034;Flinz&#034; and Dorp Limestones (Lower Bergisch
Land, Sauerland). These transitional units with thickness of more than
one hundred metres at some localities contain rugose corals which
proved to be Middle &#47; Upper Devonian mixed faunas; moreover there
is some difference between the coral faunas of the lower and upper
parts of the transitional successions. In the lower parts corals of the
Middle Devonian genera Acanthophyllum, Grypophyllum and Battersbyia (or
Fasciphyllum) are still present, whereas stringophyllids are entirely
lacking. Temnophyllum and allied forms as well as different
&#034;caespitosans&#034; also occur, but seem to be of little
stratigraphic value for a boundary discrimination. In the Lower
&#034;Plattenkalk&#034; we also meet the last (?) representatives of
Disphyllia and the first specimens of probably Wapitiphyllum. At other
outcrops which apparently represent the middle part of the transitional
succession, a more or less mixed fauna is present; the previously
mentioned genera are still recorded, but now more Upper Devonian
elements appear for the first time, with rare specimens of
Tabulophyllum sensu stricto (broad tabularium, no fossula) and of
Pexiphyllum. Finally, in outcrops of the upper parts of the
transitional beds the first representatives of the massive coral
species Hexagonaria hexagona (= sedgwicki of Paeckelmann),
```

```
Phillipsastrea hennahi and Frechastraea sanctacrucensis occur,
accompanied by small as well as large specimens of Pexiphyllum. These
upper parts often contain brachiopods and sometimes also trilobites of
Upper Devonian character. But we also found in them the very last
representatives (one specimen respectively) of the Middle Devonian
genera Acanthophyllum (probably n.sp.) and Cystiphylloides.^1";

Phaceloid-Korallen aus dem Ober-Givetium (Mittel-Devon) des
Kantabrischen Gebirges, NW-Spanien.- Palaeontographica A221, 4-6:
95-123.- <b>FC&#038;P 21-1.1</b>, p. 42, ID=3213^<b>Topic(s): </b>;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Giv; <b>Geography: </b>Spain, Cantabrian Mts^From four
outcrops of the Portilla Fm. and one outcrop of the Candas Fm. in the W
Cantabrian Mountains 17 species and subspecies of solitary and
phaceloid rugose corals are described. They belong to 15 different
genera. The stratigraphical classification of four of the localities in
question as Upper Givetian is confirmed by means of the identified
coral faunas, and this age is also probable for the fifth locality. The
rugose coral genera Breviseptosia n.gen. and Sinaxis n.gen. are erected
in this paper, moreover the following 13 new species and subspecies are
described and figured: Schindewolfia plena n.sp., Neaxon variabilis
n.sp., Catactotoechus bonarensis n.sp., Metrionaxon transitorius n.sp.,
Famennelasma antiquum n.sp., Breviseptosia pulchra n.gen. et n.sp.,
Sinaxis bulbosa n.gen. et n.sp., Cyathophyllum (C.) postarduum n.sp.,
Thamnophyllum caespitosum leonense n.ssp., Acanthophyllum confusum
```

```
n.sp., Stringophyllum buechelense cantabricum n.ssp., Stringophyllum
crassimargjnatum n.sp. and Soliptera fontainei n.sp. The number of
genera and species of the normally as ahermatypic classified small
solitary corals without dissepimentarium is unusually great with
respect to the reef facies of the Portilla Formation. A part of them
even occurs together with compact flat colonies of back reef corals of
the subfamily Phillipsastreinae. Moreover at other localities such
small corallites also occur together with aggregates of cylindrical
corals of the &#034;reef meadows&#034; or even together with large
solitary corals. So we have to assume that the &#034;Portilla
environment&#034; of the investigated localities was characterized by a
very narrow-spaced irregular morphological pattern of its sea bottom.^1";

<b>FC&#038;P 22-2</b>, p. 12, ID=3443^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Eif
&#47; Giv; <b>Geography: </b>Germany, Eifel^The traditional Eifelian
&#47; Givetian boundary is defined by the first occurrence of the
brachiopod genus Stringocephalus (boundary sensu Beyrich 1837; Struve
1961). In the Eifel Hills this boundary is located between the Upper
Eifelian Ahbach and the Lower Givetian Loogh Formation. In the light of
actual discussions of new definitions by means of conodonts, the
distribution of rugose corals has been investigated within this
stratigraphic range. In the northern Eifel Hills the Upper Eifelian is
not characterised by a typical association of rugose corals. Many of
the well known genera and species show a long stratigraphic range and
some of them are still common in the Lower Givetian. Only a few taxa
become extinct at the top of the Ahbach Formation. In the Lower
Givetian the composition of the coral association changed, caused by
the appearance of new taxa. The association is now dominated by small
cornute corals (e.g., Schlueteriphyllum looghiense, Sch. parvum,
Soetenia struvei, Aristophyllum terechovi) as well as Glossophyllum
soetenicum. From the point of coral development the traditional
Eifelian/Givetian boundary represents a crisis in the northern Eifel
Hills. The boundary is not based on the extinction of many species, but
is reflected by the appearance of the Schlueteriphyllum - Glossophyllum
- Association in the Lower Givetian.^1";

Formation of the Holy Cross Mountains.- Acta Palaeontologica Polonica
37, 2-4: 217-254.- <b>FC&#038;P 23-2.1</b>, p. 39, ID=3488^<b>Topic(s):
</b>new taxa; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography: </b>Poland, Holy
Cross^Rugose corals of the Givetian to Lower Frasnian Kowala limestone
Formationin the environs of Checiny, SW Holy Cross Mts and in its age
equivalents in the Silesian-Cracow region of Southern Poland represent
five distinct assemblages of restricted time-and-space distribution.
Within the Stringocephalus Beds the high diversity Pseudohexagonaria(?)
laxa assemblage indicates open-shelf conditions whereas low diversity
Temnophyllum occidentale assemblage represents restricted conditions.
The transgressive Jazwica Mbr. locally contains diversified and
cosmopolitan Acanthophyllum sp. n. fauna. Following temporally coral
assemblages, i.e. Disphyllum (lower Sitkówka and Checiny Beds) and
Macgeea-Thamnophyllum (Kadzielnia Mbr, upper Sitkówka Beds) are mostly
biostromes of branching corals of low taxonomical diversity typical for
relatively restricted setting, rather unfavorable for rugosans.
Exceptional are two Hexagonaria horizons with common massive colonies.
Diffusolasma gen. nov., Sociophyllum severiacum sp.nov., Temnophyllum
zamkowae sp.nov. and Hexagonaria hexagona kowalae subsp.nov. are
proposed as the new taxa. ^1";

<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Eif
&#47; Giv; <b>Geography: </b>Ardennes^Acanthophyllum heterophyllum
(Milne-Edwards &#038; Haime 1851), A. vermiculare (Goldfuss 1826) and
Aristophyllum luetti n.sp. are described in detail and have been mainly
collected at Pondrome, Wellin and Resteigne where important facies
variations appear near the Eifelian-Givetian boundary. Acanthophyllum
heterophyllum occasionally occurs at the top of the Jemelle Formation,
in the Hanonet and X Formatioms and also at the base of the
Trois-Fontaines Formation. A. vermiculare is mostly characteristic of
the Hanonet Formation, but is still present at the base of the
Trois-Fontaines Formation. Aristophyllum luetti n.sp. is usually
restricted to the upper part of the Hanonet Formation. Thin sections of
the holotype of Acanthophyllum heterophyllum, type species of the genus
Acanthophyllum Dybowski 1873, are figured for the first time.^1";
s[517] = "SCHRODER S. (1997).- Die Rugosen-Fauna des Eilenbergium der
Dollendorfer Mulde (Mittel-Devon &#47; Ober-Eifelium; Rheinisches
Schiefergebirge &#47; Eifel).- Geologica et Palaeontologica 31: 1-36.-
<b>FC&#038;P 26-2</b>, p. 67, ID=3746^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Eif; <b>Geography: </b>Germany, Eifel^As a further contribution to the
knowledge on the Upper Eifelian coral fauna of the Dollendorf Syncline
the rugose corals of the Eilenbergian (Freilingen Formation) are
investigated. The fauna comprises 20 different species; three of them
are new: Spinophyllum incompositum n.sp., Chostophyllum dollendorfense
n.sp. and Grypophyllum duplex n.sp. The insufficiently known and often
misinterpreted species Kunthia crateriformis is revised. In spite of
the fact that corals are generally very rare in the
brachiopod-dominated facies of the Eilenberg Member, the fauna shows a
remarkable high diversity and is characterized mainly by small trochoid
coral species. Next to some well known genera of the Middle Devonian of
the Eifel some species restricted to Upper Eifelian strata and also
species known as ahermatypical have been found. Additionally, two
genera typical for the eastern North American faunal realm were
recorded. The distributional patterns of some species are discussed,
especially in regard to the so called &#034;Glinski-Linie&#034; which
marks a border for faunal exchange between the North- and South-Eifel
in the Dollendorf Syncline.^1";

<b>Geography: </b>Ardennes^Acanthophyllum tortum (Tsien 1969),
Thamnophyllum germanicum Scrutton 1968, T. occlusum (Tsien 1969) and T.
tsieni n.sp. are described in detail and have been mainly collected at
Pondrome, Wellin and Resteigne. The type specimens from several of
these species as well as the holotype of Acanthophyllum vermiculare
(Goldfuss 1826) are refigured herein. Thamnophyllum germanicum has been
found at the top of the Jemelle Formation. T. tsieni and T. occlusum
also occur at the top of this lithostratigraphic unit, but are
particularly abundant in the Hanonet Formation; moreover, T. occlusum
is still present at the base of the Trois-Fontaines Formation.
Acanthophyllum tortum is characteristic of the Hanonet Formation, but
has also been observed in the X Formation and at the base of the
Trois-Fontaines Formation. Finally, the new geological surveys near
Wellin confirm the lateral changeover from the base of the
Trois-Fontaines Formation to the Hanonet Formation.^1";

Eif; <b>Geography: </b>Germany, Eifel^The rugose corals from the
Bouderath-reef and the Holler-Berg in the Frohngau-Engelgau part of the
Blankenheim Syncline have been investigated. The poor rugose
coral-fauna is characterized by a relatively low number of species:
Acanthophyllum heterophyllum, Stringophyllum cf. acanthicum,
Sociophyllum elongatum, Mesophyllum (Mesophyllum) pseudoorthoceras,
Mesophyllum (M.) cf cylindricum. Therefore a comparison with other
localities of &#034;real&#034; Niederehe-reefs of the Ahrdorfian is
impossible. With the occurrence of Sociophyllum elongatum the
stratigraphic range of this species in the Eifel Hills will be
considerably extended.^1";
s[521] = "BERKOWSKI B. (1996).- Strunian corals - examples from Poland
(in Polish with English summary).- Geologos 1: 69-78.- <b>FC&#038;P
27-2</b>, p. 12, ID=3888^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fam; <b>Geography:
</b>Poland^The Strunian, due to its facial character, has no
significant chronostratigraphical or geochronological value. This term,
however, is widely used by coral researchers because it denotes its
own, characteristic coral fauna. During the crisis at the Frasnian
&#47; Fammenian boundary, a variable and rich coral fauna became
strongly depleted. It was not until after the crisis, that in the zones
rhomboidea and marginifera, first evolutionary impulse occured, and
after a transgression in the expansa chron, a strong development of two
&#034;eco&#034;-groups of corals took place: (1) corals of basin facies
```

```
(fauna of the &#034;Cyathaxonia&#034; type), (2) corals of shallow shelf facies, the so called &#034;Strunian corals&#034; (fauna of the &#034;Canino-Clisiophyllum&#034; type). Corals of colonial type described lately as Calyxcorallia Fedorowski, 1991, in particular, should also be recognized as &#034;Strunian&#034; corals. In Poland, three areas exist of coral occurrence in the Late Fammenian, i.e.: the Swietokrzyskie Gory Mts, the Sudetes and the Krakow region. Preliminary investigation of coral faunas of these areas allows distinguishing of two regions:1. Swietokrzyskie Gory Mts region, where coral fauna typical of basin facies occurs; however, in the southern part of this region (Kowala locality) Strunian fauna of the &#034;Canino-Clisiophyllum&#034; type is also present. The fauna can be traced along the belt of outcrops from the Ardennes, through the Thuringen to the Swietokrzyskie Gory Mts. 2. The region of the Sudetes and the Krakow region, where an exceptional fauna of colonial corals occurs, which is typical of shallow shelf zone; its counterparts are known from China only.^1";

Argutastrea tenuiseptata Coen-Aubert &#038; Luette, 1990, Sociophyllum isactis (Frech, 1886) and S. wedekindi n.sp. are characteristic of its lower part whereas Sunophyllum beichuanense He, 1978, Argutastrea wangi (Tsien 1978) and Wapitiphyllum laxum (Guerich 1896) occur in its upper part. Moreover, the latter species is still present at the base of the overlying Fromelennes Formation. Sociophyllum isactis, S. wedekindi and Sunophyllum beichuanense are described in detail. A neotype is proposed for Wapitiphyllum laxum, the neotype of Sociophyllum isactis is revised and refigured.^1";
s[524] = "PEDDER A.E.H., FEIST R. (1998).- Lower Devonian (Emsian) Rugosa of the Izarne Formation, Montagne Noire, France.- Journal of Paleontology 72, 6: 967-991.- <b>FC&#038;P 28-1</b>, p. 34, ID=3966^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Ems; <b>Geography: </b>France, Montagne Noire^An anccount of the sysrematics, biostratigraphy, ecological setting and the biogeographic implications of rugose corals from olistoliths of the Cabrieres area is given. Corals of the lower member of the Izarne Formation are dated by conodonts as gronbergi Zone age, and include Lythophyllum sp. indet., Calceola sandalina (Linne), Tryplasma sp. A, Breviphrentis roharti Pedder new species, B. exigua Pedder new species, and Aqishaphyllum sp. A. Corals from the middle member of the formation include Frechocystis pertinax Pedder new genus and species, Calceola sp. undet, Rhizophyllum sp. aff. R. ukalundense Flill and Jell, Tryplasma enorme Pedder new species, Tryplasma sp. A, Breviphrentis sp. A, Platysmatophyllum halleri Pedder new genus and species, Pseudochonophyllum sentum Pedder new species, and Izarneophyllum barroisi (Frech) new genus. No age significant conodont has been recovered from the middle member. However, scutelluid trilobites, which, together with other trilobites, evidently used the underside of Izarne corals for shelter during molting, provide
```

```
correlation with conodont sequences in the nappe domain to the north
and southwest of Cabrieres. From this line of evidence, the middle
Izarne coral fauna is deduced to be nothoperbonus Zone in age. The
association of a variety of benthic trilobites, all with large eyes,
provides evidence of a photic zone environment for the middle Izarne
corals. Rugose corals from the Izarne Formation belong to the Old World
Realm and have nothing in common with similar age Rugosa of the Eastern
Americas Realm. This implies that the dissolution of the boundary
between these realms, which occurred in the Middle Devonian, did not
begin before latest Emsian time.^1";
s[525] = "SCHRODER S. (1998).- Rugose Korallen und Stratigraphie des
oberen Eifelium und unteren Givetium der Dollendorfer Mulde/Eifel.
(Mittel-Devon; Rheinisches Schiefergebirge).- Courier
Forschungsinstitut Senckenberg 208: 135 pp.- <b>FC&#038;P 28-1</b>, p.
35, ID=3968^<b>Topic(s): </b>biostratigraphy; Rugosa, stratigraphy;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Eif
Giv; <b>Geography: </b>Germany, Eifel^The distribution of several
fossil groups from the Middle Devonian of the Eifel region suggest that
it may be subdivided into three &#034;faunal regions&#034; (North-,
West-and South-Eifel). These regions are widely accepted in the
literature, and the boundary between the N and S Eifel regions, which
has become known as the &#034;Glinski sche Linie&#034;, traverses the
Dollendorfer Mulde in an E-W direction. Due to its central position in
the Eifeler Kalkmuldenzone, the Dollendofer Mulde is important in the
recognition of Devonian faunas within the Eifel. Several taxa of
brachiopods and corals are known as characteristic faunal elements of
the northern Eifel and their southward distribution seems to end
exactly at the &#034;Glinski&#039;sche Linie&#034;. However, the
geology of the Dollendorfer Mulde is not adequately known, and
consequently a detailed taxonomic-systematic study of its fossil
content has not been undertaken. As a result detailed comparison with
other Eifel synclines is currently impossible. [first part of extensive
summary].^1";
s[526] = "COEN-AUBERT M. (1994).- Stratigraphie et systematique des

Republic, Barrandian^The Eifelian Acanthopyge Limestone with the well
documented conodont zones Po. costatus partitus up to Po. hemiansatus
of the Barrandian Koneprusy area yielded diverse rugosan faunas.
Seventeen species belonging to eleven genera were recorded. The
assemblage differs from corals of the same age found in Moravia,
nevertheless, most of the taxa of both regions can be compared with
corals from the German Rhenish Slate Mountains. Bohemian Eifelian
Rugosa show striking similarities to Givetian faunas of other
regions.^1";
s[529] = "SOTO F. (1986).- Consideraciones sobre la Posicion
Sistematica del genero Angustiphyllum Altevogt (Coelenterata, Rugosa)
del Devonico medio de la Cordillera Cantabrica (NO de Espana).- Revista
Espanola de Paleontologia 01: 63-72.- <b>FC&#038;P 23-1.1</b>, p. 64,
ID=4140^<b>Topic(s): </b>systematics; Rugosa, Angustiphyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian M;
<b>Geography: </b>Spain, Cantabrian Mts^The genus Angustiphyllum
Altevogt, of a marked provincialism, is represented in the Middle
Devonian (Eifelian) of the Cantabrian Mountains by species, whose most
striking feature is its outer wedge shaped aspect. The only species, A.
cuneiforme Atevogt, shows apart from this morphology other typical
characteristics of the genus, such as an axial ridge, formed by
synapticulae arranged perpendicularly to the cardinal-counter plane and
septa consisting of fibrolamellar mirostructure. In this work the
systematic value of both characteristics is analyzed and on that basis
the diagnosis of the genus Angustiphyllum is enlarged. Its systematic
position, concerning family and subfamily, is discussed as well.
Likewise, the geographical distribution of the genus in the Cantabrian
Mountains is extended so that it constitutes a useful guide-level on a
regional scale. The finding of similar specimes of Angustiphyllum, but
lacking the axial ridge in the calice, makes it possible to propose a
new genus and species, but for the moment we prefer to keep them in
open nomenclature because of the small number of specimens collected.^1";

s[532] = "SCHRODER S. (1995).- Die Korallenfauna des Kirchen-Berges
(Freilingen-Formation) in der Blankenheimer Mulde (Rheinisches
Schiefergebirge &#47; Eifel).- Muenstersche Forschungen zur Geologie
und Palaeontologie 77: 373-421. [in German, with English abstract].-
<b>FC&#038;P 24-2</b>, p. 84, ID=4574^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Eif; <b>Geography: </b>Germany, Eifel^A rugose coral-fauna from the
Kirchen-Berg (Freilingen-Formation) in the Blankenheim syncline has
yielded the following taxa: Guerichiphyllum? sp., Enallophrentis n.sp.,
Cyathophyllum (Cyathophyllum) strigosum n.sp., Glossophyllum sp.,
Heliophyllum (Heliophyllum) halleri Schroeder, Heliophyllum
(Moravophyllum) cf. oliveri (Birenheide), Bethanyphyllum ? sp.,
Thamnophyllum sp. A, Xystriphyllum varians varians (Schlueter),
Dohmophyllum helianthoides (Goldfuss), Acanthophyllum heterophyllum
(Milne-Edwards &#038; Haime), Acanthophyllum vermiculare (Goldfuss),
Stringophyllum cf. acanthicum (Frech), Mesophyllum (Mesophyllum)
lissingenense lissingenense (Schlueter), M. (Cystiphylloides) secundum
secundum (Goldfuss), M (Cy.) secundum conistructum (Quenstedt), M.
(Cy.) secundum pseudoseptatum (Schulz). The coral-fauna is dominated by
typical Upper Eifelian taxa; like the very common Acanthophyllum- and
Cystiphylloides-species. Moreover, a strong
&#034;bohemian-american&#034; influence can be recognized. Migrations
from the North American faunal region (EAR = Eastern Americas Realm)
are visible in the occurance of Heliophyllum, Bethanyphyllum and a new
Enallophrentis-species. Enallophrentis or specimens of the family
Siphonophrentidae in general have never been collected in the
Rheinisches Schiefergebirge so far. On the other hand, the coral fauna
is influenced by eastern european taxa like Heliophyllum
(Moravophyllum) and a questionable Guerichiphyllum species.
Cyathophyllum (Cyathophyllum) strigosum is described as new. Within the
stratigraphical distribution of the Cyathophyllids C. (C.) strigosum
intercedes between the Lower Eifelian and Givetian taxa of
Cyathophyllum.^1";

&#47; Upper Emsian boundary of the Complejo de La Vid of the localities
Adrados and Colle in the Cantabrian Mountains, Spain. The first genus,
```

```
Gymnaxon n.g., with the species Gymnaxon weyeri n.sp., belongs to the
family Cyathaxoniidae Milne-Edwards &#038; Haime 1850, subfamily
Petronellinae Birenheide 1965. The second genus, Adradosia n.g., with
the species Adradosia barroisi n.sp., belongs to the family
Hapsiphyllidae Grabau 1928, subfamily Adradosiinae n.subfam. For the
first time new localities of Petronella truncata (Barrois 1882) are
recorded. * The absence of the wall on the apex of all these corals is
interpreted as resulting from a special mode of reproduction (probably
asexual) apparently developed under the ahermatypic quiet water
conditions of their environment. * The subfamily Petronellinae of the
family Cyathaxoniidae embraces at present 3 genera lacking the wall on
the apex: Duncanella Nicholson 1874, Petronella Birenheide 1965 and
Gymnaxon n.g. In the subfamily Adradosiina of the family
Hapsiphyllidae, the only genus Adradosia n.g. shows this pecularity.

Oberems (Unterdevon) im Thueringischen Schiefergebirge. [in German,
with English summary].- Abhandlungen und Berichte für Naturkunde und
Vorgeschichte 12, 3: 23-73.- <b>FC&#038;P 10-2</b>, p. 64,
ID=6080^<b>Topic(s): </b>pelagic facies; Rugosa, bathyal;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian
Ems; <b>Geography: </b>Germany, Thuringia^Rare and poorly known corals
of Lower Devonian in Thuringia (saxothuringian zone of mid-European
Variscan Mountains) are reviewed in faunal lists, based on critical
compilation of published data. There occur two autochthonous
communities of hercynian facies type, in the tentaculitid nodular
limestone horizon of Pragian or Siegenian age, and in the level C of
upper tentaculitid shale horizon of Upper Emsian or Dalejan age
(Nowakia richteri zone). A third allochthonous fauna is present in
level B of the upper tentaculitid shale horizon (Upper Emsian, Dalejan,
Nowakia cancellata zone) and yields a mixture of both rhenish and
hercynian facies fossils. * Rugosa of the bathyal upper fauna, found in
pelagic shales of the Nowakia richteri zone, belong at the least to
twelve species, mostly indeterminable at the moment due to bad
preservation (casts). Morphology and taxonomy of the two more abundant
species, Paliaxon zimmermanni (Weissermel 1941) and Bojocyclus
bohemicus Prantl 1939, are revised. The new genus Paliaxon
(Metriophyllidae) descends from Neaxon Kullmann 1965, by development of
pali similar to Scleractinian ones, which are discussed as to
terminology at variance with the primary meaning of the term palus
proposed by Edwards (1857) for Caryophyllia cyathus (Ellis &#038;
Solander 1786). Bojocyclus Prantl 1939, and its ancestor Rhabdocyclus
Lang &#038; Smith 1939, are classified as Tryplasmatidae =
Palaeocyclidae within a suborder Pholidophyllina Wedekind 1927, with
normal Rugosan septal apparatus, excluded from Cystiphyllina with
missing minor septa at counter septum. [original summary]^1";

Famennian rugose coral Scruttonia kunthi and their environmental
significance.- Palaeogeography, Palaeoclimatology, Palaeoecology 265,
1-2: 87-92.- <b>FC&#038;P 36</b>, p. 51, ID=6432^<b>Topic(s):
</b>ecology, growth bands; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>Poland,
Sudetes^Large colonies of rugose coral Scruttonia kunthi occuring in
the upper Famennian of Sudetes (southern Poland) reveal distinct growth
banding in their skeletons. They were investigated for internal
structural characteristics and stable isotopic composition. The
skeletal tissue consists of alternating light and dark bands which
differ in thickness, density and morphology of structural elements, and
in occurrence of corallite contraction and rejuvenescence. Darker parts
with densely arranged thick skeletal elements are thin in comparison to
lighter parts. In addition, they include frequently offsets and
contraction of corallites. A couplet of dense and less dense bands is
interpreted to represent most probably an annual cycle. The calculated
growth rate for Scruttonia kunthi varied from 6 mm/yr to 12 mm/yr.
Growth-band formation was influenced environmentally. Oxygen isotopic
data provide an evidence that high-density bands were formed in the
season of higher environmental stress, with relatively warmer
temperatures and higher sedimentation rates. Carbon isotopic signatures
are very uniform, and thus enigmatic. They indicate that at least
growth rate of the skeleton and seawater temperature had no influence
on the coral dC13.^1";

Tsien 1970, D. rugosum (Wedekind 1922). D. preslense n.sp. and
Peneckiella discreta n.sp. are described in detail and have been mostly
collected in beds rich in fasciculate rugose corals, occurring in
various areas of Belgium. The material investigated comes mainly from
the Palmatolepis transitans and P. punctata conodont Zones, at the
transition between the Early and the Middle Frasnian. The rugose corals
identified herein allow also interesting regional correlations.
Disphyllum hilli, D. grabaui and Macgeea rozkowskae Coen-Aubert 1982
are abundant at the base of the Moulin Lienaux Formation on the south
side of the Dinant Synclinorium and at the base of the Lustin Formation
on the north side of the same structural unit. Disphyllum preslense and
D. rugosum are widely distributed in the middle part of the Bovesse
Formation on the north side of the Namur Synclinorium, in the middle of
the reefal limestones from the lower part of the Lustin Formation and
in the middle part of the Pont de la Folle Formation which
characterizes the northwestern part of the Dinant Synclinorium.
Peneckiella discreta serves locally as basement for the small mounds
observed at the top of the Moulin Lienaux Formation. Hexagonaria
mirabilis Moenke 1954 and Tabulophyllum mcconnelli (Whiteaves 1898) are
frequently associated at the base of the overlying Grands Breux
Formation, at the top of the Pont de la Folle Formation, at the top of
the reefal limestones from the Lustin Formation and at the base of the
Huccorgne Formation capping the Bovesse Formation.^1";

Limestone, Moravia, Czech Republic, displays sharply differing
```

```
ontogenetic stages. Width of ventral side and size &#47; volume of
calice steadily increases in juvenile and adult stages but decreases in
some specimens in final stages of life; we consider these reductive
late stages to be gerontic characters. &#034;Ventral&#034; side of
juvenile specimens is flat and straight while in adults this side
becomes convex. We suggest that opening of operculum and shifting part
of polyp body mass forward would shift centre of gravity so that
calicinal part of adult coral could rock down to sea-bottom. Closing
operculum would elevate calice above bottom. Rocking movements could
help to free coral from sediment. Operculum positioning could move
coral and keep it in optimum feeding position. Single specimens show
predation injury: almost half of the &#034;ventral&#034; side is
missing between counter septum and corallite angle but has healed
within calice. [original abstract]^1";

</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Ems Eif;
<b>Geography: </b>Spain, Cantabrian Mts^Cystimorph rugose corals of
Upper Emsian - ?Lower Eifelian age (La Vid Fm., Raneces Fm., Sta. Lucia
Fm., Moniello Fm.) and of Givetian age (Lower Portilla Fm., Lower
Candas Fm.) from the Cantabrian Mountains s.l. are described for the
first time. They belong to the genera and subgenera Edaphophyllum
Simpson 1900, Mesophyllum (Mesophyllum) Schlueter 1889, Mesophyllum
(Cystiphylloides) Chapman 1893 and Cayugaea Lambe 1901. The following
species and subspecies are new: Mesophyllum (Cystiphylloides)
monielloense n.sp., M. (C.) secundum ascendens n.ssp., M. (C.)
macrocystis leonense n.ssp. and Cayugaea hispanica n.sp. Our material
of these new taxa is with one exception probably exclusively of Upper
Emsian age. It shows closer relations to N. American cystimorphs than
to contemporary corals of the Rhenish Mountains. On the other hand the
Givetian cystimorphs from the Lower Portilla and Lower Candas
```

```
Formations can easily be identified with already described taxa from
the Eifel synclines. Of the species of the subgenus Mesophyllum
(Mesophyllum) Schlueter 1889 only one – of Givetian age – has been
recorded from the Devonian of N. Spain, in spite of the worldwide
distribution of some of them. As they are normally very abundant,
mainly in Eifelian beds, it is probable that in the listed N. Spanish
localities sediments of Eifelian age are not at all, or only very
poorly, represented.^1";

ID=2427^<b>Topic(s): </b>reefs; biostromes, Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography:
</b>Ardennes^In the Belgian Namur-Dinant Basin the boundary between the
Lustin Formation and the Aisemont Formation (in the Lower rhenana
conodont Biozone) corresponds to a fall followed by a rise in sea
level, leading to the first recorded late Frasnian coral crisis. The
Aisemont Formation records a transgressive-regressive cycle. Prior to
the crisis most of the colonial rugose corals were members of the
Family Disphyllidae, but these were largely replaced by corals
belonging to the Phillipsastraeidae. Among these Frechastraea colonized
all environments of the basin and was the main constructor of a
biostromal reef in its northern-most proximal area, in the fair-weather
wave zone. Corals did not encrust each other and therefore were not
firmly attached, but they hug tightly the substrate (a dead coral
colony) and rest closely on it to resist to the turbulence of waves.
During the Silurian and Devonian, up until the late Frasnian crisis,
shallow-water reefs in turbulent water were usually built by encrusting
stromatoporoids, whereas rugose corals were restricted to waters of
lower energy. Indeed, they were unable to encrust substrates, unlike
stromatoporoids and post-Palaeozoic scleractinians, and to live in
turbulent habitats. In Belgium argillaceous sedimentation prevented the
development of stromatoporoids and provided an opportunity for the
corals to colonize empty niches and to construct biostromes in
relatively high-energy environments. At the same time Alveolites and
stromatoporoids were dominant in a mid-proximal environment below the
fair-weather wave base, but within the storm wave zone, where they also
constructed biostromes. [original abstract]^1";
s[592] = "ERRENST C. (1993).- Koloniebildende Phillipsastreidae und
Hexagonariinae aus dem Givetium des Messinghaeuser Sattels und vom
Suedrand des Briloner Massenkalkes (nordoestliches Sauerland).- Geol.
Palaeont. Westf. 26: 7-45.- <b>FC&#038;P 23-1.1</b>, p. 62,
ID=4135^<b>Topic(s): </b>; Rugosa, Phillipsastreidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Giv/Fra;
<b>Geography: </b>Germany, Rhenish Mts^The majority of the compound
rugose corals described in this paper derives from debris flow
sediments of the Messinghausen Anticline, which is situated in the
southeast of the Devonian Brilon Massive Limestone Complex. The
succession of Middle and Upper Devonian conodont zones was pointed out
for this area by Stritzke (1980, 1986, 1989 and 1990). Rugosa taken
from sections can be dated by this means. Thamnophyllum simplex n.sp.
is an abundant element within Middle Givetian initial faunas (Middle
varcus Zone), settling on volcanic sea-mountains and ridges. The
occurrence of Phillipsastrea, represented by the type species P.
hennahi (Lonsdale 1840), is confirmed for the Upper Givetian (Upper
varcus Zone up to the lower part of the Lowermost asymmetricus Zone).
This contradicts to the general opinion, that the first appearence of
Phillipsastrea marks out the beginning of the Upper Devonian in Central
```

```
Europe. The use of this genus as an index fossil resulted in wrong
datings of strata, which led to misinterpretations of sedimentary and
palaeogeographical developments even in the lastest publications
concerning regional geological circumstances. Samples of the very
similar Scruttonia sanctacrucensis (Rozkowska 1953) also have been
taken from Upper Givetian strata. In addition Kuangxiastrea julli
Pedder 1986 has been found in Givetian deposits (lower part of the
Lowermost asymmetricus Zone) as well. For this reason the species
neither can be regarded as a Frasnian index fossil in Europe, what had
been presumed in literature. The new data do not only take effect on
the interpretation of reef development within the northeastern Rhenish
Slate Mountains. Former conceptions concerning rugosan stratigraphy of
the Middle-Upper Devonian transition and derived palaeobiogeographical
models for the Devonian of Europe will have to be revised.^1";

```
species of Grypophyllum from the Middle Devonian of the Eifel and
Sauerland areas are described, one of which is new: Gr. mirabile. The
ancestors of Grypophyllum were Dohmophyllum-like and not
Acanthophyllum-like corals. Corals figured by Wedekind (1925) as
Pseudoptenophyllum sp. are placed into a new species: Dohmophyllum
wedekindi. Stratigraphical range, localities, and relationships of the
W. German Ptenophyllidae are discussed and illustrated.^1";
s[597] = "SCHRODER S. (2001).- On some western European
Siphonophrentidae.- Bulletin of the Tohoku University Museum 1
[Proceedings of the 8th International Symposium on Fossil Cnidaria and
Porifera]: 254-264.- <b>FC&#038;P 30-2</b>, p. 18, ID=1563^<b>Topic(s):
</b>; Rugosa, Siphonophrentidae; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Europe W^The
Siphonophrentidae Merriam 1974 is a family of rugose corals endemic to
the Eastern Americas Realm (EAR) during the Lower Devonian. Beginning
in the Middle Devonian the siphonophrentids migrated eastward into the
Old World Realm (OWR). This migration was controlled by sea level
fluctuations (phases of transgressive events). Thus, siphonophrentids
are useful for paleogeographic reconstructions and in identification of
migration routes during the Devonian. Taxa known from western Europe
are reviewed relative to their taxonomic status and stratigraphic and
geographic distribution. Some records from Germany and Spain are
discussed in detail and figured for the first time.^1";

pres de la limite Eifelian-Givetien a Resteigne (Ardenne, Belgique).-
Bulletin de l&#039;Institut royal des Sciences naturelles de Belgique,
Sciences de la Terre 66: 19-36.- <b>FC&#038;P 25-1</b>, p. 32,
ID=3011^<b>Topic(s): </b>; Rugosa, Siphonophrentidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Eif &#47; Giv;
<b>Geography: </b>Ardennes^Breviphrentis martinae n.sp. and
Rhytidolasma dahlemense (Haller 1936) have been collected near the base
of the Hanonet Formation at Resteigne; this level still belongs to the
Eifelian and the discovery of these two taxa implies a North American
influence which also characterizes other parts of Western and Central
Europe. Keriophyllum maillieuxi (Tsien 1969) has been observed at the
top of the Hanonet Formation and at the base of the overlying
Trois-Fontaines Formation in Resteigne, Nismes and Glageon; these
layers belong to the base of the Givetian. From a taxonomic point of
view, Keriophyllum yakowlewi Haller 1936 is placed in synonymy with
Rhytidolasma dahlemense whereas the definitions of the genus
Keriophyllum Wedekind 1923 and of the species K. maillieuxi are
emended. Several type specimens of the genera Rhtytidolasma Pedder 1989
and Keriophyllum Wedekind 1923 are also refigured.^1";

81, ID=3507^<b>Topic(s): </b>; Rugosa, Chaetetida; <b>Systematics:
</b>Cnidaria; Rugosa Chaetetida; <b>Stratigraphy: </b>Devonian Eif/Giv;
<b>Geography: </b>Germany, Rhenish Mts^From the Middle Eifelian to the
Lower Givetian strata of the northwestern Sauerland (map sheet 4612
Iserlohn, 4711 Luedenscheid and 4713 Plettenberg) 19 rugose corals and
2 chaetetid species are described. The material has been collected
mostly in the coral limestone of the Gruenewiese-Member (uppermost
Eifelian) of the Ihmert-Formation and the Bredenbruch-Member (lower
Lower Givetian) of the Unterhonsel-Formation. The compound coral
Smithiphyllum kloeckneri n.sp. is new. Glossophyllum occidentale (Hill
&#038; Jell 1971), Glossophyllum ? aff. excavatum (Hill 1942), and
Sociophyllum longiseptatum Bulvanker 1958 have been found for the first
time in Central or Western Europe. 4 other Rugosa species and 1
Chaetetida species are described from the Eastern Rhenish Massif for
the first time as well. The skeletons of reef-builders are frequently
affected by diagenetic processes - most important are alterations of
the microstructure and thickenings of skeletal elements. Some
reef-builders contain habitats of &#034;worm&#034;-commensals and some
other borings. The coral limestone of the Gruenewiese-Member and the
Bredenbruch-Member are mostly biostromes, built in a normal marine
environment of the euphotic zone between storm wave base and normal
wave base. Palaeobiographical investigations show, that the
&#034;Rhenohercynian Basin&#034; was only a marginal sea, into that
from the east faunas of the asiatic part of the &#034;Old World
Realm&#034; immigrate.^1";
s[603] = "BERKOWSKI B. (2002).- Famennian Rugosa and Heterocorallia
from southern Poland.- Palaeontologia Polonica 61: 3-88.- <b>FC&#038;P
32-1</b>, p. 21, ID=1674^<b>Topic(s): </b>; Rugosa, Heterocorallia;
<b>Systematics: </b>Cnidaria; Rugosa Heterocorallia; <b>Stratigraphy:
</b>Devonian Fam; <b>Geography: </b>Poland S^Famennian corals (Rugosa
and Heterocorallia) occur in three areas of southern Poland: the Holy
Cross Mountains and the Kraków area situated along the south-western
margin of the East European Platform, and the Sudetes located within
the Variscan orogenic belt. In the deep-water Famennian environments of
the Holy Cross Mountains (Kowala) the first corals appeared after the
Frasnian-Famennian crisis in the P. marginifera to P. trachytera zones.
They are represented by monospecific assemblages of Circellia concava,
a species able to live on a soft muddy and dysaerobic bottom. On even
more organic-rich sediment heterocorals Oligophylloides flourished;
they are suggested to feed on suspended or dissolved organic matter.
When the environment became more aerated in the P. expansa and S.
praesulcata zones more diverse coral assemblages appeared, including
large dissepimented solitary rugosans. In the extremely shallow-water
limestone facies (&#034;Stromatoporoid Rocks&#034;) of the Kraków
region, two species of the colonial rugose coral Pseudoendophyllum and
several solitary corals are represented. The shallow shelf carbonate
facies of the Sudetes (Main Limestone) starts with assemblages
dominated by three species of massive colonial Scruttonia followed by
assemblages with a few species of solitary dissepimented corals. The
```

```
colonial corals disappeared with the incursion of deeper-water
cephalopod Wocklumeria limestone facies and only solitary
non-dissepimented corals and heterocorals remained. The colonial Rugosa
of Famennian age are almost unknown in other regions of the world.
Their abundance in the Sudetes and the Kraków region suggests that
these areas represented a refuge for corals during the high sea stand
of the latest Devonian. Several Famennian corals reveal characters
typical for those of either the Frasnian or Viséan. These characters
are more likely to develop convergently than representa continuity
within lineages. Pseudoendophyllum raclaviense sp. n. Scruttonia
sudetica sp. n., S. fedorowskii sp. n., and Oligophylloides weyeri sp.
n. are proposed.^1";

Tabulata; <b>Systematics: </b>Cnidaria; Rugosa Tabulata;
<b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography: </b>Germany,
Viersen 1001 bh^Rock samples of the Viersen 1001 borehole from depths
between 1,012.85 and 1,496.80 m contain specimens of seven rugose and
nine tabulate coral species which are described and figured herein; one
of the tabulates, Remesia obscura n.sp., is new. The species
composition of the coral fauna is comparable to that of the Aachen
Massenkalk limestone and the Ardennes. The investigated material
comprises a time interval between Early (?) Givetian and Upper
Frasnian. By far the greatest part of this interval is represented by
the Polygnathus varcus conodont zone. Furthermore, the coral record
also allows a discrimination of a Middle Givetian (here: Rodert to
Kerpen Formation) and part of the Fromelennian. In thin sections, the
Fromelennian and Frasnian specimens show evidence of dispersal caused
by rough weather periods within a normally quiet, shallow-water
environment with a relatively high content of clay components. On the
other hand all the Middle Givetian and possible Lower Givetian
specimens come from the basal phyllite conglomerate of the examined
section.^1";

from the Sudetes Mountains (Poland) and endemicity of the Upper
Famennian to Uppermost Famennian (= &#034;Strunian&#034;)
stromatoporoid fauna in western Europe.- Senckenbergiana lethaea 79, 1:
51-61. [in memoriam Dr. Wolfgang Struve].- <b>FC&#038;P 29-1</b>, p.
69, ID=1520^<b>Topic(s): </b>endemism; stroms; <b>Systematics:
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian Fam;
<b>Geography: </b>Poland, Sudetes^A single large stromatoporoid
specimen collected by one of us (D.W.) from the so-called &#034;Main
Limestone&#034; at Dzikowiec (=Ebersdorf) in the Sudetes Mountains of
Lower Silesia, Poland, is here assigned to Trupetostroma Parks, 1936.
It is typical of the Upper Famennian to Uppermost Famennian (=
&#034;Strunian&#034;) stromatoporoid assemblage No. 3 defined by Stearn
(1987) and Stearn, Halim-Dihardja &#038; Nishida (1987). This
assemblage, confined to western Europe and Kazakhstan, is dominated by
clathrodictyids but without labechiids. Other genera present with
Trupetostroma in this assemblage include Amphipora, Anostylostroma,
Atelodictyon, Clathrocoilona, Clathrodictyon, Clathrostroma,
Gerronostroma, Petridiostroma, and Stromatopora. All these genera were
widespread globally through the Middle and Upper Devonian
(Givetian-Frasnian) but in the Upper Famennian to Uppermost Famennian
(= &#034;Strunian&#034;) deposits of western Europe they appear as
&#034;Lazarus taxa&#034; - a consequence of the Frasnian/Famennian
boundary Kellwasser event which terminated reefal environments world-
wide. Viewed at the generic level, the western European Upper Famennian
to Uppermost Famennian stromatoporoid fauna is essentially ubiquitous,
but at the species level endemism is pronounced. This may have resulted
from reactivation of distinct biotopes when conditions became
conducive, locally, to renewed reef development. The endemicity is
analysed using the Jaccard coefficient.^1";

terminated in the large areas during the triangularis- and gigas-Zone
(do I &#947;/&#948;). To explain this phenomenon six profiles with the
transition from reef- to non-reef facies ranging from Namur (Belgium)
to Wuppertal (W.-Germany) were investigated microscopically and
```

```
geochemically. * It turned out that the periodically increased
production and sedimentation of clayey and mainly organic material
directly controlled the Upper Devonian reef growth and finally caused
its termination. * Increased plate tectonical shifting of the land
areas during the Upper Devonian finally triggered off the following
chain of events: increasing rates of periodical rainfall - intensified
spreading of land plants - increased chemical weathering - periodically
increased transport of nutrients and clastic material into the reef
habitat - increased production and sedimentation od phytoplankton -
termination of reef growth - final euxinic sedimentation (lower
Kellwasser limestone, do I &#948;).^1";

Morena (Southern Spain) and their palaeogeographic affinities.-
Österreichische Akademie der Wissenschaften, Schriftenreihe der
Erdwissenschaftlichen Kommissionen 17: 139-151. ISBN
978-3-7001-3826-6.- <b>FC&#038;P 35</b>, p. 43, ID=2321^<b>Topic(s):
</b>biogeography; stroms, biogeography; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian L; <b>Geography:
</b>Spain, Sierra Morena^For the first time the stromatoporoid fauna
from two locations in the Penón Cortado Limestone (Upper Emsian) from
the Sierra Moreno (Southern Spain) has been examined in detail. The
fauna contains 8 stromatoporoid species. One of them, a new species, is
described as Pseudotrupetostroma anacontentoae n.sp. The absence of
stromatoporoids with branched coenostea and the scarcity of
stromatoporoids with thin-layered encrusting growth form probably
served as an obstacle to reef construction. The fauna of the Sierra
Morena is unrelated to that of the Eastern Americas Realm. However, it
is closely related to Emsian faunas of Australia and Canada. There is
no evidence to suggest that Southern Spain was a refuge for Eastern
Americas stromatoporoids.^1";

Frasne des Bergischen Landes.- Geologisches Institut der Universitaet
zu Koln, Sonderveroffentlichungen 106: 182 pp.- <b>FC&#038;P 25-1</b>,
p. 48, ID=3057^<b>Topic(s): </b>; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian Giv Fra; <b>Geography:
</b>Germany, Bergisches Land^In the lower Givetian reef builders used
littoral sediments of sand, silt and clay as a foundation for thin
biostromes which could exist in spite of repeated sedimentation. In
consequence of constant favourable conditions a reef with typical reef
facies developed in the upper Givetian. In the Frasnian these bioherms
were drowned as sea level rose. The reef evolution of the Bergisch
Gladbacher-Paflrather Mulde is analysed by the description of the
stromatoporoids which represent an important group of Devonian
reefbuilders. The descriptions include 56 species, 11 taxa comparable
with described species (cf.), and 2 taxa identified only generically
(sp.). The shapes of the skeletons are also described. To better
describe and define the species the scanning electron microscope and
image processing supplemented the usual skeletal measurements. Except
for the dendroid species, all stromatoporoids changed their growth
structure according to the predominate environment. Therefore layered
flat species appear mostly at the base of the reef and knobby, globular
or massive stromatoporoids existed mostly in high energy reef zones.
The dendroid species were often found in the lower energy reef zones
with high sedimentation rates. The stratigraphic distributions of
several species from the area were compared with those from other
areas. The distribution of the Middle Devonian Clathrocoilona abeona
and Anostylostroma columnare and the Upper Devonian Trupetostroma
cimanense are notable. [original abstract, with minor modifications]^1";

<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Devonian L M; <b>Geography: </b>Spain, Cantabrian Mts^The genus
Stromatoporella Nicholson 1886 is very abundant in the Santa Lucia
Formation (Upper Emsian-Lower Eifelian), in the Cantabrian Mountains,
NW Spain. The present study is based on more than one hundred specimens
collected from different sections, all of them located on the southern
slope of the Cantabrian Mountains. The studied specimens show large
variations in the typical characters of the genus, especially the shape
and abundance of ring-pillars. Five species have been recognized in
open nomenclature; a comparative study was made, mainly based on the
different features of the ring-pillars, in order to verify if they
allow characterization of the different species. In general, the
morphological features of ring-pillars such as shape, relative number
of shorter, higher ring-pillars or as high as one interlaminar space,
presence of dissepiments and wall thickness are suitable criteria to
differentiate the species involved in this study. Some other features,
such as density are more variable and, thus, are of less systematic
value.^1";

</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Poland, Holy Cross^Stromatoporoids have been measured
in three Upper Devonian localities: Karwow, Kadzielnia and Sitkowka
quarries. Quantitative analysis in the measurements demonstrated
several differences that have been interpreted in terms of ecological
variations between localities. Rate of deposition is proposed to be of
special importance in controlling stromatoporoid morphology. Deposits
exposed in Kadzielnia and Karwow quarries represent an environment with
periodically accelerating deposition and water turbidity, where low
domical individuals with a ragged surface and non-enveloping
arrangement of latilaminae constitute the most numerous group of
stromatoporoids. The deposits outcropping in Sitkowka-Kowala quarry,
formed in a calm setting with low deposition rate, are characterized by
the following stromatoporoid features: usually extended domical or
bulbous shape, smooth surface and an enveloping arrangement of
latilaminae. The similarity of stromatoporoid assemblages from Karwow
and Kadzielnia confirmed that dolomite exposed in the Karwow quarry
represents Kadzielnia-type reef-mound deposits.^1";

Stromatoporoid palaeoecology of the Frasnian (Upper Devonian) of 
southern Belgium.- Third International Palaeontological Congress 
Programme and Abstracts, p. 135. [abstract] - <b>FC&#038;P 36</b>, p. 
29, ID=6392^<b>Topic(s): </b>ecology; stroms; <b>Systematics: 
</b>Porifera; Stromatoporoidea; <b>Stratigraphy: </b>Devonian Fra; 
<b>Geography: </b>Ardennes^Stromatoporoid faunas from the Frasnian of 
southern Belgium are abundant in the carbonate platform and mound 
environments present in this area. Stromatoporoids dominate the large 
skeletal organisms, with their principal occurrence in biostromes and 
mound deposits. Stromatoporoid genera include Actinostroma, Amphipora, 
Euryamphipora, Atelodictyon, Clathrocoilona, Idiostroma, Salairella, 
Stachyodes, Stictostroma, Stromatopora and Trupetostroma. Comparable 
facies were observed in the carbonate platform and in the mound, so it 
appears that even if the mound and platform were independent, similar 
stromatoporoids occur in similar facies indicating a strong 
palaeo-environmental control. From the more distal to the more 
proximal, facies are: (1) outer platform or off-mound (shales, 
crinoidal packstones); (2) outer intermediate platform or deep mound 
(muddy facies with crinoids and reef-builders); (3) inner intermediate
```

```
platform or shallow mound (muddy facies with algae) and (4) restricted
platform or mound (laminites, mudstones, paleosols). Low profile
stromatoporoids (dominated by Stictostroma and Salairella) are often
observed at the beginning of sequences, as stabilizers and in facies 1
and 2 (so they likely led to expansion of the carbonate factory). High
domical stromatoporoids (dominated by Actinostroma, Atelodictyon and
Trupetostroma) occur in facies 3 and 4, in association with branching
stromatoporoids. Stromatoporoid growth forms seem to be related mostly
to environmental parameters but there is also some taxonomic control.^1";
s[641] = "LUCZYNSKI P. (2008).- Growth forms and distribution patterns
of stromatoporoids exposed on Devonian palaeobottom surfaces; Holy
Cross Mountains, central Poland.- Acta Geologica Polonica 58, 3:
303-320.http:&#47;&#47; www.geo.uw.edu.pl/agp/.- <b>FC&#038;P 36</b>,
p. 35, ID=6401^<b>Topic(s): </b>growth forms, distribution patterns;
stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Poland^Well preserved
palaeobottom surfaces with stromatoporoids are exposed in two Devonian
localities in the Holy Cross Mountains in central Poland: Skaly and
Bolechowice-Panek quarries. The stromatoporoids were subjected to
morphometric analysis and distribution studies. Stromatoporoids were
studied hitherto only in vertical cross sections; the study of
three-dimensional stromatoporoid domes has created a need to introduce
a new set of parameters describing their shapes, which includes:
horizontal length and width, vertical height, elongation ratio and
elongation azimuth. In order to make the measurements made by various
methods comparable, and thus to allow comparable interpretations,
recalculation formulas have been presented. Comparison of the results
obtained by the two methods indicates that the measurements made in
vertical cross sections substantially bias the dimensions and shapes of
the stromatoporoids, which may influence stromatoporoid-based
palaeoenvironmental reconstructions. The results of the measurements
were interpreted in terms of palaeonvironmental conditions. In
Bolechowice-Panek the stromatoporoids lived in a quiet shallow water
setting with a low and stable sedimentation rate. In Skaly the
stromatoporoids grew in a shallow subtidal setting and located
themselves on parallel ripples, most probably to escape being buried by
deposits accumulating in inter-ripple depressions.^1";
s[642] = "LUCZYNSKI P. (2009).- Stromatoporoid growth orientation as a
tool in palaeotopography: a case study from the Kadzielnia Quarry, Holy
Cross Mountains, central Poland.- Acta Geologica Polonica 59, 3:
319-340.http:&#47;&#47; www.geo.uw.edu.pl/agp/.- <b>FC&#038;P 36</b>,
p. 36, ID=6402^<b>Topic(s): </b>growth orientation; stroms;
<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Poland, Holy Cross^Growth orientation
of stromatoporoids has allowed reconstruction of the palaeotopographic
position of a large Frasnian organic buildup exposed in the Kadzielnia
Quarry in the Holy Cross Mountains, central Poland. Two main, mature
stage, stromatoporoid growth modes have been discerned: erect and
semi-buried. The growth orientations of the stromatoporoids were
studied in 17 sections that expose four different facies in the quarry.
The inclinations of the basal surfaces of specimens and direction of
the growth axes were measured and compared in terms of different growth
modes, facies and positions in the organic buildup. The results support
the earlier opinions that the inclined contact between the Kadzielnia
stromatoporoid-coral limestones and the detrital limestones is
depositional and represents an inclined depositional surface, and that
the Kadzielnia buildup developed in a calm water setting below the
storm wave base on a slope or at its foot. General conclusions emerging
from the studies are: 1) stromatoporoid growth directions hold a key to
reconstructing ancient topography; 2) erect stromatoporoids that grew
on inclined surfaces changed the growth axes to the vertical direction
during their growth; and 3) stromatoporoid growth directions and
particularly the changing mode of growth of erect forms support the

Debnik Anticline, southern Poland.- Acta Palaeontologica Polonica 54,
2: 337-350.- <b>FC&#038;P 36</b>, p. 47, ID=6427^<b>Topic(s): </b>;
stroms; <b>Systematics: </b>Porifera; Stromatoporoidea;
<b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>Poland S^Famennian
Stromatoporoidea from the Quasiendothyra communis Foraminiferal Zone
and slightly younger strata from the Debnik anticline, southern Poland,
form a succession of three consecutive assemblages. Assemblages 1 and 3
consist of representatives of the order Clathrodictyida, while
assemblage 2 is dominated by the order Labechiida. The clathrodictyids
are represented by the genus Gerronostroma, and labechiids are
represented by the genus Stylostroma. Species assigned here to the
genus Gerronostroma show a network of amalgamated pillars in the
central part of the columns, a feature regarded by previous authors as
typical of the genus Clavidictyon. Two new species, Stylostroma
multiformis sp.nov. and Gerronostroma raclaviense sp.nov., are
described. Stromatoporoids from southern Poland differ from the
Famennian fauna of western Europe, showing affinity to eastern European
and Siberian Stromatoporoidea.^1";

</b>morphology, ecology; stroms; <b>Systematics: </b>Porifera;
Stromatoporoidea; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Poland, Holy Cross^Stromatoporoid skeletons from polished slabs of
stromatoporoid- and coral-bearing limestones of the Upper Devonian
Kowala Formation from the Holy Cross Mountains in central Poland have
been measured using a classic parameterization method, introduced by
Kershaw &#038; Riding (1978) and improved by Kershaw (1984, 1998). The
```

```
stromatoporoid shape appeared to be strongly dependent on its size -
the V/B ratio decreases along with increasing B. The relation can be
well matched by a curve described by a formula: f(x) = 5.7103x0.81633.
The size of the measured specimens must therefore be taken into account
in those studies of the stromatoporoid morphology, where it is
concerned a palaeoenvironmental indicator. The stromatoporoids adopted
several types of initial surfaces, corresponding to various growth
strategies in the first phase of their growth in response to various
environmental conditions, such as substrate consistency and
sedimentation rate. Latilaminae arrangement well records the
stromatoporoid growth history and therefore its studies are crucial in
environmental interpretations, as the conclusions inferred from the
shape alone might be very misleading. [original abstract]^1";

stroms, Tabulata; <b>Systematics: </b>Porifera Cnidaria;
Stromatoporoidea Tabulata; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Ardennes^The specific biodiversity of stromatoporoids, tabulates
and brachiopods from the Ardennes (706 taxa) has been analyzed
stage-by-stage from the Lochkovian up to the Famennian. The diversity
of each group may be correlated with external factors (e.g. facies),
but it varied individually (e.g. decline of brachiopods in the
Givetian). The faunas are discussed at the order level, however some
more diversified orders are analyzed at family level. Biodiversity
shows a single peak centered on the Givetian for the bioconstructors,
and two major peaks (Emsian-Eifelian and Frasnian) for the brachiopods.
The most diversified orders are Stromatoporellida (stromatoporoids),
Favositida (tabulate corals) and Spiriferida (brachiopods).

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian M
U; <b>Geography: </b>Germany, Rhenish Mts^Middle and Upper Devonian
Alveolitids and Heliolitids of the Bergisches Land, east of Cologne,
were investigated and monographically described. 24 species of
Alveolitids were found. Nine new species and one new genus were
established. Among other criteria, statistical methods have been used
in the characterization of the species. The colonial growth forms were
reduced to three fundamental types. The microstructure of the skeleton
(especially of the tabulae and the wall neighbouring the pores) were
examined. Two budding types are described. The new alveolitid species
are: A. pseudorbicularis, A. bergeri, A. lindensis, A. bilsteinensis,
Subalveolites praetenuissimus, S. parvicorallitus, Alveolitella
schladensis. The new genus Spongialveolites is characterized as
follows: Diagnosis: Transverse sections of the corallites
kidney-shaped. At the lower wall of the corallites a robust ridge is
always developed. Pores of the wall numerous and large, mostly higher
than wide. Many pores in the corners of the corallites are arranged in
such a manner that two pores combine and mutually connect three
corallites. Thickness of wall and distance of tabulae and pores are
equal in the entire colony. Growth not known in detail and probably
varying. Remarks: The genus is clearly characterized by large oval wall
pores and the robust ridge at the lower wall of the corallites. The
different species are differentiated only by the dimensions. Two new
species are assigned to the genus: Sp. minor as the type species and
Sp. minimus. Nine subspecies of Heliolites porosus (Goldfuss 1826) can
be distinguished in this investigation area. Three new subspecies are
established. Here, statistical methods are also used in the
characterization and distinction of the subspecies. Some supplementary
data are given concerning Goldfuss&#039; originals of Heliolites
porosus which had already been revised by Lecompte (1936). The
submicroscopic structure of the skeleton as well as some perceptions on
foreign bodies and parasites are described. The new species H.
bilsteinensis and the new subspecies of H. porosus: H. p. bergeri and
H. p. schladensis are assigned to line heliolitids. Finally, the
stratigraphic range of the species and the facies in which they are
```

```
found, are indicated.^1";

Armorican Massif, and Algeria, cf. Marekostrahgulum from Portugal and
new genus A from Germany is evaluated.^1";
s[673] = "PLUSQUELLEC Y., HLADIL J. (2001).- Tabulate corals of
Ibarmaghian affinities in the Upper Emsian of Bohemia.- Geologica et
Palaeontologica 35: 31-51.- <b>FC&#038;P 31-1</b>, p. 65,
ID=1639^<b>Topic(s): </b>biogeography; Tabulata; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian Ems;
<b>Geography: </b>Czech Republic, Bohemian Massif^Some tabulate corals
belonging to a genus identified for the first time in the Barrandian
area (Bohemia, Czech Republic) were coillected in 1948-1950 by Jiri
Bouska in the vicinty of Holyne. The fossiliferous beds of the Bouska
excavation are assigne to ther Trebotov Formation which belongs to the
Upper Emsian (Upper part of Po. serotinus Zone). This part of
stratigraphic sequence consists of background sedimetation
lime-mudstone, which alternates with fine-grained tentaculit-bearing
and coarse-grained calciturbidites. Among the largely silicified
tabulate corals - many of them still remaining undetermined - three new
species have significant palaeogeographic implications, being
```

```
inconsistent with previous knowledge of Bohemian coral biofacies. These
species are Kerfernoidictyum rex n.sp., Pterodictyum holynesis n.sp.
and Taouzia vulvaria n.sp. During the Upper Emsian, these genera are
typical for the Ibarmaghian Domain of the Gondwana margin (north
Sahara, Iberian Peninsula and Armorican Massif) or in the
Maghrebo-European Realm (north Gondwana and Avalonia). Pterodictyum and
Taouzia were formerly identified only in the Ibarmaghian Domain;
Kerforneidictyum is widely distributed. The oldest occurrences of the
latter genus are from the Lower Emsian of the North Gondwana Province,
but this genus has also been recorded form the Uppermkst Emsian of the
Sauerland. The co-occurrence of Kerformeidictyum, Pterodictyum and
Taouzia in he Upper Emsian of Bohmia indicates clear affinities with
the Ibarmaghian Domain and gives supplementary evedence for retaining
central Bohemia at the north Gondwana margin.^1";

s[676] = "HLADIL J. (1981).- Devonian tabulate corals from the deep
boreholes located south of Brno. [in Czech, with English summary].-
Biostratigrafie Paleozoika: 31-36; Hodonin.- <b>FC&#038;P 11-2</b>, p.
32, ID=1845^<b>Topic(s): </b>taxonomy, distribution; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Czech Republic, Moravia^In the region described, the
tabulate coral faunas are mainly associated with the lower part of the
Devonian limestone complex. They are charateristic of dark coloured,
partially dolomitized limestones of the semilagoonal facies and of
coral bank facies. The flat fringing reef developing in the roof and
comprising laminites and breccia intercalations as well as nodular
limestone beds (Skocek 1978) ceases to include subfacies suitable to
the growth of tabulate corals. The diversity of the corals decreases
until they get gradually extinct. * The vertical trends in the
evolution of tabulate coral assemblages in the southern region are
similar to those in the central region (Hladil 1974). However, as can
```

```
be concluded from the intermittently cored boreholes, the Frasnian
associations of the southern region seem to restrict themselves even
more pronouncedly to ramose representatives of the subfamily
Natalophyllinae Sokolov. Lower Givetian age can be ascribed to the
assemblage determined in the Menin-1 borehole, core No. 12: Striatopora
cf. devonica Schlueter, Thamnopora bilamellosa Yermakova, Th. tumefacta
Lecompte, Caliapora taltiensis Yanet, Mastopora sp., Remesia sp.,
Crassialveolites crassus (Lecompte), Cr. aff. crassus (Lecompte),
Natalophyllum sp. A, Scoliopora ex gr. denticulata (Milne-Edwards et
Haime). * The presence of Chaetetes raritabulatus Deng in core No. 27
of the Nemcicky-2 borehole seems to indicate Lower Givetian age as
well. Caliapora battersbyi (Milne-Edwards et Haime) that is diagnostic
in Moravia of the upper parts of the Givetian as high as the Givetian
&#47; Frasnian boundary was recognized only in core No. 26 from the
Nemcicky-2 borehole. * Only Scoliopora denticulata (Milne-Edwards et
Haime) and Natalophyllum sp. B are present in the Frasnian
limestones.^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian
L; <b>Geography: </b>Germany, Rhenish Mts^Our revision confirms the
validity of the genus Petridictyum Schindewolf 1958. Its distinctive
features are the convex shape of the proximal surface, a concentric
mode of budding around the protocorallite (= petrioid budding), a
strong development of spiny septal crests apparently arranged in two
cycles and lack of the commensal worm Hicetes. A more precise
definition, including the microstructure, will have to await future
studies of material that is not decalcified.^1";
s[681] = "SCRUTTON C.T. (1990).- Ontogeny and astogeny in Aulopora and
its significance, illustrated by a new non-encrusting species from the
Devonian of southwest England.- Lethaia 23, 1: 61-75.- <b>FC&#038;P
19-1.1</b>, p. 33, ID=2610^<b>Topic(s): </b>ontogeny &#038; astogeny;
Tabulata, Aulopora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Britain SW^A new
non-encrusting species of Aulopora is described from the Middle
Devonian of southwest England. Its colonial form is reconstructed from
serial sections using a computer program. These sections also allow the
description of protocorallite ontogeny and the formation of offsets in
the new species. For comparison, aspects of ontogeny and astogeny were
investigated in some other auloporids: protocorallite ontogeny and
colony form in &#039;Plexituba&#039;? cucullina; increase in Aulopora
serpens and Aulocystis sp. cf. A. amica. Most reptant auloporids show a
more or less constant angle of offsetting to the parent, but in
&#039;P.&#039;? cucullina, the interoffset angle decreases with each
successive increase event in the colony. The phylogenetic significance
of the auloporids is reassessed on the basis of these new data on
protocorallite ontogeny and increase. [original abstract]^1";

The genus is characterized by the strong dimorphism of calices and the presence of two continuous septal ridges in the larger calices. It belongs to the family Pachyporidae and to the subfamily Striatoporinae.^1";
s[685] = "SCRUTTON C.T. (1990).- A new Aulopora from the Devonian of south-west England and its significance.- Proc. Ussher Soc. 7: 307. [poster abstract] - <b>FC&#038;P 20-1.1</b>, p. 24, ID=2811^<b>Topic(s): </b>astogeny; Tabulata, Aulopora; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>Britain SW^A new species of the simple tabulate coral genus Aulopora, from the Chercombe Bridge Limestone (Eifelian) of the Lemon Valley near Newton Abbot, South Devon, is free living. Its presence was detected in serial sections and its three-dimensional form reconstructed by computer. Members of this genus not occurring as weathered out encrusting material are probably much more common than recorded but usually escape detection. Characteristic features are only more apparent in sections cut in the plane of bedding, whilst most working sections are cut perpendicular to bedding. * The protocorallite of this new species shows the development of a macrospine in the plane of bilateral symmetry. Such a structure has not previously been described in a tabulate coral, but suggests comparison with the first formed counter-cardinal septal plate of rugose corals. In addition, the serial sections yield new information on the mode of origin of new corallites in the auloporid colony. * The pattern of offsetting compares closely with that seen in the genus Eofletcheria rather than with the mode typical of most tabulate corals. This supports an earlier deduction that Auloporu evolved from Eoflecteria in the Middle Ordovician, rather than the Russian view of Aulopora as ancestral to all tabulate corals (Scrutton 1984, 1990). [poster abstract]^1";

Parastriatopora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Spain,
Cordoba^Tabulate corals from the Lower Devonian Lorito Limestones
(Cordoba Province) are described in detail and they are assigned to
Parastriatopora ex gr. annulata (Le Maitre 1952), a group until now
mostly known from North Africa and Armorica. The Lorito Limestones
probably belong to the upper part of the Gedinnian, according to their
tabulate coral fauna content. The microstructural evolution of the
median lamina of the wall, from the axial part of the branches until
the periphery, is described in detail. We observed a replacement of
granules by elongated rods and, close to the surface of the corallum, a
complete disappearance of any median structure. This feature is
compared with other cases, of known branching tabulate corals.^1";

Tabulata, Caliapora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian Giv; <b>Geography: </b>Spain N^The genus
Caliapora Schlueter 1889 is subdivided in three subgenera Caliapora
(Caliapora) Schlueter 1889, limited to the Givetian; Caliapora
(Mariusilites) Mironova 1974 probably the direct ancestor of Caliapora
(Caliapora) and known from the Lowermost Devonian until the Lower
Givetian; and Caliapora (Luciaella) nov. subgen., from the Upper Emsian
- Lower Eifelian of the Cantabrian Mountains (NW Spain). The genus
Caliapora is recorded for the first time from the Cantabrian Mountains
with Caliapora (Mariusilites) cf. chaetetoides Lecompte 1939 and
Caliapora (Luciaella) daedala nov. sp. Some general considerations
concerning the genus Caliapora are developed: the systematic position
of the genus at familial level, the stratigraphical range of the
different subgenera, the paleogeographical repartition and the
paleoecological requirements.^1";
s[691] = "NOWINSKI A. (1993).- Tabulate corals from the Givetian and
Frasnian of the Holy Cross Mountains and Silesian Upland.- Acta
Palaeontologica Polonica 37, 2-4: 183-216. [monograph] - <b>FC&#038;P
22-2</b>, p. 28, ID=3485^<b>Topic(s): </b>; Tabulata; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian Giv Fra;
<b>Geography: </b>Poland, Holy Cross^Tabulate corals and single species
each of the heliolitid anthozoans and chaetetid sclerosponges mostly
from the Givetian and Frasnian stromatoporoid-coral series of the Holy
Cross Mts and the Silesia-Cracow Region are reviewed from an ecological
and stratigraphical point of view. Thamnopora, or the branched
pachyporids, and massive alveolitids are usually the most significant
reef-builders. The most distinctive fauna, with Caliapora battersbyi
and Heliolites porosus, thrived in the earlier Givetian bank habitats.
Late Givetian biostromal-complex associations with Alveolites obtortus,
Striatopora enigmatica, and especially Alveolitella fecunda, as well as
the succeeding Frasnian Alveolites-dominated reef-complex faunas with
A. maillieuxi, and later with A. tenuissimus, Aulocystis and
syringoporids, are far more uniform. In addition, a local Coenites
```

```
laminosa-Chaetetes yunnanensis fauna is re ognized in the Middle
Givetian of the Kostomloty area. The transitional biogeographic
position for Polish tabulate assemblages between Variscan Europe and
Russia is clearly evident. Forty eight species have been identified.
Pachyfavosites polonicus sp. n., Striatopora enigmatica sp. n.,
Alveolitella polygona sp. n., Armalites minimus sp. n., and
Syringoporella raritabulata sp. n, Alveolites edwardsi frasnianus
subsp. n., and Caliapora battersbyi minor subsp. n. are proposed.

tabulate corals related to Thamnopora are described in detail from the
```

```
Ferrones Formation (Lower Emsian to lower Upper Emsian) and the Aguion
Formation (Upper Emsian) of the Raneces Group and the Moniello
Formation (upper Upper Emsian to lowermost Eifelian) of the central
Asturian coast as well as from the Valporquero Formation and the
Coladilla Formation (Upper Emsian) of the La Vid group and the Santa
Lucia Formation (upper Upper Emsian to lowermost Eifelian) of Asturias.
Among them are two species and one genus new. Thamnopora ? sotoi n.sp.
from the Upper Emsian shows strong and abundant squamulae. Oekentorpia
n.gen., with the only one species Oekentorpia radigi n.gen., n.sp. from
the Upper Emsian of Asturias, has thin, three-dimensionally connected
branches with small Caliapora-like corallites. Thamnopora pulchra
savitschevae Dubatolov 1964, Thamnopora irregularis Lecompte 1939,
Thamnopora cervicornis (Blainville 1830), Striatopora tschichatschewi
Peetz 1901, Parastriatopora fallatis Yanet 1968, and Parastriatopora
obsolenta Dubatolov 1969 are found for the first time in the Emsian of
Spain. These corals have only a little biostratigraphical importance.
They show close palaeobiogeographical relations to Siberia. Furthermore
are informations given about the fossil contents of the Valporquero
Formation and then Coladilla Formation of the La Vid Group.^1";
s[696] = "BRUHL D. (1996).- Die Gattungen Alveolites Lamarck 1801 und
Squameoalveolites Mironova 1969 (Anthozoa, Tabulata) im unteren
Mittel-Devon (Eifelium) der Dollendorfer Mulde &#47; Eifel (Rheinisches
Schiefergebirge).- Senckenbergiana lethaea 76, 1/2: 1-51.- <b>FC&#038;P
26-1</b>, p. 64, ID=3633^<b>Topic(s): </b>taxonomy; Tabulata;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian
Eif; <b>Geography: </b>Germany, Eifel^The stratigraphical distribution
of the tabulate coral genera Alveolites Lamarck 1801 and
Squameoalveolites Mironova 1969 from the lower Eifelian (Middle
Devonian) of the Dollendorf Syncline &#47; Eifel Hills (Rheinisches
Schiefergebirge) has been examined in detail. Through investigation of
the morphological characters it is possible to distinguish the
following species at different stratigraphical levels: Alveolites
suborbicularis Lamarck 1801, Alveolites edwardsi Lecompte 1939,
Alveolites intermixtus intermixes Lecompte 1939, Alveolites intermixtus
minimus (Iven 1980), Alveolites megastomus Steininger 1849, Alveolites
minutus Lecompte 1939, Alveolites subaequalis Milne-Edwards &#038;
Haime 1851, Alveolites crassus Lecompte 1939, Alveolites cavernosus
Lecompte 1933, Squameoalveolites fornicatus (Schlueter 1889),
Squameoalveolites robustus (Pradacova 1938) and Squameoalveolites
straeleni (Lecompte 1939). The coral assemblage in the north-eastern
part of the Dollendorf Syncline is dominated by faunal elements of the
North Eifel area with a clear bohemian influence. In the south-western
part of the syncline a typical South Eifel fauna can be recognized. In
addition, a distinct faunal influence from the Ardennes (Belgium) can
be recognized at some stratigraphical levels. The species Alveolites
suborbicularis, hitherto considered as typical of Givetian and Frasnian
deposits, occurs first in the upper Eifelian. Also remarkable is the
first record of the species Squameoalveolites robustus (Pradacova 1938)
in the upper Eifelian. This species was hitherto known from comparable
sediments of Bohemia &#47; Moravia, Russia and Austria. The occurrence
of the rare species Alveolites megastomus Steininger 1849 in the
Freilingen Formation is also of special interest. The preservation of
the skeletal microstructure of the different species was examined
particularly with respect to diagenetic alteration. There are numerous
microstructures, which cannot be accounted for as of primary
morphological origin. These secondary pseudostructures were caused by
diagenetic recrystallization processes during fossilization.^1";
s[697] = "BRUHL D., OEKENTORP Kl. (1997).- Secondary microstructures in
tabulate corals of the genus Alveolites Lamarck 1801 from the Middle
Devonian of the Dollendorf Syncline (Eifel Hills, Germany).- Boletin de
la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92,
1/4: 87-097.- <b>FC&#038;P 26-2</b>, p. 24, ID=3705^<b>Topic(s):
</b>microstructures; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
```

```
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Germany, Eifel^The
skeletal elements of representatives of the genus Alveolites Lamarck
1801 from the Eifelian (Middle-Devonian) of the Eifel Hills
(Rheinisches Schiefergebirge &#47; Germany), especially from the
Dollendorf Syncline, were investigated in detail with regard to their
post-mortem diagenetic changes. Numerous microstructures, which cannot
be interpreted morphogenetically, have been recognized in the skeletons
of diverse species of Alveolites Lamarck 1801. The present study is
devoted mainly to the most important skeletal element of tabulate coral
colonies, the wall, which is especially affected by post-mortem
recrystallization due to fossilization. The new observatives on
Alveolites with a Scanning Electron Microscope gives impressive proofs
that the primary skeletal microstructure of the wall has been partly
replaced by different secondary textures and, moreover, has been
thickened by deposition of cement A and additional overprinting as a
result of diagenetic processes. As an important criterion of these
different alterations of the original structure, recrystallization
(&#034;aggrading neomorphism&#034;) is indicated by the formation of
coarse crystal aggregates, which appear in the shape of dark
saw-toothed rhombs. Distinct cleavage structures in the neomorphic
calcite have been observed as zigzag patterns and also as
pseudolamellar structures. Last but not least, the recrystallization of
syntaxial cements is a clear sign of diagenetic alteration.^1";

Tabulata; <b>Stratigraphy: </b>Devonian Giv; <b>Geography: </b>Poland,
Sudetes^Interpretations of a Caledonian (early to mid-Devonian)
tectono-metamorphic event in the Klodzko unit and therefore, throughout
the entire West Sudetes were largely based on the assumption of a
Silurian age for the limestones in the area of Maly Bozkow. Additional
collection of tabulate corals, restudy of previous collections and
confirmation of the presence of Caliapora battersbyi in the fauna
indicate that the deposition continued in the basin into the Givetian.
Consequently, deformation and metamorphism of the West Sudetes postdate
the Middle Devonian and cannot be associated with the Caledonian
orogeny. Post-Givetian tectonism in the Sudetes signifies that Variscan
orogenesis was the pre-eminent event in the region, mixed
```

Ems; <b>Geography: </b>Luxemburg^A new species of Kerforneidictyum, K.
oeslingensis n.sp., is described. It is mainly characterized by the
following features: apical angle reaching up to 160 degrees, deep
calices with numerous small spines roughly of the same size, setted in
two rows or scattered on septal ridges which are wider than the
interseptal furrows, no obvious cardinal ridge, tabulae scarce or
missing. The species has been collected in the lowermost Emsian of the
Givonne-Eislek Anticlinorium in Luxembourg. It is 1) the first record
of the genus in the Devonian of Luxembourg and 2) in the autochthonous
part (SE Laurussia) of the Ardenno-Rhenish Mountains and 3) very likely
the first - or one of the two first - representatives of the genus
taking into account Gondwana and Laurussia. [original abstract]^1";

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Poland, Holy Cross^Organisms of unknown biological
affinities, assigned to the genus Chaetosalpinx, are known to infest
Palaeozoic tabulate corals and stromatoporoids. Analysis of
distribution of these parasites, performed on Emsian-Eifelian material
of Favosites goldfussi (Anthozoa, Tabulata) from the Northern Region of
the Holy Cross Mountains (Poland), shows that parasites were absent in
the early astogenetical stages, and that during astogeny both the
absolute number of parasites per colony and the number of parasites per
polyp were increasing. The latter can reach 2.7 parasites per polyp.
Preferred settling places are in corallite corners (junction of three
individuals), but dense infestation also produced settlement in the
corallite walls (between two individuals). Probable causes of the
increase are insufficient protection by host&#039;s cnidae,
insufficient immune system response, and parasite ability to adapt to
the host&#039;s defences. [original abstract]^1";

</b>ecology; Tabulata, Auloporida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>Poland, Holy
Cross^Substrate specificity of Auloporida (Tabulata) from the Skaly Fm.
(Upper Eifelian-Lower Givetian) of the Holy Cross Mts., Poland, has
been recognized. Kyrtatrypa sp., a rare species in the formation (under
5%), was the most often encrusted brachiopod (59% of investigated
specimens), while the most often occurring brachiopod, Aulacella
eifeliensis (de Verneuil) was nearly not encrusted. The majority of
encrusted brachiopods were larger than 20 mm, while smaller brachiopods
occur abundantly in the Formation. The substrate specificity has been
caused mainly by the ornamentation of the host&#039;s shell. The
position of corallites along the commissure of the brachiopod shell
```

```
proves that auloporids often encrusted living hosts. The epizoan
probably used water currents produced by brachiopod&#039;s lophophore
impoverishing the host&#039;s food composition, their relationship can
therefore be described as scramble competition.^1";

Aulocystis entalophoroides Schlueter 1889, du Devonien moyen, espece-
type du genre Schlueterichonus Byra 1983, est redecrite sur la base du
materiel original de Schlueter. Ses caracteres internes, inconnus
jusqu&#039;a present, sont precises: planchers developpes sous forme de
grandes vesicules accolees aux parois, abondance des epines fusiformes
inserees dans les murailles ou reposant sur les planchers. La
microstructure, remarquablement preservee, montre, autour d&#039;une
lame mediane constitute de granules et de biocristaux etires
transversalement, des lamelles onduleuses longues; la premiere serie de
ces lamelles forme avec la lame mediane un diedre ouvert vers le haut;
les autres series sont disposees en chevrons plus ou moins reguliers.
L&#039;ensemble des caracteres structuraux et microstructuraux permet
d&#039;attribuer le genre Schlueterichonus a la famille Aulocystidae
Sokolov 1950, au sein de laquelle il se distingue par son habitus
branchu erige. Le genre est egalement represente dans le Devonien des
Etats-Unis et d&#039;Algerie.^1";

<b>Systematics: </b>Cnidaria Porifera; Tabulata Chaetetida;
<b>Stratigraphy: </b>Devonian Eif; <b>Geography: </b>Poland, Holy
Cross^The author has characterized Tabulata assemblages occurring in
Eifelian deposits obtained from boreholes in the Gory Swietokrzyskie.
She has described the state of preservation of the fossils and the
frequency of the occurrence of Tabulata and the accompanying fauna in
various lithological complexes. Eleven species of Tabulata and one
species of Chaetetida have been determined. Among these, three species
(Thamnopora angusta Lecompte, Striatopora tenuis Lecompte, Cladopora
tenuissima Dubatolov) are described for the first time in Poland. Two
species (Gracilopora sp. A and Caliapora sp. A) belong to genera which,
so far, have been described in Poland from the Upper Devonian stages
(Frasnian, Givetian). The author has distinguished index species of
stratigraphic importance. The occurrence of the particular species and
genera in the Kielce region and in the Bodzentyn Syncline has been
presented, as well as their stratigraphic range.^1";

</b>geology; geology; <b>Systematics: </b>Cnidaria; Tabulata Rugosa;
<b>Stratigraphy: </b>Devonian Giv/Fra; <b>Geography: </b>Ardennes^The
hydrogeological reconnaissance borehole Nieuwkerke has traversed the
```

```
Givetian-Frasnian boundary. Different fossil groups provide the
framework for a biostratigraphic zonation. An ecological break between
a supratidal restricted environment and a subtidal open marine
environment has been observed in a carbonate sequence, which precedes
the biostratigraphic boundary based on conodonts. * Because of its
intermediate geographical position, the Nieuwkerke borehole can be
lithostratigraphically correlated with the Tournai region of the Namur
Synclinorium (Belgium) and the Ferques region in Boulonnais (N.
France). The lower unit is equivalent to the Mazy Formation and to the
Bastien Member of the Blacourt Formation but environmental instability
and biofacies variation observed at this level are probably due to the
regressive tendencies in the Uppermost Givetian at the southern margin
of the Brabant Massif. The upper unit can be easily correlated with the
lower part of the Bovesse Formation and with the lower part of the
Cambreseque Member of the Beaulieu Formation. The transgression which
nearly marks the base of the Frasnian has probably produced a more
regular and uniform facies distribution. * [in annexes described and
illustrated are Disphyllum virgatum (Hinde 1890) by M. Coen-Aubert and
Thamnopora polyforata (Schlotheim 1820), Aulocystis sp. and Dendropora
explicita Michelin 1846 by F. Tourneur.^1";

<b>Systematics: </b>Cnidaria Porifera; Tabulata Stromatoporoidea;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Czech Republic,
Moravia^Although stromatoporoids colonized the dead surfaces of coral
skeletons there is also evidence for competition between
stromatoporoids and caliaporids. Different species and genera of
stromatoporoids display different abilities to attack the caliaporid
corals. Actinostroma devonense was, at least in the Middle Devonian of
Moravia (Central Europe), a dangerous killer of caliaporids. However,
the representatives of the genera Trupetostroma, Hermatostroma and
Clathrocoilona were less successful if forced into close,
tissue-to-tissue competition. The caliaporids responded to the
stromatoporoid attack using two strategies: escape and counter-attack.
The close competition led to malformations in the tabulate coral
skeleton, especially affecting the squamulae: reduction of squamulae to
irregular thick spines is the major malformation trend.^1";

</b>paleontology; Cnidaria, Porifera; <b>Systematics: </b>Cnidaria
Porifera; <b>Stratigraphy: </b>Devonian; <b>Geography: </b>France,
Boulonnais^Since 1970, an inventory of all the present fossil groups to
be found in the largest part of the Devonian series in the Ferques area
has been realized, after the establishment of the detailed
stratigraphic series and the updating of new outcrops (especially from
1975). This inventory has been established from all the old and recent
available material. The latter was collected bed by bed on the new
outcrops, jointly by various specialists. Thanks to the exemplary
collaboration of well informed amateurs such as Jean-Pierre Vidier and
Christian Loones, the collection has been continued allowing new
studies and discoveries.The studies and the systematic revisions, the
definitions of taxonomic and biostratigraphic units were established
with a concern for replacing the fossils in their sedimentary context,
for giving their stratigraphic and biogeographic distribution in
correlation with the international conodont scale. Since the
publication of results, the Devonian conodont scale has been revised.
Correlation between the old scale and the new one will be found in
fig.1. The affinities of the flora and the fauna with those of the more
or less remote regions were also analysed.The different taxa recognized
in the Devonian of the Ferques area (more than 780) are listed below,
following by one or several numbers referring to one or several papers
where they are described or quoted. When a taxon has been revised, the
paper quoting this taxon before the revison is not mentioned. These
taxa belong to about twenty different fossil group : Calcareous algae,
miospores, acritarchs, chitinizoans, foraminifers, moravamminids,
stromatoporoids, rugose and tabulate corals, bryozoans, brachiopods,
bivalve and cephalopd mollusks, tentaculites, crinoids and echinida,
trilobites, ostracodes, conodonts, vertebrate remains (ichtyofauna)^1";

The Elbingerode Reef Complex, which developed on an isolated submarine volcanic rise within the Renish Trough, displays an atoll-like structure of facies pattern. Correlations based upon conodonts indicate the onset of reef growth in the Middle varcus Zone and its diachronus termination up to the Upper gigas Zone. The younger, post-reef sediments ranging up to the anchoralis-latus Zone are recognized as the neptunian dykes and the pockets within the reef carbonates. The termination of reef formation in the Elbingerode Reef Complex is interpreted as result of the increasing subsidence of the sea floor. The conodont distribution within the reef carbonates is restricted to the fore-reef facies, but no clear depth segregation of conodonts is observed. Differentiation of CAI values within the Elbingerode Reef Complex is also discussed.^1";

formation (Upper Emsian) is a supplementary element of hercynian fauna
in Brittany during lower Devonian time. For the new species,
characterized by lack of a septum on the base of the corallite (basal
disc), a fibrous microstruture, perhaps trabecular, is shown. Pores are
absent. Some tabulae are deyeloped. Corallite diameters range between
1.2 - 1.9 mm (1.0 - 1.4 mm in the sense of measuring by Marek &#038;
Galle 1976). Thickness of the walls is 0.04 - 0.1 mm. The systematic
position of the genus - by Marek &#038; Galle thought to be a
representative of the suborder Alveolitina Duncan 1872 - is discussed
but ending with the suggestion to let it remain incertae sedis.^1";

<b>Systematics: </b>problematica; <b>Stratigraphy: </b>Devonian Ems
Eif; <b>Geography: </b>Czech Republic^These investigation results
relate to the Devonian Suchomasty limestone (upper Emsian - lowest
Eifelian) and basal Acanthopyge limestone (Eifelian), which is
restricted to the south-western area of the Barrandian (Czech Republic)
known as the Koneprusy area. From the beginning of the Pragian stage to
the beginning of the Eifelian stage, this region underwent is own
course of development, independent of the other Barrandian area. The
frequency and distribution of the bioliths, the associated fauna and
the sediment structures of the Suchomasty limestone and the base of the
Acanthopyge limestone indicate the formation of a shallow subtidal
environment. The sponge-cement framestone which occurs only at the base
of the Suchomasty limestone suggest that the palaeobathymetric position
of the sedimentation area was more shallow than the several tens of
metres generally assumed to date, at least at the beginning of the
sedimentation of the Suchomasty limestone. [first fragment of extensive
summary]^1";

<b>Systematics: </b>problematica; <b>Stratigraphy: </b>Devonian Ems;
<b>Geography: </b>France, Montagne Noire^Mud mounds in the Emsian of
the Montague Noire are built by red biomicrites and white sparitic
layers. The latter fall into the category of stromatactis structures.
Sponges and bryozoans are dominant in the micrites. The stromatactis
structures are interpreted as spar-filled cavity-systems, which
originated from microbial mats decaying in the sediment. The bryozoan
&#47; sponge community as well as the microbial mat community both
contributed to the growth of the mounds. Mound growth was thus
primarily biologically controlled, but influenced by sea level changes.
Spectral analysis of detailed measurements of quarry sections revealed
orbital cycles to be responsible for the sea level changes.^1";

</b>problematica; <b>Stratigraphy: </b>Devonian Ems; <b>Geography:
</b>France, Montagne Noire^The Upper Emsian mud mounds in the Montagne
Noire are composed of interlayering red micrites and Stromatactis
layers. Four types of Stromatactis were distinguished by their
morphology and cementation pattern. The micrites are characterized by a
baffling and &#47; or binding microbial &#47; sponge &#47; bryozoan
association. The formation of Stromatactis voids was caused by the
decay of extensive microbial mats which proliferated during times of
low or nondeposition. We present arguments for an early formation of
the voids after the burial of the mats by increasing sediment influx,
as well as for their early stabilization by cementation and by early
lithification of the lime mud. The frequent changes from the microbial
&#47; sponge &#47; bryozoan association to microbial mats were due to
high-frequency sealevel fluctuations. The cyclic arrangement of
Stromatactis layers is supposed to be caused by orbital cycles.^1";

</b>Czech Republic, Barrandian^The upper Emsian Suchomasty limestone
and the Eifelian Acanthopyge limestone of the Barrandian are composed
of red to gray biomicrites and white sparitic layers, which fall into
the category of Stromatactis structures. A distinction of four types of
Stromatactis fabrics by their morphology and cementation pattern is
possible. The stromatactis fabrics of type A and B are interpreted as
spar-filled cavity-systems, which originated from decaying microbial
mats. Stromatactis type A occurs only in combination with sponge-cement
framestones at the base of the Suchomasty limestone. This microfacies
type probably documents an &#034;embryonic&#034; mud mound stage in the
lowest Suchomasty limestone. The occurrence of Sphaerocodium at the
base of stromatactis fabrics type B indicates the origin of this
stromatactis type due to former presence of &#034;microbial mats&#034;.
Concerning the distribution of the stromatactis fabrics type A and B in
the section a change of sediment input was the dominant controlling
factor.^1";

B., HUMBLET M., RENARD M., COEN-AUBERT M. (2004).- Reconstructing
atoll-like mounds from the Frasnian of Belgium.- Facies 50, 2:
313-326.- <b>FC&#038;P 33-2</b>, p. 10, ID=1097^<b>Topic(s): </b>reefs,
atolls; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fra;
<b>Geography: </b>Ardennes^A succession of Frasnian mounds on the
southern border of the Dinant Synclinorium (Belgium) was investigated
for their facies architecture, sedimentary dynamics and
palaeogeographic evolution. Seven mound facies were defined from the
Arche (A) and Lion (L) members, each characterized by a specific range
of textures and association of organisms (A2/L2: red or pink limestone
with stromatactis, corals and crinoids; A3/L3: grey, pink or green
limestone with stromatactis, corals and stromatoporoids; A4/L4: grey
limestone with corals, peloids and dasycladaceans; A5/L5: grey
microbial limestone; A6/L6: grey limestone with dendroid
stromatoporoids; A7/L7: grey laminated limestone with fenestrae; and
A8/L8: grey bioturbated limestone). Laterally equivalent sediments
include substantial reworked material from the buildups and background
sedimentation. Textures and fossils suggest that A2/L2 and A3/L3 facies
developed close to storm wave base, in a subphotic environment. Facies
A4/L4, occurring near fair weather wave base in the euphotic zone,
includes lenses of A5/L5 with stromatolitic coatings and thrombolithes.
A6/L6 corresponds to a slightly restricted environment and shows a
progressive transition to fenestral limestone of A7/L7. This facies was
deposited in a moderately restricted intertidal area. A8/L8 developed
in a quiet lagoonal subtidal environment. The mounds started with A2/L2
or A3/L3 in which microbial lenses and algal facies A4/L4 became
progressively more abundant upwards. Following 20m of laterally
undifferentiated facies, more restricted facies occur in the central
part of the buildups. This geometry suggests the initiation of
restricted sedimentation, sheltered by bindstone or floatstone facies.
The facies interpretation shows that after construction of the lower
part of the mounds during a transgression and a sea-level highstand, a
lowstand forced reef growth to the margin of the buildups, initiating
the development of atoll-like crowns during the subsequent
transgressive stage. The persistence of restricted facies results from
the balance between sea-level rise and reef growth. [original
abstract]^1";
s[774] = "BOULVAIN F., COEN-AUBERT M. (2006).- A fourth level of
Frasnian carbonate mounds along the south side of the Dinant
Synclinorium (Belgium).- Bulletin de l&#039;Institut royal des Sciences

p. 29, ID=1224^<b>Topic(s): </b>reefs, carbonate mounds; reefs, Rugosa;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fra; <b>Geography:
</b>Ardennes^An additional level of Frasnian mounds has been recognized
in the La Boverie quarry at Rochefort and in four boreholes drilled in
the Nord quarry at Frasnes, on the south side of the Dinant
Synclinorium. It occurs between the Arche and Lion Members belonging
respectively to the Moulin Liénaux and Grands Breux Formations, in the
middle part of the stage. The new name of La Boverie Member is
introduced at the top of the Moulin Liénaux Formation, for the deposits
lying between the Arche and Bieumont Members; the latter is the
basement of the Lion mound. The same succession has been observed in
the sections of Moulin Bayot close to Vodelée, in the southeastern part
of the Philippeville Anticlinorium. The La Boverie Member starts with
rather deep bioclastic sediments, after the collapse of the carbonate
factory at the top of the Arche mound. In the upper part of the
lithostratigraphic unit, there is a thin buildup characterized by
relatively shallow facies. The solitary rugose corals Macgeea
boveriensis n.sp., M. socialis Soshkina, 1939 and Sinodisphyllum
posterum (Ivaniya, 1965) collected in the lower part of the La Boverie
Member are described in detail whereas the revision of S. kielcense
(Rozkowska, 1979) occurring in the Bieumont Member is also provided.^1";

s[775] = "BOULVAIN F., DEMANY B., COEN-AUBERT M. (2005).- Frasnian
carbonate buildups of Southern Belgium: the Arche and Lion Members
interpreted as atolls.- Geologica Belgica 8, 1-2: 69-89.http:&#47;&#47;
popups.ulg.ac.be/Geol/document.php?id=562.- <b>FC&#038;P 34</b>, p. 72,
ID=1308^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian U; <b>Geography: </b>Ardennes^The facies
architecture, sedimentary dynamics and paleogeographic evolution were
reconstructed for a number of Frasnian buildups developed on a
carbonate platform on the south side of the Dinant Synclinorium
(Belgium). Bed-by-bed sampling and detailed petrography were
complemented by magnetic susceptibility analysis, allowing for
high-precision lateral correlation. Six facies were recognised in the
buildups, each characterized by a specific range of textures and
assemblage of organisms: grey, pinkish or greenish limestone, with
stromatactis, corals and stromatoporoids (facies A3-L3); grey limestone
with corals, peloids and dasycladales (facies A4-L4); grey, microbial
limestone (facies A5-L5); grey limestone with dendroid stromatoporoids
(facies A6-L6); grey, laminar fenestral limestone, (facies A7-L7);
grey, bioturbated limestone (facies A8-L8). The time-equivalent
off-buildup sediments include a large amount of transported material
that originally came from the buildups. Sedimentological evidence
suggests that facies A3-L3 developed between the storm wavebase and the
fairweather wavebase, in a oligophotic environment. This facies
contains lenses of facies A5-L5, with stromatolitic coatings and
Renalcis-rich thrombolitic bushes. These lenses were developed in
greatest abundance closest to the fairweather wavebase, and they became
anastomosing. Facies A6-L6 was developed in an environment with
slightly restricted water circulation; there is a steady transition
between this facies and the fenestral limestone A7-L7, which were
deposited in a moderately protected subtidal to intertidal area. Facies
A8-L8 developed at subtidal depths in a quiet, lagoonal environment.
The buildups started with the development of facies A3-L3, with
microbial lenses and algal facies becoming progressively more abundant
upwards. Above about 20m in each buildup, more protected facies are
found in the buildup&#039;s central part. This atoll-like geometry
suggests the development of restricted sedimentation in this central
area, sheltered by bindstone or floatstone facies. The initial
development of the lower part of a buildup during a transgression and
subsequent highstand would have been followed by reefal growth along
the edge of the buildup during the succeeding lowstand; an atoll crown
would then have started to develop during the following transgressive
stage. The presence of restricted facies can be seen as the consequence
of the balance between sea level rise and reef growth. [original
abstract]^1";

I., SCHRODER St., SOTO F. (2006).- Reefal and mud mound facies
development in the Lower Devonian La Vid Group at the Colle outcrops
(León province, Cantabrian Zone, NW Spain).- Facies 52, 2: 307-327.-
<b>FC&#038;P 34</b>, p. 77, ID=1318^<b>Topic(s): </b>sedimentology;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian L;
<b>Geography: </b>Spain, Cantabrian Mts^In the locality of Colle
(Cantabrian Zone, NW Spain), the upper part ofthe Valporquero Shale
Formation (Emsian, La Vid Group) contains aninterval of shales and
marlstones (barren, greenish-grey shales and fossiliferous,
greenish-grey or reddish shales/marlstones) with beds andpackages of
homogeneous and cross-bedded skeletal limestones. Metrescalemud mounds
and coral biostromes occur encased in thefossiliferous reddish and
greenish-grey shales/marlstones, respectively,with the coral biostromes
overlying conspicuous skeletal limestonebodies. These rocks were
deposited on a carbonate ramp, ranging fromabove storm wave base for
the cross-bedded skeletal limestones tobelow the storm wave base for
the remaining deposits, organic buildupsincluded. The vertical stacking
of these facies and the occurrence of thetwo types of buildups are
```

```
interpreted to reflect the interplay amongseveral (possibly 4th and
5th) orders of relative sea-level variations,during a 3rd-order
highstand.Coral biostromes occur in early 5th-order transgressive
system tractsdeveloped within late 4th-order highstand, and are
interpreted to havethrived on a stable granular substrate (skeletal
limestones) in non-turbidwaters, being later aborted by the onset of
muddy sedimentation.Biostrome features suggest that they developed
under environmentalconditions essentially different from those related
to the sedimentationof their granular substrate. Mud mounds occur in
5th-order transgressiveand early highstand system tracts tied to early
4th-order sea-level rise.Field relationships suggest that mud mounds
grew coevally with muddysedimentation, with high-frequency variations
in carbonate vs.terrigenous mud sedimentation influencing their
development.^1";

Rhenish Mts^Middle Devonian carbonates of the Ahbach Formation are
exposed in a quarry at Weinberg, in the western Hillesheimer Syncline.
At this locality, the Hallert Member of the formation reaches maximum
thickness. The basal carbonates containing Stromatactis, bryozoans,
sponge spicules, and phylloid algae are interpreted as mud mound
sediments. The mound appears to have developed above crinoidal detrital
limestones with incipient biostromes (upper Bohnert Member), whose
depostion was initially caused by exogenic factors, such as an elevated
position, and hydrodynamic processes, such as storms, and contour
currents. Detrital and reefal limestones, and dolomites with
stromatoporoids and chaetetids, occur above the mound sediments,
indicating shallowing. The younger inter-bedded bituminous limestones
and dolomites with Amphipora/stromatoporoid biostromes of the
succeeding Hallert-Lahr Member, were deposited in shallow quiet water,
```

</b>Germany, Rhenish Mts^The Massenkalk north of Brilon 
(East-Sauerland) and north of Balve (West-Sauerland) is of lagoonal 
character and is Upper Givetian (Middle Devonian) in age. 
Stromatoporoids, which can be subdivided into different growth forms 
(spherical to tabular, encrusting, thin lamellar, branching), are the 
main reef building organisms The species of the branching 
stromatoporoid Amphipora, which are hard to distinguish, dominate. The 
two thin laminar species Stromatopora cygnea Stearn 1983 and Stachyodes 
(Keega) jonelrayi Stearn 1975 are described for the first time from 
western Europe. Tabulate corals represent about 20% of the 
reef-builders and permit important inferences about the restriction of 
environment. Rugose corals and calcareous algae are rare. Reef dwelling 
organisms are less important; among these brachiopods, molluscs, 
foraminifera, calcispheres, and ostracods are, however, widespread. 
Several associations of reef-builders that depend on different water 
depths can be distinguished. Their composition varies according to the 
restriction of environment. With increasing water depth water energy 
increased on the carbonate platform. The analysis on the 
stratigraphical distribution of the species of the reef-builder fauna 
allows no more but vague stratigraphical classifications.^1";
s[791] = "HLADIL J. (1988).- Structure and Microfacies of Middle and 
Upper Devonian Carbonate Buildups in Moravia, Czechoslovakia.- Canadian 
Society of Petroleum Geologists, Memoir 14 [McMillan N. J. et al. 
(eds): Devonian of the World], vol. 2: 607-618.- <b>FC&#038;P 18-1</b>, 
p. 47, ID=2289^<b>Topic(s): </b>reefs structures, microfacies; reefs; 
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M U; <b>Geography: 
</b>Czech Republic, Moravia^The most bulk (98%) of the carbonate 
buildups are developed on Proterozoic crystalline basement blocks. 
Lagoons with mud banks and patch reefs range in width from several to 
several tens of kilometres but the reef margin is very narrow, only 
some tens or few hundreds of metres wide. Thickness of the buildups is 
generally between 200 and 1000 m. The mean subsidence rates, calculated 
according to buildup thickness and duration of the buildup 
accumulation, varied from 20.0 to 86.7 m Myr-1. The platform margin has 
a general retreating trend up to the upper Frasnian Palmatolepis gigas 
Zone, when an advancing trend started. Coral-stromatoporoid benthic 
communities are present from Eifelian to the lower Famennian 
Palmatolepis crepida Zone. Four megacycles occur which display a 
general succession of dark wackestones, Amphipora-bearing rocks and 
boundstones. These megacycles culminate in (1) the Eifelian-Givetian 
boundary interval, (2) the upper part of the middle-Givetian, (3) the 
lower Frasnian, and (4) the uppermost Frasnian. These culminations are 
characterized by maximum rates of buildup accumulation and also the 
synchronous deposition of black anoxic sediments (generally in deeper 
```

```
environments. - the otomari, Phariceras, Manticoceras and Kellwasser
events). The volumes of limestones corresponding to the standard
microfacies (in the sense of Fluegel 1978) were calculated with
following results: Standard microfacies No. 9 (SMF 9) - biomicritic
limestones with bioclasts, 39,4 %, SMF 7 - biolitic limestones, 23.7%,
SMF 8 - biomicritic limestone with biomorphs, 7.4%, etc. The abundant
micrite formed in a variety of ways, partly mechanical, partly algal
and other biochemical origins. Cementation at various stages completely
fills porosity except for dolomitized and fractured horizons. The 129
microfacies which were distinguished during the evaluation of the
material are reclassified according to the standard microfacies system
(in the Fluegel&#039;s sense) as well as according to Devonian
microfacies associations and Devonian development stages systems (in
the sense of the author, Hladil 1986). The quantitatively restricted
dependence is shown in Table 1.^1";

www.geo.uw.edu.pl/agp/table/abstracts/57-2.htm.- <b>FC&#038;P 35</b>,
p. 107, ID=2438^<b>Topic(s): </b>biodiversity; biodiversity;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Ardennes^A survey of the principal benthic faunas from the Devonian
of the Ardennes is presented. The alpha-diversity is very high (707
species, including 138 species of stromatoporoids, 113 species of
tabulates, hydroids and chaetetids, and 456 species of brachiopods).
Analysis of their distribution through time indicates two brachiopod
diversity peaks (Emsian/Eifelian and Frasnian), a single stromatoporoid
diversity peak (Givetian), and no clear peak of tabulate corals (with
the highest diversification during the Eifelian-Frasnian). The highest
diversity of bioconstructors in the Givetian correlates with a decrease
in brachiopod diversity. Changes in the vertical distribution of the
faunas are correlated with the facies development: the development of
carbonates correlates with the abundance of stromatoporoids and
tabulates, while brachiopods were most abundant before and after the
peak of carbonate development. Bioconstructors are absent (or nearly
absent) in siliciclastic facies.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Ems Eif;
<b>Geography: </b>Czech Republic, Moravia^This paper discusses
contemporaneous knowledge of conodont, foraminiferal, stromatoporoid,
tabulate and rugosan faunas through the Devonian carbonate platform of
Moravia. In basal parts of the Moravian Devonian, upper Emsian to
lowermost Eifelian is documented by conodonts. In the Jeseniky Mts
conodonts are rare in the Middle Devonian and the Middle &#47; Upper
Devonian boundary is not yet documented by conodonts. The most
important change in the conodont assemblage lies in the upper part of
the Pa. triangularis Zone in Moravia; for detailed zonation of
Famennian, the system based on phylogeny of Palmatolepis is accepted.
Five foraminiferal zones correlated with the standard conodont zonation
are distinguished in the Upper Devonian. Several stromatoporoid
assemblages were distinguished in the interval from Eifelian to
Frasnian; stromatoporoids pass into the Famennian. Eight tabulate coral
biozones are known at present, some of which are capable of more
detailed division. Biostratigraphically significant tabulates range
from Eifelian to the Famennian Pa. crepida Zone. Seven rugose coral
biozones are described, ranging from Eifelian to the upper Frasnian Pa.
gigas or Pa. triangularis Zones with a local fauna known from the
```

```
Famennian Pa. crepida Zone. Stromatoporoid and coral faunas are
correlated with standard conodont zonation of the Upper Devonian.
Stromatoporoid and coral shallow water faunas locally pass from upper
Frasnian to Famennian without pronounced systematic changes. However,
both diversity and abundance of coral and stromatoporoid faunas
decrease noticeably across the Frasnian &#47; Famennian boundary
beds.^1";

</b>; <b>Stratigraphy: </b>Devonian Fra/Fam; <b>Geography: </b>Europe
Variscan^The worldwide Devonian reef growth was terminated in large
areas during the triangularis and gigas zone (Upper Devonian I &#47;
&#948;). To explain this phenomenon six profiles with the transition
from reef to non-reef facies ranging from Namur (Belgium) to Wuppertal
(Germany) were investigated microscopically and geochemically. It
turned out that the periodically increased production and sedimentation
of clayey and mainly organic material directly controlled the Upper
Devonian reef growth and finally caused its termination. Increased
plate tectonical shifting of the land areas during the Upper Devonian
finally triggered off the following chain of events: increasing rates
of periodical rainfalls - intensified spreading of land plants -
increased chemical weathering - periodically increased transport of
nutrients and clastic material into the reef habitat - increased
production and sedimentation of phytoplankton - termination of
reefgrowth - finally euxinic sedimentation (Lower Kellwasser limestone,
Upper Devonian I &#948;).^1";

Riffentwicklung im Elbingeroder Komplex (Harz).- Facies 23: 97-108.-
<b>FC&#038;P 20-1.1</b>, p. 66, ID=2847^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian; <b>Geography:
</b>Germany, Harz^The Elbingerode Reef developed on a volcanic rise
within the Rhenish Trough of the Variscan Geosyncline during the upper
Middle Devonian (Givetian) and early part of the Late Devonian
(Frasnian). Reef development can be recognized in the Elbingerode
Complex from the varcus Zone up to the gigas Zone of conodont
chronology. Volcanic activity came to an end in the Elbingerode Complex
nearly isochronously within the Middle and Upper varcus Zone (iron-ore
bed). Reef growth started in the Upper varcus Zone (Middle Devonian).
The lithology of the reef limestones permits a general distinction
between peripheral detrital reef limestones (fore-reef) and lagoonal
limestones (back-reef). Unbedded reef debris characteristic of the
outer reef flank is represented mainly by rudstones and packstones. The
biogenes are clasts of corals and stromatoporoids. This facies type
contains conodonts. In the lagoon facies mudstones and grainstones with
peloids are abundant. Stomatactis and birdseye structures are
characteristic. The bedded limestones of this region mainly contain
amphiporoids, gastropods, brachiopods, calcispheres and foraminifers,
and only subordinate stromatoporoids and corals. The back-reef
limestones generally lack conodonts. A division of the reef complex
into back-reef and fore-reef areas is only possible for the Middle
Devonian (pre-rotundiloba interval). The lagoon was filled during the
Late Devonian (Lower asymmetricus Zones), so that younger reef
limestones (asymmetricus to gigas Zones) lack a back-reef sedimentation
(cape stage). The central Elbingerode Complex displays the
```

```
palaeographical picture of an atoll with a leeward lagoon and an outer
circle of calcareous reef debris. The Neuwerk and Buchenberg anticlines
and other anticlines were originally volcanic rises extending in front
of the atoll in a bathymetric deeper position and with an independent
sedimentation. The transgressive character of reef development
(formation of a so-called reef onion) is deduced from the dip of the
bedding of the reef limestones. The sequence reef limestones
-brachiopod limestones (post-reef limestones) - pelagic post-reef
limestones also provides good evidence that the end of the reef
development was caused by an increasing subsidence. The reef growth in
the Elbingerode Complex terminated in different places at different
times. The last sign of reef building is known from the Upper gigas
Zone. The end of the Devonian reefs and the beginning of the flysch
stage are genetically and temporarily related, but took place
regionally separated from each other.^1";

</b>sedimentology; sedimentology; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian Eif &#47; Giv; <b>Geography:
</b>Ardennes^The sedimentology of the Eifelian-Givetian boundary beds
in the Wellin area indicates a transition from a
siliciclastic-carbonate ramp to a gently sloping carbonate platform
lacking a true reefal barrier. Prograding decametric sedimentary units
form a littoral accretion megasequence. Corallian megafauna and algal
microflora are highly diverse and abundant. Several communities are
recognized in the ramp but they cannot be used for precise
chronostratigraphic correlations. Comparison with other regions of the
Dinant Synclinorium shows that the basin was already partitioned into
blocks in Late Eifelian time. In Early Givetian several blocks of
plurikilometric extension are identified. In this context, recognition
of a new formation, provisionnally called &#034;Formation X&#034;,
between the Jemelle and Hanonet Formations, is significant. This local
unit, some 120 meters thick, is composed of crinoidal and reefal
limestones and indicates the existence of a sharply subsiding block in
the Wellin area.^1";

Upper Emsian to Lower Eifelian and consists mainly of sandy silt- and
mudstones with shallow marine fauna. It is proved by brachiopods, that
the upper part of the Cultrijugatus Beds is of Lower Eifelian age. With
no break, fossiliferous, marly beds of the Hobracke Formation (without
Paraspirifer) follows above. The upper part of the Cultrijugatus Beds
contains very fossiliferous coral limestones. The majority of coral and
brachiopod species continued to overlying beds with no visible mass
extinction by the jugleri/Chotec Event. Probably, this event was not
very important for corals and stromatoporoids. [last fragment of
extensive summary]^1";

57, ID=3356^<b>Topic(s): </b>carbonate platforms; carbonate ramp;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Fra/Fam;
<b>Geography: </b>Czech Republic, Moravia^The Frasnian-Famennian
limestone sequence of Lesni Lom displays a series of significant gaps,
especially at a stratigraphical level encompassing the final Late Pa.
rhenana Zone and the Early Pa. triangularis Zone. Mixed nearshore and
nektonic &#47; pelagic faunas, as well as mixed allochems derived from
a large spectrum of facies belts, point to an inclined outer carbonate
ramp depositional environment. The maximum water depth probably
exceeded several tens of meters. However, extreme and short-term
sea-level falls around the Frasnian-Famennian (F-F) transition might
have stripped a substantial part of the sedimentary cover on this ramp.
The presence of an increasing amount of unstable siliciclastic grains,
followed by the influx of lateritic and ferruginized particles are
typical for the Lesni Lom F-F sequence. This can be correlated with an
oolitic ironstone level, which has been described from an &#039;inner
ramp&#039; sequence at &#039;V Habesi&#039;. The latter iron-horizon,
resembles the Famennian ironstones of Belgium, but it has also good
analogues in the F-F sequences of the Russian Platform. Rebuilt corals
and foraminifers seem to indicate different biotic and environmental
controls, separately on the outer and/or inner ramp. Although more than
twenty groups of taxa are discussed, only four of them - corals, fish
remains, foraminifers and conodonts - have been described in detail.

<b>Geography: </b>Poland, Holy Cross^Givetian and Frasnian
stromatoporoid-coral limestone of the Kowala Formation in the southern
Holy Cross Mts is subdivided stratigraphically, and correlated with
strata elsewhere on the basis of identified sea-level cyclicity, with
support from conodonts and other selected benthic fossils. After the
Eifelian hypersaline sabkha phase, an extensive two-step regional
colonization of the Kielce Region carbonate platform took place during
the Eifelian/Givetian passage interval and the Middle Givetian. At
least four deepening pulses resulted in intermittent drowning of the
vast carbonate platform and sequential replacement of the
undifferentiated Stringocephalus biostromal bank by the Sitkówka bank
complex and, subsequently, by the Dyminy reef complex. The reef
developed in the central Dyminy belt as result of the early Frasnian
accelerated sea-level rise after some period of biotic stagnation near
the Givetian-Frasnian boundary. Final demise of the reef resulted from
combined eustatic and tectonic movements during the late Frasnian major
crisis interval. [original abstract]^1";

Rhenish Mts^Initial stages of Givetian reefs in the Rhenish
Schiefergebirge are characterized by short-term primary and/or
secondary ecological successions. Complete sequences from the start of
the substrate colonization to the end of the (first) domination stage
do not exceed 75 cm. The guild composition of colonization,
diversification and domination stages (sensu Miller 1991) depends on
the paleogeographic situation, the water energy and in particular on
the terrigenous input. High clastic influx led to numerous repetitions
of the colonization stage without the development of diversification
and domination stages. Good environmental conditions allowed the
development of primary and/or secondary successions from the
colonization stages to the diversification and domination stages. In
such reef sequences the limestones, up to some 100 m thick, consist of
repetitions of the diversification and/or domination stages.^1";

Controls on Biogenic Sedimentation I. Reef Evolution]: pp ???.-
<b>FC&#038;P 26-1</b>, p. 47, ID=3621^<b>Topic(s): </b>reefs, ecology,
zebra limestones; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fra; <b>Geography: </b>Germany, Harz^Mud mounds are
special cases of local hill-shaped marine accumulations of
stromatactis-bearing carbonate mud. In contrast to reefs, a rigid
framework of bioconstructors is absent. The investigated Upper Devonian
Ruebeland Mud Mound in the Harz Mountains is completely constructed by
black and white micrites with stromatactis. Intercalated are
stromatolites and zebra limestones. The carboante mud buildup was
essentially accumulated and early cemented by microbial activities.
Within the sediments of the whole buildup a distinct rhythmicity
between spreading of microbial mats respectively the formation of white
mudstones and real sedimentation of microfossiliferous wackestones is
indicated. Thrombolitic mudstones, spar layers and stromatolites are of
microbial, mostly cyanobacterial, genesis. Main controlling factors on
Ruebeland mud mound growth are endogenic block movements and the
rhythmical exogenic efficiency of microbial colonies. Hexactinellid
sponges are the only macrofossils. Their issues seem to play a second
order role in formation of carbonate mud. Most important for micrite
formation of the white mudstones are micritized and lithified,
laterally extended cyanobacterian colonies (cf. Epiphyton sp.)
representing about 40-50% of the whole mound matrix.^1";

</b>sequential stratigraphy; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Spain, Cantabrian
Mts^The laterally equivalent Portilla and Candas Formations
(Givetian-earliest Frasnian), a dominantly carbonate succession with
reef-bearing intervals, was deposited in a carbonate ramp setting,
zoned into a backreef lagoon, a reef tract and a calcarenite forereef
belt distally grading to outer shelf marls and terrigenous mudstones.
Sequential facies analysis of the reef-bearing intervals produced a
model of ramp evolution. The succession is arranged in sequences up to
several tens of metres thick. Each sequence has a sharp to rapidly
transitional base and splits into a lower transgressive subsequence
(commonly very thin or absent) and an upper regressive one. Reefs, when
present, cap the regressive subsequence. [first fragment of extensive
summary]^1";
s[817] = "HLADIKOVA J., HLADIL J., ZUSKOVA J. (1997).- Discrimination
between facies and global controls in isotope composition of
carbonates: carbon and oxygen isotopes at the Devonian reef margin in
Moravia (HV-105 Krtiny borehole).- Journal Czech Geol. Soc. 42, 1-2:
1-16.- <b>FC&#038;P 27-1</b>, p. 117, ID=3877^<b>Topic(s): </b>stable
isotopes; stable isotopes; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Czech Republic, Moravia^Relations among
the isotope ratios, chemical composition, sedimentological features,
eustatic fluctuations and diagenetical history have been documented
from the reef &#47; basin transition in the Moravian Karst (Krtiny
HV-105 borehole). The &#948;13C and &#948;18O values of the Late
Devonian limestones are within the ranges for the Late Devonian marine
sedimentary environment. Nevertheless, the originally diverse isotopic
compositions of the fossils and other rock components were changed in
closed marine pore-water &#47; rock systems, under conditions of
rapidly decreased permeability. In the studied sequence &#948;13C
values of 2 to 2,5‰ are characteristic for bioherms, parts of the
fore-reef to off-reef slope, and offshore lagoons. The &#948;13C values
close to 0 are characteristic for shallow-back-reef. The low &#948;13C
values of reef margin developed during the occasional emergence of this
```

```
facies. A significant anomaly in &#948;13C values (up to +5.5‰) has been documented at the transition between the proximal and distal forereef in the Pa. transitans Zone of the Early Frasnian, just before the maximum sea-level rise. This unusual positive excursion of the &#948;13C values does not correspond to the global-event anomalies. The existence of this anomaly on the slope of the Moravian Karst is tentatively expalined by a local IIIrd-category upwelling, a result of the diversion of the deeper contour and shallower wind-driven currents away from the shore. This anomaly corroborates the hypothesis of a strong facies control of the &#948;13C content in carbonates.^1";
s[818] = "MAY A. (1997).- Sind die devonischen Riffe des Sauerlandes heutig Korallenriffe vergleichbar? .- Dortmunder Beitraege Landeskunde., Naturwissenschaft Mitteilungen 31: 127-135.- <b>FC&#038;P 28-1</b>, p. 52, ID=3990^<b>Topic(s): </b>reefs, modern vs fossil; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M U; <b>Geography: </b>Germany, Rhenish Mts, Sauerland^In this paper reasons are given why the Massenkalk reefs (Middle &#038; Upper Devonian) of the Sauerland are not comparable to modern coral reefs. A new model is developed explaining the observed carbonate facies without contradiction. This model assumes that the &#034;reef cores&#034; of the Massenkalk reefs were no barrier, but the uppermost part of the basinward directed slope of the carbonate platform. The distribution of stromatoporoid - dominated facies on the reefs is considered.^1";

Two kinds of lithological successions have been observed, corresponding to the formations newly defined in the Philippeville anticlinorium (proximal facies) and on the southern border of the Dinant Synclinorium (distal facies). The geographic repartition of the two facies is schematically presented. A new section (distal facies) is described from the Hermeton valley (SE of the Philippeville anticlinorium). As a conclusion, the origin of the coexistence of the two facies types in the Philippeville anticlinorium is discussed.^1";
s[820] = "FERNANDEZ-MARTINEZ E., SOTO F., MENDEZ-BEDIA I. (1994).- An example of reef development in the Middle Devonian (Candas Fm., Givetian) in the Cantabrian Mountains (NW Spain).- Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 103-110.- <b>FC&#038;P 23-1.1</b>, p. 16, ID=4068^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Spain, Cantabrian Mts^A well exposed section, showing three different types of reef carbonate units of the Candas Formation (Givetian) close to the locality of Coallaju (province of Asturias, NW Spain, Cantabrian Mountains), is described in detail. This formation consists of limestones with argillaceous intercalations, marls and dark lutites. These materials were deposited probably on a carbonate ramp with gentle slope and irregular bottom. The first type with a biohermal aspect, lithologically consists of limestones; its basal part overlies a crinoid-brachiopod packstone. This bioherm, small in size, is mainly built by tabular and hemispherical stromatoporoids and alveolitids associated with smaller numbers of other organisms. The second type, developed in argillaceous limestones, consists of a series of biostromes formed by branching coral bafflestones (Thamnopora and Smithiphyllum); within them an outstanding massive rugose coral framestone (Argutastrea and Endophyllum) occurs. The third type,
```

```
biohermal in shape, is made up of massive grey limestones forming a
sharp relief on the terrain. Recrystallization of the builders and bad
exposure conditions prevented the study of the faunal content and,
therefore the analysis of this reefal unit. A detailed analysis is made
of the faunal composition, with special emphasis on the more common
fossil assemblages in these reef units. Finally, on the basis of faunal
and sedimentological data, a paleoecological interpretation is given.^1";

<b>Stratigraphy: </b>Devonian M U; <b>Geography: </b>Czech Republic,
Moravia^Maps of individual buildup facies from the prospected ME
Moravia oil field (100 x 25 km) are presented. Considering reshuffle of
the Devonian lithostrata and of the stratigraphic columns for the
individual tectonic belts, the basinal analysis is suggested, including
an expanded tentative model of the Frasnian configurations. Besides the
global climatic factors, the Emsian-Frasnian tectonic changes within
the Laurussian shelf favoured the giant growth of the Givetian-Frasnian
buildups. ^1";
s[822] = "MENDEZ-BEDIA I., SOTO F., FERNANDEZ-MARTINEZ E. (1994).-
Devonian reef types in the Cantabrian Mountains (NW Spain) and their
faunal composition.- Courier Forschungsinstitut Senckenberg 172
[Oekentorp-Kuester P. (ed.) Proceedings of the VI. International
Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 161 -183.-
<b>FC&#038;P 23-1.1</b>, p. 17, ID=4073^<b>Topic(s):
</b>classification; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Spain, Cantabrian Mts^In the Paleozoic
series of the Cantabrian Mountains, reefal carbonates occur first in
the Devonian. In this period, a sequence of terrigenous and carbonate
sediments with varied reefal development was deposited on a shallow
marine platform. The most widespread reef facies occurred at the end of
the Lower Devonian and in the Middle-Upper Devonian, coinciding with
the deposition of the Moniello-Santa Lucia (Upper Emsian-Lower
Eifelian) and Candas-Portilla (Givetian, locally Givetian-Lower
Frasnian) Formations. In addition, some reefal episodes of minor
importance were developed at slightly older and younger stratigraphic
levels (Rafieces-La Vid Group and Pineres-Nocedo Formation,
respectively). Carbonate facies in the Moniello-Santa Lucia Formation
are arranged in parallel strips with sublittoral facies towards the
west and southwest and shallower water, lagoonal and peritidal deposits
towards the north and east. In the more distal facies, biostromes and
bioherms occur. The bioherms, developed in massive limestones, consist
of large stromatoporoid and tabulate coral framestones with numerous
encrusting growths, the stromatoporoids being the dominant reef
building organisms. The biostromes are developed in the more
argillaceous limestones. Seven types have been distinguished on the
basis of their faunal composition and the morphology of the
constituting organisms (mainly stromatoporoids and corals). The study,
mainly paleontological, of the reef structures present in the
Candas-Portilla Formation suggests a sedimentation model corresponding
to a carbonate ramp, with a gentle slope towards the south and west and
a slightly irregular bottom, where biostromes and occasional bioherms
were developed. Bioherms are basically built by tabulate and massive
rugose corals, although stromatoporoids more rarely occur as one of the
main reef builders. Six types are differentiated on the basis of faunal
composition and the morphology of the principal reef building
organisms. On the basis of the faunal content and sedimentological
observations of these reefs, different paleoecological interpretations
are made of the most favourable environmental conditions for their
development.^1";

92, ID=4211^<b>Topic(s): </b>reef complexes, cyclicity; reef complex,
cyclicity; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>Germany, Rhenish Mts^The carbonate sequence (600 m
thickness) of the Asbeck quarry (Hoenneta1, Rhenish massif) belongs to
the Devonian Hagen - Iserlohn - Balve reef complex and consists of reef
core, lagoonal, and inter-/supratidal deposits. The succession of the
six principal facies types allows recognition of three orders of
cycles. 1st order cycles subdivide the section into five formations.
Complete 2nd order (decameter) and 3rd order (1-3 meters) cycles
exhibit a subtidal (reef core &#62; sublagoonal &#62; lagoonal) &#62;
intertidal &#62; supratidal succession. They represent the regressive
pulses of relative sea-level changes following rapid nondepositional
transgressions. These can eventually be explained by abrupt subsiding
movements of the Lenne inversion structure at the northeast margin of
which the depositional area was situated. During each of the following
tectonically quiet phases, seaward shoreline progradation was combined
with a progressive infilling of the lagoon behind the reef belt,
finally resulting in tidal influences and subaerial exposure. Due to
the biostratigraphical data, correlations with eustatic sea-level
curves are impossible.^1";
s[826] = "SOTO F., MENDEZ-BEDIA I., FERNANDEZ-MARTINEZ E. (1994).-
Construcciones Arrecifales del Devonico de la Cordillera Cantabrica (NO
de Espana).- Revista Espanola de Paleontologia 9, 1: 29-36.-

ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Ems
- Giv; <b>Geography: </b>Spain, Cantabrian Mts^In the Asturian-Leonese
area of the Cantabrian Zone, an important reef development took place
during the Devonian. The most widely represented reef structures
originated at the end of the Early Devonian (late Emsian) and during
the Middle Devonian (Givetian), coinciding, respectively, with the
deposition of the Moniello-Santa Lucia and Candas-Portilla limestone
formations. Minor reef episodes occurred also at older stratigraphic
level (Rafleces-La Vid Group, late Emsian) as well as younger ones
(Pifleres-Nocedo Formation, Frasnian). Most frequently, the reef units
correspond to biostromes. However, bioherms also occur. In the
Moniello-Santa Lucia Formations, stromatoporoids are generally the main
reef-building organisms; in all other formations, the most common reef
builders are rugose and tabulate corals. A palaeoecological analysis
has been combined with results of earlier sedimentological work in
order to reach conclusions regarding the most favourable conditions for
reef development as well as the role played by the different reef
building organisms.^1";

taxa in Boulonnais have Old World Realm affinities. Nevertheless about
5% of the benthic taxa in Tabulate Auloporida, brachiopods, crinoids,
ostracods are very similar to eastern Americas Realm taxa and their
occurrence, with references to the conodont zonation, comes later in
Boulonnais than in North America. The distribution of these benthic
taxa in different Givetian-Frasnian palaeogeographical reconstructions
shows large discontinuities: we must assume some trans-oceanic
migrations from North America to western Europe. To be successful,
these trans-oceanic migrations need the combination of many different
factors, including both biotic and non biotic ones. The uncertainties
of the result can explain the observed diachronisms.^1";

ID=4555^<b>Topic(s): </b>biogeography; biogeography; <b>Systematics:
</b>; <b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Czech
Republic, Bohemian Massif^Middle Devonian (Eifelian and early Givetian)
brachiopod and coral faunas of the Bohemian Prague Basin and Moravian
Celechovice and Horni Benesov regions, Czech Republic, are essentially
dissimilar to each other, although the trilobites of the Prague Basin
and Horni Benesov show some similarity. Apart from their mutually low
similarity, expressed by the Otsuka Coefficient, each of the Czech
faunas is comparable to faunas of other regions, particularly to the
Rhenish Slate and/or Harz mountains. Although some of the differences
among the respective Bohemian Massif faunas are mostly
facies-controlled, they also appear to be a consequence of dispersal
patterns of larvae by marine surface currents. Shallow water benthic
communities show that oceanic circulation at this time could have been
restricted by land masses, and perhaps by quite disjunct regions that
have since been juxtaposed. As the Bohemian massif approached southern
Laurussia, a progressive exchange of faunas from both shelves took
place. It appears, moreover, that from late Emsian to the present there
was not a significant separation between North Africa and Europe.^1";

in a Devonian atoll: Iberg Reef, Harz Mts., Germany.- Palaios 10, 2:
180-189.- <b>FC&#038;P 24-2</b>, p. 98, ID=4605^<b>Topic(s): </b>reefs,
facies pattern; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fra; <b>Geography: </b>Germany, Harz^The Middle to Upper
Devonian Iberg Reef was an oceanic atoll within the Rhenish Trough of
the Variscan Geosyncline. It existed for at least 15 million years
before it was drowned shortly before the turn of the
Frasnian-Famennian. The spatial distribution of facies and early
diagenetic features within these Frasnian reef limestones confirms the
reefs paleogeographical location between the equator and 30° south. The
southeastern, windward side of the atoll was dominated by massive
stromatoporoids and bulbous corals as well as by encrusting and
dendroid stromatoporoids. Reef-builders were rarely preserved in situ.
Several generations of early fibrous cement form thick isopachous
crusts on the limestone components, confirming early lithification. On
the northwestern, leeward side, platy and branching stromatoporoids and
corals predominated. They were mostly preserved in growth position.
Fine-grained sediment forms a large portion of the limestone matrix. A
leeward lagoon entrance was marked by large thickets of branching
rugose corals and a mixture of back reef and fore reef faunal elements
in the northwesternmost lagoonal limestones. A chain of stromatoporoid
gravel cays formed inside the lagoon due to wave-refraction on the
southern reef front.^1";
s[832] = "GISCHLER E. (1995).- Guilds and cycles in Devonian fore reef
limestones: a preliminary study (Iberg Reef, Harz Mts., Germany).-
Neues Jahrbuch fuer Geologie und Palaeontologie, Monatshefte 1995, 5:
279-294.- <b>FC&#038;P 24-2</b>, p. 99, ID=4606^<b>Topic(s): </b>reefs,
benthic guilds; fore reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fra; <b>Geography: </b>Germany, Harz^Facies and organism
guilds (constructor, binder, baffler, dweller, destroyer) were
quantitatively investigated in 497 evenly spaced samples in the upper
part (30-160m) of the borehole &#034;Iberg 1&#034; that penetrates 420m
of Devonian reef limestones. The investigated section encompasses
transitans, punctata, hassi and parts of falsiovalis and jamieae
conodont zones of the Frasnian which cover a time span of 2-2.5 Ma. The
majority (72%) of the limestones are rudstones; 19% of the limestones
are grainstones; only 9% of the core are stromatoporoid and coral
boundstones. The first component obtained by principal component
analysis of the time series can be assigned to the process of reef
construction. A Fourier spectral analysis revealed cyclic fluctuations
of the first component, although cyclic changes are not visible in the
core. The relationships of the cycles to orbital cycles and sea level
fluctuations are discussed.^1";

stratigraphy, ecology; reef complexes; <b>Systematics: </b>;
<b>Stratigraphy: </b>Devonian M U; <b>Geography: </b>Ardennes^The
Middle and Upper Devonian (Frasnian) reef-complexes are well exposed in
the Dinant, Namur and Vesdre basins. The Middle and Upper Devonian
stratigraphy and sedimentation in Belgium are briefly described. Early
work interpreted the red coloured Phillipsastraea facies as a time
stratigraphic lithologic unit. However, from detailed field
examinatiion, detailed paleoecologic study and rugose corals study,
this red coloured Phillipsastraea facies is in fact time-transgressive.
The most common and important fossil organisms found in the reef
complexes are illustrated. Their distribution in the reef complexes and
their ecological significance are discussed. The variations in
sedimentary facies within the reef complexes are described and related
to factors which influenced the changes. The depositional. history is
outlined and divided into four phases: a. the transgressive phase, b.
the relatively stable phase, c. the regressive phase and d. the
transitional phase. Finally, the terminology and classification for the
```

```
various carbonate depositional environments of the different facies are
suggested.^1";

Frasnian in Belgium.- [journal?] Symp. Namur 1974, publication 12.-
<b>FC&#038;P 4-1</b>, p. 39, ID=5142^<b>Topic(s): </b>ecology; ecology;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian M U; <b>Geography:
</b>Ardennes^The paleogeographic patterns of the Middle Devonian and
the Frasnian are first reconstructed and illustrated. Generally, the
Couvinian and the lowermost Givetian beds become more and more sandy
towards the north and east. This indicates clearly that the sediments
came from the direction of the Brabant and Stavelot massifs. Evidence
furnished by the facies distribution demonstrated the existence of the
Rocroi and the Stavelot islands. In Middle Couvinian time, the
continental regions were in the north. The Rocroi island was a very low
almost featureless area, but the Stavelot island was still high land.
It was only at Middle Givetian time that the Stavelot island became a
nearly featureless region, and the Rocroi island subsided with the
transgression of Gi2a and disappeared definitively during early Middle
Givetian time. The Upper Givetian beds represent a regressive phase.
The Gi3&#946; is a period of relative stability during the regressive
phase. The paleogeographic pattern of Frasnian time is quite different
from those of the Middle Devonian. Consequently, the development of the
reefs and the sedimentary facies distribution were in a manner totally
different. * Then the most common and important fossil growth forms are
described. Their ecological significance is discussed in detail. In the
case of Lion reef, Stromatoporoids and Corals were the principal frame
builders in the Devonian reefs. Algae were subordinate. In the case of
Neuville reef, Algae were the principal reef builders. * The reefs grew
in various environments with correspondingly different associations of
reef-building organisms. * Finally the factors which controlled the
vertical and lateral distribution of the various facies are discussed.
Several major lithic-faunal associations are recognized during the
different phases in the Middle Devonian and Frasnian rock sequence of
Belgium. Five types of organic reefs can be distinguished in the
Ardennes geosyncline. The reef development was mainly controlled by the
paleo geographic pattern and the epeirogenic movements.^1";

<b>Stratigraphy: </b>Devonian; <b>Geography: </b>Czech Republic,
Moravia^(1) At the cummulation of the facial and stratigraphical
sections trough the Devonian reef complex of Macocha - formation
defined by Zukalova - Chlupac (1982) a cyclic pattern of carbonate
sedimentation has been observed. The cycles of various order have been
documented. In the present paper four composite cycles of the greatest
magnitude are defined. Starting from the base they are the
Celechovice-cycle, the Byci-cycle, the Ochoz-cycle, and the
Mokra-cycle. (2) The range zone of the defined cycles are marked by
clastic intercalations, break and erosion levels, laminite, breccia or
limestone with many intraclasts, nodular textures, intensive
dolomitization or occasionally by silification. The development of low
magnitude and complex cycles of the greatest magnitude generally obtain
the Kassig&#039;s phasis succession. Progressively, the dark micritic
carbonate sediments go over the Amphipora limestones to predominantly
light-grey biostromal and biohermal limestones. Succession may be
modified by local factors, but ranges of major cycles are are
remarkably fast in all cases. (3) The cycles mentioned above are more
restricted to some time-scale intervals than members which are used
usually im mapping. Therefore, these cycles make possible to correlate
borehole cores in inner structures of the Macocha Formation. Each of
the cycles has particularly modified its lithological succession and
biozone sequence, essential in low taxons at least, in context to
development of the whole reef complex (see Hladil 1983). Application of
cycles defined concerns the oil wells drilled in Bohemian massive
slopes, in the &#034;South&#034; region. [original summary]^1";

</b>; <b>Stratigraphy: </b>Devonian M; <b>Geography: </b>Portugal^The
Odivelas Limestone constitutes one of the few records of Middle
Devonian sedimentation in the western Ossa-Morena Zone. Although
deformed and metamorphosed the limestones have an abundant fossil
content which allows their positioning as late Eifelian/early Givetian
in age and to relate the reef fauna with the typical Rhenish facies for
the same time period. Magnetic susceptibility analysis was attempted
and is in agreement with the biostratigraphy, but the limited extent of
sections and the metamorphism precludes firm correlations. The field
evidence, petrographic and geochemical analysis point to a close
paleogeographical relation and dependence of the reef system on
volcanic structures which are included in the Beja Igneous Complex. The
age of part of the volcanic and sub-volcanic suite of this complex is
thus constrained. [original abstract]^1";

Stratigraphic succession, facies and depositional environment of Emsian
reefal carbonates in the Ossa-Morena Zone (SW Spain).- Neues Jahrbuch
fur Geologie und Palaontologie Abhandlungen 257, 1: 69-83.-
<b>FC&#038;P 36</b>, p. 121, ID=6564^<b>Topic(s): </b>reefs carbonates;
reefs, carbonates; <b>Systematics: </b>; <b>Stratigraphy: </b>Devonian
Ems; <b>Geography: </b>Spain SW^The Devonian succession between the
Guadiana and Guadalquivir valleys in the Obejo-Valsequillo Domain
comprises more than 600m of shale and sandstone with some interbedded
limestone and marl. The most complete reefal sequences of the region
are exposed in the Guadamez-2 section, which is located on the western
bank of the Guadamez River, near Zalamea de la Serena. It consists
mainly of shale and calcareous shale in its lower part and shaly,
skeletal and reefal limestone in its upper part. Conodont and
brachiopod data indicate that this section spans the interval from the
Lochkovian to at least the upper Emsian. Eight microfacies types have
been identified in the calcareous facies: (A) brachiopod-echinoderm
wackestone/packstone; (B1) echinoderm grainstone; (B2)
echinoderm-bryozoan grainstone/packstone; (C) echinoderm packstone; (D)
tabulate coral rudstone; (E) brachiopod wackestone/packstone; (F)
brachiopod grainstone/packstone; and (G) stromatoporoid and tabulate
coral boundstone/rudstone. Microfacies A, B1, C, E and F represent a
sequence of environments from middle platform (A) to tidal flat (F),
including shoals (B1) and shallow platform facies. Microfacies B2, D
and G represent the development of patch-reefs superimposed on the
shoals. [original abstract]^1";

Fra; <b>Geography: </b>Ardennes^This memoir on the Frasnian formations
of Belgium is the result of meetings and field trips of the National
Subcommission on Devonian Stratigraphy. It was prepared in
collaboration with geologists involved in the new mapping programm of
Wallonia at scale 1/25 000. Seventeen formations are described. Six of
them (Aisemont, Barvaux, Bovesse, Franc-Waret, Matagne en Rhisnes) are
well known from literature. The eleven others (Grands Breux, Huccorgne,
Lambermont, Lustin, Moulin Lienaux, Neuville, Philippeville, Pont de la
Folle, Presles and Valisettes) were introduced during the last twenty
five years. All these formations are revised and presented in files
giving a brief historical account, location of the reference sections,
lithology, limits and thickness at the stratotype or the reference
sections, lateral variations, ages and eventual uses. Furthermore, each
formation is documented by the location of the outcrops on a portion of
the relevant topographic map (scale 1/10 000) and by a cross-section or
a stratigraphic log of the stratotype or other reference sections.
```

```
Lastly, the tables in the opening section provide information on the historical subdivisions of the Frasnian in Belgium, the stratigraphic correlation between the Frasnian formations from different structural units recognized in this work and the stratigraphic distribution of the taxa of the fossil groups cited in the text. During the Famennian and Dinantian, the reef continuously subsided relative to sea level. In the latest Dinantian the reef was covered by clastics. Five deep-water organism assemblages colonized the Famennian-Dinantian seamount successively. They are well comparable to recent organism communities on deepwater coral banks. In the Famennian, abundant crinoids and ancillary rugose corals and brachiopods colonized the reef top. During the Late Tournaisian, a coral-crinoid assemblage established on the reef. It developed into a varied fauna of corals, crinoids, trilobites, brachiopods, bivalves, gastropods, and goniatites in the Early and Middle Visean. The Late Visean assemblage was dominated by goniatites and pseudoplanktonic bivalves. In the latest Visean, a monospecific brachiopod fauna and small microbial buildups thrived in extreme environmental conditions on the reef top. The skeletal debris of the organisms was eroded post-mortem and only accumulated in current-protected depressions of the reef surface, along with carbonate mud. Local depressions include hollows on the reef top, neptunian dikes, and pore space of a breccia that formed due to intensive shattering of the reef top during nearby volcanic activity. During most of the Famennian and Tournaisian, there is a hiatus caused by non-deposition. Only reworked Famennian and Tournaisian conodonts recovered from Upper Tournaisian-Middle Visean limestones give evidence of marine conditions on top of the reef. The sedimentary environment on the drowned atoll compares well to that on recent guyots, including hiatuses, slow and patchy sedimentation, erosion and redeposition. Both the aftermath of the Frasnian &#47; Famennian extinction that drastically reduced metazoan reef builders and a trend towards lower temperatures in the Famennian and Dinantian are believed to have produced the reestablishment of a shallow water reef on the drowning Devonian atoll.^1";

Rugosa from Western Pomerania, northern Poland.- Acta Geologica
Polonica 55, 4: 393-443.- <b>FC&#038;P 34</b>, p. 30,
ID=1226^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian &#47; Carboniferous;
<b>Geography: </b>Poland NW^The taxonomic description of the Late
Devonian and Early Carboniferous Rugosa from the boundary area of the
Precambrian East European Craton and the Palaeozoic platform of Central
Europe is presented. Palaeontological analysis and the stratigraphical
distribution of the corals in Western Pomerania enabled recognition of
several faunistic events, which reflect evolutionary trends in rugose
corals. The pre-crisis Frasnian coral fauna, dominated by colonial
forms both massive [Disphyllia laxa (Gürich, 1896), Hexagonaria
hexagona kowalae Wrzolek, 1992, ?Frechastraea] and branching
[Disphyllum kweihsiense Yoh, 1937, Peneckiella ?fascicularis (Soshkina,
1952), Thamnophyllum monozonatum (Soshkina, 1939), Peneckiella
szulczewskii Rózkowska, 1979], developed on the carbonate platform
extending along the edge of the East European Craton. The similarity of
these faunas to Rugosa faunas from southern Poland is significant. The
coral fauna was reduced significantly after the Kellwasser crisis.
Colonial corals disappeared altogether and solitary dissepimented forms
were markedly reduced. The subsequent Late Famennian radiation caused a
significant quantitative and qualitative differentiation of the coral
faunas. In addition to the well-known &#039;Cyathaxonia fauna&#039;,
warm and shallow-water solitary corals appeared in the latest
Famennian. The stratigraphically important taxa of the latest Famennian
include: Campophyllum Milne-Edwards &#038; Haime, 1850, ?Palaeosmilia
aquisgranense (Frech, 1885), Bounophyllum pomeranicum sp.nov. and
Guerichiphyllum kowalense Rózkowska, 1969. The latest Famennian
regression caused subdivision of the Pomeranian area into at least two
sedimentary basins, separated by shallows, with peculiar ecological
conditions, and the appearance of numerous endemic taxa. This
regressive interval contains, however, numerous levels yielding less
restricted faunas, which suggest the intermittent appearance of more
open-sea conditions.^1";

(Wocklumeria or Gattendorfia Stage) in the Holy Cross Mts, and assigned
to nine genera (three new ones) and four families (one new family and
one new subfamily). Corals with the pentaphylloid type of septal
insertion have been separated to form a new suborder Tachylasmatina,
their separation from the superfamily Polycoelaceae being based on
their different ontogeny.^1";
s[870] = "POTY E., DEVUYST F.-X., HANCE L. (2006).- Upper Devonian and
Mississippian foraminiferal and rugose coral zonations of Belgium and
northern France: a tool for Eurasian correlations.- Geological Magazine
143, 6: 829-857.- <b>FC&#038;P 35</b>, p. 56, ID=2345^<b>Topic(s):
</b>biozonation; Rugosa, forams, stratigraphy; <b>Systematics:
</b>Cnidaria Foraminifera; Rugosa; <b>Stratigraphy: </b>Devonian U
&#47; Carboniferous L; <b>Geography: </b>Ardennes, France N^The
radiation of early Carboniferous foraminifers and rugose corals
following the Devonian-Carboniferous crisis offers the best tool for
high-resolution correlations in the Mississippian, together with the
conodonts in the Tournaisian, notable in the Namur-Dinant Basin.
However, some of the guides are facies-controlled and an integrated
approach combining biostratigraphy, Sedimentology and sequence
stratigraphy is critical to identify delayed entries, potential
stratigraphic gaps and to avoid diachronous correlations. The main
difficulty is in correlating shallow and deeper water facies at any
given time. In existing zonations, the Viséan part of the scheme is
always more detailed, reflecting the widespread development of
shallow-water platforms in the early Viséan which created conditions
more suitable for foraminifers and rugose corals over larger areas. In
contrast, the Tournaisian zones, less well documented, reflect
unfavourable environmental conditions in the lower ramp (Dinant
Sedimentation Area) and pervasive dolomitization of the inner ramp
(Condroz and Namur Sedimentation Area). Recent progress in
understanding the Belgian early Carboniferous sequence stratigraphy and
lithostratigraphy, and revision of the biostratigraphy of the key
sections, strongly modify former biostratigraphic interpretations.
Improvements mainly concern the latest Devonian, the late Tournaisian
and the early Viséan. The late Devonian and the Tournaisian are equated
with foraminifer zones DFZ1 to DFZ8 and MFZ1 to MFZ8 respectively. The
Viséan correlates with zones MFZ9 to MFZ14. Zone MFZ15 straddles the
Viséan- Namurian boundary and Zone MFZ16 is the youngest Mississippian
zone. The rugose corals allow the recognition of the zones, RC0 to RC9,
covering the Strunian (late Famennian) to Serpukhovian interval.
Discrepancies with former zonations are discussed. The Moliniacian
```

```
Stage is emended to restore the coincidence between the base and that
of the Viséan.^1";

<b>Systematics: </b>Cnidaria; Rugosa Heterocorallia; <b>Stratigraphy:
</b>Devonian &#47; Carboniferous; <b>Geography: </b>France, Montagne
Noire^Preliminary description of a small coral fauna from the Devonian
Carboniferous boundary section at La Serre, near Cabrieres, Herault
(selected as Global Boundary Stratotype to be submitted to the
International Commission of Stratigraphy, Washington 1989). * This
faunule consists of small solitary rugose corals, with tabulates and
heterocorals (Sutherlandia, Heterophyllia) partly related to the
&#034;Cyathaxonia fauna&#034; from the cephalopod facies of northern
Europe, particularly the Holy Cross Mountains. Succeeding the Famennian
metriophyllids of the basal unit (upper Palmatolepis expansa Zone) and
after an interval of beds nearly devoid of corals, an obvious change
coincides apparently with the boundary as defined by conodonts. It is
characterized by the appearance of Carboniferous genera with dominant
plerophyllids and some forms indicative of the Lowermost Tournaisian.
The very beginning of this Carboniferous fauna occurs at the base of
the Siphonodella sulcata Zone. * [Listed are] 11 genera, [with] 13
species of which most are new and provisionally described under open
nomenclature.^1";

studies on Tabulata and Chaetetida from the Givetian, Frasnian and
Visean of the Cracow-Silesian Upland (Cracow Region) and from the
Visean of south-western part of the Holy Cross Mountains (Galezice) are
presented. Fourty-one species of Tabulata (orders: Favositida,
Syringoporida, Auloporida) including eighteen new species, and six
species of Chaetetida (family Chaetetidae) including three new species
are described. Following new species are designated: Squameofavosites
megasquamatus sp.n., S. (Dictyofavosites) pachyfavositoides sp.n.,
Emmonsia czarnieckii sp.n., Michelinia aseptata sp.n., Palaeacis orlei
```

```
sp.n., Thamnopora striatoporoides sp.n., Alveolitella rarispinosa
sp.n., Crassialveolites polonicus sp.n., Natalophyllum dubiensis sp.n.,
Tyrganolites frasnianus sp.n., Syringopora sinusoidea sp.n., S.
subreticulata sp.n., S. tenuitheca sp.n., S. pachysiphonata sp.n.,
Multithecopora polonica sp.n., M. spinosa sp.n., Syringoporella
longituba sp.n., Sinopora polonica sp.n., Cyclochaetetes tuberculosus
sp.n., Chaetetella (Chaetetiporella) heterozoa sp.n., Ch.
(Chaetetiporella) rotaiformis sp.n. * It has been stated here that only
two types of asexual reproduction occur in Tabulata: (1) intracalicular
budding, and (2) longitudinal division. Three variants of
intracalicular budding have been studied in detail: (a) intravisceral
budding realized by wall outgrowths or invaginations in the wall of
parent calices; (b) mural budding, and (c) extravisceral budding. The
comparison of described Tabulata and Chaetetida assemblages with
contemporaneous assemblages of Europe and Asia indicates that: (1) the
Givetian assemblage of Debnik anticline is mixed and rather poor in
species; (2) the Frasnian assemblage of Debnik anticline displays great
similarity to West-European tabulate corals, (3) the Visean assemblage
from the Holy Cross Mountains (Galezice), except of a few local
components, is close to the West-European assemblages. The assemblages
of Chaetetida from the Visean of the Holy Cross Mountains (Galezice)
have many species common with East-European assemblages (Moscow Basin).

</b>paleontology; Cnidaria, Porifera; <b>Systematics: </b>Cnidaria
Porifera; <b>Stratigraphy: </b>Devonian, Carboniferous; <b>Geography:
</b>Ardennes^The Ardenne Massif is part of a complex of Palaeozoic
outcrops between the Channel in the west and the Rhine river and beyond
in the east. It has registered both the Caledonian and the Hercynian
orogenies. Originally part of a terrane located north of the Gondwana
supercontinent (Avalonia), it became an element of the southern margin
of the Old Red Sandstone Continent (ORSC, also called Euramerica,
Laureuropa, or Laurussia) in the Devonian and Carboniferous, when it
suffered the effects of the Hercynian orogeny by collision of the ORSC
and Gondwana. These global tectonic events, linked to climatic changes
due to continental drift, had profound consequences on the living
organisms of the Ardenne Massif. Here we focus on some aspects of a
series of animal groups of western Ardenne, being elements of either
the benthos (brachiopods, trilobites), or the reefal environments
(tabulate corals, stromatopores), or the nekton (vertebrates, including
the first tetrapods). When vertebrates (&#034;fishes&#034;) and
brachiopods were quite abundant as early as the base of the Devonian,
mostly in siliciclastic facies, reefal organisms appear only in the
Emsian, and become abundant in the Eifelian, with the development of a
carbonate platform. Reefs or reef-like buildings occur up to the Early
Carboniferous, where new fish assemblages are known. Trilobites occur
often with brachiopod-bearing communities. The trilobite-rich locality
of the &#034;Mur des Douaniers&#034;, at the former French/Belgian
boundary, is an example of an early Eifelian Fossil-Lagerstätte, now
protected as a Nature Reserve. [original abstract]^1";
s[876] = "ARETZ M., CHEVALIER E. (2007).- After the collapse of

```

```
Fam &#47; Carboniferous Tour; <b>Geography: </b>Ardennes^Reef
development in the Famennian and Carboniferous successions of Belgium
is more common than previously thought, and 10 broad time intervals of
reef development can be differentiated. Reef formation is due to a
variety of reef fabrics. Microbial communities are important for most
reef frameworks, and often crucial for formation and stabilization of
frameworks. Larger skeletal frameworks are rare. However, the
interaction of skeletal bioconstructors and microbial communities is
common, and results in successful reef building. However, microbial
communities are still the backbone of these reefs.The majority of reefs
are small, and a significant number formed in environments of
restricted marine facies. Large reefs developed only in the late
Tournaisian and late Viséan. Their initiation and formation was
controlled by the geometry of the shelf. Three hierarchical levels,
discussed below under the headings palaeobiology, local environment,
and regional and global environment, controlled reef formation.
Important limiting factors were relative water depth, sea-level
oscillations, climate, shelf geometry and the needs of the individual
bioconstructor.In general, Belgian reef diversity reflects the global
picture, but significant differences can be recognized in the different
time slices. In particular, the abundance of middle Viséan reefs is a
unique feature. The onset of the Variscian orogeny terminated all reef
development in Belgium, and reefs younger than late Viséan are
unknown.^1";

Winterberg im Harz nach Ende des Riffwachstums.- Geol. Jb. A 129:
5-193.- <b>FC&#038;P 21-2</b>, p. 57, ID=3357^<b>Topic(s): </b>reefs,
post-reefal deposits; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian Fam &#47; Carboniferous Tour; <b>Geography: </b>Germany,
Harz^Growth of the Devonian (Middle to Upper) atoll of Iberg and
Winterberg in the Harz Mts. ceased towards the end of the Frasnian.
After the death of the last reef-building organisms, from Famennian to
Gattendorfia Stage (cuI), the reef persisted in the shallow water
environment. During this time there is a hiatus caused by
nondeposition. Only conodonts accumulated in hollows on the old reef.
Reworked conodonts in Dinantian limestones provide evidence for marine
conditions during the Famennian and the time of the Gattendorfia Stage.
An exception are neptunian dikes that opened during the Upper
marginifera Zone (do II/III) and were filled with crinoidal limestones.

The first horizon is found at the base, the second one at the top of the sequence +2. Only this sequence reflects a deepening-upward and a shallowing-upward trend, in contrast to the other sequences, which display a shallowing-upward trend only. Three evolutionary stages (stabilization, colonization, diversification) can be recognised in a biostrome forming the first coral horizon. A second biostrome principally constructed by Siphonodendron junceum forms the base of the complex second coral-horizon. This horizon is followed by pebbly rudstones and a coral thicket of Siphonodendron martini. Changes in the coral-fauna are connected with changes in the paleoenvironment, caused by sea level fluctuations and/or changes in the geometry of the seafloor. Corals ot the genus Siphonodendron seem to have high ecological variability and distribution.^1";

A section from the Early Carboniferous of the Moldanubian Southern Vosges Mountains has yielded Heterocorallia, which are here described for the first time: Hexaphyllia sp. 1, Hexaphyllia sp. 2, Heterophyllia sp. and Heterophyllia aff. ornata M&#39;Coy, 1849. Their occurrence in calciblastic turbidites is an evidence for a Moldanubian carbonate platform. The fragile character of heterocoral polypars in general might be an indication for low water energy environments within the platform. A comparison from Rhenohercynian, Saxothuringian and Moldanubian Heterocorallia results in good correspondence concerning occuring taxa. Together with smaller benthic forminifera it is possible to date the Heterocorallia bearing sediments from the Southern Vosges as Arundian (Viséan).^1";

</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Vise;
<b>Geography: </b>Spain SW^Dissepimented rugose corals are common in
the Sierra del Castillo Unit (upper Viséan from SW Spain). A complete
taphonomic study has been made of the corals from three localities,
eachrepresenting different environmental conditions: Antolín rocks are
interpreted as mid-ramp andcontains mainly reworked corals from reefs,
Sierra del Castillo rocks are regarded as originating ona shallow-water
platform, and Sierra de la Estrella rocks are typical of the middle to
outer platform.The occurrence and distribution of taphonomic features
are different at each outcrop and even ineach bed, but a general
```

```
temporal scheme with the timing of all processes is proposed.
Borings,encrustations, fragmentation, abrasion, recrystallization,
compression, stylolitization, silicification,cleavage, dissolution, and
ferruginization are documented. Some processes which are
generallyregarded as biostratinomic (borings and encrustations) and
even as fossildiagenetic (cementation)began before the death of the
polyps. Other processes occurred only during the biostratinomic
phase(abrasion) or during the fossildiagenetic phase (silicification,
stylolitization, cleavage), but manyprocesses occurred during both the
biostratinomic and fossildiagenetic phases
(fragmentation,cementation).^1";

31-2</b>, p. 42, ID=1683^<b>Topic(s): </b>microfossils, taxonomy;
Rugosa, microfossils; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>France,
Montagne Noire^The disused quarry east of Castelsec offers a viwe of
shallow-marine carbonates of the poorly known Uppermost Mississippian
of the Montagne Noire. At Castelsec, sections are studied in two
characteristic facies types (bioclastic wackestone and microbial
dominated boundstone) of the Upper Mississippian. The succession is
rich in rugose corals and carbonate microfossils. Six genera with seven
species belonging to a rugose coral fauna consisting of at least eight
genera with several species are described herin; Dibunophyllum
castelsecensis sp.nov. is described as new. Twenty-seven carbonate
microfossils of different groups have been identified. The Castelsec
succession is Brigantian in age, based on the stratigraphic occurrence
of rugose corals, foraminifers, and calcareous algae observed in both
sections. The rugose coral fauna shows relationships with the
well-known fauna of northwestern Europe and the Ouralian-Asian
Province. Typical elements of northwestern Europe are missing at
Castelsec and vice versa. The differentiation between north and south
is interpreted as responses to different palaeolatitudes and tectonic
```

kolonialer rugoser Korallen im Unterkarbon (Mississippian) von
Westeuropa.- Kölner Forum für Geologie und Paläontologie 10: 1-155.-
<b>FC&#038;P 31-2</b>, p. 51, ID=1684^<b>Topic(s): </b>ecology, reefs;
Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous L; <b>Geography: </b>Europe W^The habitats of
colonial rugose corals - reef coral fauna of Hill 1938 - are
investigated in the upper Lower Carboniferous (Mississippian) of
Western Europe. The studied area consists of two geotectonic realms,
the stable southern shelf of Laurussia (Belgium, Great Britain,
Ireland) and the southern shelf of Armorica (Southern France), which
has been reworked during the Variscan orogeny. Based of the diversity
and frequency of colonial taxa, the distances of the colonies, the
lateral and vertical dimensions of the single corals occurrences, and
their facies setting, six gradually intermerging ecotypes are
differentiated: A: level-bottom communities, B: coral meadows, C:
biostromes, D: mound-dwelling communities, E: bioherms, divided into
the subtypes corals-microbe reefs (E1) and coral reefs (E2) and F: reef
complexes. This division is applicable to coral-bearing
bioconstructions on a world-wide scale.The analysis of the habitats
shows that colonial rugose corals actively contributed to
reef-formation in bioherms and reef complexes, and partly in biostroms.
Coral-dominated bioconstrcutions are more frequent than hitherto and
occur in all shallow-water carbonate systems studied. Colonial rugose
corals are dwellers in various microbial shallow-water mounds.The
potential of rugose corals to form bioconstructions is mostly limited
to frame-building due to their inability to encrust substrates. Only
exceptionally intergrowing cerioid rugose corals actively stabilized
certain bioconstructions. Normally, encrusting and binding was achieved
by associations of microbes, algae, and bryozoans. This fundamental
functional difference provide the differentiation of coral-microbe
reefs and coral reefs.Generally, Mississippian coral-dominated
bioconstructions consist only of a pioneer stage; a true
diversification is never observed and domination stages developed
rarely. The bioconstrcutions had been limited to one 4th or 5th order
sequence. Their growth was restricted by a complex system of limiting
factors. High-frequency eustatic sea-level fluctuations and/or
siliciclastic input and biotic competition are the most important
factors on a local scale. Rapidly varying, they caused only briefly
ecological niches resulting in small and undifferentiated biotic
buildups. The faunal turnover at the Mid-Mississippian Boundary caused
final collapse of the coral-dominated Late Mississippian
bioconstructions.The study of coral-dominated bioconstructions also
supplied new litho- and biostratigraphic data in the Western Europe
Asbian to Serpukhovian. The monography also includes a taxonomic
description of the important rugose corals in late Lower Carboniferous
bioconstructions.^1";

s[931] = "RODRIGUEZ S., SANDO W.J., KULLMANN J. (1986).- Utility of
corals for biostratigraphic and zoogeographic analyses of the
Carboniferous in the Cantabrian Mountains, Northern Spain.- Trab. Geol.
Univ. Oviedo 16: 37-60.- <b>FC&#038;P 16-1</b>, p. 62,
ID=1966^<b>Topic(s): </b>biostratigraphy, biogeography; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous U; <b>Geography: </b>Spain, Cantabrian Mts^Systematic
studies of Carboniferous corals in the Cantabrian Mountains of northern
Spain have progressed to the point where they are quite useful for
biostratigraphic and zoogeographic analyses. This report presents a
distribution analysis based on 1369 specimens assigned to 163 species
representing 56 genera of rugose corals. A preliminary biostratigraphic
zonation based on generic ranges is useful to identify series or stages
of Carboniferous in the area studied. Twenty-nine genera are known only
from one series or stage, 25 genera are not known to occur below a
particular series or stage, and 16 genera are not known to occur above
a particular series or stage. Future studies should be directed toward
construction of a time scale independent series of stage boundaries.
Coral abundance, frequency of occurrence, generic and specific
diversity, influx of new genera, and morphotype diversity, all known
maxima in Namurian A-B, Westphalian A, and Westphalian D, and
intervening minima in Visean, Namurian C, Westphalian B, and
Cantabrian-Stephanian A. Because most of the rugose coral genera
originated outside the area studied, these maxima and minima seem to
represent invasions and retreats of the coral fauna related with
changes in coral habitats. Although there is a general correlation of
increased abundance and diversity with regression of the sea through
Late Carboniferous time in northern Spain, smaller cyclical variations
in abundance and diversity are related to increases in habitat size
(ecospace) and habitat diversification. A general migration of corals
from deep-water environments to generally shallow water evironments
through late Carboniferous time is similar to pattern seen in the Lower
Carboniferous of the western conterminous USA and may be related to
larger regional events. Zoogeographic comparisons with North America
and the Donetz Basin of the USSR by means of similarity index (SI)
suggest that a sea way along the juncture of the African, South
American, and North American plate provided a communication route for
coral gene flow between Spain and North America during the entire Late
Carboniferous.^1";

```

```
Carbonifere inferieur, la terminologle et la classification utilisees
pour les Tetracoralliaires sont precisees. L&#039;etude systematique
porte sur des nombreux specimens, dont les caracteres externes et
internes sont decrits et figures. Des methodes d&#039;analyse
biometrique ont ete utilisees. Les taxons etudies appartiennent a
l&#039;ordre Stauriida et se repartissent dans huit sous-ordres,
quatorze familles: Stauriina (Famille Amplexidae), Metriophyllina
(Famille Cyathaxoniidae), Stereolasmatina (Familles Antiphyllidae,
Hapsiphyllidae, Zaphrentoididae), Plerophyllina (Familles
Verbeekiellidae, Lophophyllidiidae, Hexalasmatidae), Caniniina
(Familles Cyathopsidae, Uralinidae), Lonsdaleiina (Famille
Axophyllidae), Aulophyllina (Familles Palaeosmiliidae, Aulophyllidae),
Llthostrotionina (Famille Lithostrotionidae) et sous-ordre et famille
incertains; vingt-neuf genres dont quatre nouveaux (Nominoephyllum,
Delepinella, Solemnophyllum, Sabolia). alnsi que quarante-cinq especes
dont douze nouvelles. Ce chapitre comporte egalement des donnees sur
l&#039;insertion septale chez Delepinella anastomose et sur quelques
tendances evolutives relatives aux genres Siphonophyllia et
Aulokoninckophyllum. La partie biostratigraphique est consacree a la
repartition verticale des genres et des especes. Un essai de
biozonation a ete tente pour les especes d&#039;age tournaisien
superieur a viseen moyen. Enfin, divers aspects de la paleoecologie des
Tetracoralliaires ont etes traites. L&#039;environnement sedimentaire
regit la repartition des differentes especes. L&#039;analyse
paleoautoecologique montre que suivant leurs formes externes et leurs
caracteres internes, certains polypiers peuvent caracteriser un
environnement particulier. Differentes associations a Tetracoralliaires
ont ete reconnues, semblant se repartir en fonction d&#039;un gradient
bathymetrique; les differences observees aux niveaux generique et
specifique resulteraient de l&#039;influence des facteurs de
l&#039;environnement (turbulence de caux, nature des sediments). Dans
le meme chapitre, des comparaisons sont tentees avec les faunes
d&#039;autres regions (Europe occidentale, Nord de I&#039;Afrique,
Europe orientale, Asie). De fortes similitudes au niveau specifique et
generique apparaissent entre le domaine armoricain, l&#039;Europe
occidentale, le Nord de l&#039;Afrlque et meme la Siberie (Bassin de
Kuznetsk).^1";

und Berichte für Naturkunde 29: 23-71.- <b>FC&#038;P 35</b>, p. 60,
ID=2357^<b>Topic(s): </b>; Rugosa, Cyathoclisia; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L;
<b>Geography: </b>Germany, Rhenish Mts^The Late Tournaisian (Early
Chadian, Levitusia humerosa Zone, Cromford Formation) of Ratingen
(Velbert Anticline, Rhenohercynian Zone of Variscides) yields
Cyathoclisia (Cyathoclisia) modavensis (Salée 1913). There are only two
further localities of this common index coral in Germany: an olistolith
of Carboniferous limestones within the Bavarian facies of Culm measures
in Upper Franconia (Saxothuringian Zone of Variscides), and a borehole
on the Baltic Sea island of Rügen (carbonate ramp, southern margin of
Baltoscandia).The amygdalophyllid genus widely distributed in the late
Early Tournaisian (late Hastarian) and in the Late Tournaisian
(Ivorian, Early Chadian) of Europe and Asia is provisionally subdivided
```

```
into two subgenera: Clisaxophyllum Grabau in Chi 1931 (minor septa
short, never contracline) and Cyathoclisia Dingwall 1926 (minor septa
long and contracline, with biform tabulae, sometimes with diplosepta
arising in maturity), but the actual obsolete taxonomy of the genus and
the 27 named &#034;species&#034; requires much additional revisions.The
rare German materials and a comparative English sample from Clitheroe
(Lancashire) give first doubts about the current, since 1981 accepted
synonymy of Cyathoclisia tabernaculum Dingwall 1926 and Cyathoclisia
modavensis (Salée 1913).Emended future diagnosis of specific taxa are
in strong need of studied populations and revised type specimens,
especially of the extremely rich Russian Cyathoclisia communities; here
the classical collection of Ludwig (1862) from the Ural Mountains is
well preserved in the university of Göttingen.^1";

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Tour; <b>Geography: </b>Ardennes^New research in the
Tournaisian of Belgium and adjacent areas has yielded rugose coral
faunas that are generally more diversified than those from the
classical Tournai area. These faunas permit definition of three
Tournaisian coral zones. The oldest one, whose base coincides with the
Devonian-Carboniferous boundary, includes Melanophyllum, Caninia
tregaensis, Saleelasma, Siphonopyllia, and Cyathaxonia. Some of the
corals of this zone show affinities with those of Sando &#038;
Bamber&#039;s Zone I in the Western Interior Province of North America
and also with corals from the lower Tournaisian of the USSR. The second
zone is characterized by an abundant but low diversity fauna including
Lophophyllum and Siphonophyllia. The youngest coral zone has the most
diverse fauna with Caninophyllum, Uralinia, Siphonophyllia,
Cyathoclisia and Solenodendron. Corals of this zone are known in the
upper Tournaisian of Asia (USSR and China).^1";

ID=3510^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous; <b>Geography: </b>Spain
SW^Rugose corals occur in all the calcareous units. Thirty six species
are described. Colonial and solitary corals show distributions clearly
related to the original environment represented by each unit.
Nevertheless, the appearance patterns of the colonial corals are
similar to those described by Poty (1984, 1985) for western Europe,
providing higher biostratigraphic resolution than other fossil groups.
Colonial rugose corals built biostromes in unit 1. Dominant species is
Siphonodendron martini, but more than 15 other colonial and solitary
species also occur in that unit. Massive corals are common in unit 3,
where first appearance of Diphyphyllum furcatum is recorded. Units 4 to
6 yielded mainly undissepimented solitary corals, with high abundance
of Zaphrentites and Uflmia. Some colonial specimens of the species
Lithostrotion decipiens and Siphonodendron aff. pauciradiale also
occur.^1";

s[938] = "RODRIGUEZ S., FALCES S., COZAR P. (1997).- Development of dissepimented rugose corals in Moscovian soft bottom environments at Ribadesella (Asturias, NW Spain).- Boletin de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92, 1/4: 209-223.- <b>FC&#038;P 26-2</b>, p. 29, ID=3714^<b>Topic(s): </b>dissepimentate, soft bottom habitats; Rugosa dissepimented; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Mos; <b>Geography: </b>Spain, Asturias^Solitary dissepimented rugose corals occur in muddy limestones and marls at Ribadesella quarry (Lower Moscovian, Eastern Asturias, NW Spain). Diversity is low and most corals belong to the families Aulophyllidae and Cyathopsidae. Geyerophyllidae, which are dominant in most Moscovian coral localities from the Eastern Cantabrian Mountains, are scarce in this outcrop. The taxonomic features of this assemblage are described in detail. These corals inhabited soft-bottom environments, probably below the wave-base, and periodically subject to notable water movements. They developed diverse adaptations to these conditions, and many of them were able to change their growth direction several times. Additionally, they provided a substratum for development of bryozoans, auloporoids and chaetetids, which also grew on brachiopod shells. Most specimens are covered by algal crusts containing up to three kinds of algae; borings and other kinds of postmortem disturbances are not common.^1";
s[939] = "RODRIGUEZ S., KULLMANN J. (1999).- Rugose corals from the upper member of the Picos de Europa Formation (Moscovian, Cantabrian Mountains, NW Spain).- Palaeontographica A252: 23-92.- <b>FC&#038;P 28-1</b>, p. 34, ID=3967^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Mos; <b>Geography: </b>Spain, Cantabrian Mts^The &#034;Picos de Europa&#034; Formation consists mainly of massive, white to light grey limestones. In its upper member, beds of red to pink, marly, crinoidal limestones contain a rich rugose coral fauna. Its age is Upper Carboniferous (Kashirian to Myachkovian, middle and upper Moscovian, = Westphalian C, Bolsovian, and Westphalian D). Rugose corals of the suborders Cyathaxoniina Spasskiy (Metriophyllina sensu Hill, tentatively including the superfamily Duplocariniicae Fedorowski), Zaphrentoidina Schouppe &#038; Stacul (Stereoplasmatina sensu Hell) and Plerophyllina Sokolov are described. Thirty-one species belong to 18 genera are identified; 9 species are new (Cyathaxonia pinguis, Neaxon ? multitabulatus, Trochophyllum ? variabile, Kabakovitchiella triformis, Lophotichium ? espinerense, Ufimia accelerata, Lophophyllidium picoensis, Wannerophyllum carbonicum and Wannerophyllum incertum); 11 species are described in open nomenclature.^1";
s[940] = "JAVAUX E. (1994).- Paleoecology of rugose corals in the Neffe Formation (Middle Visean) of Belgium.- Courier Forschungsinstitut Senckenberg 172 [Oekentorp-Kuester P. (ed.) Proceedings of the VI. International Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 127-139.- <b>FC&#038;P 23-1.1</b>, p. 16, ID=4070^<b>Topic(s): </b>ecology; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Ardennes^In Belgium and Northern France, the middle part of the Visean is composed of massive open-marine limestones (Neffe Formation, &#034;V2a&#034;) which laterally contain two different rugose coral assemblages. The first one yields abundant Dorlodotia briarti, Siphonodendron ondulosum, Palaeosmilia murchisoni and few Caninophyllum cf. patulum and Axophyllum mendipense. This assemblage occurs mainly in very turbulent shallow-water grainstones. The second one includes numerous Axophyllum mendipense, Siphonodendron ondulosum and Palaeosmilia murchisoni, but other species are lacking; this assemblage occurs mainly in shallow-water bioclastic packstones and grainstones. These two assemblages are considered as corresponding to different bathymetric environments. Dorlodotia briarti lived in a shallower-water environment as Axophyllum mendipense, whereas the species common in both assemblages (S. ondulosum and P. murchisoni) can show more or less
```

```
important differences in their morphological characteristics which
allow recognition of ecotypes. The results are compared with an
assemblage from England (Orton, Ravenstonedale) which is composed of
similar species than the assemblage with D. briarti (additionally with
Siphonodendron sociale) and occurs in a quiet shallow-water
environment. A model of the bathymetric and hydrodynamic influences on
the morphology of these corals is suggested.^1";

limestone; reefs, reef flat; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Spain SW^The
Los Santos de Maimona Basin in Ossa Morena (SW Spain) includes 8
lithostratigraphic units numbered from 0 to 7. Unit 1, which
constitutes the subject of the present contribution, is composed of
marls and limestones with interbedded volcanic rocks of basaltic
composition. Limestones and marls contain abundant colonies of the
rugose genus Siphonodendron. Large brachiopods, algae and tabulate
corals participate in the framework. Solitary corals, gastropods,
bryozoans, ostracodes and foraminifers are also common. The
Siphonodendron Limestone shows a vertical lithologic evolution from
marls at the base to limestones at the top. Facies are ordered into
five associations which correspond to reef-flat sequences and storm
episodes. This unit, interpreted as a reef-flat, extends over the whole
basin, although the thickness, the development of the framework and the
distribution of organic components vary from SE (seaward) to NW
(landward). The main environmental factors controlling the development
of the organic framework are the tidal regime, minor subsidence pulses
and periodical storms.^1";

(2010).- Habitats of colonial rugose corals: the Mississippian of western Europe as example for a general classification.- Lethaia 43, 4: 558-572.- <b>FC&#038;P 36</b>, p. 49, ID=6429^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Europe W^Colonial rugose corals are a major constituent of shallow-water marine benthic communities in Mississippian times. The study of western European rugose coral habitats from the base of the Tournaisian stage to the Serpukhovian stage allows the recognition of four basic habitat types, which can be divided into a total of 11 subtypes. The classification is mainly based on field data, and thus rapidly applicable. Level-bottom communities in which large colony distances are characteristic (type A) represent the most basic community type; polyspecific (subtype A1) and monospecific (subtype A2) subtypes occur. Reduced colony distances result in the formation of coral meadows (type B), which either show homogeneous coral distribution (subtype B1) or the development of patches (subtype B2). Coral biostromes (type C) represent a spectrum between hydrodynamically controlled biostromes (nothing in place, subtype C1) and biologically constructed and controlled biostromes (subtype C2). The bulk of the biostromes represent mixtures of these two subtypes (subtype C3). Colonial rugose corals are widely encountered in Mississippian bioherms where they are dwellers (subtype D1), form capping beds (subtype D2), support framework building along with other organisms (subtype D3) and form coral framework (subtype D4). The latter is probably the most uncommon of all subtypes in Mississippian times. The classification is widely applicable to other groups. [original abstract]^1";
s[965] = "GOMEZ-HERGUEDAS A., RODRIGUEZ S. A detailed study of Serpukhovian rugose corals from La Cornuda section (Guadiato Area, SW Spain) by means of thin sections allowed the identification of environments where they lived. All corals were collected in unit 1 of the section where three different but intimately connected environments have been identified. Corals developed mainly in small mounds built jointly by microbial communities, algae and corals. Some corals also lived in calcareous shoals mainly composed of echinoderm plates. Finally, some corals occur in oncoidal limestone that represents a shallow ramp, but they were mainly transported from shoals and mounds. [original abstract]^1";

[short note] - <b>FC&#038;P 14-2</b>, p. 26, ID=6714^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography: </b>Spain, Cantabrian Mts^Horn corals from the Lower Visean of Northern Spain, e.g. the &#034;Marbre Griotte facies&#034; of the Cantabrian Mountains, are subject of a recent investigation program together with J. Kullmann, Tubingen. Corals are rather rare in this facies, but their taxonomy is surprisingly diversified. In addition to the earlier description by Kullmann (1966) it was possible to distinguish some new species of Ufimia Stuckenberg 1895, as well as other not fully identified plerophyllids and polycoeliids, several new species of Rylstonia Hudson &#038; Platt 1927; Rotiphyllum Hudson 1942; Weyerelasma Kullmann &#038; Liao 1985 and some forms of Zaphrentites Hudson 1941; Cyathaxonia Michelin 1846; &#034;Permia&#034; Stuckenberg 1895, and another aulate coral similar to Neaxon Kullmann 1965, as well as corals showing close similarity to Metriophyllum Milne-Edwards &#038; Haime 1851. A new genus similar to Claviphyllum Hudson 1942, was already distinguished, but possessing the alar septa equal to other major septa and a kind of the key-hole counter pseudofossula developed. There are also some forms represented by single corallites showing morphology so strange that we decided to postpone the detailed description of them to the time of collecting additional material. The fauna being investigated can by now be compared only to the Lower and Middle Visean faunas described from Great Britain in the series of papers by Hudson (1936 to 1945) and to the Upper Tournaisian fauna described by Weyer (1975) from the Island Hiddensee. Some elements of that fauna can also be found in Thuringia (Weyer 1984) and other regions of Europe in which the corals-bearing cephalopod facies of the Lower Carboniferous is developed. [paleontological note]^1";
s[968] = "FALCES S., RODRIGUEZ S. Oekentorp (eds)].- <b>FC&#038;P 31-1</b>, p. 33, ID=7099^<b>Topic(s): </b>redeposited; Rugosa Sychnoelasma; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Spain SW^Four reworked specimens of Sychnoelasma Sando 1961 have been collected from Serpukhovian olistolithic beds of Guadiato Valley (SW Spain). No strata of the usual age of Sychnoelasma (Tournaisian to Lower Visean) occur in Guadiato Valley. Several factors, including evidence of reworking, the age of associated fossils, and the biostratigraphic distribution of Sychnoelasma at other localities, suggest that the corals were derived from older strata, subsequently exhumed by erosion, and deposited in younger beds. Morphological and microstructural analyses of the Guadiato Valley specimens show the presence of fossular crests which are conspicuous only in specimens with deep calices. These observations suggest a close relation between Sychnoelasma and the genus Ankhelasma. [original summary]^1";

(2003).- Contribution of rugose corals to Late Viséan and Serphukovian bioconstructions in the Montagne Noire (Southern France).- SEPM Special Publications 78 &#47; AAPG Memoir 83 (Permo-Carboniferous carbonate platforms and reefs): 119-132.- <b>FC&#038;P 33-1</b>, p. 47, ID=7204^<b>Topic(s): </b>coral reefs, geohistory; Rugosa, reefs; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous, Vise Serp; <b>Geography: </b>France, Montagne Noire^Coral-bearing bioconstructions are described
```

```
for the first time from upper Lower Carboniferous (Upper Mississippian)
shallow-water limestone olistoliths of the southern Montagne Noire (
Mont Peyroux Nappe), southern France. Microbial-induced wackestones and
microbial boundstones dominate major parts of the Brigantian Roque
Redonde Formation and Serpukhovian Roc de Murviel Formation, which
follows on top of a paleokarst. Further subtidal facies are
intercalated. The short-lived bioconstructions consist of thin
monospecific and polyspecific coral biostromes, coral bioherms (patch
reefs) growing in high-energy turbulent environments, and a single
example of a large shallow-water microbial buildup that formed below
fair-weather wave base in dimmed light. The contribution of rugose
corals to the bioconstructions varies from active framebuilding in the
biostromes and bioherms to passive dwelling of sparse fauna in the
microbial buildup. Microbial structures are of special importance
within polyspecific biostromes and patch reefs. In a delicate balanced
system they are responsible for growth or suffocation of the
coral-dominated bioconstructions. That co-occurrence of coral
boundstones and microbial boundstones appears to be a widespread
characteristic of small reefs in Late Visean and Early Serpukhovian
time. Factors limiting the growth of the bioconstructions in southern
France include rapid sea-level variations, tectonic instability of the
shelf, and intrinsic paleobiological features of the rugose corals,
like their fragility and inability to encrust mobile substrates.
Comparable upper Lower Carboniferous coral-bearing bioconstructions of
the Paleotethys realm and the epeiric seas of northwestern Europe are
discussed. [original abstract]^1";

corals from Sierra del Castillo, Sierra de la Estrella (both near
Espiel, Córdoba) and Antolín (near PeÔ arroya, Córdoba) have been
```

```
studied. Ten species belonging to the genera Aulophyllum, Auloclisia,
Clisiophyllum, Axoclisia, Dibunophyllum, Arachnolasma, Koninckophyllum
and Amygdalophyllum have been described. The genus Axoclisia is for the
first time described in Europe. The microstructure of all species is
described in detail.^1";
s[973] = "BOLAND K. (1997).- Caninoid Rugose Corals of the Lower
Tournaisian (Hastarian) of Belgium: systematics and evolution.- Boletin
de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 91,
1/4: 73-084.- <b>FC&#038;P 26-2</b>, p. 10, ID=3673^<b>Topic(s):
</b>systematics; Rugosa, Caninoid; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Carboniferous Tour; <b>Geography:
</b>Ardennes^The revision of the caninoid rugose corals of the Lower
Tournaisian (Hastarian) of Belgium and the comparison with species from
others regions allow recognition of 4 species and 9 subspecies
belonging to 3 genera: Siphonophyllia, Uralinia and Conilophyllum and
to establish some of their phylogenetic relationships. Conilophyllum is
first represented by a small opportunist species (Conilophyllum priscum
(Muenster), which colonized the deep water and platform areas just
after the Devonian &#47; Carboniferous boundary crisis (top of the
Siphonodella praesulcata conodont biozone). It gave rise through a
process of hypermorphosis to Conilophyllum streeli, a species which
seems to be adaptated to the shelf facies. Siphonophyllia cylindrica
hasteriensis appears near the base of the Tournaisian and gave rise to
Siphonophyllia rivagensis through a process of acceleration.
Morphotypes of Conilophyllum streeli show morphological characters
which are similar to these observed in the genus Siphonophyllia and
suggest a homeomorphic trend. The relationships between the genus
Uralinia and Siphonophyllia are defined on the basis of their ontogeny.
The latter probably gave rise to the former. The stratigraphic
distributions of all these species are defined.^1";
s[974] = "POTY E., BOLAND K. (1996).- Revision des Tetracoraliaires
caninomorphes de l&#039;Hastarien (Tournaisien) belge.- Annales de la
Societe geologique de Belgique 117, 1: 201-225.- <b>FC&#038;P 25-2</b>,
p. 47, ID=3135^<b>Topic(s): </b>revision; Rugosa caninomorpha;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Carboniferous Tour; <b>Geography: </b>Ardennes^The caninoid Rugosa
from the Belgian Hastarian have been revised from specimens found in
some sections of the namur-Dinant Basin and the Vise-Maastricht area
(Campine Basin), and from the original material of Salee (1913). This
author has described two species: Siphonophyllia (&#034;Caninia&#034;)
cylindrica hasteriensis Salee and Caninia dorlodoti Salee. The second
one has been defined from specimens which are assigned here to
Siphonophyllia cylindrica hasteriensis, and other ones considered as
being Hastarian, but coming in fact from the Strunian (Campophyllum
flexuosum Goldfuss). So, that species, and in the same way Endophyllum
transitorium Groeber 1910, are considered as not valid. Four other
species, including three new ones, and a new genus are described:
Conilophyllum streeli nov. gen. nov. sp. from the subzone RC1P,
Siphonophyllia rivagensis nov. sp., from the zone RC2, and Uralinia
lobata nov. sp. from the subzone RC1, and the zone RC2.^1";

Rugosa, Cyathaxonia fauna; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous Mos; <b>Geography: </b>Spain,
Cantabrian Mts^Upper Carboniferous (Westphalian) solitary corals
(Rugosa) of the type &#034;Cyathaxonia fauna&#034; are described from
the Ojosa formation of Casavegas in the eastern part of the Cantabrian
Mountains (North Spain) belonging in the Upper Westphalian D
(corresponding to the upper &#034;Myachkovian&#034;, uppermost
Moscovian). The described coral fauna comprises 7 species belonging to
the genera Cyathaxonia, Amplexocarinia?, Zaphrentis, Calophyllum,
Sochkineophyllum, Ufimia and Lophophyllidium. Two species are new:
Amplexocarinia? palentina n.sp. and Sochkineophyllum accelerans n.sp.
The characteristic composition of the Casavega fauna with
representatives of Cyathaxonia, Zaphrentites and Polycoeliids (s. l.)
is only known from four Cantabrian localities ranging from middle
Westphalian D till Cantabrian (lower Stephanian A); no other coeval
faunas of comparable composition seem to exist. The Casavegas fauna
seems to be restricted to still water facies of slightly greater water
depth; it marks the highest point within the sea-level changes at the
end of the Westphalian. Regional tectonic unrest hindered the spreading
of this fauna.^1";
s[977] = "KULLMANN J., RODRIGUEZ S. (1994).- Biostratigraphic range and
biogeographic relationships of the undissepimented solitary corals from

Cyathaxonia fauna; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Carboniferous Mos; <b>Geography: </b>Spain,
Cantabrian Mts^The &#034;Picos de Europa&#034; Formation consists
mainly of massive, white to light grey limestone. Its upper member
contains some beds of red to pink, marly crinoidal limestone with a
rich rugose coral fauna. Laccophyllidae, Cyathaxoniidae,
Lophophyllidiidae and Lophotichiidae are predominant. The environmental
conditions of these beds seem to be those of a shallow shelf. The fauna
is unquestionably of Moscovian age, determined by the presence of
Fusulinella, and it is similar to uppermost Carboniferous and lower
Permian coral assemblages from North America and the Carnic Alps. The
presence of some elements characteristic of uppermost Carboniferous and
lower Permian (e.g. Wannerophyllum) suggests that the &#034;Picos de
Europa&#034; fauna is a precursor of Permian coral faunas. The
affinities of the &#034;Mediterranean&#034; Picos de Europa fauna with
corals of the North American realm suggest a close connection between
these regions during the Late Carboniferous.^1";

<b>FC&#038;P 13-1</b>, p. 40, ID=0478^<b>Topic(s): </b>biostratigraphy;
Rugosa, Heterocorallia; <b>Systematics: </b>Cnidaria; Rugosa
Heterocorallia; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography:
</b>Ardennes^^1";
s[982] = "POTY E. (1981).- Recherches sur les Tetracoralliaires et les
Heterocoralliaires du Viseen de la Belgique.- Mededelingen Rijks
Geologische Dienst 35, 1: 1-161.- <b>FC&#038;P 11-1</b>, p. 47,
ID=1762^<b>Topic(s): </b>; Rugosa, Heterocorallia; <b>Systematics:
</b>Cnidaria; Rugosa Heterocorallia; <b>Stratigraphy: </b>Carboniferous
Vise; <b>Geography: </b>Ardennes^Des recherches effectuees sur les
coraux du Viseen beige ont abouti a l&#039;identification de 72 especes
de Tetracoralliaires, dont 63 (parmi lesquelles 19 sont nouvelles) sont
decrites ici, et de 4 especes de Heterocoralliaires, dont 3 sont
egalement decrites. Des variations morphologiques observees dans
certaines de ces especes, comme par exemple la presence ou Tabsence de
processus de connexion chez les Siphonodendron, ou encore le
developpement temporairement fascicule de certaines colonies de
Lithostrotion deeipiens, ont par-fois pu etre mises en relation avec
des conditions particulieres de 1&#039;environnement. Par centre,
d&#039;autres variations paraissent etre la manifestation de tendances
evolutives et ont permis de preciser les relations phyletiques
probables existant entre les especes des genres Lithostrotion,
Siphonodendron et Diphyphyllum reconnues en Belgique et en
Grande-Bretagne, eellesexistant entre le genre Bothrophyllwn et le
genre Caninophyllum ou, encore qui semblent lier les genres Lonsdaleia,
Dorlodotia, Corphalia et Thysanophyllum. Les coraux presents dans
chacune des deux grandes aires paleogeo-graphiques reconnues en
Belgique — lebassinde Namur-Dinant et le bassin de Campine-Brabant --
peuvent etre distincts ou posseder des repartitions stratigraphiques
differentes qui suggerent 1&#039;ansence relative de communications
entre ces aires. Les coraux du bassin de Namur-Dinant ne montrent gueYe
d&#039;affinites qu&#039;avec caux connus en Angleterre dans la
province du Sud-Ouest et en Irlande, ce qui suppose 1&#039;existence de
relations etroites entre ces regions. Ceux du bassin de Campine-Brabant
posse&#039;dent par contre de nombreuses affinites avec ceux du centre
et du Nord de 1&#039;Angleterre, d&#039;Afrique du Nord et
d&#039;U.R.S.S.; ce bassin etait done apparemment plus ouvert aux
influences exterieures que le bassin de Namur-Dinant. Une zonation du
Viseen basee sur les coraux est proposee pour le bassin de
Namur-Dinant. ^1";

s[984] = "POTY E., HANNAY D. (1994).- Stratigraphy of rugose corals in
the Dinantian of the Boulonnais (France).- Memoires de l&#039;Institut
Geologique de l&#039;Universite Catholique de Louvain 35: 51-82.-
<b>FC&#038;P 24-2</b>, p. 83, ID=4572^<b>Topic(s): </b>biostratigraphy;
Rugosa, Heterocorallia; <b>Systematics: </b>Cnidaria; Rugosa
Heterocorallia; <b>Stratigraphy: </b>Carboniferous L; <b>Geography:
</b>France, Boulonnais^35 species of Rugosa and 2 species of
Heterocorallia have been recognized in the Dinantian of the Boulonnais.
Their stratigraphic distribution and new information about the
lithostratigraphy support, and in some cases improve the accuracy of,
correlations with Belgium proposed in earlier studies. Several
formations defined in the Belgian Namur-Dinant Basin can be formally
recognized in the Boulonnais. The Hure Dolomite equates with the Namur
Formation as it is known in the south part of the Namur Synclinorium.
It yields two Coral assemblages belonging to the RC3 Zone (Ivorian) and
to the RC4a Zone (Lower Moliniacian). The Haut-Banc Limestone comprises
three units: the Terwagne Formation, the Neffe Formation and the
members &#945; and &#946; of the Lives Formation. The Neffe Formation
contains the guide corals of the Dorlodotia briarti and Corphalia mosae
RC5 Subzones (Upper Moliniacian); member &#946; includes at its base
the Lithostrotion araneum horizon, which marks the base of the RC6
Zone, and, in the overlying beds, the same coral ecozone as in Belgium.
Another ecozone defined in the sequence n°+1 of the member &#945; of
the Lives Formation characterizes the same sequence in the
Siphonodendron martini Dolomite. The Lunel and Napoleon Limestones are
respectively equivalent to the Seilles and Grands Malades Formations.
The Joinville Limestone includes three units: the Thon-Samson
Formation, a stromatolitic unit similar to the Poilvache Formation, and
an upper unit rich in Gigantoproductids and Rugose Corals. The latter
are distributed in two assemblages corresponding to the RC7&#946;
Subzone (&#034;V3b&#947;&#034;) and the RC8 Zone (&#034;V3c&#034;). The
Joinville Limestone is capped by beds which have yielded coral species
known in the &#034;Rylstonia shale&#034; in Yorkshire. Differences in
the lithology of the upper part of the Neffe Formation and in the
member a of the Lives Formation have been observed between the Ferques
autochthonous tectonic unit and the Haut-Banc allochthonous tectonic
unit: the facies of the first may be compared with those known in the
northern part of the Namur syncline, and that of the second with those
known in the southern part. The &#034;Banc d&#039;or de Bachant&#034;,
which is between the Neffe and Lives Formations, and the Lunel,
Napoleon and Joinville Limestones are considered as isochronous rather
than diachronous units, as suggested in recent publications.^1";

</b>reefs, cryptalgal-bryozoan; reefs; <b>Systematics: </b>algae
Bryozoa; <b>Stratigraphy: </b>Carboniferous Vise; <b>Geography:
</b>Ardennes^Cryptalgal-bryozoan carbonate buildups are reported from
the Middle Visean (Upper Dinantian) near Namur, Belgium. They occur in
a 20m-thick, upward-shallowing, carbonate rhythm - the thickest in a
succession of such rhythms. The rhythm comprises three phases; from
bottom to top: (1) packstones-grainstones with rich and diverse biota,
indicating open, shallow marine conditions; grading to (2) wackestones,
with a poorer and more restricted biota, passing upwards to cryptalgal
boundstones; and (3) mudstones with highly restricted and reduced
biota. Small- to medium-sized mounds (2-11m thick) occur at the top of
phase 2 where they settled on coral thickets. The buildups consist of a
meshwork of bryozoans encrusted by finely laminated cryptalgal coatings
and encrusting bryozoans. Brachiopods, sponges and vermetid gastropods
are also present. Voids were filled by internal sediments and early
marine cements. The growth of the buildups was probably interrupted by
a short-lived sea-level drop, recorded laterally as what seems to be a
karstic surface. Vadose internal sedimentation and minor leaching by
meteoric water occurred in the ?exposed buildups. Marine conditions
were then restored and, at the beginning of phase 3 deposition, coral
thickets (with cryptalgal coatings) colonized the top of the largest
buildup. Most remaining pore space was filled by burial cements. Other
minor diagenetic processes include neomorphism, dolomitization,
precipitation of Ca-sulphates and silicification.^1";
s[997] = "COZAR P., RODRIGUEZ S., SOMERVILLE I.D. (2003).- Large
multi-biotic cyanoliths from relatively deep-water facies in the early
Serpukhovian of SW Spain.- Facies 49, 1: 31-48.- <b>FC&#038;P 32-2</b>,
p. 13, ID=7152^<b>Topic(s): </b>ecology; cyanoliths; <b>Systematics:
</b>Cyanophyta; <b>Stratigraphy: </b>Carboniferous Serp; <b>Geography:
</b>Spain SW^Large cyanoliths reaching up to 12cm in size and mainly
prolate, discoidal and spheroidal in shape occur in early Serpukhovian
rocks from the San Antonio-La Juliana Unit (Guadiato Area, SW Spain).
The main component in the cyanoliths is Girvanella, but other important
components are the problematic-algae Sparaphralysia, Calcifolium and
crustose Fasciella. A diverse assemblage of invertebrates, algae and
aoujgaliids also occur in the cyanoliths. The internal structure of
cyanoliths shows discontinuous cortices with tabular and columnar
growth of Girvanella domes, and bafflestones of Calcifolium. These
cyanoliths were constructed in a quiet water, low-energy dysphotic
environment, in relatively deep water facies, and on the upper part of
the slope or deep outer shelf. The probably dominant factors necessary
for their growth were bioturbation and gravity. The shape, size,
architecture, depositional setting, multibiotic composition and lumpy
structure of these cyanoliths are similar to those of Cenozoic-Recent
rhodoliths. Similarities to Osagia-type oncoids are few, and mostly
related to the cyanobacterial composition. Only some Mississippian
cyanoliths from Britain (digitate growth of cyanobacteria) and NW Spain
and Poland (multibiotic composition) show notable similarities with
cyanoliths from San Antonio-La Juliana. The San Antonio cyanoliths can
be readily distinguished from coeval shallow-water oncoids in the
Guadiato Area. [original abstract]^1";
s[998] = "CHEVALIER E., ARETZ M. (2005).- A Microbe-Bryozoan Reef from
the Middle Visean of the Namur Syncline (Engighoul Quarry).- Geologica
Belgica 8, 1-2: 109-119.

<b>Geography: </b>Ardennes^A microbe-bryozoan patch-reef was
temporarily exposed in the Lives Formation (middle Visean) at the
Engihoul Quarry, southern limb of the Namur syncline. It developed
```

```
within the Corphalie Member during the transition from bioclastic to
stromatolitic facies. Reef formation is the result of a complex
meshwork of calcified microbes, which formed complex layers which
resemble &#034;Osagia&#034;-biocenose and individual columnar
aggregates, fenestellid bryozoans, and early cements. Reef growth began
on a hard- substrate provided by brachiopods and microbial crusts.
Brachiopods (Composita sp.) are locally abundant in the reef facies,
and contributed substantial firm ground for encrustation. Reef growth
was controlled mainly by the abundance of fenestellid bryozoans. Their
presence indicates reef formation during normal marine conditions. The
reef developed in a high-energy area of the inner shelf. Reef growth
probably stopped with the establishment of a peloidal mudstone facies,
eventually indicating hypersaline conditions.The Engihoul reef is
similar to Bomel reefs (also in the Lives Formation). All are the same
age and developed in the transitional phase of the Corphalie Member,
but minor differences in the individual reef fauna occur. The
transitional phase of the Corphalie Member is an important horizon for
reef formation with clear independence from other reef forming episodes
within the Belgian Dinantian succession.^1";

Montagne Noire^The &#39;Calcaires á Productus` of the Montagne Noire
are microbial build-ups. Two formations are defined and dated
respectively as Uppermost Visean (Upper Warnatian-Brigantian) and
Serpukhovian on the basis on corals. That makes these limestones out to
be younger than previously stated (Lower and base of Upper
Warnatian-Asbian and base of Brigantian) and indicates that the
development of the olistoliths and thrusts including them, due to
Variscan orogeny, was at least as young as the Upper Serpukhovian. The
Serpukhovian limestones of the Montagne Noire are correlated with the
Lanet Limestone (Mounthoumet Massif, Corbières) and Ardengost Limestone
(central Pyrenees).^1";
s[1001] = "MINWEGEN E. (2001).- Die Biokonstruktionen im Pennsylvanium
des kantabrischen Gebirges.- Kölner Forum für Geologie und
Paläontologie 9: 1-139.- <b>FC&#038;P 32-1</b>, p. 32,
ID=1430^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Carboniferous U; <b>Geography: </b>Spain,
Cantabrian Mts^The Pennsylvanian organic buildups from the northeastern
Cantabrian Zone (Pico de Europa Unit and Ponga Nappe) occur in
different topographic settings of a foreland basin with an adjoining
external carbonate platform during synorogenic to later orogenic
stages. They display spatial and temporal changes in biological
structure and organism association, distribution and morphology. Eleven
types are distinguished:1. Beresellid-chaetetid buildups, 2) chaetetid
biostromes, 3) coral-chaetetid reefmounds, 4) rugose corals meadows, 5)
Petschoria meadows, 6) phylloid algal boundstones, 7) Anthracoporella
mounds, 8) Archaeolithophyllum banks, 9)
bryozoan-pelmatozoan-brachiopod reefmounds, 10) pelmatozoan mounds and
10) sphinctozoan-algal boundstones.2. During ther Moscovian the typical
Donetzella mounds of the Serpukhovian and Bashkirian were replaced by
equivalent shallow water communities of beresellid algae (Dvinella,
```

```
Beresella, Uraloporella), chaetetids and corals. Frequently, colonies
of syringoporids characterize the base, chaetetids the top of
shallowing upward-sequences. Relative small, typically
&#034;immature&#034; buildups and low-diverse biostromal and biohermal
structures reflect dynamic habitats due to sea-level changes.
Bryozoan-pelmatozoan-communities dominated especially in deeper water
environments. The platform slopes are stabilized by microbes and/or
pure or not calcifying organisms. Bioconstructing communities from the
Cantabrian Pennsylvanian in general have a low reef-building potential.
Early diagenetic cementation of the sediments is rare.Similarities
between North America and the northeastern Cantabrian zone concerning
the decrease of chaetetids at the unconform base of the Missourian (=
base of the Kasimovian) point to paleozoogeographic relationship, which
had been already observed in the coral fauna.Most benthic communities
are supressed by siliciclastic and nutrient input. Archaeolithophyllum
obviously tolerated such environments and built low diverse banks at
the border of the carbonate platform, which episodically was influenced
by deltaic deposition; thus these algal banks mark the progradation of
the orogen. The bioconstructions of the mixed siliciclastic-carbonate
sections of the Kasimovian are mainly domoinated by algae. Especially
Anthracoporella and Archaeolithophyllum are of great volumetric
importance. The proof of widespread Anthracoporella mounds in the
Cantabrian Mountains is of special interested because of the
Palaeobiogegographic relations to the Anthracoporella mounds of the
Carnic Alps.The decline of chaetetid dominated bioconstructions at the
end of the Moscovian and the rise of algal dominated structures is a
globally observed phenomenon. It coincides with an important floral
change and, moreover, an important excursion of stable isotopes.
Therefore, a global climatic change and associated changes of the
carbon budget/nutrient input seem to be of first order importance for
the reorganisation of the buildups. In ^1";

Campine Basin^The Poederlee borehole is situated in the Campine Basin
and has been drilled in the center of a domal structure at the top of
the Visean, identified by reflection seismic studies. The Visean
limestones in this borehole have an Early Warnantian (Late Visean) age.
They belong to the Carboniferous foraminifer 6&#947; subzone and to the
rugose coral 7&#945; and &#946; subzones. Two types of lithofacies,
namely microbial boundstones and bioclastic packstones and grainstones,
are present in these limestones. The first type represents the core of
a reef mound, which developed below and near the wave base. The second
type occurs above the boundstones, forms the flank and top facies of
the reef mound and has been deposited above wave base. Five
superimposed reef mounds have been recognized in the Lower Warnantian
and are interpreted as a reef complex. A comparison of the Lower
Warnantian reef mounds in the Campine Basin indicates that the
paleogeographical position is a factor which influences their
evolution. Diagenesis started with the precipitation of isopachous
fibrous and fibrous radiaxial calcites under oxidizing conditions in
marine pore-waters. After the precipitation of the fibrous calcites,
dissolution of these cements and of the host limestone possibly
occurred in meteoric waters. Rim cements around crinoids and blocky
calcites developed in a pore fluid which evolved from oxidizing to
reducing.^1";

<b>Geography: </b>France, Avesnois^Paleontology, sedimentology and
tectonic fields are investigated. They allow a new paleogeographical
approach of the western part of the Ardennes (Ardennes-area). The
northern part contains Ivorian and Moliniacian facies with Waulsortian
variations, they are similar to the &#034;Auge Dinantaise&#034; facies.
* The southern part contains shallow water facies identical to those of
Condroz area. A stratigraphic log is proposed using paleontological,
sedimentological and lithological markers. Near Avesnes a wide quarry
provides a tectonic model which can be applied to the Condroz area
where outcrops are sparse. A detailed study of this quarry led us to a
progressive deformation sequence, where narrow deformation bands follow
wide less deformed bands. Regional shortening must have been
accomodated by minor folding and slipping over many faults. [original

in northern France). Together with the sea-level variations
(third-order sequences), local controls influenced the nature of the
sedimentary deposits, so the lithostratigraphic successions in each
sedimentation area distinctive. The depositional setting was that of a
```

```
carbonate platform which evolved from a ramp in the early Tournaisian to a rimmed shelf during the early Visean and then to a regionally extensive shelf during the middle and late Visean. Before the Livian, open marine facies were developed to the south, but from Livian onwards open marine facies were restricted to the north while evaporites developed in the south. This inversion of a normal pattern was probably related to an early phase of the Variscan shortening. Dinantian biostratigrpahy is mainly based upon foraminifera, rugose corals and conodonts. Fifty formations (including members), 3 groups and 2 informal lithostratigraphic units are briefly described. [original abstract]^1";
s[1009] = "WEYER D. (1979 ).- Korallen-Funde im europaischen Zechstein-Meer.- Zeitschrift der geologischen Wissenschaften 1979, 7: 981-1021.- <b>FC&#038;P 9-1</b>, p. 38, ID=0274^<b>Topic(s): </b>taxonomy, biogeography; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Permian Zechst; <b>Geography: </b>Europe, Central^The coral fauna of the European Zechstein (Werra cycle) is made up of only two species of Rugosa (family Polycoeliidae), Calophyllum profundum (Geinitz 1842), and Calohyllum quadrifidum (Howse 1848). Eleven additional taxa based on Zechstein materials are synonyms of these very variable species, as demonstrated by a rich collection of about one thousand specimens from 35 localities. A possible generic division between normal (Gerthia Grabau 1928) and ampleximorph polycoeliids (Calophyllum Dana 1846) would be premature. There are no Zechstein Tabulate, most old records now referring to Bryozoa. Corals lived everywhere in the Zechstein sea and are found both in near-shore and basinal regions. Other Rugosa communities, generally dominated by polycoeliids, from the Upper Permian of the boreal realm are reviewed. Relations are only indicated by striking similar species of Calophyllum from Zechstein sea, Kazanian sea, and eastern Greenland: Calophyllum profundum (Geinitz 1842), Calophyllum permianum (Nechayev 1894), Calophyllum permicum Fluegel 1973. Remarkable regional differences occur in Upper Permian Rugosa faunas of the palaeotethyan realm, too (Armenian assemblage of plerophyllids and southern Chinese Lophophyllidium-Waagenophyllidae assemblage, both of lower Dzhulfian = Baisalian age).^1";

<b>Stratigraphy: </b>Permian Zechst; <b>Geography: </b>Europe
central^Stromatolites and laminated mats are characteristic of
Zechstein reefs which reach heights of 100 m. Bryozoans and other
macroscopic fauna are only additional attributes. Their baffling
effects are of minor importance. Reef-types vary from fringing and
barrier reefs to patch and pinnacle reefs. Occurrence and construction
of these reefs are very similar to those of modern coral reefs, mostly
depending on hydrodynamic conditions and the influx of siliciclastics.
Extensive reef-flats are controlled by sealevel. Macrofossils are
missing at the uppermost part of the reefs as a result of increasing
salinity. Very early marine lithification protected the buildups
against browsing and wave action, but pervasive dolomitization
destroyed the microstructures of reef-builders. Sealevel fluctuation
and changes in salinity are the most important parameters controlling
growth and termination of Zechstein reefs.^1";

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Triassic M; <b>Geography: </b>Poland, Silesia^This
paper deals with the mode of occurrence, growth forms, skeletal
preservation and the life conditions of some of the oldest,
stratigraphically well-documented Anisian (Pelsonian-early Illyrian)
scleractinian corals, occurring in situ, in shallow-water carbonate
rocks in the Lower and Middle Muschelkalk of the Cracow-Silesian
region, Southern Poland (northern Peri-Tethys, Central Europe). Among
18 species (from 14 genera; some of generic names require emendation),
one of the important Anisian coral species is Pamiroseris silesiaca
(Beyrich) (=former Thamnastraea silesiaca Beyrich), frequently
occurring and widely distributed in the Peri-Tethyan (Germany, Poland)
and found in the Tethyan provinces (Alps and S. China). The paper also
presents skeletal growth bands of P. silesiaca and its septal
microarchitecture, important because of high morphological homeomorphy
of thamnasterioid corals e.g. Pamiroseris, Thamnasteria.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Triassic Anis; <b>Geography: </b>Poland, Upper Silesia^Anisian
scleractinian corals are known from the Lower and Middle Muschelkalk of
the Cracow-Silesian region, but in bioherms they occur only in the
western part, i.e., in the Upper Silesian area, in the higher part of
the Lower Muschelkalk (Karchowice Beds). Silesian reefs of Anisian
(middle Pelsonian-early Illyrian) age are, so far, the oldest in situ
coral reefs following the Permian &#47; Triassic extinction. In Anisian
time, Silesian corals formed a Tethys marginal reefal rim, separating
offshore Tethyan open marine waters from the backreef area (Germanic
Basin). The shallow-water coral-bearing facies capped sponge buildups,
following a general shallowing trend in the basin. Final emersion in
the early Illyrian halted coral reef growth. Anisian scleractinian
corals appear to have been zooxanthellate, as suggested in Morycowa,
1988. [original abstract]^1";

<b>Stratigraphy: </b>Triassic M; <b>Geography: </b>Poland, Upper
Silesia^Sponge &#47; crinoidal &#47; coral bioherms have been found in
the Karchowice Formation which is the uppermost lithostratigraphical
unit of the Lower Muschelkalk in the Upper Silesian region. Taxonomic
composition and biohermal structure show similarities to younger
buildups, well-known during the Jurassic. Their lower part is made of
primary lime mud with loosely packed clumps of siliceous sponges
Hexactinoderma trammeri, accompanied by echinoderms, brachiopods,
ecologically diversified bivalves, polychaetes, solitary corals,
ostracos and foraminifers. In the middle part, sponges are successively
replaced by encrinids, and infaunal bivalves disappear. In the upper
part, both sponges and encrinids are replaced by corals (mainly
Pamiroseris silesiaca) which form a rigid skeletal framework. Moreover,
a significant increase in the number of species and individuals of
herbivore gastropods is visible in this part of the bioherms, as well
as the dominance of cemented and byssate bivalves. Such development of
the biohermal structure can be referred to the shallowing of the
sedimentary basin and to taphonomic feedback. Sponges (and other
reef-builders) served as a substratum for the epifauna which was a
```

```
source of skeletal hardparts. In this way, a hard substratum was
originated, infaunal bivalves disappeared and the rigid coral framework
developed. The bioherms developed at the edge of a shallow carbonate
platform during regression of the Lower Muschelkalk sea. The coral
community lived in shallow, euphotic water.^1";

Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Jurassic M; <b>Geography: </b>Spain, Cordoba^The presence of coral
colonies and oncoid facies in the Dogger of the External Subbetic is
first shown in this paper. It is worthy of remark that the Dogger
materials (ooid limestones basically) are placed between pelagic
formations. Really, they represent a part of a shallowing-upward
sequence which begins with the pelagic sediments of the
Domerian-Toarcian. Over these materials a shallow carbonate shelf is
established where bioherms, coral colonies, oncoid and ooid facies are
developed, caping the sequence a hard-ground of the Upper Bathonian.
The Upper Jurassic materials are clearly pelagic with &#034;ammonitico
rosso&#034; facies. This work represents a contribution to the
scientific controversy about the interpretation of the ooid limestones
of the Dogger. In other areas (Venetian Alps, Balearic Islands, etc.),
```

```
these limestones have been interpreted as deep redeposited sediments
and attempts to extend this interpretation to all the Dogger ooid
limestones of the Alpine realm have been made. The features shown in
this paper about the shallow marine nature of these materials in the
External Subbetic are conclusives.^1";

NW Iberian Range^The Upper Jurassic marine strata in the northwestern
Iberian Range and in adjacent areas have been studied by using sections
from 78 localities. The main subjects of research are the coral-bearing
beds of the Lower Kimmeridgian. A model of the palaeogeographical
development is presented, with the northern epicontinental borders of
the betic syncline in the Southeast and with the Jurassic Cantabrian
basin in the North. The differenciated facies development prooves the
shallow character of this channel over the entire area. With only few
exceptions the facies succesion shows continuously open-marine
conditions which merely end just before the continental
&#034;Wealden&#034;-sedimentation starts. Striking is the widespread
occurrence of corals. Thick coralline limestones are to be found in the
Sierra de los Cameras, the Sierra del Madero and the
Noviercas-Ciria-Torrelapaja-Bijuesca-region. They generally indicate a
decreasing sea-level in three steps: The &#034;initial stage&#034; is
characterized by the flat colonies, especially by Microsolena settling
in the different lithofacies. Even in sandy sediments and micritic
limestones they are to be found, forming a widely extended biostromal
slab up to 20 m in thickness. The following &#034;stage of
differenciation&#034; shows a great variety, both in lithofacies and in
the composition of coral faunas. A &#034;terminal stage&#034; with
pebbly oolitic Chaetetid-limestones, originating from very shallow
water, brings the marine development of the Upper Jurassic in the
central part of the investigated region to an end. In spite of its
shallowness and morphological impediments (reefs, oolite-and sandbars)
permanet currents passed through the channel; otherwise the widespread
coral growth and the complexity of the coral faunas could not have been
developed. The palaeontology of the rich coral fauna from the
northwestern Iberian Range is examined for the first time. The research
is supplied by additional collections and investigations in the
surrounding areas, mainly the Montes Universales, from where Geyer
already has described a coral fauna. Altogether 1366 corals have been
determined belonging to 49 genera with 96 species, including 7 new
ones. The coral fauna described in part 1 is distributed to the
families Actinastraeidae, Amphiastraeidae, Cyathophoridae, Stylinidae,
Euhellidae, Montlivaltiidae, Isastraeidae, Placosmiliidae, Faviidae and
Dermosmiliidae. The voluminous fauna shows close connections to other
Upper Jurrasic coral occurrences in Central Europe, the Mediterranean
and Caucausian areas, thus marginal domains of the Tethyan sea.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic
```

```
U; <b>Geography: </b>Germany, Wurttemberg^The silicification of the
corals of the Upper Jurassic of Wuerttemberg (SW Germany) is described
in regard to the different observed silica-phases. LS-chalcedony
(quartzine) is the most common silica-phase; it occurs generally as a
replacement of the neomorphic spar of the corals, rarely as a cavity
filling. It is spherolithic and nearly always found beneath the surface
of the corals, where it can form a skin. LF-chalcedony and megaquartz
exist in corals only as cavity fillings, whereas megaquartz may occur
in other shell fragments as a replacement. Microquartz is not too
abundant and is only found as a replacement in micritic fillings of
cavities between the septa of the corals. Lutecite was only found in
echinoderm fragments, opale not at all. The aragonite of the coral
skeletons was transformed into neomorphic spar in a marine environment.
The Mg content of the neomorphic spar made the silica precipitate as
LS-chalcedony, whereas in the adjacent cavities LS-chalcedony developed
only initially but mainly LF-chalcedony and megaquartz. This is
connected with an increasing burial under marine cover and concurrent
decrease of the bulk pore-water in Mg2+ and SO42- - contents. As the
sea retreated from the area of the Swabian Alb after the Lower
Tithonian, the silicification has to be supposed to be of early
Tithonian age. The silicified areas were submitted to beginning
recalcitisation.^1";

- Taxonomie, Oekologie, Verteilung.- Palaeontographica A226, 4-6:
77-123.- <b>FC&#038;P 22-1</b>, p. 38, ID=3398^<b>Topic(s):
</b>hermatypic, distribution; reef corals; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic U; <b>Geography:
</b>Germany N^During Late Oxfordian and Middle Kimmeridgian (Late
Jurassic), small patch reefs were formed at numerous localities in
northern Germany. The richly structured neritic sea was characterized
by seasonally varying environmental factors, such as water movement and
illumination as ecological requisites, and sedimentological conditions
and bioerosion as ecological addends. These factors evidently affect
the faunas. Thus, palaeontological facies interpretation is possible
according to qualitative and quantitative criteria supported by
sedimentological results. Twenty six species of reef corals are
described in detail and arranged in various guilds (builders, bafflers,
binders, dwellers) on the basis of the impact of growth forms on the
skeletal frame. However, intraspecific variation of guild membership
may occur due to different reefal architecture. The most important
synecological parameters, dominance and diversity, are calculated for
all localities. Thamnasteria concinna (Goldfuss) which can tolerate
partial mortality well is the dominant species in various environments,
thus showing ubiquitous characteristics. The diversities of the
associations examined are generally low and strongly vary within
comparable facies. These facts prove the oscillation of important
environmental factors. Despite the ecological preferences of some taxa,
the distribution of reef corals seems to be mostly random, at least in
more favourable environments. [list of species: Actinastrea

26, ID=3709^<b>Topic(s): </b>reefs coral, geography, geology; reefs,
coral; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Jurassic U; <b>Geography: </b>Spain, Cameros Basin^The studied
reefs are situated around the Cameros Basin (Late Jurassic-Early
Cretaceous; North Spain) in a rim of marine Jurassic outcrops. The last
marine Jurassic sediments in the area are characterized by the
development of coral reefs which correspond to the Kimmeridgian. These
reefs were situated in an epicontinental seaway which lay between the
Iberian and Ebro massives. This sequence is best exposed near
Torrecilla en Cameros where a fringing reef has been identified. In
each buildup of this reef complex, the reef-core, with a fore-reef and
long-shore carbonate sand bars can be distinguished. The reef complex
in Soria has a different geometry for vertical growth dominates,
although some progradation occurs and a back reef grainstone facies
prograded over the core reef facies. Many diagenetic processes have
affected these reefs although cementation is particularly important
because it has provided a clear paragenetic sequence related to the
diagenetic evolution of these limestones. The most common sequence
evolves from submarine cements (only present in primary cavities) to
cements precipitated under active fresh-water phreatic conditions,
stagnant phreatic afterwards, and finally under burial conditions. This
sequence represents progressive burial of these reefs when a very thick
series of essentially continental sediments was deposited. Another less
common sequence is present in some dissolution cavities generated in
the subsurface. This sequence evolved from cements precipitated in a
reduced environment to shallower oxidizing ones precipitated under
telodiagenetic conditions.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic
U; <b>Geography: </b>Germany N^Coral associations occur in situ within
fine-grained siliciclastics in the Oxfordian (Late Jurassic) of
northern Germany. Compared with contemporaneous localities representing
other environments, their diversity was slightly lower; species
tolerating sedimentation were more important. The morphology of their
coralla with large well-integrated calices and strongly ornamented
septa was flat, resulting from reduced light levels; no branching forms
occur. Terrigenous clastics reached the areas of coral growth
seasonally during times of increased runoff in a warm-temperate
climate, probably without being fenced off somehow. Corals show strong
partial mortality but were able to recover by overgrowing the
sediments. Since coral surface was quickly covered unless living polyps
removed sediment continuously, encrusters and borers found hardly any
suitable substrate; their abundance in the associations was very low
therefore.^1";

<b>FC&#038;P 27-2</b>, p. 59, ID=4242^<b>Topic(s): </b>ecology, siliciclastic setting; coral biocoenoses; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Portugal, Lusitanian Basin^Upper Jurassic coral communities of Portugal (Lusitanian Basin) grew despite high siliciclastic influx. Small, reef-rimmed carbonate platforms existed on basement uplifts over an extended period of time. Other reefs grew whenever episodes of tectonic quiescence and/or rising sea level reduced siliciclastic influx. Reefs grew within a coarse siliciclastic fan delta and on a fine grained, siliciclastic slope system. The latter is developed as a distally steepened mixed carbonate-siliciclastic ramp system, which provided excellent examples for constantly or periodically sediment-stressed reefs. Sedimentation rather than water depth was the major modifier of diversity of coral communities and coral growth forms. For example, massive to foliose Microsolena agariciformis changed to a &#039;pseudobranched&#039; morphology composed of thinly stacked encrusting layers during elevated sedimentation. Depth distribution patterns and morphologic changes clearly show that Jurassic hermatypic corals had photosymbionts. However, their frequent occurrence within, or very close to, siliciclastic settings indicates that they could tolerate higher nutrient rates than modern reef corals, probably because of a still imperfect symbiotic relation. Consistent with this interpretation are the slower growth rates and the lower low to high density band ratios of Upper Jurassic reef corals even in very shallow, non sediment-stressed reef settings.^1";
s[1038] = "ROMAN J., ATROPS F., ARNAUD M. (1994).- Le gisement tithonien inferieur des calcaires lithographiques de Canjuers (Var, France): etat actuel des connaissances.- Geobios; Memoire Special 16: 126-135. The biostromes are dominated by phaceloid forms and are characterised by a typical shallow-marine microencruster assemblage with photophilic microencrusters and scarce microbial crusts. The abundance of stylinid corals and light-dependant microencrusters suggest oligotrophic conditions. Coral colonies were located among oolitic shoals which were unfavourable for coral growth. The corals were developed in phases without oolitic production alternating with phases of oolitic production, forming metric-scale sequences. A relative sea-level fall would have reduced the ooidal production and led to the deposition of thin layers of micritic facies in intertidal areas. The cementation and hardening of the bottom resulted in a hardground that was colonized by corals after a subsequent relative sea-level rise. The progressive increase of the energetic conditions induced an increasing production of ooids and the migration of oolitic shoals, which covered and finished the coral biostromes. Repetition of this process gave rise to sequences reflecting small pulses of oscillations in the relative sea level. [original abstract]^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Jurassic
U; <b>Geography: </b>France NE, Germany SW^The environmental conditions
during the growth of Upper Jurassic coral reefs Northeast France and
Southwest Germany were reconstructed by the detailed analysis of the
reef fauna and sedimentological criteria in comparison with modern
coral reef environments. The ecological interpretation of all exposed
reef bodies in this regions makes up the base for the reconstruction of
the local and regional environment. While the Oxfordian reefs of
Lorraine and the Isteiner Klotz where situated on an extensive and low
relief carbonate ramp, the comparatively small platform reef of Arnegg
developed on a submarine shallow during the Kimmeridgian. For the
comparison of a multitude of structurally different coral reef types in
different time sections a new reef classification was worked out. This
classification is based on ecological meaningful and exactly defined
faunistical and structural features of the reef body and facilitates
the comparison of different reef bodies, reef types and over geological
time periods. As the determining physically-chemical factors for reef
growth light, sedimentation rate, oxygen- and nutrient content,
temperature and salinity could be worked out which secondarily were
influenced by the topography of the seafloor, the substrate consistence
and the position of the reefs on the shelf profile. In all examined
sequences the succession of coral faunas and reef types documents a
shallowing upwards. The onset of coral reef growth is generally caused
by the lowering of sedimentation rates: for the Oxfordian reefs because
of a global transgression - for the Kimmeridgian Arnegg platform
because of an elevated structural position. Increasing sedimentation
rates during the following sea-level highstand (Oxfordian reefs) and
relief compensation (Arnegg platform reef) were finally leading to the
killing of coral growth. [original English summary]^1";

models of Bajocian coral-microbialite reefs of Chargey-les-Port
(eastern France): palaeoenvironmental interpretations.- Facies 52, 1:
113-127.- <b>FC&#038;P 34</b>, p. 98, ID=1363^<b>Topic(s): </b>reefs;
reefs; <b>Systematics: </b>Monera Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Jurassic Baj; <b>Geography: </b>France E^Very large amount of
microbialites, up to 70% of the reef volume takespart in the
edification of Lower Bajocian coral reefs in the Chargey-les-Port
quarry (Haute-Saône, France). Such high amounts of microbialiteswere
unknown within bioconstructions of Middle Jurassic age. Alongthe 16
m-thick section, seven successive biohermal or biostromal units
developed on a shallow platform. Bioconstructions display a first
coralgrowth phase with either constratal or superstratal growth
fabrics. Coralfauna is relatively poorly diversified and is dominated
by massive forms(Isastrea, Thamnasteria, and Periseris) or branched
phaceloid(Cladophyllia) and ramose (Dendraraea) colonies. Corals can
beheavily encrusted by microbialites of diverse forms and fabrics
(leiolitic,thrombolitic, and stromatolitic). According to the coral
growth fabrics,microbialite crusts developed on top of or at the
underside of coralcolonies, forming a coral-microbialite elementary
unit. Microbialitesshow a multiphase development: (i) directly at the
coral surface, a firstand mm-scale microbialite layer locally
developed; (ii) a second, cmscalemicrobialite layer (up to 8 cm thick)
covered the entire coral reefframework and assumed the main building
role; and (iii) a third, mm- tocm-scale, laminated microbialite layer
may also be observed onlappingprevious reef structures, before having
been progressively buried undersediments. Contemporaneously to the
coral growth phase, the firstmicrobialite layer developed on dead
portions of coral colonies. Thetransition between coral growth and
```

```
microbialite development (i.e.,second layer of microbialites) is
interpreted as a result of a coral reefcrisis, probably reflecting more
nutrient-rich conditions. The passage toa stromatolitic (third) layer
suggests a control of the accumulation rate.Composition and
architecture of coral-microbialite reef units ofChargey-les-Port
highlight the relations between high-frequencyfluctuating environmental
factors (mainly accumulation rate and trophicconditions) and reef
development.^1";

Porifera corallina; <b>Systematics: </b>Porifera; Corallina;
<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Portugal^From the
Kimmeridgian (Upper Jurassic) of Portugal, the coralline sponge
Sobralispongia densespiculata nov. gen. and nov. sp. is described. Main
characteristics are a crustose habit, a primary spicule skeleton of
very densely packed styles and subtylostyles arranged in a plumose
architecture, microscleres of possibly aster-type, and a microgranular
to fibrous secondary calcareous skeleton. The primary mineralogy of the
calcareous skeleton was probably high-Mg calcitic. An assignment to the
demosponge Order Axinellida is proposed.^1";
s[1050] = "WERNER W., LEINFELDER R.R., FURSICH M., KRAUTTER M. (1994).-
Comparative palaeoecology of marly coralline sponge-bearing reefal
associations from the Kimmeridgian (Upper Jurassic) of Portugal and
Southwestern Germany.- Courier Forschungsinstitut Senckenberg 172
[Oekentorp-Kuester P. (ed.) Proceedings of the VI. International
Symposium on Fossil Cnidaria and Porifera, Vol. 2]: 381-397.-
<b>FC&#038;P 23-1.1</b>, p. 25, ID=4095^<b>Topic(s): </b>reef
complexes, ecology; reef complexes; <b>Systematics: </b>Porifera;
Corallina; <b>Stratigraphy: </b>Jurassic Kimm; <b>Geography:
</b>Portugal, Germany SW^Three marly reefal associations from the
Kimmeridgian of Portugal (Alcobaca, Serra Isabel) and southwestern
Germany (Faulenhau), which share a high proportion of coralline sponges
as a main unifying element, were studied in a comparative manner. The
two Portuguese associations are dominated by corals and coralline
sponges (Alcobaca), and by crinoids and corals (Serra Isabel),
respectively. Both sedimentological and palaeoecological analysis
evidence a very shallow environment at Alcobaca and a deeper slope
setting at Serra Isabel. The association at Faulenhau, occurring within
the sponge mound fades of Southern Germany, is dominated by
hexactinellid and lithistid siliceous sponges, but contains an
unusually high proportion of coralline sponges. Comparison of the three
associations allows the establishment of bathymetric gradients and
enables interpretation of the somehow enigmatic association at
Faulenhau. All three associations grew in a fully marine, low-energy,
```

```
low-sedimentation environment. The compositional differences are due to
increasing bathymetry (presumably Alcobaca less than 20 m, Serra Isabel
50-60 m, Faulenhau 70-90 m). This is well reflected only at the generic
and species level, where several taxa from various groups (coralline
sponges, bivalves, microbes and microproblematica) are stenobath,
whereas many others are not. The main trends towards deeper water are
decrease in the diversity of corals, coralline sponges and
&#034;algae&#034;, increase in the diversity of siliceous sponges,
change in the composition of encrusting bivalves, and decrease in the
activity of boring bivalves. Changes in morphotypes and dominance of
guilds occur among corals, sponges and bivalves, but are only partially
helpful in discriminating environmental differences. Bathymetric change
is commonly, but not necessarily correlated with a change in nutrient
and oxygen levels. Partial decoupling of these factors is obvious at
Serra Isabel, where siliceous sponges are, at a cm-scale, replaced
upwards by a hermatypic coral-crinoid association. However, the
dominance of sponges at Faulenhau cannot be explained solely by
slightly increased nutrient levels, since the diversity of coralline
sponges is much lower than at Alcobaca and Serra Isabel. It is expected
that the bathymetric position of the majority of the Upper Jurassic
sponge-crust mounds grew in water deeper than for the Faulenhau
example, i.e. below 70-90 m, although siliceous sponge facies could
have occurred at lower depths in regions or at times of lowered oxygen
contents or slightly increased nutrient levels, e.g. during rapid
sea-level rise.^1";

<b>Stratigraphy: </b>Jurassic Baj; <b>Geography: </b>France^Lower
Bajocian (Propinquans and Humphriesianum) reef-building corals of
France are rather poorly diversified: 16 to 19 genera (including
morphogenera) and 17 to 26 species. The new genus Atelophyllia is
created and the poorly known genus Ebrayia is revised. Synonymies of
species are well understood, owing to a statistical analysis of
populations sampled in the field (1410 samples, 900 thin sections). The
taxonomic list and statistics offer first paleogeographical tool to
study the trends of diversitry. Because this diversity increases
southwards (South Jura, Maconnais), it suggests that a climatic control
underlies the diversity gradient. Functional morphological analysis of
various taxa offers a second method to evaluate ancient light
intensities and sedimentation rates. For instance, a comparision with
Montastrea, a recent zooxanthellate coral, shows that the variations of
the colonial shape of Isastrea are ligth-dependant. An interpretation
of Bajocian bioherms as lithoherms built by nonzooxanthellate corals
must be rejected. The avarage annual growth rates of Bajocian corals
are very low. The new findings suggest evolutionary and climatic
explabations. ^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Jurassic Baj; <b>Geography: </b>France^The present statistical
study of two Bajocian populations of Isastrea from eastern France uses
different methods of measurement taking into account the colonial
```

```
character. The results of the univariate and the multivariate analyses
together with direct observation of qualitative characters show that
only two species are present in the samples: Isastrea bernardiana and
I. tenuistriata. A new synonymy is suggested for the Bajocian species.
Genera such as Andemantastraea Alloiteau and Parisastraea Alloiteau
correspond to the common variation of Isastrea. The taxonomic position
of other Jurassic Isastrea is examined. It is probably possible to use
extreme morphotypes as stratigraphic markers owing to an eventual
anagenesis. A comparison between the two samples denotes that the
variation range or the mean value of some quantitative characters
(number, thickness of septa, dimension of corallites, trabecular
density) contributes to the paleoecological interpretation. The present
paper emphasizes the necessity of well-defined species based preferably
on population study, for a reliable generic definition.^1";

confused with Thamnasteria Lesauvage 1823, in spite of their different
septal morphology. A new diagnosis of the genus, a specific
redefinition using a numerical population approach and an illustration
```

```
of the type species, Periseris elegantula (d&#039;Orbigny) are given
here. The studied colonies have been collected at several Bajocian
outcrops in Eastern France. The data used consist of measurements of
the distance between corallite centers, the corallite density, the
number of septa, the septal density, the trabecular density, the
pennular width, the trabecular width and the vertical distance between
pennulae. Direct observation of qualitative characters, univariate
analyses and principal component analysis suggest the presence in the
samples of one single variable species: Periseris elegantula.
Discriminant analysis shows that outcrops are well explained by the
variations of characters. These variations are ascribed to an
environmental origin. Among Middle Jurassic species, 14 junior synonyms
have been enumerated. [communication presentee au premier congres

</b>Jurassic Oxf; <b>Geography: </b>Germany NW^The stratigraphic and
regional distribution of the Oxfordian scleractinian reef corals in the
Korallenoolith Formation (NW German Malm Group) is described from the
Suntel, Deister, Kleiner Deister and Osterwald Mountains. In the study
area four horizons with (par-)autochthonous corals are developed two of
which can be traced region-wide (Untere Korallenbank Member and
florigemma-Bank Member &#47; ObereKorallenbank Member). * The coral
fauna of the biostromes, forming the Untere Korallenbank Member, is
impoverished and dominated by ubiquitous r-strategists. In contrast,
the reefal bioconstructions of the florigemma-Bank Member show a high
variability in their regional appearances, partly forming highly
diverse coral associations. The highest diversity is developed in the
patch reefs from the Obere Korallenbank Member of the Osterwald
Mountains (about 40 species). * Corals are an important part of te
Korallenoolith fauna. Altogether 20 species belonging to 15 genera have
been identified which were formerly unknown from NW German Oxfordian
successions. [original abstract]^1";

coraux simples et coloniaux montlivaltiides du Bajocien de France.-
Geobios 29, 5: 577-603.- <b>FC&#038;P 26-1</b>, p. 70,
ID=3642^<b>Topic(s): </b>populations; Scleractinia, Montlivaltiidae;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Jurassic Baj; <b>Geography: </b>France^A population study has been
carried out on Bajocian montlivaltiid corals. Some colonies determined
as Complexastrea come from reef-building environments; others, non reef
builders, were collected from the outcrop of Denney and display all the
transitional morphological steps between the genera Montlivaltia,
Coenotheca, Latiphyllia, Complexastrea and Thecosmilia. A statistical
study shows an unimodal distribution of usual quantitative specific
characters, a comparable mean for reef building and non reef building
forms but a larger variability range for non builders. Discriminant
analysis does not allow to separate infallibly these two sets. Both are
put in a common specific, transgeneric, taxonomic unit through use of
the spectral nomenclature. The study of serial sections confirms the
non-reef building population as corals stopped at a young phase of
their astogeny. This kind of populations is not exceptional in the
Jurassic, probably controlled by the unstable nature of the substrate.
Relatively to evolutionary patterns, it is impossible at present to
consider the cited genera as being phyletic. Several alternative
hypotheses are proposed, among which, some renew our vision of this
group, emphasizing the iterative production of generic morphologies
explainded by the hypothesis of heterochronic process. The study of the
microarchitecture demonstrates that the laminar layers of the septa in
montlivaltiid corals are in full continuity with the dissepiments of
the endotheca. Their geometry supports the idea of a genesis of
dissepiments linked to a rising of the soft body.^1";

Spongiolite development include biostromes and bioherms which overlie a generally regressive succession of bioclastic limestones punctuated by occasional hardgrounds. Spongiolite development was surrounded by coeval biomicritic or ooid-bearing detrital limestones. Spongiolites of the humphresianum zone are dominated by hexactinosan (dictyid) porifera, brachiopods and bivalves, whereas &#039;lithistid&#039; demosponges and crinoids are the predominant elements of the superimposed spongiolites of the parkinsoni zone. Glauconite grains and layered to nodular siliceous concretions are abundant within the Spongiolites. Clear differences in faunal composition exist between firm bottoms (on frequent hardgrounds as well as within bioherms and biostromes) and soft bottoms (in evenly bedded limestones and intermound areas). Firm bottom communities are composed of sponges, brachiopods (rhynchonellids, Septaliphoria ssp, Loboidothyris ssp.) limid and pectinid bivalves, gastropods (Pleurotomariacea, Trochidea, Loxonematacea, Naticacea and Muriacea) regular echinoids, crinoids, &#039;algae&#039;, serpulids, bryozoans as well as a distinct spectrum of foraminifers characteristic of sponge facies. Soft bottom communities comprise sponges (rarely in life position), brachiopods (rhynchonellids, Tetrarhynchia ssp., Lobothyris ssp.), burrowing bivalves (Myophoriidae and Pholadomyidae), rare gastropods, irregular echinoids and foraminifers which are clearly different from the sponge facies. The spatial arrangment of different lithofacies and biofacies is characteristic of a ecologically &#47; bathymetrically and sedimentologically differentiated ramp. Spongiolites only developed in selected areas with optimum condition. Towards East and West Spongiolite facies is substituded by oolitic bioclastic limestones of higher energy settings. During the late Bajocian changing environmental conditions resulted in a retreat of sponges from the Celtiberian region.^1";

sponge reefs; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Jurassic Bath; <b>Geography: </b>France, Normandy^Platychonia magna
(d&#039;Orbigny), a lithistid sponge previously regarded as a
calcisponge (Cupulospongia magna) forms small bioherms in rocks of
Upper Bathonian age (sub-zone of Clydonioeras hollandi) at
Saint-Aubin-sur-Mer on the Normandy coast. In addition to the main
frame-builder, four subsidiary faunal groups are preserved. These are:
(i) encrusting organisms which attached to the sponge fronds and gave
the reef additional strength: (ii) byssate and pedically attached
filter-feeding nestlers; (iii) vagile strollers which predated,
scavenged, or grazed; (iv) borers. The encrusters may be further
subdivided into a low diversity assemblage on the upper sides of the
Platychonia fronds, and a high diversity assemblage on their
undersides. The reefs are envisaged as having grown in the lower photic
zone, below normal wave-base but above that reached during storms. The
fauna and habitat of the reefs are compared with those of Upper
Jurassic lithistid sponge reefs in southern France and Germany, and
with those of Middle and Upper Jurassic sponge accumulation in Great
Britain. * The Platychonia magna fronds underwent early diagnetic loss
of their original hyaline silica skeleton, together with early
lithification of the fine sediment which permeated their canals after
death. This appears to be a common occurrence in fossil lithistids.^1";
s[1077] = "FLUGEL E., STEIGER T. (1981).- An Upper Jurassic
sponge-algal buildup from the northern Frankenalb, West Germany.- SEPM

</b>reefs; reefs; <b>Systematics: </b>Porifera algae; <b>Stratigraphy:
</b>Jurassic U; <b>Geography: </b>Germany, Frankenalb^During Upper
Jurassic time (middle-upper Oxfordian) a number of relatively small
organic buildups, principally composed of siliceous sponges and algae,
developed in the area of southern Germany. This study concentrates on
one of these organic structures, the Mlillersfelsen buildup (northern
Franconian Alb near Streitberg). It is demonstrated that the dominant
buildup constructional organisms are siliceous sponges, principally of
two morphologies (cup-shaped and dish-shaped forms), and cyanophycean
algae, which aided in forming the mound configuration. * The
Mullerfelsen buildup developed during several cyclic stages which
occurred in relatively deeper water subtidal depositional environments,
without strong current and wave actions. Three facies types have been
recognized, these are: (1) sponge-crust boundstone facies characterized
by micritic bound-stone rich in calcified siliceous sponges, tuberoids,
and crusts; (2) lithoclastic packstone facies in which spheroidal
sedimentary particles (lithoclasts, tuberoids, and bioclasts) are the
dominant grain-supported allochems; and (3) tuberolitic wackestone
facies in which mud-supported sedimentary particles are dominant. * The
spatial distribution of these microfacies indicate that the
sponge-crust boundstone facies is the mound constructional facies,
whereas both the tuberolitic wackestone and packstone facies are only
developed in those areas marginal to the main organic buildup. The

ID=4610^<b>Topic(s): </b>environmental indicators; Porifera,
Silicispongiae; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Jurassic Oxf; <b>Geography: </b>Spain^The siliceous sponge fauna of
the Oxfordian spongiolites of eastern Spain clearly demonstrates that
the shape of morphovariable sponges as well as the taxonomic
composition of morphoconstant sponges precisely mirrors external
environmental factors. Richness of hardgrounds, automicrites and
glauconite, very reduced sediment thicknesses as well as overall
character, abundance, low diversity and uniformity of benthic fauna
over a minimum area of 75000 qkm suggest a moderately deep, uniform
low-energy ramp setting with extremely reduced carbonate and
terrigeneous background sedimentation. The very reduced influx is
interpreted to have resulted in a very low nutrient level, which is
reflected by a strong reduction in filter-feeding organisms such as
bivalves, crinoids, brachiopods or serpulids frequent in other Late
Jurassic sponge settings. The sponge fauna itself is characterized by
the almost exclusive occurrence of a uniform low-diversity, specimen
rich fauna of hexactinosan dish-shaped sponges, uncommon in most other
Late Jurassic sponge faunas. These observations indicate that the major
factors controlling the morphological and taxonomic composition of
siliceous sponge faunas are sedimentation rate and food supply. When
food is available filter-feeding sponges live on free bacteria. The
mesohyl of these sponges shelters a rich microflora of symbiotic
bacteria. At low nutrition rates two different strategies are
developed. Demosponges enlarge their mesohyl so that more bacteria can
be stored during times of reduced food supply. In morphoconstant
demosponges, this strategy results in a thickening of the sponge walls
in order to increase the available volume. Morphovariable sponges are
able to completely change their form and will preferably develop thick
knob-like or tube-like morphologies. [part of extensive summary]^1";

```

```
NW^Based on microfacies analysis, the sedimentary succession of the
Korallenoolith Formation cropping out in the Hainholz limestone quarry
in the Osterwald Mountains has been studied. The 42m thick deposits
almost completely represent the Korallenoolith Formation in the
Osterwald Mountains and allow the subdivision into three lithological
units: the section starts with (1) the Ahrensberg Member, a 26m thick
succession with an alternation of oolithic bioclastic limestones and
marls at its base that swiftly grades into a monotonous oolite
sequence. It is separated from (2) the overlying Hainholz Member
(&#034;Obere Korallenbank&#034; of Hoyer 1965) by a prominent erosional
unconformity. The Hainholz Member represents reefal deposits 12m in
thickness. It is followed by (3) an unit of quartz-bearing calcarenite
vertically grading into oolite, and cortoid limestone upsection, the
Barenburg Member. Although the Korallenoolith Formation is
traditionally subdivided into three (litho-) stratigraphical subunits
(&#034;Unterer Korallenoolith&#034;, &#034;Mittlerer
Korallenoolith&#034;, and &#034;Oberer Korallenoolith&#034;, see
Schulze 1975), they cannot be equated with the tripartite lithology of
the studied section. According to comprehensive geological mapping and
microfacies analysis, the lithological units recognized in the Hainholz
quarry can be traced - with lateral variations in facies development
and thickness - throughout the Osterwald Mountains. However, even at a
distance of few km from the Osterwald Mountains, the Korallenoolith
Formation differs in facies development and vertical facies patterns,
so that a correlation of the sedimentary succession up to now appears
almost impossible. When compared to the overall development of the
Korallenoolith Formation in NW Germany, the reduced thickness of the
Korallenoolith Formation exposed in the Osterwald Mountains is a
notable feature. Furthermore, the erosional unconformity at the top of
the basal oolite succession indicates a prominent hiatus in the
Osterwald Mountains that is positioned at the base of the reefal
deposits. Whether or not this unconformity can be correlated with the
well developed lowstand unconformity at the top of the widely
distributed florigemma-Bank Member
(&#034;Hauptdiskontinuitätsfläche&#034;) that terminates reefal
development remains unsettled. The middle lithological subunit
(Hainholz Member) is developed as a reef complex with abundant coral
thrombolite patch reefs imbedded in and interfingering with reef
rubble. Its exposed dimensions make it the largest reef complex known
from the Late Jurassic sedimentary succession in the Lower Saxony
Basin.^1";

The Pagny-sur-Meuse section shows coral-microbialite reefs that developed both in pure carbonate limestones and in mixed carbonate-siliciclastic deposits. Phototrophic coral associations dominated in pure carbonate environments, whereas a mixed phototrophic/heterotrophic coral fauna occurred in more siliciclastic settings. Microbialites occur in pure carbonate facies but are more abundant in mixed carbonate-siliciclastic settings. Reefs seem to have lived through periods favourable for intense coral growth that was contemporaneous with a first microbialitic layer and periods more favourable for large microbialitic development (second microbialitic layer). The first microbialitic crust probably developed within the reef body and thus appears to be controlled by autogenic factors. The second generation of microbialites tended to develop over the entire reef surface and was probably mainly controlled by allogenic factors. Variations in terrigeneous input and nutrient content, rather related to climatic conditions than to water depth and accumulation rate, were major factors controlling development of reefs and their taxonomic composition.^1";
s[1087] = "HELM C., SCHULKE I., FISCHER R. (2001).- Palaeobiogeographie des Korallenooliths (Mittleres Oxfordium - Unteres Kimmeridgium): Tethyale Faunen- und Florenelemente auf höherer Paläobreite (Niedersächsisches Becken, NW-Deutschland).- Geologische Beiträge Hannover 02: 51-64.- <b>FC&#038;P 30-2</b>, p. 10, ID=1593^<b>Topic(s): </b>carbonates; carbonates Scleractinia; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf; <b>Geography: </b>Germany NW^An overview is given here on the palaeobiography of the Korallenoolith Formation (middle Oxfordian to early Kimmeridgian) in NW Germany (Lower Saxony Basin). Based on microfcies observations, abundant faunal and floral elements of the tropical tethyan realm are recognized in shallow-marine calcareous sediments s of the Korallenoolith Formation. Foraminiferal fauna is both highly diverse and abundant and mostly of
```

```
mediterranean character. Also, there is a small flora recorded, which
includes heavily calcified red algae, aragonitic green algae, and
cayeuxiid algae. They display restricted diversity when compared to
those of shallow-marine tropical tethyan seas. Chaetetids and
diceratids are locally abundant. Lithocodium aggregatum and Bacinella
irregularis have been observed in Late Jurassic palaeolatitudes north
of the Tethys for the first time. Corals are present in numertous
genera and species. Their occurrence is restricted to a few horizons of
the Korallenoolith formation where they build patch reefs, coral
biostroms and coral meadows. The overall character of the
coral-thrombolite-reefs (florigemma-Bank Member) is very similar to
those of the Tethys. The presence of these marine tethyan taxa assigned
the position of the Lower Saxony Basin during middle Oxfordian to early
Kimmeridgian paleobiographically into the submediterranean province and
reflects northward migration of tropical tethyan fauna and flora which
reach in the Lower Saxony Basin their northern limit. These biota seem
to be biogeographically transitional between communities present in
England and the Tethys.^1";

</b>reef complexes, facies; reef complexes; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic Oxf; <b>Geography: </b>Germany,
Niedersachsen^The Hainholz quarry in the Osterwald hills of NW-Germany
is the most impressive outcrop in the Lower Saxony Basin exposing Late
Jurassic (Korallenoolith, Oxfordian) coral buildups. The Korallenoolith
deposits in the quarry commence with a oolitic sequence about 20 m
thick which is limited by a distinctive hardground at its top. This
sequence is overlain by the so called &#034;Obere
Korallenbank&#034;-Member about 13 m in thickness which is mainly build
up by coral reef complexes. Throughout a lateral extend of about 400 m
exposed in the quarry, the Obere Korallenbank Member shows numerous
pillar-shaped reefal build ups which are flanked by a reefal debris
limestone. The coral fauna of the in situ reefal bioconstructions
comprises not less than 37 taxa most of which have been described from
the Lower Saxony Basin for the first time. Probably, the pillar-shaped
reefs formed a small positive relief of only a few dm against the
debris deposits during deposition. The interreef debris limestones in
the lower and middle part of the Obere Korallenbank Member show three
intercalated biostromal coral layers. In the upper part of the member,
the interreef facies is represented by a mikritic peloidal limestone
rich in sponge remains and, unusual in such a depositional environment,
ammonites (Dichotomosphinctes bifurcatoides, D. sp.). Additionally, at
the top of the peloidal limestone a layer enriched in nerineids and
other gastropods limits the reefal constructions of the Obere
Korallenbank Member against the overlaying &#034;humeralis-Oolith&#034;
sequence. On the basis of the facies development of this depositional
sequence the reef formation in relation to sea-level changes is
discussed.^1";

</b>Germany, Franconia^The coral patch-reef of Laisacker (Neuburg a.d.
Donau, Southern Franconian Alb) exhibits three facies zones: the reef
core consists of reef debris, there is almost no reef framework. The
core facies, interfingering with the reef debris facies is built up by
fine-grained reef detritus with intercalated coarse-grained layers of
partly high porosity (up to 24%). They mainly consist of coral
fragments (up to 83%) and reach 0.80 m in thickness. These
coarse-grained layers have been formed by storms. The interreef facies
corresponds to massive limestones. Destruction of the reef framework
was favoured by bioerosion. The high still open porosity of the
coarse-grained reef rubble was caused by high freshwater flow rates
delimiting cementation and favouring dissolution.^1";
s[1092] = "HELM C., SCHULKE I. (2006).- Patch reef development in the
florigemma-Bank Member (Oxfordian) from the Deister Mts (NW Germany): a
type example for Late Jurassic coral thrombolite thickets.- Facies 52,
3: 441-467.- <b>FC&#038;P 35</b>, p. 95, ID=2418^<b>Topic(s):
</b>reefs, patch reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Jurassic Oxf; <b>Geography: </b>Germany, Deister Mts^Small reefal
bioconstructions that developed in lagoonal settings are widespread in
a few horizons of the Late Jurassic (Oxfordian) succession of the
Korallenoolith Formation, exposed southwest of Hannover, Northwest
Germany. Especially the florigemma-Bank Member, &#034;sandwiched&#034;
between oolite shoal deposits, exposes a high variety of build-ups,
ranging from coral thrombolite patch reefs, to biostromes and to coral
meadows. The reefs show a distribution with gradual facies variations
along an outcrop belt that extends about 30 km from the Wesergebirge in
the NW to the Osterwald Mts in the SE. The patch reefs from the Deister
Mts locality at the &#034;Speckhals&#034; are developed as
coral-chaetetid-solenoporid-microbialite reefs and represent a reef
type that was hitherto unknown so far north of its Tethyan
counterparts. They are mainly built up by coral thickets that are
preserved in situ up to 1.5m in height and a few metres in diameter.
They contain up to 20 coral species of different morphotypes but are
chiefly composed of phaceloid Stylosmilia corallina and Goniocora
socialis subordinately. The tightly branched Stylosmilia colonies are
stabilized by their anastomosing growth. The coral branches are coated
with microbial crusts and micro-encrusters reinforcing the coral
framework. Encrusters and other biota within the thicket show a typical
community replacement sequence: Lithocodium aggregatum, Koskinobullina
socialis and Iberopora bodeuri are pioneer organisms, whereas the
occurrence of non-rigid sponges represents the terminal growth stage.
The latter are preserved in situ and seem to be characteristic so far
poorly known constituents of the Late Jurassic cryptobiont reef dweller
community. The distance and overall arrangement of branches seems to be
the crucial factor for the manifestation of a (cryptic) habitat
promoting such community replacement sequences. Widely spaced branches
often lack any encrusting and/or other reef dwelling organisms, whereas
tightly branched corals, as is St. corallina, stimulate such biota.
Hence, such reefs are well suited for research on coelobites and
community sequences of encrusting and cavity dwelling organisms.^1";

Sequence stratigraphy and tectono sedimentary history of the Lower and
Middle Oxfordian of eastern Paris Basin (Northeastern France).-
Sedimentary Geology 197, 3-4: 235-266.- <b>FC&#038;P 35</b>, p. 104,
ID=2434^<b>Topic(s): </b>sequence stratigraphy; sequence stratigraphy;
```

```
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf; <b>Geography:
</b>France, Paris Basin^In the present study, the difficulty which lies
in the identification of sea-level fall discontinuities in deep
depositional environments led the authors to use the transgressive
surfaces (i.e. the most noticeable surfaces in the present case) to
determine depositional cycles. Four (3rd order?) Lower and Middle
Oxfordian cycles were identified (S1, S2, S3, and S4) in the Eastern
Paris Basin. These four cycles can be organised into two lower
frequency cycles (So I and So II) which comprise the S1, S2 and the S3,
S4 cycles respectively. During the time intervals of the S1, S2, and S3
cycles, sedimentation occurred along a southward dipping
carbonate-siliciclastic ramp, prograding from the northern Ardennes
area. The S4 cycle shows the development of a reefal distally steepened
ramp which subsequently evolved into a flat-topped platform as a result
of the compensation infill of the available accommodation space by the
carbonate production during a climatic warming, in this case reef
growth. Isopach and facies maps suggest synsedimentary activities of
hercynian faults coevals with the floodings of the So I and So II
cycles. One of these events generated a diachronism of the maximum
flooding (Plicatilis Zone) during the So II cycle between the
northwestern and southeastern parts of the studied area. The
depositional patterns found in the Eastern Paris Basin and the Swiss
Jura show great similarities for the Early-Middle Oxfordian. Both
regions were probably connected and recorded the same
tectonosedimentary evolution. In contrast a tectonic control certainly
generated differences between the sequence-stratigraphic framework of
the Eastern Paris Basin and the eustatic chart.^1";

<b>Stratigraphy: </b>Jurassic Oxf; <b>Geography: </b>France, Paris
Basin^Oxfordian reefal episodes of Lorraine and Burgundy have a long
time been considered as contemporaneous. Biostratigraphic data and
sequential evolutions peculiar to each region indicate their structural
autonomy during Oxfordian times. A north-south oriented well-logging
transect shows that, during the Middle Oxfordian, a shallow reefal
platform developed in Lorraine while thin deeper deposits occurred in
Burgundy. In spite of their different ages, reefal episodes of Middle
Oxfordian in Lorraine and Upper Oxfordian in Burgundy exhibit a broadly
similar vertical evolution of coral communities. During the Late
Oxfordian, the contemporaneous occurrence of a diversified assemblage
in the Burgundy region, a colder coral assemblage characterized by
eurytopic genera and the decrease in seawater isotopic temperatures in
Lorraine can be explained by a shift in trophic conditions, a climatic
change related to structural rearrangements in this strategic place and
a modification of oceanic circulations between the arctic and the
Tethyan regions.^1";

Burgundy^The coral limestones from the Lower Callovian of Etrochey,
near Chatillon-sur-Seine (Cote-d&#039;Or) represent one of the last
sequences of the Burgundy platform at the end of the Middle Jurassic.
The geometrical arrangement of the reefs and associated facies shows a
progressive development with competition between constructive and other
organisms, and interference between biological and physical factors of
the environment. Three sedimentary units can be recognized,
corresponding to three successive steps in the coral complex formation.
The size and the frequency of corals decrease up through the reef. The
development of the biological frameworks, their biodegradation by
borers (bivalves and clionid sponges) and their colonization by
encrusting organisms (sponges and oysters) are controlled by the amount
and frequency of the oolitic and bioclastic sand supply which is a
major limiting factor. The successive steps of biological constructions
and biological destructions, controlled by organisms can be considered
as a palaeoecological succession. However the action of the limiting
factor, linked with a decrease in water depth results in a termination
of the reef growth and biodegradation, and this occurs at an earlier
stage in the younger units. Thus the three successive units appear as
an upside down palaeontological succession, reflecting a stronger
external control on reef development.^1";

Basin^During the late middle Oxfordian, patch reefs grew on the
northern margin of the Paris Basin. According to the facies analysis of
the reef and inter-reef sediments, the environment was a warm, clear
```

```
and agitated sea with highly episodic sedimentation. The bioherms were
a short-lived phenomenon during the third phase of regional reefal
development. Sequence stratigraphically, they are associated with a
highstand system tract. Volumetrically and trophically dominant
organisms were microbes now represented by massive clotted leiolite;
&#039;stalactitic&#039; hemispheroids with purely thrombolitic texture
are restricted to open caves. Corals were of structural, reef-building
importance due to their rapid upward growth. The patch reefs are
characterized by thickets of ramose corals which developed a very open
framework. In the vicinity of these patch reefs, though in
hydrodynamically higher-energy environments, grew thickets of more
stoutly branched corals; however, they are rarely preserved in situ and
are generally represented as abundant coral rubble. The reef taxa are
characterized by the notable absence of several groups (e.g. oysters,
serpulids, bryozoans, pectinids) occurring at other localities where
reefs of similar age developed in similar environmental conditions. The
reefs also have strikingly modern aspects to them, in particular the
presence of cryptic elements within caves and a sponge-dominated borer
association. Dwellers belong to various life-form types although
encrusting taxa are exceedingly rare. This may be explained by the
presence of soft microbial films on most surfaces. The palaeoecological
analysis suggests that the major controls on faunal composition and
high diversity were elevated nutrient levels, highly episodic
sedimentation and probably seasonal environmental disturbances.
Structural and functional aspects of the reef community (grazers
trigger framebuilders, borers trigger binders, binders hamper borers)
allow ecological comparisons to be made with contemporaneous, as well
as Recent, reefs. The unique combination of ecological comparisons to
be made with contemporaneous, as well as Recent, reefs. The unique
combination of ecological factors resulted in a specialized, previously
undescribed, community which differs from both Tethyan and northern
localities in various aspects; these include cavities with cryptofauna,
prominence of grazing gastropods and high faunal diversity in a
microbially dominated build-up.^1";

p. 70, ID=4439^<b>Topic(s): </b>reefs, structure, history; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic U; <b>Geography:
</b>Portugal^During the Late Jurassic, the Lusitanian Basin of Portugal
experienced an intensive rifting phase which caused pronounced
bathymetric and, hence, facies differentiation. Particularly during the
Kimmeridgian and Tithonian, siliciclastics were fed into the basin,
resulting in a mixed carbonate-siliciclastic basin fill. Carbonate
platforms and isolated coraliferous reefs of different dimensions and
composition frequently developed within this setting. A shallow-water
carbonate platform exhibiting distinct facies zonation is represented
by the narrow Ota Platform (Kimmeridgian). The buildup exhibits an
aggradational architecture and is rimmed by a high-energy,
high-diversity coral reef. In contrast to most other Upper Jurassic
high-energy reefs, the Ota coral reef contains abundant microbial and
algal crusts. This was due to the achievment of equilibrium conditions
between production and export of debris, which can be explained by the
existence of a tectonically caused, steep by-pass margin. Sedimentation
in interior platform settings is mostly characterised by stacked,
autocyclic, small-scale shallowing-up sequences. The narrow Ota buildup
developed over a basement horst and was protected from surrounding
siliciclastics by its elevated position and a strong longshore current.
The Castanheira slope-type fan delta (Kimmeridgian) also formed at the
strike-slip margin of a continental pull-apart subbasin. The fan
sediments are dominated by coarse arcosic conglomerates.
Coral-microbial reefs grew on deactivated fan areas during two phases
of relative sea-level rise. Collapse events in the course of sea level
falls led to resedimentation of allochthonous limestones in more distal
fan areas. [part of extensive summary]^1";

reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic U;
<b>Geography: </b>Portugal^Upper Jurassic deposits occur widespread
along the northern Tethyan shelf and the marginal basins of the young
North Atlantic Ocean. This work focusses on the sedimentological and
palaeoecological comparison of two Portuguese sedimentary basins
(Arruda Subbasin, eastern Algarve Basin) and the Celtiberian zone of
eastern Spain. Based on this comparative analysis, regional and global
factors controlling the depositional development are deduced. The Upper
Jurassic sediments in all three Iberian basins are characterised by
large-scale, mixed carbonate-siliciclastic, shallowing-upward
successions. Typically the development started with Oxfordian,
ammonite-bearing deeper water carbonates which were overlain by slope
deposits consisting of marls, turbiditic sandstones and intraclastic
limestones (Lower Kimmeridgian). Superimposed were reefal shallow water
carbonates of Lower &#47; Upper Kimmeridgian age. Besides rimmed
shelves (Ota Limestone, Arruda Subbasin) and buildups on deactivated
fan-lobes (Castanheira reef, Arruda Subbasin), the mixed
carbonate-siliciclastic systems were more frequently arranged in ramp
configurations. The Celtiberian zone, located on the stable northern
Tethyan shelf represented a homoclinal ramp situation, whereas the
Arruda Subbasin was characterised by an intense differentiation due to
tectonic activity. Hence distally steepened ramp settings could only
develop on the shallow dip slope of the tectonically inactive eastern
margin of the half-graben basin. The eastern Algarve Basin exhibited
both distally steepened and homoclinal ramp configurations, which was
due to halokinetic differentiation and regional tectonic. This study
concentrates on the coral-bearing shallow water deposits, which
encompass a great variety of different reefal structures. According to
their morphology and composition (amounts of metazoans, microbial
crusts and reefal debris) 16 reef types with at least 15 faunal
assemblages and associations could be distinguished. [first part of

stratigraphy; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Jurassic U; <b>Geography: </b>France^Le récif de Bellême signalé
par L. Dangeard (1939-1940) et décrit par le même auteur (1950), est
étudié à nouveau à la lumière des nouvelles méthodes de pétrologie
sédimentaire et de paléoécologie. Ainsi, nous avons pu donner des
détails plus précis sur sa description et établir des comparaisons plus
objectives avec certaines formations actuelles. * La répartition
stratigraphique des faunes a permis de donner un âge Séquanien
supérieur - Kimméridgien inférieur à la formation. L&#039;étude de la
répartition écologique des fossiles récoltés, celle des différents
faciès, microfaciès, nanofaciès et de leurs répartitions dans le
&#034;complexe récifal&#034;, ainsi que les variations géochimiques
mesurées au sein de la formation ont conduit à conclure que le terme de
récif ne peut être appliqué à la formation du jurassique supérieur de
Bellême et qu&#039;il doit être remplacé par le terme de mud bank
(l&#039;élément madréporique de la lentille est monospécifique,
l&#039;espèce Thamnasteria cf. dendroidea est une espèce à branches
ténues, les colonies ne sont pas jointives mais séparées les unes des
autres par une fine micrite). Ce mud bank situé dans la zone subtidale
pouvant passer en zone intertidale avec formation de calcarénite,
d&#039;oolithes et de beach rock, était probablement entouré de chenaux
de marée divagants où la vitesse de l&#039;eau était plus grande que
celle des eaux des zones contiguës. Les conditions de vie étaient
confinées (faible taille des individus, nombre restreint de genres et
d&#039;espèces). * Le remplacement du terme récif par celui de mud bank
à cette place du Jurassique supérieur de Normandie a probablement une
signification paléogéographique qui sera étudiée dans la suite de nos
recherches sur les formations carbonatées de Normandie.^1";

microbialites; <b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic U;
<b>Geography: </b>France W^During the Early Kimmeridgian, the northern
margin of the Aquitaine Basin (Western France) is characterised by a
significant development of coral reefs. The reef formation of the Chay
Peninsula comprises two main reefal units, in which the microbial
structures can contribute up to 70% of framework. The microbial crusts,
which played an important role in the stabilisation and growth of the
reef body, show the characteristic clotted aspect of thrombolitic
microbialites. Corals are the main skeletal components of the
build-ups. The bioconstructions of the Chay area are thus classified as
coral-thrombolite reefs. Four main morpho-structural types of microbial
crusts are distinguished: (1) pseudostalactitic microbialites on the
roof of intra-reef palaeocaves; (2) mamillated microbialites, found
either on the undersides or on the flanks of the bioherms; (3)
reticular microbialites in marginal parts of the reefs and between
adjacent bioconstructed units; and (4) interstitial microbilaites in
voids of bioclactic deposits. Thrombolitic crusts developed on various
substrates such as corals, bivalves, or bioclasts. The thrombolites
formed a dense, clotted and/or micropeloidal microbial framework, in
which macro- and micro-encrusters also occur. Variations in
```

```
accumulation rate strongly influenced the reef morphology, in
particular its relief above the sediment surface. The coalescence of
the coral-microbialite patches created numerous intra-reef cavities of
metre-scale dimensions. The direction of microbial growth, which
defined the macroscopic microbialite forms, strongly depended on the
position within the reef framework but was also controlled by water
energy, accumulation rate and light availability. [original abstract]^1";

18-2</b>, p. 39, ID=2490^<b>Topic(s): </b>; Anthozoa; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Cretaceous Cen - Sant;
<b>Geography: </b>Czech Republic, Beskides^The coral fauna from the
Pribor area has already been known on the basic of F. Trauth&#039;s
(1911) paper. The corals form part of the clastic rocks redeposited in
the Frydek and Trinec Members (Senonian to Paleogene) of the
Subsilesian unit of the Carpathian Flysch. Thus, the probably Upper
Cenomanian to Lower Santonian age of the coral fauna, does not agree
with the age of the host rock which is younger. In the present paper 18
coral species are described, of which one belongs to a new genus and 3
species are new. The coral assemblage is of a transitional character
between the Cretaceous coral assemblages of the epi-Variscan platform
and those of the Tethys (the Carpathians and the Alps). The coral fauna
from the Pribor area represents a pioneer assemblage existing during a
short stage of favourable conditions, probably on the western side of
the Baska cordillera. During the Laramian or younger movements, the
already silicified coral colonies were redeposited in rather deep parts
of the Subsilesian basin.^1";

Sedimentation of a Lower Cretaceous (Aptian) coral mound complex,
Zaraya Mountains, northern Spain.- Geological Magazine 120, 4:
423-434.- <b>FC&#038;P 18-2</b>, p. 43, ID=2498^<b>Topic(s): </b>coral
mound; reefs; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Cretaceous Apt; <b>Geography: </b>Spain N^A Lower Cretaceous mixed
carbonate-siliciclastic sequence is well exposed in Zaraya Mountains in
Guipuzcoa Province, northern Spain. The sequence begins with
interfingering deltaic platform facies and marine patch-reef
carbonates. This unit is dominated by mudstones and sandstone with
minor interbeds of shallow-water carbonates (calcareous mudstones and
sandstones and grain-stone-packstones). A thick mixed
carbonate-terrigeneous unit overlies the siliciclastics and is composed
principally of limestones and marls. Periodic influx of terrigenous
sediments over a dominantly carbonate sea-floor gave rise to repeated
cycles typical of a mixed shallow-water platform. Demise of a southerly
derived deltaic input allowed the development of a mainly carbonate
third unit. Large (several metres across) bioherms resulted from high
in situ organic productivity (mechanical breakage of bioclasts,
algal-induced precipitation, trapping and baffling of lime mudstone).
The mounds grew making up a coral carbonate mound complex. This
progrades to the south, towards a small backreef basin, and slightly
retreated in its forereef margin. A period of tectonic instability is
thought to have been responsible for the drowning of the shallow-water
complex, which was unable to keep pace with relative sea-level rise.^1";

nannofossils are introduced and their stratigraphical value
discussed.^1";
s[1128] = "GOTZ S., LOSER H., SCHMID D.U. (2005).- Reef development on
a deepening platform: two Early Cretaceous coralgal patch reefs (Catí,
Llacova Formation, eastern Spain) compared.- Cretaceous Research 26, 6:
864-881.- <b>FC&#038;P 34</b>, p. 59, ID=1280^<b>Topic(s): </b>reefs,
patch reefs; reefs ecology; <b>Systematics: </b>Cnidaria algae;
Anthozoa; <b>Stratigraphy: </b>Cretaceous Haut; <b>Geography: </b>Spain
E^Two coralgal patchreefs of the Hauterivian Llacova Formation
(Maestrat Basin, E-Spain), subsequently exposed within one section,
were investigated to reveal the taxonomical implications of changing
environmental controls on reefal palaeocommunities. After taxonomical
work on the coral fauna, microfacies analysis and palaeoecological
interpretation, two communities could be distinguished that differ in
coral taxonomical composition, microbialite formation pattern and in
abundance and composition of encrusters and bioeroders. The coral fauna
comprises 14 species (e.g. Actinastrea pattoni, Cladophyllia aff.
catalaunica, Dimorphocoenia cf. crassisepta, Dimorphocoenia rudis,
Eocomoseris raueni, Eocomoseris sp., Holocoenia jaccardi, Latusastrea
irregularis, Mesomorpha sp., Microsolena kugleri, Polyphylloseris cf.
mammillata, Polyphylloseris mammillata, Polyphylloseris sp., Stylina
parvistella) and differs on the species level between the reefs. Only
one coral species (S. parvistella) occurs in both the lower (abundant)
and the upper reef (rare, occurs near the reef base). The lower reef
was dominated by phototrophic fauna and coral species that show small
corallites with nonperforate septa (a stylinid, thamnasteriid,
heterocoeniid, actinastreid association) predominate together with
Abacinella-Lithocodium dominated encruster association. The upper reef
had a balanced phototrophic-heterotrophic fauna that gradually passed
into a heterotrophic-dominated fauna during its latest growth stage
where microsolenid corals predominated. The encruster spectrum is
dominated by an association of sponges, polychaets and bryozoans.
Moderate deepening during a transgressive systems tract (TST)
depositional sequence and elevated nutrient supply are interpreted to
represent the driving environmental parameters that caused this change
in reefal palaeocommunity composition. In addition, we determined nine
coral species that were only known from younger strata (Barremian,
Aptian, Albian, Cenomanian) which emphasizes the importance of the
Hauterivian as a time of evolutionary transition from Late Jurassic to
Cretaceous coral faunas. ^1";

Porifera Hexactinellida; <b>Systematics: </b>Porifera; Hexactinellida;
<b>Stratigraphy: </b>Cretaceous Camp; <b>Geography: </b>Germany,
Munsterland^In the district of Coesfeld near the villages of Holtwick,
Osterwick, Darup and Lette, northwest area of the Muenster Cretaceous
Basin, extraordinary associations of hexactinellid and lithistid
sponges are exposed. These occur in Late Senonian strata [late Lower
Campanian (Campanian 2-3)]. The regional so-called Osterwicker
Schichten include alteration layers of glauconitic-sandy, argillaceous
and calcareous marls, and marly limestones. A first systematic review
indicates a dominance of hexactinellid sponges as opposed to lithistid
ones. The Lithistida are represented by species of the genera
Callopegma, Seliscothon, Verruculina, Jerea, and Siphonia. The
Hexactinellida comprise species of the genera Aphrocallistes, Becksia,
Camerospongia, Coeloptychium, Coscinopora, Lepidospongia, Leptophragma,
Plocoscyphia, Sporadoscinia, Tremabolites and Ventriculites (Gasse et
al. 1988). Well known from this region is the occurrence of specimens
of the genus Becksia. Also from this area the type species Becksia
soekelandi was erected by Schluter (1868). Recently collected and
well-prepared individuals of this species have stimulated the following
remarks [on Becksia]. ^1";

Annelida; <b>Systematics: </b>Cnidaria Annelida; Hydrozoa;
<b>Stratigraphy: </b>Cretaceous Cen; <b>Geography: </b>Germany N^The
colonial hydroid Protulophila gestroi Rovereto, 1901, a common serpulid
symbiont, is recorded for the first time from the lower Middle
Cenomanian Praeactinocamax primus Event of northern Germany. It is
represented by a reticulate system of thin stolons, small subcircular
openings or chimney-like bosses, and elongate polyp chambers preserved
by in vivo bioimmuration in the outer layers of the calcareous tubes of
serpulid worms. From the rich serpulid fauna of the primus Event, only
representatives of the genus Rotulispira Chiplonkar &#038; Tapaswi are
infested whereas other genera (e.g., Nogrobs (Tetraditrupa) Regenhardt
and Pentaditrupa Regenhardt) appear to be not affected. This
observation may indicate that P. gestroi was selective in the choice of
its hosts, a phenomenon known also from recent colonial hydroids living
as polychaete symbionts. A commensalic relationship is inferred for P.
gestroi from the primus Event as the percentage of infestation (ca.40%)
indicates that infested and non-infested serpulids were roughly equally
successful in the same environment.^1";
s[1135] = "REHFELD U., ERNST G. (1998).- Hydrozoan build-ups of
Millepora irregularis sp nov. and fungiid coral Meadows of Cunolites
Alloiteau (Anthozoa). - Palaeoecological and Palaeooceanographical
implications for the Upper Cretaceous of North Cantabrica (Northern
Spain).- Facies 39, 1: 125-138.- <b>FC&#038;P 27-2</b>, p. 76,
ID=3945^<b>Topic(s): </b>reefs hydrozoan-fungiid; reefs
hydrozoan-fungiid; <b>Systematics: </b>Cnidaria; Hydrozoa Scleractinia;
<b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>Spain N^The
Cantabrian Basin of northern Spain yields an Upper Santonian &#47;
Lower Campanian carbonate sequence, where both milleporid hydrozoans
and fungiid corals established uncommon and hitherto unknown
bioconstructions. The section where these bioconstructions are exposed
can be divided in four lithological units. The hydrocoralline
bioconstructions are developed as biostromes in unit one and as
bioherms in unit three. Biostromes and bioherms are separated by unit
two, a carbonate facies rich in &#034;lithistid&#034; and hexactinellid
sponges. The hydrozoan colonies were preserved due to early diagenetic
silicification of their formerly aragonitic skeleton. The examined
fauna strongly resembles the Recent milleporid taxon Millepora
alcicornis. Significant differences between fossil and Recent skeletal
structures can be recognized only in the distribtuion of zooecial tubes
within the coenosteum. The hydrozoan facies is topped by unit four, a
quartz-rich limestone, with at least a dozen bed surfaces, each covered
by dense meadows of a more or less monospecific fungiid coral fauna,
assigned to the genus Cunnolites Aloiteau. The milleporids developed
in, at least intermittently agitated, shallow water environment with
normal, open marine salinities. The sediment yields a microfacies rich
in benthic foraminifera and bioclasts and poor in terrestrial
components. The Cunnolites fauna, instead, probably spread in a quiet,
more restricted environment of a deeper lagoonal facies, poor in marine
biogenes, except for some rare associated gryphaeid oysters and
irregular echinoids. This facies is conspicuously influenced by
terrigenic input, as is substantiated by abundant quartz minerals, wood
fragments and small coal flakes. The conspicuous environmental change
from the hydrozoan into the fungiid coral facies matches an approach of
the coastline, obviously related to an Upper Santonian &#47; Lower
Campanian &#034;tecto-event&#034;, which has been proved on a
superregional scale. Both the milleporid hydrozoans and the fungiid
corals point to a temporary influx of subtropical Tethyan ocean waters
in the Boreal Realm of the Biskaya Ocean during this time.^1";

Montlivaltia multiformis Toula (Scleractinia) from the Aptian of the
Prebetic domain (SE Spain).- Revista Espanola de Paleontología 16, 1:
131-144.- <b>FC&#038;P 33-2</b>, p. 34, ID=1169^<b>Topic(s):
</b>ecology; Scleractinia, Montlivaltia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous Apt; <b>Geography:
</b>Spain SE^Montlivaltia multiformis Toula (Scleractinia, Faviina,
Montlivaltiidae), formerly reported from the Carpatho-Balkanic domain
is described from Lower Aptian beds of the Prebetic Domain (SE Spain).
Taxonomic attributes include the organisation of radial elements,
septal trabeculae, carinae and endothecal elements while the external
morphology of the coralla is fairly variable. The sedimentological
context suggests a circalittoral environment also supported by
palaeoecological features of the surrounding fauna. Owing to its
stratigraphic position in the Carpatho-Balkanic region and in Spain,
Montlivaltia multiformis appears as a potential marker for both shallow
carbonate or outer shelf settings of the Lower Aptian Tethys European
margin.^1";

<b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>Germany N^The
chalk quarries of Lägerdorf, Kronsmoor (southeast of Itzehoe, Holstein)
and Hemmoor (northwest of Stade, Lower Saxony) expose an early complete
section from the upper Cretaceous (Middle Coniacian to the Upper
Maastrichtian) which has a thickness of 520m. It is chalk facies. Most
of the solitary corals in this section are of the genera Parasmilia and
```

```
Trochosmilia (Coelosmilia). From 300 corals more than 50% belong to
these genera. The genus Parasmilia can be found from the Coniacian to
the Maastrichtian, Trochosmilia can only be found inthe Maastrichtian.
Material for comparison from other quarries in North-Germany were not
studied.^1";
s[1146] = "STOLARSKI J., VERTINO A. (2006).- First Mesozoic record of
the scleractinian Madrepora from the Maastrichtian siliceous limestones
of Poland.- Facies 53, 1: 67-78.- <b>FC&#038;P 34</b>, p. 69,
ID=1303^<b>Topic(s): </b>new records; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous Maas;
<b>Geography: </b>Poland^The objective of the present article is to
document the first stratigraphic occurrence of the colonial oculinid
Madrepora, known from the modern seas as azooxanthellate taxon that
contributes to formation of deepwater coral reefs. The Upper Cretaceous
specimens of Madrepora sp. reported herein from Poland were recovered
from Upper Maastrichtian (Nasilów and Bochotnica localities) and Lower
Maastrichtian (Blizów locality) siliceous limestones. The corals are
preserved as imprints of the branch fragments and molds of the calices.
Despite their moldic preservation, the coral remains exhibit key
generic features of the genus Madrepora: (1) sympodial colony growth
form with calices arranged in opposite and alternating rows in one
plane of the branch, and (2) imprints of the granular coenosteum
texture, occasionally showing peculiar reticulate patterns. Some
features of the Cretaceous Madrepora sp., such as the reticulate
coenosteum texture, the range of the corallite diameter (2.8-4 mm), and
the arrangement of the septa in three regular cycles resemble the
skeletal features of the modern, typically constructional, species M.
oculata (type species). The lack of any evidence of coral buildups and
related debris in the whole Upper Cretaceous/Paleogene sequences from
Poland and the sparse occurrence of colony fragments, suggests that the
Cretaceous Madrepora sp. formed small, isolated colonies.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous Apt; <b>Geography: </b>Spain, Murcia^Three species of
colonial scleractinian corals are reported from Early Aptian sandy
marls of the so-called Montlivaltia marls from a section exposed on the
SE flank of the Sierra de Sopalmo, south of Jumilla in Murcia, Spain.
While solitary corals of the genus Montlivaltia are extremely common in
```

```
the marls, colonial corals are rare. The three colonial coral species
presented here (Cryptocoenia sp. n. aff. C. pygmaea, Holocystis
elegans, and Columnocoenia aragonensis) are all common Early Cretaceous
species. They range in age from the late Barremian to early Albian with
the exception of Columnocoenia aragonensis, which ranges from the
Valanginian to Cenomanian. Their geographical distribution is large and
all species were found in the central Tethys as well as in the
Caribbean province. All species were previously found in siliciclastic
environments and while Holocystis elegans occurs primarily in such
facies, the other two species occur in pure carbonates as well.^1";
s[1150] = "TOMAS S., LOSER H., SALAS ROIG R. (2008).- Low-light and
nutrient-rich coral assemblages in an Upper Aptian carbonate platform
of the southern Maestrat Basin (Iberian Chain, eastern Spain).-
Cretaceous Research 29, 3: 509-534.- <b>FC&#038;P 35</b>, p. 86,
ID=2407^<b>Topic(s): </b>ecology; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous Apt;
<b>Geography: </b>Spain, Iberian Chain^A Lower Cretaceous (Aptian)
succession of carbonate rocks in the southern Maestrat Basin (Iberian
Chain, Spain) was analysed in terms of sedimentological and
palaeontological criteria. The shallow marine sequence was deposited
upon a homoclinal carbonate ramp. Five main facies types were
distinguished: (A) peloidal and bioclastic grainstones and rudstones of
the inner ramp shoals; (B) orbitolinid wackestones-packstones of the
distal outer ramp; (C) peloid and Ostrea wackestones-packstones of the
middle outer ramp; (D) coral-algal sheetstones of the proximal outer
ramp; and (E) coral-algal platestones-domestones of the middle ramp.
Coral-bearing facies types (D) and (E) showed similar major
environmental factors: low energy hydrodynamism, low light intensity
and apparently nutrient-rich water. Slight differences in these
conditions are reflected in the different growth forms and coral
assemblages. Coral-algal sheetstones are characterized by sheet-like
and lamellar forms with a low coral diversity not clearly dominated by
any taxon. Coral-algal platestones-domestones develop platy, tabular
and irregular massive forms with a slightly higher coral diversity
characterized by a Microsolenina-Faviina association. The coral fauna
is revised taxonomically and yielded a total of 22 species in 18 genera
(21 Scleractinia species, one Octocorallia species). Genera of the
suborders Microsolenina and Faviina predominate, those of the suborders
Stylinina, Fungiina, Rhipidogyrina and the order Coenothecalia are
subordinate.^1";

</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous Cen;
<b>Geography: </b>Germany N^A systematic account of the fauna from the
early Middle Cenomanian Praeactinocamax primus Event, a 50-60cm thick
marl bed, at the type locality, Wunstorf quarry, to the west of
Hannover (northern Germany), is given. Numerous invertebrate taxa (over
50 in total) have been collected, including two species of belemnites,
ten ammonites, at least 12 bivalves, a single scaphopod, five
gastropods, at least eight brachiopods, two solitary corals, a single
hydrozoan, four echinoids, and ten polychaetes. The benthic community
of the primus Event clearly represents a soft-bottom fauna, with
hard-bottom elements limited to secondary hard substrates. Most of the
macrobenthic elements constitute suspension feeders; shallow-infaunal
deposit feeders, grazers and microcarnivores occur as well, while
deeper infaunal elements are largely missing. [first fragment of
extensive summary]^1";

<b>Geography: </b>Spain^Two new genera of Cretaceous Scleractinia are
described. They belong to superfamily Montlivaltioidae but the familial
assignement is open. The diagnosis of the first one, named
Pseudocunnulites is as follows: Solitary circular or discoidal. Lower
face epithecate with many growth concentric rings. Upper faci with
numerous radial septa strongly perforate. Columella fasciculate.
Endotheca very thick. Without synapticula. The type species is
Pseudocunnulites rosendoi n.sp., coming from Santonian of La Llobera
(Villanova de Meia), Prepyrenees of Catalonia, NE of Spain. The
diagnosis of the second genus, Angelismilia, is: Solitary, trochoid and
with parathecal wall, covered by a smooth epitheca, followed by a
second inner wall. Perforate septa. Abundant endotheca. Columella
spongy and pseudolamellar. This new genus encloses the following
species, described by De Angelis (1905): portisi (type species),
neviani and sandalina. They were collected in Cenomanian of Castelvi de
la Marca (Catalonia, NE of Spain).^1";

Cretaceous scleractinian corals from the Albian of Cabo de Ajo
(Cantabria Province, N-Spain).- Paläontologische Zeitschrift 71, 1-2:
35-40.- <b>FC&#038;P 26-2</b>, p. 70, ID=3748^<b>Topic(s): </b>;
Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Alb; <b>Geography: </b>Spain N^For the
first time a detailed stratigraphic section of the Lower Cretaceous
(Albian) of Cabo de Ajo peninsula (Cantabria Province) is logged. The
Ajo facies represents a subtropical shallow-water carbonate platform
environment. When the platform was subjected to relatively high-energy
conditions, calcarenite skeletal shoals developed. In periods of higher
sealevel, deeper-water marls were deposited in intraplatform basins.
The outcrops yield abundant fossils of scleractinian corals. Three
selected stratigraphic horizons containing corals were sampled. Fauna 1
and 2 grew on a shallow-water soft bottom substrate (marl) below
wave-base level and contain very small plocoid and phaceloid growth
forms. Fauna 3 is associated with a calcarenitic matrix and large forms
suggesting a more agitated and wave-influenced environment. 16 species
of corals belonging to 7 suborders are described taxonomically. These
```

```
rather diverse coral associations are among the youngest from the
Urgonian facies of Europe, and compare well with other Urgonian Tethyan
faunas.^1";

auto-mobility and host substrate relationship in &#034;Cycloseris&#034;
escosurae Mallada 1887, scleractinian coral from Lower Aptian of
Spain.- Bolletino della Societa Paleontologica Italiana, Spec. vol. 3:
191-220.- <b>FC&#038;P 27-1</b>, p. 95, ID=3844^<b>Topic(s):
</b>auto-mobility; Scleractinia,&#039;Cycloseris&#039;;; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous Apt;
<b>Geography: </b>Spain^&#034;Cycloseris&#034; escosurae is an Early
Aptian solitary coral from Spain created [described!] by Mallada
(1887). The taxonomic revision indicates that the species of Mallada
shows intermediate characters between the genus Cycloseris Lamarck and
Cyclophyllopsis Alloiteau 1959, and, may be, it is pertaining to a new
genus. This small, discoidal coral is commonly settled on Palorbitolina
tests and, occasionally, on bivalve fragments, conchostracan shells,
and others. Few specimens do not display apparent attachment. The
hypothesis of Alloiteau (1952) concerning an association of Eocene
solitary corals to macroforaminifera as a case of commensal
relationship is here discussed. Architectural criteria for self induced
mobility, such as trabeculae directed also basally and the lack of
epitheca, as demonstrated within Recent Cycloseris cyclolites (Lamarck)
suggest that the species from Spain had been auto-mobile (Gill &#038;
Coates 1977). The relationship between the coral and its host substrate
```

```
is analyzed.^1";

s[1175] = "LOSER H. (2008).- A new solitary coral genus of the suborder Heterocoeniina (Scleractinia) from the Aptian (Cretaceous) of Spain.- Paläontologische Zeitschrift 82, 3: 279-284.- <b>FC&#038;P 36</b>, p. 94, ID=6509^<b>Topic(s): </b>new genus; Scleractinia Hexasmiliopsis; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous Apt; <b>Geography: </b>Spain^The new scleractinian coral genus Hexasmiliopsis is described on the basis of material from the
```

```
Early Aptian (Early Cretaceous) of Murcia (Spain). The new genus of the
Heterocoeniidae family is characterised by its solitary growth form, a
very strong main septum and the presence of apophysal septa. It is
closely related to the genera Hexasmilia (phaceloid growth form),
Rodinosmilia and Tiarasmilia (both without main septum). The genus is
monospecific and represents only the type species, Hexasmiliopsis
saldanai. [original abstract]^1";
s[1176] = "LOSER H. (2008).- Remarks on the genus Hexasmilia
(Scleractinia; Cretaceous) and description of a new species from the
Aptian of Spain.- Neues Jahrbuch für Geologie und Palaeontologie,
Abhandlungen 250, 1: 45-52. [revision] - <b>FC&#038;P 36</b>, p. 94,
ID=6510^<b>Topic(s): </b>new species; Scleractinia Hexasmilia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous Apt; <b>Geography: </b>Spain^The morphological
characteristics of the genus Hexasmilia de Fromentel, 1870 are analysed
for the first time, using material from the type locality of the type
species. The position of the genus within the Heterocoeniidae family
(Heterocoeniina suborder) is confirmed. The genus differs from
Heterocoenia by its phaceloid growth mode and the presence of apophysal
septa. Up to now, Hexasmilia was believed a monospecific genus, but in
addition to the type species, the genus includes the species Hexasmilia
pachythecalia (Kuzmicheva, 1980), previously attributed to Hexapetalum.
Hexasmilia elmari n.sp. from the Aptian of Spain is newly described and
further material is presented in open nomenclature. The genus reaches
from the Late Barremian to the Santonian. [original abstract]^1";
s[1177] = "LOSER H., CASTRO J.M., NIETO L.M. (2010).- A small Albian
coral fauna from the Sierra de Seguilí (Alicante province, SE Spain).-
Neues Jahrbuch fur Geologie und Palaontologie, Abhandlungen 255, 3:

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Alb; <b>Geography: </b>Spain,
Alicante^From the Early to Middle Albian of south-eastern Spain
(Prebetic) a small coral fauna is reported. Five species are described.
Four species belonging to the Leptophyllidae, Montlivaltiidae, and
Cyathophoridae families are quite common in outcrops of an Aptian to
Early Cenomanian age, mainly in the central Tethys and Western
Hemisphere. One species belongs to the Hemiporitidae family and
represents only the second colonial coral genus known from the
Meandrinina suborder in the Early Cretaceous, the first being
Phyllocoenia. A short account is therefore given of the suborder
Meandrinina, its history, taxonomic composition and diversity through
the time. Due to the low quality of the material and the availability
of only one sample, the material is preliminarily assigned to the genus
Lamnastrea Reig Oriol 1997, which is herein revised on the basis of
thin sections obtained from the type of the type species. [original
abstract]^1";
s[1178] = "GOTZ S. (2003).- Biotic interactions and synecology in a
Late Cretaceous coral-rudist biostrome of southeastern Spain.-
Palaeogeography, Palaeoclimatology, Palaeoecology 193, 1: 125-138.-
<b>FC&#038;P 33-2</b>, p. 28, ID=1148^<b>Topic(s): </b>reefs,
coral-rudist biostrome; Scleractinia, ecology; <b>Systematics:
</b>Cnidaria Mollusca; Scleractinia Bivalvia; <b>Stratigraphy:
</b>Cretaceous Camp; <b>Geography: </b>Spain SE^A coral-rudist
biostrome exposed in Campanian limestones near the village of Tabernas
de Valldigna in southeast Spain was analysed with respect to its
palaeontology, sedimentology andpalaeoecology. Special attention was
given to possible evidence for synecological interactions between
corals and rudists. Changes in the rudist shell accretion process are
evident in somepo lished slabs and thin sections and resulted from in
vivo contact with coral colonies. These unusual balcony-like shell
protuberances exist where the rudist&#039;s commissure was in contact
with corals. They likely represent defence-reactions of rudists against
the coral cnidia. Nevertheless, the fossil record of these biotic
```

```
interactions is rare. This may be due to different growth-rates of
rudists and corals, differing shape and size of interacting areas, or
different life-spans. In consequence, the discrete &#039;window&#039;
of intergroup biotic interaction was small. Sedimentation and
resuspension rates were high in the biostrome and corals only
established pioneer associations under these unfavourable conditions. A
higher diversity of corals is reached, however, when rudists are
present. This increase in diversity resulted from the availability of
additional ecological niches such as rudist-shell hard substrates and
elevation above mobile sediment surface. Rudists on the other hand,
received support from stabilisation of their shells through coral
encrustation and framework building. In consequence, both groups
benefited from their co-existence.^1";

According to microfacies and sedimentological analyses the bathymetric position of the Lithocodium &#47; Bacinella banks ranges from deeper subtidal to shallowest subtidal &#47; intertidal conditions. The maximum depth is related to the photic zone, which itself is controlled by the amount of muddy suspension. The upper bathymetric limit is mechanically defined and corresponds to increased depositional energy (i.e. waves and tidal currents). Together with other algae and microbes Lithocodium &#47; Baccinella is a major constitutent of thrombolitic mud mounds (Gandara mound). In the context of mud mound genesis the functional role of Lithocodium &#47; Baccinella includes baffling and binding, the production of micrite via the calcification inside of mucilagenous sheaths, and via intensive boring activities upon and inside of skeletal hard parts. The mass occurrence of Lithocodium &#47; Baccinella with associated algae and microbes may be explained by a longer ranging eutrophism of the environment or by shifts in seawater carbonate alkalinity.^1";

Lower Albian sponges crop-out in great abundance as a rich necrocoenosis embedded in a marly matrix. Demosponges make up
```

```
the bulk of an 11 m thick succession, which is interpreted as having
formed in a slope setting. The sponges show body preservation and were
buried &#034;in situ&#034;. All types of growth forms are present; they
grew so tightly that they often fused secondarily. Shape polarity
suggests steady low energy, predominantly easterly palaeocurrents. The
mam factor limiting the community seems to have been space competition.
A preliminary documentation of the systematic palaeontology is
presented: only taxa from the families Tetracladinidae, Megamorinidae
and Corallistidae were found. Geometrical restoration of the
platform-basin transect allows estimation of a depth of approximately
40 m for the lithistid sponges. Sea-level variations driven by
block-faulting controlled the available accommodation space. Sponges
occur just below and above a sequence boundary and are associated with
a major tectonic event linked with the opening of the Bay of Biscay.^1";

Sant; <b>Geography: </b>Poland S^Phosphatized sponges from the
Santonian of the Wielkanoc Quarry are represented by 11 species of
Hexactinosida and 16 species of Lychniscosida. The taxonomic
composition is most similar to the Micraster coranguinum Zone fauna
(Middle Coniacian-Middle Santonian) of England. Three preservational
groups of sponges are distinguished: &#034;white&#034;,
&#034;beige&#034; and &#034;dark&#034;. They are infilled by
phosphatized foraminiferal/foraminiferal-calcisphere wackestone and are
contained in the marly calcareous inoceramid packstone. The sponges
indicate a calm and relatively deep (> 100m) life environment. After
burial, phosphatization and exhumation, the fossil sponges were
redeposited in Upper Santonian strata. The &#034;white&#034; and
&#034;beige&#034; groups were displaced a very short distance or
represent only lag deposits. The rolled and crushed sponges of the
&#034;dark&#034; group were exhumed and phosphatized more than once.
They could be redeposited (reworked) nearly in the same place and/or
transported from some longer distances (but not from outside of the
Cracow Swell). The phosphatized wackestone infilling the sponges, and
the phosphatized clasts, are the only remains of the deposits, which
formed on the Cracow Swell after the late Early Coniacian but before
the Late Santonian.^1";

palaeoecological significance.- Annales Societatis Geologorum Poloniae
76, 3: 227-296.BUS7-0001-0058.- <b>FC&#038;P 35</b>, p. 47,
ID=2330^<b>Topic(s): </b>ecology; Porifera, Silicispongiae;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Cretaceous U;
<b>Geography: </b>Poland, Middle Vistula^Siliceous sponges are
extremely abundant in the Upper Campanian-Maastrichtian opokas and
marls of the Middle Vistula River Valley, situated in the western edge
of the Lublin Basin, part of the Cretaceous German-Polish Basin. This
is also the only one area in Poland where strata bearing the Late
Maastrichtian sponges are exposed. The presented paper is a taxonomic
revision of sponges collected from this region. Based both on existing
and newly collected material comprising ca. 1750 specimens, 51 species
have been described, including 18 belonging to the Hexactinosida, 15 -
to the Lychniscosida and 18 - to Demospongiae. Among them, 28 have not
been so far described from Poland. One new genus Varioporospongia,
assigned to the family Ventriculitidae Smith and two new species
Varioporospongia dariae sp. n. and Aphrocallistes calciformis sp. n.
have been described. Comparison of sponge fauna from the area of
Podilia, Crimea, Chernihov, and Donbas regions, as well as literature
data point to the occurrence of species common in the analysed area and
to the basins of Eastern and Western Europe. This in turn indicates
good connections between particular basins of the European
epicontinental sea during the Campanian-Maastrichtian. Analysis of the
taxonomic composition of the Middle Vistula assemblage suggests that
the occurring sponge fauna is transitional between the faunas of
Eastern and Western Europe, what may be linked with the central
location of the Lublin Basin in the European epicontinental sea. The
gradual upward decrease of taxonomic diversity of the Hexactinosida and
Lychniscosida in the studied succession points to gradual basin
shallowing, what is consistent with the global regressive trend by the
end of the Cretaceous. The domination of the Hexactinellida over the
lithistids in terms of diversity and abundance in the entire section
allows us to estimate the maximum depth of the Late Campanian basin as
200-250 m and to constrain the minimum depth during the latest
Maastrichtian as about 100 m.^1";

Oberapt im Becken van Organya (Nordspanien).- Coral Research Bulletin
06: 1-139.- <b>FC&#038;P 27-2</b>, p. 34, ID=3977^<b>Topic(s):
</b>geology, fossils; geology paleontology; <b>Systematics: </b>;
<b>Stratigraphy: </b>Cretaceous Apt; <b>Geography: </b>Spain N^During
the Late Mesozoic, thick successions of marls and limestones were
sedimented. The basin was situated at the northern margin of the
Iberian Peninsula and its formation was influenced mainly by the
opening of the Bay of Biscaya in the northwest. During the Aptian
homoclinal carbonatic ramps were developed with biohermal buildups
mainly of rudists and corals. Parts of the ramps were preserved in the
Boixols thrust sheet, which is situated in the central Catalanian
Pyrenees, in the middle part of the Segre valley. Biostratigraphical
indications showed that the carbonate ramps were of Upper Aptian age.
Selected sections provided data on the sedimentology, microfacies and
palaeontology of the ramp. The development of the facies and fossil
assemblages is described. The formation of bioconstructions is
discussed in detail. The association of corals and rudists shows clear
distribution patterns of middle and inner ramp areas. Whilst rudists
lived on the shallowest parts of the ramp, corals preferred slightly
deeper environments. In ranges of a changing sedimentation rate, corals
and rudists settled in the same area. Corals show three types of
```

```
colonization: shallow coral meadows, lens-shaped biostromal buildups
and coral banks (bound-and framestones). Their various morphotypes
indicate a clear adaption to soft bottoms and changing sedimentation
rates. The formation of bioconstructions is mainly due to regional
factors, less to global ones. For two time spans (Senyiis and Font
Bordonera Formation), palaeogeographical reconstructions are provided.
Based on the microfacies and the distribution of fossils, the sea level
changes in the Basin of Organya are documented. [part of extensive
summary]^1";

Tur; <b>Geography: </b>Czech Republic, Bohemian Massif^A study of the
Late Cretaceous rocky coast deposits of the Unhost&#039;-Tursko High
lying west-northeast of Prague is undertaken here. Based on the record
of the rocky bottom characters, overlying sediments, phosphates,
distribution of foraminifers, palynomorphs and macrofaunal
taphocoenoses, two sedimentary settings each with its own
phosphogenesis have been distinguished. The phosphogenic products are
in part reworked and redeposited into younger beds. The older
phosphatic remains are reported from the conglomerate in which the
taphocoenose with Gisilina? rudolphi and Goniopygus cf. Menardi occurs.
Parts of the two sections (Predboj and Cernovicky) characterized by
this taphocoenose belong to the upper part of Metoicoceras geslinianum
Zone and are discussed here in more detail. The younger phosphogenic
episode is probably of the early Turonian age. Both the proper
phosphogenic episodes and subsequent development of strata are
correlated with the updip succession of the Pecinov Member and the Bila
Hora Formation in the Pecinov quarry. The palaeoenvironments of
principal intervals are briefly discussed to elucidate problems of
phosphogenesis and distribution of faunal remains.^1";
s[1204] = "REITNER J., WILMSEN M., NEUWEILER F. (1995).- Cenomanian
&#47; Turonian sponge microbialite deep-water hardground community

community of sessile metazoans dominated by coralline sponges (e.g.
Acanthochaetetes and Vaceletia) is found within a Cenomanian-Turonian
deep water hardground succession cropping out at the coastal area of
the Bay of Biscay near Santander. The characteristic K-strategic
community exhibits a very close taxonomic relationship with modern
communities from the Pacific realm, which allows for a comparison with
Recent environmental conditions. The sponge community was associated
```

```
with automicrites, microbialites, and thin mineralized limonitic biofilms. This biofacies is typically found in cryptic niches of reefal buildups (&#034;telescoping&#034;). The iron-rich biofilms had a strong electrochemical corrosive ability which explains the distinct submarine dissolution patterns. The hardground conditions are controlled, in part, by strong contour current regimes linked with extremely oligotrophic water masses. This system was established during the drowning of a distal carbonate ramp during the early Middle Cenomanian (A. rhotomagense zone). In the uppermost portion of the hardground (Late Cenomanian, upper R. cushmani zone) the coralline sponge community was replaced by thick limonitic stromatolites with numerous encrusting foraminifera (Miniacina-type) and by colonies of the problematic iron bacterium Frutexites. This event is accompanied by an increase of terrigenous influx and detrital glauconite, indicating a fundamental change in food web, and terminates the sponge dominated basal hardground interval. The hardground was buried by hemipelagic sediments during the Middle Turonian (upper R. kallesi zone).^1";

</b>Porifera; <b>Stratigraphy: </b>Oligocene Rup; <b>Geography:
</b>Germany NE^The hexactinellid sponge fauna, which is described here
for the first time, originates from the &#034;Septarienton&#034;
(Rupelium, Oligocene) of the &#034;Kirchenziegeleigrube&#034; near Bad
Freienwalde (NE Germany). This fauna includes lyssacinosan, as well as
hexactinosan species, represented by Asconema oligocaena n.sp.
(Hexasterophora, Lyssacinosa), the first occurrence of this genus from
the fossil record, Aphrocallistes sp. (Hexasterophora, Hexactinosa),
and Hyalonema sp. (Amphidiscophora). The three-dimensional, pyritic
body-preservation of these non-rigid sponges suggests fossililization
by rapid burial. Episodic mudflows are suggested to be responsible for
this. The environment of deposition is suggested to have been a
moderately shallow shelf, possibly in the distal range of a delta,
characterised by relatively low sedimentation rates and no turbulence,
except when disturbed by episodic mudflows. Low energy conditions are a
precondition for the settlement of the described Hexactinellida.

biofacies; <b>Systematics: </b>; <b>Stratigraphy: </b>Eocene Bart;
<b>Geography: </b>Spain, Ebro Basin^The thick marly deposits of the
Bartonian of the Vie area are very rich in various benthic fauna. The
analysis of this fauna, especially sponges, bryozoans and larger
foraminifera allows these deposits to be interpreted as having been
```

```
laid down in a deep, outer shelf setting. It is possible to distinguish
in these deposits two groups of biofacies, euphotic and aphotic
respectively. The biofacies of the deep euphotic shelf are
characterized by the alternation of marls and marly limestones, and
include abundant siliceous sponges, but also larger foraminifera,
brachiopods, bivalves and crustaceans among other fauna. The fauna of
the marls is less diverse and is represented almost exclusively by
bryozoans. The deposits of the aphotic shelf are composed of marls, and
different biofacies may be distinguished: small bryozoan bioherm
biofacies; bryozoan mud mound biofacies; siliceous sponge bed
biofacies, and siliceous sponge and ahermatypic coral bed biofacies.
The sponge fauna is dominated by hexactinosan and lychniscosan sponges,
but other hexactinellids are also present. The detailed characteristics
of other faunal elements common in particular biofacies and the
interpretation of each biofacies are also discussed.^1";
s[1225] = "CAHUZAC B., CHAIX C. (1996).- Structural and faunal
evolution of Chattian - Miocene reefs and corals in Western France and
Northeastern Atlantic Ocean.- Concepts in Sedimentology and
Paleontology 5: 105-127.- <b>FC&#038;P 34</b>, p. 72,
ID=1310^<b>Topic(s): </b>reefs, Anthozoa; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Oligocene Miocene; <b>Geography: </b>France
W^Chattian and Miocene coral reefs and faunas of the western France
basins are reviewed within a paleogeographic context. Several new
outcrops have been discovered, and extensive new and historic
collections have been studied. Coral diversity was very high in the
Aquitaine basin during the Chattian(1) (ca. 150 species) and a little
less so during the Early Miocene (110 species); during these times,
relatively small reefal buildups formed in a tropical climate. The
Mid-Miocene coral faunas show a marked decrease in diversity (some 75
species in all), with &#034;subreefal&#034; facies in the Langhian of
southwestern and northwestern France. The Upper Miocene fauna is even
poorer (just about 20 species) and only known in northwestern France.
Throughout the Miocene, the proportion of hermatypic taxa also
decreased notably; in the coral assemblages, these species were
strongly predominant from Chattian to Burdigalian. Afterwards, the
ahermatypic taxa became progressively predominant. Other northeastern
Atlantic areas (Portugal, Morocco) are also investigated. Some
biogeographic data sketch the evolutionary trend of these coral
communities. During the Chattian, an (eastern and western)
Atlantic-Mediterranean bioprovince was differentiated. During the Early
Miocene, this bioprovince was restricted to eastern Atlantic and
Mediterranean. From the Mid-Miocene, the coral faunas were disconnected
from the Mediterranean, and an impoverished eastern Atlantic
bioprovince became established without real renewal. A comparison with
Mediterranean reefs shows that maximum coral building took place within
the Mid-Miocene in the Mediterranean realm (with continuation of reefs
in the Late Miocene), instead of Chattian (and Early Burdigalian) as in
the Atlantic areas. [original abstract]^1";

Anthozoa; <b>Stratigraphy: </b>Miocene Tort - Mess; <b>Geography:
</b>Spain SE^Coral reefs represent on of the main carbonate factories
that contributed to the control of stratigraphic architecture of
carbonate platforms, which had a widespread development during the late
Miocene in the paleo-Mediterranean area. The late Miocene reef
complexes of the Lorca basin in southeastern Spain are composed of five
mixed siliciclastic/carbonate units, middle Tortonian to early
Messinian in age. The development of coral reefs probably ceased when
the first evaporite event occurred in the basin centre in the early
Messinian.^1";
s[1228] = "GORKA M. (2002).- The Lower Badenian (Middle Miocene) coral
patch reef at Grobie (southern slopes of the Holy Cross Mountains,
Central Poland), its origin, development and demise.- Acta Geologica
Polonica 52, 4: 521-534.- <b>FC&#038;P 32-1</b>, p. 30,
ID=1736^<b>Topic(s): </b>reefs, coral patch reef; reefs;
<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Miocene;
<b>Geography: </b>Poland, Holy Cross^The Lower Badenian (Middle
Miocene) patch reef of Grobie (southern slopes of the Holy Cross
Mountains, Central Poland) is the only coral buildup in the Polish
Miocene. It contains four hermatypic coral taxa, of which
Tarbellastraea reussiana (Milne Edwards &#038; Haime) and Porites
collegniana Michelin dominate, whereas Montastraea sp. and Stylophora
reussianaMontanaro-Gallitelli &#038; Tacoli are subordinate. Wide
diversities of colony shapes in this coral nassemblage reflect natural
development of the reefal structure and/or energy of environment; it
varies from platy colonies (first settlers on an unconsolidated,
pebble.strewn substrate), through branching, to massive forms. Wave
activity was the most significant factor that influenced the reef core
and distribution of associated facies. Disintegration and removal of
reef core sediment led to the formation of crack crevices in freshly
lithified deposits. Redeposited sediment formed the back-reef talus,
where its composition varied with distance from the reef core.
Reef-associated molluscs and decapods are abundant, the bivalves being
represented by high-energy resistant borers (Lithophaga sp., Jouannetia
(J.) semicaudata Des Moulins) and the squatter Sphenia (S.) anatina
(Basterot). Among 21 decapod taxa, the species Dardanua hungaricus
(Lörenthey, 1929) is reported from Poland for the first time.
Recognition of the diversity of facies and their distribution enabled
reconstruction of Grobie area during the Early Badenian transgression.
Slowing and/or stopping of sealevel rise encouraged development of the
patch reef, while the subsequent, rapid transgression pulse caused its
demise. Shortly after all reefal deposits were buried, diagenetic
processes of neomorphisation and/or dissolution of aragonitic skeletal
elements took place. This diagenesis could have continued till the Late
Miocene and Pliocene, synchronously with rapid erosion that progressed
since the Early Sarmatian until the Pleistocene glaciation.^1";

climatique.- Annales de Paleontologie 91, 1: 33-72.- <b>FC&#038;P
34</b>, p. 54, ID=1274^<b>Topic(s): </b>biogeography; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Miocene; <b>Geography: </b>France W^The Aquitaine and Loire basins
show in the Middle Miocene numerous marine littoral deposits, often
shelly or crag-type. Scleractinia are present, with a distribution and
```

```
an abundance very variable according to the outcrops. A detailed study
of all the available material, recently or historically cropped,
allowed to draw up an accurate faunal inventory and to compare the
distribution of taxa between the two basins. Out of 90 taxa in total,
62 are known in Aquitaine and 48 in Loire. In the Aquitaine Langhian,
when is noted an obvious reduction of hermatypic taxa in comparison
with the rich regional Burdigalian faunas, the association includes 44
species (25 reef-building ones). In the Serravallian, the reef-building
taxa become significantly scarce and are residual (9 taxa out of 33 in
Aquitaine, present in levels belonging to the lower sequence of the
stage, and located in sheltered internal parts of the south-Aquitaine
and central-Aquitaine gulfs). In the Loire basin, the corals are quite
diversified in the Pontilevian facies (19 reef-building taxa out of
48), and much scarcer in the Lublean and Savignean facies. Globally,
the Scleractinia are few abundant everywhere. If in the two basins
hermatypic taxa persisted in the Langhian, indicating subreefal type
facies, varied factors have impeded permanently the settlement of
reefs. In comparison with the Burdigalian, the thermic deterioration
gradient, evidenced since the Chattian on the northeastern Atlantic
frontage, had an important influence, and the Langhian waters were only
subtropical. Other factors acted, at least locally, as the
hydrodynamics, the bathymetry, the kind of substratum, the salinity
proparte. Moreover, a latitudinal gradient between the two basins is
evidenced by the global species richness and by the ratio of
hermatypicity, created here and defined as the fraction of hermatypic
taxa reported to ahermatypic ones from a same basin. This ratio can be
used at generic level or specific one as well. In the Serravallian,
when the diversity was everywhere obviously lower, the influence of the
climatic gradient went on, together with other unfavourable conditions
(often abundant detritic supplies, high hydrodynamics, spatial
biocompetition). Diverse biogeographic and paleogeographic data are
also reported. A vast East-Atlantic coralline bioprovince, settled as
early as the Chattian with a dispersion center located in Aquitaine,
was still active in the Middle Miocene, when large transgressions
favoured the faunal exchanges; its history was to be completed at the
end of this period.^1";

p. 72, ID=2380^<b>Topic(s): </b>ecology; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Miocene; <b>Geography:
</b>France, Aquitaine^An abundant fauna of Scleractinian corals has
been studied from a Mid Miocene (Serravallian) new outcrop in the North
Aquitaine Basin (SW France). It consists of more than fifteen taxa,
with a noticeable diversification in the genera Flabellum and
Balanophyllia; 10 of these taxa are new in the Miocene of the Aquitaine
Basin. This is probably the richest assemblage of the French
Serravallian. The name Flabellum montanaroae nov. nom. is set.
Biogeographically, the studied locality bears witness to Northern,
Atlantic and Mediterranean influences. The ahermatypic content of the
fauna agrees with the observed general trends to a gradual
disappearance of reefal species and to a cooling in neritic waters
during the Mid Miocene along the Northeastern Atlantic frontage. In
terms of paleoecology, the corals-rich deposit contains an abundant
malacofauna, which indicates an infralittoral, euhaline, and fairly
calm environment, with a marly-sandy substrate; this biofacies looks
like the muddy facies of the modern assemblage SFBC (&#034;Sables Fins
Bien Calibrés&#034;).^1";

213-221.- <b>FC&#038;P 14-2</b>, p. 39, ID=0924^<b>Topic(s):
</b>regeneration; Scleractinia; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Miocene; <b>Geography: </b>Poland,
Holy Cross^A common case of regeneration from very small fragments
(composed even of those containing at least one entoseptum) is reported
in some scleractinian corals coming from a specific,
solitary-coral-dominated community of the near-to-shore facies of the
Korytnica Clays (Middle Miocene, Badenian; Holy Cross Mountains,
Central Poland). It concerns the specifically indeterminable
caryophyllids, some individuals of which underwent regeneration twice.
The regeneration itself (growth from tiny fragments of the primary
individual) is discussed in its relation to the reparation (a repair of
an injury within the animal&#039;s skeleton). The whole population of
the regenerated caryophyllids, which dominated a near-to-shore
community within the Korytnica Basin, characterizes by the size
distinctly smaller than that of normal individuals. This event is
compared to that recognized in some populations of the present-day and
ancient free-living bryozoans, those inhabiting the Korytnica Basin
including. In both these groups (caryophyllid corals, and free-living
bryozoans) the regeneration is discussed as an important mean of some
selected reproduction of these species, and as an immanent biological
feature of some selected taxa. (Original summary)^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Miocene Mess; <b>Geography:
</b>Spain, Betic Cordillera^The Carboneras area is located at the NE of
the Miocene volcanic massif of Cabo de Gata. The &#034;red
brecchia&#034; is an olistostrome that resulted from mass sliding, in
bathyal environment, of a large volcanic structure, in which fissures
opened by traction. The fissures preserved an upper bathyal hard ground
fauna, and foraminiferans indicating a Messinian age. The fauna is
remarkable by its diversity, comprising notably calcified sponges,
stylasterids, scleractinians, gorgonians (Isididae, Primnoidae,
Corallium), various gastropods (some of them living associated with
corals), stalked crinoids. Various genera that seem to be faunal
elements from Tethys, no longer exist in the Mediterranean and the NE
Atlantic. With at least 14 species in at least 8 genera, the
stylasterids from Carboneras are the most diversified fossil assemblage
presently known of this group, and comparable to Recent upper bathyal
faunas of the Indo-Pacific (e.g. of New Caledonia). Three types of
stylasterid symbionts, or their traces, have been recognized: the
gastropod Pedicularia, a polynoid polychaete and a siphonostomatoid
copepod, the two latter causing characteristic galls. Polynoid galls
have also been found on Corallium, and an ascothoracid gall (of the
Isidascus type) on an isidid gorgonian (the latter from the marls of La
Atalaya de Mazarron, a deposit of similar age).^1";

```
<b>Stratigraphy: </b>Miocene Mess; <b>Geography: </b>Spain SE^Excellent
exposures in Cabo de Gata area reveal two major Messinian depositional
sequences, the Reef Complex and the Terminal Complex, which are
overlying a complicated erosional morphology with several terraces on
the volcanic basement. A typical Porites reef developed on the 200m
platform and originated extense fore slope deposits adosed to the
terraced volcanic basement. This Reef Complex is severely truncated by
an important erosion surface, which also presents a terraced morphology
(80, 160, 220m) and follows similar trends than the erosion surface on
the volcanic basement. This intra-Messinian erosion surface is onlaped
by the Terminal Complex, consisting in alternating layers of oolites,
stromatolites and Porites thickets. Hypothetically, layers of
evaporites could had been associated to the stromatolites in the lower
section of the Terminal Complex before the pre-Pliocene erosional
episode. [original summary]^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Quaternary erratics; <b>Geography: </b>Germany N^Upper-Jurassic
geschiebe-corals (Thamnasteria concinna) from a gravel-/sandpit at
Freden/Leine are described. They are slightly bored by bivalves
(Gastrochaenolites) and worms (Trypanites). Some oysters (Nanogyra )
encrusted the surface. The corals grew as massiv head-like (bulbous)
colonies in a &#034;multicolumnar growth form&#034; with a ragged
outline. Similar shaped colonies are reported from East-European Upper
Jurassic (Pomerania), but are never reported from NW-Germany. Beds in
which the coral-geschiebe were found - Drenthe stage in age - contain a
high content of local geschiebe material. The low degree of abrasion of
the coral-geschiebe indicates short glacial transportation. It is
possible, that the drift material originates from the Heersumer
Schichten from Selter to Thiister Berg. [modified abstract]^1";

ID=2889^<b>Topic(s): </b>lithostratigraphy; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>Ardennes^The authors present
proposals to standardize the subdivision into formations of the Middle
Devonian strata of the Dinant Synclinorium, the Namur Synclinorium and
the Vesdre Massif. They recognize ten formal formations, and one
informal, in the Couvinian (uppermost Emsian and Eifelian) and the
```

```
Givetian strata of the southern flank of the Dinant Synclinorium. These
formations are from older to younger : the St.-Joseph Fm, the Eau Noire
Fm, the Couvin Fm, the Jemelle Fm, the Lomme Fm, the &#034;X&#034;
Formation at Wellin, the Hanonet Fm, the Trois-Fontaines Fm, the Terres
d&#039;Haurs Fm, the Mont d&#039;Haurs Fm and the Fromelennes Fm. The
Middle Devonian succession of the northern flank of the Dinant
Synclinorium and of the southern flank of the Namur Synclinorium
comprises the Riviere Fm, the Nevremont Fm and the Le Roux Fm. On the
northern flank of the Namur Synclinorium, the Middle Devonian is
represented by the Bois de Bordeaux Fm. In the Middle Devonian
succession of the Vesdre Massif, the authors recognize the Vicht Fm,
the Pepinster Fm, the Nevremont Fm and the Le Roux Fm. The authors
describe and figure a stratotype and, in some cases, an other reference
section for each formation. Lateral changes and age of the formations
are also discussed.^1";

3, ID=2983^<b>Topic(s): </b>geology; <b>Systematics: </b>;
<b>Stratigraphy: </b>; <b>Geography: </b>France, Avesnois^The Glageon
quarry in northern France is situated west of the classical Givetian
outcrops on the southern margin of the Dinant Synclinorium. Because of
its location and the excellent outcrop, a detailed sedimentological and
paleontological study has been carried out. Sixteen carbonate
microfacies, ranging from open marine to supratidal environments have
been described. The Terres d&#039;Haurs, Mont d&#039;Haurs and
Fomelennes Formations are relatively similar to their equivalents from
the Givet type area. However, the Trois-Fontaines Formation is partly
different, due to the absence of a lagoonal complex above the first
biostrome. Sequential analysis shows that sedimentation is controlled
by three orders of paleobathymetric cycles. The diagenctic sequence has
been established. The burial diagenesis is very important, after a
brief distal meteoric cementation phase.^1";

non-tropical; <b>Systematics: </b>; <b>Stratigraphy: </b>;
<b>Geography: </b>Spain SE^The lower Tortonian and upper Tortonian
&#47; lower Messinian carbonates of the Agua Amarga Basin in Southern
Spain (Prov. Almeria) provide examples for neritic non-tropical,
&#034;Mediterranean-type&#034; carbonates, which occur alternating with
subtropical to tropical chlorozoan reefs. The carbonate factory of the
non-tropical depositional systems was situated in a shallow water area
around wave base. Main carbonate producing organisms were nodular and
robust bryozoans, bivalves, and red algae. We demonstrate that sequence
stratigraphy of these non-tropical carbonates markedly differs from the
established sequence stratigraphy models of tropical carbonates. The
non-tropical carbonate depositional sequences display many features of
siliciclastic depositional sequences. In addition, we show that the
intrinsic link of surface water temperature fluctuations and sealevel
changes has a high potential to shape carbonate depositional
sequences.^1";

<b>FC&#038;P 33-2</b>, p. 11, ID=1101^<b>Topic(s): </b>sequence
stratigraphy; stratigraphy, correlation; <b>Systematics: </b>;
<b>Stratigraphy: </b>Carboniferous L; <b>Geography: </b>Ardennes,
British Isles^The Lower Carboniferous of Southern Belgium (Dinantian
Subsystem) is well documented andserves as reference for the
Tournaisian and Visean Series. Hundreds of sections and boreholes
weremeasured bed by bed and collected for faunas. Biostratigraphy
relies mainly on information onforaminifers, conodonts and corals, but
most of other fossils groups typical of platform carbonatesare abundant
and diversified.Despite this great amount of data, many correlations
remained questionable, mainly due to rapidfacies changes and scarcity
of fossils in some levels. During the Tournaisian and the Lower
Visean,these changes are related to the facies evolution from nearshore
to outer shelf with building of adistant Waulsortian barrier during
Upper Tournaisian. Moreover, extensional synsedimentary faultsacting
during Lower Visean, have played a major role, controlling subsidence
and faciesdistribution. During Middle to Upper Visean (up to the base
of the Upper Warnantian), aspectacular cyclothemic sedimentation
developed over a large area, reflecting a quite regularpaleotopography,
that later reduced in surface under the influence of the early phase of
Variscandeformation. The uppermost part of the Visean was not
deposited. Re-evaluation of the formerDinantian biostratigraphical
pattern in a sequence stratigraphical approach gives new
insight.particularly for the Tournaisian-Visean transition. From the
base of the Tournaisian to the base ofthe Upper Warnantian
(=Brigantian), 9 third-order sequences have been recognized in
southernBelgium. Most of the lowstand systems tracks (LST) are lacking,
probably because the high rate ofeustatic variation exposed of the
studied areas.12One of the most striking events is the important sea
level fall followed by a relatively low rise, atthe time of the T-V
transition, with deposition of the transgressive systems tract (TST)
and thehighstand systems tract (HST) of a third-order sequence
(sequence 5, corresponding to most of theSovet Formation) only in the
deeper part of the outer shelf. The recognition of this sequence and
ofits corresponding stratigraphic gap on the shallow shelf allows a
better understanding of the T-Vboundary and, therefore, merited
reinvestigation (Devuyst, XIV ICCP).The duration of the Dinantian
third-order sequences are variable, including different amounts
ofparasequences (fourth and five order) and resulting in the variable
```

```
thickness of the sequences. Several sequences defined here have been
recognized in the Bristol area of England and are more tentatively
correlated with the cycles of Ramsbottom (1979) established for the
Lower Carboniferous of Great Britain. These however do not correspond
exactly with the third-ordersequences.^1";

</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fam &#47;
Carboniferous Tour; <b>Geography: </b>Ardennes, China S, Siberia NE^The
Rugosa remained almost totally absent from the platform environments of
southern Belgium and surrounding areas, Hunan and Omolon during the
long time interval between the end-Frasnian crisis and the early part
of the late Famennian (marginifera Zone), probably owing to cool
climatic conditions. They first appear in the Upper marginifera Zone,
but are uncommon and poorly diversified. Few of them belong to
pre-Famennian genera. It is only near the beginning of Strunian time
that rugose corals radiated and became common. Their morphological and
allometric variabilities were very large, indicating their high
potential for adaptation to free niches. This first radiation was
```

```
abruptly terminated by an extinction event, and a second radiation
quickly began, mainly from new taxa and only from a few previously
known ones. In western Europe and in Hunan, this second radiation was
also stopped abruptly, while species were evolving, by the Hangeberg
event at the end of the Strunian. In Omolon, where the position of the
Devonian-Carboniferous boundary is doubtfull, the second radiation may
have been completed before the end of the Strunian, and probably the
corals affected by the end-Famennian event were new ones, resulting
from a third radiation. In the three regions and at each recovery, the
rugose corals are endemic, indicating that marine connections were
poor. After Hangenberg event, surviving Rugosa reappeared almost
immediately (except in South China) and were widespread, indicating
good marine connections. However, they remained poorly diversified,
sometimes until the late Tournaisian. The two major extinctions
(end-Frasnian and end-Famennian) and the Strunian ones were responsible
for the major taxonomic differences between pre-Famennian and
post-Famennian Rugosa. ^1";

Tabulata, Dendropora; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Devonian Giv; <b>Geography: </b>France,
Boulonnais, Afghanistan^Dendropora explicita Michelin 1846 has only
been known until now, in the Boulonnais, by the two small specimens
from the Michelin&#039;s collection discovered and described by Lafuste
(1981). Eighty-two new specimens have been picked out recently in the
type stratum of the type area (Frasnian of Ferques area, bottom of the
Patures Member, Beaulieu Formation). A new species Dendropora briceae
nov. sp., very similar to D. explicita is particularly abundant (180
specimens) in the Givetian of the Boulonnais and is also present in the
Givetian of the Avesnois (19 specimens). D. briceae differs
fundamentally from the former type species D. explicita by closer
calices. The study of those samples brings new information about the
morphological features of the genus Dendropora (reticulate rhomboic
network); some structural characteristics (few distal tabulae, pores)
are specified; the particular microstructure of the genus is confirmed.
The stratigraphic distribution of the two species is specified.
Moreover, the genus Dendropora is also recognized in the Givetian and
the Frasnian of Afghanistan.^1";

Oligophylloides and Mariaephyllia are widely distributed in Lower to
Upper Famennian strata of the cephalopod facies (Cheiloceras,
Platyclymenia, Clymenia, and Wocklumeria genozones), abundant records
now extend to the German Rhenish, Thuringian and Upper Franconian
Mountains and to the Moroccan Anti-Atlas (Tafilalt), with additional
discoveries in France (Montagne Noire) and Poland (Sudetes Mountains
&#47; Lower Silesia). New morphological features are described,
including: large colonies with corallites fused by heterothecal layers;
lateral talon structures for temporary attachment to possible sea-weed;
the probable anomalous occurrence of an aseptal early ontogenetic phase
with preseptal heterotheca.^1";
s[1293] = "WEYER D. (1995).- Heterocorallia aus
Famenne-Cephalopodenkalken im Rheinischen Schiefergebirge und
Tafilalt.- Abhandlungen und Berichte für Naturkunde 18: 103-135.-
<b>FC&#038;P 24-2</b>, p. 88, ID=4584^<b>Topic(s): </b>cephalopod
facies, new taxa; Heterocorallia; <b>Systematics: </b>Cnidaria;
Heterocorallia; <b>Stratigraphy: </b>Devonian Fam; <b>Geography:
</b>Germany, Morocco^New records of heterocorals from the Wocklumeria
stage are given for the German localities Oberrodinghausen (railroad
cut), Hasselbach valley near Hohenlimburg, Ense, Dasberg, Effenberg,
Muessenberg, and Wocklum. Eight specimens of the three first mentioned
sections are described: Oligophylloides pachythecus Rozkowska 1969,
Oligophylloides tenuicinctus Rozkowska 1969, Oligophylloides parvulus
n.sp., Mariaephyllia famenniana (Rozkowska 1969), Mariaephyllia aff.
famenniana (Rozkowska 1969). The Moroccan locality Bordj Est near
Erfoud yielded Oligophylloides sp. and Mariaephyllia n.sp. II from the
Wocklumeria stage, and Mariaephyllia n.sp. I from the Cheiloceras
stage. Heterocorals mostly come from dysphotic cephalopod limestones
(together with large-eyed trilobites), rarely from aphotic environments
(accompanied by blind trilobites). The enlarged knowledge of
distribution (within the cephalopod facies) indicates a cosmopolitic
habitat during the Famennian, surely favoured by the postulated
pseudoplanctonic mode of juvenile life. Concerning the Mid-European
Variscan Mountains, both Oligophylloides and Mariaephyllia now are
known in the Rhenohercynian zone (Holy Cross Mountains, Rhenish
Mountains), and in the Saxothuringian zone (recent collections from
Dzikowiec, Polish Sudetes, and from Schuebelhammer, Upper Franconia). *
Intensive serial sectioning provides new morphological data, above all
about ontogenetics of heterocorals (with insertions and reductions of
septa). The complete 12-septal apparatus of Oligophylloides occurs
already at a minimum diameter of 0.4 mm. A completely aseptal initial
stage is surprising: it consists of a larval fixing talon and a hollow
tube of purely tabular heterotheca. The original collection of the
famous Heterocorallian study of Schindewolf (1941) was used for a
revision of his fundamental error (upside down, with presumed concave
tabulae) in corallite orientation.^1";

<b>Geography: </b>Alps, Carnic^Aunque en el Devonico Medio los
arrecifes tenian una amplia distribucion (casi mundial), durante el
Praguiense (Devonico Inferior), los arrecifes fueron escasos. En la
formacion &#034;Calizas de Hohe Warte&#034; en el Macizo de Seewarte y
Hohe Warte en los Alpes Cârnicos (Hubmann et al., 2003). en la frontera
entre Austria e Italia esta represenatado uno de estos pocos arrecifes
praguienses. * Se estudia la formacion &#034;Calizas de Hohe
Warte&#034; en los afloramientos situados en la base del acantilado de
la Seewarte. Esta formacion representa al Praguiense y una parte del
Emsiense inferior (Hubmann et al., 2003). La secuencia empieza con
calizas de crinoideos; sobre ellas se desarrollan estructuras
arrecifales; especialmente en la parte superior se observan arrecifes
parches bien desarrollados. Los bioconstructores son estromatopôridos,
corales tabulados, corales rugosos y Fistullella undosa Shuysky, que se
interpréta como un hidrozoo problemâtico. La facies de las
&#034;Calizas de Hohe Warte&#034; ha sido descrita por Pohler et al.
(2007). A continuacion, se proporciona una lista con los fosiles
identificados en las laminas delgadas: * corales tabulados: Heliolites

```

```
Limestone Succession of the Cima Ombladet (Carnic Alps, Italy).- Facies
12: 97-112.- <b>FC&#038;P 14-1</b>, p. 66, ID=1080^<b>Topic(s):
</b>carbonates; carbonates; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Italy, Carnic Alps^This study deals
with a paleoenvironnental analysis of the shallow-water limestones in
the Cima Ombladet succession (Carnic Alps, Italy), which range in age
from Givetian to Frasnian. The major depositional environments are reef
flat, open lagoon, semiresttricted lagoon and sand cays. Their vertical
and lateral variations suggest a regressive sequence. Rocks deposited
within these sub-environments can be subdivided into twelve sub-units
on the basis of lithological and faunal content. Rocks of the reef flat
consist of an alternation of sparitic facies (detrital crinoidal
facies, detrital crinoid-stromatoporoid facies, and detrital Thamnopora
facies) and micritic facies (crinoidal facies, micritic Thamnopora
facies). The open lagoon is characterized by
Stringocephalus-Trypanopora facies, a thin-shelled brachiopod facies
and a detrital brachiopod facies. The semirestricted lagoon environment
includes the dark Amphipora facies and the dark ostracod-calcisphere
micrite facies, which underwent reworking by means of lagoonal storms
(detrital Amphipora facies). The sand cay consists of an intraclastic
facies. The facies interrelationships can be explained by a general
change in water energy responsible for the progradation of
bioclast-intraclast sand bodies and the shift into the lagoons. This
process has a modern analogue in most of the reefs inside the Great
Barrier Reef, Australia. (Original Summary)^1";
s[1343] = "KREUTZER L.H. (1990).- Mikrofazies, Stratigraphie und
Palaeogeographie des Zentralkarnischen Hauptkammes zwischen Seewarte
und Cellon.- Jb. Geol. B.-A. 133: 275-343. [in German, with English
summary].- <b>FC&#038;P 20-1.1</b>, p. 68, ID=2850^<b>Topic(s):
</b>carbonates; carbonates; <b>Systematics: </b>; <b>Stratigraphy:
</b>Devonian; <b>Geography: </b>Austria, Alps S^By a combination of
microfacies analysis, stratigraphical and tectonical methods, the
Devonian of the central Carnic Alps between Seewarte and Cellon was
investigated in comparison with neighbouring areas. 14 profiles were
taken, which were only accessible by alpinistic methods. 10
microfacies-types with 7 subtypes could be distinguished. Conodont
samples and reef-fossils provided data for stratigraphical
classification. Previous workers suggest that the Devonian rocks in the
western Seewarte area developed in subtidal facies and in the eastern
Cellon area, in forereef to pelagic facies. The central Kellerwand and
Hohe Warte was believed to represent an east-west orientated transition
between the different facies types. The influence of the two
subordinate nappes (Cellon subordinate-nappe and Kellerwand
subordinate-nappe) was considered unimportant. As a result all further
workers suggested a facies differentiation from the west to the east.
New investigations discussed in this paper indicate that both the
subordinate nappes are facies nappes: The Kellerwand nappe is developed
in intertidal, back-reef or reef facies with more than 150 meters of
Givetian reefs, the Cellon nappe in transition or pelagic facies.
Overthrusting came from the south-southwest. After moving back the
complicated tectonics (Abb. 33) there is a obvious north-south
differentiation of facies. In comparison the facies change from the
west to the east in the area is unimportant. Based upon facies
differentiation, stratigraphy, tectonics and with analogies to
neighbouring areas, a paleogeographical reconstruction for the central
Carnic Alps was developed (Abb. 33-35). In spite of the difficulties
encountered while sampling vertical walls and the destruction of
fossils and sediment structure by diagenesis, an important gap was
filled in the geology of the Carnic Alps.^1";

Paloekologie der Barrandeikalk-Formation (Eifelium) des Grazer
Palaeozoikums.- Jb. Geol. B.-A. 136, 2: 393-461.- <b>FC&#038;P
23-1.1</b>, p. 60, ID=4128^<b>Topic(s): </b>carbonates microfacies;
<b>Systematics: </b>; <b>Stratigraphy: </b>Devonian Eif; <b>Geography:
</b>Austria, Styria^The &#034;Barrandei Limestone&#034; Formation of
the Palaeozoic of the Graz area (Austria) represents a highly
fossiliferous sequence whose stratigraphic boundaries are not clearly
identificable at this stage. Locally the sequence may range from Upper
Emsian to lower Givetian. In this paper the depositional conditions of
the formation are discussed. Four types of microfacies and thirteen
types of submicrofacies have been recognized. The comparison of
Wilson&#039;s types of microfacies with the Barrandei Limestone
sequence suggests that this limestone was deposited in restricted,
semirestricted and open platform environments and on the platform
margin and foreslope. Microfacies and palaeoecological data indicate a
depositional environment of very shallow water, with some biohermal and
biostromal (reefal) development as well as areas of deeper water, i.e.
quiet depositional conditions. Distribution patterns and growth habits,
i.e. skeletal morphology and shape of colonies, especially of
stromatoporoids and tabulate corals (favositids) and special
composition of the faunal content (e.g. Thamnopora-Amphipora
associations) indicate typical back reef biocoenoses. Also trace
element concentrations support the sedimentological and
palaeoecological evidence of the depositional environment. Deposition
of higher energy mud facies is predominant. Also characteristic are
sequences with a &#034;muddying-upward trend&#034; which indicates
sedimentation under stormy conditions (&#034;tempestites&#034;). The
introduction into the system of large amounts of fine grained clastic
material is a cyclic event that accounts for the alternating deposition
of limestones, marls and shales and for the highly variable amounts of
acid-insoluble residue in the limestone sequence itself. It is
suggested that the cyclicity is a function of eustatic fluctuations
(transgressions and regressions) as observed from the &#034;Rheinische
Schiefergebirge&#034;. Some taxa indicate palaeobiogeographical
connections with the Rhenohercynian basin and the Aquitaine-Cantabrian
terrane.^1";

<b>Geography: </b>Austria, Italy, Alps S^The Carnic Alps of Southern
Austria and Northern Italy represent one of the very few localities on
the Earth in which an uninterrupted fossiliferous sequence is exposed
and well documented from Ordovician to Middle Triassic times. This
paper describes and illustrates the Lower Paleozoic part of the
mountain chain and in particular the Central Carnic Alps, where
fieldwork only was possible by alpinistic methods (Kreutzer 1986,
1990). During the Devonian in the Carnic Alps an ecological reef
complex occurs with all facies belts ranging from intertidal to pelagic
environments following upon an Ordovician &#47; Silurian carbonate
platform with pioneer fauna. The Lower Paleozoic rocks are
chronologically documented and illustrated on 46 plates. The
paleogeographical implications of the tectonically complicated Carnic
Alps are presented in an updated version. Important sections are shown
with stratigraphical specifications.^1";

<b>FC&#038;P 3-1</b>, p. 27, ID=4885^<b>Topic(s): </b>revision;
Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Carboniferous Vise; <b>Geography: </b>Hungary ^Die Fauna, die in
den beiden Strukturbohrungen von 1969-1970 angetroffen worden ist, hat
die Revision der frueheren Ergebnisse berechtig. Im Kalksteim des
bituminoesen Kalkstein Komplexes - dessen Maechtigkeit auf Grund der
Bohrungen zwischen 40 und 70m variiert - wurden 10 Anthozoa-Arten
gefunden, von denen 3 Arten den Tabulaten, 6 Arten der Pterocorallien,
1 Art den Heterocorallien angehoeren. Besonders wichtige Angerbe fuer
die Stratigraphie ist die grosse Anzahl der Heterocorallia Art
Hexaphyllia mirabilis (Duncan) denn dies beschraenkt das Alter des
Sedimentes eindentig auf die Visee-Stufe des Unter Karbons, genauer
gesagt auf die Dibunophyllum - 2 biozone des oberen Viseen. Auf Grund
```

```
der stratigraphischen Reichweite der anderen Arten ist jedoch wohl
moeglich, dass der ganze Komplex dem Viseen + der Basis des unteren
Namur angehoert. Fuer die Richtigkeit der Altersbestimmung spricht auch
des Vorhandensein der Art Gigantoproductus transdanubiana
(Foeldvari).^1";

Turnacipora; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Carboniferous Tour; <b>Geography: </b>Transcaucasus^Study of
increase in a specimen of Turnacipora using serial acetate peels shows
several types of increase within one corallum. All belong to the broad
category of intravisceral increase but none begins with a simple basal
mural pore (i.e. lateral increase). Of 4 cases of increase described 3
are variations on a basic type: 1, a basal mural pore partitioned by a
structure derived from the wall, 2, a partitioned basal mural pore of
mixed origin (partly angle mural pore), and 3, a basal mural pore
derived from an angle mural pore (- intravisceral - poral increase). In
the fourth case, the new wall stems partly from an altered tabella,
partly from a pair of mural processes (- intravisceral - epitabular
budding). This case may be teratological. Increase with a partitional
basal mural pore and/or screen-like basal mural pore may have evolved
in the Micheliniinae during the Tournaisian.^1";

Alps^The development of small-scaled auloporid coral mounds within the
transgressive Late Carboniferous (early Kasimovian) highstand system
tract of the Carnic Alps south of the Italian &#47; Austrian border was
chiefly controlled by global and regional conditions (rising sea-level
and reduced terrigenous influx), rather than by autogenic biological
factors. The tabulate coral Multithecopora did not framebuild but
baffled homogenous micritic mud. This effect was enhanced by episodic
slight increases of turbulence levels. Otherwise the mound sediment is
the same as in background situations (calcareous siltite). This model
differs from current reef mound models but may be applied to many
fossil occurrences.^1";

<b>Systematics: </b>algae; <b>Stratigraphy: </b>Permian L;
<b>Geography: </b>Alps, Carnic^The coral patch-reef of Laisacker
(Neuburg a.d. Donau, Southern Franconian Alb) exhibits three facies
zones: the reef core consists of reef debris, there is almost no reef
framework. The core facies, interfingering with the reef debris facies
is built up by fine-grained reef detritus with intercalated
coarse-grained layers of partly high porosity (up to 24%). They mainly
consist of coral fragments (up to 83%) and reach 0.80 m in thickness.
These coarse-grained layers have been formed by storms. The interreef
facies corresponds to massive limestones. Destruction of the reef
framework was favoured by bioerosion. The high still open porosity of
the coarse-grained reef rubble was caused by high freshwater flow rates
delimiting cementation and favouring dissolution.^1";

<b>Geography: </b>Italy, Dolomites^The new &#034;coralline&#034; sponge
Chaetosclera klipsteini n.gen. n.sp. from the Early Carnian Cassian
Beds (Dolomites, Italy) is described. The chaetetid basal skeleton is
composed of aragonitic spherolites. The spicular skeleton consists of
long styles which are arranged in groups of 3 to 4 inside of the
skeleton walls or along the internal sides of the tubes. The scleres
and the sclere arrangement indicates a halichondriid demosponge. It is
the first record of a halichondriid demosponge with a basal skeleton
from the Triassic.^1";

</b>Porifera; Demospongiae; <b>Stratigraphy: </b>Triassic U;
<b>Geography: </b>Italy, Dolomites^The calcareous skeletons of 17
species of Triassic demosponges from the northeastern Dolomites have
been analyzed for microstructure and diagenesis. The four
microstructures recognized (irregular, spherulitic, penicillate
aragonitic, and homogeneous granular Mg calcite) are described in terms
of mineralogy; shape, dimension, and arrangement of microstructural
elements; mode of growth; and possible biomineralization. The
diagenesis in these sponge carbonate skeletons is of an aggrading type
that occurred in diagenetic units, semi-closed systems, delineated by
organic phragmas, which controlled the flux of diagenetic fluids. We
tentatively interpret these phragmas as the remains of water-insoluble
macromolecules for space delineation during the biomineralization
process. In the aragonitic skeletons the preservation grade is
correlated with Sr content, and the replacement of aragonite by calcite
is marked by a Sr value around 4,000 p.p.m. Calcitized aragonite still
retains a detectable amount of Sr. In Mg calcite skeletons the
continuous and regular increase of grain size is inversely correlated
with Mg content and directly with the distance from the organic
phragmas.^1";

<b>Stratigraphy: </b>Triassic Anis; <b>Geography: </b>Austria, Alps
S^In the southalpine Triassic of the central Karawanken Mountains
(Carinthia, Austria) Late Anisian reef limestones at places are sharply
overlain by a thin sequence of red pelagic limestones. These pelagic
limestones are dated as Early Fassanian (Xenoprotrachyceras reitzi
zone; Spongosilicarmiger italicus zone; Paragondolella trammeri
praetrammeri zone) based on conodonts and radiolarians. The siliceous
sponges from the red nodular limestone (Weisse Wand Member) of Early
Fassanian age represent an autochthonous soft-ground fauna of an
```

```
aphotic pelagic enviroment. Demospongiae are represented by 42 types of
spicules, three of them being new. They constitute only about 30% of
the total fauna, the rest is comprised by the Hexactinellida.
Calcisponges are lacking. The Hexactinellida are represented by 55
types of spicules, 11 of them are new. Three of them, monospecific
genera, belonging to the Amphidiscphora, Hexactinosa and
&#039;Lyssakinosa&#039; are described. Of importance is the first
appearance of the genus Farrea (Clavulari), which till now could only
be traced back to the Late Cretaceous and now must be taken back to the
Fassanian. The same is true for the genus &#039;Eurete&#039;, whose
oldest species have been reported from the Late Cretaceous till now.
Finally the stratigraphic significance of the siliceous sponges is
disussed to point out that distinct differences exist between siliceous
sponges of the Early and Late Fassanian, although they are all derived
from the same environment.^1";

<b>Stratigraphy: </b>Triassic Nor; <b>Geography: </b>Austria,
Dachstein^This is the first report concerning an Early Norian coral
fauna from the Northern Calcareous Alps. The coral-bearing limestones
outcrop in the vicinity of the Feisterscharte, in the southern
Dachsteinplateau. In this Alpine region, aside from the
Dachsteinplateau, Early Norian corals have been recorded only from the
Gosaukamm range, which is also a part of the Dachstein massif. The
exposures at Feisterscharte show one on the most taxonomically
diversified Early Norian coral assemblages known so far. In the
assemblage, Carnian genera are prevailing in number, and Early Norian
index species, Pachysolenia cylindrica Cuif and Pachydendron
microthallos Cuif are frequent. The Early Norian age is proved by
conodonts. Some remarks on microfacies and foraminifera content of the
reef and associated limestones are given. The rocks represent the
initial growth stage of the Norian to Rhaetian Dachstein carbonate
platform.^1";

The specimens are still preserved in their original mineralogical composition (aragonite, with high strontium content) and structure. * Bilateral symmetry of septal insertion, peripheral insertion of septa two-by-two, absolute predominance of protosepta, non cyclic insertion of metasepta, are all characters more reliable to the late Paleozoic Rugosa than to the Scleractinia. On the other hand, no pinnate septal insertion occurs, as in Rugosa, and a theca is constantly present as an essential element of the skeleton. * Theca is given by aragonitic fibrolamellae, longitudinally finely folded. Contiguous, terminal surfaces of c-axes of aragonitic aggregates of contiguous fibrolamellae [are] knit together and give origin to a typical fibrous tissue. * Septa - discontinuous, frequently spiny and inwardly inclined - seem to have a fibrolamellar microstructure too: they seem to arise from a progressive infolding of thecal fibrolamellae. This structure cannot be relied either to the Rugosa or to the Scleractinia. * Further investigations are in course on the peculiar structure of Protoheterastraea leonhardi (Volz) (pars).^1";

furcate septal increase in a Triassic scleractiniamorph.- Acta
Palaeontologica Polonica 49, 4: 529-542.- <b>FC&#038;P 33-2</b>, p. 38,
ID=1178^<b>Topic(s): </b>structures, furcate septa; Scleractiniamorpha;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Triassic; <b>Geography: </b>Italy, Dolomites^Triassic corals with
septa that branch repeatedly and centripetally are here assigned to a
new genus Furcophyllia. Septa of F. septafindens (Volz, 1896),
re-described from the Italian Dolomites, arecomposed of 3–10 blades
(&#34;septal brooms&#34;). Distances between adjacent septa and their
branchesare equal, and the thickness of all blades is approximately the
same throughout ontogeny. However,none of the septal brooms show the
same branching pattern. Proposed herein is a simple computermodel that
reproduces septal pattern, similar to that of Furcophyllia, based on a
minimal set of rules: (i) uniform coverage of intra-calicular space;
(ii) regular bifurcations following some probability; (iii) keeping
some minimal distance between septal branches. The elaborate septal
pattern ofFurcophyllia suggests a distinct organization of the
polyp&#39;s soft tissue, especially mesenterieswhose appearance in
modern corals is associated with insertion of sclerosepta. Hypothesis
1suggests that mesenterial pairs flanked only &#34;septal brooms&#34;
and that septal branches functionallycorresponded with septal
microarchitecture. Hypothesis 2 suggests that mesenterial pairs
developedbetween all septal branches that functionally correspond with
conventional septa. Delicate menianae, which developed on Furcophyllia
septal faces (and many other Triassic corals) resemble similarseptal
microarchitecture of the Recent agariciid Leptoseris fragilis and may
be closely related to thesuspension feeding strategy of this coral. The
furcate septal arrangement in Furcophyllia is unique among Triassic
corals, and generally, among Mesozoic and Cenozoic corals. The only
analogouscorals are Cretaceous aulastraeoporids (e.g., Preverastrea,
Paronastraea), Trochoidomeandra, andsome Jurassic rhipidogyrids having
secondary (apophysal) septal branches. In some Recent caryophylliids
(Trochocyathus rhombocolumna, Phacelocyathus flos) primary septa may
also splitdichotomously and centripetally.^1";

The latter has been successfully used to estimate the organic content and diagenetic history of skeletons. Recent investigations yield the differentiation of three steps in the secretion of the skeleton in coralline sponges, according to which skeletal elements can be classified. The identification of these elements renders information on the way of secretion of the basal skeleton, the relative position of the soft tissue, and the function of skeleton. Two basic types of spinctozoan organisation can be distinguished: a matrix type, where a rigid framework, secreted in an organo-spicular matrix penetrates the soft tissue (as in stromatoporoid coralline sponges) and a cortex type, where the skeleton is secreted by a specialized subdermal layer (cortex) surrounding the sponge body. These organizational types bear no phylogenetic implication.^1";

beds, Italian dolomites.- Lethaia 17, 2: 133-138.- <b>FC&#038;P
13-2</b>, p. 48, ID=0569^<b>Topic(s): </b>aragonite, trace elements;
sponges; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Triassic;
<b>Geography: </b>Italy, Dolomites^The minor elements Sr, S, K, Mg, Fe,
and Mn were detected by electron microprobe EDS (electron dispersive
spectrometer) in small regions of the skeletal tissue of the Triassic
sponges Sestrostomella robusta (Zittel), Hartmanina involuta
(Klipstein), Atrochetetes medius Cuif &#038; Fischer, Ceratoporella
sp., and Eudea polymorpha (Klipstein) from Alpe di Specie (St. Cassian
Beds, Dolomites, Italy). Data were compared with analyses of the modern
sponges Astrosclera willeyana Lister from the Mozambique Channel and
Ceratoporella nicholsoni (Hickson) from the Bahamas. Sr content in
Triassic sponges (mean value 9,300 ± 600 ppm) is similar to the Sr
content of Recent samples (mean value 8,500 ± 1,500 ppm). This
concentration of Sr shows very slight biochemical fractionation like
oolitic aragonite. It is therefore possible to infer that the Triassic
sea of the St. Cassian Beds had the same Sr/Ca ratio and equal
aragonitic depositional conditions as those presently found in the
Bahamas and the Channel of Mozambique, i.e. warm shallow waters.
Generally, we did not observe a preferential distribution of minor
elements with respect to structure. Only when a lower concentration in
the center of spherules is observed does a preferential distribution
pattern seem to exist. This could mean an initial stage of Sr leaking
indicative of an incipient diagenetic process (excluding experimental
errors or morphological effects). Excluding these exceptions, the Alpe
di Specie spongial fauna is surely diagenetically unaltered. The Sr
content shows that the micritic microstructure of Eudea polymorpha is
not due to a diagenetic process either. The constant, clearly
detectable occurrence of sulphur (mean value 1,000 ppm) was observed.
In addition, the S content was found to be linearly correlated with the
strontium content. Sulphur is probably of primary organic origin.

U; <b>Geography: </b>Italy, Dolomites^Preliminary report on the
microstructure of some aragonitic Upper Triassic Sponges. The
microstructure of 8 species of calcisponges (Inozoina) found in St.
Cassian strata (Dolomites region, Italy), has been studied. *
Histologic study and mineralogic analyses show that the calcareous
skeleton is entirely built by aragonite. * Three chief types of
microstructure have been recognized: spherulitic, in which the
aragonite crystals radiate out from a central point; penicillate, in
which the aragonite crystals fan out from centers in &#034;water
jet&#034; structures; micritic appearance, characterized by an
aggregate of microcrystals isooriented. * A comparison with recent
calcareous sponges is given. The skeletons of examined species bear a
certain striking resemblances to that of Murrayonidae and particularly
of Sclerospongiae.^1";

More than 70% of the Dachstein limestone samples studied are bioclastic and lithoclastic rudstones and bioclastic grain/packstones composed of reworked and encrusted reef biota. Low-growing frame-building organisms (predominantly calcisponges) were responsible for the formation of primarily non-rigid frameworks situated at the margin or on protected parts of the foreslope. Stabilization of the reef framework was possible due to the very strong biogenous encrustation (mainly by algal crusts) and by a rapid submarine cementation. Destruction of the marginal reefs by hurricanes and mass flows was influenced by eustatic changes of sea level. Therefore, no clear distinction can be made with regard to various parts of a &#34;reef-complex&#34; (back-reef, central reef area, fore-reef) even though the bulk of the sediment can be compared with &#34;fore-reef breccia&#34;. s[1439] = "NICOL S.A. (1987).- A Down-slope Upper Triassic Reef Mound: Aflenz Limestone, Hochschwab Mountains, Northern Calcareous Alps.- Facies 16: 23-36.- <b>FC&#038;P 16-2</b>, p. 29, ID=2073^<b>Topic(s): </b>reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic; <b>Geography: </b>Germany, Alps N^A small reef mound occurring within the well-bedded, chert-bearing Norian Aflenz Limestones of the Aflenzer Buergeralm (south eastern Hochschwab Mountains, Styria, Austria) is described with respect to microfacies and paleontological criteria. The mound was formed in a down-slope position near the transition between basinal sediments (Aflenz Limestone, exhibiting a shallowing-upwards sequence) and marginal platform carbonates (Dachstein Limestone). The
```

```
transitional zone is characterized by a change from open-marine pelagic
carbonates with allochthonous intercalations at the base to protected
platform environments as well as shallow-marine platform slope deposits
near the top. The biota of the reef mound (corals, calcisponges,
hydrozoans, calcareous algae, foraminifera, microproblematica)
correspond with those of Dachsteinkalk reefs. Three communities can be
distinguished according to dominant corals and calcisponges
(Thecosmllia-Paradeningeria community, Astraeomorpha community,
Paravesicocaulis community). The microfacies of the massive, partly
dolomitized and stylolytized reef limestone is characterized by a
bioclastic floatstone at the base of the mound, overlain by sponge
bafflestone, coral-bafflestone, spongiostromate bindstone, coral-sponge
framestone, and sponge-hydrozoan bafflestone, without regular
distributional patterns. The bedded limestones below the reef
carbonates consist of bioclastic lime mudstones with radiolarians; the
overlying bedded limestones are composed of peloidal and bioclastic
grainstones and packstones as well as rudstones indicating a
termination of the reef growth by a rapid allochtonous sedimentation
perhaps caused by slumping or storm effects.^1";
s[1440] = "STANTON R.J.jr, FLUGEL E. (1987).- Paleoecology of Upper
Triassic Reefs in the Northern Calcareous Alps: Reef Communities.-
Facies 16: 157-186.- <b>FC&#038;P 16-2</b>, p. 30, ID=2074^<b>Topic(s):
</b>reefs, ecology; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Triassic U; <b>Geography: </b>Germany, Alps N^The community is the
standard unit of analysis In ecology because through it both physical
and biological aspects of the ecosystem can be determined. It offers
the same potential in paleoecology. The communities of the upper
Triassic reefs are analyzed from the literature and our own field work
in order to determine their characteristics and to assess their
usefulness. Six communities are recognized on the basis of R-mode
cluster analysis of the dominant frame-builders in Roetelwand reef and
from descriptions and our observations in other reefs. The Thecosmilia
or High-growing coral, the Hydrozoan-tabulozoan and the Sponge
communities are most widespread. The High-growing Astraeomorpha,
Low-growing coral and Solenopora communities are less common. Each
community is characterized by a few dominant taxa and a larger number
of associated taxa. The fidelity of the dominant taxa to their
community is generally high; the fidelity of many of the associated
taxa are typically lower and these taxa occur in a number of
communities. Consequently, there is considerable overlap in composition
between stands of different communities. In addition, the communities
typically occur in patches only a few meters in diameter, and
particularly in the Hydrozoan-tabulozoan community, the composition may
differ considerably between adjacent patches.^1";

Bioconstructions: Implications for the Platform Evolution in the
Lombardy Basin (Southern Alps, Italy).- Facies 35, 1: 143-162.-
<b>FC&#038;P 25-2</b>, p. 64, ID=3166^<b>Topic(s): </b>reefs, geology;
reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic Nor;
<b>Geography: </b>Italy, Lombardy^The development of peculiar margin
facies and abundant talus breccias within the Dolomia Principale inner
platform is commonly observed in the Lombardy Basin during the Norian.
The organisms building these margins are mainly serpulids, benthic
microbes, subordinate porostromata and other encrusting forms; typical
margin organisms, as sponges or corals, are extremely rare or absent.
The buildups form narrow rims along the borders of tectonic-controlled
intraplatform basks. Regional back-stepping and progradation of the
margin facies on the talus breccias produced by the erosion of the reef
is commonly observed in the uppermost Dolomia Principals depositional
system Widespread occurrence of serpulids and rnicrobial margins in
middle-late Norian times is indicative of stressed environmental
conditions - fluctuation of salinity and temperature on the inner
platform and in the intraplatform basins - controlled by
palaeogeographic setting. Physical characteristics allowed the bloom of
forms able to develop in a wide range of environmental conditions, such
as serpulids. In the Late Norian, major input of fine-grained elastics
is recorded; close to the Norian-Rhaetian boundary, carbonate ramps
were regionally restored. Locally, small serpulid and rnicrobial
bioconstructions still persist in the lowermost part of the shaly
succession, even if they are less abundant with respect to the Dolomia
Principale. Patch-reefs generally do not build a platform margin, but
represent isolated mounds within shaly deposits. These build-ups occur
on the edge of former structural highs; the communities survived the
environmental change responsible for the siliciclastic input and
locally managed to produce mounds during the deposition of the lower
part of the upper depositional system (Riva di Solto Shale).^1";

Reef Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 40, ID=3604^<b>Topic(s): </b>carbonate platforms; carbonate platforms; <b>Systematics: </b>; <b>Stratigraphy: </b>Triassic M; <b>Geography: </b>Alps, Calcareous, Tyrol, Bavaria^The sedimentation of the North-Alpine Middle and early Upper Triassic (&#034;Wetterstein Reefs&#034;) passed through three stages, a homoclinal ramp in the late Anisian, a distally steepened ramp in the Fassanian, and a rimmed platform in the Longobardian and early Julian. This evolution from homoclinal ramp to rimmed platform was a continous, dynamic process, creating a morphologically accentuated reef-basin topography. It is partly controlled by biota and by accommodation changes, which were due to sealevel fluctuations and tensional tectonics. In contrast to earlier assumptions, the start of the first North-Alpine reefs after the crisis at the Permian &#47; Triassic boundary was caused by a basin-wide or global sealevel rise in the late Anisian to early Ladinian.^1";

Ladinian-Carnian Reef Facies of Monte Caramolo (Calabria, Southern
Italy).- Facies 30: 101-118.- <b>FC&#038;P 23-1.1</b>, p. 85,
ID=4197^<b>Topic(s): </b>reefs facies; reefs, facies; <b>Systematics:
</b>; <b>Stratigraphy: </b>Triassic Lad - Carn; <b>Geography:
</b>Italy, Calabria^In the Triassic of the San Donato Unit (Calabrian
Apennines, Italy) a perireefal facies association of limestones and
dolomites, hosting a Ladino - (?Carnian) fauna, has been recognized.
This facies association is flanked by black, ostracode-bearing,
calcareous marbles and evolves to peritidal dolomites, Carnian and
possibly Norian in age, characterized by strong synsedimentary
tectonics. The San Donato Unit has been strongly affected by alpine
tectonics, resulting in pervasive deformation and metamorphic
recrystallization (greenschist facies); nevertheless, careful
observation on selected outcrops enabled the distinction of the
following main facies: - Sponges-biogenetic crust-cement boundstone; -
Reef debris rudstone; - Dasycladacean packstone-grainstone. [part of
extensive summary]^1";
s[1453] = "SATTERLY A.K. (1994).- Sedimentology of the Upper Triassic
Reef Complex at the Hochkonig Massif (Northern Calcareous Alps,
Austria).- Facies 30: 119-150.- <b>FC&#038;P 23-1.1</b>, p. 91,
ID=4209^<b>Topic(s): </b>reef complexes, sedimentology; reef complexes;
<b>Systematics: </b>; <b>Stratigraphy: </b>Triassic U; <b>Geography:
</b>Austria, N Calcareous Alps^The Upper Triassic Dachsteinkalk of the
Hochkonig Massif, situated 50 km south of Salzburg in the Northern
Calcareous Alps, corresponds to a platform margin reef complex of
exceptional thickness. The platform interior limestones form equally
thick sequences of the well known cyclic Lofer facies. Sedimentation in
the reef complex was not so strongly controlled by low-amplitude
sea-level oscillations as was the Lofer facies. The westernmost of the
8 facies of the reef complex is an oncolite-dominated lagoon, in which
wave-resistant stromatolite mounds with a relief of a few metres were
periodically developed. The transition to the central reef area is
accomplished across the back-reef facies. In the back-reef facies patch
reefs and calcisponges appear. The proportion of coarse bioclastic
sediment increases rapidly over a few hundred metres before the central
reef area is encountered. The central reef area consists of relatively
widely spaced small patched reefs that did not develop wave-resistant
reef framework structures. The bulk of the sediment in the central reef
area is coarse bioclastic material, provided by the dense growth of
reef organisms and the wave-induced disintegration of patch reefs.
Collapse of the reef margin is recorded by the supply of large blocks
of patch material to the upper reef slope. Additionally, coarse, loose
bioclastic debris was supplied to the upper reef slope and this was
incorporated into debris flows on the reef slope and turbidites found
at the base of the slope and in the off-reef facies. Partially
lithified packstones and wackestones of the middle reef slope were
modified by mass movement to form breccia and rudstone sheets. The
latter reach out hundreds of metres into the off-reef facies
environment. A reef profile is presented which was derived by the
restoration of strike and dip formation. In conjunction with
constraints imposed by sedimentary facies related to slope processes,
the angle of slope in the reef margin area ranged from 11 to 5, forming
a concave (dished downwards) slope. Water depth estimations require
that the central reef area did not develop in water less than 10 metres
```

```
depth. At the reef margin water depths were about 30 metres, at the
base of the reef slope 200 metres and deepening in the off-reff facies
to 250 metres. While previous work on reef complexes from this type of
setting suggests growth on heavily storm-dominated environment, the
present author finds little evidence for storm-influenced sedimentation
and reworking in the central reef area. Post-depositional processes
were characterized by continued slope processes causing brecciation and
hydraulic injection of red internal sediments downwards into the reef
slope and off-reef limestones. Hydrothermal circulation caused a number
of phases of post-depositional (diagenetic) brecciation. There appears
not to have been an important period of emergence at the
Triassic/Jurassic boundary.^1";

of microfacies analysis the Upper Rhaetian and Lower Liassic sediments
of the Wallberg-Blankenstein region (Tegernsee, Upper Bavaria) are
described and classified. The Upper Rhaetian Limestone, developing from
the marly &#47; calcareous Kossen basinal sequence, exhibits 10 main
microfacies types which partly can be further subdivided. The lateral
```

```
arrangement of microfacies types displays a mosaic-like distribution.
Shoaling upward tendency is obvious already throughout the Kossen beds
by the development of reef patches. This pattern also influenced
distribution of reefal organisms and sediment types in the superimposed
Rhaetian calcareous sedimentation. Ecological restrictions (e.g. water
energy) limited, however, a more pronounced occurrence of reef biota
and thus inhibited the development of &#34;true&#34; reefs. Besides
these shallow subtidal patch reefs and related deposits, shoal
sediments were deposited in higher energy settings. Dark intertidal
algal bindstones and occurrence of black pebbles correspond to the peak
of shoaling. The studied Upper Rhaetian limestones reflect the
development of a ramp-like initial limestone platform within the Kossen
basin. Reefoid development ceases with the discontinuous drowning of
the depositional area at the end of the Rhaetian. This led to strongly
differentiated shallow to deep subtidal deposits at the beginning of
the Liassic, reflecting tectonic uplifts and predepositional Triassic
topography. Further break-up and sinking of the Tethyan shelf resulted
then in the superposition of bathyal, grey basinal deposits.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Mesozoic; <b>Geography:
</b>Slovenia^Monographs like that with the description of several
hundred species became rare the past times; summarizing monographs on
the corals of one country were published the last time hundred years
ago. Therefore this book is a great surprise and a great pleasure. In
the &#34;Mesozoic Corals of Slovenia&#34; the results of Slovenian
Mesozoic coral research of the past 30 years are compiled. But it
exceeds a simple compilation: all species are carefully checked, new
items aded to the synonymy lists and new illustrations provided. Each
species is represented at one text page and one page of illustration
side by side. The text page contains a synonymy list, a short
description, the localities in Slovenia, the age and remarks on the
geological setting and environment. A stratigraphical table and a map
is provided, where the occurrence of the species concerned is plotted.
The illustration page encompasses horizontal and vertical thin sections
magnified four or eight times, and microstructure details in greater
magnification. The illustrations are good as long the material is well
preserved. The latter is maybe the main problem of the monograph: many
species are indicated by poorly preserved material and in some cases it
is difficult to follow the determination. * The book contains a short
but satisfactory description of the geological situation and
stratigraphy of the localities where the corals are found. A rich
appendix encompasses a list of the described specimens - sorted
according to species and generic names, alphabetically and according to
their age, and a list of localities, alphabetically and according to
the geological unit. A general index summarizes the coral assemblages
with their species. * At all, the compilation is very careful: each
```

```
locality has a number and is plotted at a map. The species description
refers to this number. In the list of localities in the description
part and in the explanation to the illustration the collection number
of the specimens is given. This makes reference to previously published
papers and to own notes on the material easy.^1";

Coral zonation of an Oxfordian reef tract in the northern French Jura.-
Facies 50, 3-4: 545-559.- <b>FC&#038;P 34</b>, p. 61,
ID=1284^<b>Topic(s): </b>reefs, biological zonation; reefs,
Scleractinia; <b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Jurassic Oxf; <b>Geography: </b>France, Jura^During the Middle
Oxfordian, numerous coral reefs flourished on the northern margin of
the Tethys Ocean. The outcrop of Bonnevaux-le-Prieur (northern French
Jura mountains) provides a rare opportunity to observe a nearly
complete section allowing the installation, evolution and demise of
this global carbonate reef rich event to be studied. Quantitative data
on coral assemblages together with sedimentological and
palaeoecological observations lead to the reconstruction of a reef
tract coral zonation. Starting from the outer slope, Dimorpharaea,
Microsolena, Dendraraea, Comoseris, and Stylina ecozones are
recognized. This new facies model implies a central position for an
oolitic shoal in the highest energy zone, within the Comoseris ecozone.
Applying this facies model to the sequence stratigraphic interpretation
of the vertical succession results in recognising a third-order
relative sea-level fluctuation, which can be correlated at least within
Lorraine (France) and Switzerland.^1";

S^The oldest known Jurassic coral reef is exposed in the Ardeche region
of southern France. This reef site, consisting of at least three reefal
bodies, is of early Hettangian age and thus immediately postdates the
end-Triassic mass extinction, which is well known for its catastrophic
effect on reef building. Bulk carbonate carbon isotopes of the
limestones below the reef are likely to record environmental
perturbations subsequent to the mass extinction. The main reef is
```

```
surprisingly well developed (20m in thickness, 200m in lateral extent)
and composed of at least four genera and six species of corals ? not
only holdover genera from the Triassic, but also one newly evolved
genus (Phacelophyllia), contributed to reef construction. Just like
their latest Triassic counterparts, the reef is dominated by phaceloid
corals with a considerable contribution of microbialite. The reef
predates similarly well developed structures by almost ten million
years. The shelf setting of the reef renders it unlikely that refuges
around oceanic islands are needed to explain survival of corals across
the end-Triassic mass extinction. [original abstract]^1";

</b>Cnidaria Monera; Anthozoa; <b>Stratigraphy: </b>Jurassic Oxf;
<b>Geography: </b>Switzerland^Detailed study of Oxfordian
coral-microbialite reefs in the Swiss Jura Mountains has identified
major paleoecological variations in space and time, which are
attributed to environmental changes.Micro- and macroscale
semiquantitative analyses of microbialite types,
micro-encrusters,bioerosion, corals, and other macrofauna composing the
reefal facies were performed. Three maintrophic structures (dominant
nutritional modes) were recognized: phototrophic-dominated,
balancedphoto-heterotrophic, and heterotrophic-dominated. A
phototrophic (light dependant) faunadominated reefs growing in pure
carbonate and nutrient-poor environments, where sedimentationrate was
the main factor controlling reef growth. In mixed
siliciclastic-carbonate platformenvironments, a balanced
photo-heterotrophic fauna with periodical shifts to
heterotrophicdominatedassociations was induced by freshwater and
sediment run-off into closed, shallowlagoons. In this case, the main
factors controlling reef growth were the distribution andaccumulation
of terrigenous sediment on the platform and &#47; or associated
nutrient availability. Thebalanced photo-heterotrophic structure found
in mixed carbonate-siliciclastic settings produced themost diversified
reefs, suggesting that these Oxfordian reefs preferentially thrived in
watermoderately charged with nutrients (mesotrophic environment). In
the case of strong siliciclasticaccumulation and &#47; or strong
increase in nutrient availability, coral reef diversity dropped
drasticallyand heterotrophs dominated the trophic structure. A model of
the evolution of trophic structure inthese reefs as a function of the
governing environmental factors is proposed. Focusing on thedominant
nutritional mode at each step in reef evolution allows a detailed
characterization of reefalstructure and a better understanding of the
processes leading to coral reef settlement, development,and demise.^1";
s[1501] = "MOSTLER H. (1990).- Mikroskleren von Demospongien (Porifera)
aus dem basalen Jura der Nordlichen Kalkalpen.- Geol.-Palaeont. Mitt.
Innsbruck 17: 119-142. [in German, with English summary].- <b>FC&#038;P

Demospongiae; <b>Systematics: </b>Porifera; Demospongiae;
<b>Stratigraphy: </b>Jurassic L; <b>Geography: </b>Alps N^For the first
time microscleres of Demospongea from the Liassic Kirchsteinkalk
(Allgau Formation as basin facies to Liassic Kirchstein Limestones) are
described and presented by 6 plates. In contrary to previous opinions
microscleres can be proved frequently in scarcely diagenetically
altered limestones and calcareous marls. With the help of microscleres
and in consideration of accompanying megascleres for the first time it
was possible to link with recent Demospongiae. Specific microsleres
```

```
like cricorhabds, toxa, sigmata, diancistors and various chelate
scleres, clavidisks, oxasters, sphaerasters, sterrasters and
amphiasters are of special importance. With few exceptions these types
of microscleres are only known from the Late Tertiary and in some cases
even only recently. In particular this concerns chelate scleres. By
evaluation of these microscleres from the Lower Liassic of the Northern
Calcareous Alps the following Demospongiae are provable: The
Ceratinomorpha are represented by the order Poecilosclerida and their
families Myxxillidae, Cladorhizidae, Crellidae, Amphilectidae,
Desmacellidae and Desmacitidae. Partly correlation on generic level is
possible. Within the Tetractinomorpha the order Astrophorida (=
Choristida) is represented by the families Geodiidae, Ancorinidae and
Pachastrellidae; with the help of microscleres it was possible to prove
the families Theonellidae and Corallistidae. The order Hadromerida is
represented by the family Clionidae. All the mentioned families are
widespread by numerous genera. By the proof of the above mentioned
microscleres in the Lower Liassic it was possible to enlighten the
evolutional history of Poecilosclerida and especially Astrophorida.
Particular attention is drawn to the sharp faunal break between
Triassic and Jurassic, revealed by evaluation of the deep water
Porifera (demosponges and hexactinellids).^1";

Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic L M; <b>Geography: </b>Hungary, Bakony
Mts^Hettangian, Pliensbachian and Bajocian corals were examined from 6
localities of the Bakony Mountains. All of the suborders existed in
Early and Middle Jurassic are present in the 80 specimens. The
determined 6 genera belong to 4 suborders. 88% of the fauna is derived
from the Domerian formations, but the number of taxa are nearly equal
in Carixian, Domerian and Bajocian. Four genera appeared earlier in the
Bakony Mountains, than in other areas. Seventy-seven specimens belong
to solitary corals, and only 3 specimens are colonial. Two-third of the
fauna is hermatypic at the Pliensbachian localities, but at the same
time 80% of the specimens are ahermatypic in Bajocian. Fissures of
seamounts and the edge of a seamount are represented at these
localities. This means, that the top of the seamounts were not sinking
below the depth of 100m during the Pliensbachian, but it may have been
below 100m in Bajocian. The elongated morphotypes of corals stabilized
themselves by root-like fixation, or the specimens had to be sunk in
the loose sediments. Because the loose sediments were rare at the top
```

```
of seamounts, the corals are sometimes overturned (scolecoid
specimens).^1";

<b>Stratigraphy: </b>Jurassic M; <b>Geography: </b>Alps, Swiss^Grâce à
la complaisance de M. Wiedmann, Conservateur du Musée Géologique de
Lausanne, que nous remercions ici très vivement,nous avons pu réviser
les types de Koby provenant des couches à Mytilus des Alpes romanes
(Suisse) que nous croyions perdus (L. Beauvais, Eclog 1966). Ces 25
échantillons furent décrits par Koby dans la Monographie des Polypiers
jurassiques de la Suisse (1883-1889). Les résultats de notre étude sont
exposés dans le tableau ci-joint (pages suivantes). * Parmi les 25
espèces de Madréporaires provenant des couches à Mytilus (= Dogger) des
Alpes Suisses, nous en avons reclassé 10 dans des genres différents de
ceux que leur avait attribué Koby. Six sont mises dans la synonymie
d&#039;espèces déjà connues et les 10 autres sont maintenues dans leur
classification générique et spécifique originale. * De plus, du point
de vue répartition stratigraphique et géographique, 15 espèces sont
endémiques, 7 ont été rencontrées dans le Dogger d&#039;autres régions
et 3 n&#039;étaient connues jusqu&#039;à présent que dans le Malm.

Stylophyllidae; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Jurassic Sine; <b>Geography: </b>Italy,
Sicily^Coralla of the three species of solitary corals described herein
from the Sinemurian (Lower Jurassic) of Sicily, i.e., Haimeicyclus
haimei (Chapuis and Dewalque 1853), Stylophyllopsis sp. cf. S. rugosa
(Duncan and Wright 1867), and Stylophyllopsis sp.A., conform to the
overall stylophyllid morphology. Their septa consist of spines that are
increasingly covered with sclerenchyme and low in the calice form
compact blades. The pattern of diagenetic alteration of septa is
diverse but consistent within particular taxa. It suggests that the
spectrum of the original microstructures is wider than traditionally
suggested for stylophyllids. In H. haimei, the septa are covered with
dense granulations and completely recrystallized. Granulations also
cover septal faces of Stylophyllopsis cf. rugosa and have rod-like
foundations. In Stylophyllopsis sp. A., vestiges of the narrow
mid-septal zone (similar to that in minitrabecular corals) occur in the
proximal part of larger septa, whereas septal spines which are similar
to those in Stylophyllopsis cf. rugosa occur in their distal parts.
Similar diversity of microstructures is reported also in Triassic
stylophyllids that have aragonitic coralla. The presence of distinct
septal spines along with wide-ranging microstructural diversity of
traditional Triassic-Jurassic stylophyllids, casts light on their
possible evolutionary relationships, and can be a useful criterion for
further revision of the group. For example, Jurassic thecocyathids,
considered ancestral to caryophylliinans, share similar spiny/lobate
septa with stylophyllids. Also Recent deep-water anthemiphylliids with
spiny/lobate septa are strikingly similar to stylophyllids. Although
this may be another example of parallel evolution, the separation of
anthemiphylliids from other scleractinian clades on a mitochondrial 16S
RNA tree topology suggests their ancient roots and enable us to suggest
a stylophyllid ancestry. The supposed cyclic pattern of protoseptal
insertion in Early Jurassic H. haimei supports the hypothesis of
scleractinian-like (and not rugosan) ancestry of the stylophyllid
evolutionary lineage.^1";

spongiolites; <b>Systematics: </b>Porifera; <b>Stratigraphy:
</b>Jurassic U; <b>Geography: </b>Germany S^The spongiolitic facies
reaches its widest distribution along the epicontinental to
pericontinental margin of the Northern Tethys during the Upper
Jurassic. These buildups formed by siliceous sponges represent a
singular event within the evolution of reef communities during
Earth&#039;s history. In this paper the present knowledge of causal and
environmental aspects of the spongiolithic limestones in Southern
Germany and adjacent areas is discussed. With regard to the research
project &#34;Evolution of Reefs&#34; (a major part of the
Schwerpunktprogramm &#34;Biogenic Sediments&#34; established by the
Deutsche Forschungsgemeinschaft in 1990) the following genetically and
process orientated aspects are of interest: 1) The stratigraphic
classification using biostratigraphic, lithostratigraphic and
mineralostratigraphic methods. 2) The paleogeography, oceanography and
geotectonics along the broad passive northern shelf of the Tethys are
discussed with regard to width and stability of the shelf, distance to
the land mass and terrigenous influence and sea level fluctuations. 3)
Certain sedimentological features seem to be indicative of climatic
fluctuations, but this is not always proved by the distribution
patterns of organisms. 4) The classical interpretation that
spongiolites formed below the wave base gets opposition by the
significance of biogenic carbonate crusts as well as sedimentological
and paleogeographic arguments. 5) Important sedimentological factors of
the Upper Jurassic spongiolites are paleobathymetry, sedimentary
cycles, possible control of spongiolike growth by sea level
fluctuations, as well as biogenic interactions which probably initiated
the fossilization of siliceous sponges as well as the formation of
spongiolitic buildups. 6) Paleoecological conditions can be
reconstructed by the community patterns of benthonic organisms and
substrate control patterns, both changing through time. Phylogenetic
innovations of related sponge groups (hexactinellids, lithistide
demospongeans) most probably are not responsible for the initial growth
of buildups. 7) Comparison of the spongiolites with the laterally and
vertically associated coral facies is of major importance for the
interpretation of controlling parameters (bathymetry, sedimentation
rates, nutrient and nutrient availability) of the sponge facies. 8) The
genetic significance of diagenetic processes in spongiolites is
discussed with regard to early lithification, dissolution, epigenetic
dolomitization and dedolomitization. ^1";

Deposits in Western Central Dobrogea.- www.tesionline.com; 108
pp.www.tesionline.com. [M.Sc. thesis] - <b>FC&#038;P 36</b>, p. 45,
ID=6421^<b>Topic(s): </b>ecology; sponge deposits; <b>Systematics:
</b>Porifera; <b>Stratigraphy: </b>Jurassic U; <b>Geography:
</b>Romania, Dobrogea^The present work is the first paleoecological and
systematic study of the Upper Jurassic sponge deposits in Western
Central Dobrogea. It is a brief synthesis of all the information
published yet regarding that subject together with the author&#039;s
research results, that completes the picture. * In Upper Oxfordian, on
a slightly inclined slope-like sea floor, far from the Tethys Ocean
northern shore, a great community of sponges has developed. It was a
world of high diversity, part of the European Upper Jurassic Sponge
Megafacies. Its remains are now enclosed in stromatolithic limestone of
microbialithic origin. Even though studies had been carried out in time
dealing with the ammonite or brachiopod fauna here, none of them had
paid attention to the sponge association. That is the reason for the
necessity of that study. * Presenting some similarities with the German
```

```
or Polish Upper Jurassic sponge fauna, the sponge community in Dobrogea has some particular features that make that eastern part of the European sponge megafacies different from all the rest. The work tries to point out some of them, but not to complete the research, as the sponge fauna here needs revision. [original abstract]^1";
s[1538] = "UNGUREANU D. (2005).- Faciesul cu spongieri din vestul Dobrogei centrale in Jurasicul superior - intrepretari paleoecologice [The facies with sponges in Western central Dobrogea during Upper Jurassic - paleoecological interpretations; in Romanian].- www.tesionline.com; 47 pp.www.tesionline.com.- <b>FC&#038;P 36</b>, p. 45, ID=6422^<b>Topic(s): </b>sponge facies; sponge facies; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Romania, Dobrogea^The present study deals with paleocological aspects of the Upper Jurassic sponge facies in the Western area of the central Dobrogea. There is also, an attempt to include the occurences of the facies in Dobrogea within the frame of the sponge reefs developed across Europe and beyond, marking a global significance event at the end of Jurassic. An argumentation is also included for the place of the sponge reefs in Dobrogea within the geo-historical evolution of that kind of biological buildings. Finally, there are few comparisons between the sponge facies in Western Dobrogea and its fauna against the status of other occurrences along the siliceous sponge reef belt, in Germany, Poland, Spain.^1";
s[1539] = "UNGUREANU D., BARBU E. (2004).- Endemic Features of the Upper Jurassic Sponges in the Western Central Dobrogea (Atarnati-Cechirgea Perimeter).- Acta Palaeontologica Romaniae 4: 493-502.- <b>FC&#038;P 36</b>, p. 46, ID=6424^<b>Topic(s): </b>taxonomy biogeography; Porifera; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Romania, Dobrogea^In the Upper Oxfordian, central Dobrogea hosted the far eastern end of the Upper Jurassic Sponge Megafacies. Its closest relations are the occurrences in Poland and those in the Swabian Alb (Germany). The Oxfordian sponge fauna in Dobrogea is also most related with that in Poland and in Germany. However, in Dobrogea, the support of the faunal association was a slight slope, unlikely the rest of the European occurrences. * As the closest Upper Jurassic sponge communities were quite far, their weak influence allowed the development of some different sponge populations in the specific conditions of life here. The differences are mostly related to shape and size, and this study tries to present some of them. * Several genera are considered: Laocoetis, Cribrospongia, Trochobolus, Cnemidiastrum and Melonella. The Cribrospongia phylloidea (Antonescu 1928) species is particularly analyzed and it is suggested that it is only a variety of Cribrospongia reticulata (Goldfuss 1826), and not a separate one. It is, also, particularly analyzed the Trochobolus dentatus (Kolb 1910) species identified in that area. * Unfortunately, diagenetic conditions did not allow the conservation of the skeleton structure. That is why all taxonomical identifications of fossil sponges in Dobrogea, both previous and present ones are based entirely on the macroscopic morphologic descriptions.^1";

Using seven microfacies types as reference, respective specific diagenetic sequences and their variations are traced. The general diagenetic history includes early marine phreatic, burial partly hydrothermal and late meteoric stages in all microfacies types. Various controlling factors are effective at different stages and in different dimensions. Early marine diagenesis is largely controlled by rock fabric and composition as well as primary porosity; in contrast, burial and meteoric stages are influenced by fluid chemistry, secondary porosity and regional structural processes. Dolomitized and dedolomitized microbial sponge bafflestones including non-dolomitized, pervasively dolomitized or dedolomitized portions were quantified by digital image analysis. Pathways of the fluids were stylolites and fractures. Spatial heterogeneity of dolomite products increases with dolomite percentage. Dolomite cements of non fabric selective pores did not contribute volumetrically to dolomitization. Pore cementation was controlled by a complex network of factors including effective porosity and total dolomite percentage.^1";

Besides the well-known Moroccan sponge carbonates, these Lower Jurassic spongioliths from the Trento Platform are presently the second mass occurrence of siliceous sponges, which is known from the southern margin of the Tethys. They differ from each other in regard of the composition of the sponge fauna and the absence of microbial crusts in the spongioliths of the Trento Platform. There, hexactinosans and lithistid demosponges occur in equal proportions. Sphinctozoans are another very characteristic element. Because of the richness in both spinctozoans and siliceous sponges, the Trento occurrences may be considered as a transitional fauna between the late Paleozoic-Triassic sponge fauna dominated by Sphinctozoans and the post-Liassic sponge fauna dominated by more modern groups of siliceous sponges. Two new siliceous sponge genera with their species are established: Misonia
```

```
baldensis n.gen. n.sp. (Hexactinosa) and Benacia princeps n.gen. n.sp. (lithistid Demospongiae). The rarity of siliceous sponge-dominated spongioliths in the Early Jurassic is due to the restricted occurrence of low energy, deeper shelf areas.^1";
s[1546] = "PISERA A. (1997).- Upper Jurassic Siliceous Sponges from the Swabian Alb: Taxonomy and Paleoecology.- Palaeontologia Polonica 57: 3-216.- <b>FC&#038;P 27-1</b>, p. 104, ID=3854^<b>Topic(s): </b>monograph; Porifera, Silicispongiae; <b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Germany, Swabian Alb^The fauna of siliceous sponges (hexactinellids and demosponges) from the Upper Jurassic of the Swabian Alb is described and revised. It consists of 124 species representing 67 genera. Only 15 species show frequency higher than 1% of the whole assemblage. Nearly all sponges represent groups with solid skeletons: Hexactinosa and Lychniscosa, and lithistid Demospongea. Loose spicules occurring are also described and illustrated. Two new species are proposed: lithistid Amphibleptula jurassica sp.n. and hexactinosan Sphenaulax irregularis sp.n. Several other new species are described in an open taxonomy. The presence or absence of dermal and/or gastral layers of pentactines or stauractines in Hexactinosa and Lychniscosa is of no taxonomic value, because it is mostly a taphonomical phenomenon, and both types of spicules can be present in the same species. Lithification of sponges leading to origin of the so called &#34;sponge mummies&#34; preserves (except in one lyssacinosan sponge) only parts of the sponges delimited by solid skeletal structures. The Oxfordian assemblage is dominated by hexactinosan and lychniscosan sponges, while beginning with the Kimmeridgian lithistid demosponges are very common. The proportion of lithistid sponges in the assemblage increases steadily and the uppermost Kimmeridgian assemblage consists mostly of lithistids. This trend is interpreted here in terms of superimposed bathymetric changes and type of food dominant in the environment: particulate (domination of lithistid demosponges) and colloidal (hexactinellids domination). Ecological analysis of the sponge fauna and sedimentological analysis of sponge-bearing sequences point to a relatively deep-water settling of the Upper Jurassic siliceous sponge biofacies: the most shallow mixed sponge-coral Upper Kimmeridgian assemblages dominated by lithistid demosponges could be from 60-100 meters, while Oxfordian hexactinellid dominated assemblages in the Upper Jurassic is mostly ecological phenomenon since the numerous genera contributing to this assemblage are rooted in the Lower Jurassic at least. Generally high sea level during the Upper Jurassic produced large, relatively deep water areas, remote from the shore and thus with slow sedimentation. Such new habitats suitable for sponges have been colonized by immigrants from refugia existing on continental and island slopes. Large sponge populations were supported by high nutrient availability characteristic for the Upper Jurassic.^1";

microtaphonomic traits and foraminiferal assemblages from Upper
Jurassic oolitic-coral limestones: stratigraphic fluctuations in a
shallowing-upward sequence (French Jura, Middle Oxfordian).- Facies 53,
4: 553-574.- <b>FC&#038;P 35</b>, p. 113, ID=2449^<b>Topic(s):
</b>microfacies; geology fossils Anthozoa; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic Oxf; <b>Geography: </b>France, Jura^The
characterization and distribution of the microfacies and the
microfossil assemblages of a Middle Oxfordian section from Jura
Mountains composed by thick oolitic-coral limestones is analyzed. Six
microfacies types (mainly grainstones) are differentiated mainly
composed by ooids, intraclasts and bioclasts. Foraminiferal assemblages
are dominated by agglutinated forms. Benthic microbial communities and
sessile foraminifera are the main components of the encrustations. The
whole set of microfossil assemblages is typical of shallow subtidal
environments rich in &#34;algae&#34; (Cayeuxia, &#34;Solenopora&#34;,
Thaumatoporella, Bacinella, Girvanella and Terquemella) and
foraminifera such as Nautiloculina oolithica, Redmondoides lugeoni,
Ammobaculites coprolitiformis, Troglotella incrustans and
Rectocyclammina. The increasing upward record of debris of algae and
Nautiloculina, and the decrease of serpulids, bryozoans, nodosariids
and ophthalmidiids indicate a shallowing-upward trend. The
stratigraphic distribution of microfacies and microfossil assemblages
```

```
lead to differentiate two main successive phases. The first is a deeper
subtidal environment in an open shelf, while the second is a shallow
subtidal environment with evolution from winnowed to more restricted
conditions. Microfabrics of radial to concentric ooids upwards in the
section correspond to higher energy environments related to an oolitic
shoal. This study shows how a very detailed analysis of microfacies,
which integrates oolitic features, microfossil assemblages and
microtaphonomy is potentially a useful tool for interpreting
hydrodynamism and sequence evolution in marine carbonate shallow
environments.^1";
s[1553] = "POMONI-PAPAIOANNOU F., FLUGEL E., KOCH R. (1989).-
Depositional environments and diagenesis of Upper Jurassic subsurface
sponge- and Tubiphytes reef limestones: Altensteig 1 Well, Western
Molasse Basin, southern Germany.- Facies 21: 263-284.- <b>FC&#038;P
19-1.1</b>, p. 59, ID=2680^<b>Topic(s): </b>reefs, sedimentology,
ecology, diagenesis; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Jurassic Kimm Tith; <b>Geography: </b>Germany S^An up to 300 m
thick Kimmeridgian and Tithonian &#34;reef sequence&#34;, occurring in
the Altensteig 1 well southwest of Augsburg, Bavaria, has been studied
with regard to facies types, depositional environment and diagenesis.
The reef sequence consists of oolitic sands and sand bars, stabilized
by binding organisms and overgrown by siliceous sponges and the
enigmatic organism Tubiphytes. The biota consists of siliceous sponges,
sclerosponges, bryozoans, brachiopods, molluscs, serpulid and
terebellid worms, and echinoderms. Foraminifera exhibit no significant
distribution patterns. Algae occur in samples of core 4 (Malm zeta 3).
Four facies types (sponge &#47; algal boundstones, tuberoid-peloid
wackestone &#47; packstone, ooid-intraclast grainstone and Tubiphytes
packstone &#47; boundstone) can be differentiated. The Tubiphytes
boundstones represent a particular reef type not yet described in
detail from the Upper Jurassic. As can be deduced from subsurface
samples and from surface samples (Graisbach quarry near Donauwoerth),
Tubiphytes formed an organic framework within shallow subtidal
environment. The diagenesis of most of the section is characterized by
the existence of early marine-phreatic cements, except for the Malm
delta &#47; Malm epsilon interval. For this interval, an widespread
subaerial exposure of Upper Jurassic carbonates is indicated by the
absence of marine-phreatic cements, the occurrence of meteoric-vadose
meniscus cements, meteoric-phreatic granular to blocky cements, and of
asymmetric radiaxial-fibrous cements.^1";
s[1554] = "LIEDMANN W., KOCH R. (1990).- Diagenesis and Fluid
Inclusions of Upper Jurassic Sponge-Algal Reefs in SW Germany.- Facies
23: 241-268.- <b>FC&#038;P 20-1.1</b>, p. 68, ID=2851^<b>Topic(s):
</b>reefs, diagenesis, fluid inclusions; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Germany
SW^Petrographic and fluid inclusion studies were carried out on
limestones, dolomites and dedolomites from Upper Jurassic sponge-algal
reefs in SW Germany (Geislingen and Herrlingen areas) to reveal their
general diagenetic development and especially their deeper burial
history. The first results of this study allow a 12-phase diagenetic
history to be reconstructed, which includes two karstification and
three dolomitization phases. In addition granular meniscus cements
indicate local early diagnetic subaerial exposure and meteoric vadose
conditions. A very early dolomitization, which was underestimated up to
now due to later diagenetic overprinting, largely closed the primary
pores. The characteristic growth of scalenohedral calcite cements (dog
tooth) probably indicates alterations in the pores water chemistry
which were related to the early dolomitization. Early blocky cements
(phase 8) and late diagenetic dolomite (phase 9) were analyzed
micro-thermometrically. The measurements of fluid inclusions in blocky
cements indicate homogenization temperatures of 55°C to 65°C with
salinities of 3.5 to 8.5 weight % NaCl (equiv.). The data indicate
their formation under meteoric shallow-burial conditions. The late
```

```
diagenetic dolomite is charcterized by higher homogenization
temperatures (65°C to 11[??!]°C) and salinities of 4.5 to 15.5. weight
% NaCl (equiv.). Data on geothermal gradients during the Upper Jurassic
are not available. Therefore a reliable estimation of the formation
temperatures and pressures is very difficult. With regard to a normal
geothermal gradient of 30°C/km, formation temperatures of 75°C (Blocky
cements) and 105°C (dolomite-II) could be expected by an overburden of
2 km; a fact, which is also known from the general geological data of
the study area. As documented in the literature gradients of
50°C-60°C/km can occur in sedimentary basins. Comparable or even higher
gradients are locally present in the area of the &#034;Swabian
Lineament&#034;. This would reduce the burial depth considerably
whereas the formation temperatures are lowered only very little. In
this calculation the surface temperature has to be also taken into
account. ^1";

<b>Geography: </b>Germany, Swabian Alb^About 200 masive limestone
bodies (sponge-algal-reefs, &#34;Massenkalke&#34;) of meters to tens of
meters in size were examined in the Eyb valley near Geislingen
(Oxfordian-Tithonian). The largest part of the massive limestones is
made up of oncoid-lithoclast-ooid sands forming large areas (some km2)
of mobile &#34;platform sands&#34;. Different biogenic buildups with
varying composition occur within and at the flanks of the sand facies
as well as in adjacent basins. Three types of buildups (sponge-algal
mud mounds, algal-sponge boundstones, brachiopod-algal-sponge mounds)
are found in relation to the sand facies. Zoned sponge-algal mud mounds
occur in intraplatform channels (Malm &#949; and &#950;) and nodular
sponge-algal mud mounds occur in the marly basin sediments. Another
buildup type, rich in brachiopods, may occur in the basin facies.
Generally, the composition of massive limestones in the Upper Jurassic
of S-Germany must be analyzed in much larger detail for recognizing
their real facies distribution.^1";
s[1556] = "KOCH R., LIEDMANN W. (1996).- Diagenesis and Fluid
inclusions of Upper Jurassic &#034;Sponge-Algal-Reefs&#034; in
SW-Germany.- Goettinger Arbeiten zur Geologie und Palaeontologie,
Special Volume 2 [Reitner J., Neuewiller F. &#038; Gunkel F. (eds):
Global and Regional Controls on Biogenic Sedimentation I. Reef
Evolution]: pp ???.- <b>FC&#038;P 26-1</b>, p. 36, ID=3596^<b>Topic(s):
</b>reefs, diagenesis; diagenesis, fluid inclusions; <b>Systematics:
</b>; <b>Stratigraphy: </b>Jurassic U; <b>Geography: </b>Germany SW^The
recent study deals with the diagenetic development of massive
limestones (&#034;sponge-algal reefs&#034;) in S-Germany. During early
diagenesis isopachous, marine-phreatic radial fibrous cements (high
Mg-calcite) and peloidal cements were formed. Moreover, very minor
dolomite, early equigranular cement, scalenohedral cement and first
syntaxial overgrowth cements occur. Emersion of small areas resulted in
the meteoric-phreatic and vadose stage near the Malm &#948;/&#949;
boundary. During the shallow burial stage differential compaction (at
about 200 m) between bedded and massive facies and the main
dolomitization of massive limestones occurred. Pore fluids migrated
along microfractures and micropores. During increasing burial, massive
replacement dolomite was formed. Its crystals show a characteristic
homogeneous cathodoluminescence. Deeper buried Malm dolomites
(temperatures >50°C) in the Molasse basin show increased crystal size,
increase in Fe and Mg contents, crystallinity and ordering. Isotopic
data confirms the interpretation of the replacement character of the
```

```
main dolomitization phase. Formation temperatures of 40-90°C are shown
by the homogenization temperatures of 2-phase inclusions. Salinities
(3.5-14 weight-% NaCl-equiv.) indicate primary marine to highly
concentrated waters. A hydrothermal dolomitization (temperature of
formation >85°C) only occurred in the deeply buried (>3,000 m) areas in
the eastern Molasse basin. During karstification meteoric waters from
the surface could percoalte along tectonic fractures resulting in late
cementation by calcite blocky cements (formation temperature of <40°C)
and dedolomitization.^1";

siliceous sponge facies (spongiolite facies) in Europe. The
spongiolites are part of the Lower to Upper Oxfordian Casimcea Fm.
which was deposited on a gently westward dipping carbonate platform
(homoclinal ramp). This platform was surrounded by deep marine basins
in the south, west and north, while to the east the existence of a land
area with low relief is assumed. The gently sloping carbonate ramp
shows an E-W facies zonation. A lagoonal belt is followed towards the
open sea by a coral patch reef belt, a bioclastic-oolitic sand belt,
and a spongiolitic belt. [first part of extensive summary]^1";
s[1558] = "DUPRAZ C., STRASSER A. (1999).- Microbialites and
Micro-encrusters in Shallow Coral Bioherms (Middle to Late Oxfordian,
Swiss Jura Mountains).- Facies 40, 1: 101-129.- <b>FC&#038;P 28-1</b>,
p. 61, ID=4003^<b>Topic(s): </b>carbonates microbial; microbialites;
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf; <b>Geography:
</b>Switzerland, Jura^Benthic microbial crusts (microbialites or
microbolites) are an important component of Middle to Upper Oxfordian
shallow-water coral bioherms in the Swiss Jura. They display
stromatolitic (laminated), thrombolitic (clotted), and leiolitic
(structureless) fabrics, which are distributed heterogeneously
throughout the studied sections. The bioherms can be subdivided into
coral-microbialite facies, microbialite-dominated facies, and sediment
matrix. Macroscopic and microscopic study reveals that microbialitic
encrustations commonly occur in two layers. The first one is directly
in contact with the substrate and composed of leiolite (locally
stromatolite) and a well-diversified micro-encruster fauna; the second
one fills the remaining porosity partly or completely with thrombolite
and low-diversity micro-encrusters. The growth of the first layer
accompanies the growth of the coral reef and thus formed under the same
environmental conditions. The second layer is the result of a moving
encrustation front filling the remaining porosity (micro- and
macrocavities) inside the reef, below the living surface. Both layers
play an important role in early cementation. Phototrophic cyanobacteria
probably intervene in the formation of the first encrustation zone,
whereas hetefotrophic bacteria associated to acidic, Ca2+-binding
macromolecules in biofilms are thought to contribute to the thrombolite
inside the reef body. When coral growth cannot take pace with
microbialite development, the thrombolite front reaches the surface of
the construction and finally covers the reef. The result is a thick
interval of thrombolite, which can be interpreted as being related to
an ecological crisis in coral-reef evolution. [part of extensive
summary]^1";
s[1559] = "MEYER R.K.F., SCHMIDT-KALER H. (1994).- Fazieswandel und
Probleme der Stratigraphie im Obermalm (Tithon) zwischen Solnhofen und
Neuburg &#47; D. (Bayern).- Erlanger geologische Abhandlungen 123:
1-49. [in German, with English abstract].- <b>FC&#038;P 24-2</b>, p.
101, ID=4612^<b>Topic(s): </b>facies; geology; <b>Systematics: </b>;
```

```
<b>Stratigraphy: </b>Jurassic Tith; <b>Geography: </b>Germany, Bavaria^Based on new drill core holes an attempt has been made to eludicate the intricate facies interrelationships of the Upper Malm between Solnhofen and Neuburg &#47; Donau. In the Solnhofen-Langenaltheim Basin the facies changes in the west-east direction from marl-rich shales to pure lithographic limestone of the Upper Solnhofen beds (Zeta 2b). Despite similar configuration of the basin bottom the lithographic limestone in the east measures twice the thickness of the marl-rich shales in the west. These important differences in thickness can therefore only be explained by a heavier compaction of the marl-rich sections in the course of diagenesis. The differences in relief thus generated within the basin were subsequently leveled out by differently thick sediments of the &#34;Hangende Krumme Lage&#34; (lump structures) and particularly the Mornsheim beds (Zeta 3) (see fig. 5 and 7). Even more pronounced is, of course, the change in facies between different basins. Fig. 9 shows the differing sequence in the Malm Zeta 2 and 3 above the bedded limestone of Zeta 1. While in the protected Solnhofen basin pure lithographic limestone was deposited the same series in the Rennertshofen basin was strongly affected by the reef: the rough bituminous shales rich in radiolarians and sponge-rhaxes are repeatedly interspersed with fine and coarse reef detritus beds. Here in contrast to the situation at Solnhofen the nannoplankton is present throughout. Discernible are only coccoliths and spiny, thin-skinned dinoflagellates. It can, however, be surmised that red tides of thick-skinned and pore-rich dinoflagellates (Tasmanacea) can be held responsible for the generation of bitumen and fine lamination (Meyer &#038; Schmidt-Kaler 1993), similar to the situation in the Posidonienschiefer (Toarcian). From the Malm Zeta 3 upward coral biostromes growing on decaying sponge reefs furnish reef debris to all sides. Similary bioturbated beds point to a better oxygenation of the sea bottom. Overlying these rocks are the marly limestones and shales of Malm Zeta 4 and 5 whose delineation becomes yet more difficult owing to the small scale facies changes (fig. 10). A clear cut double cycle of bedded limestones and shales (Fesefeldt 1962) does not exist. In the holes drilled near the reef (Spindeltal and Finkenstein) the fine debris content extends upward into Malm Zeta 4 and 5 and demonstrates that the reef evolution and development here in the south lasted longer. Further to the south underneath the Tertiary Molasse sediments, up to more than 500m thick sponge and coral reef detritus limestones have been proved (Meyer &#038; Schmidt-Kaler 1989 and 1990). In the Appendix (chapter 5) as well as on plates 2 to 10 the drill hole columns and special investigations (Macro-, Micro-, Nannofacies, clay minerals, geochemistry, palynology) are presented.^1";

</b>Slovenia^In the year 1988 detailed regional geological research
began in the Logatec plain area in order to make a Thematic geological
map of Slovenia in the scale of 1:50 000. On the basis of significant
and biofacies [?] as well as their superposition, the shallow water
Jurassic sedimentary sequence in the Logatec plain area was divided
into the following seven lithostratigraphic units: (1) grained
bituminous dolomite - Lower Lias, (2) lithiotid limestones and
dolomites - Middle Lias, (3) micritic and biomicritic [limestones] -
Upper Lias and Dogger, (4) oolitic limestones - Upper Dogger and Lower
Malm, (5) reef limestones - Oxfordian and Lower Kimmeridgian, (6)
bauxite - Lower/Upper Malmian boundary, and (7) Clypeina - tintinnid
limestones and dolomites - Upper Kimmeridgian and Tithonian. [...] In
the reef limestones of the Logatec Plain area seven new species of
corals and stromatoporoids were established: Allocoenia trochiformis,
Dehornella crustans, Enallhelia sp., ?Milleporidium somaense,
Plesiosmilia compressa, Pseudocoenia limbata in Thamnasteria concina.

s[1563] = "RONIEWICZ E. (2008).- Kimmeridgian-Valanginian reef corals
from the Moesian Platform from Bulgaria.- Annales Societatis Geologorum
Poloniae 78, 2: 91-134.www.asgp.pl/2008/78_2/contents.html.-
<b>FC&#038;P 36</b>, p. 102, ID=6531^<b>Topic(s): </b>hermatypic,
taxonomy, stratigraphy; reef corals; <b>Systematics: </b>Cnidaria;
Anthozoa; <b>Stratigraphy: </b>Jurassic Kimm - Cretaceous Val;
<b>Geography: </b>Bulgaria, Moesian Platform^The coral fauna of the
Late Kimmeridgian?Valanginian interval from the Slivnitsa Formation,
Lyubash monocline, SW Moesian Platform, is presented. Coralliferous
interbeds from a continuous, over 350m thick sequence of well-bedded
platform limestones, cropping out near the village of Lyalintsi,
yielded 72 species (29 determined in open nomenclature) classified into
50 genera and 23 families belonging to the orders Scleractinia and
Hexantiniaria. The following genera and/or species are described as
new: Epistreptum communeformae gen. et sp. n., Lyubasha gracilis gen.
et sp. n., Oedalmiopsis cretacaea gen. et sp. n., Siderastreites
lyalintsensis gen. et sp. n., and Latomeandra obliqua sp. n.,
Microphyllia elevata sp. n., M. amalla sp. n.; a new family
Solenocoeniidae is erected. The fauna shows a mixed Late Jurassic/Early
Cretaceous character, with Jurassic taxa prevailing over Cretaceous
taxa. Epithecate phaceloid (pseudocolonial), lamellar, and ramose
(colonial) growth forms dominate over massive (hemispherical) and
solitary corals. Rich microencrusting organisms are associated. The
predominantly pelmicritic sediment of thrombolite macrofabric, and the
character of the fauna show that the palaeoenvironment was situated
below wave base. The stratigraphical distribution of the Cretaceous
coral taxa is conformable with the micropaleontological (foraminifera,
calcareous dinocysts, diploporids) stratigraphical zonation established
in the Slivnitsa Formation. [original abstract]^1";

Scleractinia; <b>Stratigraphy: </b>Jurassic U, Cretaceous L;
<b>Geography: </b>Poland, Carpathians^Similarities between
scleractinian corals from extinct suborders Pachythecaliina Eliasova
1976 and Rhipidogyrina Roniewicz 1976 are discussed. Corals of the
```

```
former suborder are considered by some authors as possible descendants
of Palaeozoic Rugosa because of their unusual skeletal characters. Some
rhipidogyrinans, especially the family Aulastraeoporidae, despite
different septal microstructure, share more common features with
pachythecaliinans than with other scleractinians. The following
skeletal features are discussed to show similarities between these two
suborders: (1) wall microstructure and its relations to septa, (2)
corallite bilateral symmetry, (3) marginarium, (4) lonsdaleoid and
apophysal septa, and (5) internal septal margin. These similarities can
be explained by convergence, although phylogenetic relationships of
both suborders can not be excluded. This hypothesis needs to be
verified by more studies, especially on early blastogeny of
rhipidogyrinans and wall microstructure of pachythecaliinans. The
systematic part gives descriptions of discussed corals occuring in the
Stramberk-type limestones, Polish Outer Carpathians
(Tithonian-?Berriasian, ?Valanginian). Similarly as in the Stramberk
Limestone (Moravia), pachythecaliinans are highly diversified (17
species, 12 genera, including Pachythecophyllia eliasovae n.gen.,
n.sp.). Rhipidogyrinans are represented by 4 species of 4 genera,
including ?Ogilvinella morycowae n.sp. [original abstract]^1";

```

```
<b>Systematics: </b>; <b>Stratigraphy: </b>Jurassic Oxf - Cretaceous
Val; <b>Geography: </b>Bulgaria, Moesian Platform^Three sections
(Rebro, Lyalintsi and Velinovo) of the Upper Jurassic-Lower Cretaceous
carbonate sequences from the Lyubash unit (Srednogorie, Balkanides, SW
Bulgaria) have been studied for elucidation of biostratigraphy and
palaeoenvironmental evolution. Palaeontological studies of
foraminifera, supplemented by studies of calcareous dinoflagellate
cysts and corals, enabled the determination of the
Oxfordian-Valanginian age of the analysed sequences. They were
deposited on the Dragoman Block (western part of the Moesian Platform),
and during Mid-Late Cretaceous included to the Srednogorie. A possible
Middle to Late Callovian age of the lowermost part (overlying the
Bajocian-Lower Bathonian Polaten Formation) of the studied sections
assumed till now has not been confirmed by the present studies. Eleven
facies have been distinguished and attributed to depositional
environments. Marine sedimentation on a homoclinal ramp started in the
Oxfordian and till the Early Kimmeridgian - in all three sections - was
dominated by fine-grained peloidal-bioclastic wackestones to
grainstones. Since the Late Kimmeridgian, when a rimmed platform
established, facies pattern underwent differentiation into (i) the
inner platform (lagoon and tidal flat facies) - only in Velinovo, (ii)
reef and peri-reef facies/bioclastic shoals - mainly in Lyalintsi, and
(iii) platform slope - mainly in Rebro. Sedimentation generally
displays a shallowing-upward trend. Two stages in evolution of the
rimmed platform are postulated. The mobile stage lasting till the
Tithonian/Berriasian boundary was followed by a more stable stage in
the Berriasian to Valanginian time. Reefs are developed mainly as
coral-microbial biostromes, lower coral bioherms or coral thickets, in
the environment of moderate energy and sedimentation. They contain
highly diversified corals (72 species) [see Roniewicz (2009)].
Microbialites contributed to the reef framework, but they never
dominated. Locally, microencrusters and cement crusts formed important
part of reefal framework. During the mobile stage of the platform
evolution a relative sea-level rise interrupted reef development, as
evidenced by intercalations of limestones with Saccocoma. During the
second stage high carbonate production and/or regressive eustatic
events, not balanced by subsidence, decreased accommodation space,
limiting reef growth and enhancing carbonate export to distal parts of
the platform. [original abstract]^1";

habitats in the reef ecosystem, and rudist communities generally
populated the shallow-water, carbonate-sand substrates. During the
middle Cretaceous, however, coral-algal communities became less common,
and Late Cretaceous reef communities consisted of both rudist-dominated
and rudist-coral communities. In the Pyrenean basins and other basins
in the Mediterranean, coral associations co-existed with rudists
forming complex buildups at the shelf-edge. In some parts of these
```

```
buildups corals were nearly as abundant as rudists; in some complex
buildups large coral colonies encrusted the rudists. Behind the shelf
margin cylindrical, elevator rudists dominated the lenticular thickets
that were interspersed with carbonate sands. Global changes in oceanic
conditions, such as marine productivity and oxygen content, may have
stressed the deeper coral-algal reef communities leaving rudists as the
major shallow reef biota in Caribbean reefs. However, the co-occurrence
of corals with rudists in these Pyrenean complex buildups suggests that
corals were able to compete with rudists for resources. The corals in
the complex buildups generally belong to genera different from those in
the coral-algal communities. Perhaps this ecological stress in the
mid-Cretaceous resulted in the evolution of new coral taxa.^1";
s[1578] = "LUKENEDER A. (2008).- The ecological significance of
solitary coral and bivalve epibionts on Lower Cretaceous
(Valangianian-Aptian) ammonoids from the Italian Dolomites.- Acta

<b>Systematics: </b>Cnidaria Mollusca; Anthozoa Bivalvia;
<b>Stratigraphy: </b>Cretaceous L; <b>Geography: </b>Italy,
Dolomites^Lower Cretaceous deposits of the Puez section in the
Dolomites (northern Italy) yielded a rich ammonoid fauna (28 genera,
n=424) showing unique epifaunal encrustations by the ahermatypic
solitary scleractinian ?Cycloseris Lamarck, 1801. The coral encrusted
only the outer shell surfaces of the ammonoids; the inner surface
remained unaffected. such a Cretaceous community and the relationship
between the two fossil groups are described for the first time. The
shells of dead ammonoids sank to the sea bottom and became colonized by
the coral larvae, as documented by the location of the epibionts on
only one side of the shells. The coral was fixed to the ammonoid shell
for its entire life. Only the &#34;sediment free&#34; upper side of the
ammonoid shells could be inhabited by epibionts such as corals and
serpulids. The encrustation of ammonoid shells by the bivalve
Placunopsis represents a different situation in that both sides of the
ammonoid shells were affected, pointing to encrustation of floating
ammonoids. This long-term infestation in the water column contrasts
with coral settlement on the sea-floor. Ammonoid specimens encrusted by
Placunopsis never exhibit encrustation by corals. The ammonoid-coral
relationship from the Dolomites is documented from the Valanginian to
Aptian interval. examples of coral epibionts on ammonoids and other
fossil groups throughout the geological column are briefly reviewed.

and Albian limestone from Slovenski vrh is treated. Lower Orbitolina
Limestone contains foraminifers typical for Lower Aptian. Upper
Orbitolina limestone contains foraminifers of Upper Aptian - Lower
Albian age. Next to it the reef fauna of corals and rudists has been
found ascribed to Aptian and Albian stages. 13 species of foraminifers
have been determined, 6 coral species have been systematically
described (among them 2 new species), as well as rudists which belong
to 4 genera. From the paleoecological aspect the limestone with
```

```
orbitolinas was deposited in a lagoon of the shallow Dinaric platform, and in the favorable circumstances the reef organisms (rudists and corals) built the smaller patch reef.^1";
s[1581] = "SANDERS D., BARON-SZABO R.C. (1997).- Coral-Rudist Bioconstructions in the Upper Cretaceous Haidach Section (Gosau Group; Northern Calcareous Alps, Austria).- Facies 36, 1: 69-90.- <b>FC&#038;P 26-1</b>, p. 91, ID=3660^<b>Topic(s): </b>reefs, coral-rudist; reefs; <b>Systematics: </b>Cnidaria Mollusca; Anthozoa Bivalvia; <b>Stratigraphy: </b>Cretaceous U; <b>Geography: </b>Austria, N Calcareous Alps^In the area of Haidach (Northern Calcareous Alps, Austria), coral-rudist mounds, rudist biostromes, and bioclastic limestones and marls constitute an Upper Cretaceous shelf succession approximately 100 meters thick. The succession is part of the mixed siliciclastic-carbonate Gosau Group that was deposited at the northern margin of the Austroalpine microplate. In its lower part, the carbonate succession at Haidach comprises two stratal packages that each consists, from bottom to top, of a coral-rudist mound capped by a rudist biostrome which, in turn, is overlain by bioclastic limestones and, locally, marls. The coral-rudist mounds consist mainly of floatstones. The coral assemblage is dominated by Fungiina, Astraeoina, Heterocoeniina and Agathelia asperella (Stylinina). From the rudists, elevators (Vaccinites spp., radiolitids) and recumbents (Plagioptychus) are present. Calcareous sponges, sclerosponges, and octocorals are subordinate. The elevator rudists commonly are small; they settled on branched corals, coral heads, on rudists, and on bioclastic debris. The rudists, in turn, provided settlement sites for corals. predominantly plocoid and thamnasterioid coral growth forms indicate soft substrata and high sedimentation rates. The mounds were episodically smothered by carbonate mud. Many corals and rudists are coated by thick and diverse encurstations that indicate high nutrient level and/or turbid waters. The coral-rudist mounds are capped by Vaccinites biostromes up to 5m thick. The establishment of these biostromes may result from unfavourable environmental conditions for corals, coupled with the potential of the elevator rudists for effective substrate colonization. The Vaccinites biostromes are locally topped by a thin radiolitid biostrome. The biostromes, in turn, are overlain by bioclastic limestones; these are arranged in stratal packages that were deposited from carbonate sand bodies. Approximately mid-section, and interval of marls with abundant Phelopteria is present. These marls were deposited in a quiet lagoonal area where meadows of sea grass or algae, coupled with an elevated nutrient level, triggered the mass occurrence of Phelopteria. The new genus belongs to suborder Rhipidogyrina Roniewicz, 1976, family Trochoidomeandridae Turnsek, 1981. It distinguishes from the other two genera in the family - Trochoidomeandra Morycowa, 1971 and Rhipidomeandra Morycowa &#038; Masse, 1998 by the simultaneous presence of long and short radially arranged series, tectiform collines and microstructure (mid-septal clear zigzag line located between two dark parallel lines). The corallums are obtained in the terrigenous sediments from the lower part of the Lovech Urgonian Group - the Balgarene Formation, which is of Early Barremian age. [original abstract]^1";

</b>microstructures, geochemistry; Scleractinia; <b>Systematics:
</b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Cretaceous U;
<b>Geography: </b>Austria, Gosau^Extremely well-preserved specimens of
the species Rennensismilia complanat and Aulosmilia cuneiformis occur
in Santonian (Upper Cretaceous ) strata of the Lower Gosau beds, near
Gosau, Austria. Two of these, here reported, have aragonite skeletal
mineralogy and skeletal structures that are typical for their families,
and, in addition, show distribution of trace elements (Sr and Mg above
all) that confirm the biogenic origin of these structures observed. R.
complanata also has proteinaceous matrix surrounding bundles of
skeletal crystallites. Matrix is most abundant along the axial plane of
septa, which also is the first-formed part of each septum. Although A.
cuneiformis lacks observable organic matrix materials, its skeletal
strcuture and its distribution and amount of trace elements are
analogous to that seen in R. complanata and also in modern corals.^1";

solitary corals in soft-substrate habitats: the example of Cunnolites
(upper Santonian, Eastern Alps).- Lethaia 41, 1: 1-14.- <b>FC&#038;P
35</b>, p. 84, ID=2405^<b>Topic(s): </b>soft-substrate habitats;
Scleractinia, ecology; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Sant; <b>Geography: </b>Alps E^The
upper Santonian Hofergraben Member (Eastern Alps) provides an example
of a soft-substrate habitat suited mainly for solitary corals
(Cunnolites), for colonial forms of solitary coral-like shape
(Placosmilia, Diploctenium), and for colonial corals of high sediment
resistance (e.g. Actinacis, Pachygyra). The Hofergraben Member consists
mainly of silty-sandy marls of wave-dominated, low-energy shore zone to
shallow neritic environments. Substrates of soft to firm mud supported
level-bottoms of non-rudist bivalves, gastropods, solitary corals,
colonial corals, rudists, echinoids, and benthic foraminifera. Boring
and/or encrustation of fossils overall are scarce. In the marls,
Cunnolites is common to abundant. Both a cupolate shape and a
lightweight construction of the skeleton aided the coral to keep afloat
soft substrata. Cunnolites taphocoenoses are strongly dominated by
small specimens (about 1-3 cm in diameter). Cunnolites was immobile and
mostly died early in life upon, either, smothering during high-energy
events, rapid sedimentation associated with river plumes, or by
toppling and burial induced by burrowing. Comparatively few large
survivor specimens may show overgrowth margins interpreted as records
of partial mortality from episodic sedimentation or tilting on unstable
substrate. Scattered pits and scalloped surfaces on large Cunnolites
may have been produced, in some cases at least, by predators
(durophagous fish?). Post-mortem, large Cunnolites provided benthic
islands to corals, epifaunal bivalves and bryozoans. In a single
documented case of probable in vivo contact of Cunnolites with the
colonial coral Actinastraea, the latter prevailed.^1";

Prof. Geyer started his study of Biology at the Technische Hochschule
Stuttgart, but changed to Geology and Palaeontology in 1948. With his
thesis &#34;Die oberjurassische Korallenfauna von Württemberg&#34; he
finished his studies in 1952. Between 1952 and 1961 he worked as
assistant professor at the Geologisch-Paläontologisches Institut of the
Technische Hochschule Stuttgart. In 1959 he finished his Habilitation
with a work; &#34;Monographie der Perisphinctidae des unteren
Unterkimmeridgium (Wei&#223;er Jura &#947;, Badenerschichten) im
süddeutschen Jura&#34;. With that the venia legendi was bestowed on
him. Thesis and Habilitationsschrift already marked his main field of
work: Mesozoic corals and ammonoids, but he was interested in
stratigraphy and paleogeography as well. Widely known is his textbook
&#34;Grundzüge der Stratigraphie und der Fazieskunde&#34;, which was
published in two volumes in 1973. List of his works contains 115
publications. * His obituary has been published by Winfried Reiff,

s[1632] = "MASSE J.-P., MORYCOWA E., FENERCI-MASSE M. (2008).-
Valanginian-Hauterivian scleractinian coral communities from the
Marseille region (SE France).- Cretaceous Research 30, 1: 178-192.-
<b>FC&#038;P 36</b>, p. 99, ID=6519^<b>Topic(s): </b>ecology,
stratigraphy; Scleractinia, communities; <b>Systematics: </b>Cnidaria;
Scleractinia; <b>Stratigraphy: </b>Cretaceous Val - Haut; <b>Geography:
</b>France S^Coral beds associated with Valanginian and Hauterivian
platform carbonates from the Marseille region show two faunal
assemblages corresponding with a Stylosmilia-Baryphyllia community
(late Valanginian) and a Mesomorpha-Dimorpharaea community (early
Hauterivian). The stratigraphic position of this fauna is based on the
associated microfossils and correlation with ammonite-bearing beds. The
internal architecture of the coral beds is loosely packed, the geometry
of the corresponding bodies is tabulate and flat, and their
depositional setting being the deeper, muddy part of the infralittoral
zone. The biostratigraphic significance of the encountered species
which include: Stylosmilia cf. corallina, Eocomoseris raueni,
Mesomorpha ornata, Dimorpharaea catalaunica and Baryphyllia haimei, is
low and our data tend to broaden the stratigraphic range of some of
them. Assuming that the corresponding species were zooxantellate
suggests the existence of an oligotrophic rather than a mesotrophic
oceanic regime, postulated by some workers for the time span in
question. [original abstract]^1";

<b>Stratigraphy: </b>Cretaceous Barr Apt; <b>Geography: </b>France,
Provence^In the Urgonian limestones from Provence of Barremian - Early
Aptian age, 29 scleractinian species are described, belonging to 14
families and five suborders: Amphiastreina, Rhipidogyrina,
Archaeocoeniina, Stylinina et Astreoina. The suborder Stylinina
Alloiteau, 1952, is emended. Twenty genera are recognized among with
two new: Saltocyathus and Rhipidomeandra (Rhipidogyrina). Among the 29
species identified, six are new: Donacosmilia massaliensis,
Paraclausastrea valclusensis, P. pulchra, Diploastraea crassicostata.
Two species belong to the new genera (Saltocyathus urgonensis,
Rhipidomeandra bugrovae). On a European scale this fauna tends to
characterize the Barremian - Early Aptian interval and shows a strong
affinity with the Carpathian fauna even if some of the species are also
found in other regions. [original abstract]^1";

Cretaceous (Barremian-Aptian) coral communities of southern France.-
Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th
International Symposium on Fossil Cnidaria and Porifera]: 96-113.-
<b>FC&#038;P 30-1</b>, p. 20, ID=7064^<b>Topic(s): </b>ecology,
biocoenoses; Scleractinia; <b>Systematics: </b>Cnidaria; Scleractinia;
<b>Stratigraphy: </b>Cretaceous Barr Apt; <b>Geography: </b>France S^A
palaeoecological study of a significant number of Lower Cretaceous
(Barremian and Aptian) coral bearing sequences in southern France has
permitted the classification of coral bearing units according to their
litho and biofacies. Schematic depositional models have been produced,
and major developmental controls of the coral communities elucidated.
Three main types of coral bearing unit and one associated facies are
recognized, based principally upon sedimentological criteria. Sub
divisions of these groups are determined by the nature of the coral
fabric and fauna. The classification scheme comprises: (1a) biostromal
units developed within pure carbonate facies and typified by tabulo
lenticular coral colony morphotypes; (1b) a biostrome developed within
pure carbonate facies, characterized by lamellar to tabulo lenticular
colonies; (2a) biostromal units developed within mixed carbonate
siliciclastic facies, dominated by lamellar and tabulo lenticular
colonies; (2b) biostromal units developed within mixed carbonate &#47;
siliciclastic facies, dominated by phaceloid colony morphotypes; (3)
lenticular units developed in relatively pure carbonate facies with
evidence for early cementation and dominated by lamellar colonies; and
(4) coral gravels comprising numerous rounded coral fragments
associated with type 1a units. Unit types 1,2 and 3 developed under
```

```
different ranges of environmental conditions, with type 4 units the
associated facies fitting into the type 1 depositional model. Important
abiotic factors controlling development of the coral communities were:
light intensity, degree of siliciclastic input and sedimentation rate.
In contrast to many shallow marine depositional systems associated with
zooxanthellate corals, hydrodynamic energy was not an important control
on community development. [original abstract]^1";

ID=1173^<b>Topic(s): </b>reefs, overview; reefs; <b>Systematics: </b>;
<b>Stratigraphy: </b>Cretaceous; <b>Geography: </b>Alps E^During
Cretaceous times, in the area of the future Eastern Alps,
bioconstructions with corals flourished in pure carbonate and mixed
clastic-carbonate environments, each with a distinct coral assemblage.
In the early Aptian, on the Helvetic carbonate shelf, coral-sponge
biostromes and mounds with a coral assemblage accumulated that is
diversified with respect to corallite size, growth forms, polyp
integration and taxa. These assemblages grew in clear, well-lit waters
of moderate energy. Episodic, destructive high-energy events kept the
assemblage at diversification level. The coral fauna is similar to
faunas from other locations along the northern, European margin of
Neo-Tethys .In the Austroalpine domain, subsequent to a phase of nappe
stacking and emergence, upon middle Turonian to early Campanian
transgression, deposition in mixed siliciclastic-carbonate environments
prevailed. The resulting succession, the Gosau Group, contains abundant
corals in a pure coral buildup, in coral/rudist mounds, and in
coral-rudist level-bottoms. The corals grew under episodic stress from
sediment-nutrient input. Widespread red algal encrustation indicates
transient takeover of macroalgae. In mounds and level-bottoms, the
coral assemblage records sedimentation and lowered light incidence by
prevalence of taxa with large polyparia of plocoid, thamnasterioid
orcerioid integration, and of (sub)hemispherical, foliose-lamellar and
pedestal-shaped growth form; these features aid in sediment removal
and/or maximize light catchment. Coral diversity ranges from 16 species
in a pure coral buildup to 29 in coral-rudist mounds, and peaks at 36
species in level-bottoms within &#034;coral marls&#034; with abundant,
diverse solitary forms. Each coral assemblage is dominated by a few
&#034;ubiquists&#034;. The coral fauna shares species with faunas
mainly from France, Spain and Slovenia, but to a part was endemic at
```

```
least to the area of the future Eastern Alps. The coral-dominated assemblages of the Gosau Group highlight that corals can grow under low to moderately high, medium to long-term terrestrial input of siliciclastics and particulate organic matter. Fossil coral assemblages subject to sediment/nutrient stress show a range of geologically reconcilable features closely similar to Holocene &#034;turbid-water reefs&#034;.^1";

Twenty five species of corals are reported for the time from the Hungarian Cretaceous. Fossils derived from the carbonate platform are often found together with those of pelagic origin and monomictic volcanoclastics,
```

```
indicating a special sedimentary environment. Based on this study the
following model is proposed for the Early Cretaceous geological history
of the Mecsek Mountains: instead of overall uplift and erosion giant
basalt volcanoes grew above sea level until the Valanginian, whilst
bathyal conditions were preserved between them. The volcanoes were
bordered by gravel beaches, then sandy and silty lagoons, and the edges
of submarine slopes were crowned by atoll-type build-ups. Fossils and
rocks of different environments were transported down the slopes of the
volcanoes and mixed. As a result of widespread erosion during the Late
Cretaceous or Palaeogene only the basal parts of a few volcanoes are
preserved.^1";

L; <b>Geography: </b>Poland, Tatra Mts^The biostratigraphy of platform
carbonates outcropping in the Polish Tatra Mountains is reappraised
after a study of three sections located in the autochtonous (including
the Wysoka Turnia type section for Urgonian limestones) and
allochtonous tectonic units. Age assignments are mainly based on
calcareous algae, benthic foraminifera and rudists. Heterochrony of
coral-rudist facies and their associated bioclastic and orbitolinid
facies shows that the platform development and demise occurred at
different times in different places. Regional tectonic processes are
recognized as the dominant factors of these phenomena. The majority of
foraminifera as well as rudists are considered cosmopolitan whereas
some dasyclads could be potential palaeobiogeographic markers of the
Preapulian Domain. [original abstract]^1";

&#47; Paleogene; <b>Geography: </b>Slovenia SW^An integrated
sedimentological, magnetostratigraphic, and paleontological study of
the Vallcebre section (south eastern Pyrenees, Spain) is carried out in
order to define and portray the transition from the Cretaceous to the
Tertiary in a continental setting. A robust magnetostratigraphy is
correlated to the standard polarity scale in light of known
biochronological constraints (charophyte, marine invertebrates,
eggshells and other dinosaur remains). Our results show that this
section is among the thickest stratigraphic records for the continental
Maastrichtian in the Old World. Sedimentology indicates a progressive
regression from marine through lagoonal to entirely continental
environments. The section is dominated by mudstones deposited under low
energy conditions. Exceptionally, a basin-wide regression maximum is
recorded some time before the Cretaceous-Tertiary boundary (K/T). This
regression maximum is marked by the input of coarse-grained (alluvial)
sediments that record a dramatic change in the landscape (quiet mud
plains changed to sandy floodplains deposited by high-energy currents).
After a period of renewed quiescence following the regression maximum,
a Cenozoic flooding took place. Such terminal Cretaceous sequence of
```

```
events has been recorded in shorter sections in several other basins
from southwestern Europe. This energetic sediment input suggests that
some time before the K/T event, a sudden paleoenvironmental
reorganization took place in the continental basins of south western
Europe.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Cretaceous - Paleogene;
<b>Geography: </b>Alpine-Mediterranean Realm^The studies of selected
Cretaceous and Paleogene bioconstructions of the Alpine-Mediterranean
realm show a dominance of simple and complex dendriform rudist
biostromes since Albian times, especially mono- and paucispecific
monopleurid, caprinid and radiolitid biostromes until the Turonian,
radiolitid &#47; hippuritid biostromes in the Late Cretaceous. They
occurred in internal as well as external carbonate platform areas,
sometimes in open subtidal environments. Rare rudist bioherms are
limited to transgressive sequences. Massive-nodular
coral-stromatoporoid-dominant bioherms and biostromes of outer and
internal platform and carbonate ramp areas are characteristic for the
Valanginian-Aptian time interval. Rudist-dominated reef mounds can be
found frequently in Aptian-Albian and Coniacian-Campanian sequences. In
the Paleogene corallinacean-dominated coral bioconstructions are
numerous. Mainly tectonically controlled regional sealevel changes
directed the reef growth in the Alpine realm whereas high-frequency
sealevel fluctuations were responsible for the development of most of
the Mediterranean platform-based bioconstructions.^1";

<b>FC&#038;P 33-2</b>, p. 25, ID=1139^<b>Topic(s): </b>; Scleractinia;
<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Cretaceous Maas - Miocene; <b>Geography: </b>Austria^This is the
first review and compilation of Austrian scleractinian corals from the
K/T-boundary to the Miocene. The Austrian corals of the K/T-boundary
(here defined as the period MiddleCampanian-Upper Paleocene) show
closest affinities to forms that are typical of the UpperCretaceous,
especially taxa of the Turonian-Lower Campanian strata of the Gosau
Group. A firstmajor transition in the faunal composition took place
during the late Paleocene. When the &#039;typicalCretaceous forms&#039;
(e.g., Heterocoenia, Paraplacocoenia, Calamophylliopsis) disappeared
and thefirst species of modern genera (e.g., Astreopora, Acropora,
Goniastrea, Alveopora) appeared; allspecies of the latter vanished
during the Eocene together with all genera which are characteristic
ofthe Eocene-Oligocene period (Stylocoenia and Pattalophyllia) in other
geographic areas. With thebeginning of the Miocene another significant
change of the Austrian coral fauna was observed dueto the occurrence of
both numerous solitary taxa (e.g., Caryophyllia, Deltocyathus,
Discotrochus,and Flabellum) as well as colonial hermatypic genera
(e.g., Porites and Tarbellastraea).^1";

<b>Stratigraphy: </b>Oligocene; <b>Geography: </b>Italy, Liguria^1 km
south of Cairo Montenotte, a small fringing reef in limestone facies
was formed in terrigenous sediments during the Oligocene transgression.
It has a thickness of 40-60m. The lower part consists of
terrigenous-influenced to pure limestone and contains isolated corals,
```

```
or concentrations of massive corals in coral mounds. The upper part is
principally characterized by a dense framework of massive, sometimes
branching corals. The coral fauna consists of 27 species, dominated by
Goniopora ramosa or Actinacis rollei. 23 species were found on the reef
front, non of which predominate. The reef tapers off in various
directions in small units of reef limestone and biocalcarenite. The
coral fauna and the reef facies are studied in detail. The vertical
development of the coral limestones and lateral variations in the reef
core, as well as the distal facies, are described. The corals are
identified and the general character of corals and reef framework
investigated. Communities and palaeoecological relations are
described.^1";
s[1674] = "BOSSELINI F.R., PAPAZZONI C.A. (2003).- Palaeoecological
significance of coral-encrusting foraminiferan associations: A
case-study from the Upper Eocene of northern Italy.- Acta

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Eocene; <b>Geography:
</b>Italy N^Encrusting foraminiferans, although representing an
important component of the so-called cryptic assemblages in both modern
and ancient reef environments, are in general poorly described and
little is known as regards their association with corals. In this
paper, we describe coral-encrusting foraminiferan associations in the
different facies that characterize the shallowing upward parasequences
of the Nago Limestone (Upper Eocene, Trentino, northern Italy). From a
relatively deep reef slope up to the shallow shelf-edge, corals have
been recognized to be encrust4ed by different types of foraminiferan
assemblages that differ on the basis of relative abundance of species,
growth form and different type of encrusted coral surface. The
succession of encrusting foraminiferan assemblages is interpreted as
controlled mainly by light, competition with coralline algae,
hydrodynamic energy, and coral growth fabric.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Oligocene Rup;
<b>Geography: </b>Italy N^The Castelgomberto Limestone is a 200m thick
unit of Early Oligocene age (Rupelian) outcropping in the Eastern
Lessini Mountains (Southern Alps of Northern Italy). The internal
cyclic organization of this Oligocene unit is described and analyzed on
the basis of four selected sections; about thirteen well-bedded
grainstone units alternate with marly horizons rich in corals. This
peculiar cyclicity is here interpreted as a response to variation in
platform hydrodynamics, i.e. to smaller eustatic fluctuations affecting
the Lessini Shelf reef-lagoonal complex. During highstand periods, the
shelf was open and relatively deep (20-50 m), and tidal currents and
periodic storms were able to distribute bioclastic sands (bars, sand
waves and spillovers). During lowstand the shelf was more protected by
the occurrence of mariginal reefs and was colonized by patches of
poritid corals, mainly branching. Moreover, the largely exposed
northern areas supplied fine detritus to the shelf itself.^1";

<b>Systematics: </b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Eocene;
<b>Geography: </b>Spain, Pyrenean Foreland^An integrated field,
petrographic, and geochemical study has determined the fluid-rock
interaction history in part of an Eocene reef complex on the margins of
```

```
the siliciclastic-dominated Catalan sector of the South Pyrenean
foreland basin. Results show that at least four distinct fluid systems
influenced the basin margin, and demonstrate the sensivity of reef
rocks as paleohydrological archives in siliciclastic environments. The
earliest calcite cements precipitated from meteoric waters at shallow
burial depths, and mineralogical stabilization of reef carbonate was
mostly completed during this episode. Textural and isotopic trends
typical of paleoexposure surfaces are lacking, and trace elements
results suggest that meteoric waters were transmitted laterally and/or
upward into the reef via delta-lobe sandstone aquifers. The
distribution of late cements is highly variable and fracture-fed,
demonstrating the importance of deformation in controlling fluid flow
subsequent to reef lithification. Isotopic and elemental compositions
of burial calcites, plus their paragenetic association with barite and
dolomite, show that fluids of marine parentage were expelled from
compacting.^1";

s[1679] = "BOSSELINI F.R., PERRIN C. (1994).- The coral fauna of
Vitigliano: qualitative and quantitative analysis in a back reef
environment (Castro Limestone, Late Oligocene, Salento Peninsula,
Southern Italy).- Bolletino della Societa Paleontologica Italiana 33,
2: 171-181.- <b>FC&#038;P 24-1</b>, p. 54, ID=4460^<b>Topic(s):
</b>ecology; Anthozoa; <b>Systematics: </b>Cnidaria; Anthozoa;
<b>Stratigraphy: </b>Oligocene Chatt; <b>Geography: </b>Italy S^The
Castro Limestone, Middle Chattian in age, consists of various reef
facies and has been described as a fringing reef complex developed
along the Cretaceous-Eocene rocky coast of the Salento Peninsula. The
reef facies outcropping near Vitigliano and the associated coral fauna,
which have been previously interpreted to be part of a back reef
subenvironment, are here defined both qualitatively and quantitatively.
Together with palaeontological and sedimentological observations, three
main quantitative methods have been used for the characterization of
the back reef facies: 1) count of coral colonies on a subvertical
measured surface, 2) line-transect, 3) quadrat. The composition of the
coral was identified in the field mainly at the generic level and
```

```
abundance of different genera has been analyzed. The results obtained
from the various quantitative methods were compared and discussed.
Moreover, the coral density has been quantified from both linear and
area measurements and has been evaluated to be around 20%. However,
corals occur as scattered colonies and do not form a true framework.^1";

Oligocene coral and algal reef and related facies of Valzemola (Savona,
NW Italy).- Rivista Italiana di Paleontologia e Stratigrafia 100, 1:
423-456.- <b>FC&#038;P 24-1</b>, p. 84, ID=4519^<b>Topic(s): </b>reefs;
reefs; <b>Systematics: </b>Cnidaria algae; Anthozoa; <b>Stratigraphy:
</b>Oligocene; <b>Geography: </b>Italy NW^The terrigenous and carbonate
sediments of the transgressive Oligocene cycle of the Tertiary Piedmont
Basin outcropping in the area of Valzemola (Savona, western Liguria,
Northwest Italy) and which are referable to the Molare Formation are
analysed. The terrigenous sequence, represented by breccias,
conglomerates and sandstones, overlies with an angular unconformity
dolomitic or calcareous-dolomitic lithologies referable to the San
Pietro dei Monti Dolomite Formation. These sequences are locally
characterized by rich associations of coralline algae and corals, which
by providing a stable substrate allowed the development of a true reef
buildup. Subsequently the bioherm was suffocated by fluvial sandstone
and conglomerate. This may be associated with an intensification in the
amount of terrigenous material being brought into the basin. A
progressive shallowing continues until the introduction of conditions
suitable for calcareous deposition in an intertidal or supratidal
environment. The analysis of this reef deposit was carried out by
examining seven stratigraphic sections. The paleoecological study of
the coral fauna and the algal assemblage, the latter characterized by
the significant presence either of the genus Lithophyllum, or of
Lithothamnion, allowed some hypothesis on the environmental conditions
which characterized this sector during the Late Oligocene. Nine
different facies could be shown, from those seven directly connected to
the reef and two to nearshore environments proving a regressive phase.
Facies I: conglomeratic-sandstone representing a stage of colonization
in a dominantly terrigenous environment. Facies II: coral framestone,
representing a stage of diversification (&#034;an inner reef
front&#034; near to the &#034;reef crest&#034;).Facies III: coral
```

```
bafflestone representing a colonization stage in an &#034;inner reef
slope&#034;. Facies IV: coral bindstone representing a stage of
domination in a &#034;reef crest&#034; environment. Facies V: coral
bindstone alternating with floatstone, gives evidence of a colonization
stage in a carbonate environment. Facies VI: coral and algae
floatstone, representing a facies of accumulated reef debris. Facies
VII: coral rudstone, representing an accumulation facies comparable
with that of the &#034;rubble &#038; pavement zone&#034; of the back
reef. Facies VIII: conglomerates and sands of a shallow marine
environment, represent a regressive sequence. Facies IX: massive
limestones with undulated-zoned structures, rhizoliths, calcite veins

is a molasse basin with thick sequences of predominantly terrigenous
sedimentary rocks. Nevertheless, coral growth occurred during short
periods in the Early and Late Oligocene: (1) a coral reef formed during
the initial phase of basin subsidence on a palaeotopographic high, and
(2) during a regressive stage in the Late Oligocene when shallow
sublittoral conditions prevailed. The fauna of the coral reef is highly
diverse (31 species &#47; 25 genera) and is composed of massive
dome-shaped, bulbous, branching, foliaceous, and solitary species. Like
other Oligocene coral faunas from the central Mediterranean Tethys, the
coral fauna is rich in members of the family Faviidae (Caulastraea,
Favites, Hydnophora, Leptoria, Montastraea) and Agariciidae
(Cyathoseris, Leptoseris, Pavona). The second coral horizon is
dominated by allochtonous branches of Acropora, massive growing
colonies are associated and partly use these accumulations as
substrate. These accumulations are interpreted as former densely
growing thickets of lagoonal environments which were destroyed by storm
events. Again, the most important genera are found in the family
Faviidae (Agathiphyllia, Antiguastrea, Hydnophora, Montastraea,
Tarbellastraea). This study presents for the first time a comprehensive
taxonomic study of Early and Late Oligocene corals from Greece. It is
the first time that an Acropora dominated assemblage is reported from
sedimentary sequences as old as the Late Oligocene. This study
concentrates on the taxonomic description of the coral fauna.^1";

<b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy: </b>Eocene
U; <b>Geography: </b>Italy N^During the Late Eocene, shelf-edge patch
reefs developed on the western margin of the Lessini Shelf. The coral
fauna, studied in the Nago Limestone type locality, is described and
interpreted for the first time, and provides further data for better
understanding of the generally poorly known Eocene reef communities. *
Facies analysis was carried out across the shallowing upward succession
that characterizes the well exposed type-section of the Nago Limestone.
Four distinct facies are identified and a detailed
qualitative-quantitative investigation has been applied to the
coral-bearing facies in particular, in order to describe and quantify
the distribution and palaeoecological zonation of corals. * By a
comparison of sedimentological and palaeoecological data, it is
possible to reconstruct a depositional model of the Nago Limestone at
its type locality. In particular, the palaeoecological study clearly
reveals that corals change with depth in taxonomic composition, in
percentage and proportion within the framework and in growth form,
allowing the definition of a relative depth coral zonation. * Three
coral associations are recognized from the base to the top of the
shallowing upward sequence. These differ from each other in the
relative abundance of main reefbuilders, in the growth form exhibited
by corals in growth position and in the density of the reef framework.
These variations are interpreted as responses to major environmental
controls which prevailed during the deposition of the different facies
(mainly light intensity and hydrodynamic energy). * The coral
speciesActinacis rollei Reuss is the most abundant and ubiquitous coral
of the Nago Limestone. Its adaptation to low-light levels is described
here for the first time, confirming the high plasticity of this
important Paleogene reef-builder. * The results of the present study
are finally compared with data from other Middle-Late Eocene European

Actinacis; <b>Systematics: </b>Cnidaria; Scleractinia; <b>Stratigraphy:
</b>Oligocene; <b>Geography: </b>Italy N^The scleractinian coral
Actinacis is an important component of reef communities from the
Oligocene Lessini Shelf of Northern Italy. The coral-rich
Castelgomberto Limestone of Rupelian age contains abundant Actinacis
that occur as massive-laminar colonies or thin to thickly branched
thickets. These two growth forms respectively dominate the coral
assemblages in the alternating biocalcarenite and marly facies that
compose the Castelgomberto Limestone. In the present study, we have
used a combination of discriminant analysis and principal component
analysis of corallite measurements to show that these two distinct
colony morphs cannot be distinguished on the basis of corallite
characteristics. Thus, the two growth forms represent a single species,
A. rollei, with a colony shape that varied as an autoecological
response to the differing environmental conditions that prevailed
during deposition of the two facies. The massive to laminar growth form
probably developed as a response to the unstable coarser-grained
substrate and higher wave energies represented by the biocalcarenitic
facies. The branched form is most probably adapted for coping with the
large volume of fine grained sediment deposited in the quiet water,
marly lagoonal environments of the Oligocene Lessini Shelf. Similar
coral morphologies are found among modern corals in analogous reefal
environments, although few living coral species possess a range of
shape variation comparable to that of A. rollei. This plasticity of
colony form could be partly responsible for A. rollei dominance in many
Oligocene reef communities.^1";

As reconstructed from several measured sections, the Castro Limestone, which is Middle Chattian in age from our own data, disconformably mantles a tectonically deformed falaise of Cretaceous-Eocene rocks and is overlain by a remarkable erosional surface characterized by a very peculiar rhodolite rudstone. The Castro Limestone unit can be considered as a classic unconformity bounded depositional sequence representing, most probably, a shelf margin prograding complex, related to the major Middle Oligocene sea level lowstand. Stratigraphic and sedimentologic features, together with paleontological characters, allow recognition of a virtually complete range of reef environment across the reef profile. Several geomorphic zones and associated facies are described, from the most landward reef area (&#034;back reef&#034;) across the reef flat and reef front downward to the fore reef slope, contributing to better knowledge of the evolution of Oligocene reefs and reef communities in Italy and in the Mediterranean area.^1";
s[1697] = "DARGA R. (1992).- Geologie, Palaeontologie und Paloekologie der sudostbayerischen unter-Priabonen (Ober-Eozaen) Riffkalkvorkommen des Eisenrichtersteins bei Hallthurn (Noerdliche Kalkalpen) und des Kirchberges bei Neubeuern (Helvetikum).- Muenchner Geowiwss. Abh. A23: 1-166.- <b>FC&#038;P 21-2</b>, p. 54, ID=3352^<b>Topic(s): </b>reefs, geology; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Eocene Pria; <b>Geography: </b>Alps^Litho-, bio-, as well as palecological analysis of two Lower Priobanian (Upper Eocene) reef complexes (Eisenrichterstein near Hallthum, Northern Calcareous Alps and Kirchberg near Neubeuem, Helveticum) enable depositional reconstruction models to be established. Based on these analyses, significant deviation from previous models is suggested. The Eisenrichter complex, whose tectonic control has for the first time identified, constitutes rocks derived from a beach area (conglomerates), a lagoon (calcarenites), and a reef complex (coral limestones and associated rocks). The reef complex is characterized by distinctive bedding and the absence of a reef core. Consequently, the Eisenrichterstein complex can be regarded as a carbonate ramp. The coral limestones of Kirchberg are olistholithes. The Kirchberg quarry may, therefore, be considered as an olisthostrome exposure which is genetically related to the turbiditic Lithothamnium limestones of the Rohrdorf quarry. The geology of the southern margin of the Intrahelvetic High, from which the Kirchberg olisthostrome is derived, can be updated, due to data
```

```
gathered from the Kirchberg region and the accompanying olistholithes.
The depositional model depicts a shelf rimmed with algal
bioconstructions. The qualitative determination of fauna provided
evidence of many different taxa (foraminifera, bivalves, gastropods,
corals, bryozoans and echinoderms), which are treated in the second
part. The corals Stylocoenia polypostyla n.sp., Astreopora schedakena
n.sp., Ewaldocoenia pollaplasia n.sp., Cyathoseris krepidoblasta n.sp.
and the gastropod Turritella caecisutilis n.sp. have been newly
described.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Paleocene; <b>Geography:
</b>Italy, Maiella platform^The Maiella platform provides an example of
the innovation and evolution of coral-algal reefs during the Paleocene.
After the disappearance of rudist-dominated reefs around the Cretaceous
&#47; Tertiary (K/T) boundary, coral-algal reefs grew along the
platform margin and top during two subsequent sealevel highstands in
the Danian-Early Thanetian and Late Thanetian. The Danian-Early
Thanetian reef communities are more diverse, and the constructional
types more evolved than those previously known from this time. The
Danian-Early Thanetian coral association differs from the Upper
Thanetian association and from upper Cretaceous coral faunas,
indicating that it represents a distinct evolutionary phase. Repeated
emergence of the Danian-Early Thanetian reefs resulted in a complex
diagenetic history. All these Paleocene reefs were displaced by
gravitative redeposition.^1";
s[1699] = "VECSEI A., MOUSSAVIAN E. (1997).- Paleocene Reefs on the
Maiella Platform Margin, Italy: An Example of the Effects of the
Cretaceous &#47; Tertiary Boundary Events on Reefs and Carbonate
Platforms.- Facies 36, 1: 123-140.- <b>FC&#038;P 26-1</b>, p. 93,
ID=3661^<b>Topic(s): </b>reefs, facies, events; reefs; <b>Systematics:
</b>; <b>Stratigraphy: </b>Paleocene; <b>Geography: </b>Italy, Maiella
platform^Reef facies, reef types and their biotic associations in the
Maiella platform margin (central Italy) provide qualitative evidence
for a significant reef decline across the Cretaceous &#47; Tertiary
(K/T) boundary, and indicate two phases of reef recovery during the
Paleocene. Rudists dominated the reef community until the latest
Cretaceous. A significant sea-level fall around the time of the K/T
boundary is documented by a truncation surface associated with
emersion. During sea-level highstands in the Danian to Early Thanetian
and, more extensively, during the Late Thanetian, coral-algal
patch-reefs grew along the platform margin and top. Already in the
Danian to Early Thanetian, the reef communities were more diverse and
the constructional types more evolved than previously known from this
time. Differences between the Danian to Early Thanetian coral
association, the Late Thanetian association, and Late Cretaceous coral
faunas may have ecological or evolutionary causes. Repeated emergence
produced a complex diagenetic history in the Danian to Lower Thanetian
limestones. All Paleocene reefs were displaced by gravitative
redeposition. Coral-algal reefs are less important in the Early to mid
Eocene, when alveolinid foraminifera dominated on the Maiella shelf.
Reefs on the Maiella platform diversified and attained large sizes in
the Late Eocene to Early Oligocene, as known from other Mediterranean
platforms. The external controls on the Late Cretaceous to Oligocene
evolution and demise of reef communities that are most easily
demonstrated with our data are sea level fluctuations and climate
change. We propose that the change in reef biota and reef types across
the K/T boundary and during the Early Tertiary were important causes of
the parallel changes in platform growth style.^1";

Coral patches and small patch-reefs developed here in a lagoon environment, not having yet found any evidence of the existence of a barrier-reef in the most distal counterparts. Maximum extent of the reef environment occurred during the Upper Priabonian and Lower Stampian. The study of corals yielded 23 species in 18 genera, most of these are reported for the first time in the Balearic Islands. The new species Acropora ramosi is described. ^1";
s[1703] = "MARTINIUS A.W., MOLENAAR N. (1991).- A coral-mollusc (Goniaraea-Crassatella) dominated hardground community in a siliciclastic-carbonate sandstone (the Lower Eocene Roda Formation, Southern Pyrenees, Spain).- Palaios 06: 142-155.- <b>FC&#038;P 23-2.1</b>, p. 32, ID=4226^<b>Topic(s): </b>hardground biocoenoses; hardground community; <b>Systematics: </b>; <b>Stratigraphy: </b>Eocene L; <b>Geography: </b>Spain, Pyrenees^Provided sufficient time is available, hardground faunas may develop in mixed siliciclastic-carbonate sandy environments. The coral Goniaraea elegans and the bivalve Crassatella depressa are the dominant members of a Lower Eocene clastic hardground community, which developed on top of a
```

```
mixed siliciclastic-carbonate sandstone body. Sedimentological data
indicate that the sandstone body was formed in a shallow marine,
tidally influenced deltaic environment. Hardground formation was
initiated by the development of an early carbonate fringe-cement,
matrix infiltration and bioturbation. Initially, these processes caused
the formation of cemented nodules. When clastic sedimentation ceased
long enough, these nodules accreted into laterally continuous
concretionary layers. In a few cases only, a pause in sedimentation
lasted long enough for settlement of a typical hardground community.
The latter hardgrounds can be easily recognized on the basis of
paleontological criteria. This fauna is dominated by a
Goniaraea-Crassatella assemblage; the associated fauna consists mainly
of epifaunal or shallow infaunal species. Sponge boring in C. depressa
valves has been intense and gives further evidence for a prolonged
cessation of sedimentation in this shallow environment. The boulder
shape of the hermatypic coral Goniaraea elegans is an ecomorph
adaptation to slightly turbulent, but shallow and clear marine hard
bottom environments.^1";
s[1704] = "MOUSSAVIAN E., VECSEI A. (1995).- Paleocene reef sediments
from the Maiella carbonate platform, Italy.- Facies 32: 213-222.-
<b>FC&#038;P 24-2</b>, p. 102, ID=4614^<b>Topic(s): </b>reefs,
sediments; reefs; <b>Systematics: </b>; <b>Stratigraphy: </b>Paleocene;
<b>Geography: </b>Italy, Maiella platform^Upper Cretaceous and
Paleocene reef limestones from the Maiella carbonate platform show how
reefs evolved during a time of faunal turn-over. Biostratigraphy and
facies analysis of the reef limestones reveal the details of reef
growth, composition, and age. Rudists disappeared as reef builders from
the Maiella platform shortly before the Cretaceous &#47; Tertiary
boundary. Small coral-algal reefs became established in the Danian to
Late Thanetian. These scleractinian-red algal dominated boundstones and
framestones represent two periods of reef sedimentation and the
subsequent interruption of reef growth by emersion and erosion,
controlled primarily by fluctuations of relative sea-level. The
coral-algal reefs evolved as the taxonomic composition of reef
organisms changed. The Paleocene reef sediments are preserved as large
slide blocks and as boulders redeposited from the shallow-water
platform onto the slope during the course of the Paleocene.^1";
s[1705] = "SAVAZZI E. (1982).- Commensalism between a boring mytilid
bivalve and a soft bottom coral in the Upper Eocene of Northern Italy.-
Paläontologische Zeitschrift 56, 3/4: 165-175.- <b>FC&#038;P 12-1</b>,
p. 44, ID=6187^<b>Topic(s): </b>commensalism; bivalve coral
commensalism; <b>Systematics: </b>; <b>Stratigraphy: </b>Eocene;
<b>Geography: </b>Italy N^The mytilid bivalve Botula cordata (Lamarck)
from the Upper Eocene of the Venetian region, northern Italy, bored
into live soft bottom corals, which reacted by forming a calcareous
interseptal filling around the borehole. A chemical etching mechanism
is inferred from the presence of &#034;etch marks&#034; on the borehole
walls. The association with free-living corals capable of counteracting
burial by sedimentation or accidental overturning enhanced the survival
potential of the bivalve on the soft bottoms. Commensalism with soft
bottom corals appears to have evolved convergently at least three times
within the Mytilidae, but is unknown among other bivalves. [original

Aquitaine Basin^A new species of the genus Epiphaxum (family
Lithotelestidae) is described and illustrated in detail, and compared
to other species. Epiphaxum arbuscula sp.nov. has been collected from
Upper Eocene (Priabonian), Upper Oligocene (Chattian) and Lower Miocene
```

```
(Upper Burdigalian) deposits of the Aquitaine Basin, south-west France. Epiphaxum is a poorly documented genus but its fossil record extends back to the Late Cretaceous; it was previously known only from the Paleocene (Danian). Epiphaxum arbuscula differs from all others species of the genus in the form of its colony. In contrast to the creeping colonies of previously known species, it has branched colonies. It is very common at one Upper Oligocene outcrop from which an assemblage with submarine cave remains has been described. A close relationship between the three extant species (two from the Caribbean Sea and one from the Indo-West Pacific region) and the Paleogene species is also noted. These constitute a group that has not undergone any important morphological changes for the last 65 million years. [original abstract]^1";

The succession of initiation and development of the microbial crusts is described in relation to the reef architecture. The main features of the palaeoenvironment are discussed., with focus on the associated invertebrate faunas, mostly corals, molluscs, bryozoens, and crabs. We conclude that the microbial crusts developed under normal marine conditions and were a significant contributor to reef framework development, including strengthening through calcification of the microbial organisms. Microbiolites are anticipated in other Early and Middle Miocene coral reef occurrencies of the Mediterranean-Paratethys realm, and to date may have simply escaped positive recognition.^1";

The morphometric analysis of several colonies of Cladocora caespitosa (Linnaeus) is based on measurements concerning both the colony and the individual corallites. The significant correlations obtained from a statistical analysis indicate that the regular and unchanged growth of the bioconstructions occurred in quite a dim environment, and a deep infralittoral allocation is also suggested by the associated molluscan fauna. The paleoenvironment suffered a sudden, strong sediment input, correlated to tectonic activity, which caused the burial of the colonies. The re-colonization of the bottom took place while the bathymetric conditions remained unchanged. The definitive burial of the coral bank is marked by a transgressive phase which yielded the deposition of circalittoral clayey sediments. [original abstract]^1";

In the Scannelle quarry near Belsito (Cosenza), four stratigraphic sections were studied to define the sedimentological and paleoecological setting. The carbonate body records the development of a deep-water coral bank characterized by a low-diverse community of azooxanthellate scleractinian (Oculina and Dendrophyllia) and stylasterine hydrozoans colonies. Two main stages of bioconstruction development can be distinguished: a thicket and a bank stage. Among the biostromal dwellers the more common are bryozoans, echinoids, benthic foraminifers, gastropods, and bivalves. A higher content of planktonic foraminfers occur in the thicket stage. The coral bank flourished within the aphotic zone, with deep currents loaded with nutrients and siliciclastic sediments.The upper part of the &#34;Calcare di Mendicino&#34; carbonate body has been affected by a pervasive dolomitization destroying almost completely the sedimentary structures and the biofacies. The lower part, the main object of this paper, preserves the microfacies but it experienced a widespread recrystallization obliterating the primary geochemical characteristics. The diagenetic history, partly hidden, reveals three main stages: primary marine with isopachous fibrous cements, deep burial with cavities infilled by sparry calcite, and meteoric-phreatic with dog-tooth cements.^1";
s[1728] = "PERRY C.T. (1996).- Distribution and Abundance of Macroborers in an Upper Miocene Reef System, Mallorca, Spain: Implications for Reef Development and Framework Destruction.- Palaios 11, 1: 40-56.- <b>FC&#038;P 25-2</b>, p. 41, ID=3126^<b>Topic(s):
```

```
</b>reefs, macroborers; macroborers; <b>Systematics: </b>;
<b>Stratigraphy: </b>Miocene U; <b>Geography: </b>Spain, Mallorca^The
importance of boring organisms within reef environments, as agents of
framework destruction, and thus as controls to rates of reef accretion,
has been widely recognized. Relatively little, however, is known about
variations in the distribution of macroborers (principally sponges,
bivalves and worms), within individual reef systems. The Upper Miocene
reefs of Mallorca present a unique opportunity in which to assess such
distributional variations. Borings are preserved as casts within the
molds of former corals, and these trace fossils typically exhibit
highly characteristic morphologies. Based on the distribution of
different bore morphologies, it has been possible to assess variations
in both the distribution and abundance of individual borers, and the
intensity of boring activity across the reef system. Different parts of
the reef are characterized by different associations of boring
organisms, with the highest diversity of borers, and the most intense
boring activity, observed within corals from the lagoonal facies. The
principal control on distributional patterns appears to have been the
morphology and structure of the reef framebuilders. Massive corals are
always more extensively bored, and typically contain a higher diversity
of boring organisms than branched or platy corals. On a more local
scale, variations in sediment accumulation rates, and degree of
substrate encrustation appear to have exerted some degree of control.
Rates of reef accretion would have been influenced not only by the
abundance of different boring organisms in different parts of the reef,
but on the response of different framebuilders to boring activity.
Platy and branched corals, whilst typically less intensely bored, would
have been more vulnerable to the effects of boring, while massive
corals, which were often extensively bored, were more capable of
surviving such damage. This preservational bias has important
implications for interpreting styles and rates of reef accretion.^1";

</b>; <b>Stratigraphy: </b>Miocene U; <b>Geography: </b>Spain,
Mallorca^The upper Miocene Reef Complex of Mallorca is a 20km
prograding unit which crops out in sea cliffs along the southern side
of the island. These vertical and exceptionally clean outcrops permit:
(i) identification of different facies (lagoon, reef front, reef slope
and open platform) and their geometries and boundaries at different
scales, ranging from metre to kilometre, and (ii) construction of a
6-km-long high-resolution cross-section in the direction of reef
progradation. This cross-section shows vertical shifts of the reefal
facies and erosion surfaces linked to a general progradational pattern
that defines the accretional units. Four hierarchical orders of
magnitude (1-M to 4-M) of accretional units are identified by
consideration of the vertical facies shifts and by which erosion
surfaces are truncated by other erosion surfaces. All these orders show
similar patterns: horizontal beds of lagoonal facies in the upper part
(landward), reefal and slope facies with sigmoidal bedding in the
central part and open-platform facies with subhorizontal bedding in the
lower part (basinwards). The boundaries are erosion surfaces,
horizontal over the lagoon facies, dipping basinwards over the
reef-front facies and connecting basinwards with their correlative
conformities over the reef-slope and open-platform facies. [first
fragment of extensive summary]^1";

coralgal facies; <b>Systematics: </b>; <b>Stratigraphy: </b>Miocene
Bad; <b>Geography: </b>Ukraine, Fore-Carpathian Basin^A peculiar
coralgal facies is recognized in the Lviv-Ternopil region, Ukraine,
from the northern shores of the Middle Miocene (Badenian)
Fore-Carpathian Basin. Its complex structure is dominated by algal
buildups composed of interfingering red-algal (lithothamnian) colonies
and blue-green-algal crusts, associated locally with numerous
hermatypic corals (Tarbellastraea reussiana, Porites vindobonarum
prima), either isolated, or overlapping each other. The holes amidst,
and the crevices in, the buildups are filled with coarse bioclastic
sediment (shell-grit), burrowed commonly by crustacean decapods
(alpheid shrimps). The alpheid burrows, filled with coarser or finer
shell-grit, served frequently as taphonomic traps for crustacean
decapods (squat lobsters and crabs) and echinoids. Special attention is
paid to the activity of rock-boring bivalves (Jouannetia semicaudata,
Lithophaga lithophaga) in coralgal buildups and/or in particular coral
colonies, some of which are redeposited, and riddled densely by bivalve
borings. Emphasis is given to the environmental significance of alpheid
shrimps, the tiered burrows of which are recorded in the
Fore-Carpathian Basin for the first time. Crustacean decapods and
echinoids are systematically studied. A comparison of the studied
coralgal facies with others of the Lviv-Ternopil region, and those from
the territory of Poland, indicates their faunistic and biogeographic
identity. [original abstract]^1";

theGulf of Corinth Field Trip, Patras University, Greece, Patras,
September14-16, 1998}. Reef history has four phases: a) growth and
lithificationof reef; b) development of smooth-walled dissolution pipes
and caves inthe reef; c) colonisation of dissolution surfaces by Mn-Fe
crusts (thatmay be bacterially formed), barnacles, serpulid worms, and
rock-boringbivalves; and d) uplift to present position where much of
the reef iseroded. Sea-level history after 11,500 years BP, when rising
post-glacialsea level overtopped the Rio sill and returned the Gulf of
Corinth to amarine environment, is reconstructed. Calculations of
interplay betweensea-level rise and tectonic uplift suggest that
between 11,500 and 10,000years BP sea level rose very quickly,
associated with deglaciation at theclose of the Younger Dryas, MWP-1B,
at a maximum of 25.6 mm/year(broadly consistent with other studies),
then slowed to ca. 4.4 mm/yearuntil 6000 years BP when sea level was
ca. 3 m below modern, afterwhich sea level rose at ca. 0,5 mm/year to
modern day. Tectonic upliftrate of maximum 3 mm/year, slower than
sea.level rise, means that thereef could not catch up to sea level
until recent times.^1";

<b>FC&#038;P 25-1</b>, p. 11, ID=2998^<b>Topic(s): </b>geomorphology,
coastal instability; <b>Systematics: </b>; <b>Stratigraphy:
</b>Quaternary; <b>Geography: </b>Italy, Sicily^The eastern flank of
Mount Etna, Sicily has been recognized as being unstable, and three
contrasting models have been proposed to account for this phenomenon,
these being deep-seated spreading, shallow sliding and tectonic block
movements. These models are examined by making reference to the rates
and patterns of crustal movement along the eastern coastline of Sicily
as determined from palaeoshoreline data. The south-eastern coastline of
Sicily (Portopalo to Catania) provides no evidence of Holocene
emergence. In contrast the volcanic coastline (Catania to Capo Schiso)
and the northeastern shoreline (Taormina to Milazzo) display widespread
evidence of coastal emergence. Radiocarbon dated remains indicate that
both the volcano and northeastern Sicily have been uplifted at a rate
exceeding 1.5mm per annum during Holocene times, although more recent
rates of uplift may have been greater. The pattern of uplift suggests
that the northeastern coastline of Sicily, including the volcanic
edifice, is apparently uplifting as a coherent unit, with superficial
flank movements being superimposed on a regionally uplifting
sub-volcanic basement. [original abstract]^1";

```

```
</b>; <b>Geography: </b>Germany, Bavaria^The drill hole Moosburg 4
intersected 985m of Tertiary and Cretaceous sediments followed by 134m
of Purbeck-facies and the whole of the Malm with a thickness of 453m
wich was cored through-out. The Malm alpha and beta (Oxfordian, 67m
thick) an the Malm gamma (Lower Kimmeridgian, 30-35m thick) underneath
the Molasse could be compared bed by bed with the equivalent beds in
the Franconian Alb and their identical development could be shown in
detail. The individual marl beds of the Malm gamma in particular could
be traced in similar thickness over a distance of 100km thus reflecting
the very quiet depositional conditions on the southern Bavarian
platform. The sponge limestones and dolomites of the Malm delta/epsilon
(Middle/Upper Kimmeridgian) show a similar thicknesses in both areas of
approximately 100m (here a leveling out of the relief by shallowing of
the sea occurred at the boundary between Malm delta/epsilon). Two
sections, one from Neuburg to Ampfing (fig. 9), the other from Anzing
to Giftthal (fig. 10), however, show the variable facies developments
in the platy limestones and the shallow water reefs of the Malm zeta
(Tithonian). The microfacies proves an increasing constriction of the
sea basin beginning at different points in time in the individual
basins and reaching its climax in the evolution of the saline facies of
the Purbeck. Without a sharp boundary the partly fossil-rich limestones
of the Upper Malm pass into the fossil-free limestones and dolomites of
the Purbeck with its characteristic dark &#034;tonflaser&#034; texture.
Oolites, evaporitic laminites and solution breccias are interspersed
throughout. In the Moosburg area a clear subdivision into a lower
oolitic and an upper breccia bearing Purbeck is absent.^1";

reef complex (Male Karpaty Mts., Western Carpathians): isotope
geochemistry, cathodoluminescence, and fluid inclusion data.- Geologica
carpathica 45, 4: 239-254.- <b>FC&#038;P 24-2</b>, p. 107,
ID=4620^<b>Topic(s): </b>reef complexes, stable isotopes; reef complex,
stable isotopes; <b>Systematics: </b>; <b>Stratigraphy: </b>???;
<b>Geography: </b>Slovakia, Carpathians^The void structures of the
Veterlin Limestone are cemented by radiaxial fibrous calcite (RFC),
which originated by transformation from the original metastable forms
of carbonate. In the transmitted light, the cement of the remaining
pores is shaped as blade and blocky pseudospar, while under
cathodoluminescence it is structured as zonal luminescent scalenohedral
calcite (SHC) and dull euhedral calcite (EHC). Nucleation of neomorphic
pseudospar on crystals of predate high-Mg cement occurred in conditions
of relatively shallow burial. Saddle dolomite is an another product of
the burial diagenesis. Seawater values of &#948;18O (-1.2 to -4.5‰) and
&#948;13C (+1.5 to +4.1‰) or marine values influenced by mixing (values
with a wider distribution of &#948;13C) are characteristic for isotopic
composition of cements in the Veterlin Limestone. The final generation
of cements (blocky pseudospar BPS) shows the influence of burial fluids
with depletion of &#948;18O (-6 to -9‰) and preservation of positive
values of &#948;13C (marine burial trend). The calculated isotopic
temperatures from cements ranged between 18 to 60 ˚C. Homogenization
temperatures of fluid inclusions are not consistent with
crystallization temperatures of the burial cement, in accordance to
their reequilibration under overheating and neomorphism. The Th of the
fluid inclusions (155 - 350 ˚C) probably correspond to the
peak-temperature conditions of the Veterlin Limestone, which is also
partly the same as that obtained from the CAI of conodonts (110 - 200
˚C). The presented diagenetic (cementation) model reflects more really
our knowledge about the depositional conditions and also spatial
distribution of facies in the Veterlin reef complex.^1";

sponge from North America, its relationship to archaeocyaths and the
nature of early sphinctozoans.- Geol. Mag. 127, 5: 435-443.-
<b>FC&#038;P 20-1.1</b>, p. 71, ID=2856^<b>Topic(s): </b>; Porifera,
Sphinctozoa; <b>Systematics: </b>Porifera; Sphinctozoa;
<b>Stratigraphy: </b>Cambrian; <b>Geography: </b>America N^A new early
Cambrian sponge of sphinctozoan organization named Polythalamia
americana nov. gen. et sp. is described from Nevada and Alaska, USA. P.
americana nov. gen. et sp. shows little resemblance to other Cambrian
reported sphinctozoans, but is similar to late Palaeozoic to early
Mesozoic forms from Europe and Asia, e.g. Stylothalamia and
Amblysiphonella. The polyphyletic origin of sphinctozoans based upon
spicule criteria from younger examples is therefore corroborated by the
varied morphology and clearly widespread palaeogeographic distribution
of Cambrian forms, which were hitherto recognized only from Australia.
P. americana nov. gen. et sp. possesses a relatively small, globular
multi-chambered calcareous skeleton, with thin but densely perforate
walls and a central retrosiphonate, perforate spongocoel. The skeleton
is composed of an irregular rnicrostructure of unknown, but probable
calcitic, original mineralogy. There are no spicules or primary
internal structures, but secondary vesicular filling tissue is present.
The pore organization, however, is directly comparable to
archaeocyaths, e.g. coscinocyathines, and this character is taken to be
```

```
the only synapomorphy available for taxonomic and phylogenetic
purposes. Indeed, P. americana nov. gen. et sp. is closely associated
with a diverse archaeocyath assemblage and draws attention to
morphological similarities between some archaeocyaths and
sphinctozoans, thus questioning the criteria at present used to
distinguish between these groups. Accorsingly, a list of nomenclatural
synonymies is given to aid comparison. Coscinocyathine archaeocyaths
possess chambered juvenile stages and P. americana nov. gen. et sp. is
suggested to represent an aspiculate lineage of sphinctozoan grade
which may be derived from forms such as Clathricoscinus by neoteny. It
appears that at least three clades of sphinctozoan-grade calcified
sponges were present by end of early Cambrian time and their occurrence
in association with island arcs of the palaeopacific rim is
confirmed.^1";

Nyctopora and Calapoecia (Ordovician corals from North America).-
Geological Magazine 113: 457-467.- <b>FC&#038;P 8-1</b>, p. 54,
ID=5496^<b>Topic(s): </b>revision; corals; <b>Systematics:
</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Ordovician; <b>Geography:
</b>America N^Material from the H.A. Nicholson&#039;s collection,
University of Aberdeen, provides information on three of
Nicholson&#039;s species. Syntypes of Favistina calicina are described
and the lectotype designated. Topotypes of Nyctopora billingsii are
compared with an earlier description of the type thin sections.
Columnopora cribriformis is considered synonymous with Calapoecia
huronensis Billings, itself a poorly understood species; redescription
of the type of the latter species shows it to be separate from C.
canadensis Billings. Calapoecia ungava Cox is reinterpreted with a
lectotype designated, and Nicholson&#039;s material is placed with this
species. All specimens are from eastern North America and of Upper
Ordovician age excluding the Middle Ordovician N. billingsii and G.
canadensis. [original summary]^1";

Rugosa; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>America
N^Stratigraphic sequences within the Red River-Stony Mountain Province
record two major environmental cycles in a vast area of epicontinental
seas. The Red River Cycle began with a transgressive phase in the
middle Edenian that reached its maximum in the early Maysvillian, and
was followed by a regressive phase during the later Maysvillian and
early Richmondian. The transgressive phase of the Stony Mountain Cycle
reached its peak in the middle Richmondian, and was followed by a
regressive phase during the later Richmondian and Gamachian. In
general, the greatest water depth and most open marine conditions were
attained during the first cycle, and seas were shallowest and most
restricted toward the end of the second cycle. Recognition of the
transgressive maxima, when deposition was most widespread, permits
chronostratigraphic correlation throughout the province (and likely
beyond). Bioevents involving evolution and dispersion of solitary
rugose corals in the Red River-Stony Mountain Province, as well as
fluctuations in the relative abundance taxa, were closely related to
changes in water depth and degree of environmental restriction during
the two cycles. The first major evolutionary event took place during
the transgressive maximum of the Red River Cycle, when water depth in
some areas exceeded the limit for corals and they were confined to
basin margins and structural highs. The second occurred at the end of
the Red River regressive phase, when most areas became inhospitable and
corals were restricted to the centres of cratonic interior basins and
to cratonic margin areas of the province. Corals became widely
dispersed during the subsequent transgressive phase of the Stony
Mountain Cycle. Late in the regressive phase of that cycle, taxa were
introduced from outside the red River-Stony Mountain Province, and the
endemic corals became extinct.^1";

stability strategies; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>America N^In the
Late Ordovician Red River-Stony Mountain Province of North America,
four closely related genera of solitary rugose corals are represented
exclusively by liberosessile species: Salvadorea, Grewingkia,
Deiracorallium, and Lobocorallium. These rugosans benefitted from
innovative and in some cases unique strategies involving corallum form,
which improved stability with respect to the substrate and currents,
and took advantage of water flow during life. Trochoid form was a
compromise for ensuring adequate stabilization of the corallum by
sediment, while keeping the calice rim sufficiently elevated above the
substrate. In life orientation with the convex cardinal side of the
corallum facing down, triangulate and trilobate cross-sectional shapes
offered resistance to lateral tipping or rotation. Depressed coralla
resisted gravity-induced subsidence or tilting. With the convex side
facing downcurrent, the streamlined shape of compressed and triangulate
forms improved stability by reducing drag. Trilobate form may have had
a drag-reducing &#034;splitter plate&#034; effect. Strategies for drag
reduction were especially beneficial for corals inhabiting relatively
high-energy environments, but the greatest significance may have been
in reducing fatalities due to dislodgement during storms. The
hydrodynamic behavior of coralla in life position, especially if
leaning downcurrent, resulted in beneficial water flow. Vortices
ascending from the substrate on the downcurrent side provided the polyp
```

```
with water drawn from both the mainstream and the substrate surface.
Such circulation facilitated feeding, enhanced the quantity and variety
of food, and delivered other necessary substances. Wastes and gametes
could be effectively expelled from the polyp and removed downcurrent
without entrainment into the food-bearing flow. Functional analysis of
the fascinating range of corallum forms in the Red River-Stony Mountain
Province provides insight into paleobiology and paleoecology, which is
applicable to many Paleozoic solitary rugosans.^1";

ecology; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>America N^Tabulate corals are common in
reefs of the Silurian (Wenlockian) Racine Formation in Wisconsin and
Illinois, North America. Variation in size and spacing of corallites in
this fauna represents an aspect of niche-partitioning that is probably
related to feeding. Corallite morphospace, represented by a plot of
corallite diameter versus number of corallites per square cm, is
characteristically partitioned among favositines, alveolitines,
halysitines, syringoporids, and heliolitines, usually with minimal
overlap between these major taxonomic groups. Within all groups except
alveolitines, morphospace occupied by each major taxon is partitioned
further between forms with small corallites and forms with larger
corallites. This is probably related to differences in feeding, with
larger corallite forms specializing in tentacular capture of larger
prey, and smaller corallite forms specializing in smaller prey
involving capture by cilia-directed sheets of mucus as well as by
tentacles. Feeding-based differences among tabulates augmented
niche-partitioning effected by colony form and relation to substrate.
Cerioid, cateniform, coenenchymal, and fasciculate colony types in the
Racine fauna were primarily adapted to a soft substrate. Ragged edges
of colonies indicate growth during episodic sedimentation and colonies
were partially buried during life. Most tabulates are scattered through
wackstone and packstone and were not major contributors to reef growth.

Milne-Edwards &#038; Haime, 1850 (Coelenterata, Rugosa) du Dévonien
d&#039;Amerique du Nord et discussion sur la systématique des
Hadrophyllidae.- Geodiversitas 28, 2: 199-226.- <b>FC&#038;P 34</b>, p.
35, ID=1238^<b>Topic(s): </b>revision; Rugosa, Hadrophyllum;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian;
<b>Geography: </b>America N^The revision of the types and
&#34;topotypes&#34; of Hadrophyllum orbignyi Milne-Edwards &#038;
Haime, 1850 brings new data on this species and on the genus
Hadrophyllum. The type species, H. orbignyi, is known from the Eifelian
(costatus-kokelianus conodont zones) of Eastern Americas Realm. A
lectotype is selected in the original material. A detailed study of the
morphology shows important variations concerning the shape of the
corallum, the length of the cardinal septum, the interseptal ridges and
the fossuloids. The septal apparatus consists of costosepta, it is why
the &#34;epitheca&#34; is lacking. The corallum is massive, no
dissepiments nor tabulae, and the wall is septothecal. The fibrous
nature of the septa is pointed out. The polyp enclosed widely the
corallum; H. orbignyi was capable of automobility. The synonymy of the
genus is reviewed; only two species can be referred to it, the type
species and H. asturicum. The systematics of the
&#34;Hadrophyllidae&#34; is revised, especially the Weyer&#39;s one
(1975) and two new sub-families, the Hadrophyllinae and the
Microcyclinae n. subfam., are erected.^1";

When viewed in paleogeographic terms, this Recent westward retreat represents a Devonian northward and equatorward retreat. It is concluded that during the Early Devonian eustatic sea level was the major factor controlling stromatoporoid distribution. The influx of siliciclastic sediments, resulting from the Acadian Orogeny in particular, progressively forced stromatoporoids from the then southern parts of North America during the Middle and Late Devonian. It was not until the latest Devonian (Famennian) that global cooling seems to have had a significant impact on stromatoporoid distribution in North America.^1";

[Thesis abstract] - <b>FC&#038;P 26-1</b>, p. 17, ID=6876^<b>Topic(s): </b>phylogeny, cladistics; Rugosa Lophophyllidae; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Carboniferous M; <b>Geography: </b>Americas^A phylogenetic analysis including some Amazonian lophophyllid corals and similar forms from the Midcontinent region in USA was done. The Amazonian forms included Stereostylus lemzi and S. mendesi; whereas Lophophyllidium proliferum, L. girtyi, L. compressum, L. minutum, L. idonium, L. ignotum, L. angustifolium, Stereostylus lenis and S. perversus are the North-American species under analysis. S. leinzi and S. mendesi were regarded as metaspecies, for their lack of synapomorphies. having L. ignotum as sister group according to the cladogram produced (Figure 1). * The inclusion of the Amazonian metaspecies into the genus Lophophyllidium is also suggested. The derived phylogenetic tree brings new insigths to the North-American species, as follows: (1) S. perversus should be included in the genus Lophophyllidium and (2) either the range extensions of L. proliferum, L. compressum, L. girtyi and &#34;Stereostylus&#34; perversus are older than previously considered or their type localities are of Morrowan age. The paleobiogeographic pattern depicted by the phylogenetic tree suggests a faunal connection between the Amazon Basin and the US Midcontinent region during the late Morrowan (Figure 2). * The information provided by another phylogenetic analysis including Lophophyllidium palaeum and L. wewokanum (Meridas Andes, Venezuela) and L. sauridens (Western Interior, New Mexico, United States) also supports the previous phylogenetic tree and further suggests (1) either a longer range extension for the Venezuelan species or (2) a Morrowan age to the Merida part of the Palmarito Formation (Figure 3 and 4). reefs, calcimicrobial; <b>Systematics: </b>; <b>Stratigraphy:
</b>Neoproterozoic; <b>Geography: </b>Canada NW^Neoproterozoic buildups
of the Little Dal Group grew in a deep-water epicratonic basin. These
kilometer-scale reefs display aggradational and progradational
geometries comparable to those described from Phanerozoic reefs. Four
phases of reef growth correspond to four regional shale-to-carbonate
packages in laterally equivalent offreef strata. The lower, shaly part
of each package is interpreted to reflect transgressive to highstand
deposition. The upper carbonate part of each package reflects carbonate
precipitation in the water column as a result of postulated basin
restriction and increased salinity during sea-level lowstand. Reefs
nucleated at the beginning of the first major transgressive event.
Reefs typically aggraded during transgressive intervals, but could also
prograde or contract, likely depending on the rate of relative
sea-level rise versus reef growth rate. Reefs prograded during
regressions, probably owing to reduction of accommodation space. They
shed talus at lowstand in response to increased erosion and &#47; or
progradation over unstable substrates. Reef growth ended with return of
shallow-water conditions. The overall architecture of aggradation and
progradation demonstrates that the Neoproterozoic alcimicrobial reef
ecosystem was capable of responding to environmental changes in the
same way as the more extensively studied, ecologically complex, and
faunally diverse buildups of the Phanerozoic.^1";

The probable worm boring Trypanites was the dominant macroboring, penetrating more than 40% of 2,500 massive tabulate corals and stromatoporoids examined, occasionally in dense concentrations. The frequency of macroboring was influenced by conditions at the facies level reflected by changes in grain size, water depth, storm reworking of sediments, and the nature of the skeletal mass bored. These factors regulated exposure time of the host-substrate surface to the watermass and thus influenced bioerosion. Bored specimens are most common in muddy off-reef facies, moderate in sandy off-reef facies, and less common in reefs. In off-reef facies, storm-enhanced deposition and reworking of sediments were most important in the burial of eligible host substrates. In reefs, the high competition for space by encrusting epizoans, combined with sedimentation, limited macroborers that preferred to excavate dead skeletal substrates. Skeletal density was the most important property of the host substrate in controlling boring frequency. Macroborers favored a dense host skeleton likely for its enhanced mechanical strength and adaptability for unlined borings, despite requiring greater energy for excavation. High-relief host skeletons were bored more frequently than tabular forms, since their greater capacity to shed sediment would have resulted in more prolonged exposure above the seafloor. The probable bivalve boring Petroxestes pera is rare. Temporal changes in boring frequency appear to reflect local shifts in facies and relative sea level. Mass-extinction events near the O/S boundary, which eliminated some host corals and stromatoporoids, had no apparent effect on boring frequency.^1";

Spicule types, skeletal architecture and canal systems realized by the lithistid demosponges are described and illustrated. Further the special problems of taxonomic classification within the polyphyletic &#34;Lithistida&#34; are summarized. Descriptive systematic paleontology is the major part of this work. All the sponge genera and species investigated belong to the Orthocladina, which have been investigated after thorough statistical analyzes of traditional classification characters such as channel distribution and pore size. The new findings leads to important revisions of the Orthocladina.] Extract from the abstract: Fossiliferous strata with abundant lithistid demosponges were studied at several horizons and localities within the Lower and Middle Ordovician Pogonip Group of the Great Basin. The collection of over 700 excellently preserved lithistid sponges from these localities has allowed a much-needed description and revision of the suborder Orthocladina. The family Anthaspidellida has been
```

```
redefined to include only those orthoclads with a fairly regular
channel disposition and a skeleton typically dominated by dendroclones
that horizontally join adjacent trabs. A new family, the
Strepsolenidae, has been erected to hold those genera that have a more
irregular channel pattern and a skeleton in which polyclonid
dendroclones usually connect to each other to traps of different
distances from the exterior. The taxonomy of many previously described
sponges has also been revised. Four new genera and thirteen species are
described.^1";

Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>Canada, Manitoba^Borings occur in
solitary rugose corals from the Selkirk Member of the late Middle or
Upper Ordovician Red River Formation in southern Manitoba. They are
assigned to Dictyoporus garsonensis n. ichnosp., which was produced by
algae, and Trypanites weisei Magdefrau 1932, made by spionid polychaete
annelids. Most, and possibly all, borings occurred while the host
corals were alive and in life position. The location and relative
abundance of borings support interpretations that unattached curved
solitary corals lay with the convex cardinal side in the sediment and
the concave counter side facing upward during life, whereas straight
conical forms were oriented upright in the sediment. These ichnospecies
suggest that host corals lived in very shallow marine environments.

s[1828] = "ELIAS R.J. (1983).- Late Ordovician solitary rugose corals
of the Stony Mountain Formation, southern Manitoba, and its
equivalents.- Journal of Paleontology 57, 5: 924-956.- <b>FC&#038;P
13-1</b>, p. 31, ID=0439^<b>Topic(s): </b>; Rugosa; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician U; <b>Geography:
</b>Canada, Manitoba^Two large cratonic interior basins, the Williston
and Hudson, were situated within the Red River - Stony Mountain
Solitary Province, which occupied most of North America during Late
Ordovician time. Helicelasma selectum (Billings 1865), Deirocorallium
angulatum gunni n.subsp., Loboccrallium trilobatum trilobatum
(Whiteaves 1895), and Bighornia cf. B. patella (Wilson 1926) are known
from the Stony Mountain Formation of southern Manitoba. The presence of
identical species in Saskatchewan and Wyoming suggests that one
assemblage inhabited the Williston Basin. The Hudson Basin assemblage
comprises species that also occur in the Williston Basin, species
closely resembling Williston Basin forms, and taxa that do not occur in
the Williston Basin. Solitary Rugosa within the Red River - Stony
Mountain Province in eastern North America are most closely related to
those of the Williston Basin. The eastern cratonic margin assemblage
includes species that were introduced from the continental interior,
species not found in the interior, and the genera Streptelasma and
Bodophyllum, which were restricted to cratonic margin areas of the
province. Taxa in western Canada and northern North America appear to
be most closely related to those of the Hudson Basin. Assemblages in
the southwestern United States are not known at the specific level, but
the presence of Bighornia, Deiracorallum, and triangulate to trilobate
species of Grewingkia and possibly Lobocorallim indicates that they
belong to the Red River - Stony Mountain Province. Studies of
```

```
Ordovician solitary Rugosa suggest that cratonic interior basins were centres of evolution, diversification, and dispersion. The Middle to Late Ordovician diversification of Paleozoic corals coincide with the Tippecanoe transgression, which was the most extensive in the Phanerozoic, and with the initial development of cratonic interior basins, which were characteristic of much of the Paleozoic. These factors may have been important in the Ordovician radiation of the &#034;Paleozoic fauna&#034; in general.^1";
s[1829] = "ELIAS R.J. (1982).- Latest Ordovician solitary rugose corals of Eastern North America.- Bulletins of American Paleontology 81, 314: 1-116.- <b>FC&#038;P 11-2</b>, p. 29, ID=1828^<b>Topic(s): </b>solitary; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>America NE^This study comprises comprehensive taxonomic, paleoecologic, biostratigraphic, and paleobiogeographic analyses of latest Ordovician (Richmondian and Gamachian; Ashgill) solitary rugose corals in eastern North America. The corals are assigned to three provinces distinguished on the basis of assemblages and characteristic species. The distribution of these provinces, as well as taxa within them, was determined by regional environmental parameters related to paleogeography. [initial fragment of extensive summary; described taxa are: Streptelasma divaricans (Nicholson 1875), Grewingkia canadensis (Billings 1862), G. deltensis n.sp., and G. rustica (Billings 1858) in Richmondian of the Province; Helicelasma randi Elias 1981 and Bighornia cf. B. patella (A.E. Wilson 1926) in the Maquoketa Subprovince; Streptelasma rankini n.sp., S. affine (Billings 1865), Helicelasma selectum (Billings 1865), Deiracorallium angulatum (Billings 1862), Grewingkia penobscotensis n.sp., G. pulchella (Billings 1865), Grewingkia sp., Lobocorallium trilobatum vaurealense (Twenhofel 1928), Kenophyllum? sp., Bodophyllum neumani n.sp., Bodophyllum? sp., B. englishheadense n.sp., Bighornia cf. B. patella (A.E. Wilson 1926), and Paliphyllum ellisense (Twenhofel 1928) in the Maritime Subprovince; Streptelasma leemonense n.sp., Streptelasma sp., S. subregulare (Savage 1913), and Bodophyllum shorti n.sp. in the latest Ordovician (?Gamachian) Edgewood Province]^1";

Grewingkia canadensis (Billings 1862) appears in the upper part of the Nicolet River Formation (upper St. Hilaire Member) and is far more common in the overlying Pontgravé River Formation. A single specimen of Streptelasma divaricans (Nicholson 1875) is known from the Pontgravé River. Their presence confirms that this area is situated within the Richmond Province and that the upper Nicolet River, as well as the Pontgravé River, is Richmondian in age. Solitary Rugosa were introduced to this biogeographic province during an early Richmondian transgression, marked in the upper Nicolet River Formation by a coarser clastic interval. That event permits correlation between the St. Lawrence Lowland in the eastern part of the Richmond Province and the North American type Upper Ordovician (Cincinnatian Series) of the Cincinnati Arch region in the western part of the province. A comparative morphologic, paleoecologic, and biostratinomic analysis of
```

```
solitary corals indicates that normal, low-energy conditions were
interrupted occasionally by high-energy events (probably storms) during
deposition of the upper Nicolet River and Pontgravé River Formations.
Water depth increased northwestward in the St. Lawrence Lowland area.
Deposition of these siliciclastic prodelta to delta front sediments was
generally continuous and the sedimentation rate was usually high
because of rapid basin subsidence and comparatively close proximity to
the Taconic Mountains. In the western part of the Richmond Province,
farther from the source area, carbonate as well as clastic sediments
accumulated, periods of nondeposition were more frequent, and the
sedimentation rate was relatively low. Corals disappeared from the St.
Lawrence Lowland area during the Richmondian, when delta top facies of
the Bécancour River Formation succeeded the Pontgravé River Formation
due to a glacio-eustatic regression and progradation of the Queenston
Delta. [original abstract]^1";

and colonial corals hosting borers and linguloid brachiopods,
Ordovician of Manitoba, Canada.- Palaeoworld 19, 3-4: 249-255.-
<b>FC&#038;P 36</b>, p. 133, ID=6596^<b>Topic(s): </b>endobionts;
endobionts, stroms, corals; <b>Systematics: </b>Porifera Cnidaria;
Stromatoporoidea Anthozoa; <b>Stratigraphy: </b>Ordovician;
<b>Geography: </b>Canada, Manitoba^There have been very few published
reports of stromatoporoids and colonial corals with borings that
contain linguloid brachiopods; all are from the Ordovician and/or
Silurian in just four areas of eastern Canada and northwestern Europe.
Here, we report the discovery of an earlier Ordovician occurrence, in
both stromatoporoids and corals, and expand the geographic range of
such associations to central Canada. In the Upper Ordovician Selkirk
Member of the Red River Formation, southern Manitoba, the
stromatoporoid Stratodictyon and tabulate coral Protrochiscolithus
commonly contain cylindrical macroborings representing the ichnogenus
Trypanites, almost certainly produced by worms. In a few specimens, a
small proportion of borings contain single linguloids. The linguloids
occur predominantly in borings with relatively large diameters, but
their occurrence with respect to boring length and their vertical
location within borings are random. They are interpreted as nestlers
that occupied vacant borings throughout life. Although some of the
borings were covered over by subsequent growth of the host or
recolonization of its surface, there is no evidence of embedment
structures in stromatoporoids or corals that would indicate interaction
of the host with either the borers or linguloids. This is comparable to
occurrences in the Ordovician of Manitoulin and Anticosti islands in
eastern Canada, in that the linguloids are found within Trypanites
borings without associated embedment structures. In the Silurian of
Anticosti, Gotland, and the Welsh Borderlands, however, some borings
were further developed into embedment structures during upward growth
of the hosts, indicating that these relationships involved some type of
symbiosis. [original abstract]^1";

```

```
Tabulata; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>Canada,
Anticosti Island^Conoidal shells of Cornulites celatus n.sp. occur
commonly within host coralla of Propora conferta Milne-Edwards and
Haime, 1851, sensu lato, from the Laframboise Member of the Ellis Bay
Formation (Ashgill: Upper Ordovician) at Pointe Laframboise on western
Anticosti Island. Examples have also been found at the same locality in
the tabulate corals Paleofavosites sp., Acidolites arctatus Dixon,
1986, and A. compactus Dixon, 1986, and the stromatoporoid
Ecclimadictyon sp., but not in other associated tabulate coral species.
Growth interference between the shells and their hosts indicates a
commensal relationship. C. celatus apparently had a more limited
paleoenvironmental range than its principal coral host species, which
occurs abundantly elsewhere on the island without its endobiotic
partner. The diagnosis of Cornulites is emended to include forms having
a two-layered shell wall with a distinctive outer layer consistently
preserved as prismatic calcite. This new species extends the known
stratigraphic range of cornulitids in commensal relationships with
corals and stromatoporoids from the Silurian back to the Upper
Ordovician. [original abstract]^1";

Manitoba).- Journal of Paleontology 74, 3: 404-425.- <b>FC&#038;P
29-1</b>, p. 60, ID=1118^<b>Topic(s): </b>increase; Tabulata,
Saffordophyllum; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Ordovician; <b>Geography: </b>Canada,
Manitoba^Saffordophyllum newcombae Flower, 1961, displays unique
abilities and an unprecedented range in types of corallite increase.
Cerioid growth was characteristic, but colonies on soft substrates
could grow in a tollinaform manner during early astogeny. The capacity
for recovery from damage and partial mortality is amazing. Rejuvenation
may have been accompanied by peripheral expansion in some cases. Rapid
regeneration could involve axial increase. Circular lacunae that formed
during recovery became sites of rapid lateral increase or corallite
decrease. * Two types of axial increase occurred within coralla.
Lateral increase was concentrated mainly along the basal wall and
adjacent to certain circular lacunae. In typical cerioid parts of the
corallum, lateral increase seldom yielded &#34;adult&#34; corallites,
but incipient lateral offsets could be numerous. The level of colony
integration was probably moderately high. There was likely soft-tissue
continuity among polyps, coordination of polyp behavior, subjugation of
individuals for the good of the colony, and perhaps astogenetic
control. * Saffordophyllum newcombae is considered to be a tabulate
coral, although one type of axial increase is similar to that in a few
rugose corals and the other type of axial increase as well as possible
peripheral expansion resemble modes of increase in some coralline
sponges. Lateral increase is considered compatible with cnidarian
rather than poriferan biology. Corallite size is typical of tabulates.
Saffordophyllum may not be the direct ancestor of favositid tabulates,
and may not even be closely related to them; S. newcombae is very
different from Paleofavosites and Favosites. * The remarkable range in
forms of increase discovered in S. newcombae demonstrates the critical
need for detailed paleobiologic studies, if we are to understand the
early evolutionary history of corals and to establish reliable criteria
for distinguishing various coral groups and homeomorphs. [original

s[1843] = "LEE D.-J., ELIAS R.J. (2004).- Paleobiologic features of
Trabeculites maculatus (Tabulata, Late Ordovician, southern Manitoba).-
Journal of Paleontology 78, 6: 1056-1071.- <b>FC&#038;P 33-2</b>, p.
18, ID=1119^<b>Topic(s): </b>biology; Tabulata, Trabeculites;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy:
</b>Ordovician; <b>Geography: </b>Canada, Manitoba^Detailed analysis of
certain growth characteristics in Trabeculites maculatus contributes to
anunderstanding of the paleobiology and phylogeny of early tabulate
corals. Some coralla of T.maculatus contain peculiar, vertically
oriented cylindrical lacunae (open areas) that are lenticular, orin one
case circular, in cross section. The nature of these structures and
their relation to adjacentcorallites suggest that they were formed by
the coral in response to soft-bodied biotic associates ofunknown
taxonomic affinity.Trabeculites maculatus is an unusual tabulate coral
featuring both axial and lateral modes ofcorallite increase. Axial
increase was common, often occurring in association with
rejuvenationfollowing injury and less commonly involving normal,
undamaged corallites. Lateral increase ofnormal corallites was typical,
but this form of increase could also be involved in the termination
oflacunae and occurred in response to a divergent growth pattern around
the circular lacuna. Corallitedecrease was fairly common, usually
taking place adjacent to lenticular lacunae but in some casesinvolving
normal corallites not associated with lacunae. Corallite fusion was
uncommon; it could beeither temporary or permanent. Conspicuous
relocation of corallites and restructuring of corallitearrangement
generally involved mass rejuvenation and/or regeneration, usually over
a large surfacearea of the corallum. The growth features in T.
maculatus are fundamentally the same as those in the co-occurring
Saffordophyllum newcombae, including types of axial increase unknown in
other tabulate corals. The basic paleobiologic similarity of these
species supports the interpretation that the genera they represent are
closely related phylogenetically. The relationship of these taxa to
other tabulates,however, remains unresolved.^1";
s[1844] = "BAE BOO-YOUNG, LEE DONG-JIN, ELIAS R.J. (2006).-
Life-history strategies of a species of Catenipora (Tabulata; Upper
Ordovician; southern Manitoba, Canada).- Lethaia 39, 2: 141-156.-
<b>FC&#038;P 34</b>, p. 43, ID=1248^<b>Topic(s): </b>growth style,
chronometry; Tabulata, Catenipora; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>Canada,
Manitoba^Detailed study of coralla by transverse serial sections
permits the determination and evaluation of life-history strategies
(survival and growth characteristics) in response to different physical
environments, for Catenipora foersteri Nelson, 1836 from the Selkirk
Member, Red River Formation, in Manitoba. We recognize various modes of
corallite increase: one type of axial increase, four types of lateral
increase, and agglutinated patches of corallites in association with
normal, undamaged corallites; and one type of axial increase, one type
of lateral increase, and temporary agglutinated patches from the
recovery processes of corallites damaged by sediment or bioclast
influx. Inaddition, the formation of new ranks by lateral increase is
the most effective method for rapid growth of a corallum or for
reconstructing part of a corallum damaged by physical disturbances.
Fluctuations in the tabularial area of corallites occur in cycles over
vertical intervals ranging from 3.20 - 7.90 mm. We consider each cycle
to represent annual growth. Average annual growth of three coralla
ranges from 4.20- 6.27 mm. According to correlations between annual
growth cycles and other growth characteristics, a high frequency of
offsetting is associated with rapid vertical growth. Specifically,
annual growth is relatively high in association with episodes of
sediment or bioclast influx, probably generated by storms. In some
coralla, however, annual growth is highest in the cycle characterized
by few new corallites or by extraordinarily high rates of offsetting by
normal, undamaged corallites as well as damaged corallites. This
```

```
suggests that the vertical growth could also be affected by factors
other than storm-related disturbances.^1";

problematica; Tabulata; <b>Stratigraphy: </b>Ordovician U;
<b>Geography: </b>Canada, Ontario^Spiral embedment cavities that formed
around metazoan endosymbionts are preserved in the septaand
intercorallite spaces of Columnopora and Calapoecia corals from
Manitoulin Island, Ontario.These are the oldest described Helicosalpinx
asturiana, and this report extends the range of thesetrace fossils from
the Richmondian (Ashgill, Upper Ordovician) to the Givetian (upper
MiddleDevonian). The sinistrally coiled traces show regular morphology,
suggesting a physiological basisfor their shape. Coral growth
parameters are not affected by the presence of Helicosalpinx,suggesting
that the endosymbiont was not parasitic and not in direct competition
for resources withthe host. H. asturiana is interpreted as trace fossil
evidence of commensalism.Two additional endosymbiotic traces occur in
Late Ordovician Columnopora. The particularassociation of straight,
cylindrical Chaetosalpinx with Columnopora is widespread during
theRichmondian. A dependent association is suggested to have originated
between the endosymbiontand Columnopora prior to the Richmondian
expansion and to have continued into the Hirnantian(latest Ordovician).
The association between this endosymbiont and host is the earliest
knowntemporally and globally significant inter-metazoan symbiosis.
Although host corals, Columnoporaand Calapoecia, did not survive the
end-Ordovician mass extinction events, both Chaetosalpinx
andHelicosalpinx occur in other host corals during the Silurian and
Devonian.^1";

39-43.- <b>FC&#038;P 19-1.1</b>, p. 58, ID=2677^<b>Topic(s): </b>reefs,
microatolls; reefs; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Ordovician M; <b>Geography: </b>Canada, Ontario^A
disc-shaped massive colony of Tetradium, from the Middle Ordovician
Bobcaygeon Formation in southern Ontario, displays features of a coral
microatoll. This is the first pre-Holocene coral microatoll yet
described, indicating that some tabulate corals in level-bottom
communities were growing as microatolls as do many modern colonial
skeleton-secreting organisms. The microatoll therefore is not strictly
a Quarternary or even a Cenozoic phenomenon, but has a fossil record
that may span most of the Phanerozoic. This indicates that the special
conditions necessary for microatoll growth have existed outside of reef
environments, and were present before the advent of scleractinian coral
reefs. It may be possible to use ancient microatolls to estimate
absolute water depth at low tide, thereby providing a means for
estimating maximum water depth on a local and regional scale.^1";

Ordovician of Manitoba.- Canadian Journal of Earth Sciences 32, 9:
1393-1400.- <b>FC&#038;P 25-1</b>, p. 37, ID=3022^<b>Topic(s): </b>new
taxa; corals, Tetradiida; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Ordovician U; <b>Geography: </b>Canada,
Manitoba^Tetradiids are common Ordovician fossils in many parts of the
world. Their occurrence in the western interior of North America has
been noted, but they have never previously been described from this
region. Rhabdotetradium garsonense n.sp. occurs in the Selkirk Memher
of the Red River Formation at Garson, Manitoba (Late Ordovician,
Maysvillian). This species is characterized by small corallites with
diameters commonly 0.6 - 1.1 mm; in transverse sections these are
separated from one another or occur in clumps or chains. The
variability of corallite arrangement within single coralla of this
species illustrates the difficulty of discriminating tetradiid genera.
The diagnosis of Rhabdotetradium is revised to more clearly delineate
the boundary between it and Paratetradium, which has corallites
arranged contiguously in elongate chains.^1";

and a possible bathymetric gradient in tetradiid morphology.- Boletin
de la Real Sociedad Espanola de Historia Natural, Seccion Geologica 92,
1/4: 177-186.- <b>FC&#038;P 26-2</b>, p. 27, ID=3711^<b>Topic(s):
</b>microatolls, bathymetry; corals Tetradium; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Ordovician M;
<b>Geography: </b>USA, Oklahoma^Tetradiid corals are abundant in the
uppermost Pooleville Member of the Middle Ordovician Bromide Formation
in South-central Oklahoma (USA). The regressional Pooleville Member
consists of a series of stacked peritidal carbonate cycles, culminating
in a regional unconformity. The vertical succession of facies in each
cycle suggests an on-shore to off-shore transition from
intertidal/supratidal desiccated microbial laminites, through
bioturbated, poorly fossiliferous marls and micrites, to deeper
subtidal fossiliferous marls and grainstones. Tetradiids occurred in
the subtidal portion of each cycle. In successive cycles, the subtidal
portion was shallower, or closer to shore, than that of the immediately
```

```
preceeding cycle. The highest two cycles contain massive Tetradium,
with microatolls confined to the highest cycle. The third highest cycle
contains a Phytopsis (bundled tetradiid) biostrome and the next cycle
down contains the finely-branching Rhabdotetradium. The occurrence of
different tetradiids in successive cycles suggests a bathymetric
gradient in tetradiid morphology with massive Tetradium in the
shallowest settings and branching tetradiids in deeper settings. Recent
scleractinian corals show a similar generalized bathymetric morphology
gradient in many Indo-Pacific reefs. Pooleville Tetradium microatolls
are the second oldest described metazoan microatolls, the oldest also
being Tetradium.^1";

<b>Systematics: </b>; <b>Stratigraphy: </b>Ordovician U; <b>Geography:
</b>USA, Alabama^Paleontological and lithological studies of a
carbonate mound provide the necessary data from which characterizations
for that mound or locality can be constructed. These data-based
characterizations are convenient mechanism for making qualitative
comparisons with other mounds, as has been done in some previous
studies that discussed Middle Ordovician (now considered Upper
Ordovician) mounds of the Appalachian Basin. Each of these studies had
a different focus, including the paleoecology of individual mound
localities, issues of ecological zonation, and regional stratigraphical
investigation. Quantitative comparisons are precluded among these
studies because each mound was sampled using different procedures,
resulting in paleontological data sets of dissimilar density and depth.
Two mound localities from carbonates of the Upper Ordovician Chickmauga
Group (Stones River equivalent) of Jefferson and Blount counties, AL,
were chosen for study to investigate the application of random sampling
techniques to mound populations in outcrop. One mound from each
locality was completely censused to generate population compositional
and structural data. The location and higher-level identification of
each macrofossil on the surface of these mounds were recorded. These
bryozoan-dominated data sets represent the best estimates available
concerning the underlying population of mound constructors., dwellers,
and occasional &#034;visitors&#034;. Rarefaction analysis was used to
predict the number of randomly chosen fossils needed to detect the
major taxonomic groups from each of these populations. A computer
program (TARGET) was written to validate rarefaction predictions by
conducting random sampling experiments using census data sets. The
program prompts for input of three user-defined variables that set the
parameters of a sampling experiment and then throws randomly located
sampling boxes at the mound data set, recording the results.
Statistical analysis of results from these sampling experiments
validated the predictions of rarefaction analysis and led us to employ
a conservative approach for sampling additional mounds at these
localities.^1";

</b>Cnidaria; Anthozoa; <b>Stratigraphy: </b>Ordovician Silurian;
<b>Geography: </b>USA central E^Uppermost Ordovician (Gamachian) to
lowermost Silurian (lowermost Llandovery) strata in the east-central
United States contain a distinctive association of corals, the Edgewood
Assemblage. This assemblage is dominated by solitary Rugosa of the
genus Streptelasma. Other Rugosa, including the solitary forms
Keelophyllum, Grewingkia, and Bodophyllum, and colonial forms
Pycnostylus and Palaeophyllum, are rare. The solitary rugosans were
evidently derived from species previously restricted to the North
American continental margin, and are similar to those in the
Dalmanitina Beds (Hirnantian) or possibly lowermost Llandovery beds of
Ostergotland, Sweden, and the Guanyinqiao Beds (Hirnantian) of Guizhou
Province, China. Among the Tabulata, Paleofavosit.es, Propora, and
Halysites are most common. Catenipora, Aulopora, Rhabdotetradium,
Protaraea, Acidolites, and Plasmopora are rare. Closest affinities are
with tabulates in the Ellis Bay (Gamachian) and Becscie (uppermost
Gamachian-lowermost Llandovery) formations of Anticosti Island and the
Grande Coupe beds (Ashgill), Matapedia Group, of Gaspe Peninsula,
Quebec. The Edgewood Assemblage and succeeding Silurian coral
assemblage are useful for age determination and correlation of
Gamachian to lower Llandovery (Rhuddanian) strata in the east-central
United States.^1";

<b>Stratigraphy: </b>Ordovician Silurian; <b>Geography:
</b>Laurentia^The latest Ordovician to earliest Silurian Edgewood
Province in the cratonic interior of Laurentia contained a
post-extinction coral fauna. These corals inhabited a broad range of
shallow-marine, carbonate environments. Diversity generally increased
```

```
along a gradient from restricted, low-energy, relatively turbid
conditions, to open, high-energy, low-turbidity conditions. Changes in
diversity involved progressive addition or subtraction of stenotopic
species within a single association dominated by opportunistic,
ecologic generalists. Patterns and trends in diversity, abundance, and
distribution reflected locally variable environmental parameters and an
overall gradient from the continental interior toward the open ocean.
Structural characteristics of the Edgewood Province differed from those
of Late Ordovician pre-extinction and Early Silurian recovery faunas in
the Laurentian cratonic interior. These included the low total
diversity, the abundance and strong dominance of a single, solitary
rugosan species, and the lack of distinct, specialized, recurring
species associations. The origin, overall structure, and fate of the
province were dtermined by factors operating on a broad scale. Nutrient
enrichment and related environmental destabilization in the Laurentian
epeiric sea during the end-Richmondian regression were probably
significant factors in extinctions among Late Ordovician &#034;perched
faunas&#034;, including corals. This would have occurred as nutrients
provided by runoff from expanding terrestrial areas became concentrated
in the shrinking sea. During the Gamachian and early Rhuddanian,
elevated nutrient levels and environmental instability within the small
sea were likely instrumental in maintaining the structure of the
Edgewood Province. By the late Rhuddanian, transgression had expanded
the sea and reduced the effects of runoff sufficiently to permit the
Silurian recovery of corals.^1";

earliest Silurian solitary rugose corals of the east-central United States.- Oklahoma Geological Survey, Bulletin 145 [Chaplin J.R. &#038; Barrick J.E. (eds.): Special Papers in Paleontology and Stratigraphy - A Tribute to Thomas W. Amsden]: 113-125.- <b>FC&#038;P 22-1</b>, p. 32, ID=3384^<b>Topic(s): </b>new records; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician U &#47; Silurian L; <b>Geography: </b>USA central E^New information on latest Ordovician to earliest Silurian solitary Rugosa of the east-central United State is of biostratigraphic, paleoecologic, and paleoenvironmental significance. The distribution of these corals indicates an age of Early Llandoverian for the youngest strata of the Keel Formation in south-central Oklahoma. Basal beds of the Cochrane Formation, which overlies the Keel, are evidently diachronous, ranging in age from the Early Llandoverian to late Early or younger Llandoverian. In west-central Illinois and northeastern Missouri, solitary corals indicate that the Bowling Green Dolomite is a discrete unit that is younger than the Noix Limestone and Bryant Knob Formation and the Cyrene Formation, which is a lateral facies equivalent of the Noix-Bryant Knob. In northeastern Illinois, Streptelasma subregulare occurs beneath a bed containing Early Llandoverian graptolites in the Schweizer Member of the Wilhelmi Formation. That coral has a range of Gamachian to early Early Llandoverian, and it remains a possibility that Schweizer strata below the position of the graptolite bed are Gamachian in age. Coralla of S. subregulare are abundant on several beds immediately above stromatolithes in the basal Wilhelmi at one locality, suggesting that the species could live in very shallow water and thrived when normal marine conditions appeared during the latest Ordovician-earliest Silurian transgression that brought seawater over the eroded surface of the underlying Maquoketa Group. Directional orientations of those coralla indicate currents from the south and possibly southwest. Data from the Mosalem Formation in northwestern Illinois and eastern Iowa confirm that solitary rugose corals of the Edgewood and Silurian assemblages do not co-occur and that the Edgewood assemblage was succeeded by the Silurian assemblage.^1";
s[1874] = "ELIAS R.J., YOUNG G.A. (2001).- Rugose coral morphology during time of crises: the latest Ordovician to earliest Silurian Edgewood Province in Laurentia.- Bulletin of the Tohoku University Museum 1 [Proceedings of the 8th International Symposium on Fossil Cnidaria and Porifera]: 034-040.- <b>FC&#038;P 30-1</b>, p. 19, ID=7060^<b>Topic(s): </b>morphology, time of crisis; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Ordovician U &#47; Silurian L; <b>Geography: </b>America N, Edgewood Province^Analysis of the post extinction Edgewood rugosan fauna reveals that basic morphologic patterns related to the latest Ordovician mass extinction are similar to those for the Late Devonian and latest Permian mass extinctions. Advantageous characters during times of crisis are solitary form, fasciculate colony type, simple morphology, and high variability. Characters associated with susceptibility to extinction are colonial form in general, cerioid colony type in particular, and complex morphology. * Nutrient enrichment and related environmental destabilization in the Edgewood sea probably favored solitary corals and colonies with low integration. Such conditions would have been ideal for the dominant species Streptelasma subregulare, a solitary, morphologically simple but extraordinarily variable, opportunistic, ecologic generalist. Solitary and fasciculate corals were perhaps best able to cope with increased movement of sediment, which may have occurred during the latest Ordovician regressive phase. * Within the Edgewood Province, diversity and morphologic complexity generally increased along an environmental gradient from low energy, relatively turbid, restricted conditions, to high energy, low turbidity, comparatively open conditions. Only species that produced morphologically simple skeletons were able to survive in restricted, presumably stressful conditions. The more complex coralla
```

```
of species confined to favorable open marine conditions may have
permitted firmer attachment of polyps and greater polyp activity. This
would have been advantageous for survival in higher water energy and
for rejection of coarser sediment. The ability of S. subregulare to
produce a wide range of morphologies suitable for survival throughout
the environmental gradient was evidently instrumental in its success
during this time of crisis. [original abstract]^1";

Stromatoporoidea; <b>Stratigraphy: </b>Ordovician U - Silurian L;
<b>Geography: </b>Canada, Anticosti Island^During Late Ordovician and
Early Silurian time, from 450 to 428 million years ago, stromatoporoid
sponges were some of the most common and abundant fossils in shallow
water tropical settings of the Anticosti Basin (Gulf of St Lawrence).
They formed dense, massive coralline skeletons of calcium carbonate,
some up to a meter or more across, especially in reef environments, but
also in deeper waters of the Anticosti shelf, down to the margins of
the photic zone, where light faded. The Anticosti Basin reveals one of
the most fossiliferous carbonate sequences worldwide for rocks of this
age, straddling a global mass extinction boundary, and thus revealing
not only those taxa that became extinct, but also how the seas were
repopulated in an equatorial setting after the mass extinction. The
mass extinction has been correlated to globally cooling climates of the
time, and southern hemisphere glaciation in North Africa. This
```

```
monograph describes, for the first time, the skeletal architecture of
these abundant and exquisitely preserved sponges from Anticosti, and
includes more than 300 skeletons selected from ca. 2000 field
localities [3000 skeletons from 200 localities?!], assigned to 14
genera, of which 4 are new, and 35 stromatoporoid species, of which 18
are new. These are illustrated by 56 figures and plates and fill a
major gap in our global knowledge of the reef building stromatoporoids,
especially during the Early Silurian and latest Ordovician. All
materials are precisely geographically and stratigraphically defined
from the Vaureal through Chicotte formations over a nearly a kilometer
thick section, and their ecologic distribution plotted across shallow
to deeper water facies. Oil and gas exploratory drilling in the Gulf of
St Lawrence will ultimately reveal what happened in the deeper water
offshore facies, not exposed on Anticosti Island itself. [original

endolithic trace fossils; <b>Systematics: </b>Porifera Cnidaria;
Stromatoporoidea Anthozoa; <b>Stratigraphy: </b>Ordovician Silurian;
<b>Geography: </b>Canada E^Bioerosion was a significant process in the
destruction of reef-building skeletons in early and mid-Paleozoic
marine carbonate settings. Ordovician-Silurian corals and
stromatoporoids from Anticosti Island show a limited diversity of
macroborings, dominated by Trypanites, but also includes rare of an
Ordovician bivalve boring (Petroxestes pera), described for the first
time in Early Silurian stromatoporoids. Two problematic embedment
structures, one containing lingulid brachiopods, resemble borings but
did not contribute to bioerosion. The distribution of the embedment
structures and Petroxestes pera are restricted by facies and skeletal
substrate. Trypanites is relatively nonspecific, occurring in reef and
off-reef facies and in most skeletal substrates; it does not appear to
have been affected by the Late Ordovician mass extinction. ^1";
s[1879] = "JOHNSON M.E., BAARLI B.C. (1987).- Encrusting corals on a
latest Ordovician to earliest Silurian rocky shore, southwest Hudson
Bay, Manitoba, Canada.- Geology 15: 15-17.- <b>FC&#038;P 16-1</b>, p.

<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Ordovician
&#47; Silurian; <b>Geography: </b>Canada, Manitoba^Paleozoic tabulate
corals are generally thought to have been free standing, with flattened
disc-shaped to dome-shaped morphology providing a degree of stability
in shallow-water, high-energy environments. The ability to encrust has
previously been suggested by patterns of competitive overgrowth in
certain species. Definitive proof of encrustation by favositid corals
is exhibited in an extraordinary example of an ancient rocky shore
exposed for 350 m on Hudson Bay near Churchill, Manitoba. Carbonate
strata attributed to the Upper Ordovician Port Nelson or Lower Silurian
Severn River Formation locally transgress a massive Precambrian
quartzite. An ancient shoreface is clearly marked by large, smoothly
eroded boulders of the dark quartzite, commonly 2-10 m in diameter. The
boulders are burried in coarse carbonate debris, but corals up to 20 cm
in diameter are found cemented directly onto the surface of some
boulders. Deep pitting of many boulders to a depth of 2-3 cm was
contemporaneous and may have been promoted by unpreserved encrusters
such as sponges or anemones.^1";

the Ordovician-Silurian boundary: Anticosti Island, eastern Canada, and
worldwide.- Canadian Journal of Earth Sciences 38, 2: 153-171.-
<b>FC&#038;P 30-1</b>, p. 5, ID=1608^<b>Topic(s): </b>reefs,
extinctions; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Ordovician &#47; Silurian; <b>Geography: </b>Canada E^Multiple
latest Ordovician (Rawtheyan-Hirnantian) glaciations in central Africa,
with concomitant global sea-level lowstands and cooler, restricted,
equatorial carbonate shelves and ramps, interrupted by warmer
interstadial highstands, had a dramatic global impact on the tropical
shallow-water reef ecosystem and carbonate production. With the
Ordovician-Silurian boundary strata on Anticosti Island as a global
standard for a carbonate shelf-ramp setting, the latest Ordovician and
earliest Silurian reveal three reef phases, ended by three extinctions.
The first extinction, towards the end of the Rawtheyan, affected the
last &#34;Richmondian&#34;-type reefs (Vaureal Formation, Mill Bay
Member). The second extinction was less pronounced, ending with reefs
at the base of the Prinsta Member (Ellis Bay Formation), interpreted as
the top of the Normalograptus extraordinarius graptolite Subzone. The
third and most severe extinction phase capped the Laframboise patch
reef complex (Ellis Bay Formation), at the top of the Normalograptus
persculptus Zone. In the paleotropics, the Hirnantian interglacials
showed higher biodiversity than either the preceding Rawtheyan or
following Rhuddanian (early Llandovery) warm intervals, a feature
perhaps achieved by high innovation rates via introduction of
&#34;Silurian&#34; reef biotas during the Hirnantian. The Anticosti
reef succession is compared with latest Ordovician reefs from
northwestern Europe (Baltic Basin and UK), the northwestern margins of
Gondwana (Spain and Austria), the Urals, Siberia, Kazakhstan, northeast
Russia, and China. Reefs show a global decline from the late Caradoc
through late Ashgill, marked by hiatuses towards the O-S boundary. A
protracted 3-4 million-year recovery phase for Early Silurian tropical
marine biotas, generally without reefs, marked the succeeding
Rhuddanian; full reef recovery was delayed until the mid-Aeronian.

Llan; <b>Geography: </b>America N, Cincinnati Arch^Fifty-four species
of corals (29 rugose, 19 tabulate, 6 heliolitid) have been identified
from the Brassfield Formation (limestone, dolomite and claystone of
mid-Llandovery [Lower Silurian] age) in the Cincinnati Arch region of
the United States. Included are one new rugosan genus
(Schizophaulactis), four new rugosan species (Streptelasma
scoleciforme, Dinophyllum semilunum, Paliphyllum regulare, Pycnactis
tenuiseptatus), three new tabulate species (Favosites densitabulatus,
Catenipora favositomima, Syringolites vesiculosus), and one new rugosan
subspecies Paliphyllum suecicum Neumann 1968 brassfieldense). Coral
assemblages of different, apparently environmentally controlled
character are concentrated in the north and the southeast parts of the
region. The Brassfield coral fauna appears to have been largely
restricted to the present Cincinnati Arch region during mid-Llandovery
time. Closest affinities on the species level during this period are
with the corals of Anticosti Island (Canada). Eight of twelve species
pre-date the mid-Llandovery, some existing as early as the Late
Ordovician. The oldest members of the Brassfield coral fauna were found
in a number of areas throughout the world, rather than in a single
ancestral homeland. At least half the coral species survived the end of
the mid-Llandovery, and spread into a large portion of the submerged
continental areas of the world.^1";

reefs; <b>Systematics: </b>Cnidaria Monera; Anthozoa; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>Canada, Arctic, Greenland N^A recently
discovered Silurian reef tract in the high Canadian Arctic has an
exposed length of more than 150km and is locally more than 500m thick.
The reefs occur within a Silurian ramp and rimmed shelf-margin sequence
about 2km thick. Conodont biostratigraphic data indicate that the
reefal strata are late Llandovery to Ludlow in age, and reefs are
composed largely of coral-microbial boundstone, The corals are mainly
digitate rugosans and large halysitids, associated with fewer
stromatoporoids and lithistid sponges. However, most of the reefal
strata consist of microbialite, which encrusts skeletal metazoans or is
massive or thromboidal. Microbialite microstructure consists mainly of
clotted micrite or laminated micrite associated with common Renalcis,
other calcimicrobes, and locally abundant early marine cements. Other
reef rock types include stromatactis-rich lime mudstone, cementstone,
zebroid stromatactis-bearing lime mudstone, crinoidal grainstone, and,
rarely, stromatoporoid boundstone. The reefs formed on the shelf margin
and prograded basinward in three distinct phases during Wenlock and
Ludlow time. Underlying Llandovery, shelf-margin facies are highly
dolomitized and may represent an original stromatoporoid boundstone.
Overlying late Ludlow to Pridoli carbonates were deposited on a
prograding carbonate ramp, dotted with small coral-stromatoporoid and
other biostromes. [first fragment of extensive abstract]^1";

```
Cnidaria; Anthozoa; <b>Stratigraphy: </b>Silurian L; <b>Geography:
</b>Canada E^Vertical annual skeletal growth rates were compared for 27
species of tabulate corals, solitary and colonial rugose corals, and
two species of stromatoporoid sponges from the shallow water, tropical,
biostromal Upper Llandovery Fossil Hill Fm. of Manitoulin Island,
northern Ontario. All displayed clear periodicity in density band
variations from internal tabulae, cysts, lamellae, septa and pillars,
or external annuli, indicating a common environmental growth factor.
Growth banding is attributed largely to seasonal cycles: finer
circadian growth banding was not observed, lunar peaks were difficult
to verify. Growth rates varied from 2 to 9 mm/yr for tabulates, from
4.3 t0 27.2 mm/yr for rugosans and 0.8 to 3.1mm/yr for stromatoporoids.
Growth rates had a strong genetic component varying generically and
architecturally, with rugosans able to grow faster than tabulates, and
with stromatoporoids exhibiting the slowest rates. Such rates are
comparable to growth rates in some Recent hermatypic scleractinians,
suggesting that mid- Palaeozoic corals possessed zooxanthellate
symbionts. Stromatoporoids, like living cryptic sclerosponges, possibly
lacked symbionts: their growth rates were among the slowest measured.^1";

high-diversity Silurian community, Milwaukee County, Wisconsin.-
Palaios 06: 465-478.- <b>FC&#038;P 23-2.1</b>, p. 68,
ID=4436^<b>Topic(s): </b>reefs, guild structures; inter-reef biota;
<b>Systematics: </b>Porifera Cnidaria; Anthozoa; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>USA, Wisconsin^Fine-grained, inter-reef
carbonates of the Silurian (Wenlockian) Racine Formation, Milwaukee
County, Wisconsin, formed in a generally quiet-water environment below
wave base. These strata preserve a level-bottom community which
contains 27 guilds and 89 species of skeletal macrofauna. No
sedimentary transport of the fauna is apparent, but breakage of shells
by predation and reorientation and dispersal of skeletal material by
bioturbation are significant taphonomic features. Most
suspension-feeding guilds are represented by epifaunal sponges, corals,
bryozoans, brachiopods, conocardiids, cornulitids and annelids which
occupied a tier from 0 to 2cm above the bottom. This tier was also
occupied by a vagile fauna of gastropods and trilobites. Most skeletal
material, as determined by point count, was produced by three guilds of
suspension-feeding crinozoans which occupied two higher tiers, from 2
to 6cm and 6 to 25cm above the bottom. Soft-bodied burrowers included
suspension-feeding worms which fed at the sediment surface and extended
to at least 2cm depth, and a lower tier of deposit feeding worms which
extended to about 10cm depth. Three guilds of cephalopods represent
predators within the community. The brachiopod component of this
community represents a typical Silurian &#034;Dicoelosia
community&#034; a type of Silurian assemblage which has been previously
characterized as an ecologically simple, brachiopod-dominated fauna.
Detailed results from the Racine study suggest that many so-called
Silurian brachiopod communities were actually tiered, high-diversity
communities dominated by crinozoans.^1";

(1984).- The Llandovery-Wenlock heliolitid corals from New Brunswick, Canada.- Journal of Paleontology 58, 3: 867-884.- <b>FC&#038;P 13-2</b>, p. 42, ID=0562^<b>Topic(s): </b>taxonomy; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian Llan Wen; <b>Geography: </b>Canada, New Brunswick^A large collection of heliolitid coral from the Silurian Limestone Point Formation and La Vieille Formation of northern New Brunswick is described. They include at least seven species. Two species of Propora, two species of Plasmopora and three species of Heliolites are recognized, of which several are new in North America and one new species of Heliolites is erected.Analysis of variance statistics on detailed measurements of morphological parameters used in taxonomy, based on a series of sections cut through selected colonies, indicate that any random section except that cutting the most juvenile stage of growth will provide a good estimate of the colony mean and variance for each parameter.^1";
s[1897] = "DIXON O.A. (1999).- Upper Silurian Heliolitine corals, Canadian Arctic: Taxonomic method, keys to identification, and biogeographic relationships.- Journal of Paleontology 73, 6: 1002-1014.- <b>FC&#038;P 29-1</b>, p. 59, ID=1494^<b>Topic(s): </b>taxonomy; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian U; <b>Geography: </b>Canada, Arctic^Taxonomy of heliolitine corals, and tabulate corals in general, benefits from analysis of larger assemblages of coralla that approximate populations. Quantitative data derived from such assemblages allow intraspecific variation to be tested rigorously and illustrated, and similar, co-occuring species to be discriminated using normal patterns of continuous population variation. Field collection and analysis necessarily involve recording and comparing assemblages from the full spectrum of sedimentary facies available at any one straigraphical level and from the maximum available stratigraphic range. The large published taxonomic literature on heliolitine corals is a daunting obstacle to indentification at the species level because a substantial part appears to involve taxonomic splitting to a degree inconsistent with variation known in modern coral species. The heliolitine corals studied occur in Ludlow-age ramp and shelf carbonate facies in the Boothia Uplift region in the southern Arctic archipelago of Canada. The &#034;population&#034; approach resulted in
```

```
discrimination of 18 morphotaxonomic species, belonging to five genera and four families. A few select morphologic characters, incorporated in simple identificcation keys, are particularly helpful in distinguishing the 11 heliolitid and four stelliporellid species present, and are useful in screening the voluminous literature on species of Heliolites. Six of the species compare closely to Silurian species reported from central Kazakhstan, West Siberia, and Northern China; few are shared with other regions. The principal affinities are consistent with occurrence in the Uralian-Cordilleran paleogeographic region in the Silurian northern hemisphere. Eight species do not appear to be recorded in published literature elsewhere and are apparently endemic.^1";
s[1898] = "YOUNG G.A., NOBLE J.P.A. (1990).- Silurian Heliolitidae (Anthozoa, Tabulata) from the Chaleurs Bay region, Canada.- Journal of Paleontology 64, 1: 44-60.- <b>FC&#038;P 19-1.1</b>, p. 24, ID=2590^<b>Topic(s): </b>distribution; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Baie des Chaleurs^The Early to Late Silurian sedimentary rocks of the Limestone Point and La Vieille Formations of Northern New Brunswick and the Anse a Pierre-Loiselle, La Vieille, and Gascons Formations of the Gaspe Peninsula possess diverse and abundant tabulate coral faunas that include six species of Heliolitidae distributed among Heliolites and Stelliporella. Two species, Heliolites laxus and Heliolites distinctus are new. A revised concept of the genus Heliolites is proposed. The Heliolitidae from this region show a substantial degree of endemism and are most similar to northern European faunas. * The distribution of individual heliolitid species was under a high degree of facies control. The heliolitids are more restricted in distribution than are other groups of Tabulata in this region and are most abundant in open shelf and carbonate bank facies.^1";
s[1899] = "DIXON O.A. (1989).- Species Definition in Heliolitine Corals of the Lower Douro Formation (Upper Silurian), Canadian Arctic.- Journal of Paleontology 63, 6: 819-838.- <b>FC&#038;P 19-1.1</b>, p. 50, ID=2662^<b>Topic(s): </b>species concept; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian U; <b>Geography: </b>Canada, Arctic^Specimens representing Heliolites diligens Bondarenko 1966, H. aff. H. luxaboreus Yang 1978, and H. tchernyshevi Bondarenko 1966, are common and Heliolites sp. and Stelliporella sp. are rare in diverse coral assemblages associated with lithistid sponge reefs in deep shelf or ramp limestone facies of the Douro Formation. Heliolites diligens, a more widely adapted, possibly &#34;opportunist&#34; species, occurs abundantly in lower diversity stromatoporoid &#47; coral assemblages from nonreefal, shallower shelf limestone facies. Detailed systematic study of approximately contemporaneous populations of these Ludlovian heliolitid species shows that all are morphological variable; assessment of this variability qualitatively and quantitatively is critical to species definition and recognition. Heliolites diligens is the most variable, with wide intercolony variation in septal development, corallite wall configuration, and spacing of horizontal skeletal elements. This apparently represents morphological plasticity rather than differences that can be ascribed to distinct species. Conspecifity of the more extreme and dissimilar variants can be inferred from study of large assemblages of coeval specimens. The other species, with more narrowly defined, discrete variation fields, are more readily distinguished from each other.^1";
s[1900] = "LEE D.-J., YOUNG G.A., NOBLE J.P.A. (1990).- Heterochronic evolution in the Heliolites interstinctus-decipiens lineage of the Chaleur Bay region, eastern Canada.- Lethaia 23, 1: 11-20.- <b>FC&#038;P 19-2.1</b>, p. 34, ID=2752^<b>Topic(s): </b>heterochronic evolution; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada E^A study of the Heliolites interstinctus-decipiens lineage from the Silurian of the
```

```
Chaleur Bay region, eastern Canada, indicates that most morphological characters of this lineage, including tabularium diameter, coenenchymal tubule diameter and corallite spacing, remain relatively invariate through a Llandovery to Pridoli interval of about 20 million years. In contrast, septal development and corallite wall crenulation show pronounced evolutionary changes due to heterochrony, as shown by comparison of astogenies throughout the lineage. The reduction of septa and the replacement of crenulate corallites by smooth ones in the &#039;decipiens&#039; type descendent appear to have been by paedomorphosis from the &#039;interstinctus&#039; type ancestor. The problems of speciation in this lineage are discussed including the alternative hypotheses of a speciation event in the early Ludlow or a phyletic trend within a single species whose longevity is due in part to the stabilization processes of niche separation.^1";
s[1901] = "YOUNG G.A., NOBLE J.P.A. (1990).- Silurian Proporidae and Plasmoporidae (Anthozoa, Tabulata) from the Chaleurs Bay Region, Canada.- Journal of Paleontology 64, 2: 184-199.- <b>FC&#038;P 19-2.1</b>, p. 35, ID=2754^<b>Topic(s): </b>taxonomy, facies; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Baie des Chaleurs^Six species belonging to the families Proporidae and Plasmoporidae occur in the Lower and Upper Silurian rocks of the Limestone Point and La Vieille Formations of northern New Brunswick and of the Anse a Pierre-Loiselle, La Vieille, and Gascons Formations of the Gaspe Peninsula of Quebec. The three species of Propora are widely distributed but show varying faunal affinities, while both species of Plasmopora, Plasmopora logani and Plasmopora corrugata, are new and are almost endemic. Revised concepts of Propora and Plasmopora are proposed. The holotype specimen for the type species of Camptolithus was examined and confirms the genus as distinct from Propora, rather than a synonym as has been previously suggested. * The facies distribution of these corals is variable. In general, the proporids, which mostly occur in facies indicating shallow carbonate banks and patch reefs, are more restricted in distribution than the plasmoporids, which occur in these facies and also in others representing a variety of open-shelf environments.^1";
s[1902] = "DIXON O.A. (1993).- Coral communities and implications for paleonenvironments: Silurian heliolitine corals in a carbonate ramp setting, Canadian Arctic.- Palaios 8: 18-30.- <b>FC&#038;P 23-2.1</b>, p. 41, ID=3365^<b>Topic(s): </b>ecological indicators; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Arctic^Heliolitine corals occur in the Ludlow-age Douro Formation on Somerset and neighboring islands. The corals occur in argillaceous carbonate rocks deposited on a regionally extensive ramp. Contemporaneous coral assemblages from different areas show marked differences in community characteristics that reflect a range of paleoenvironments, some more suited and others less suited to the heliolitines. Some of the paleoenvironmental differences are implied more strongly by the coral assemblages than by regionally subdued variations in enclosing carbonate facies. Optimal conditions for heliolitine corals in the region were apparently in a &#34;mid-ramp&#34; position, as suggested by numerically abundant, diverse, low-dominance species assemblages, with a greater proportion of flat-based and discoid colonies. These grew more rapidly and to larger sizes, had greater longevity, and show less growth interference from sedimentation than contemporaneous assemblages elsewhere in the formation. Variations in growth form in different species suggest differences in the relative importance of inheritance and environment as controls.^1";
s[1903] = "DIXON O.A. (1996).- Heliolitine corals of the upper Douro formation (Upper Silurian), Canadian arctic islands.- Journal of Paleontology 70, 5: 718-740.http:&#47;&#47; www.jstor.org/pss/1306476.- <b>FC&#038;P 26-1</b>, p. 65, ID=3634^<b>Topic(s): </b>; Heliolitida;
```

```
<b>Systematics: </b>Cnidaria; Heliolitida; <b>Stratigraphy:
</b>Silurian U; <b>Geography: </b>Canada, Arctic^Heliolitine corals are
closely associated with lithistid sponge-dominated reef mounds in
Ludlow carbonate ramp facies on Somerset Island. The corals occur
abundantly in argillaceous, fossiliferous wackestone immediately
flanking and capping the reef mounds, less commonly in calcilutite
mudstone within the reefmounds, and with sharply decreasing abundance
in nodular argillaceous wackestone to mudstone away from the reef
mounds. Exhaustive field collection, and systematic study that included
biometric analysis of collected assemblages, indicates that ten
heliolitine species are present, including the new species Heliolites
furyi, H. garnieri, and H. greineri, and two unidentified species,
Heliolites sp. A, and Podollites? sp. The occurrence of H. subdecipiens
Klaamann 1984, H. tchernyshevi Bondarenko 1966, H. cf. H. rariformis
Tchi 1976, Stelliporella cf S. podolica Bondarenko 1971, and
Squameolites anomalus Tchi 1976 indicates an affinity with Eurasian
rather than North American faunas of equivalent age. Many new species
have been ascribed to Stelliporella since the mid- 1970s; most lack the
diagnostic axial structures of the genus and are more appropriately
regarded as belonging to Heliolites. Newly defined structures termed
septal florets occur commonly in H. garnieri and very rarely in three
other species of Heliolites. Effective taxonomic use of septal
development requires very careful study because of the degree of
intraspecific and intracolony variation in some species.^1";

</b>soft parts; Heliolitida; <b>Systematics: </b>Cnidaria; Heliolitida;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Arctic^Calices
within a substantially silicified corallum of Heliolites garnieri
Dixon, 1996, from the lower part of the Barlow Inlet Formation (Ludlow)
on south-western Devon Island, contain what appear to be the silicified
remains of soft tissues of coral polyps. These remains apparently
represent the peristomal portion of an oral disc, incorporating a
symmetrical radial array of 12 spicules (intra-polyp sclerites), and a
membrane-like, possibly epidermal structure. These remains, and more
non-descript material in a few coralla belonging to two other species
of Heliolites, occur at local intra-corallum discontinuities where
polyps died, but the surrounding colony continued skeletal
construction. Their preservation indicates that, before the organic
remains were fully destroyed by decomposition, they were rapidly
enclosed and sealed by precipitation of micro crystalline quartz or a
precursor, and that the failed calices were capped rapidly by local
construction of basal epitheca. Clusters of hollow microspheres were
also preserved at these discontinuities, suggestive of micro-organisms
with a predilection for sites of tissue decay; these microbial decay
agents possibly helped to isolate microenvironments conducive to early
precipitation of silica. [original abstract]^1";

Territories^Several specimens of the small hexactinellid, Cyathophycus
mackenziensis n.sp., were collected from pale brown, shaly mudstone of
the Road River Formation. The sponges are of Wenlock age and were
collected from near Avalanche Lake, Mackenzie Mountains, Northwest
Territories, Canada. The small, steeply obconical sponges have
skeletons in crudely ranked quadrules to at least third-order, with
first-order openings generally 2mm high and 1mm wide. Successive orders
decrease in stages approximately half that of larger elements. A
moderately irregular dermal(?) layer with circular parietal gaps is
suggested in some specimens. The new species is consistently finer
textured than either the type species Cyathophycus reticulatus Walcott,
1879, or the later described Cyathophycus quebecensis Dawson, 1889.

reefs; Porifera Lithistida; <b>Systematics: </b>Porifera; Lithistida;
<b>Stratigraphy: </b>Silurian U; <b>Geography: </b>Canada, Arctic^The
Upper Ludlow Douro Formation contains the first reported Silurian
sponge reefs. These relatively small (5-35m diameter) mound-shaped
structures contain, on average, 35% lithistid demosponges. Reefs are
surrounded by irregular haloes of crinoid debris; abundance and
diversity of all fossil groups decrease away from the reefs. Each reef
is underlain by a lens of crinoid wackestone to grainstone rich in
crinoid holdfasts; trepostomate bryozoans, solenoporacean algae and
rhynchonellid brachiopods are locally common. The bulk of each reef
consists of lime mudstone with abundant lithistid sponges. This is
capped by a thin layer of wackestone with abundant tabulate and rugose
corals and fewer lithistid sponges, calcareous algae, trepostomate
bryozoans and stromatoporoids. This zonation, in which a sponge
colonization community was replaced by a coral diversification
community, is similar to that reported from some Middle Ordovician,
Upper Jurassic and Holocene sponge reefs. * The Douro sponge reefs were
relatively low structures, with about 3m maximum topographic relief.
They grew on a broad carbonate platform, probably in warm, tranquil,
turbid waters of normal or near-normal marine salinity. Periodic
influxes of terrigenous mud adversely affected reef size, and caused
biotic changes. Some of the reef lime mud was derived from non-reef
sources, but significant quantities were also produced on the reefs.
Reefs underwent synsedimtary 1ithification, bioerosion and minor storm
erosion. Fabrics and compositions of sparry calcite in cavities record
three generations of meteoric cementation. Originally siliceous
spicules of the lithistid sponges were dissolved and the moulds later
filled with sparry calcite. Early dissolution of siliceous spicules is
common in reef environments, and may have caused fossil sponges to be
under-represented in ancient reefs.^1";

and Southwest-Great Basin.- US Geol. Survey Prof. Paper 777: 66 pp., 16
pls.- <b>FC&#038;P 4-2</b>, p. 59, ID=5281^<b>Topic(s): </b>; Rugosa;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>USA, Great Basin^Corals representing 13 families of
Silurian Rugosa from limestones and dolomites of the central and
southwest Great Basin are described, classified and figured.
Coral-bearing Silurian beds of this province occur in two contrasting
carbonate rock facies: the eastern dolomite belt and the intermediate
limestone belt. A third major Silurian rock suite characterizes the
western, or Pacific Border, belt, which extends from the western Great
Basin to northern California and southeastern Alaska. * On the basis of
rugose corals and associated fossils, the Great Basin Silurian is
subdivided as five coral zones, lettered A through E in ascending
order. These provisional zones are a result of detailed stratigraphie
studies and geologic mapping of reference sections in areas extending
from the Inyo Mountains northeastward to the Roberts Mountains and
northern Simpson Park Mountains. * Of importance environmentally, as
well as with the identification and correlation of Great Basin
Silurian, are the large dasycladacean algae associated with Rugosa. As
the genus Verticillopora, these algae appear to have peaked in coral
zone D. * Rugose corals of special importance in correlation with
distant Silurian rocks are Palaeocyclus, Dalmanophyllum, Kodonophyllum,
Mucophyllum, Arachnophyllum, Toquimaphyllum, and the lykophyllids. The
closest foreign correlations are with the Gotland section, a Silurian
carbonate standard for western Europe. Fairly close similarities are
recognized with Silurian of Czechoslovakia and Eastern Australia.^1";

<b>Systematics: </b>Porifera; Stromatoporoidea; <b>Stratigraphy:
</b>Silurian L; <b>Geography: </b>USA, Ohio^Stromatoporoids from the
Brassfield Formation (Early Silurian, Llandovery) near Fairborn, Ohio,
provide substrata for a diverse epizoic community. The stromatoporoids
were colonized by at least 28 taxa including bryozoans, cnidarians,
echinoderms, annelids, and endolithic organisms. Analysis of the
occurrence, diversity, distribution and coverage of the epizoans
recognized patterns of site-selective attachment. The upper surface of
the stromatoporoids has a slightly higher epizoan coverage than the
lower surface. Concentric zones outlined from the margin also had
differences in area and percent coverage. On their upper and lower
surfaces epizoan occurrence decreased from the margin to the interior.
Epizoan coverage of the lower surface also decreased inward. On the
upper surface the echinoderms were randomly distributed. Bryozoans,
cnidarians and miscellaneous taxa including borers, cornulitids and
spirorbids were distributed nonrandomly. Over 95 percent of the area
analyzed is not covered by epizoans. However, epizoans are commonly
clumped or in direct contact with one another. These physical
```

```
interactions are the result of site-selective attachment by epizoans in close proximity rather than competition for available surface.^1";

Although they are generally placed in the phylum Coelenterata (Cnidaria), the recent discovery of living sclerosponges that share architectural affinity with some tabulates, has renewed debate about the evolutinary relationships of the latter. In particular, the tabulates have been assigned to the sponges (phylum Porifera). I report here the discovery of fossilized polyps in a Favosites from the Silurian of Quebec. This incontrovertibly demonstrates that the tabulates belong to the phylum Cnidaria, and details of the soft-part morphology suggest that the Tabulata form a group distinct from other corals. (Original summary)^1";
s[1923] = "LEE D.-J., NOBLE J.P.A. (1988).- Tabulate coral distribution - Upper Silurian West Point reef complex, Gaspe, Quebec.- 002 Bulletin of Canadian Petroleum Geology 36, 4: 379-387.- <b>FC&#038;P 18-1</b>, p. 42, ID=2215^<b>Topic(s): </b>distribution; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian U; <b>Geography: </b>Canada, Quebec^The Upper Silurian West Point Reef Complex of Gaspe consists of a variety of mixed carbonate - siliciclastic lithofacies representing, in total, deeper-water basin, shallow shoal, barrier reef, fore reef, lagoon and intertidal environments of a shallow-water platform. Stromatoporoids, tabulate corals and algae dominate the fossil assemblage. Favositids, halysitlds and heliolitids are the most important of the tabulate corals within the complex. Alveolitids and proporids are rare, and most syringoporids occur symbiotically with Stromatoporoids. Five species of Favosites, four of Paleofavosites, three of Heliolites, two of each of Alveolites and Caunopora, and one of each of Halysites, Syringopora, Cladopora, Striatopora, Thamnopora
```

```
and Propora have been identified. Favositids were generally more
tolerant of a wide range of ecological conditions, and Favosites
forbesi was the most varied, abundant and tolerant species. It has many
of the characteristics of an opportunistic species. Heliolites
decipiens had similar ecological distributions except that it is rare
to absent in facies representing shallow water, high energy
environments. Favosites hisingeri, Paleofavosites epinosus, Halysites
nitida and most heliolitid species are commonly associated with
deeper-water, mixed siliclastic - carbonate sediments of the open
platform but are otherwise rare. Paleofavosites epinosus and Heliolites
daintreei are especially characteristic of these deeper-water
sediments. Paleofavosites asper is restricted to shallow water
limestones and biohermal algal reefs. Cladopora sp. occurs in most
facies, but is only common in the limestones of subtidal environments.
Syringoporids occur almost entirely as the symbiotic Caunopora in a
variety of stromatoporoid-dominated facies. Favosites niagarensis,
Paleofavosites epinosus and Heliolites decipiens also occur as
transported cobbles in basinal facies. Water energy evidently was
important in controlling tabulate coral and stromatoporoid
distribution, with tabulate coral preferring calm and stromatoporoids
more turbulent conditions.^1";
s[1924] = "CHATTERTON B.D.E., COPPER P., DIXON O.A., GIBB S. (2008).-
Spicules in Silurian Tabulate corals from Canada, and implications for
their affinities.- Palaeontology 51, 1: 173-198.- <b>FC&#038;P 35</b>,
p. 62, ID=2361^<b>Topic(s): </b>soft body; Tabulata, Polyps, Sclerites;
<b>Systematics: </b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>Canada^Specimens of Favosites from upper Llandovery
strata of Anticosti Island show three types of calcite structures,
herein interpreted as spicules, preserved within their calices and on
top of the last tabula. This is stratigraphically younger material,
some 50m higher than fossils described two decades earlier, in which
calcified polyps, each with 12 retracted tentacles, were noted. These
more recently found structures show striking similarities in form and
position to point, collaret and capstan spicules found in the soft
tissues of modern pipe corals, i.e. the Octocorallia (Alcyonacea).
Where preserved in a distinct pattern on top of the calcite tabulae,
the spicular sclerites in Favosites occur in a particular sequence.
Twelve individual, or sometimes six pairs of, triradiate point spicules
have shrunk to a circlet near the middle of the calice (resting on the
last, outermost, tabula). Surrounding the point spicules are 3-6
circlets of curved, usually perforated, lenticular collaret spicules;
and surrounding these are scattered, much smaller, capstan spicules.
The spicules display variability, probably ontogenetic, in their form
and relative sizes; and they are more similar in form to calcareous
spicules of alcyonacean corals than to those known from calcareous
sponges. Structures with 12-fold radial symmetry in Heliolites,
originally described by one of us as &#039;septal florets&#039;,
consist of elements that are considered comparable with the point
spicules found in Favosites. They have been recognized in ten species
of Heliolites from Silurian (Wenlock-Ludlow) strata in the Canadian
Arctic islands. [original abstract]^1";
s[1925] = "LEE D.-J., NOBLE J.P.A. (1990).- Reproduction and life
strategies in the Paleozoic tabulate coral Paleofavosites capax.-
Lethaia 23: pp ?.- <b>FC&#038;P 20-1.1</b>, p. 59, ID=2795^<b>Topic(s):
</b>colony growth; Tabulata, Palaeofavosites; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian L; <b>Geography:
</b>Canada, Quebec^Asexual and sexual modes of colony formation in a
tabulate coral Paleofavosites capax are recognized from the early
Silurian Gun River Formation of Anticosti Island, Quebec. Colonies
produced by asexual fragmentation comprise monospecific &#34;clumped
populations&#34;. They are characterized by circular and concave bases,
and lack a protocorallite origin of colony growth. Sexually produced
colonies, where in situ, are always dispersed and characterized by
```

```
conical bases with a definite protocorallite point origin of colony
growth. Asexual colony formation by fragmentation in P. capax appears
to have been an adaption to a habitat of muddy substrates. Sexual
reproduction in this species probably played a minor role but was
necessary for the maintenance of gene diversity and long-distance
dispersal. A comparison of corallite size distributions between
populations demonstrates that intrapopulation variation in the
&#34;dispersed population&#34; and the conical colonies in
&#34;transported populations&#34; of P. capax is significantly larger
than the variation in the &#34;clumped populations&#34;. It is
suggested that this difference reflects the two modes of reproduction.
The above observations are significant to systematic studies because
they show that estimates of species morphologic parameters can be
seriously biased even when based on a relatively large sample size from
a well-defined population if that population is largely a result of
asexual colony formation.^1";

biostratigraphy and biofacies of northern New Brunswick and the
southern Gaspe Peninsula.- Canadian Journal of Earth Sciences 27:
1143-1158.- <b>FC&#038;P 20-2</b>, p. 64, ID=2797^<b>Topic(s):
</b>biostratigraphy; Tabulata zonation; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Baie
des Chaleurs^Diverse Early and Late Silurian tabulate coral faunas
occur in the Baie des Chaleurs region. Analysis of relative abundance
data of tabulate corals from the Limestone Point and la Vieille
formations of northern New Brunswick and the Anse a Pierre-Loiselie, La
Vieille, and Gascons formations of the southern Gaspe Peninsula allowed
the recognition of three recurrent large-scale biofacies: the
Propora-HelioIites, Cystihalysites, and Syringopora biofacies. The
Syringopora Biofacies lacks the characterictics that would allow a
zonation to be produced, but in each of the other biofacies, two zones
are erected. These can be applied throughout the Baie des Chaleurs
region and may be used for correlation with other areas having faunal
affinities with this region.^1";
s[1927] = "NOBLE J.P.A., LEE D.-J. (1991).- First report of allogeneic
fusion and allorecognition in tabulate corals.- Journal of Paleontology
65: 65-74.- <b>FC&#038;P 20-1.1</b>, p. 61, ID=2798^<b>Topic(s):
</b>allogenic fusion; Tabulata; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada, Quebec^Adult
intercolony fusion occurs in Paleofavosites capax (Billings) and P.
asper (d&#039;Orbigny) in the Silurian of Anticosti Island. This
represents the first documented example of allogeneic fusion seen in
tabulate corals. The occurrence of allogenic fusion and non-fusion and
the documentation of antagonistic behaviour in the same species attest
to the presence of some degree of allorecognition specifity, now well
established for modern corals, already in these Silurian corals. The
implication is that the evolution of allorecognition systems, probably
by polymorphism at allorecognition loci, was already well established
400 million years ago in corals. Banding, probably seasonal, appears to
be more likely environmentally than genetically controlled.^1";
s[1928] = "SORAUF J.E. (1974).- Growth lines on Tabulae of Favosites
(Silurian, Iowa).- Journal of Paleontology 48, 3: 553-555.-
<b>FC&#038;P 4-1</b>, p. 38, ID=5136^<b>Topic(s): </b>tabulae, growth
lines; Tabulata, Favosites; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Silurian; <b>Geography: </b>USA, Iowa^Growth lines
and a central junction line seen on the underside of tabulae in
silicified Favosites (Silurian, Iowa) are apparently the same as those
noted on scleractinian dissepiments. In living genera, these may be
equated with the presence of symbiotic algae and life in sunlit water.
It is suggested that favositid tabulate corals have analogous growth
lines for the same reason.^1";

</b>taxonomy, new taxa; Tabulata, Halysitida; <b>Systematics:
</b>Cnidaria; Tabulata; <b>Stratigraphy: </b>Silurian Llan Wen;
<b>Geography: </b>Canada, New Brunswick^A large collection of Silurian
halysitids, mainly from the Limestone Point, La Vieille, and Petit
Rocher Formations of northern New Brunswick, includes nine species
distributed among Catenipora Lamarck, Halysites Fischer von Waldheim,
and Cystihalysites Tchernyshev. One species, Cystihalysites
belledunensis, is new, and, of the others, half are previously unknown
in the Chaleur Bay region and half have been described before from this
area. All species are defined using both qualitative and quantitative
data. Statistical analysis of serial sections of a corallum of
Cystihalysites belledunensis suggests that any random section of a
halysitid will yield quantitative data representative of that colony.
Preliminary analysis of the relationships between species distributions
and stratigraphy and sedimentary associations suggests strong
facies-control on the distribution of the four most abundant species.
Both Catenipora simplex (Lambe) and Catenipora micropora (Whitfield)
occur mostly in outer shelf facies. Cystihalysites belledunensis n.sp.
and Cystihalysites encrustans (Buehler) never occur together, the
former being found in predominantly high-energy inner shelf facies and
the latter in the outer shelf facies.^1";
s[1930] = "YOUNG G.A., LEE D.-J., NOBLE J.P.A. (1991).- Halysitid and
Auloporid Tabulate Corals from the Gascons and West Point Formations
(Silurian), Gaspe, Quebec, Canada.- Journal of Paleontology 65, 5:
715-726.- <b>FC&#038;P 20-2</b>, p. 63, ID=2958^<b>Topic(s): </b>;
Tabulata, Halysitida, Auloporida; <b>Systematics: </b>Cnidaria;
Tabulata; <b>Stratigraphy: </b>Silurian; <b>Geography: </b>Canada,
Quebec^The uppermost Lower Silurian and Upper Silurian Gascons and West
Point Formations of the Southern Gaspe Peninsula were deposited under a
broad range of environmental conditions from deep offshore-shelf to
reef facies. Halysitid and auloporid tabulate corals occur in a number
of facies and show a high degree of endemism. Two species of
Halysitidae and three species of Auloporidae are found in these
formations. Both halysitids have been previously described from this
region. The auloporids include the new species Syringopora minuta and
an other species that may represent the first known Silurian occurrence
of the fletcherillid genus Pseudofletcheria. A neotype for the
halysitid Cystihalysites amplitibulatus (Lambe) is proposed.^1";
s[1931] = "YOUNG G.A., NOBLE J.P.A. (1987).- The Llandovery-Wenlock
Syringoporidae from New Brunswick, Canada.- Journal of Paleontology 61,
2: 268-283.- <b>FC&#038;P 17-1</b>, p. 27, ID=2141^<b>Topic(s): </b>;
Tabulata, Syringoporidae; <b>Systematics: </b>Cnidaria; Tabulata;
<b>Stratigraphy: </b>Silurian Llan Wen; <b>Geography: </b>Canada, New
Brunswick^A large collection of Silurian Syringoporidae, mainly from
the Limestone Point and La Vieille formations of northern New
Brunswick, includes one new species and three species previously
described from this area. Syringopora lambei n.sp. is distinguished
from the superficially similar S. bifurcata Lonsdale by its larger
corallites with much broader axial tubes and less frequent corallite
contacts. Similar problems which have existed in the past in the
distinction of S. compacta Billings and S. retiformis Billings can be
resolved, as shown in this study, on the basis of the larger,
geniculate and densely-packed corallites of S. retiformis. All four
species are defined using more quantitative data than has previously
been applied to syringoporid taxonomy. A new lectotype for S. compacta
is proposed. Recognition of epibionts on a corallum of S. bifurcata as
virtually identical to the &#34;epithecal scales&#34; used to
distinguish Syringoalcyon Termier et Termler from Syringopora Goldfuss
argues strongly against the continued recognition of the former as a
separate genus. Preliminary analysis of syringoporid distributions in
relation to stratigraphy and sedimentary associations suggests strong
facies and paleoenvironmental control on these distributions. For this
```

```
reason and because of their long stratigraphic ranges, no well-defined
biozonal scheme can be proposed at this time.^1";
s[1932] = "LEE D.-J., NOBLE J.P.A. (1988).- Heliolitid corals of the
Upper Silurian West Point Formation Gaspe, Quebec.- Journal of
Paleontology 62, 6: 855-865.- <b>FC&#038;P 18-1</b>, p. 43,

<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Silurian;
<b>Geography: </b>USA, Tennessee^Astraeospongium is found to form
secondary calcareous basal skeletons and thus may be attributed to the
morphological grouping &#034;coralline sponges&#034;. In A. meniscum, a
bowl-shaped sponge with a massive skeleton of octactins, the
ontogenetically youngest and still uncemented spicules are found at the
upper, concave surface, particularly close to the edge. Towards the
bottom, the spicules soon become altered through epitaxic cementation
and recrystallization. From this skeletal architecture can be inferred
that the soft tissues occupied only the uppermost portions of the basal
skeleton. The skeletal structure is in many respects similar to that of
the recent Petrobiona massiliana, although the ecological adaptations
of the two species are fundamentall different. [original abstract]^1";
s[1935] = "FREITAS T.A.de (1991).- Ludlow (Silurian) lithistid and
hexactinellid sponges, Cape Phillips Formation, Canadian Arctic.-
Canadian Journal of Earth Sciences 28, 12: 2042-2061.- <b>FC&#038;P
21-1.1</b>, p. 16, ID=3200^<b>Topic(s): </b>taxonomy; Porifera;
<b>Systematics: </b>Porifera; <b>Stratigraphy: </b>Silurian Ludl;
<b>Geography: </b>Canada, Arctic^Abundant hexactinellid and lithistid
sponges occur in Ludlow (Silurian) platform slope strata of the Cape
Phillips Formation, Canadian Arctic Islands. The following are new: in
the Anthaspidellidae Miller, 1889, Rhodesispongia simplex n.gen and
sp., Climacospongia snowblindella n.sp., and Climacospongia undulata
n.sp.; in the Sphaerocladina Schrammen, 1910, Caryospongia tuberosa
n.sp.; in the Hexactinellida Schmidt, 1870 Malumispongium? cornwallisi
n.sp., of the monospecific superfamily Malumispongium Rigby, 1967.
Other previously described sponges recognized in the study assemblage
include Hindia sphaeroidalis Duncan, 1879 and Caryospongia juglans
Rauff, 1894. These occur in association with abundant Archaeoscyphia
sp. in thin, laterally extensive lithistid sponge biostromes which
throve on platform slope sediments during the Late Silurian. Based on
the dominant dendroclone forms in the skeletons of these and other
genera, Anthaspidellidae can be divided informally into two groups: (i)
```

```
the polyclonids, possessing complex skeletons built of variable
dendroclones types, including I-, X-, and Y-shape dendroclones, and
accessory spicules, including rhizoclones, chiastoclones, and
monactines; and (ii) the monoclonids, possessing simpler parenchymal
canal systems and skeletons constructed mainly of I-shaped
(amphiarborescent) dendroclones and lacking accessory spicules. The
classification, based chiefly on skeletal architecture, suggests two
main evolutionary trends in the family. The monoclonids generally
maintained structural simplicity, inherited from the probable ancestral
monactinellid, whereas the polyclonids evolved a varied and complex
skeletal architecture that was more successful. [original abstract]^1";

southwestern Ohio).- Palaios 17, 3: 237-248.- <b>FC&#038;P 32-1</b>, p.
19, ID=1421^<b>Topic(s): </b>reef builders, ecology; reef builders;
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian L; <b>Geography:
</b>USA, Ohio^The framebuilding fauna of an Early Silurian (Aeronian,
Llandoverian), Brassfield Formation reef from west-central Ohio is
examined in detail. Brassfield reefs are among the very few Silurian
reefs of the mid-continent United States that are not dolomitized.
Species-level taxa identified in the framebuilding fauna include two
favositid corals, two proporid corals, two halysitid corals, two
colonial rugosan corals and at least four stromatoporoids.Favositids,
crinoid holdfasts, and bryozoans are distributed fairly evenly across
the reef; colonial rugosans and solitary rugosans are more abundant
along the windward side of the reef; and stromatoporoids are more
abundant on the leeward side. The Brassfield reef fauna resembles that
from the Jupiter Formation (Aeronian), Anticosti Island, and the
Manitoulin Formation (Aeronian), Manitoulin Island; however, there are
differences in total diversity and composition. Paleogeographic
positioning, local water depth, and access to open-ocean circulation
are inferred as reasons for the differences among Aeronian reefs.^1";

(1993).- The Silurian (Wenlockian) reef fauna of southeastern Wisconsin.- Palaios 8, 4: 325-338.http:&#47;&#47;www.jstor.org/pss/3515264.- <b>FC&#038;P 23-2.1</b>, p. 69, ID=3548^<b>Topic(s): </b>reef fauna, taxonomy, guild structure; reef fauna; <b>Systematics: </b>; <b>Stratigraphy: </b>Silurian Wen; <b>Geography: </b>USA, Wisconsin^The Racine Formation of southeastern Wisconsin contains a diverse reef fauna of Silurian (Wenlockian) age. A collection of more than 10,000 specimens from this fauna includes 191 species and 38 guilds of reef constructors, binders, bafflers and dwellers. Constructors and binders include stromatoporoids, tabulates, rugosans and bryozoans; bafflers include branching tabulates and dendroid rugosans. Only locally do these groups form a skeletal framework, and for the most part, their remains are separated by reef
```

```
matrix. Reef dwellers are represented by diverse guilds of brachiopods, gastropods, cephalopods, trilobites and echinoderms, and they also include receptaculitids, sponges, solitary rugosans, bryozoans and bivalves. Tiering within the fauna is well developed and probably extended to a height of 1m above reef surfaces. This reef fauna exhibits higher species diversity, greater numbers of guilds and more extensive tiering than Silurian level-bottom communities. Relatively few of its taxa, however, are restricted to Silurian reef environments. Constructors, binders and bafflers in the reef fauna have morphologic and taxonomic parallels in level-bottom communities, as do nearly all taxa of reef dwellers. Higher diversity in the reef fauna is not a function of specialized reef guilds and species, but results from packing of more species into the same guilds which are present in level-bottom communities. In this regard, the Silurian reef fauna differs fundamentally from that of today and reflects the generally low grade of ecologic complexity of the Paleozoic evolutionary fauna.^1";

23-1.1</b>, p. 88, ID=4202^<b>Topic(s): </b>reefs; reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian; <b>Geography:
</b>USA midwestern^Vertical tension fractures that crosscut proximal
flank beds exposed in the Pipe Creek Junior Quarry in north-central
Indiana formed during compaction of underlying interreefal carbonate
mud, and are commonly filled with well-sorted pisolitic grainstone made
up of coated grains ranging up to 1 cm in diameter. Pisolith cortices
are petrologically indistinguishable from marine cement between
pisoliths, from marine cement lining tension fractures, and from marine
cement lining vugs in surrounding flank beds. Isotopic signatures for
these components are also consistent (&#948;13C = -0.6 to 2.3‰ PDB;
&#948;18O = -8.7 to -3.9‰ PDB). In adddition, pisolites are present
exclusively within tension fractures, and commonly show lateral size
grading, with grain size increasing toward fracture interiors. These
features show that pisoliths are in fact mobile marine cements that
precipitated from Silurian seawater in synsedimentary tension cracks
that formed soon after deposition of flank beds. Requisite conditions
for the formation of such large coated grains include high-energy,
shallow-water settings, where sea level is generally coincident with
the depositional surface of the reefal complex. This origin supports an
interpretation that allochthonous material formig flank beds was
predominantly generated immediately upslope on wave-swept platforms,
that in situ accumulation of biotic debris was insignificant in the
formation of Pipe Creek Junior complex, and that many of the larger
Silurian &#034;reefal&#034; buildups like Pipe Creek Junior throughout
the midwestern United States probably had a similar origin.^1";

pinnacle reefs of the Canadian Arctic.- Palaios 8: 172-182.-
<b>FC&#038;P 23-2.1</b>, p. 65, ID=4426^<b>Topic(s): </b>reefs,
pinnacle reefs; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>Canada, Arctic^Silurian pinnacle reefs,
the first described in the Canadian Arctic Archipelago, are exposed on
Ellesmere and Devon islands. Two main reef trends occur, one of early
middle Llandovery to middle Ludlow age and a second of middle Ludlow to
Late Silurian or Early Devonian age. Reefs of both phases contain lime
mudstone cores: some are stromatactoid-rich, and others consist
predominantly of microbialite-rich lime mudstone or microbial
boundstone. Facies sequences of both reef phases show evidence of
upward-shallowing overall, but in the older reefs, isochronous capping
facies are dominated either by coral-microbial boundstone, an unusual
reef facies for the Silurian, or by stromatoporoid boundstone and
floatstone. This difference perhaps reflects variation in wave stress
and the apparent ability of a few corals thickly encrusted by, or
associated with, microbial boundstone and skeletal algae to withstand
greater wave energy than a stromatoporoid-coral-rich reef community.^1";

```

```
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian L; <b>Geography:
</b>Canada, Quebec^Reefs of the Lower Silurian Chicotte Formation are
the largest and most faunally diverse known on Anticosti Island,
Quebec. They reach up to 25m in thickness and 250m in diameter and are
present predominantly at two intervals, forming a lower and upper reef
cluster. Remnants of bioherms are represented on the present-day
wave-cut terrace as 60 to 100m diameter, subcircular erosional
depressions known as Philip structures or as outcrop. The bioherms were
relatively low structures, with approximately 3 to 5m maximum synoptic
relief, some of which developed on hardgrounds and possible paleokarst
surfaces of crinoidal wackestone and packstone. Dominant skeletal
framework builders and sediment producers within all of the reefs are
laminar to low domical stromatoporoids, colonial cerioid and
fasciculate rugose corals, colonial tabulate corals, and cryptostome
bryozoans. Vertical zonation of reef biota is evident within
well-exposed reefs of the lower reef cluster. Three to four stages are
recognizable: 1) a low-diversity tabulate dominated pioneering
community including large tabulate coral colonies (halysitids and
favositids), and few stromatoporoids (clathrodictyids,
ecclimadictyids), fasciculate rugosans, large generally monotypic
stalked crinoids, and shelly benthos (brachiopods, few ostracodes and
trilobites); 2) an intermediate- to high-diversity, mixed tabulate
coral-stromatoporoid-dominated reef-core community; 3) a slightly lower
diversity stromatoporoid-tabulate coral-dominated climax community with
laminar coenitids and alveolitids, and, 4) in a few localities, a
capping, low-diversity tabulate coral-dominated (alveolitid and
coenitid), and stromatoporoid-bearing community comprising laminar
forms. Amelioration of Early Silurian climates, following Late
Ordovician glaciation, allowed gradual reestablishment of extensive
shallow-water reef growth, by mainly new and increasingly diverse
genera and species of metazoans. Reef development within the Chicotte
Formation coincided with global, widespread development of latest
Llandovery and earliest Wenlock reefs in subtropical to tropical areas.
Chicotte reefs have broad characteristics, in terms of overall biotic
composition, vertical successions recognized, and paleogeographic
setting, similar to those of equivalent and slightly younger age from
intracratonic settings in Baltica (Gotland, Sweden and Estonia) and
central and northern Laurentia (Midcontinent, U.S.A.; Hudson Bay,
Canada; and North Greenland, Denmark).^1";
s[1957] = "KAHLE C.F. (1994).- Facies and evolution of a Silurian coral
microbialite reef complex, Maumee, Ohio, USA.- J. sediment. Res. A, 64,
4: 711-725.- <b>FC&#038;P 24-1</b>, p. 86, ID=4522^<b>Topic(s):
</b>facies, history; reefs; <b>Systematics: </b>; <b>Stratigraphy:
</b>Silurian; <b>Geography: </b>USA, Ohio^Silurian dolomite that crops
out in a quarry at Maumee, Ohio, USA, forms a thick reef complex
roughly 600m in diameter and about 68m thick. It is composed, in
ascending stratigraphic order, of the Lockport Dolomite and the
Greenfield Dolomite. The Lockport Dolomite at Maumee contains
multistory stromatolite, thrombolite, and coral-microbialite reefs.
Such reefs have never been reported previously in this unit in Ohio and
Indiana. Thrombolite and stromatolite reefs are interpreted to have
formed in a subtidal setting, possibly within a hypersaline lagoon.
Wave stress affected the coral-microbialite reefs by limiting the
number of metazoans and promoting the formation of fibrous cement
inferred to have been marine precipitates originally in the form of
magnesian calcite. Thrombolites and stromatolites form 20-60% by volume
of coral-microbialite reefs, and they contributed substantially to the
syndepositional stabilization of these reefs by serving as binders and
encrusters of metazoans, especially branching corals. Such
stabilization sharply limited the amount of sediment available for the
formation of flank beds next to coral-microbialite reefs. Evolution of
the Maumee reef complex (MRC) involved two shallowing upward sequences,
each of which was terminated by subaerial exposure. The older interval
```

```
of subaerial exposure is represented by an intraformational
unconformity within the Lockport Dolomite. The younger unconformity at
the top of the Lockport Dolomite is correlated with the base of the A-1
evaporite in the Michigan Basin. Parts or all of patterns shown by
coral-microbialite reefs and microbialite reefs in the MRC may provide
an analogue for better understanding the nature and evolution of
pinnacle reefs and patch reefs in the Michigan Basin region and other
reefs elsewhere.^1";
s[1958] = "ERDTMANN B.D., PREZBINDOWSKI D.R. (1974).- Niagaran (Middle

Geol. Palaeont. Abh. 144, 3: 342-372.- <b>FC&#038;P 3-2</b>, p. 37,
ID=4945^<b>Topic(s): </b>reefs, inter-reefs; inter-reefs;
<b>Systematics: </b>; <b>Stratigraphy: </b>Silurian M; <b>Geography:
</b>USA, Indiana^Analysis of petrology and fossil contents,
preservation and diagenesis of Middle Silurian Mississinewa Shale in
northern Indiana suggests interpretation of the depositional history of
this lithostrome. Autochthonous dendroid graptolites, sponges,
inarticulate brachiopods and algal structures are considered pioneering
communities which were cyclically buried by storm or turbidite induced
sudden deposition of ultrafine grained carbonate-clastic muds in
interreef microbasins. The degree of bioturbation and carbonate removal
through early diagenesis under reducing conditions permits
reconstitution of individual stages of &#034;maturity&#034; reached by
each biosere prior to subsequent burial. These stages of bioseral
resettlement locally determined the development of interreef
(Mississinewa), patch reef (Liston Creek) or biohermal (Huntington)
facies within the Wabash Formation.^1";

stratigraphic control and with classic paleontology. * The nearly 400
identified species of the Niagaran macrofauna belong to either reef or
interreef (or nonreef) faunas and have been assigned precise
stratigraphic levels.^1";
s[1960] = "CONIGLIO M., FRIZZELL R., PRATT G.R. (2004).- Reef-capping
laminites in the Upper Silurian carbonate-to-evaporite transition,
Michigan Basin, south-western Ontario.- Sedimentology 51, 3: 653-668.-
<b>FC&#038;P 33-1</b>, p. 83, ID=7231^<b>Topic(s): </b>reefs,
laminites; reefs laminites; <b>Systematics: </b>; <b>Stratigraphy:
</b>Silurian U; <b>Geography: </b>Canada, Ontario^Silurian pinnacle
reefs in the subsurface of the south-western Ontario portion of the
Michigan Basin display a variety of laminated carbonates (laminites)
within predominantly muddy reef-capping facies in the upper part of the
Guelph Formation and the overlying A-1 Carbonate of the Salina Group.
Laminites, which are limestone, dolomite or partially dolomitized
limestones, have a range of morphologies, from simple planar to a
variety of wavy and serrated forms. Individual laminae are composed
mainly of micrite, microspar or replacive dolomite, and vary internally
from isopachous and continuous over the diameter of the core to
non-isopachous and often discontinuous. Clotted and peloidal micrite,
sometimes defining small knobs and chambers, is interpreted as being
microbial in origin and occurs within all types of laminites. Fibrous
cement locally comprises laminite clasts in breccias or coats clasts in
breccias, and also occurs as spherulites in the interparticle spaces in
breccias. Although similar laminites have been described from elsewhere
in the Michigan Basin and interpreted as caliche, travertine and
abiotic subtidal stromatolites, the laminites in south-western Ontario
```

```
are most realistically regarded as microbial. The causes for the
variations in morphology and characteristics of the constituent laminae
are uncertain, although fluctuations in local microenvironmental
conditions would have been important, set against a backdrop of an
increasingly restricted overall setting. Caliche or travertine origins
for these laminites are unlikely in general, except perhaps locally at
the subaerial exposure surface at the tops of pinnacle reefs. [original

Early Devonian Graptolite, Brachiopod and Coral faunas from the
Northwestern and Arctic Canada.- Geological Association of Canada,
Special Paper 17: 1-71.- <b>FC&#038;P 8-1</b>, p. 51,
ID=0220^<b>Topic(s): </b>; paleontology; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Silurian Devonian L; <b>Geography:
</b>Canada, Arctic^Emphasis of this paper is biostratigraphic, and
illustrations (Pls. 1-4, graptolites; 5-14, brachiopods and two
trilobites; 15-44, rugose corals) arranged by faunas and regions, not
zoological affinities. Age estimations primarily are based on
graptolites and conodonts in Pragian and earlier strata, and on
conodonts and a goniatite occurrence in later strata. Ages are argued
as much as possible in terms of the European Hercynian magnafacies
stages. Twelve formally defined graptolite zones are recognized in
shale facies: nilssoni, leintwardinensis primus Zones (Ludlovian),
formosus, bugensius, chelmiensis, bouceki, transgrediens, angustidens
Zones (Pridolian), uniformis uniformis, hercynicus Zones (Lochkovian),
thomasi and yukonensis Zones (Pragian). The zone of Monograptus thomasi
is new. Corals figured are referred to 11 units, which take their names
either from associated conodonts, or from their stratigraphic
occurrence between conodont or graptolite faunas. In ascending order
with approximate stage assignments these are: index associates (early
Pridolian), post bugensis and pre transgrediens praecipuus Fauna, and
confluens &#948; associates (middle Pridolian), post index and pre
hesperius Fauna (late Pridolian), hesperius associates (early
Lochkovian), post hesperius and pre pesavis Fauna (middle Lochkovian),
pesavis associates (late Lochkovian), late sulcatus associates (late
Pragian), dehiscens associates (early Zlichovian), aff. perbonus
associates (late Zlichovian) and serotinus associates (Dalejan). In
Prongs and Royal Creeks areas, where the best dated coral faunas are
mostly allochthonous in debris flows, migrations caused by minor
transgressive &#47; recessive cycles considerably affected the
composition of the coral faunas. Several forms present have no known
ancestors or descendants in other local faunas. Halysitids are not
known in Pridolian or later faunas and Lower Devonian heliolitids are
extremely rare in the region. Coral provinciality was most marked in
Pridolian time, when Yukon faunas were still entirely Silurian, while
arctic faunas included obvious Devonian forerunners, and in late
Pragian to early Zlichovian time, when the Yukon and arctic faunas
```

```
continued to be of Old World Faunal Realm aspect, while contemporaneous
faunas in Nevada appear to have included forms developed from Eastern
North Americas Realm species. The following taxa are described:
Ogilvilasma discors gen. &#038; sp.n., Werneckelasma multiseptata gen.
&#038; sp. n., Spongonaria guttata sp.n., and Windelasma werneckensis
gen. &. sp. n. [extracted from original summary]^1";

xenoliths^Eighteen samples containing sedimentary rock xenoliths were
obtained from cores drilled into eight Mesozoic kimberlite pippes in
the Kirkland Lake area, Ontario and in Ontario and Quebec near Lake
Timiskaming. Nine samples from five pipes contained fossils that were
used for age determinations. These fossils are Middle or Late
Ordovician graptolites,inarticulate brachiopods and conodonts; Silurian
and (or) Devonian conodonts; Early Devonian colonial corals; a Devonian
stromatoporoid; Early and Middle Devonian conodonts. These fossils
provide the first physical evidence for a connection between a Lake
Temiskaming &#34;basin&#34; and other Ontario Basins during at least
part of the Devonian. These strata persisted at least until the
Mesozoic before they were removed by erosion.The stomatoporoid is
illustrated in longitudinal section and described as &#34;The Late
Silurian or Devonian multilayered stromatoporoid Densastroma sp. This
form has short, thick pillars that are highly replaced.&#34;^1";

```
Hexactinellida; <b>Stratigraphy: </b>Devonian L; <b>Geography: </b>USA,
Tennessee^A fauna of eight taxa of demosponges and hexactinellid
sponges has been collected from the Lower Devonian (Lochkovian) Ross
Formation, largely out of the upper Birdsong Shale Member in Benton
Decatur, and Perry Counties in west-central Tennessee. The Upper
Birdsong Shale (&#34;bryozoan zone&#34;) in which the sponges are most
common appears to have been deposited below normal wave base in a quiet
marine environment, and represents a terrigenous clastic sediment
influx onto a carbonate shelf that had existed in the area from at
least the middle Silurian. Benton Quarry in Benton County was the most
productive locality for fossil sponges. The new demosponge genera and
species Ginkgospongia foliata and Coniculospongia radiata occur with
the new species Haplistion lobatum and skeletal mats of fine spicules,
along with moderately rare specimens of Hindia sphaeroidalis Duncan.
The new hexactinellid genus and species Stiodermiella amanita and
Stiodermiella tetragona are characterized by peculiar ornamented
papillose, swollen spicules that produce a massive, armored layer on
the upper part of the sponge. The latter are associated with the new
hexactinellid species Twenhofelella bulbulus, which has relatively
normal-appearing hexactines, and with an indeterminate hexactinellid
genus, which has spinose hexactines in irregular orientation in a
small, platelike fragment. Root tufts of probable hexactine origin also
occur. Swollen spicules in Stiodermiella are reminiscent of swollen
spicules in the family Stiodermatidae Finks, largely from the Permian
of western Texas, but elements of the family are also known from Lower
Carboniferous to Permian rocks in Europe and North America.^1";

Hydrozoa; <b>Stratigraphy: </b>Devonian Fam; <b>Geography: </b>USA,
Montana^Three remarkable fossil medusoid hydrozoans (Plectodiscus
latinautilus n.sp.) with disc, topsail, and pendant tentacular
appendages were recovered from the latest Late Devonian beds of the
Sappington Member of the Three Forks Formation in the Gallatin Range,
southwest Montana. This is the first velellid reported from a Paleozoic
beach paleoenvironment. Top and underside patterns of these
chondrophorine velellids display well-preserved casts and mold imprints
in fine siltstone. Outlines of the circular disc and the profile of the
wide sail and tentacular structures embedded in soft tissue can be
recognized. These floating colonial animals were moved along the
southeast shores of the Sappington Basin during a time of eustatic sea
level lowering and regression in a tropical setting. Colonies were
washed up on the upper beach where they were stranded in the bubbling
swash left behind by the surf. The foreshore was constructed of
tabular, planar cross-bedded, seaward-dipping, foreset accretionary
beds which contain parallel laminations and lime-coated grains. Bedding
is inclined 17 to 24 seaward.^1";
s[1976] = "McLEAN R.A., KLAPPER G. (1998).- Biostratigraphy of Frasnian
(Upper Devonian) Strata in western Canada, based on conodonts and
rugose corals.- 002 Bulletin of Canadian Petroleum Geology 46, 4:
515-563.georef/1999022410.- <b>FC&#038;P 28-1</b>, p. 10,
ID=3951^<b>Topic(s): </b>biostratigraphy; stratigraphy; <b>Systematics:
</b>Chordata Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fra;
<b>Geography: </b>Canada W^A total of 13 conodont zones and 11 rugose
coral faunal assemblages currently provides a subdivision of the
Frasnian of the Western Canada Sedimentary Basin. The conodont zonation
adopted is that first developed in the Montagne Noire area of southern
France and subsequently found to have widespread applicability,
especially when supplemented through the use of graphic correlation.
The rugose coral faunal scheme is based on the overlapping ranges of
species with wide geographic distribution, but with relatively short
stratigraphic duration. Integration of these faunal schemes allows for
```

```
more precise biostratigraphic control and provides a basis for refined
correlation of the sequences of basin fill. * As all fossil groups have
varying degrees of facies control on their distribution, we do not have
conodont and coral biostratigraphic data for all units in the basin.
Significant conodont data have been obtained mainly from the margins of
the larger bank and reef complexes, rather than their relatively
shallow water interiors, and from the basinal strata enclosing them.
These data generally support a reciprocal process of reef and off-reef
sedimentation throughout the Frasnian. Rugose corals are most commonly
developed within the reef and bank complexes (especially the Winterburn
Group and equivalents), and particularly near their margins. They are
rarer and of less biostratigraphic value in basinal strata. * Some of
the more significant formational time spans, expressed in terms of
Montagne Noire (MN) Frasnian conodont zones, are summarized as follows.
The Beaverhill Lake Group of Alberta ranges from the norrisi Zone of
the latest Middle Devonian to lower Zone 5. The succeeding Cooking
Lake-Majeau Lake interval is in Zone 5 to possibly lower Zone 6, and
the overlying Duvernay Formation extends into Zone 10. The Perdrix
Formation in outcrop of the Rockies is largely equivalent in age to the
Cooking Lake-Majeau Lake-Duverny, but locally at least ranges into
lower Zone 11. The black/grey shale facies of District of Mackenzie and
northeast British Columbia (Canol Formation, Horn River Group) ranges
at least as high as Zone 6 and locally as high as Zone 10. The Ireton,
Leduc, Peechee, lower Mount Hawk interval of Alberta extends through
Zone 11, while most of the Nisku, Arcs/Grotto and upper Mount Hawk lie
within Zone 12 The &#034;Z-marker&#034; within the clastic basin fill
of subsurface Alberta lies approximately at the boundary of Zones 11
and 12 In the southern District of Mackenzie and northeast British
Columbia, the Jean-Marie Member and equivalents are in Zone 12.
Finally, the Blue Ridge, Simla, Kakisa and equivalents lie primarily
within Zone 13. [original abstract]^1";

Devonian) species of the rugose coral genus Zelolasma from the Eids
Formation of Ellesmere Island, Northwest Territories.- Current Research
B, Geological Survey of Canada 83-1B: 195-200.- <b>FC&#038;P 13-1</b>,
p. 34, ID=0445^<b>Topic(s): </b>new taxa; Rugosa, Zelolasma;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian L;
<b>Geography: </b>Canada, Arctic^Zelolasma sensu stricto, is known from
the Pragian of Tadzhikistan, late Pragian or early Zlichovian of New
South Wales, early Zlichovian of Ellesmere Island, and Dalejan of
Taymyr. Reported occurrences in the late Lochkovian of Salair and the
Dalejan or Eifelian of Gansu have yet to be substantiated. Forms
resembling Zelolasma, but differing from it by lacking discrete adaxial
septal fragments, are known from the Ludlow Series of New South Wales
and the Upper Silurian (Ludlow or Pridolian equivalent) of the southern
Urals.Zelolasma apsidiferum sp.n. is described from high strata of the
Eids Formation, 20.5 km west of the head of Sor Fiord, southwestern
Ellesmere Island. The type horizon of the new coral is in the
Polygnathus dehiscens Zone, which spans the Pragian/Zlichovian
boundary. However, the age of the type stratum is judged to be early
Zlichovian, rather than late Pragian, because it overlies probable
Zlichovian brachiopods, as well as spores dated approximately as middle
Emsian (equivalent to late Zlichovian).^1";
s[1979] = "PEDDER A.E.H. (1983).- New Dalejan (Early Devonian) rugose
corals from the Blue Fiord Formation of Southwestern Ellesmere Island,
Northwest Territories.- Current Research B, Geological Survey of Canada

</b>new taxa; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa;
<b>Stratigraphy: </b>Devonian L; <b>Geography: </b>Canada, Arctic^The
family Columnariidae Nicholson 1879, is revised, so that it comprises
the subfamilies Columnariidae Nicholson 1879, Hexagonariinae Bulvanker
1958, Paradisphyllinae Jell 1969, Utaratuiinae Spasskiy, Kravtsov and
Tsyganko 1975, Spongonariinae Crickmay 1962, and Tropidophyllinae
subfam.n. Stereophyllum Schlueter 1889, is likely to be a synomym of
Digonophyllum Wedekind 1923. However, Digonophyllum, which is a widely
used generic name, is retained on the grounds that Stereophyllum
appears to be a nomen oblitum. Aulacophyllum Milne-Edwards &#038; Haime
1850, and its probable synonym Pinnatophyllum Grabau 1922, are
discussed because of similarities between them and a new genus
Thoulelasma. Digonophyllum primitivum confertum subsp.n. (Family
Cystiphylliidae) and Thoulelasma loewei. gen. et sp.n. (Family
Halliidae) are described from high in the inversus Zone in the Sor
Fiord section. Paraspongonaria delicata gen. et sp.n. (Family
Columnariidae) is described from the same horizon and locality, as well
as from the overlying serotinus Zone near Vendom Fiord. Newly prepared
type material of Paraspongonaria sverdrupi (Loewe 1913) is figured from
the Zlichovian (Early Devonian) Db Series of Schei (1903; 1904) in the
vicinity of Goose Fiord.^1";

Dorothy Hill Jubilee Memoir]: 237-259.- <b>FC&#038;P 13-1</b>, p. 35,
ID=0449^<b>Topic(s): </b>blastogeny; Rugosa, Phillipsastrea;
<b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian U;
<b>Geography: </b>Canada N^Protocorallite ontogeny, corallite increase
and colony development in Phillipsastrea nevadeneis Stumm 1940 are
described from serial section of four complete colonies from the Late
Devonian of northern Canada. The protocorallite shows characteristic
rugosan septal insertion, with serial insertion of minor septa.
Increase is almost exclusively marginarial, non-parricidal. Offset
development displays subtle distinctions between peripherally and more
centrally located offsets. In both, most septa are inherited from the
parent and no regular pattern of insertion can be detected. All
corallites have the potential to offset repeatedly. Increase shows a
weak to strong periodicity, interpreted as seasonal, from which linear
growth rates of 4-10 mm yr-1 can be calculated. The balance between
peripherally and centrally located offsets, and the pattern of
distribution of corallites at the colony surface are the results of
space competition and simple geometric constraints operating during
growth. These factors, and different corallite growth rates are
responsible for the range of colony form. The most important variable
```

```
in the environment imposing space competition during growth is probably
rate of soft sediment accumulation around the colonies, with the
suspension and resedimentation of calcareous mud by seasonal storms
causing corallite or colony mortality. (Original summary)^1";

growth and diagenesis of skeletal structure in Tabulophyllum
traversensis (Winchell 1866).- Boletin de la Real Sociedad Espanola de
Historia Natural, Seccion Geologica 92, 1/4: 77-086.- <b>FC&#038;P
26-2</b>, p. 24, ID=3704^<b>Topic(s): </b>incremental growth; Rugosa,
Tabulophyllum; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian Giv; <b>Geography: </b>USA, Michigan^Understanding
biogemic structures within fossil corals, and diagenetic changes in
skeletal material is basic to taxonomy in the Rugosa and Tabulata.
Incremental growth has long been known in living and fossil
scleractinian corals, and likewise recognized in Paleozoic rugose and
```

```
tabulate corals. Study of very well-preserved rugose corals from
Devonian rocks of Michigan reveals skeletal growth banding within
fibrous septotheca, shown by variation in the trace element magnesium.
Modern electron microprobes (superprobes) allow detailed mapping of
minor element distribution on a less than 1µm scale, with material
studied here of Tabulophyllum traversensis from Traverse Group strata
(Givetian) of Michigan. Element mapping of magnesium distribution
clearly shows incremental skeletal banding within fibrous walls that
marks growth, with alternating bands of magnesium-rich (maximum
concentrations of 0,5%) and magnesium-free carbonate. Such a
geochemical marker of growth provides the opportunity to evaluate
diagenesis of corals and possibly recognize precursors of secondary
structures in skeletal carbonates of fossil corals.^1";
s[1994] = "SORAUF J.E. (1998).- Frasnian (Upper Devonian) rugose corals
from the Lime Creek and Shell Rock Formation of Iowa.- Bulletins of
American Paleontology 113, 355: 1-159.- <b>FC&#038;P 27-2</b>, p. 53,
ID=3914^<b>Topic(s): </b>; Rugosa; <b>Systematics: </b>Cnidaria;
Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography: </b>USA,
Iowa^Rugose corals from Frasnian Lime Creek (&#034;Hackberry&#034;) and
Shell Rock strata are known largely from the works of Fenton and Fenton
(1924) and Belanski (1927, 1928), each of which described outcrop
stratigraphy and major parts of the fauna. The Shell Rock Formation
includes three members, two of which contain rugosans, the basal Mason
City and the uppermost, or Nora Member. The overlying Lime Creek
Formation contains the Juniper Hill Member, lacking corals, overlain by
the very fossiliferous Cerro Gordo Member, source of much of the famous
&#034;Hackberry&#034; coral fauna described by Fenton and Fenton in
1924. The uppermost, Owen Member, also contains abundant Rugosa.
[&#8230;] Based on the brachiopod and conodont zonation, the Shell Rock
and Lime Creek coral faunas are medial and late, but not latest
Frasnian. [excerpts from extensive summary]^1";

corals of the Central Great Basin.- U.S. Geological Survey Prof. Paper
805: 83 pp., 25 pls.- <b>FC&#038;P 4-1</b>, p. 35, ID=5120^<b>Topic(s):
</b>; Rugosa; <b>Systematics: </b>Cnidaria; Rugosa; <b>Stratigraphy:
</b>Devonian L M; <b>Geography: </b>USA, Great Basin^Rugose corals of
the Great Basin Devonian seaways underwent three major bursts of
evolutionary activity: (1) in late Early to early Middle Devonian
(early Eifelian) time; (2) in the medial Middle Devonian (late
Eifelian); (3) in Late Devonian (Frasnian) time. No Rugosa are known in
the highest Devonian (Famennian) of this province. The product of the
first of these bursts of evolution is part of the subject of this
paper. * Devonian rocks of the central Great Basin occur in three
north-south facies belts of which the Antelope-Roberts Mountains belt
is the more important in terms of Early and Middle Devonian coral
distribution. No Rugosa were found in Early and early Middle Devonian
rocks of this age of the Diamond Mountains facies belt on the east,
where strata of this age are barren dolomite and siliceous sandstone.
Within the Monitor-Simpson Park facies belt on the west, only the
earliest Devonian Rabbit Hill Limestone coral fauna is known. * Nine
successive coral zones are defined in the Nevada Formation and
```

```
overlying Devils Gate Limestone of the Antelope-Roberts Mountains belt.
These zones have been designated A through I in ascending stratigraphic
order. Described and illustrated herein are Rugosa and Early Devonian
coral zones A, B, and C and those of coral zone D, which is Early and
early Middle Devonian. Rugosa of coral zone A are best known in the
westerly Monitor-Simpson Park belt, where they characterize the
Syringaxon facies of the Helderbergian Rabbit Hill Limestone.[part of
extensive summary]^1";

2006 s[2003] = "McLEAN R.A. (2010).- Frasnian (Upper Devonian) colonial
disphyllid corals from western Canada.- NRC Research Press, Ottawa,
Ontario; 189 pp. [monograph] - <b>FC&#038;P 36</b>, p. 61,
ID=6452^<b>Topic(s): </b>; Rugosa Disphyllidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography:
</b>Canada W^Colonial rugose corals of the Family Disphyllidae occur
abundantly in Frasnian (lower Upper Devonian) strata in western Canada.
The branching genus Disphyllum is the most diverse, being represented
by D. fasciculum (Meek), D. rugosum (Wedekind), D. catenatum Smith, D.
iowense Sorauf, D. fumosum n.sp., and D. sp. cf. D. major Jia. The
other branching genus recognized is Pantophyllum, and the species P.
camselli (Smith) and P. oliveri n.sp. are described. The remainder of
the described fauna are massive forms. Argutastrea is represented by a
single species, A. bompasi (Smith). Four species of Hexagonaria are
included: H. davidsoni (Edwards and Haime), H. magna (Webster and
Fenton), H. oweni (Belanski), and H. arietina n.sp. The new genus
Whittakeria comprises the type species, W. schucherti (Smith), together
with W. caurus (Smith), while a single species of Kuangxiastraea is
described, K. mirabilis n.sp. Biostratigraphic distribution of this
assemblage is reviewed and related to the rugose coral faunal sequence
and Montagne Noire conodont zonation previously applied in western
Canada. Contrary to some earlier opinions, the Disphyllidae is shown to
be unrelated to the Columnariidae, following new study of the holotype
of the type species of Columnaria, C. sulcata Goldfuss. [original
abstract]^1";
2007 s[2004] = "McLEAN R.A. (2007).- Kyphophyllid rugose corals from the
Frasnian (Upper Devonian) of Canada and their biostratigraphic
significance.- Palaeontographica Canadiana 26: 1-109. ISBN

</b>biostratigraphy; Rugosa, Kyphophyllidae; <b>Systematics:
</b>Cnidaria; Rugosa; <b>Stratigraphy: </b>Devonian Fra; <b>Geography:
</b>Canada^Representatives of the family Kyphophyllidae form a diverse
and geographically widespread group in Frasnian (lower Upper Devonian)
strata of Canada. From early to late Frasnian strata in western Canada
the species Tabulophyllum athabascense (Whiteaves), T. mcconnelli
(Whiteaves), T. magnum Fenton and Fenton, T. mineatum n.sp., T.
whiteavesi n.sp., T. asymmetricum n.sp., and T. vesiculosum n.sp. are
described, while a further species of Tabulophyllum is left in open
nomenclature. T. telfordi n.sp. is described from the early Frasnian of
eastern Canada. Other described species are from the late Frasnian of
western Canada and comprise Mictophyllum nobile Lang and Smith, M.
nobile large variety, M. semidilatum Smith and M. betulinum n.sp., with
the new genus Plectophyllum being represented by P. kindlei (Smith), P.
whittakeri (Smith) and P. pilatum n.gen. et n.sp. Biostratigraphy of
these taxa is discussed, together with that of previously described
western Canadian representatives of the kyphophyllid genera
Smithiphyllum, Tarphyphyllum, Mikkwaphyllum, Parasmithiphyllum,
Bouvierphyllum, Wapitiphyllum and Kakisaphyllum. The biostratigraphic
distribution of these species is related to the Montagne Noire conodont
zonation previously recognized in the Frasnian of western Canada, and
modified western Canadian rugose coral faunal assemblage^1";
