Taxonomic and molecular data were utilized to test the hypothesis that moss diversity is greatest near the equator. Species richness estimates from 86 taxonomic checklists representing global moss diversity do not support the hypothesis that, in general, mosses are more species-rich in the tropics than at higher latitudes. A significant latitudinal gradient was, however, detected for North, Central, and South American samples when analyzed alone. Taxonomic estimates of biodiversity patterns were compared to molecular estimates based on standing nucleotide diversity, and on phylogenetic diversity, the latter taking into account the historical information contained in a molecular phylogenetic tree for the mosses. Molecular estimates suggest that moss diversity is highest in the Southern Hemisphere and lowest in the Northern Hemisphere, with the tropics having an intermediate level. The differences, however, are slight, and analyses of molecular variance (AMOVA) indicate that there is virtually no generalized differentiation between major latitudinal zones. These results reflect the fact that virtually all moss lineages have representatives in all three latitudinal zones. At the nucleotide level, mosses best fit the pattern of “everything is everywhere”.

KEYWORDS: latitudinal biodiversity gradient, moss phylogeny, *nad5* intron, *rps4*, phylogenetic diversity, tropical biodiversity.

INTRODUCTION

A latitudinal gradient of decreasing species diversity from the tropics toward the poles is considered to be one of the few truly general patterns in biogeography and ecology (Rosenzweig, 1995). As a result, a voluminous body of literature has accumulated over the last 30 years, dedicated to explaining the basis of the latitudinal gradient (Rohde, 1992). Substantial progress has been made toward cataloging moss diversity through floristic treatments of many tropical areas. During this effort, bryologists have repeatedly noted that there appear to be high levels of species diversity in the tropics (e.g., Argent, 1979; Gradstein & Pocs, 1989; Frahm, 2003). Frahm (2003) indicated that about two-thirds of all bryophyte species (mosses, hornworts, and liverworts) occur in the tropics. To date, however, no formal analyses of global distribution patterns have been undertaken to test the hypothesis that mosses are in fact more diverse in tropical than higher latitude regions.

Crosby & al. (2000) recognized 12,800 moss species in their worldwide checklist. The number of species increases as new taxa are described and decreases as species are synonymized during the course of revisionary work (Touw, 1974). Given these contradictory trends, the current number is probably a pretty good, albeit rough, estimate for the total number of mosses.

The statistical analysis of broad-scale trends in biodiversity must be undertaken with care. In addition to complicating factors such as uneven sampling intensity, differing sample area sizes, and non-comparable habitats and levels of habitat heterogeneity among areas, species themselves are unequal in “biodiversity value”. Some, for example, are closely related to congeners while others are more isolated; some species contain high levels of genetic diversity while others are relatively invariant. For these reasons, some have advocated alternative metrics for quantifying biodiversity that do not rely on subjective and sometimes arbitrary definitions of what constitutes a species (Faith, 1992, 1994; Vane-Wright & al., 1991; Nixon & Wheeler, 1992; Humphries & al., 1995).

The primary purpose of this study was to test the hypothesis that mosses are more diverse near the equator than at higher latitudes. Data were compiled from regional checklists to estimate species richness (“taxonomic diversity”), and these were compared to geographic patterns in molecular diversity derived from nucleotide sequences from the plastid *rps4* gene and an intron in the mitochondrial *nad5* gene. Two estimates of molecular diversity were compared to the species richness data: nucleotide diversity, which represents standing levels of biodiversity at the DNA level, and phylogenetic diversity (PD; Faith, 1992, 1994), which provides a phylogenetic (i.e., historical) estimate of molecular biodiversity.

The molecular dataset utilized here to investigate moss diversity patterns was assembled for phylogenetic analyses of moss genera based on multiple loci. Names of taxa included in the analysis are provided in Appendix 2 but are omitted from presented trees because they are not relevant to the purpose of this study. Measures of clade support (e.g., bootstrap percentages, posterior probabilities) are also omitted because the biodiversity analyses explicitly take phylogenetic uncertainty into account, and the results are averaged across equally optimal trees. Topological relationships among the genera will be described in subsequent papers; we presently focus on the shape of the moss phylogenetic tree, which reflects the distribution of branch lengths on the reconstructed phylogram. These branch lengths estimate the “amount of evolution” that has occurred along internodes, and therefore permit analyses of biodiversity patterns.

MATERIALS AND METHODS

Regional checklists. — Numbers of species recorded from 86 geographic regions were obtained from checklists available in journals, on the World Wide Web (WWW), and by personal communication (Appendix 1). Subspecific taxa are not included. The area covered by each checklist was either obtained from the original publication, or was available on the WWW. In some cases (e.g., North American Pacific Northwest), the total area was estimated by adding together nested political units. When a fraction of some state, province, or country was included in the region covered by a checklist, the area was estimated as accurately as possible. Each area was assigned a geographic latitudinal center obtained from the WWW for all politically-defined regions (<http://www.cia.gov/cia/publications/factbook/index.html> and <http://www.netstate.com/states/index.html>). In cases where regions consisted of multiple political units (e.g., Pacific Northwest), latitudinal centers were estimated from maps. Checklists of some U.S. states were obtained from relatively old sources, and species have undoubtedly been added to these lists. Although species are regularly added to regional checklists, no systematic attempt was made to update published lists to their currently accepted species counts. Only checklists dating from 1968 or later were used for U.S. states.

Statistical analysis. — The relationship between species richness and latitude was assessed by several methods that were designed to take sample area into account. For graphical purposes, the number of species per 10,000 km² was plotted against latitude. The number of species per 10,000 km² was itself related to sample area size, but over a broad range of sample area sizes this

relationship could be ignored (see below). For statistical analyses of the latitudinal trend, regression analyses were conducted using SAS software (SAS Institute, 1991). Species counts were regressed against sample area (in km²) or the log of sample area, and latitudinal center. In this way, the relative contributions of sample area and latitude could be separated. Species counts per 10,000 km² were also regressed against latitude. Variations in how the regressions were conducted did not affect inferences about latitudinal trends in species diversity, so only the regressions of species richness on log sample area and latitude are presented.

Molecular dataset. — Nucleotide sequences for the chloroplast encoded *rps4* gene and the mitochondrial encoded *nad5* intron were obtained from 556 moss accessions representing 555 different genera. All of the major lineages of mosses were sampled; the dataset includes a species from 64% of all moss genera recognized by Crosby & al. (2000). Herbarium voucher information and GenBank accession numbers for all sequences are provided in Appendix 2. Protocols for DNA extraction and sequencing of these regions, including primer information, were given by Cox & al. (2004).

Phylogenetic analyses. — Analyses of the 556-taxon dataset were conducted using Bayesian statistical inference. Heterogeneous Bayesian analyses were performed using MrBayes3 (Huelskenbeck & Ronquist, 2002). Separate substitution models were applied to each codon position at the *rps4* locus and for the *nad5* intron region. The appropriate substitution models were determined by hierarchical likelihood ratio tests with the aid of MrModeltest 1.1b (Nylander, 2002). Bayesian analyses were conducted starting from a “usertree” calculated using the Neighbor-joining algorithm under maximum likelihood distances in PAUP (Swofford, 2001) with 10,000,000 generations using default, uniform priors. Model parameters including trees were sampled every 500th generation. The number of trees needed to reach stationarity (i.e., the “burnin”) in the MCMC algorithm was estimated by visual inspection of the plot of ML score at each sampling point using Excel (Microsoft Corp.). Trees of the burnin (i.e., those before the chain reached stationarity) for each run were excluded from the tree set, and the trees from each run were combined to form the full sample of trees assumed to be representative of the posterior probability (p.p.) distribution. 19,200 trees were saved from the Bayesian analyses. This tree set was filtered using the FILTER command of PAUP to include only those trees that were compatible with well-supported nodes relating the same taxa included in the backbone topology of moss relationships described by Cox & al. (2004). Topological details and support for each node will be presented in subsequent papers.

Molecular biodiversity. — Each accession was assigned to one of three latitudinal zones based on where it was collected. Collections from north of 30° N latitude were considered “Northern Hemisphere”, those from between 30° S and 30° N were assigned to the “Tropical” zone, and those collected south of 30° S were considered “Southern Hemisphere.” Although it is acknowledged that not all habitats between 30° N and 30° S are ecologically tropical (e.g., high elevation sites), characterizing each site climatically or vegetationally was neither possible in all cases, nor fully objective. The same scoring approach was used by Shaw & al. (2003a).

Accessions included in the molecular analyses were selected to represent moss genera for purposes of resolving phylogenetic relationships. However, most genera of mosses have at least one species that occurs in each of the zones. Thus, most genera could not be assigned to one and only one zone. Indeed, many of the species included in these analyses are distributed across more than one of our three latitudinal zones. Biogeographic patterns are therefore based on the accessions themselves rather than the genera (or even species) they represent. The accessions represent random samples from each of the three latitudinal zones. The estimates of phylogenetic diversity, described below, therefore test the null hypothesis that random samples of mosses from the three latitudinal zones contain the same (i.e., indistinguishable) levels of molecular biodiversity.

Nucleotide variation and diversity. — Analysis of molecular variance (AMOVA) was used to estimate components of molecular variance among versus within latitudinal zones, and test for significant genetic differentiation among samples from the zones. AMOVA addresses the hypothesis that nucleotide frequencies are non-uniform among latitudinal zones. Nucleotide diversity within each latitudinal zone was estimated from the sample of sequences representing that region using ARLEQUIN (Schneider & al., 2000).

Phylogenetic diversity. — Phylogenetic diversity (PD; Faith, 1992) was estimated on 10 randomly selected trees from the posterior probability distribution with branch lengths optimized under a General Time-Reversible substitution model with a discrete gamma distribution of rate (four categories) and a proportion of invariant characters (GTR+I+G). PD utilizes information inferred from phylogenetic relationships among accessions included in the dataset. PDs for each geographic region were estimated as the total length of the minimum-spanning subtree connecting all accessions representing that region. The sum of all branch lengths on the object tree constitutes the total PD contained in our sample. Partitioning of PD among regions was estimated by deleting all taxa other than those in the region of interest, and branch lengths were again summed for the remaining

subsample.

PD is based on total (i.e., cumulative) branch length for each geographic region, so estimates are affected by sample sizes. The substantial differences in sample sizes among regions (see Table 1) make the effect of sample size potentially significant. In order to correct for differing sample sizes among geographic regions and make direct comparisons possible, PDs were estimated for randomly sampled subsets of the Northern and Tropical accessions at $N = 87$, the size of our Southern Hemisphere sample. PD was recalculated for each of 100 taxon subsamples (of $N = 87$), so that we could estimate PD based on sample sizes equivalent to the least extensively sampled region (Southern Hemisphere). This subsampling procedure assessed the effect of which Northern Hemisphere accessions we used to estimate PD for the region. In order to account for phylogenetic uncertainty, which can also affect PD estimates, this subsampling procedure was repeated on each of 10 randomly selected trees from the Bayesian posterior probability distribution.

Differences in PD among regions were tested by analysis of variance (ANOVA), implemented in SAS. The model included latitudinal region ($N = 3$) and tree ($N = 10$) as main effects, with error variances provided by taxon subsamples. The model was unbalanced because estimates for Northern Hemisphere and Tropical regions had 100 taxon subsample replicates whereas the Southern Hemisphere region had no such replication. Variance components attributable to the main effects were estimated using the VarComp procedure in SAS, using the ML option.

RESULTS

Global patterns in species richness.

Numbers of species, sample areas, and the latitudinal centers for each area used to analyze species richness patterns are shown in Appendix 1. Species richness is, not surprisingly, significantly related to the size of the area covered by checklists (Fig. 1). In addition, there are more species per unit area (10,000 km²) in the largest sample areas compared to smaller areas (Fig. 2). The trend is not strong except for the largest areas, possibly because these areas encompass an exceptionally broad

Table 1. Nucleotide diversity in Northern Hemisphere (> 30° N), tropical, and Southern Hemisphere (> 30° S) accessions.

Region	Sample size	Nucleotide diversity
Northern Hemisphere	224	0.057214 ± 0.027320
Tropical	245	0.057601 ± 0.027491
Southern Hemisphere	87	0.062655 ± 0.030116

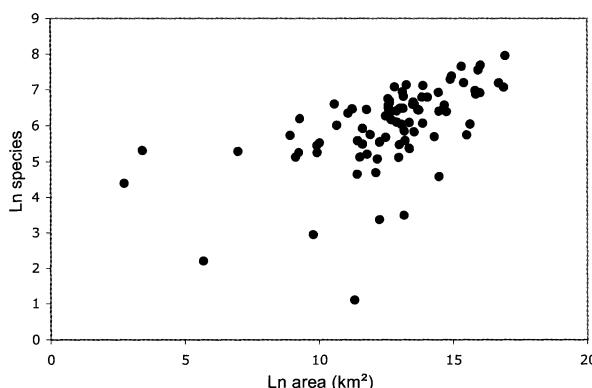

Fig. 1. Plot of species number versus (log) sample area.

range of climatic zones and topographic features; for example, North America north of Mexico, which includes subtropical to high arctic habitats. The size of the sample area and scale at which biodiversity occurs can have a strong effect on analyses of this type.

When no sample areas are excluded from the analysis, some samples from low latitudes had the highest numbers of species, but other tropical areas had much lower species richness (Fig. 3). The relationship between species richness and latitude is not significant when sample area is taken into account, but the trend is apparent from the fact that the latitude effect is nearly significant (Table 2).

To test whether a latitudinal pattern is obscured by the largest sample areas, these were separated from smaller sample areas and the two groups were analyzed separately. However, the effect of latitude is not significant for either the large sample area dataset (Fig. 4; Table 2) or the smaller sample area dataset (Fig. 5; Table 2). Various other subsets of the data based on area sizes were analyzed separately, but the latitudinal effect was not significant in any regression. Some of the samples from the tropical zone were from desert countries of northern

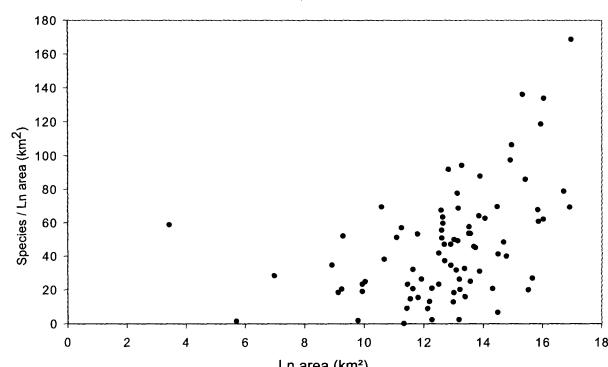

Fig. 2. Plot of number of species per unit area versus sampling area size included in moss checklists.

Africa, for example, where the flora is incompletely known and the dry climate may obscure a general latitudinal pattern. Nevertheless, even when these countries (Cyprus, Israel, Jordan, Kuwait, Lebanon, Oman, Syria, United Arab Emirates) plus the smallest sample areas (Hong Kong, Maldives Islands, Simeonof Island [Alaska], and Barro Colorado Island [Panama]) were excluded, the latitudinal effect was not significant. However, when only samples from North, Central, and South America were included, the latitudinal effect was significant (Table 2).

Nucleotide diversity. — Molecular diversity is lowest in the Northern Hemisphere, intermediate in the tropical zone, and highest in the Southern Hemisphere, but standard errors of nucleotide diversities are high (as is typical of such estimates) and the differences are small (Table 1). The AMOVA shows that there is virtually no molecular differentiation between accessions from the three latitudinal zones (Table 3). Indeed, almost 99% of the total diversity at the *rps4* and *nad5* loci exists within latitudinal zones.

the Bayesian posterior probability space on which the phylogenetic diversity analyses were conducted is shown as Fig. 6. The tree has a characteristic shape that has been documented in previous studies (Cox & al., 2004); internode branch lengths are fairly consistent until the origin of hypnalian pleurocarps, after which they are abruptly short (Fig. 6). The sister group to Hypnales, Hookeriales, does not exhibit short branch lengths that characterize Hypnales (Fig. 6). Other small regions of the tree suggest more local changes in diversification rate, or substitution rate, or both (e.g., a clade that includes seven genera of Polytrichaceae [*Notologotrichum*, *Polytrichadelphus*, *Meiotrichum*, *Polytrichastrum*, *Oligotrichum*, *Atrichum*, *Psilopilum*, *Dawsonia*, *Polytrichum*]: marked I in Fig. 6; a haplolepidous clade that includes *Syrrhopodon*, *Mitthyridium*,

Anthrocormus, *Exodictyon*: short arrow in Fig. 6A).

Accessions from Northern Hemisphere, Tropical, and Southern Hemisphere localities are rather scattered throughout the moss phylogenetic tree (not shown). Nevertheless, some groups, such as Hookeriales, are clearly most diverse in tropical regions. The moss phylogeny therefore reflects both the efficacy of dispersal, and evolutionary radiations following dispersal.

Phylogenetic diversity. — PD estimates follow the same pattern as standing nuclear diversity: Southern Hemisphere $>$ Tropical $>$ Northern Hemisphere (Table 4). An analysis of variance for PD estimates indicates that although the differences among regions in PD are small, they are significant and account for 64% of the total variation in PD (Table 5). One possible explanation for the relatively high PD in Southern Hemisphere accessions is that Southern Hemisphere harbors early diverging and relatively isolated taxa. On average, Southern Hemisphere taxa are indeed closer to the root of the moss phylogeny, although the standard deviations associated with these estimates are large and overlapping (Table 6).

DISCUSSION

This study provides only weak evidence that the tropics are richer in moss species than are high latitude regions, although there is a statistically significant relationship between species numbers and latitude for New World floras. Our inference from this exercise is that moss diversity, measured by the numbers of species, is

Note that branch lengths in the Hypnales (panels C and D) are exceptionally short. This tree was randomly selected from the Bayesian posterior probability space. I = Polytrichaceae, II = Funariales and Encalyptales, III = haplolepidous mosses, IV = acrocarpous (and cladocarpous) taxa with diplolepidous-alternate peristomes, V = Garovagliales, and VI = Hookeriales. Panels C and D are all Hypnales.

Table 4. Phylogenetic diversity (PD) in Northern Hemisphere (> 30° N), tropical, and Southern Hemisphere (> 30° S) accessions.

Region	Sample	PD (\pm standard deviation)
Northern Hemisphere	1000	2.2027276 \pm 0.1577044
Tropical	1000	2.4655070 \pm 0.1136834
Southern Hemisphere	1000	2.6576010 \pm 0.0100686

probably highest in the tropics, but the pattern is not striking. The lack of an obvious pattern is itself noteworthy. A pronounced latitudinal gradient is well-known for angiosperms (Gentry, 1988) and has been evident for over 100 million years (Crane & Lidgard, 1989). Many early botanists accepted the center of diversity = center of origin hypothesis put forth by Willis (1922) but it is now widely accepted that high levels of species diversity may reflect relatively low regional extinction rather than a center of origin (Stebbins, 1974).

Latitudinal gradients in species richness have been documented for a broad range of plants and animals (Rosenzweig, 1995), and most of the earth's top 25 biodiversity hotspots are in the tropics (Meyers & al., 2000). Tropical rainforests are said to contain very high levels of angiosperm diversity. The moss flora of Amazonia, in contrast, is notably depauperate (Churchill, 1998). There are high levels of moss diversity in tropical mountains (Churchill & Linares, 1995), as in many other organisms (Churchill & al., 1995), but the numbers presently available for mosses do not support the view that tropical mountain systems, including the Andes, are obviously richer than some regions at higher latitudes. In one of the only other studies to attempt a test of increasing moss diversity toward the equator, Vitt (1991) found no such diversity gradient among South Pacific Islands.

The analysis of broad-scale trends in species richness is fraught with methodological and statistical difficulties (Conner & McCoy, 1979; Rahbek, 1995, 1997). The confounding effects of area are substantial, and area itself may be the primary explanation underlying both altitudinal and latitudinal gradients (Terborgh, 1977; Rosenzweig, 1995). In addition, regions within a latitudinal zone are ecologically heterogeneous because of differences in, for example, rainfall, humidity, and topography. Regions within latitudinal zones also differ in history, which can be an important determinant of species richness. In fact, the general absence of a clear latitudi-

nal trend in the current study may be due in part to ecological and historical variation among sampling regions within latitudinal zones. Attempts were made to explore this possibility for mosses by examining subsets of the data, but except for a significant but weak trend in the Americas, we were not able to tease out a clear latitudinal pattern from any subset of the data. Despite all the weaknesses in our data, we would expect to see a trend if the global latitudinal patterns were strong. They are not, at least not at the geographic/ecological scales at which floristic data provide insight.

Areas covered by the moss checklists differ in sampling intensity; that is, how completely known the flora is. Tropical moss floras are obviously less intensively sampled than are at least the Northern Hemisphere areas, and species richness is almost certainly higher in the tropics than current numbers suggest. Nevertheless, the numbers would have to change relatively much for a clear pattern to emerge; moreover, the same inequality of floristic knowledge is true of angiosperms and most other organisms. Incomplete sampling is unlikely to explain the lack of a clear latitudinal gradient in moss species richness.

Another factor that could affect our ability to detect latitudinal trends is the superimposed patterns of diversity at different scales. Beta (regional) diversity could be higher in tropical moss flora even though alpha (local) diversity is not. The moss flora of Costa Rica might not include an exceptionally high number of species, but there might be higher species turnover between Costa Rica and Mexico than, for example, between Montana and California. Our data are not sufficient to address this issue because the analyses are based on species numbers alone for each region; additional studies in which the primary data are species lists are needed so that floristic turnover among sampling areas could be evaluated.

There are some exceptions to the general trend of increasing biodiversity toward the equator, and organism body size appears to be related to the magnitude (or existence) of the latitudinal gradient (Hillebrand & Azovsky, 2001). Small species tend to have cosmopolitan distributions and the slopes of species-area curves decrease with body size (Fenchel & Finlay, 2004). Microorganisms represent the extreme case, in which population sizes are so huge that "everything is everywhere" (Fenchel &

Finlay, 2004). Hillebrand & Azovsky (2001) posit that community patterns of species diversity in big organisms are determined by large-scale and long-term processes such as speciation rates and patterns, biogeography, and history, whereas communities of small organisms may be more influenced by ecological processes such as competition and other biotic interactions. In other words, assemblages of large organisms are “unsaturated” and are limited by dispersal (i.e., who got there—biogeography, history), whereas assemblages of smaller organisms are not so dispersal limited. At the level of taxonomic species, mosses do not display the “everything is everywhere” biogeographic extreme, but it is well known that moss distributions tend to be much broader, on average, than are those of angiosperms. Mosses fit the pattern of a relationship between body size, apparent dispersal ability, and strength of the latitudinal gradient.

Another factor that can affect inferences about biodiversity patterns are species delimitations. Clearly, not all species “were created equally” with regard to biodiversity value. Species that are part of a recent radiation may be very closely related genetically, even if morphologically distinct (e.g., Baldwin, 1997; Meyer, 1993). Moreover, some species contain high levels of genetic diversity while others are depauperate. How do broad scale biodiversity patterns based on species richness compare to patterns based on molecular diversity? At least in the moss genus, *Sphagnum*, the patterns can be quite different (Shaw & al., 2003a).

Nucleotide and phylogenetic diversity show congruent, even if subtle, geographic trends. A random sample of tropical mosses has higher molecular diversity than a comparable Northern Hemisphere sample, but Southern Hemisphere accessions have the highest diversity. The patterns in phylogenetic diversity are significant, but the degree of molecular differentiation among regions is very minor: about 1% of the total diversity among mosses at the two loci sampled in our study. Moreover, the statistical analysis of PD should be interpreted with caution since the Southern Hemisphere estimate did not incorporate taxon subsampling. Our results are clear, however, in showing that phylogenetic uncertainty contributes little to the variance in PD estimates, at least in this study where the phylogenetic tree was relatively well resolved and statistically supported (such that equally optimal trees were very similar in both shape and topology).

The fact that there is little differentiation in mitochondrial and plastid DNA (for the loci we sampled) between broad geographic regions across a clade that is several hundred million years old demonstrates that there has been substantial inter-regional migration. Tropical accessions are found throughout our phylogenetic reconstruction for the mosses, and few clades are completely restricted to particular latitudinal zones. These observations attest to the migratory prowess of mosses; every major and most minor lineages of mosses have successfully dispersed between northern, tropical, and southern latitudinal zones. On the other hand, some nonrandom geographic clustering of accessions also indicates that radiations have followed some dispersal events. Species level phylogenies for smaller clades are required to further elucidate such evolutionary patterns. Nevertheless, because of extensive dispersal at a global scale, mosses as a whole come close to displaying the “everything is everywhere” pattern at the nucleotide level. Perhaps it is not therefore surprising that the latitudinal trend in moss diversity is weak, at best.

There is suggestive evidence that moss molecular diversity might be higher in the Southern Hemisphere than in either the tropics or the Northern Hemisphere. The difference in phylogenetic diversity is significant, and the same pattern is present for nucleotide diversity estimates. Even if the pattern is real, the basis for it is obscure. Our analyses suggest that two randomly selected Southern Hemisphere accessions are, on average, more distinct in terms of DNA sequences than are randomly selected tropical or Northern Hemisphere samples.

One possible explanation is that mosses are older in the Southern Hemisphere, raising the possibility that they originated there. This hypothesis is difficult to test by reconstructing geographic ranges on the generic phylogeny because most moss genera span more than one of the latitudinal zones that we have defined. The Sphagnopsida are cosmopolitan, although it appears that the early diverging lineages of Sphagnopsida are Southern Hemisphere and/or tropical (Shaw & al., 2003b). The two species of *Takakia* are both Northern Hemisphere; Andreaeopsida are most diverse in the Southern Hemisphere, but there are species from the subantarctic to the arctic. The only clear pattern is that none of the early diverging lineages of mosses are primarily tropical, but no other inferences are presently possible. Only a species-level phylogeny for the mosses, in which early-diverging species of all major clades are identified, might be capable of resolving the geographic origin of mosses. Our results, including the observation that Southern Hemisphere accessions tend to be closer to the root of the moss phylogeny, are consistent with a Southern Hemisphere origin.

ACKNOWLEDGEMENTS

This study was supported by NSF grants DEB-0089131 to AJS and DEB-0089633 to BG.
