## PUBLISHED BY MR. JOHN VAN VOORST:

## CONCHOLOGY.

INTRODUCTION TO CONCHOLOGY; or Elements of the Natural History of Molluscous Animals. By George Johiston, M.D., LL.D., Fellow of the Royal College of Surgeons of Edinburg, author of 'A History of the British Zoophytes.' $8 \mathrm{vo}, 102$ Illustrations, $21 s$.
history of british mollusca and their shells. by Professor Edward Forbes, F.R.S., \&c., and Sylvanus Hanley, B.a. F.L.S. Illustrated by a figure of each known Animal and of all the Shells, engraved on 203 copper plates. 4 vols. 8 vo ., £6 10 s ; royal 8 vo , with the plates coloured, $£ 13$.

Synopsis of the mollusca of great britain. Arranged according to their Natural Affinities and Anatomical Structure. By W. A. Leach, M.D., F.R.S., \&c. \&c. Post 8vo, with 13 Plates, $14 s$.
history of the british marine testaceous mollusca. By William Clark. 8vo, 15 s.
gesera of recent mollusca ; arranged according to their Organization. By Henry and Arthur adams. This work contains a description and a figure engraved on steel of each genus, and an enumeration of the species. 3 vols. $8 \mathrm{vo}, \mathfrak{£ 4} \mathbf{1 0 8}$; or royal 8 vo , with the plates coloured, $£ 9$.

Malacologia monensis. A Catalogue of the Mollusca inhabiting the Isle of Man and the neighbouring Sea. By Edward Forbes. Post 8vo, 3s., Edinburg, 1838.

Gatherings of a Naturalist in australasia; being observations principally on the Animal and Vegetable Productions of New South Wales, New Zealand, and some of the Austral Islands. By George Bennett, M.D., F.L.S., F.Z.S. 8vo, with 8 Coloured Plates and 24 Woodeuts, $21 s$.
travels and researches in crete. By Captain Spratt, R.N., C.B., F.R.S. With Map, Twelve full-page Chromo-lithographic Views, and many Head pieces and other Vignette Illustrations. 2 rols. $8 \mathrm{vo}, £ 2$

## NATURAL HISTORY OF THE BRITISH ISLES.

This Series of Works is Illustrated by many Hundred Engravings; every Species has been Drawn and Engraved under the immediate inspection of the Authors; the best Artists have been employed, and no care or expense has been spared.

A few Copies have been printed on Larger Paper.
SESSILE-EYED CRUSTACEA, by Mr. Spence Bate and Mr. Westwood. Parts 1 to 17 , price $2 s .6 d$, each.
QUADRUPEDS, by Professor Bell. A New Edition preparing.
BIRDS, by Mr. Yarrel,l. Third Edition, 3 vols. £4 14 s .6 d .
COLOURED ILLUSTRATIONS OF THE EGGS OF BIRDS, by Mr. Hewitson. Third Edition, 2 vols., £ $414 \mathrm{~s}, 6 \mathrm{~d}$.
REPTILeS, by Professor Bell. Second Edition, 12s.
FiSHES, by Mr. Yarrell. Third Edition, edited by Sir John Richardsos, 2 vols., £3 3 s.
STALK-EYED CRUSTACEA, by Prof. Bell. 8vo, £15s.
STAR-FISHES, oy Professor Edward Forbes. $15 s$.
ZOOPHYTES, by Dr. Johnston. Second Edition, 2 vols., £2 28.
MOLLUSCOUS ANIVALS AND THEIR SHELLS, by Professor Edward Furbes and Mr. Hanley. 4 vols. 8yo, f6 los. Royal 8vo, Coloured, £13.
Forest Trees, by Mr. Selby. £1 8 s.
FERNS, by Mr. Newman. Third Edition, 18 s.
FOSSIL MAMMALS AND BIRDS, by Prof. Owen. fl11s.6d.

## THE RECORD OF ZOOLOGICAL LITERATURE.

The object of the 'Record' is to give, in an annual volume, reports on, and abstracts of, the various zoological publications which have appeared in the preceding year, to acquaint zoologists with the progress of every branch of their science in all parts of the globe, and to form a repertory which will retain its value for the student of future years. The several departments of the work have been undertaken by the following authors:-

Manmalia .................... Albert Gunther, M.D., F.Z.S.
Aves.............................. Alfred Newton, M.A., F.L.S.
Reptilia ........................ Albert Gunther, M.D., F.Z.S.
Pisces ........................... Albert Gunther, M.D., F.Z.S.
Mollusca ........................ Eduard von Martens, M.D.
Crustacea........................ C. Spence Bate, F.R.S.
Arachnida and Myriopoda... W. S. Dallas, F.L.S., M.E.S.
Insecta........................... W. S. Dallas, F.L.S., M.E.S.
Annelida and Rotifera ...... E. P. Wright, M.D., F.L.S.
Helmintha .................... E. P. Wright, M.D., F.L.S.
$\left.\begin{array}{l}\text { Echinodermata, Cœlenterata, } \\ \text { and Protozoa ............... }\end{array}\right\}$ E. P. Wriget, M.D., F.L.S.
The first volume consists of 634 pages, containing résumés of about 25,000 pages of the Zoological Literature of 1864 , with references to more than 5000 species described as new.

The second volume consists of 798 pages, containing résumés of about 35,000 pages of the Zoological Literature of 1865 , with references to more than 7000 species described as new.

The price of a volume is 30 s .
All communications, papers, or memoirs should be addressed to "The Editor of the Zoological Record, care of Mr. Van Voorst, 1 Paternoster Row, London."

JOHN VAN VOORST, 1 PATERNOSTER ROW.

## BRITISH CONCHOLOGY,

OR AN ACCOUNT OF

## THE MOLLUSCA

WHICH NOW INHABIT THE BRITISH ISLES AND THE SURROUNDING SEAS.

VOLUME IV. MARINE SHELLS,

IN CONTINUATION OF THE GASTROPODA AS FAR AS THE BCLLA FAMILY.

By JOHN GWYN JEFFREYS, F.R.S., F.G.S., \&c.

## LONDON:

JOHN VAN VOORST, PATERNOSTER ROW.
mDCCCLXVII.

YRINTED BY TAyI.OR AND FRANCIS, red lion coult, fleet street.

## Genus III. RISSO ${ }^{\prime} A^{*}$, Fréminville. Pl. I. f. l.

Bony rather slender: mantle furnished at the upper corner (and in some species also at the lower corner) of the mouth of the shell with a minute tentacular process: head depressed above and extended in front, where it forms a long and stout snout-like projection, which is divided at the extremity into two lobes, that serve as lips; it is armed with a pair of jaws and a very short spinous tongue: tentacles wholly or partially setose or hairy; tips blunt: eyes on small prominences or tubercles, one at the outer base of each tentacle: gills composed of from a dozen to twenty separate strands: foot lanceolate, narrow, double-edged, broader and more or less truncated in front, somewhat contracted in the middle, and pointed behind; sole grooved down the middle for about half its length towards the tail, whence it emits a glutinous thread by which the animal suspends itself to foreign bodies or to the surface of the water: opercular lobe large, divided into two wing-like expansions: beneath it at its hinder extremity issues a short tentacular appendage, which is in some species double or triple.

Shell oblong or oval, seldom umbilicate: epidermis very slight: spire usually elongated: mouth oval or trumpet-shaped, angulated above and slightly expanded below; its lips or margins are continuous.

The Rissore are minute, but elegantly shaped :. . . . "inest sua gratia parvis."
They are spread over all the globe-although the tropical scas have not been so well searched as those of the northern hemisphere for such small shells. Of the 25 species known in the British Isles, 15 inhabit the littoral and laminarian zones, and 10 the coralline and deep-sea zones. Woodward says that there are altogether 70 recent and 100 fossil species.

* Dedicated to M. Risso, the well-known naturalist of Nice.

In a valuable paper by M. Mörch, "On the Homology of the Buccal Parts of the Mollusca" (Ann. and Mag. N. H., August 1865), the cheek-plates or immoveable mandibles of this and other genera are described as two lateral plates, without cutting-edges, composed of scaly or needle-shaped particles, which seem only of use to protect the inside of the mouth from being injured by the spinous tongue. The opercular appendage was first noticed by Bivona. It seems strange that Philippi could not detect it, and that notwithstanding he had figured seren species (including Barleeia rubra) he should have remarked, "Hæ species omnes simillimis animalibus incoluntur." The pallial filament protrudes at the will of the animal from the upper or anal corner of the aperture of the shell. Hydrobia and Odostomia have similar processes. In Rissoa striatula and R. cancellata there are two, one on each side. These, therefore, are certainly not organs of generation. The filament is found in every individual; and all the abovenamed genera are diœccious or unisexual. It may be an auxiliary tentacle. The spawn-cases are solitary and hemispherical.

The 'Transactions of the Imperial Academy of Sciences at Vienna' for 1863 contain an elaborate and admirably illustrated monograph by Gustav Schwartz v. Mohrenstern of part of this difficult group; I hope the remaining portion will soon be published. He has provisionally adopted the views of Messrs. H. and A. Adams to the extent of considering Alvania a distinct genus ; but his reason for so doing seems to have originated in a misapprehension. According to the learned Austrian conchologist, Alvania is distinguished from Rissoa by having three caudal filaments instead of one. 'The authors of the 'Genera of recent Mollusca' say as
to Alvania, "Operculigerous lobe winged on each side, usually with three caudal cirrhi." Now their type of this genus (R. abyssicola) has but a single caudal filament; and Barleeia rubra (which, under the name of R. fulva, is comprised in the same genus) has none at all. Of the 16 other species of Alvania enumerated by them, the animal of one only ( $R$. reticulata or Beanii) appears to have been known to them. In their genus Cingula, however, we find R. semistriata, which notoriously has three caudal filaments, although the characters assigned to that genus are as follows:-" Opercular lobe and caudal cirrhus indistinct or rudimentary." This last-named genus comprises also Barleeia rubra, var. unifasciata. Under these circumstances it is well that Herr v. Mohrenstern has not absolutely decided on retaining the genus Alvania. I may here observe that the type of Risso's genus Alvania (from Leach's MS.) and 20 others out of the 23 which he described are cancellated shells, the remaining two being fossil species and erroneously referred to the Turbo interruptus and T. parvus of Montagu. The generic characters given by Risso will apply to almost every convoluted shell with an entire mouth and horny operculum ; and at the most Alvania can only be a synonym of Rissoa. The other genera proposed by Messrs. Adams are in my opinion not more maintainable. Onoba is described as having the whorls not longitudinally ribbed, and the peristome not dilated. In the type ( $R$. striata) both these characters exist to a certain extent. The only species assigned to Ceratia (viz. R. proxima) cannot be distinguished generically from R. vitrea (placed by Messrs. Adams in Rissoa) or from R. striata. Their genus Setia is characterized as having the tentacles pilose, and the operculigerous lobe destitute of a caudal filament;
R. pulcherrima is its solitary representative. In every species of Rissoa the tentacles are pilose ; and R.pulcherrima has an unusually long and pointed caudal filament.

My examination of the Rissoce has been on the same extensive scale as that of the Pisidia. The apology frequently offered for neglecting such tiny objects is unsatisfactory and unworthy of a naturalist-as if the Creator had bestowed more care in framing leviathan than in constructing the microscopic diatom, or as if the faculty which we enjoy of observing His varied works ought to be restricted to the contemplation of great things as being alone worthy of our exalted notions!

Fleming gave the name of Cingula to this genus, apparently being unacquainted with the scientific literature of the continent ; and he proposed another genus ( Cy clostrema) for R. Zetlandica. According to Philippi other species were separated by the Baron Bivona, under the generic title of Loxostoma. But such modest attempts at classification were far excelled by Leach, who repudiated Rissoa, and divided it into no less than eight genera, some of which contained the very same species as those described in others of these so-called genera.

The species being numerous, it may be convenient to divide them on a conchological basis :-
A. Cancellated; outer lip usually strengthened by a rib, and sometimes notehed within. 1. striatula; 2. lactea; 3. cancellata; 4. calathus; 5. reticulata; 6. cimicoïdes; 7. Jeffreysi; 8. punctura; 9. abyssicola.
B. Ribbed lengthwise and spirally striated ; outer lip thickened and reflected. 10. Zetlandica; 11. costata.
C. Mostly ribbed lengthwise, and spirally striated; outer lip usually strengthened by a rib. 12. parva; 13. inconspicua; 14. albella; 15.membranacea; 16.violacea; 17. costulata; 18. striata.
D. Spirally striated, or smooth; outer lip plain. 19. proxima;
20. vitrea; 21. pulchervima; 22. fulyida; 23. soluta; 24. semistriata; 25. cingillus.

It will be seen, however, by the following description of the species, that some of them cannot be placed strictly in one group more than in another.
A. Cancellated; outer lip usually strengthened by a rib, and sometimes notched within.

## 1. Rissoa stria'tula*, Montagu.

Turbo striatulus, Mont. Test. Br. p. 306, t. 10. f. 5. R. striatula, F. \& H. iii. p. 73, pl. lxxix. f. 7, 8.

Body yellowish-white, with a blood-red mark orer the head: mantle forming a small oval lappet or lobe on each side of the neck as in Trochus ; its outer edge is furnished with two threadlike and finely ciliated processes, one at each of the corners of the mouth of the shell, and which project or hang down, seemingly at the will of the animal: snout longish, narrow, cloven at the extremity: tentacles thread-shaped, somewhat flattened on the upper and lower surfaces, with blunt tips; they are clothed with a rery few short cilia: eyes on small tubercles: foot squarish in front, and pointed behind; when extended it is apparently divided (as in many other, perhaps every, species of Rissoa) into two parts, anterior and posterior: opercular or caudal appendage single, rather long, but not projecting beyond the tail or point of the foot; it issues from beneath the operculigerous lobe: excrement oval, dark-green.

Shell conic-oval, with a turreted outline and a slightly twisted base, solid, opaque, somewhat glossy when the surface is not obscured by a mineral coating: sculpture, several laminar transverse ridges, 10 or 11 of which are on the body-whorl, and 3 only on each of the next three whorls; those encircling the body-whorl are very unequal in size, the 3 uppermost being by far the largest and most apart one from another; the 3 basal ridges are also widely separated, the intermediate ones being close together ; the uppermost ridge is placed at some distance from the suture ; the interstices of all the ridges are crossed by numerous incurved striæ, so as to give the appearance of very fine lattice-work; these are stronger and more conspicu-

[^0]ous on the upper than under part of the shell; labial rib thick, sometimes double, or else having a varix on the body-whorl; top whorls quite smooth and polished: colour that of alabaster, with a scarcely perceptible tinge of yellow and occasionally an ochreous stain : spire moderately produced and pointed: whorls $\overline{5}-6$, convex, the last composing rather more than two-thirds of the shell : suture distinct, but not deep or channelled; the separation of the whorls is chiefly indicated by the prominent spiral ridge which surmounts each: mouth large, occupying about half the length of the spire, roundish-oval, angulated somewhat acutely above and obtusely below, and slightly expanded outwards; inside plain : outer lip semicircular, forming a very narrow rim within the labial rib: inner lip broad and thick, reflected on the pillar, and united with the outer lip at the upper corner of the mouth : operculum pale horncolour, with a short lateral spire, and very delieately striated. L. 0.215 . B. 0.15.

Habitat: Lower part of the littoral zone in the Channel Tsles, and on the coasts of Dorset, Devon, and Cornwall; by no means common. It has also been found at Margate (Hanley), Tenby (Lyons), Arran Isles, co. Galway (Barlee), Miltown Malbay, co. Clare (Harvey, fide Thompson), Bantry Bay (J. G. J.), Dublin Bay (Waller), off Larne, co. Antrim (Hyndman and J. G. J.), Cumbrae, Arran, N.B. (J.Smith), Lamlash Bay (Norman). Fossil in a bone-cavern at Mardolce in Sicily (Philippi). North and west of France (De Gerville, Cailliaud, and others) ; Cadiz ( $\mathrm{M}^{\text {c Andrew) }}$; south of France (Michaud and others) ; Dalmatia (Brusina) ; Spezzia (J. G. J.) ; Naples (Scacchi, fide Philippi).

This, as well as $R$. cancellata, adheres with some tenacity to the stones on which it is found; and when detached it also spins a fine byssal thread, by means of which it suspends itself in the water. The carving of the shell is inimitable. One of my specimens (probably a male), although full-grown, is little more than threequarters of a line in length, and of proportionate breadth.

The Turbo striatulus of Linné appears to have been Parthenia varicosa of Forbes=Chemnitzia pallida, Philippi. Da Costa described and figured the present species as T. carinatus; and I would have adopted that original and expressive name, were it not for the consideration that, no subsequent author having done so, I have no wish to be singular, or to make any unnecessary change in the nomenclature. Turton called this shell T.monilis, Michaud R. cochlea, Philippi R. labiata, and Leach Persephona brevis.

## 2. R. Lac'tea*, Michaud.

R. lactea, Mich. Descr. esp. Riss. p. 9, f. 11, 12; F. \& H. iii. p. 76, pl. lxix. f. 3, 4.

Shere oval, compressed towards the mouth, rather thin, semitransparent and somewhat glossy when living, opaque and lustreless when dead : sculpture, slight and gently curved longitudinal ribs, which are seldom continued below the periphery and are crowded near the outer lip; there are about 20 on the last and 10 on the penultimate whorl ; these ribs are crossed by fine spiral strix, 15 of which are on the last and 9 on the penultimate whorl; the ribs are more prominent than the strix, the points of intersection never being nodulous; there is sometimes, but rarely, a slight labial rib; the first two whorls are perfectly smooth : colour whitish, with a faint tinge of yellow, in dead shells milk-white : spire abruptly pointed: whorls 5-6, moderately convex, compressed towards the front; the last composes nearly three-fourths of the shell, and the first two are minute: suture slight but distinct : mouth oval, produced and angulated above, spread out below, not expanded outwards ; inside plain : outer lip rather thick : inner lip broad, reflected over the pillar, and united with the outer lip at the upper corner of the mouth, where there is a considerable thickening: operculum pale horncolour, with a short spire, and not conspicuously striated. L. $0 \cdot 233$. B. $0 \cdot 15$.

Habitat: Under stones at extreme low water of spring tides, and thrown upon the beach: St. Aubin's

[^1]Bay, Jersey (Hanley, Norman, and Dodd) ; Herm (Macculloch, Lukis, and Barlee) ; Barricane, north Devon (Miss Jeffreys, who never was in the Channel Isles or abroad). It is our raxest Rissoa. Sicilian tertiaries (Philippi). The ouly northern locality to my knowledge is Bohuslän in the south of Sweden, where Malm dredged two specimens (both dead) in different places. By his kind permission one of them, from 12 f ., is now before me. Its southern range is extensive, and embraces the north and west of France (Collard des Cherres, Cailliaud, Aucapitaine, and others), Vigo, 4 f., Gijon and Faro in Algarve, and Corunna (M‘Andrew), Adriatic (Heller), Dalmatia (Brusina), northern shores of the Mediterranean (Michaud, J. G. J., and others), Ajaccio (Requien), Naples (Scacchi), near Catania (Philippi), Algeria (I'Andrew and Weinkauff).

Turbo cancellatus (Beudant) of Lamarck.

## 3. R. cancella'ta*, Da Costa.

Turbo cancellatus, Da Costa, Br. Conch. p. 104, pl. viii. f. 6, 9. R. crenulata, F. \& H. iii. p. 80, pl. lxxix. f. 1, 2.

Bony milk-white, with a pinkish spot above the head : pallial lappet small, as in $R$. striatula: pallial filaments slender and microscopically ciliated, resembling minute auxiliary tentacles, one at each corner of the mouth of the shell: snout narrow and cloren at the point, extensile: tentacles cylindrical, but somewhat compressed on the upper and under sides, fincly and closely ciliated all over; they are occasionally borne erect, or now and then upturned : eyes on small tubercles: foot squarish in front, with small angular corners, contracted in the middle, and attenuated towards the tail, which is bluntly pointed: appenclage short, not projecting beyond the tail, apparently bicuspid, but really consisting of three filaments, one of which is smaller than the other two and is sometimes a mere bulb.

Shele conic-oval, solid, opaque, somewhat glossy : sculpture, strong longitudinal ribs, 16 of which are on the body-whorl,

[^2]15 on the peaultimate, 14 on the succeeding whorl, and 13 on the next, not more than half the last number being discernible on the upper whorl, when they altogether disappear; these ribs are continued to the base, which is furnished with an angular projection or knob, owing to this part of the pillar being greatly thickened; there are also equally strong spiral ribs, 6 of which are on the body-whorl, 3 or 4 on the penultimate, and 2 ouly on each of the succeeding three whorls; the first two or three whorls are apparently quite smooth and glossy, but under the microscope exhibit extremely fine and numerous longitudinal wase strix: the two sets of ribs cross each other, leaving between them square carities and forming at the points of intersection raised and rather sharp tubercles, imparting to the surface a prickly aspect; labial rib broad, and traversed by the spiral ribs up to the mouth, the edge of which consequently becomesscalloped or indented: colour yellowish-white, with often more or less of a rufous tinge, or indistinctly marked by two reddish-brown bands, a narrow one below the suture and a broad one round the periphery; sometimes the colour is milk-white; the throat or inside of the mouth is frequently stained by reddish-brown : spire short and acute: whorls 6-7, convex, the last occupying two-thirds of the total length; the first two or three whorls are disproportionately small: suture broadly excarated: mouth roundish oval, expanding outwards, fincly and closely ridged lengthwise on the inside of the labial rib; there are 12 of these ridges, besides usually a blunt tubercle on the lower part of the pillar: outer lip thin: inner lip forming a rather broad glaze on the pillar, which is imperforate: operculum not very thin, having a somewhat lateral spire (as in Littorina), and conspicuously and closely striated in a curved direction corresponding with the line of growth. L. $0 \cdot 185$. B. $0 \cdot 115$.

Var. paupercula. Dwarfed, more regularly oral and solid, with a proportionally longer spire. L. 0.135. B. 0.065.

Habitat: Rocks and stones at low water of spring tides, and the coralline zone, in the Channel Isles and on many parts of the Cornish coast ; rather common, especially at Herm. Received from Sandwich (Montagu) ; west bay of Portland, 15 f . (M'Andrew and Forbes) ; Torquay (Hanley) ; Salcombe Bay (Barlee) ;
off Lundy Island (M'Andrew) ; Manorbeer, Pembrokeshire (J. G. J.) ; Isle of Man, " one broken specimen from deep water on the north coast" (Forbes) ; Nymplı bank, 50 f. (M'Andrew) ; Bantry (Miss Hutchins, Thompson, and Barlee); Dublin Bay (Turton and Brown); Belfast Bay (Hyudman) ; off Larne, co. Antrim, 18-20 f. (J. G. J.) ; Lough Strangford, 7-20 f. (Dickie) ; Tyningham sands, N.B. (Brown); Lamlash (Landsborough); Loch Fyne, and the Hebrides as far north as Stornoway (Barlee and J. G. J.). A single dead and worn specimen of the variety was found by me at Herm; it may belong to a distinct species or be exotic. $R$. cancellata is fossil in the Sussex beds (Godwin-Austen) ; Ireland (J. Smith) ; Calabria (Philippi). Its living range is mostly southern, from Cherbourg (Récluz and Macé) and Morbihan (Taslé) to the Gulf of Gascony (D'Orbigny père, and J. G. J.), and Corunna (M‘Andrew and H. Woodward), throughout the Mediterranean (Michaud and others) ; Adriatic (Heller) ; Dalmatia (Brusina) ; Mogador, 3 f . (M‘Andrew) ; Egean (Forbes, fide $\mathrm{M}^{\text {‘An- }}$ drew) ; Madeira, 15-24 f., and Canary Isles, 12-60 f. (M'Andrew). The last-named naturalist also took some dead specimens in his Norwegian dredgings.

It is active and bold, floats like its congeners, and spins a byssal thread instantaneously on being detached from a crawling position. The incessant play of the cilia that fringe the tentacles is very striking ; it appears to be caused by the action of a double row of muscles in each tentacle, arranged in the form of a siphon, which is perceptible through the transparency of the integument. The pallial filaments probably serve the purpose of supplementary tentacles to warn the animal of impending danger. In spite of its stoutness the shell is sometimes perforated, possibly by Murex erinaceus or M. corallinus.

This is the Turbo cimex of Donovan, Montagu, and other conchologists (but not of Linné), $R$. crenulata of Michaud, and Persephona Hutchinsiana of Leach. The R. lactea of Michaud having been previously described by Lamarck as Turbo cancellatus (but subsequently to Da Costa's publication), we must either call that species cancellata and give up the name lactea, retaining crenulata for the present species, or else adhere to the strict rule of priority. Convenience, as well as justice, makes the latter alternative more desirable. $R$. cancellata of Desmarets is the Linnean $R$. cimex, which (as Turbo. calathiscus of Montagu) Mr. Thompson of Belfast seems to have mistaken for the species now described.

## 4. R. ca'lathus *, Forbes and Hanley.

R. calathus, F. \& H. iii. p. 82, pl. lxxviii. f. 3.

Sherl more conical and coarsely sculptured than the next species (Th. reticulata); longitudinal striæ more prominent; penultimate whorl not quite so broad in proportion to the bodywhorl, and haring usually but 4 rows of spiral striæ-although this last character is not constant, there being sometimes 5 and even 6 rows. Colour, size, and other particulars the same as in $R$. reticulata.

Habitat: Guernsey and Herm; rather common. Land's End (Hockin) ; Whitesand Bay (Mrs. Flack) ; off Penzance, $15-20$ f. (M‘Andrew and Forbes) ; Shellness, Kent (J. G. J.); off the Mizen Head, 50 f. (M'Andrew); Kilkee, co. Clare (Warren, fide Thompson); Isle of Man (Packe) ; co. Antrim (Hyndman and J. G. J.) ; Clyde district (Smith and Landsborough) ; Loch Carron (J. G. J.) ; Hebrides (Barlee). Coralline Crag at Sutton (S. Wood, as R. abyssicola). Drontheim, 5-40 f., and Vigo (M‘Andrew) ; Morbihan (Taslé) ; Gulf of

Lyons (Martin) ; Nice (Vérany) ; Spezzia (J. G. J.) ; Canaries ( $\mathrm{M}^{\prime}$ Andrew in mus. Brit.).

This is a very doubtful species; and conchologists must exercise their own discretion as to admitting it. My impression is that it constitutes only a variety of $R$. reticulata. The authors of the 'British Mollusca' say that the two " may usually be distinguished with readiness by the smaller size of their latticcwork. Every degree of reticulation, from coarse to fine, may be seen by comparing a sufficient number of specimens.

## 5. R. reticula'ta*, Montagu.

Turbo reticulatus, Mont. Test. Br. p. 322, t. 21. f. 1. R. Beanii, F.\& H. iii. p. 84, pl. lxxix. f. 5, 6.

Body yellowish-white: mantle furnished with a single filamental process: snout "near its termination at the upper surface appears to have attached to it two very small similar shields, one on each side, independent of the terminal minute subcircular flat lobes:" tentacles compressed, slender, rather long, "not setose" [?]: eyes on short light-yellow or orange pedicles: foot "subrotund, scarcely auricled, but groored in front sufficiently to form a shallow labium, slightly constricted anteriorly at one-third the length, gently tapering to a rather obtuse lanccolate but not emarginate termination: " opercular. lobe plain, moderately expanded : appendage consisting of three blunt, cylindrical, short cirri : gill composed of 12-15 single, pale-yellow, short strands, which are visible when the neck is much protruded. (Clark.)

Shell oblong, solid, nearly opaque, more or less glossy: sculpture, numerous somewhat obscure and slightly curved longitudinal ribs, seldom extending to the base, and crossed by equally numerous but much more distinct and thread-like spiral ribs, which cover the surface of the last 4 whorls; the points of intersection are sometimes nodulous, but rarely on the lower part of the body-whorl; there are 6 or 7 rows of spiral striæ on the penultimate whorl; labial rib thick and traversed by the spiral strix, occasionally forming a separate varix; top whorls smooth and glossy, showing under the microscope faint

[^3]traces of punctures: colour pale yellowish-brown, with now and then two bands of a tawny hue, one immediately under the suture and the other below the periphery ; pillar-lip often stained with reddish-brown: spire acute: whorls 6-7, rather conrex, and gradually enlarging, the last occupying about threefifths of the spire ; the penultimate is nearly as broad as the last whorl: suture slight, narrowly excavated: mouth roundishoval, somewhat expanded outwards, finely and closely furrowed on the inside of the labial rib; the furrows correspond with the spiral strix: outer lip thin and very narrow, as in all the other species of this section: inner lip slight and reflected on the pillar, behind which there is a narrow groore, but never a decided umbilical chink: operculum filmy, with a short spire, and finely striated in the line of gromth. L. $0 \cdot 15$. B. $0 \cdot 075$.

Habitat: Nearly every part of our coasts, from the Land's End to Lerwick, in 7-50 f. ; not uncommon. Fossil in the south of Italy and in Sicily (Philippiassuming this to be his R. textilis). R. reticulata of S. Wood, from the Coralline Crag, more resembles $R$. calathus, and may be an intermediate variety. Lovén, Sars, M'Andrew, Danielssen, and Malm have recorded the present species as Scandinavian, from Molde in Finmark to Bohuslän in the south of Sweden, the two last-named authors giving respectively $40-60$ and $20-30 \mathrm{f}$. North coast of Holland, 17 f. (Malm) ; Vigo (M‘Andrew); Gulf of Lyons (Martin); Dalmatia (Brusina, as Alvunia Beani); Cannes (Macé); Spezzia (the Marquis Doria and J.G. J.); Algeria (Weinkauff) ; and Ægean 30-185 f. (Forbes).

The sculpture of some specimens is rather stronger than that of others. Mediterranean specimens are frequently marked by highly coloured bands. This shell is more oblong than $R$. cimicoïdes, and not so conical (partly in consequence of the penultimate whorl being prominent in $R$. reticulata), and the cancellation is finer and closcr. "The animal is active, and frecly shows its points" (Clark).

It is the R. Beanii of Hanley. R. textilis of Philippi is probably the immature state. Adams's Turbo reticulatus ("T. quatuor anfractibus reticulatis, apertura subrotunda. Obs. color albus.") appears to have been the young of $R$. striata ; but that of Montagu is unquestionably the one now under consideration. R. reticulata of Philippi, a Sicilian fossil, is very different. Turton, in his 'Conchological Dictionary,' interchanged the characters of the present species and R. punctura, and reversed the admeasurements.

## 6. R. cimicoï'des *, Forbes.

R. cimicoides, Forb. in Rep. Br. Assoc. for 1843 , p. 189. R. sculpta, F. \& H. iii. p. 88, pl. 1xxx. f. 5, 6.

Body milk-white and almost transparent: suout short, bifid, of a brownish hue: tentacles slender, with blunt tips: eyes small : foot broad, squarish in front, and pointed behind.

Shell conic-oval, solid, opaque, somewhat glossy : sculpture, sereral stout and slightlycurred longitudinal ribs, not extending to the base, and crossed by more regular and thread-like spiral strix or riblets, which cover the surface of the last four whorls; small tubercles or nodules are formed at the points of intersection; there are 4 rows of spiral strix on the penultimate whorl; labial rib thick (sometimes double), traversed by the spiral strix, and marked with minute and numerous lines of growth; top whorls encircled with close-set and punctured striæ: colour pale yellowish-white, more or less deeply tinged with reddish-brown, and having usually an imperfect streak of the latter colour close to the labial rib on the outside, which. terminates at the periphery in a broad mark, covering three of the spiral strix; these markings appear to result from two obscure bands, one below the suture and the other round the base; apex light orange: spire sharp-pointed: whorls 6-7, sloping upwards, compressed, somewhat gradually enlarging, the last occupying about three-fifths of the spire: suture slight, but distinctly channelled: mouth more round than oval, expanding a little outwards, finely notched or furrowed on the inside of the labial rib; these notches or furrows are not caused

[^4]by the impress of the spiral strix, although they correspond in number and position : outer lip thin : inner lip slight, reflected on the pillar; there is no umbilical chink: operculum filmy, with a short spire. L. $0 \cdot 15 . \quad$ B. 0.085.

Var. minima. Dwarf; spire very short.
Habitat : Coralline zone, Guernsey (J. G. J.); Helford (Hockin) ; Exmouth (coll. Clark) ; Coquet and Berwick Bay (Mennell); Cork Harbour (Wright); west coast of Ireland (Hoskyns); Larne, co. Antrim (J.G.J.); Skye and Hebrides (M'Andrew and others) ; Aberdeenshire coast (Dawson); Shetland (Barlee and J. G. J.). The variety was found at Plymouth by Mr. Barlee. R. cimicoïdes inhabits the Egean, 2-69 f. (Forbes); Dalmatia (Brusina) ; Gulf of Lyons (Martin) ; Bohuslän, 50-80 f. (Martin) ; Bergen (Lilljeborg) ; upper Norway (M'Andrew) ; and Greenland (coll. M'Andrew).

I have no doubt that this is the $R$. cimicoildes of Forbes, having compared specimens so named by him in the British Museum and Mr. M'Andrew's collection with the original description of that species, as well as with the Scotch specimens from which the description and figures of R. sculpta in the 'British Mollusca' were taken. The R. sculpta of Philippi appears to have a more regularly oval shape, the larger whorls are cross-barred (" clathrati"), and the inside of the mouth is smooth. This agrees with $R$. calathus of Forbes and Hanley, except in the latter having the throat crenated. Lovén regarded R. abyssicola as Philippi's shell. Pasithea nigra of Totten, from Rhode Island, is allied to the present species.

## 7. R. Jeffrey'si ${ }^{*}$, Waller.

R. Jeffreysi, Wall. in Ann. \& Mag. N. H. s. 3. xiv. p. 136.

Shell conic-oval, with a somewhat turreted outline, mode-

[^5]rately solid, semitransparent and rather glossy: sculpture, numerous fine longitudinal striæ, which are crossed by stronger, fewer, and rib-like transverse strix, forming by their intersection an open network; the longitudinal striæ are gently curved, and they do not reach the base, although there are sometimes traces of them below the periphery; the labial rib is strong but not thick, and traversed by the spiral striæ only; of these strix 3 or 4 are more conspicuous than the rest on the body-whorl; examined microscopically the whole surface is corered with extremely close-set spiral lines; and even by the aid of a Coddington the top whorls may be seen to have a few spiral rows of salient and reentering angles, which last prefigure the cancellated structure of the adult shell : colour clear-white: spire ending in a blunt and almost truncated point: whorls 5, convex, gradually enlarging, the last exceeding all the others put together in the ratio of nearly 5 to 3 when viowed with the mouth upwards, but when placed with the mouth downwards these proportions are reversed; the apex is compressed: suture very deep and channelled: mouth more round than oval, scarcely expanding outwards: outer lip thin, incurved above : inner lip slightly reflected, and having behind it a more or less distinct umbilical chink. L. $0 \cdot 1$. B. $0 \cdot 065$.

Habitat : Sandy ground off Unst (the most northern of the British Isles), at distances of about 8 and 30 miles from the land, in $70-8$ g f ; rare. Norway (Lilljeborg and Malm; the locality mentioned to me by the latter is Eggersbank, and the depth 150 f.) ; North America ( $\mathrm{M}^{\prime}$ Andrew, by whom it was received from a correspondent).

The dried remains of the animal exhibit an orange tint in the region of the liver. Although of the same size as $R$. punctura, this is of a somewhat turreted shape, clear-white, and nearly transparent, the reticulation is much less crowded (resembling open lacework), the spiral strix in the middle are more prominent, the suture decper, whorls more gradually increasing, and the apex is blunt and marked with a Vandyke pattern instead of having rows of punctures. The present case exemplifies
what I said in the Introduction to this work (vol. i. p. xlvii), viz. that the nucleus of the shell often furnishes the conchologist with an important character for discriminating species. This part, in fact, represents the earliest stage of growth, before external conditions have had any power in influencing or modifying the structure.

## 8. R. punctulka*, Montagu.

Turbo punctura, Mont. Test. Br. p. 320, t. 12. f. 5. R. punotura, F. \& H. iii. p. 89, pl. lexx. f. 8, 9.

Body yellowish, streaked with purple (marked with a small red dot under the neck near the eyes, Clark): mantle furnished at each upper corner of the aperture of the shell with a short cylindrical process: tentacles thread-shaped, rather short, indistinctly ringed, scalloped at the edges, and sparsely but finely setose: eyes slightly raised: foot squarish in front, and bluntly pointed behind: (opercular lobe very pale muddy-red-dish-brown, and having on each side, close to the junction of the foot with the rest of the body, an irregular, rather large, dusky or lead-coloured stripe, Clark): appendage simple and short.

Shell conic-oval (in some specimens more oblong), rathor solid, nearly opaque, and somewhat glossy: sculpture, numerous fine longitudinal and spiral ribs or striæ, which by their decussation form minute squares, and are muricated at the points of intersection; the longitudinal ones are slightly curved and do not reach to the base; the labial rib is more or less thick, according to age, and it occasionally leaves one or two varicose excrescences on the body-whorl; sometimes it is placed close to the mouth, and at other times at a short distance from it ; the spiral ribs or strix are thread-like and usually are more conspicuous than the others; the uppermost whorls exhibit under the microscope a few rows of punctures: colour dirty white, often tinged with cellow or reddish-brown, and now and then having the last whorl partially spotted or doublebanded with the latter hue; there is frequently also a blotch of reddish-brown outside the mouth, and a similar stain on the pillar-lip : spire pointed, usually rather elongated, rarely very short: whorls 6 , convex, the last occupying about three-fifths

[^6]of the spire, the first minute and somewhat prominent: suture deep: mouth roundish-oval, scarcely expanding outwards: outer lip thin, not much incurved above: inner lip reflected on the pillar and at the base, behind which is a slight depression or chink: operculum filmy, with a short spire, and delicately striated. L. $0 \cdot 1$. B. 0.065.

Var. diversa. Longitudinal ribs finer and more prominent,a character which gives this variety a different aspect.

Habitat : Widely distributed, in the lower part of the laminarian zone and throughout the coralline zone, from Guernsey to Unst, at a depth of from 1-95 f. The variety is from Skye and Shetland. R. punctura occurs in upper tertiary deposits in Sussex (Godwin-Austen), Ayrshire (Landsborough, fide Thompson), and at Uddevalla (Malm), and in the post-glacial beds of Norway at various heights from the present level of the sea to 100 feet above it (Sars). Wood includes it (although with a doubt as to the identity of the species) in his 'Crag Mollusca,' from the Coralline formation at Sutton; but his description shows that the outer lip is notched within, a character which the recent shell does not possess. It inhabits Bohuslän, according to Lovén, who called it $R$. textilis of Philippi; Malm dredged it in the same district in 10-60 f., Danielssen at Christiansund. in 40-60 f., M'Andrew in Nordland, and Sars at Tromsö, Oxfjord, and elsewhere in Norway in 10-50 f. ; Taslé found it in Brittany ; Martin has taken it in the Gulf of Lyons, Macé at Antibes, Vérany at Nice, Brusina in Dalmatia, and M'Andrew off Orotava, Canary Isles.

Of this species, again, we have two sizes, a large and small one.

It appears to be the Turbo retiformis of Montagu (from Walker's doubtful description and figure), R. puncturata of Macgillivray, R. approxima of Brown, and Turritella Dorvilleana of Leach.

## 9. R. abyssi'cola*, Forbes.

R. abyssicola, F. \& H. iii. p. 86, pl. lxxviii. f. 1.2, and (animal) pl. JJ. f. 3.

Body whitish, with a faint tinge of yellow or saffron on the front, and microscopically speckled with flake-white: mantle rather thick-edged; pallial processes one on each side, short and not protruded beyond the mouth of the shell ; snout small and narrow, decply cloven, carried somewhat in advance of the foot: tentacles thread-shaped, flattewed, clothed with minute and short but not numerous cilia: eyes large and black, on bulbs at the lower base of the tentacles: foot squarish in front, with short angular corners, narrowing behind to a rounded and slightly bilobed tail: appendage single, placed far behind the tail, and issuing from the opercular lobe.

Shell oval, with a slight tendency to oblong and a somewhat oblique outline, rather solid, semitransparent and glossy: sculpture, numerous slight longitudinal ribs on the last three or four whorls, but not extending to the base; they are flexuous on the body-whorl and curred on the others; the labial rib is strong, and placed close to the mouth ; the whole surface is corered with close-set and fine, apparently (but not really) undulating spiral striæ, which are as prominent although not so large as the ribs, and by their intersection give a somewhat muricated appearance; these strix cross the labial rib, as in the preceding species, and reach to the outer lip; the interstices of the striæ on the base show, under a high magnifying pomer, indistinct traces of longitudinal ribs; the uppermost whorls are microscopically reticulated: colour clear-white, with occasionally a blotch of reddish-brown behind the labial rib: spire short and abrupt: whorls 5, somewhat compressed but rounded, the last occupying about two-thirds of the spire, and the first minute and flattened : suture deepish, and sometimes slightly channelled: mouth roundish-oval, obliquely expanding outwards: outer lip narrow, thin, and sinuous, incurved above : inner lip reflected on the pillar and at the base, united with the outer lip, but not forming a distinct peristome: operculum filmy, few-whorled, with a small excentric spire, and finely striated in the line of growth; through it may be seen the opercular lobe, of a yellow colour. L. $0 \cdot 085$. B. $0 \cdot 05$.

## Habitat: Mud in 50-70 f., Loch Fyne (where M'An-

[^7]drew and Forbes discovered it), Sliye and Hebrides (Barlee and J. G. J.), Shetland (Forbes and Barlee); and Mr. M'Andrew has dredged it also 15 miles south-west of Mizen IIead, co. Cork. Norway (M‘Andrew) ; Bohuslän (Lovén, as R. sculpta of Philippi) ; off Vigo Bay and Malaga (M‘Andrew) ; Gulf of Lyons (Martin, as R. scabra of Philippi) ; 40 miles off Malta in 350 f. (Spratt). It is a local and somewhat rare species.

It floats like its congeners, and suspends itself in the water by a single byssal thread. Mediterranean specimens are smaller than ours, and have rather stronger sculpture. Two different sizes occur, as is also probably the case with every other species of Rissoa. One of my specimens shows in the middle of the last whorl a distinct varix, caused apparently by a new growth having taken place after the shell had arrived at maturity.
> B. Ribbed lengthwise, and spirally striated; outer lip thickened and reflected.

## 10. R. Zetlańdica*, Montagu.

Turbo Zetlandicus, Mont. in Tr. Linn. Soc. xi. p. 194, t. xiii. f. 3. R. Zetlandica, F. \& II. iii. p. 78, pl. \xxr. f. 1, 2.

Shell between oral and oblong, turreted or scalariform, solid, nearly opaque, glossy when living or fresh: sculpture, fine and rather sharp longitudinal ribs, of which there are 16 on the last whorl, 15 on the penultimate, 14 on the next, and 13 on the succeeding whorl, where they usually disappear; the ribs on the body-whorl do not extend quite to the base, but are cut off by a strong keel or ridge which winds spirally round that part from the upper corner of the mouth; between this keel and the mouth is a deep groove or depression, which partly arises from the prominence of the keel, and is indistinctly ribbed across; there is also a slighter and incomplete ridge (sometimes two) noar the month, between the basal keel and the inner lip; the labial rib is exceedingly thick and pro-

[^8]minent; its edge on the side of the mouth is furrowed or furnished with a double ridge, the inside one of which forms the outer lip; the last four whorls are covered with spiral ridges equal in size and prominence to the longitudinal ribs, and intersecting them at a right angle, so as to produce a series of square excarations ; the points of intersection are muricated or spiky; the last mhorl has 4 of these ridges (besides that at the base), each of the next two whorls has 3 , and the succeeding whorl 2, the uppermost whorls being spirally and delicately striated; the ridges extend to the mouth : colour clearwhite, sometimes golden-yellow, especially the basal ridge: spire rather short, abruptly pointed: whorls $6-7$, convex, the last occupying three-fifths of the spire, the first minute and rounded: suture very deep and channelled: mouth roundishoval, considerably expanding outwards: outer and inner lips forming a continuous and slightly elevated rim. L. $0 \cdot 125$. B. 0.075 .

Habitat: Sparingly found in the coralline and deepsea zones, Guernsey (Barlee and others), Porth Curnow Cove, Cornwall (Miss Lavars), Hayle (Hockin), co. Antrim (Hyndman and J. G. J.), Lamlash, Bute (Landsborough), Skye and Hebrides (J. G. J.), St. Fergus bay, Peterhead (Bingham, fide Brown), Aberdeenshire (Dawson), Caithness (Gordon), Orkneys (Thomas), Shetland (Fleming and others), at depths ranging from 18-70 f. Fossil in the Coralline Crag at Sutton (Wood), and in the miocene formation near Vicnna (Hörnes). Living on the coast of South Sweden, in 12-75 f. (Lovén and Malm), Cherbourg (Réchz), off Vigo Bay (M'Andrew), Antibes (Macé), Nice (Vérany), and Naples (Plilippi).

With respect both to this and the next little shell, we may well say with Cicero, "Quid potest esse aspectu pulchrius?"

The synonyms are $R$. cyclostomata of Récluz, R.obtusa of Brown, R. scalariformis of Metcalfe (Thorpe's ' British Marine Conchology'), and R. clathrata of Philippi.

## 11. R. costa'ta*, Adams.

Turbo costatus, Ad. in Tr. Linn. Soc. iii. p. 65, t. 13. f. 13, 14. R. costata, F. \& H. iii. p. 92, pl. lxxviii. f. 6, 7.

Body clear-white: snout long, cloven vertically at the extremity, and exposing the buccal disk, which is pale-red: tentacles slender, flattened, apparently not setose: eyes large: foot long, rounded in front, where it has a snow-white mark like the letter $V$, behind which it is constricted at the sides and divided across, thence somewhat expandiug, and tapering to a blunt point behind; the lower lip or edge of the foot in front extends much beyond the upper lip: opercular lobe dilated into rounded lateral wings: appendage single, distinct.

Shell oblong and slender, obliquely twisted, solid, nearly opaque, glossy when inhabiting clean ground, but usually lustreless: sculpture, ridge-like, sharp, high-shouldered, and Hexuous longitudinal ribs, of which there are 9 on the last whorl, 10 on the penultimate, 11 on the next, and 12 on the succeeding whorl, where they mostly disappear; the ribs on the body-whorl do not extend quite to the base, being cut off by a strong (sometimes double) keel or ridge which winds spirally round that part; between this keel and the mouth is a deep groove or depression caused by the prominence of the keel; the labial rib is thicker than any of the rest, and its inside edge is flattened and finely notched; the last four or five whorls are covered with numerous delicate spiral striæ, which cross the ribs; the top whorls are quite smooth : colour clearwhite, with a slight golden tinge: spire long and pointed: whorls 6 , compressed, the last occupying three-fifths of the spire, and the first being minute and rounded: suture deep: mouth roundish-oval, expanding outwards: outer and inner lips sinuated, continuous, and forming a complete and slightly elevated rim round the mouth : operculum ear-shaped, thin, yellowish-horncolour, with a small excentric spire, and finely striated. L. $0 \cdot 125$. B. $0 \cdot 06$.

Habitat : Coralline and lower part of the laminarian zones; more generally distributed in the south than in the north. Dr. Gordon and Mr. Dawson find it on the coast of Aberdeenshire; I have dredged it in the He-

[^9]brides; and Mr. Barlee sent me specimens from Shetland. It is rather common in the Channel Isles, and occurs there at the base of seaweeds on the recess of high spring tides. Fossil in Sussex (Godwin-Austen), Largs in Ayrshire (Landsborongh), Palermo and Tarento (Philippi). Its northern limits comprise Norway, Sweden, and Holland; and southwards it ranges along the shores of the North Atlantic as far as the Canaries (M'Andrew), and of the Mediterranean on both sides: the depths given by different observers vary from $4-70 \mathrm{f}$.

Mr. Clark remarked the rapidity and freedom of its movements. In showing that it is a true Rissoa, he said "it is a very simple creature." This, of course, he meant in a zoological and not psychological sense. Specimens from Teneriffe and Spezzia are unconmonly small.

It is the Turbo lacteus of Donovan-in index, "Turbo parvus (lacteus),"-T. crassus of Adams's work on the Microscope, T. plicatus of Mühlfeld, R. exigua of Michaud, and $R$. carinata of Philippi. R. costata of Desmarets is the $R$. variabilis of Mühlfeld, and very different from the present species.

> C. Mostly ribbed lengthwise and spirally striated; outer lip usually strengthened by a rib.

## 12. R. Parva*, Da Costa.

Turbo parvus, Da Costa, Br. Conch. p. 104. R. parva, F. \& H. iii. p. 98, pl. lxxvi. f. 2, 6, lxxrii. f. 6, 7, and laxxii. f. 1-4.
Body pale-yellowish-white, with a purplish blotch in the middle, and sometimes more or less tinged in other parts with the latter colour : pallial filament occasionall $\Gamma$ protruded : snout narrow and deeply cloven : tentacles whitish, extensile, somewhat flattened, finely scalloped at the edges, and covered with minute cilia, which are not easily perceptible unless by using

[^10]a strong magnifying power: eyes on short stalks, occasionally nearly sessile : foot squarish or slightly rounded in front, contracted in the middle, where it is apparently divided across into tro unequal portions (the front being about half the size of the other portion); it tapers behind to a blunt point; sole speckled with frosted white, and finely slit from the centre down to the tail : opercular lobe large, dark-purple : appendage cylindrical, slender, rather long, and whitish, placed over the tail or hinder part of the foot, and now and then projecting beyond it; it is microscopically ciliated, and resembles a small auxiliary tentacle.

Shels conic-oval, rather solid, nearly opaque, somewhat glossy: sculpture. strong and slightly curved ribs, like buttresses, of which there are 8 on the body-whorl, and 12 on the penultimate and next whorl (the succeeding whorls having no ribs) ; the ribs do not extend to the base; their interstices are frequently cancellated, and their termination on the lower part of the last whorl defined by more or less distinct spiral strix, arising from the intensity or concentration of microscopical lines which cover the whole surface in that direction; the labial rib is thick and white, placed at a short distance behind the outer lip : coluur mostly pale yellowish-white, sometimes brown or chocolate, obscurely marked occasionally with rays hetween some of the ribs, and with a band round the base, always haring a falciform streak from the suture behind the labial rib towards the middle of the outer lip; the rays, band, and streak are chestnut-brown; sometimes the ribs are white, the tip is pinkish, and the mouth is edged with chest-nut-brown : spire short, bluntly pointed: whorls 6-7, cousex, the last occupying nearly two-thirds of the spire: suture rather slight, but distinct: mouth roundish-oval, somewhat expanded: outer lip thin, contracted and incurved above: inner lip reflected on the pillar and at the base, where there is no appearance of an umbilical crevice: operculum thin, whitish, with a small excentric spire, and delicately striated. L. $0 \cdot 165$. B. $0 \cdot 1$.

Var. 1. interrupta. Smaller, slenderer, thinner, semitransparent, and ribless, with much less convex whorls, usually marked with longitudinal rays of chestnut-colour, which are curved on the body-whorl, or divided into two rows, so as to make the middle appear girdled with a whitish band; occasionally these rays become confluent and form dark bands; labial rib slighter ; the spiral striæ are sometimes distinct, although irregular. Turbo interruptus, Adams in Tr. Linn. Soc. F. p. 3, t. i. f. 16, 17.

Var. 2. exilis. Dwarf, very slender, thin and smooth, tawny, without any conspicuous markings ; labial rib wanting or rudimentary.

Habitat: Swarming on seaweeds and Zostera at lowwater mark and throughout the laminarian zone. According to Alder a variety has been taken among corallines from 20 f . The typical form is more common in the south, and the variety interrupta in the north ; both live together, as well as every conceivable gradation as regards shape, size, solidity, sculpture, and colour. Some are full-ribbed, some half-ribbed, and some have only the traces of ribs on one or other of the larger whorls; but the top whorls are invariably smootli. The 2nd variety was found by me in Lerwick Sound. Sars has recorded the typical form as fossil in the postglacial beds of Norway, at heights between 40 and 200 feet; and the variety interrupta has occurred in upper tertiary deposits in Ireland (Brown), Fort William (J. G. J.), Dalmuir and Clyde beds (Crosskey and others), Uddevalla (J. G. J.), Christiania district, in the newer or post-glacial strata, at 100 feet (Sars), Nice (Risso). The foreign distribution of this species and its principal variety comprises the coasts of Upper and Lower Norway, Sweden, Denmark, Holland, France, Spain, Portugal, Italy, Dalmatia, Greece, Algeria, and the Canary Isles, from the shore to 40 f . In the 'Zoological Record' for 1864, von Martens questions the R. obscura of Philippi (which is the typical form of this species) being Mediterranean, because he had not found it there. It is not uncommon at Spezzia.

Lying on a rock by the brink of a seaweed-covered pool left by the receding tide, it is no less pleasant than curious to watch this active little creature go through its different exercises-creeping, floating, and spinning.

It has evidently no fear of man or fish, being fortunately unconscious that the conchologist and the blenny are its natural enemies. Its heart, however, beats fast in confinement, giving about 60 pulsations per minute. Clark informs us that "the branchial plume consists of 15-18 minute vessels attached under and to the mantle and back of the neck;" and according to Mr. Alder the teeth are arranged in 40 or 50 rows. The spawn-capsules are semicircular, yellowish-brown, and sometimes deposited on the shells of other individuals. Specimens from the Hebrides and Shetland are much larger than usual, but of a paler hue. The one noticed and figured in the 'British Mollusca' as $R$. Sarsii is an extraordinarily fine example of the variety interrupta, and not Lovén's species of that name; it is a quarter of an inch long. Mediterranean specimens are very inferior in size to those of our coasts. Mr. Williams Hockin has noticed that now and then the ribs are slightly furrowed down the middle. This species may always be known from any of its allies by a character which Forbes and Hanley pointed out, viz. the falciform streak outside the mouth.

To give all the old synonyms (including those of Adams) would be unnecessary. The modern oncs are Cingula alba, Fleming, R. pulchella, Forbes, R. tristriata, Macgillivray, R. fuscata and $R$. discrepans, Brown, $R$. obscura and R. simplex, Philippi, R. Matoniana, Récluz, Sabancea paucicostata and Persephona Scotica, Leach, and $R$. cerasina, Brusina. Perhaps $R$. lineolata and $R$. marginata of Michaud may be added to the list.

## 13. R. inconspícua*, Alder.

R. inconspicua, Ald. in Ann. \& Mag. N. H. xiii. p. 323, pl. viii. f. 6, 7: F. \& H. iii. p. 113, pl. lxxvi. f. 7,8 , and lxxxii. f. $5,6$.

Body white, with blotches of yellow; it is also marked length-

[^11]wise with two lines of dark-purple or black, the upper one being on the side of the back, and the lower bordering the foot: pallial filament pendent: snout short, wedge-like, and bilobed, tinged with muddy yellow or orange: tentacles very long and slender, hairy : eyes black, on minute yellow prominences: foot narrow and extensile, slightly labiated in front, bluntly pointed behind; sole depressed in the centre, from which a line runs to the tail: opercular lobe expanded beyond each side of the foat, and margined with deep-purple or black, forming with the lines on the upper surface a dark blotch: appendage very long and distinct, projecting above the tail. (Alder and Clark.)

Shell conic-oval, moderately solid, semitransparent, highly glosss, and sometimes haring a prismatic lustre: sculpture, usually numerous fine stria-like and curred longitudinal ribs on all except the topmost whorls; these ribs are unequally distributed, and occasionally are fewer and stronger on the bodywhorl; labial rib thick and white in adult specimens, now and then forming a varix in the middle of the last whorl; the surface is also more or less distinctly impressed by delicate spiral striæ, especially about the periphery; the uppermost whorls are quite smooth: colour pale fellowish-white or whitish, rarely milk-white, sometimes variegated by obscure spots or short streaks of reddish-brown; tip of the spire pink: spire mostly short and acute: whorls $6-7$, somewhat convex, but not tumid; the last occupies about three-fifths of the spire: suture well defined, although not deep : mouth roundish-oral : outer lip thin, contracted at the upper corner: inner lip thickened and slightly reflected at the base, where there is a small umbilical crevice: operculum resembling that of the next species, except that this is famncolour. L. $0 \cdot 085$. B. $0 \cdot 05$.

Var. 1. ventrosa. Thinner, with the whorls more swollen, but having the peculiar sculpture and other characters of this species.

Var. 2. variegata. Much smaller, more conical, with an argular periphery, smooth or having a few ribs only, with flatter whorls and distinct broad tawny longitudinal streaks or rays; there is no umbilical cleft. R. variegata, v. Mohrenstern, Riss. p. 28, t. ii. f. $1 \overline{0}$.

Monstr. Slightly scalariform, the last whorl being partly detached from the preceding one,

Habitat : Coralline zone everywhere ; especially common in trawl-refuse at Plymouth. The lst variety was dredged by Mr. Barlee at Exmouth and in the Hebrides, and by myself in the estuarine river Roach in Essex ; the 2nd, although widely distributed, seems more to frequent the Dorset coast ; and the monstrosity is from the west of Scotland (Barlee) and Aberdeenshire (Dawson). Mr. Robertson has found this species in a posttertiary deposit at Crinan; the late Dr. Woodward enumerated it as a fossil of the Norwich Crag ; and Professor Sars records it from a post-glacial bed in Norway, at a height of 50 feet. It inhabits the Norwegian coast as far north as Oxfjord in the laminarian zone (Sars), Christianiafiord (J. G. J.), the south of Sweden (Malm), the Cattegat (mus. Copenhagen), north of France (Macé, Cailliaud, and 'Taslé), Gulf of Lyons (Martin, fide Petit), Dalmatia (Brusina), Spezzia (J. G. J.), Corsica (Susini), and Algeria (Weinkauff). A species very closely allied to this, if not a dwarf or southern variety of it, was obtained by Mr. M'Andrew off Teneriffe.

This may have been the Turbo albus of Adams (T'. albulus of Maton and Rackett, not of Fabricius), $R$. Ballice of Thompson, and $R$. maculata of Brown ; but the specific name inconspicua is in general use, and must be retained. I regard the 2nd variety as a stunted form. If I had contented myself with examining a few specimens only, I should probably have arrived at the same conclusion that Herr v. Mohrenstern did, and made this variety a separate species; but the comparison on an extensive scale of both forms and of intermediate specimens has convinced me that such a distinction cannot be maintained. The shell described-or rather shadowed forth-by Adams as Helix variegata may not even have belonged to the present genus. All the species
of Rissoa which can be safely identified with his descriptions or figures were placed by him in the genus Turbo.

## 14. R. albelíla*, Lovén.

R. allella, Lov. Ind. Moll. Scand. p. 25. R. inconspicua, var. tenuis, F. \& H. iii. p. 115, pl. lxxxiii. f. 7, 8.
Bony yellowish-white, with a purplish blotch in the middle: pallul process single, issuing from the upper angle of the mouth of the shell : snout rather short, deeply cloven lengthwise, not extending as far as the foot: tentacles cylindrical, with blunt tips, usually spotted with yellow or opaque-white, and fincly setose: eyes on rery small tubercles: foot truncated (occasionally somewhat bilobed) in front, constricted near the middle, and pointed behind; sole slightly grooved in the centre of the posterior half: appenduge single, leaf-like, flat and large.

Shell conic-oval, thin, semitransparent, and glossy ; sculpture, usually a few minute slight spiral strix, but sometimes also rather sharp and curved longitudinal ribs, of which there are from 12 to 15 on the penultimate whorl; these ribs never cover the uppermost whorls, nor extend to the mouth, and now and then they appear on the middle whorls only; between the labial rib (which rarely occurs on smooth specimens) and the outer lip there is a greater or less space left, so as sometimes to give this rib the aspect of a rarix : colour yellowish-white of different shades, often rariegated by longitudinal reddishbrown or tawny streaks, which are straight and rather numerous on the upper whorls, and more or less flexuous on the body-whorl; the base is occasionally marked with a broad but indistinct tawny band; some specimens are of a bright bronze hue: spire varying in length, sharp-pointed: whorls $6-7$, tumid, gradually increasing in size; the last occupies about three-fifths of the spire: suture remarkably deep : mouth oval or roundish-oval, not expanding: outer lip rery thin, contracted and incurved at the upper corner: inner lip somewhat thickened, and reflected, especially over the base, where a small umbilical crevice is formed: operculum slightly concare, horncolour, with a short spire, and rather strongly striated. L. $0 \cdot 15$. B. 0.075 .

Var. Sarsii. Thinner, smooth, and seldom having the labial rib. R. Sarsii, Lov. l. c. p. 15.

* For allula, whitish.

Monstr. Body-whorl spirally and tinely but irregularly ridged, the outer lip now and then expanded or contracted above, or a notch formed close to the suture.

Habitat: Bantry Bay at low water (Barlee). The variety is tolerably common on Zostera at Southampton, and abundant among seaweeds in the west of Scotland and east of Shetland, associated with $R$. parva var. interrupta. The monstrosity is sometimes met with in the latter district. The typical form inhabits Bohuslän (Lovén), Kiel Bay (Meyer and Möbius) and Christianiafiord (J. G. J.) ; the variety was found by Professor Sars at Bergen.

My largest specimens are those from Southampton and Loch Carron, some of them measuring 2 lines in length. A dwarf form, which is much less numerous, may be the male. The spawn-cases are generally solitary, semiglobular, membranous, and light-yellowish-brown ; the fry emerge from a large round hole at the top, which appears when they are developed.

Mr. Alder was quite right in considering this distinct from $R$. inconspicua; but the name (tenuis) which he proposed, being maccompanied by a published description, must cede to one of these which Lovén has given. It is thinner and considerably larger than $R$. inconspicua, the whorls are more ventricose, the suture is much deeper, and the sculpture very different. It is possible that the present species may have been the $R$. similis of Brown, which was found by the Rev. William Molesworth at Padstow.

> 15. R. membrana'cea*, Adams.

Turbo membranaceus, Ad. in Tr. Linn. Soc. v. p. 2, t. i. f. 12, 13. R./ahiosa, F. \& H. iii. p. 109, pl. lxxvi. f. 5, lxxvii. f. 1-3, and lxxxi. f. 3.
Bony pale-yellow, or slightly tinged with brown: tentacles

[^12]subulate, white : eyes surrounded by white spaces: foot squarish in front and pointed behind; the central or contracted part of the sides is dark-purple: operculas lobe of the same hue, and well developed: appendage conspicuous and white. (Forbes and Hanley.)

Shell conic-oblong, with an oblique outline, varying in solidity according to the nature of the habitat, semitransparent, and more or less glossy : sculpture, usually strong, prominent, somewhat curved or flexuous longitudinal ribs, from 15 to 18 of which are on the penultimate whorl; those on the last whorl extend only halfway down, and almost disappear towards the mouth; the upper three whorls are perfectly smooth; the rest of the surface is covered with numerous extremely minute and delicate transverse or spiral striæ, some of which on the lower part of the body-whorl are raised and form slight obsolete ridges; these striæ are never punctured or cancellated as in $R$. violacea and $R$. costulata; the labial rib is remarkably thick, broad and white: colour whitish, with sometimes a tinge of yellow or light-brown ; the mouth is occasionally of a violet hue or edged with purplish-brown ; now and then specimens occur which are light-horncolour and marked with reddishbrown, occasionally zigzag, streaks or blotches; the apex of dark-coloured specimens is pale-violet: spire rather short, terminating in a sharp point: whorls 7 , somewhat compressed; the last occupies about two-thirds of the spire ; this is exceedingly large in proportion to the next, and considerably dilated: suture rather slight: mouth oval, widely expanding outwards: outer lip thin : inner lip rery broad, refiected on the pillar and over the base (in some cases to such an extent as to form an umbilical chink) ; the angle incident on the junction of the two lips is a right one: pillar furnished near its base with a strong tooth-like projection or fold : operculum horncolour, with a very small spire, and strongly striated. L. $0 \cdot 3$. B. $0 \cdot 125$.

Var. 1. minor. Much smaller, and smooth.
Var. 2. venusta. More solid, with a shorter spire and stronger ribs. R. venusta, Philippi, Moll. Sic. ii. p. 124, t. xxiii. f. 4.

Tar. 3. elata. Body light-grey, with small white specks, mottled with brown in front : snout short and thick, bilobed at the extremity: tentacles thread-shaped and slender, setose: eyes on swellings of the tentacles at their outer base: foot rounded and double-edged in front, with angular corners, bluntly pointed behind; sole of a paler hue than the rest of the body, closely dappled with white, and haring in the centre
a short internal process (analogous to the byssiferous stylet of Mytilus?), which lies in a slanting direction with the outer point towards the tail: operculur lobe of the same colour as the sole : appendage whitish and conspicuous. Shell thinner, with a longer spire, often smaller, and usually ribless. R. elata, Phil. l. c. t. xxiii. f. 3.

Habitatr: Zostera and seaweeds, from low tide-mark to a few fathoms, on nearly every part of our coasts ; although it is rather local. The lst variety occurs at Tenby and in Dublin Bay, the 2nd was found at Poole by Mr. Barlee, and the 3rd frequents estuaries and brackish water. The typical form is fossil at Belfast (Grainger) ; Bute (Smith) ; Uddevalla (Malm) ; postglacial beds in Norway, 50-150 feet (Sars) ; and Sicily (Philippi, as R. ventricosa). Its foreign range in a living state extends from Norway, where it is very large (Lovén and others), to Malaga (M‘Andrew), Dalmatia (Brusina), Corfu (Hanley, as R. elata), Black Sea (Middendorff, as $R$. oblonga and $R$. elata), Algeria ( $\mathrm{M}^{‘}$ Andrew and Weinkauff"), and Canary Isles (v.Mohrenstern), at depths rarying from low-water to 35 f . Philippi's specimens of his $R$. venusta were Venetian.

The animal occasionally floats, or suspends itself by a viscous thread. The shell varies greatly in size, thickness, and length of spire; but it may always be known from $R$. violacea and $R$. costulata by its wide mouth, plain and scarcely perceptible transverse striæ, and the tooth or fold on the pillar.

The synonyms are inconveniently numerous. Some of them are (either certainly or probably) Turbo costutus, Pulteney, T. labiosus, Montagu, R. oblonga, R. ventricosa, and R. hyalina, Desmarets, R.grossa and R.fragilis, Michaud, R. turricula and R. pulla, Brown, and R. Souleyetiana, Récluz. $R$. cornea of Lovén may be also a local variety.

## 16. R. violi'cea*, Desmarets.

R. violacea, Desm. in Bull. sc. soc. phil. Paris, p. 8, pl. i. f. 7. R. ruffLabrum, F. \& H. iii. p. 106, pl. lxxvii. f. 8, 9.

Body orange-white, striped in front with purplish-brown: mantle not exhibiting any process: tentacles slender, setose, marked lengthwise with an orange line: eyes conspicuous on bulbs at the outer base of the tentacles: foot rounded and doubleedged in front; sole constricted in the middle to such an extent that the front part of the foot appears to issue from the hinder part, as if out of a sheath, and it is finely grooved lengthwise towards the tail: appendage single, short, and conical ; ic proceeds from the hinder edge of that lobe of the mantle which forms the operculum.

Shell conic-oral inclining to oblong, solid, nearly opaque, rather glossy : sculpture, usually strong, prominent, and slightly curred longitudinal ribs, about 15 of which are on the penultimate whorl, those on the last whorl being present only on the under side; there are none on the upper whorls, which are quite smooth; near the mouth is a rery large and broad labial rib or callus; the interstices of the ordinary ribs and the ribless part of the last whorl are corered with numerous rows of fine transrerse striæ, which are regularly and closely punctured: colour whitish, frequently tinged with jellow, reddishbrown, violet, or purple; some specimens are marked lengthwise by reddish-brown streaks, especially on the upper part; the tip is usually orange; the outside edge of the labial rib is mostly tawny, and the inside of the lip violet: spire short, more or less abruptly tapering to a fine point: whorls 7 , rather tumid; the last occupies nearly three-fifths of the spire, and is somewhat compressed and dilated towards the mouth: suture slight, overlapping the preceding whorl: mouth roundish-oval, wide, and slightly expanding in every direction : outer lip thin : imner lip broad, reflected on the pillar and towards the base: operculum horncolour, thin, composed of three rapidly increasing rolutions, and marked with very fine and close flexuous strie in the line of growth. L. $0 \cdot 2$. B. $0 \cdot 1$.

Yar. 1. ecostuta. Destitute of the ordinary ribs.
Yar. 2. porifera. Body fellowish and stained with darkpurple on the upper side, whitish on the under side: matle
fringed with fine and short cilia, and furnished at the left hand or upper corner with a long but slight filamental process: snout comparatively large, bilobed: tentacles cylindrical, long and slender, strawcolour with a yellowish-brown streak down the middle of each, thinly clothed with fine and short hairs resembling those on the border of the mantle: eyes on small offsets: foot divided into two parts; the front part is transversely oblong, and the hinder part is triangular, or shaped like a spear-head, and ends in a blunt point; the line of division is margined by a purple border: appendage long. Shell thinner, ribless, and horncolour, with a much shorter spire. R. porifera, Lovén, Ind. Moll. Scand. p. 24.

Habitat: Laminarian zone, in Guernsey, Hants, Sussex, Dorset, and Devon; Barmouth (J. G. J.); Bantry (Barlee) ; Connemara (Farran and others) ; Belfast (Thompson and Hyndman) ; Lough Strangford, 7-20 f. (Dickie) ; west coast of Scotland, and Shetland (Barlee and J. G. J.). The lst variety inhabits the last two districts, and the 2nd the West Voe at the Whalsey Skerries in east Shetland. "Subfossile," Nice (Risso) ; post-glacial bed in Norway, 50 feet (Sars). Living from Finmark to the Cattegat, in 1-40 f., as $R$. rufilabrum and $R$. porifera; north of lirance to Vigo, the Mediterrancan, Adriatic, and Egean, in 7-25 f., as $R$. violacea; Villafranca (Hanley), as R. rufiabrum.

The animal of the variety porifera twirls about restlessly at intervals, using its foot as a pivot; the male is not half as large as the female. The shell of the ordinary form varies extremely in size, as well as in the length and sharpness of the spire. Mediterranean specimens are more narrow and slender, and their colour is much brighter, presenting the same analogy that exists between southern and northern specimens of $R$. costulata. That species differs from the present in having a longer and more tapering spire, a smaller base and contracted
mouth, and in the striæ being cancellated instead of punctured.

This is probably the $R$. Guerinii of Récluz. The same author also described it as R. lilacina, Delle Chiaje as Turbo Rissoanus, Chiereghini as T. Mavors, Renier as T. amethystinus, and Potiez and Michaud as R. punctata.

## 17. R. costula'ta*, Alder.

R. costulata, Ald. in Amn. \& Mag. N. H. xiii. p. 324, pl. viii. f. 8, 9; F. \& H. iii. p. 103, pl. lysvii. f. 4,5 .

Bony fellowish, tinged with brown in front: snout rather long, wrinkled, and cloven at its extremity: tentacles threadshaped, slender, retractile, finely setose, sulphur-coloured, with a greenish line or rein down the middle of each : eyes on small bulgings of the tentacles, at their outer bases : foot rounded in front, divided across in the middle, so as to make the anterior and posterior portions appear separate, bluntly pointed behind; posterior half of the sole grooved lengthmise : appendage white, retractile.

Shell conic-oblong, somewhat spindle-shaped in consequence of the apex being pointed and the base narrower than the middle, rather solid, nearly opaque, more or less glossy; sculpture, strong, prominent, and nearly straight longitudinal ribs, 10 of which are on the penultimate whorl, those on the last whorl usually disappearing towards the mouth; there are none on the upper three or four whorls, which are quite smooth; near the mouth is a rib, much larger and broader than any of the rest; the ribs on each whorl are either continuous or arranged alternately, so as to appear dovetailed; the spaces between the ribs and the space near the mouth are covered with fine and rather numerous transverse or spiral striæ, the interstices of which are delicately and closely cancellated, especially at the base of the shell: colour pale-yellowish or dirty white, often tinged with lilac, or streaked lengthwise with reddish-brown, sometimes pure-white; the ribs are mostly of a lighter hue or whitish, and are therefore conspicuous; the inside edge of the mouth is nearly always lilac or reddish-brown; occasionally the whole surface, except the labial rib, is ornamented by longitudinal zigzag streaks of reddish-brown, and

[^13]the ribs are encircled by a white line; the tip in worn specimens is frequently purplish: spire abruptly tapering to a fine point: whorls 8 , convex, the lower two being equal in breadth, and the penultimate sometimes even slightly bronder than the last; the upper whorls rapidly diminish in size; and those forming the point of the spire are disproportionately small and flattened: suture rather deep: mouth roundish-oval, contracted and incurved above, slightly expanding at the sides and below: outer lip thin beyond the large rib or callus which strengthens the mouth : inner lip considerably reflected ou the pillar and towards the base : operculum pale-horncolour, of three rapidly increasing volutions, and finely striated. L. 0.2. B. $0 \cdot 075$.

Habitat: Codium tomentosum and other small seaweeds at low-water, in the Channel Isles and on the coasts of Dorset and Devon; also at Ryde (Hanley); Worthing (Rich) ; Manorbeer in Pembrokeshire, and Cork (J. G. J.) ; Scarborough (Bean) ; Lamlash (Landsborough). Probably the last locality, and certainly Connemara (given by Forbes and Hanley on the late Mr. Thompsou's authority), appertains to $R$. violacea, instead of to the present species. R. costulata inhabits the northern and western coasts of France (Macé and others), Gijon, Corunna, and Vigo (M'Andrew), and both sides of the Mediterranean. Specimens from that sea are smaller and more slender than those from the North Atlantic. There are two sizes everywhere, apparently representing a differeuce of sex.

1 found a living specimen at Lulworth which had the lower half broken off and a new mouth formed among the ruins.

It is not $R$. costulata of Risso (which is R. costata, Desmarets, and $R$. variabilis, v. Mühlfeld), nor $R$. costılata of Searles Wood, from the Coralline Crag. Leach called the present species Persephona Goodallana and $P$. rufilabris, judging from his description of the former,
and from typical specimens of the latter in the British Museum. It is also the R. subcostulata of v . Mohrenstern. I regard $R$. similis of Scacchi as a small variety.

18. R. stria'ta*, Adams.

Turbo striatus, Ad. in Tr. Linn. Soc. iii. p.66, t. 13. . . 25, 26. R. striata, F. \& H. iii. p. 9f, pl. lxxviii. f. $8,9$.

Body white, with a tinge of yellow : pallial filument nearly hyaline, and pendent: snout rather long and narrow: tentacles cylindrical, very finely and closels ciliated : eyes black, almost sessile : foot narrow, truncated in front and slightly auricled, contracted in the middle, and tapering behind to a round point: appendage short, white, and pointed.

Shell oblong, inclining to cylindrical, rather solid, nearly opaque, and usually lustreless: sculpture, numerous threadlike spiral strix, of which there are about 20 on the body-whorl; frequently the upper part of each of the three next whorls (and occasionally also the body-whorl) has a few longitudinal slightly flexuous ribs, that reach only about halfway down and are crossed by the spiral strix; the two uppermost whorls are quite smooth and glossy: colour white or various shades of yellow, with sometimes two indistinct but broad reddishbrown bands round the middle of the last whorl, which do not extend to the mouth: spire elongated, with a blunt point: whorls 6, somewhat compressed, graduallyenlarging, the last two being nearly equal in breadth, and the largest occupying about three-fifths of the spire: suture very distinct and rather deep: mouth proportionally small, having a somewhat flexuous outline: outer lip thin, mostly strengthened outside by a thick rib: inner lip reflected, and forming with the other lip a complete peristome: operculum transparent, and delicately striated. L. $0 \cdot 125$. B. $0 \cdot 05$.

Far. arctica. Without longitudinal ribs or coloured bands. R. arctica, Lovén, Ind. Moll. Scand. p. 24.

Habitat: All our coasts, under stones and at the base of seaweeds on the recess of spring tides; living in clusters. It inhabits also the laminarian and coralline zones; and I have dredged it in upwards of 80 fathoms.

The variety is more peculiar to the north, although occurring everywhere with the typical form. As an upper tertiary fossil this variety has been noticed in Ireland (Brown), Clyde beds (Crosskey), Fort William (Bedford and J. G. J.), post-glacial deposits in Norway, 130 fect, and glacial shell-banks in Aremark, Norway, 280-460 feet (Sars), and Coralline Crag (S. Wood). Its foreign range comprises Spitzbergen (Torell), Greenland (Möller), Sca of Okhotsk and coast of Russian Lapland (Middendorff), Iceland (Steenstrup), and Scandinavia (Lovén and others), 0-50 f., where the typical form also occurs : this last ranges from Heligoland (Philippi) to Corunna and Vigo (M‘Andrew), and thence to the Gulf of Lyons (Martin) and the Egean in 20 f. (Forbes). M'Andrew found a dwarf variety at Tencriffe. The variety arctica (under the specific name aculeus, given to it by Professor Stimpson) inhabits the northern sca-board of the United States.

This little creature is by no means slyy or sluggish. It probably feeds on decayed seaweeds. Females are the better halves in point of size. Some specimens are slender, some ventricose, some of thin texture and delicately striated, others are distorted by being twisted on one side in the most lackadaisical fashion. Those from deep water are much smaller than littoral specimens.

Synonyms:-R. minutissima, Michaud, R. communis, Forbes, R. gracilis, Macgillivray, R. decussata, Pyramis candidus, and $P$. discors, Brown, and $R$. pedicularis, Menke. The young is the Turbo semicostatus of Montagu and Odostomia Mariona of Macgillivray, and the variety is the $R$. saxatilis of Möller. Philippi considered a species which he described in the 'Zeitschrift für Malakozoologie' for 1849 as R. delicata (from the Red Sea) to be a tropical variety of our $R$. striata.

## D. Spirally striated, or smooth ; outer lip plain.

## 19. R. phox ${ }^{\prime}$ MA $^{*}$, Alder.

R. proxima (Alder), F. \& H. iii. p. 127, pl. Ixxp. f. 7, 8.

Body brilliant and almost clear white, dotted with minute opaque-white flakes: mantle even, and (as well as the next species, $R$. vitrea) not exhibiting the usual filamental process: snout somewhat cylindrical and extensile, quite smooth and rounded at its extremity, where it forms a rose-like disk; when fully extended it is blotched at the sides and on the tip with claret-red: tentacles rather short, flat, strong, tapering, and minutely bulbous at the tips, each of which is clothed with six comparatively long and fine needle-shaped hairs: eyes remarkably large, black, and placed on miuute and nearly semicircular lateral excrescences at the outer bases of the tentacles, which are so amalgimated with them as scarcely to present any prominence: foot large, fleshy, grooved and slightly labiated in front, with a deep notch or indentation, and expanded into large, long, arched, and pointed auricles; it is divided behind into two long distinct and diverging tails or streamers: opercular lobe close to the point of such bifurcation, and destitute of a caudal cirrus. (Clark.)

Shell closely resembling the next species ( $R$. vitrea) in shape and size ; but it is never lustrous ; and when examined with even a low magniffing porter, instead of being smooth it is seen to be encircled by numerous distinct and rather spiral strix; the colour is snow-white bencath a pale-yellowish epidermis; the spire tapers more gradually, and has a somewhat abruptly truncated apex; the whorls are compact, and not loosely coiled; the inner lip is more closely attached to the pillar; and the operculum is white, formed of 4 or 5 volutions, and marked with delicate striæ in the line of growth.

Habitat : Exmouth, eight miles from shore, in 15 f., on a bottom of shells and mud (Clark); Torbay and Plymouth, in $15-20$ f., with R. vitrea (J. G. J.) ; Falmouth (Barlee) ; Helford (Hockin) ; Cork, Bantry, and Dublin (J. G. J. and others). Mr. Searles Wood has lately found two specimens in the Coralline Crag at

[^14]Sutton. Its foreign known or supposed distrilbution is southern and limited, as follows:-Gulf of Lyons (Martin); Spezzia (Doria and J. G. J.); Ajaccio (Requien); Naples (Tiberi); Teneriffe (M'Andrew).
R. proxima appears to be a rare as well as "critical" species. Besides its affinity to $R$. vitrea, it is nearly related to the variety arctica of $R$. striata. In the lastnamed species, however, the texture and sculpture of the shell are coarser, the spire is pointed and not truncated, and the suture is less deep and not so oblique. The present species may be distinguished from $R$. vitrea by its being striated and never glossy. May one be the male and the other the female of the same species?

It is probably the R. pupoides of Requien. I described it about twenty years ago in the 'Annals of Natural History' as R. striatula, not remembering that the name had been preengaged for a supposed Linnean species.

$$
\text { 20. R. vittrea }{ }^{*} \text {, Montagu. }
$$

Turlo vitreus, Mont. Test. Br. p. 321, t. 12. f. 3. R. vitrea, F. \& H. iii. p. 125, pl. $15 \times v$.f. $5,6$.

Bony white, and appearing as if veined, with a frosty hue: snout short, cloven at the extremity, fleshcolour: tentacles threadshaped, long and compressed, setose at the tips only, and serrated at the outer basos: eyes conspicuous, placed on small bulbs or eminences: foot double-edged in front and indented so deeply as to form two distinct broad lobes, rounded behind: no appendaye observable.

Shell nearly cylindrical, thin, semitransparent, and of a glassy lustre: sculpture none, examined with a hand-lens; but under the microscope or even a Coddington lens the surface exhibits extromely fine regular and close-set spiral striæ: colour of live or fresh specimens pale yellowish-white, which soon becomes bleached by exposure to the air: spire elongated and slender, ending rather abruptly in an obtuse point: whorls

[^15]6, conrex, loosely and obliquely coiled, the last three being nearly equal in breadth, and the first minute; the body-mhorl occupies nearly two-thirds of the spire: suture remarkably deep: mouth exactly oral, small, and slightly expanding : outer lip thin, contracted, and incurred above: inner lip somewhat reflected, and more or less detached from the pillar: operculum few-whorled, light-horncolour, with the spire placed excentrically. L. 0.135. B. 0.05.

Habitat : Mud in the coralline zone, Dorset, Devon, Cornwall, Bristol and English Channels; Northumberland coast (Alder) ; south and west of Ireland and Dublin Bay; Dunbar (Bingham, fide Brown) ; Moray Firth (Macgillivray and Macdonald) ; west coast of Scotland (Barlee and J. G. J.) ; Orkneys (Thomas) ; and Bressay in Shetland (Fleming). It is local and somewhat rare. Fossil in the Coralline Crag at Sutton (Wood). Professor Sars has dredged it of a very large size off Floröen in Finmark; Malm obtained forty-five specimens, of which several were living, in 20-30 f. on the Bohuslän coast; La Hogue Bay near Cherbourg (Macé) ; Vigo (M'Andrew) ; Gulf of Lyons, in the stomach of $A s$ tropecten irregularis, with $R$. proxima (Martin) ; Spezzia (J. G. J.).

Very active, and suspends itself by a single byssal thread, keeping the mouth of the shell closed by the operculum.

Captain Brown made of this species three, which he called vitrea, crystallina, and virginea. A shell kindly given me by M. Nyst, from the Belgian tertiaries, as $R$. vitrea, is twice as large as our shell; it has an angulated periphery, a shallower and straight suture, fewer though more conspicuous spiral striæ, and an acuteangled outer lip, the inner lip being closely attached throughout to the pillar.

## 21. R. pulchertmima*, Jeffreys.

R. pulcherrima, Jeffr. in Ann. \& Mag. N. H. ser. 2. ii. p. 351; F. \& H. iii. p. 129, pl. lxxv. f. $1,2$.

Body whitish, with yellow specks: snout convex, projecting beyond the foot, and bilobed at the extremity: tentacles rather short, thickly and exquisitely setose, with rounded tips: eyes large: foot slender, rounded in front, divided across in the middle by a fine line (as in many other species of Rissoa), and bluntly pointed behind; sole slightly grooved down the middle on its posterior half: opercular lobe margined on each side with dark purplish-brown: appendage very long and pointed.

Shell conical with a broad and dilated base, thin, semitransparent, and glossy : sculpture none: colour whitish, prettily variegated by 4 rows of reddish-brown spots on the bodywhorl, the spots in the upper two and lower two rows (or in the upper two only) being sometimes confluent and forming short longitudinal streaks; the penultimate whorl has 2 or 3 rows, and the next 1 row: spire short, ending in a romarkably obtuse and mammiform point: whorls 4 , ventricose; the last equals three-fourths of the spire, and expands considerably towards the mouth: suture very deep: mouth nearly round: outer lip thin: inner lip reffected on the pillar, behind which is a small but distinct perforation : operculum thin, impressed with a few strong diverging lines; the nucleus of the spire is rather more central than in any of the preceding species, and resembles that of a Littorina. L. $0 \cdot 075$. B. $0 \cdot 05$.

Habitat: Among small seaweeds and on Zostera at low-water in all the Channel Isles; not uncommon. Some years ago, at Exmouth, after washing a quantity of Corallina officinalis which I had collected on that coast, I found two or three specimens of R.pulcherrima, and I was at first delighted at having discovered a new habitat; but I have since recollected that Mr. Barlec lent me for the examination sieves which he had last used in Guernsey. Such trifling accidents may cause great confusion in our ideas of geographical distribution. I have taken this pretty shell at Sestri di Levante; and

[^16]I observed it in the collections of MM. Susini from Corsica and of M. Macé at Cannes.

It is exceedingly agile both in creeping and swimming, aud spins a delicate thread of attachment. Mr. Clark states that this species "is a dwarf, nearly ribless $R$. inconspicua." The latter, however, has a much narrower base, the spire is more tapering and sharp-pointed, and the outer lip is furnished with a rib; and the shell is never so thin in proportion to its size, and is invariably sculptured. I have carefully compared the young and adult of each species, in order to satisfy myself as to their distinctness. Truncatella fusca of Philippi is allied to the present species.

> 22. R. ful'gida*, Adams.

Helix fulgidus, Ad. in Tr. Linn. Soc. iii. p. 254? R. fulgida, F. \& H. iii. p. 128, pl. lxxxi. f. 1, 2.

Body whitish, with more or less of a jellow hue, and microscopically suffused with flake-white points: mantle not exhibiting any filament: snout short, bifid at the point: tentacles cylindrical but somewhat compressed, rather short, sparingly and minutely setose : eyes large in proportion, on small protuberances of the tentacles, at their outer bases: foot flexible, usually rounded in front and bluntly pointed behind; sole grooved lengthwise down the middle on the posterior half. Neither Mr. Clark nor myself could detect any distinct opercular cirrus or appendage-although he says, "in some specimens I hare fancied I saw a very short blunt one."

Shele conic-oral, inclining to glooular, rather thin, semitransparent, and glossy: sculpture none, even under the microscope: colour pale yellow or creamy, with two reddish-brown bands on the body-whorl, one narrower just below the suture, and the other broader below the periphery; there is also a streak of the latter colour on the base ; the penultimate whorl is mostly reddish-brown: spire very short: whorls 4, tumid; the last equals three-fourths of the spire, and is somewhat expanded towards the mouth: suture deep: mouth nearly round: outer lip thin:

[^17]inner lip haring sometimes a pink tinge, thickened and slightly reflected at the base, behind which is a small chink : operculum ear-shaped, depressed in the centre, with a minute and nearly excentric spire. L. 0.035 . B. 0.025.

Var. pallicla. Strawcolour, without the upper, and sometimes without either band, occasionally having merely a pink or reddish-brown streak on the base.

Habitat: Abundant in the lower part of the littoral zone, among Zostera marina and small seaweeds, in the Channel Isles, Dorset, Devon, Cornwall, and the south and west of Ireland. I have also found it sparingly in Langland Bay near Swansea, and Lough Larne near Belfast. Mr. Lyons noticed it at Tenby, and Mr. Norman in the Clyde district. The variety occurred to me feeding on Zostera at Lulworth. R. fulgida is fossil in Calabria (Philippi). It inhabits the Atlantic and Mediterranean coasts of France, as well as Corsica, Piedmont, Sicily, Dalmatia, and Candia.

This mite of a shell is not half the size of the next species ( $R$. soluta), from which it differs in colour, want of sculpture, shorter spire, having the last whorl more expanded, and a less distinct umbilical cleft. It is often encrusted with Melobesia polymorpha. Mr. Clark's first impression, adopted by Forbes and Hanley, that the operculum is not spiral, was properly corrected by him in his own work. He says that the animal does not walk straight; that it " often jerks or screws the shell a quarter of a round, and carries it almost perpendicularly;" and that " on the march the eyes are always under the shell, as are usually the muzzle and foot, the ends of the tentacula only being visible." I frequently observed it spinning a fine transparent slimy thread, and thus hanging suspended to a bit of seaweed or to the surface of the water. It also swims freely, like its congeners.

It is the R. pygmaca of Michaud, and probably R. fasciata of Requien.

$$
\text { 23. R. solu'ta }{ }^{*} \text {, Philippi. }
$$

R. soluta, Pbil. Moll. Sic. ii. p. 130, t. xxiii. f. 18; F. \& H. iii. p. 131, pl. Lxxv. f. 3, 4.
Body palc-yellowish-white, minutely speckled with flaky points: mantle lining the mouth of the shell: filament conspicuous: snout short, having a pink or dull-reddish-brown tinge above, and a patch of bright sulphur-yellow on each side below: tentacles cylindrical but somewhat compressed, slender, thickly covered with fine and rather long cilia: eijes scarcely raised, usually seen within the shell : foot long and narrow, labiated in front and slightly auricled at the corners, bluntly pointed behind: appendage rery long and distinct, flattish at the base, and tapering to a fine point.

Shell conic-oval, with a tendency to globoseness, solid for its size, semitransparent, and rather glossy: sculpture, extremely fine and somewhat numerous spiral strix, which are not perceptible except by a very strong magnifier or (in some specimens) under a microscope: colour uniform buff or pale-yellowish: spire very short, with a blunt point: whorls 5 , convex, the last equalling two-thirds of the spire: suture deep : mouth more round than oral: outer lip rather thick: inner lip reflected at the base, behind which is a small umbilical chink: operculum ear-shaped, marked with a few diverging lines of growth. L. 0.05 . B. 0.035.

Var. Alderi. Larger and thinner, with a more produced and pointed spire. R. Alderi, Jeffr. in Ann. and Mag. N. H. ser. 3. iii. p. 127, pl. г. f. 5 a-c.

Habrtat : Coralline zone in Shetland, the Hebrides, and Guernsey ; also in Dunnet Bay, Pentland Firth, and Moray Firth (Gordon), Aberdeenshire coast (Dawson), Clyde district (Webster and others), Belfast Bay (Hyndman and J. G. J.), Dublin Bay (Kinahan), Cork (J. G. J.), Bantry Bay (Bcevor), Arran Isle, co. Galway (Barlee), west coast of Ireland (Hoskyns), Fowey and Kingsbridge (Barlee), Helford (Hockin), Exmouth (Clark),

[^18]and Plymouth (J. G. J.). The variety occurred to me in the laminarian zone at Skye, and the Whalsey Skerries in the east of Shetland. Fossil in the post-glacial beds of Norway from the present level of the sea to 100 feet above it (Sars). This author has also noticed it living on the Norwegian coasts as far north as Oxfjord in Finmark; I found it at Etretat in Normandy, Martin in the Gulf of Lyons, Macé at Antibes, and Philippi at Sorrento and Palermo. Although local, it is not uncommon.

It is an active and restless little creature. I observed in this and other species of Rissoa an upward and downward current or movement on the surface of each tentacle, apparently caused by the action of the cilia.

Having carefully compared British and Mediterranean specimens, I still believe that Philippi's description and figure of $R$. soluta fairly represent our shell. It varies considerably in the length and compactness of the spire, as well as in the degree of sculpture. Indeed the strix cannot be detected in most specimens unless by means of a high magnifying-power, which possibly Philippi was not in the habit of using. He especially mentioned the umbilical fissure that characterizes the present shell. Searles Wood proposed to call our species intersecta, in case its identification with Philippi's species should prove to be erroneous; Bean gave it the MS. name of minutissima, and Martin that of globosa. The last two names I have seen in collections.

## 24. R. semistriáta *, Montagu.

Turbo semistriatus, Mont. Test. Br. Suppl. p. 136. R. semistriata, F. \& H. iii. p. 117, pl. lxxx. f. 4, 7.

Body pale-yellowish-white : pallial filament short: snout

* Half-striated.
not so long as in many other species, grooved in the centre above, and deeply cloren at the extremity: tentacles cylindrical but somewhat compressed, rather long, and covered with close-set cilia: eyes on scarcely raised tubercles: foot squarish in front, with slightly angular corners, and tapering behind to a blunt point : appendage tricuspid and short, placed over the tail but never projecting beyond it.

Shell conic-oval, rather solid, semitransparent, and somewhat glossy: sculpture, on the body-whorl below the suture about half a dozen slight spiral striæ, of which the upper two close to the suture are much stronger than the rest, and about a dozen similar and distinct strix below the periphers, the intermediate space being faintly also striated or frequently quite smooth; the other whorls exhibit the subsutural striæ only : colour pale yellowish-white, with a row of reddish-brown short and broad longitudinal streaks or blotches on the upper part of each whorl, and a second row of smaller and narrower streaks on the lower part, which last are often interrupted or broken; the other whorls are seldom marked in this way: spire rather short but pointed, with a blunt tip: whorls 6 , rounded but not convex, the last occupying nearly two-thirds of the spire: suture slight, encircled by the uppermost and strongest stria of each whorl: mouth open, though not expanded: outer lip sharp: inner lip reflected on the pillar and base, united above with the outer lip: operculum yellowish, and thin, slightly striated. L. 0.01 . B. 0.065 .

Var. pura. White and spotless.
Habitat : Littoral and laminarian zones, in England, Wales, Ireland, and Scotland as far north as the outer Hebrides (J. G. J.), Aberdeenshire (Dawson), Moray Firth (Gordon), and Shetland (Barlee). The variety is equally diffused, but more common in Guernsey than elsewhere. Lilljeborg found this species in Norway, and it occurs in the Cattegat; but southwards it becomes more frequent, both on the eastern coasts of the North Atlantic and in the Mediterrancan; Adriatic (von Schröckinger) ; Algeria (Weinkauff).

This pretty little mollusk, which Clark called "a bashaw with three tails," congregates in family groups
on the under surfaces of stones laid bare at low water of spring tides. It swims, like its congeners, with the sole of the foot uppermost.

It is possibly the Turbo scriptus of Adams, and unquestionably $R$. pulchra of Johnston, R. tristriata of Thompson, and R. subsulcata of Philippi. R. semistriata of the last named author, from the Red Sea, appears to be different from our species.

## 25. R. cingil'lus *, Montagu.

Turbo cingillus, Mont. Test. Br. p. 328, t. 12. f. 7. R. cingillus, F. \& H. iii. p. 1:22, pli. 1xxix. f. 9, 10, and (animal) pl. J J. f. 4.

Body pale-yellowish -white or milk-white; snout semitransparent: tentacles long, nearly cylindrical, flexible, with somewhat bulbous tips: eyes black and conspicuous, sometimes on whitish tubercles: foot narrow, but proportionally short, squarish in front and bluntly pointed behind; caudal cirrus not observed.

Sheil conic-oblong, rather solid, semitransparent, and somewhat glossy: sculpture, on the body-whorl from 12 to 20 slight spiral ridges, which are sharp and distinet below the periphery, but more or less obsolete above it ; these ridges are scarcely perceptible on the otner whorls; they are crossed by numerous fine strix in the line of growth, causing an imperfect decussation ; the last whorl is slightly angulated : colour buff or yellowish-white, with two chocalite or reddish-brown bands on the last whorl, and one on each of the upper whorls, besides part of a second band above the suture; there is also a third, shorter band or streak at the base; and occasionally, when the bands are narrow, a fourth may be seen between the lower band and the basal streak : spire long and gradually tapering, with a blunt tip: whorls $6-7$, flattened, the last occupying about two-fifths of the spire: suture distinct and slightls channelled: mouth rather small: outer lip sharp: imner lip forming a glaze on the pillar, and united with the upper lip at the outer angle : operculum horncolour, marked with diverging lines of growth. L. 0.175 . B. 0.085 .

Var. rupestris. Creamcolour or mills-white, and bandless. R. rupestris, Forbes in Ann. N. H. v. p. 107 , pl. 2. f. 13.

[^19]Hibitat: Gregarious, between tide-marks, on nearly every part of our shores. The variety is equally diffused, but nowhere so common as at Weymouth and Lulworth. The only locality recorded for this species as fossil is Ireland, on the authority of Capt. Brown. Its foreign rauge probably extends from Iceland (Zoega, fide Linné), along the Scandinavian coast from Bergen, southwards to the Ægean (Forbes). It has been found in several parts of France, Spain, and the north of Italy.

It appears to subsist on decayed seaweeds. Every shade and gradation, as regards the colour and bands, may be observed ; and I have a slightly turreted distortion.

Linné's description (in the 12th volume of his 'Systema Nature') of Helix pella may suit this species; and there is no doubt that it is the Turbo trifasciatus of Adams, and T. vittatus of Donovan. Although all these names have precedence of that given by Montagu, I must retain his as now universally accepted. Custom wills that, in science as well as in literature, names and words in general use should be preferred to those which are obsolete, although the latter may have the claim of priority ; nor will the feeble cry of justice to the memory of the author be listened to while the loud and imperious demand of public coivenience is ringing in our ears. Michaud called this species R. cingilus, and Macgillivray R. cingillata. A variety of a paler hue is Turton's: Turbo graphicus; and the variety rupestris is R. fallax of Brown.

The "spurious" or un-English species of Rissoa are as follows :-

1. R. auriscalpium (Turbo, L.) =T. marginatus, Mont. $=T$. arcuatus, Dillw. $=$ R. acuta, Desm. $=$ R. acicula, Risso $=$ Zippora Drummondii and Z. Drummondiana,
[^20]Leach : said to have been found at Dunbar by Laskey -an authority not to be relied on, seeing that Tellina carnaria, Amphidesma nitens, Siliquaria bidens, and several other exotic shells are enumerated by him from that locality; Dunbar also (Bingham, fide Brown); Cork (Leach). Yt is a common Mediterranean shell.
2. R. disjuncta (T. disjunctus, Mont.). West-Indian.
3. R. Montagui, Payr. = R. Binghami, Brown: St. Fergus's Bay, Peterhead (Bingham, fide Brown). Mediterranean and Adriatic.
4. R. glabrata, v. Mühlf. $=$ R. punctulum, Phil. $=$ R. nitida, Brusina : Shetland and Skye (J. G. J., in consequence of sifting shell-sand through sieves which were not properly cleaned after I had used them on the Piedmontese coast). Mediterranean and Adriatic.
5. R. cimex $($ Turbo, L. $)=$ T. calathiscus, Mont. $=$ Alvania Europea, A. mamillata, and A. Fremingvillea, Risso $=$ R. cancellata, Desm. $=$ R. granulata, Phil. : Isle of Jura (Laskey) ; Cumbrae (J. Smith). Mediterranean and Adriatic.

In the same category may be placed several species of Rissoina, a genus instituted by D'Orbigny to receive certain shells allied to Rissoa, which have the lower part of the mouth slightly channelled, and the operculum furnished underneath with a process like that of Neritina. There is no British species of Rissoina. Those erroneously recorded as such are :-
' 1. Rissoina Bruguieri, Payr.: Scarborough (Bean). Loire-Inférieure (Cailliaud); north coast of Spain (M‘Andrew) ; Adriatic (Heller) ; Mediterranean (Payraudeau and others) ; Ægean (Spratt).
2. Rissoina Bryerea (Turbo Bryereus, Mont.) $=T$. costatus, Don.: Margate (Donovan); Weymouth (Bryer); Dunbar (Laskey) ; Cornwall, Portmarnock, and Firth of

Forth (Brown); Peterhead (Crombie, fide Macgillivray). West Indian.
3. Rissoina decussata (Turbo decussatus, Mont.) $=R$. pyramidella, Brown: Weymouth (Bryer) ; Portobello Sands (Laskey) ; Dunbar (Brown). West-Indian.
4. Rissoina conifera (Turbo coniferus, Mont.): Weymouth (Bryer) ; north of France (De Gerville). WestIndian.
5. Rissoina denticulata (Turbo denticulatus, Mont.): Weymouth (Bryer) ; Cornwall and Dunbar (Brown) ; Herm (Lukis). West-Indian.

The following are irrecognizable:-1. Rissoa sulcata, Brown: Dunbar (Bingham). Apparently a Rissoina. 2. Rissoa candida, Brown : "Belton Sands near Dunbar." Perhaps the same species as the last. 3. Rissoa lactea, Brown (not of Michaud): "Dunbar." Another Rissoina, probably R. Chesnelii of Michaud, a native of the West Indies and Mauritius.

## Genus IV. HYDROBIA.

(See vol. i. p. 63.)
I would remind my readers that the chief characters by which the present genus is distinguishable from Rissoa (to which it is closely allied) consist in the foot of Hy drobia wanting the opercular appendage or caudal filament, and in Rissoa being truly marine, while this lives in estuaries and brackish water only. In the latter respect both genera may be regarded as the creatures of habitat. Their shells are equally small.

When I placed Hydrobia in the Paludinide, I had not sufficiently considered its systematic relations. I now withdraw it from that family. The description of the operculum (vol. i. p. 55 ) must be amended by omitting the words " or paucispiral."

## Hyorobla ulva*, Pennant.

Tu•bo ulvor, Penn. Br. Zool. iv. p. 132, t. Ixxxvi. f. 120. Rissoa ulvce, F. \& H. iii. p. 141, pl. lxxxi. f. 4, 5, 8, 9, pl. lxxxvii. f. 2, 8, and (animal) pl. JJ. f. 8 .

Body light-slatecolour, dark-grey, or sootcolour, with more or less of a purple tinge, speckled with yellow, and haring occasionally a few markings of purple-brown on the upper part: pallial process thread-shaped, short, and ciliated: snout nearly cylindrical, prominent, and extensile, cloven at the extremity, edged in front by a purplish-brown line, and having two yellow spots in the middle: tentacles thread-shaped but somewhat compressed, long, slender, and diverging, irregularly speckled with Jellow, marked across a little below the tips by a bar or ring of purplish-brown, and edged with the same colour ; they are covered with fine and short, but not conspicuous, vibratile cilia, and often (especially the left-hand tentacle) scalloped or serrated at the sides, like the weapon of a sword-fish, apparently in consequence of voluntary contraction ; tips rounded: eyes on small protuberances: foot lanceolate, squarish and double-edged in front with short salient corners, narrower in the middle, and rounded behind; it is margined with a narrow purplish-brown line; sole light-grey, with yellow specks: opercular lobe large and expanding on each side, darkpurplish-brown ; it has no filament, process, or appendage of any kind.

Shell oblong, rather solid, opaque, and of a dullish hue: sculpture, under a hand-lens exhibiting occasionally a few slight spiral lines on the last whorl; with a higher microscopic power may be detected on all the whorls extremely fine, close-set and numerous concentric wary strix ; there are also the usual longitudinal lines of growth; the body-whorl is more or less distinctly keeled in the middle: colour yellomish or reddishbrown of various shades passing into horncolour: epidermis rery thin, and mostly obscure: spire rather long and tapering, with a blunt tip: whorls 7-8, compressed, the last occupying about one-half of the spire viewed in a supine position: suture well-defined although not deep: mouth oval, narrowly angulated above, and effuse or spread out below, where it is also somewhat angular: outer lip thin and plain: inner lip white, reflected on the pillar and over the base of the shell, behind which it forms a small cleft or umbilical chink; the

[^21]lips are continuous and make a complete peristome: operculum horny and thin, marked with flexuous and rather strong lines of growth, and having a small lateral spire of three whorls. L. 0.25 . B. $0 \cdot 12 \overline{\text { an }}$.

Var. 1. allida. Of a whitish colour.
Var. 2. Barleei. Smaller and spindle-shaped, the last whorl being contracted at the base, and the mouth much smaller than usual. Rissoa Barleei, Jeffr. in Ann. \& Mag. N. H. xix. p. 310 .

Var. 3. octona. Smaller, thin, glossy, and horncolour, with the whorls more slowly increasing and divided by a deeper suture. IIelix octona, Linn. S. N. p. 1248.

Habitar : All our tidal rivers, inlets, and bays; covering mud-flats and oozy sands in countless profusion. Var. 1 is occasionally found. Var. 2. Hebrides (Barlee and J. G. J.) ; the typical form occurs in Loch Carron and at Stornoway. This variety is littoral-although the specimens (dead ones) which I described as Rissoa Barleei were dredged in deep water, having accidentally got there. Lindström noticed the same variety on the eastern shores of the Baltic. Var. 3. In a large pool of brackish water, called Arnold's Pond, near Grand Havre Bay, Guernsey. This last variety inhabits the southern shores of the Baltic ; and M. Taslé sent me specimens from Brittany. It may be a distinct species; but we do not know the effect of local conditions and consequent change of food on the shape of animals. H. ulve is fossil in a post-tertiary deposit at Belfast (Grainger), Clyde beds (Smith and Crosskey), Norwich Crag (Woodward), Red and Coralline Crag (S. Wood), Uddevalla (J. G. J.), Norway, in post-glacial beds (with the variety Barleei), from the present level of the sea to 130 feet above it (Sars). Its foreign range extends from Finmark to Spain and throughout the Mediterranean; and Dr. Philip Carpenter has recorded it as a
native of the Gulf of California, An allied species (Turbo minutus, Totten) appears to be its representative on the east coast of North America; this has a smaller and more oval shell, with convex whorls.
"In summer it is the chicf food of the grey mullet; in winter various sea-birds feed upon it" (Hyndman). Its own subsistence is derived from Enteromorphe, Conferve, and other delicate seaweeds; and I can testify that it can fast a long while, having kept live specimens for many days in a vessel which contained nothing but water, without observing any diminution of their vivacity. Males are very much smaller than females (from which my description has been taken), and their shells have no keel. The former sex is probably the Turbo subumbilicatus of Montagu. The hollow space between the two edges in front of the foot is lined with vibratile cilia, by the action of which a fluctuating motion is produced when the animal is crawling, and a tremulous one when it is at rest. The frees are elliptic. Occasionally the surface of the shell is eroded and pitted, so as to expose the innermost layers ; or the top whorls are trincated. In the latter case a rude semispiral partition is formed by the upper fold of the mantle, as in Truncatella truncatula. The spire is now and then seen to be unnaturally lengthened, evidently owing to some accident in early growth, when a fresh start had to be made. The shell is extremely variable in size and comparative convexity. My largest specimen (from Southampton) is upwards of four lines long.

It is the Bulimus anatinus of Poiret, and Turbo muriaticus of Beudant, generically changed by Draparnaud and Lamarck to Cyclostoma and Paludina. Örsted described it as Paludinella vulgaris. I regard also the Paludina balthica of Nilsson and P. minuta of Requien
as local varieties. The Rissoa rubra of Macgillivray is cortainly the present species, and not Barleeia rubra as he supposed.

Family X. HE'TEROPHROSY'NIDÆ, Clark.
Body spiral: mantle plain-edged: head snout-shaped: tentacles cylindrical and short, with rounded tips: eyes sessile, or nearly so: foot double-edged in front; hinder part of the sole slightly grooved down the middle.

Shell small, conical, and spiral: operculum not spiral but increasing by concentric layers, with the nucleus on the inner side. next to the pillar ; that side is strengthened br a rib, and furnished underneath with a spike-like process or plate, which projects from the nucleus.

As the name imports, these mollusks are abnormal, allied to the Littorinide, and distinguishable from that family not much more than the Turbinidee are from the Trochide*. The operculum is very peculiar. It has an excentric nucleus, like that of Buccinum, and an internal process analogous to that of Neritina.

Although the appellation given by Mr. Clark is a long one, it must in justice and on other grounds be preferred to either of those subsequently proposed by Dr. Gray, viz. Rissoellidee and Barleciade. In the system of the latter author these families are separated by Cuaplida and several others.

The Heterophrosynidee are not restricted to the Atlantic Ocean: Dr. P. Carpenter has described some from the Pacific. They inhabit the laminarian zone, and appear to be gregarious.

[^22]
## Genus I. BARLEE'IA*, Clark. Pl. I. f. 2.

Body stout: snout gibbous: eyes placed on small bulgings outside the tentacles, at their bases.

Shell solid and smooth : mouth oval, angulated abore and below : operculum solid, ear-shaped, and gibbons, having the nucleus at the lower end of the inner side.

Differing from Rissoa not only in the structure of the operculum, but also in the mantle and opercular lobe of the animal in the present genus being destitute of filaments.

## Barleela rubra†, Montagu.

Turbo ruber, Mont. Test. Br. p. 320. Rissoa ruïra, F. \& II. iii. p. 120, pl. lxxviii. f. 4, 5 .

Bony yellowish-white, often transversely brindled with smokecoloured lines: snout projecting beyond the foot, cloren in front, lleshcolour or pink on the upper part: tentacles clubshaped, sparingly setose in some specimens and smooth in others, marked internally down the middle by a brownish line, or speckled with yellow: eyes rather large and black, scarcely raised, sometimes encircled by a bright sulphurcoloured line : foot lanceolate, short, rounded in front and behind; tail rery slightly bifurcated: opercular lobe dark-purplishbrown.

Shell forming a short cone, remarkably strong, semitransparent, and glossy: sculpture, apparently none, but under a good magnifier consisting of a few indistinct spiral striæ: colour dark-red, claret, yellowish-brown, or tawny: spire bluntly pointed: whorls $5 \frac{1}{2}$, compressed, gradually enlarging; the last occupies threc-fifths of the spire: suture slight, having frequently a dark band below it on each whorl, caused by the donble layer of shell in that part: mouth rather small : outer lip slightly incurved at the upper angle, thickened in fullgrown specimens, and spread out at the base: inner lip reflected on the pillar, and united with the outer lip, but not so as to form a distinct peristome: operculum dark-crimson,

[^23]composed of 5 or 6 irregularly concentric portions, the marks of dirision or growth being obscure ; columellar side groored near the margin, and haring a corresponding rib underneath. L. $0 \cdot 1 \because 5$. B. $0 \cdot 6$.

Var. 1. unifasciata. Creamcolour or whitish, with a broad band of reddish-brown encircling each whorl, sometimes divided into two narrower zones. Turbo unifasciatus, Mont. T'est. Br. p. 320 ; F. \& H. pl. lxxx. f. 3.

Var. 2. pallicla. White, with a faint tinge of blush colour.
Habitat: Seaweeds at low water in the Channel Isles, and on many parts of the coasts of Dorset, Devon, and Cornwall ; Cork (Wright and J. G. J.); Bantry (Barlee and Normau) ; Connemara (Barlee and Alcock); Bundoran, co. Donegal (J. G. J.). The following require confirmation:-Southampton (Montagu); Teuby (Lyons); Whitley, Northumberland (Fryer); Dublin Bay (Turton) ; Lamlash Bay, Bute (Landsborough); Dunbar (Laskey) ; Aberdeenshire (Macgillivray). Both varieties occur with specimens of the usual colour. The foreign localities are Cherbourg and adjacent coast (Macé); Rochelle (D'Orbigny père and J. G. J.) ; Biarritz (v. Martens, fide Troschel) ; Gulf of Lyons (Michaud and Martin) ; Nice (Vérany) ; Spezzia (J. G. J.) ; Corsica (Michaud, D'Orbigny père, and Requien); Dalmatia (Brusina) ; Sicily (Philippi) ; and Teneriffe (M'Andrew).
$B$. rubra is tolerably active. It occasionally secretes a slight mucous filament, by which it suspends itself from a seaweed or the surface of the water ; and it also floats, with the foot uppermost, like the Rissoce. The fæcal pollets are oval and whitish. The male is smaller than the female. I unfortunately misled the authors of the 'British Mollusca' by communicating the description which they published as that of the animal of the varity unifusciata; it was taken from Hydrobia ulve (as Mr. Clark suspected). The living shell of the present
species is frequently encrusted by the common Melobesia or nullipore in its earlier stage of growth. The dark-crimson colour of the operculum offers a remarkable contrast to the white shell of the 2nd variety. In Professor Troschel's 'Gebiss der Schnecken' (vol. i. t. x. f. 8) the lingual riband is represented as nearly similar to that of Rissoa parva.

Turbo ruber of Adams (from the Pembrokeshire coast) appears to have been derived from a reddish specimen of Rissoa parva, var. interrupta. Our shell is R. fulva of Michaud, and Sabancea Binghamiana of Leach.

## Genus II. JEFFREI'SIA*, Alder. Pl. I. f. 3.

Body slender: snout cloven so deeply that in some species the lobes thus formed resemble a second pair of tentacles: eyes placed behind the tentacles, on their inner side, either on small bulgings or sessile.

Shell thin, smooth, and glossy: mouth oval or roundishoval, with a complete peristome : operculum rather thin, having' the nucleus on the middle of the inner side, and a short rib on the under side, which proceeds from the nucleus in the direction of the outer margin.

The above characters show a greater departure from Rissoa than those of the last genus. According to Mr. Alder the lingual armature of Jeffreysia closely resembles that of the common Rissoa; and indeed we find that the animals of both genera are vegetarians. Mrs. Collings detected in the stomach of J. diaphana a species of Lythocystis allied to L. Allmani.

Dr. Gray makes this synonymous with his undescribed genus Rissoella. The type indicated by him, in lieu of a description, is Rissoa glabra of Brown, which is evidently an Odostomia (probably O. rissoides), having "a

[^24]slight plication at the base." In Gray's classified list of the Mollusca, published in 1847, Rissoella is given as a synonym of Odostomia.

## 1. Jeffreysia dia'phana*, Alder.

Rissoa? glabra (afterwards R.? diaphana), Ald. in Ann. N. II. xiii. p. 325, pl. 8. f. 1-4. J. diaphana, F. \& II. iii. p. 152, pl. lxxvi. f. 1.
Body pale yellowish-white, faintly tinged with fleshcolour, and of a grauular texture: snout expanding into two clubshaped lobes or processes, which direrge at the same angle as the tentacles, hut are shorter and smaller : tentacles cylindrical, compressed (both the false and true tentacles are covered with vibratile cilia. Alder) : eyes rather distinct than large, sessile and placed far back ou the neck within the shell; each is encircled by a slight integument, so as to appear raised: foot lanceolate, somewhat bilobed in front, and angulated at each corner, rounded or bluntly pointed behind: opercular lobe mottled with brown, extending a little beyond the edges of the foot.

Sirell forming a rather short and oblique cone, rery thin, quite transparent, and of a somewhat iridescent lustre: sculpture, apparently none, but under a good magnifier consisting of delicate although obscure spiral strix; the lines of growth are equally microscopical, but finer and more numerous: colour whitish: spire having a blunt and abrupt point: whorls $4 \frac{1}{2}$, convex, gradually enlarging; the last occupies three-fifths of the spire; first whorl rounded: suture dcep: mouth rather large : outer lip sharp, incurved above, rounded and slightly expanded below: inner lip rather flexuous, its outline being accommodated to the curve of the pillar; behind it is a narrow umbilical chink : operculum yellowish-white, depressed in the centre, composed of 4 or 5 segments or layers, which are indistinctly defined, and closely striated in the same concentric direction; the inner side forms a very obtuse angle, the opposite side being rounded; spike triangular and flattened, having its narrower end at the base; medial rib short, diverging from the spike at a right angle; rib on the inner side marginal and slight. L. 0.075 . B. 0.05 .

Habitat: Delesseria hypoglossum and various other

* Transparent.
seaweeds, at low-water mark and a little beyond it, on many parts of our coast from Shetland to the Channel Isles inchusive. It was first noticed near Dublin and at Cullercoats by Mr. Alder. The only foreign localities of which I am aware are Cape Lévi near Cherbourg (Macé), and Spezzia (J. G. J.).

At the Whalsey Skerries $J$. diaphana occurs in company with its two congeners, J.globularis and J. opalina: the scale of their comparative frequency is the order here given, the last-named being the most numerous of the three. The present species is very active in crawling and floating; and it spins a slimy suspensile thread. When many specimens are left for some hours in a vessel of water, they congregate in small clusters, as if actuated by a social instiuct. The spawn deposited by one individual consisted of only two ova, which were enclosed in a gelatinous hemispherical case. Owing to the extreme and glassy transparency of the shell, the dark reddish-brown liver is very conspicuous, even after the animal has dried up.

Perhaps this shell was the Turbo mitidus of Adams, from the Pembrokeshire coast, where it is not uncommon.

> 2. J. opa'Lina*, Jeffreys.

Rissoa (?) opalina, Jeffr. in Ann. \& Mag. N. H. ser. 2. ii. p. 351 . J. opalina, F. \& H. iii. p. 154, pl. lxxvi. f. 3, 4; iv. (app.) p. 267, pl. cxxxiii. f. 6, and (animal) pl. MM. f. 2, $a-b$.

Bonr, above, dark-grey, mottled with purplish-brown or sootcolour ; below, dirty yellow : snout short, rounded, seldom projecting beyond the foot; front edge finely scalloped: tentacles club-shaped, and of a paler colour [" very moderately setose," Clark]; they appear four in number, arranged in two $1^{\text {rairs, }}$ each tentacle being nearly equal in length and thickness; the second or lower pair are scarcely part of the snout, because they issue from the neck, like the other pair: eyes sessile, rather

[^25]close together, and surrounded by pale rings; they are visible only through the shell: foot large, triangular, bilobed, and slightly auricled in front, bluntly pointed behiud.

Shell oval, extremely thin, semitransparent, highly glossy and of an opaline lustre : seulpture as in the last species: colour bronze or dark horncolour when the shell is living or contains the remains of the animal, yellowish when it is empty: spire short, with an abrupt and blunt point: whorls $3 \frac{1}{2}$, swollen, rapidly enlarging ; the last occupies at least three-fourths of the spire, and the first is mammiform: sutwe broad and deep: mouth oval, capacious, and more than half the length of the spire: outer lip sharp and thin, incurved above, slightly angulated and expanding below: inner lip flexuous and thickened on the lower part of the pillar, behind which it forms a narrow umbilical chink: operculum similar to that of J. diaphance; but the spike or apophysis is slightl $\bar{y}$ curved, and occasionally double, so as to make two separate leaves. L. 0.1. 13. 0.075 .

Habitat: Guernsey and Sark, in rock-pools among Corallina officinalis (Barlee); Falmouth (Cocks and Barlee); Cumbrae, Clyde district (Norman); Skye (A. M'Nab); Whalsey Skerries, Shetland, on Laminaria saccharina, a little beyond low-water mark (J. G. J.). Although very local, it is abundant. I found a single specimen at Lerici ; and Vérany has recorded this species from Nice.

At the Whalsey Skerries it especially frequents a sheltered part of the sound, close to a fish-curing station, where the offal is thrown out. The other species of Jeffreysia and Trochus helicinus are its companions. Do all these feed on decaying animal matter, or on Infusoria produced from it? The spawn is deposited on leaves of the Laminaria; it is of a semioval shape, with a large hole in the middle. When ripe it forms a thick mass, and contains an immense number of yellowish unispiral shells which are agglutinated together by a gelatinous matrix. The adult shell resembles Hydrobia
similis; but it is not so turreted, and the spire has a blunt instead of a sharp point. A dead specimen from Falmouth is marked with flexuous and close-set longitudinal striæ, arising probably from a partial decay of the surface.

A comparison of the description of this species with that of J. diaphana, as regards their soft parts, may serve to show that the tentacles of all the Mollusca, whether univalve or bivalve, are nothing more than a development of the mantle, endued with special sensibility as organs of touch or of some other less direct medium of sensation. In some cases (e. g. Chiton, Homalogyra, certain species of the Bulla family, and inferior kinds of the naked Mollusca) tentacles are entirely wanting; while in others (e.g. the present species of Jeffreysia, and most of the Pulmonobranchiata) the usual pair becomes double, as if for the purpose of increasing the sense of perception. In Pecten and those bivalves which have the mantle open the tentacles are numerous; the cirri fringing the tubes of the majority of bivalves which have the mantle more or less closed appear to be supplementary organs of a similar nature; and so are the appendages of the head and opercular lobe in Trochus, Rissoa, and many univalves, as well as the cilia that cover the body in Stilifer. But I must not get out of my depth. We cannot all be physiologists,
"And take upon us the mystery of things, As if we were God's spies."

## 3. J. globula'ris*, Jeffreys.

J. globularis (Jeffreys, MS.), F. \& H. iv. app. p. 268, pl. cxxxiii. f. 5.

Body dark-grey, finely streaked with purplish-brown, paler underneath: snout forming two short cylindrical processes,

[^26]which resemble tentacles but are close together: tentacles cylindrical, rather short, with blunt tips: eyes large, round, and scssile, placed far behind the tentacles: foot lanceolate, short, deeply cloven and bilobed in front, bluntly pointed or almost round behind.

Shell globosely conical (like that of Valuata piscinalis), extremely thin, transparent, highly glossy, and partially iridescent: sculpture the same as in the preceding two species: colour whitish when the shell is empty, dark horncolour when containing the animal or its dried remains: spire short and compressed; apex blunt: whorls $3 \frac{1}{2}$, Fery tumid, rapidly enlarging ; the last occupies three-fourths of the spire : suture remarkably deep : mouth roundish-oval, somewhat detached, half the length of the spire: outer lip sharp and thin, considerably incurred above, slightly expanding and rounded below : inner lip separated from the pillar to a greater extent than in either of the other species, so as to make the peristome more distinct: umbilicus rather narrow but deep: opercutum shorter and more oral compared with that of the other species; the marks of growth are also more conspicuous, and evidently show a concentric arrangement. L. $0 \cdot 05$. B. $0 \cdot 065$.

Monstr. Partly scalariform, in consequence of the suture being excavated and becoming much broader near the mouth.

Habitat : On Laminario at Croulin Island, in Skye (Barlee), and, with J. diaphana and J. opalina, at the Whalsey Skerries (Barlee and J. G. J.) ; rather plentiful.

The tentacular processes of the snout in this species are much smaller and further apart than the true tentacles. In J. opalina the snout is very prominent, and quite distinct from the second pair of tentacles. In both species the hinder tentacles are usually borne at a right angle to the axis of the shell, and the other processes in front diverge at an angle of about $45^{\circ}$.

## Family XI. SKENEIDE, (Skeneadce) Clark.

Body coiled in a circle: head large and snout-shaped: tentacles cylindrical in one genus, and wanting in another: eyes proportionally large, either almost sessile and placed at the outer bases of the tentacles, or quite sessile and placed behind the head: foot short: opercular lobe not furnished with any process or filament.

Sherl minute, circular, with a wide umbilicus: spire much depressed, or cven involute: mouth round, having united edges that form a complete peristome: operculum horny, circular, and spiral.

There is a seeming incongruity in the above description, with regard to the characters founded on the soft parts ; but certain genera of Bullida are provided with tentacles, while others have none. The form of the shell in the present family exhibits a greater concordance than that of the animal. At all events some kind of classification is indispensable: as with heraldry, so with our science,

> "Order is Nature's beauty, and the way To order is by rules that Art hath framed."

The Skeneidse are at present not much known, owing to their minute size. All the species hitherto described (three in number) inhabit the North Atlantic and Mediterranean ; two are post-tertiary. In a recent or living state they are gregarious, and are sublittoral or frequent the higher part of the laminarian zone.

$$
\text { Genus I. SKE NEA*, Fleming. Pl. I. f. } 4 .
$$

Body depressed: tentucles cylindrical: eyes almost sessile, and placed at the onter bases of the tentacles.

Shell having the spire very little raised: whorls cylindrical:

[^27]mouth placed below the spire, and more or less detached from the body-whorl: operculum many-whorled, with a central nucleus.

Although the definition of this genus by its founder, Dr.'Fleming, is extremely vague ("spire depressed, and destitute of spinous processes"), common usage has established it. It originally contained three so-called species, viz. S. depressa, S. serpuloides, and S. divisa. The first of these (or S. planorbis) is the type and sole representative; the other two are synonymous, and belong to the genus Cyclostrema. More species were afterwards added, but doubtfully, by Forbes and Hanley; these have now been assigned to what I consider their proper places. The tongue of Skenea is very much like that of Rissoa.

The present genus is partly Delphinoidea of Brown.

## Skenea planor'bis*, Fabricius.

Turbo planorbis, Fabr. Fn. Grœenl. p. 39t. S. planorbis, F. \& H. iii. p. 156, pl. Ixxiv. f. 1-3, and (animal) pl. GG. f. 1 \& $1 a$.
BonY greyish-white : snout rounded and gibbous; tentacks long and widely divergent; they are not, as in Rissoa, setose: eyes seated on broad and scarcely raised protuberances: foot truncated in front and rounded behind; sole marked down the middle of the posterior half with a slight groove or line.
Shesur resembling in shape a miniature Helix ericetorum, thin, opaque, and seldom glossy: sculpture, only a few slight and obscure puckers in the line of growth : colour reddish-brown, or pale tawny: spire scarcely risible, unless viewed edgewise or with the mouth of the shell towards the observer; apex blunt and rounded: whorls 4, rather loosely coiled; the last much larger in proportion to the others, and occupsing at least three-fourths of the shell : suture deep: mouth projecting outwards, with a sharp and somewhat flexuous edge; umbilicus forming a wide, open, and rather deep funnel, usually exposing the interior of the spire: operculun clear-white, concare, with

[^28]7 or 8 obliquely striated turns, the last of which is proportionally much the largest; the under side has a small boss or nipple-shaped point in the centre. L. 0.03 . B. $0 \cdot 06$.

Var. 1. trochiformis. Spire more prominent, and umbilicus consequently coutracted.

Var. 2. maculate. Yellowish-white ; the last whorl spirally ornamented by a double row of circular reddish-brown spots, one above and the other below the periphery.

Var. 3. hyalina. Clear-white and transparent.
Habitat: Plentiful under stones and on seaweeds between tide-marks all round the coast. Var. l. Shetland, Skye, and Lough Larne; this seems to bear the same relation to the common form as the Helix rupestris of Studer and Draparnaud does to the H. umbilicata of Montagu. Var. 2. Channel Isles. Var. 3. Skye and Channel Isles. Fossil: Clyde bods (Smith and Crosskey) ; Fort William (J. G. J.); post-glacial and glacial beds in Norway, 130-380 feet (Sars). Recent: Spitzbergen (Torell); Iceland (Steenstrup and Torell) ; Scandinavia (Lovén and others) ; north of France (Macé, Cailliaud and J. G. J.) ; Cannes (Macé) ; Nice (Vérany) ; Spezzia (J. G. J.) ; Madeira (Johnson, fide Hanley); Grecnland (Fabricius and Möller); Massachusetts (Gould, as S. serpuloides) ; from Cape Cod northwards (Stimpson). Although it is a sublittoral species, Malm has dredged it in 10 f . on the Swedish coast, and M'Andrew in 15-40 f. on that of Upper Norway.

This little mollusk feeds upon Lichina pygmaa and small Conferver. It swims with facility in an inverted posture, and occasionally suspends itself in the water by spinning a viscous thread with its foot. When crawling, the shell is carried sideways, not erect. Mediterrancan specimens are frequently spotted, like our 2nd variety.

It is the Helix depressa of Montagu.

## Genus II. HO'MALOGY'RA* (formerly Omalogyra), Jeffireys. Pl. I.f. ō.

Body flattened: tentucles wanting: eyes quite sessile, and placed behind the bead.

Shell forming a flat coil, and having an involute spire: whorls more or less angulated: mouth clasping both sides of the periphery: operculum few-whorled, with a central nucleus.

The animal is unlike that of any known Pectinibranchiate mollusk ; and, if we except Omalaxis or Bifrontia, the shell has no existing parallel among the marine univalves. In the latter respect it may be regarded as the analogue of Planorbis. The upper part of the body of $H$. atomus is partially ciliated. This character is exhibited to a greater extent in Stilifer, as well as in the tentacles of Trochus, Rissoa, Cœcum, and other genera. Dr. Fischer was rather too positive in stating (Journ. Conch. vii. p. 365) that my observations proved, "d'une manière iuréfragable," the animal of the present genus to be the fry of some mollusk. The only instance adduced by him in support of such a conjecture is the change which many of the Nudibranchs undergo in the larval state. Their embryonic shells, however, have a rudimentary spire of scarcely a single whorl, and are all of the same size in each species, the animals are natatory, and the metamorphosis is of short duration. The shells of Homalogyra, on the contrary, have a complete spire of from 3 to 4 whorls, and are of various sizes (indicating different stages of growth); the animals crawl about, and they are met with at all seasons of the year. There is no more reason to suppose that Homalogyra is an immature mollusk than Skenea, Cyclostrema, or any other minute kind. The tongue of

[^29]H. atomus, examined by Dr. Lukis and Mr. Alder, has only a single row of teeth (as in some of the Pleurobranchiata and sea-slugs), resembling miniature sharks' teeth. The snout or head-lobe and position of the eyes remind us of Akera bullata. Mr. Alder remarks that "the animal is altogether of very simple structure, and one of what Milue-Edwards calls degraded forms, occupying a similar position among the Testacea to what Limapontia does among the naked mollusks." I have placed it provisionally in the Skenea family.

I am still of opinion that this is a legitimate but diminutive descendant of the ancient genus Euomphalus. From a dislike to offend the prejudices of palæontologists, who treat the notion of reviving an "extinct" genus as a scientific heresy, I have substituted another name; but so notoriously imperfect is the geological record that we ought not to be surprised if the pedigree of Euomphalus cannot be traced down to the present time. Homalogyra is an upper tertiary fossil ; and several species of flat-spired shells, which have been as. signed to Solarium, occur in older formations, and may be the missing links of the genealogical chain. The description of Euomphalus in Sowerby's 'Mineral Conchology' (vol. i. p. 97) is as follows:-" An involute compressed univalve ; spire depressed on the upper part, beneath concave or largely umbilicate. Aperture mostly angular." The tiny living representative of the great Trilobite family offers au analogy to the present case. Has all creation dwindled, and are these its last days? Brown's genus Planaria was founded on young specimens of Planorbis spirorbis and P. albus, which had been washed down by a freshwater stream into the sea. His genus Spira is characterized as "nearly globular or semiovate," and comprised the fry of some common
species of Rissoa. In the 'Microdoride Mediterranea' of Costa (1861) the present genus is described under the name of Ammonicerina.

## 1. Homalogyra átomus *, Philippi.

Truncatella atomus, Phil. in Arch. f. Nat. (1841) vii. pt. 1. p. 54, t. ₹. f. 4. Skenea nitidissima, F. \& H. iii. p. 158, pl. lxxiii. f. 7, 8.

Body yellowish-white on the upper side, and of a paler hue underneath, nearly hyaline: snout or head-reil short, broad, expansile and rery flexible, forming in front two semicircular lobes; these lobes are sometimes separated by an intermediate membrane, which slightly projects, so as to make the extremity appear trilobed; the front part is usually, but not always, clothed with numerous irregularly disposed cilia of different lengths and sizes; when fully extended this part is so transparent that the foot can be seen through it : tentacles none, nor the slightest restige of any, in whatever position or light the animal is riewed : eyes large in proportion, seated abont halfway between the front edge of the shell and the extremity of the snout: foot lanceolate, slightly bilobed in front, and rounded or bluntly pointed behind: opercular lobe sometimes having on its upper margin a few cilia like those on the snout.

Shell resembling in shape a miniature Planorbis corneus, not very thin, semitransparent, and glossy: sculpture, usually fine and close-set indistinct striæ in the line of growth, but occasionally also some obscure ridges in the same direction on the first-formed whorls, and a few white varicose streaks on the body-whorl: colour reddish-brown or pale tawny: spire sumk below the level of the last whorl ; apex blunt: whorls 3, compactly coiled, rounded on the upper side, and somewhat angulated or flattened on the under side; the last nearly enwraps all the rest, which are exceedingly small : suture deep : mouth projecting a little outwards, with a sharp and even edge ; it is indented behind by the periphery: umbiticus wide, open, and almost flat, fully exposing the interior of the spire: operculum clear-white, fiat, with 3 or 4 gradually increasing turns, which are defined by a thickened edge, and obliquely but slightly striated. L. $0.012 \overline{5}$. B. 0.03.).

Var. vitrea. Shell of a glassy transparency.

> * An atom.

Habitat: Abundant almost everywhere in the upper region of the laminarian zone, just beyond low water, on seaweeds and Zostera marina. I will mention a few localities to show the extent of distribution :-Shetland, Skye, all Ireland, Scarborough, Bristol Channel, Land's End, Torbay, and the Channel Isles. The variety was found in Loch Fyne by Mr. Barlee. This spesies is fossil in the Clyde district (Crosskey), near Fort William (J. G. J.), and in post-glacial beds, Norway, from the present sea-level to 100 feet above it (Sars). In a living or recent state it ranges abroad from Norway, in the laminarian zone (Sars) to Bohuslän, 10 f. (Malm), Cattegat (mus. Copenhagen), Etretat (J. G. J.), Cherbourg and Vallognes (Macé), Provence (Petit), Nice (Vérany), Corsica (D'Orbigny père), Sardinia (Costa), Spezzia and Sestri di Levante (J. G. J.), Sorrento (Philippi), to Lacalle in Algeria (Deshayes).

This little creature, on being captured and placed in a watch-glass with seawater, was at first shy ; but when left for a short time undisturbed it crawled about freely and rapidly, like a snail, with its shell raised in a slanting position ; and on its getting to the water's edge it turned upside down, and floated on the under surface. I observed it last year feeding on a Conferva, which it dragged into its mouth by means of its rake-like teeth. The snout was then contracted, and the rest of the body bunched up ; the front appeared to be delicately scalloped or crenellated. The heart beat quickly, about 100 per minute ; but the pulsation was intermittent. It afterwards retired into its house (perhaps to digest the meal), whence it seemed to reconnoitre me through the shell, with its dark eyes, like a porter from within the window of a hall. The shell is sometimes encrusted, on one side or the other, with Polyzoa and species of Discorbina.

Spawn-capsules which are occasionally found in the upper cavity of the last whorl in dried specimens, and which may be presumed to belong to the Homalogyra, are of a tawny colour and oval, with a wide slit or orifice at the top of each, and agglutinated together in a cluster of $\overline{5}$ or 6 ; they are much larger than the capsules that I hare observed of any Rissoa.

Philippi must have made a mistake (an infirmity that is common to us all) in describing and figuring this mollusk as similar to the animal of Truncatella truncatula; and in the same work (Archiv für Naturgeschichte, vii. pt. i. p. 53, t. v. f. 7) Assiminea litorina is equally misrepresented. Instead of all these thrce species having the eyes seated on the inner base of the tentacles, one only ( $T$. truncatula) can be said to be in this category. H. atomus has not the slightest appearance of tentacles; and in A.litorina the eyes are placed on their tips.

The present species was regarded by the authors of the 'British Mollusca' as Adams's Helix nitidissima. But that shell is cvidently the fry of Zonites radiatulus, his $H$. bicolor being the fry of $Z$. cellarius. L. Pfeiffer referred our shell, with a doubt, to his genus Paludinella. It is the Ammonicerina simplex of Costa.

## 2. H. roт a*, Forbes and Hanley.

Skenea rota, F. \& H. iii. p. 1G0, pl. lxxiii. f. 10, and lxxsriii. f. I, 2.
Srecl resembling in shape a miniature Ammonite (of the section Capricorni, De Buch), thin, semitransparent, and lustrous : sculpture, several ring-like ribs, from 20 to 25 on the last whorl of a full-grown specimen, besides 3 spiral keels (which vary in strength and are not always perceptible) and a few fine intermediate strix; one of these keels encircles the periphery, and the other two the middle of each whorl on the
upper and under sides; the ribs become slightly nodulous at the points where they are crossed by the keels, and they seldom extend on either side to the periphery: colour reddish-brown or pale-tawny, the keels being of a bright golden hue: spire not so much sumk below the level of the last whorl as in $H$. atomus; apex blunt: whorls 3, compactly coiled, somewhat compressed, with a slope from the peripheral keel in an equal degree on both sides; the last whorl is much larger than the next, but not so disproportionately large as in the other species : suture deep: mouth slightly expanding outwards, with a thin but even edge: it has somewhat of a horseshoe shape, with the rounded end in front, the indentation behind by the periphery being considerable: umbiticus wide, open, and nearly flat, completely exposing the inturior of the spire: operculum clear-white, rather concave, and having 2 or 3 rapidly enlarging turns. L. 0.0115 . B. 0.025 .

ILabitat: In rock-pools among seaweed; a scarce species, although equally diffused with H. atomus. The following list of places where it has been found may be useful to collectors :-Lerwick, Skye, Bantry Bay, Cork, Scarborough, Sandwich, Isle of Wight, Weymouth, Falmouth, Tenby, and Manorbeer in Pembrokeshire, Oxwich and Caswell Bays near Swansea, and Guernsey (J. G. J.) ; Moray Firth (Gordon) ; "Landsborough's Bay" in Arran, N.B. (Norman) ; co. Donegal (Warren) ; Roundstone, co. Galway (Barlce and Alcock) ; Exmouth (Clark); Mousehole near Penzance (Templer); Land's End and other parts of Cornwall (Webster); Sark (Mrs. Collings). Its exotic range is less known ; it comprises a sounding in N. lat. $55^{\circ} 36^{\prime}$, W. long. $54^{\circ} 33^{\prime}$, at the cnormous depth of 1622 f . (Wallich), Bohuslän, in 10 f . (Malm), Gulf of Lyons (Martin), Spezzia (J. G. J.), Sardinia and the Mediterranean shores of Africa (Costa).

This is the smallest known species of British shells. It is an object

You are shown what appears a minute speck of dust. Examine it under a microscope: the wheel of Aurora's charjot, with its refulgent spokes, must have been a piece of ordinary workmanship compared with this; its compactly convoluted shape, fine curved ribs, and encircling rings of gold call forth an admiration which, if expressed with regard to human feelings, might be termed doating; it unquestionably bears

> " The signature and stamp of porrer divine."

Mediterranean specimens of this and the last species are smaller than ours; that from Greenland is still larger. Clark fancied the present shell to be the spiral posterior terminal portion of Cacum trachea; but that is a very different object. I believe Montagu was acquainted with $H$. rota, because in a letter of his to Mr. Dillwyn, dated 8th March 1814, he mentions the discovery of a very minute Ammonite-like shell. In the Turtonian collection it was named "Cornu Ammonis."

It is the Skenea tricarinata of Webster, and the Ammonicerina pulchella and (young) A. paucicostata of Costa.

## Family XII. VERME'TIDÆ, D'Orbigny.

Body tubular: mantle having a circular border, and closely fitting the neck: head snout-shaped: tentacles cylindrical: eyes sessile, at the bases of the tentacles, and placed more or less externally : foot short. Hermaphrodite?

Shell tubular, attached or free, usually (perhaps always) spiral or convoluted when young: mouth round: operculum horny, circular, and many-whorled, with a central nucleus.

I prefer following Clark, who placed in the present family the singular genus Caccum, to arranging it among
the Turritellide as proposed by Forbes and Hanley, or adopting Gray's name of Ccecida. The affinity of Crecum to Vermetus is certainly very close, in respect not only of the animal, but also of the shell and operculum.

## Genus CRCUM *, Fleming. Pl. I. f. 6.

Body short.
Suell free, forming a curved and small cylinder, having in an early stage of growth a loose but regular coil of whorls, which afterwards falls off, the truncated extremity being then closed by a plug: operculum solid.

Costa would not believe the strange metamorphosis which the shell undergoes ; but it is constant in every species. Such similitude in dissimilitude teaches us, as it did Charles Lamb,

> "That harmonies may be in things unlike."

From Professor Stimpson's account of C. pulchellum it would seem that a fresh truncation takes place during each of the last thrce stages of growth, when a separate plug or septum is formed. This genus is evidently allied to Omalaxis or Bifrontia, in the convolution of the spire and form of the operculum. Our knowledge of the animal is entirely derived from Mr. Clark's excellent observations. Mr. Alder says, as to the tongue of C. trachea, " the lateral spines, in two longitudinal rows, are slender and very numerous, with a minute plate in the centre." The 'Proceedings of the Zoological Society of London' for 1858 contain an elaborate monograph on the recent Cacide by Dr. P. Carpenter. Fossil species occur in the Eocene and Pliocene strata of this country and Italy.

$$
\text { * } \mathrm{A} \text { blind gut. }
$$

In his 'History of British Animals' Fleming placed these shells in Orthocera (Orthoceras, a genus of fossil testaccousCephalopoda), along with recent Foraminifera; and he thus drew on himself from Philippi perhaps the most severe reproof that could be administered to a naturalist, in the comment " horribile dictu." The censor himself classed them among the Pteropods! Montagu called the adult Dentalium, and the young Vermiculum; Brown gave the name of Brochus to the former, and Cornuoides to the latter. Other synonyms are Odontina, Zborzewsky, Odontostoma, Cantraine, Odontidium, Philippi, Corniculina, Münster, and Dentaliopsis, Clark. The fry constitute Costa's genus Spirolidium.

## A. Solid and ringed ; operculum flat.

1. Cecum trachéa*, Montagu.

Dentalium Trachea, Mont. Test. Br. p. 497, t. 14. f. 10. C. trachea, F. \& H. iii. p. 178, pl. kxix. f. 4, and (animal) pl. FK. f. 1, a-c.

Bodx white, minutely grained, with two frosted, pale-yellow-ish-white contiguous raised lines on the upper part, forming a canal or groove, the points of which terminate anteriorly at the immediate base of the eyes, and posteriorly at the furthest end of the neck : mantle very thick and fleshy: neck slender, ridged lengthwise: snout long, flat, and cloven, with fine, close, contractile annular ridges; it is always in adrance of the foot, and appears to assist in locomotion : tentacles frosted-white, rather long, divergent, at the extremities thickened, setose, and slightly clavate: eyes very minute and black; they " have decidedly an external bias" (relatively to the position of the tentacles) : foot narrow, truncated in front when in action, sloping behind to an obtusely pointed or rather a rounded termination. (Clark.)

Shell of nearly equal breadth throughout, solid, opaque. and somewhat gloss5: sculpture, numerous fine, regular, and

[^30]flattened concentric ring-like ribs, which are packed so closely as to allow very littie space betweon them; ther are sometimes arranged in joints or interrupted strangulations, denoting probably the limits of successive curtailment; under a microscope the entire surface (especially the interstices of the ribs) is seen to be marked lengthwise by excessively minute and crorrded strix: colour jellowish- or reddish-brown, occasionally variegated by circles of a darker hue: spire none in the adult, its place at the posterior extremity being closed by a solid shelly plug, which slopes from the rentral margin to a bluntly conical point on the opposite or dorsal side: mouth annular, slightly contracted, and strengthened by the last-formed rib: operculum brown or dark-horncolour, consisting of about a dozen gradually increasing whorls, defined by a narrow raised spiral line or suture; they become less distinct towards the centre, which is concare. L. $0 \cdot 125$. B. 0.033 .

Habitat: Rather common in the coralline zone of Dorset, Devon, and Cornwall; Sandwich (Walker); Guernsey (Barlec); Swansea, Tcnby, and Barmouth (J. G. J.) ; Bantry Bay (Thompson and J. G. J.) ; Arran Isle, co. Galway (Barlec) ; Clyde district (Norman and Robertson). I do not consider it a British fossil ; for I believe the shells described and figured by Searles Wood from the Coralline Crag are not this species, but his C. mammillatum. Philippi, however, has given it as a Sicilian fossil, under the name of Odontidium rugulosum; and Professor Hörnes includes it in his great work ou the Miocene formation near Vienna. It inhabits the coast of Brittany, beyond low-water mark of springtides, according to Cailliaud; M'Andrew dredged it in 8 f. at Vigo ; and several authors have noticed it as Mediterranean (both on the European and African coasts) and Adriatic; on sponges from the Archipelago (Hean); Canary Isles, 50 f. (M'Andrew); Cuba (Philippi).

Clark informs us that the animal is not at all shy, and that all the specimens which he examined had an ovary. He expressed some doubt whether the branchial
apparatus consists of two plumes or one only. Young shells are more convex and tapering, and their mouth is bell-shaped. The fry is exceedingly curious. It is long and twisted, not unlike the horn of an antelope; its posterior termination is formed of a minute coil of two whorls. The concentric ridges are then perceptible towards the mouth only, and are very slight; the rest of the shell is quite smooth and glossy. I am indehted to the Marquis James Doria for baby specimens which he dredged at Spezzia.

This is the Dentalium imperforatum of Adams 'On the Microscope' (from Walieer's figure), as well as of Montagu who described the young as $D$. irachea; but the latter specific name is now geuerally used. Brown called it Brochus striatus and B. truchiformis; Cailliaud spelt the name C. $\operatorname{tr}$ achcea. The fry is Costa's Spirolidium Mediterraneum.

Brochus arnulatus and (young) B. reticulatus of Brown (" Loch Strangford') is an exotic species. Dr. P. Carpenter found no less than 53 specimens of it by washing the common sponge of commerce from the West Indies; and Mr. Bean has some from Aden. I mention this because C. annulatum has been noticed and figured in the 'British Mollusea' on the authority of a specimen received by Mr. Alder from Mr. Clark. Fleming's description of his Orthocera trachea (Br. An. p. 237) evidently applies to the same foreign species.
B. Thin and smooth ; operculum convex. Brochina, Gray.

## 2. C. glabrum *, Montagu.

Dentalium glabrum, Mont. Test. Br. p. 497. C. glabrum, F. \& II. iii. p. 181, pl. 1xix. f. 5 .

Body pure-white, with the lines forming the canal or groore

[^31]on the neck less conspicuous than in the other species: foot carried much more laterally. It is similar in other respects, taking into account the difference of size and greater delicacy of the present species. (Clark.)

Shell of nearly equal breadth throughout, not quite so much curved as in C.truchea, rather thin, transparent, and glossy: sculpture, none except under the microscope, which exhibits a slightly frosted appearance: colour clear-white: spire replaced by a rounded but not very convex shelly plug: mouth annular, thickened at its edge : operculum resembling an inrerted tea-cup without a handle, yellowish-brown, and consisting of about 10 regularly increasing whorls, 6 of which are raised, one above another (like circular steps), and are defined by a narrow spiral ridge; they are distinct on the crown on rentre, which is depressed. L. 0.075. B. 0.0135.

Habitat : All our coasts, from Shetland to Guernsey, in the coralline zone ; common. Fossil in the Coralline Crag at Sutton (S. Wood) ; Norway, in newer or postglacial deposits, 50-80 feet (Sars). Living in Norway (Lilljeborg) ; Mangerfiord, near Bergen, in 10-50 f. (Sars) ; Bohuslän, 10 f. (Malm) ; Danish coast (mus. Copenhagen) ; Brittany (Macé and Cailliaud) ; Provence (Forest, Martin, and Macé) ; Nice (Vérany) ; Spezzia (Doria and J. G. J.) ; Canary Isles, 12-50 f. (M‘Andrew).
"I thought the Cacum trachea very active, but it is far surpassed by this animal; I put one of each in a watch-glass of sea-water, and with a camel's-hair brush gave them a fair start, but the little one beat its competitor hollow, and accomplished a space of 2 inches in 55 seconds; thus affording a proof, even in the Mollusea, that Nature compensates for the small volume of the minute beings in giving them greater energy, vivacity, and quickness." (Clark.) Half-grown shells are more slender and curved, with a proportionally wider mouth. The spire of the fry has two whorls-the inner one
being sometimes broken off, so as to make the centre pervious.

This species may possibly have been the Dentalium minutum of Linné, from Plancus. It is the Odontostoma levissima of Cantraine ; and it is the Brochus glabrus and B. lavis of Brown, the young being his B. arcuatus, and the fry his Cornuoides major and C. minor. Adams ('On the Microscope') named the last-mentioned state of growth Serpula incurvata; and Montagu called it (from another of Walker's figures, showing the centre whorl broken off) Vermiculum pervium. Sars does not believe the S. incurvata of Adams can be the young of C. glabrum, because he has found specimens of each equally large; but it must be borne in mind that the adult are of different sizes, and that many species of mollusca have a dwarf or small variety. Besides, when the spire is truncated and gone, the shell becomes proportionally shorter, although it increases in diameter.

## Family XIII. TURRITEL/LIDÆ, Clark.

Bobr elongated: mantle forming a slight canal or fold in front: head snout-shaped: tentacles cylindrical : eyes ontside the tentacles, at their base: foot short : gills consisting of a single plume. Hermaphrodite?

Sheli spiral and turreted, many-whorled, not umbilicate: spire tapering, with a blunt apex : mouth having a thin and flexuous outer lip: operculum horny and circular.

The founder of this family afterwards sacrificed it by uniting it with Vermetide. Most conchologists, however, think they ought to be separate. The Turritellida, in all probability, subsist on animal food.

Genus TURRITEL'LA*, Lamarck. Pl. II. f. 1.
Body cylindrical: mantle fringed at its edge: snout short, contractile: tentacles separated by the snout: eyes placed on slight prominences : opercular lobe entire.

Shell pyramidal, spirally ridged or striated: spire having the top whorls, when disused, partitioned off by a solid hemispherical plug : mouth round, or inclining to square : operculum rather solid, with numerous whorls, the outermost of which overlap one another, or are imbricated, and all are finely puckered in an oblique direction ; nucleus central.

Old English naturalists called these shells "screws." They are not, like their human namesakes, confined to the civilized part of the globe, but are met with everywhere, in great variety. The species are numerous and prolific, inhabiting the coralline and decp-sea zones.

In a fossil state they have been found in formations certainly as far back as the Greensand. Our common species is either very shy or very sluggish; it rarely shows more than its foot and the tips of its tentacles. I have been obliged to deprive it of the greater part of its sliell in order to examine the soft parts. The lingual membrane is minute : each row of teeth consists of a broad central plate or rhachis, flanked on either side by three narrow and incurved pleure.

Turritella has several obsolete synonyms.

## Turritella térebra $\dagger$, Linné.

Turbo terebra, Linn. S. N. p. 1239. Turritella communis, F. \& H. iii. p. 172, pl. lxxxix. f. 1-3, and (amimal) pl. II. f. 4.

Body yellowish, mottled with brown and speckled with white: mantle thick, fringed on its outer and inner edges with fine filaments [arranged in a triple row, and reflected (Lovén)]: snout broad, depressed, bilobed towards the extremity, which is delicately scalloped round the margin [tuberculated at the

[^32]edge (Lorén)]: tentacles conical, pointed, slender, and rariable in length: eyes small, on bulbs or offsets at the outer base of the tentacles: foot lanceolate, dilated and rounded in front, bluntly angulated and abruptly terminating behind [" groored below" (F. \& H.); sole marked on its hinder portion with a depressed line down the centre (Clark)].

Shell forming a slender and elongated pyramid, with a more or less narrow base which is somewhat angulated; it is solid, opaque, and of a dull hue : sculpture, rather sharp spiral ridges, of which there are 3 on each of the upper whorls, and double that number on the last whorl, besides several intermediate and smaller ribs on the lower whorls, and sometimes also on the upper ones ; the whole surface is covered with fine and closeset indistinct flexuous striæ in the line of growth: colour. yellowish-brown of rarious shades, with occasionally darker lougitudinal streaks: spire sharply pointed, although the tip is usually broken off: whorls 16-20, convex but compressed, shelving above and below the suture; they increase rery gradually: suture distinct, becoming deeper towards the base of the spire: mouth squarish, angulated above and slightly expanding below: outer lip incurred on the upper side: inner lip reffected over the pillar, and in adult specimens united with the outer lip : operculum dark-horncolour with a tarny coating, composed of about 30 imbricated turns, which are invested with minute and delicate tuberculated threads arranged obliquely and sometimes projecting beyond the margin so as to make it appear spinous; the centre is slightly concare. L. $2 \cdot 25$. B. $0 \cdot 65$.

Var. 1. nivea. Snowy-white.
Var. 2. gracilis. Narrower and more slender.
Habitat : Sand and mud in 3-100 f., throughout our seas ; gregarions. The lst variety is not uncommon on the west coast of Scotland and in Shetland, mixed with coloured specimens : I have also dredged it at Exmouth. The 2nd variety is local, and occasionally white; it has been taken at Torquay with the ordinary kind by Mr. Alder, in Shetland by Mr. M'Andrew and others, in Cork Harbour by Mr. Humphreys, and in Bantry Bay by myself. The latter variety also occurs on the coasts
of Spain and Portugal, and in the Mediterranean. If it had not been for an intermcdiate form which Mr. Barlee obtained near the Arran Isles in the west of Ireland, I should have been inclined to consider this variety a distinct species. Deshayes refers it to the T, comea of Lamarck; but the description, "point de strics," is surely inapplicable to our shell. Plate 449 of the 'Encyclopédie Méthodique,' citcd by Lamarck, represents likewise a smooth shell. T. terebra abounds in almost every newer tertiary and quaternary deposit here and abroad, occasionally at great heights, as on Mocl Tryfaen ; of which we have accounts from many a conchologist

> "And him that voxed his brain, and theories built Of gossaner upon the brittle winds, Perplesed exceedingly why shells were found Upon the mountain-tops, but wondering not Why shells were found at all, more wondrous still!"

It inhabits a considerable part of the European scas, from the Loffoden Isles to the Ægean and the African shores of the Mediterranean, at depths varying from 5 to 100 f .

The "Auger" of Pennant. It sometimes attains the length of 3 inches. In aged specimens the outer lip is very thick, being formed of numerous layers. The whorls are sometimes flattened, or scalariform.

This common species was described and figured as English by Lister, whom Linné quotes for it in the 'Fauna Suecica;' and that work is cited in his 'Systema Naturæ,' where Turbo terebra was first named, with "Habitat in O. Europæo." No such references are giveu in Linnés description of Turbo ungulinus, which may therefore have been exotic. Our shell was called by Risso not only Turritella communis, but $T$. striatula and by many other names. It is the T. Linnai
of Deshayes: the fry was probably Adams's Turbo strigatus.

Turbo duplicatus of Linné, as well as his T. imbricatus and T. exoletus (the last being T. cinctus of Da Costa) are tropical species of Turritella; they were erroneously introduced by Lister, Leach, Da Costa, and Montagu into the list of British shells.

Two arctic species of the present or an allied genus occur in our glacial formation, viz.:-T. polaris of Beck $=$ T. erosa, Couthouy, at Bridlington (Woodward), and Elie in Fife (Rev. Thomas Brown, fide Geikie) ; and T. reticulata of Mighels and Adams $=$ T. lactea, Möller, at King Edward in Aberdcenshire (Jamieson). The former of these has also been found in a fossil state by Mr. Searles Wood in the Coralline Crag at Sutton, and by Principal Darson in Canada.

## Family XIV. TRUNCATEL'LIDe, Gray.

Body elongated : mantle plain-edged : head forming a cylindrical, contractile, and bilobed snout: tentacles conical, separated by the snout: eyes sessile, or nearly so, placed a little above (rather than outside) the bases of the tentacles: foot short, and rounded at each end: gills consisting of a single plume.

Shell cylindrical: spire truncated on the animal arriving at maturity, the opening thus made being filled up with a fresh layer of shell: mouth oval, with a complete peristome: operculum horny, ear-shaped, with a very short spire, having its nucleus on the columellar or inner side of the mouth, near the base of the shell.

There is a great gulf between this family and the Turritellide. Perhaps it is owing to a fault in the system of classification-our motto being " nil deest nisi clavis"
(as in the mysterious frontispiece that represents the Domus Naturce in 'Ripley revived,' by Eirenæus Philalethes) ; or perhaps the intermediate space is occupied by exotic and fossil forms. At any rate I can place the Truncatellide nowhere elsc. The European seas have only a single generic and specific representative, which appears not to be found north of the English Channel.

Genus TRUNCATEL'LA *, Risso. Pl. II. f. ${ }^{2}$.
Generic characters those of the family.
The habits of these mollusks are littoral. They live chiefly on the brink of high-water mark, under stones and decaying sea-weeds, which are periodically covered by the sea; and in this sense they may be termed amphibious. Considerable doubt has been entertained by many naturalists whether Truncatella is marine or terrestrial, and whether it is furnished with gills like Littorina, or with an air-pouch like Melampus. The careful and long-continued experiments made by the Rev. R. T. Lowe, which were published in the 5th volume of the 'Zoological Journal,' seem to prove that it is truly marine, one of his specimens having lived 14 weeks constantly immersed in sea-water; and Mr. Clark has given us full particulars of the branchial apparatus.

Lowe proposed at one time to call this genus Erpetometra (from its peculiar mode of creeping) ; Christophori and Jan have given it the name of Choristoma, Leach those of Zeanoë, Glaucothö̈, and (according to Gray) Truncatula; the young constitutes the genus Fidelis of Risso.

[^33]
## Truncatella trunca'tula *, Draparnaud.

Cyclostoma truncatuhum, Drap. Tabl. Moll. p. 115. T. Montagui, F. \& II.
iii. p. 317, pl. xcix. f. 1, and (animal) pl. FF. f. 10.

Body rery pale jellowish-white, with grey specks: snout long, narrow, and very extensile, annulated when at rest, auricled at each end; it is finely groored down the middle: tentarles short, broad, flat, and somerthat triangular : fyes black, with white pupils, on expansions of the tentacles: foot roundishoval and thick.

Shell forming a short and turreted cylinder, nearly equal in breadth throughout; it is rather thin, semitransparent, and glossy: sculpture sometimes none, in other specimeus more or less distinct and strong longitudinal ribs on all or part of the whorls; under a good magnifier mar also be detected faint traces of spiral and close-set striæ: colour pale yellowish-brown or tawny, with a creamy tint: spire having an extremely blunt tip in the young, and abruptly truncated in the adult; the line of fracture where the first-formed whorls were rubbed off is conspicuous: whorls $6 \frac{1}{2}$ in the young, and $3 \frac{1}{2}$ only in the adult; although rounded they are compressed, especially in the middle of each, and increase very gradually, the penultimate whorl being in fact a trifle broader than the last; the original whorls are fragile, and (like the milk-teeth of certain Mammalia) deciduous at the proper season: suture deep: mouth small in comparison with the size of the last whorl : it is somewhat contracted above, rounded and expanded below: outer lip reflected, and not very thin: inner lip thickened in full-grown specimens, and a little detached from the pillar; there is no chink behind it, much less an umbilicus: operculum thin, yellowish, marked with slight flexuous strix in the line of growth. L. $0 \cdot 175$. B. $0 \cdot 06$.

Habitat: Muddy shores near high-water mark, under stones, at Southampton, and at Salcombe, Plymouth, and in other parts of South Devon (Montagu) ; Weymouth (Bryer and others) ; Poole (Maton and Rackett) ; Newhaven (J. G. J.) ; Guernsey (Lukis). It is rather plentiful in the backwater behind Portland Island.

[^34]Laskey says that he dredged it off Dunbar, Fleming that he found a specimen in the cavity of a dead Spatangus purpureus from the Firth of Forth, Macgillivray that it has been taken in sea-sand from Cruden in the Moray Firth, and Thompson that Mrs. Hancock obtained a young shell of this species at Bundoran in co. Donegal; Bean enumerates it in his list of Scarborough shclls. I suspect that there has been some mistake as to the specimens from all these last five places. A large WestIndian species (T. succinea, C. B. Adams) has been often mistaken for ours. Philippi records the present species as fossil in Sicily; and I found specimens in a quaternary or more recent deposit near Martigues in the Département of Bouches-du-Rhône. It inhabits the Atlantic shores of France, both sides of the Mediterranean, as well as the Adriatic and Egean seas; and M'Andrew has noticed it at Malaga and Lancerote.

It crceps slowly, in the fashion of a caterpillar. The action of the foot is thus described by Clark :-" on the march maintaining posteally and anteally the oval contour, with a vermicular motion, like an advance of one half to the other; this action gives an apparent creasc, simulating an incised transverse line, but on the step being completed, the foot becomes entire." I could not detect any pulsation: the gill-pouch was transparent, and appeared to be filled with air. The shell varies considerably in bulk. Possibly the smooth kind, which is smaller than the other, may be the male, and the ribbed kind the female; the transition from one kind to the other, however, is very gradual.

Helix subcylindrica of Linné may be this species; but " Habitat in aquis dulcibus Europæ borealis" makes it rather doubtful. Montagu called the adult shell Turbo truncatus, and the young T. subtruncatus; Risso
distinguished the smooth and ribbed forms as Truncatella levigata and T. costulata, and the young as Fidelis Theresa. The last appears to be the T. Desnoyersii of Payradeau. Lowe gave this species the name of $T$. Montagui, his T. truncatula from Madeira being different. The young is Macgillivray's Eulima nitidissima. According to Philippi our shell is Cyclostoma concinnum of Scacchi, and the young is Paludina strigilata of Parcyss. The corresponding name for each state of growth bestowed by Leach on this polyonomatous shell are Zeanoë nitida and Glaucothoë Montaguana. Draparnaud, in his 'Tableau des Mollusques,' expressed his belief that his Cyclostoma truncatulum ought to constitute a distinct genus, an opinion of which Risso unskilfully availed himself.

## Family XV. SCALARI'IDÆ, (Scalaridx) <br> Broderip.

Genus SCALA'RIA *, Lamarck. Pl. II. f. 3.
Body screw-shaped: mantle plain-edged, forming an incipient or slight fold at the base of the shell : head short, snoutshaped, furnished with a cylindrical and retractile proboscis: tentacles awl-shaped, with blunt tips: eyes on short stalks, at the outer bases of the tentacles: foot lanceolate, double-edged in front; sole grooved down the middle: gills consisting of a single plume. Sexes separate.

Shell turreted, longitudinally ridged or plaited, and often also transversely striated: spire elongated and pointed ; apex slightly inflected: mouth nearly round, with a complete and thickened peristome, angulated below : operculum horny, earshaped, few-whorled, and haring the nucleus on the columellar or inner side of the mouth but not far from its centre.

[^35]In this family and genus occurs for the first time a retractile proboscis or "haustellum," instead of a contractile snout or "rostrum." Mörch* suggests that there may be no greater difference between these two organs than between a long and a short siphon. The armature of the tongue is very simple, and consists of a single row of uniform teeth on each side without any in the middle; it agrees nearly with that of Homalogyra and the Bulla tribe. Without presuming to disparage the labours of those couchologists who may be termed odontological systematists, I think an undue importance has been given to this character as a basis of classification for the Gastropoda. The alimentary and masticating organs of all animals depend on the nature of their food; and every division oif the Gastropoda contains some kinds which are plytophagous and others which are sarcophagous or zoophagous. Scalaria belongs to the latter class. According to Dr. Gould, a specimen of S. Groenlandica which Mr. Couthony kept alive for the purpose of examination "fed eagerly upon fresh beef, especially if somewhat macerated." The animal of every species of Scalaria emits a purple dye, like Planorbis corneus, Ianthina, and Aplysia. The use of this secretion is not sufficiently known $\dagger$. Montagu made some curious experiments with the dye of $S$.communis, showing that the colour is changed by the application of mineral acids, and that it is not affiected by cream of tartar, nor materially by either volatile or fixed alkali; that it is not diminished by putrefaction, nor fixable by any then known astringent; it resisted for some months the action of the air and sun; but being exposed for a whole summer to the solar rays in a south

[^36]aspect, it almost vanished. Ever since the cultivation of conchology (in the limited sense of the word and not as a science), the truc " wentletrap" or "windeltreppe" has been regarded as an object of especial admiration for its graceful shape and exquisite sculpture; it fetched at one time as high a price as some of the rarest cones and cowries, which (in my opinion) it far excels in beauty. Lamarck states that the ridges which adorn the shell are marks of growth, each forming in succession the border of the mouth. This is probably the case, if we consider them marks of periodical rather than annual growth : a full-grown S. communis has about 100 of these ridges, and we can hardly suppose that it lives as many jears. The number of varices or stronger ridges, distributed at intervals and observable in S. Turtone and other species, may indicate the age. Scalariee inhabit cerery sea, although frequenting more the Indian Ocean. About 200 species have been described, recent and fossil. We are told by Nyst that many of the latter occur in the cretaceous and tertiary formations; one has been recorded from the Coral Rag, and another as Silurian.

Among the synonyms are Scala of Klein (pre-Linnean), Scalarus of Montfort, and Clathrus of Oken.

## 1. Scalaria Tur'tone**, (Turtonis) Turton.

Turbo Turtonis, Turt. Conch. Dict. p. 208, f. 97. S. Turtonis, F. \& II. iii. p. 204, pl. lxx. f. 1, 2.

Body dark-coloured : proboscis long: eyes placed on prominent tubercles: foot white behind and underneath, folded in front when withdrawn into the shell. (Birona, fide Philippi).

Shell slender, solid, opaque, somewhat glossy: sculpture, slightly curred, flattened, and more or less imbricated Iongi-

[^37]tudinal ridges, 12 being on the last whorl, 11 on the penultimate, and 10 on the next, after which they diminish in number; these ridges are broader and foliaceons at the top of each whorl; they are not continuous throughout the spire, but are usually disposed in alternate order, and some of them, at irregular intervals, are double or multiple, so as to form broad and strong varices; the interstices of the ribs are fincly and closely striated in a spiral direction: colour light yellowish-brown, with 3 purplish-brown or coffcecoloured bands on the body-whorl and 2 on each of the other whorls; of the 3 bands the upper two are above the periphery and sometimes confluent, the third (which is generally broader) encircling the base: spire tapering gradually to a fine point: whorls $15-16$, rounded, although compressed, and increasing very gradually: suture well defincd, but not deep : mouth more round than oval, angulated above, and much more so below: outer lip encircled or strengthened by the last-formed ridge, having a slight sinus near the upper part, and somewhat reflected: inner lip broad, extremely thick at the base and lower angle of the mouth; there is no umbilicus behind it: operculum dark-horncolour, having about 6 turns, rather concave, and strongly striated in the line of growth; it resembles that of a Littorine, but the nucleus is more central. L. $1 \cdot 7$. B. B. 0.5 .

Habitat : Coralline zone in Guernsey (Lukis); Devon and Cornwall (Turton and others) ; Tenby (J. G. J.) ; Laugharne, Carmarthenshire (Barlee, and Lindsay); estuary of the Mersey (Collingwood) ; Scarborough (Bean and Leckenby); Aberdeen (Macgillivray) ; Clyde district (Forbes and others) ; co. Down (Thompson) ; Dublin Bay (Turton and others); south of Ireland (Ball and others) ; co. Galway (Barlee). It is by no means common. Dr. Turton states that "in many parts of Ireland, but especially about Balbriggan, they are found crawling among the rocks"! In a fossil state this species has been recorded from the Belfast deposit by Hyndman and Grainger, under the name of S. Trevelyana; Ireland, Ayr, and Bute (Smith); Nice (Risso); Sicily (Philippi). It inhabits the North Atlantic from

Bergen (Lovén and others) to Madeira (M‘Andrew), and every part of the Mediterranean, Adriatic, and Egean, at depths ranging between 5 and 45 f .

Sereral specimens having the operculum were in Mr. Clark's collection, from Exmouth : I wish he had given us an account of the animal. Young shells have the base somerhat angulated.

It was possibly the Turbo ambiguus of Linné, described as inhabiting the Meditcrranean, and very like T'. clathrus (but fleshcolour, with 3 reddish-brown bands, and haring twice as many ribs) ; this, however, is said to be umbilicate, a character that belongs to none of the European species. Risso appears to have given our shell the specific names of Turtonia and (as fossil) elegans, Michaud that of tenuicosta, Bivona planicosta, Scacchi plicata, Broun alternicosta, and Leach Turtoniana.

## 2. S. commu'vis*, Lamarek.

S. communis, Lam. An. s. Vert. vi. (2) p. 228; F. \& H. iii. p.206, pl.1xx. f. $9,10$.

Bodr milk-white, irregularly streaked with black or mottled with dark-purple on the upper part: mantle thick, tight about the neck, its margin forming a round collar: snout vertically cloven in the centre, whence the proboscis (which is white) frequently protrudes as if in search of food: tentacles long and slender [black, Alder]: eyes on the inner side of small bulbs or excrescences [white spaces, Alder], which rise from the outer bases of the tentacles: foot, when fully extended, long and narrow, somewhat angulated and notched or bilobed in front, with a very slight rounded auricle at each corner, and tapering behind to a point; it is often carried far beyond the head; sole marked in the middle from one end to the other with a groove or impressed line. [Male organ long, bent, and pointed, of a dusky hue (Clark).]

Sherc more conical than the last species, solid, opaque, and of rather a dull hue: sculpture, slightly curred longitudinal

[^38]ridges, which are reflected or folded backwards, but not flattened as in S. Turtonce; there are 9 on the last whorl, 10 on the penultimate, and 8 on the next, diminishing in number towards the apex; the ridges are somewhat broader at the top of each whorl, and cemented to those in the preceding whorl, so as to make the series continuous in an oblique direction; ther do not (unless very rarely) form varices, nor is one larger than any of the others except in the course of growth; under a good magnifying-power their interstices are seen to be sometimes marked with a few extremely slight and indistinct spiral striæ, and occasionally also with delicate and close-set longitudinal striæ or impressed lines, which latter especially corer the ridges; the first 3 or 4 whorls are quite smooth : colour varying from cream to fawn, with frequently (as in S. Turtonce) 3 purplish-brown or coffeecoloured bands on the body-whorl, and 2 on each of the other whorls; these bands, however, are not continuous, but broken and divided into short streaks; sometimes the shell is beautifully mottled all over with pur-plish-brown, although retaining the lowest band; apex lightbrown: spire rather abruptly tapering to an apparently fine point; apex flattened, slightly reversed or inflected, but not so decidedly as in the genus Aclis: whorls $15-16$, conrex, gradually enlarging: suture deep: mouth more round than oval, more or less angulated above and below: outer lip encircled and strengthened by the last-formed ridge, somewhat reflected: inner lip broad, extremely thick at the base and lower angle of the mouth; no umbilicus: operculum dark-horncolour, having about 6 turns, concave in the middle, and marked with coarse flexuous striæ in the line of growth. L. $1 \cdot 5 . \quad$ B. $0 \cdot 6$.

Habitat: English, Bristol, and St. George's Channels; all the coasts of Ireland; Kent (Montagu and others); Dogger bank (Rich); Scarborough (Leckenby); Leith (Da Costa) ; Dunbar (Laskey) ; Clyde district (Hennedy and others). It is usually an inhabitant of the coralline zone; but Mr. Sturges-Dodd found living specimens at very low tides in Pontac Bay, Jersey. Estuarine deposit at Selsea, Sussex (Godwin-Austen) ; Ireland (Smith) ; post-glacial bed in Norway, 50 feet (Sars) ; North Italian tertiaries (Brocchi) ; Sicily (Philippi). Its foreign range, as recent, extends from Fin-
mark (Lilljeborg) to the Canary Islcs (I'Andrew) in the North Atlantic, as well as throughout the Mediterranean, Adriatic, and Ægean. The depths given by different authors vary from 8-40 f.; and Mr. M‘Andrew found this species alive on the shore at Vigo and Gibraltar.

Montagu says that the purple dye issues from a gland behind the head: the great beauty of its colour was first noticed by Plancus in Mediterranean specimens. The shell is the "small stair-case" of Petiver, " bastaard wenteltrapje" of the Dutch according to Klein, "barred wreath " of Pennant, and "false wentletrap" of Da Costa, the "true wentletrap" being $S$. scalaris or pretiosa. Our shell barely exceeds 2 inches in length.

It is the Turbo clathrus of the 10th and previous editions of the 'Systema Nature,' as well as of the 'Fauna Suecica; ' but the species so named in the 12 th edition of the 'Systema' is described as having the base encircled by a spiral keel or ridge, and is consequently not the British species. Da Costa called it Strombiformis clathratus, apparently from a habit, in which he indulged with a most inconvenient pertinacity, of substituting new names for old; the latter specific name, not having been adopted by any subsequent writer, must be considered obsolete. Gmelin and Mohr evidently mistook the Turbo clathrus of Linné for his T. clathratus, which is a Trophon.

## 3. S. Tretelya'ia*, Leach.

S. Trevelyana, (Leach, M.S.) Winch, on the Geology of Lindisfarn, Ann. Phil. new ser.iv. p. 43-; F. \& H. iii. p. 213, pl. lxx. f. 7, 8, and (animal) pl. FF. f. 1-3.
Bony yellowish-grey or pale-fawneolour, with a faint tinge of purple, minutely streaked and speckled with white: snout

[^39]broad and semicylindrical, slightly cloven in the middle, and delicately stippled with brown: tentacles gradually tapering, although rather short, margined on each side with a purplishbrown line, and streaked with white underneath: eyes small, round, and black, immersed in bulgings at the outer bases of the tentacles: foot very long and slender, extending far beyond the head, in front somewhat rounded and with small angular corners, bilobed behind ; on the upper side a long furrow runs from the hinder edge of the operculum to the tail, as in Trochus, with a well-defined ridge on each side of it.

Shell conical and of about the same proportions as S. communis, much thinner than that or the preceding species, opaque, somewhat glossy: sculpture, longitudinal ridges, arranged usually in continuous but oblique rows, as in $S$. communis; they are, however, narrower, less folded, and more flattened, and are occasionally varicose; the upper part of each ridge is broader and generally (especially towards the point of the spire) expands into a short spur-like projection, so as to give a turreted appearance to the shell; there are 14 ridges on each of the last two whorls, 13 on the next, diminishing in number upwards; the interstices of the ridges are delicately and microscopically striated in a spiral direction; the first 4 or 5 whorls are smooth and polished: colour fawn; the ridges are white : spire tapering to an apparently fine point; apex as in the last species: whorls 14-15, convex, increasing. gradually: suture deep: mouth considerably more angulated below than abore, the pillar being somewhat strait, especially in the young: outer lip thick, formed of the last ridge: inner lip rather thin above, and less connected than usual with the outer lip, thickened and broad below; behind it is a depression, but no umbilicus: operculum light-horncolour, haring about 6 turns, the inner ones being defined by a slightly raised edge; it is concare in the middle, and marked with coarse flexuous strix in the line of growth. L. 1. B. 0.4.

Habitat: Shetland, in 75-100 f. (M'Andrew and others) ; Orkneys, $15-100 \mathrm{f}$. (Thomas) ; Moray Firth (Gordon) ; Firth of Forth (Gerard); northern coasts of England, from Berwick to Scarborough (Johnston and others) ; Macgilligan, co. Londonderry (Thompson); co. Cork (Humphreys and Wright); off Mizen Head and Cape Clear in 50-60 f., and on the Nymph bank
in 50-55 f. (M'A Andrew) ; Arran I., co. Galway (Barlee) ; Tenby (Lyons) ; Laugharne, Carmarthenshire (Lindsay) ; Plymouth (Jordan); Hayle (Miss Hockin); 15 miles from the Land's End in 50 f . ( $\mathrm{M}^{6}$ Andrew, fide Forbes). Norwich Crag (Wigham, Thomas, and Woodward); Red Crag (S. Wood). It has been dredged off Christiansund in 60 f . by Danielssen, and in $40-50 \mathrm{f}$. by Sars, in Christianiafiord by Asbjörnsen, off Bohuslän by Lovén, and in 40-80 f. by Malm, and in the Kattegat, with Craniu anomala, by the last-named writer; Tiberi procured it in an immature state from coral-fishers at Naples.

The animal is extremely shy ; it takes alarm and shuts itself up, even when you touch the table on which the vessel containing it stands. Like its congeners it emits a purple dye. The denticles of the tongue are slender and curved. The shell may be distinguished from that of S. Turtonce by its smaller size, greater delicacy of texture, finer and more numerous ribs (each of which is generally furnished on the upper part with a short spur), and by its pretty fawn- or fleshcolour variegated by white ribs. My largest specimen is not much more than $1 \frac{1}{8}$ inch long. Some are more elongated than others; those from Ireland have a broader base and faint traces of bands, disposed as in the preceding two species, but of the same colour as the body of the shell, although of a somewhat darker hue. Distortions occur in which the spire is more or less bent; and one has a distinct but narrow umbilicus.

This species was first described by Dr. Johnston, in the Proceedings of the Berwickshire Naturalists' Club for 1841. In Thorpe's (or Hanley's) 'British Marine Conchology' the specific name is spelt Treveliana. S. frondicula of Scarles Wood, from the English and

Belgian Crag formations, is closely allied to it, if not the same shell.

## 4. S. clathra'fula*, Adams.

Turbo clathratulus, Ad. Micr. t. 14. f. 19. S. clathratula, F. \& H. iii. p. 209, pl. lxx. f. 3, 4.

Body clear-white, with a very faint dusky tinge on the upper part, and thickly interspersed with minute opaquewhite flakes: mantle fleshy, even with the mouth of the shell: snout very short, compressed and erescent-shaped: proboscis long and strong, frequently protruded: tentacles of moderate length, and divergent: eyjes very black, placed not on offsets, but on scarcely raiscd eminences at the outer bases of the tentacles, of which they form part : foot often carried considerably in advance of the head and tentacles; it is short, narrow, in front nearly semicircular and with a minute auricle at each corner, and tapers gradually behind to a slender rounded termination; hinder half of the sole deeply grooved in the middle lengthwise, with a depression in the centre. (Clark and Alder.)

Shell elegantly pyramidal, rather thin, semitransparent, and glossy: sculpture, fine, sharp, laminar, erect, and curved longitudinal ridges, set rather obliquely, either in a continuous or alternate order ; each is nearly of the same height and size throughout, and very seldom are any of them varicose; there are 18 on each of the last two whorls, and 16 or 17 on the next, diminishing in number upwards; their interstices are spirally but indistinetly and irregularly striated, as in the other species, and on the upper part of the body-whorl some fine longitudinal striæ may occasionally be observed; the first 3 or 4 whorls are smooth and polished: colour uniform, snowwhite: spire finely tapering ; apex like that of the other species : whorls 12-13, convex, gradually enlarging : suture deep: mouth inclining to oval, dccidedly angulated below: outer lip incurved above, and slightly expanding: inner lip reflected, especially at the base: operculum yellowish-brown, having from 4 to 5 turns, concare in the middle, and marked with strong flexuous striæ in the line of growth. L. 0.6. B. 0.02.

> Habitat : Sparingly distributed throughout all our seas, from the Shetland to the Channel Isles. It pro-

[^40]perly belongs to the coralline zone ; but Mr. Clark found a living specimen "in the middle of the littoral district, at the roots of the Corallina officinalis, at Exmouth." Mr. Humphreys took a dead one from the stomach of a Red Gurnard at Cork. Fossil in the Coralline Crag, Sutton (S. Wood) ; Belgian Crag (Nyst). Professor Hörnes has described and figured a miocene species, from the Vienna basin, under the name of S. clathratula, supposing it to be our species; I regard them as distinct. The only foreigu locality known to me, north of Great Britain, is Bohuslän, where Malm dredged it in 70 f . It inhabits the coasts of France, Spain, Portugal, Italy, and Algeria, at deptlis ranging from 4 to 36 f .
"This creature is very free in showing its peculiarities " (Clark). He noticed the usual purpuriferous vein behind the neck. According to him the operculum is white: in a specimen from his collection the colour of that appendage is yellowish-brown. The shell is a most graceful object.

It appears to be the Turbo lamellosus of Delle Chiaje, S. pulchella of Bivona, and S. Georgetina of Kiener.

Mr. Mr'Andrew dredged two fragments of S. Greenlandica in 38 f. off Duncansby Head in the north of Scotland. Although these fragments have every appearance of being recent, I must request the reader to bear in mind the remarks which I made in the Introduction to vol. i. (pp. xciv-xevi) with respect to the difficulty of distinguishing fossil from recent shells procured under similar circumstances. Not more than 30 miles below Duncansby Head Mr. Robert Dawson traced a newes tertiary deposit of great extent, containing Pecten Islandicus and other arctic species. S. Grcenlandica is not uncommon in the high northern seas of both hemispheres, its southern limit in Europe being Bergen. It
occurs in the glacial or post-glacial beds of Aberdeenshire (Jamieson), at Bridlington (Forbes), as well as in the Norwich and Red Crag. The shell has remarkably strong and conspicuous spiral striæ between the ridges, and its base is encircled by a keel.

I have a specimen of S. pseudoscalaris, Brocchi, which the late Miss Lavars of Penzance picked up in Porthcurnow cove near the Land's End, together with $S$. Turtona, S. communis, and S. clathratula. Its nearest ally is $S$. communis, from which it may be known by the more conical shape, sharper ridges, and basal keel or* ridge. This species may be British; for Taslé has recorded it from Morbihan, and Aucapitaine and Fisher from the Charente-Inféricure.

Acirsa borealis of Beck has been dredged in 18-20 f. off the coast of Antrim by Mr. Hyndman, Mr. Waller, and myself, and on the Aberdeenshire coast, from 3 to 8 miles from land, in $30-45 \mathrm{f}$. , by Mr . Dawson. This species has not been found living south of Iceland. It is the S. Eschrichti of Holböll (fide Möller), and Turritella Hibernica of Waller. Mörch's genus Acirsa seems to connect the present family with the next.

## Family XVI. PYRAMIDEL'LIDÆ, Gray.

Bony spirally twisted: head furnished with a long cylindrical and retractile proboscis; flap ("mentum" of Lovén) extensile, but rarely projecting beyond the foot: tentacles conical or triangular, flattened, and smooth, with more or less inflated tips: eyes sessile at the inner base of the tentacles, and placed near to each other : foot lanceolate, and doubleedged in front. Branchial apparatus consisting of a single gill-plume. Tongue unarmed or toothless.

Shell small, conical or pyramidal, smooth or rariously sculptured : spire pointed, with an inflected and mostly a reversed apex: mouth oval, somewhat angulated but not channelled below: outer lip thin: operculum ear-shaped, with a short imperfect spire of very few whorls; nucleus excentric, on the inner side near the base.

This family contains sereral genera, some of which (especially Odostomia) abound in prolific species. They are widely diffused over the present marine area of our globe, and appear to have had an equally extensive range in periods which we call geological. The Pyramidellide inhabit all the zones, and are probably sarcophagous, not zoophagous or predaccous. Their shells are graceful in shape, and often beautifully sculptured; but, being minute, they can be appreciated by those only who have accustomed themsclves to see

> "Form in things which to the eye Half-read is but deformityGrandeur in mean things and small, And God's great handiwork in all!"

Although it does not appear that any direct observations have been made as to the reproductive system of the Pyramidellida, it may be inferred from an unpublished drawing by Möller of the soft parts and operculum of Monoptygma albulum (Turbo albulus, Fabricius), which is allied to Aclis and belongs to the present family, that the sexes are distinct. In that drawing (for a tracing of which I am indebted to Dr. Mörch) the male organ is very conspicuous.

Genus I. ACLIS*, Lovén. Pl. II. f. 4.

Body slender: tentacles long, approximating at their bases : eyes placed rather more on the outer than the inner base of the tentacles.

> * A small javelin.

Shell elongated: mouth slightly expanded, and having a more or less complete peristome : pillar never furnished with any fold or tooth.

Perhaps this is an ill-assorted genus. More information is desirable to clcar up some doubts as to the organization of its component species.

Leach's genus Alvania, adoptcd by Scarles Wood, subsequently to Lovén's publication, for Aclis supranitida, comprised (according to Risso, who first described that genus on Leach's authority) only certain species of Rissoa. In Leach's own work the type of Alvania is R. striata.

## 1. Aclis u'nica*, Montagu.

Turbo unicus, Mont. Test. Br. p. 299, t. 12. f. 2. A. unica, F. \& II. iii. p. 222, pl. xc. f. $4,5$.

Bony clear-white, with very minute and close-set flaky specks: mantle furnished with a cylindrical filament (as in Rissoa) at the upper angle of the month of the shell: " muzzle slender and rather long, having the first half from the neck, on its upper part, clothed with a very close tunic or tight overlay; the disk is smooth, compressed, bevelled to a fine edge, and almost circular, with a median vertical fissure on the under surface, in which I have often seen the delicate white corneous plates, jaws, and lingual riband:" tentacles moderately long, fiat, rounded or obtuse at the tips, quite smooth even under high magnifying powers, and divergent: eges large and black, not on peduncles or prominences, but fixed each on the centre of the base of either tentacle, with very little external inclination, and widely apart; on the march the eyes are usually carried within the margin of the shell: foot slender, greatly hollowed out in front, and deeply labiated, having distinct, long, arched linear auricles which play or vibrate when the animal is crawling, beneath [behind?] which it is slightly constricted; it terminates in a rounded, rather broad point: no median line is apparent in any part of the sole: opercular lobe simple. (Clark.)

Shell needle-shaped, thin, semitransparent, somerhat

[^41]glossy: sculpture, numerous delicate and flexuous longitudinal rits, crossed by as many fine spiral ridges or strix, and producing by their mutual intersection an exquisitely reticulated appearance; the ribs are usually stronger on the upper wholls; apex smooth and polished: colour white, with a faint tinge of yellowish-brown in live or fresh specimens: spire elegantly tapering to a blunt point, which when viewed sideways appears button-shaped, and projects a little becond the succeeding part of the spire; if viewed from above it appears slightly inflected: whorls 9-10, moderately convex, and gradually increasing; the first whorl and half of the next form the apex of the spire: suture deep, rather oblique: mouth exactly oval, effuse below : outer lip slightly flexuous, incurved abore: inner lip thin, adhering to the pillar, connected with the outer lip at the upper corner; there is no umbilicus, but the base is narrowly depressed behind the pillar [: operculum "light yellow and suboval, with distinct grossly spiral turns" (Clark)]. L. $0 \cdot 115$. B. $0 \cdot 02$.

Habitat: Local in the littoral zone. I will enumerate some of the places where this species has been noticed:-Haroldswick Bay in Unst (Dawson) ; Moray Firth (Murray, fide Gordon); Hebrides (J. G. J.); Dunbar (Bingham, fide Brown) ; Lamlash (Landsborough); Northumberland and Durham (Alder); Scarborough (Bean and J. G. J.) ; Dublin Bay (Turton); Cork (J. G. J.); Sandwich (Walker and J. G. J.); Barmouth, Tenby, and coast of Gower (J. G. J.) ; Cornwall and Devon (Montagu and others); Guernsey (Barlee and J. G. J.). Mr. Clark found the living specimen from which his description was taken in Littleham cove near Exmouth, at low-water mark, on the margin of a deep and quiet rock-pool, among débris of small decayed shells mixed with sand and mud that had an offensive odour. Loire-Inférieure (Cailliaud) ; Spezzia (J. G. J.).
"This creature is not at all shy ; it remained lively for thirty-six hours, and gave every facility for good ex-
amination ; it readily creeps up the deepest glasses, and, however often brushed down, starts again with unabated vigour" (Clark).
It is the Turbo albidus of Adams's work on the Microscope (from Walker's figure), and Turritella Clealandiana of Leach. The latter writer was of opinion that "unicus is a very improper name for a species." Surely no shell has a better claim than the present to be considered alone of its kind, or unparalleled, which is the the meaning of the name. It once belonged to the genus Turbo, afterwards to Turritella, then to Chemnitzia (or Odostomia), since to Aclis, and it was last transferred to Rissoa. Our dainty Ariel has long served many masters, and perhaps it is time that he should have lis liberty. Should such an emancipation take place, and a new genus be required for the distinction of this unique species, Graphis might be a suitable name.

## 2. A. as'caris*, Turton.

Turho ascaris, Turt. Conch. Dict. p. 217. A. ascaris, F. \& H. iii. p. 219, pl. lxexviii. f. 8.

Shell forming an elongated and slender cone, rather solid for its size, semitransparent, and somewhat glossy: sculpture, strong spiral ridges, of which there are 5 on the body-whorl, and three or four on each of the other mhorls; the uppermost ridge on each whorl is placed at some little distance from the suture; the base of the shell is smooth; some slight and flexnous longitudinal strixe or wrinkles may be detected by using a Coddington lens: colour milk-white: spire tapering to apparently a fine point: whorls 8-9, convex in the middle, but compressed or sloping on the upper part of each towards the suture ; they enlarge rather suddenly : suture deep and rather oblique: mouth exactly oval, effinse below: outer lip slightly flexuous, incurved above, more or less thickened near the edge, so as occasionally to form a varix in an earlier stage of growth: inner lip somewhat thickened and adhering to the pillar, re-

[^42]fiected near the base; it is imperfectly connected with the outer lip at the upper corner ; behind it is a small and uarrom umbilical chink. L. $0 \cdot 1$. B. $0.02 \overline{5}$.

Habitat: East Shetland, 82 f. (M‘Andrem); Aberdeenshire (Dawson); west coast of Scotland (Barlee); Scarborongh (Bean) ; Barmouth, Tenby, and Plymouth (J. G. J.); Burrow Island (Beevor); Exmouth (Barlee) ; Bude (Lindsay); Guernsey (Lukis, Barlee, and J. G. J.); Dublin Bay (Warren and Alder); Bundoran (Mrs. Hancock, fide Thompson); Arran Isle, co. Galway (Barlee) ; Seafield, in the west of Ireland (Turton). Coralline Crag, Sutton, with A. supranitida (coll. Wood in mus. Brit.). Bergen (coll. Lovén in mus. Stockh.), and in 70 f . (Lilljeborg) ; Quinéville, near Cherbourg (Macé) ; Loire-Inférieure (Cailliaud).

It appears to be the Pyramis acutissimus of Brown, "found on Belton sands, near Dunbar, by General Bingham."

## 3. A. supranitida*, S. Wood.

Almania supranitida, S. Wood, Cat. Crag Moll. Aclis supranitida, F. \& II. iii. p. 320 , pl. xc. f. $2,3$.

Body slender [" entirely white" (Hanley)]: heacd not beaked [not snout-shaped]: proboscis long, strong, and retractile : tentacles cylindrical, slender, somewhat inflated at the top, close together at the base [" subulate and truncated "(Hanley)]: eyes immersed at the base of the tentacles, and placcd rather laterally [" placed far back, sessile, and rather distant " (Hanley)]: foot having the "mentum" [or upper edge] somewhat detached, narrower than the sole, and extended [" tail simple and obtuse " (Hanley)]: opercular lobe ample, of a different shape on each side, being on the right larger and forming 3 or 4 folds, on the left produced into a single rounded lobe which is folded behind; sole tongue-shaped, truncated in front: tongue unarmed? (Lovén.)

Shell ten times greater in bulk than A. ascaris, and otherwise differing from that species in not being so slender, and in

[^43]haring a much broader base; it is distinctly and deeply umbilicate in every stage of growth; sometimes there are 5 ridges on each whorl, at other times 3 only on the body-whorl and $\underline{2}$ on each of the other whorls, occasionally none on the bodywhorl and 2 or 3 on each of the upper ones, or else there are no ridges at all and the whole surface is quite smooth and glossy; the suture is more deeply excavated, and nearly straight; this species has 12 whorls, and the mouth is more round than oral. L. $0 \cdot 25$. B. $0 \cdot 1$.

Habitat: Oceasionally procured by dredging and trawling, as well as by examining drifted shell-sand, Aberdcenshire and the Hebrides (Dawson), Aberdeen (Macgillivray), Blackpool (Kenyon), Belfast (Hyndman and Waller), Dublin Bay (J. G. J.), Bantry Bay (Niss Hutchings, fide Leach, and Hanley), Barmouth (J.G.J.), Tenby (Lyons and J.G.J.), Langland Bay near Swansea (J.G.J.), Bude (Lindsay), Land's End (Hockin), Falmouth (Cranch, fide Leach, and Hockin), Plymouth (Prideaux, fide Leach, and J. G. J.), Hastings (Leach), and Guernsey (Hanley, Lukis, and J. G. J.). Coralline Crag (S.Wood). Bohuslän (Lovén and Lilljeborg, and, in 12 f., Malm) ; Cattegat, 10-20 f. (Malm) ; Brittany (Taslé and Cailliaud); Vigo Bay,8f., and Madeira(M'Andrew); Gulf of Lyons (Martin); Algeria (Weinkauff).

This shell is Brown's Turritella minor, the type of which I examined in the collection of the late Mr. Lyons at Tenby ; but I certainly should not have recognized it by the description. That gives the length as $\frac{3}{8}$ of am inch, and the breadth "not an inch." The specific name minor is obsolete and very incorrect. It is apparently the Turritella nivea and T. nitida of Leach, and perlaaps also his Alvania glabra (according to Wood), and Alvania albella. Weinkauff described the present species in the 'Jourual de Conchyliologie' for 1862 as the Turritella unzbilicata of Dunker.

## 4. A. Walle'ri*, Jeffreys.

Shell forming an elongated cone, very thin, transparent, and lustrous: sculpture, none to the naked eye or with a low magnifying power, but under a Coddington lens may be detected a few faint and obscure spiral raised lines and very fine flexuous marks of growth: colour white: spire tapering to a blunt point, which is unmistakeably introverted: whorls 10 , rather conrex in the middle, with a slope above and below: suture deep and nearly straight: mouth roundish-oval, considerably dilated at the base : outer lip flexuons, prominent, and somewhat expanding: imer lip nearly straight, and reflected at the base, apparently wanting on the upper part of the pillar, and therefore separate from the outer lip: umbilicus small but distinct: operculum filmy, wrinkled in the line of growth, composed of three turns, the last and outermost of which is disproportionately large; the line of division between these whorls is raised or ledge-like. L. 0.135. B. $0 \cdot 05$.

Habitat : East Shetland, $40-45$ miles off the Whalsey Skerries, in 78 f ., one live and three dead specimens. Coralline Crag, Sutton (coll. S. Wood in mus. Brit.), a single specimen, mixed with $A$. ascaris. Lilljeborg has dredged the present species off Molde in Norway, at a deptl of 70 f .; and I found a specimen among some smali shells procured by Dr. Wallich in $1622 \mathrm{f} . \dagger$, about 100 miles N.E. of Hamilton's Inlet, Labrador.

All that I could see of the animal in the living Shetland specimen were two black eycs, which were visible through the shell, as in Jefireysia and Eulima; it appeared to be in a dying or collapsed state. The abysmal specimen from North Amcrica is much larger than any of those from the European seas and the Coralline Crag. The shell is distinguishable from $A$. supranitida by being of a much smaller size (intermediate between

* Named in honour of Elward Waller, Esq., of Aughnacloy, co. Tyrone, an assiduous and good British conchologist. Perhaps the specific name ought, classically, to be F'alleri.
+ See vol, ii. pp. is and x of the Introduction.
that of the latter species and of A. ascaris , thimer and of a more delicate texture, and exquisitely polished, having the whorls less convex, the outer lip more expanded, and the pillar-lip nearly straight and spread out at the base, and in the umbilicus being contracted.

## 5. A. Gulso' ${ }^{\prime} A^{*}$, Clark.

Chemnitzia Gulsona, Clark in Ann. \& Mag. N. M. 3rd ser. vi. p. 459. Odostomia Gulsonee, F. \& H. iv. (app.) p. 281, pl. cxxxii. 1. 6.

Body flake-white, with a faint tinge of yellow : mantle eren with the shell : neck very long, cylindrical (like that of Odostomia spiralis), and finely wrinkled across : the vertical fissure of the mouth lies under the tentacular membrane: tentacles thick, broad, short, not very membranous, rounded at the tips, each of which has a minute flake-white lobe or inflation; they are united by an intermediate membranc: eyes black, not very near together, immersed close to the base of the tentacles, on minute white circles; they do not in the least invade the area of the neck, but rather infringe on the tentacles : foot exceedingly short, narrow, deeply bifurcated in front, rounded behind when at rest, and a little lengthened in action; the front edge (or mentum) is long, slender, grooved at the margin in front and on each side, the upper and lower surfaces being entire: opercular lobe plain: liver light green: ovary very pale red, and granular: branchial plume narrow and curved, consisting of about $15-18$ rather coarse, opaque, pale drab strands : heart and curicle intense snow-white. (Clark.)

Suell slender, rather cylindrical than conical, very thin, transparent, and lustrous: sculpture, none : colour clear white : spire gradually tapering to a blunt and nearly globular point, which is decidedly introverted but not sinistral: whorls 6-7, convex: suture deep, rather oblique: mouth roundish-oval, having the outer base somewhat truncated and deeply sinuated or almost notched : outer lip remarkably fexuous, prominent, and expanding : imer (or pillar) lip short, ncarly straight, and slightly reflected near the base, not united with the outer lip; behind it is a slight depression and narrow chink, but no umbilicus [: operculum "an almost invisible film, pear-shaped

[^44]or suboral, with a narrow border of pale bistre with a pinkish hue; the strire of increment radiate as in most of the other Chemnitzice" (Clark)]. L. 0.065 . B. 0.025.

Var. tenuicula. Comparatively diminutive, and more slender.
Habitat : Coralline zone in Shetland and Skye (Barlee and J. G. J.) ; off Larne, co. Antrim (Hyndman and J. G. J.) ; Falmouth (Barlee and Hockin); Helford (Hockin) ; Fowey (Barlee) ; Exmouth (Clark and Barlee); Weymouth and Sandwich (J. G. J.); and Guernsey (Barlce and J. G. J.). The variety, which may be the male, is from Lamlash Bay (Bean) ; L. Strangford (Waller); Land's End (Hockin); and Guernsey (J. G. J.). A. Gulsonce has been found by Mr. S. Wood in the Coralline Crag at Clacton, and dredged in Yigo Bay by Mr. M'Andrew. It is rare.

Mr. Clark noticed that the animal seldom protrudes its eyes and tentacles. He mentions " a rudimental denticle on the pillar-lip." I have minutely examined more than 20 specimens, but could not detect any such process.

This and A. unica are aberrant forms of Aclis. Each has peculiar characters, which render their systematic allocation very difficult. Having suggested another generic name for $A$. unica, in the event of its being considered necessary to separate it from the present genus, I would also venture in the like contingency to propose the generic name of Menippe for $A$. Gulsonce.

Genus II. ODOSTO'MIA *, Fleming. Pl. II. f. 5.
Bobr usually slender : mantle plain-edged, somewhat folded on the right, so as to form a slight canal : snout (or headflap) projecting beyond the foot: proboscis long, issuing from a slit just below the space in front between the tentacles; it

[^45]is only evolved when feeding: tentacles triangular and folded inwards (not unlike an ass's ears), united at their base by an intermediate membrane; tips bulbous and ciliated: eyes immersed in the skin or outer integument, and placed oin the neck a little behind the tentacles.

Shell forming a cone of various lengths: spire having the first or top whorls sinistral and turned backwards: mouth expanding at the base: inner lip rery rarely united with the outer lip: pillar usually straight and furnished in the middle with a single tooth or plait: operculum semitestaceous, having a thin flap on the outer side and a short apophysis or process underneath the nucleus of the spire.

The name and limits of this peculiar genus have been the subject of much controversy.

The history of its name is as follows. In the Supplement to the 4 th, 5 th, and 6th editions of the 'Encyolopredia Britannica' (published at intervals between 1818 and 182t) will be found the article "Conchology," by Dr. Fleming. The genus Odostomia is there described as consisting of certain specics of marine shells, placed by British writers in the genus Turbo, in which the columella is furnished with a tooth. "The Turbo interstincta, unidentata, plicata, Sandivicensis, and insculpta of Montagu are of this genus." This article was separately republished, with plates, in 1837. Fleming's 'Philosophy of Zoology' (1822) enumerates Odostomia as one of the genera of the " marine Turbonides;" and it is therefore most probable that the number of the Encyclopædia which contained the article "Conchology" had then appeared. In 1862 Risso (Hist. Nat. l'Eur. mér. iv. p. 22t) formed the genus Turbonilla, on the MS. authority of Leach, for three fossil species; all are described as longitudinally ribbed, and one of them furnished with a fold. In Turton's 'Enumeration of Marine Shells found on the Devonshire coast' (1829) Odontostoma was proposed by him as the generic name,
and is thus characterized : "Shell conic oval ; pillar with a single tooth or fold towards the middle; operculum none. Includes Turbo unidentatus and others." This description, in respect of the absence of an operculum, is obviously wrong. Fleming's 'History of British Animals' (1828) gave a more correct definition of the present genus. The 7 th volume of the 'Ediuburgh Encyclopædia' (1830), under the head "Conchology," has full descriptions of the genus Odostomia and of the abovenamed species of Montagu ; but Pupa and other landshells are by some mistake confounded with them. Alcide D'Orbigny's account of the Mollusca, in the Supplement to Barker-Webb and Berthelot's Natural History of the Canary Isles ( 1839 or 1840 ), gives Chemnitzia as a subgenus of Melania; it is inadequately defined, the animal being described as "incomnu," and the shell as intermediate between Eulima and Bonellia or Niso. The Turbo elegantissimus of Montagu (T. Iacteus, L.) is the sole type of D'Orbigny's subgenus. Much more precise and accurate, howerer, was the definition by the Rev. R. T. Lowe, in the 'Proceedings of the Zoological Socicty' for 1840, of his genus Parthenia, which corresponds with Chemnitzia. Three ınore synonyms are Pyrgiscus, Philippi (Wiegmam's Archiv, 1811), Orthostelis, Aradas and Maggiore (Atti Accad. Gioenia, 1841), and Loxonema, Phillips (Palæoz. Foss. Cornwall, 1841) ; to which may be added, in part, $J a$ minia of Brown (not of Leach or Risso), Turbonella of Leach, and for certain species Eulimella of Forbes, and Auriculina of Gray. Clark proposed, but never published, the significant name Manoptaxis for the whole group of species. It is evident that the generic name Odostomia is prior to all the others which I have enumerated; and I am inclined to think that the definition
given by its founder was sufficient. At all events that uame is universally recognized.

The next question is, what are the limits of this genus? i.e. do the species furnished with a tooth (whatever may be their sculpture) belong to Odostomia, the ribbed species without a tooth to Turbonilla or Chemnitzia, and the smooth and toothless species to Eulimella? I cannot admit any such distinction ; nor can I draw a line between Odostomia and Chemnitzia, or between either of them and Eulinella. I have detected the tooth in several so-called species of Chemnitzia, e. g. fenestrata, lactea (or elegantissima), pusilla, and gracilis; Philippi described his C. densecostata as having the aperture "superne subplicata;" and Clark observed in a specimen of O. acicula (Eulimella acicula, F. \& II.) " a decided pillar-fold." This last observation I will confirm. Every naturalist is aware that a generic character which pervades the species taken as a whole may not be possessed by all of them. In the present case there are other characters that serve as ties of union ; and not a single character can be found to distinguish any one of the three supposed genera from its allies.

The group of shells now under consideration-call it a single genus or a collection of genera-appears to be intimately related to Aclis on one side, and less closely on the other side to Ianthina, which leads through Stilifer to Eulima. Montagu suggested the conchological affinity of $O$. spiralis and other species to Tornatella (or Acteon) - a view that has been lately advocated by A. Adams, Clark, and Mörch on malacological grounds. But that genus has not a retractile proboscis, nor is the apex of its shell either reversed or inverted; and the operculum is constructed on a different plan from that of Odostomia. Their lingual ribands are also very
distinct, although this may depend on the nature of their food.

For our knowledge of the animal we are mainly indebted to Professor Lovén, Mr. Clark, and Mr. Alder. An admirable paper by the first of these writers, on the genus Turbonilla of Leach (Kongl. Vet.-Akad. Förh. 1846), illustrated by figures of the animal, shell, and operculum, forms the groundwork, and is especially deserving of careful study. Mr. Clark has supplied us with elaborate details of many species. Although he exalted the science of malacology as the only method of natural classification, he could not help remarking on the singular sameness of his descriptions, and admitted that "indeed it is difficult to divest oneself of the idea that all of them appertain to the same animal "*. Sometimes his power of observation with the microscope must have been more acute than at other times. I cannot otherwise account for his stating that the tentacles of several species which he described are "setose" or "setaceous." This is but partially the case ; and the following account by Mr. Alder of a remarkable peculiarity of the structure of the animal will probably explain Mr. Clark's meaning. "There exists near the apex of each ear-shaped tentacle, just within the inner margin, a circular area or lobe, set with strong vibratile cilia, which are in constant motion during the life of the animal, giving that part the appearance of a revolving wheel, while no cilia are to be found on the other part of the tentacle, except a few rigid, immoveable setre at the apex. In one species, O. Eulimoides [O. pallida], I have observed the vibratile cilia to extend in a line from the disk down the centre of the tentacle, but confined to a very limited space. These ciliated disks are

[^46]very curious, and no doubt indicate the seat of a particular function; probably they are a modification of the organs of smelling. They have not been observed in other genera." The suout (" mentum " or chin, Lovén) corresponds in position with the head of a Risson, but has a different office. It is like the snout of a pig; useful for finding food, not for eating it. The head of an Odostomia occupies the central space between the tentacles in frout; it consists of a true proboscis, which is protruded only now and then, and appears to be suctorial. There are no jaws or spiny tonguc. Some species of Odostomia, particularly those of the typical kind, iuhabit the coasts at low-water mark, lurking beneath loose stones, and at the base of Corallina officinalis and small seaweeds in rock-pools; others are found in the laminariau zone; a few occur in deep water, beyond the range of vegetable life. In all probability they subsist on polyparia and other animal substances of a soft nature, because the tongue or lingual riband is edentulous. I think M. Petit must have been mistaken in saying (Journ. Conch. viii. p. 250) that they live on seaweeds. T'wo of our most common species ( $O$. pallida and $O$. unidentata) are frequently met with on the "ears" of living Pecten maximus and P. opercularis; and, from their habitual proximity to the excretory passage of the scallop, it may not be unreasonable to infer that they subsist on its fæces. Mr. Norman was of opinion that specimens of $O$. pallida, which he dredged in the Firth of Clyde, fed on a red sponge (Halichrondria farinaria, Bowerbank) that occasionally covers $P$. opercularis. I have often taken specimens from the ears or wings of scallops which had no such incrustation. The shell is usually white ; but a few species are banded with reddish-brown, or tinged more or less decply with that
colour. The inrersion of the apex was first pointed out by Montagu. That this part of the spire is likewise sinistral, or turns to the left hand instead of to the right, has been since ascertained, and is a still more anomalous fact: it is a good and constant feature of the genus. Owing to the species being generally so prolific and widely diffused, it is excessively difficult to define their exact limits, and to say which forms are specific and which varietal. I endeavoured to perform this undertaking in a monograph which was inserted between eighteen and nineteen years ago in the 'Amals and Magazine of Natural History.' With the aid of subsequent experience and greater opportuwities of comparison, I will now revise my work, professing (and indeed intending, so far as human nature permits) to treat my own discoveries with a share of justice not less rigorous than that which I measure out to my brother conchologists. I have no ambition to be a speciesmaker, much less have I any desire to invite that appellation. I will do my best, by descriptions and figures, to help collectors in making out what I consider true species. But I must at the same time confess having been not seldom puzzled by intermediate forms; when I almost fancied that these paradoxical lines in the 'Passionate Pilgrim' had reference to my perplexity:-
> " Reason, in itself confounded, Saw division grow together; To themselves yet either neither, Simple were so well compounded;

That it cryd, how true a twain, Seemeth this concordaut one."

To show how other conchologists have failed in determining certain species, let me instance O. plicata, Mont. Macgillivray mistook for it a worn O. spiralis, S. Wood
and Lovén $O$. conoidea, and Malm O. albella. Again, Turbo unidentatus of Montagu is a different species of Odostomia from T. unidentatus of Turton, as well as from O. unidentata of Fleming, while the shell described by Hanley, in 'British Marine Conchology,' as the lastnamed species, does not agree with any of the above. But, as I ask forbearance for my own faults,

> Equum est
> Peccatis veniam poscentem reddere rursus.

The geographical distribution of the species is very extensive. Many species in public and private collections are undescribed, and an infinitely greater number remains undiscovered in the South Atlantic, Indian, Southern, and Pacific Oceans, notwithstanding the labours of Philippi, A. Adams, Pfeiffer, C. B. Adams, Gould, Stimpson, P. P. Carpenter and others. Few species have been detected in the arctic seas; and they are equally rare in glacial deposits. The geological relations of the genus have not been sufficiently investigated.

The European species were placed by writers of the Limnean school in Turbo, Helix, and Voluta; by the followers of Lamarck they were assigned to Eulima, Melania, Turritella, Phasianella, and Rissoa.

The following synopsis may be useful for the more easy discrimination of our native species:-
A. Oval or oblong, smooth, spirally striated, or (rarely) reticulated ; pillar slightly curved, and invariably furnished with a tooth. (Typical.) 1. minima; 2. nivosa; 3. truncatula; 4. clavula; 5. Lukisi; 6. albella; 7. rissoides; 8. pallicla; 9. conö̈lea; 10. umbilicaris; 11. acuta; 12. conspicua; 13. unidentata; 14. turrita; 15. plicata; 16. insculpta; 17. diaphana; 18. obliqua; 19. dolioliformis; 20. decussata.
B. Elongated, longitudinally ribbed, or reticulated; pillar
straight, and seldom furnished with a tooth. (Turbonilla or Chemnitzia.) 21. clathrata ; 22. indistincta; 23. interstincta; 24. spiralis; 20. eximia; 26. fenestrata; 27. excavata; 25. scalaris; 29. rufa; 30. lactea; 31. pusilla.
C. Elongated, smooth and polished ; pillar straight, very rarely furnished with a tooth. (Eutimella.) 32. Scillue; 33. acicule; 34. nitidissima.

## A. Typical.

## 1. Odostomia mi'nima *, Jeffreys.

O. minima, Jeffr. in Ann. \& Mag. N. H. 3rd ser. i. p. 45, pl. ii. f. 3.

Shell forming an oblong cone, very thin, transparent and lustrous: sculpture, a few slight longitudinal wavy strix: colour clear white: spire gradually tapering to a blunt, nearly globular, and inrerted point: whorls $4-5$, convex; the last is proportionally broader than the next, and exceeds in length the rest of the spire when the shell is placed with its mouth uppermost: suture deep, scarcely oblique: mouth exactly oval, slightly expanded but entire at the base; it occupies nearly one-third of the shell : outer lip somewhat flexuous, but neither prominent nor expanded: imer lip thin, adhering to the upper slope of the base and slightly reflected below ; it is united with the outer lip so as to form a continnous but indistinct peristome : umbilicus small and narrow : tooth or fold slight and seldom risible: operculum pale ycllow, delicately striated in the line of growth; spire consisting of $2-3$ whorls. L. $0 \cdot 05$. B. 0.025.

Habitat: Living on decayed fronds and at the base of Laminarixe, procured by grappling just beyond lowwater mark, in Lerwick Sound, and at Kyleakin in Skye (Barlee) ; dead in Shetland and the Hebrides, 50-60 f. (J. G. J.) ; St. Mawes, Falmouth (Hockin) ; in dredged sand from Guernsey (Waller). It either is rare or from its minuteness has escaped observation.

This is the shell noticed by Forbes and Hanley in the Appendix to their work (p.282) as allied to Aclis Gul-

[^47]sona. From that shell it is distinguishable by its smaller size, conical rather than cylindrical shape, having fewer whorls and flexuous striæ, and especially in the mouth being entire instead of notched at the base, and in the outer lip not being expanded nor united with the inner lip. It is the smallest known species of Odostomia. The Chemnitzia minima of Hörnes, from the miocene formation near Vienna, is different from this.

## 2. O. nivo'se *, Montagu.

Turbo nirosus, Mont. Test. Br. (ii.) p. 226. O. cylindrica, F. \& H. iii. p. 287, pl. xevi. f. 7.

Shell forming a cylindrical cone, not very thin, transparent and glossy : schtpture, 2 or 3 narrow spiral ridges on the periphery, and a single stronger one immediately below the suture of each whorl, besides close-set and extremely fine but obscure flexuous striæ in a longitudinal direction; one of the spiral ridges usually encircles the base of each upper whorl; under a microscope the whole surface appears more or less covered with numerous indistinct fine spiral lines: colour white, with occasionally a slight fulvous tint : spire tapering to an abrupt rounded and inverted point, the apex being sunk or involved in the extremity of the spire: whorls $4-5$, somewhat compressed; the last exceeds all the rest in length and bulk: suture rather deep, distinctly marked by the uppermost spiral ridge: mouth oval, much narrower above than below, where it is expanded ; it is scarcely equal in length to one-fourth of the spire: outer lip flexuous, inflected and contracted at the upper part: inner lip not very thin, adhering to the pillar, slightly reflected orer the base, and occasionally united with the outer lip: umbilicus none; but a narrow chink may be observed in aged specimens: tooth small, usually concealed behind the pillar: operculum yellowish, strongly striated or furrowed in the line of growth, the strix being more close-set and flexuous towards the outer side: spire very short and nearly terminal. L. $0 \cdot 0625$. B. $0 \cdot 03325$.

Habitat: The lower part of the littoral zone, and the

[^48]upper part of the laminarian zone, in the Channel Isles and south of England; Ilfracombe, and Kilkee in the west of Ireland (Alder); Cork and co. Antrim (J. G. J.); Dublin Bay (B. W. Adams) ; Scarborough (Bean); Clyde district (Norman, Bean, and Robertson) ; Skye (Barlee) ; outer Hebrides (J. G. J.) ; Aberdecnshire (Macgillivrar) ; Dumnet Bay, Pentland Firth (Gordon); Cruden in the Moray Firth, and Hillswick Bay in Unst (Dawson); Lerwick (Barlee). Specimens from the last two places are larger than any of those from our southern coasts.

Montagu's type, with " nivosus" in his hand-writing, is still preserved in the British Mnseum ; and his description confirms its identity with the present species. Alder described and figured this shell as $O$. cylindrica. Macgillivray gave it another name (Anna) in honour of one of his danghters. It reminds one of Dr. Johnston's review of the Professor's "History of the Molluscous Animals of the counties of Aberdcen, Kincardine, and Banff" (Ann. \& Mag. N. H. 1843), in which the frequent mention of his children by the author is noticed in a good-natured way, concluding with a fervent " God bless them!"

## 3. O. trunca'tula *, Jeffreys.

O. truncatula, Jeffr. in Ann. \& Mag. N. H. 2nd ser. v. p. 109; F. \& H. p. 291, pl. xcri. f. 8.

Suele having a considerable resemblance to 0 . nivosa in shape; but it is of a far greater size, proportionally much thinner, and of a more delieate texture ; it has no spiral ridges at the base, nor the peculiar single one at the top of each whorl, although the whole surface of the present species is more or less covered obscurely with remote spiral lines; the longitudinal strix are stronger and impart sometimes a

[^49]puckered appearance to the upper part of each whorl ; the colour is often jellowish in fresh specimens; the whorls are 6 or 7 , and flatter or more compressed than in 0 . nivosa ; the suture is channelled, and gives a turreted aspect to the spire; the mouth is longer in proportion to its breadth; the outer lip is emarginate or notched near its junction with the body-whorl; the tooth is plait-like or twisted ; and the operculum is conspicuously striated. L. $0 \cdot 175$. B. $0 \cdot 065$.

Habitat: Among trawl-refuse from Plymouth (Barlee and Jordan), and Falmouth (Miss Vigurs, fide Cocks) ; dredged in St. Mawe's Creek, near Fahnouth (Hockin), and in 20 f . on the Turbot-bank, near Larne, co. Antrim (J. G. J.).

The proportion of length to breadth varies considerably in the Plymouth specimens. Mr. Clark called this a variety of the last species. But each has its own characters, and I have not yet seen any connecting link; the difference of size also, considered with regard to the habitat (see vol. iii. p. 27), would disincline me to unite these species. The present species is in shape not unlike the young of Truncatella truncatula.

## 4. O. cla'vula *, Lovén.

Turbonilla clavzla, Lov. Ind. Moll. Scand. p. 18. Eulimella clavula, F. \& H. iii. p. 314, pl. xcviii. f. 8.

Bony clear frosted-white: neck greatly protruded, showing on the mouth a canal or groove bounded by two parallel longitudinal lines: snout very narrow, not grooved nor bilobed, but rounded at the extremity [rounded, bilobed (Lovén)], carried just before the foot: tentacles extraordinarily short and broad [mutually connected in front, and vibrating very actively (Lovén) $\rfloor$, swelling out behind like a minute leaf; they are not divergent, but borne straight and close together; each terminates in two white inflations, viz. one quite apical, and the other immediately below it, both being nearly semicircular and as if soldered to the external sides of the points or tips: eyes

[^50]at the inner bases of the tentacles, not rery close together: foot flexible, more or less concare in front, with longish auricles, below which it is gradually constricted ; the margins are thin, and often folded upwards; it is either bluntly or sharply pointed behind; when the animal is in motion there is on each side of the foot a marginal series of about eight very minute glossy points. Animal very active and free. (Clark.)

Shell nearly cylindrical, with a rounded and produced base, thin, transparent and polished: sculpture, extremely fine and close-set longitudinal strix, which can only be detected by the aid of the microscope and in certain lights : colour clear white: spire turreted, and apparently truncated at the point, which is rounded and inverted: whorls 4-5, rather convex, although compressed and gradually enlarging; the last two are almost equal in breadth, and the body-whorl somewhat exceeds in length the rest of the spire: suture nearly straight, slightly channelled above ; it is defined on the under side by a narrow rim, arising from the double layer of shell in that part, the upper edge of the lower whorl being soldered on the periphery of the preceding whorl: mouth oval, expanded below; it occupies about one-third of the shell: outer lip rounded but not prominent, contracted and somewhat sharply inflated abore, just below the periphery: inner lip not perceptible on the upper slope of the base, slightly reflected and but little curred below : umbilicus very small and narrow, but distinct: tooth or fold inconspicuous or scarcely discernible: operculum thin, finely striated. L. $0 \cdot 08$. B. $0 \cdot 0 t$.

Habitat: Dredged off Teignmouth (Clark) ; Torbay (Battersby and J. G. J.) ; Brixham (Hanley) ; Plymouth (Barlee) ; other parts of south Devon (Webster); Hebrides (Barlee and J. G. J.). It is rare, and occurs in muddy sand, between 6 and 50 f . Lovén discovered it on the coast of Sweden, in mud, among Pennatule, at a depth of 30 f . On reexamining his description and a specimen with which he favoured me, I observe that the whorls are more convex, and the suture consequently deeper, than in our shell; but such characters perhaps rary in this as they do in other species of Odostomia.

## 5. O. Lu'kisi *, Jeffreys.

O. Lukisi, Jeffr. in Ann. \& Mag. N. H. 3rd ser. iii. p. 112, pl. iii. f. $19 a, b$.

Shrel nearly cylindrical, solid, opaque, glossy: sculpture, only very slight and almost microscopical scratch-like longitudinal striæ: colour ivory-white : spire abruptly terminating: uhorls 5-6, convex, compact, gradually enlarging: the penultimate one projects a little, and is ncarly as broad as the last, which oceupies about three-fifths of the shell: suture rather deep: mouth oval, contracted above and expanded below, somewhat excceding in length one-third of the spire; throat quite smooth: outer lip incurved on the periphery: inner lip thickened and spread on the pillar, joining the outer lip at the upper corner of the month, and slightly reflected on the lower side : umbilicus small but distinct: tooth small, prominent. and placed opposite the umbilicus: operculum yellowish, with a white streak in the line of the spire, very slightly striated across; flap broad; there is the same groove and corresponding ridge as in 0 . conö̈dea. L. $0 \cdot 1$. B. $0 \cdot 045$.

Habitat: Guernsey, 18-20 f., dead, and Lulworth, 10-12 f., living (J. G. J.) ; among seaweeds at lowwater mark on the south Devon coast, living (Webster); Cornwall (Hockin) ; Dogger bank (J. G. J.) ; Bundoran, co. Donegal, in drift shell-sand (Waller) ; Oban, dredged in 20-25 f. (M‘Kenzie) ; Skye and Shetland (Barlee and J. G. J.).

This shell is remarkable for its ivory whiteness and solidity, in which respects it agrees with $O$. conoïdea; but that species has a more or less distinct peripheral keel, the suture is not so deep, and the throat or inside of the outer lip is invariably grooved, like the barrel of a rifle. Should the latter, however, prove not to be a permanent character, this specics may be regarded as a sublittoral variety of $O$. conoïdea. The umbilicus is developed in the adult only of the present species. From

[^51]the next species ( $O$. albella) this differs in colour, texture, abrupt termination of the spire, greater convexity of the whorls, contraction of the outer lip, the presence of an umbilicus, and prominence of the tooth.

## 6. O. albel'la *, Lovén.

Turbonilla albella, Lov. Ind. Moll. Scand. p. 19. O. rissoides, var. (provisionally), F. \& H. iii. p. 2s6, pl. xevi. f. 5.

Body creamcolour, streaked with sulphur, sometimes clear white, gelatinous, and of a granular texture under a high magnifying-power: snout or mentum narrow, not always extended berond the foot: tentacles leaf-like, rather short and thick: ejes small, placed close together: font short, squarish in front, narrow or constricted in the middle, broader and bluntly pointed behind; sole edged with yellow.

Shell crlindro-conical, rather thin, semitransparent, and of a dullish hue: sculpture, as in 0 . rissoides; the young exhibit faint spiral striæ under a microscope: colour pale yellowish-white, rariegated in fresh specimens by reddishbrown blotches on the upper part, which represent the dried remains of the animal: spire tapering to a blunt point; the apex shows distinctly the reversed and inverted embryonic nucleus: whorls $j-6$, rounded but somewhat compressed, gradually enlarging; the last occupies about three-fifths of the shell: suture shallow but incised; below it cach whorl appears encircled by a narrow band, as in $O$. rissoides: mouth oral, contracted on the outer side, slightly expanded and obtuscly angulated at the base; it usually equals in length onethird of the spire: outer lip slightly curved: inner lip not much spread on the pillar, nor united above with the outer lip, thickened and slightly reffected on the lower side: umbilicus none, althongh there is sometimes a narrow chink behind the inner lip: taoth small, retired and nearly hidden within the pillar: operculum yellowish, marked with white down the spire, finely and deeply striated in the line of growth, the striæ becoming rery close towards the nucleus; flap not striated; groove and ridge as in 0 . conoidea; spire very short, indistinct, and nearly terminal. L. $0 \cdot 115$. B. $0 \cdot 05$.

Habitat : Underneath loose stones at low-water mark * Whitish ; properly albula.
and in the laminarian zone, on various parts of our coast from Guernsey to Shetland. Fossil in the boulder-clay of Caithness (Peach), and at Uddevalla, 40 feet above the sea-level (Malm) ; post-glacial shell-bank at Kirkoën, Norway, 50 feet (Sars, as O. plicata, Malm). Living in Norway (M‘Andrew, Sars, and others), Sweden (Lovén and Malm), coasts of Deumark (mus. Copenh.), La Hougue Bay, near Cherbourg (Macé), Loire-Inféricure (Cailliaud), Sardinia (Vérany) ; Cailliaud gives the laminarian zone, Sars $10-40 \mathrm{f}$., and Danielssen $30-40 \mathrm{f}$. as the range of depth.

In Shetland and the Hebrides it lives between tidemarks in company with Rissoa striata and $R$. cingillus; it floats in a supine position, like its neighbours. At Guernsey and Filey I found this species in the same spot as $O$. rissoides. When scalded, the colour of the animal becomes bright orange. Owing to Mr. Clark having included in his description not only the present species, but also $O$. rissoides and pallida, with their varieties, I have been unable to make any use of it, and therefore rely on my own notes as to the soft parts.

## 7. O. Rissioi'des *, Hanley.

O rissoides, Hanl. in Proc. Zool. Soc. pt. xii. p. 18; F. \& H. iii. p. 284, pl. xcvi. f. 4 , and seir. f. 7 (as 0 . nitida, var.?).
Shell conic-oblong inclining to oval, thin, transparent, and glossy : sculpture, microscopical only, and consisting of very fine and numerous, but irregular and scratch-like strix in the line of growth, besides still finer and less distinct spiral striæ: colour pale jellowish-white or whitish: spire turreted, and tapering to a blunt point; the nucleus is concealed: whorls 5 , convex, rapidly enlarging; the last occupies two-thirds of the shell : suture rather deep; in living or fresh specimens the dark spiral band noticed in other species is observable below the suture on the top of each whorl : mouth regularly oval,

[^52]not much expanded nor at all angulated below; it usually equals in length tro-fifths (sometimes nearly one-half) of the spire: outer lip curved and rather prominent: imer lip very slight on the upper part, forming a mere film on the pillar, thickened and somewhat reflected on the lower part: umbilicus usually none, although in specimens which have a short spire there is a more or less developed chink or indentation : tooth small and partly concealed: operculum like that of $O$. albella. L. $0 \cdot 12 \overline{5}$. B. $0.062 \overline{5}$.

Var. 1. alba. Thinner; spire produced; suture deeper and more oblique; umbilical chink rery distinct. O. alba, Jeffr. in Ann. \& Mag. N. H. 2nd ser. ii. p. 337, and 3rd ser. iii. pl, iii. f. $20, a, b$.

Var. 2. nitida. Whorls more rentricose, and umbilicus distinct. O. nitida, Alder, in Ann. \& Mag. N. II. xiii. p. 326, pl. riii. f. 5; F. \& H. iii. p. 280, pl. xciv. f. 6.

Var. 3. glabrata. Nearly oblong; nucleus of spire exposed and mammillary ; suture deep. O. glabrata, F. \& H. iii. p. 283, pl. xcriii. f. 3 (not Helix glabrata of г. Miihlfeld, nor Rissoa glabrata—afterwards punctulum-of Philippi).

Var. 4. dubia. Oval, and of a more solid consistency; bodywhorl longer than usual; umbilical chink distinct; tooth stronger and rather more conspicuous. O. dubia, Jeffr. in Ann. \& Mag. N. H. 3rd ser. ii. p. 338.

Var. 5. exilis. Smaller and more slender; spire elongated, and suture slight.

Habitat: The lower part of the littoral zone and throughout the laminarian zone, on all our coasts. Var. 1. Oxwich Bay near Swansea, Guernsey, Skye, and Shetland (J. G. J.) ; Sark (Barlee) ; South Devon (Webster) ; co. Autrim (Waller). Var. 2. Shetland (Barlee) ; South Devon (Webster). Var. 3. Tynemouth (Alder). Var. 4. Lower part of the laminarian zone in many places. Var. 5. South Devon (Webster). The foreign localities are Bohuslän (Lovén, in mus. Stockh.) and 15-30 f. (Malm, as O. albella) ; Danish coasts (mus. Copenh.) ; Etretat (J. G. J.) ; Morbihan (Taslé) ; Loire-

Inférieure (Cailliaud) ; Spezzia (J. G. J.) ; and Algiers (Wcinkauff).
This is a common and therefore variable species. It may be recognized, in comparison with $O$. albella, by its more oral and less cylindrical shape, its usually thinner texture and greater lustre, more convex whorls, deeper suture, and having the mouth rounded and never angulated at the base; the last whorl is larger in proportion to the rest. Shetland specimens are very fine. Scalariform and stunted distortions sometimes occur.

Macgillivray described it as $O$. scalaris, which specific name would be entitled to priority, if Philippi had not used it for another well-known species. It is apparently the Rissoa glabra of Brown, and Turbonella transparens of Leach. The fry is probably Helix resupinata of Montagu, from Walker's figure 24.

## 8. O. pal'lida *, Montagu.

Turbo pallidus, Mont. Test. Br. (ii.) p. 325, t. 21. f. 4. O.eulimoides, F. \& II. iii. p. 273, pl. xev. f. 1-3.

Body white, corered with minute yellow specks: snout narrow, expanded and rounded in front, marked down each side with a pale-yellow line: tentacles bevelled and pointed like an awl; each has also a yellow longitudinal line; tips inflated and white: eyes placed somewhat apart: foot short, truncated, and slightly notched in front, where it is indistinctly auricled at each corner, terminating behind in an abrupt and short point.

Shell somewhat spindle-shaped, in consequence of the elongation and angularity of the base, rather solid, nearly opaque, and moderately glossy: sculpture, fine and close-set microscopical spiral strix; these may be detected with a lens of ordinary power : colour milk-white, with a faint orange or purplish tinge on the upper part of live specimens, derired from that of the liver; immature specimens are often yellowish: spire finely and regularly tapering to a blunt point:

[^53]nucleus concealed: whorls $6-7$, rather compressed, rapidly enlarging ; the last occupies nearly two-thirds of the shell : suture more or less oblique, not deep, but distinct ; the marginal band is observable in young specimens only: mouth more oblong than oral, contracted abore, considerably expanded and angulated below; its length is about threc-sevenths of the whole spire: outer lip gently curced, not very prominent: inner lip very slight on the npper part, forming a mere film on the pillar, thickened and decidedly reflected on the lower part, where it is nearly straight: umbilicus none ; the chink, when it exists, is extremely narrow or small : tooth strong, partly concealed; it is (as usual) placed on the pillar in the middle of the inner lip, just where the reflexion of the latter commences: operculum as in the last tro species; the ridge is well marked, and the striation very distinct. L. 0.2. B. 0.1.

Var. 1. crassa. Smaller and thicker; some of the spiral strix confluent and forming elevated ridges. O. crassa, Thompson, in Ann. \& Mag. N. H. xv. p. 315, pl. xix. f. Ј.

Var. 2. notata. Whorls more conrex; spiral striee more conspicuous. O. notata, Jeffr. op. cit. 2nd ser. ii. p. 336.

Var. 3. angusta. Thinner and more slender. Jeffr. op.cit. 3rd ser. iii. pl. iii. f. 18, $a, b$.

Monstr. Cylindrical, with flattened whorls; or having the spire turreted.

Mabitat : Chiefly (if not only) on the cars of Pecten opercularis and $P$. maximus, in the coralline zone ; it is widely distributed and rather common. The trawlrefuse at Plymouth and Brixham is especially productive of this shell. Yar. I. Birterbuy Bay, Connemara (M'Calla, fide Thompson, and Barlee) ; Torquay (Hanley). Var. 2. Five miles east of Lerwick, in 40 f . (J. G. J.) ; a single specimen. Var. 3. Several places from Guernsey to Shetland, but rare; a specimen of this last variety is nearly a quarter of an inch long, and not a line in breadth. The monstrosities were dredged by Mr. Barlee in Birterbuy Bay. Fossil at Belfast, in a newer pliocene deposit (Grainger) ; Clyde beds (Cross-
key). Recent: Mangerfiord (Sars); upper Norway, 15-70 f. (M'Andrew and Barrett, as O. plicata) ; Bohuslän, and the variety crassa on Pecten maximus (Lovén); Gottenburg, 12-20 f. (Malm); coasts of Denmark (mus. Copenhagen); Loire-Inférieure (Cailliaud); Arcachon (Fischer, as O. conoidea); Vigo (M‘Andrew); Gulf of Lyons (Martin); Nicc (Macé) ; Spezzia (J. G. J.); Dalmatia (Brusina, as 0 . Novegradensis). The variety angusta has been dredged by M. Jean Susini at Ajaccio.

Differs from $O$. rissoides in its larger size, solid texture, and milk-white colour ; the spire is more tapering, and the base is pointed or angulated ; the whorls are not so convex ; and the mouth is considerably expanded below the pillar, where the inner lip becomes nearly straight, instead of being curved as in that species.

I have no doubt that this was Montagu's Turbo pallidus, judging from his detailed description and figure : although he at first says that the pillar-lip is "destitute of any tooth," in the Supplement to his work (p. 133) he expressly notices the "ridge or lengthened denticle on the columella " of that shell, as well as of O. spiralis, unidentata, interstincta, and plicata. But the specimen now in the British Museum, which has the name " palidus" in Montagu's handwriting affixed to the under side of the tablet, is a broken and worn Rissoa parva, var. interrupta. It is unfortunately too probable that when Dr. Leach rearranged this part of the national collection, sufficient care was not taken to preserve the identical specimens which had belonged to the firstnamed excellent zoologist, and that in the present case the type may have been lost, and replaced by the wretched substitute now on the museum tablet.
It is the Voluta ambigua of Maton and Rackett, Turbo unidentatus of Turton (not of Montagu), O. unidentata
of Fleming and Macgillivray, O. Eulimoides of Hanley, and Turbonilla oscitans of Lovén. The variety crassa seems to be Brown's Jaminia pullus.
9. O. conoï'dea *, Brocchi.

Turbo conoideus, Brocchi, Conch. Foss. Subap. ii. p. 659, t. xri. f. 2. 0.
conoidea, F. \& H. iii. p. 260 , pl. xcr. f. 4.
Body clear bluish-white throughout, with faint streaks of flake-white: snout or mentum grooved lengthwise and cloven at the extremity, so as to form a lobe on each side, divided by a narrow depressed line, and resembling a second pair of tentacles: proboscis issuing at the termination of the groove close . under the eyes and below the centre of the tentacular reil: tentacles flat, bevelled, not very short (" slightly setose," Clark); tips moderately large, rounded, infiated, and flake-white : eyes very black, situated exactly at the internal bases of the tentacles, immersed in the skin, so close to each other that a hair can scarcely be laid between them ("I never saw the eyes so contiguous in any other mollusk," Clark) : foot large, rather long, membranous, gently reflected at the sides on itself (which reflexion it in some measure retains on- the march), deeply arched in front, causing the flanks to be pointed, and gradually tapering behind to a bluntly angular point; sole slit in the middle in front. (Lovén, Clark, and J. G. J.)

Sheld, oblong-conical, with a narrow and somewhat pointed base, solid, nearly opaque, of a polished lustre: sculpture. the usual microscopical lines of growth, besides a slight impressed line round the periphery, which is more or less distinctly keeled, especially in young or immature specimens: colour ivorywhite: spire tapering to an abrupt extremity; nucleus concealed and twisted inwards : whorls 8, nearly flat, and gradually enlarging; the last constitutes about one-half of the shell: suture narrow and slightly channelled; it slopes downwards from the peripheral keel on each of the upper whorls : mouth oval, contracted above, somewhat expanded but scarcely angular below: its length is about one-third of the whole spire: outer lip gently curved, inflected just below the periphery; inside deeply groored in the direction of the spire, like the barrel of a rifle; the grooves are 8 or 9 in number and terminate in small denticles or notches within the mouth; they

[^54]are often visible outside: inner lip adhering to the pillar above the tooth, and joining the outer lip at its upper angle, reflected and curved below the tooth : umbilicus small but deep, partly covered by the reflexion of the inner lip: tooth strong, prominent and conspicnous, placed just behind the umbilicus; it winds round the pillar from one end of the spire to the other, like the worm of a corkscrew : operculum sellowish-brown, of equal proportionate solidity with that of Cyclostoma elegans, and exquisitely sculptured by close-set flexuons strixe in the line of growth: it has a curved groove down the middle, which ands in the spire of the operculum, and gives to the portion thus separated in front a cornucopia-shape; this groove is deep and very distinct; side-flap rather broad, widening with the growth of the operculum, and divided from the spiral part by a narrow line. L. $0 \cdot 25$. B. $0 \cdot 1$.

Var. australis. Smaller and narrower.

Habimat : Coralline and deep-sca zones, in mud, from 25 to 80 f., throughout Shetland and Scotland; Isle of Man (Forbes, as O. plicata apparently). It is locally plentiful in the Clyde district and Hebrides. The variety has a southern range, comprising the Channel Isles, Dorset, Devon, Cornwall, Galway, and Cork ; in rockpools, Falmouth (Barlee, and Miss Vigurs, fide Cocks) ; among Zostera, Jersey (Dodd). This species was originally described as a fossil by Brocehi from the Subapennine tertiaries, and it has been recorded by Philippi from basaltic tufa at Militello, by Nyst (as O. plicata) from Belgium; and by Scarles Wood (under the latter name) from our Coralline Crag ; the Rev. H. W. Crosskey has found it in the Clyde beds, and M. Macé in an upper miocene deposit near Antibes. The ordinary or typical form inhabits the North Sea, from Hammerfest, 40 f . (Sars), to Gottenburg, 12 f. (Malm) ; and the variety is distributed along the European coasts of the Atlantic from Brittany, in the laminarian zone (Cailliaud), to Gibraltar, 8-30 f. (M'Andrew), every part of the Mcdi-
terranean, from 10 to 50 f . (Scacchi and others), the Adriatic (Brusina, as O. Nagli), the Agean, $7-41$. (Forbes and Spratt), perhaps the Red Sea (Philippi), and the Canaries, 12-60 f. (M'Andrew).
"The animal is vivacious, displays the eyes on the march, and makes rapid progression. The head and cloven muzzle nearly resemble those organs in Jeffreysia diaphana" (Clark, MS.). The front side of the foot is fringed with microscopical and extremely short cilia, which are in a state of incessant motion when the animal is crawling. Brocchi imagined that this species was terrestrial or lacustrine, and belonged to the genus $A u$ ricularia [Auricula] of Lamarek. The shell is certainly not rery unlike Melampus bidentatus.

It is probably the $O$. plicata of Fleming-certainly that of S. Wood, -and the Turbonilla plicata of Lovén. Scacchi described and figured it as Rissoa polita. IIanley called it O. unidentata, myself O. eulimoides, and Leach Alvania Crancliana. The typical form appears to be the Odontostomia erythrcea of Philippi as well as his $O$. sicula (cf. Zeitschr. f. Mal. 1849 and 1851).

## 10. O. vibilicáris*, Malm.

Terbonilla umbilicaris, Malm, Götheb. k. Vet. Handl. (new series) no. viii. p. 128, pl. 2. f. 10.

Shell forming a short cone, thin, transparent, and remarkably glossy : seulpture, none except under a high microscopical power, when some extremely slight spiral strize are discernible in a favourable light: colour clear white, with a very faint bluish tint: spire short, ending in a rather blunt and rounded point, owing to the inversion of the apex: whorls ⿹-6, convex, very compact, gradually enlarging; the last occupies threefifths of the shell ; suture deep, imparting a slightly turreted appearance to the whorls; owing to the transparency of the shell the periphery of each of the upper whorls appears like a

[^55]narrow band round the top of the succeeding whorl : mouth oval, expanding below; it somewhat exceeds in length onethird of the spire : outer lip slightly reflected, not much spread over the pillar, nor extending to the upper part of the outer lip; it is more or less angulated below: umbilicus very distinct although small : tooth small, prominent, and placed opposite the umbilicus: operculum yellowish and rather solid, closely and finely striated across ; it is divided lengthwise about one-third the distance from the pillar by a curved groove, which forms a ridge on the under side; inner side straight; flap narrow; spire consisting of 2 or 3 whorls. L. $0 \cdot 1$. B. 0.05 .

Var. elongata. Spire more produced.
Habitat: Coralline zone, in Torbay (Battersby); south of Devon(Webster); Land's End (Hockin); Oban (M‘Kenzie) ; Loch Fyne, west of Scotland, and Lerwick (Barlee) ; Aberdeenshire (Dawson); Shetland (M‘Andrew). Of the variety I found a single specimen by dredging in Zostera-ground at Southampton. The only extra-British localities to my knowledge are the coast of Bohuslän, in 12 f. (with Mytilus Adriaticus) and also in 20 f., as well as on Eggers Bank, Norway, in 150f. (Malm), and in Finmark (Lilljeborg); the Norwegian specimens are of unusually large size, but possess all the characters of the species. It seems to be everywhere rare.

Malm has well remarked that this species is easily distinguished from any other by its conspicuous umbilicus, glossy surface, and convex whorls.

## 11. O. acu'ta $^{*}$, Jeffreys.

O. acuta, Jeffr. in Anm. \& Mag. N. H. 2nd ser. ii. p. 338 ; F. \& H. iii. p. 269 , pl. xcvii. f. 8, 9.

Body dirty white, speckled with pale-yellow, red, brown or leadcolour points, which are irregularly distributed over many of the external organs: mantle folded at the upper angle of the mouth of the shell, so as to form a tubular canal: snout slender,

[^56]deeply channelled or hollowed out lengthwise, and having a spoon-shaped extremity: tentacles moderately long, and divergent; each has a flake-white longitudinal line in the middle, running from base to point; edges slightly folded; tips less white and inflated than in allied species: eyes rather close together in the centre behind the tentacles: foot short, of a more opaque white than the rest of the body; it is excavated in front, and so deeply divided or lobed as occasionally, when fully extended, to present the appearance of a second pair of short tentacles; it terminates behind in a more or less obtuse point. (Clark.)

Shell pyramidal, with a broad base, rather solid but semitransparent, and lustrous : sculpture, extremely fine and rather numerous microscopical spiral strix, and still more minute and close-set flexuous lines of growth ; a slight peripheral keel is also observable in every stage of growth, but especially in young and balf-grown specimens : colour whitish, with a tinge of pink or fleshcolour: spire gradually tapering; nucleus exposed and inverted on the back, in nearly a horizontal position : whorls 6 (besides the embryonic ones), rounded although compressed, compact and gradually enlarging; the last ocenpies about one-half of the shell: suture very narrow and slightly excarated, sloping a little downwards in consequence of the peripheral keel : mouth roundish-oval, contracted above, and somewhat expanded but scarcely angular below; its length is less than a third of the whole spire: outer lip gently curved, inflected just below the periphery : inner lip adhering to the pillar above the tooth, and joining the outer lip at its upper angle, slightly reflected and more or less curved below the tooth: umbilicus developed and conspicuous, although small; its entrance is through a channel behind the lower part of the inner lip: tooth strong and prominent, placed just behind the umbilical opening; in construction and extent it resembles that of the last species: operculum yellowish-brown, finely and closely striated; the curred groore is unusually distinct. L. 0.175 . B. 0.075 .

Var. umbilicata. Shell larger, stronger, and white, with a broad base and usually a wider and deeper umbilicus; peripheral keel obscure. 0. umbilicata, Alder, in Trans. Tyneside Nat. Field Club, i. p. 359.

Habitat : Coralline zone in various parts of the sea, especially in South Devon. Cornwall, Dorset, the Chan-
nel Isles, Ireland, west of Scotland, Aberdeenshire, and Shetland may also be mentioned as localities. The variety was taken at 'Tynemouth by Mr. Alder, in Bantry Bay by Mr. M‘Andrew, and in St. Catherine's Bay, Jersey, by the Rev. Mr. Norman. Mr. Searles Wood's collection of Crag shells in the British Muscum contains a specimen of the typical form. Its known distribution in a living state beyoud our seas is as follows:-Upper Norway (M‘Andrew); Bohuslän (coll. Lovén in mus. Stockh., 10-30 f., Malm and Lilljeborg); Loire-Inférieure (Cailliaud); north coast of Spain, 30 f ., Cape Trafalgar, and Teneriffe (M‘Andrew); Spezzia (J. G. J.).

According to Clark, the animal is lively, active, and bold. He says that in some of his Exmouth specimens the throat of the shell is grooved. I have failed to detect this character in any of the specimens (at least 100) which I have examined. The umbilicus is visible even in the young. This species may be distinguished from O. umbilicaris by its greater solidity, the periphery being always keeled, the spire much longer, and the whorls compressed instead of convex. From $O$. conoïdea it differs in its smaller size, pyramidal shape, wider base, and in the throat or inside of the outer lip being usually (if not invariably) smoath.

## 12. O. conspi'cua ${ }^{*}$, Alder.

O. conspicua, Ald. in Trans. Tynes. Nat. Field Club, i. p. 8.59 ; F. \& H. iii. p. 263 , pl. xev. f. 6.

Shell forming an elongated cone with rather a broad base, solid, opaque, glossy and of a polished appearance: sculpture, fine and numerous, but irregular microscopical spiral strix, and still more minute and close-set flexuous lines of growth; the periphery is slightly but distinctly keeled or angulated, as is also the base of each of the upper whorls : colour pale cho-

[^57]colate, or creamcolour stained with madder: spire pyramidally tapering; nucleus exposed and lying in nearly a horizontal position across the apex: whorls 8 (besides 2 , which are embryonic and reversed), flattened; the last occupics about onehalf of the shell: suture narrow, but excavated, sloping downwards in consequence of the peripheral keel : mouth thomboidal, contracted above, considerably expanded and angulated below; its length somewhat exceeds a third of the whole spire : outer lip obtuse-angled in the middle, and incurved just below the periphery; the inside or throat is finely but obscurely groored in the direction of the spire: inner lip slight on the upper part, where it adkeres to the pillar and joins the outer lip, reflected and nearly straight on the lower part, the angle at the base being very remarkable : umbilicus extremely small, and almost covered by the lower part of the inver lip: tooth strong, prominent and conspicuous, placed opposite and behind the umbilicus; it forms a sharp fold or ridge, which winds along the pillar throughout the spire. L. $0 \cdot 35 . \quad$ B. 0.15.

Habitat : Coralline zone, off Whitburn, and Douglas in the Isle of Mau (Alder) ; Herm, on the shell-beach (Metcalfe), and Guerusey, in 18-20 f. (J. G. J.); Larne, co. Antrim (Hyndman, fide Alder) ; Loch Fyne (A. M‘Nab) ; Aberdeenshire (Dawson) ; Shetland (Barlee). Bohuslän (Lovén in mus. Stockh., and Malm in mus. Gottenb.) ; La Hougue Bay, Brittany (Macé) ; Lisbon (MI'Andrew) ; Gulf of Lyons (Martin); Spezzia, in 10-12 f. (J. G. J.) ; Adriatic (Nardo) ; Sardinia and Naples (Tiberi).

By far the largest and rarest species in this section; it deserves its specific name. Independently of size, the whorls are less compact than in O. acuta, the keel is stronger, the mouth squarish, and the umbilicus reduced almost to nothing.

It is the O. unidentata of Hanley, in Thorpe's ‘ British Marine Conchology.' Malm mistook for this species an old and imperfect specimen of the next.

## 13. O. unidenta'ta *, Montagu.

Turbo unidentatus, Mont. Test. Br. (ii.) p. 324. O. unidentata, F. \& H. iii. p. 264, pl. xev. f. 7, 8.

Bony clear bluish-white: snout compressed, bevelled at the margin, and truncated in front: tentacles short, broad, awlshaped, "setose" [?], blunt, with a fine transparent line down the middle of each : eyes close together, sunken in the membrane which conneets the tentacles: foot short, truncated in front and slightly eared, sloping behind to a broad, obtuse, lanee-shaped point; sole in front flake-white, behind hyaline, with a fine longitudinal line along the centre of the posterior half; it is divided from the upper disk by a shallow groove, giving the foot a labiated aspect. (Clark.)

Shele, a rather long cone with a broad base, solid, almost opaque, and glossy: sculpture, microscopical and slight but close-set spiral striæ, and a more or less distinct keel round the periphery, as well as at the base of each of the upper whorls: colour milk-white, with a bluish tint in immature specimens: spire shortish; nucleus exposed, twisted in some specimens backwards, and in others forwards: whorls 6 , besides those of the embryonic nucleus; they gradually enlarge, and are nearly flat; the last equals in length the rest of the spire; suture narrow but distinct, defined above by the peripheral keel, from which it slopes downwards: mouth squarish, expanded and forming nearly a right angle at the inner base; its length is about a third of the whole spire: outer lip nearly semicircular, incurved (but not much) just below the periphery: inner lip extremely thin on the upper part, where it adheres to the pillar but does not join the outer lip, reflected and nearly straight on the lower part, the angle at the base being well marked: umbilicus none, although there is sometimes a small chink: tooth large, strong, prominent and conspicuous, placed as in several of the species last described; it is continued throughout the spire: operculum as in 0 . conoïdea. L. 0.2. B. $0 \cdot 1$.

Var. elcta. Spire more elongated, and base narrower.
Habitat: Under stones at low-water mark of spring tides, and on old oyster-shells and Pecten maximus in the laminarian and coralline zones, on every part of our

* Single-toothed.
coasts. Fossil in the Clyde beds (Crosskey), and in the glacial and post-glacial formations in Norway at the respective heights of 400-460 feet and 50-100 fect (Sars). Its foreign distribution is doubtful, because this species has not been satisfactorily ideutified by some continental authors. For instance, Petit has recorded it from the Gulf of Lyons on the authority of M. Martin, and Vérany from Nice; but in both these cases I ascertained that $O$. pallida had been mistaken for the present species. I must for the same reason question the locality of Algeria given by M. Weinkauff. The following, however, may be relied on:-Norway as far north as Hammerfest, in 10-50 f. (Sars) ; Strömstad, Bohuslän, on an oyster from 12 f. (Rubenson, fide Malm) ; and LoireInférieure (Cailliaud).

From Mr. Clark's account the animal differs little from that of $O$. acuta. The shell may be distinguished from that and other allied species by its squarish mouth and nearly rectangular base, and from $O$. conspicua by its smaller size, colour, and smooth throat. I found a living specimen which had lost all the upper part of the spire.

It is the Sabancea Montaguana of Leach, taking his synonymy as my guide: his description is so vague and almost unintelligible, that it would serve for any of the smooth species.

## 14. O. turbi'ta*, Hanley.

O. turrita, Manl. in Proc. Zool. Soc. pt. xii. p. 18. O. unidentata, var. ?,
F. \& H. iii. p. 267, pl. xcv. f. 9.

Body white, with a bluish tinge, and transparent, covered with exceedingly minute granules, which give the surface (especially the foot) a frosted appearance: snout narrow, rounded
in front, a little in advance of the foot: tentacles rather long and leaf-like, with blunt tips: eyes very small, placed close together on the middle of the neck between the tentacles at their inner base : foot rather broad, more or less indented (and now and then deeply bilobed) in front, obliquely truncated and irrcgularly bilobed behind.

Seeli forming a somewhat cylindrical cone, strong and solid, semitransparent and glossy: sculpture none, unless examined with a magnifying-power, when the surface appears covered by fine and regular spiral striæ; the periphery is slightly keeled: colour pale fellowish-white or whitish, with a dark border below the suture in each whorl as in many other of the smooth and semitransparent species: spire rather long, turreted, and abruptly terminating ; nucleus exposed, usually twisted forwards: whorls 5-6 (besides those composing the nucleus), convex, and gradually enlarging; the last forms onehalf of the spire, and scarcely exceeds the next in breadth: suture narrow, but well defined: mouth squarish, not much expanded or angulated at the inner base; it is proportionally small, and its length is scarcely a third of the whole spire: outer lip projecting but little bejond the periphery, below which it is considerably incurved towards the pillar, thus contracting the mouth: inner lip thin, and adhering to the pillar on the upper part, without joining the outer lip, thickened, reflected, and gently curved on the lower part, the basal angle being usually slight: umbilicus none: tooth small, not prominent, nor vers conspicuous: operculum of a thinuer texture and less strongly striated than that of $O$. conoidea or the last species. L. $0 \cdot 125$. B. $0 \cdot 05$.

Var. striolata. More conical, with a shorter spire and larger mouth; the periphery is bluntly angulated; the tooth is stronger, and prominent; and the spiral strix are unusually distinct. O. striolata, (Alder) F. \& H. iii. p. 267, pl. xcr.f. 5.

Habitat: Under stones and in rock-pools at low-water mark, and among seaweeds in the laminarian zone ; it is widely distributed and not uncommon. A specimen of the variety was found by Mr. Alder in shell-sand from Ilfracombe; Mr. Norman has taken it in Bantry Bay, and Mr. Hockin at the Land's End. I noticed the typical form in the Royal Museum at Copenhagen (from the

Cattegat), and also among shells collected by M. Cailliaud in Brittany, by M. Macé at Cannes, and by Mr. M‘Andrew (of a smaller size) off Teneriffe ; it was likewise procured by me while dredging in the Gulf of Spezzia.

The animal floats, like a Jeffreysia; and, when crawling, it has the same habit of withdrawing its eyes, which are visible through the shell. It appears to be inactive, because Foraminifera are sometimes seen attached to living specimens. This species is remarkable for its contracted mouth ; it is much more slender than O. unidentata, the peripheral keel is less distinct, the base is scarcely angulated, and the tooth is proportionally smaller and not so prominent or conspicuous. Although variable in size, it never attains half the dimensions of that species.
I have united $O$. striolata with the present species, in consequence of finding intermediate forms which may belong to one or the other. I must also refer to it the varieties $a$ and $b$ of $O$. plicata, described in my monograph.

## 15. O. plica'ta *, Montagu.

Turbo plicatus, Mont. Test. Br. (ii.) p.325, t. 21. f.2. O. plicata, F. \& H. iii. p. 271 , pl. xeviii. f. 1, 2.

Bony whitish, with minute and close-set yellow specks: snout small, wedge-shaped, flexible and extensile: tentacles leaf-like, and presenting three equal-sized, angular and flattened sides, which are folded a little inwards; tips rounded but not much inflated: eyes not quite so close together as in some other species, seated on the tentacles, at their inner bases: foot squarish in front and bluntly pointed behind; sole slightly groored lengthwise on the posterior half.

Sheal slender, with a narrow and attenuated base, thin,

[^58]transparent, and of a lustrous polish: sculpture none, except microscopical and extremely slight but numerous spiral striæ, which can only be detected at certain angles of light; periphery not kceled or angulated : colour very pale yellowishwhite or whitish, with a dark border below the suture, caused by a thickening of that part: spire long and finely tapering to a blunt point ; nucleus exposed, and twisted in different direetions: whorls 5-6 (exclusive of the nucleus), rounded but much compressed, and gradually enlarging; the last occupies rather more than one-half of the shell if vicwed with the mouth upwards, and about two-fifths if viewed with the mouth downwards: suture slight, somewhat more oblique than in the last species : mouth oval, inclining to oblong, narrow and acuteangled above, rounded and scarcely expanded below; its length equals a third of the whole spire : outer lip rather flexuous, not projecting beyond the periphery : inner lip thin, adhering to the pillar on the upper part, and united with the outer lip; the lower portion is thickened, reflected, and curved: umbilicus none, although full-grown specimens have a narrow chink: tooth small, more prominent and conspicuous than in the last species: operculum thicker on the inner than the outer side of the mouth, coarsely striated, and sometimes having a white streak down the middle. L. $0 \cdot 1$. B. $0 \cdot 04$.

Habitat: Under loose stones and among seaweeds at low-water mark, in the Channel Isles, South Devon, Dorset, Cornwall, and Bristol Channel, as well as at Fishguard, Barmouth, and Cork; it is tolerably abundant in the sublittoral zone at Exmouth. These are all the places which I can vouch for; O. turrita has been frequently mistaken for the present species. This probably has only a southern range, comprising the north of France (J. G. J., Macé, Taslé, and Cailliaud), Provence (Martin), Antibes (Macé), Nice (Vérany), Spezzia (J. G. J.), Corsica (Susini), and Dalmatia (Brusina). Weinkauff has enumerated it among his Algerian shells.

The characters by which this species may be known from the last are, narrower and slenderer, thin, transparent, and much more glossy, having a longer and
tapering spire, a slight suture, nearly flat whorls, a differently shaped mouth, and no peripheral keel.

It is the Voluta plicatula of Dillwyn, and apparently the Eulima unidens of Requien, Turbonella angusta of Leach, and O. vitrea of Brusina.

## 16. O. insculp'ta*, Montagu.

Turbo insculptus, Mont. Test. Br. Suppl. p. 129. O. insculpta, F. \& II. iii. p. 289, pl. xcri. f. 6.

Body opaque frosted-white, with a rather large patch of dull claret-red on the back : mantle having the usual fold at the upper angle of the aperture of the shell : snout short, cioren nearly to the eyes, each lobe being deeply curved outwards: tentacles coalescing at their bases, very broad and short; tips very small, white, and slightly inflated: eyes close together: foot deeply notched in front, forming at each corner a dirergent acute auricle, behind which it becomes a little constricted, and terminates in two symmetrical distinct pointed tails or streamers, which describe an angle of separation equal to that of the fore and middle fingers when placed as far apart as possible. (Clark.)

Shell somewhat cylindrical, with a narrow base, thin, semitransparent and glossy: sculpture, distinet and regular spiral incised lines or narrow grooves, which cover the lower threefourths or even more of the last whorl, and the lower half of cach of the preceding whorls; these lines are not microscopical, but visible to a sharp eje without a lens; the upper part of each whorl below the suture is marked by fine, slight, and numerous flexuous lines in a longitudinal direction, which by crossing the upper rows of spiral striæ produce in the latter an imperfectly punctured appearance; the whole surface is also sculptured with microscopical and close-set spiral striæ, which can only be detected in "live" or fresh specimens and at a certain incidence of light : colour pale white, assuming an irory lustre in "dead" or faded specimens : spire long, somewhat turreted, and having a truncated apex; nucleus obliquely declining, and concealed : whorls 6 , convex although more or less compressed ; each has a narrow and thick rim immediately below the suture; the rate of their enlargement is rather quick, the last occupying about one-half of the shell: suture narrow,

[^59]slightly channelled, and somewhat oblique: mouth irregularly oblong, owing to the inflexion and curvature of the outer lip; it is acute-angled above (but not so sharply as in O. plicata), and decidedly expanded below; its length equals a third of the whole spire: outer lip remarkably flexuous, retreating at the npper corner of the mouth, where it forms a deep sinus, and inflected in the middle, so as to contract the mouth on that side: inner lip as in the last species; the lower part, however, is more reflected and straight in the present species: umbilicus small and narrow: tooth-or rather an oblique fold-retired and inconspicuous, although always present: operculum remarkably thin, light-horncolour, narrow, and obliquely striated. (This description of the operculum is taken from Mr. Clark's account.) L. 0.15 . B. 0.0625.

Habitat: Coralline and deep-sea zones, throughout the British seas, from 10 to 85 f .; not common. I have noted 26 localities. Coralline Crag, Sutton (S. Wood); post-glacial shell-banks near Drontheim, 60-80 feet (Sars). It has been found living at Dröbak in Christianiafiord, in 50 f., and at the Loffoden Isles, in $50-$ 100 f., by Sars, at Kullen in South Sweden by Örsted (and named by Lovén Turbonilla obliqua), at Gottenburg, in 16 f., by Malm (who described it as T. Warrenii), and in Brittany by Cailliaud and Taslé.

The incised revolving lines round the lower part of each whorl readily serve to recognize this species in comparison with any of the foregoing.

It is in all probability the Turbo divisus of Adams, with rather more doubt Pyramis nivosus of Brown, and unquestionably Turbonella transparens of Leach, if reliance is to be placed on the authenticity of his type in the British Museum. But, in his 'Mollusca of Great Britain,' the last-named species is described as "very smooth," and the few other characters there given are common to all its congeners of the present section.

## 17. O. dia phana*, Jeffreys.

O. diaphana, Jeffr. in Ann. \& Mag. N. H. 2nd ser. ii. p. 341 ; Sowerby, Ill. Ind. pl. 17. f. 23.

Bodr brilliant frosted subhyaline-white: mantle forming a conspicuous tubular fold at the upper angle of the aperture of the shell : snout short, cloven in the centre almost to the eyes; each segment or lobe has an outrard curre equal to an angle of $40^{\circ}$ : tentacles strong, rather long, without much auriform folding, roundish and taper, terminating in minute circular snow-white inflated tips; instead of the tentacles moderately diverging on each side of the snout, they are widely curred and carried at a right angle to the axis of the shell : eyes close together, at the internal basal angles of the tentacles: foot long, broad, and thin, rather concare in front, slightly auricled, and when fulls extended reaching beyond the body-whorl in front; it terminates in a distinct bifurcation, which is rery apparent in slow march, but, on a quicker pace being attained, the fork in some measure decreases in consequence of the greater extension of the foot. (Clark ; as Chemnitzia obliqua.)

Shell inclining to spindle-shaped, very thin, nearly transparent, and lustrons: sculpture none, except slight flexuous and numerous microscopical striæ in the line of growth: colour Whitish: spire rather long, abruptly truncated; nucleus obliquely declining and concealed, raised in front and twisted backwards: whorls 4, convex, and rapidly enlarging; the last occupies two-thirds of the shell; the upper part of each is encircled by a thickened 1 im : suture narrow, but well defined, and oblique: mouth rather oblong than oval, narrow and acuteangled above, expanded below; its length exceeds two-fifths of the whole spire: outer lip flexuous, retreating at the upper corner of the mouth, where it forms a rather deep sinus, and projecting in the middle: inner lip extremely slight on the upper part, thickened, and gently curred, but very little reflected, on the lower part: umbiticus developed in the adult only, when it is small and inconspicuous, being approached by a narrow canal or groove from the base : tooth consisting of an insignificant and retired fold: operculum extremely thin, except on the inner side, light-yellow, scored obliquely by fine and close-set flexuous lines, and having a distinct but short and nearly terminal spire of two minute whorls; it resembles in shape a Cristellaria. L. $0 \cdot 1$. B. $0 \cdot 05$.

* Transparent.

Habitat : Coralline zone, 12-50f., Gucrnsey (J. G. J.), Fowey (Barlee), Exmouth (Clark), Hebrides (J. G. J.), Aberdeenshire (Dawson), Shetland (Barlee and J. G. J.); it is both local and rare. I am not aware of any geological or foreign locality.
This species differs from $O$. insculpta in being more spindle-shaped than cylindrical, of a thinner texture, quite smooth instead of spirally striated, having fewer whorls (the last being disproportionately large), with a more oblique suture, and in the umbilicus being narrow and inconspicuous. It is certainly not the young of O. obliqua, as Forbes and Hanley supposed. The present species is in every state of growth more slender (in consequence of the whorls not being so tumid); nor is it ever striated, like that species ; the umbilicus also is smaller, and the nuclens of the spire less prominent. Mr. Clark's description of the animal of O. obliqua was taken from a specimen of $O$. diaphana, which is now in the fine collection of Mr. Leckenby at Scarborough.

## 18. O. oblíqua*, Alder.

O.? obliqua, Alder in Ann. \& Mag. N. H. xiii. p. 327, pl. viii. f. 12. 0.
obliqua, F. \& H. iii. p. 291, pl. xevi. f. 1.

Body clear white, with a slightly frosted appearance: manthe occasionally forming a small conduit or fold at the upper angle of the aperture of the shell: snout short, cloven as far as the eyes, having the segments curved to the right and left: tentacles short, bevelled, not broad, tapering to a fine point, and having small white inflated tips ; they are carried in front of the head with an angular divergence of about $75^{\circ}$ : eyes close together, at the united internal bases of the tentacles: foot short, concave in front, slightly auricled, terminating obtusely behind. (Clark.)

Siell shaped like that of a miniature Limnoed of the stagnalis type, extremely thin, transparent, and glossy : sculpture,

[^60]fine and close-set strix, which become stronger and more remote on the base: colour whitish: spire long and tapering, somewhat turreted; nucleus partly exposed, and prominent, twisted upwards in front, and sloping towards the back: whorls 5 (including the uppermost, from which the nuclens springs), tumid, and rery rapidly enlarging; the last constitutes more than two-thirds of the shell : suture deep and oblique: mouth oblong or pear-shaped, narrow and contracted above, considerably expanded or effuse below; it exceeds in length twofifths of the whole spire: outer lip flexuous, retreating, and sinuated at the upper corner of the mouth, where it is incurred on the periphery: inner lip receding (almost concealed from view), and remarkably thin on the upper part, thickened and reflected, but not much curved, on the lower part ; it forms an obtuse angle or point at the base: umbilicus none, or consisting of an oblique depression, which sometimes ends in a small chink: tooth, only a slight and obscure fold: operculum as in the last species, but less strongly striated. L. $0 \cdot 2$. B. $0 \cdot 075$.

Var. Warreni. Smaller; haring the basal striæ more distinct, and the umbilicus more developed. Rissoa Warreni, Thompson, in Ann. \& Mag. N. H. xv. p. 315, pl. xix. f. 4. 0. Warrenii, F. \& H. iii. p. 292, pl. xcvi. f. 2, 3.

Habitat : Tynemouth (Alder), west of Scotland (Barlec), Aberdeenshire (Dawson), Skye, Shetland; Cork, Bantry, Caswell Bay near Swansea, Exmouth, Falmouth, Guernsey, and Herm (J. G. J.), Herm (Hąnley), west of Ireland (Thompson, fide Alder), Helford (Hockin). Its foreign range appears to be, Löken in South Sweden, 20 f. (Malm); and Etretat in Normandy, at the same depth (J. G. J.). The variety has been taken in Dublin Bay by the late Mr. T. W. Warren, on the Turbot-bank off Larne, co. Antrim (Waller), Birterbuy Bay, co. Galway, Burrow Island near Kingsbridge, and in rock-pools at Gwyllyn-vase near Falmouth (Barlee), living at low-water mark at Budleigh Salterton near Exmouth (Clark), Land's End and Falmouth (Hockin). M. Macé found the variety at Cannes; Mr. Hanley dredged it at Villafranca, and I at Spezzia.

A monstrous specimen, from Guernsey, of this comparatively rare species has a remarkably thick and strong varix or rib-like callosity in the middle of the body-whorl. Mr. Alder noticed the striæ on the typical form.

This species may be the Auriculina exilissima of Brusina, from Melada in Dalmatia.

## 19. O. doliolifor'mis*, Jeffreys.

O. dolioliformis, Jeffr. in $\Delta \mathrm{nn}$. \& Mag. N. H. 2nd ser. ii. p. 342; F. \& H. iii. p. 301, pl. xcvii. f. 5.

Body hyaline pale azure: mantle slightly channelled at the upper angle of the shell on the right side : snout considerably in advance of the foot when the animal is in active motion, scarcely extending to its front edge when at rest: tentacles proportionally larger than in other species, not so triangular, nor furnished with such broad lateral membranes, nor do they coalesce so decidedly as in other species to form a veil; the tip of each has a point of flake-white: eyes as usual : foot apparently divided into two parts; the anterior or front portion is constricted, slender, attenuated, and very extensile, slightly auricled and notched, and nearly clear white; the posterior or hinder portion is somewhat oval, short, broad, fleshy, of an opaque pale drab, and divided in the middle by a deep longitudinal fissure or groove, that seems almost to separate this portion into two equal lobes, which terminate together in a rounded point with a narrow central notch. (Clark.)

Shell oval, resembling Dolium perdix in shape, rather thin. semitransparent, and somewhat glossy: sculpture, about 20 remote and sometimes wary spiral striæ, which are almost perceptible by the naked eve; the microscopical lines of growth are numerous and very slight; these do not cross the striæ, nor impart any "quasireticulated" appearance, as noticed by Mr. Clark: colour whitish, with a faint tinge of yellow in live specimens: spire remarkably short; nucleus twisted horizontally in different directions: whorls 3 only, besides those of the nucleus or apex ; they are ventricose, but compressed towards the suture and front edge, and suddenly enlarge; the last occupies nearly the whole of the shell when riewed with

* Maring the aspect of a small species of Dolium.
the mouth upwards, and at least two-thirds of it when riewed in an opposite position: suture channelled, rather oblique: mouth roundish-oral, not contracted abore, slightly expanded below ; it considerably exceeds in length one-half of the whole spire: outer lip abruptly incursed on the periphers: inner lip thin on the upper part (where it is united with the outer lip), broad, thickened, a little reflected, almost straight, and shelving outwards on the lower part, which is more than thrice as long as the other : umbilicus consisting of a narrow, although distinct, depression, which terminates in a small chink: tooth strong, conspicuous, like a short thorn, projecting from the middle of the inner or pillar-lip: operculum, according to Mr. Clark, cartilaginous and flexible, with the striæ of growth arranged in elliptical curves, as in 0 . pallidu. L. 0.075. B. 0.05 .

Habitat: Aberdeenshire (Dawson); Hebrides (Barlee) ; Scarborough (Bean and J. G. J.) ; Barmouth, Tenby, Swansea, Sandwich, Paington, and Guernse: (J. G. J.) ; littoral zone, Exmouth (Clark) ; Burron Island (Barlee); Hayle and Land's End (Hockin). Local and rare. M. Taslé has found this species at Morbihan in. Brittany ; and I dredged it in the Gulf of Spezzia.

It is impossible to determine Walker's shell, fig. 55, which Montagu named Turbo Sandvicensis. The characteristic word "reticulatis," used by Walker in his short diagnosis, with reference to the whorls, is applicable to $O$. decussata, but not to the shell which I have now described; if the figure were the sole criterion, I should be disposed to assign it to the present species.

## 20. O. decussa'ta ${ }^{*}$, Montagu.

Turbo decussatus, Mont. Test. Br. (ii.) p. 322, t. 12. f. 4. O. decussatu. F. \& II. iii. p. 303, pl. scrii. f. 6, 7.

Body clear white, except the head, which is pale-pink or red: snout small, somewhat cylindrical, narrow, and attenuated

[^61]vol. Iv.
towards the point, where it assumes a clavate or hammer-like appearance, becoming thick, angular, bevelled to a sudden edge, and straight or truncated in front: tentacles very short, not much folded, terminating in indistinct flake-white lobes; the lateral membranes, which are not so extensive as in other species, coalesce and form a shallow veil : eyes very close together, exactly at the internal bases of the tentacles, " not immersed, but a little elcvated on minute prominences: " foot rather broad and truncated in front, without the usual earshaped points at the corners, becoming a little constricted behind, and having a very rounded extremity: opercular lobe simple. (Clark.)

Shell conic-oblong with a rather narrow base, thinnish, semitransparent and somewhat glossy : sculpture, rather strong longitudinal ribs, which are flexuous on the body-whorl and cxtend to the base, and are curved on the next two whorls, the upper ones being smooth; there are about 25 ribs on the last whorl, 20 on the penultimate, and 15 on part of the antepenultimate whorl, where the ribs cease altogether : the interstices of these ribs are crossed by finer and thrcad-like spiral or transverse strix, of which about a dozen may be counted on the body-whorl, 7 or 8 on the next, and 5 or 6 on the succeeding whorl ; the strix do not extond to the suture ; the mutual intersection of the ribs and strix gives a finely cancellated or reticulated appearance: colour whitish: spire produced, slightly turreted; nucleus raised in front or on one side, and twisted inwards: whorls 4 (besides those forming the nucleus), convex, and rather quickly enlarging; the last occupies nearly three-fifths of the shell: suture deep and channelled, somewhat oblique: mouth oval, scarcely contracted above or expanded below; its length is almost two-fifths of the whole spire: auter lip not much curred, abruptly inflected on the periphery: inner lip thin on the upper part, continuous with the outer lip in adult specimens, thickened, reflected, and inclining to straight on the lower part, which is twice as long as the other: umbilicus slight, forming a narrow chink behind the inner or pillar-lip: tooth very retired and inconspicuous, consisting of a narrow oblique fold, which on breaking the shell may be seen winding round the pillar: operculum rather thin and delicately striated. L. $0 \cdot 125$. B. $0 \cdot 05$.

Habicat : Coralline zone on the coasts of Devon and Cornwall (Montagn, Ba:lee, and others) ; Guernsey,

Barmouth, Bantry Bay, co. Antrim, Oban, and Shetland (J. G. J.) ; Dublin Bay (Turton and Kinahan); co. Galway (Barlee) ; Clyde district, in nullipore (Norman); and Moray Firth (Gordon). Not uncommon. Coralline Crag at Sutton (S. Wood). Département of Morbihan (Taslé).

The exquisite latticework of this shell is more than worthy of the following lines attributed to Bishop Mant:-

> "These by the microscopic glass Survey'd, you'll see how far surpass The works of nature, in design And texture delicately fine, And perfectness of every part, Each effort of mimetic art."

Perhaps Adams's description of Turbo pellucidus, to which I formerly referred the present species, may be too vague for identification : it is, "T. quinque anfractibus reticulatis, apertura subrotunda. Obs. Color albus." It would suit as well a bleached Rissoa punctura. Our shell is the Helix arenaria of Maton and Rackett; and it is possibly, but little more than guessingly, Brown's Pyramis spirolinus. If the 'Illustrations of the Recent Conchology of Great Britain and Ireland ' had been written in the seventeenth century, some allowance might be made for the abundance of its errors, both of graphic and pictorial delineation; but it is of modern date. The task of scrutimizing this author's numerous ill-defined and often questionable species, and the mental torture caused by hammering at the horrible names which he invented, are enough to give any one not having nerves of catgut a most excruciating headache. His stilted and often ungrammatical language, too, hardly suits the present age ; "his words are a very fantastical banquet, just so many strange dishes." Why
could he not say grooved instead of "sulcated," lengthwise and not "longitudinally," and for "undulated" wavy? and how do the whorls (or "volutions," as he calls them) "oblique towards the suture?"

## B. Turbonilla or Chemnitzia.

## 21. O. clathba'ta *, Jeffreys.

O. clathrata, Jeffr. in Ann. \& Mag. N. H. 2nd ser. ii. p. 345 ; F. \& H. iii. p. 258 , pl. xciv. f. 4.

Shell cylindro-eonical, solid, opaque, and not so glossy as most of its congeners: sculpture, somewhat flexuons, strong and flattened longitudinal ribs, of which there are about 20 on the body-whorl, extending to the base; their interstices are of the same breadth as the ribs, and crossed by short transwerse strix or much smaller ribs, of which there are 3 rows on the last whorl, and 2 on each of the upper whorls; these transrerse strix occupy the middle or greater part of the last whorl and the lower half of each of the other whorls; the topmost or apical whorl is smooth: colour white, in one specimen stained with pale reddish-brown : spire elongated and tapering to an abruptly pointed extremity; nucleus raised on one side and twisted inwards: whorls 6-7, evenly convex; the last occupies more than two-fifths of the shell : suture rather wide and deep, somewhat oblique: mouth roundish-oval, or regularly oval, very little contracted above or expanded below; length about one-fourth of the whole spire: outer lip rounded, sharply inflected bolow the periphery: inner lip retreating obliquely (but not very thin) on the upper part, where it is united with the outer lip, so as to form a nearly complete peristome, scarcely reflected and gently currod on the lower part: umbilicus deroloped more than in the allied species, and consisting of a narrow depression and chink behind the pillar-lip : tooth or fold none. L. 0.165 . B. 0.05 .

Habitat: Birterbuy Bay, co. Galway, where Mr. Barlce and I found two specimens by dredging in about 15 f . Hanley procured it at Malta, I at Spezzia, and Ms Andrew at Orotava. It is evidently very rare.

* Latticed.

Although.I have only seen very few examples of this species, they all agree in shape, texture, sculpture, and other characteristics. It is intermediate between $O$. decussata and $O$. indistincta, but has perhaps a greater affinity to the latter. From O. decussata it differs in having a more elongated spire, much fewer, stronger, and more prominent longitudinal ribs, with short transverse interstitial striæ, which are confined to part of each whorl, instead of the whole surface being fincly reticulated : from $O$. indistincta it may be known by its more conical and less cylindrical outline, and being proportionally broader, having the apex of the spire obliquely pointed instead of abruptly truncated, the whorls more convex, and the suture larger ; the longitudinal ribs are thicker, broader, and flattened ; and there are but three rows of spiral striæ on the body-mhorl, and two on each of the upper whorls. It is also a more solid shell than either of the above-named species.

## 22. O. indistincta *, Montagu.

Turbo indistinctus, Mont. Test. Br. Suppl. p. 129. Chemnitzia indistincta, F. \& H. iii. p. 255, pl. xciv. f. 2, 3.

Body nearly clear white, with a pale yellowish tinge, overspread or powdered with minute snow-white flakes or lemoncoloured points: snout long, rather narrow, with a rounded extremity; it is somewhat grooved on its upper surface as far as the tentacular reil, where the slit for the issue of the proboscis is marked by a slight prominence: tentacles rery short, united at the bases; their thin edges are unrolled on the march, which gives them a rery large subtriangular, broad. leafy aspect, instead of the usual ear-shaped figure; tips large and inflated: eyes very black, conspicuous, and close together: foot large, long and extensile, thin, nearly transparent, either truncated or concare in front (depending on the will or action of the animal), with very large auricles, which in progression

[^62]are used as fcelers; the edges are often folded inwards; it ends in a needle-point: operculur lobe simple and obscure. (Clark.)

Shell cylindrical and slender, rather thin, semitransparent and glossy : sculpture, numerous and close-set fine longitudinal ribs, which are flexuous on the body-whorl, curred on the middle ones, and oblique on those near the apex; they disappear towards the base ; their interstices in nearly the lower half of each whorl are crossed by extremely short transverse or spiral strix, of which there are from 6 to 8 rows on the last whorl, 3 or 4 on the middle whorls, and 2 only on each of the top whorls; in worn specimens the decussation thus produced gives a punctured appearance; the base exhibits microscopic spiral lines, and the apex is quite smooth : colour white: spire considerally elongated, and gradually tapering to an abruptly truncated extremity; nucleus twisted inwards: whorls 7-S, convex, depressed below the suture and also on the upper part of the spire; they shelve abruptly downwards towards the suture on the lower side; each has the usual thickened rim immediately below the suture; the last occupies about two-fifths of the shell: suture narrow and deep, nearly straight on the upper part of the spire, becoming somewhat oblique on the lower part: mouth oval, contracted above and considerably expanded bclow; length not one-fourth of the whole spire: outer lip flexuous, retreating and forming a sinus above, incurved below the periphery: inner lip extremely thin on the upper part, reflected and nearly straight below : umbilicus consisting of a slight depression which ends in a small narrow chink: tooth or fold none: operculum having a thin fiap, and obliquely striated. L. $0 \cdot 165$. B. 0.04 .

Tar. brevior. Proportionally smaller, with a shorter spire and more conver whorls.

Habitat: Various places from Guernsey to Shetland, in from 4 to 40 f.; "not uncommon alive in rock-pools" at Cumbrae (Norman). The variety is equally distributed, and, according to Mr. Clark (who erroneously considered it O. clathrata), it inhabits " a peculiar district of shelly mud, between the laminarian and coralline zones in 10 fathoms watcr, off Teignmouth." Sars has recorded this species as occurring in a post-glacial shell-bank at

Kirkoën in Norway, at a height of 50 feet above the level of the sea; and Searles Wood gives it as a Coralline Crag fossil. It has been taken in a living or recent state by Sars in Christianiafiord, in 10-50 f., by Malm in 12 f . on the coast of Bohuslän, by Cailliaud in the Département of Loire-Inférieure, by $\mathrm{II}^{\text {s Andren }}$ off Gibraltar and in the Mediterranean, by Martin in the Gulf of Lyons, by me at Spezzia, by Acton (on the authority of Dr. Tiberi) at Naples, by Tiberi at Magnisi in Sicily (of a much smaller size than usual), and by MrAndrew among the Canary Isles, in 40-60 f.

The synonyms are Turritella truncatu of Fleming, Rissoa Ballice of Thompson, Terebra speciosa of Bean (from a broken specimen), and Chemnitzia curvicostuta of Searles Wood.

## 23. O. interstinc'ta*, Montagu.

Turbo interstinctus, Mont. Test. Br. (ii.) p. 324, t. 12. f. 10 . O. interstincta, F. \& H. iii. p. 296, pl. xcrii. f. 1.

BoDr white and transparent: snout small, narrow and slender: tentacles varying in length, yather broad, with a small white bulb on each at the tip; they are retractile, as in Rissar : eyes small, rather close together, at the inner base of the tentacles, sometimes withdrawn under the shell when the animal is crawling: foot short and narrowish, truncated or slightly indented in front, with small auricles, behind which it is coustricted for about one-third of its length ; tail bluntly pointed.

Shell conic-oblong, rather solid, semitransparent and glossy: sculpture, numerous strong and slightly curved longitudinal ribs, broader than the interstices, about 20 on the bodr-whorl; these are cut off at the periphery by two (very rarely three) rows of obscure spiral striæ, which are placed close together below the periphery, and cross the interstices of the ribs in such a manner as to form oval cavitics or punctures having their greater axis in the direction of the spire; each of the

[^63]upper whorls is similarly marked just above the suture ; the base of the shell is almost always smooth : colour white: spire more or less elongated, and tapering to a blunt extremity; nucleus smooth, higher on one side and twisted inwards: whorls 5-6, compressed rather than convex, shelving abruptly towards the suture, each having a thickened rim round the top; the last occupies more than one-half of the shell: suture narrow, but deeply excavated, scarcely oblique: mouth oval, somewhat contracted above and much expanded below; its length equals, and in some cases excceds, one-third of the whole spire: outer lip Hexuous, slightly sinuated above, where it is gently incurved on the periphery: imer lip undistinguishable and apparently wanting on the upper part, not much reflected (although sloping inwards) and nearly straight below, terminating in a rectangular base, like 0 . unidentata : umbilicus none, or consisting at the most of an indistinct and narrow chink, which, however, becomes considerably developed in aged specimens: tooth short and retired, but strong: operculum fexible, with a very thin flap, clusely and finely striated in the line of growth, and presenting the usual triangular ridge on the pillar-side and a minute almost terminal spire. L. $0 \cdot 125 . \quad$ B. $0 \cdot 04$.

Var. 1. terebellum. Much larger, with an elongated spire; ribs set more obliquely, especially on the body-whorl; tooth prominent. Chemnitzia terebellum, Philippi, Moll. Sic. ii. p. 138, t. xxiv. f. 12.

Var. 2. suturalis. Much smaller, more cylindrical and narrower; ribs finer, decidedly curved, or even flexuous, on the body-whorl, and occasionally covering the base. Rissoct striata (afterwards changed to R.suturalis), Phil. l.c.i. p. 154, t. x. f. 8 .

Habitat: Everywhere, in the laminarian and coralline zones; nestling among stones and old shells, and occasionally at the base of seaweeds in rock-pools at spring tides. Post-glacial shell-banks in Norway, 0-100 feet (Sars). Extensively distributed over the North Atlantic and Mediterranean, from the Loffoden Isles, $10-50 \mathrm{f}$. (Sars), and Bohuslän, $10-20 \mathrm{f}$. (Malm), along the north coast of France (De Gerville and others), to Spezzia (J. G. J.), at depths varying from 3 to 20 f .

Var. 1. Oxwich Bay near Swansea, and Cork Harbour (J. G. J.). Fossil at Palermo (Philippi). Living in Norway (Lovén), Denmark (mus. Copenh.), Loire-Inférieure (Cailliaud), Arcachon (Fischer, as O. Moulinsiana), Gulf of Lyons (Martin), Antibes (Macé), and in sand from Rimini (J. G. J.). Var. 2. Many parts of our coasts, from Shetland to Guernsey, in the coralline zone. Searles Wood has described and figured the latter varicty from the Coralliue Crag as O. pupa of Dubois. This is not uncommon in the Mediterrancan, and M'Andrew has dredged it off Orotava. It is the O.oblonga of Macgillivray.

This species cannot be well mistaken for $O$. indistincta (although the two names are inconveniently similar), if their shape and sculpture be compared; the other species has, moreover, a truncated apex and is never furnished with a tooth. In distorted examples of the present species from Gucrnsey and co. Antrim the base is contracted, causing an expansion of the outer lip and a deep umbilicus.

The following description of Adams's Turbo interstinctus (Linn. Trans. 1795) evidently does not apply to O. interstincta :-"T. testa lævi, quinque anfractibus costa tenui interstinctis. Obs. Color albus, apertura subrotunda." Our shell is not smooth, nor are the whorls divided by a slight rib; and the mouth is not roundish. That description may have been taken from a worn specimen of Rissoa semistriata. The present species is much more likely to have been his Turbo canaliculatus. It is also apparently Rissoa Deshayesiana of Récluz, whose collection I unfortunately have not yet, in accordance with his kind promise, had the privilege of seeing. Brown's Pyramis Lamarckii, P. lacteus, and Jaminia obtusa, and Leach's Turbonella Montaguana may
also be referred to the same category of probable synonyms. The variety terebellum agrees with Requien's too succinct notice of Chemnitzia perlata.

24. O. spiralis*, Montagu.

Turbo spiralis, Mont. Test. Br. (ii.) p. 323, t. 12. f. 9. O. spiralis, F. \& H. iii. p. 299, pl. xcvii. f. 2, and (animal) pl. FF. f. 8, 9.

Body clear white, delicately suffused with snow-white points of different sizes [white (Lovén), sulphur-yellow (F. \& H.)]: snout of moderate length [narrow and entire (Lovén)], flattened, and rounded in front, extending from the tentacular membrane beyond the foot: tentacles united at the base in front and widely diverging, short, flat and broad, "setose" [?], with a snowwhite line from base to point and a round flake-white dot at each of their tips: eyes large and black [near each other (Lovén)], placed behind the fork of the tentacles, on their internal angles: foot rather broad, slightly auricled, and sinuated on each side; sole slightly grooved lengthwise in the middle [notched in front (Lovén)]; tail rounded when the animal is at rest or at half stretch, and bluntly pointed in full march. (Clark.)

Shell conic-oval, inclining to oblong, with a wide base which is somewhat angulated, rather solid, semitransparent and glossy: sculpture, numerous strong and straight or slightly curved longitudinal ribs, broader than the interstices, about 30 on the body-whorl; they are cut off at the periphery by the first of a series of spiral striæ that revolve round the base and are in number from 6 to 8 ; these strix are often closely punctured, owing to a decussation in that part by longitudinal ribs which have otherwise disappeared, and they become less distinct as they approach the base; the apex of the shell is quite smooth : colour white: spire pyramidal, and ending in a blunt point; nucleus obliquely twisted inwards: whorls 5-6, convex but flattened, rapidly enlarging, and abruptly shelving towards the suture; the last occupies about three-fifths of the shell: suture narrow and deeply excavated, nearly straight: mouth irregularly rhomboidal, forming an acute angle above and considerably expanded below ; its length equals two-fifths of the whole spire : outer lip sinuous, contracted on the upper purt, sloping upwards to the under side of the periphery : inner

[^64]lip more or less distinct on the upper part of the pillar, according to the degree of maturity of the specimen, in other respects like 0 . interstincta, but not so straight on the lower part as in that shell, and terminating in an obtuse angle : umbilicus consisting of a more conspicuous chink than in the last-named species: tooth very short, blunt and obscure, being seated far within the pillar : operculum as in O.interstincta; the inner side is slightly notched to receive the tooth. L. $0 \cdot 125 . \quad$ B. $0 \cdot 0 \overline{5}$.

Habitat: Equally distributed with the last species, and inhabiting the same zones. Fossil: Dalmuir (Robertson and Crosskey); glacial and post-glacial shell-banks in Norway, the former at 400-460 feet, and the latter at 50-100 feet (Sars). Recent: Norway, as far north as Öxfjord in Finmark, 10-10 f. (Sars) ; Sweden, 10-17 f. (Lovén and Malm) ; Cattegat (mus. Copenh.) ; Loire-Inférieure, among Corallina officinalis (Cailliaud) ; Rochelle (D'Orbigny père) ; off Gil)raltar, 8-30 f. (M‘Andrew).

Specimens in my collection from Shetland are covered with Discorbina globularis. Some are distorted in the same way as those which I noticed when treating of $O$. interstincta. The strix which encircle the base of the shell distinguish the present from any other species.

It is the Voluta pellucida of Dillwyn. A worn specimen was described by Macgillivray as $O$. plicata.

> 25. О. exi'mia*, Jeffreys.

Rissoa eximia, Jeffr. in Ann. \& Mag. N. IT. new ser. iv. p. 299. Chemnitzia eximia, F. \& H. app. p. 278, pl. xc. f. 1 (as R. eximia).

Shell oblong, rather solid, semitransparent and glossy : sculpture, fine curved longitndinal ribs, which do not reach the base; 15 or 16 of them may be counted on the last whorl; these (or more frequently their interstices) are crossed by 3 spiral strix or finer ribs, which traverse the middle of this whorl, and give a partially cancellated appearance to the shell: the next whorl has 2 or 3 similar strix near the base, the

[^65]lowermost being partly concealed by the suture; the succeeding whorl exhibits 2 strix only; the top whorl is smooth: colour white: spire tapering to a rounded point; nucleus globular, and twisted inwards in various directions: whorls 4-5, very convex and almost tumid, gradually onlarging; the last occupies more than half the shcll : suture very deep, and nearly straight: mouth proportionally small, oval, expanded below; its length scarcely equals one-third of the whole spire: outer. lip rounded, recurved on the lowermost spiral stria: inner lip nearly indistinct on the upper part, gently curved and slightly reflected below, and terminating at the base in an obtuse-angled point: umbilicus extremely small and narrow, but distinct: tooth minute, somewhat retired, and obscure. L. $0 \cdot 06$. B. $0 \cdot 03$.

Habitat : The deep-water zone in east Shetland from $60^{\circ}$ to $61^{\circ}$ N. lat.; also in the Minch, off Loch Ewe, Ross-shire, in 60 f. (J. G. J.).

This minute shell, not much larger than O. minima, was discovered by Mr. Barlee. I have never found living specimens, although some had evidently not long been vacated by the animal. Sars has recorded this remarkable species as fossil in post-glacial shell-banks near Skien in the Christiania district, at a height of 100 feet, and as living at Öxfjord, Bergen, and Christianiafiord; Lilljeborg also dredged it at Bergen, and obligingly gave me a specimen for comparison.

Clark described it as Chemnitzia Barleei-a well-deserved compliment to the discoverer, but an unnecessary synonym. Turbonilla eximia of A. Adams, one of his recent discoveries in Japanese waters, is not the present species.
26. O. Fenestra'ta*, Forbes.
O. fenestrata, (Forbes) Jeffr. in Ann. \& Mag. N. H. Ind ser. ii. p. $3 \pm 5$. Chemnitzia fenestrata, F. \& H. iii. p. 249, pl. xciii. f. 6, 7.

Body nearly clear white, with a frosted aspect; the neck is marked on each side, as far as the tentacles, with a pale lead-

[^66]coloured stripe of unequal breadth, which is composed of very minute points so as to give the stripes a mottled look ; a tinge of the same colour pervades the basal portion of the tentacles and upper surface of the foot: mantle having a small offset at the upper angle: snout long and slender, greatly thickened at its base, and much compressed towards the other extremity, which is slightly funnel-shaped: tentacles comparatively long and slender, united at the bases, and having very distinct white inflated tips: eyes conspicuous, close together, and imbedded at the inner angles of the tentacles: foot in slow march short, broad and obtuse; but when the pace is accelerated it becomes attenuated and extends to the bottom of the penultimate whorl; it makes in front a concare sweep, ending on the right and left in very slight ear-shaped points; it has a somewhat lanceolate shape behind. (Clark.)

Shell forming an elongated pyramid, rather solid, almost opaque, glossy: sculpture, numerous fine and oblique or sometimes tiexuous longitudinal ribs which do not reach to the base; the last whorl has about 20 of these ribs; they are interrupted at the periphers and crossed by 3 prominent spiral ridges placed near together, which occupy the middle of the body-whorl, and there is also another but slighter spiral ridge (and occasionally a 5th, rudimentary one) below the periphery; the lower part of each of the upper whorls has 2 ridges; the points where the ridges cross the ribs are nodulous or tubercular ; the top whorl is smooth : colour whitish : spire remarkably turreted, in consequence of each whorl being broader at the base than the upper part of the succeeding whorl, and appearing to overlap the suture in an imbricated manner; nucleus somewhat excentric and prominent, abruptly twisted inwards : whorls 8-9, compressed or shelving upwards towards the suture, and moderately conrex on the lower part; the last occupies about one-third of the shell : suture deep and slightly oblique: mouth proportionally small, rhomboid-oval, contracted above, wide, slightly expanded, and decidedly angulated below; length scarcely exceeding one-sixth of the spire: outer lip gently rounded, recurved on the lowermost of the 3 main spiral ridges, by all of which it is notched or indented at the edge: inner lip forming on the upper part of the pillar a thin film which is united with the outer lip, ou the lower part nearly straight and not much reflected, terminating in a rectangular point: umbilicus wanting, or now and then represented by a minute and narrow chink: tooth or fold none in any of the specimens (more
than 50) which I have examined: operculum thin, exquisitely and closely striated in the line of growth. L. $0 \cdot 15$. B. $0 \cdot 05$.

Habitat: Muddy ground, in 7-12 f., Dartmouth ( $\mathrm{M}^{\wedge}$ Andrew and Forbes), Southampton (M‘Andrew), Exmouth (Clark and Barlee), Torbay (Hanley and others), Fowey (Barlee), Falmouth (Hockin), St. Catherine's Bay, Jersey (Norman). Loire-Inférieure (Cailliaud) ; Vigo Bay, 4 f. (M‘Andrew) ; Spezzia (Marquis J. Doria and J. G. J.) ; in sand from Rimini, nearly 40 years ago (J. G. J.) ; Algiers (Weinkauff).

A specimen which I dredged in Torbay exemplifies the mode of growth under accidental conditions. It had been broken; and a new outer whorl smaller than the preceding one was added, followed by another which increased in size at the usual rate; so that the shell had the appearance of being double, one placed above the other. The egg-capsule is semiglobular, attached by its round and broad base, membranous and thin; when the fry are devcloped, they find their way out through an oval hole in the centre of the upper part, which then becomes enlarged from what was at first a narrow slit.

This is the Turbonilla Weinkauff of Professor Dunker. Parthenia fenestrata, lately described by Mr. Arthur Adams, from Japan, is a different species; such duplicate names must be changed.

## 27. O. excava'ta*, Philippi.

Rissoa excavata, Phil. Moll. Sic.i. p. 154, t. x. f.6. O. excavata, F. \& II. iii. p. 305, pl. xcvii. f. 3, 4.

Surce pyramidal, solid, opaque, rather glossy: sculpture, prominent spiral ridges, of which there are 3 on the main part of the body-whorl, and 2 short ones on the base, the last bcing close behind the pillar-lip; the 3 principal ridges are equidistant, one just below the suture, another in the middle, and the lowermost encircling the periphery; each of the other

[^67]whorls has 2 similar ridges, representing the upper two of the body-whorl ; all the ridges are crossed obliquely by sharp and raised longitudinal ribs, which extend to the base and impart a strongly and deeply cancellated appearance, the points of intersection being nodulous or tubercular ; of the longitudinal ribs about 25 may be counted on the last whorl of a full-grown individual; the top whorl is smooth: colour white: spire tapering to a bluntly rounded point; nucleus somewhat excentric, and twisted inwards: whorls 6, turreted, flattened (except for the angularity caused by the excavated sculpture), and gradually enlarging; the last occupies rather more than half the shell: suture broad and remarkably deep, slightly oblique : mouth squarish-oval, not contracted above, expanded and angulated below; length about one-third of the spire: outer lip projecting, marked by four angular points, being the terminations of the spiral ridges; it is abruptly recurred on the peripheral ridge : inner lip slight on the upper part, but united with the outer lip, reflected and almost straight below, where it also joins the outer lip at a right angle : umbilicus narrow and contracted, but distinct: tooth small and retired, although risible in erery specimen, and winding round the pillar. L. $0 \cdot 1 \overline{5}$. B. $0 \cdot 06$.

Habitat: Coralline zone in Jersey (Dodd), Guernsey (Metcalfe, Barlee, and J. G. J.), Falmouth (Hockin), Fowey and Burrow Island (Barlec), Exmouth (Clark), Miltown-Malbay, co. Clare (Harvey and Humphreys), Turbot-bank, off Larne (Waller), Lamlash Bay, N.B. (Landsborough, Bean, and Norman). Cailliaud has taken it, among Corallina officinalis, in the Département of Loirc-Inférieure, Gay at Toulon, Macé at Cannes and Antibes, the Marquis J. Doria and mysclf at Spezzia, von Schröckinger and Brusina in the Adriatic, Philippi in Sicily, and Weinkauff at Algiers in 5-20 f. Mediterranean specimens are much smaller than ours.

Professor Harvey, the discoverer of this species on our coasts, proposed to call it Cinyula sculpta; Mr. Thompson of Belfast described it as Rissou Harveyi; and in Mr. Hanley's 'British Marine Conchology' it bears the name of Parthenia turrita, Mctcalfe, MS.

## 28. O. scala'ris*, Philippi.

Melania (afterwards Chemnitzia) scalaris, Phil. Moll. Sic. i. p. 157, t. ix. f. 9. C. scalaris, F. \& IH. iii. p. 251, pl. xciv. f. 5, and (animal) pl. FF. f. 5.
Body nearly clear frosted-white, or pale red-brown [of a brownish-madder hue (F.\& H.)]: mantle having a small cloven fold at the upper angle of the mouth of the shell: snout deeply notched in front, with the segments gently curved: tentacles rather long, strong, and divergent ; they do not quite coalesce at their bases, being separated by a distinct groove which is the continuation of one on the snout from the point where the notch ceases; terminal bulbs not much developed : eyes black, not rery close together : foot short, slightly auricled, and bluntly pointed behind. (Clark.)

Shecl forming a very elongated cone, moderately solid, opaque, rather glossy: sculpture, numerous laminar longitudinal ribs, varying in number from 25 to 30 on the body-whorl ; they are sometimes nearly straight, at other times set obliquely, or curved, occasionally flexuous, and they seldom extend to the base; their interstices are crossed by fine and more close-set spiral striæ, which are often arranged in pairs aud cover the base; no cancellation is produced, because the ribs are always more prominent than the striæ; the top whorl is, as usual, smooth : colour pale-yellowish or creamy, with frequently 2 or 3 faint tawny bands round the last whorl (one broader in the middle, another below the periphery, and sometimes a third under the suture) ; the preceding whorls have only the upper band or that and the middle one: spire tapering somewhat abruptly to a rounded point, which forms the nucleus or crown; this is remarkably prominent, and, although twisted inwards, it exposes nearly the whole of the reversed portion of the spire: whorls 8 (exclusise of the nucleus), turreted, convex but compressed, and gradually enlarging ; the last occupies about twofifths of the shell: suture deep, slightly oblique: mouth irregularly rhomboidal, owing to the angular shape of the pillarside; it is somewhat contracted above and expanded below; length about a fourth of the spire: outer lip rounded, not much projecting, incurved a little below the periphery: inner lip, adhering to the upper slope of the pillar (although scarcely perceptible), straight below, and slightly reflected towards the base, where it shelves inwards: umbilicus or tooth none: oper-

[^68]culum thin and flexible, irregularly striated; spire extremely short, minute and terminal. L. 0.25 . B. 0.085.

Var. rufescens. Bodr white, slightly tinged with brown: snout rather narrow and bilobed: tentacles longish, lanceolate, and set well apart: eyes placed almost centrally at the bases of the tentacles: foot oblong, lanceolate, obtusely angled in front, triangular behind. (F. \& H.) Shell longer in proportion to its breadth, and thinner, haring the whorls more convex and the ribs crowded and slighter, so as to give a less turreted appearance: colour more uniformly tawny, with darker bands. Chemnitzia rufescens, (Forbes) F. \& H. iii. p. 253, pl. xcir. f. 1, and (animal) pl. FF. f. 6.

Habitat : Coralline zone, Guernsey (Hanley, Barlee, and J. G. J.), Land's End (Hockin), Dartmouth (M'Andrew), Torquay (Batterslyy), Exmouth (Clark), Tenby (Lyons), Milford Haven (Forbes and M'Andrew), Goodwick Bay, Pembrokeshire (J. G. J.), Dublin coast (Ball and Warren, file Thompson, as Eulima Jeffreysii). Its foreign distribution extends from Cherbourg (Macé) to Vigo Bay and Gibraltar (M'Andrew), and throughout the Mediterranean, to the Egean, at depths varying from 8 to 35 f . The variety has a more northern habitat, viz. Lough Strangford (Dickie), co. Antrim (Hyndman, Waller, and J. G. J.), Aberdeenshire (Macgillivray and Dawson), west coast of Scotland, and Shetland. A specimen of this rariety is in Mr. Searles Wood's collection of Crag fossils in the British Museum. Sars has dredged it in Finmark, Danielssen and others in the lower parts of Norway, Lovén and Malm in Bohuslän, Totten and Professor Adams in Massachusetts, and Stimpson in New England. These give a bathymetrical range of $20-60 \mathrm{f}$. for the European, and 3 f . for the last-named American locality.

One of my specimens in Mr. Clark's collection from Exmouth has the sculpture of the body-whorl the same as that of the variety, while the sculpture of the
rest of the shell is as usual in the typical form. The Milford specimens appear also to be intermediate.

The variety is the Turritella indistincta of Fleming, T. interrupta of Totten, and Eulima decussata of Macgillivray.

## 29. O. rufa*, Philippi.

Melania (afterwards Chemnitzia) rufa, Phil. Moll. Sic. i. p. 156, t. ix. f. 7 . C. rufa, F. \& H. iii. p. 245, pl. xciii. f. 4.

Body of a clear pale-azure colour, irregularly aspersed with snow-white Hakes: snout extending from the conjoined tentacular membrane to a little beyoud the foot, and forming a sort of head-veil ; it is long, flat, and bilobed : tentacles short, broad, very little folded, and diverging; tips rounded: eyes placed on the inner bases of the tentacles: foot large, moderately long, auricled in front, tapering behind to a point when at full stretch, but rounded when at rest. (Clark.)

Siell forming an attenuated cone, moderately solid, opaque, and glossy: sculpture, narrow and shallow longitudinal ribs, from 20 to 30 on the body-whorl; they are nearly straight, and never reach the base, being sharper and more distinct on the upper whorls; their interstices are crossed, and the base encircled, by rather broad impressed lines, of which there are from 8 to 10 below the periphery, and 4 to 6 above it ; these lines, when magnified, appear double, or sometimes composed of several threads; the whole surface is covered with microscopic and close-set strix in the line of growth; nuclens quite smooth : colour pale-fawn or tarny, with frequently a narrow reddish-brown or orange band round the middle of each whorl: spire greatly elongated, tapering to a rounded point which forms the nucleus; this is remarkably prominent and exposes the reversed and compact spire of the embryo, which bends downwards on the first regular whorl in various directions: whorls 10-13 (exclusive of the nucleus), convex although more or less compressed, and gradually enlarging; the last occupies from a third to a fourth of the shell: suture narrow and deep, slightly oblique: mouth irregularly rhomboidal, acute-angled above and expanded below; length from a fifth to a sixth of the spire: outer lip somewhat contracted, very little incurved below the periphery: inner lip

[^69]forming a thin film on the upper slope of the pillar, slightly reflected and nearly straight below: umbilicus none, except a slight depression of the base in adult specimens: tooth very retired, slight, and indistinct, formed on the pillar near its junction with the upper slope of the base: operculum as in the last species. L. $0 \cdot 35$. B. $0 \cdot 1$.

Far. fulvocincta. Body whitish: snout long and bilobed: tentecles leaf-like, rather short and broad, set well apart: eyes small, sessile on the inner bases of the tentacles: foot squarish in front, with small angular corners, and pointed behind. Shell more slender than the typical form, with a narrower base, and of a thinner texture : colour whitish, the band being always present and more conspicuous: whorls not so much compressed. Turritella fulvocincta, Thompson in Ann. © Mag. N. H. v. p. 98. Chemenitzia fultocincta, F. \& H. app. p. 276 , pl. xeiii. f. 3, and (animal) pl. FF. f. 4, as C. rufa.

Habitat : Coasts of Cornwall, Devon, and Dorset, in trawl-refuse and at comparatively small depths; Langland and Oxwich Bays near Swansea, in 15 f., and Fishguard in 8 f. (J. G. J.) ; Tenby (Lyons) ; Anglesea (M'Andrew). A local or rare species. Coralline Crag at Sutton, according to S. Wood; but his specimens appear to belong to a different and probably an extinct species. It has an extensive range southward, along the Atlantic coasts of France, Spain, Portugal, Madeira, and the Canary Isles, and also throughout the Mediterranean and Adriatic, at depths of from 8 to 30 f . The variety occurs on our northern, Scotch, and Shetland coasts, from the Dogger bank to Unst, at various depths from 30 to 90 f., and in the north, east, and south of Ireland. Sars has recorded it as fossil from a post-glacial shellbank at Skien, $70-80$ feet above the sea; he and many other Scandinavian naturalists have enumerated the same variety as living in Sweden and Norway, at depths of from 20 to 60 f .

My largest specimen, which is from Exmonth, measures half an inch in length; and a fragment of another
(from Shetland) represents even a larger size. I regard the typical form as southern or inhabiting shallower water, and the variety as northern or inhabiting greater depths.

This may be the Turbo simillimus of Montagu, which he described from a specimen (probably a bleached and worn onc) said to lave been found by Laskey on the shores of Jura-although he omitted to notice the interstitial striæ. It is the Pyramis crenatus of Brown, Chemnitzia fasciata of Requien, and Turritella Danmoniensis of Leach, whose Turbonella Hibernica may be the variety.

With respect to the species described by me in the ' Annals and Magazine of Natural History' (ser. 2. ii. p. 347) as O. formosa, and well figured by Forbes and Hanley (pl. xciii. f. 5) as Chemnitzia formosa, I am bound to say that I am not satisfied about the origin of the specimen on which the description and figure were founded. I received it from the late Mr. G. B. Sowerby as having been collected at Shellness in Kent; but I suspect that he was misinformed, and that the shell is exotic. The other specimens which I referred to this species are $O$. rufu, var. fulvocincta. O. formosa is certainly distinct, however, from any other known species; it is remarkably slender, with flattened whorls and a deeply channelled suture, which makes the spire appear scalariform.

$$
\text { 30. O. } \operatorname{LAC}^{\prime} \text { TEA }{ }^{*} \text {, Linné. }
$$

Turbo lacteus, Linn. S. N. p. 1238. Chemnitzia elegantissima, F. \& H. iii. p. 242, pl. xciii. f. $1,2$.

Bony clear white: mantle even, with hardly a trace of the usual branchial fold : snout or upper flap-skin (mentum) deeply grooved in the middle on the upper surface, and entire at the

[^70]extremity, which is rounded when at rest, and apparently truncated when carried before the foot on the march : tentacles short, very bluntly pointed and leaf-like, having large and extremely flexible lateral membranes which coalesce for half their height, and are capable of instantaneously assuming various shapes: eyes at a little distance from the internal line of the tentacular bases: foot truncated in front, vers slightly auricled, narrow, not rery long, attenuated and tapering behind to a rounded broad termination: opercular lobe obscure. (Clark.)

Shell forming a greatly clongated cone, rather solid, nearly opaque, and gloss5: sculpture, strong, narrom, and close-set longitudinal ribs, from 20 to 25 on the last whorl; they are more or less curred or flexuous, and placed obliquely, and they terminate abruptly a little below the periphery, the base being perfectly smooth; although no other sculpture is visible with a low magnifying-power, the whole surface of a live specimen exhibits under the microscope extremely numerous spiral lines; the first whorl is glabrous: colour milk-white, with a slight bluish tinge in live specimens: spire tapering to a rounded point; embryonic nucleus as in the last species: whorls 12 (exclusire of the nucleus), moderately conres, and gradually enlarging; the last occupies from a fourth to a third of the shell: suture narrow and deep, slightly oblique: mouth irregularly rhomboidal, longer and more expanded at the base than in O. rufa, but similar in all other respects: outer lip gently rounded, except under the periphery, where it is very slightly incurred and shelves outwards: inner lip forming a thin glazing or layer on the upper slope of the pillar, very little reflected and nearly straight below, where it is more extended than in the last species: umbilicus none: tooth nsually wanting; but in some specimens an obscure tubercle may be detected on the upper part of the pillar, far within the mouth: operculum as in the last tro species, sometimes slightly notched on the inner side to accommodate the tooth when present. L. $0 \cdot 3 \overline{5}$. B. $0 \cdot 1$.

Var. puullula. Drarfed and depauperated.
Habitat : English, Bristol, and St. George's Channels, all Ireland, and the west coast of Scotland, as far north as Loch Ewe; Aberdeen (Macgillirray); Dunbar (Laskey, fide Brown); Sandwich (Walker); Roach River,

Essex (J. G. J.). A common but most elegant shell. It is found living at low-water mark of spring tides, and in the laminarian zone, as well as dredged without the animal in the coralline zone. Post-tertiary deposit in Sussex (Godwin-Austen) ; ? Norwich Crag(Wigham, fide S. P. Woodward) ; ? Coralline Crag (S. Wood); Italian tertiaries (Risso, as Turbonilla plicatula, and Philippi). The variety has occurred to me in several localities; this is far less slender or needle-shaped than the Chemnitzia gracilis* of Philippi, for which I at one time mistook it. Beyond our shores the present species is widely distributed, from Tromsö in Finmark (Sars) to the Canary Isles (D'Orbigny and M‘Andrew), and in every part of the Meditcrranean and Adriatic; Æyean(Forbes). The Red Sea is given by Philippi, on the authority of Hemprich and Ehrenberg, but, it seems, crroneously. No mollusk is at present known to be common to the Red Sea and Mediterranean. The depths rccorded by various authors range from the shore to 50 f .

One of my specimens, which wants the first 4 whorls, has no fewer than 12 left, and is nearly six-tenths of an inch long. Mr. Bretherton says, in the 'Zoologist' for 1858, that it will continue lively in the aquarium for at least a month.

There can surely be no valid reason why any well ascertained name, given by the " princeps naturæ curiosorum" (тódєs $\left.\delta \grave{\eta} \kappa \epsilon i ̂ \theta_{\iota} ~ т \iota \mu \iota \omega ́ т a t o t\right) ~ t o ~ a ~ s p e c i e s ~ d e-~$ scribed in his 'Systema Nature,' should sink into oblivion. In the present instance there is no ambiguity of definition, no question of identification, no risk of increasing the confusion which unfortunately pervades our scientific nomenclature. If the author, indeed, had

[^71]been obscure or local, instead of cosmopolitan, I should have hesitated at adopting the name in preference to one subsequently proposed by some naturalist of equal reputation, but which was in gencral use. It is true that the restoration of ancient names, however accredited, may for a time cause some inconvenience, and oblige many to go to school again ; but is not the latter a condition of scientific and even intellectual existence? Let us, therefore, not be too indolent, nor too selfish. Posterity has its claims; and I write (as every one does on a subject of natural history) not only for this generation, but for all those to succeed it. After Linné, this species was (although loosely) described and figured by Peunant as Turbo albus, by Donovan as T. acutus, by Adams as T. subarcuatus, by Montagu as T. elegantissimus, by Scacchi as Rissoa turritella, and by Philippi as Melania Campanella. Risso misquoted Montagu in describing his Eulima elegantissima, which appears to be our E.polita. A specimen having the ribs somewhat more oblique than usual was described by Leach as Cerithium Spencerianum.

## 31. O. pusil'la* Philippi.

Chemnitzia pusilla, Phil. Moll. Sic. ii. p. 224, t. xxviii. f. 21.
Body differing from that of 0 . lactea in the following particulars :-the snout has a palish purple streak on either side; each of the tentacles is marked with a similar streak; when spread, they hare the lateral membranes united almost to the tips. which are minute and acutely pointed, so that the tentacles then appear like a single united leaf; the foot is much longer, extending on the march to the last whorl but two, and terminating in almost a needle-point; whilst in the other species, under the same circumstances, it is quite rounded, and does not reach beyond the last or body-whorl. (Clark and Bretherton.)

[^72]Shell shorter and more cylindrical than 0 . lactea, being of nearly equal breadth throughout, instead of pyramidal and becoming gradually broader towards the base; it is also more solid; the ribs are always curved, but not set obliquely, and they do not terminate quite so abruptly below the periphery; the whorls, although equal in number, are more rounded and compact, those near the apex rapidly increasing, so as to give that part a quasi-truncated appearance; the base is usually more contracted; and the tooth (or rather the fold or plait) is frequently visible, just below the angle formed by the pillar with the upper slope of the base, and by breaking the shell this may be traced winding round the pillar. L. $0 \cdot 275 . \quad$ B. 0.075.

Habitit : With the last species, but hitherto noticed as found only in the undermentioned places:-St. Catherine's Bay, Jersey (Norman) ; Guernsey, Lulworth, and Torbay (J. G. J.) ; Littleham Cove, Exmouth (Clark) ; Burrow Island (Barlee); Falmouth (Hockin) ; Barrycane, North Devon (Miss Jeffreys); and Ilfracombe (Alder). Loire-Inférieure, among Zostera marina (Cailliaud) ; Gibraltar (M‘Andrew) ; Gulf of Lyons (Martin); Canues (Macé) ; Spezzia (Marquis J. Doria and J. G. J.) ; Tarento (Philippi) ; and Algiers (Weinkauff).

According to Mr. Bretherton, this species creeps quickly over the sand at the bottom and along the sides in an aquarium, but very frequently falls off the slippery surface of the glass; the shell is dragged rather than borne. In comparing it with what Mr. Clark appropriately calls its stately congener ( $O$. lactea), size is not the only distinctive mark. A specimen of the present species as large as an ordinary one of the other, presents all the peculiar characters which I have pointed out. In at least 100 specimens of each examined by me, not one occurred of an intermediate kind.

Chemnitzia pusilla of the late Professor Adams (1850), from Jamaica, is a different species.

## C. Eutimella.

## 32. O. Scille*, Scacchi.

Mclania Scille, Scacchi, Notizie int. alle Consh. p. 51, no. 147. Eulimella Scillce, F. \& IH. iii. p. 300, pl. xcviii. f. 5, 6, and (animal) pl. FF. f. 7, as Chemnitzia M Andrei.

Bonr milk-white, microscopically speckled with flake-white: snout gibbous in front, with an auricle or lobe on each side: tentacles short, often folded inwards like a young and undeveloped leaf, protruded horizontally : eyes small, black, placed close together behind the tentacles: foot long and broad, truncated in front, with rather acnte angles or corners, abruptly ending behind in a minute point or tail.

Suexc forming a greatly elongated cone with a comparatively broad base, rather solid, semitransparent and of a polished lustre: sculpture none, except lines of growth; the microscope, however, shows an infinite number of excessively minute and close-set spiral strix, which permeate the tissue of the shell and are apparently connected with its structure : colour, that of glass in live specimens, becoming white in dead ones: spire tapering to a rounded point; muclens exposed, twisted horizoutally across the top of the first regular whorl, and resembling a joung Spirialis retroversus: whorls 11-12 (exclusive of the nucleus), gradually enlarging, flattened (especially on the upper part), more or less angulated on the lower part and at the base of the shell, which is remarkably depressed and contracted inwards; the last whorl occupies about one-third of the shell : suture rery narrow, slightly excavated, and nearly straight; it appears, like many of its congeners, edged by a darkish band ou the upper part of each whorl, owing to the periphery of the preceding whorl being visible through the partial transparency of the shell: mouth irregularly rhomboidal, contracted above and expanded belorv ; length between a fourth and a fifth of the spire : outer lip curved, except the upper side, which shelves gently outwards a little below the periphery: inner lip, a mere film on the upper slope of the base, somewhat reflected and straight below: umbilicus usually none, although the above-mentioned depression of the base sometimes produces a small central cavity: tooth obscure, in one specimen like that of 0. pusilla. L. $0 \cdot 35$. B. $0 \cdot 1$.

Var. compactilis. Shell thinner, much smaller, and not so strongly keeled. L. $0 \cdot 1$. B. $0 \cdot 03$.

* Dedicated to the memory of an Italian naturalist and poet of the 17th century.

Habitat: Muddy sand in 12-87 f., Shetland and west of Scotland ; Aberdeenshire (Dawson); Whitburn (Abbes and Howse, fide Alder) ; Berwick Bay and off Coquet Island (Mennell) ; Larne, co. Antrim (Hyndman and Waller), perhaps from a post-glacial deposit; Land's End (Hockin). Of the variety Mr. Barlee dredged one specimen, and I another, in the Hebrides; it may be a distinct species. The typical form is fossil at Gravina in South Italy (Scacchi), and Palermo (Philippi). Taken on many parts of the Scandinavian coast from Finmark to Bohuslän, in 15-200 f. (Lovén and others), Croisic in Brittany (Cailliaud), Madeira, in 18-24 f., and the Canaries, in 20 f . (M‘Andrew).

When crawling, the animal trails its long shell horizontally behind it. The upper portion of the spire is now and then twisted a little on one side, as in species of Eulima.

I named this well-marked shell Eulima crassula, and Forbes E. MacAndrei.

## 33. O. act'cula*, Philippi.

Melania (afterwards Eulima) acicula, Phil. Moll. Sic. i. p. 158, t. ix. f. 6. Eulimella aciculd, F. \& 1H. iii. p. 311 , pl. xcriii. f. 9, 10.

Body nearly clear frosted-white, mixed with minute snowy flakes: mantle having the usual small fold at the upper corner: snout rather long, very broad, square in front, where it is deeply notched in the middle so as to divide that part into two minute roundish lobes; it is grooved the whole length, the groove being continued towards the neck, just separating the tentacles at their basal centre; at its upper surface, close to the base, is the orifice for the proboscis: tentacles diverging almost at a right angle, and resembling short, broad, minute leaves, each marked with an opaque-white stripe or vein through the middle; they bevel to a fine edge, and can, with theirlarge flexible margins

[^73][like the tentacles of all other species of Otostomica], simulate ear-shaped folds; tips but slightly developed: eyes very black, not quite close to each other, and placed a little behind the inner bases of the tentacles: foot long (often extending on the march to the antepenultimate whorl) and rery thin, square in front and expandiug at the corners into rather sharp-pointed auricles, behind which it is gradually constricted towards the upper part of the body, and terminates in a narrow slender and acute point. (Clark.)

Sheric forming an attenuated and somewhat cylindrical cone, rather thin, semitransparent and of a polished listre: sculpture, none to the naked eye or when examined with a hand lens, although, by applying the microscope with a high power, spiral striæ similar to those observable in 0 . Scillue may be here also detected: colour clear white or glassy in live specimens, milkwhite in dead ones : spire gradually tapering to a blunt point; nucleus like that of the last species: whorls 8-9 (besides the nucleus), regularly increasing in size; they are usually flattened, but never angulated; the last occupies from nearly half to a third of the shell : suture very narrow, slightly excavated, somewhat oblique, and margined in the manner clescribed in my account of other species: mouth irregularly and obliquely rhomboidal, contracted or narrow above and expanded below; length about one-fourth of the spire: outer lip gently curved on the lower part, shelving or sloping downwards from a little below the periphery: inner lip imperceptible above the pillar, slightly reflected and straight (but now and then recurved or twisted) below : umbilicus none: tooth or fold rarely developed : operculum thin, and most delicately striated, with a very short spire. L. 0.175 . B. 0.05 .

Var. 1. turris. Shell of nearly equal breadth throughout, with rather convex whorls. Parthenia turris, Forbes, in Rep. Br. Assoc. 1843, p. 188.

Var. 2. ventricosa. Shell of a thinner or delicate texture, with tumid whorls and a deep suture. Parthenia ventricosa, Forb. l. c. EuTimella affinis, F. \& H. iii. p. 313, pl. xcviii. f. 7.

Var. 3. obeliscus. Shell smaller and narrower, with more compact whorls. O. obeliscus, Jeffr. in Ann. \& Mag. N. H. 3rd ser. i. p. 46, pl, ii. f. 5.

Habitat: Sand, with an admisture of mud, in the coralline zone, on different parts of the British coasts;
local and by no means common. Peach has found it in the boulder-clay of Caithness, and Philippi in a posttertiary bed at Palermo. It ranges north and south, from Upper Norway (M'Andrew and Barrett) and Bergen (Sars), through the Mediterranean and Adriatic, to the Ægean (Forbes), at depths of from 10 to 41 f . The lst variety was procured by me in the Hebrides, and by Forbes in the Ægean ; it resembles the Chemnitzia nitidissima of Scarles Wood, a Crag fossil. The 2ud variety is rather widely distributed in our seas, from Guernsey to Shetland; and it has been recorded as Dalmatian by Brusina, Egean by Forbes, and AIgerian by Weinkauff under Dunker's name of Eulima subcylindrica. This variety has also been found by M•Andrew in Upper Norway, by Lovén in Bohuslän, by Martin in the Gulf of Lyons, by Macé at Antibes, and by Duminy at Ajaccio. Upwards of twenty years ago I referred the latter variety to the Eulima affinis of Philippi, but (as I am now convinced) erroncously. The size of that species is stated by him to be more than half as large again as $O$. acicula; and he compared it with $E$. nitida. I had previously described it under the name of Eulimella gracilis, and Requien as Eulima turritellata. My present and more matured opiuion coincides with that of Clark and Malm in uniting it with $O$. acicula, because some specimens evidently form a passage from one to the other, and the distinction rests only on a single and variable character, viz the comparative convexity of the whorls. The 3rd variety was dredged by Mr. Barlee in Skye and Shetland, and by Mr. Waller on the north-east coast of Ireland.

Specimens from Tarbert in Loch Fyne are more or less eroded, and sometimes truncated, owing probably to certain chemical properties or ingredients of the water
in that inland gulf being unsuitable to the uniform composition of the shell. O. Scillee is much larger and more conical than the present species, and has an angulated base.

The typical form is the Turbonilla producta of Lovén and, apparently, the Pyramis lavis of Brown.

## 34. O. nitidis'sima*, Montagu.

Turbo nitidissimus, Mont. Test. Br.(ii.) p. 299, t. 12. f. 1. Aclis nitidissima, F. \& H. iii. p. 223, pl. ェc. f. 6, 7 .
Sheti needle-shaped, rery thin, transparent and lustrous: sculpture, none in worn specimens such as are usually picked out of shell-sand from the beach, but in live or fresh specimens it consists of extremely fine and regular spiral striæ or impressed lines, which are slightly flexuous, rather widely and not close-set; they are easily discernible with a Coddington lens: colour clear white: spire gracefully tapering to a blunt point; nucleus entirely exposed and twisted obliquely uprrards in various directions, resembling a miniature Spirictis: whorls 7 (besides the nucleus), very conrex, and gradually enlarging; the last occupies rather more than one-third of the shell: suture wide and deep, decidedly oblique, and microscopically notched across: mouth regularly oval, not much expanded below ; length about one-sixth of the spire: outer lip rounded, inflected just below the periphers: inner lip not so much curved, adhering to the upper slope of the base, where it is united with the outer lip, not reflected below: umbilicus and tooth none: operculum rather solid, delicately striated in the line of growth, and having a narrow flap. L. $0 \cdot 1$. B. 0.02 .

Habitat : Guernsey, Cornwall, Devon, Ireland (west, south, and east), Scarborough, Berwick, Moray Firth, Pentland Firth, West of Scotland, and Shetland, from 5 to 30 f . It has not occurred in any of our post-tertiary or quaternary deposits. I recognized in Professor Lilljeborg's collection at Upsala specimens which he had dredged at Mangerfiord in Finmark, in M. Cailliaud's collection at Nantes smaller specimens found by him at

[^74]low water among Gigartina mammillosa and Corallina officinalis on the Plateau du Four in Lower Brittany, and in M. Martin's collection at Martigues other specimens similar to the last from Cape Couronne in the Gulf of Lyons; and I took this species myself at Spezzia.

It is the most slender of all the Odostomice. My largest specimen (Zetlandic), which is a line and a quarter in length, has a diameter in the widest part equal to one-fifth only of that dimension.

## Family XVII. IANTHI'NID.E, Deshayes.

Recluzia is the only genus besides Ianthina that has any good claim to be a member of this select and peculiar group ; and as the systematic position of the former genus is somewhat doubtful, I will content myself with giving the characters of Ianthina only.

De Blainville called the family Oxystoma, Brown Ianthineea, and Agassiz Ianthinoide.

## Genus IANTHINA*, Bolten. Pl. III. f. 1.

Body globular, with a short posterior convolution: mantle folded at the base of the shell, and expanding into two irregular flaps or lobes, that probably serve as imperfect natatory organs (" epipodial fins," Mörch), and are fringed with fine cilia : head consisting of a thick, cylindrical, and occasionally swollen muzzle, terminating in a cloven mouth, which is eacircled with minute and flexible cilia; and it is provided with a pair of cartilaginous jaws and a spinous tongue; this latter organ is armed with very long and awl-shaped uncini or lateral teeth, arranged in two rows, but it has no rhachis or central tooth : tentacles conical, cach furnished at its base with a short finger-shaped

[^75]offset or prong, so as to make the tentacles appear double or forked : eyes either wanting or said to be in certain species very small and indistinct and placed on the offsets of the tentacles : foot narrow, elongated, rounded in front and tapering behind; it searetes a large oblong foam-like apparatns, formed of aircells and serving as a float to keep the animal always buoyant : gills 2 , unequal in size.

Shecl shaped like a Helix, with a broad and imperforate base, always of a purplish-blue or fiolet colour, but differently tinted according to the species : epidermis none: spire short, the last whorl being disproportionately large ; apex styliform, and obliquely twisted on one side, but never heterostrophe: mouth somewhat triangular, and wide ; lips disconnected: pillar more or less straight, ending in an angular point. No operculum.

Did Edmund Spenser ever see Ianthince in their native haunts? or were they visible to his inner eye only, when he wrote,

> "So likewise are all watr'y living wights, Still tost and turnéd with continuall change, Never abyding in their stedfast plights"?

Such is the wandering and restless course of the Ianthina, floating passively on the surface of the ocean, with its shell downwards and its foot to the skies, the continual sport of winds and waves, and driven hither and thither without choice, without hope of reaching any goal. But woe to them if they approach the shore! That is not the haven where those sailors would be; for here they are inevitably wrecked and stranded: it is thus that we claim one kind of Ianthina as a product of the British seas.

The earliest notice which we find of this remarkable mollusk, or "blue snail," is in the 'Opusculum de Purpura' of Fabio Colonna (one of the many noble authors whose writings are not less illustrious than their names), published at Rome in 1616 . It contains a fair repre-
sentation of the naked animal, with its forked tentacles, and the cellular apparatus or float by which it is suspended in the water. This apparatus he compares to a mass of cartilaginous and glassy foam, or to a cluster of small soap-bubbles, such as the Neapolitan boys were in the habit of making for their amusement and launching out of a window, balloon fashion, which he, perhaps feelingly, called "jocum non jucundum!" The beautiful purplish-bluc dye which is copiously emitted by the Ianthina, staining not only the hands of those who collect it but also white paper and linen, and which gives the shell its permanent colour, was likewise the theme of his learned and accurate observation. But either the simplicity or the prurience of the scientific language used in his time mufortunately prohibits the above excellent treatise being now reproduced at greater length. Even some of the works of Linné, whose style was more severe than loose, are not free from what in the present day would be reckoned faults of indecency. Ncarly a century after the date of Colonna's work Breyn again figured the animal of Iunthina, although badly. Further information seems to have been wanting until 1757, when Carburi, a noted Greek mechanician, briefly redescribed it in a letter țo Marco Foscarini. He mentions a strange notion entertained by his countrymen, viz. that the Ianthina produces the Velella, a well known kind of oceanic Hydrozoa, which usually accompanies the Iunthina and is wafted along by means of its erect gnomon-like crest. They consequently gave it the name of "Armonistarimane," compounded of two Hellenic words signifying mother of the sail-berry. That idea must have originated in the mollusk being sometimes found attached to the hydrozoon, as if the latter issued from it. Carburi had often seen this, and he observed
that the Ianthine held the Velella by its mouth, not unfrequently swallowing half of it ; he also on several occasions discovered young Velella in the stomach of an Ianthina. In 1776 the celebrated Eastern traveller Forskal gave, among other interesting particulars of the Ianthina, an account of its fry. The species which he examined was evidently a viviparous one, I. communis. He says that each of the fry has in front of its shell two transverse roundish lobes (vela), covered with vibratory cilia, with which it rowed itself through the water. His further statement that the float adheres to the mantle of the animal, aud his supposition that the ovary or matrix is placed in the proboscis, are incorrect. The figure given by Bosc is merely a copy of Colonna's; he hazarded the unwarrantable assertion that the Ianthina absorbs the air contained in its float-cells and refills them at pleasure. Admirable details of the anatomy were published in the 'Mémoires' of Cuvier, who acknowledged the aid he received in these investigations from three zealous naturalists, MM. Homberg, Savigny, and Péron. He regarded the float as the rudiment of an operculum, transmuted by organic action; and he believed that the animal could withdraw it into its shell, as well as that some individuals have naturally no float, or that it is only developed at a certain age or at a particular season of the year. All these opinions would unquestionably have been modified, if not renounced, by the illustrions zoologist, had better opportunities occurred to him of examining the organization of this mollusk. Mr. Bennett tells us (Med. Gaz. 1834, p. 233) that when the Ianthina was purposely irritated, it had no power of withdrawing the float, which always remained stationary, even when the animal retired into its shell. Subsequent experiments have shown that this apparatus
is necessary to the existence of the animal. While on this part of the subject I would call especial attention to a paper by Dr. Reynell Coates, which appeared in the 'Journal of the Academy of Natural Sciences of Philadelphia' for 1826, entitled " Remarks on the floating apparatus, and other peculiarities of the genus Ianthina." The author's observations were made during a voyage to the East Indics. As to the mode in which the float is constructed, or rather repaired, he says that on a living specimen being placed in a tumbler of seawater, and a portion of the appendage being removed by scissors, the animal very soon commenced supplying the deficiency in the following manner:-the foot was advanced upon the remaining vesicles until about twothirds of it rose above the surface of the water ; it was then expanded to the uttermost, and thrown back upon the water, like the foot of a Limncea when about to swim; in the next place it was contracted at the edges, and formed into the shape of a hood, enclosing a globule of air, which was slowly applied to the extremity of the foot. A vibratory movement could now be perccived throughout the foot, and when it was again thrown back to renew the process, the globule was found enclosed in its newly constructed envelope. The vesicular membrane is evidently secreted by the foot, and is probably of the same nature as the byssus and glutinous filaments of other mollusea. The shape of the float varics according to the species. He adds, "It does not appear that the janthinæ ever sink below the surface, when they remain attached to the vesicle; but when they are entirely separated, they immediately fall to the bottom of the tumbler, and are unable afterwards to rise from their position, and though they continue to be vigorous for some time, they generally die in a few
days." Mr. Arthur Adams has also furnished some important information* with respect to the habits of the Ianthina and the structure of its float. He says, "The animal floats shell downwards, with the vesicular buoy above it directed backwayds. The anterior part of the foot is mobile, free, rounded and dilated, and the sides are usually folded inwards, forming a shallow cup, which embraces the smooth anterior rounded end of the float. When the animal wishes to bring its head to the surface of the water, this part of the foot is made to glide over the back of the float. Thus the animal can raise and lower itself at pleasure by means of its own float." . . . ."When the animal is weakly or dead, the float readily becomes detached, for there is no organic connexion between it and the foot." [I may suggest, by way of parenthesis, that when an Ianthina is snapt up by a fish, its float would be detached and remain on the surface of the water. This may account for the number of loose floats observed by Mr. Adams, Dr. Wallich, and others.] "When a portion is cut off, the float is enlarged at the end next the foot of the animal, and is not regenerated at the excised part." . . . . "With a pair of sharp-pointed scissors I made incisions into the floats, and allowed the air to escape, when the animals gradually descended, and remained helpless at the bottom of the vessel : the floats were not regenerated or renewed during the period the animals remained alive. Crepitating portions, when separated, continue buoyant until the vesicles of which they are composed gradually collapse from the escape of the air with which they are distended; and the floats, when pounded in a mortar, are readily reduced to a mucus." Professor LacazeDuthiers has very lately (Ann. Sc. Nat. Dec. 1865)

$$
\text { * Ann. \& Mag. N. H. Dec. } 1862 .
$$

confirmed the observations of Dr.Coates and Mr. Adams. He had an opportunity in 1862 of examining several living specimeus which were blown ashore in the Bay of Bouliff near Calles in Algeria. They were placed in an aquarium, where they commenced to put their damaged floats in repair. The float is formed with tolerable regularity, the cells of which it is composed being polygonal, owing to their mutual pressure. The original form of the cells, however, is circular, as may be seen in those on the extremities of the float. The foot of the animal is divided into two distinct parts. The hinder and larger part is flat, and to this the float adheres; the anterior part is rounded in front, and it is this part which constructs the float. Without the beautiful drawings which accompany the paper it will be difficult to give a clear idea of the modus operandi. The anterior part of the foot is extremely flexible, and the animal has the power of causing its extremity to assume a cupslape; when in this position the foot is laid on the float at the spot where a new cell is to be added, the cdges of the foot embrace the float, and the extremity or point is raised up, out of the water, in the cup-shape already mentioned, so as to collect a small portion of air. The animal is now seen to move the foot backwards and forwards, as if to secure the firm attachment to the float of a glutinous film or layer which at the same time exudes from the foot. When the animal removes its foot, this glutinous film has become a cell and remains attached, with its imprisoned air-bubble. M. LacazeDuthiers noticed that all the specimens which had lost their floats, although perfectly alive, remained at the bottom of the water, and that some of the more lively crept with the foot, slowly and painfully, up the sides of the vessel, and on reaching the top they turned on their
backs, but usually without being able to make a new float; these fell again heavily to the bottom and soon died. He never saw any swim, like other Gastropods. Clark combated the idea that the float or vesicular mass attached to the foot is a hydrostatic apparatus; and he asserted that this organ is "the membranous vehicle of the contents of the ovarium and matrix, that has descended from under the mantle, and fixed itself to the foot, for a very obvious purpose of the animal economy in reference to the pulli in the genial season." I will not comment on this curious assertion further than by observing that every Ianthina of both sexes, viviparous as well as oriparous, has a float, and that the mode of its construction was fully explained more than a quarter of a century before Mr. Clark wrote. Ianthince can scarcely be considered gregarious, their locomotion being almost involuntary. It is only when driven together by winds or currents that they appear to congregrate in shoals near coast lines. Some of the old naturalists must have drawn largely on their bank of imagination in making up their accounts of the Ianthina. Born gravely assures us that it lives in the depths of the sea, and in stormy weather rises to the surface, shining with a phosphoric light. I do not know where he got this idle tale. All modern naturalists, who have observed the Ianthina during long royages, speak of its appearance in fine weather, dotted here and there over the ocean. Dr. Wallich says that in actual calms it was easy enough to see its floating standard, partly raised above the surface, but at other times it was only by dint of the keenest watching and getting gradually accustomed to detect the outline of the float, that he could distinguish it from the surrounding foam ; and he further remarks that the colour of the shell so nearly
approaches that of the waters of the open sea as to render it almost invisible, except at close quarters-as, for instance, from the gunwale of a boat. Mr. Benson (Ann. \& Mag. N. H. 3rd ser. vi. p. 405) compares the float, seen under these circumstances, to a minute flock of cotton, broad at one end and pointed at the other. It is still a question whether any species of Ianthina is furnished with eyes. Risso describes the animal as having "les ycux pédonculés;" but his authority is not infallible. Lesson and Rang also placed the eyes at the points of the tentacular prongs; D'Orbigny at the outer base of the tentacles. According to Arthur Adams, the " eyes are very small and indistinct, and are placed on a short peduucle on the outside of the conical tentacles." He, however, has since given a different account, as follows :-" The animal is entirely blind. I sought in vain for eyes, both at the base and apex of the longer, external, pointed tentacle, and likewise at the truncated apex of the inner and shorter tentacular process. No trace of eyes was visible, although an accidental dark round spot of pigment may have been mistaken for these organs." My own examination of specimens, preserved in spirits, of I. communis and I. globosa induces me to agree with the last observation : I could not detect any vestige of eyes. The habitat of the Iunthina is determined by the nature of its food, which principally consists of Velellee and similar animals. Coates indeed found that some were cannibals, having in their digestive tube shells of other Ianthine, whose diameter was three times that of the cesophagus in its usual state. Its zoophagous tastes appear to be even more varied. "Although doubtless the chief food of Ianthina consists of Physulice, Porpite, and Velelle, which are usually seen floating in its society, on the surface, in calm weather,
yet an occasional Barnacle does not seem to come amiss to the blind Suail of the Ocean. From the stomachs of several I extracted fragments of the tufted feet of Lepas; and in one which I examined the Lepas-remains occupied the entire length of the œesophagus." (A. Adams.) Mr. Benson says that when the snout is protruded, the flexible cilia round the mouth are extended and agitated with great rapidity, apparently in search of food. The top of the living shell is now and then crowned with a cluster of Lepas pectinata or of L. fascicularis. I may also mention, on the authority of Mr. Benson and Dr. Wallich, that the float is often infested with a small swimming crab of a brilliant blue colour like that of the shell; this uses the float as a raft.

The sexes of Ianthina are separate. Fritz Müller has minutely described the spermatozoa of the male, which are clothed with long delicate microscopical hairs or filaments, forming a swimming-apparatus. As in Littorina, so in the present genus, some species are oviparous, and others viviparous. In the former case the eggs, when excluded from the orary, are enclosed in cells, and attached (probably by the foot of the parent) to the under side of the float, from which they hang thickly but separately. Achille Costa computed the number produced in the breeding-season by each individual at no less than a million. Owing to the pelagic and wandering habits of the animal, its own float would certainly be the best nidus it could have, if indeed any other were at hand at the time of parturition. Professor Costa (not Achille) erroneously stated that the egg-cases attached to the float belong to another mollusk. It reminds one of the famous controversy, which so long disturbed the peace of conchologists, about the supposed parasite that inhabited the shell of Argonauta, and (cuc-
koo-like) laid its eggs there. According to Philippi (Handbuch, p. 179) the fry of $I$. communis, before it is excluded from the matrix, has an operculum, and its velum or hood is furnished with vibratile cilia and two large black eyes. Embryonic shells of this species and of $I$. rotundata which I have examined under a microscope are nautiliform, of a yellowish-brown colour, and resemble in shape those of Stilifer. I could not discover an operculum in any of the specimens, although the mouth was closed by a film of dried animal matter. The Ianthina, wheu irritated, discharges a beautiful purple or violet-coloured liquid in considerable quantities. Captain Cook observed that each individual yields about a tea-spoonful. This liquid, says Mr. Adams, " is at first equally diffused, but shortly sinks to the bottom in the form of a deposit, leaving the water pellucid. The bag or reservoir containing the colouring-fluid is visible through the skin on the back of the neck; and the fluid is poured direct into the branchial cavity, and makes its escape from under the free edge of the mantle. My dyeing operations with this purple fluid were not crowned with success, the beautiful colour fading gradually away, leaving magenta and mauve yet possessors of the field." It was suggested, in a revier of the first volume of the present work, which appeared in the 'Parthenon' of 21 June 1862, that the colour of this fluid is due to chloride of gold, and that the secretion is of a poisonous nature. I am no chemist ; and I regret that my literary gleanings have not enabled me to solve the former problem. The origin of the colouring-matter of shells and other animal productions, as well as of that of vegetables, seems to be involved in nearly equal obscurity. Liebig attributed the red and blue colours of flowers to ammonia; but whence is the ammonia derived? We
know that gardeners can produce differently tinted flowers in an Hydrangea or a Dahlia by the empirical application to the soil of certain mineral admixtures. Cannot Nature do as much for marine animals by a prescient combination of similar ingredients in the seawater? With respect to shells Mr. C. Stewart has satisfied me that Littorina obtusata, when calcined or even subjected to the heat of a lamp-flame, quite loses its colour, which, he remarks, would not be the case if that colour had a mineral for its base. But many minerals possess an intense colour which they lose entirely when heated to a certain temperature. This phenomenon has been lately explained by M. Wyrouroff of Moscow in the Bulletin of the Chemical Society of Paris. The late Professor Forchhammer, in a lecture on the metals in ashes of plants (Report of the Danish Association of Agriculturists, 1855) stated that manganese constitutes the colouring-matter of the brown rings or bands and lip of certain snails (e. g. Helix nemoralis), -the snail getting the manganese from the plants on which it feeds, and these again from the soil. He also confirmed a discovery previously made by chemists, that the field and garden slugs contain copper, which occurs in wheat and other cultivated plants. Here I must for the present leave the question. The oceanic distribution of Ianthina is coextensive with that of the temperate and torrid zones, although it especially frequents the latter. None have been found in the arctic or antarctic seas, or in a fossil state. Five species occasionally visit our shores, being brought hither by the Gulf-stream and a continuance of westerly gales. One only I regard as British, and that not without considerable doubt.

The systematic position of the genus is scarcely settled. Its founder, Bolten, associated with it several
widely dissimilar shells. Lamarck defined the genus and made it recognizable. It was at one time placed by the last-named author in his class Heteropoda, a division based on the anomalous character of the foot and pelagic nature of the animal ; but this class was repudiated by Cuvier, and is not maintainable in a scientific point of view. The organization of Ianthina does not differ in any essential respect from that of other Gastropods. Its synonyms are not numerous; they are chiefly mere MS. names, viz. Neritoidea, Humphreys, Ianthinus, De Montfort, Amethistina, Schintz, Iodes, Leach, and Achates, Gistel. The old Dutch naturalist Rumph called it "Quallebootje," translateable as the boat of a Holothuria; and De Montfort agreed with him in the propriety of the name, believing that Ianthina had a greater affinity to that animal than to the Mollusea!

## Lanthina rotunda'ta*, Leach.

I. rotundatr (Teach, MS.), Dillwyn, Contributions towards a Mistory of
Swansea (18 10 ), p. $\overline{0} 9$. I. communis, F. \& H. ii. p. 549 , pl. lsix. f. 6,7,
\& cxxxiii. f. 1.

Shell forming a depressed cone above and a shorter one below, somewhat globular, with a bluntly angulated periphery, thin, semitransparent, and glossy : sculpture, minute and closeset spiral striæ, which are often wavy and interrupted by the flexuous lines of growth; the base exbibits stronger intermediate spiral strix: colour white, tinged with purple or mave on the upper side, deepening into violet beneath; a broad and deeper-lued band sometimes encircles the base, which is then whitish, like the upper side ; the apex or nucleus is pale am-ber-colour: spire abrupt: whorls 4' (besides 3 which constitute the stiliform apex), swollen and bulging outwards, compressed and sloping towards the suture ; the last is three or four times the size of all the rest put together; the apex or nucleus (which resembles in shape the shell of Stilifer Turtoni)

[^76]is partls sunk within the spire, and obliquely turned in various directions: suture rather slight but distinct: mouth irregularly triangular ; the base of the triangle is the pillar, the lower part of which is reflected outwards, and forms a more or less sharp angle: outer lip gently incurved below the periphery, widely and deeply sinuated in the middle : inner lip consisting of a white film, which lines the upper side of the base within the mouth and is folded back on the under side over the pillar; this is twisted and nearly perpendicular. L. 1.2. B. 1.35.

Habitat: Occasionally cast on shore, from July to November, in the south and west of England and Ircland, and the Bristol Channel. To these localities may be added the north of Ireland (Turton and Thompson), Portrush, co. Antrim (Turton and Brown), Loch Ryan (James Smith), and Skye (Forbes, MS.). The foreign distribution of this species is doubtful ; I can only venture to give Brittany (Cailliaud and Taslé), Madeira and the Canary Islands (M'Andrew), and probably the Azores (Drouet). Dr. Mörch informs me that no Ianthina or other oceanic animal has been observed on the shores of Deumark.

When I found living specimens on the Welsh coast (nearly forty years ago) I was a boy, and cared for the shells only ; the animal did not then interest me. Clark's description of the latter is generic ; and that given by Forbes and Hanley seems to represent some species of the oviparous section, because it mentions the eggvesicles. The present species is certainly viviparous. Young as well as adult specimens contain perfectly formed fry of a whorl and a half. The shell is sometimes distorted, owing to an imperfectly repaired fracture, or to the mantle having been injured. In ' Loudon's Magazine of Natural History ' for July 1834 will be found an interesting notice by Dr. Turton of the appearance of this Iunthina in the small coves about the

Land's End. He says it is there " occasionally wafted, by a gentle south-west wind, in prodigious fleets, all alive, and borne upon the water by their clusters of tough bubble-like vesicles. By the retreating waves most of them are carried back into the ocean; so that it requires a fortunate combination of tide, wind, and wave to see them in all their splendour. This mostly happens about the months of July and August. The fishermen's wives call them bullhorns." According to M. Drouet the inhabitants of Pico in the Western Isles give these shellfish the name of "agoa viva," and pretend that they fasten themselves on the limbs of persons bathing. Did they not mean the Physalia, or some animal of the Medusa kind?

I do not consider the present species the Helix janthina of Linné or I. fragilis (afterwards communis) of Lamarck. That has a smaller and lilac-coloured shell, with a sharp peripheral keel ; and it is exotic. Our shell is the I. Brittanica of Leach's later MS., and I. communis of the Index to Wood's Supplement and of Brown's Illustrations; the young has been figured and described by Reeve as I. Smithice. One manuscript name is as good as another; in adopting rotundata I select the oldest.

Other species which have been carried northwards by the Gulf-stream, and driven ashore on our southern and western coasts, are I. communis, I. globosa of Swainson (a tropical species), I. pallida of Harvey (Straits of Magellan), and I. exigua of Bruguière, from Chili and the South Atlantic. With respect to the last species, the late Professor Harvey told me that he once received a box of specimens, at least 500 in number, which a relation of his had picked up in a single day on the beach at Kilkee in county Clare, not one of them containing
the animal. Several Spirula were found at the same time. It shows the capability of certain shells keeping afloat during so extensive a voyage and for such a long time as must here have been the case. No species of Ianthina, except rotundata, has been noticed on our shores with the animal, alive or dead, in its shell.

## Family XVIII. STILIFE'RIDA, (Styliferidce)

 H. \& A. Adams.None but the typical genus Stilifer being known, it is superfluous to repeat the characters, which will be presently given in the generic description. This family is evidently distinct from any other, in respect of the quasi-parasitic habits of the animal, its tongueless and suctorial mouth, and the absence of an operculum.

## Genus STI'LIFER*, Broderip. Pl. III. f. 2.

Body spiral, corered with cilia : mantle folded on the rightband side, so as to form a slight branchial canal, and spread over the base of the shell: head snout-like, furnished with side-lobes, and terminating in an unarmed and suctorial mouth : tentacles cylindrical: eyes sessile, placed on the neck behind the tentacles : foot tongue-shaped, and partly tubular, with a slit in the sole : gill onc only? Sexes separate.

Shell oval or elongated, not umbilicate: spire compact, with a stiliform and excentric apex: mouth roundish or oval ; lips disconnected: operculum none.

The shell resembles the nucleus of that of Ianthina; and the animal is also destitute of an operculum ; but

[^77]that mollusk has a denticulated or spinous tongue, and the body is not ciliated. Their habits also are very different. Eulima, although allied to the present genus, has a smooth body and an operculum, and it is not parasitic ; nor is the apex of its shell style-like or irregular.

For the discovery of this curious mollusk science is indebted to the indefatigable labours of Dr. Turton. In the 'Zoological Journal' for October 1825 an article by him, entitled "Description of some new British Shells," comprised one which he named Phasianella stylifera, and of which he says, "we found a dozen of these beautiful little shells alive, and attached to the spines of the Echinus esculentus, dredged up in Torbay." Not many years afterwards Mr. Broderip made known the peculiar nature of the animal, in consequence of Mr. Cuming having brought home, amongst other conchological rarities, specimens of another species (S. astericola) burrowing or imbedded in a tropical kind of starfish. Mr. Arthur Adams subsequently published an account of another species ( $S$. ovoideus) having the same apparently parasitic habits; and our British species (S. Turtoni) has been repeatedly observed attached to several kinds of Echinus. Another species (S. Orbignyanus) having been detected by M. Hupé enclosed in the basal portion of the spines of a Cidaris, which had been enlarged for its accommodation, Dr. Fischer suspected that Stilifer is not a true parasite, and does not feed on the Echinoderms infested by it. I have come to a similar conclusion, from a careful and long-continued observation of living individuals of S. Turtoni ; and I believe that Stilifer subsists on the excretions of Echinoderms. This opinion is founded on the facts that all the Stilifers, British and forcign, which I have seen (and they were numerous) invariably occupied only the area of
the vent or anal orifice of Echinoderms, and that some which I watched with close and almost unremitting attention for many hours, although they were most lively, nestling or slowly crawling about among the spines of an Echinus, never attempted to touch with the proboscis or mouth either the protruded suckers or the pedicellarice of the Echinus, or any part of its investing membrane. As far as I have been able to observe, the Stilifer does not put its host to the slightest inconvenience. No Stilifer has been noticed in any other habitat; and its connexion with seaeggs and starfishes is evidently neither accidental. nor merely for the purpose of shelter. The suctorial proboscis, as well as the want of a denticulated tongue in S. Turtoni, strengthens the supposition that its food consists of extremely soft or semifluid matter, and not of organisms which have any degree of solidity. Dentalium, which preys on hard-shelled Foraminifera, has a complicated lingual apparatus; and even the little Rissoa, that feeds on seaweeds, often of the most delicate and filmy texture, possesses a pair of horny jaws, besides a tongue armed with a strong central tooth, flanked on each side by a formidable row of serrated lateral teeth. Stilifer has nothing like a jaw or tooth. For these reasons I do not consider Stilifer a true parasite, nor yet an epizoic organism, like Montacuta substriata, deriving its nutriment from the vicinity of the animal to which it attaches itself-but as holding an intermediate relation. Its scavenger-habits are not unlike those of the dung-bcetle. I would recommend those who care to pursue this inquiry to consult Hupés paper in the 'Rcrue et Magasin de Zoologie' for March 1860, and Fischer's monograph on the genera Stilifer and Entoconcha in the 'Journal de Conchyliologie' for April 1864. They may also see in the 'Report
of the British Association,' published in 1865, some further remarks of mine on the subject. In the 'Record of Zoological Literature' for 1804 Mr . Greene says that the "opiaion" which I have above expressed is "by no means proven." It is impossible to prove an opinion ; but the facts on which mine was based remain undisputed. The spawn of S. Turtoni is deposited on the upper surface of the Echinus on which it settles. Although the present distribution of Stilifer is very extensive, no species appears to have been discovered in a fossil state.

Various have been the positions which conchologists have from time to time assigned to this remarkable mollusk in their systems of classification. Turton, as we have seen, placed it in Phasianella ; Fleming in Velutina, although he pointed out the incongruity of the allocation; Reeve at first between Turritella and Cerithium, but recently between his Canalifera and Turbinacea; Macgillivray among his Turbinina, next to Lacuna; Forbes and Hanley, as well as Woodward, in Pyramidellida; H. \& A. Adams as a distinct family between Eulimida and Cerithiopside; Clark in Pyramidellidee, between Actis and Scalaria; and Gray also in the same family between his genus Hyala (Rissoa vitrea) and Entoconcha. I am inclined to agree with Messrs. Adams in making Stilifer the type of a separate family ; but it is much more difficult to say to what other families it has the nearest affinity. Pyramidellide, as represented in our seas by Odostomia, ought not to be far off; and Ianthinide have similar relations to it, in respect of the nuoleus or apex of the shell. Homalogyra has sessile eyes, placed on the neck, as in Stilifer, and it is also finely ciliated all over; but in that genus the animal has no tentacles, and the shell is discoid and
operculate. The presence or absence of an operculum is, to a limited extent, a good generic character, although certain allied genera (c.g. Mangilia and Conus) comprise species some of which have an operculum and others not. The stiliform spire in the present genus, although remarkable, is not peculiar to it, nor to Odostomia or Ianthina. Melampus bulleoiddes has the apical whorls formed in the same mammillated fashion; and in several genera of the Bullida the shell exhibits the same feature. These, however, may be regarded as cases of aualogy rather than of affinity. The first formed whorls or nucleus of the spire, in many univalves, cease to be occupied by the animal after it has attained a certain growth, being too small for its requirements,-like a householder, who usually moves, once at least during his life, into a tenement larger than the one he at first inhabited. In the case of the Mollusca above referred to, the original and now useless tenement remains affixed to the new one ; but in Bulimus decollatus, some species of Clausili', and in Truncatella truncatula the topmost story is knocked off and replaced by another roof. Cacum glabrum and C. trachea even undergo a partial metamorphosis, the shell of each having at first a regular spire, and when this is lost becoming a slightly curved cylinder. The genera Leptoconchus of Rüppell and Campulotus of Guettard (Magilus of De Montfort) also appear to be related to Stilifer in their quasi-parasitic habits. The first-named genus is destitute of an operculum, except in its younger state; the second has an operculum at all ages. The conjecture of the late Professor D'Orbigny that Stilifer ought to merge in Eulima, because the latter may likewise be parasitic, has no foundation. It is true that species of Eulima have been found in the stomachs of Holothurie; and the " trepang,"
or dried "bêche de mer," of which the Japanese are so fond, frequently contains these shells. But this is not a case of parasitism : the Eulima feeds the Holothuria, instead of feeding upon it.

The name of this genus has been of late years, probably from carelessness, incorrectly spelt with a $y$, viz. Stylifer. Although the Greek orthography is followed in our word style, the Latin word is stilus, and not stylus ; it is, of course, from the Latin that Stilifer is derived. Broderip was too good a scholar to have made such a mistake. It has been lately suggested that the name is compounded of the Greek words $\sigma \tau \hat{v} \lambda o s$ and $\phi \epsilon \rho \omega$; but if that were so the name would be Stylipher, as in œenophorum. Whether it is correct to form a generic name with an adjective, may be open to doubt; but use has sanctioned it in the present instance, as well as in Sjnirifer, Stiliger, Lobiger, Ianthina, Vitrina, and many other names of general acceptation. Fleming suggested that the Phasianella stilifera of Turton " should probably constitute a new genus-Stylina." This was prior to Broderip's publication. However, Fleming's suggestion was not accompanied by any diagnosis ; and the name Stilina had been twelve years previously engaged by Lamarck for a tropical genus of stony Polypes. Its adoption for the mollusk also would, moreover, be contrary to the law of usage, Stilifer having now been recognized for between thirty and forty years. I am aware that this is one of the questions of scientific nomenclature upon which naturalists are by no means agreed. I do not pretend to set myself up as a judge, and my opinion may be taken for what it is worth.

## Stilifer Turtosi**, Broderip.

Phasianella stylifera, Turton in Zool. Journ. ii. p. 367, t. xiii. f. 11. Stilifer Turtoni, Brod. in Proc. Zool. Soc. 1832, p. 61. Stylifer Turtoni, F. \& H. iii. p. 296 , pl. xc. f. 8,9 , and (animal) pl. OO. f. 5.

Body white and delicately stippled ; cilia innumerable, arranged in scale-like bundles, and in constant action: mantle thickened at its edges ; canal terminating in an oval or roundish hole: heud-lobes (which perhaps may be expansions of the foot, as in Natica) rounded and flattened, nearly transparent, one on each side, and placed a little below the mouth: snout rather long Then extended, but usually folded or curling inwards, like an elephant's trunk. slightly bilobed at the extremity; it lies between the tentacles and the foot: tentacles club-shaped, somewhat compressed, thick, and rather long, sometimes enlarged towards the tips (which are blunt), widely diverging, but united at their bases; they are more or less strangulated or constricted, usually at about one-fourth of the distance from their bases; the cilia with which they are corered seem to produce a circulating current : eyes exceedingly small, placed at some distance behind the tentacles: foot clongated, in front bulbous and forming a creeping disk, behind somewhat tubular and tapering to a fine point; the sole is slit backwards down the middle for more than three-fourths of its length, the opening or commencement of the slit being of an oral shape: male organ spiked and resembling an auxiliary tentacle.

Suexl globosely conical or oval, with an obliquely rounded base, thin, semitransparent, and lustrous: sculpture, microscopical and flexuous lines of growth, and a few extremely slight and indistinct spiral strix: colour light reddish-brown or amber, which appears to be superficial, as it soon fades and becomes whitish : spire divided into two parts, the first-formed part or nucleus consisting of a minute and rery short cylinder, which is erect, although tristed slantingly in different directions; the otlier part or main body of the spire is short and abruptly separated from the nucleus: whorls $3-4$ (besides 2-3 which compose the stiliform apex), very tumid, and rapidly enlarging: the last is enormous in proportion to the others: suture rather slight, but distinct: mouth more round than oral. not much expanded at the base: outer lip thin, inflected just below the periphery, whence it slopes obliquely downwards: inner lip consisting of an almost invisible film on the upper

[^78]part, thicker below and folded back over the pillar, which is decply curved and flexuous. L. 0.15. B. 0.1.

Habitat: On Echini in several parts of the British seas, from 20 to 80 f : : viz. on E. esculentus, Linn., or $E$. spheera, Müll., Torbay ('Turton); on E.saxatilis, Linn., or E. miliaris, Lam., Plymouth (Stewart and others) ; on trawl-refuse containing E. esculentus from Plymouth (J. G. J.); Falmouth (Miss Vigurs, ficle Cocks) ; Filey (Miss Backhouse, fide Leckenby); on E. saxatitis, Scarborough (Bean) ; on $E$. esculentus, Cullercoats (Alder); on $E$. saxatilis, or an allied species for which Mr. Norman has proposed the name of pictus, Sunderland (Howse); on E. esculentus, Berwick (Johnston) ; on E. Dröbachiensis, Müll., or $E$. neglectus, Lam. (if the former is not $E$. Flemingii of Ball), Shetland, 40 miles N.E. of the Whalsey Skerrics, in 78 f. (J. G. J.); Dublin, mised with Lacuna divaricata (IImphreys). The shell described by Professor Macgillivray, in his 'Molluscous Animals of Aberdeen, Kincardine, and Banff,' as Stylina stylifera, and stated to have been found by one of his pupils " adhering to an Actinia brought up by the lines," was the young of a common West-Indian land shell, belonging to the Cyclophorida. The habitat alone might have induced a suspicion that this shell was not our Stilifer ; and I had an opportunity of ascertaining what it really was. The foreign distribution of S. Turtoni is little known. According to Lovén it inhabits $E$. neglectus on the Swedish and Norwegian coasts; Asbjörnsen found it on E. esculentus at Dröbak and from fishinggrounds at two other places in Christianiafiord; Sars in Finmark; Malm on E. neglectus at Löken in the Götha estuary; and $\mathrm{M}^{\prime}$ Andrew in the Canary Isles. Fischer has recorded it as not uncommon on $E$. lividus near the mouth-onening; but he cites no authority for
such a strange habitat. E. lividus excavates holes in slate and gneissic rocks, within tide-marks, its mouth and the whole of the lower surface being pressed closely to the stone. A parallel instance of the same species of mollusk infesting different Echinoids is that of Montacuta substriata, which has been obscrved not only on Spatangus purpureus, but also on S. meridionulis, Amphidetus ovatus, Brissus lyrifer, Echinus esculentus, and Cidaris lystrix.

The Shetland specimens (a pair) were attached by the foot to an Echinus, on its upper surface at the base of the spines. They did not adhere firmly to the Echinus, like the Caligus to a codfish, but frequently shifted their places by creeping between the spines. I gently moved one of the specimens with a stiff camel's-hair brush, and placed it in a glass tube with sea-water. It was at first very sluggish or timid, and evidently unaccustomed to its new quarters, and lay at the bottom of the tube; it afterwards recovered itself, and crept up the side by means of the anterior portion of its foot, very slowly and by an imperceptible movement; the other part of the foot was not applied to the glass, but rested on the mantle. The foot was occasionally twisted about and contracted, as if through aueasincss. The animal was nerer wholly withdrawn into the shell, although I irritated for that purpose. The slit in the foot probably serves for the admission of water into some tubular cavity or vessels which permeate this organ ; it would have the effect of enlarging and swelling the foot, so as to protect the Stilifer from being crushed by the spines of the Echinus. The force exerted by the Echinus in moving its spines may be insufficient to counteract even the slight pressure of the Stilifer against them at their base. The upper part of the sea-egg was covered
with about 40 clusters of spawn, in various stages of development, evidently belonging to the pair of Stilifers above mentioned. The fccundity of this specics must be very great; and the shell therefore ought not to be rare. I counted at least 100 fry in one of the clusters of spawn; so that one sea-egg would yield in a single year a prospective harvest of 4000 specimens-enough to supply almost all the conchologists in the world, unless some of them were more greedy than usual. Moreover one of the adult Stilifers appeared to be full of spawn, which was perceptible through the transparent shell. Since an Echinus could barely accommodate half a dozen individuals when they arrived at maturity, what would have become of the rest, supposing they escaped being the prey of other animals? Would they have migrated, and formed colonies on other sea-eggs? The Stilifer possesses both a foot and cyes; and appropriate quarters are by no means wanting in the same part of the sea-bed whence I procured the specimens which have given rise to the above remarks. The spawn-masses are oval, each enveloped in a gelatinous case. When detached, and examined under a microscope, the fry was seen to have three lobes, the larger two of which were in front; the lobes were finely ciliated, the cilia being rather long, and their points sometimes touching the surface of a small glass tube which contained the detached fry. These rapidly whirled about by the aid of their cilia, on which they now and then rested. They occupied nautiloid shells of a single whorl, into which (unlike the adult) they were capable of entirely withdrawing. The embryogeny of Stilifer has also been noticed by Dr. Otto Semper in Siebold and Kölliker's 'Zeitschrift für wissenschaftliche Zoologie' for 1864, and placed by him in the same category with that of Eulima and So-
larium ; but he scarcely gave any other result of his observations. The late Mr. Stewart of the College of Surgeons (whose untimely death is still deplored by all who study the British Echinodermata) was of opinion that S. Turtoni infests Echini for the sole purpose of depositing its spawn. We know, from the observations of Mr. Peach, that Lamellaria perspicua resorts to the shore between tide-marks at Wick, every spring, and makes a nidus for its spawn in Leptoclinum punctatum, one of the compound Tunicata. But Lamellaria is not, like Stilifer, restricted to a particular habitat. 'Ihe former attaches itself to the underside of loose stones, and is also found generally distributed orer the sea-bed, except perhaps in the spawning-season. Tery few individuals of the species of Echinus on which S. Turtoni has beeu taken are covered with spawn; and Stilifers of all ages, from one to half a dozen, occur on Echini, and nowhere else. The Shetland specimens are larger than those from Plymouth. One found by Miss Backhouse is said to be $\frac{3}{8}$ of an inch long; I have not seen it. Mr. Alder has failed to detect, notwithstauding repeated examination, any traces of a denticulatiou or spinous tongue. He says that " the otolites are circular, with a central dot, that the gill consists of a single series of triangular lobes, and that the mouth breaks up into squarish angular fragments, not crystalline, perhaps horny."

The name of the present species has been spelt in two ways. We have S. Turtoni of Broderip and S. Turtonii of Lovél. The former seems to be correct, according to a precedent of inverted translation which we find in the case of Galenus becoming Galen. I am not aware, however, of any rule for Latinizing modern proper names. Euphony is often consulted in such matters, and is preferable to pedantry-although it would
certainly be desirable to have a uniform mode of spelling. Some purists contend that the specific name given by the discoverer, if subsequently adopted as generic, ought to be also retained; so that our shell would be Stilifer stilifer. Examples of such a reduplication of the name under similar circumstances occur in Volva volva and Turricula turricula. But it would be very inconvenient to substitute the generic name for that of Turtoni, which is so familiar to all conchologists,-to say nothing of the inelegance of this method of nomenclature, or of its being contrary to one of the rules recommended by a committee of the British Association. Dr. Johnston called this species Stylifer globosus, and Brown Stylifer astericola : the latter confounded it with the tropical species of that name.

## Family XIX. EULI'MID®, H. \& A. Adams.

This, too, is a case where the description of the typical genus will suffice. I do not know any other; Leiostraca, H. \& A. Adams (not Leiostracus, Albers), which has Eulima bilineata for its sole representative, is undistinguishable from Eulima.

$$
\text { Genus EULI'MA*, Risso. Fl. III. f. } 3 .
$$

Body spiral and smooth : mantle having a rudimentary branchial fold: snout forming a bilobed flap or mentum : proboscis long, cylindrical, and retractile ; it consists of an outer and inner tube: tentacles awl-shaped, approximating at their bases: eyes almost sessile, placed at the external bases of the tentacles, or nearly behind them on the neck: foot lanceolate, doubleedged, as well as truncated and usually bilobed in front: gills supposed to consist of a single plume. No tongue. Male organ small, flat, and curved like a sickle.

* A compound of a Greek and a Latin word, signifying finely polished.

Siect awl-shaped, many-whorled, polished and lustrons, not umbilicate: spire finely tapering to a regular point, with an extremely slight suture or line of separation between the whorls: mouth pear-shaped; lips discontinuous: operculum horny, with a short and incomplete spire, haring its nucleus on the columellar or inner side.

From the absence of a spinous tongue, or" odontophore," it may be inferred that the mode of feeding is suctorial, as in Odostomia and Stilifer. It also shows that this organ is not indispensable for the classification of the Gastropoda. Forbes says that the animal of Eulima creeps with the foot greatly in advance of the head, which is almost always concealed beneath the front edge of the shell, the tentacles alone protruding. Scacchi and Philippi noticed the peculiarity of the eyes being apparently withdrawn, and peeping out under cover of the shell. The shell has an enamelled surface, shining like porcelain. There are many species, recent and fossil. None inhabit very high latitudes.

Other names of this genus are Pasithea, given by Dr. Lea, and Balcis, by Dr. Leach.

## 1. Eulima polita* ${ }^{*}$, Linné.

Turlo politus, Linn. S. N. p. 1241. E. polita, F. \& H. iii. p. 229, pl. xcii. f. $1, \stackrel{2}{2}$, and (animal) pl. KK. f. $3 a, 3 b$.

Bony whitish; front tinted with pale yellow, and more or less speckled with golden-yellow or bright orange: mantle Heshy, with a plain margin, not reflected over any part of the shell: snout or mentum flattish, not much extended, marked with a golden-yellow streak, like the letter V inverted: proboscis strap-shaped: tentacles short, but slender, and pointed, slightly diverging outwards; every part except the base is streaked lengthwise with golden-yellow or orange, and the whole is corered with a transparent gelatinous sheath: eyes large, black, and round, placed close together on siight and minute eminences, each of which is encircled by a ring of

* Polished.
golden-5ellow, on a level with the base of the tentacles ; this part is seldom protruded, although the eyes are conspicuous through the shell: foot small and mostly short, squarish and broader in front, with angular corners or lobes edged with yellow, narrower towards the middle, and sharply rounded behind; the inmer fold or groove formed by the front edges is closely lined with vibratory cilia in constant and rapid motion; sole flake-white, slightly furrowed down the middle: gill or branchial plume small, narrow and finely pectinated, having $12-15$ short strands with a central vein; it issues on the left side and ascends obliquely to the right: liver purplish.

Shell club-shapêd, solid, opaque, and extremely glossy: sculpture, none if examined with a hand lens; but the microscope shows the entire surface to be covered with countless and close-set longitudinal strix, which are crossed by less numerous and distinct but equally fine spiral lines, so as to produce a partial decussation; the periphery is more or less keeled or angulated, especially in immature specimens : colour ivory-white: spire long, somewhat cylindrical, and sharppointed; the upper part is occasionally curved: whorls $15-18$, nearly flat, compact and gradually enlarging, except the last, which occupies about one-third of the spire; the first is semiglobular, and it appears to be inverted and to have a bright spot or nucleus in the centre: suture slightly oblique, defined more by the darker colour of the line where one whorl envelopes the periphery of the next above it than by any groove: mouth acute-angled above, widening and expanded below; its length cquals about one-fourth of the shell: outer lip flexuous, with a rather thick edge, not inflected on the periphery, but sloping from it downwards: inner lip consisting of a broadish porcellanous deposit, which is considerably thickened behind the pillar; this last is flexuous: operculum thin, pale yellowishhorncolour, marked with microscopical and numerous flexuous striæ in the line of growth. L. $0 \cdot 75$, B. $0 \cdot 2$.

Habitat: Every part of the British scas, from Unst to Jersey, in muddy sand, $7-50 \mathrm{f}$. ; Mull of Galloway 145 f. (Beechey). Fossil in post-glacial beds, Norway, 50-80 ft. (Sars), Red and Coralline Crag (Wood), Sicily (Deshayes and Philippi), Miocene formation near Vienna (Hörnes). It ranges from Finmark (Sars) to the Egean (Forbes), at depths varying from $2-80 \mathrm{f}$.

A closely allied species, from Puget Sound, has been described by Dr. P. Carpenter, in the 'Proceedings of the Academy of Natural Sciences of Philadclphia' for 1865, as E. micans; respecting which he observes, "An E. politue varietas Pacifica?"

This would be a beautiful object for the aquarium, with its peneilled tentaeles, golden markings, and its bright eyes peering through the porcelain shell, which slowly trails along the ground. The spire is seldom perfect: the top whorls, being useless, are broken off; and the truncated portion is covered by a shelly plate, formed by the hindmost lobe of the mantle. I have a specimen coutaining the animal, but having only three whorls left. Sometimes the sheil exhibits several varices, caused by a repetition of the outer lip at successive periods of growth. My largest example is more than an inch long and of proportionate breadth.

It appears to be the Turbo levis of Pennant, and is the Strombiformis albus of Da Costa, Rissoa Boscii of Payraudeau, E. elegantissima (aud perhaps also E. glaberrima) of Risso, Melania Gervillii of Collard des Cherres, and E. anglica of G. B. Sowerby.

## 2. E. interme'dia*, Cantraine.

E. intermedia, Cantr. Mral. Mréd. (Suppl.) p. It.

Body milk-white: mantle rather thin; edges even with the mouth of the shell: tentacles cylindrical, rather short and diverging, with blunt tips : eyes small and black, placed close together on short bulbs; they are always conspicuous (and open ; do mollusks ever sleep?); each is encircled by a darkorange disk: foot shortish, slightly cloren in front, and bluntly pointed behind, expanded towards the sides.

Sheir smaller than E. politu, having a narrower base, and consequently more spindle-shaped; it is not quite so solid,

* Intermediate, i.e. between E. polita and E. distorta.
and live specimens are semitransparent: sculpture consisting of extremely fine and obscure microscopical spiral lines only; there is no peripheral keel at any stage of growth : colour less white in live specimens: spire proportionally shorter, and never twisted: whorls $15-16$, more compact and less flattened than in the other species: suture marked by a broad clear band: mouth narrower: outer lip rather more deeply sinuated above : inner lip slighter and thinner. L. 0.45 . $13.0 \cdot 125$.

Var. rubro-tincta. Half the usual size and sometimes a little curved; upper part exhibiting the pink ramifications of the liver.

Habitat : With the last species, from 20 to 73 f., in Shetland (J. G. J.) ; west of Scotland (Barlee, Norman, aind J. G. J.) ; Coquet and Berwick Bay (Mennell); Arran Isles, co. Galway (Barlee) ; Cork (Humphreys); Exmouth (Clark) ; Plymouth (Barlee); Falmouth (Miss Vigurs, fide Cocks) ; Guernsey (Barlee and J. G. J.). The variety occurs in Loch Fyne, Shetland, and the Channcl Isles. Red Crag at Walton-on-the-Naze (Wood) ; Palermo (Philippi) ; tertiaries of Sienna and Pelora (Cantraine) ; upper Miocene at Biot near Antibes (Macé). Distributed in a living state along the coasts of the North Atlantic, from Finmark (Sars) to the Canary Isles (M'Andrew), and throughout the Mediterranean (Cantraine, Philippi, and others) and Adriatic (Brusina) to the Agean (Forbes) ; the recorded depths range from 15 to 60 f .

The animal floats; and it remains suspended in that posture, by means of a byssal thread, the operculum then closing the mouth of the shell. It differs from that of E. polita in the tentacles being white instead of tipped with orange; nor has the head-flap any coloured V-shaped mark. The upper whorls of the shell are empty in this and every other species of Eulima that I have observed in a living state.

I am inclined to refer to this species the E. subulata
of Risso. Philippi described and figured our shell as E. nitida, under the impression that it was the Melania nitida of Lamarck ; but that is much more slender, and belongs to the Paris Basin. Although all the colourless Eulime are much alike, it must not be forgotten that the fauna of the Eocene period was very different from that which now exists in temperate latitudes.

## 3. E. Distor'ta*, Deshayes.

Melania distorta (Desh.), Philippi, Moll. Sic. i. p. 158, t. ix. f. 10. E. distorta, F. \& H. iii. p. 230, pl. xcii. f. t, $\overline{0}$, und (animal) pl. KK. f. 4.

Body whitish, mottled with reddish-brown [" rubrum " (Philippi) ; "Jellow, beautifully variegated with carmine, which forms an irregular band on each side" (Alder); "flakeor pure white, and the anterior part of the body is marked irregularly with 15-20 distinct minute red dots" (Clark)]: snout, or mentum, narrow and projecting bejond the foot: tentocles long and slender, placed close together at their origin, and diverging at an acute angle ["white" (Alder); "the bases and about a third of their lower parts of a brilliant vermilion colour" (F. \& H.)]; tips flake-white, and bulbous: eyes black, placed on slight bulgings of the tentacles at their outer base ["parvos" (Philippi); "rery large" (Alder)]: foot elongated, rounded in front, and bluntly pointed behind: [liver "green" (Alder) ; " yellow, red, pinik, light-green and white" (Clark)].

Sirell much smaller, slenderer and thinner than either of the foregoing two species; it is nearly transparent: sculpture, none to be detected, even by the aid of the microscope: colour clear white: spire narrow, more or less curred, so as to give the shell a distorted appearance: whorls 10-15, flattened : suture marked by a fine line: mouth as in $E$. intermedia. L. 0.2 . B. 0.05 .

Var. gracilis. Rather larger, more tapering, and scarcely (if at all) distorted. F. \& H. iii. p. 233 , pl. xeii. f. 6.

Habitat : Widely diffused (although local) from lowwater mark of equinoctial tides in rock-pools, among

Zostera and understones, at Jersey, to a saudy bottom in the greatest depths of the North Sea. The variety inhabits deep and sheltered water at Oban, and in Loch Fyne and Shetland. Sars has enumerated this species as a post-glacial fossil from a shell-bank at Kirköen in Norway, 50 fect above the present level of the sea, and Calcara from Altavilla in Sicily; Macé found the variety in an upper Miocene bed at Biot near Antibes. Both the typical and varietal forms are generally distributed in the North Atlantic, from Finmark to the Canaries, as well as throughout the Mediterranean, Adriatic, and Archipelago, at depths of from 10 to 140 f . A Mazatlan shell in Mr. M'Andrew's collection, from Dr. P. Carpenter, cannot be distinguished from ours.

This species was evidently known to Montagu; for he says, "minute specimens [of E. polita] are sometimes found on oysters and scallops. In this infant state they are of exquisite polish, and when the animal is alive, frequently appear mottled with pink and palegreen; are also somewhat arcuated and very seldom found perfectly straight." The discrepancies in the several descriptions of the animal which I have collated show a considcrable variation of colour; Clark's and mine agree best with that of Philippi in Wiegmann's Archiv for 1841, viz. that the body is ornamented with purple-red or crimson confluent spots and points, which colouring extends to the base of the tentacles. The animal is agile, and swims well for a mollusk. Malm tells us that the easiest way to procure specimens is by allowing the dredged silt to stand in a tub for an hour, when they may be seen floating on the surface of the drained water. The shell is sometimes truncated to such an extent as to have only four whorls left, the uppermost being plugged off.

I consider this species to be the Rissoa sinuosa of Scacchi, although Philippi makes that a synonym of his E. nitida. Chiereghini named it Turbo curvatus, and Leach Bulcis arcuata. Macgillivray mistook it for E. polita.

> 4. E. steno'stoma*, Jeffreys.
E. stenostoma, Jeffr. in Ann. \& Mrg. N. II. 3rd ser. ii. p. 128, pl. v. f. 7.

Bodr milk-white: mantle thin, stippled with lrown: snout crescent-shaped, bilobed, flexible, and transparent, projecting a little beyond the foot: tentucles rather long and slender, with rounded tips: ther diverge at an angle of abont $25^{\circ}$; at the base of each is a patch of flake-white: eyes entirely wanting in all the specimens (at least a dozen) examined by me at different times: foot broad, squarish, and slightly bilobed in front, narrowing behind to a bluntly rounded point.
Sferil spike-shaped, slender, thin, transparent, glossy and of a brilliant lustre: sculpture, extremely slight and close-set spiral lines, which are discernible only under the microscope and in certain lights; the surface when examined by the aid of a strong lens or hand magnifier appears quite smooth and polished: colour milk-white: spire clongated, ending abruptly in a blunt and semiglobular point: whorls 9 , drawn out and gently swelling; the last occupies nearly one-half of the spire: suture oblique, defined by a rather broad hem or border of flakewhite, which is encircled underneath by a clear and narrow line ; this hem or border arises from a thickening of the shelly material to form the suture or commissure: mouth narrow. extending from a sharp angle abore to an expanded and rounded base; the inner or columellar side represents a very obtuse angle : outer lip fexuous, with a rather thin edge, receding at the top and advancing outwards towards the base: inner lip reflected and twisted over the lower part of the pillar: operculum filmy, pale yellowish-horncolour, marked with slight flexuous strix in the line of growth. L. $0 \cdot 35$. B. 0.055.

Habitat: Fine sandy mud, in 75-90 f., $45-50$ miles S.E. by E. of the Whalsey Skerries, Shetland (J. G. J.); 30 miles off the same coast, in 82 f . (M'Andrew). Upper Norway (Lovén and M'Andrew).

[^79]It is as beautiful as it is searce. The animal is active, and will not stay in the water. Ovary of a bright pink hue; I did not observe it in every individual. The liver is orange. No eyes could be detected, although they were very conspicuous in specimens of $E$. distorta and E. bilineata (both of smaller size than the present species) taken at the same time and from the same ground ; nor could such organs be subcutaneous, because the tissues of the animal are transparent and were thoroughly examined. The shell rcsembles a large Achatina acicula.

## 5. E. subula'ta*, Donovan.

Turbo subulatus, Don. Br. Sh. pl. clxxii. E. subulata, F. \& H. iii. p. 235, pl. xcii. f. 7, 8.

Shell awl-shaped, rather thin, semitransparent, of a polished lustre: sculpture, numerous fine spiral lines, visible only under the microscope; examined as a transparent object, the texture appears delicately stippled in the line of growth: colour yellowish-white, variegated by narrow tawny spiral bands, which are arranged on the body-whorl in 3 double sets or pairs, one below the suture, another round the periphery, and the third encireling the base; these sets are sometimes more or less confluent, so as to form single broad belts, or they diverge near the mouth, in which latter case the outer edges unite and the bands are not continued to the outer lip; each of the succeeding six whorls has only 2 bands: spire tapering to a fine point: whorls $12-13$, rounded but compressed, the last occupying about threc-sevenths of the spire: suture oblique, defined by a narrow dark line: mouth contracted, acute-angled above, and rounded but not much expanding below ; edges thickened: outer lip folded inwards at the upper part, and slightly flexnous: inner lip reflected over the whole pillar, which is decidedly flexuous: opercutum very thin, pale drab, and rather coarsely striated. L. 0.5. B. 0.1.

Habitat : Coralline zone in Devon, Dorset, and Corn-

* Awl-shaped.
wall ( Da Costa and others) ; estuary of the Dce (Collingwood) ; Isle of Man, 25 f . (Forbes) ; Scarborough (Bean); Anglesea (M'Andrew); Bantry Bay, sometimes in the gizzard of Scaphander lignarius (Humphreys) ; dredged of' Cork (MI'Andrew) ; Youghal and Dublin (Ball, fide Thompson); Dundrum, co. Down (Thompson); Orkneys, 12 f., and Shetland, 5-90 f. (Forbes). I suspect that all the more northern localitics should be referred to $E$. bilineata, instead of to the present species. This is not the E. subulata of Searles Wood (a Crag shell), nor that of Nyst; and I doubt the identification with it of the species described and figured under the same name by Hörnes from the Miocene formation of Viemna. Our species occurs on all the coasts of France, Spain, Portugal, Italy, Dalmatia, Greece, and North Africa, from 2 to 140 f .; and $\mathrm{M}^{\prime}$ Andrew has taken it near Madeira in 18-24 f. The Norwegian localities given by Lovén and Danielssen for this species probably belong to E. bilineata.

It is the Strombiformis glaber of Da Costa. I do not know why all modern British conchologists have repudiated that specific namc. Donovan, with more ingenuity than ingenuousness, misquoted his predecessor, and endeavoured to show that the latter had contravened the Linneau rule by making the specific name a sentence instead of a single word. But such was not the case ; and Da Costas description is quite as appropriate and complete as that of Donovan. However, since the older name has never been adopted, I will not revive it. Payraudeau called it Melania Cambessedesii, G. B. Sowerby E. lineata, Forbes Melania Donovani, Renieri Turbo fasciatus, Mühlfcld (according to Philippi) Helix flavocincta, and Leach Balcis testacea. E. subulata of Risso and Delle Chiaje differ from this and from each other.

## 6. E. bilinea'ta*, Alder.

E. lineatce (as probably of Sowerby, but proposed to be changed to bilineata), Ald. Cat. Moll. North. \& Durh. in Trans. Tyn. Nat. Field Club, p. 47. E. bilineata, F. \& H. iii. p. 237 , pl. xcii. f. 9, 10, and (animal) pl. kK. f. 5.

Bodr whitish, with a faint tinge of yellow: snout rather narrow, seldom projecting beyond the foot: tentacles rather long: eyes small and black, persistent after death, when they are distinctly seen through the shell : foot having a slight earshaped expansion at each corner in front, finely pointed behind.

Snell a miniature resemblance of $E$. subulate, with 10-11 whorls. It is proportionally more solid and not so slender; and the coloured bands are fewer and differently arranged. The present species has a well-marked pair of bands round the middle of the last whorl, besides sometimes an obscure band just below the suture; and the upper whorls are encircled by a pair, or occasionally by a single band. The pair on the body-whorl converge (instead of diverging) towards the mouth. There is also in some specimens a tawny streak or blotch at the baso (apparently representing the lowermost sct of bands in the allied species), which stains the lower part of the pillarlip. The mouth is not so narrow, and the outer lip is more flexuous. L. $0 \cdot 3$. 13. $0 \cdot 075$.

Habitat : Locally but widely dispersed, from lowwater mark at Jersey under loose stones (Dodd), to 82 f . off the east coast of Shetland in muddy sand (J. G. J.). Montagu and many other writers mistook it for a small variety of the last species; and the published accounts of its distribution are therefore somewhat confused. The present species has been taken by Luovén, Sars, M'Andrew, and Malm on the Scandinavian coasts, at depths of foom 15 to 200 f . ; and Martin found it among the refuse of fishing-boats in the Gulf of Lyons. I have verified all these instances of foreign localities.

The animal crawls at a tolerably fast pace, and gets out of the water whenever it is immersed. My largest specimen is not quite ${ }^{4}$ to of an inch long. The

[^80]relation of this species to the last appears to be nearly similar to that which Tellina pusilla bears to T. donacina.

## Family XX. NATI'CIDE, Swainson.

Bodr spirally rolled into a more or less globular form : mantle rather thin: snout (or mentum) wedge-shaped. forming part of the front lobe of the foot: proboscis long and retractile, usually concealed: tentacles triangular, flattened, and pointed, widely separated, and pressed against the front of the shell by the anterior flap or extension of the foot: eyes either immersed in the skin (one at the outer base of each tentacle, and rery small) or wanting: foot thick and largely developed, folded back orer the front of the shell in the shape of a broad flap or hood, and behind over the base of the shell, so as to cover the greater part of it: gills divided into 2 plumes: orlontophore, or lingual riband, short and straight [rhachis 1-toothed; pleuræ having 3 uncini (Lovén)]. Sexes distinct: verge sickle-shaped.

Shell globular or inclined to oral, smooth or finely striated in a spiral direction : spire blunt, usually vers short: epidermis slight: mouth large, semicircular: outer lip thin: operculum ear-shaped and fer-whorled, with the spire on the inner side of the mouth, near the base of the pillar.

In gencral aspect the animal resembles that of the Bullide, especially in the hood-like expansion of the foot in front. But other parts, as well as the shell, are dissimilar; so that the relation of the two families may be merely one of analogy, such as occurs in many distinct groups of the Mollusca whose habits of life are the same. Both these families are zoophagous. The Naticidee live in sand. While preying on weaker shellfish, they are in their turn devoured by the flounder, haddock, and cod. It is geologically an ancient family, dating (according to M. Pictet) from the upper Silurian epoch. De Blainville called it Hemicyclostoma, Menke Sigaretea.

## Genus NA'TICA*, Adanson. Pl. III. f. 4.

For generic characters sec those of the family.
I thought of separating one species (N. Islandica), because it has a thinner shell and scarcely any umbilicus, and of adopting the genus Globulus of Sowerby, or Bulbus of Brown (not of Humphreys), for which Mörch lately substituted Amauropsis. But in all other characters, both of animal and shell, it agrees with Natica; and I have therefore considered it best, on the whole, not to increase the number of genera.

Probably the v $\boldsymbol{\nu \rho i \tau \eta s \text { of Aristotle, which Casaubon }}$ interpreted as natex. The shell was merely enumerated by Aristotle among univalves, and said to be inhabited by a kind of hermit crab. Of Nerites it is fabled that he was the son of Nereus and Doris, and that Venus, indignant at his refusal to accompany her to Heaven, metamorphosed him into a beautiful shell. Pliny would have us share his marvellously facile belief that the nerite swims with the mouth of its shell uppermost, raising the front or outer lip to serve as a sail, and thus catching the breeze. The word natice is therefore supposed to be derived from the natatory habit of this shell-fish, according to the Bolognese Professor, Aldrovandi, the fruit of whose laborious investigations of the natural history known to the ancients was not inferior to the similar compilation of Pliny. Natica seems thus to have acquired the vernacular synonyms of "Schwimmschnecke" in the German, and "svömskiæl" in the Danish language. The pretty spots with which some species of Natica (e.g.N.millepunctata) are ornamented attracted the attention of Olivi, who, in his 'Zoologia

[^81]Adriatica,' endearoured to explain the action of light and temperature on the colouring-glands of the Mollusca; but, although the development and intensity of colour may be stimulated by the above-mentioned agents, his conjectures contributed nothing to the elucidation of a problem so difficult as this. The observations of Baldassini ("Memoria sopra le conchighie considerate come parte integrante del corpo dei molluschi') show that the intensity of colour in a shell depends on the age, food, and health of the mollusk. Gould says that the Nuticae are very voracious, and play a conspicuous part in devouring the dead fish and other amimals which are thrown up by the tide. The small circular holes with which bivalve shells are often drilled are also (according to hini) the work of these Gastropods, and made by them to gain an entrance to the animal apparently so well secured against such a foe. Their foot is so large as to completely euvelope their prey. When moving, they burrow just below the surface of the sand ; and their resting-place is generally indicated by a small heap, resembling that made by a mole. The foot is permeated by numerous tubular cauals or ressels, which absorb water like a sponge (probably through pores opening inwardly) and thus cause this organ to be enormously disteuded. Mr. Osler suspected, with scarcely any reason, that Natica and Ianthina are insectivorous; he imagined that the foot of the one and the float of the other might be baits to attract the prey which these mollusks were unable to pursue! The eyes, when present, are subcutancous, and have escaped the notice of most naturalists; those of $N$. Alderi have been described by Mr. Clark. Being always covered, they can be of little, if any, use as organs of vision. The nidus or matrix of the spawn is strap-shaped and convoluted,
assuming a quoit-like form ; it is of a gelatinous consistency, but rendered tolerably firm by the admixture of grains of sand. These curious bodies may often be seen lying on the sand at low water of spring-tides in summer. They have been mistaken for zoophytes, and were placed by Solander and Ellis in the genus Flustra, by Pallas in Eschara, and by Lamarck in Discopora. "The cells are arranged in quincunx order" (Gould).

The Rev. L. Guilding (Linn. Trans. vol. xvii.) divided this genus into Natica and Naticina, the former having a shelly, and the latter a horny operculum. Gray proposed to adopt the genus Neverita of Risso for the species with a horny operculum; but Risso retaincd Natica for these, and his description and figure of Ne verita represent a different kind of shell (apparently Natica olla), which has the umbilicus closed by a solid pad. In all our species the operculnm is horny. Reeves's list contains 137 recent species of Natica. There are many obsolete generic synonyms.
A. Shell rather thin, with a produced spire; umbilicus small.

## 1. Natica Islan ${ }^{\prime} \mathrm{Dica}^{*}$, Gmelin.

Nerita Islandica, Gmel. ed. S. N. p. 3675. Natica helicoides, F. \& H. iii. p. 339, pl. c. f. 6.

Bony pale yellowish-white, minutely and closely speckled with flake-white: snout broad and large, with rounded corners: tentacles small; they cither project at the sides of the front foot-lobe, or are pressed back by it on the outer lip of the shell: eyes, none observable: fo'st narrower at the sides, expanded and forming short ear-sh.aped lobes in front, thicker and folded back behind into an argular point.

- Sifell conic oval, less solid than any other recent British species of Nutica, semitransr ${ }^{\text {parent, }}$ not glossy when fresh and

[^82]covered with the epidermis; base somewhat attenuated and angular: sculpture, apparently none; but the lens discloses numerous slight spiral strie, irregularly disposed and often wary; by the aid of a microscope may also be seen much more numerous and still finer lines of growth, which, however, do not produce any decussation of the surface: colour milk-white under the epidermis, which is pale-yellow or lemon-colonr in young specimens, brownish-yellow in the adult : spire turreted, abruptly and bluntly pointed : whorls $5-7$, rounded but compressed; the last occupies nearly fire-sixths of the spire; the first is very minute, and scarcely projects beyond the second: suture rather oblique, deeply and conspicnously channelled or grooved inwards, so as to leave a narrow ledge at the top of each whorl and to give the appearance of their partly overlapping one another: mouth eqnal in area to one-third of the shell, and in length to two-thirds of the spire, expanding and somewhat angulated at the base: outer lip incurred above, and joining the imer lip, which is spread over the pillar and almost conccals a narrow and small umbilicus : operculum thin, goldenyellow, minutels, very finely, and closely striated in the line of growth : whorls 4, defined by a raised edge or rim, the last disproportionately large. L. 1. B. O.Eढ̃.

Habitat : Rare, in the coralline zone, from 7 to 79 f., Shetland (Barlee, M‘Andrew, and J. G. J.); Orkneys (Thomas) ; Wick (Peach) ; Aberdeenshire (Macgillivray, Gordon, and Dawson); Banff (Edwards); Firth of Forth (Knapp); Berwick Bay (Johuston); Northumberland coast (King) ; Sunderland (Howse) ; Scarborough (Leckenby); Cork (Humphrcys). In most of these cases the specimens were caught by fishermen, or taken from the stomachs of haddocks. It occurs in most of our quaternary or post-glacial beds in Scotland, Ireland, and Yorkshire; Norwich and Red Crag (Lyell and S. Wood); Uddevalla (Lyell and others); Christiansund, 30-40 feet (Sars) ; Gardiner, in the State of Maine (Lyell). Recent in Scandinavia, Iceland, Faroe Isles, coasts of Russian Lapland and the White Sea, Spitzbergen, Greenland, Massachusetts northwards to Canada,

Icy Cape, and Behring's Straits, at depths ranging from 3 to 60 f .

It is more sluggish than any of the other Natica which I have examined. A specimen dredged by Mr. Barlee and myself in Shetland is more than an inch and a half long and an inch broad. Mr. Edwards of Banff got another specimen nearly as large from the stomach of a cod.

Olafsen and Povelsen accurately described this shell in the account of their journey through Iceland, 1772. The Latin part of this description was republished by Müller and Gmelin; and the latter gave a name to the specics. It is the $N$. helicoides of Johnston, N. canaliculata of Gould (not of Lamarck), N. exulans of Lovén's MS. (according to Gould), and N. cornea of Möller.
B. Shell more or less solid, with a short or compressed spire ; umbilicus of various sizes.

## 2. N. Grevlańdica*, Beck.

A. greenlandica (Beck), Möller, Ind. Moll. Gr. p. 7. N. pusilla, F. \& H. iii. p. 341 , pl. c. f. 7.

Body creamcolour. tentacles very short: eyes not perceptible, if any : foot smaller than in many other species.

Surll globose, resembling that of typical species of Helix, moderately solid, almost semitransparent, lustreless : sculpture, consisting only of extremely fine and obscure spiral strix and equally minute but more numerous lines of growth: colour white under the epidermis, which is creamcolour: spire short, slightly prominent: whorls $4-5$, tumid; the last occupies eight-ninths of the spire; apex always croded : suture nearly straight, very narrowly exeavated inwards: mouth equal in area to one-third of the shell, and in length to five-eighths of the spire, expanding and rounded or slightly angulated at the base: outer lip somewhat incurved above, and having a bevelled

[^83]edge: inner lip broad, considerably thickened on the lower part, and forming a callons ridge just below the junction of the outer lip with the periphery; it is reflected over the pillar and a great part of the umbilicus; this is narrow, and further contracted by a broad and obliquely twisted buttress, issuing outwards towards the base from the centre of the cavity on the side of the pillar: operculum thin, lemoncolour, closely and irregularly striated in the line of growth, and marked in every direction mith microscopical short and curved scratchlike lines; spire irregular, defined by a broad chalky-white suture, and terminating in a minute nucleus. L. O.S5. B. $0 \cdot 85$.

Habitat: Not uncommon in muddy sand, at a considerable distance from the coasts of Northumberland, Durham, and Yorkshire, in 40-60 f. (Bean and others); Shetland (Barlee). Fossil in the Scotch "drift" formation (Smith and others) ; 20-25 f. on the Turbotbank, co. Antrim (J. G. J.) ; Bridlington (Wood); Kelsey Hill, near Hull (Prestwich) ; Norwich Crag (Woodward) ; Uddevalla (J. G. J.); glacial and post-glacial beds in Norway, the former at 0-460 and the latter at 30-10 feet (Sars) ; "post-pliocene" deposits, Canada (Dawson). Recent on the coasts of Scandinavia, Faroe Isles, Iccland, Greenland, White Sca, and Sea of Okhotsk, north-east and south-west America, from the shore to 150 f .

It appears to be a delicate animal, as it soon dics when kept with other and more hardy molluslis. The fishermen at Staithes call it the "white snail." Mr. Howse tells me that it takes the bait freely, and that, when the lines are drawn, it gripes or drives the hook into its body and is thus caught. Very young specimens of this Natica have a semicircular pad on the ontside of the pillar, which projects over the umbilicus and covers part of it; this grows into the buttress or ridgelike process mentioned in my description of the shell.

It is the N. pusilla of Gould, but not of the original describer, Say, which latter species is oval and very much smaller than ours, having a calcareous operculum and the umbilicus completely closed by a pad. N. nana of Möller appears to differ from Say's shell merely in laving a horny operculum. Our shell is the N. livida of Bean, N. borealis of Gray, N. Gouldii of Philippi, N. alba and N. lactea of Lovén's MS. according to Philippi, and $N$. bulbosa of Reeve; probably also the N. Beverlii of Leach, being one of the " invertebrate animals discovered by HisMajesty's Ship Isabella" [!], and described in 'Sir John Ross's Voyage to Baffin's Bay.' It is difficult to decide, from the too short diagnosis given by Broderip and Sowerby, whether their N. pallida is the present species or N. Islandica. Mörch placed N. Grcenlandica in the genus Mamma of Klein, an olla podrida of Nerita, Natica, Dolium, Buccinum, Turbo, and Purpura. We cannot say of such systematists, "Et quo antiquius, eo melius."

## 3. N. sor'dida*, Philippi.

N. sordida, Phil. Moll. Sic. ii. p. 139, t. xxiv. f. 15; F. \& H. iii. p. 334, pl. c. f. 5,8 , and (animal) pl. PP. f. 3.

Body fleshcolour or pale tawny : snout strong and very large, whitish except at the extremity, which is reddish-brown : tentacles haring fine and tapering points: eyes, none perceptible: foot enormous, very slimy, truncated or cloven in front, and rounded behind.

Shell globose, inclining to oval, thick and solid, opaque, somewhat glossy : sculpture, minute, irregular, flexuous, and slight spiral lines, which are stronger or more conspicuous below the suture of the body-whorl and on the base: colour buff, passing into chestnut: epidermis thin, of a lighter shade than the main colour of the shell: spire short, slightly prominent; apex abraded or decorticated: whorls 5-6, tumid

[^84]and rapidly enlarging; the last occupies ten-elevenths of the spire; the upper part of each (especially of the body-whorl) is compressed or sometimes flattened, so as to present a bluntly angular edge in front: suture rather straight, very narrowly excarated inwards: mouth equal in area to nearly one-third of the shell, and in length to tro-thirds of the spire, expanding and decidedly angulated at the base: outer lip gently incurred above, and haring a blunt edge: inner lip broad and remarkably thick, forming above a callosity or small protuberance, which is separated from the outer lip at its origin by a short and shallow groove; it is reflected over the pillar and upper part of the umbilicus, and has a stain of pale chocolate ; the middle portion is spread further backwards and forms an angular pad: umbilicus rather large and decp, for the most part open; a broad ridge winds spirally inwards down the centre and towards the base of the shell; it exhibits also two or three parallel indistinct grooves and some strix: operculum horncolour, narrowly edged with pearl-white, microscopically and closely striated in the line of growth; last whorl (as usual) excessively large, defined by a white orerlapping suture; termination or nucleus of the spire concare. L.1.3. B. 1.2.

Habitat: Muddy sand in 7-90 f., Shetland (M'Andrew, Barlee, and J. G. J.) ; west of Scotland (Forbes and others); Moray Firth (Gordon); Firth of Forth (Knapp); Dunbar (Laskey); Exmouth, dredged with N. catena (Clark) ; St. George's Channel, between Scilly and the Smalls (M‘Andrew); Lough Strangford (Dickie); Dublin Bay (Kinahan); Youghal (Miss E. Ball, fide Thompson); Cork (Humphreys); between Cape Clear and Baltimore ( $\mathrm{I}^{\prime}$ Andrew) ; Arran Isle, co. Galway (Barlee). Fossil in the south of Italy and in Sicily (Philippi); Coralline Crag (Wood, as N. cirriformis of Sorterby and probably N. proxima). Its foreign range in a living state appears to be entirely southern, viz. south-west of France (Fischer); Gibraltar, 12 f., and Malaga, 30 f. (M‘Andrew); Corsica (Susini); Naples and Palermo (Scacchi and Philippi) ; Algiers, caught by a fishing-line in deep water (Wcinkauff).

In Shetland also it occasionally takes or sucks the fish-baits. Its horny jaws are large; and when expanded they form a triangular plate. The size of my largest specimen is $\frac{~_{10}}{10} \times \frac{5}{10}$ inch. This species differs from N. Grenlandica in size, solidity, colour, aud the umbilicus.

It is parhaps the Nerita levida of Laskey (Mem. Weri. Soc. i. p. 409), who says, "It bears some resemblance to N. glaucina [ N. catena], but has a more produced apex, and is divested of the markings of that shell." It appears to be the N. glaucina? of Scacchi. Swainson's $N$. sordida is $N$. plumbea of Lamarck, an exotic species, to which Philippi erroneously referred the European shell.

## 4. N. cateina*, Da Costa.

Cochlea catena, Da Costa, Br. Conch. p. 83, t. v. f. 7. N. monilifera, F. \& If. iii, p. 326, pl. c. f. 1, and (animal) pl. PP. f. 6 (by mistake as N. canrena).

Body yellowish or drab, with a purplish tinge on the upper part, and faintly lineated with purplish-brown: snout fleshy: mouth or orifice of the proboscis globular, small, lying underneath the snout: tentacles rather long, slender, and pointed, placed in the middle above the snout, and nearly concealed by the front lobe of the mantle: [eyes "so excessively minute as scarcely to be risible" (Clark):] foot very voluminous, and when at rest enveloping the greater part of the shell, divided across so as to form two unequal portions, the posterior of which is the larger, bluntly pointed behind; front lobe notehed or indented in the middle: male organ situate under the right tentacle: ovary pale sellow: liver dull olive.

Shell globose, and somewhat resembling an Ampullaria in shape, moderately thick and solid, opaque, glossy: seulpture. microscopical and rery elose-set flexuous spiral striæ: colour pale yellowish-white or buff, ornamented with a row of red-dish-brown or light chocolate short, oblique, or zigzag, longitudinal streaks at the top of each whorl, and sometimes (fre-

[^85]quently in immature specimens) with also one or two similar rows round the periphery of the last whorl : epidermis very thin, buffcolour, to be seen ouly within the umbilicus, haring been rubbed off in other parts by the continual friction of the sand which this species inhabits: spire short, slightly prominent; apex entire, Hattened: whorls 7, tumid and rapidly enlarging; the last occupies eleren-fourteenths of the spire: suture nearly straight, rather deep, and well defined: mouth of the same relative dimensions as in the last species, slightly expanding and angulated at the base: outer lip rather sharply incurred above, and having a blunt edge : inner lip broad. not very thick on the upper part of the pillar, forming a slight ridge along that corner of the mouth, and a white solid pad or callus in the middle, which projects orer that side of the umbilicus; the inner layer is more or less tinged with reddishbrown, and sometimes also the inside rim of the upper part of the borly-whorl: umbiticus rather large and deep, for the most part open, marked with several slight obliquely spiral grooves : operculum horncolour, microscopically and closely striaterl in the line of growth, giving a fibrous appearance; in other respects like that of $N$. sordida. L. $1 \cdot 4$. B. $1 \cdot 4$.

Tar. conico-ovalis. Spire somewhat clongated or drawn out.

Habiram: Large sandy bays from Jersey (Dodd) to Unst (J. G. J.), at low-water mark of spring tides and down to about 10 f .; common. Shells inhabited by hermit crabs (which had probably carried them into deeper water) were dredged by Mr. Hyndman off the Mull of Cantire in 40 f ., and by Professor Dickie in Lough Strangford, from 15 to 25 f . ; this shows the advisability of recording in dredging-lists whether the species so procured were living or dead. A specimen of the variety was taken by me on Rossilly sands near Swansea; and M. Martin obtained the same variety on the coast of Provence. This species is said to occur in almost every upper tertiary fossiliferous bed in England, Scotland, and Treland, including the deposit near Macclesfield, $500-600$ fect (Darbishire), that on the Sussex
coast (Godwin-Austen), Clyde beds (Smith), Mammalian and Red Crag (Wood). The account of its geological distribution is not satisfactory. N. catena does not appear to inhabit any part of the arctic seas, like other Mollusca whose remains are found in formations for that reason assigned to the glacial period. Moreover the coloured markings of this species are not exhibited in the Crag shells so named by Mr. S. Wood, although they are retained in his N. millepunctata. Its foreign range extends from Bohuslän (Lovén) to Corsica (Requien).

It was first described and figured by Lister, and is the "English chain-headed sea Button-shell" of Petiver. Specimens in Macgillivray's collection from Aberdeen measure full two inches in leugth and breadth. I dredged at Guernsey a small one the spire of which is reversed or sinistrorsal. The fry are globular, orangecolour, and umbilicate; they assume the purplish-brown markings after they are excluded from the leathery band noticed in my account of the genus, and which in the present case when dry looks not unlike a piece of thin Scotch oaten bread. Bouchard-Chantereaux informs us that the sexual coition lasts many hours; and that the spawn-envelope consists of a great number of rounded cells, each containing from 12 to 15 fry, which emerge in succession at an interval of two or three days after at least two months of foetal life. The eggs are laid usually in March and April, and the young are produced in May and June. This mollusk was justly admired by Mr. Clark, who says, " When just taken, in vigour, and immersed in sea-water, it is scarcely possible to contemplate a more beautiful and interesting object, with its shell rising as a globular pyramid from its immense circular disk, elegantly marked with fine dark lines on
a clear-drab ground." It is not always so sluggish as it seems. According to Mr. Bretherton ('Zoologist' for 1858, p. 6232) it crawls quickly in pursuit of its prey (chiefly Mactrea and Telline), which it seizes by means of its large and flexible foot, and, after drilling their shells with its tongue, devours them while buried in the sand. This will account for most of the small round holes that are so often seen in bivalve shells thrown up on the beach. I am not disposed to concur in the opinion commonly entertained by naturalists that the front of the tongue is worn away by use. That portion is firmly and intimately connected with the jaws; and it would be difficult to explain how such a union could be dissolved or a new attachment formed from time to time. The present species differs from the last in its larger size and plumper form, the whorls not being compressed at the top, its decper and wider suture, the umbilicus being groored instead of ridged, and particulariy in the coloured streaks and the different hue of the pad formed by the inner lip.

It is the Nerita glaucina of Pennant, Pulteney, and Donovan, but not of Linné, which is now considered a tropical species-although under that name Linné eridently included our shell with several others. Dale called it Cochlea parva, Forbes Natica Nicolii. Potiez and Michaud referred it to the N. ampullaria of Lamarck, Lovén to his N. collaria, Deshayes to his $N$. castanea, and Forbes and Hanley to his $N$. monilifera. Without discussing the question which, if any, of these Lamarckian species the one now under consideration may have been, I prefer following Alder and Searles Wood in adopting the older name given by Da Costa.

## 5. N. Aldéri*, Forbes.

N. Alderi, Forb. Mal. Mon. p. 31, pl. ii. f. 6, 7. N. nitida, F. \& II. iii. p. 330, pl. c. f. 2 t, and (animal) pl. PP. f. 5, as N. Alderi.

Body creamcolour, spotted or streaked with reddish- or purplish-brown : snout broad, thick, and flexible, margined by a line of purplish-brown: tentacles sharp-pointed, tipped or edged with the same colour: [eyes "distinctly visible, immersed in the centre of the anterior bases of the tentacula" (Clark):] foot expansile, minutely reined.

Shell conic-globose, inclining to oval, very thick and solid, opaque, glossy : screlpture numerous and minute lines of growth, which are not discernible without a magnifying-power ; occasionally a few slight spiral strix may also be observed: colour buff, adorned with spiral rows of reddish-brown or light chocolate spots and streaks; of these there are 5 on the bodywhorl, and 1 on each of the next two or three whorls; all the rows except the middle one on the body-whorl (which is composed of short zigzag longitudinal streaks) are usually formed of blunt arrow-headed spots, the uppermost row being frequently more dark-coloured and conspicuous than the rest; the umbilicus and inner lip are also stained with reddish-brown or light chocolate: epidermis yellowish-brown and somewhat fibrous, preserved within the umbilicus only: spire short, but prominent, ending in a blunt point: whorls 6 , convex, compressed, and shelving upwards towards the suture; the last occupies eleven-twelfths of the spire: suture oblique and slight: mouth equal in length to nime-twelfths of the spire, scarcely expanding, and bluntly angulated at the base: outer lip sloping from the periphery, and having a blunt edge : inner lip broad, forming a very thick ridge or callosity at the upper angle of the mouth, and a large thick pad in the middle, which is obtusely triangular and projects over the upper side of the umbilicus; this part is narrow and oblique, two-thirds open, separated on the lower side by a slight ridge, between which and the pad are some obscure and smaller ridges : operculum light-horncolour, striated as in the last species, and marked with a few indistinct revolving lines; spire defined by an orerlapping and raised edge. L. 0.7 . B. $0 \cdot 65$.

Var. 1. lactea. Shell milk-white.

[^86]Far. 2. subovalis. Smaller, and of a somewhat oval shape, with a longer spire; farneolour or whitish.

Tar. 3. ventricosa. More globose, and short-spired.
Habitat: Everywhere, in sand, from the extreme verge of low-water mark to the greatest depth within the line of soundings. Var. 1. Widely distributed, but not common. Var. 2. Shetland and west of Scotland, in deep water (J. G. J.); Silverpits on the nortle-eastern coast of England (Rich). Var. 3. Hebrides (J. G. J.). Fossil in many of our quaternary deposits (Smith and others) ; glacial and post-glacial beds in Norway, $0-440$ feet (Sars). Its range, as a rceent species, comprises the North Sea from the Loffoden Isles southwards, the western coasts of the North Atlantic, the Adriatic, and both sides of the Mediterranean; depths recorded from various places $5-80 \mathrm{f}$.

It glides swittly along by means of its broad foot. Mr. Demis writes me word that it is a very ravenous mollusk, and that, when placed in a basin of sca-water with Scrobiculariu alba or other small bivalves, it will, as soon as night falls, pierce the shells and commence devouring its prey. The spawn-case is not so tough and leathery as that of $N$. catena; one now before me measures an inch and a quarter in diameter, the circular lole at the top being half an inch. The pad in very young shells covers about one-half of the umbilicus, aithough this latter part is nearly closed in some specimens firom Shetland. The ground-colour varies from pure white to dark orange ; occasionally the spots are confluent, or they are replaced by broad bands, or else by a white zone at the top of each whorl ; now aud then the upper whorls only are encireled by a single row of spots; and the streak outside the umbilicus is not unfrequently wanting. Specimens procured by Mr. Jordan
at Falmouth not only exhibit an irregular style of colouring, but the last whorl has a tendency to diverge from the one above it in almost a scalariform fashion. The present species differs from N. catena in its smaller: size and comparatively greater solidity, more produced and pointed spire, slighter suture, diversified arrangement of the coloured markings, and contracted umbilicus.
This species was described in the 'Fauna Suecica,' and in the second edition of that work bears the name of Nerita glaucina. It seems to have been mistaken by all the old writers on British conchology for the young of Natica catena. The Nerita nitida of Donovan is a common tropical shell. Indeed he admitted that the authority on which he at first hesitated to insert that species in his work was "vague;" and his statement that "the same kind was discovered, in the course of last summer, upon the coast of Scotland near Caithness," is not so satisfactory to me, as evidence that the exotic shell which he figured is British, as it appears to have been to him. In Loudon's Magazine for April 1836, Forbes adopted the name nitida for our shell, believing it to be Donovan's species; but two years afterwards, in his 'Malacologia Monensis,' he substituted for it Alderi. I am rejoiced at being thus able to cut the Gordian Knot by perpetuating a name endeared to all lovers of British marine zoology. Philippi at first called the present species intermedia; this he subsequently cancelled in favour of marochiensis, under an erroneous impression that the European species was Neritu marochiensis of Gmelin (founded on the Neritce Maroccana of Chemnitz), said to inhabit Morocco, the West Indies, and Guiana. Philippi's mistake originated with Menke. Nor is our species N. castanea of Lamarck, as Buuchard-Chantereaux supposed, nor $N$. pulckella of Risso, to which Lovén
has assigued it. According to the last-named author it is the N. similis of Koch. Leach named it N. Lamarckiana. Nerita pellucida and N. alba of Adams (Limn. Trans. iii. p. 67) were possibly the fry of this species. Natica immaculata of Totten is allied to the variety lactea, but has a much more open umbilicus.

## 6. N. Montacu'ti*, (Montagui) Forbes.

V. Montagui, Forb. Mal. Mon. p. 33, pl. ii. f. 3, 4; F. \& H. iii. p. 333 pl. ci.f. 3,4 , and (animal) pl. PP. f. 4.
Body pale brownish-yellow, creamcolour, or whitish with a brownish or yellowish-brown tint above, whitish underneath : snout very broad, light-brown, and rounded in front: tentacles moderately long and pointed, white; they are sometimes carried nearly erect, or project sideways : eyes, none observable : foot capable of great dilatation, and, when fully extended, occupying twice the area of the shell; anterior portion divided above into tro ear-shaped or triangular lobes, and edged with reddish- or purplish-brown ; middle portion squarish in front, with a slight indentation in the middle and rather sharp, corners; posterior portion oval, with a rounded tail.

Shelu globular, thick and solid, opaque, having very little gloss ; sculpture, none except minute irregular lines of growth : colour fawn of rarious shades passing into buff or reddishbrown; there is often a whitish band round the top of each whorl: epidermis yellowish-hrown, usually preserved within the umbilicus only: spire short, with a blunt point: whorls ${ }^{5}-6$, tumid, enlarging more gradually than in $N$. Alderi; the last whorl occupies nine-tenths of the spire: suture nearly straight, wide and narrowly channelled : mouth equal in length to nearly four-fifths of the spire, not much expanded, and bluntly angulated at the base; throat reddish-brown: outer lip gently incurved on the periphery, haring a rather thick edge: inner lip white, irregularly spread over the pillar, forming a small callosity or tooth-like process at the upper angle of the mouth, besides a slight pad in the middle, being the termination of the umbilical ridge, the lower part is very thick: umbilicus rather large and roundish, not much contracted by the inner lip; it has on that side a strong and wide ridge,

[^87]winding into the interior of the spire, and separated from the basc of the shell by a deep furrow, which notches the pillar: operculum horncolour, somewhat more solid than in other British species, microscopically and very closely striated in the line of growth ; spire concave, defined by an overlapping and raised edge. L. $0 \cdot 5$. B. $0 \cdot 475$.

Var. 1. albula. Whitish.
Var. 2. conica. Spire more produced.
Habitat: Not uncommon on a sandy or gravelly bottom mixed with mud, and among nullipore, in 1590 f., throughout the Scotch, Irish, and north of England coasts ; Isle of Man and Devon (Forbes) ; Plymouth (Jordan) ; Cornwall (Peach, M‘Andrew, aud Hockin) ; 110-140 f. off the Mull of Galloway (Beechey, fide Thompson) ; in the stomachs of gurnards at Cork (Humphreys). Both the varieties are Zetlandic. Clyde beds (J. Smith) ; Aberdeenshire (Jamieson) ; post-glacial deposits in Norway, 0-80 feet (Sars). Philippi's shell, of which he found a single specimen at Palermo, and doubtfully referred by him to the Nerita helicina of Brocehi, although it is not that species, may be ours, and fossil also. Its foreign range is entirely northern, from Iceland (Steenstrup and Torell) and Finmark (Sars) to the south of Sweden (Lovén and others); depths 3-70 f.
N. Montacuti sometimes swims in an inverted position; and it emits a thick slime from its foot. The jaws are small and thin; tongue thickly but not sharply spinous, with an unarmed and curled point at the inner extremity. This is the smallest of our native Natico. It is, besides, distinguishable from $N$. Alderi by its colour, more globular shape, shorter spire, tumid whorls (the last of which is not so disproportionately large, viewed with the mouth downwarls), wider and channelled suture, and by the umbilicus being rounder and
more open, and furnished with a broad ridge, which is defined on the lower side by a deep groove.

It is the Nerita rufa of Montagu; but Born's species of that uame (which belongs to the present genus) is a large tropical shell. Macgillivray described our species as Natica rutila, and the young as $N$. squalida. I have ventured, for the sake of uniformity, to slightly alter the spelling of the specific name given by Forbes. Moutagu's ancestor in Domesday Book was Drogo de Monte acuto, afterwards Montacute and Montagu; the Latinized form of the name is therefore Montacutus, and not Montaguus. Thus we have the well-known genus Montacuta.

One of the most common shells in our newer tertiary and quaternary formations is the Nerita affinis of Gmelin, alias Natica clausa of Broderip and Somerby. I will mention only a few of the localities, to show the extent of oscillation to which the area of the British Isles and of the surrounding sea has been subjected within a comparatively recent period :-Mammalian and Red Crag, not much above the present level of the sea (S. Wood); Moel Tryfaen, 1330-1360 feet (Darbishire); dredged in $25 \mathrm{f} .=150$ feet, off Larne, co. Antrim, and from a raised sea-beach near high-water mark, at Fort William (J. G. J.) ; Clyde district, at a considerable height (Watson and others) ; Shetland sea-bed, 80 f. = 480 feet (Barlee). It now inhabits the circumpolar and northern ocean in both hemispheres, its southeru limit on this side of the Atlantic being Dröbak in Christianiafiord (Sars), with a bathymetrical range from the shore to 150 f . It occurs in a fossil state throughout Scandinavia and Canada; and Dr. Van Geuns discovered it in a pliocene bed near Palermo. I need not particularize the synonyms of this species.

Another relic of the glacial epoch is $N$. Smithii of Brown, a specimen of which was found by the late Duchess of Argyll at Ardincaple near Helensburgh. This is the N. flava of Gould and N. aperta of Lovén, as well as probably N. fragilis of Leach and N. glacialis of Danielssen-an arctic species. Finmark, in 40-60 f., is its most southern known habitat.

The following species of Natica and allied genera have been wrongly introduced into the British fauna :-

1. Nerita nitida, Donovan $=$ Naticina lactea, Guilding; West Indies.
2. Nerita intricata, Don. = Natica Valenciennesii, Payr. ; Mediterranean.
3. Nerita tuberosissima, Mont.; West Indies.
4. Nerita virginea, Linn.; West Indies. This is perhaps also the Nerita glabrissina (horresco referens!) of Brown $=$ Nerita sulcaia of Turton, not of Born $=$ Natica Browniana of Leach.

## Family XXI. SOLARI'IDIE, Chenu.

Genus ADEOR'BIS*, Scarles Wood. Pl. III. f. o.
Antwal unknown.
Suble small, trochiform with a flattened base, porcellanous, few-whorled, deeply umbilicate : spire depressed: mouth obliquely rhombie, angulated above and slightly notehed or emarginate below: operculum horny, having an excentric or lateral spire.

The position of this family and genus is unsatisfactory; we want more information as to both. The animal of the typical genus, Solarium, is thus described by Reeve

[^88]in his 'Elements of Conchology : '-_" disk small, oval, elevated on a short pedicle, and furnished at its hinder extremity with a small horny operculum ; head flattened, and prolonged into two tentacles, at the base of each of which is a short pedicle, supporting the eyes; the mantle is reflected into a collar around the aperture." And he remarks that it differs from Turbo and Trochus in the head not being snout-shaped, " but prolonged, somewhat after the manner of Buccinum and Purpura, into two elongated tentacles." The family is called Architectonicide by Messrs. Adams, and Architectomida by Dr. Gray ; the former place it near Eulimide. Searles Wood was anticipated in giving a name to the present genus. In an "Enumeration of Marine Shells" found on the South Devon coast, published in 1829 (a copy of which was presented to me by Dr. Turton "from the author '"), the genus Tornus, signifying a turner's wheel or lathe, was characterized as follows :-"Shell orbicular, depressed, aperture oval or roundish; pillar none. Operculum horny. Includes Helix subcarinata." This publication was anofymous, a circumstance which may deprive the author of the right of precedence according to the laws of scientific nomenclature. I therefore retain Adeorbis, although the othar name is preferable. Perhaps this genus should merge in Solarium. Many species assigned to it by Mr. S. Wood and others must be removed from it, and placed in different genera.

Adeorbis subcarinátus*, Montagu.
Helix subcurinata, Mont. Test. Br. p. 438, t. 7. f. 9. A. subcarinata, P. \& HI. ii. p. $\overline{5} 41$, pl. lxviii. f. 6-8.
Suell nearly circular, solid, semitransparent when fresh,

[^89]and having very little gloss: sculpture, stroug and prominent, but narrow, spiral ridges, of which there are 6 on the budywhorl, 2 on the next, and none on the upper two whorls, which are quite smooth and polished; the ridges on the bodywhorl are thus disposed, -1 close to the sutural line, 2 below it, 1 on the periphery, and 2 encircling the base; the interstices of all the ridges are crossed by numerous longitudinal strix, which are sometines curved or flexuous; there are also still more numerous microscopical lines that traverse the whole surface obliquely; the effect of all these markings is an exquisitely beautiful ornamentation : colour white, with sometimes a yellowish- or reddish-brown stain, apparently the remains of an epidermis: spire extremoly short: whorls $3 \frac{1}{2}-4$, compressed, rapidly enlarging; the upper part of the bodywhorl slopes towards the peripheral ridge, which forms a sort of keel : this whorl, viewed with the mouth downwards, occupies more than two-thirds of the spire: suture well defined, but not deep, in consequence of the upper part of each whorl shelving towards the next: mouth large, indented by the ridges: outer lip projecting far beyond the other lip, rounded and sharp-edged; upper angle or corner acute: inner lip reflected on the upper part of the base (where it joins the outer lip) and slightly over the umbilicus, thickened and angulated on the under side, below which it makes a straight course outwards, where it ends in a small notch; this is rery conspicuous when the shell is held on one side, with the spire from the observer: umbilicus rather large, obliquely sloping: inwards, defined by the lower basal ridge, and striated lengthwise, more strongly as the shell adrances in age: operculum thin, obliquely striated in the line of growth; spire extremely small, comprising several minute and close-set turns, and not unlike that of the operculum of a Natica; the onter whorl is disproportionately large. L. 0.04 . B. $0 \cdot 1$.

Habitat : Laminariali and coralline zones, Sandwich (Walker and J. G. J.) ; Dover (Lyons, fide Montagu) ; Dorset, Devon, Cornwall, and Bristol Channcl (Montagu and others) ; Guernsey and Barmouth (J. G. J.); Irish coasts (Turton and others) ; Lamlash Bay, Bute (Norman) ; Aberdeenshire (Dawson). Red and Coralline Crag (S. Wood) ; Belgian tertiaries (Nyst, as $A$. supronititla) ; Dax (Basterot); Martillac (Grateloup);

Carubbare, near Rhegio (Philippi). It inhabits all the coasts of France (D'Orbigny père and others); Vigo Bay, 4.f. (M'Andrew) ; Corsica (Duminy, fide Requien); Algiers (Wcinkauff) ; Mogador, 3 f. (M‘Andrew) ; Sicily (Philippi) ; Adriatic (v. Schröckinger); 䖝gean (Forbes).

Although this pretty little shell is by no means rare -indeed it is very common at Guernsey-the animal has not yet been discovered. Through the kindness of Mr. M'Andrew, who dredged a living specimen at Mogador, I am fortunately able to describe the operculum. For an account of the false operculum, which has misled systematists as to the position of this geuus, I would refer to page lv of the Introduction to the first volume of the present work.

It is the Trochus rugosus of Bromn, Delphinuta trigonostoma of Basterot, and $D$. minuta of D'Orbigny père.

## Family XXII. VELUTI'NIDÆ, Gray.

Bonr semioral: mantle notched in front, or folded so as to form a short branchial canal: snout or mentum prominent: proboscis retractile, issuing from a vertical slit in the middle of the tentacular reil : tentacles widely apart, and separated by a veil-like membrane: eyes on bulbs or tubercles at the outer bases of the tentacles: foot oblong, double-edged in front: gills double, formed of unequal-sized plumes (Cuvier, Bou-chard-Chantereaux, and others ; "single," Clark): odontophore long, flat, and coiled; rhachis 1 -toothed; pleure consisting of 3 claw-shaped and similar uncini, or of a single very large one. Sexes distinct.

Shell ear-shaped: spire lateral, small, and rery short: mouth occupring nearly the entire base of the shell, and exposing the interior of the spire.

The use of the pallial notch or fold is to conduct water to the gills.

Genus I. LaMEL'LARIA*, Montagu. Pl. III. f. 6.
Bony depressed: mantle shield-like, completely enveloping and concealing the shell: snout small.
Shell internal, white, and very thin : epidernis filmy.
This resembles a Doris (one of the sea-slugs) in appearance; and no one who is unacquainted with the varied structure of the Mollusca would suspect that the soft body of the Lamellaria had an internal spiral shell to protect its vital organs. It usually inhabits the lowest margin of the littoral zone, but is sometimes found in very deep water,

> "Lying with simple shells."

The anatomy of the genus has been most carefully worked out by Dr. Bergh of Copenhagen.

Lamellaria, as a genus, was instituted by Montagu (Trans. Linn. Soc. xi. pt. 2. p. 184), and divided into two sections, the former being represented by Pleurobranchus membranaceus, and the latter by L. perspicua. The genus Pleurobranchus having been afterwards cstablished by Cuvier, Menke in his 'Synopsis' restricted the present genus to the species comprised in Montagu's second section. It forms part of the genus Sigaretus of Cuvier, and is the Coriocella of De Blainville. Leach called it Marsenia, H. \& A. Adams Cryptocella; Gray made out of it three genera, viz. Ermea for L. perspicua, Lamellaria (which he placed in another family with Cypraa) for L. tentaculata-these, by the bye, being different sexes of the same species,-and Marsenina for L. prodita. Both he and Troschel consider that Lamellaria (or Marsenia) and Marsenina belong to different families, their opinion being based on the differences of

[^90]the lingual apparatus. According to Macdonald the genera Brownia of D'Orbigny, Echinospira of Krohn, and Calcarella of Souleyet, as well as his own genus Jasonilla, are the young of exotic species of Lamellaria. Lamarck's genus Sigaretus lias an external and operculated shell, and belongs to the Naticida ; it was founded on the Sigaret of Adanson, being the Helix haliotoidea of Linné. A great deal has been written on the historical part of this subject, with more or less correctness. I do not claim any merit for endeavouring to elucidate it ; nor, while making the attempt, do I feel that I incur the satirical reproach of Persius :-

Scire tuum nihil est, nisi te scire hoc sciat alter;
which Gifford reuders,
"Is science only useful as 'tis shown, And is thy knowledge nothing if not known?"

## Lamellarta perspicua*, Linné.

Helix perspicua, Linn. S. N. p. 1250. L. perspicua, F. \& H. iii. p. 355, pl. scix. f. 8, 9, and (as L. tentaculata) f. 10; (animal) pl. PP. f. 1 and (as the last-named species) f. 2.

Bodr rarying greatly in colour, which is sometimes lemon with oval clear specks or else tessellated with milk-white, lightyellowish mottled with reddish spots and a few white flakes, orange or whitish with orange blotches interspersed with Hakewhite spots, or in other cases reddish-brown or umber speckled with a few irregular yellow dots, which are darker in the centre: mantle thickly studded with large and coarse roundish-oral warty tubercles or pustules of nearly the same size, each surrounded by a border of flake-white and haring a small dark speck in the middle; underneath are two lobes which fold nearly halfway orer the foot: pallial sinus narrow, deep, and short: snout semicircular and thick, cloven at the point, and projecting beyond the foot: tentacles awl-shaped, rather long, slender, and finely pointed, slightly scalloped at the edges, diverging at an angle of about $30^{\circ}$; they are never carried

[^91]erect, but pressed downwards by the mantle : eyes black, placed on extremely short offsets; they are seldom visible from the outside, in consequence of their being covered by the edge of the mantle, but are exposed when the animal floats or swims: foot large and long, squarish in front with a short triangular lobe at each corner, bluntly pointed behind.

Shell resembling in shape a very small Haliotis without holes (although it is more raised or convex), of a somemhat membranous consistency, transparent when fresh, and of a more or less iridescent lustre: sculpture, minute, irregular, but distinct lines of growth, which are especially conspicuous just below the suture, and more numerous microscopical spiral strixe, that sometimes become confluent and form stronger lines: colour clear white, with occasionally either a darker or a paler zone on the upper part of the body-whorl: spire oblique, very small, placed near the end of the shell: whorls $2 \frac{1}{2}-3$, tumid, the last occupying eleven-twelfths of the spire (viewed with the mouth downwards); the first whorl is apparently semidetached from the next, and twisted: suture wide and deep): mouth expanding outwards, exceeding in length fivesixths, and in breadth seven-tenths of the shell ; its base is entire: outer lip sloping from the periphery, with a curved outline, but somerhat contracted; edge thin: inner lip nearly semicircular, forming on the pillar a thin glaze, slightly striated lengthwise, and continuous with the upper edge of the outer lip. L. $0 \cdot 65$. B. $0 \cdot 45$.

Malc. Body white, with a few flake-white spots on the head, yellowish with black spots, or plain dirty white: verge falciform. Shell much smaller and flatter, with the spire placed somewhat less obliquely, and having a proportionally larger mouth.

Var. lata. Shell smaller, broader, more compressed, but not flattened as in the last form, nor contracted in front.

Habitat: Adhering to the under surface of loose stones, and in rock-pools, at low-water mark of spring tides, in the laminarian zone, as well as in the coralline and deep-sea zones down to 87 f . ; generally diffused throughout our seas. Both scxes are found together. I dredged the variety in deep water off Unst; it may be the Bulla latens (Ström) of Müller's 'Prodromus,'
and Sigaretus Stromii of Sars. Fossil in the Coralline Crag at Suttou (S. Wood); Palermo (Philippi). Abroad this species ranges from Norway (Lovén and others) to Madeira and the Azores (M'Andrem), and throughout the Mediterraneau, Adriatic, and Egean (Limné, v. Schröckinger, Forbes, and others), the coasts of the United States (Gould and Stimpson), and Canada (D'Urban) ; shore to 69 f .
The mantle, tentacles, and foot assume different positions when the animal is quiescent and in active motion. It swims or floats with apparent ease. The gill-plume (whether single or double I could not make out) is of a yellowish-brown colour. Mr. Daniel found constantly in the stomach portions of branched corallines, probably indicating that the Lamellaria feeds on Polyzoa. According to Mr. Peach the female eats a round hole in a jelly-like compound Ascidian (Leptoclinum punctatum), for the purpose of making her nest and depositing in it her eggs. This nest is pot-shaped, and covered by a circular lid; it is at first bright yellow, which after some time fades and changes, becoming at last dirty white. As the embryo increases in size the nest rises up beyond the surface of the Ascidian, having been previously covered on all sides. The spawn is deposited from February to May ; it arrives at maturity in four or five weeks. The embryo, when enclosed and swimming in the glairy matrix, is of a somewhat triangular shape ; the front portion is trilobed, each lobe being furnished with delicate vibratile cilia which are in constant motion ; the central portion is granular, and the hinder bluntly pointed. On the pot-lid bursting open, and the fry emerging, the latter is found to have a pellucid nautiliform shell, retaining in other respects the appearance of its foctal state, and destitute of tentacles, eyes, or foot.

Mr. Peach's excellent observations were continued regularly for ten years. Every season the Lamellaria, as if impelled by the same instinct which takes the salmon to the river, and the herring to shallower water, migrated inshore and sought its proper spawning-ground. Mr. Hennedy had previously to Mr. Peach, ('Zoologist' for 1853, p. 4185) noticed this instinctive habit in Lamellaria. The only mistake Mr. Peach appears to have made-a very pardonable one-was in supposing that his specimens belonged to the species called teniaculata by Forbes and Hanley. They are undoubtedly the typical form, which I have ascertained to be the fcmale. That the other form is the male is manifest from the descriptions of M. Bouchard and Dr. Johnston. The epidermis of the shell becomes blistery if soaked in water, like that of some exotic snails.

The types of both Montagu's species are in the British Museum, and represent the two sexual forms. The male is the Marsenia complanata of Leach, the female his M. producta. The latter is the Bulla haliotoidea of Montagu, and has half a dozen other less known-synonyms.

Genus II. VELUTI'NA*, Fleming. Pl. III. f. 7.
Bonr compressed: mantle thick or puffy: snout large and gibbous.
Snell external, yellowish-brown, not very thin : epidermis thick, velvety.

Indicated by Fabricius in 1780. It was founded on the Bulla velutina of O. F. Müller by Dr. Fleming, in his 'Philosophy of Zoology,' 1822; and M. de Blainville, apparently without any knowledge of Fleming's prior publication, proposed the same generic name for

[^92]that species, in his 'Manuel de Malacologie et de Conchyliologie,' 1825. Brown called it Galericulum. There are but fers species known of this genus or of Lamellaria.

## 1. Velutina plica'tilis*, Müller.

Lulla plicatilis, Müll. Prod. Zool. Dan. p. 242. V. fleailis, F. \& H. iii. p. 35̃0, pl. xcix. f. 6, 7, and (animal) pl: OO. f. 6.

Body bright orange, sometimes speckled with yellow; back and tentacles of a paler hue: mantle tumid, partly reflected over the spire and hinder edges of the mouth of the shell: branchial opening large, on each side of the head: snout broad: tentacles cylindrical, rather long; tips blunt: eyes small and black, on swollen offsets: foot lanceolate, broad, and rounded in front with large ear-shaped corners, bluntly pointed behind : gills pale-red, forming a siagle plume.

Shell more oblong than oral, nearly membranous, semitransparent, having scarcely any lustre: sculpture, obscure spiral strix and irregular lines of growth ; the apex is microscopically and closely striated in a spiral direction: colour rellowish, becoming yellowish-brown or coppery in aged specimens; apex usually whitish: epidermis tough, but casily separated into slight fibrous plaits: spire obliquely twisted upwards : whorls $2 \frac{1}{2}$, ventricose in fresh, but compressed (from collapse) in dried specimens; the last occupies almost the whole of the shell: suture decp, and exposing a considerable part of the penultimate whorl: mouth oval, placed below the periphery, expanding outwards, and equalling in length four-fifths of the shell; base rounded: outer lip not much curved, reflected when the shell is dried--often so much so as to form a blunt and thickened edge: inner lip semicircular, dark orange, of a uniform width, thick, slightly reflected, and forming with the outer lip a complete peristome. L. $0 \cdot 5$. B. $0 \cdot 35$.

Habitat: Among Tubularia indivisa and other zoophytes, on stony or hard ground, in the coralline zone, Northumberland and Durham (Alder and others), Hebrides and west of Scotland (Forbes and others), Aberdeen (Macgillivray), Dunnet Bay, Caithness (Peach),

* Flexible.

Orkneys (Goodsir and Forbes), Tresta Voe, Shetland (J. G. J.) ; no less rare than local. Scandinavia (Müller and others); Iceland (Steenstrup); Greenland (Mörch); Kamptschatka (Steller, fide Middendorff), and perhaps the Kurile Islands (Pallas).

Lives in company with $V$. lavigata. Both seem fond of floating, and of getting out of the water if confined in a vessel. The middle plate of the tongue in the present species is much deeper and proportionally narrower than in V. levigata; and it has fewer notches, the central one of which does not extend half way down, instead of to the base as in the other species; and the first side-plate has no claw, nor are the second and third pleure so long or so much incurved.

It is perhaps the Helix coriacea of Pallas, and undoubtedly the Bulla flexilis of Montagu. Müller's description is not less full and precise than that of his $B$. velutina, the identity of which, as the type of this genus, has never been questioned. Gray raised the present shell to generic rank as Velutella.

## 2. V. leviga'ta*, Pennant.

Helix levigatum? Penn. Br. Zool. iv. p. 140, pl. lxxxvi. f. 139. V. laerzgata, F. \& H. iii. p. 347, pl. xcix. f. 4, 5, and (animal) pl. OO. f. 7.
Body milk-white, or whitish with a frosted appearance (caused by fine anastomosing lines), sometimes having a faint yellowish or pinkish hue: mantle pale yellow, often puekered (as if distended with water); border slightly reflected upon the shell or extending beyond its edges; pallial sinus narrow, leading to a small round hole, which constitutes the branchial opening: snout broad, thin, somewhat bilobed, and longer than the front edge of the foot: tentacles contractile and varying in length (usually short, and widely diverging) ; tips blunt: eyes small and black, placed on tubercles: foot broad and thick, truncated or gently curved in front, with ear-shaped corners,

[^93]deeply indented and narrowed on cach side, and rounded or bluntly pointed behind when at rest; it occupies nearly all the aperture of the shell; when extended, the sole is shaped like a shoe: [gills arranged in two plumes, which are unequal in size (Clark) :] mule organ falciform, short and yellow, issuing on the right-hand side of the head.

Shell triangularly oval, not so thin as the last species, semitransparent, lustreless except when the epidermis has been remored, or (as is sometimes the case) has failed to grow: sculpture, conspicuous and regular, but slight, spiral ridges, and numerous minute longitudinal strix, which cross the ridges in the early stages of growth; there are also the usual lines of increase: colour whity-brown, tinged with fleshcolour or pink (especially in southern specimens) : epidermis tough, yellowish-brown, folded on the ridges of the shell, and longitudinally fibrous: spire twisted upwards: whorls $3 \frac{1}{2}$, ventricose, the last occupying nearly the whole of the shell and expanding outwards: suture deeply channelled, so as to expose a considerable portion of the penultimate whorl: mouth roundish-oral, dilated, placed a little below the periphery, and equalling in length seven-eighths of the shell, slightly angular above and rounded below; inside white, pale orange, or fleshcolour: outer lip forming almost an are of a circle; the edge, being thin and covered by the epidermis, shrinks when the shell is dried, and is usually broken or cracked: inner lip lying at a lower level than the other, flexuous, and mostly white, broadly reflected on the upper part of the pillar (where it joins the outer lip), haring elsewhere a thick edge; behind it is a slight umbilical depression or chink. L. $0 \cdot 8$. B. $0 \cdot 7$.

Var. candida. White.

Habitat: Everywhere beyond tide-marks, on hard ground. The variety occurred to me on the coasts of Antrim, the Hebrides, and Shetland. Fossil in the Clyde beds (Smith and others); Mammalian Crag at Thorpe (S. Wood); post-glacial deposits at Uddevalla (J. G. J.), and in Norway, 30-120 feet (Sars). Inhabiting the North Atlantic, from Greenland, Spitzbergen, Lapland, and Kamptschatka to Vigo (M'Andrew) and Spezzia (J. G. J.), with a range from low-water mark
to 150 f. ; United States (Gould and others) ; Canada (D'Urban) ; North Pacific (Stimpson and P. Carpenter).
"The animal discharges a very copious and tenacious clear white slime," Clark. According to Fabricius this secretion is frothy (like that of Helix aspersa), and serves the Velutina for concealment. Its locomotion is slow; and its sedentary habit may be presumed from Foraminifera being frequently attached to the shell. This presumption, however, is not quite tantamount to a fact, because (as Mr. Alder reminds me) Foraminifera and Polyzoa are found on the carapace and legs of some of the smaller crabs, which are anything but stationary animals. Greenland specimens of $V$. levigata are very much larger and thicker than ours. Extremely young shells have a small umbilical cavity.

The Helix lavigata of Linné appears to be a lost species. It is described as of the size of a pea, transparent, very smooth, nearly oval, and glossy, with scarcely any umbilicus. He placed it next to Limnea auricularia; no habitat is given. Pemnant appears therefore to have considered the present species a freshwater kind. His description and figure almost suffice to identify our shell ; but were it not so, it would be inexpedient to change the familiar specific name of lavigata. It is the Bulla velutina, Müller, Helix haliotoïdes, Fabricius (not of Müller, nor H. haliotoïdea of Linné), V. capulö̈dea, De Blainville, V. vulgaris, Fleming, V. striata, Macgillivray, V. rupicola, Conrad, Galericulum ovatum, Brown, V. Mülleri, Deshayes, and V. haliotoïdea, Stimpson.
V. undata of J. Smith (V. zonata, Gould) is fossil in the Clyde beds, the Mammalian Crag at Bramerton, Uddevalla, and Canada; it inhabits the arctic seas of
both continents. Another high-northern species, $V$. lanigera of Möller (V. elongata, Forbes and Goodsir), has been found by Mr. Searles Wood, according to Forbes, in the Mammalian Crag at Thorpe.

## Family XXIII. CANCELLARI'IDE, (Cancellaricudce) Forbes and Hanley.

Body regularly spiral : mantle haring an incomplete or rudimentary branchial fold: head snout-shaped, and short: proboseis long, retractile: tentacles awl-shaped : eyes on stalks amalgamated with the tentacles at their outer base: foot lanceolate, comparatively small : gills double. Sexes separate.

Shell turbinated, more or less umbilicate: spire erect: mouth groored within at the base, and haring continuous lips: pillar plaited, or else furnished with a single fold or a tubercle: operculum horny, not spiral, butincreasing by semielliptic oblique layers.

In Troschel's classification of the Gastropoda, founded on the structure of their lingual apparatus, the present family is arranged alongside of the Velutinide, Sigaretide, and Naticide; the same natural position is indicated by their shells. But it is questionable whether the odontophore affords constant characters to distinguish species; for, in the supplement to his excellent and elaborate treatise, the learned German Professor notices a difference as to the development of the notches in the teeth of certain specimens of Trichotropis borealis. The typical genus, Cancellaria, is not British, although abounding elsewhere in recent and fossil species of elegant shape and beautiful sculpture. It is said to have no operculum. So little, however, is known of the animal of that genus that $I$ cannot compare it with the soft parts of Trichotropis; and I will therefore omit this part of the description, in treating of the latter genus.

## Genus I. TOREL'LIA*, Lovén, MS. Pl. IV. f. 1.

Shell globose, covered with a velvety epidermis: spire very short; apex depressed: mouth roundish, furnished with a blunt tubercle on the pillar, at its base; groove internal, scarcely perceptible [: operculum horny (Lorén)].

One species only has been discovered ; it is Zetlandic and Scandinavian, and appears to be very rare.

## Torellia vestitta $\dagger$, Jeffreys.

Recluzia aperta, Jeffr. in Ann. \& Mag. N. II. 3rd ser. iii. p. 11f, pl. iii. f. $22 a-c$.

Shecl intermediate in shape between that of a Littorina and a Nutica, rather thin, semitransparent, and of a dull hue: sculpture, numerous fine spiral strix, besides more close-set and minutc longitudinal strix, which are chiefly discernible on the base; these latter cross the spiral strix and form short rows in their interstices: colour chalky-white: epidermis pale yollowish-brown, velvety, and marked like the surface of the shell: spire conical, with a blunt apex: whorls 5-6, tumid and rapidly enlarging; the last occupies three-fourths of the spire (viewed mouth downwards), and is considerably dilated: suture deeply and narrowly channelled: mouth nearly round, expanding and somewhat funnel-shaped; the basal groove is extremely short. and is not indicated by any notch in the outer margin: outer lip semicircular and sharp-edged: inner lip somewhat flexuous, broad, and folded back over the pillar, from which it is for the most part separate: pillar curved, having at its base a callons protuberance, below which is the short groove above mentioned: umbilicus rather small, narrow, and oblique, partly concealed by the reflexion of the inner lip. L. $0 \cdot 6$. B. $0 \cdot 6$.

Habitat: East coast of Shetland (Barlce); a single dead specimen. Although perfect, it is not in grod condition. Professor Lovén showed me at Stockholm a specimen which he had dredged alive on the coast of

[^94]Norway : he said the animal has the produced lips and lingual dentition of Capulus, and that the operculum is like that of Trichotropis, and supported by a rounded lobe on each side.

When I first described this remarkable shell, I erroneously supposed it to belong to the genus Recluzia of M. Petit, and that it might be the Natica aperta of Lovén. I have therefore now withdrawn these generic and specific names, and substituted others in their stead.

Genus II. TRICHO'TROPIS*, Broderip and Sowerby. Pl. IV. f. 2.

Shele conical, covered with a horny epidermis, which rises into bristly points on the ridges encircling the whorls : spire more or less elongated, with a pointed apex : mouth angularly oval, furnished with an oblique and blunt fold on the pillar, near its base; groove shallow, conspicuous, but not indicated outside by any notch : operculum pear-shaped, small, formed of curved laminx in the line of growth, with a nearly terminal nucleus.

Trichotropis makes an approach to the canaliferous univalves or Siphonobranchiata. It inhabits stony ground in the coralline zone and sometimes in deeper water. "Lingual dentition similar to Strombus; teeth single, hamate, denticulated ; uncini 3,1 denticulate, 2 and 3 simple," Woodward. The species are mostly arctic and antarctic; one has been described and figured by M. Petit from the Mauritius.

Trichotropis borea'list, Broderip and Sowerby.
T. borealis, Brod. \& Sowr in Zool. Journ. iv. p. 305. T. borealis, F. \& H iii. p. 361, pl. ci. f. 5, 6, and (animal) pl. II. f. 1 .

Bony creameolour, or milk-white, minutely and irregularly speckled with pale yellow : mantle thick; branchial fold ex-

[^95]tremely short, and widely open: snout short, deeply bilobed, placed between the tentacles so as to keep them far apart : tentacles rather long and tapering, with blunt tips, much thicker on the lower third portion: eyes small and black; stalks about one-third the length of the tentacles: foot thick and narrow, rounded and double-edged in front, with a small triangular lobe at each corner, angulated and wedge-shaped behind.

Shell turreted, somewhat spindle-shaped or pointed at each end, with the base much shorter than the apex; it is solid, opaque, and lustreless: sculpture, several spiral cord-like ridges or ribs, of which 3 or 4 on the body-whorl, and 2 on each of the upper whorls are the strongest and most prominent; between these are smaller ribs, viz. 3 between the suture and the uppermost of the principal ridges on the body-whorl, 1 between that and each of the next two or three ridges, and 4 or 5 between the lowest ridge and the basal peak; the whole surface is also covered with microscopic spiral lines; besides the spiral sculpture the shell is closely and obliquely traversed lengthwise by fine thread-like strix, so that the crests of the ridges and smaller ribs are delicately beaded: colour whitish, sometimes tinged with reddish-brown: epidermis pale yel-lowish-brown, forming thorn-like points or bristles on the crests of the principal ridges; these bristles are sometimes double: spire considerably elongated and finely pointed: whorls 7, moderately convex, but having a sharply angulated appearance, owing to the prominence of some of the spiral ribs; the last occupies seren-twelfths of the spire (viewed mouth downwards), and is somewhat dilated; top whorl smooth and glossy, twisted upwards : suture deep, channelled between the lower two or three whorls but not between the upper ones: mouth inversely pear-shaped, somewhat expanding outwards, not much more than half the length of the spire; inside white, pale orange, or yellowish-brown ; the basal groove is angular, but not indicated by any notch in the outer margin: outer lip rounded, incurved ou the periphery, with thin and scalloped edges, and fringed by the epidermis; the inside, or throat of the mouth, is grooved beneath the spiral ridges: inner lip flexuous, broad, and reflected on the pillar, to which it is for the most part attached : pillor also flexuous, having near its base a blunt fold, which extends obliquely upwards along the spire; below this fold is the short siphonal canal: umbilicus small, narrow, and curved: operculum obliquely oral, with a pointed termination, yellowish-brown, composed of
flexuous laminx, and irregularly striated; nucleus small, seldom if ever retained, in consequence of the terminal portion being easily broken off. L. $0 \cdot 6$. B. $0 \cdot 325$.

Tar. acuminata. Spire much longer and more tapering.
Habitat: Hard ground, in the coralline and deepsea zones, on our northern coasts, from the Dogger bank to the extremity of the Shetland Isles; local, but not rare. It is tolerably plentiful in the west of Scotland. North Channel, Irish Sea(Hyndman and J. G.J.); Lough Strangford (Dickie); co. Galway (Barlec). The variety is Zetlandic. Fossil on Moel Tryfaen, 13301360 feet (Darbishire); Clyde beds (Crosskey); "Ireland, Bute, Richmond" (Smith); Cruden, Aberdeenshire, "from Crag beds" (Jamieson) ; Mammalian Crag at Bridlington, and Coralline Crag (Wood) ; post-glacial deposits in Norway, 0-80 feet (Sars); Uddevalla(J.G.J.); Canada (Dawson). Living in the Arctic Ocean of both hemispheres, Sitka Island, Iceland, Faroe Isles, Norway, United States, and Canada; depths recorded 5-150 f.

In crawling it swaggers from side to side. The verge is falciform, above the right-hand tentacle. Stimpson says that the shell is frequently found in the stomachs of haddocks in Casco Bay. Nothing can exceed the beauty of the sculpture with which the shell is decorated; it is a piece of really dainty work. My largest specimen measures seven lines in length, and belongs to the variety. Sometimes either the spire or the mouth is twisted on one side. North American specimens are larger, thinner, and have more tumid whorls.

The discoverer of this shell was Capt. Laskey, who figured it in the lst volume of the 'Memoirs of the Wernerian Society; ' he considered it the young of Pennant's Murex carinatus. For the same reason which I gave for changing the specific name of Torellia,
borealis must replace carinata in the present case; and it has, besides, the advantage of being in general use. It is the Fusus umbilicatus of Smith, F. Laskeyi of Macgillivray, Trichotropis costellatus of Couthouy, T. acuminata of myself, T. atlantica (Beck) of Möller, and T. cancellata of Hinds.
T. insignis of Middendorff occurs in the post-glacial deposit at Bridlington, and was noticed by Searles Wood as a variety of T. borealis. It inhabits Behring's Straits.

Admete or Cancellaria viridula (Tritonium viridulum of Fabricius) is also extinct in these seas, its shell being not uncommon in the Bridlington bed, as well as in the Red and Coralline Crag at Sutton. It survives in more northern latitudes, and on the east coast of North America. J. Sowerby described and figured this shell as Murex costellifer; it is the Admete crispa of Möller, and has other names as a species of Cancellaria. Troschel regards $A$. viridula as distinct from $A$. crispa, and the geuus Admete as the type of a family distinct from that of Cancellaria.

## Family XXIV. APORRHAÏDÆ, Troschel.

Body spiral: mantle large and loose, forming a very short branchial fold at the partially channelled base of the shell, which it lines : snout cylindrical, contractile, notched in front: tentacles awl-shaped, separate : eyes on bulgings or short stalks, at the outer base of the tentacles: foot small, lanceolate: gills arranged in a single narrow plume: odontophore enveloped in a sheath, straight; rhachis single ; pleuræ or uncini 3, plainedged.

Shell, when young, spindle-shaped, never umbilicate: spire turreted and tapering: mouth widely expanding: operculum
small, horny, pear-shaped, increasing by semielliptical layers; nucleus nearly terminal, at the base of the mouth.

Included, with Strombus, in "Les Ailées" of Lamarck.

Genus APORRIIA'ÏS*, Da Costa. Pl. IV.f. 3.
Shell sculptured with nodulous ribs and fine spiral strix: spire ending in a blunt button-shaped point : whorls numerous: mouth angulated: outer lip usually dilated into several digitations or wing-like processes, each of which is narrowly and slightly groored and terminates in an angular point or spike: base forming a shallow and beak-like rudimentary canal.

A shell-fish so peculiar and common in the Archipelago as $A$. pes-pelecani must have been known to " the father of natural history." He mentions it as one of the univalves possessing an operculum ( $\epsilon \pi \iota \kappa \bar{\lambda} \lambda v \mu \mu a$ or $\pi \hat{\omega} \mu a$ ) which makes such shells bivalve. The muzzle seems to be of an intermediate kind between the snoutlike head of Trichotropis and the true proboscis of Purpura. The difference of shape in the immature shell was pointed out by Lamarck; and its resemblance to that of Cerithium was urged by Swainson as a reason for merging the last-named genus in the Strombide.

Aporrhais of Aldrovandi and Aporrais of Gualtieri is the Pterocera of Lamarck. Petiver was the first to use the present name in its restricted sense ; and the genus was sufficiently defined by Da Costa. The Aporrhais of Klein was one of the Voluta family. Klein's genera ought not to be recognized; they are ill-compounded, and much too extensive. In some cases each of his species comprises several modern genera. On the other hand, he calls Murex a class, and divides it into two

[^96]genera, viz. Murex frondosus and Murex costosus. The present genus is his Pes anserinus. Philippi more correctly, but unnecessarily, renamed it Chenopus.

## 1. Aporrhaïs pes-peleca'ni*, Linné.

Strombus pes pelecani, Linn. S. N. p. 1207. A. pes-pelecani, F. \& H. iii. p. 188, pl. 1xxxix. f. 4, and (animal) pl. II. f. 3.

Body creamcolour, mottled in front with purplish-brown, or light purplish-brown, with white flakes and specks: snout extending far beyond the foot, often pinkish, minutely speckled with yellow or white dots ; edges sometimes yellow; extremity cloven perpendicularly: tentacles diverging, fleshcolour, with a scarlet or white line down the middle, speckled like the snout; tips blunt, sometimes dark brown: eyes small, black, placed on prominent bulbs : foot extensile, narrow, white (occasionally spotted with ,pink), attached to the rest of the body by a broad and thick neck or stalk, square in front and rounded behind: verge long, strap-shaped, recurved, and yellow: odontophore short [; rhachis broad and convex above, narrower below, the front or cutting edge having a central spire and notched on each side; uncini, 1st nearly transverse, with its upper margin folded, 2nd and 3rd claw-like, slender, elongated, and intercrossing with those on the opposite side. (Lovén)].

Shell having an irregularly triangular or shoulder-of-mutton shape, with a jagged outline, solid, opaque, somewhat glossy: sculpture, short longitudinal ribs, which are thick and nodose or tubercular on the lower whorls, thin and curved on the upper whorls, becoming more numerous and very fine towards the point of the spire; there are 3 rows of nodules on the body-whorl, those of the uppermost row being the largest, those of the middle row next in size, and those of the lowest row small, bead-like, and more or less confluent ; the rows are continued and project in the form of ridges on the pterygoid or wing-like processes of the outer lip (all of which are similarly strengthened), like the joints of a bat's wing; each of the next two or three whorls has only 2 rows, viz. one of large nodules in the middle, the other (which is frequently iudistinct) of small beads close to the suture; the entire surface of the shell is covered with delicate and close-set impressed
spiral lines or strix: colour pale fellowish-white, sometimes tinged with fleshcolour or reddish-brown: spire elongated; apex compressed: whorls 12 , conrex, all but the last of those near the apex angulated in the middle; the body-whorl is trristed upwards, and occupies more than five-eighths of the spire; the first two or three whorls are tumid, quite smooth, and glossy: suture distinct, deeper between the upper than between the lower whorls: mouth narrow, shaped like a lancehead with the point downwards: outer lip large, white, microscopically granulated inside; it is expanded into a broad flap in front, a triangular and incurred process at the base, and another triangular process at the upper corner of the mouth; the flap has 3 angular processes, the uppermost being larger than either of the other two, which approximate; each of these different processes ( 5 in number) is groored in the middle, but the smallest process (which is situate next to the base, and is sometimes rudimentary) less distinctly; the process above the outer lip direrges from the spire, and seldom extends higher than within six whorls from the apex: inner lip spread like a white enamel over the under side of the last and penultimate whorls, as well as over the basal process or beak, behind which it is folded so as to make a slight cavity : operculum closely laminated, with an obscure and irregular nucleus, faintly striated lengthwise. L. $1 \cdot 85 . \quad$ B. (to the extreme point of the outer lip) $1 \cdot 25$.

Var. albida. Whitish.
Habitat: Coralline zone (occasionally the deep-sea zone also) on all our coasts. The variety was found by Mr. Waller in Dublin Bay, and by myself in Shetland. This common shell has been recorded from the upper Miocene, Pliocene, and almust every newer tertiary and quaternary deposit in Europe, from the sea-level to 1360 feet above it. North Atlantic from Finmark and Iceland to Gibraltar, the Mediterranean, Adriatic, and Ægeau, at various depths between 5 and 100 f.

It is shy, slow, and awkward in its movements, twisting about its long neck and foot in order to gain a creeping posture. Among other fanciful names given to this odd-looking shell are "blobber-lipt Edinburgh whilk"
of Petiver, "aile de chauve-souris femelle" or "patte d'oye" of D'Avila, and "zamarugola" of the Venetians, by the poorer class of which people the animal wasperhaps is still-eaten. According to Mr. Couch, Solaster papposus also reckons it an agreeable kind of food: when the soft portion has been digested, the empty shell is rejected, and becomes the habitation of a Sipunculus, which narrows the too capacious entrance with agglutinated sand. Specimens from deep water are smaller than those from the coast. The top of old but living shells which had lost their upper story is sometimes closed by a semispiral plug or septum of new shelly matter; the apex is very seldom perfect in full-grown specimens. When the outer lip is complete the subsequent growth takes place by adding fresh layers inside ; so that the age of the individual is probably shown by the number of such layers. In immature specimens the commencement of the pterygoid or wing-like flap of the outer lip is defined by a rib of enamel along the mouth, which likewise lines the canal at the base as well as the upper process of the flap. Still younger specimens, before any sign of the flap appears, have the outer lip flexuous, with a wide and deep sinus at the upper part, and a long straight canal at the base. In this stage of growth they strongly resemble Fusi. The fry form a short cylinder. Monstrosities are not uncommon, especially in the shape and relative size of the digitated processes; the basal point, however, is always formed like a spear-head.

Da Costa altered the specific name to quadrifidus.

## 2. A. Macan'dref*, Jeffreys.

A. pes-carbonis, F. \& H. iii. p. 186, pl. Inxxix. f. 5, 6.

Bony whitish, with a triangular patch of light pink on the neck: snout not extending as far as the foot, tinged on the upper side with pink, and divided down the front by a flakewhite line or streak : tentacles sometimes curred like the horns of an ox, one on each side of the snout, speckled towards the tips with flake-white, and marked on the upper side by a white line down the middle; tips blunt, and yellow : eyes prominent, on short tubercles or stalks: foot narrow, in front obtusely rounded or nearly truncated, with a short angular corner at each side, behind pointed.

Shell much smaller and of a more delicate shape and finer texture than the last species; when young it is thin, transparent, and glossy: sculpture nearly similar; but the ribs on the last two whorls are less knotts; the riblets on the upper whorls are more numerous; the spiral strix are stronger and fewer on the lower part of the body-whorl and on the back of the outer lip, and are sometimes alternately large and small: colour whitish, sometimes having a pale fawn tinge: spire rather short; it does not taper as in the other species, nor is the apex so liable to be broken off: whorls $7-8$, convex, but not angulated: suture less distinct between the lower whorls, owing to the above want of angularity: mouth proportionally shorter and wider: outer $7 i p$ relatively larger, more palmated and flatter, divided into 4 processes, besides the basal point; all these form spikes, and far exceed in length the digitated processes of $A$. pes-pelecani; in the present species the uppermost spike frequently extends beyond the spire in a parallel direction, and is bent backwards; the lowermost spike has about the same length, and is also finely pointed, being slightly curved outwards; the three spikes which belong to the ptersgoid flap or expansion project considerably, and are separate; the smaller two resemble the fork made by divided fingers; all the spikes are similarly grooved; the inside of the outer lip is microscopically pustulated: inner lip thin, spread over the lower side of the last three whorls; basal

[^97]fold long and narrow: operculum slighter than that of A. pespelecani, but agreeing with it in other respects. L. 1-2. B. (to the furthest spike of the pterygoid flap) 1.

Habitat : Muddy sand in 40-85 f. on the east coast of Shetland, at a distance from land of $6-50$ miles (M‘Andrew, Barlee, and J. G. J.) ; it is gregarious, although very local. M‘Andrew and Barrett dredged a single dead specimen off the coast of Upper Norway, at a depth of 70 f ; but no Scandinavian zoologist appears to have met with it.

This mollusk is not so inactive as its associate, $A$. pespelecani. Its fæces are oval and brownish. Monstrosities of the shell sometimes occur: one has the top spike double or forked, another has four digitated processes on the outer lip, and in a third the top spike is attached to the lower five whorls. Some specimens are much smaller than others; I lave given the average dimensions.
A. pes-carbonis of Brongniart (a fossil of the upper Miocene formation of Bordeaux and Antwerp) is equally small, but a much stronger shell; and the basal process is short, spear-head-shaped and incurved, as in A. pespelecani. The present species differs from $A$. Serresiana (a Mediterranean shell) in its smaller size, delicate texture, fewer and rounded (instead of angulated) whorls, and in the spire being much less tapering. Size alone is, of course, not an infallible criterion of distinctnessespecially if we take into account the depth of water and distance from land; but it is remarkable that Zetlandic specimens of Pecten aratus ( $P$. Bruei), P. Testa, P. septemradiatus, var. Dumasii, Tellina balaustina, and many other species are larger than those from the south of Europe. If Philippi had not described his Chenopus desciscens (a Palermitan and Calabrian fossil) as having
four keels or rows of tubercles on the last whorl, I should have been inclined to consider our shell identical with it.

## Family XXV. CERITHI'IDA, (Cerithiadm) Fleming.

Body spiral, elongated : mantle fringed at its outer edges, and forming in front a very short semitubular fold, which is not protruded beyond the notch in the shell: head snout-like and contractile ; there is no proboscis: tentacles awl-shaped, separate at the base, and comnected by a sinuons reil or membrane: eyes placed on bulgings outside the base of the tentacles: foot lanceolate: gill-plume single, composed of triangular plates: jaus or cheek-plates triangular : odontophore very short and straight, spinous; tecth 3.1.3. Sexes distinct.

Shell pyramidal, nearly always tuberculated, sometimes furnished with varices or persistent edges of the mouth, never umbilicate: spire tapering to a fine point: whonls numerous: suture slight: mouth small ; groove at the base short and recurred : operculum horny, nearly circular, and spiral, with few whorls; nucleus not quite central, but on the inner side of the mouth.

An extremely prolific and widely diffused family, having perhaps few genera, although these abound in species both recent and fossil. The latter are almost countless. Deshayes, a long time ago, enumerated between 400 and 500 fossil species of Cerithium; and they have since multiplied beyond all reasonable bounds. Quousque? Their sculpture is very elegant and dirersified ; Lamarck recommended it to architects as a pattern for the ornamentation of columus. With respect to the animal, I would advise conchologists to study the careful observations of my friend Mr. Berkeley, on the anatomy of C. telescopium, in the 5th volume of the ' Zoological Journal.'

This family has some relations to Turritellide and Scalariidæ; but, in the present state of our knowledge, it is impossible to make a complete system of arrangement for the Mollusca, or one which will fit every group into its proper place.

## Genus CERI'THIUM*, Adanson. Pl. IV. f. 4.

Body slender: head broad and short: [mentum distinct, nearly free in front, actively vibrating: (Lovén)] foot notched or bilobed in front: opercular lobe simple.

Suell as described in the account of the family.
The difference between a true canal, indicated by an outside notch, and a mere groove inside the base of the shell was not unobserved by Linné, who says of his Trochus perversus (C. perversum), "columella basi prominula, at non in canalem evidentem." Deshayes separated this and other sinistrorsal species as a distinct genus (Triforis), because the mouth is apparently divided into three orifices. Their structure, however, is essentially the same as that of the smaller dextrorsal species, which Leach called Bittium. Colonna first applied the name Cerithium to this kind of shell; Prévost spelt it (perhaps more corectly) Ceritium. There is no end of synonyms ; and if I were to give all in every genus and species which I describe, this work would be unnecessarily swollen to twice its present size.

## 1. Cerithium mettulat, Lovén.

C. metula, Lov. Iud. Moll. Scand. p. 23 ; F. \& II. iii. p. 198, pl. xei. f. 3, 4.

Body thick and muscular, milk-white: pallial fold distinct:

[^98]head rounded, never much protruded: tentacles slender, but short, separated by an intermediate membrane, widely diverging outwards and usually curved, apparently annulated, owing to their contractility; edges flattened, and scalloped or slightly serrated; tips blunt and rounded: eyes black, very small, seated on bulbs outside the thickened and broad bases of the tentacles : foot long, narrow, and angular, truncated and doubleedged in front, with ear-shaped or triangular corners, pointed behind.

Sheli shaped like a miniature obelisk, solid, opaque, glossy and somewhat prismatic; base slightly concare: sculpture, thread-like spiral ridges, of which 4 or 5 are on the last whorl, and three on each of the preceding whorls except the first two; there are also some slight and mieroscopic intermediate striæ and lines of growth ; the ridges are crossed by numerous curved and fine ribs, producing nodules or small tubercles at the points of intersection; the spaces between the ribs are depressed; the base is usually devoid of all the principal markings; the first whorl and a half are smooth, and the next in succession has one ridge only, besides close-set longitudinal ribs : colour pale yellowish-white: spire greatly elongated; apex bulbous and twisted obliquely, slightly exceeding in breadth the first regular whorl: whorls 18-20, compressed, gradually increasing; the last occupies a quarter of the shell: suture slight, defined merely by the peripheral ridge: mouth bluntly rhombic, with a deep and rather wide groove at the base, which bends abruptly to the left, but does not form a complete canal ; the entire length of the mouth searcely exceeds one-sixth of the spire: outer lip curved, thin, and indented by the spiral ridges: inner lip forming a thickish glaze on the pillar, which is short and flexuous: operculum thin, pale-sellowish, rather coarsely striated in the line of growth ; spire indistinct, with a minute nucleus. L. $0 \cdot 8$. B. $0 \cdot 2$.

Habitat: Gravelly sand with mud, on the Shetland fishing-banks, in 45-96 f. (M‘Andrew, Forbes, Barlee, and J. G. J.); rare. Post-glacial formation in Norway, 0-36 feet (Sars). Norwegian coasts, from Bergen to Öxfjord, in 20-150 f. (v. Duben, Sars, Lovén, M‘Andrew and Barrett, Danielssen, Asbjörnsen, and Lilljeborg) ; Villa franca (Hanley) ; United States (C. B. Adams, as C. Emersonii, according to Danielssen).

It is sluggish, but not shy; the tentacles are sometimes folded back against the front of the shell, as in Natica. Professor Sars dredged an abnormal specimen in Mangerfiord, which had only two ridges on each whorl, in that respect analogous to the monstrosity Clarkii of Cerithiopsis tubercularis; he named his shell Cerithium bicinctum, with a doubt as to its being specifically distinct.

Described and figured by M‘Andrew and Forbes as C. nitidum.

## 2. C. reticula ${ }^{\prime}$ tum ${ }^{*}$, Da Costa.

Strombiformis reticulatus, Da Costa, Br. Conch. p. 117, pl. viii. f. 13. C.
reticulatum, F. \& II. iii. p. 192, pl. xci. f. 1, 2, and (animal) pl. II. f. 2 .
Bodr yellowish-white or whitish, mottled and streaked with purplish-brown or faintly tinged with pink [ashcolour, speckled with brown (Philippi)]; the tentacles and foot are of a paler colour, the former spotted with purplish-brown, and the latter with flake-white: mantle not furnished with any filament or process : pallial fold wide, open, and scalloped at its edges, lining the notch at the base of the shell: head nearly cylindrical, long, strongly and closely wrinkled across (unless when fully extended), or marked with dark bars: mouth vertically cloven and bilobed when the animal is crawling, but expansile and forming a circular disk when it is feeding or at rest; underneath is a pink stripe on each side: tentacles slender, although not pointed, somewhat compressed above and below, slightly serrated or jagged at their edges; a double line of pink frequently runs down each tentacle in a siphonal form: eyes rather large in proportion, placed on short pale-coloured offsets or bulbs : foot long, squarish or gently curved and doubleedged in front, with slight angular corners, attenuated towards the tail, which is sometimes rounded and rather broad, at other times bluntly pointed; sole finely grooved down the middle: opercular lobe expanded on each side, and extending beyond the operculum at the hinder end of the foot; I could not detect any such cirral process as is presented by Rissoa, notwithstanding the statement of Lovén, "An. Rissoce lobo operculigero utrinque subalato, cirro postico rotundato-lanceolato."

[^99]Shell forming an extremely elongated pyramid with a narrow base, rather solid, opaque, having scarcely any gloss : sculpture, thread-like spiral ridges, of which from 8 to 10 are on the last whorl ( 4 above the periphery, and the rest below it), 4 on each of the preceding 7 or 8 whorls, 3 on each of the next two whorls, 1 or 2 on each of the upper two whorls, where they cease; the ridges are crossed by strong longitudinal ribs, which make the former nodulous; of these ribs there are about 20 on the penultimate whorl; they do not extend to the outer lip nor below the periphery; besides the above sculpture, closeset longitudinal strix are perceptible with a magnifying power, and some of the ribs (but never more thar one on a whorl) are varicose or unnaturally distended; the first whorl and a half are smooth and glossy : colour chestnut or reddish-brown of various shades, often dusky; the nodules sometimes whitish from friction : spire drawn out to a considerable length ; apex bulbous, and twisted obliquely: whorls $15-16$, rather conrex; rate of increase very gradual, the last whorl equalling nearly one-third of the shell: suture deep, defined by the peripheral ridge: mouth triangular; basal groove rather wide, but not deep, turning abruptly to the left, not exhibiting any notch on the outside; the entire length of the mouth does not much exceed one-fifth of the spire: outer lip rounded, and slightly reflected; inside indented by the spiral ridges: inner lip forming a fine glaze, which is thicker on the pillar; the latter is rery short and flexnous: operculum stouter than in the last species, obliquely and coarsely striated; its spire is composed of about half a dozen whorls, which are defined by au imbricated or overlapping edge. L. $0 \cdot 5$. B. $0 \cdot 125$.

Yar. 1. simplex. Shell rather thinner, and glossy, without any rarix; colour jellowish-white, the ridges marked by purplish-brown lines.

Var. 2. lactescens. Becoming milk-white.
Habitat: Very common in the littoral and laminarian zones, on the southern and western coasts of England, Wales, and Scotland, as well as all round Ireland; Sandwich (Montagu). Var. 1. Sark (Barlee); Guernsey and Herm, living under stones and in rock-pools at lowwater mark, and dead in 20 f . (J. G. J.) : this is more frequent than the typical kind in the south of Europe.

Var. 2. Land's End (Hockin). C. reticulatum is fossil in the brick-earth of the Nar, west Norfolk (Rose); Lochgilphead (Geikic) ; post-glacial beds in Norway, 20-200 feet (Sars) ; Uddevalla (J. G. J.) ; tertiaries of the south of France and Italy (Potiez and Michaud, Brocchi, Scacchi, and Philippi). Its present distribution in a living state extends from the Loffoden Isles (Sars) to the Canaries (M'Andrew), and throughout the Mediterranean, Adriatic, and Ægean ; recorded range of depth, shore to 140 f .

It crawls actively and quickly by means of its long foot, and occasionally suspends itself by a byssal filament to a bit of floating seaweed or to the side of the vessel in which it is kept. It seems to be not very particular in its diet, feeding on all sorts of animal and vegetable matters, especially such as are putrid or decaying; "we observed it sucking in ropes of molluscan mucus with great gusto and avidity." Clark. The shell varies extremely in size; it is usually sombre-looking, and may be called sad; but

> "Oh, idle thought!
> In nature there is nothing melancholy."

Monstrosities have been noticed by Mr. Thompson of Belfast and Mr. Cocks. In some specimens the spiral ridges, in others the longitudinal ribs are the stronger or more conspicuous. The spire, being long, is apt to be twisted on one side.
"The small needle whelke" of Borlase, Murex acuminatus of Pennant, M. scaber of Olivi, C. Latreillii of Payraudeau, C. Danicum of Beck (according to Örsted), and Rissoa vulgatissima of Clark. The Trochus punctatus of Linné might be this species, but for the description "anfractibus serie triplici punctorum;" our shell has never less than four rows. Bruguière gives Guada-
loupe as the habitat of his C. lima, a name which many subsequent writers have adopted for the European species, which may be his C. ferrugineum. C. afrum of Danilo and Sandri appears to be nothing more than a small and dark-coloured sort of this most variable shell. I have the same from the Adriatic; Brusina crroneously referred it to the genus Cerithiopsis. Forbes and Hanley say that "the specific name scabrum was undoubtedly prior to that of reticulatum." My copies of Da Costa's and Olivi's publications show, however, that reticulatum is fourteen years older than scabrum.

## 3. C. perver'sum*, Linué.

Trochus perversus, Linn. S. N. p. 1231. C. adversum, F. \& H. p. 195, pl. xei. f. 5, 6.

Body slender: head broad, short; proboscis capable of being concealed? (recondenda?) : mentum distinct, in front somewhat detached, and actively vibrating: tentacles long, cylindrical, slender, somewhat club-shaped at the top, separated at the base, connected by a flexuous veil: eyes on very short stalks or processes, at the base of the tentacles : opercular lobe simple. (Lovén.)

Shell sinistrorsal, forming a more or less elongated pyramid, with a narrow and somewhat contracted base, solid, opaque, rather glossy : sculpture, rows or bands of small and close-set tubercles (about 25 in the lowest row), produced by the mutual decussation of spiral and longitudinal ribs; of these rows there are usually 3 , sometimes 4 , on the body-whorl above the periphery; the tubercles on that whorl are generally oblong with the greater axis in the direction of the spire, the others being granular or bead-like ; each of the next 5 or 6 whorls has 3 rows, the next 5 or 6 whorls have 2 rows cach, the following 3 or 4 whorls are not tuberculated, but exhibit very minute and numerous longitudinal striæ, which are encircled in the middle by a delicate spiral thread, in such a manner as to make the primary whorls appear keeled or angulated; the nucleus or top whorl is smooth and glossy; the middle row (when there are 3 ) is frequently smaller

[^100]than either of the other two, and high up on the spire this is always the case, preparatory to the middle row being squeezed out or disappearing; the base of the shell is girded by 3 strong spiral ridges, two just below the periphery, and the third very short and winding obliquely round the semitubular and recurved groove or fluting at the extreme base ; the uppermost of the basal ridges is occasionally beaded : colour dark chestnut, fading into yellowish-brown ; tubercles mostly of a lighter hue : spire tapering to a fine point; apex as in the last species, but reversed: whorls 15-16, compressed, gradually enlarging; the last nearly equals one-third of the shell : suture narrowly excavated: mouth squarish; groove narrow and deep, turning abruptly to the right; it is nearly closed above, in consequence of the inner lip orerlapping one side of the groove and of the outer lip being contracted into a small but deep sinus on the other side; the relative length of the mouth is the same as in the last species: outer lip semicireular and prominent, slightly reflected in the middle, having the upper and lower corners contracted into a small and deep sinus or indentation, and considerably retreating. on the upper side where it joins the periphery; cdge scalloped by the spiral ridges; inside smooth : inner lip broad, forming a thick pad or deposit on the pillar, with which it makes an obtuse angle; this lip is united with the other at the upper corner of the mouth : pillur short, strong, and curved: operculum rather thin, obliquely and irregularly striated; spire small, indistinct, with a circular and many-whorled nucleus. L. 0.35. B. 0.1.

Var. pallescens. Whitish, faintly tinged with yellowishbrown.

Habitat: Southern and western coasts of England and Wales, the Channel Isles, and all Ireland ; Sandwich (Walker and J. G. J.) ; Clyde district (Smith and Norman); Dunbar (Laskey); Aberdeenshire (Dawson); Caithness (Gordon); Orkneys (Forbes and M'Andrew); Shetland (F. \& H.). Not uncommon in the lower part of the littoral zone, and down to the coralline. I dredged the variety at Guernsey. Italian tertiarics (Brocchi and Philippi); Irish beds (Smith); Coralline Crag (S. Wood); post-glacial formation in Norway, 120 feet (Sars). The present distribution of the larger or typical form ranges
from Brittany (Cailliaud) to Madeira and the Canary Isles (M'Andrew), and throughout the Mediterranean, Adriatic, and Egean (shore to 69 f .) ; that of the smaller, which is our form, is more extensive (shore to 100 f .), and comprises also the Scandinavian coast from Christiansund (Danielssen) and Boluuslän (Lovén and Malm) to Hrellebæk in Zealand (mus. Copenh.). West coast of North America (Cooper, fide P. Carpenter).

The shell is never varicose. Linné noticed that in this species also there is no canal as there is in Buccinum.

I can see no other difference than that of size between Mediterranean and British specimens, said to belong to two species, viz. C. perversum and C. adversum. They agree in shape, sculpture, colour, form of the mouth, and all other particulars. The greater size of the former shows a deviation from the general rule; the same exception appears in $C_{8}$ reticulatum also. It must be observed, however, that size is an extremely variable character in the genus Cerithium and its allies. I have specimens of $C$. reticulatum and of the present species from the south of Europe smaller than any from the north. The only distinction pointed out by the authors of the 'British Mollusca' between C. perversum and C. adversum is that the latter is "far scarcer and less diffused." Besides the name (Murex adversus) given by Montagu, this shell has 11 others, which my readers will not thank me for specifying. It is almost time that the tedious and useless practice of repeating obsolete synonyms should cease.

The "large, subpellucid, white variety" of the last species, noticed by Montagu on Bryer's authority from Weymouth, and on Laskey's authority as Scotch, is West-Indian. C. cancellatum of Brown (having four
rows of tubercles on each whorl), said to have been found at Lindisfarne, is likewise tropical. C. fuscatum of Linné= Melania Matoni, Gray, was given by Pulteney as one of Bryer's Weymouth shells ; it inhabits brackish water in Senegal, and is not British.
C. tuberculatum, Linn.,=C. vulgatum, Bruguière, was recorded by Pennant as Northumbrian, and by the late Mr. W. Thompson as Irish. These localities are more than questionable, and must have originated in some mistake ; but I dredged in the summer of 1865 a feir dead specimens on the coast of Jersey. M. Cailliaud states that he has frequently found rolled specimens on the beach in different places of the Département of LoireInférieure. I believe the occurrence of this species under the above circumstances in the Channel Isles and Brittany is owing to geological changes, by which the sea-bed has been upheaved and lowered, so as to make the shells semifossil. C. tuberculatum is common everywhere in the Mediterranean, Adriatic, and $\not$ Ægean, as well as on the coasts of Spain, Portugal, and the Canaries, from the shore to 50 f . Sars mentions a specimen having been taken at Bergen from the throat of a codfish.
C. costatum (Strombiformis costatus, Da Costa $=$ Strombus turboformis, Montagu) should also be rejected as exotic; it is a common West-Indian shell. Dillwyn mistook C. reticulatum for this species; Leach was as far wide of the mark in considering it the young of Aporrhais pes-pelecani.
C. subulatum (Murex subulatus, Mont.) must be consigned to the same limbo. Laskey is reported to have found it at Scalasdale in the sound of Mull!

## Family XXVI. CERITHIOP'SIDÆ, Gray.

Contains only the

> Genus CERITHIOP'SIS*, Forbes and Hanley. Pl. IV. f. 5.

Bony spiral, elongated: mantle plain-edged: pallial tube lining the canal at the base of the shell, but not protruded beyond it: head short and broad, furnished with a retractile proboscis: tentacles cylindrical: eyes placed on bulgings in front of the tentacles, at their base : foot lanceolate, byssiferous: operculter lobe simple. [Teeth 3.1.3; central large, bifid; lateral linear. (Alder.)]

Shell more or less cylindrical and slender, closely tuberculated or beaded, never varicose, nor nmbilicate: spire tapering to an abrupt but elongated point: whorls numerous, the earliest very slender in proportion to the rest: suture narrow, excarated: mouth small: conal extremely short, truncated, and straight: operculum hurns, ear-shaped, having an incomplete spire ; nucleus nearly terminal, at the inner base of the mouth.

The Siphonobranchiata here commence. The shell has a distinct, although exceedingly short canal, iustead of a mere groove, as in Trichotropis and Cerithium; the base of Cerithiopsis is truncated, and notched outside, while in the other genera the base is entire. The canal in the present genus and its allies is a semitubular sheath, to receive the branchial fold of the mantle. Montagu pointed out the difference between Cerithium reticulatum and Cerithiopsis tubercularis in nearly similar terms. Woodward made Cerithiopsis a subgenus of Cerithium; Clark went further, and merged Cerithiopsis in Murex. Perhaps the separation of Cerithium and Cerithiopsis into two families may be an equally extreme mode of classification. The present genus contains

[^101]VOL. IV.
many species; and doubtless more hare been placed or retained in Cerithium, owing to a misapprehension of the distinctive characters.

## 1. Cerithiopsis tubercula'ris*, Montagu.

Murex tubercularis, Mont. Test. Br. p. 270. C. tuberculare, F. \& H. iii. p. 365, pl. xci. f. 7, 8, and (animal) pl. OO. f. 1, 2.

Bony white, with three broad longitudinal stripes of dark grey [the lateral ones composed of minute brown points (Clark)], one along the ncek, and another on each side: pallial tube extremely short: head small and compressed: tentacles rather short, slightly intated at the base [" banded or ringed with lead-colour" (F. \& H.) ]; tips blunt: cyes black, placed rather close together [behind each are some sulphur-coloured points (Clark)]: foot thick, squarish, and double-edged in front, with small angular corners; from each corner runs a series of transrerse fiake-mhite plates (like those of the gillplume), which are imbedded in the tissue; the foot is usually protruded considerably bejond the head; it becomes attenuated behind, and ends in a blunt point; sole perforated in the middle, whence a narrow but deep groove extends to the tail : opercular lobe margined with yellow on each side.

SHecl cylindro-pyramidal, with a narrow and somewhat contracted base, which gires the cylindrical shape; it is solid, opaque, and glossy : sculpture, rows of small and closeset tubercles (from 20 to 25 in the lowest row), caused by the mutual decussation of spiral and longitudinal ribs; of these rows there are 3 on the body-whorl, above the periphery; the tubercles on that whorl are oblong, and have their greater axis in the line of the spire (by reason of the transverse ribs being broader there); the other tubercles are granular or beadlike, and proportionally equal in size; each of the preceding 8 whorls has also 3 rows; the first 4 or 5 whorls are quite smooth; the base of the shell (which is slightl $\Gamma$ excavated) is girded by 2 strong, rather broad and obliquely twisted spiral ridges, one just below the periphery, and the other very short and winding round the canal; nccasionally the upper of the basal ridges is indistinctly beaded, and in that case the longitudinal ribs may be traced below it: colour dark-chestnut or chocolate: spire somewhat turreted; the terminal portion

* Covered with tubercles.
becomes suddenly very much narrower, and consists of 4 or 5 whorls; ajex twisted a little domimards: whorls 13-14, compressed, the last exceeds onc-third of the shell: suture narrowly chonnelled: mouth oral, truncated at the base; its length, with respect to that of the spire, is as 2 to 7 : canal nearly tubular, and cxhibiting outside a deep and rounded notch at the base-quite different from what appears in any species of Cerithium: outer lip semicircular and rather promineut, haring a thick edge, which is scalloped by the spiral ridges; inside smooth ; this lip is contracted at the upper corner of the month into a small sinus (formed by an indentation of one of the ridges), but it does not retreat or slope backwards as in Cerithium perversum: inner lip rather broad, forming a rather thick fold on the lower part of the pillar, and continuous with the outer lip at the upper corner: pillar extremely short, and nearly straight: operculum thin, marked with very delicate and minute flexuous strix; spire excentric, minute. L. $0.25 . \quad$ B. 0.085.

Var. nana. Dतarf and spindle-shaped. (Is this the male ?')
Monstr. Clarkic. Lower and middle whorls haring but two rows of tubercles, all of which are oblong; the earlier whorls have the usual number of rorss.

Habitat: Under stones in the lower part of the littoral zone, and hard ground in the laminarian and coralline zones, along our southern and western coasts, including the Channel Isles, Bristol Channel, and St. George's Channel, all Treland, the west of Scotland, and Shetland; Sandwich (Boys, fide Montagu). The varicty is from Guernsey, Bantry Bay, and other places. The monstrosity was taken by Mr. Clark at Exmouth, and by me at Guernsey. Hossil: "Treland; Clyde" (J. Smith) ; Coralline Crag at Sutton (Wood) ; Belgian tertiaries (Nyst). Its extra-British habitat ranges from Christiansund (Lilljeborg), southward to Fayal in the Azores (Drouet), and throughout the Mediterranean and Adriatic, at depths of from 10 to 60 f . ; Charlestown Harbour in South Carolina (C. B. Adams, as Cerithium Greenei). Malm found a specimen of the monstrosity
at Löken in the south of Sweden, and Martin another in the Gulf of Lyons.

The animal crawls and swims actively and with apparent ease. When at rest, it spins a fine transparent thread, which issues from the opening in the centre of the foot-sole, its end being attached by the point of the toot to some foreign substance. I drew the shell up by this thread with a camel's-hair brush, and lept it thus suspended in the water for several seconds, the foot being doubled up. Several other univalves and many bivalves possess the same faculty of anchoring themselves. There are giants as well as dwarfs among the shells of this species. My largest specimen is barely $3 \frac{1}{2}$ lines long ; but Mr. Norman has one from the Clyde district measuring half an inch.

Philippi described and figured it as Cerithium pygmeum, and Nyst as C. Henkelusii (afterwards Henkelii); C. acicula and C. minimum of Brusina appear also to be the same as our species. Cerithiopsis tuberculata of P . Carpenter, from the west coast of North America, is different. "The elegant subpellucid white variety" noticed by Montagu as having been found by Laskey near Dunbar, was probably an exotic shell.

## 2. C. Barlefin*, Jeffreys.

Shfil forming an elongated pyramid with a broadish base (which is excavated), thinner than the last species, nearly semitransparent, and glossy : sculpture, that of C. tubercularis, except in not haring any basal ridge, and in the whole surface being marked by numerous microscopical lines of growth; the top whorls are also glossy, but the succeeding two, instead of being smooth, are finely and closely striated in the direction of the spire : colour pale yellowish-white, with a faint tinge

[^102]of brown : spire regularly tapering; the terminal portion becomes abruptly narrower, as in the preceding species: whorls 12, compressed; the last slightly exceeds one-third of the shell : suture deeply channelled: mouth irregularly rhomboidal, truncated at the base, but not so abruptly as in the last species : canal semitubular, somerrhat curved, exhibiting outside a deep and obliquely rounded notch at the base; length of the mouth, compared with that of the spire, as 1 to 4: outer lip forming an obtuse angle, with a gentle curre, not prominent, having a thin edge, which is scalloped by the spiral ridges; inside groored from the same cause ; this lip is inflected at the upper corner of the mouth on the peripheral ridge, without forming a distinct sinus, nor does it retreat or slope backwards : inner lip rather broad, thicker on the lower part of the pillar, continuous with the outer lip at the upper comer: pillar rery short, slightly curved: operculum thin, jellowish, without any perceptible spire, very faintly striated. L. $0 \cdot 3$. B. $0 \cdot 1$.

Habitat: Among trawl-refuse at Plymouth (Barlee and Jordan) ; Falmouth (Hockin); Cork (Wright); co. Galway (Barlee and J. G. J.). It is either rare or has not been sought for.

This interesting addition to the European fauna has somewhat the aspect of Cerithium metula, which young specimens especially resemble in colour; but the shell of the present species is a pyramid rather than an obelisk, the ridges are more strongly tuberculated, the apex is very different (partaking of the gencric character), and there is a true canal. It may be known from Cerithiopsis tubercularis by its colour, much wider base, having no basal keel, and by some of the upper whorls being finely striated in the line of the spire.

## 3. C. pulchel'la* ${ }^{*}$, Jeffreys.

C. pulchella, Jeffr. in Ann. \& Mag. N. H. 3rd ser. ii. p. 129, pl. v. f. 8 a-c.

Shell forming a short eylinder, rather solid, nearly semitransparent, and glossy: sculpture, 4 spiral thread-like and
equidistant ridges on the body-whorl, the uppermost of which is close to the suture and retreats considerably, the lowermost encircles the periphery, and the two middle ones are more prominent; these ridges are crossed by numerous longitudinal ribs of the same size (from 20 to 25 in the lower of the middle rows), which intersect the ridges so as to form a latticework of excavated squares; the points of intersection are sometimes nodulous; each of the preceding 5 or 6 whorls has the upper 3 ridges, and is cancellated like the body-whorl; occasionally the penultimate whorl exhibits the 4 spiral ridges; top whorls smooth : below the peripheral ridge there is a small and very slight ridge or keel, obliquely minding round the base (which is excavated), and the longitudinal ribs are in that part more or less distinct; the whole surface is covered by some fine microscopic spiral lines or strix: colour yellowish-brown, the base having frequently a darker or reddish-brown hue ; the body-whorl now and then exhibits two or three abscure bands of the latter colour: spire tarreted; the terminal portion is pinched up and very small: whorls 10, rather convex; the last occupies two-fifths of the shell : suture wide and deep: mouth obliquely rhomboidal, abruptly truncated at the base; its length in proportion to that of the spire is as 2 to 7 : canal extremely short, rather more open than in the last two species, producing a corresponding notel at the base: outer lip semicircular and somewhat prominent, having the edse scalloped by the four spiral ridges, apparently smooth within; at the upper corner of the mouth it forms a small sinus or indentation as in C. tubercularis: inner lip narrow and slight, reHected on the pillar, continuous with the outer lip: pillar very short, slightly curved: operculum filmy, nearly smooth. L. $0 \cdot 175$. B. $0 \cdot 075$.

Monstr. Much narrower, and of an elegant slender shape, quite or almost destitute of longitndinal ribs on the last two whorls, the spiral ridges being consequently very conspicuons.

Hibifat : Coralline zone in Plymouth and Guernsey (J. G. J.) ; Falmouth (Barlee) ; Cornwall (Hockin); 'Furbot bank, co. Antrim (Waller). Villafranca (Hanley). The monstrous form was found by Mr. Hockin at the Land's End; it has some relation, or at least a resemblance, to the Cerithium trilineatum of Plilippi.

This differs from both the preceding species in its more cylindrical shape, cancellated sculpture, shorter and turreted spire, and in having fewer whorls.

## 4. C. Metaxa*, Delle Chiaje.

Murex Metaxa, Delle Ch. Mem. iii. p. 2?2?, t. xlix. f. 29-31.
Shell forming an elongated cylinder, solid, opaque, glossy when fresh : sculpture, 5 strong and rather broad spiral ridges on the body-whorl, and 4 on each of the other whorls, except on those at the apex, which are quite smooth; the two ridges on the middle of the body-whorl, and the upper two on the other whorls, are more prominent than the rest; all the ridges are crossed by fine longitudinal ribs (about 25 on the lowest ridge), Which by decussation produce sharpish tubercles, and give a muricated aspect to the shell; the peripheral ridge, however, is less tuberculated and sometimes smooth; the base (which is rounded in adult specimens) is obliquely girded by a slight ridge: colour pale sellowish-brown: spire finely tapering, and greatly extended ; the terminal part is not so disproportionately small or narrow as in any of the species before described: whorls 14-15, convex and romnded, the last occupying onethird of the shell, viewed with the mouth upwards: suture wide and deep: mouth small, roundish-oval, abruptly and widely truncated at the base; its length in proportion to that of the spire is as 1 to 5 : canal extremely short, and rather wide, open, and terminating in a deep notch : outer lip semicircular, but not prominent; edge scalloped by the five ridges; inside smooth; upper side contracted into a small sinus: inner lip rather slight, reflected on the pillar, and continnous with the outer lip at the upper corner of the mouth: piller very short, more or less curred. L. $0 \cdot 25$. B. $0 \cdot 075$.

Habitat: Guemsey, 22 f. (Lukis and J. G. J.); Herm (Barlee and Norman) ; Land's End, and St. Merryn near Padstow (Hockin); Shetland (Barlee). It is a scarce shell. Coralline Crag at Sutton (S. Wood). Sestri di Levante (J. G. J.); Naples (Delle Chiaje and

[^103]Scacchi) ; Bona, among coral-refuse (Tiberi); Algiers (Weinkauff) ; Ægean (Forbes); Pantellaria, Smyrua, Madeira, and Orotava in the Canary Isles (M‘Andrew): depths $7-60 \mathrm{f}$.

It may be known from every other British species of Cerithiopsis by its extremely elongated spire, narrow shape, muricated sculpture, having five spiral ridges on the last whorl and four on each of the preceding ones, and by the whorls being convex and rounded.

The synonyms are Cerithium angustissimum, Forbes, C. creperum and C.cribrarizm, S. Wood, C. angustinum, M‘Andrew, and C. Crosseanum, Tiberi.

## 5. C. costula'ta* Möller.

Turritella? costuluta, Möl. Ind. Moll. Greenl. p. 10.
Shell resembling in shape a slender obelisk, solid, semitransparent, and glossy : scutpture, curved, sharp, and prominent longitudinal ribs; there are aboat 16 on the body-whorl, which are cut off at the periphery by a spiral ridge, giving the base an angulated appearance; the ribs are traversed and indented by thread-like impressed lines or striæ ( 3 on the bodywhorl, and 2 or 3 on each of the other whorls), besides finer and slighter intermediate strix in the interstices of the ribs as well as on the base ; the latter (which is somewhat excavated) is encircled by a narrow ridge; the second whorl from the apex is closely striated lengthwise, the first being smooth : colour white: spire fiuely tapering; the terminal part is very slender in proportion to the rest of the spire ; the point is blunt, and obliquely twisted inwards: whorls 12 , rather convex, the last occnpying about one-third of the shell : suture wide and deep: mouth small, roundish-oval, slantingly truncated at the base; its length, compared with that of the spire, is only as 1 to 6 : canal short, wide, and open, ending in a deep noteh at the base: outer lip curved and slightly inflected; edge and inside smooth; upper side not contracted: inner lip rather slight, reflected on the pillar, and continuous with the outer lip at the upper corner of the month : pillar curved. L. $0 \cdot 4$. B. $0 \cdot 1$.

[^104]Habitat: Shetland, 89-86 f., in fine muddy sand (J. G. J.) ; rery rare. Fossil on the Turbot bank, near Larne, 20-25 f. (Hyndman, Waller, and J. G. J.); Boulder-clay, Wick (Peach); Uddevalla (J. G. J.). Living in Upper Norway (M‘Andrew and Barrett, as Chemnitzia elegantissima,Lovén, Danielssen, and Malm); Väderöarne in South Sweden, 80-100 f. (Malm, as Cerithium metula, var.) ; Iceland (Torell) ; Greenland (Möller), and in 65 f. (Holböll, fide Mörch); long. $54^{\circ} 33^{\prime} \mathrm{W}$., lat. $55^{\circ} 36^{\prime} \mathrm{N}$. in 1622 f., from which extraordinary depth a fragment was procured by means of the 'Bulldog' sounding-machine (Wallich).

Mörch changed the name given by the discoverer to Cerithium arcticum, because the latter had described the shell as Turritella? costulata, it not bcing Lamarek's nor Risso's so-called species. But the present species is not a Turritella (as, indeed, Möller suspected); and the reason assigned by Mörch is, therefore, insufficient. I described the fossil shell as Cerithiopsis nivea, and S. P. Woodward proposed to name the recent one Cerithium Naiadis.

## Family XXVII. BUCCI'NIDE, Fleming.

Bodr spiral, short: mantle large, forming a head-reil in front, plain-edged: pallial tube cylindrical, protruded beyond the canal of the shell: head small, wedge-shaped: proboscis retractile, long, and cylindrical: tentacles conical or triangular, separated by the head-veil : eyes placed outside, some way up the tentacles: foot short: opercular lobe roundish-oval and simple: gills forming two long unequal-sized plumes : oclontophore long and straight ; central tooth armed below and on each side with spines or crested points, squeezed and bent backwards abore; lateral teeth small and separate, each ending in a hook. Siexes separate; verge falciform.

Shell oral, spirally sculptured; base strengthened by an oblique ridge : epidermis, if present, velvety or membranous: spire short; body-whorl consequently large : mouth oral : pillar twisted: canal short and recurved: operculum horny, oval, never spiral, increasing by concentric or elliptical layers; nucleus placed within the edge, at the outer side of the mouth.

The 'Purpurifères' of Lamarck. Adanson noticed that the shell of the male is usually smaller than that of the female, and that the former has a longer spire and more whorls although pot so tumid. He included this family and the Muricide in his genus Purpura. Müller outbid Adanson by composing his genus Tritonium of the same extensive groups, and throwing Aporrhaide and Nasside into the bargain; his Buccinum is our Limnaa. The egg-cases are membranous ; those of Buccinum are cup-shaped, and piled one upon another like the cells of a honeycomb; in Purpura they are separate, resemble grains of barley, and are placed upright. Although the lingual riband in all the Rhachiglossata (which comprise the Siphonobranchiata) is armed with spinous teeth, none of this division appear to have the jaws (cheek-plates or immoveable mandibles, Mörch) with which the Tænioglossata (including the Pectinibranchiata) are provided. The muscle by which the body is attached to the pillar of the shell in families of the present order is unusually strong.

## Genus I. PUR'PURA*, Bruguière. Pl. V. f. 1.

Seell conic-oval, thick, destitute of an epidermis: spire sharp-pointed: whorls more or less compressed: outer lip tuberculated within : pillar flattened, sloping inwards with a sharp. edge: canal narrow.

[^105]The Purpura of the Romans，from which they pro－ cured their famous colour，was Murex trunculus，a com－ mon Mediterranean shell ；it is the principal subject of Colomna＇s essay．A similar dye is yielded by the two European species of the present genus．It is secreted by an organ which Lacaze－Duthiers considers a kidney， urea having been detected in the liquid by chemical analysis．I shall have occasion to say more about this when I treat of $P$ ．lapillus．Another point of resem－ blance，common to the ancient and modern Purpurce，is their power of drilling holes in the shells of other mol－ lusca，for the purpose of feeding on them．The mussel is especially the prey of $P$ ．lapilitus．A living naturalist was mistaken in supposing that it invariably chooses that part of the mussel－shell from which the epidermis had been previously removed－as if the latter could be any impediment to its operations．The late Mr．Osler imagined that＂the perforation is effected by a succes－ sion of strokes，following each other at intervals shorter than a second：＂perhaps he was thinking of a woed－ pecker．Neither is the discovery of the perforating－ faculty possessed by whells a new one as is generally believed．It was mentioned more than twenty－two centuries ago，by Aristotle，in the 4th chapter of the 4th book of his wonderful＇History of Animals．＇He there describes the stout proboscis of the $\pi о \rho \phi \dot{\rho} \rho a$（which he compares to that of the gadfly）and its use，as well as its sharp minute and slender tecth，like those of snails． Nor was he ignorant of its acute sense of smell，evi－ denced by the $\pi ⿰ ㇒ ⿻ 二 丨 冂 巾 \phi u ́ p a ~ b e i n g ~ a t t r a c t e d ~ f r o m ~ a ~ c o n s i d e r-~$ able distance by the bait laid for its capture．He like－ wise noticed the honeycomb－mass of spawn deposited by that shell－fish；and all his obscrvations are marked by a degree of accuracy which scientific men now－a－days
might well endeavour to emulate. What does Shakespeare say of the boasted discoveries of the present age?
" If there be nothing new, but that, which is, Hath been before, how are our brains beguil'd, Which, labouring for invention, bear amiss The second burden of a former child!"

## Purpura lapil'lus*, Linné.

Buccinum Iapillus, Linn. S. N. p. 1202. P. lapillus, F. \& H. iii. p. 380, pl. cii. f. $1-3$, and (animal) pl. LL. f. 4.
Body varying in colour from white to yellowish, with a faint tinge of brown, and minutely speckled with flake-white : mantle thick, with sometimes a brown margin: pallial tube short, not much nor often protruded: head small: probascis short: tentacles conical, rather long and tapering; the part above the eye is much more slender than the lower part (which is tumid and rounded), and is from one-half to one-third of the entire length: eyes small, although conspicuous from their dark colour, slightly raised on long and thick stalks (" ommatophori," Lovén), which are amalgamated with the lower part of the tentacles: foot oblong, rounded at each end, or bluntly angular behind, double-edged in front, with ear-shaped corners; sole divided lengthwise by a slight fold or crease: opercular labe short.

Shell forming a short cone with a bluntly pointed base, thick, opaque, nearly lustreless: sculpture, numerous flattened spiral ridges, which are sometimes thread-like, or alternately large and small, and always become sharper near the apex; the surface is also covered with rather close-set striæ in the line of growth; these latter are sometimes wary where they are interrupted by the spiral ridges, so as to produce a more or less distinctly fimbriated appearance; embryonic whorls quite smooth and glossy ; the base is encireled by an ubliquely twisted keel : colour most rariable, usually whitish, pale orange, reddish-brown, or dark chocolate, often banded, and the base staiued with reddish-brown; one specimen (from Shetland) has the body-whorl white and the upper whorls marked with narrow brown bands in the interstices of the ridges : spire regularly but suddenly tapering; apex blunt and rounded, twisted on one side : whorls 6-7, convex, although compressed

[^106]ıpwards; the last occupies from two-thirds to fire-sixths of the shell : suture rather slight, decper towards the apex: mouth oval, somewhat contracted by the pillar; its length is from one-half to two-thirds of that of the spire : canal deep, exhibiting outside a corresponding and oblique notch: outer lip curred, bevelled on the inside to a rather sharp edge (which is slightly indented by the ridges in young shells), notched or tuberculated within, sloping above from the periphery : inner lip broad, continuous with the outer lip at the upper corner of the month: pillar broad and smooth, angulated where the canal begins; between the lower part of the pillar and the basal ridge there is an oblique carity as in Trichotropis: operculum dark horncolour; lines of increase distinct; nucleus placed nearer the base than in the middle of the outer side ; it exhibits underneath four or five irregularly elliptical layers, being apparently the marks of annual growth. L. $1 \cdot 5$. B. 1.

Var. 1. imbricata. Longitudinal strix more developed, and forming a flounce-like ornamentation. P. imbricata, Lam. An. s. Vert. vii. p. 244.

Var. 2. major. Larger and having a longer spire. L. 2-5. B. $1 \cdot 25$.

Var. 3. minor. Smaller, more strongly ridged, with a shorter spire and wider mouth. L. 0.75 . B. 0.5 .

Monstr. Spire reversed, scalariform, or having scarcely any canal.

Habitat : Gregarious everywhere on rocks and stones, exposed to the tidal waves of

> . . . . " the sea, that fleets about the land, And like a girdle clips her solid waist."

Here it gets abundance of food, which mainly consists of mussels, limpets, and sessile barnacles. It sometimes finds its way into dceper water. The 1st varicty was dredged by Mr. M'Andrew on an oyster-bed from 4 to 7 f. in Rhoscollyn Bay, near Anglesea; Mr. King, the natural-history dealer, also found it near Holyhead, and Dr. Knapp in the Firth of Forth. Var. 2. Off the Mumbles Head, near Swansea, in 18 f. (J. G. J.). Var. 3. Burrafirth Caves, Shetland (J. G.J.). A speci-
men of the reversed monstrosity is in the collection of the late Mr. Bean at Scarborough. Many years ago he sent his little granddaughter to the pier on an crrand, and on her return he scolded her for loitering. She held up her pinafore to wipe her eyes, when down fell some of these whells which she had picked up; his quick eyes lit on a left-handed specimen, and it is needless to say that he at once forgave her. A scalariform specimen occurred to me in Swansea Bay; and one almost without a canal was given to me by Mr. Dillwyn as Irish. The last may possibly be a hybrid between this species and a Littorina. P. lapillus has been recorded as fossil in the Red Crag and every subsequent deposit, including Moel Tryfaen ; post-glacial formation in Norway, $0-100$ feet (Sars). Its foreign distribution in a living state comprises the Arctic seas of both hemispheres, the European coasts of the North Atlantic ( $0-20$ f.) southwards to Santander (E. J. Lowe), Corumna and Vigo (M‘Andrew) ; Mogador, a dwarf state or variety, abundantly, with P. hemastoma (R. T. Lowe) ; Canada (D'Urban) ; United States (Gould and others) ; Mexico (Brit. Mus.) ; north-west coast of America (P. Carpenter). Senegal, Teneriffe, and Fayal in the Azores, as well as the coast of Brittany, are given by Adanson as localities for the present species; he also described and figured $P$. hemastoma. The variety $i m$ bricata was noticed by Fabricius as Greenlandic ; and I have taken it in the south-west of France.

This mollusk has a shambling gait, and sedentary habits; it seems to be always eating, or digesting its food. Lister, however, observed it early in the morning, at the commencement of June, otherwise engaged, viz. in perpetuating its species on a dry rock after the tide had receded. It is very destructive to mussel-beds, and is
said by Linné to eat the dead fish left in fishermen's nets. I have seen it busily feeding on Balanus balanoïdes, its strong proboscis being inserted between the opercular valves of the barnacle. According to Mr. Osler, it also devours Littorince, Trochi, Natica, and even its own kind. From what I have observed of the mode by which it perforates the shell of a mussel, I am inclined to agree with Mr. A. Hancock that it uses its tongue. The siliceous spines with which this organ is closely studded would scrape a hole in any layer of carbonate of lime, however compact. I cut off the end of the proboscis of a Purpura, while it was attacking a mussel ; the part thus lopped still remains in the hole, with the front of the tongue exposed. The hole is shaped like an inverted cone, and exhibits under the microscope extremely fine scratch-like striæ, as if caused by the rasping action of the lingual apparatus. I believe the movement to be rotatory, because the sides of the hole are quite even. The process is an extremely slow one. Mr. Osler states that, after watching for some hours a Purpura attached to a limpet, he found the perforation incomplete; and Mr. Spence Bate and Mr. Bretherton noticed that it took two days to get tlirough the shell of a moderate-sized mussel. It does not appear that the prey is destroyed by any poisonous secretion of the whelk, after it has gained access to the interior. The proboscis is at first thrust into the hole which it had drilled, and the whelk eats in that way; but when, from the death of the mussel or limpet, the former gapes or the latter separates from the rock, the Purpura devours the remainder by the natural opening. Perhaps they exercise some abstinence in the winter and early spring, to make up for their continual gormandizing during the warmer portion of the year. Mr. Peach
informs me that on the coast of Caithness, throughout the winter, the Purpure assemble in clusters low down towards the sea, where they are left dry at spring tides only, and that they also huddle together in crevices of the rocks; he could hardly find a single individual in the usual summer habitat in the course of an hour's walk which he took along the shore in the middle of March. Their voracity and cannibal propensities begin at a very early age. Dr. Carpenter has shown (and his observations are confirmed by Mr. Busk, Professor Huxley, and Dr. Dyster) that the embryo of P. lapillus, before it leares the nidus or capsule, swallows the yelk around it. The observations of Claparède on the development of Neritina coincide with those of Carpenter as to Purpura. Koren and Danielssen, however, give a different account of the matter. They say that each capsule is at first hermetically closed, and filled with a liquid, which is as transparent as water, viscous, and resembles the white of a bird's egg; in this liquid are enveloped a mass of eggs, 60 or even more; in process of growth these eggs agglomerate, and form from 20 to 40 embryos, which are developed in the same manner as those of Buccinum undatum, the shell taking the shape of a Nautilus, and that at the end of the 9th or 10th week, and not before, the fry quit the capsule. The latter then bursts at the top, and shows an open split. The capsule adheres to the rock, sometimes to Balani or to the shells of other Purpure, by a sliort and narrow stalk, which is connected with a membranous and broad base; each is distinct and scparate. They are slightly striated across. At one time they were classed among the Polypes, and called Hydra triticea; Ellis gave them the name of sea-cups. Mr. Peach has furnished some interesting particulars of the embryogeny of P. lapillus.

According to him it deposits its spawn all the year round, but more actively from January to April. Spawn which he collected in January 18.43 was hatched four months afterwards; he took 47 fry from a single capsule. They soon began to assume the peculiar habit of their parents, "by getting out of the water, where they would remain for hours, answering to the period of the ebb and flow of the tide." Cailliaud counted 245 capsules which had been produced by a single Purpura about the same time; each capsule contained from 16 to 28 perfect embryos [making therefore an average total of 5390]: they were hatched in turn by the parent, which (as he supposes) thus not only supports them by her nutritious moisture, but protects them against accidents. I have only seen the Purpura covering with her shell the egg-cases while they were being laid. M. Cailliaud adds that some of the inhabitants of St. Michel-Chef-Chef eat this shell-ifish after the spawning-season. It does not seem to be anywhere else an article of foodalthough our remote ancestors were probably less fastidious in their tastes; for the shells are found in the refuse-heaps or kitchenmiddens of 'Picts' houses' near Wick, mixed with shells of the common periwinkle, and occasionally of the limpet and mussel. Within the period of civilization this mollusk has been made useful in another way; and a great deal has been published concerning the purple dye which is yielded by our Purpura, as well as by that of the Greeks and Romans. The Venerable Bede mentions it, in terms of admiration, in his Ecclesiastical History of England : as to its pernanency, he says, "quo vetustior, eo solet esse venustior." The subject has been since discussed, in both an economical and philosophical point of view, by a crowd of writers, English, French, Norwegian, Spanish, Italian, German,
and Dutch, each contributing something to our knowledge. Professor Lacaze-Duthiers has lately given an excellent résumé. From all these publications and my own observations I may state that the dye-stuff, when extracted from the living animal, is of the consistency of cream, and at first colourless or more or less yellowish; exposed, in a moist state, to the light of the sun, it passes through all the different shades of green to violet, then to a beautiful purple, and ultimately becomes crimson ; the colour is photogenic or produced by solar action. A smell of garlic is given out during the process. Lineu was formerly stained or marked with it. The liquor contained in the egg-capsules is also purpuriferous, and tastes like the strongest pepper. $P$. hamastoma and Murex crinaceus possess the same colouringmatter. When amusing himself by some experiments as to the faculty of hearing possessed by the mollusca, Dr. Johnston ascertained that neither this kind of whelk, the periwinkle, nor the common banded snail appeared to be affected by loud and harsh noises about them. M. Susini, however, informs me that at Corsica Trochus tessellatus or T. fragurioildes (which is there gathered by the fishermen, and after being scalded eaten with a pin, like our periwinkle) invariably drops down from the rock when any one approaches it. The shell of the male $P$. lapillus is longer, more slender, and has a finely tapering spire, with a plicated but not tubercular throat. Specimens from brackish water in the Solent and River Orwell are smaller and of a thinner texture. In one from Guernsey there is a strong fold on the upper part of the pillar, extending inwards. Occasionally the shell is truncated at the top, or the first whorls are broken and deserted, the animal occupying the remainder. In aged specimens the throat has not unfre-
quently a succession of tubercular rows, forming internal varices. None of the specimens which I have seen from Canada and the United States are as large as ours; and I am consequently disposed to take a view opposite to that which Forbes snggested, viz. that this species is of American origin, and was introduced to the European shores during the glacial epoch. The common character of the fossils of that period in both continents shows that a close connexion by continuity then existed throughout the circumpolar area; and there is no evidence that any migration took place from one continent to the other. We must go back to the antecedent epoch in order to trace the origin of this species ; and we there find that it occurs for the first time in the Red Crag of Suffolk. It is remarkable how the numerous varieties figured by Mr. Searles Wood from that formation correspond with those of the adjacent coast.

The present species was named by Lister Purpure anglicance, or "white couvins;" it is the Buccinum Cornubiense of Petiver, " le sadot" of Adanson, "the purple-marling whelke" of Borlase, B. purpuro-buccinum of Da Costa, B. anglicum of Gmelin, and B. anglicanum of Lamarck; the vulgar name in Ireland, according to Smith and Rutty, is "horse winkles:" the fry is probably $B$. breve and B. lave of Adams's papers in the 'Linnean Transactions.' The P. lapillus of Risso is Buccinum hremastoma of Linné. This latter species inhabits the North Atlantic, from Brest southwards to the Azores (including the coast of Sencgal), as well as the Mediterranean and Archipelago; Mörch gives the Brazils as a locality, in the sale catalogue of the Count de Yoldi's collection of shells. Between forty and fifty years ago Mr. Charles Macculloch picked up three specimens of this shell near St. Peter's Port, Guernsey, at
the lowest point of a spring tide. Mr. Lukis had these specimens; two were living, and are now in his or his late son's collection; the third (which was dead) Mr. Lukis kindly presented to me. Not being an eatable shell-fish, French sailors would hardly take the trouble of bringing it from the coast of Brittany, and throwing it overboard, for the purpose of puzzling English conchologists.

## Genus II. BUC'CINUM*, Linné. Pl. V. f. 2.

Shell oval, not so thick as that of Purpera: spire bluntly pointed: whorls more or less tumid: outer lip sometimes slightly grooved within, never tuberculated : pillar rounded: canal wide.

The bucca or buccina of the Romans was the same as the $\kappa \dot{\eta} \rho \cup \xi$ of Aristotle and the Greeks, and represented the large Triton nodiferus, which was the trumpet used in land- and sea-fights, as well as for setting the watch and calling together assemblies of the people:-

> "Buccina cogebat priscos ad rerba Quirites."

This linc of Propertius was misquoted by Linné (who was apparently misled by Buonanni), so as to make the buccina a war-trumpet only. The type of the present genus, as established by Linné, is our common whelk $\dagger, B$. undatum. It has been grotesquely metamorphosed into an heraldic emblem, and forms part of the armorial bearings of the ancient family of Shelley. In blazoning their coat of arms, old Gwillim enjoins us to glorify God for the infinite variety of Nature's workmanship, " manifest even in the very shells of fishes," which he considers "things of meanest

[^107]reckoning." In his orderly fashion he placed these in the lowest rank, but the cherub, unicorn, and phomix foremost in the scale of creation. The Buccina affect principally, if not exclusively, the temperate and colder seas of both hemispheres. Dr. Stimpson has given a review of the northern species in the 'Canadian Naturalist' for October 1865. Whether all those which he reckoned distinct will stand the test of a more extensive examination of this extremely variable group is questionable.

## 1. Buccinum unda'tum*, Linné.

B. undatum, Linn. S. N. p. 1204; F. \& H. iii. p. 401, pl. cix. f. 3, 5, and (animal) pl. LL. f. 5.

Body varying in colour from dirty white to yellowish, speckled or streaked with black: mantle rather thick, folded over the pillar of the shell: pallial tube extensile, protruded an inch or more beyond the canal, recurved, and obliquely truncated at the extremity: head small, narrowish : proboscis very long and powerful, enclosing a muscular sheath, within which lies the tongue: tentacles flattened, long, and pointed, abruptly thickened at the base : eyes very small, placed nearly one-third of the way up the tentacles: foot oblong, with shelring sides, capable of considerable expansion and distention, rounded in front, with small ear-shaped corners, and bluntly pointed behind: verge large and fleshy, with a short point at the extremity [: odontophore; central tooth armed with 7 cusps or points in a comb-like manner ; shaft of the side tooth having 3 notches, the lowest being the largest. (Lovén)].

Shell conical abore the periphery or centre of the bodywhorl, and somewhat truncated at the base, more or less solid (according to the habitat), opaque, and usually lustreless: sculpture, numerous fine thread-like spiral ridges, some of which are much stronger than others and are arranged in bands (from 3 to 7 small ridges between every large one); the whole surface is covered with extremely delicate and closeset longitudinal strix, which seldom, however, cross the spiral ridges so as to cause any decussation; the upper portion of the body-whorl and of the four or five preceding whorls is often

[^108]strengthened by curved ribs or folds (like buttresses), of which there are from 12 to 15 on the penultimate whorl; top whorl smooth; the base is girded by a very large, strong, and obliquely twisted keel: colour mostly Jellowish-white, tinged with reddish-brown, sometimes white banded with the latter colow, or reddish-brown with a pink tinge and beautifully mottled with white; inside yellow, white, pale reddish-brown or chocolate : epidermis pale brownish-yellow, rather thin, usually rising into close-set laminar folds, corresponding with the longitudinal striæ, which form short spinous processes on the spiral ridges: spire regularly tapering; apex blunt and irregular, or mammiform : whorls 7-8, rounded; the last occupies about two-thirds of the shell: suture deep: mouth oval, and somewhat expanded; length about one-half that of the spire: canal open and deep, exhibiting outside a similar and oblique notch: outer lip semicircular, flexnous, and having a large sinus or bay in the middle; it slopes outwards from the periphery; edge reflected and thickened in full-grown specimens; inside slightly and indistinctly grooved: inner lip broad, consisting of a rather thick glaze on the pillar and adjacent part of the body-whorl: pillar smooth and highly polished, microscopically freckled or pustulated by the lower fold of the mantle: operculum pale brownish-yellow, rather solid, more or less concare towards the nucleus; the layers of growth are laminar and numerous, resembling the epidermis in texture. L. 3.25. B. 2.

Var. 1. flexuosa. More slender, with a produced spire; whorls apparently twisted, in consequence of the ribs being obliquely curred.

Var. 2. littoralis (King). Ventricose; spire shorter, and body-whorl disproportionately large ; longitudinal plaits strong; throat often coffcecoloured.

Var. 3. paupercula. Dwarf and depauperated.
Var. 4. striata. Thinner than usual, with the longitudinal ribs nearly obliterated. (B. striatum, Pennant, Br. Zool. iv. p. 121, t. Ixxiv. f. 91.)

Far. 5. pelayica (King). Twice the usual size, and also thinner, with a longer spire and proportionally smaller mouth.

Var. 6. Zetlandica (Forbes). Smaller, and of a thin and delicate texture, destitute of longitudinal ribs; epidermis smooth and membranous.

Monstr. 1. sinistrorsum. Spire reversed. 2. carinatum.

Upper part of each whorl encircled by a keel or more prominent spiral ridge. (B. carinatum. Turton, Conch. Dict. p. 13, pl. xxri. f. 91.) 3. imperiale. Body-mhorl compressed and clongated, so as to give it the shape of a Voluta. (B. imperiale, Recre, Conch. Icon. iii. pl. ii, f. 8.) 4. atuminatum. Spire extending to a considerable length; whorls flattened, and the periphery consequently angulated. (B. acuminatum, Broderip in Zool. Journ. г. p. 44, pl.iii. f.1, 2.) 5. conico-operculatum. Operculum pateliform or conical. 6. bioperculatum and trioperculatum. Haring two or three opercula.

Habitat : Every kind of ground, in all parts of the British seas, from the shore to the greatest known depth. The lst variety is peculiar to hard ground in the coralline zone, throughout the Hebrides, Orkneys, and Shetland ; it is not common. 2nd, among stones and on mud, in the higher part of the laminarian zone, north of England, as well as Ireland, Scotland, and Shetland. 3rd, brackish water at Southampton and Ipswich. 4th, coralline zone of England, Wales, and Ireland; not common. 5th, Dogger bank; Mr. Leckenby has a specimen $6 \frac{1}{2}$ inches long. 6th, soft ground in the deep-water zone, west of Ireland, outer Hebrides, Orkneys, and Shetland; I have a specimen of a pure white colour. Besides these, which I regard as the principal varieties, others have been described by Professor King and Mr. A. Hancock. In horticultural language, the species is very much given to sporting. The monstrosities have been noticed in the following places :-1, coasts of Kent, Sussex, Lincolnshire, and Yorkshire; it is the $B$. Bornianum \&c. of Chemnitz. I have both solid and thin specimens of this monstrosity. 2, with the last, and at Exmouth, Sunderland, and in the west and south of Ireland; not B. carinatum of Phipps, which is B. glaciale. 3 , Kent and Sussex. 4 , the same, and in various other places, as far north as Aberdeen (Macgillivray) ; this was mistaken by Turton for B. glaciale; the upper
whorls are more or less regular. 5 and 6 , Kent and Sussex; in a bioperculate specimen, procured by Mr. Rich, one of the opercula is conical and borne on a cylindrical stalk-like lobe, the other being of the usual shape ; in a second specimen one operculum is longitudinally oval with the nucleus nearly terminal (as in Fusus), the follow operculum being placed at a right angle to it. Other monstrosities are found, of a less marked kind. Every abnormal growth of the shell can be distinguished from those of a specific or varietal sort by examining the apex or nucleus; this will be seen to be regular, the malformation having subsequently taken place, and being in most instances caused by some injury to the outer edge of the mantle. The typical form and variety striata have been recorded from every recent geological formation in the northern latitudes of both hemispheres, and as far back as the Coralline Crag ; Palcrmo (Philippi). Mr. James Smith found the monstrosity carinatum fossil at Bute, and Mr. Grainger at Belfast. The geographical range of the species at the present time appears to be restricted to the North Atlantic, from the North Cape (Sars) and Iceland (Steenstrup) to Rochelle (D'Orbigny père and Aucapitaine), and Massachusetts (Gould); Gulf of Lyons, in the stomach of a Trigla gurnardus (Martin). The variety Zetlandica is Scandinavian, and was mistaken by Lovén and others for B. Humphreysianum; Iceland (Torell). The monstrosity acuminatum was procured by the late M. Beruardi in the north of France. American specimens of the common sort are smaller than European; and Stimpson endeavours to show that they belong to distinct species, because of "a facies difficult to describe." If the supposed difference cannot be defined by any words or delineation, ahd the only substitute
offered is the nearly exploded idea of representation of species, it is a pity that naturalists should be so unnecessarily perplexed.

In Scotland and Shetland this common shell-fish is called "buckie," in the Isle of Man (according to Forbes) "mutlag," in Holland "wulk" (Born), in France " bouche-aurore " (Lamarck), at Brest " grosse bigorne" and at Rochelle "burgau morchon" (De Montfort), and in La Manche "ran" (De Gerville). The animal emits a thin and copious slime. From its size and toughness it makes a good subject for anatomical demonstration-although Cuvier has left very little to be known about that part of its history. It burrows in the sand, like Natica catena; and its foot is similarly traversed by numerous canals, which admit of its being distended by water: this enters by an orifice at the upper corner of the mouth of the shell, and finds its way, through the abdominal cavity, into the rascular system of the foot. When it burrows, the end of the pallial tube or siphon is either exposed or but slightly covered by the sand, so as to supply the gills with water or air as the case may require. Beudant's experiments show that it cannot live in fresh water. The formation of two opercula by the same individual appears to be congenital, and not owing to an injury of the opercular lobe, which would cause an aborted or defective growth; for in some of these monstrous specimens the twin opercula are so large that they are doubled or folded inwards, side by side, in order to fit the mouth of the shell. This mollusk is very voracious, and is often caught on the fishermen's hooks. Örsted tells us, in his interesting treatise "De regionibus marinis," that great numbers of $B$. undatum and Fusus antiquus are collected in the Cattegat for
fish-bait, by putting a dead cod into a wicker basket and letting it down on a muddy bottom; it is soon taken up half filled with whelks. The same method is adopted for their capture on the English and Irish coasts. The whelk affords an illustration of the lex talionis ; fishes in their turn devour it with equal greediness. I have seen between 30 and 40 shells of B. undatum extracted from the stomach of a single cod. After the shell has been cleared out and ejected by the fish, it makes a convenient habitation for the hermit-crab. Other nations have not quite so great a fancy as ours for eating the whelk: perhaps it is an indigenous taste; for when the Romans were in this country, they seem to have acquired it-being one which they could not gratify in Italy. Shells of B. undatum, mixed with those of the oyster, have been noticed among the ruins of a Roman station at Richborough. At the enthronization feast of William Warham, Archbishop of Canterbury, on the 9 th of March 1504, there were provided " 8000 whelkes at 5 s . $\mp 1000$." In the shell-fish market at Billingsgate the present species goes by the name of the "white" or "common" whelk, in contradistinction to Fusus antiquus, which is there called the "red" or " almond" whelk; they are brought chiefly from Whitstable, Ramsgate, Margate, Grimsby, and Harwich. My obliging informant Mr. Baxter says, "Wilks must be sold the same day we receive them at market in the summer, being the day after they are caught; if the supply is greater than the demand, we boil them, and they keep good for several days." Evidence was given before a select committee of the House of Commons in the Session of 1866 , on the ' Whitstable oysterfishery extension Bill,' that the whelk-fishery on a sandy flat in that bay yielded $£ 12000$ a year,-part of the
produce being disposed of in the London market for food, and the rest sent to the cod-fishing banks for bait. They are seldom eaten in the northern part of our isles. At Dieppe and Nantes they may occasionally be seen exposed for sale in the fish-markets. The embryology of B. undatum has been investigated by Baster and many other writers. Its curious spawn-cells are figured in Ellis's 'Corallines' as "Alcyonium, scu Vesicularia marina of Bauhin ;" they were also called "Sea wash balls," because of their being used instead of soap by sailors to wash their hands. Dr. Johnston compares this resicular mass to the nest of the humble-bee. It is composed of numerous cartilaginous pouches, of the shape and size of a large split pea, piled irregularly one upon another, and attached by their edges at the base. Cailliaud counted 544 of these cells in one of the spawnmasses. Each cell contains at first several hundred eggs, which are afterwards so greatly reduced in number that only from 15 to 30 fry come to maturity. The process by which this reduction takes place has been disputed by Scandinavian and English physiologists, not less as to Buccinum than with respect to Purpura. Koren and Danielssen state that the eggs are at first spherical, that they afterwards separate into distinct portions, and then amalgamate or agglomerate and assume a different shape. Sir John Lubbock, on the contrary, ascertained that the more advanced embryos swallow the other yelks whole, and in such quantities as to become greatly distended; his paper in the 'Report of the British Association' for 1860 contains a representation of "a young embryo in the act of swallowing an egg." Dr. M‘'Intosh observed two specimens of the variety littoralis, on the 19th of October 1863, in the act of depositing spawn under a stone, about midtide, in a
rock-pool at St. Andrews. An egg-case, extruded from one of these whelks, which he held in his hand, was quite soft, and fell into the water like a ball of jelly. Before the fry leaves its cell, it is furnished with two rounded and ciliated lobes in front, a proboscis, eyes, foot, gills, heart, otolites or ear-stones, and other organs, besides a perfectly formed shell of two whorls and an operculum. The spawning-season takes place, according to the latitude and climate, between October and May; about two months are required for the development of the fry. The shells vary exceedingly in thickness ; some are solid and coarsely ribbed ; others are thin, and their sculpture is very delicatc. Sometimes the top of the shell is broken off, and the opening is closed by a plug. In young specimens the nucleus of the operculum is more central than in the adult, the lateral extension of growth being inwards or towards the pillar. Mr. Dennis and Mr. Norman believe that the scalariform distortion of the whorls, which is not unfrequent, is occasioned by an annelid occupying the suture; but the epidermis in such cases may be traced covering that part, and the distinction between post hoc and propter hoc may apply to the opinion of the above naturalists, as well as to the arguments of lawyers. The shell is the "roaring buckie" of Scotch bairns. Wordsworth has amplified this idea in the following pretty lines :-

> "I have seen
> A curious child, who dwelt upon a tract
> Of inland ground, applying to his ear
> The convolutions of a smooth-lipp'd shell;
> To which, in silence hush'd, his very soul
> Listen'd intensely, and his countenance soon
> Brighten'd with joy: for murmurings from within
> Were heard, -sonorous cadences, whereby,
> To his belief, the monitor express'd
> Mysterious union with its native sea."

Laudor's rerses express a similar idea as entertained by children of a larger growth. In the 30th Problem of Buonanni will be found a satisfactory explanation of this phenomenon, on acoustic principles.

It is the B. vulgare of Da Costa, B. porcatum of Gmelin, and B. Labradorense of Reeve. The Tritonium undatum of Fabricius is B. Grocnlandicum.

## 2. B. Humphreysia'num*, Bennett.

B. Humphreysianum, Benn. in Zool. Journ. i. p. 298, pl. xxr. (upper figures) ; F. \& H. iii. p. 410, pl. ex. f. 1.

Bodr whitish or yellowish-white, speckled with black: pallial tube cylindrical: tentacles conical, contractile and therefore varying in length, widely diverging, and separated by an intermediate membrane: eyes on short stalks or protuberances: foot broadly lanceolate, rounded or slightly bilobed in front, with a small triangular process at each corner, bluntly pointed behind.

Shell of a more regularly oral shape than $B$. undatum, thin, but nearly opaque, somewhat glossy : sculpture, numerous and delicate, wary, spiral impressed lines or striæ, risible only with a magnifying glass ; the surface is also corered with still finer, slighter, and much more numerous longitudinal striæ, which require a stronger power to observe them; no distinct reticulation is produced, but the interstices of the spiral striæ are microscopically punctured: colour yellowish or whitish, mottled with fawn or reddish-brown, or irregularly banded with rows of spots or chain-like markings of the last colour: epidermis none : spire rather short, regularly tapering : apex blunt and depressed: whorls $7-8$, rounded and convex; the last occupies more than three-fourths of the shell : suture deep: mouth forming an obtuse angle on the inner or columellar side, contracted above into an acute angle, and expanding outwards with a curred outline; length about fire-ninths that of the spire: cancl wide, open, and deep, exhibiting outside a corresponding notch : outer lip semicircular, flexuous, scarcely sinuated in the middle, sloping outrards from the

[^109]periphery; edge in full-grown specimens reflected; inside smooth : imner lip imperceptible, consisting merely of a slight glaze which imparts a polished appearance to that side : pillar microscopically pustulated: opercutum rery small, triangular, with a rounded outline, not very thin, somewhat concare; lines of growth fibrous and close-set. L. 1•75. B. 1.

Var. lactec. Milk-white.

Habitat: The outer "haaf" or fishing-banks, east and north of the Shetland Isles, in 73-90 f. ; also in Vidlom voe on the mainland of Shetland, 18 f . (Norman) ; Hebrides (Forbes, M'Andrew, and Barlee) ; co. Cork, 40 f. (Humphreys and Armstrong) ; Connemara (Professor King). ? Fossil in Palermo and Calabria (Philippi, as B. striatum). Living in Manger fiord (Sars, mus. Christ.). The shells received by the late Mr. G. B. Sowerby from Newfoundland, and referred by him to this species, appear to be B. Grænlandicum; and the same remark applies to those recorded by Professor Geikic from the Clyde beds. Dr. Stimpson must have mistaken some other species (perhaps B. ciliatum) for $B$. Humphreysianum when he described the latter as having a ciliated epidermis; and I therefore cannot recognize the North American localities indicated by him. B. ventricosum of Kiener (from the coast of Provence) is closely allied to our shell; but the whorls are more tumid and gibbous, and the operculum is not so disproportionately small. They bear the same relation to each other as Aporriais Serresiana docs to A. Macandrere.

This shell differs from the varicty Zetlandica of $B$. undatum in its more regularly oval shape, thinner texture, much finer sculpture, entire absence of an epidermis, not having a basal kcel or an inner lip, and in its extremely small and triangular operculum ; from all
the other varieties it is easily known by its far greater delicacy, the want of longitudinal ribs, and remarkable style of colouring. The operculum bears the same proportion to the size of the mouth as that of Aporrhais; it seems to be more ornamental than useful, like the coquettish hats worn by the girls of 'Tuscany on the crown of their heads. The opercular lobe covers only the centre of the operculum, the upper and under sides of which are sometimes encrusted with sessile Foraminifera. The egg-cases are separate and hemispherical. Some of the above characters are so peculiar as perhaps to warrant the generic separation of B. Humphrey-sianum-under the name of Mada, its surface being glabrous.

It is the B. Puxleianum of Leach; not B. Humphreysianum of Möller, Lovén, Middendorff, Sars, Danielssen, or Malm. Forbes (Mem. Geol. Surv. pp. 381 and 426) hastily considered it identical with the $B$. ciliatum of Fabricius ; his suggestion that the B. fusiforme of Broderip (which is a true Fusus) may be "an extreme form" of the same species is equally incxact.

The following are spurious or not British :-
B. glaciale, Linn. $=$ B. carinatum, Phipps., " Orkney Islands, Mr. Agnew, gardener to the Duchess of Portland" (Donovan) ; in the Portland-sale catalogue it is stated to be from Greenland, which is the true habitat. Fleming's Zetlandic specimen was, I believe, given to him by the captain of a whaler.
B. Grenlandicum, Chemn., with no end of synonyms, is one of our glacial fossils; it does not now live south of Finmark. Fabricius broached an odd idea, that by means of the pallial tube (which he called a cirrus) the animal was accustomed to catch hold of the leaves of fuci, so as to facilitate its progress, and when
that prehensile organ was not used it did not get on so well!
B. ciliatum, Fabr. With Scalaria Gronlandica, from Shetland (Bean) : Greenland. See p. 97 of this volume.
B. plicosum, Menke $=$ Fusus cinereus, $\mathrm{Say}=F$ F Forbesi, Strickland. Isle of Man (Forbes) : Arctic Ocean and United States. See vol. ii pp. 58 \& 59.

Dolium perdix, Linn. Weymouth (Pulteney) and Jura (Laskey) : South-European and African.

Cassis testiculus, Linn. (young), B. decussatum, Penn. $=$ B. porcatum, Pult. Weymouth (Pennant); Firth of Forth (Laskey) ; Plymouth (Lambert, fide Fleming): West-Indian.

## Family XXVIII. MURI'CIDE, Fleming.

Body spiral, usually long: mantle, pallial fold, head, and proboscis as in the last family : tentacles forming an clongated cone: eyes on stalks, which are combined with the outer part of the tentacles and placed some way up the latter: foot lanceolate, longer than in the other family: opercular lobe, gills, and odontophore as in the Buccinidce. Sexes separate.

Shell conic-oval or oblong, variously sculptured : spire produced: mouth oval: pillar not twisted: canal more or less extended: operculum horny, never spiral, increasing by semielliptical or curved layers; nucleus terminal.

This huge collection of mollusea has been divided, for scientific convenience, into many genera, which are distinguishable solely by their shells, never by their soft parts. Still, mere conchological characters, and even the structure of the operculum, are in some cases not less useful for the purpose of classification than characters based on the animal. Very few groups of higher rank than species are equivalent, or can be coordinated. I do not propose, on the one hand, to follow

Mr. Clark in out-Linneanizing Limé, and restricting nearly all the British Siphonobranchiata to the single geus Murex, nor, on the other hand, to adopt what I consider the excessive multiplication of genera proposed by the Messrs. Adams, Dr. Mörch, and other systematists of the extreme party of progress.

The Muricida, like the Buccinide, prey on other mollusca, and eat dead fishes. They frequent every part of the globe.

## Genus I. BUCCINOP'SIS*, Jeffreys. Pl. V.f. 3.

Sheil oval, spirally striated : epidermis filmy : spire short, with a blunt point: outer lip smooth rithin: pillar also smooth : canal short and open: operculum triangular ; nucleus placed on the inner base of the mouth.

The principal difference betreen this genus and Buccinum consists in the operculum, the nucleus of which is in Buccinopsis terminal, at the inncr base of the mouth, the increase taking place by semielliptical layers; while in the other genus it is placed within the edge, at the outer side of the mouth, the increase taking place by concentric layers. The egg-cases of Buccinopsis are separate, and shaped like a well-filled leather purse, the opening for the egress of the fry being at the top and rery wide. According to Mr. Alder, " its tongue differs from that of Buccinum undatum, as well as from those of the allied species of the genus Fusus, and makes a slight approach to that of Mangelia. It has a single plain and slightly curved tooth on each side, and a very thin non-denticulated plate in the centre."

I am not over fond of repeating the opsis-composition in generic names; but the resemblance of the shell

[^110]which 1 am about to describe to that of Buccinum is very close, and the name Buccinopsis is of some years' standing, as well as peculiarly appropriate. Dr. Stimpson lately proposed (without a description) another name, Liomesus, for our British species: that name would convey an erroneous impression, if derived from the Greek, as the shell is not smooth in the middle. The Buccinum deforme of Reeve (a sinistrorsal shell), from Spitzbergen, appears to belong to the present genus.

## Buccinopsis Da'lei*, James Sowerby.

Duccinum Dalei, J. Sow. Min. Conch. p. 139, pl. 486. f. 1, 2; F. \& H. iii. p. 408 , pl. cix. f. $1,2$.

Body pale yellowish-white, with a faint tinge of fleshcolour: pallial tube rather long: head broadish: tentacles short, diverging at an angle of about $25^{\circ}$; tips blunt: eyes on short stalks (the extremities of which appear like prominent tubercles) near the outer base of the tentacles; they are very small and black: foot large and thick, expanded and rounded, as well as double-edged, in front, minutely tubercled at the sides, and bluntly pointed behind: verge falcate, very long and narrow.

Shell egg-shaped, with a truncated base, moderatcly solid, semitransparent, somewhat glossy: sculpture, numerous very slight and delicate spiral strix, and still more close-set lines of growth ; these marks are only discernible with a magnifyingpower, the surface appearing smooth to the naked or unarmed eye: colour that of ivory: epidermis extremely thin, pale yellowish-white, with a faint tint of brown: spire short and terminating rather abruptly; apex compressed and regular: whorls 5-6, tumid, rapidly enlarging; the last occupies at least three-fourths of the shell: suture wide and slightly excavated, but not very deep: mouth forming an obtuse angle on the inner side, and curved outwardly; upper corner contracted and acute-angled; the length of the mouth is more than fiveeighths that of the spire: canal wide and deep, a little recurved to the left, with a corresponding noteh on the outside; its edge is thickened and reflected: outer lip semicircular ; edge

[^111]also thickened and reflected: imer lip thin, consisting of a porcellanous glaze : pillar broad, smooth and polished; microscopically riewed it is curred with pustules, which are arranged in lines lengthwise: operculum obliquely triangular, pale yellowish-brown, thin, marked by several faint lines, which diverge from the nucleus uptrards; layers of growth numerous and irregular. L. 1•⿹. B. 1.

Yar. eburnea. Shell smaller and thinner, with the spire more produced. Tritonium eburneum, Sars, Reise i Lofoten og Finmarken, 1849, p. 73.

Habitat: Co. Cork, in the stomach of the red gurnard and haddock (Humphreys), from which source I have reason to believe Dr. Turton's typical specimen, now in my possession, was derived, instead of from Plymouth as stated by him; west coast of Ireland, 100 f. (Hoskyns, fide King) ; soft ground beyond the Dogger bank, $40-50 \mathrm{f}$. (King and others) ; Aberdeenshire (Macgillivray and Dawson). The variety has been dredged by me, on a bottom of fine sand mixed with mud, in $72-87$ f., off the northern and eastern coasts of Shetland (with Fusus Norvegicus and F. Berniciensis), by Sars at different places between the Loffoden Isles and the North Cape, at depths of from 40 to 50 f., and by $\mathrm{M}^{\prime}$ Andrew and Barrett also in Upper Norway, in 100-160 f . The typical form occurs in the Red and Coralline Crag, but is more rare in the latter; Antwerp Crag (Nyst). I noticed a specimen from the last-mentioned deposit in the Royal Museum at Brussels, which measured $3 \frac{3}{4}$ inches in length by $1 \frac{3}{4}$ in breadth. Mr. Searles Wood found a specimen in the Red Crag having the spire reversed. The following localities recorded for this species in a living state require confirmation :-Sea of Okhotsk (Middendorff, as Tritonium ooïdes), and Behring's Straits (P. Carpenter).
The animal is slimy, and rather active. Its egg-cases
are sometimes deposited on the under side of the maternal shell; the base of their attachment is narrower than the upper portion. The shell is known among the Staithes fishermen as the "white whelk." Its home appears to be the German Ocean and the Nymplı bank, instead of the arctic seas. Mr. S. Wood's speculation as to the reason why fossil are more distinctly striated than recent specimeus is ingenious. He took for granted that the species is "dying out," and suggested that the faint and imperfect striæ on the shells of the surviving race may be "from failure of vigour in those organs necessary for such distinction, consequent upon the approaching demise of the species." Some of the Crag specimens, however, are not less smooth than recent ones, and were described by Sowerby as his variety " (a), ventricose, rarely sulcated."

It is the Buccinum ovum of Turton (not Tritonium ovum of Middendorff), and probably B. crassum of Nyst; the young was described by Macgillivray as Halia Flemingiana.

Genus II. TRITON*, De Montfort. Pl. V. f. 4.
Shecls thick, each whorl strengthened lengthwise by a raricose rib: epidermis skin-like: spire bluntly pointed: outer lip and pillar plaited or tuberculated: canal rather short, open throughout, and nearly straight: operculum oval or oblong; nucleus placed at the outer base of the mouth.

The two fine species which I now give as additions to our mollusca inhabit that part of the sea which washes the extreme southern coast of England. Those who reject Haliotis because it has not been found north of Guernsey would of course consider the Tritones and a few species of other genera extra-British. With such

[^112]I will not dispute, but leare them to their own opinion. If a time should arrive when the Channel Isles cease to be part of this country, all the above items may be omitted, and transferred to another account in the ledger of European fania.

The name of Triton has long been established and in use for a well-known genus of lizards. Link aud Curier called the shell Tritonium, and Schumacher Lampusia: the former name, however, was preoccupied by Müller ; and, although it has been superseded, some confusion might arise from the new application of it. Should any change be necessary, Lampusia may be adopted.

## 1. Triton yodi'ferus*, Lamarck.

Triton nodiferum, Lam. An, s. V. vii. p. 179.
Body of a vermilion tint, marbled with diffused spots of reddish-brown: mantle white [prettily variegated (Costa)]: tentacles adorned with two black bands: foot having the sole orangecolour. (Philippi.)
Suexic conic-oblong, with an angulated outline, very strong and solid, opaque, rather glossy: sculpture, a thick rib behind the outer lip on the body-whorl, and one in a corresponding position on each of the other whorls, which form varices and are apparently the marks of annual growth ; the whole surface is irregularly covered with numerous spiral ridges and finer intermediate striæ (besides close-set microscopic lines in the same direction), the ridges being more or less tuberculated or nodose : colour whitish, with a pale flesh tinge, variegated by coffeecoloured spots, stripes, and blotches : epidermis brownishyellow, thin, and easily peeled off : spire elongated: whorls 8-10, swollen, and compressed upwards; the last occupies nearly two-thirds of the shell: suture rather slight: mouth acute-angled at the upper and lower corners; length about one-half that of the spire : canal wide and deep, ending outside in a shallow notch; its edge is thick, but not reflected: outer lip semicircular, sloping or bevelled inwards, and furnished inside with from 15 to 20 short coffecoloured

[^113]ridges which terminate inwards in small tubercles, and outwards in points, giving a scalloped appearance to the outer edge; some of these ridges are double or arranged in pairs : inner lip forming a polished glaze, which is thicker on the outside of the canal : pillar broad, furrowed across with numerous plaits or narrow ridges, the uppermost of which is the largest, and the lowermost are sometimes broken or interrupted; there is a smooth space between the top plait and the upper corner of the mouth : operculum obliquely oblong, horncolour, rather solid; layers of growth slightly imbricated or overlapping one another. L.6. B. 2•75.

Habitat: Guernsey coast, where three living specimens were trawled at different times between 1825 and 1832. Two were procured by Mr. Lukis (who kindly presented one of them to me), and the third by Sir Thomas Mansell: the largest was taken near the Caskets, by James Ozanne of Paridis Vale, on the 25th of August 1825. Mr. Lukis kept this specimen alive for some time. I was assured both by him and Mr. Gallienne that the Guernsey fishermen trawl only within a short distance from their own land, and never go on the opposite coast of France, and that French trawlers never come to the Channel Isles. Fossil at Piacentino (Brocchi) and Palermo (Calcara, ? Philippi). It inhabits the North Atlantic from Brest (Fréminville, fide Collard des Cherres) to the Azores (Drouet), both sides of the Mediterranean (Lamarck and others), the Adriatic (v. Schröckinger), and Archipelago (Linné).

It seems to have the same faculty as the snails and slugs for reproducing amputated parts. Madame Power lopped off a tentacle; and at the end of 20 days a new one had been formed, six lines in length; previously to amputation it measured fourteen lines. According to Philippi, the animal, shortly before death, emits a fluid which he calls "pulcherrime coolestem." The Sicilian fishermen not only use the shell as a trumpet, but eat
the leathery inhabitant and estecm it a delicacy ; M‘Andrew saw it offered for sale with other shell-fish in the market at Algiers. Vérany tells us that at Nice the shell of T. nodiferus, with a hole at the top, serves as a trumpet for the fishermen and countrypeople, and that the braying noise produced by it renders this musical instrument indispensable for the old-fashioned charivari, which he describes as a deafening serenade to signalize the marriages of widows and ill-assorted couples. My specimen is incrusted with several kinds of Lepralia not noticed south of the British coasts, Spirorbis yranulatus, S. corrugatus, and Truncatulina lobatula.

Murex Tritonis of Linné is a large tropical shell (the true Triton's trumpet), although his description included the present species.

## 2. T. cuta ${ }^{\prime}$ ceus*, Linné.

Murex cutaceus, Linn. S. N. p. 1217.
Body on the upper part painted with irregular spots of dark purple, which are separated by narrow white lines: foot pale violet above, marbled on the sides, and speckled here and there with reddish spots which are edged with white. (Philippi.)

Shell conic-oval, with a twisted and angulated outline, very strong and solid, opaque, rather glossy : sculpture, a thick and expanded rib behind the outer lip, a prominent and someWhat crested rib on the middle of the body-whorl, another on the penultimate whorl, and frequently a fourth on the preceding whorl (all but the labial rib being varicose) ; there are also broad flattened spiral ridges (from 6 to 10 on the bodywhorl), besides a few irregular thread-like strix in the interstices; the penultimate whorl has 3 or 4 ridges, and each of the next tro whorls has 2 ridges; the ridges on the upper part of the shell are more or less tuberculated or nodose; the whole surface is covered with fine and close-set longitudinal strix, which produce an imperfect cancellation: colour yel-lowish-white, tinged or obscurely streaked with purplish-

[^114]brown: epidermis brownish-yellow, moulded on the longitudinal sculpture, more adhesire or persistent than in the last species: spire turreted, short; apex depressed, and smooth, consisting of an incomplete turn : whorls 5-6, convex, strongly angulated by the varices, and compressed upwards; the last occupies three-fourths of the shell: suture deep, interrupted by the varices: mouth narrow, acute-angled above and below, contracted at the upper corner by a tooth on each side, so as to leave an excavation like the top of a key-hole; length, exclusire of the canal, about two-fifths that of the whole spire: cancl narrow and contracted, ending outside in a rather deep and oblique notch with a thick edge: outer lip nearly semicircular ; that part which consists of the last-formed rib is Rat, thick, and strengthened by a continuation of the spiral ridges; the inside of the lip is furnished with 7 or 8 strong tuberculated plaits, the spaces between which, where the lip is inflected, are deeply excavated: inner lip broad and rather thick, united above with the outer lip, reflected orer the lower part of the pillar, behind which there is a shallow groove terminating in a small umbilical hole, caused by the superposition of the new mouth on that of the preceding whorl: pillar broad, shelving inwards, curved above, and sloping below to the left; close to the upper corner of the mouth is a tooth or short tubercular plait, and frequently another minute tooth just below it ; at some distance within may also be detected four or five ridge-like plaits; the lower part of the pillar is indistinctly corrugated or wrinkled across : opercutuon obliquely oval, yellowish-brown or horncolour, rather solid ; layers of growth numerous. L. $2 \cdot 4$. B. $1 \cdot 7$.

Habitat: Guernsey, dredged by Dr. Lukis and Mr. Barlee; from a crab-pot (Macculloch); taken by Mr. John Rougier on a large flat stone at the extreme verge of the lowest spring tide, while gathering ormers (Haliotis tuberculata) in the island of Lihou (Dr. Lukis) : dead shells have also been found by Mr. Lukis and others on the beaches at Guernsey and Herm. Forty years ago Dr. Turton recorded the capture of this species at Padstow, and afterwards at Falmouth and Guernsey; but the Cornish localities have not been verified by any subsequent discovery. For my specimens I am indebted
to the liberality of Dr. Lukis and Mr. Macculloch; I likewise have one in the Turtonian collection. T. $\mathrm{cu}-$ taceus is not uncommon on the coasts of the north, west, and south of France, and those of Spain, Portugal, Italy, Algiers, and the Canary Isles.

Young shells resemble stunted specimens of Murex erinaceus.

No habitat is given by Linné for his Murex cutaceus ; his description and reference to Seba's figure may apply to some tropical species of Triton. I should have preferred considering the present species his M. pileare, which he says is Mediterranean. Our shell is the type of De Montfort's genus Aquillus.

The obliging attention of the Rev. Dr. Robinson has enabled me to examine and compare the unique specimen of T. elegans, Thompson (Ann. \& Mag. N. H. xv. p. 317, pl. xix. f. 1), stated to have been found by the late Dr. Farran alive at Portmarnock in Dublin Bay, and now in the public museum at Armagh. It is the Hindsia anyusticostata of Pease, a common shell of the Sandwich Islands. Portmarnock has been from the time of Turton a prolific source of such erroneous additions to the catalogue of British shells.

## Genus III. MUREX*, Linné. Pl. V. f. 5.

Streli more or less turreted, ribbed lengthwise and ridged spirally, so as to form an imbricated kind of sculpture, often with prickly points; the body-whorl has more than one varix : spire prominent and sharp-pointed; apex mammiform : outer lip plaited or tuberculated within : pillar smooth : canal rather long, narrow, corered over, turning obliquely to the left: operculum oval; nucleus placed at the lower side of the outer lip.

The name of this genus (as well as $\pi$ oo ${ }^{\prime} \dot{\rho} \rho a, ~ p u r p u r a$,

[^115]and ostrum) was in familiar use among the ancients, and signified not only the Tyrian dye but also the shell-fish (M. trunculus) which produced it. It is related by Isidorus that the dye results from the purple tears shed by the murex when wounded. Aldrovandi collected an immense number of poetical quotations having reference to this highly prized colour, which was for so many ages the emblem of rank and distinction. Sumptuary laws were then very strict: indeed two centuries have not elapsed since they were in force in England and much commended by our great philosopher, Bacon. The deposit of the spawn and production of the young murices were described by Aristotle with his usual accuracy ; and yet he persisted in asserting that all testaceous mollusea were generated from putrefying matter and slime. The shells of this genus are remarkable for their elegant sculpture; some are ornamented by elaborately carved leaf-like varices, others by a series of flounced ribs, a few by rows of long almost tubular spines; occasionally the aperture is profusely enamelled, and tinged with roseate hues. The temperate zone, however, cannot boast of such beauty. It was supposed by the late Mr. G. B. Sowerby that, when the outer lip of a Murex is fringed with spines, the animal can remove these processes by some means, probably a solvent liquor, to enable it to enlarge its shell. But his own admirable figures are opposed to the conjecture, and show that the spines are persistent.

## 1. Murex erina'ceus*, Linné.

M. erinaceus, Linn. S. N. p. 1216 ; F. \& H. iii. p. 370 , pl. cii. f. 4, and (animal) pl. TT. f. 1.
Body yellowish of different shades, mottled or lineated with

[^116]flake-white: pallial tube short: [proboscis 8-10 lines long (Bouchard-Chantereaux):] tentacles sometimes saffroncolour, slender, and tapering to a fine point; they are nearly close together at the base, and diverge at a right angle : eyes on long stalks, which are united with the tentacles outside and extend two-thirds of their length from the base : foot rather small and narrow, rounded and double-edged in front with short angular corners, bluntly pointed behind; sole slightly groored down the middle: [gills very small, brownish (Bou-chard-Chantereaux):]oclontophore cylindrical, rather long [central tooth convex, keeled, projecting in the middle in front, the angles extended behind, base curved and prominent, cutting-edge finely notched in a groove-like manner on each side, and having 3 crested points, the middle of which is larger and expanded, grooved on the inner side; lateral teeth haring a long claw-like hook (Lovén)].

Shell conical, rugged, solid, opaque, of a rather dull hue: sculpture, strong buttress-like longitudinal ribs, of which there are 7 or 8 on the body-mhorl, 8 or 9 on the next, and one more (in a progressive ratio) on each of the preceding whorls; some of these ribs are varicose; but there seems to be no regularity in this respect, as the number probably depends on the quick or slow growth of the individual; there are also several cord-like spiral ridges on all the whorls (except those which form the apex), alternating in size, two on each of the upper whorls being more prominent ; the surface is also corered with small and close-set wavy plait-like striæ, which are arranged in transwerse rows of short vaulted scales on the lower whorls, and give an imbricated or flounce-like aspect; the upper whorls are coarsely cancellated: colour jellowish-white, sometimes mottled or streaked with reddish- or purplish-brown, and the upper part of each whorl is now and then encircled by a white or pale band: spire turreted, rather short; apex somewhat cylindrical, smooth and glossy, obliquely twisted upwards: whorls $8-10$, convex, but angulated, more or less flattened at the top; the last occupies three-fourths of the shell: suture wide and deep, partly interrupted by the ribs: mouth regularly oval, with the upper corner curred; it is proportionally larger and somewhat expanded in half-grown spocimens; length (exclusive of the canal) between one-third and one-fourth that of the shell: canal open throughout in the young, and in after growth becoming tubular except at the base, in consequence of the overlapping on each side of the
outer and pillar lips, which are ultimately welded together; it is obliquely truncated towards the base, and terminates outside in a deep and rounded notch with a thick edge: outer lip nearly semicircular ; that part which consists of the last-formed rib slopes outwards, and is strengthened by a continuation of the spiral ridges; the edge is slightly prominent; inside fluted, and furnished with 7 or 8 small tubercles or tecth: inner lip thick, united above with the outer lip; at the base of the pillar is a groove and umbilical chink, as in Triton cutaceus, but it is much smaller and less distinct: pillar broad and glossy : operculum reddish-horncolour, thinner than in the last-mentioned species, irregularly laminated, and microscopically and superficially wrinkled. L. $2 \cdot 25$. B. 1•125.

Var. sculpta. Spiral ridges much more prominent and keellike, especially those on the upper part of each whorl, giving the shell a scalariform appearauce; space below the suture deeply excavated.

Habitat: Stony ground, at low-water mark and in the laminarian and coralline zones, on the southern and western coasts of England and Scotland, and throughout Ireland and Wales; estuary of the Thames (Thomas and J. G. J.) ; trawled off Yarmouth (Rose) ; Scarborough (Bean); Northumberland and Durham (Alder); dredged in Berwick Bay, 50 f. (Mennell); Moray Firth (Gordon) ; Aberdeen (Macgillivray). All the specimens procured from the northern coasts were dead. I dredged the variety off Guernsey. M. erinaceus occurs in quaternary deposits at Strethill (Maw) ; Macclesfield (Darbishire); Kelsey Hill (Prestwich); Moel Tryfaen (Darbishire and Drury Lowe); Belfast (Grainger); Ireland and Clyde beds (J. Smith and Forbes); "Mammalian Crag" at Bramerton (S. Wood) ; "Norwich Crag" (Witham, fide Woodward) ; Italian tertiaries (Brocchi, Scacchi, and Philippi). Living in the Cattegat (Lovén); North Atlantic from Boulogne (Bouchard) to Madeira (M'Andrew) and the Azores (Drouet); Mediterrancan (Linné
and others); Black Sea (Middendorff). Bathymetrical range, shore to 30 f .

The animal yields a purple dye, like that of Purpura lapillus, but not in such quantity ; the tint is violet, and is said to become more vinous, more blue, or more rosy under apparently the same conditions. It is the "stingwinkle" of our fishermen, who do their best to get rid of it on account of the ravages which it commits in oyster-beds. This destructive habit has been well described by Dr. Fischer in the 'Journal de Conchyliologie' for January 1865. He says that at Arcachon M. erinaceus goes by the name of "cormaillot" or " perceur," and preys on the young oyster (from 6 to 8 months old), drilling the shell between the muscular impression and the beak, generally in the concave and larger valve. The shells of old, oysters are too hard for the Murex to penetrate. The drilling-operation takes 3 or 4 hours. When a hole is made, the whelk uncurls and inserts its long proboscis, and leisurely devours its victim. MM. Petit, Cailliaud, and Taslé have also noticed the damage done by this noxious mollusk on other parts of the French coast. Man is not the only animal that relishes an oyster. M. Cailliaud attributes the perforating power of the Murex to its "trompe acidulée;" the spinous tongue, however, is usually considcred the agent. The egg-cases are separate, of a triangular shape, and compressed at the sides, with a small round hole at the top for the egress of the fry; the stalk is short and narrow. They are deposited indiscriminately on shells and stones, and form a cluster of from 15 to 150 , each containing from 12 to 20 perfect whelklings. I caught a small M. erinaceus fceding on an Anomia, and found that the perforation in the shell of the latter was one-sixth of an inch in diameter, being greater than
that of the proboscis at its point ; it therefore seems that the hole had been eularged after it was made. Some specimens of $M$. erinaceus are very much larger than others, even in the same locality; in the Mediterranean they attain a comparatively gigantic size.

The "urchin-shell" of Pennant, Buccinum porcatum of Da Costa, and perhaps $M$. cinguliferus of Lamarck, when half-grown it is the M. Tarentinus of the lastnamed author. M. decussatus of Gmelin (from Adanson) is closely allied, if not identical. M. torosus of Lamarck is, according to the Rev. R. T. Lowe, a variety, probably sculpta; but most conchologists refer to that species a tropical shell with smooth ridges. Leach called the present species Ocinebra erinacea. What right have naturalists to play such pranks,
"And nickname God's creatures"
in this fashion?

## 2. M. acicula'tus*, Lamarck.

M. aciculatus, Lam. An. s. V. vii. p. 176. no. 66. M. corallinus, F. \& II. iii. p. 374 , pl. cii. f. 5,6 .

Body bright coral-red or scarlet [vermilion (Philippi)], occasionally speckled with yellowish-white or golden-jellow: mantle thick, lining the mouth of the shell: pallial tube rather long: head small: tentacles extensile, of a paler colour than the rest of the body, microscopically ciliated, especially at the tips, which are bluntly pointed : eyes small, placed on stalks which are amalgamated with the tentacles at their outer bases and extend between one-third and more than halfway up: foot rather slender, rounded or truncated and double-edged in front, contracted and narromer in the middle, and bluntly pointed behind; sole having a clear edge or margin.

Shell oblong, approaching to spindle-shaped, solid, opaque, Iustreless : sculpture, strong, broad, and rounded, but not very prominent longitudinal ribs ( 8 to 10 on the last whorl, and

[^117]one more on the penultimate), some of which are occasionally varicose, as in $M^{M}$. erinaceus; all the whorls except the uppermost are encircled by thread-like ridges, of which there are about 20 on the body-whorl, 7 or 8 on the sixth, 5 or 6 on the fifth, 3 on each of the fourth and third, and 2 on the preceding whorl, the whorl and a half which constitute the apex being smooth and glossy ; many of these ridges on the body-whorl alternate in size, and some of those below the periphery are often larger and coarser than the rest ; the surface is also covered lengthrise with numerous and close-set twilled strix, which form transrerse rows of short vaulted scales on the crests of the ridges upon the lower whorls, the ridges upon the upper whorls being tuberculated: colow dark reddish-brown: spire produced ; apex somewhat cylindrical, with a globular extremity, which is obliquely twisted on one side: vhorls 7-8, conrex, but compressed upwards; the last occupies two-thirds of the shell : suture wide, not deep, more or less interrupted by the ribs: mouth exactly oval, expanding outwards; length (exclusive of the canal) fire-trelfths of the shell: canal short, turning to the left, corered over on the lower part by the interjunction of the two lips, and terminating in an oral fistulous orifice: outer lip nearly semicircular, sharp and thin, slightly scalloped by the spiral ridges, and sloping inwards to the throat, which is furnished with 6 or 7 small white tooth-like tubercles: inner lip detached at its edges, and reflected on the pillar and canal; it is continuous with the outer lip at the upper corner of the mouth; behind it on the lower part is a narrow depression or groove, which separates the new from the old caual, the base being twisted: pillar broad and glossy: operculum reddish-horncolour, rather thin, irregularly laminated, and microscopically fretted; muscular impressions on the underside elliptical, and nearly central. L. 0.5 . B. 0.25.

Tar. badia. Baycolour.
Habitat: Channel Isles, on stony and rocky ground at low-water mark and in the laminarian and coralline zones. I obtained the variety by dredging in 22 f . off St. Martin's Point, Guernsey. Scacchi and Philippi have recorded this species from the Italian tertiaries, and Woodward from the Coralline Crag at Gedgrave. Its existing distribution comprises the North Atlantic
from Brittany to the Canary Isles and the Azores, the Mediterranean, and the Adriatic ; depths 4-4.0 f.
M. Martin showed me the spawn-cells, attached to the underside of the shell. I have dredged similar capsules at Guernsey. These are solitary, barrel-shaped and strongly corrugated ; the ova are elliptical and prismatic. Specimens of M. aciculatus from the coralline zone are not unfrequently covered with a sponge, or now and then with one of the minute tubular Hydrozoa, which gives the shell the appearance of having a hairy epidermis.

Lamarck's descriptions are usually too concise or too vague to identify species; but in the present case no doubt can arise, and I must retain the name imposed by him, in preference to the later one (corallinus) of Scacchi. Lamarck received this species from the coast of Brittany, where it is not uncommon; and it is enumerated in the list of Collard des Cherres under the name of M. aciculatus. Philippi placed it in the genus Fusus, and referred it to the F. lavatus of Basterot. Sowerby and Reeve called it M. inconspicuus.

Genus IV. LA'CHESIS*, Risso. Pl. VI. f. 1.
Shell having the shape of a short spindle, strong, ridged spirally, and ribbed lengthwise but not varicosely: spire produced; apex mammiform: outer lip notched within: pillar smooth : canal short, wide, nearly straight, open throughout: operculum oval, bluntly pointed at the base; nucleus placed at the lower side of the outer lip.

The species are few and of small size ; they inhabit the littoral and laminarian zones. Risso appears to have ingeniously constructed another genus (Nesaa) out of the same type.

* One of the Fates.

## Lachesis minha*, Montagu.

Buccinum minimum, Mont. Test. Br. (i.) p. 2t7, t. 8. f. 9. L. minima, F. \& H. iii. p. 377, pl. ci. f. $7,8$.

Bodr yellowish, speckled with flake-white : pallial tube long and crlindrical: tentucles extensile (short and club-shaped when the animal is at rest), diverging from their base at an acnte angle, compressed in front and behind: cyes small, on the extremity of stalks which extend about halfway up the tentacles: foot comparatively long and slender, although shorter than the shell, squarish and donble-edged in front with small angular corners, becoming narrower behind, and ending in it bluntly pointed tail.

Shele oblong, solid, opaque, and rather glossy : sculpture, at broad rib or callus behind the onter lip, and narrower longitudinal ribs on all the whorls except the first; these ribs seldom, howerer, cover the last half of the body-whorl ; when they do so, 9 may be counted on that whorl, and 10 on the next; they are crossed by broad and flattened spiral ridges, which are defined by impressed lines or strix ( $15-20$ on the body-whorl, and 4 on each of the preceding four whorls, the first or apical whorl being closely and microscopically striated in the same direction) ; the ribs consequently become more or less nodulons or tuberculated; marks of growth close-set: colour that of coffee or reddish-brown, farying in intensity: spire abruptly pointed: apex globular, twisted on one side: whorls 5-6, rather convex, compressed upwards; the last occupies foursevenths of the shell: suture distinct, but not deep: mouth oral, somewhat expanding outrards; length (exclusive of the canal) two-fifths of the shell: cuarel bending a little to the left, terminating at the base in a deep rounded notch with a thick cdge: outer lip curved, slightly inflected on the periphery, plain-edged; throat furnished with half a dozen toothlike ridges or plaits, the largest of which is close to the canal: inner lip rather thin and narrow, spread orer the pillar and side of the canal, indistinctly united with the onter lip; there is no trace of an umbilical chink, the base being eren and rounded: pillai obtnsely angulated at the entrance of the canal: opercutum yellowish, closely and finely striated in the line of growth. L. $0 \cdot \%$. B. $0 \cdot 1$.

Tar. pallescens. Of a paler colour, and occasionally milkwhite.

> * The smallest (viz. of the Duccina.

Habitat: Rocky and stony ground at low-water mark, and in the laminarian zone, on the coasts of Cornwall, Dorset, Devon, and the Channel Isles; common, but local. The following recorded notices are by no means reliable or prove that $L$. brunnea is indigenous to these places:-Langland Bay, near Swansea (Dillwyn); St. Cyrus, Kincardineshire (Brown); Tynemouth and Cullercoats (Alder). With regard to the last two localities Mr. Alder tells us that this species has never been found there alive, and that " the sand of the coast is rather vitiated with ballast from the ships." I found the variety at Guernsey. L. brunnea is fossil at Pezzo in Calabria (Philippi); ? Ireland (J. Smith). It inhabits the Atlantic shores of France, Spain, Portugal, and Madeira, the Mediterranean, and Adriatic ; depths, shore -35 f .

This has a different habit from most other whelks, viz. swimming with its foot upwards. It does not seem to require the use of the top whorls, the spire being sometimes truncated in living and vigorous specimens.

Donovan, simultaneously with Montagu, described the present shell as Buccinum brunneum; this specific name is not Ciceronian, but appropriate, and better than minima, which gives a wrong standard of comparison. However, the latter name is sanctioned by Philippi having also used it, without being aware of. Montagu's publication ; he afterwards noticed the curious coincidence. The Buccinum minimum of Turton, in his translation of the 'Systema Naturæ,' is Nassa incrassata. It is the $L$. mamillata of Risso (and apparently also his Nesaa mamillata), Murex Massence of Delle Chiaje, according to Philippi Fusus turritellatus of Deshayes, Buccinum rubrum of Potiez and Michaud, and Fusus subnigris of Brown.

Murex gyrinus of Montagu (not of Linné), a base coin from the Laskeyan mint, is exotic ; Turton's specimen shows it to be a Lachesis.

Genus V. TROPHON**, ? De Miontfort. Pl. VI. f. 2.
Surlu spindie-shaped, never umbilicate, lengthwise plaited or having laminar (oceasionally varicose) ribs, and sometimes cancellated by spiral ridges: epidermis none: spire clongated; apex mammiform : outer lip seldom notched or toothed within: pillar smooth, more or less twisted : canal usually long and beak-like, open thronghout: operculum pear-shaped, flexuous ; nucleus placed at the imer base of the mouth : eyg-cuses separate, membranous, hemispherical, and attached by the circular base.

De Montfort has the credit of instituting this genus; but his definition does not correspond with our idea of it. He describes the shell as globular, with an expanded mouth, the outer lip foliated or plaited, the base umbilicate, and the canal short; indeed he lays great stres: on its having a very deep and conspicuous umbilicus, as distinguishing Trophon from Buccinum. The genus, as now recognized, possesses scarcely one of the characters attributed to it by the founder. The name, however, is immaterial. Whether Trophon is distinct from Fusus, or is merely
. . . . . "et nomen et genus inutile,"
are other questions that require much consideration. I adopt the genus provisionally.

Trophon frequents the laminarian and coralline zones, and appears to be restricted to the North Atlantic.

[^118]
## 1. Trophon murica'tus, Montagu.

Murex murricatus, Mont. Test. Br. (i.) p. 262, t. 9. f. 2. T. muricatus, F. \& H. iii. p. 439, pl. exi. f. 3, 4, and (animal) pl. SS. f. 5, as T. echinatum.

Body whitish: pallial tube short [often extending beyond the canal of the shell (Clark)]: head inconspicuous: tentacles rather long and taporing to a point; two-thirds of each on the lower side are more than twice the thickness of the upper portion, owing not only to the addition of the eye-stalk, but to the tentacle itself being broader at the base: eyes small and black: foot rather long and expansile, squarish in front with a gently curred outline, somewhat angulated at the corners, and bluntly pointed behind; sole slightly grooved: verge large, sickle-shaped.

Stell slender, not very solid, nearly opaque, and having searcely any gloss: sculpture, numerous longitudinal ribs, which (especially on the body-whorl) are often laminar, and more or less varicose ; these ribs usually do not extend to the infrasutural part of each whorl; there are also thread-like spiral ridges, about 12 on the body-whorl, 4 or 5 on the next, and gradually lessening in number towards the apex, which is microscopically and closely striated in the same direction: the points of intersection between the longitudinal and spiral sculpture on the crests of the ribs are tubercular, or corrugated, sometimes prickly like the vaulted scales on the ribs of many species of Pecten; the lines of growth are minute and irregular: colour yellowish-white, or fleshcolour tinged with reddish-brown: spire extending to an abrupt point; apex globular, twisted either on one side or downwards: whorls $7-8$, convex and rather tumid, angulated and flattened on the upper part, so as to give a turreted aspect to the spire; the last occupies nine-fourtcenths of the shell: suture wide and deep : mouth proportionally small, triangularly oral, expanding ontwards; length two-sevenths of the shell: canal semitubular, inclining a little to the left, and terminating in a deep and obliquely rounded notch ; externally it is devoid of any sculpture except the marks of growth : outer lip prominent, contracted above, and abruptly incurved under the periphery : edge thin, scalloped by the spiral ridges; inside, or throat, finely plicated or furrowed: inner lip reflected over the pillar and canal, continuous with the outer lip: pillar curred, broad,

[^119]and flattened, sloping inwards to a sharp cutting edge: ope:culum yellowish (horncolour in darker specimens), obliquely and irregularly striated in the line of growth. L. 0.625. B. 0.25 .

Var. lactea. Milk-white.
Habitat: Muddy sand in the coralline zone of Devon, Cornwall, and Guernsey; Tenby (Lyons); Fishguard (J. G. J.) ; Isle of Man (Forbes) ; Dublin Bay (Turton and others) ; Cork (Humphreys) ; Arran Isle, co. Galway (Barlee) : not uncommon. Other localities have been published; but I believe T. Barvicensis was in these cases mistaken for the present species. One is off the Mull of Galloway, in 145 f . (Becchey). The variety oceurs on the coasts of Devon and Gucrnscy, particularly in 'Hurd's Deep,' a submarine trough near the latter island, in about 60 f . Red and Coralline Crag (Wood); ? co. Wexford (Forbos). The T. muricatus of Nyst, from the Belgian tertiaries, is a different species. Living on the Atlantic coasts of France, Spain, Portugal, the Mediterranean, and Ægean; depths 8-150 f. Dr. Gould enumerated it among the shells of Massachusetts, on what he admitted was unsatisfactory authority ; the lamented death of that excellent zoologist may, I fear, preclude the appearance of the expected new edition of his 'Report,' which would have doubtless cleared up the point.

The capsules are about a line in diameter, and have an oval orifice; they contain a purplish liquor, together with the fry. The shell is often incrusted with a fine reddish sponge, regarded by Montagu as an epidermis, My largest specimen is more than four-fifths of an inch long. After the spire has been accidentally truncated, the rest of the shell is sufficient for the animal.

Philippi described it as the Fusus echinatus of J.

Sowerby, and referred to it the Murex variabilis of Cristofori and Jan. The type of Leach's Fusus asperrimus, in the British Museum, is a specimen of the white variety of T. muricatus, having the ribs more prickly than usual.

## 2. T. Barvicensis*, Johnston.

Murex Barvicensis, Johnst. in Edinb. Phil. Journ. xiii. p. 225. T. Barvicensis, F. \& H. iii. p.442, pl. exi. f. 5, 6, and (animal) pl. SS. f. 4, as T. Barricense.

Budy white, and microscopically veined or speckled with chalk-white flakes: mantle thick: palliul tube very short: tentacles cylindrical, rather short, widely diverging, with blunt tips; the upper third part is more slender, and the lower part twice as thick; they are flattened, as well as narrower, above the eye-stalks : eyes small and black, placed outside the tentacles, about two-thirds of the way up, at the top of stalks, which are amalgamated with the tentacles and appear to form part of them: foot extensile, donble-edged and nearly square in front, becoming narrowor behind, and ending in a rounded or bluntly pointed tail; the front corners are slightly auricled or angular.

Shell rescmbling the last species in many respects; but this is broader, more delicate and glossy; the longitudinal ribs are much fewer (about two-thirds of the number), more laminar, prominent, and flounce-like; they extend to the suture ; the spiral ridges are numerically in the same proportion as the ribs; the top of each whorl is encircled by an elegant coronet of spines: colour pure white: spire distinctly scalariform or turreted: mouth more triangular, and narrower: canal rather straighter: outer lip sometimes upturned at the upper corner of the mouth, which ends in a sharp point: pillar straighter : operculum of a paler colour, thinner, and smoother. L. 0.65 . B. 0.25 .

Habitat: Stony ground in the laminarian, coralline, and deep-water zones, on the coasts of Yorkshire, Northumberland, Durham, Berwick, Aberdeenshire, the west of Scotland, the Orkneys, and Shetland; Cork,

[^120]with T. muricatus (Humphreys) ; Dublin Bay (Kinahai and Walpole); Lough Strangford, 12-15 f. (Dickie); co. Antrim, 8-25 f. (Hyndman and J. G. J.) ; perhaps also Dunbar (Laskey, as Murex muricatus). "Irish Drift" (Forbes). All the foreign localities are Scandinaviau, viz. from Oxfjord in Finmark (Sars and Danielssen) to Bohuslän (Lovén and Malm), at depths of 40-150 f.

It creeps, like Lachesis, foot upwards, on the surface of the water. A capsule, in a valve of Leda minuta (now before me), is very thin, semitransparent, and marked with delicate, close-set, microscopic concentric lines; orifice oval. Some shells are more elongated than others. The outer point of the old canal is occasionally visible, so as to make the base double, or (when neither of the two previous canals has been corered with new shelly matter and incorporated with the base) triple. Specimens from beyond the Dogger bank, in $50-60 \mathrm{f}$., are of unusual size, being nine-tenths of an inch in length.

I consider this species not less distinct from T. muricatus than the following species from T. clathratus; they bear the same analogy to each other.

## 3. T. truncatus*, Ström.

Buccinum (truncatum), Ström in Norsk. Vid. Selsk. Skr. iv. p. 369, t. xri. f. 26. T. clathratus, F. \& H. (not Murex clathratus, Linné) iii. p. tion, pl. cxi. f. 1, 2, and (animal) pl. SS. f. 3, as T. Bamffum.
Body whitish, pale yellowish-white, or creamcolour, with sometimes a faint tinge of fleshoolour, and thickly covered with milk-white specks : pallial tube rery short, scarcely protruded: tentacles awl-shaped, rather short, and diverging, with blunt tips ; that part which surmounts the eye-stalk is slender: eyes small, placed on long and thick stalks which reach about two-thirds up the tentacles, on their outside: foot narrow, double-edged and bilobed or nearly truncated in

[^121]front, with small angular corners, rounded or bluntly pointed behind.

Shell conic-oral, rather solid, nearly opaque, somewhat glossy: sculpture, numerous laminar longitudinal ribs (about 20 on the body-whorl, and 25 on the penultimate), which are folded or incline towards the mouth; they extend to the suture, but not to the base or the canal; the surface of all the whorls except the upper two is covered with minute and slight, close-set, spiral impressed lines or strix, which do not cause any decussation or make the ribs tubercular; top whorls smooth and of a polished lustre ; the lines of growth are irregular: colour yellowish-white or pale fleshcolour : spire rather short, ending in an abrupt and somewhat truncated point; apex angular, twisted at first obliquely upwards, and then inwards : whorls $6-7$, convex and rather tumid, the last occupyins two-thirds of the shell: suture wide and deep: mouth oral (with a triangular outline, when the outer lip is flattened on the upper part), expanding outwards; length (exclusive of the canal) a little more than one-third of the shell: canal shorter than in either of the foregoing species of Trophon, slightly recurved to the left, and terminating in an obliquely rounded notch; externally it exhibits only the marks of growth: outer lip curved, sometimes flattened above and abruptly inflected on the periphery; edge sharp, somewhat reflected in adult specimens; inside smoth: inner lip slight and inconspicuous, coating the pillar and mper part of the canal, not continuous with the outer lip: piller curved, broad, and somewhat Hattencd: operculum thin, yellowish, irregularly puckered by the oblique lines of growth. L. $0 \cdot 6$. B. $0 \cdot 275$.

Var. 1. alba. White.
Var. 2. sctlaris. Ribs deeper, abruptly truncated and crested at the top of each whorl.

Habirat : Hard ground in the laminarian and coralline zones, from 2 to 50 f ., on the eastern and northern coasts of England, all Scotland, Shetland, and the southern and eastern parts of Ireland; Isle of Man (Forbes) ; Goodwick, near Fishguard, 18 f. (J. G. J.) ; Tenby (Lyons) ; off the Mull of Galloway, 110-140 f. (Beechey). Both the varieties are Zetlandic. It is less common than T. clathratus as a post-glacial fossil, but
is generally difiused; they occur in the same deposits, and also in the Norwich Crag (Woodward), and Red Crag (S. Wood). The existing distribation of the present species is arctic and boreal, extending from Greenland (Möller) to Bohuslän (Lovén and Malm) in the eastern hemisphere, and from Canada (D'Urban) to Massachusetts Bay (Gould and Stimpson) in the western hemisphere; depths recorded 35-120 f.

The 2nd variety of this species corresponds with the variety Gunneri of T. clathratus. For my largest specimen of the present species $I$ am indebted to Mr. Rose, who procured it by trawling off Yarmouth ; it is ninetenths of an inch in length, and has the usual number of ribs. T. clathratus of the same size has only 14 ribs on the body-whorl; it is a thinner and more tumid shell, and attains far greater dimensions than our species. T. clathratus is a characteristic fossil of all glacial and post-glacial beds here and abroad; in a recent or living state it inhabits Spitzbergen (the extreme limit of the European fauna), Iceland, Normay, and the Faroe Isles, the coasts of Northern Asia southwards to Japan (A. Adams), as well as Greenland, the eastera and western coasts of North America(Fabricius, Gould, P. Carpenter, and others), from the shore to 100 f . According to Olafsen and Povelsen it was called by the Icelanders "St. Peders-snekke," or St. Peter's snail; the tradition or superstition in which this name originated seems to have been lost. Mohr gave a somewhat similar remacular name (" Peturs-kongr," or King Peter) for Fusus Islandicus.

Both species of Trophon have several synonyms; but those best known are Murex Bamffus of Montagu for T. truncatus, and Fusus scalariformis of Gould for $T$. clathratus. Murex Bamffius of Donovan includes the
two species; his figured type is T. clathratus, and what he considered the young is T. truncatus. The Fusus scalariformis of Nyst, from the Belgian tertiaries, is different from that of Gould.

Another arctic species, found by Sir Henry James in the Wexford postglacial deposit, is T. craticulatus of Fabricius (not of Linné) ; it is the Fusus Fabricii (Beck) of Möller, and Murex borealis of Reeve. This inhabits Greenland and the White Sea.

A specimen of T. Syracusanus was picked up by Dr. Lloyd of Malahide on the sauds at Portmarnock in Dublin Bay; it is a rather common Mediterranean shell. Owing to some mistake this specimen is noticed in the 'History of British Mollusca' (vol. iii. p. 440, footnote) as the Murex rostratus of Olivi, and as having been found by Mrs. R. Smith at Tenby: possibly the Fusus decussatus of Brown (said to have been discovered by him at Killough, co. Down) may be the plain-coloured varicty of the first-named species.

Genus VI. FUSUS*, Bruguière. PI. VI. f. 3.

Sheli spindle-shaped, never umbilicate, spirally striated, and sometimes also ribbed, although not varicosely: epidermis membranous, occasionally pilose or hispid: spire long and tapering; apex usually mammiform, but in certain species symmetrical: mouth nearly always plain-edged and having a smooth throat and pillar: canal and operculum as in Trophon.

Although it is very difficult to distinguish this genus from Trophon, its operculum is constructed on a different plan from that of the Buccinum family. Their habitat also must he taken into account. Purpura and for the most part Buccinum are littoral ; this never lives

[^122]above low-water mark, and its bathymetrical range probably extends to the yet "unsounded deeps." The egg-cases of Fusus are membranous, double-sheathed, semioval or hemispherical, and attached by their base: in F. antiquus they are agglomerated (as in Buccinum undatum) ; but in the other British species they are separate, and resemble those of Trophon. The tongue is enclosed in a sheath of muscular fibre. According to Lovén the odontophore of $F$. antiquus agrees with that of B. undatum, and differs from F. gracilis and $F$. Berniciensis in having the central tonth broader across, with the front margin extended on each side in a truncated form; while in the last two species it is squarish. Judging, however, from drawings, kindly furnished by my friend Mr. Alder, of this apparatus in seven of our .native species, the plan of construction varies considerably in all but F. Islandicus, F. gracilis, and F. propinquus, the odontophores of which are similar.

Klein was the original author of the name Fusus; but he applied it to a large group which he called a genus, each of his species containing several modern genera. Bruguière's definition was likewise too extensive; and Lamarck restricted this genus to nearly its present limits. The species are apparently peculiar to the northern hemisphere.
A. Sculptured only by slight spiral ridges or strix.

1. Fusus antiques*, Limé.

Murex antiquus, Linn. S. N. p. 1222. F. antiquas, F. \& H. iii. p. 4.3. pl. civ. f. 1,2 .

Body whitish or yellowish-white, with a faint tinge of fleshcolour, sometimes partially speckled with black: pallial

[^123]tube short but broad. upturned, streaked across with purplishbrown, or speckled like other parts of the body: tentacles triangular and flattened, very short, widely diverging, spread out at the base: eyes small, on broad lobes which surmount the stalks, and placed near the outer base of the tentacles: foot oblong, squarish, and double-edg.d in front, with short angular corners, expanding at the sides, and bluntly pointed behind; sole often straweolour or light orange: odontophore having the central tooth oblong, broadly excavated above, and armed below with three short equidistant and equal-sized points; lateral teeth palmated or deeply divided by two wide notches, which leare three thorn-like processes, the outermost being longer and larger than either of the other two.

Shell conic above and expanded in the middle, with a short and bluntly pointed base, solic, opaque, having scarcely any gloss: sculpture, numerous spiral ridges, which are sometimes regular, at other times alternately large and small, or arranged in equidistant rows or series haring one of the strix more prominent than the rest; the ridges do not extend to the suture; lines of growth microscopic and more conspicuous on the upper whorls: colour sellowish- or reddish-white decpening into fawn: epidermis very thin, nearly always wanting: spire tapering to a blunt point; apex mammiform : whorls $7-8$, convex and rather tumid, compressed on the upper part towards the suture; the last occupies more than two-thirds of the shell : suture wide but not deep : mouth (exclusive of the canal) angularly oval, cousiderably expanding outwards; length altogether about four-minths of the shell : canal broad, turning to the left, and ending in a deep obtuse-angled or curved notch: outer lip semicircular, bevelled to a reflected and thickened edge, not much contracted above; inside smooth, oftern of a deeper hue than the outside, and sometimes arange: inner lip in aged specimens continuous with the outer lip, and making together an angle corresponding with that of the mouth; it varies in thickness, being frequently perceptible on the lower side only : base strengthened by a thick and occasionally rugged fold or ridge : pillar flexuous and broad, sharply angulated on the lower part: operculum strong, marked by numerous semielliptical strix in the line of growth. L. $3 \cdot 25$. B. 2.

Yar. 1. alba. White, and of a much larger size; bodywhorl and mouth often greatly expanded. 2. ventricose. 'lhiuner; whorls more swollen. 3. striata. Spiral strix stronger, and two on each of the upper whorls forming pro-
minent ridges. (Murex corinutus of Turton, not of Pennant.) 4. gracilis. Slender, thinner, and spirally ridged.

Monstr. 1. contrarium. Spire reversed. (INurex contrarius, Linn. $=$ r. sinistrorsus, Desh.) 2. acuminatuin. Spire clongated. 3. sculariforme. Whorls more or less detached. 4. cinctum. Encircled with a sharp ridge at the top or in the middle of the lower whorls, now and then bicarinated. 5. sulcatum. Lower whorls furrowed in the middle, and outer lip notched, like a Pleurotoma. 6. Babylonicum. Spire turreted. (F. Babylonicus, Brown.) 7. compressum. Squeezed in at the sides; month narrow. S. colutaforme. Shaped like a Voluta. (Bucimum undatum has an analogous form.) 9. varicosum. Former outer lip, sometimes two or three, persistent. 10. contortum. Spire twisted on one side or inwards. 11. suffultum. Basal ridge continued to the periphery. 12. bioperculatum. Haring two opercula.

Habitat: Coralline zone, from Cornwall (Couch) and the south-eastern coast of England northwards to Shetland, where it lires also in the laminarian and deep-water zones; on the western coast it ranges from Fishguard and Barmonth (J. G. J.) to Shetland ; throughout Ireland, from Bantry Bay (Humphreys) eastward to Dublin Bay, and along the North Channel. It has not been found, or noticed, in Devon or the Bristol Channel ; but Pulteney gives Dorset, and Dodd Pontac in Jersey, as localities. The lst variety seems peculiar to the Cheshire coast ; the 2nd to deep water outside the Dogger bank; the 3rd to the south and south-east of Ireland, Dublin Bay (O'Kelly, fide Turton), the Hebrides, and Shetland; the 4 th was dredged off Cape Clear. The monstrosities are chiefly from Kent and Lincolnshire; Mr. Hyndman has noticed one having an intorted spire as found at Groomsport by Mr. Vance. F. antiquus occurs in most, if not all, of our raised beaches (including Moel Tryfaen, Wexford, and Stornoway) ; Belfast (Grainger) ; boulderclay at Wick (Peach) ; Clyde beds (Smith and others) ; Mammalian and Red Crag (S. Wood) ; Belgian Crag
(Nyst). Var. striata, Kelsey Hill (Prestwich) ; Norwich Crag (Woodward); Uddevalla (J. G. J.). Monstr. contrarium, Wexford (Sir H. James) ; Kelsey Hill (Prestwich); Aberdeenshire Crag-beds (Jamieson); Sicily (Philippi); Red Crag (S. Wood); Antwerp Crag (Nyst). Monstr. contortum, Red Crag (S. Wood). The present distribution of this species extends from Havösund (Sars) to the Boulonnais (Bouchard), and further southwards to the Loire-Tuférieure (Coilliaud), and the Cha-rente-Inférieure (Cassaigneaud, fide Aucapitaine, and Des Moulins, fide Fischer) ; depths 20-40 f. The Tritonium antiquum of Middendorff is apparently a different species, having the upper part of the whorls more or less flattened, and being destitute of the spiral sculpture. The monstrosity contrarium has been recorded as taken by Michaud at Barcelona, and by M‘Audrew as living on the shore at Vigo; I have it from Sicily.

This is a good bait for codfish, and a favourite delicacy of the lower working-classes in London. At Billingsgate it is sold under the name of "almond" or " red whelk;" according to Rutty's History of Dublin the Irish call it "barnagh," the tail [liver] being said to be more fat and tender than a lobster. The egg-cases or capsules overlap one another in an imbricated fashion, each being firmly attached by its base to the underlying capsule; they are deposited in clusters of from a dozen to a hundred, the capsules in each cluster being equal in size. Those which compose one cluster, however, are not half as large as those forming another cluster; although in both cases the fry are in the same state of maturity. When they are dry, the upper or convex side shrivels, and is wrinkled or pitted; the under or flat side (which by contraction becomes concave) is of a silky texture, and divided across by a few lines; the opening is a wide slit,
lying just under the top which makes a narrow flap. Before leaving the capsule the fry are perfectly formed, with conspicuous tentacles, eyes, and operculum ; their shell has two whorls, the first being smooth, and the other showing a few slight incipient striæ. Each capsule produces only from two to four fry. The latter end of winter scems to be the spawning-season: on the 26 th of January 1861 I examined fresh capsules which contained merely eggs immersed in a glairy liquid; and seven days afterwards I found in other capsules fullsized and living young whelks. The spawn and fry have been well described and figured by Baster in his ' Opuscula subseciva.' The sculpture of the adult shell differs according to the locality and nature of the growad; sometimes it is coarse, and at other times scarcely perceptible. Specimens from Kiel Bay are stunted and "depauperated," owing probably to the admixture of fresh water from the Baltic. In Shetland and at Berwick the fishermen make an elegant lamp of the shell, suspending it horizontally, mouth upwards, by a string round the middle, from a nail in the wall; the cavity contains oil, and the canal a wick. Now and then giants are seen, 7 or 8 inches long. The body-whorl of the female is larger than that of the male. Chemnitz knew the reversed form as a Crag fossil of Harwich; and he deplored in moving terms the indolence and apathy of naturalists in not procuring live specimens of this "most delicate monster." It is still very rare. Not only the spire of the shell, but also the curve of the operculum is reversed. I am not aware of any explanation of the phenomenon having been offered on physiological grounds. Many of the spiral mollusca are liable to this remarkable kind of malformation. Moquin-T'andon has enumerated 38 species of French land and freshwater
shells, usually dextral, that have been noticed as heterostrophe, and 5 sinistral species of which orthostrophe specimens have been diseovered. I have been able to add a few more examples from our own fauna. Conditions of habitability (suel as the depth and mineral ingredients of water, the soil, food, and elimate) do not afford any cluc to the solution of the problem; for the normal and abnormal forms live together. Nor, if such be the agents, can we tell
> "Why all these things change, from their ordinance, Their natures and preformed faculties To monstrous quality."

This is the "whelke" (par éminence) of Lister, and Buccinum magnum of Da Costa. Pennant and others of the old English school of conchology mistook it for the Murex despectus of Linné; the fry is M. decollatus of Pennant, but not of Gmelin. The Tritonium antiquum of Fabricius is F. Islandicus. Bolten founded his genus Neptunea, and Swainson his genus Chrysodomus on the present species.
F. despectus is an arctic species, having a bathymetrical range of $8-160 \mathrm{f}$. ; its southern limit is Christiansund, in lat. $63^{\circ} 7^{\prime}$. I procured two live specimens in the Billingsgate market, mixed with F. antiquus. It seems that a vessel sailed from Hull for the long-line fishery at Iceland, and took a quantity of our common whelks as bait; that when the supply was exhausted, the fishermen used refuse portions of fish to eateh fresh whelks on the spot; and that, on bringing their cargo of fish to England, some of the Iceland whelks that remained found their way into the London fish-market. This is one way of accounting for the casual introduction of foreign species into the British fauna. F. despectus is mentioned by Mr. S. Wood (as a carinated variety of
his Tropkion contrarius) from the glacial bed at Bridlington, and by Forbes (as F. tornatus of Gould) from Bramerton, Dalmuir, and Bridlington ; it was first described by Linné, in his 'Wâstgötha Resa,' as an Uddevalla fossil. It is the Murex carinatus of Pennant. Donoran figured a half-grown and much cleaned (or "doctored ") specimen under the name of M. despectus (M. subantiquatus, Maton and Rackett), supposing it to be Orcadian, on the vague belicf of a friend. Pennant's shell (from the Portland cabinet) and that of Donoran are now in my collection.
F. fornicatus (Tritonium fornicatum, Fabr.) was also figured as a British species, but withont any anthority, by Donovan; he at first referred it to the Murex antiquus of Linné, but subsequently called it M. duplicatus. This is Greenlandic.

## 2. F. Norvégicus*, (Norvagicus) Chemnitz.

Strombus Norvagicus, Chemn. Conch. Cab. xi. p. 218, t. 157. f. 1497-8. F. A̛orvegicus, F. \& H. iii. p. 428, pl. crii. \& criii. f. 7 -9.

Body pale orange or yellowish-white, irregularly streaked with purple: muntle thickened on the pillar-side of the shell; head-veil broad: pallial tube rather long, curved, and wide: tentacles conical, short, and flattened, bordered outside by a narrow line of purple, widely diverging; tips, sometimes dark purple: eyes proportionally small, on bulbs or offsets at the outer base of the tentacles, where the latter are much swollen : foot huge, oblong, double-edged, and rounded in front, with small angular corners, rery broad at the sides, and rounded or bluntly pointed behind: verge large: odtontophore having an oblong rhachis, armed with five small equal cusps or points which occupy the entire base; pleure large, the base very long and sloping, middle deeply and widely excarated, outer fang hooked, inner fang smaller and tooth-like.

Shell shaped like a Voluta (the body-whorl and mouth being disproportionately large, compared with the spire, which is abruptly attenuated) ; it is of a porcellanous texture, not

[^124]very solid, nearly opaque, and somewhat glossy: sculpture, extremely slight, close-set, and minute spiral strix, which are stronger and more perceptible on the base and near the summit of the shell; some of these striæ in the middle of the last whorl form obscure ridges; top whorl smooth; there is no basal ridge or keel: colour pale yellowish-white or creamy: epidermis very thin, light yellowish-brown: spire short; apex bulbous, of an amber tint, larger than in the last species: whorls 5-6, tumid ; the last is considerably produced or elongated towards the base, and occupies three-fourths of the shell: suture wide and deep: mouth angularly oval, capacious, and widely expanding outwards; length (including the canal, which appears to be part of the mouth) nearly three-fifths of the shell : canal very short, wide, open, nearly straight, and ending in a large and obliquely curved notch : outer lip semicircular, not contracted above; edge reflected, and in aged specimens thickened bs the addition of many layers; inside smooth and brilliantly polished, sometimes having at the base a lovely tinge of pale fleshcolour: inner lip usually consisting of only a thin glaze, which is spread over the greater part of the lower side of the body-whorl ; in aged specimens it is considerably thickened and folded over the lower part of the pillar and the canal; it has (as well as the inside edge of the outer lip) a prismatic lustre: pillar gently curved in the middle, and slightly angulated where the canal commences: opercutum small, light horncolour, rhomboidal with three rounded corners, the fourth or basal corner being angular and forming the nucleus; layers of increase oblique; a few slight lines radiate upwards from the base. L. $4 \cdot 2 \overline{5} . \quad$ B. $2 \cdot \overline{5}$.

Habitat: Coasts of Yorkshire, Durham, and Northumberland, in 50-60 f. (Bean and others) ; Shetland, in fine muddy sand, 70-85 f., at a distance of from 40 to 50 miles from land (J. G. J.). The locality of Bute, given by the late Mr. James Smith, must be a mistake. A variety having the spire rather longer, and approaching $F$. Turtoni, occurs in the glacial shell-mounds at Uddevalla; Norwich Crag (Middleton and Fitch, fide Woodward). This species ranges from Spitzbergen and the north-eastern coast of Greenland (Torell) to Norway (Spengler, fide Chemnitz, and others), at a dcpth of 100 f .
(specimens from Yadsö being very large) ; Iceland (Steenstrup); sea of Okhotsk (Middendoff). The Uddevalla form ( $F$. Largillierti, Petit) has been recorded from Newfoundland by Petit on the authority of M. Largilliert, and from Greenland by Mörch on the authority of Herr Jörgensen.

The egg-cases were first noticed by Professor King, and figured by Mr. Howse. They are solitary. Each forms a compressed hemisphere, measuring about an inch in diameter; it is of a dirty lemoncolour, semitransparent, attached by the whole of its base to the inside of old bivalve shells and other flat substances, and edged by a rim or strip of membrane. The upper surface is covered with a thin whitish crust, which breaks up into crystalline particles, and it is finely corrugated; the underside is satiny. Ova pink or bright fleshcolour. There are in each capsule from two to four perfect fry, which make their escape through a slit in the rim. The shell has the expressive name of "wide mouth" among the northcountry fishermen.

It is the type of Mörch's subgenus Volutopsius, and of Gray's genus Strombella.

3. F. Turtóni*, Bean.

F. Turtoni, Bean in Mag. N. H. viii. p. 493, f. 61 ; F. \& H. iii. p. 431 , pl. cv. f. 3, 4, and cvi. f. 2-4.
Body white, with purple markings (Howse): odontophore having a small plain oblong rhachis without any cusp; pleure irregularly triangular, the base broad and straight, inner side sloping outwards, outer fang shaped like a canine tooth, inner fang short and cloven.

Shell of an elegant shape (not unlike that of $F$. antiquus, monstr. acuminatum, but having a much shorter and straight canal and a shallower suture), rather solid, nearly opaque,

[^125]scarcely glossy: sculpture, slight and flattened, but conspicuous and regular spiral ridges, which are numerous on the bodywhorl, and consist of about 15 on each of the preceding whorls; ther become less distinct on the upper part of the body-whorl; top whorl smooth; there is an obscure basal ridge or keel: colour whitish, tinged inside with purple: epidermis thin, bright yellow passing into olive-green : spire elongated and tapering; apex remarkably conical: whorls 7-8, convex and somewhat angulated in the middle, compressed and shelving upwards to the suture; the last slopes towards the base, and occupies about two-thirds of the shell : suture distinct but not deep: mouth angularly oval, expanding outwards; length (including the canal) about one-laalf of the shell : canal extremely short, wide, and open, almost straight, and ending in a large, deep, and obliquely curved notch: outer lip semicircular and prominent, not contracted above; edge somewhat reflected; inside or throat smooth and polished, often purplish-brown: inner lip consisting of a porcellanous glaze, which varies in thickness according to the age of the individual; it is broad, bat does not extend far beyond the pillar as in the last species: pillar flexuous: operculum large, horncolour, forming a long and oblique triangle with a pointed apex and rounded base; layers of increase close-set; a few impressed lines radiate upwards from the nucleus. L. $4 \cdot 75$. B. $2 \cdot 5$.

Habitat: With $F$. Norvegicus, on soft ground, in the coralline zone of Yorkshire, Durham, and Northumberland. I dredged a capsule in 78 f . on the east coast of Shetland; the same haul yielding the other species and its capsule. Vadsö, 100 f . ; two large specimens (Sars).

This fine sholl was discovered by a naturalist who has just passed away, full of years, aiter a long and zealous carcer. Old Bean of Scarborough (as he was familiarly called) did much by example and kind assistance to promote the cultivation of natural history in the north of England; and he was just and true in all his dealings -not a common virtue in these times. The capsules of $F$. Turtoni are pale orange, either solitary, or two together and attached side by side, not to each other, but to a rather broad membranous substratum; they are
triangularly oval, the base being the narrowest part, and consist of an outer filmy sheath and an inner and thick fibrous case; the latter resembles in structure a cocoanut husk; the opening is a wide slit at the top. Mr. Howse found six young in one capsule. The fry are almost cylindrical and of a dark reddish-brown hue. The shell goes by the name of "long neck" among the Staithes fishermen. F. Turtoni is distinguishable from $F$. Norvegicus in having a longer spire, shallower suture, compressed whorls, much stronger sculpture, a conical apex, different colour, greater solidity, and especially in the shape of the operculum.

4. F. Islan'dicus*, Chemnitz.

F. Islandicus, Chemn. Conch. Cab. iv. p. 159, t. 141. f. 1312-3.

Shell regularly spindle-shaped, in consequence of the elongation of the base, not very solid for its size, nearly opaque, slightly glossy: sculpture, numerous spiral ridges, which are somewhat flattened on the body-whorl, but prominent on the upper whorls and the base; there are about 14 on the penultimate and each of the next four whorls, besides a few slight intermediate strix; they do not extend to the margin below the suture; the upper two whorls are smooth; lines of growth extremely fine and close-set: colour white beneath the epidermis (Icelandic specimens hare a pale flesh tint) : epidermis cortical (like the bark of a birch-tree), fawncolour or jellowishbrown : spire elongated and gradtually tapering; apex stiliform, and exhibiting a prominent bulbous point, which is broader than the first regular wholl: whorls 9, consex, compressed upwards; the last is attenuated towards the base, and occupics three-fifths of the shell : suture well defined and rather broad, but not deep: mouth (exclusive of the canal) oval, not expanding outwards as in the last tro species; length (including the canal) rather more than two-fifths of the shell: canal rery long, more or less straight, semitubular, ending in a wide and curved notch: outer lip nearly semicircular and somewhat flexuous, slightly contracted above ; edge rather thin; inside

[^126]smooth and polished: inner lip forming a glaze, the limit of which is parallel with the outer lip. not spread on the lower side; it becomes thicker towards the base, and lines the inner side of the canal: pillar slightly curved, and bevelled inwards: operculum (in a specimen from Iceland) pear-shaped, and rather thick, with oblique layers of increase. L. $5 \cdot 5$. B. 2.

Habitar: South-eastern coast of Shetland, 40-50 miles from land, in 78 f ; two specimens only were procured, both dead, but one in an excellent state of preservation. Mr. Walpole possesses a specimen from the Wexford coast. Sars, Lovén, and Danielssen have taken this species, together with F. gracilis, on many parts of the Norwegian coast, north of Christiansund, in $40-100 \mathrm{f}$. ; M ${ }^{\text {c }}$ Andrew and Barrett also dredged both in Finmark, in 30-50 f.; Iceland (Chemnitz, Mohr, and Steenstrup) ; Faroe Isles (Mörch); Greenland (Fabricius, as Tritonium antiquum, Möller, and Pingel).
It is much larger than the next species ( $F$. gracilis), which has been confounded with it by many authors; F. Islandicus is more spindle-shaped, being produced and attenuated towards the base; the canal is much louger, and in some specimens quite straight ; the whorls are more rounded ; the apex is stiliform and prominent; and the ridges are less crowded, and are sharper or more raised, especially on the upper whorls. The odontophore differs nearly as much from that of $F$. gracilis as the latter does from $F$. propinquus in the same respect. The pleuræ in F. Islandicus and F. gracilis are exactly similar ; but the rhachis in the present species is broader, and has three distinct and nearly equal points at the base. In $F$. propinquus the pleure have a more decply lobed fang in front; and the rhachis is still broader and straight behind, with cuspidations as in $F$. Islandicus.

Dr. Jonas pointed out the distinction between F. Is-
landicus and F. gracilis (which latter he described as F. Listeri) in the 'Transactions of the Society of Natural Sciences at Hamburg.' The young of the present shell appears to be the F. Sabini of Hancock; Buсcinum Sabinii of Gray is another species. Dr. Mörch tells me that he regards $F$. Islandicus as bearing the same relation to $F$. gracilis as $F$. despectus docs to $F$. antiquus. The Tritonium Islandicum of Lovén is $F$. Berniciensis.

> 5. F. gra'clils*, Da Costa.

Buccinum gracile, Da Costa, Br. Conch. p. 1•-4, t. vi. f. 5. F. Islandicus, F. \& H. iii. p. 416, pl. ciii. f. 1, 3, and (animal) pl. SS. f. 2.

Bodr white, with frequently a tiuge of pale rellow : pallial tube short but broad, upturned when the animal crawls : proboscis cylindrical, very long. and muscular, fleshcolour on the underside: tentacles triangular and flattened, short, with rounded tips; they diverge in consequence of being separatcd by the head-reil, which forms an intervening membrane: eyes small and black, nearly sessile, about halfway up the tentacles, on their outer side: foot oblong, squarish and double-edged in front, with angular corners, expanded at the sides, and bluntly pointed behind.
Shell broader near the base than towards the other extremitr, rather solid, almost opaque, somewhat glossy: sculpture, numerous slight spiral ridges, which are defined on the upper whorls by impressed lines; there are about 16 on the penultimate whorl, 14 on the antepenultimate, 12 on the next, 10 on the next, 8 on the next, and 6 on the next whorl, the upper two whorls being smooth; the ridges extend to the suture on each side; lines of growth curved and very fine: colour white (with rarely a tinge of fleshcolour) beneath the epidermis: this is membranous, usually yellowish-brown, lemoncolour, or even of a paler hue in specimens from deep water; the epidermis is frequently wanting below the periphery, near the upper part of the inner lip, so as to expose a broad triangular patch the base of which is uppermost: spire elongated and abruptly tapering ; apex irregularly mammiform, and twisted in front, but not prominent or forming a bulbous point as in the last

[^127]species: whorls 9, less conrex than in F. Istandicus, but likewise compressed upwards; the last is much broader towards the base, and occupies more than two-thirds of the shell: suture narrowish, and slightly channelled: mouth oblong-oval, narrower than in the last species, and acute-angled above; length (including the canal) rather more than half the shell: canal very much shorter than in $F$. Islandicus, turning somewhat abruptly to the left, wide, and two-thirds open, ending in a large and obliquely curved notch : outer lip romded aud slightly flexuous, not projecting so much as in the last species, nor contracted or incurved above; edge sharp; inside smooth and polished: inner lip forming a glaze, the limit of which is coextensive with the outer lip: pillar curred, and bevelled inwards; it is sharply angulated at the commencement of the canal: opereutum triangularly oblong, rather solid, yellowishbrown or horncolour, marked with fine and close-set lines of growth, and lengthwise with a few slight and irregular strix or impressed lines, which radiate from the nucleus. L. 3. B. $1 \cdot 25$.

Var. convoluta. Smaller, narrower, and somewhat cylindrical, more solid, with a longer spire, having sharper ridges and a deeper suture; mouth proportionally smaller.

Habitat : Coralline and deep-sea zones, on all our coasts, from 20 to 145 f . ; common on the northern fishing-banks, but rare in the south of England. The late Lord Vernon procured a specimen in the Scilly Isles, and Dr. Lukis one at Guernsey. The variety occasionally occurs in rather shallower water. F. gracilis has been found in quaternary deposits at Kelsey Hill (Prestwich), Macclesfield and Moel Tryfaen (Darbishire), and Wexford (James). I do not consider the Crag specimens which have been referred to this species by Searles Wood, Woodward, and Nyst identical with the above. These last agree with the North-American form, which is smaller, more tumid, and has a short spire. If such should prove to be distinct, it might be called curtus. The present species appears to inhabit Bchring's Straits (Wossnessenski, fide Middendorff), White Sea
and coasts of Russian Lapland (Middendorff), Iceland (Chemnitz), Faroe Isles (Mörch), Norway, as far north as Havösund, 30-100 f. (Sars and others), Sweden (Lovén and Malm), the Cattegat (Jonas), Boulonnais (Bouchard), Pirou in Brittany (De Gerville), and LoireInférieure, 25-30 f. (Cailliaud).

Of many hundred specimens which I have at different times examined, the males were more numerous than the females. One had no operculum nor the usual lobe by which that part is formed. The capsules are solitary, small, membranous, pouch-shaped, and attached by a broad base to stones and corallines; their surface is microscopically and closely reticulated; orifice extremely large, and sometimes having the edge partly stained with pink. Each capsule contains only a single embryonic shell, which is transparent, and through it may be seen the orange liver and two unequal-sized plumes of pale yellow gills. My largest specimens (from the Dogger bank and Exmouth) are nearly four inches long. Specimens from deep and still water are thinner than those from the coast line; others are more slender. Monstrosities now and then occur, riz. some of the ridges being prominent and keel-like; spire twisted on one side or downwards; penultimate whorl swollen; apex broken off and replaced by a shelly plug ; or the operculum aborted and concave. This whelk is occasionally brought to Billingsgate market, mixed with the common eatable kinds; but it is not saleable. The fishermen call it " borer."

Lister first made known the present species, giving it a compound name (Buccinum angustius \&c.); and it is comprehended in Linnés description of Murex corneus, which now represents the F. lignarius of Lamarck, a Mediterraneau shell. Chemnitz distinguished it, as a subvoL. IV.
species, from $F$. Islandicus: he says that it is smaller and slenderer, has a shorter beak (canal), and that its operculum, when held against the light, is of a honeycolour. Pennant and his followers called it, after Linné, Murex corneus. W. Wood went further back, and adopted the first specific name given by Lister. The Buccinum gracile of Costa is the species at present known as $F$. corneus.

## 6. F. propinquUs*, Alder.

F. propinquus, Ald. Cat. Moll. North. \& Durl. (Trans. Tynes, Nat. Field Club), p. 63 ; F. \& H. iii. p. 419, pl. ciii.f. 2, and (animal) pl. SS. f. 1.
Bons milk-white, faintly tinged with light brownish-yellow: pallial tube cylindrical, rather long: head extremely short: tentacles conical, tapering to a rather fine point, and diverging; lower half disproportionately thickened: eyes on small bulbs or offsets at the top of the stalks or enlarged portions of the tentacles: foot oval and thick, broader, rounded, and doubleedged in front, bluntly pointed behind: verge falciform and Hattened, on the right-hand side above the foot.

Shele resembling F. gracilis in shape, but narrower, thinner, less opaque, and somewhat more glossy : sculpture, numerous fine spiral ridges, which extend to the suture on each side: they are rather sharp (often alternately large and small) on the lower two whorls, flattened, broader, and defined by impressed lines on the upper whorls; the penultimate and antepenultimate whorls have quite as many ridges as in the last species, but each of the preceding whorls in this has only 7 or 8 the first two whorls are smooth; lines of growth microscopic, curved, and close-set: colour white: epidermis yellowish-brown of various shades according to the habitat, being very pale and almost creamcolour in specimens from deep water, and below the periphery often of a still lighter hue; it is thin and hispid on the ridges, rising into small whitish thorn-like points; as in the last species, it is generally wanting outside the mouth, where a bare triangular patch is exposed : spire elongated, turretcd, and gradually tapering; apex blunt, but regularly spiral and compressed, never mammiform or distorted: whorls 8-9, not so convex as in the last

[^128]species, and rather slowly increasing; the last occupics a little more than fire-eighths of the shell: suture narrow, deeply channelled: mouth oblong-oval, acute-angled above; length (including the canal) nine-sixteenths of the shell : canct rather short and wide, turning to the left, half open, ending in a large and obliquely curved. notch: outer lip rounded and slightly flexuous, not projecting so much as in $F$. gracilis, but more contracted or incurred above ; edge sharp and thin; inside smooth and polished: imner lip forming a thin glaze: pillar curved, bluntly angulated at the commencement of the canal: operculum triangularly oblong, with an oblique contour, thin, yellowish-brown or light horncolour, somewhat concave aud furrowed lengthwise at the distance of about onethird from the outer lip, marked with fine and numerous but irregular laminæ of growth, and sometimes with a few slight impressed lines down the middle, which radiate from the nucleus. L, $1.7 \overline{7} . \mathrm{B} .0 \cdot 75$.

Far. turvita. Smaller and thinner, more slender and almost cylindrical. with a longer spire. Tritonium turritum, Sars, Aret. Moll. Norg. in Vet. Forh. Christ. (1858) p. 39.

Habitat: Muddy and sandy ground in the coralline and deep-water zones on the coasts of Yorkshire, Durham, and Northumberland,Berwick Bay, Aberdeenshire, Hebrides, and Shetland; New Brighton, near Liverpool (Collingwood)'; Dublin Bay (Kinahan) ; Cork (Humphreys, fide Walpole). The variety is from 78 f . off the east of Shetland. Fossil in the Wexford raised beach (Sir H. James) ; glacial beds, Aberdeenshire, at a height of 150-200 feet (Jamieson). Finmark, 20-150 f. (Sars, M'Andrew, and Barrett) ; Kullaberg, in South Sweden (Lilljeborg); Cattegat (Jonas, as F. Listeri, var.).

The shell of the female is more tumid than that of the male. Capsules solitary, and attached to the inside of old bivalves; they are hemispherical, and resemble those of $F$. gracilis, but have a smaller and oval orifice; the base is margined by a narrow membrane. Embryo the colour of a pomegranate. In
a young monster from Shetland the last two whorls are unnaturally swollen, so as to be not unlike the $F$. ventricosus of Gray-if that species be not identical with his Buccinum Sabinii, although the latter is described as having the inside of the outer lip "slightly crenated." The smaller size and more delicate texture, finer and closer sculpture, longer, turreted, and regularly tapering spire, deeper suture, hispid epidermis, less abrupt curvature of the canal, and especially the symmetrical apex will readily serve to discriminate this from the last species.

It was discovered by the late Sir Walter Trevelyan at Seaton, and noticed by Brown as a variety of F. gracilis. Its recognition as a species is due to the lamented Joshua Alder*. This admirable naturalist was so beloved by all his friends, that to each may be said of him,-

> "Nulli fiebilior quam tibi."
F. Islandicus, var. pygmeus, of Gould (a North-American species) scems to bear the same relation to F. propinquus as his F. Islandicus does to F. gracilis.

> 7. F. buccina'tust, Lamarck.
F. buccinatus, Lam. An. s. V. vii. p. 132.

Shell differing from that of $F$. propinquus in being much larger, more ventricose and solid, and in having a conical and shorter spire ; the whorls are more convex, and the last occupies cight-elevenths of the shell; the ridges on the back of the canal are stronger; the surface is covered with microseopic spiral strix, which intersect the equally fine lines of growth, so as to produce a slight and partial decussation ; the cpidermis is membranous and deciduous, fibrous near the outer lip, never hispid, and of a brownish-yellow colour ; the alternation of

[^129]size in the spiral ridges gives a lineated appearance to that part of the epidermis on the body-whorl which is of a paler colour and situate below the periphery; the canal is proportionally shorter, much wider, and more open ; the outer lip is sinuated in the middle; operculum ambercolour. L. 2.25. B. $1 \cdot 15$.

Habitat : Exmouth (coll. Clark) ; Torquay (King) ; Brixham and Plymouth (Jordan); Bantry Bay (Humphreys and J. G. J.); Waterford, Wexford, and Dublin coasts (Walpole). It inhabits sandy ground in the coralline zone, and was in most of the above instances procured by trawling; I dredged it in about 18 f . Belleîle, Morbihan (Delaunay, fide Taslé, as F. propinquus); Loire-Inférieure, with F. gracilis (Cailliaud, as the same); Gulf of Gascony (D'Orbigny père) ; ? south-west of France (Fischer, also as $F$. propinquus); Gulf of Lyons, from the stomach of a gurnard (Martin).

The fry are as distinct from those of $F$. propinquus as the adult of each from the other.

Lamarck gave no habitat; but his description is quite suitable to the present species. His reference to Born's figure of $F$. vulpinus was conjectural and erroneous.
B. Decussated by longitudinal strix or ribs and spiral ridges.

## 8. F. Bernicien'sis*, King.

F. berniciensis, King in Ann. \& Mag. N. H. sviii. p. 240; F. \& H. iii. p. 421, pl. cr. f. 1, 2, and cri. f. 1.

Bony white or creamcolour, with a slight tinge of fleshcolour : mantle sometimes edged with brown : pallial tube extensile, occasionally protruded beyond the canal, with an expanded or trumpet-shaped opening: proboseis excecdingly long, measuring nearly two inches eren when contracted after the death of the animal : tentacles conical, rather short, and close

* From Bernicia, the ancient name of the kingdom said to have keen founded by Ida and comprising some of the northern English counties.
together, with bluntly pointed tips: eyes small and black, sented on the top of long stalks, about halfway up the tentacles: foot lanceolate, thick, rounded and double-edged in front; tail either pointed or blunt and somewhat truncated: odontophore long; rhachis square, armed below with a single projecting spine; pleure comb-shaped, and decply serrated.

Shecl forming a spindle of moderate length, rather solid, nearly opaque, not glossy: sculpture, numerous thread-like spiral ridges, which are alternately large and small on the lower whorls and equal in size on the upper whorls; there are about 6 of each size on the penultimate and each of the two preceding whorls, and 5 or 6 of the larger size only on each of the next two whorls; the larger ridges extend to the base and suture; the surface is also covered with minute and close-set curved longitudinal strix, which by crossing the ridges produce a slight decussation, especially towards the apex ; the first two whorls are smooth and glossy: colour pinkish-white: epidermis rather thick, brownish-yellow, or sometimes fawncolour, rising into crowded prickly points on the ridges, so as to give a regularly hispid appearance : spire tapering to a blunt point; apex symmetrical and compressed, resombling that of the last two species: whorls 8 , convex and in the middle tumid, rather slowly enlarging; the last occupies about twothirds of the shell: suture deep: mouth oval; upper corner nearly rectangular; length (including the canal) about foursevenths of the shell: canal of moderate length, wide, nearly straight, two-thirds open, ending in a large and obliquely curved notch : outer lip semicircular. flexuous, incurved above; edge somewhat thickened, refiected, and expanded; inside pinkish, slightly grooved beneath the larger ridges: inner lip forming a more or less thick glaze (according to the age of the individual), which is spread over a considerable part of the underside of the shell; it is reflected over the lower part of the pillar and inner side of the canal : pillar curved, slightly augulated at the commencement of the canal : operculum carshaped, rather thin, amber or light horncolour, somewhat concave, marked with fine and close-set oblique strix in the line of growth and with a few impressed lines which radiate from the mucleus. L. $3 \cdot 25$. B. $1 \cdot 625$.

Var. elegans. More slender, and the spire clongated.
Haritat: Muddy or soft ground in the coralline zone, on the coasts of Yorkshire and Northumberland;

Aberdeenshire (Bell, fide Dawson). Mr. Barlee procured the variety from the outer haaf or fishing-banks on the east of Shetland ; and I dredged it there in fine sand, at depths of 78-100 f., with F. Norvegicus and Buccinopsis Dalei. It is a rare species. Norway (Rasch, fide Lovén, as Tritonium Islandicum) ; Vadsö, 140 f. (Danielssen) ; Loffoden Isles and Christiansund (Sars). The last-named author likewise gives the north coast of Russia and north-west America, but without citing any authority.

The young, when fresh caught and living, look like tiny rose-buds. The colour of full-grown specimens (especially of the inside) is not less beautiful; these may vie with
> . . . . . . "the dappled shells,
> That drink the wave with such a rosy mouth."

## 9. F. fenestra ${ }^{\prime}$ tus*, Turton.

F. fenestratus, Turt. in Mag. N. H. vii. p. 351 . Buccinum fusiforme, F. \& H. iii. p. 412, pl. cx. f. 2, 3.

Body uniform white, or jellowish-white with the exception of the branchial tube, the upper or conrex surface of which is deep grey with rather close-set black transverse streaks, its extremity being white: head narrow: tentacles rather short and pointed: eyes on the outer side of the tentacles, at about one-fourth of their length: foot large, truncated in front, acute-angled on every side. (Sars.)

Shell having a short base and long spire, rather thin, semitransparent, lustreless: sculpture, eurved longitudinal ribs, which do not extend to the lower part of the body-whorl; there are from 20 to 25 on that whorl, 18 on each of the next tro, and 12-15 on each of the next two whorls, where they cease; the whole of the shell is encircled by thread-like spiral ridges or striæ, of which there are from 18 to 20 on the bodywhorl, 8 on each of the next two, 6 on each of the next two, and 4 on the next whorl, the top whorl being smooth and

[^130]glossy ; a few small intermediate striæ traverse also all or some of the whorls; the points of intersection on the ribs are slightly nodulous: colour pale yellowish-white or whitish: equidermis rather thin, brownish-yellow, rising into mumerous fine prickles on the spiral strix ; the same bald triangular patch is observable below the periphery near the mouth as in several atlied species: spire elegantly tapering to a blunt point; apex button-shaped, symmetrical and much compressed, like that of the last three species: whorls 8, convex, gradually enlarging ; the last occupies fire-eighths of the shell : suture deep : mouth angularly oral; length (including the canal) about one-half of the shell: canal short, very wide, bending to the left, twothirds open, ending in a large and obliquely curved notch: outer lip nearly semicircular, flexuous, abruptly incurved above; edge sharp; inside plain: inner lip forming a thin glaze on the pillar, but not spread orer the underside of the shell : pillar deeply curved, bevelled inwards, and sharply angulated at the commencement of the canal : operculum (in a Norwegian specimen) pear-shaped, light brown, with the nucleus as in other species of Fusus. L. 1•7. B. 0.8.

Habitat : "Outside Cork Harbour," in 40 f., with Buccinum Humphreysianum, and in the stomachs of haddock and red gurnard (Humphreys) ; very rare. Two living specimens were dredged between Cape Clear and Newfoundland by the master of a vessel on her voyage from Bristol (Stutchbury); Finmark, 30-160 f. in sand (M'Andrew and Barrett); Mangerfiord and Vadsö, 50-100 f. (Sars); Christiansund, 50 f. (Danielssen).

Buccinum fusiforme of Broderip; but as it belongs to the genus Fusus, that specific name is of course inappropriate. I proposed at one time to change it for Broderipi, not being then aware that Turton had described the shell under the name which I have now adopted : Murex fenestratus of Chemnitz is a species of Triton.
F. latericeus of Möller (an arctic species) was found by Sir Henry James in the Wexford deposit; it is the Tritonium incarnatum of Sars.

Pyrula Carica was wrongly given by Turton, in his 'Conchological Dictionary,' as a Dublin-Bay shell; it is a native of the North-American coasts. His relation of the supposed discovery made my cyes when youthful expand with prospective joy, not unmixed with wonder. Now the latter feeling is almost extinct-perhaps both of them.

## . Family XXIX. NAS'SIDE, Stimpson.

Body spiral, usually short; in other particulars agreeing with the last two families. Sexes also separate.

Shell conic-oval or oblong, of small size, variously sculptured: spire more or less turreted: canal short and abrupt: pillar plicated: operculum horny, increasing by semielliptical or curved layers; nucleus blunt and terminal.

This family has been founded lately, by Professor Stimpson, on an odontological basis, "on account of the arched form and very numerous denticles of the rhachidian tooth of the lingual ribbon." Mr. Macdonald had previously adduced another character of the same kind, in distinguishing Nassa from Buccinum, viz. "the absence of smaller denticles between the two principal fangs of the pleuræ." The shells of Nasside differ from those of Buccinida and Muricide in having the pillar plicated; the nucleus of the operculum is placed as in the last-named family.

## Genus I. NASSA*, Lamarck. Pl. VI. f. 4.

Body short: pallial tube narrow and extended: tentacles of moderate length : eyes placed on stalks from one-third to half the way up the tentacles: foot large, in front broad and with angular corners; tail cloven, and furnished with two tentaclelike processes: [odontophore; rhachis broad, arched, pectinated; uncinus having a tooth at the base. (Lovén.)]

[^131]Sheld solid: spire having a regular nipple-shaped apex: mouth oval: outer lip strengthened by a rib, and furrowed inside: inner lip expanded and thick, haring a small ridge or tooth-like process on the upper part: canal truncated, recurved, and deeply notched : pillur furnished at the base with a single retired plait or fold : operculum ear-shaped or oval, serrated on the outer edge, and occasionally also on the inner edge near the base.

The animal of $N$. mutabilis, with its forked tail, was well described and figured by Colonna in 1575 : it was in his time esteemed at Naples as a palatable and diges. tible morsel ; and this popular taste is still the same.

The generic name originated with Klein, but it was properly applied by Lamarek. According to Woodward there are 210 recent, and 19 fossil species; the latter are comparatively modern. The recent species chiefly inhabit shallow water-although I have taken $N$. incrassata living on the shore and at a depth of 90 fathoms, and Capt. Beechey found it dead at 145 fathoms. Risso, in his unscientific fashion, quadrupled the genus.

## 1. Nassa reticula'ta* , Linné.

Buccinum reticulatum, Linn. S. N. p. 1204. N. reticulata, F. \& H. iii. p. 383 , pl. cviii. f. 1, 2, and (animal) pl. LL. f. 3.

Body yellowish, mottled with dark brown or sootcolour, sometimes varicgated by minute fiake-white points: mantle loose about the neck : pallial tube long and narrow: tentacles widely separated by an intermediate flap or head-veil, awlshaped, long and slender, more than twice as thick below the eyes as above them: eyes small, on the top of rather long stalks, about one-third of the way up the tentacles, and forming part of them: foot long and broad, squarish, rounded, or bilobed, and double-edged in front, with triangular and pointed corners, notched behind: caudal appenduges short; when the animal is in motion these are folded back orer each side of the notch at the tail: odontophore rather long; [rhachis haring

[^132]the corners produced in front, and smooth-edged on each side ; uncinus having a plain shaft. (Lovén.)]

Simerl haring a broad base, thick, opaque, nearly lustreless: sculpture, strong, but not prominent, and slightly flexuous longitudinal ribs, of which there are from 15 to 20 on the bodywhorl, 20 to 25 on the penultimate whorl, and nearly as many on the next whorl, the number gradually decreasing on the upper whorls; these ribs are crossed by rather deep and wide spiral strix, 12 to 15 encircling the body-whorl (besides those at the base), 6 the penultimate, 5 the antepenultimate, and 4 each of the preceding whorls, except those constituting the apex, which are quite smooth and glossy ; the basal portion is separated from the rest of the body-whorl by a broad groove (as if pinched up), and has half a dozen spiral ridges; a tubercular decussation is produced by the intersection of the ribs and strix ; the whole surface is also covered with fine microscopic spiral lines : colour buff, with a narrow band of purplishbrown below the suture on each whorl, and now and then traces of a broader band in the middle of the body-whorl and of another at the base, which are discernible only near the outer lip ; fresh specimens are more or less distinctly marked with fine thread-like spiral lines of yellowish-brown, some of which are interrupted and form rows of spots; in such cases the number of these lines or rows is from two to four on each ridge; the mouth is white: cpidermis extremely thin and membranous: spire rather short, ending in an abrupt point; apex formed of the two first whorls, and nipple-shaped : whorls 10 , the last or bods-whorl more convex than the others, but compressed towards the suture; the body-whorl occupies about two-thirds of the shell : suture slight: mouth irregularly oval : length (including the canal) about five-twelfths of the shell: canal rather narrow, obliquely turning to the left, and ending in a remarkably deep notch, which is very conspicuous when the shell is placed mouth downwards: outer lip squeezed in and acute-angled above, curved in the middle and below, with a thick edge which is scalloped at the bottom ; inside thickened, and regularly fluted with from 8 to 12 tooth-like processes: inner lip forming a fine enamel, which is spread over a considerable part of the underside of the shell and folded behind the pillar; it is more or less tuberculated, one tubercle or tooth being more prominent and placed near the upper angle of the mouth : pillar nearly semicircular, furnished at the base with a retired flexuous fold or plait: operculum ear-shaped, light
horncolour, serrated on the outer edge, and often also on the inner edge near the base ; the serrature arises from the laminx of which the operculum is composed being spinous or angulated at their external margins ; lines of growth numerous and obliquely elliptical. L. 1.25. B. 0.7.

Habitat : Sand at low-water mark, and in the laminarian zone, throughout the British Isles; common. It occurs in many of our quaternary deposits, including those at Selsea, Moel Tryfaen, and Belfast; Norway, $0-440$ feet (Sars) ; Uddevalla (J. G. J.); Baltic provinces of Prussia (Lehmann, fide Rosmer); French and Italian tertiaries (Basterot, Brocchi, and others); marine beds of the Viemna basin (Hörnes). An inhabitant of the North Atlantic (from Bejan near Drontheim to Gibraltar), the Mediterranean, Adriatic, and Black Sea, at depths of 0-70 f.

The "small lattic'd Whelk" of Petiver. At the recess of each tide this mollusk buries itself in the sand in a slanting position, its lurking-place being betrayed by a little hillock. It also gets into lobster-pots, for the sake of the bait. Bouchard-Chantereaux attributes to this, as well as to other whelks, the habit of piercing and devouring bivalves. . According to M. Lespés $N$. reticulata is preyed upon by a parasitic Trematode (Cercaria sagittata) which infests its liver. Its spawn-cases are deposited on the leaves of Zosiera and on various other things which are left dry only at spring tides; the capsules are arranged in rows, and so closely that they overlie each other "like the brass scales of the cheek-band of a hussar" (Johnston). They are compressed pouches, each of the size of a large spangle, supported on a very short stalk, with a small opening at the top to allow the fry to escape. Mr. Peach described and figured the capsules in the Reports of two Cornish Societies for 1843 and

1844 ; and he has given us some amusing particulars of the fry. These behaved themselves like the fry of other Gastropods, skipping about and whirling round by means of their ciliated lobes, apparently in a state of pleasurable excitement; but it seems that the exercise was compulsory, or necessary to prevent the attacks of a swarm of Infusoria, which made short work of any tired or feeble infant Nassa. The shell varies considerably in size and in the length of the spire; an adult specimen, from Mr. Clark's collection, is not half an inch long.

Linné gave the Mediterranean as the only locality known to him. The present species is the Buccinum cancellatum \&c. of Lister, B. vulgatum of Gmelin, and probably the B. tessulatum of Olivi ; B. reticulatum of the last-named author may be the next species. The young appears to be the B. pullus of Pennant but not of Linné.

## 2. N. nitrida*, Jeffreys.

Body greyish, with a slight tinge of purple, and closely speckled with flake-white: pallial tube cylindrical, rery long, slender, and flexible: tentacles flattened, tapering to a fine point: eyes small, on stalks conjoined with the tentacles on their outside; these stalks are about half the length of the tentacles, so that the eyes are placed about the middle of the latter: foot broadly lanceolate, squarish and double-edged in front, with small and pointed corners, blunt and wedge-shaper behind; tail forked and ridged : appendages rather short and yellowish.

Shell differing from $N$. reticulata in the following particu-lars:--It is smaller, narrower, and remarkably glossy ; the ribs are much fewer, viz. 10 to 12 on the body-whorl, 15 on the next, 16 or 17 on the next, and 18 on the next whorl, when they diminish in number upwards; occasionally the ribs are varicose; the spiral striæ or ridges are also less numerour,

[^133]being 10 on the body-whorl (besides the basal ridges), 4 on the penultimate and antepenultimate, and 3 on each of the preceding whorls ; the apical whorls are quite smooth and lustrous ; the basal portion is smaller, and has only three or four ridges ; the ribs being much more prominent than the striæ, the lower half of the shell never displays the tubercular or cancellated appearance of the other species, although the upper whorls in this are somewhat nodulous; the surface is microscopically marked with close-set longitudinal lines and a few less distinct spiral lines: colour purplish on a yellowish-white ground, with the ribs of the latter hue; the purple bands and lines are brighter in this species, the lines being from two to three in number : epidermis inconspicuous, or obscured by an carthy incrustation: spire turreted: whorls flattened; apex more globular than in the last species: suture deeper: mouth proportionally larger: canal not so abruptly recurved: outer lip strengthened by the last-formed rib, ridged within by the undersides of the spiral striæ; the intermediate furrows are sometimes stained with purple: inner lip much thinner, and never tuberculated: pillar having a slighter fold: operculum oval, more solid, but smaller. L. 1. B. 0.5.

Habitat : Muddy estuaries of the Thames and Orwell rivers, in $3-5 \mathrm{f}$. ; abundant. Brittany (Cailliaud) ; (Gulf of Lyons (Martin and J. G. J.); Bonifacio, with N. reticulata (Susini); Mogador, in mud (M‘Andrew); Adriatic (Nardo).

Among a number of specimens which I dredged in the Roach River, one had two eyes on the right-hand tentacle; the eyes were smaller than usual, and close together.

This was noticed by Montagu as a variety of N. reticulata. I propose it as a distinct species with some misgiving ; for, although I have not yet seen any intermediate form, it has not been ascertained that the two live together, and the present form seems to be peculiar to brackish water and mud. Both these last conditions, however, prevail in Kiel Bay, where N. reticulata occurs in a depauperated state. The difference between that
species and $N$. nitida is not less than between $N$. incrassata and N. pygmea. Kiener's variety of N. reticulata is cvidently not our shell : he distinguishes it solely by the spiral strix being less marked.

> 3. N. inclassa'ta*, Ström.

Buccinum (Incrassatum), Ström in Kong. Norsk. Vid. Selsk. Skr. ir. p. 369, t. xri. f. 25. N. incrassata, F. \& H. iii. p. 391 , pl. criii. f. $3, \frac{1}{}$, and (animal) pl. LL. f. 1.

Body yellowish of rarious shades, closely and minutely but irregularly speckled or marked with black; there are also some milk-white flakes scattered over different parts : pallial tube cylindrical, very long and flexible, projecting when the animal is in motion, and recurved when it is at rest; this serves as an auxiliary tentacle or organ of touch, as well as to supply the gills with water: head extremely small, of a pinkish hue: proboscis thicker towards the point: tentacles threadshaped, rather long, with rounded tips: eyes on stalks conjoined with the tentacles at their outer base, each stalk being nearly equal in length to that part of the tentacle which is above the eyes: foot triangular and expansile, slightly indented in front, with a small ear-shaped lobe or flap at each corner, bluntly pointed behind; tail forked, or furnished with two short flattened prongs or cirri; in specimens from deep water the foot is largely bilobed behind, but has no point at the tail, which is merely cloven in the middle: odontophore narrow; [rhachis having the corners incurved and produced in front, edge smooth on each side; uncinus broad, with a large single-spined tooth at the base. (Lovén.)]

Shell, although small, stout and thick, opaque, somewhat glossy : sculpture, strong but not prominent, obliquely curved longitudinal ribs, from 15 to 18 on each of the last three whorls, the number decreasing on the upper whorls; that which margins the outer lip is extremely large and broad: the ribs are crossed by conspicuous spiral ridges or striæ, of which there are from 12 to 16 on the body-whorl, 9 to 11 on the penultimate whorl, the number proportionally diminishing upwards; the ridges below the suture are narrow and close together, those in the middle of each whorl being broader and more apart; in some specimens the ridges are

[^134]finer and more thread-like than usual; the intercrossing of the sculpture produces a tubercular or nodulous decussation, the tubercles being transversely elongated; top whorls quite smooth and glossy ; the basal part is separated from the rest of the body-whorl by a deep and oblique groove (as if pinched up), and has about a dozen oblique ridges or strix, which become slight and indistinct towards the base ; the whale surface (especially the interstices of the ridges) is covered with microscopic and close-set longitudinal lines: colour pale buff or yellowish-white, passing into purple, pink, orange, or brown, and often variegated by three broad and interrupted bands of reddish-brown, or by a narrow and broken white zone; it is occasionally milk-white; the base has a purplish-brown or chocolate blotch, the mouth is white (rarely pinkish), and the tip frequently purple or pink: epidermis thin and somewhat fibrous, usually abraded but sometimes retained in the interstices of the ridges: spire rather short, and abruptly terminating in a nipple-shaped point: whorls 8-9, convex, indistinctly angulated in the middle, and rapidly enlarging; the last occupies about three-fifths of the shell: suture rather deep: mouth oval, comparatively small, acute-angled above; length (including the canal) nearly one-half of the shell: canal narrowish, obliquely recurved to the left, ending in a remarkably deep notch, which is very conspicuous when the shell is placed with its mouth downwards: outer lip somewhat compressed and nearly straight above, semicircular in the middle ; edge rather thin, and slightly reflected ontwards; inside thickened, as well as strengthened by the labial rib, and fluted by 8-10 narrow plaits: inner lip forming a thick coat of enamel, which is spread over a considerable portion of the under side of the shell, and folded behind the pillar ; it has just below the outer lip a plait or ridge-like process that partially winds round the upper part of the pillar, and a few other irregular and obliquely transverse processes of the same kind (or wrinkles) towards the base : pillar curved, furnished at the base with a flexuous fold: operculum ear-shaped, light horncolour, more or less serrated on the outer edge, and often deeply jagged or notched on the inner edge near the base; lines of growth numerous, and obliquely elliptical. L. $0 \cdot(j$. B. 0.3 .

Var. 1. major. Much larger. 2. minor. Dwarf. 3. simulans. One of the ribs on the body-whorl varicose.

Habitat: Everywhere, on stony ground, from lowwater mark to 145 f . (Beechey). Var 1. Channel Isles. Var. 2. Filey Brigg ; west coast of Scotland, 50-60 f.; Lerwick Sound. Var. 3. Whitburn (Alder); Connemara (Barlee) ; Lerwick (J. G. J.). This last variety, although varicose, differs from N. pyymea in the angularity of the whorls, and in sculpture. Fossil in all our quaternary deposits; Norwich Crag (Witham, fide Woodward); Red and Coralline Crag (S. Wood) ; glacial and postglacial Norwegian beds, $0-460$ feet (Sars); Uddevalla, 40 feet (Malm and J. G. J.); upper, mildle, and lower Crag at Antwerp (Nyst); Italian tertiaries (Brocchi and others); Vienna basin (Hörnes). The present distribution in space of this common species is not less extensive, viz. from Iceland (Steenstrup) and Finmark (Sars and others) to the Azores (Drouet) and throughout the Mediterranean, Adriatic, and Egean; depths, shore ( $\mathrm{M}^{`}$ Andrew) to 100 f . (Malm).
$N$. incrassata is a very active mollusk, and now and then changes its crawling position by leisurely floating with its foot upwards. It often gets into lobster- and whelk-pots. In the half-grown shell the outer lip is excavated within and folded inwards. The spawn-cases are solitary, yellowish, and shaped like a round flask, with a small neek or opening at the top.

It is the "small Gibraltar Ruggle" of Petiver. Out of 14 synonyms which I have collated it may be unnecessary to specify more than Buccinum minutum, Pennant, B. ambiguum, Pulteney, B. Ascanias, Bruguière, B. mucula, Montagu, B. coccinella, Lamarck, and apparently B. asperulum, Brocchi. B. incrassatum of the ' Mineral Conchology' is a different species.

> 4. N. PYG'MEA*, Lamarck.

Ranella pygmea, Lam. An. s. V. vii. p. 154. N. pygmea, F. \& II. iii. p. 394, pl. cviii. f. 5, 6, and (animal) pl. LL. f. 2, as N. varicosa.

Body more slender and invariably of a much lighter colour than that of $N$. incrassata; the pallial tube and tentacles are longer ; the anterior processes of the foot are larger and more recurved ; and the tail is not only forked, but has two long and pointed diverging filaments. (Clark and F. \& H.)

Shell not so stout and thick as the last species, of a more delicate texture, and decidedly glossy : sculpture as in $N$. incrassata, but the ribs are finer; there are from 15 to 22 on the body-whorl, 15 or 16 on the penultimate whorl, 12 on the next, becoming gradually less upwards; the labial rib is larger, and one or more of the whorls are varicose, or have extra labial ribs denoting previons periods of growth or repose; the spiral ridges or strix are likewise fewer, never exceoding 12 on the body-whorl, and 6 on the preceding whorl; points of cancellation granular, instead of elongated tubercles ; basal ridges fewer and stronger: colour uniform yellowish-white with a tawny tinge; the labial rib and varices are nearly white and very conspicuons; mouth purplish-brown throughout (there being no basal spot as in the last species) ; apex never purple or pink, although sometimes ambercolour: spire less abrupt: whorls evenly rounded, instead of angulated: suture not quite so deep: mouth less contracted: canal broader: outer lip not so much compressed above ; inside fluting more prominent and toath-like: inner lip thicker at the edge; plaits fewer, and not so wrinkly : pillar haring a sharper fold : operculum more deeply serrated on the inner edge. L. $0 \cdot 45$. B. $0 \cdot 225$.

Habitat : Coralline zone on the South Devon, Dorset, and Cornish coasts; Connemara (Alcock); Bantry Bay (M‘Andrew, fide Thompson); Dublin Bay (Kinahan); co. Antrim (Waller). Brick-earth on the Nar, West Norfolk (Rose) ; Belfast deposit, with N. incrassata (Grainger). Norway, with the last species, $10-40 \mathrm{f}$. (Danielssen and Asbjörnsen) ; Bohuslän(Lovén); and, with the same, $4-100 \mathrm{f}$. (Malm); French coasts of the Atlantic and Mediterranean (Lucas, fide Lamarck and others);

[^135]Spain and Portugal, 4-30 f. (M'Andrew); Italy (Costa and others) ; Algiers, 6-10 f. (M‘Andrew and Weinkauff) ; Black Sea and Crimea (Middendorfi); Ægean, 27 f. (Forbes).

Dr. Goodall told me that Turton introduced himself to him at Torquay, by sending in his card on which was written "Sic pictores Coi," accompanied with specimens of this shell. It reminds us somewhat of the epilogue in one of the Idyls of Theocritus, in which Menalcas is supposed to be presented with a ка入òv ŏ $\sigma$ дакоу as a compliment. The learned Provost of Eton, however, was anything but a piping shepherd.

It is the Buccinum tuberculatum and Tritonia varicosa of Turton, and (according to Fischer) the B. tritonium of De Blainville in the 'Faune Française.'

Some tropical spccies of Nassa and of the allied genus Planaxis have been erroneously described as European. Such are:-
N. hepatica: Weymouth (Pulteney); Lough Strangford (Brown) ; St. Germain-sur-Ay (De Gerville). West Indies.
N. ambigua: Weymouth (Bryer); Cork Harbour (Humphreys) ; Portmarnock, Dublin Bay (Turton); Herm (Lukis); north of France (De Gerville and Bou-chard-Chantereaux); 'Toulon (Martin). A common WestIndian shell.

Planaxis lineatus $=$ Buccinum pediculare, Lam., inserted in several local lists as English and French : an abundant West-Indian shell.
P. Brasilianus = Hima lerigata, Leach (Syn. Moll. Gr. Brit.), said to be from Plymouth (Prideaux or Cranch) : South America.

Genus II. COLUMBEL'LA*, Lamarck. Pl. VI. f. ò.
Bodr more extended than in the last genus: pallial tube very long and flexible : tentucles short and cylindrical : eyes on the outer base of the tentacles: foot long and thick, sometimes cloven at the extremity, but without any caudal processes: [odontophore ; rhachis crescentic, laminar, bent forward (?): uncinus having a double hook at the point, and furnished with a round wing-like lobe before the base. (Lovén.)]

Shell varying in thickness: mouth contracted and narrow: outer lip slightly sinuated on the upper part: inner lip not expanded, nor thick: pillar having a single fold at the base: canal deeply notched : operculum horny, roundish-oval, plainedged; nucleus rounded, and obscurely concentric, placed near the base.

This connects the Nasside with the Pleurotomatida. We have but one or two species of Columbella, although several inhabit the coasts of North America. Two species (C. rustica and C. minor) are Mediterrancan.

De Montfort capriciously changed the generic name to Columbus.
A. Outer lip thickened and furrowed inside ; apex of the spire regularly nipple-shaped.

## 1. Columbella maliméetit, Jeffreys.

Bodr whitish, delicately suffused with flesheolour: pallial tube cyliudrical, broader and expanded at the orifice, which is plain-edged; when the animal crawls, this part projects in front, and is struight, and nearly as long as the shell; when it is placed on its back the tube is coiled round and (as if uneasily) twisted about from side to side: anus at the upper corner of the mouth of the shell, on the outside; I frequently observed fecal peliets expelled from it : tentacles short, cylindrical, close together at their base, and diverging outwards; tips blunt: eyes small, black, and globular, at the outer base

[^136]of the tentacles; they appeared to be sessile and not placed on any stalk or protuberance: foot lanceolate, long, narrow, and thick, truncated, or bilobed and double-edged in front, with angular corners, considerably expanding towards the tail, which is in some specimens blunt and in others cloven.

Shell between oval and oblong, rather solid, nearly opaque, glossy: sculpture, narrow and rather sharp longitudinal ribs, from 12 to 16 on the bodj-whorl, $1 \pm$ to 20 on each of the two preceding whorls, and nearly as many on the next whorl, where they cease and are replaced by a remarkable kind of ornamentation which will be noticed presently; the ribs are flexuous on the body-whorl, and do not extend to the base, curved on the upper whorls; labial rib broad and thick; the whole surface is covered with numerous spiral strix, which are minutely and closely beaded, in consequence of their being decussated by microscopic lines of growth; the striæ at the base are stronger than elsewhere; the three or four top whorls that form the apex have a dichotomous kind of sculpture, the lower half of each being closely and minutely striated lengthwise, and the upper half striated spirally with a Vandyke or scallop pattern : colow whitish, more or less distinctly but irregularly mottled with reddish-brown: epidermis, none perceptible: spire somewhat turreted, rarying in length, nerer slender: apex swollen, nipple-shaped and abrupt: whorls 8, compressed but rounded, rapidly enlarging; the last occupies two-thirds of the shell: suture rather deep: mouth oral, comparatively small; length (including the canal) three-sevenths of the shell : canal rather broad, abruptly bending to the left, and ending in an obliquely curred notch: outer lip flexuous although not much curved, somewhat expanding ontwards; the sinus on the upper part is rery slight, but distinct; iuside thickened, and fluted by half a dozen tooth-like plaits, the lowermost of which is the strongest: inner lip forming a glaze on that side of the mouth, not much spread over the underside of the shell; its outer edge is thickened and well defined; some specimens have two or three obscure tubercles near the base, as in typical species of Columbella: pillar curved, furnished at the base with a strong and sharp flexuous fold: operculum roundish-oral, thin; lines of gromth semicircular. L. 0.35. B. $0 \cdot 175$.

Habitat: Gravelly sand, in $85-95$ f. about 25 miles N.N.W. of Unst, with Limopsis aurita, Trochus amabilis,
and Cylichna alba; extremely local, and nearly as rare. The deep-sea soundings taken by Capt. Hoskyns in H.M.S. 'Porcupine' off the west coast of Ireland yielded a very young specimen. Vienna tertiaries (Hörnes, as C. corrugata) ; Faluns of Touraine (Cailliaud). I also noticed in the Gottenburg Museum a very young specimen procured by the Curator, Dr. Malm, from the Eggers bank in Norway at a depth of 150 f .

The animal is very lively and active. When placed in a vessel of seawater it creeps rapidly to the surface, being apparently actuated rather by a necessity of better aërating its gills than by a curiosity to see the outer world. It also floats, like the Rissoo. It is sometimes preyed on by other zoophagous mollusks, judging from the perforation of its shell. The discovery of this tertiary fossil, as well as of Limopsis aurita, in a living state, within a very circumscribed part of our sea-bed, shows the imperfection of the zoological record, and militates strongly against the doctrine of the successive creation of species. We must do more than scrape here and there to justify the conclusion somewhat hastily formed by certain naturalists that all the British marine mollusca are known; and after all, what an insignificant proportion do these bear to the marine mollusca of the whole globe!

Hörnes referred his shell to the Buccinum corrugatum of Brocchi; but that is evidently a species of Nassa, and, according to Philippi, one of the innumerable varieties of N. variabilis.

To this section of Columbella belong :-1. Buccinum cinctum, Pulteney, as from Weymouth (Bryer), which is West-Iudian: 2. Purpura picta, Turton (not of Scacchi), as from the British Channel; Cork Harbour (Humphreys); Gulf of Lyons (Martin) ; this also is

West-Indian: 3. Voluta hyalina, Montagu, as from Dunbar (Laskey); young of C. lactea, a common WestIndian shell. The V. heteroclita of Montagu, a sinistrorsal shell, introduced on the last more than suspicious authority, is likewise exotic.
B. Outer lip thin and smooth ; apex of the spire irregularly coiled. Thesbiu (one of the sea-nymphs of Hesiod).

> 2. C. nava*, Loyén.

Tritonium ? nanum, Lor. Ind. Moll. Scand. p. 12. Mangelia nana, F. \& H. iii. p. 461, pl. exii. f. 8.

Body milk-white, all but the gills and liver, which are light brown: tentacles cylindrical, rather short [slender (Lovén)]: eyes proportionally large, placed on the tentacles, close to their outer bases: foot narrow and thin: [odontophore haring a pleural spine almost like that of "Manglia costata." (Lovén.)]

Shell spindle-shaped, resembling Fusus gracilis in miniature, thin, semitransparent, and glossy: sculpture, numerous fine and narrow spiral impressed lines, of which there are about a dozen on the peultimate whorl; they are closely and regularly punctured, so as to form rows of circular dots ; top whorls very closely and microscopically corrugated in the same direction: colour uniform milk-white: epidermis, none perceptible : spire tapering; apex abruptly twisted: whorls $4 \frac{1}{2}-5 \frac{1}{2}$, conrex and evenly rounded, rather suddenly enlarging; the last occupies about three-fifths of the shell: suture deep, somewhat oblique: mouth irregularly oblong, acute-angled above; length (including the canal) two-fifths of the shell: canal rather broad, inclining a little (but not abruptly) to the left, and ending in a slight and obliquely curved notch : outer lip flexuous, retreating at the upper part, but without exhibiting any fissure or notch; it folds inwards rather than outwards; edge sharp and thin; inside quite smooth: inner lip slight, narrow, and even : pillar flexuous; fold obscure: operculum, none that I could detect in the moistened animal of a specimen from which I have taken an imperfect description of the soft parts. L. $0 \cdot 2 \overline{5}$. B. $0 \cdot 12 \overline{5}$.

Habitat: Shetland, in the coralline zone, rare (J.

[^137]G. J., M‘Andrew and Forbes, and Barlee) ; Orkneys (Thomas, fide F. \& H.). Finmark (Lovén); Christiansund, 30-40 f. (Lilljeborg); Upper Norway (M‘Andrew and Barrett).

It is variable in size. We do not know the exact position, in a generic point of view, of this delicate little shell. In 1841 I named it Fusus albus. The Pleurotoma nanum of Scacchi is a very different species. Our shell is allied to C. Holböllii; but that has a small shield-like operculum, and is longitudinally ribbed at the top.

The last-named species is one of our glacial fossils; it has been dredged by Mr. Waller, Mr. Hyndman, and myself on the Turbot bank, co. Antrim, in 20-25 f., by Mr. Norman and myself in the Hebrides, at a depth of 60 f., and by Mr. Dawson off the Aberleenshire coast. I found it also in the Fort William deposit. It inhabits every part of the Arctic seas, from Bergen, northwards, and the United States. The late Professor Gould described it as Buccinum rosaceum. This species was erroneously placed by Mörch in the genus Mitrella (as " Mitsella") of Risso.

## Family XXX. PLEUROTOMATIDA, (Pleurotomacea) Lovén.

Bony spiral, more or less elongated: mantle forming a short fold above the head for excretal purposes, the fold occupying a fissure or notch in the outer lip of the shell : pallial tube not protruded much beyond the canal of the shell: head small: proboscis retractile: tentacles placed far apart, with slender points : eyes on the extremity of stalks, which are conjoined with the lower portion of the tentacles, and placed outside them : foot lanceolate, double-edged in front, with a pointed tail : gills arrauged in two unequal-sized plumes : odontophore having no central tooth ["rhachis edentula," Lovén]; pleuræ
consisting of spines, which are arranged in a single row on each side and terminate in sharp points. Sexes distinct.

Shell spindle-shaped, or forming a lengthened cone with a pointed base: spire tapering or turreted: mouth oblong: outer lip fissured or notched: canal nearly straight: pillar smooth: operculum (when present) like that of Trophon or Fusus.

This family ought to be separated from the Conidre, with at least as much justice as Muricide and Nasside have been remored from the Buccinidre. According to Lovén the proboscis in Conus is not retractile. Woodward enumerated 430 recent and 378 fossil species of Pleurotoma; the geographical and bathymetrical distribution of the former is very extensive.

## Genus I. DEFRAN'CIA*, Millet. Pl. VII. f. 1.

Shell spindle-shaped: spire tapering; apex somewhat stiliform (as in Cerithiopsis), finely pointed, and minutely reticulated : mouth open: outer lip fissured at its junction with the periphery; inside grooved: operculuin none.
M. Millet constructed the present genus from some shells of the "calcaire grossier," which have the outer lip "sinué a sa partie supérieure," in contradistinction to Pleurotoma, in which the outer lip is notched at the side. The apex of the spire is also very different. There is, besides, a certain diversity of form and sculpture in each of these groups of species, although they are
"all affin'd and kin."

Defrancia was used by Bronn for a genus of Polyzoa; but that is a synonym of Pelagia, Lamouroux.

* Named in honour of M. Defrance, a well-known French naturalist and geologist.

## 1. Defrancia teres*, Forbes.

Pleurotoma teres, Forbes in Ann. \& Mag. N. H. xiv. p. 412, pl. ii. f. 3. Manqelia teres, F. \& H. iii. p. 462, pl. cxiii. f. 1, 2, and (animal) pl. RR. f. 3.
Body white, minutely frosted: pallial tube rather short: head (or mentum) wedge-like, never protruded beyond the foot: tentacles nearly cylindrical, of moderate length, widely diverging, slightly scalloped at the edges; tips blunt: eyes small, on short stalks at the outer base of the tentacles: foot deeply indented and angulated in front, with ear-shaped and pointed corners which occasionally curl inwards and are very flexible; it is expanded at the sides, and tapers to a fine point behind.

Shell slender, rather thin, semitransparent, and somewhat glossy: sculpture, numerous cord-like spiral ridges, which are nearly always much broader than their insterstices; from 20 to $2 \overline{5}$ of these ridges encircle the body-whorl, 8 to 10 the next whorl, 6 or 7 the next, and others at the same rate of decrease the remaining whorls; many of those on the body-whorl and all on the upper whorls are alternately large and small; the top whorls are minutely and closely reticulated by curved cross striæ in an exquisitely beautiful fashion ; the wide groove immediately below the suture (which indicates the former course of the fissure characteristic of this genus) is marked with close-set curved striæ in the line of growth; the rest of the surface is thickly covered with oblique and microscopic lines in the same direction: colour pale yellowish-white, prettily but irregularly spotted with reddish-brown; the spots appear to be produced by interrupted longitudinal streaks; some specimens are spotless; apex yellowish-brown: spire elongated and finely tapering: whorls 10 , convex and evenly rounded; the last occupies three-fifths of the shell viewed mouth upwards, and about one-half of the shell in the contrary position : suture very deep, formed by the fissural groove: mouth pear-shaped; length a little more than two-fifths of the shell : canal rather broad, a little inclining to the left, and ending in a slight and obliquely curved noteh: outer lip semicircular, furrowed within by the underside of the ridges; edge thin, scalloped or indented by the spiral sculpture: fissure remarkably distinct and broad, extending some way along the suture; its course can be traced throughout every part of the

[^138]spire except at the apex (the fissure being apparently formed subsequently to the embryonic growth) by the striated groove, which is of a thinner substance than the other part of the shell : inner lip rery slight and narrow : pillar long and nearly straight. L. $0 \cdot 6$. B. $0 \cdot 2$.

Habitat: Shelly and sandy ground, in $15-85 \mathrm{f}$., Shetland and the west of Scotland (Forbes and others); Orkneys, in 15 and 80 f. (Thomas, fide F. \& H.) ; co. Antrim (Hyudman) ; Connemara, 14 f. (Barlee and J. G. J.); deep-sea soundings off the west of Ireland (Hoskyns); Berwick Bay (Mennell) ; Durham and Northumberland (Abbes, Howse, and Alder) ; Plymouth (Jordan) ; Cornwall (Peach, Cocks, and Hockin): not common. Apparently an Appulian and Calabrian fossil, as the Pleurotome Renieri of Scacchi (Philippi). It has both a northern and southern range, comprising Norway (Lovén, as P. boreale, and others), Sweden (Malm), north of .Spain (M'Andrew), both sides of the Mediterranean (Testa, as $P$. Trecchi, Philippi, M'Andrew, and Martin), Egean (Forbes), Adriatic (Barbieri, fide Brusina, as Raphitoma Barbierii), and Madeira and the Canaries (N‘Andrew); depths 18-120 f.

It crawls slowly, and floats in a supine position like many of its congeners. My largest specimen is threequarters of an inch long.

## 2. D. Gra'cilis*, Montagu.

Murex gracilis, Mont. Test. Br. (i.) p. 267, t. 15. f. 5. Mangelia gracilis, F. \& H. iii. p. 473 , pl. cxiv. f. 4 , and (animal) pl. RR. f. 8.

Bodr white, closely but irregularly speckled with pink and flake-white: pallial tube somewhat extensile, usually short: head bulbous: tentacles extremely short-mere points above the eyes; below the eyes they are cylindrical and stout: eyes

[^139]proportionally large, on long stalks conjoined with the tentacles: foot rounded in front, with small angular corners, pointed behind.

Siele of an elegant shape, rather solid, opaque, moderately glossy: sculpture, several strong longitudinal ribs, which are usually oblique on the body-whorl and straight on the upper whorls; the rib near the mouth, which is placed at a little distance from the outer lip, is much longer and broader than the rest ; in some specimens a similar rib or varix may be observed. in the middle of the body-whorl ; there are from 14 to 16 ribs on this as well as on the penultimate whorl, 12 on the next, aud at the same rate of decrease upwards; the top whorls are ribless; the ribs do not extend much below the periphery, nor across the sutural groove ; all the whorls except that at the top (but including the sutural groove) are encircled by flattened or thread-like spiral ridges, which are very close-set and mostly alternate in size ; the second whorl from the top (and sometimes also the succeeding whorl) has but a single ridge, which being in the middle imparts a keeled aspect to that part ; top whorl reticulated; a slightly nodulous, but not cancellated, appearance is produced by the intersection of the ribs and ridges ; the whole surface is microscopically and densely granulated lengthwise, especially in the insterstices of the ridges: colour pale fawn, passing into reddish-brown, or indistinctly streaked lengthwise with the latter colour; the periphery is marked by a white band, and the part below the suture is sometimes margined by a reddish-brown line which is occasionally interrupted so as to become a row of spots; the lines which separate the ribs are paler, and the ridges often of a dark hue; apex yellowish-white: spire elongated: whorls 10-11, moderately convex, the upper ones somewhat angulated; the last occupies three-fifths of the shell: suture broad and rather deep, formed by the fissural groove: mouth pearshaped and long; length nine-twentieths of the shell : canal rather loug, broad, and expanded at the opening ; it is somewhat twisted or bent backwards, and ends in a deepish and curved notch: outer lip rounded; inside thickened, finely and closely furrowed; edge rather sharp, notched by the spiral ridges; it is often deeply coloured within : fissure deep and broad, incursed at the further extremity ; it is defined outwardly by a sharp angular point; its previous course is indicated by a closed groove similar to that of the last species: inner lip slight and narrow, furnished very near the top of
the mouth with a small tubercle or tooth : pillar long and flexuous. L. 1. B. 0.375.

Habitat : Not uncommon in the coralline zone on the coasts of Guernsey, Cornwall, Devon, Bristol Channel, Ireland (west, south, and east), and the Clyde district; Anglesea (M‘Andrew) ; Coldingham Bay, Berwickshire (Maclaurin); Dunbar (Laskey); Orkneys (Forbes); Shetland (Barlee and J. G. J.). Italian tertiaries (Philippi and Calcara). Its present known distribution is entirely southern as regards the British Isles, and comprises the sea-board of the Atlantic from Cherbourg to the Canary Isles, the Mediterranean, Adriatic, and Ægean ; depths recorded by Forbes and M‘Andrew 4-80 f.

Like all its molluscan kindred, it prefers, when in captivity, darkness to light. My largest British specimen is from Unst, my smallest from Guernsey ; some from Corsica are very diminutive. The tubercle on the upper part of the inner lip and the angulated point on the outer lip at the commencement of the fissure are especially noticed by Millet among the characters of his genus Defrancia.

It is not the Murex gracilis of Brocchi, nor that of Scacchi. Donovan described our shell as M. emaryinatus, Michaud as Pleurotoma Comarmondi, Bronn as $P$. suturale, and Costa as P. Cyrilli; Chiereghini called it M. Poelarius. The young appears to be P. fallax of Forbes, and is the Fusus Branscombi of Clark.
D. sinuosa (Murex sinuosus, Mont.) is allied to the present species; it is a native of the west coast of Africa. Bryer is reputed to have found it at Weymouth, Laskey at Dunbar, De Gerville at Quinéville in the north of France, and Martin in Provence.

## 3. D. Leufro'yi*, Michaud.

Pleurotoma Leufroyi, Mich. in Bull. Soc. Linn. Bord. ii. (1828) p. 121, f. 厄̄, 6. Mangelia Leufroyi, F. \& H. iii. p. 4(G8, pl. cxiii. f. 6, 7, and (animal) pl. RR. f. 1, as M. Lefroyi.

Body white, with a faint tinge of yellow ("sometimes slightly tinged with purple," F. \& H.) : pallial tube conical, short, not protruded beyond the canal of the shell: tentacles cylindrical, rather short ("long and slender," F. \& H.), with blunt tips; they widely diverge, and sometimes assume the shape of the letter V : eyes on thick stalks united with the tentacles at their outer base : foot ("very large and expanded," F. \& H.) broader and indented in front, with small ear-shaped corners, bluntly pointed behind.

Suele broad towards the base, more or less solid according to habitat (being much thicker in the lower part of the littoral zone than in deep water), and for the same reason either opaque or semitransparent, rather glossy : sculpture, several strong curved longitudinal ribs, which extend to the base but do not cross the fissural groove or subsutural area; the body-whorl has from 14 to 18 ribs, the next 14 to 16 , the next 12 to 14 , and the next 10 to 12 , when they rapidly decrease in number, disappearing towards the apex; the rib immediately behind the mouth is not disproportionately large ; all the whorls except those which compose the apex are encircled by fine threadlike ridges or striæ, which are very close-set and occasionally alternate in size; of these may be counted more than 30 on the body-whorl, 12 on the next, 8 on the next, 6 on the next, and so on; the third whorl from the top sometimes is indistinctly kecled in the middle ; fissural groove not only having 3 or 4 slight spiral ridges, but crossed by numerous fine curved strix ; the points of intersection on the upper whorls form oblong nodules, with the major axis in the direction of the spire, and are now and then muricated or prickly; the whole surface is microscopically and closely marked by the lines of growth ; top whorls exquisitely reticulated by curved strix, which cross each other diagonally, like the wirework of a fire-guard: epidermis thin, yellowish-brown, persistent only in the fissural groove: colour whitish, passing into creamcolour, variegated by irregular purplish- or reddish-brown blotches, which are arranged in two very broad zones or bands

[^140]on the body-whorl (one above and the other below the periphery), and in a single band on one or more of the upper whorls; the spiral striæ are generally lineated with purplishor reddish-brown; apex pink, orange, or reddish-brown : spire rather short; apex proportionally much smaller than the succeeding part, and of a different appearance: whorls 8-9, swollen, rapidly enlarging: the last occupies two-thirds of the shell : suture deep: mouth pear-shaped, sinuated abore, and expanding outwards; length from the commencement of the fissure to the extremity of the canal about half the shell: canal rather short, wide, nearly straight, and ending in an obliquely rounded but not conspicuous notch: outer lip curved; inside more or less thickened, and slightly furrowed; edge rather sharp, finely and closely notched by the spiral striæ: fissure wide but not very deep, forming an incurred notch rather than a slit; it is defined outwardly by an angular point : inner lip slight, frequently exhibiting an attrition by the foot in that part instead of the usual layer deposited by the mautle: pillar rather long and flexuous. L. $0 \cdot 6$. B. $0 \cdot 25$.

Var. carnosuta. Pale fleshcolour; length sometimes eightand even nine-tenths of an inch.

Habitat: Stony ground, from low-water mark of spring tides at Herm (Gallienne) to 90 f . off Unst (J. G. J.); local. I will mention the principal places where it has been taken:-Guernsey (Metcalfe and others); Falmouth (Hockin); Whitburn (Abbes, fide Alder); Connemara (Barlee and J. G. J.); Cork (Humphreys) ; co. Antrim (Hyndman and Waller); west of Scotland (Smith and others); Orkneys (Thomas, fide F. \& H.); Shetland (Fleming and others). The variety is from the last-named district. Glacial deposit at Wick (Peach); Red Crag (S. Wood); upper tertiaries of Italy (Philippi, Calcara, and Hörnes). Inhabiting the coasts of Bergen (Sars), Bohuslän, 20-30 f. (Malm), Brittany (Delaunay, fide Taslé), Corunna (M'Andrew and H. Woodward), Gibraltar, 10 f., and Canary Isles, 12 f. (M‘Andrew), Mediterranean (Michaud and
others), Adriatic (Chiercghini and others), and Ægean (Forbes).

It frequently turns upon its back and floats. The shell varies in size and in the length of the spire. Specimens from the Clyde district resemble those of the Mediterranean in their deep but bright colour.

Fleming described this species as Pleurotoma sinuosa, supposing it to be the Murex sinuosus of Montagu ; it is the $P$. zonalis of Delle Chiaje, $P$. inflata of Cristofori and Jan, P. concinna of Scacchi, Fusus Boothii of Brown, and (according to Nardo) Murex caudicula of Chiereghini. P. Leufroyi of Hörnes appears different.

## 4. D. linea'ris*, Montagu.

Murex linearis, Mont. Test. Br. (i.) p. 261, t. 9. f. 4. Mangelia linearis, F. \& H. iii. p. 470, pl. cxiv. f. 1-3, and (animal) pl. RR. f. 6.

Body white, with occasionally a faint tinge of yellow or fleshcolour, and sometimes minutely speckled with flake-white: pallial tube varying in compactness and length, with a wide opening: head very small, short, and flat: tentacles conicocylindrical, extensile, occasionally saffroncolour, with bulbous tips: eyes rather prominent, about halfway up the tentacles, on the usual stalks: foot expansile, sometimes narrow and rery long, more or less deeply cloven in front, with triangular and recurved corners, tapering behind to a fine point.

Shell very much smaller than D. Leufroyi, and of a narrower shape, always solid, opaque, and not so glossy: sculpture, strong, curved, and buttress-like longitudinal ribs, which extend not only to the base but to the suture; the body-whorl and the next have each about a dozen, the next about 10, and in the same proportion upwards ; these ribs are traversed by thread-like spiral striæ, of which about a dozen are on the body-whorl, 5 or 6 on the next, 4 or 5 on the next, and so on ; crests of the ribs muricated; third whorl slightly keeled in the middle, and top whorls reticulated, as in the last species ; the entire surface is microscopically and closely reticulated, and the lines of growth are rather distinct: colour.

[^141]yellowish-white, variegated by reddish-brown lines which wholly or partially decorate the spiral striæ; apex orange or purple: spire rather long; apex shaped as in the last species: whorls S-9, rather convex; the last occupies three-fifths of the shell: suture deep : mouth pear-shaped, angulated above, and contracted; length nearly half that of the shell: canal rather short, moderately open, and turning to the left; notch obliquely rounded, and somewhat distinct: outer lip curved; inside thickened, and furrowed or toothed, the uppermost and lowermost teeth being the largest ; edge sharp, crenellated by the spiral strix : fissure as in the last species: inner lip slight and retired : pillur long and flexuous. L. 0.35 . B. $0 \cdot 175$.

Var. cequalis. Body white, microscopically frosted : pallial tube rather short and wide : tentucles of moderate length above the eje-stalks, compressed on the upper and under sides: eyes proportionally large, black, placed on longish stalks: foot leaf-shaped, indented in front, with angular corners, broad and expanded towards the sides, and obtuse-angled behind. Shell broader than the typical form, with the whorls more rounded; ribs more numerous, and not so prominent or rugged; spiral striæ closer and fincr; apex yellowish-white; coloured lines regularly distributed, and of a paler hue ; in some specimens these markings are very faint or altogether wanting. L. 0.5. B. 0.225 . Mangelia linearis, vars. intermedta and pallida, F. \& H. iii. pp. 471, 472.

Habitat : Laminarian, coralline, and deep-water zones, on all our southern coasts, and occasionally also in the north. The distribution of the variety, which is equally common, is the reverse of this. Fossil in Ireland (J. Smith) ; post-glacial bed in Norway, 0-100 feet (Sars); Italian tertiaries (Philippi and Calcara). The typical form and the variety have an extensive range throughout the north Atlantic, from Iceland (Steenstrup) and Finmark (Sars) to Madeira and the Canaries (M'Andrew), as well as in the Mediterranean, Adriatic, and Ægean; depths 8-70 f.

The animal is sluggish; it has the same habit of floating as its smaller congeners. The spawn-cases are se-
parate, hemispherical, membranous, and thin, one-fifth of an inch in diameter, with a small oval hole in the centre. They are attached at the base to the inside of old bivalve shells and to other smooth surfaces. Each capsule contains from 200 to 300 fry. These are of a brown colour and exquisitely reticulated, each haviug a single whorl, globular, and partially umbilicate, with a roundish mouth and an incomplete canal like that of Ianthina. The fry, when in the capsule, are very restless, and gyrate freely by means of their ciliated front lobes. The young shell may be distinguished from that of $D$. Leufroyi by its microscopical texture, as I have described in the account of each.

Among the numerous synonyms are Murex elegans of Donovan, Pleurotoma versicolor (including D. purpurea, var. Philberti) of Scacchi, Fusus multilinearis of Brown, F. Buchanensis of Macgillivray, Mangelia Cranchiana of Leach, and Raphitoma rosea of Brusina. Clavaiula linearis of S . Wood is unknown to me as a recent species.

## 5. D. reticula'ta*, Renier.

Murex reticulatus, Renier, Tâv. alf. conch. Adr. p. 2.
Body white, with a few scattered and minute flake-white specks, and having a tinge of yellow in front and a streak of the same colour down the upper part of the foot; the tissue, examined microscopically, appears veined : pallial tube extensile, and therefore varying in length: head broad, deeply cloven in front, with an angular ridge on each side: tentacles rather long, slender above the eye-stalks, with pointed tips : eyes black and distinct; stalks about half the length of the tentacles: foot large and broad, deeply notched or bilobed in front, with recurved ear-shaped corners, finely pointed behind; this last character (as well as others derived from parts of an expansile nature) depends on the state of activity of the animal

[^142]when observed, the tail being sometimes sharply pointed, and at other times bluntly angular or even rounded in the same individual.

Shell having the last whorl produced into a rather long beak, of a thin texture between the ribs, semitransparent, partially glossy (especially the fissural groove and the interstices of the ribs, which frequently are glistening) : sculpiure, longitudinal and spiral ribs, nearly equally prominent, and forming by their intersection oblong spaces in a transverse direction; the points of junction are prickly; of the longitudinal ribs there are usually 15 or 16 on the bod 5 -whorl, and one or two less on the penultimate whorl, the number diminishing in that proportion upwards; they extend to the base, but never cross the fissural groove; the spiral ribs are slighter, 15 or 16 on the body-whorl, 5 on the next, 4 on the next, and so on; sometimes a very fine intermediate stria is observable between some of the spiral ribs; the third whorl from the top, and part of the second whorl are bluntly keeled by the first spiral rib, and all the apical whorls are exquisitely reticulated ; the surface is faintly marked with microscopic and distant lines of growth, but not reticulated: colour yellow, irregularly mottled or streaked with purplish-brown; apex yellowish-brown: spire long and turreted; apex rery small, slender, and distinct: whorls 9-10, convex; the last occupics three-fifths of the shell: suture deep: mouth as in the last species, but not so much contracted; length nearly half that of the shell: canal rather long, wide, more or less reflected at its extremity ; notch obliquely rounded, not conspicuous outside: outer lip curved; inside thickened, and fluted by about 10 tooth-like ridges; edge sharp, crenellated by the spiral ribs : fissure deep, broad, and incurved; its former course is distinctly traceable: inner lip slight and retired : pillar long, in some cases nearly straight, and in others flexuous. L. 0.5 . B. $0 \cdot 2$.

Tar. formosa. Pure snow-white, or with a slight tinge of fleshcolour or pink, and occasionally encircled by a pale band below the periphery; spire elongated; whorls tumid. Mangelia purpurea, var. asperrima, F. \& H. iii. p. 467, pl. cxiii. f. $\overline{\bar{b}}$ (not Fusus asperrimus of Brown).

Habitat: Coralline zone, at Guernsey (J. G. J.); Plymouth (Jordan) ; Falmouth (Hockin) ; Birterbuy

Bay, co. Galway (Walpole) ; Cork (Humphreys) ; co. Antrim, in 60 f . off Loch Ewe, and in 43 f . on the Shetland coast (J. G. J.). The variety is from Falmouth (Cocks and Barlee); Shetland, 78-86 f. (Barlee and J. G. J.). D. reticulata belongs to our Red and Coralline Crag (S. Wood, as Clavatula cancellata), and to the Italian tertiaries (Philippi and Calcara). It is spread along the north-Atlantic coasts, from Brittany (Collard des Cherres and Taslé) to Gibraltar (M‘Andrew), and throughout the Mediterranean, Adriatic, and Ægean, at depths of from 4 to 35 f . The variety has been dredged by Lilljeborg in Norway, by Lovén and Malm in Bohuslän (by the latter in 40 f .), and by Forbes in the Ægean (as var. spinosa) in $10 \check{\mathrm{f}}$.

This species varies remarkably in size. An Irish adult specimen is only three lines long; another, from Shetland (the varietal form), measures nearly an inch and a quarter. Those from the Mediterranean are of two kinds, one like ours, and the other (which is more usual) having a shorter spire and very tumid whorls, and averaging three-quarters of an inch in length. The latter may therefore be considered the typical form. The variety is extremely bcautiful, and almost "paragons description;" it will be figured in the next volume.

It is the Murex cancellatus of J. Sowerby (not Pleurotoma cancellata of Calcara, nor Fusus cancellatus of Mighels and Adams, both of which appear to be also species of Defrancia), M. echinatus of Brocchi, Pleurotoma Cordieri of Payraudeau, P. rude of Scacchi, and P. purpureum of Philippi-not M. purpureus of Montagu; I described the present species as $P$. scabrum, under the impression that it was distinet from the Mediterranean shell and not merely a variety.

## 6. D. purpulrea*, Montagu.

Murex purpureus, Mont. Test. Br. (i.) p. 260, t. 9. f. 3. Mangelia purpurea, F. \& H. iii. p. 465, pl. cxiii. f. $3,4$.

Bony whitish, with a tinge of purple, minutely and closely speckled with flake-white : pallial tube cylindro-conical, rather long: head conical, short: tentacles spike-shaped, very short above the eye-stalks, and bluntly pointed: eyes placed about one-third of the way down the tentacles, from which part the tentacles increase considerably in thickness: foot squarish in front, with angular corners (to each of which a ridge runs from the neck or back of the head, forming an inverted V ), pointed behind.

Shell less fusiform than the last species, owing to the base not being so much produced or elongated, rather solid, nearly opaque, and of a somewhat dull hue: sculpture, numerous and crowded, but not prominent, longitudinal and spiral ribs, which produce by their mutual decussation a granular (not prickly) appearance; the interstices are rery narrow, and do not form any oblong spaces ; of the longitudinal ribs there are from 20 to 24 on the body-whorl, and 18 to 20 on the next; they extend to the base, and nearly to the suture ; the spiral ribs are narrower and thread-like, 24 to 28 on the body-whorl, and abont a dozen on the next whorl, besides a few slight intermediate striæ; the third whorl and part of the second are bluntly keeled, and all the top whorls are finely reticulated; the microscopic texture is closely but indistinctly frosted: colour purplish brown, chocolate, or reddish-brown, sometimes variegated with white, fawncolour, pale yellow, or occasionally pure white, now and then encircled by a pale narrow zone below the periphery; top orange or pale yellow : spire long, tapering, and somewhat turreted; apex as in the allied species, but more slender: whorls 12, convex and rounded; the last occupies rather more than half the shell : suture deep: mouth narrowly pear-shaped, contracted above to form the fissural sinus; length two-fifths of the shell: cancl rather short, wide, and expanding towards the orifice; it bends a little to the left ; notch broad and rounded, scarcely visible outside: outer lip gently curved; inside white and thickened, fluted by about 15 tooth-like ridges; edge sharp, notched by the spiral ribs: fissure deep, rather narrow, and incurved; its previous course

[^143]is not so conspicuous in this as in the last species, being partly covered by the sculpture : inner lip slight and retired: pillar flexuous. L. 1. B. $0 \cdot 4$.

Far. 1. Phillerti. Bonx pale yellowish-white, more or less tinged in front with purplish-brown, and covered with minute round flake-white dots : pallial tube cylindrical, rather long, projecting, and somewhat curved; it is of a darker hue than the rest of the body: tertacles forming compressed cylinders, rather long above, the eye-stalks : eyes on the tops of short stalks, which are amalgamated with the teutacles: foot elongated and thin; front deeply indented or notched in the middle, and expanding at each corner into au arched lobe or auricle; hinder part broad, and abruptly pointed. Sherl dwarf, more solid, and particoloured; ribs less numerous, but not in proportion to the size of the shell. L. $0 \cdot 4$. B. $0 \cdot 2$. Plewrotoma Philberti, Michaud in Bull. Soc. Linn. Bord. iii. p. 261, f. 2, 3.

Var. 2. oblonga. Bodx light grey, mottled with purple: pallial tube long, purplish-brown, finely wrinkled: tentacles rather short, cylindrical, light grey; lower portion speckled with white: eyes on long stalks amalgamated with the tentacles, about halfway up the latter: foot narrow; front indented in the middle, with angular corners ; hinder part finely pointed; sole white. Shelle of the same size as the other variety, but having the spire much shorter and not turreted; the body-whorl is proportionally much larger ; sculpture finer, and not so tubercular.

Habitat: Chiefly in the coralline zone and deeper water, on stony and shelly ground, along the coasts of Guernsey, Dorset, Devon, Cornwall, and Shetland; Lundy Island (M‘Andrew) ; Isle of Man (Forbes); Cork (Humphreys). The first variety is mostly confined to the laminarian zone, and is more diffused: I dredged it off Croulin Island, Skye, in 30-40 f., close to the shore ; and I found it in the Channel Isles under stones, and among Zostera at low-water mark; Mr. Peach and Mr. Norman have also procured it on the recess of the tide, the former at Paignton, and the latter in the Clyde district. The 2nd variety appears to be peculiar to the

Channel Isles; I obtained it alive by dredging off St. Catherine's Bay, Jersey, in 10-12 f., and dead at Guernsey, in 18 f . Fossil (var. Philberti)? Ireland (Smith); Coralline Crag (Wood); Touraine, south of France, and Italy (Hörnes and others). The range of this species and the variety Philberti, as recent, comprises Christiansund, 30-50 f. (Danielssen), Bergen (Sars), Bohuslän, 18-ธ0 f. (Malm), north Atlantic, from Normandy to Madeira and the Canaries, Mediterranean, Adriatic, and Æegean; shore to 5 5 f.

The animal is sluggish. Very young shells of the typical form are extremely slender and finely pointed.

There are several obsolete or useless synonyms. Mangelia purpurea of Risso can scarcely be this species; he described it as subfossil only.

Genus II. PLEURO'TOMA*, Lamarck. Pl. VII. f. 2.
Suril forming a more or less lengthened cone: spire turreted; apex regular and blunt: mouth narrow: outer lip notched at the side, below its junction with the periphery; inside smooth : operculum possessed by some species, and resembling in shape an elongated pear, with the nucleus or point at the base.

Although the notch in the outer lip of British species is usually slight, such is not the case in $P$. nivalis, which has as deep a slit as many typical species of Pleurotoma; the depth of the notch or slit is merely a comparative character.

This genus has been very unscientifically and needlessly divided by authors, and has received various names. Mangelia (correctly Mangilia, from Mangili, an Italian naturalist) is one of these synonyms, and has been attributed to Risso on Leach's authority; but Risso

[^144]did not notice either the canal at the base or the notch in the outer lip, and his description might serve for Rissoina, species of which he in fact included in Mangelia.

## A. Inoperculated.

## 1. Pleurotoma striola'ta*, (Scacchi) Philippi.

P. striolatum, Phil. Moll. Sic. ii. p. 168, t. xxri. f. 7. Mangelia strio-
lata, F. \& H. iii. p. 483, pl. cxiv. A. f. 1, 2.

Bony white, minutely and closely speckled with flake-white, and marked with 8 or 9 bright pink spots on the pallial tube, which is short and rather open or scoop-shaped : tentacles short and thread-shaped abore the eye-stalks: eyes placed very near the tips of the tentacles: foot truncated in front, very slightly auricled at the corners, and tapering behind to a point; the sole has no medial groove. (Clark.)

Shell slender, rather solid, semitransparent, not glossy, except in dead and rubbed specimens : sulpture, flexuous and prominent longitudinal ribs, which are remarkably highshouldered or angulated at the top of each whorl, and extend to the suture and base; there are 9 or 10 on the body-whorl, and one less on the penultimate whorl, decreasing at the same rate upwards; the whole surface (with the exception of the apex) is traversed by fine and numerous spiral strix, which are discernible with a low magnifying-power, but not by the naked eye; the third whorl is marked with numerous longitudinal strix, besides the spiral striæ (which latter are stronger than usual), but there is no appearance of reticulation; the first and second whorls are smooth and glossy: colour buff or pale yellow, sometimes variegated by several obscure and narrow bands of reddish-brown; and occasionally the periphery is encircled by a broader purplish band, and the upper part of each whorl (just below the suture) has a second band of a purplish hue: spire long, tapering, and turreted; apex somewhat mammiform, but not haring the peculiar eharactor of any Defrancia: whorls 9, moderately convex, angulated by the ribs; the last whorl occupies rather more than one-half of the shell: suture deep: mouth contracted, exhibiting the labial notch near the upper part; length five-twelfths of the shell : canal rather long and wide; basal notch obliquely rounded :

[^145]outer lip not much curved, somewhat inflected; edge thin and plain: labial notch rather short, very distinct, and incurved; it is situate below the periphery, to which the upper corner of the outer lip is attached: inner lip retired, forming a moderately thick glaze: pillar flexuous. L. $0 \cdot 6$. B. $0 \cdot 2$.

Habirat: Coralline zone at Exmouth (Clark and J. G. J.) ; Torbay (Alder) ; Falmouth and Land's End (Hockin) ; Weymouth and Guernsey (Hanley); Goodwick Bay, Pembrokeshire, 20 f. (J. G. J.); Bantry Bay, 12-15 f. (M‘Andrew); Connemara (Forbes and others); west coast of Scotland (Smith and others); co. Antrim (Hyndman). Fossil in Sicily (Philippi and Calcara). Living in Christiansund, 30-40 f. (Danielssen); Norway (Lilljeborg, fide Danielssen); Loire-Inférieure (Cailliaud); Vigo and south coast of Portugal, Madeira, and Canary Isles, 8-60 f. (M‘Andrew) ; Mediterranean, 8-50 f. (Philippi and others).
P. Smithii of Forbes, P. Farrani of Thompson, Fusus elegans of Brown and Leach, and Mangelia Loveneana of Reeve. This last-named author made also a great many other so-called species from the late Mr. Cuming's collection, which will not stand the test of criticism; but the excellent illustrations that form the chief merit of his 'Conchologia Iconica' amply compensate for such failures. Mangelia striolata of Risso is apparently $P$. attenuata.
P. accincta (Murex accinctus, Mont.), one of Laskey's pscudo-discoveries, is West-Indian.

## 2. P. adtenua ${ }^{\prime}$ ta *, Montagu.

Murex attenuatzs, Mont. Test. Br. (i.) p. 266, t. 9. f. 6. Mangelia attenuata, F. \& H. iii. p. 488, pl. cxiii. f. 8, 9, and (animal) pl. RR. f. 5.
Boor white, with flaky specks [there are a few pink or red

[^146]spots near the extremity of the pallial tube (Clark)]: pallial tube rather more slender than usual: tentacles avl-shaped, comparatively very long, close together at their bases: eyes on bulgings, very low down, and not far from the origin of the tentacles: foot truncated and acutely angulated, with auricles in front ( $\mathrm{F} . \& \mathrm{H}$ ), [when fully extended, as long as the shell (Clark)].

Shell slender, attenuated towards each extremity, rather thin, semitzansparent, very glossy : sculpture, fine, sharp, narrow, and flexuous longitudinal ribs, which extend to the base as well as to the suture, being apparently continued along the spire in an uninterrupted line; there are 9 on the body-whorl, and usually the same number on the next whorl, after which they dwindle upwards; the whole surface (except the apex) is covered with very slight microscopic and close-set spiral strix, which can be detected only by a high magnifying-power; the third whorl is keeled in the middle, and has rather numerous and curved longitudinal riblets, the first two whorls being quite smooth: colour pale tawny, encircled by several reddish-brown lines and by a chestnut band below the periphery, sometimes also by a narrow and obscure band just below the suture; the ribs are paler: spire long and gradually tapering; apex as in the last species: whorls $9-10$, moderately convex, somewhat angulated by the ribs; the last whorl occupies four-sevenths of the shell: suture rather deep: mouth contracted ; length three-sevenths of the shell: cranal straight, rather long and wide; basal notch rounded : outer lip flexuous, incurved; edge narrow, sharp, and plain: labial notch small and shallow but distinct, situate as in the last species: inner lip retired, forming a tolerably thick glaze: pillar nearly straight. L. 0.6. B. 0.2.

Habitat: Gravelly and muddy sand in the coralline zone, on the coasts of Devon and Cornwall (Montagu, Couch, and others); Guernsey (Forbes); Sark (Barlee); Bideford (Montagu) ; Scarborough (Bean); Goodwick Bay, Barmouth, and Bantry (J. G. J.) ; Cork (Humphreys) ; Connemara (Alcock) ; Dublin Bay (Turton); Lough Strangford (Dickie) ; Oban (Barlee) ; Hebrides (M'Andrew and Forbes). Fossil in Calabria and Tarento (Philippi); Professor Geikie's statement that it had been
found in the Bute deposit by Mr. Crosskey is erroneous. Its present distribution is mostly southern-although Lovén and Malm have dredged it in the south of Sweden, and Sars has recorded it with doubt from ÖxfjordAtlantic coasts of France, Spain, and Portugal, from Boulogne to Gibraltar ; Teneriffe ( $\mathrm{II}^{\text {A }}$ Andrew); Mediterranean, Adriatic, and Ægean: depths $2-40 \mathrm{f}$.

This elegant shell differs from $P$. striolata in being more slender, and highly polished ; the ribs are not angulated at the top, nor is the spire turreted ; the surface is smooth; and the linear markings are very peculiar. My finest specimen (for which I am indebted to the kindness of Dr. Battersby, who dredged it at Torquay) is three-quarters of an inch long.

It appears to be the Mangelia striolata of Risso, $P$. Villiersi of Michand, P. gracilis of Scaçchi, and P.nuperrimum of Tiberi.

## 3. P. costa'ta*, Donovan.

Murex costatus, Don. Br. Sh. iii. pl. xci. Mangelia costata, F. \& H. iii. p. 485 , pl. cxiv. A. f. 3-5, and (animal) pl. RR. f. 4.

Bony clear white, with a bluish tinge, more or less closely speckled with light purplish-brown or yellow, or with irregular flakes of milk-white: pallial tube cylindrical, rather long and flexible, exhibiting a notch-like fold at the opening: tentacles rather short, with bulbous tips, doubled in thickness for the lower half by the eje-stalks: eyes rather large, placed on swollen terminations of the stalks : foot elongated, narrow, and thick, in front truncated, gently curved, or slightly indented with small angular corners, attenuated and finely pointed behind; when the animal is at rest, the sole is strangulated or divided across in the middle: [odontophore, pleural spine strong, with the head or top folded back, and the side indented and gaping or incurved. (Lovén.)]

Shell agreeing in many particulars with that of $P$. atte-

[^147]nuata; but this is much smaller, thicker, less slender, not attenuated towards either extremity, nor glossy; the base is considerably broader in proportion; the ribs are stronger, blunter, and more angulated, and there are only 7 (or at the most 8) on the body-whorl; their interstices are somewhat concave; the spiral strix are closer and finer: colour less regular, with the lines and bands broader, sometimes mottled, or the upper part of the shell chocolate, and the lower yellowish; the outside of the mouth and the throat or inside of the outer lip usually exhibit a purplish-brown blotch: spire less taper: whorls not so convex, the last occupying three-fifths of the shell: suture not so deep: mouth much narrower ; length twofifths of the shell: canal more curved, shorter, and broader : outer lip continuous with the inner lip, considerably thickened within, where it is frequently furnished with a narrow white ledge; edge not so thin or sharp: labial notch much deeper: inner lip thickened, and reflected above: pillar flexuous. L. 0.45 . B. $0 \cdot 185$.

Habitat: Generally distributed; living at low-water mark of spring tides, in rock-pools, on the coasts of Devon and Cornwall (Clark and Templer), in 95 f., on fine sand, off Unst (J. G. J.), and in 145 f. off the Mull of Galloway (Beechey). The "P. coarctata" of Forbes is merely the northern, and consequently larger, form of this common species. Fossil in the glacial deposit at Wexford (Sir H. James) ; Belfast (Grainger); Red and Coralline Crag (Wood); Norway, 70-80 feet, retaining its coloured band (Sars); Lillo near Antwerp (De Wael) ; Antibes (Macé). Finmark to Bohuslän, 10-70f. (Sars, Lovén, and others); Zealand (mus.Copenh.); Brittany (De Gerville and others) ; Arcachon (Fischer) ; Rochelle (D'Orbigny père); Spain and Portugal, 7-12 f. (M‘Andrew) ; Provence (Gay); Spezzia (J. G. J.); and probably every part of the Mediterranean and Adriatic, as $P$. teniata and under other less known names.

The Murex costatus of Pennant is a mixture of small shells belonging to different genera. Da Costa's Bucci-
num costatum is $P$. septangularis. The present species is probably Fusus fasciatus, F. pyramidatus, and F. crassus of Brown, and the young his $F$. minimus; Hanley described it as $P$. Metcalfei, and Leach as Mangelia Pennantiana.
P. lineolata (Mangelia lineolata, Risso) $=P$. multilineolatum, Desh. =Fusus lineatus, Brown, is a Mediterranean and Adriatic shell, closely allied to $P$. costatum; it was described and figured by Leach as Mangelia lineata and recorded from Cork on the authority of Dr. Drummond.
P. proximum (Murex proximus, Mont.) is TVest-Indian. Laskey pretended to have found it on "Tyningham sands, near Dunbar." The specimen in the British Museum, marked " mus. Montagu," however, is a worn $P$. nebula, and quite unlike the description and figure given by the author.

## 4. P. rugulo'sa ${ }^{*}$, Philippi.

P. rugulosum, Phil. Moll. Sic. ii. p. 169, t. xxri. f. 8.

Shell at first sight mistakeable for a small and stumpy $P$. costata ; but the following characters will serve to distinguish it. The present species is more solid, and has a broader base and shorter spire; the ribs are thicker, and angulated near the top of each whorl, so as to give a turreted appcarance to the shell ; another and peculiar difference is that, instead of the spiral striæ being uniform, some of them are larger and more raised than the rest, viz. about a dozen on the body-whorl, and 4 on the preceding whorl ; the colour is tawny, or yellowishwhite, with sometimes an obscure reddish-brown band on the periphery; the whorls are only 7 in number, and end abruptly; the canal is truncated; and the outer lip is remarkably thick, and never has a ledge on the inside. L. $0 \cdot 25$. B. $0 \cdot 125$.

Habitat : Bay in St. Merryn Parish, Cornwall (Hoc-

[^148]kin) ; Padstow (Goodall, fide Leach). Fossil in Sicily and Calabria (Philippi and Calcara). Au inhabitant of the Mediterranean, Adriatic, and Ægean seas.

Mangelia Goodalliana, Leach (whose typical specimen is in the British Museum), and Raphitoma Sandrii, Brusina.

## 5. P. brachy'stoma*, (brachystomum) Philippi.

#### Abstract

P. brachystomum, Pliil. Moll. Sic. ii. p. 169, t. xxvi. f. 10. Mangelia brachystoma, F. \& H. iii. p. 480, pl. cxiv. f. 5, 6, and (animal) pl. RR. f. 2.

Bony whitish, minutely speckled with flake-white [purplishwhite (F.\&H.)]: pallial tube cylindrical and long, projecting in front: tentacles short, with blunt tips: eyes large, on the thickened end of stalks which are two-thirds the length of the tentacles: foot very long and narrowish, truncated or indented in front, with a rather large flap or auricle at each corner, bluntly pointed behind.

Sherl cylindrical, and pointed at each extremity, solid, nearly opaque, of a rather dull aspect: sculpture, strong, broad, rounded, and rather prominent longitudinal ribs, from 7 to 9 on each of the last three whorls; they extend to the base, but not quite to the suture, the space below which is strongly and spirally sculptured; the whole surface (except the apex) is covered with thread-like spiral ridges, which are finely and closely reticulated by microscopic longitudinal strix, making the crests of the principal ridges (especially of those below the suture) beaded and the surface roughened; these ridges are more or less wavy and of different sizes, the larger and more conspicuous numbering about 15 on the body-whorl, 5 or 6 on the next whorl, and decreasing upwards; the third whorl has several minute curred striæ in the line of growth, their interstices being pitted, or the striæ granulated, by the intersection of four or five equally minute spiral strix; the top whorls are smooth and glossy : colour yellowish-white, orange, or occasionally deep reddish-brown ; paler specimens sometimes exhibit traces of a broad orange band below the periphery : spire turreted, and gradually tapering to a somewhat abrupt and blunt point: whorls $8-9$, moderately convex,

[^149]somewhat flattened or shelf-like at the top, and angulated by the ribs; the last whorl occupies six-elevenths of the shell: suture deep: mouth narrow, compressed and acute-angled above, and broader in the middle; length nearly four-elevenths of the shell: canal short, straight, and wide, expanding at the extremity in full-grown specimens; basal notch obliquely incurred: outer lip flexuous, slightly bent inwards; edge sharp and muricated by the extremities of the spiral striæ: labial notch small and short, situate on the shelf-like ledge at the top of the body-whorl: inner lip retired, fincly polished: pillar short and nearly straight. L. $0 \cdot 275$. B. $0 \cdot 1$.

Habitat: Mud among stones, and muddy sand, in 10-60 f., Weymouth (Thompson), Exmouth (Clark), Torquay (Battersby and J. G. J.), Plymouth (Barlee and Jordan), Falmouth (Barlee and Hockin), Cornwall (MㄷAndrew), Whitburn (Alder), Dogger bank (Mennell), Bantry (Barlee), co. Antrim (Waller), Oban, Skye, and Loch Carron (J. G. J., Forbes, and others), Moray Firth (Gordon), Aberdeenshire (Dawson), Wick (Peach), Shetland (MI'Andrew and others). Newer tertiaries at Tarento (Philippi). Christiansund, 40-50 f. (Danielssen) ; Bohuslän (Lovén, and in 16-50 f. Malm); Loire-Inférieure (Cailliaud); Arcachon (Fischer); Corunna to Gibraltar, 8-30 f. (M‘Andrew); Malaga (M‘Andrew) to Naples (Philippi) on the European coast of the Mediterranean, in $10-50 \mathrm{f}$., and on the North African coast, in 35 and 36 f . (M‘Andrew and Weinkauff); Adriatic (Brusina); : gean (Forbes, fide Reeve, as $P$. Cycladensis).

Most of the specimens which I received from the late Mr. Clark under this name belong to a dwarf and deepwater variety of $P$. nebula. The Clavatula brachystoma of Searles Wood appears to be an extinct species. Lovén described our shell as Mangilia tiarula.

## 6. P. nébila*, Montagu.

Murex nebula, Mont. Test. Br. (i.) p. 267, t. 15. f. 6. Mangelia nebula, F. \& H. iii. p. 476 , pl. cxiv. f. 7 , and (animal) pl. RR. f. 7.

Body whitish, minutely speckled with yellow: pallial tube long and narrow: head small and compressed : tentacles short, diverging, cylindrical from the base to the eyes, and afterwards becoming less than half the size to the tips: eyes small and black, seated externally on the top of the thickened part of the tentacles, about one-third from their extremities : foot long and broad, truncated or slightly indented in front, with small and obscure angular corners, gradually tapering behind to a blunt point.

Shell forming an elongated cone having its base or greater diameter just above the periphery, and abruptly attenuated towards the canal; it is solid, opaque, and of a rather dull and rough aspect: sculpture, strong, broad, rounded, and somewhat prominent longitudinal ribs, from 10 to 12 on the body-whorl, diminishing by degrees upwards; they are flexuous on the body-whorl, and nearly straight on the upper whorls; they scarcely extend to the base, and never to the suture, the space below which is spirally sculptured and is margined on the upper whorls by two close-set wary rows of bead-like strix; the whole surface (except the apex) is covered with very numerous spiral strix, which are crossed by microscopic and oblique longitudinal striæ, and reticulated as in the last species; the spiral striæ are equal in size, and three times as many as in P. brachystoma; the third whorl has three rows of granulated strix, the top whorls being smooth and glossy: colour chocolate, with the ribs sometimes of a paler hue: spire somewhat turreted, gradually tapering to a rather fine point: whorls 10-11, moderately convex, somewhat compressed towards the top of each and sloping downwards; they are angulated by the ribs; the last whorl occupies five-elevenths of the shell: suture rather shallow: mouth lozenge-shaped, compressed and acute-angled above, broader in the middle; length four-elevenths of the shell: canal short and wide, turning a little to the left, expanding at the extremity; basal notch incurved, and conspicuous outside: outer lip gently curved, slightly bent inwards; edge sharp, and closely muricated by the points of the spiral strix: labial notch rather deep, placed a little below the

[^150]slope which surmounts the last whorl: inner lip as in the preceding species: pillar flexuous. L. $0 \cdot 5 \overline{5}$. B. $0 \cdot 2$.

## Far. 1. abbreviata. Dwarfed, of the usual colour.

Var. 2. lactea. Also dwarfed, white or yellowish-white.
Var. 3. elongata. Bony pale 5ellowish-white or whitish, marked with purplish-brown or tlake-white spots of different sizes, which appear opaque when the animal is examined as a transparent object: pallial tube eyindrical, long and extensile: head semicircular, very small : tentacles short, cylindrical, and (without the eye-stalks) slender; the free extremities are remarkably short and finger-like, with rounded tips: eyes prominent, on nearly oval bulbs at the top of long and thick stalks which are conjoined with the tentacles, on their outer side (like a spliced rope), and extend from two-thirds to three-fourths of their length: foot rery long and flexible, rounded in front, with sbort triangular or ear-shaped cormers, narrower in the middle, and bilobed or obliquely truncated behind: verge falciform, situate behind the right-hand tentacle. Shell larger, and having the spire more elongated, of a thinner and more delicate texture: sculpture finer and smoother: colour yel-lowish-white with the interstices of the ribs purplish-red, sometimes wholly milk-white. L. 0.75 .

Habitat : Common in sand on all the coasts of the south of England, Wales, and Treland, from low-water mark of spring tides to the depth of a few fathoms; Scarborough (Bean) ; Coldingham Bay, Berwickshire (Maclaren, fide Johnston); Clyde district (Smith); Lamlash (Landsborough); Moray Firth (Macdonald). Var. 1. Coralline zone at Exmouth (Clark); Falmouth and co. Galway (Barlee); Whitburn (Alder). Var. 2. Aberdeenshire (Dawson). Var. 3. Deep water, Guernsey (Hanley and J. G. J.) ; Plymouth (Jordan) ; Exmouth (Clark); Arran Isle, co. Galway (Barlee); Hebrides and Shetland, in 30-90 f. (Barlee and J. G. J.). I am by no means certain that this last variety may not be specifically distinct ; but I prefer reducing to increasing the number of species, unless some valid and persistent
character can be made out. The typical form has occurred in a fossil state at Moel Tryfaen (Trimmer), Macclesfield (Darbishire), Italian tertiaries (Philippi and Calcara) ; and the variety elongata in the glacial drift of Caithness (Jamieson). The geographical distribution of this species at present is as follows :-As to the typical form, from the north of France (De Gerville and others) to Madeira (M‘Audrew), throughout the Mediterranean (Risso and others), Adriatic (Heller and others), and Fgean (Spratt); depths $4-2 \tilde{5} \mathrm{f} .:$ as to the variety elongata, from Finmark (Sars) to Gottenburg, 10-30 f. (Malm), Brittany (Cailliaud), and Vigo (M‘Andrew).

The animal is exceedingly active ; it gives out a very dark purple dye, like that of Scalaria communis. Between thirty and forty years ago I observed the present species burrowing in sand at Oxwich, near Swansea, on the recess of a high tide; and I also procured it by dredging on the same coast. The Rev. R. N. Dennis tells me that specimens from Seaford Bay, when placed in a basin of sea-water, crawled to the edge and suspended themselves by a thread. A monstrosity which I found at Tenby (where $P$. nebula is very abundant) has the spire twisted and curved on one side.

Among the synonyms may be mentioned $P$. Ginnanianum of Philippi (who, by the by, omitted to notice the spiral strix), P. nigra of Potiez and Michaud, and Raphitoma polita of Brusina. According to Vérany it is the Mangelia costulata of Risso's collection. Clavatula nebula of Searles Wood is not our species.

> 7. P. Leviga'ta*, Philippi.
P. lavigatum, Phil. Moll. Sie. i. p. 199, t. xi. f. 17.

Body clear white, speckled all over with opaque white : pal-

[^151]liat tube long and cylindrical: hecel short, cloven in front: tentacles cylindrical, mere club-shaped and slender points abore the eyes, three or four times as thick below them: eyes placed outside the tentacles, at the extremities of rery long stalks, which are conjoined with the tentacles in the usual manner: foot elongated, truncated or bilobed in front, with angular corners, bluntly pointed or sometimes swallow-tailed behind: odontophore simple: pleure diamond-shaped, with a minute notch just below the middle on the inner side.

Sirll spindle-shaped, having the base broader than the apex, rather solid, nearly opaque, of a dull but smooth aspect: sculpture, broad and rounded, although not prominent, somewhat flexuous longitudinal ribs, which are more or less wanting on the body-whorl and do not extend to the base or suture; there are 10 or 11 on each of the preceding three whorls; the space below the suture is girded by a thickened rim, and is always ribless ; the whole surface (except the apex) is covered with exceedingly numerous and fine spiral strix, which are crossed and indistinctly beaded by still more delicate flexuous striæ in the line of growth; the spiral strix on the bodywhorl alternate in size, but elsewhere are equal ; the third whorl has four rows of spiral strix, which are not beaded as in the foregoing two species; top whorls quite smooth and lustrous: colour jellow, variegated with chocolate; the former colour is more perceptible as a broad band round the upper part of the body-whorl, and on the ribs in the other whorls, the interstices of the ribs in all the whorls being of the darker colour; apex chocolate: spire tapering to a somewhat abrupt point: whorls 9-10, moderately convex and rounded, shelring upwards, not angulated by the ribs; the last whorl occupies seven-twelfths of the shell: suture shallow: moutl obliquely lozenge-shaped, compressed and acute-angled above, broader at about one-third from the upper part; length five-twelfths of the shell: canal very short, wide, and truncated, turning slightly but abruptly to the left; basal notch incurved, conspicuons on the outside: outer lip curved; edge blunt and even: labial notch broad and ratber deep, placed below the sutural rim: inner lip slight, but more spread and not so retired as in many other species: pillar broad and flexuous. L. $0 \cdot 6$. B. 0.225 .

Var. minor. Dwarfed or stunted, and more slender. L. $0 \cdot 3$. B. $0 \cdot 1$.

Habitat: Between tide-marks in Belgrave Bay,

Guernsey (Gallienne). The varicty or smaller form inhabits the coralline zone, and occurs in the Channel Isles also, and on the coasts of Dorset, Devon, and Cornwall; Connemara (Alcock). North Atlantic, from Cherbourg (De Gerville and Macé) to Gibraltar, and westward to the Azores (M‘Andrew) ; both sides of the Mediterranean, the Adriatic, and Egean: depths 215 f .

When the tide goes out this little mollusk burrows in the sand, but not deeply, in a slanting position; and it rises to the surface when the tide comes in, like several other univalves of similar habits. Dead shells thrown up on a sandy beach, and rolled about by the waves, become polished by the attrition and appear smooth. The chief differences between $P$. brachystoma, $P$. nebula, and P. levigata consist in the first being small and cylindrical, and having some of the spiral striæ larger and more prominent than the rest; the second forms an elongated cone, the spiral striæ being equal in size and more numerous; the present species is spindleshaped and smoother, the body-whorl is nearly ribless (especially near the mouth), and the suture is thickened by a strap-like rim.

This is the $P$. Metcalfei of Hanley, and apparently the Raphitoma polita of Brusina.

> B. Operculated.
8. P. niva'lis*, Lovén.

## P. nivale, Lov. Ind. Moll. Scand. p. 14.

Body milk-white: head prominent, and slightly cloven in front: mouth or proboscidal orifice knob-like, and placed in the middle beneath the tentacular membrane: tentacles rery

[^152]short, cylindrical, and diverging, with blunt tips; they are somerthat curred and resemble the prongs of a dung-fork: eyes none, nor any eye-stalks : foot long and slender, truncated in front, and obtuse-angled behind; sole broad: verge falcate, on the right hand: [oclontophore composed of thin and somewhat curred spine-shaped pleuræ, with a large head which is excavated or gapes on the lower side. (Lovén.)]

Shell elegantly spindle-shaped, attenuated towards each end, the axis or greater diameter being nearer the base and formed of the upper portion of the body-whorl; it is of a delicate and rather thin texture, semitransparent, and not glossy : sculpture, numerous oblique longitudinal ribs, which are plaitlike and slight on the lower two whorls (nearly wanting on the last), more prominent and nodulous on the upper whorls; they neither extend to the base nor to the suture, and occupy only the middle portion of each whorl ; the whole surface (except the apex, which is quite smooth and glossy) is corered with fine and close-set spiral striæ, some of which on the bodywhorl alternate in size; lines of growth microscopic and flexnous; colore uniform milk-white: spire gradually tapering to a blunt point: whorls 10 , convex, somewhat angulated in the middle, and compressed or slightly excavated below the suture; the last whorl occupies about one-half of the shell: suture shallow: mouth of an irregular shape, long and narrow, acuteangled above; length nearly one-third of the shell: canal rather short, but slender, rery wide and open, bending a little to the left, and ending in an obliquely curred notch : outer lip rounded from the labial notch to the base, with a thin and even edge: labial notch broad, deep, and remarkably distinct; it is placed considerably below the junction of the outer lip with the periphery: inner lip consisting of a thin glaze or polish, which is spread over the pillar; its limit is coextensive with the outer lip: pillar broad and flexuous: operculum pearshaped, having the point or nucleus at the base on the inner side; it is rather small, ambercolour, and marked with elliptical lines of increase, like the valves of a Pinna. L. $0 \cdot 85$. B. 0.25 .

Habitat : Fine muddy sand, east of Shetland, in 78 f.: apparently very rare; for several dredging-voyages which I have made in these seas yielded only one live and three dead specimens. Its discoverer, Professor Lovén, re-
corded it as Norwegian (Bergen to Finmark) ; and it has also been taken on the same coast by M'Andrew and Barrett, Danielssen, Sars, and Lilljeborg, at depths of from 30 to 150 f .

My largest specimen of this graceful and remarkable species exceeds an inch in length.

As Lovén well observed, it is allied to $P$. torquatum of Philippi, a Calabrian fossil; but the dimensions and figure given in the latter's work represent a much less slender shell. The lines of growth vary in strength, and are not so conspicuous in living as in dead specimens.

## 9. P. septanguláris*, Montagu.

Murex septangzlaris, Mont. Test. Br. (i.) p. 260, t. 9. f. 5. Mangelict (Eelce) septangularis, F. \& H. iii. p. 458, pl. cxii. f. 6, 7, and (animal) pl. TT. f. 3.
Body white, powdered with minute flake-white points: mantle rather thick at the edges: pallial tube fleshy, extending. beyond the canal of the shell: head compressed, narrow, with a vertical fissure below it, from which the retractile proboscis issues: tentacles short, "setose" [?], coalescing at their bases: eyes on the external points of thick stalks annexed to the tentacles, at about two-thirds of their length : foot rather narrow, truncated in front, and slightly auricled, moderately long, with the termination nearly as broad behind as in front, without a trace of a distinct point, although the tail is often more or less notched. (Clark.)

Shell forming an elongated cone with a produced base, remarkably thick, opaque, somewhat glossy: sculpture, strong, angular, and rather prominent longitudinal ribs, which extend to the suture but not to the base; they are flexuons on the liody-whorl, and nearly straight on the upper whorls, where they usually form a continuous series along the spire; their interstices are concave; the labial rib is very large, and aged specimens frequently have a similar rib or varix on the middle of the body-whorl ; there are from 7 to 9 ribs (usually 7 only) on the body-whorl, and one less on the next whorl, the number

[^153]diminishing in the same ratio upwards; the whole surface (except the apex, which is quite smooth and glossy) is corered with extremely fine and close-set minute spiral striæ, which become stronger towards the base; these spiral strix are partially decussated by irregular microscopic lines of growth: colour chestnut or reddish-brown, the ribs being (probably from attrition) of a paler hue or sometimes whitish; throat or inside of the outer lip purplish: spire extending to an abrupt point: whorls 8-9, moderately convex, but compressed towards the base and strongly angulated by the ribs : the last whorl occupies nearly three-fifths of the shell; the first two or three are cylindrical, and the topmost whorl is button-shaped: suture slight : mouth irregularly oblong, acute-angled above; length about two-fifths of the shell: canal short, nearly straight, extremely wide and open, truncated at the point, and ending in a curved notch : outer lip flexuous, with a sharp and eren edge; it seems to form a wedge-like margin to the labial rib: labicel notch very broad, but shallow, placed at some distance from the upper corner of the mouth : inner lip forming a porcellanous glaze, and occasionally thickened abore so as to produce a pad or callus at the junction of the two lips: pillar curred in the middle, and nearly straight below: operculum as in the last species, sometimes folding inwards or concave down the middle. L. $0 \cdot 5 \overline{5}$. B. $0 \cdot 2$.

Habitat : Laminarian and coralline zones, in 7-25 f., on our southern and western coasts (including the Bristol Channel), from Guernsey (J. G. J.) to Anglesea (M‘Andrew), all Ireland, and the west of Scotland; Firth of Forth (Forbes, MS.), ? Dunbar (Laskey). ? Fossil in Ireland (Forbes); south of Italy and Palermo (Philippi and Calcara). The only northern locality that I can find recorded is Bergen, on the excellent authority of Professor Sars: the distribution south of Britain is very extensive, and comprises the coasts of France, Spain, and Portugal, the Mediterranean, Adriatic, and Egean; Madeira and the Canary Isles (M'Andrew, as $P$. secalinum). Bathymetrical range $6-40 \mathrm{f}$.

My finest specimens were collected in Langland

Bay near Swansea; one measures three-quarters of an inch in length, and is proportionally broad and stout. An operculum in a Scotch specimen is shaped like a weaver's shuttle, and has the nucleus nearly central and the lines of growth irregularly elliptical.

This is the Buccinum costatum of Da Costa, Murex septangulatus of Donovan, and P. ageensis of Forbes; to these may probably be added the following synonyms -Mangelia Ginnania, Risso, P. Bertrandii, Payraudeau, P. heptagona, Scacchi, and P. costulatum, Cantraine. $P$. secalinum of Philippi appears to be a dwarf form, having the ribs less angular and the spiral striæ more distinct. The name proposed by Da Costa takes precedence of that which I have adopted and which is so well known; but we have another still more common species called costata: let the older name, therefore, be consigned to oblivion, so far as it relates to the present species.

## 10. P. rufa*, Montagu.

Murex rufus, Mont. Test. Br. (i.) p. 263. Mangelia (Bela) rufa, F. \& II. iii. p. 454 , pl. cxii. f. 3-5, and (animal) pl. TT. f. 4.

Body white, speckled with chalky flakes, and having a slight tinge of purple: pallial tube rather long: tentacles cylindrical; upper part (above the eyc-stalks) extremely short, club-shaped, and of a bluish hue: eyes black and distinct, on the top of thick stalks : foot thick and broad, slightly rounded in front, and bluntly pointed behind.

Shell oblong-fusiform, solid, nearly opaque, lustreless: sculpture, flexuous and rather narrow longitudinal ribs, which extend to the suture but seldom to the base, and often become indistinct or are entirely absent towards the mouth; the upper part of each rib is angular ; there are usually 14 or 15 on each of the last five whorls, becoming more numerous and threadlike on the preceding whorl, and disappearing on the top whorls; the ribs are narrower than their interstices; the

[^154]whole surface (except the apex, which is smooth and glossy) is corered with numerous and fine spiral striæ or lines, many of which are double; the spiral strix or lines on the ledge or shelf below the suture are slighter and obscure, the strongest being those on the upper whorls; they are nowhere decussated by the microscopic lines of growth: colour purplish-brown, the ribs being frequently paler ; inside of the mouth occasionally of a rich purple: spire turreted, and regularly tapering; apex twisted: whorls 7, rather convex, shelving abruptly to the suture, so as to give the turreted aspect to the spire; the last whorl occupies three-fifths of the shell: suture rather deep: mouth shaped as in $P$. septangularis, but not so acute-angled above; length two-fifths of the shell: canal as in the last species, except that the basal notch is more rounded: outer lip arched, with a thin and even edge ; it is slightly angulated above: labial notch small, but distinct, forming an indentation in the infrasutural shelf: inner lip somewhat expanded, and presenting a polished appearance: pillar broad and flexuous : operculum ear-sbaped, and elongated, marked lengthwise by a furrow on the pillar side; layers of increase numerous and obliquely curved. L. $0 \cdot 5$. B. $0 \cdot 2$.

Var. 1. lactea. Body milk-white; pallial tube short and rather broad: tentacles cylindrical, very short and club-shaped above the eyes, much thicker below them: eyes proportionally large, on the top of stalks which are amalgamated with the tentacles: foot rounded in front, with small angular corners, bluntly pointed behind. Shell milk-white.

Var. 2. semicostata. Lower whorls ribless; shell often larger than the usual size.

Var. 3. Ulideana. Shell orange-brown or fawncolour, with stronger sculpture. P. Ulideana, Thompson in Ann. \& Mag. N. H. xv. p. 316, pl. xix. f. 2.

Var. 4. Cranchii. Ribs twisted. Fusus Cranchii, Brown, Ill. p. 6, pl. v. f. 5.

Var. 5. angusta. Shell narrower, and slender, with sharp and oblique ribs.

Habirat : Sand in the laminarian and coralline zones, on our eastern, southern, and western coasts, the Bristol and St. George's Channels, all round Ireland, and the west of Scotland ; Scarborough (Bean and J. G. J.) ;

Northumberland and Durham (Alder and others); Aberdeenshire (Dawson) ; Durness, Sutherlandshire (Mrs. M•Pherson, fide Gordon). Var. l. Guernsey, living with P. levigata in Belgrave Bay, and dredged in 18 f . (Gallienne and J. G. J.) ; Exmouth (Clark): a small form of this pretty variety, mostly having the upper part of the spire tinged with purplish-brown, was procured by Mr. Hyndman from Port Ballintrae, co. Antrim. Var. 2. Channel Isles and Fishguard (J. G.J.). Var. 3. Connemara (Farran) ; Clyde district (Eyton) ; Oban, Loch Carron, and Skye (Barlee and J. G. J.). Var. 4. Falmouth (Cranch, fide Brown), and Plymouth (Cranch, fide Leach). Var. 5. Exmouth (Clark) ; Tenby and Manorbeer (J. G. J.). As a post-glacial or quaternary fossil this species has been in most cases mistaken for $P$. pyramidalis, Ström; I have identified $P$. rufa from only the Belfast deposit. A somewhat similar remark auplies to their foreign distribution in a living state. Sars dredged some very large specimens of $P$. rufa (mixed with the other species) in Finmark; Mace and Taslé have correctly included it in their lists of Breton shells, Dr. D'Orbigny found it at Rochelle, and Fischer gives Arcachon as a locality; French coast (Potiez and Michaud).
It is the $P$. nigra of the last-named authors, and Fusus fuscus of Brown; the young is Turton's Murex chordula. Leach described the 4 th variety as Bela Cranchiana.
P. pyramidalis is not uncommon as a post-tertiary fossil, in the Clycle beds, as well as at Macclesfield, Moel Tryfaen, Bridlington, Kelsey Hill, Wexford, and Fort William, and in Aberdeenshire and Caithness; Norwich Crag (Woodward); Uddevalla (J.G.J.); Canada (Dawson and Bell). It inhabits the arctic seas from

Bergen to Spitzbergen in one hemisphere, and from Cape Cod to Greenland in the other. This species differs from $P$. rufa in having a longer body-whorl, a smaller and more abruptly tapering (but not turreted) spire, an oblique and shallow suture, and slighter ribs. It is the Fusus pleurotomarius of Couthouy, and Defrancia Vahlii of Beck in Möller's Index.

## 11. P. turrícula*, Montagu.

Murex turricula, Mont. Test. Br. (i.) p. 262, t. 9. f. 1. Mangelia turriculc, F. \& H. iii. p. 450, pl. cxi. f. 7, 8, and (animal) pl. 「Т. f. 2.

Bodr creamcolour, faintly suffused with brown, and sometimes closely covered with very minute chalk-rhite specks: head small and thick: pullial tube cylindrical and rery long, sometimes projecting in front like a horn : tentacles cylindrical, extremely short above the eyes, with blunt tips: eyes small, placed on the extremities of stalks which are nearly threefourths of the length of the tentacles and are annexed to (but not amalgamated with) them, giving to this part of the animal the shape of an elongated and irregular cone: foot large and broad, truncated or bilobed in front, with small angular corners, and bluntly pointed or rounded behind: [odontophore, pleural spine straight, with a conical head and the side excarated and open. (Lovén.)]

Shell oblong-fusiform, rather solid, semitransparent, and lustreless : scutpture, strong, sharp, and narrow, but not very prominent longitudinal ribs; these are angular on the top of each whorl, curved on the body-whorl, and nearly straight on that portion of the other whorls which lies below the sutural ledge or step; they extend to the suture and mouth, but not to the base ; each of the last five whorls has from 12 to 15 ribs, the next has more, and on the preceding whorl ther become fine and close-set strix and are separated by the stronger spiral strix; they disappear towards the apex ; the ribs are much narrower than their interstices; the whole surface (except the apex, which is quite smooth and glossy) is thickly covered with fine, and usually equal-sized, spiral striæ (with frequently slighter intermediate strix), which are more

[^155]crowded on the base as well as on the top or upper shelf of each whorl; the second whorl has only three of these spiral strix, and two are more prominent than the rest on all the top whorls; on the third whorl and the top of the fourth the longitudinal ribs and spiral striæ, being equal in size, intersect each other and produce a cancellated appearance, the interspaces being excavated; the points of junction on the edge of the shelf at the top of each whorl are slightly nodulous: microscopic lines of growth slight: colour milk-white or tinted with yellow: spire remarkably turreted or scalar, gradually tapering to a small but truncated point: whorls $7-8$, convex, each having on the upper part a wide step-like shelf, which is strongly angulated; the last whorl occupies four-sevenths of the shell: suture not deep, but well defined by a wavy line : mouth oblong, angular above; length three-sevenths of the shell: canal short and wide, nearly straight, ending in an obliquely rounded motch: outer lip angular at the top, and sloping downwards with a gentle curve; edge slightly crenellated by the points of the spiral strix: labial notch small, having its greatest depth in the angle of the infrasutural shelf: imer lip rather large, presenting (as usual in this section of Pleurotoma) a smooth and polished surface ; pillar broad and flexuous, sloping inwards to a rather sharp edge : operculum ear-shaped and elongated, marked lengthwise by a furrow on the inner or pillar side, and sometimes by one or two slight strix in the same direction; layers of growth numerous and oblique; nucleus at the base, on the inner side. L. $0 \cdot 65$. B. $0 \cdot 25$.

Var. rosea. Fleshcolour or reddish-brown. Tritonium roseum (Sars), Lovén, Ind. Moll. Scand. p. 12.

Habitat : Sand, at various depths, in the Bristol Channel, and in the western, eastern, and northern parts of England and Wales, and on all the Trish, Scotch, and Zetlandic coasts. Donovan gives Brighton and Weymouth as localities; but I am not satisfied that this species has been found in any of our southern counties. The variety is from Oban. $P$. turricula has been noticed in all our quaternary deposits (including that at Selsea), and in the Norwich and Red Crag; Uddevalla (J. G. J.); Canada (Dawson). Its present range is mostly northern,
and comprises Greenland, Spitzbergen, Iceland, Scandinavia, Heligoland (Frey and Leuckart), the Boulonnais (Bouchard-Chantereaux), Cherbourg and La Hougue (De Gerville), and the United States (Mighels and Stimpson) ; depths 10-150 f.

The length of the spire is a very uncertain character. Monstrosities are rare; I have one in which the mouth and canal are considerably curved. A specimen in my cabinet, from the body-whorl of which a large picce had been at one time taken away, exhibits a peculiar sort of repair : the rencwed portion has no trace of longitudinal ribs, although the spiral sculpture is replaced. The largest specimens I have cever seen were dredged in from 50 to 60 f. off the Dogger bank on the Yorkshire coast; they measure three-fourths of an inch in length, and about one-third of an inch in breadth. One from Shetland is as long, but narrower.

It is probably the Turbo albus of Pennant, certainly the Murex angulatus of Donoran, and the Fusus turricola of Fleming and Forbes; the fry is apparently Adams's Buccinum minutum. Leach also placed it in the genus Buccinum. Through the kindness of Dr. Mörch I have compared the types of Möller's Greenlandic species with British specimens in my own collection; and I would refer the Defrancia nobilis, scalaris, and exarata of the last-named author to the present species. Fusus discors, discrepans, and castaneus of Brown may be placed in the same category. The $M u$ rex turricula of Brocchi (which is also a Pleurotoma) is very different from ours, and must have another specific name.
12. P. Trevelya'na*, (Trevellianum) Turton.

#### Abstract

P. Trevellianum, Turt. in Mag. N. H. vii. p.351. Mangelia Trevelliana, F. \& H. iii. p. 452 , pl. exii. f. $1,2$.

Seell approaching $P$. turvicula, but essentially distinct. This is smaller, and more oval than oblong; the spire is not so decidedly and abruptly turreted or scalar; the whorls are rounded; the sculptare is very much finer and closer (there being twice as many longitudinal ribs) ; and the whole surface is decussated, in consequence of the ribs and spiral striæ being equal-sized and intercrossing; the second whorl is marked by minute and numerous spiral lines; the colour is uniformly milk-white ; the canal is shorter; the labial notch is deeper; and the operculum has a strong ledge on the inner side, and is microscopically striated (as well as slightly reticulated) lengthwise. L. $0 \cdot 45$. B, $0 \cdot 2$.

Habirar: With P. turricula in the stomachs of haddocks, Scarborough (Bean); muddy sand outside the Dogger bank, on the Yorkshire coast, in 50-60 f. (Leckenby) ; Durham and Northumberland (Alder and others) ; Berwick Bay (Mennell) ; Firth of Forth (M'Andrew); Aberdeenshire (Macgillivray and others); Eda Sound, Orkncys (Thomas, fide F. \& H.) ; Shetland (Forbes and others); west coast of Scotland (Barlee and J. G. J.). Fossil in the Clyde beds (Brown and Crosskey); Hebrides (J. G. J.); Turbot-bank, co. Antrim (Hyndman and others) ; boulder-clay, Wick (Peach); Bridlington (Woodward) ; Bramerton (Witham, fide Woodward) ; Uddevalla (J. G. J.); glacial deposits in Norway, 50-240 feet (Sars); Canada (Dawson). This species is exclusively northern, and is distributed from Zealand to Spitzbergen, along the coast of Greenland westward to Massachusetts; west coast of North America (P. Carpenter) : depths 8-200 f.

For my largest specimen I am indebted to my able

[^156]and assiduous fellow-labourer, Mr. Robert Darrson, of Cruden, who dredged it off Kinnaird's Head; it is five lines and a half in length.

Synonyms: P.reticulata, Brown, Fusus decussatus, Couthouy (not P. decussata of Lamarck, which is a Grignon fossil), and Defrancia Woodiana, Möller. American specimens are much smaller than ours, as is also the case with Purpura lapillus and Buccinum undatum.

## Family XXXI. CYPREIDE, (Cyprcadae) Fleming.

Body oval or oblong: mantle expanded over the back of the shell in the form of two lobes (one on each side): pallial tube projecting or recurred: heal furnished with a retractile proboscis or a contractile snout: tentacles cylindrical or awlshaped: eyes on short stalks, which are conjoined with the tentacles, as in the last family : foot tongue-shaped, doubleedged in front, weg e-shaped or bluntly pointed behind: gills arranged in a single plume: octontoptiore long, partly contained in the visceral carity; rhachis 1-cusped; uncini 3 -cusped. Sexes distinct.

Shell having incariably an external spire in the young state: spire short, usually concealed in the adult; axis nearly horizontal: mouth very long: cancl short and somewhat truncated: no epidermis, nor any operculum.

These are animal-eaters, and are said to subsist principally on zoophytes. Individuals of the same species vary greatly in size; the young, before the outer lip is formed, has been in many cases considered a distinct species.

Genus I. MARGINEL'LA*, Lamarck. Pl. VII. f. 3.
Body oral: mantle pustrilated: head furnished with a retractile proboscis.

Shell conic-oval, smooth and polished: spire visible in every state of growth: mouth nearly as long as the shell, narrow, channclled at the base only : pillar plicated.

Risso proposed the genus Erato for the reception of our only species; but I agree with Deshayes and Philippi that Erato cannot be distinguished from Marginella.

## Marginella levis $\dagger$, Donovan.

Voluta levis, Don. Pr. Sh. v. pl. clxv. M. levis, F. \& H. iii. p. 502, pl. cxiv. b. f. 4, 5, and (animal) pl. NN. f. 8, 9.

Bony milk-white. closely and minutely speekled all over with orange, pink, and black; these markings are arranged in various patterns: mantle thick, forming two flaps which cover from one-half to two-thirds of the shell, leaving the back only exposed; these flaps or lobes are elegantly tessellated with purplish-brown, and are more or less studded with small pale yellow pustules or nipple-shaped tubercles of different sizes; the front and lower portions of each side are often marked with purplish-brown spots: pallial tube rather long, folded in a cylindrical form : proboscis white and cylindrical, more than half an inch long: tentacles extensile, usually rather short, with blunt tips, forked at their bases and widely diverging : eyes on short stalks: foot long and slender, slightly rounded in front, with angular corners, contracted in the middle and tapering to a blunt point or tail: verge rery large, beut and triangular.

Shell harp-shaped, solid, opaque, porcellanous and highly lustrous: sculpture, none except linear marks of growth, and a fow slight and microscopic spiral strize on the top whorls: colour milk-white, with a pale orange-brown tint and a pink onter lip in southern specimens: spire prominent, although blunt; apex somewhat globular and excentric: whorls 5-6 ; the last is gibbous, and occupies $\frac{15}{18}$ of the shell: suture very slight and indistinct: mouth nearly equal in width

[^157]throughout, incurred and acnte-angled abore; length coextensive with that of the body-whorl : canal wide and open, slightly bending to the left: outerlip thick and broad, forming a distinct rim which is continued round the base; inside closely notched, or furnished with about 15 small teeth : inner lip apparently wanting: pillar flexuous, having two or three slight transverse plaits or folds at the base (the lowermost being the strongest or most conspicuous), besides a row of minute tubercles abore the plaits, which exceed in number the teeth of the outer lip. L. $0 \cdot 4 . \quad$ B. $0 \cdot 25$.

Yar. oblonga. Pure white, more elongated, and compressed in front.

Habitat : Sandy ground, from 12 to 85 f., on every part of our coast, from Guernsey to Unst; local. Laskey gives Dunbar; but his specimen in the British Museum is M. Maugerice, a tropical species. The variety is Zetlandic. M. lavis occurs in the Red and Coralline Crag, and (according to Woodward) in the Norwich Crag also; Pont le Roy, in the Faluns of Touraine (Cailliaud); Vienna basin (Hörnes); Italian and Grecian tertiaries (Brocchi and others). Brittany (Delaunay, fide Taslé); Corunna to Gibraltar (M'Andrew) ; both sides of the Mediterranean, the Adriatic, and Ngean : depths $8-55 \mathrm{f}$.

The animal is very lively and active, a great beauty, and by no means bashful. When on the march it carries the branchial tube in an upturned position. One pair, having crawled out of the water in a glass jar, coupled for seven or eight hours; their union was cruelly dissolved by immersion in boiling-water. The size of the shell is extremely variable. The outer lip is at first thin and sharp; then it becomes inflected, and has a plain edge; afterwards the lip is thickened and notched.

This is the Cyprea Voluta of Montagu, Voluta cypreola of Brocchi, and M. Donovani of Payraudeau;
the young is probably Voluta pallida of Adams (not of Linné), and it agrees with the type in my possession of Turton's V. fusiformis.
M. catenata and M. alba were erroneously described as British by Colonel Montagu, M. catenata on the authority of Swainson and Laskey, and M. alba on the unsupported testimony of the last-named witness; both species are common in parcels of West-Indian shells.

## Genus II. CYPR.E'A*, Linné. Pl. VII. f. 4.

## Bony like that of Marginella.

Srect oval, usually smooth and polished: spire in most species covered over and concealed when the shell is fullgrown : mouth narrow, stretching from one end of the shell to the other, and channelled at the top and bottom : outer lip folding inwards : pillar notched or tuberculated.

Mucianus and Rondelet supposed that this shell-fish was the famous $\epsilon \chi \epsilon v \eta i s$, which is said by Herodotus to have arrested, at the instance of Venus, the course of Periander's ship, and to have thus prevented the execution of his barbarous design with regard to the Corcyrian youtlis. Hence the name of Cyprea or Concha Venerea. The $\dot{\epsilon} \chi \epsilon \mathrm{r} \eta$ is of Aristotle was evidently the sea-lamprey or lumpsucker.

The young shell has a prominent spire, like that of Marginella, which it resembles in shape also; in the adult or perfect state the spire is covered and usually concealed by successive layers of porcellanous matter, and the shell then exhibits a close affinity to Ovula. The outer lip in the earlier state of growth is thin and has a sharp edge ; it is subsequently folded inwards and thickened, so as to contract the mouth. Bruguière

[^158]stated, and Lamarck believed that, as the animal increased in size, it was obliged to leave its shell, in order to make a new and more capacious one. The notion of Sowerby and Reeve, that Cyprea can absorb the outer lip and form another, is not less fanciful. Such hypotheses were founded on the circumstance that full-grown shells are often smaller than half-grown specimens; but the difference of size in individuals of the present family offers a simple explanation. In a very curious report by Dr. Brückmann of Brunswick (1722) on the "Concha Venerea" and another shell, it is mentioned that, by applying the former closely to the ear, " sie konnten das Meer brausen hören." The embryology of Cypraa must be somewhat anomalous; for Mr. A. Adams observed at Singapore some fry, supposed to belong to C. annulus, adhering in masses to the mantle of that mollusk, or swimming (some in rapid gyrations, and others with abrupt jerking movements) by means of their headlobes.

Some of the ancient Greeks called this well-known shell $\chi$ ôpos, and the Romans porcus or porculus; the old English name is "gowrie" (now "cowry"), and the French " pucelage" or " pou-de-mer."

While tropical seas are enriched by so many and such beautiful species, our own has but a single puny representative of the genus.

## 

C. Europer, Mont. Test. Br. (ii.) p. 88 ;; F. \& H. iii. p. 495, pl. cxiv. a.
f. 6-9, and (animal) pl. NN. f. 5-7.

Body of various hues, the predominant ones being yellow, brown, and pink; it is sometimes marked with transverse stripes or lines : mantle very large, spread (in the adult) over

[^159]the back or upper part of the shell, which it oftens covers completely; it is more or less studded with conical or wartlike processes, some of which frequently are branched and others longer than the rest; colour pale orange-brown with the papillæ yellow or white, and occasionally variegated by red spots and a few purplish blotches : pallial tube conicocylindrical, rather long, projecting horizontally or somewhat upturned; this is also studded with papillæ, and is orange or light yellowish-brown ; cdges of the orifice slightly reflexed : probosicis long: tentacles long, flexible, tapering to a blunt point, and widely diverging; they are speckled with yellow: eyes on short stalks at the outer bases of the tentacles: foot expansile, so as to be twice the length of the shell, in front truncated, with small angular corners, behind rounded or obtuse-angled; it is pale yellowish-brown, and edged with a rather broad border of a lighter tint; sole whitish, yellow, or orange: verge large, orange: jaws elliptical and horny: odontophore short.

Shell roundish-oval, solid, opaque, and glossy: sculpture, from 20 to 25 fine thread-like ribs, which cross the back of the shell or body-whorl, and are continued within the mouth; a fow of these ribs anastomose, or are shorter and placed between others of full length; those at each end are fork-like ; their interstices (especially on the underside of the shell) are microscopically pustulated: colour pale reddish-brown or fleshcolour (sometimes whitish) above, often variegated by three purplish-brown spots along the back, one at each end and the third in the middle; the underside of the shell is white; ribs paler in highly coloured specimens: spire very short, more or less concraled in the adult; apex of young shells (in which alone it is visible) not unlike that of Natica: whorls, apparently a single one which enwraps all the others; in the young between 3 and 4 may be counted: suture in the early state of growth slight, afterwards coated over: mouth slit-like, nearly of the same width throughout, and somewhat arched : canal very short and straight, exhibiting on the outside a conspicuous notch: outer lip very thick, broad, and rounded; edge notched by the ribs: inner lip scarcely perceptible: pillar gently curred, angulated or ridged on the outside, with a cavity or depression underneath; inside trarersed by the ribs, and notched. L. $0 \cdot 45$. B. $0 \cdot 35$.

Habitat : All our coasts, on stony and coral ground, $_{\text {g }}$
from low-water mark to 100 f . Dead shells are common on sandy beaches, having been washed up by the tide and waves from the laminarian zone. Fossil in most quaternary and upper tertiary deposits in Europe, as far back as the Coralline Crag aud Vienna basin, but not found in the Clyde or other glacial beds. The range of this species, in a recent or living state, extends from Drontheim to Gibraltar, and throughout the Mediterranean, Adriatic, and $\mathbb{E g}$ ean; depths $0-100 \mathrm{f}$.
"It is surprising to see with what facility the expanded animal withdraws itself-foot, mantle, head, and tube-through the narrow opening of the shell'" (Clark's MS.). Like Buccinum undatum it continually discharges an immense quantity of clear slime. Couch says that it often gets into crab-pots; so that it seems to be fond of all kinds of animal food. The colour and spots appear on the shell when it is half-grown. Northern specimens, whether from shallow or deep water, are almost invariably plain-although I have a spotted one, dredged alive in 86 fathoms. Those from the south are more frequently spotted; but bathymetrical conditions do not seem to affect the colour. Young shells are transparent and ribless. The variation in size is very great. A specimen from Shetland is $5 \frac{1}{2}$ lines in length, while another from Guernsey measures barely $2 \frac{1}{2}$ lines; the bulk of the former is therefore five times that of the latter. Some are more globular than others ; and monstrosities or misshapen forms now and then occur. Spanish and Mediterranean specimens are remarkably small.

According to Lister these pretty playthings of children used to be called "nuns" at Hartlepool : he distinguished ours from the Jamaica shell (C. pediculus) by not having a furrow along the back. Linné noticed
three geographical varieties of his C. pediculus, viz. Indica, Europrea, and Anglica, the last being without spots. Our species is the C. arctica, (Solander) Pulteney, C. coccinella, Lamarck, C. mediterranea and C. Europaa, Risso, and C. norvegica, Sars. The half-grown shell is C. bullata of Pulteney, and the young (before the outer lip is formed) is Bulla diaphana of Montagu and B. candida of Macgillivray. Among other provincial names are " John-o'-Groat's buckie " and "sea-cradle." The present species is the type of Gray's genus Trivia.
C. pediculus has been erroneously recorded as European by Turton and Collard des Cherres. C. moneta (the money-cowry of South Africa) has been picked up on the shore near Bangor, co. Down (Hyndman), in Provence (Martin, fide Petit), and at Algiers (Weinkauff) ; but these cases by no means prove that it inhabits either the Irish sea or the Mediterranean.

## Genus III. $O^{\prime}$ VULA*, Bruguière. Pl. VII. f. 5.

Body oblong: mantle pustulated or smooth: head furnished with a contractile snout.

Shell forming a complete spindle, glossy, but spirally striated: spire very short, perceptible in the young only, and concealed in the adult: mouth extending the whole length of the shell, channelled at each end: outer lip in some species folded inwards and notched or thickened, in other species prominent and thin : pillar smooth.

The difference between a retractile proboscis and a contractile snout is not, in my opinion, so important, taken by itself, as to justify the separation of this genus from the Cypraida. The passage from Cypraa to Ovula is very gradual ; and these genera are closely allied, as regards both the animal and the shell. The genus

[^160]Simnia of Leach's MS. was founded on the solitary species which our seas produce ; the two Mediterranean species assigned to it by Risso (if they are not identical) have the outer lip inflected, with a notehed edge ; although he describes that genus as having the mouth thin.

## Ovula pa'tula*, Pennant.

Bulla patula, Penn. Br. Zool. iv. p. 117, t. lxx. f. 85A. O. patula, F. \& H. iii. p. 498, pl. cxiv. b. f. 1, 2, and (animal) pl. NN. f. 1-4.

Bony yellowish-white tinged with brown : mantle smooth, loose about the neck, and haring two lateral lobes, which are reflected on the back of the shell, so as at times to cover the whole of it ; these lobes are striped transversely with pale red-brown or brownish fine lines, interrupted by small spots or dots: pallial tube not extending one-eighth of an inch beyond the canal or beak of the shell ["rather long," F. \& H.]: head consisting of a rather large and moderately long contractile muzzle (not a proboscis), the mouth being placed at its extremity underneath, with a concave disk which is marked in a star-like fashion with white lines on very fine plates; at the bottom of this disk is a vertical orifice, within which is the buccal mass, containing two strong white semicircular jaws with a short rough lingual riband running betmeen them: tentacles rather long and conical, somewhat bluntly pointed; they are white, and their extremities pale brown tipped with white: eyes on very large broad stalks (which are considerably raised) on the external angles of the tentacles: foot very large, exceeding the limits of the shell [" scarcely broader than the shell," F. \& H.]; it is truncated or subangular in front ["its frontal angles are rounded," F. \& H.], marked lengthwise with intensely flake-white lines, which, when the animal is at rest or not fully extended, corrugate into distinct folds or plaits, and the front margin of the foot then seems notched; it expands considerably beyond the right side of the shell, and tapers behind, terminating in a sharpish [" obtuse," F. \& H.] point, much bejond the posterior part of the shell ; sole grooved down the middle : gills coarsely pectinated, forming a single plume: verge large and flat, curved, and ending in a point. (Clark, MS.)

[^161]Shell forming a short spindle, thin, semitransparent, and glossy: sculpture, minute, delicate, and rather close-set spiral strix, which are more conspicuous at the extremities and in young shells; they are somewhat wavy, and slightly reticulated by microscopic lines of growth : colour pale yellowishwhite, sometimes orange, and occasionally tinged with pink: spire excentric, visible only in young shells, extremely short, lying within the level of the upper canal; it exhibits under a strong magnifying-power a finely punctured appearance, like the apex of Rissoa Jeffreysi: whorls, apparently a single tumid one which envelopes all the rest; in the young may be counted 3 conrex whorls, the first of which is blunt and mammiform: suture in the early ${ }^{\circ}$ state of growth slight, afterwards covered over: mouth large and wide, somewhat expanding, of an irregular shape in consequence of the periphery projecting into it; it is narrower above than below : upper canal semitubular, expanding outwards, and having the inner side or wall more or less twisted, thickened, and white: lower canal very short and broad, usnally straight; notch obliquely but not deeply incurved: outer lip flexnous; edge plain and prominent, now and then thickened within: pillar excavated or indented, and girded by a twisted ridge. L. 1. B. $0 \cdot 5$.

Habitat: Coralline zone, on the coasts of Dorset, Devon, and Cornwall ; Guernsey (J. G. J.) ; co. Galway (Barlee); Macgilligan, co. Londonderry (Mrs. R. A. Hyndman, fide Thompson); Turbot bank, co. Autrim (Waller) ; Sound of Mull (Bedford). Mr. Horace Marryat found it living among tufts of Tubularia indivisa, in the Gouliot caves at Sark, at low water. Laskey gives "Porto-bello sands;" but such a locality seems improbable. M. Martin has taken this species in the Gulf of Lyons, regarding it as the young of $O$. carnea (Bulla carnea, Gmelin), of which the O. Adriatica of Sowerby is perhaps a variety.

If the present species should prove to be also a variety of $O$. carnea (which differs only in its outer lip being inflected and the edge notched), Pennant's name patula
has the precedence. Our shell varies in thinness, in comparative length and breadth, and in the turgidity of the body-whorl. O. carnea is not uncommon in the Mcditerranean; the young is probably Risso's Simnia nicceensis.

## Order IV. PLEUROBRANCHIATA, Gray.

 (See Vol. III. p. 200.)In the same year that Dr. Gray proposed the name which I have adopted for this order, Professor Lovén published another name, viz. Pomatobranchia. I now place it immediately after the Siphonobranchiata, and postpone the Pulmonobranchiata (as being more perfect Gastropods) not only to the present order, but also to the Nudibranchiata and Pellibranchiata. I accidentally omitted in page 265 "Order III. SIPHONOBRANCHIATA." The families Cerithiopside to Cypreide inclusive belong to the last-named order ; and the numbers prefixed to them (viz. XXVI. to XXXI.) ought therefore to be I. to VI.

## Family I. BUL'LIDA, (Bulladx) Clark.

Bodx gelatinous, generally divided into separate parts or lobes, and not always containable within the shell: hear snout-shaped: tentacles either united and forming a hood or head-reil, or consisting of two distinct and broad lappets: eyes, when present, sessile or subcutaneous, at the base of the tentacles or at the sides of the head: foot usually large, sometimes expanded on each side, like fins (epipodia) which serve for strimming, as well as behind into a single lobe (metapodium), so as to cover the cromn or apex of the shell : gills forming a single triangular plume, which is placed across the back on the right side, and protected by the shell: gizzard peculiar to most (if not all) genera, and composed of several
(usually three) calcareous or horny plates. Both sexes common to each individual.

Sherl convolute, external or internal: epidermis thin: spire mostly short, frequently truncated or concealed: mouth extending the whole length of the shell, or the greater part of it; it is entire (i. e. not channelled) at the base: outer lip having a prominent and sharp edge : operculum very seldom present.

As to the characters founded on the tongue, Lovén says, "Typus armaturæ lingualis vagus:" this is not a strong recommendation of the odontological system. The structure and anatomy of Bulla, Scaphander, and Philine have been admirably investigated by Cuvier; he first showed the affinity of the last-named genus to Aplysia. Some of the Bullide are zoophagous, others feed indifferently on fresh or decayed animal matter. The former swallow their prey (which chiefly consists of other mollusca) entire ; and the calcareous plates of the gizzard, moved by muscles of great strength, serve to crush the most solid shells. This family does not appear to be ancient. According to Mr. Searles Wood a species of Bulla has been found in the Cornbrash, and another in the Wealden formation. Many are tertiary; and the existing members of this group have a very wide geographical and bathymetrical range. Most of them are truly marine, while a few prefer brackish water ; all live in sand and ooze or in

> . . . . "the slimy bottom of the deep."

Bonanai and Gualtieri called the present family "nux marina," D'Argenville "gondole," and Pennant "dipper." It is the Bullaina of Macgillivray.

Genus I. CYI_ICH'NA*, Lovén. Pl. VIII. f. 1.
Body containable within the shell: mantle thickened at the

[^162]edge: head depressed : tentacles united with the head. and forming together an elongated and right-angled disk, which is recumbent on the front of the shell : eyes none (?) : foot very long, expansile behind: gizaard calcareous.

Shell altogether external, and cylindrical ; spire concealed : mouth extending the whole length of the shell, contracted above and widening below : pillar furnished with a more or less obscure fold: operculum none.

Lovén included in this genus several species of Utriculus. Cylindrella, Swainson, has priority of publication; but that author gave the same name to a genus of Conida, and Pfeiffer also applied it to a genus of Helicide: the latter application has been confirmed by general usage.

## 1. Cilichna acumina'ta*, Bruguière.

Bulla acurninata, Brug. in Enc. Méth. (Vers) t. vi. p. 376. no. 9. Ovelu? acuminata, F. \& H. iii. p. 500, pl. cxiv. в. f. 3, as O. acuminata.
Shell regularly spindle-shaped, or forming an elongated oval which is pointed above and broad below; it is thin, almost transparent, and glossy: sculptere, slight spiral striæ at each end, and rery faint microscopic lines in the same direction on the iutermediate space; the striæ near the apex are fewer and more remote than those near the base: epidermis inconspicuous: colour clear white : mouth very long, commencing at the top in a short and slightly recurred spike, and gradually widening towards the base, where it is expanded and rounded: outer lip flexuous, with a sharp edge: inner lip consisting of a mere film on the upper part and in the middle, but thickened and reflected at the base, so as to give the pillar the appearance of having a short fold : pillar twisted, and bending a little to the left. L. $0 \cdot 15$. B. $0 \cdot 075$.

Habitat: Muddy sand in the coralline zone, on the coasts of Cornwall (M'Andrew, Barlee, and Hockin) ; Plymouth among trawl-refuse, and dredged off the Arran Isles in co. Galway (Barlee) ; south of Ireland (M'Andrew) ; co. Antrim, 25 f. (Hyndman and Waller) ;

[^163]Loch Fyne and west of Scotland (Barlee, Alder, and J. G. J.) ; Banff (Edward, fide Gordon) ; Aberdeenshire (Dawson) ; Wick (Peach) ; Shetland (Barlee and J. G. J.). It is somewhat rare. Coralline Crag at Sutton (Wood); black or lower Crag at Antwerp (Nyst) ; Dax (Grateloup) ; Italian tertiaries (Soldani, Brocchi, Cantraine, Philippi, and Calcara). Inhabiting the coast of Norway (Danielssen, 40 f., and Lilljeborg) ; Sweden (Lovén, and Malm who found this species and Mytilus Adriaticus living together in 12 f.) ; Gibraltar, 20 f . (M‘Andrew) ; both sides of the Mediterranean, in many places, at depths of from 20 to 35 f. (Plancus and others) ; Adriatic (Chiereghini, v. Schröckinger, and Brusina) ; Agean, 40 f. (Forbes).

Lovén has examined the animal, and ascertained that it is undoubtedly a Cylichna. The shell differs generically from Ovula in the mouth not being channelled or open at the upper end.

It appears to be the type of De Montfort's genus Rhizorus, founded on the Nux marina minuscula of Soldani, and named by the former $R$. Adelaidds. According to Nardo it is the Bulla fucicola of Chiereghini. Not B. acuminata of the ' Mineral Conchology,' which is a Barton fossil.

> 2. C. nitídula*, Lovén.
C. nitidula, Lov. Ind. Moll. Scand. p. 10; F. \& H. iii. p. 515, pl. cxit. c. f. 6.

## Body clear white.

Siele oblong and somewhat elongated, attenuated behind or towards the top, thin, semitransparent, glossy and slightly iridescent : sculpture none, even under the microscope; lines of growth extremely slight, forming wrinkles towards the top: epidermis inconspicuous: colour clear white: mouth narrow abore and in the middle, and wide at the base, where it is
Rather glossy.
expanded and rounded: outer lip gently curved; the upper part projects beyond the apex or crown; this latter part is considerably contracted, and encircled by a solid rim, and it exhibits a very small opening through which part of the involute spire is indistinctly visible: ioner lip usually slight, but thickened in older specimens, a little reflected below: pillar short, and furnished with a small slight tooth-like fold near the base ; it is somewhat curved to the left. L. 0.125. B. 0.06 .

Habitat: On the same kind of sea-bottom as the last species, in $30-50 \mathrm{f}$., Loch Fyne and the west coast of Scotland (Barlee and J. G. J.) ; off Larne, co. Antrim, and outside the Dogger bank (J. G. J.) ; Berwick Bay (Johnston, as Bulla umbilicata); Banff (Edward, fideGordon); Aberdeenshire coast (Dawson) ; Shetland (Barlee and J. G.J.). It is more local than rare. Daniclssen records this species as Norwegian, and Lovén, Malm, and Lilljeborg from the south of Sweden: depths 12-40 f.

## 3. C. umbilica'ta ${ }^{*}$, Montagu.

Bulla umbilicata, Mont. Test. Br. (i.) p. 222, t. 7. f. 4. C. umbilicata, F. \& H. iii. p. 519, pl. exiv. c. f. 8, 9.

Shell oblong, not so much attenuated behind as the last species, more solid, nearly opaque, and glossy but not prismatic: sculpture, slight and sometimes waFy spiral striæ or impressed lines, which vary in strength and remoteness on the body, and are more or less close-sct near the base; they are risible in fresh specimens by means of a low magnifyingpower, but are not easily observable in rubbed specimens picked out of drift sand: epidermis brownish-yellow, liable to pecl off: colour creamy, becoming bleached and white in dead shells: mouth somewhat open at the top, contracted and narrow in the middle, pear-shaped and wide at the base, where it is expanded and rounded: outer lip gently curred: the upper part is obliquely truncated, but it does not project so far beyond the apex or crown as in the last species : apex twisted and somewhat contracted, encircled by a solid white rim (periomphalus, Lorén), and exhibiting a perforation in the

[^164]centre, like that of $O$. nitidula: inner lip as in the last species : pillar short and thick, furnished with a rather strong toothlike fold near the base; it has a sharp curve to the left. L. $0 \cdot 125$. B. $0 \cdot 065$.

Var. conulus. Larger, narrower at the apex, and conical ; the upper angle of the outer lip is higher and more projecting. Bulla conulus, S. Wood, Crag Moll. pt. i. p. 173, pl. 21. f. 2 a-c. C. conulus, F. \& H. iii. p. 517, pl. cxiv. c. f. 7.

Habitat : With C. nitidula in the north, and southwards to Cornwall, as well as on our eastern and western coasts, and in Ireland; local, but extensively diffused. Of the variety a single specimen only has occurred, and was dredged by me in Deal Voe, Shetland, at a depth of about 10 f ; it is not uncommon in the Coralline Crag at Sutton (Wood), and in the Belgian tertiaries (Nyst). The typical form is fossil in a postglacial deposit at Skien in Norway, 100 feet (Sars); Bordeaux and Asti (Cantraine) ; and Italian tertiaries (Brocchi and others). The geographical range of this species is considerable, comprising the Scandinavian coast, from the Loffoden Isles (Sars) to Bohuslän (Lovén and Malm), the oceanic shores of France (Récluz, Taslé, and Cailliaud), Vigo Bay and Gibraltar (M‘Andrew), both sides of the Mediterranean (Cantraine and others), the Adriatic (Brusina), and Ægean (Forbes); depths $4-50 \mathrm{f}$. Weinkauff gives the variety conulus as common at the entrance of and inside the harbour of Algiers, in from 10 to 20 f .

Differs from C. nitidula in being somewhat broader in proportion to its length, and not so much attenuated behind, being spirally striated instead of smooth, having frequently a conspicuous epidermis, in the upper angle of the outer lip not being so prominent, the apical perforation being larger, and the columellar fold more distinct.

This appears to be the Bulla Blainvilliana of Récluz, and Volvaria subcylindrica of Brown. The C. strigella of Lovén was founded on fresh specimens of the present species, having the striæ more distinct than usual. I do not regard the variety as the Bulla conulus of Deshayes (an Eocene and Miocene species), which is represented as much narrower at the top and wider at the bottom, with the apex abruptly truncated, and the spiral striæ more remote.

## 4. C. cylindra'cea*, Pennant.

Bulla cylindracea, Penn. Br. Zool. iv. p.117, t. lx̌. f. 85. C. cylindracet, F. \& II. iii. p. 508, pl. cxiv. в. f. 6, and (animal) pl. VV. f. 3.

Body milk-white, pale stramcolour, or dirty white with a faint tinge of yellowish-brown: [" mantle not thick, rarely prodnced beyond the front and lateral margins of the shell; it is edged with a series of minute red papillæ" (Clark): ] heced snout-like, broad, wrinkled across, and truncated or slightly cloren in front: tentacles united with the head, and forming a kind of hood, which folds back over the front of the shell, and is indistinctly bilobed abore: eyes, none that Mr. Clark, Mr. Alder, or myself could detect, although I carefully examined many specimens for that purpose; but Forbes and Hauley say, after describing the tentacles, "some way in front of their bases are two very minute and obscure eyes:" foot rather short, assuming rarious shapes, being sometimes triangular and at other times square, oval, or oblong, occasionally semicylindrical and wedge-shaped in front, where it meets the edge of the snout or head-flap; it is slightly folded up at the sides, and usually broader behind, which part is furnished with two angular points: verge small, conical, and hyaline: gizzard composed of three minute shelly plates, imbedded in a muscular mass; these are semicylindrical and narrow.

Shell forming a long cylinder of nearly the same breadth throughout, solid, opaque, and rather glossy : sculpture, numerous fine and wayy spiral strix, which are visible in fresh specimens by the aid of an ordinary lens, but being slight easily disappear: epidermis brownish-yellow, darker at the base : colour white under the epidermis, and haring a bluish

[^165]or slaty tinge in worn specimens: mouth narrow and of equal width in the upper and middle portions, pear-shaped and very wide at the base, which is rounded although somewhat truncated: outer lip nearly straight in the middle, with a curved slope at each end; the outer corner at the top is bluntly rectangular, and not prominent; inner corner obliquely incurved: apea twisted and slightly contracted, obliquely truncated, encircled by a solid white rim or keel, and concave in the centre ; perforation small and indistinct: inner lip conspicuous, sometimes thickened, and partly folded over the apex: pillar short, curved or somewhat twisted, and having a broad fold at the base ; it abruptly turns to the left. L. $0 \cdot 6$. B. $0 \cdot 2$.

Var. linearis. Shell somewhat shorter, nearly smooth and decidedly glossy, marked at each end with yellowish-brown spiral lines, which are few and remote at the top, and closeset at the bottom ; apex invariably perforated and exhibiting part of the internal spire.

Monstr. Base irregularly cup-shaped, with the edge reflected.

Mabitat : Muddy sand in the coralline zone, on all our coasts, from Guernsey to Unst; rather common. I obtained the variety in Loch Fyne and Shetland; it may be specifically distinct. The monstrosity is from Tenby. This species occurs in the Clyde beds (Smith); Red and Coralline Crag (Wood) ; Antwerp crag (Nyst) ; French tertiaries (Grateloup and Mayer) ; Nice (Risso) ; Italian tertiaries (Brocchi and others); Viema basin (Hörnes) ; Rhodes (Hedenborg, fide Hörnes). Its diffusion, as recent, extends from Vadsö in East Finmark (Danielssen) to Madeira and the Canaries (M'Andrew), and throughout the Mediterranean (Risso and others), Adriatic (Brocchi and Cantraine), and Egean (Forbes) ; depths recorded 3-160 f.

Its habits are sluggish; and its progress is painfully slow, although by means of its foot it can crawl up the side of a glass vessel. When irritated it emits a saffroncoloured liquid. The head and the front of the foot,
being of the same length, make a broad wedge, which probably serves for probing the muddy sand in quest of prey, like the snout of a pig grubbing for earthworms. The apex of specimens from tenacious mud in Loch Fyne and Shetland is coated with a thick and prominent crust, having the appearance of a blunt spire ; this may be owing to an accumulation in that part of fæces and slime mixed with fine sand and mud, which had been trailed along in the progress of the animal.

It is the Bulla Oliva of Gmelin, B. cylindrica of Bruguière, Pulteney, and Donovan (not of Chemnitz), B. convoluta of Brocchi, and Cylindrella alba of Swainson; the young is the Bulla producta of Brown, and Bullina producta of Macgillivray. The Bulla cylindracea of Da Costa is Marginella pallida, a common West-Indian shell.

## 5. C. alba*, Brown.

Volearia alba, Brown, Ill. Conch. G. B. \& I. p. 3, pl. xix. f. 43-ㄴ4.
Budy clear white, with a faint tinge of fleshcolour on the upper part: mantle thick, extending as a prominent fuld or process at each extremity of the shell : head thick, bilobed in front: tentacles forming an entire and rather short disk in extension or continuation of the head, and folded back over the front of the shell : eyes, none perceptible: foot lozenge-shaped, short, bluntly rounded in front, and opposed to the head (so as to make together a blunt wedge), expanded and rounded behind, with an angular lobe on each side in that part: [odontophore, rhachis small, compressed, erect, broader above, with the cutting-point slightly produced and jagged ; uncini 6 , the first by far the largest and having the base extended ons each side, with the cutting-point strong, bent inwards, and jagged or notched on the inner side, the others minute and shaped like curved claws (Lovén):] gizzard like that of C. cylindracea; but the plates in the present species are oblong, thicker, gibbous (instead of rounded) on the upper side, with a boss in the centre, and more convex beneath.

[^166]Shell forming a short cylinder, or oblong, broader in the middle, and less solid than in the last species, semitransparent, and decidenly glossy : sculpture, mumerous and close-set but extremely fine and slight spiral striæ, which can only be detected by the aid of a strong magnifier : epitlermis, a pellucid creamy film: colour white: mouth more open than in C. cylindracea, although having the same shape: outer lip gently curred throughout; it is higher at the top than in the last species, and at the outer corner it recedes or slopes more abruptly; inner corner obliquely incurved: apex twisted (not contracted); it is encircled by a strong and angulated rim, and concave in the eentre, with a minute perforation in some specimens: inner lip forming at the upper end a thick fold, which is reflected on the apex and usually corers the perforation; it is conspicuous, but thin, in other parts: pillur short, broad, curved and twisted to the left, with an obscure plait. L. $0 \cdot 35$. B. $0 \cdot 175$.

Habitat: Fine sand, in 84-95 f., about 25 miles N.N.W. of Unst, with Limopsis aurita and other rare mollusca. It is one of our post-glacial fossils, and has been found at Greenock (Stewart Kerr, fide Brown), Paisley and Lochgilphead (Crosskey), Dalmuir (Robertson), and Annochie in Aberdeenshire (Jamieson); Mammaliferous Crag near Norwich (Witham, fide S. Wood as Bulla cylindracea, var. monstrosa) ; Norway 2-40 feet (Sars). Its existing range is arctic and high northern, and comprises Norway, Iceland, Spitsbergen, (ireenland, and North-east America; west coast of North America (P. Carpenter) : depths 10-160 f. The most southern limit appears to be Bergen.

This lives with C. cylindracea; and its movements are equally slow. In one Norwegian specimen the colour of the epidermis is brownish-yellow, as in the other species. I have figured the tongue, from a drawing kindly made for me by my late friend Mr. Alder.

It is the Bulla triticea of Couthouy, and B. corticata (Beck) of Mäller.
C. striata (Bulla striata, Brown) $=$ B. insculpta, Totten $=$ B. Reinhurdi, $($ Holböll $)$ Möller = C. propinqua, Sars, is one of the Clyde-bed fossils; but it cloes not now exist in our seas. The late Mr. Thompson of Belfast erroneously noticed this arctic species as found at Bangor, co. Down, by Mr. Hyndman. It inhabits the eastern coasts of North America, Greenland, and Finmark.

## Genus II. UTRI'CULUS*, Brown. Pl. VIII. f. 』.

Bony containable within the shell: mantle slightly thickened at the edges: head broad: tentacles separate and triangular: eyes minute, placed at the base of the tentacles: foot oblong or oval, shorter than the shell, more or less dirided or bilobed behind: [odontophore, according to Lovén's description of that organ in his Amphisphyra globosa, having the rhachis broad and nearly rectangular, with the cutting-point transrerse and jagged ; the uncinus is single, claw-shaped, slender, expanded at the base, and winged outside :] gizzard small, horny.

Shell altogether external, forming a short cylinder, or globular: spire exposed, mostly truncated : whorls angulated or keeled, the first being nipple-shaped: mouth usually extending the whole length of the shell, narrow at the upper part, and expanding in front: pillar furnished at the base with a small fold or plait: operculum none.

This genus differs from Cylichna in the tentacles being separate, eyes distinct, gizzard horny, and the shell having a visible spire with a mammillar apex. It is the Bullina of Risso and De Blainville, and perhaps of Férussac also ; but that name has been appropriated to another genus allied to Aplustrum. I regard Amphisphyra of Lovén as a synonym of the present genus. Brown had many years previously proposed the objectionable name Diaphana; but he afterwards cancellerl

[^167]or discarded it in favour of Utriculus, which has also precedence of Amphisphyra.
A. Shell cylindrical or oblong, and solid.

## 1. Uthiculus mammilátus*, Philippi.

Bulla mammillata, Phil. Moll. Sic. i. p. 122, t. vii. f. 20. Cylichnat mammillata, F. \& H. iii. p. 514, pl. cxiv. c. f. 4.5.
Shell forming a short cylinder, somewhat constricted in the middle, and having the same breadth at each end; it is semitransparent and glossy: sculpture, minute and rather slight strix, which vary in number and contiguity, and in fresh specimens examined under a microscope appear delicately and closely punctate: epidermis inconspicnous: colour clear white: spire truncated, and encircled by a narrow and solid rim; it is sunk below the level of the apical rim or periomphalus: whorls 2-3; the last (as usual in this genus) envelopes all the rest ; the penultimate whorl exhibits the outside rim only ; the innermost is globular, prominent, and turned inwards or inflected, but not reversed : suture deep : mouth narrow above, more contracted in the middle, pear-shaped and wide at the base, which is rounded: outer lip flexuous, curved and folded inwards in the middle; the upper part projects a little beyond the apex; outer comer rounded; inner corner receding and incursed, so as to make the suture transversely excarated in front: inner lip continuous with the outer lip above, where it is slightly folded on the apex, as well as on the pillar below : pillar short, flattened, and curved: fold indistinct. L. 0.1. B. 0.05 .

Habitat: Laminarian and coralline zones in the Channel Isles, Devon, and Cornwall; co. Galway (Barlee) ; Turbot bank, co. Antrim (Waller) ; Hebrides and west coast of Scotland (J. G. J. and others) ; Dunbar (Brown) ; Aberdeenshire (Macgillivray and Dawson) ; Shetland (Barlee and J. G. J.). Fossil at Dalmuir (Crosskey) ; post-glacial beds in Norway, 30-50 feet (Sars) ; Bordeaux (Cantrainc) ; Sicily (Philippi and Calcara). Recent: Grip, Finmark, in

[^168]the stomach of an Astropecten Mülleri, and southwards to Christiansund (Sars) ; Norway (Lilljeborg) ; Bohuslän, with Mytilus Adriaticus (Malm) ; Loire-Inférieure (Cailliaud); Orotara in the Canaries ( $\mathrm{I}^{6}$ Andrew) ; Mediterrancan, from the Gulf of Lyons (Martin) to Sicily (Philippi) ; Algiers (Weinkauff) ; Adriatic (von Schröckinger and Brusina) ; Egean (Forbes) : depths 7 to 60 f .

It is the Bulla striatula (sec. typ. in mus. Brit.) of Forbes, B. minuta of Macgillivay, and B. truncatula of myself.

## 2. U. truncátulus*, Bruguière.

Dulla truncatula, Brug. in Enc. Méth. (Ters) t. vi. p. 37. no. 10. (Ylichna truncata, F. \& H. iii. p. 510, pl. cxiv. в. f. 7, 8, and (animal) pl. TV. f. 4.

Bony nearly clear white, with often a tinge of brownishyellow on the upper part, and minutely frosted: mantle lining the mouth of the shell, and forming an excretal canal at the posterior extremity: head squarish, depressed, cloven and slightly advanced in front of the foot: tentucles large, flat, triangular and rather long, with pointed tips, usually folded or curling back towards the front of the shell [" lying like the ears of a hare close to each side of the neck" (Clark)], but carried nearly erect when the animal is crawling: eyes very small and round, apparently sunk within the outer integument, placed rather close together in the middle between the head and tentacles: foot oblong, indented in front, and rounded or occasionally nicked behind [" this organ is at times considerably reflected laterally on itself and the front of the shell, and, when the animal is quiescent, assuming a quadrilobate form "(Clark's MS.)]: gizzard cartilaginous, enclosing three oval corneous yellowish-brown plates, which are studded with squarish black tubercles of different sizes.

Shell forming a conical cylinder, narrow on the upper half, more or less deeply constricted in the middle, and expanding on the lower half; it is nearly opaque, and glossy: sculpture, numerous longitudinal striæ or fluted ribs on the upper half;

[^169]these are often sharp at the apex, not so distinet in the middle of the shell, and usually disappear towards the base, where they are replaced by lines of growth; the spire is frequently striated across, like an Ammonite: epidermis filmy: colour white: spive involute, abruptly truncated, and encircled by a narrow and solid rim or rounded keel : whorls 3-4, gradually clecreasing in size towards the centre of the apex; the first or innermost whorl is globular: suture deep: mouth narrow for more than half its length on the upper part, pear-shaped and very wide at the base, which is rounded: outer lip gently curved, and folded inwards in the middle; the upper part projects (sometimes considerably) beyond the apex; outer corner rounded; inner corner receding and obliquely incurved: inner lip slight, continuous with the outer lip above, where it is folded a little over the apex, as well as over the pillar, behind which it forms a small and narrow umbilical chink: pillar short, thick, and flattened: fold tooth-like and strong. L. $0 \cdot 175$. B. $0 \cdot 075$.

Tar. pellucitla. Smaller, shorter, thinner, more transparent, and less strongly ribbed (sometimes quite smooth) ; epidermis slightly prismatic. Volvaria pellucida, Brown, Ill. p. 4, pl. xix. f. 45,46 .

Habitat: Everywhere (chiefly in the laminarian zone) on muddy ground and at the base of seaweeds, from low-water mark to 15 f . The variety appears to be northern, having been noticed by Brown from Dunbar, and found at Aberdeen by Macgillivray, and in Shetland by myself. This species occurs in the Coralline Crag (Wood) ; post-glacial beds, Norway, $0-100$ feet (Sars); Courtagnon (Bruguière); Italian tertiaries (Brocchi and others) ; Vienna basin (Hörnes). It ranges from Öfjord in Finmark (Sars) to the Canary Isles (M‘Andrew), and throughout the Mediterranean, Adriatic, and Egean ; depths 4-100 f.

Rather active and fond of floating with its shell downwards. Professor Lovén having informed me that it possesses an operculum, I carefully dissected and examined several live specimens, but I could not detect
any. Those from Kiel Bay, which Dr. H. A. Meyer kindly gave me, when I looked over his collection at IIamburg, have a brownish-yellow epidermis.

Walker described it as Bulla crassa, \&c., Adams as B. truncata (nine years after Bruguière's publication), Maton and Rackett as B.retusa, Schröter (according to Menke's Synopsis) as B. ieverensis, Scacchi (according to Philippi) as B. cylindrica, Chiereghini (according to Nardo) as B. cylindracea, Philippi as B. semisulcata, and Brusina apparently as Cylichna leptoeneilema. The B. truncata of Gmelin is a different species.

## 3. U. obtu'sus*, Montagu.

Bulla obtusa, Mont. Test. Br. (i.) p. 223, t. 7. f. 3. Cylichna obtust, F. \& H. iii. p. 512, pl. exiv. c. f.' 1-3.
Body whitish: head remarkably short: tentucles placed laterally and standing up like ears, rounded above, and not terminating in points like those of $U$. truncatulus: eyes not perceptible. (Alder.)

Shell forming an oblong cylinder, constricted in the middle, and becoming broader towards the base; it is usually opaque, and rather glossy: sculpture, numerous slight lines of growth; and in joung and fresh shells may be sometimes detected under the microscope extremely close-set and fine wary spiral lines ; spire indistinctly striated across : epidermis skin-like, creamcolour passing into brownish-yellow : colour white : spire short, but very variable in that respect, being in some cases almost truncated, while in others it is more or less extended: whorls 4 , slightly angulated at the top; those in the middle gradually enlarge; the apical or central whorl is globular and turned inwards: suture deep and narrowly excavated: mouth flexuous; upper half narrow; lower half wide, with a rounded base: outer lip gently curred, never extending to the apex; it recedes above, so as to leare a space between the outermost whorl and the next, and is contracted and inflected in the middle; outer corner rounded; inner corner obliquely incurred : inner lip thicker than in the last species, continuous with the outer lip above ; it is reflected over the pillar, behind

[^170]which it occasionally forms a small umbilical chink: pillar broad, flatteued, and curved: foll obscure. L. $0 \cdot 225$. B. $0 \cdot 115$.

Var. Lajonkaireana. Smaller and proportionally narrower, with the spire more produced. Bulla Lajonkaireana, Basterot, Mém. géol. Bord. (1825) p. 22, t. 1. f. 25.

Habitat: Muddy estuaries (such as those of the Solent, Thames, Wash, Humber, Mersey and Dee, Solway Firth, Severn, Shannon, Belfast Lough, Loch Fyne, and the Firths of Clyde and Forth), and in brackish water on many other parts of our coast from Jersey to Unst; gregarious at low-water mark, and ranging thence to 15 f . The variety inhabits deeper water in the open sea, off the Channel and Shetland Isles (20-85 f., J. G. J.) ; it has a wide distribution, as fossil, from our Coralline Crag (Wood) to the Vienna basin (Hörnes). The typical form is recorded from the Mammalian Crag at Bramerton (Wood), and has been found by the Rev. H. W. Crosskey at Dalmuir and Oban. Its extra-British habitat, as recent, appears to be limited, and comprises Iceland (Torell), Denmark (mus. Copenh.), Holland (Menke), Normandy (Macé), Loire-Inféricure (Cailliaud), Bay of Biscay (D'Orbigny père and Fischer), from Massachusetts Bay southwards to New England (Gould and Stimpson, as Bulla obstricta), and probably Greenland (Möller, as B. turrita).

Mr. Bretherton says ('Zoologist,' p. 6236) that it feeds on Hydrobie (which abound on the sand-banks where the present mollusk is found), and that it lives in sand, slowly moving about with the head-disk and fore part of the shell buried, and leaving a very distinct trail. It is to be regretted that this gentleman did not describe the animal. I have given a figure of it from a drawing by Mr. Alder. Judging from the contents of the stomachs of mullets caught in Lough Larne, that
fish must commit as great ravages among the Utriculi as the latter are said to do with regard to the Hydrobice. This is the Voluta alba \&c. of Walker, Bulla Regulbiensis of Adams on the Microscope, B. minuta of Woodward, and the U. plicatus and U. discors of Brown; the fry is apparently B. denticulata of Adams. The second of these names, although prior to that given by Montagu, is local and obsolete.

## B. Shell globular or oval, and thin.

4. U. ventro'sus*, Jeffreys.

Amphisphyra glozosa, Jeffr. in Ann. \& Mag. N. H. 3rd ser. i. p. 47, pl. ii. f. 6 (not A. globosa of Lovén).

Shell globosely ear-shaped (not unlike a Velutina), nearly transparent, glossy, and slightly prismatic: sculpture, numerous fine, curved, minute longitudinal striæ, which are very closeset on the upper edge of the body-whorl; these strix are crossed by a few indistinct spiral lines, but not so as to make the surface reticulated : epidermis inconspicuous: colour whitish, with a faint tinge of reddish-brown near the outer lip: spire small, truncated, and flat: whorls 3 , slightly angulated at the top; the last is disproportionately large, and the first or central whorl is oral and intorted: suture very deep and channelled : mouth expanded, nearly oval, contracted above by the projection of the periphery; base even and curved: outer lip semicircular; the upper part is on a lerel with the spire; outer corner rounded; inner corner not receding, nor incurved, as in the last species (but my solitary specimen is imperfect in this part) : inner lip forming a whitish film, which is spread over the upper part of the underside; it is folded over the pillar, behind which it forms a narrow umbilical groove : piller slight and curved : fold obscurc. L. 0.125. B. $0 \cdot 1$.

Habitat: Mr. Barlee procured a single specimen by dredging off Glenelg in Skye ; this is now in my collection. I tried the same ground with Mr. Norman

[^171]last year, in the hope of confirming the discovery ; but we were unsuccessful.

Its nearest ally appears to be the Amphisphyra globosa of Lovén (a Scandinavian species) : our shell, however, is ear-shaped, instead of globosely oval, the spire is proportionally broader, the mouth much wider, and the sculpture peculiar, U. globosus exhibiting only the lines of growth.

## 5. U. expan'sus*, Jeffreys.

Amphisphyra expansa, Jeffr. in Rep. Brit. Assoc. 186t, p. 330.
Bony gelatinous, clear white, sprinkled all orer with minute black specks: head or suout broad, bilobed in front: tentacles large, triangular or ear-shaped, expanding sideways: eyes none: foot oval, cloven in front, widely, deeply, and evenly forked behind: ovary yellowish-brown.

Shele barrel-shaped, narrower at the top, dilated and somewhat angular at the sides, and expanding towards the base; it is nearly transparent, glossy, and slightly prismatic : sculpture apparently none; but under the microscope may be seen a few slight and indistinct spiral lines and a frosted appearance: epidermis inconspicuous: colour whitish, except the nucleus or embryonic whorl, which is brownish-yellow: spire abruptly truncated: whorls $3-4$, compact, and angulated at the top; the first is oval, twisted inwards, and slightly projects beyond the rest: suture deep and channelled : mouth pear-shaped, not extending to the spire; base expanded and rounded : outer lip flexuous; outer corner bluntly angular; inner corner receding and incurved: inner lip folded over the pillar, wanting on the upper part : pillar nearly straight above, and curved below: fold obscure: umbilicus narrow and groove-like, but well defined by the flexure of the inner lip. L. $0 \cdot 225$. B. $0 \cdot 175$.

Habitat: Muddy sand in 43 f. near Fetlar Island, and in 82 f . between 40 and 50 miles S.S.E. of the Whalsey or Out Skerries, both localities being in Shetland; rare. Professor Sars informs me that in 1865 his son dredged this species off the Loffoden Isles.

[^172]This little creature is bold, and crawls rapidly. The absence of eyes is a remarkable character; and there can be no question of the fact, so far as the best optical instruments, long and patient examination under the most favourable circumstances, and the concurrent testimony of three practised observers (Mr. Waller, Mr. Peach, and myself) can establish it. Living specimens of $U$. expansus and $U$. hyalinus were placed side by side, and fully displayed themselves. The latter had distinct eyes at the base of the tentacles, outside the shell. The other, which was three times as large and equally exposed to niew, showed no trace of eyes anywhere, although it was carcfully examined in every position, in order to detect them. They could not have been subcutaneous; because the tissues of the animal were almost transparent, and I used a high microscopic power, by means of which the internal structure was clearly seen. Similar anomalies in respect of these so-called visual organs occur in the genera Eulima, Natica, and Pleurotoma among our native mollusks.

> 6. U. HYA'LINUS*, Turton.

Bulla hyalina, Turt. in Mag. N. H. vii. p. 353. Amphisphyra hyalina, F. \& H. iii. p. $5 \geqslant 1$, pl. crir. d. f. 1, 2 , and (animal) pl. UU. f. 2.

Body white, with a faint tinge of brownish-yellow: head large and broad, deeply cloven or bilobed in front: tentacles triangular, flanking the head, folded back or carried erect at the will of the animal : eyes rery small, but distinct and black, widely separated; when the animal is crawling ther are outside the shell, some way behind the head; when it is at rest this part of the animal is to some extent mithdramn, and the eycs are seen through the front of the transparent shell: foot oblong, rounded in front (where it is broader than in the middle), and uncqually forked behind, like the tail of a shark: gill-plume pale jellow : ovary brown.

Shell cylindric-oval, dilated in the middle, and nearly * Glassy.
equally broad at each end; it is quite transparent and lustrous : sculpture, very slight and indistinct spiral lincs (perceptible towards the spire only) and the usual marks of growth : epidemis inconspicuous: colour clear white, except the nucleus or embryonic whorl which is brownish-yellow : spire abruptly truncated: whorls $3-4$, angulated at the top; the first is oval, twisted inwards, and slightly prominent: suture deep and channelled: mouth rather narrow on the upper part and very wide bolow; in full-grown specimens it never extends to the spire, and is shorter than in the last species ; base expanding and obliquely rounded: outer lip flexuous, contracted and inflected at about one-third of its length from the top; outer corner bluntly angular; inner corner considerably receding and incurved: inner lip folded over the pillar, elsewhere wanting: piller short, almost straight above, and curved below : fold obscure: umbilicus distinct and deep, although small. L. $0 \cdot 2$. B. $0 \cdot 125$.

Habitat: Living in the laminarian zone, on various parts of the British coast, and dead in deeper water. I will mention a few localities (out of about thirty which I have noted), to show the extent of distribution:Guernsey, Cornwall, Dorset, South Devon, South Wales, Donegal, Galway, Cork, Dublin, west and east of Scotland, Shetland, and the north of England. Fossil at Dalmuir (Crosskey and Robertson) ; post-glacial bed in Norway, 50 feet (Sars) ; Sparebakken near Christiania (Robertson). Its existing range abroad comprises Kiel Bay (Meyer and Möbius), Sweden (Lovén and Malm), Norway (Daniclssen and others), Iceland (Torell), Greenland (Möller and others), Massachusetts (Gould), New England (Stimpson), Madeira and Canaries (M‘Andrew) ; depths 10-60 f.

The animal differs from that of $U$. expansus in having eyes, and in the extremity of the foot being unevenly lobed or heterocercal ; the shell may be distinguished by its smaller size, want of angularity in the middle, and by its larger and more conspicuous umbilicus.
U. pellucidus of Brown is the adult, his U. minutus the half-grown shell, and his $U$. candidus the young; Gould described this species as Bulla debilis, and Möller as $B$. subangulata. It is not the $B$. hyalina of Gmelin.

Genus III. A'CERA*, (Akera) Müller. Pl. VIII. f. 3.
Bodr gelatinous, not containable within the shell: mantle forming at the rear a cylindrical or thread-shaped process, which occupies a slit in the front of the spire when the animal is at rest: head snout-like and extensile: tentacles none: eyes placed on each side of the head, near the front: foot very large and flexible, expanding into broad wing-like lobes (one on each side), which fold back orer the shell and front of the body, a great part of which is covered by them : gizard horn5.

Siell tumid, very thin and elastic : spire exposed, and truncated: uhorls angulated or keeled at the top; the first is nipple-shaped, and the last is partly separated from the preceding one: suture deeply excarated : mouth occupying nearly the whole length of the shell, open in front and contracted behind: pillar sharp-edged : no operculum.

Perhaps this and Bulla subsist on soft organisms; their gizzards seem adapted to such food, not being, like the calcareous millstones with which Scaphander and Philine are provided, strong enough to crush hard shells. The odontophore or tongue of Acera is broad, and has numerous spines in each row; that of Utriculus is narrow, and has only two spines in a row. The shell consists of two layers-the inner one membranous, and the outer testaceous.

It is not the "Acère" or Bulla carnosa of Cuvier (Acera, Lamarck), which belongs to the Aplysia family and is shelless. Leach called the present genus Eucampe.

[^173]
## Acera bullata*, Müller.

Akera bullata, Müll. Prodr. Zool. Dan. p. 242, no. 2921 ; F. \& H. iii. p. 527 , pl. exiv. D. f. 4-6, and (animal) pl. VF. f. 6.

Body varying in colour from greyish or nearly clear white to pale yellowish-white or orange, covered with minute and numerous flake-white or dark specks, and usually streaked in front with interrupted lines of purplish-brown: mantle spread over the underside of the shell, and partly orer the spire or crown: head, when the animal is crawling, attenuated, and sheathed underneath by the side lobes of the foot; it is wedgeshaped and bilobed in front (so that occasionally the corners assume the shape of ears or tentacles), and margined by a narrow purplish-brown line : eyes small and black, but always perceptible: foot oblong, swollen at its base; side lobes or flaps slightly tuberculated; front rounded and narrower than the posterior portion, where the foot dilates and is truncated at the extremity, with angular corners: [odontophore, rhachis minute, erect, broader at the base, which is produced on each side, having the top expanded and compressed on the upper part, the cutting-edge bent downwards and one-cusped, with a notched crest on each side; uncini about 21, forming long hooks which are longer in the middle row, the first furnished on the inner side with short wings and jagged, the rest always more slender (Lovén):] gizzerd composed of a dozen triangular plates.

Shell forming a short oval, dilated in the middle, and almost equally broad at each end, semitransparent and glossy: sculpture, extremely fine, close-set, and wary microscopic spiral strix, which pervade the whole surface: epidermis filmy but distinct, brownish-yellow of different shades: colour, under the epidermis, whitish with sometimes a faint tinge of green: spire truncated, sometimes slightly prominent: whorls 6, ridged or keeled at the top; the first is globosely oval and intorted: suture deep and chanuelled, with sloping sides; it is slit or narrowly open in front for a considerable distance, so as to disconnect the outer part of the body-whorl from the preceding whorl, and to make the shell elastic when held between the thumb and fingers: mouth somewhat contracted above, and very wide below, with a rounded base; it extends nearly the whole length of the shell : outer lip flexuous. folding inwards

[^174]on the upper part; outer corner rounded; inner corner incurved at the further extremity: inner lip consisting of a rather thin glaze on the pillar and within the mouth: pillar slightis folded, and projecting; there is no umbilicus. L. 1.25. B. $0 \cdot 8$.

Var. nana. Undistinguishable except by its dwarf size.
Habitat : Oozy ground and mud-flats (often among Zostera) in the laminarian zone, in many estuaries, and along our southern, Irish, Scotch, and Zetlandic coasts; Walton-on-the-Naze (W. B. King) ; Orwell River (Clarke); Scilly Isles (Lord Vernon); Guernsey (Hanley); Jersey (Dodd). It is gregarious. The variety occurs in Lough Larne and Balta Sound at low-water mark and in 3-5 f. (J. G. J. and M‘Andrew); Norway (Lovén). Mr. Grainger found the typical form in the Belfast deposit. The forcign distribution of this species extends from Oxfjord in Finmark (Sars) to Vigo Bay (I'Andrew), the French and Italian coasts of the Mediterranean, the Adriatic, and Egean; depths recorded 2-20 f.
A. bullata flits about, like a Pteropod, by means of its ample and flexible foot-lobes. The account given by Olivi of its swimming and migratory habits is very interesting, and helps to explain the sudden appearance and disappearance of certain marine mollusca in particular localities. "The fishermen call them sea-snails, and assured us they were very lively in warm weather, and sometimes quitted their shells; this circumstance, however, is to be doubted" (Montagu). Mr. Hyndman says that when touched they give out a purple liquid. The fact of Acera having eyes was, I believe, first noticed by me in the 'Annals and Magazine of Natural History' for September 1859. The head bears a fanciful resemblance to the snout of a restored Dino-
therium. According to Professor Lovén the egg-case of the present mollusk may be compared to a rope twisted in different ways. I have some remarkably large specimens of the shell, which the late Dr. Farran procured in Connemara; they are upwards of an inch and a half in length, and nearly an inch and a quarter in breadth. The flounder appears to feed on it, Müller having taken the shells from the stomach of one caught in the Cattegat.

This is probably the Bulla canaliculata of Linné ; but his diagnosis being too concise, and no habitat given, there may be some doubt as to the identification. It is the Voluta Jonensis of Pennant, B. voluta parva \&c. of Chemnitz, B. akera of Gmelin, B. Norvegica of Bruguière, B. resiliens of Donovan, B. fragilis of Lamarck, Eucampe Donovani of Leach, and B. elastica of Danilo and Sandri.

## Genus IV. ACTA'ON ${ }^{*}$, (Acteon) De Montfort. Pl. VIII. f. 4.

Body fleshy, containable within the shell: head contractile, squarish, depressed, and cloven in front: tentacles ear-shaped or lobular: eyes placed in the middle of the head, below the tentacles: foot oblong, cloven in front, but not expanding at the sides: [odontophore, rhachis none ; uncini 11, shaped like long broken hooks, the largest of which form the middle row, inner side resembling a rounded wing, outer side having a notched crest at the bending (Lovén).]

Shell moderately solid, oral, spirally striated: spire prominent and bluntly pointed: whorls rounded, and connected throughont ; the first is twisted inwards: suture well marked. but not excavated: mouth occupying about two-thirds of the shell in length : piller furnished near the base with a ridgelike fold, which is continued within the spire : operentum fitting the irregular shape of the mouth, and altogether horny (not

[^175]partly testaceous, as in Odostomia) ; spire small, with the nucleus on the inner side at the base of the shell, ear-shaped, and defined or separated from the greater part of the operculum by a furrow on the upper-and a ridge on the underside.
'This generic name and its synonym Torratella were applied by Grateloup, Nyst, and Sismonda to species of Odostomia; and their shells have certainly a degree of similarity. But the apex of the spire in Actcon is regular, instead of being reversed; and the animal is different from that of Odostomia. (See page 110 of this volume.) Nearly twenty years ago Mr. Alder pointed out the affinity of Actceon to Bulla; and his views have been confirmed by the observations of other conchologists. Indeed Linné at first placed our typical species in Bulla, although he afterwards removed it to Voluta. The operculum was described by Turton, in his little treatise entitled "Conchology, arranged on the amended system," which was published in 1829. Delle Chiaje was the first to make known the animal. The present genus exhibits also a slight analogy to Melampus; but the spire of that shell is hollow, and has no internal partition.

Actaon has an extensive distribution, both in time and place; according to Woodward it comprises 16 recent and 70 fossil species.

It is the genus Tornatella of Lamarck and Speo of Risso. The name Actron was used by Oken (subsequently to De Montfort's work) for a genus allied to Aplysia, which is now recognized as the Elysia of Risso.

## Acteon torna'tilis*, Linné.

Voluta tornatilis, Linn. S. N. p. 1187. Tornatella fasciata, F. \& II. iii. p. 523 , pl. cxiv. ․ f. 3 , and (animal) pl. VV. f. 7 , as T. tornatilis.

Body pale yellowish-white, with a slight purplish tint aand

> * Turned in a lathe.

VOL. IV.
minute specks of flake-white: mantle thick, sometimes folded over part of the underside of the shell, and forming an angular lobe or process just below the junction of the outer lip with the body-whorl of the shell : hered large and broad, deeply lilobed in front, and extending (when the animal is in motion) beyond the foot: tentacles large, leaf-like or obtusely triangular, either carried erect or partly reflected on the front of the shell: eyes black, minute, and sometimes concealed beneath the outer integument, or " immersed in the skin:" foot large and widely expanded, bilobed in front, with small but sharp angular corners on each side of that part. bluntly pointed behind; the lobes of the head, the tentacles, and the front of the font occasionally correspond in position, so as to present a triple row of curves: verge scimitar-shaped and thick, placed behind the right-hand tentacle: [gills consisting of a single long and coarsely pectinated plume (Clark).]

Shell conical above, somewhat attenuated at the base, and barrel-shaped in the middle; it is opaque and rather glossy : sculpture, numerous fine spiral impressed lines, which are more or less distinctly punctate on the upper part; at the base (where the lines become broader and groove-like) they are crossed by finer and close-set longitudinal striæ; the spiral lines are not quite regular in their relative distance, and some are deeper than others; in one specimen I counted 70 on the body-whorl, 12 on the penultimate, 8 on the next, and 4 on the preceding whorl, the top whorls being eroded : epidermis inconspicuous: colour light pink or fleshcolour, with three white bands on the body-whorl, and one beneath the suture on each of the other whorls; those on the body-whorl are thus disposed-a narrow one beneath the suture, a second and broader band on a level with the top of the outer lip (which band is usually continued round the base of the upper whorls), and the third (which is equally broad, but occasionally wanting) encircling the middle of the body-whorl; the latter two bands are often defined by lines of a deeper pink: spire short and conical : whorls 7 -8, compressed although convex ; the last (as usual in this family) is disproportionately large, but the rest gradually decrease in size towards the apex; the first is tunnid and obliquely intorted: suture fine and apparently slight, but scen to be narrowly channelled by looking down upon the spire: mouth narrowly and irregularly pear-shaped. acute-angled above and obtuse-angled below, with the base rounded and effuse or expanding outwards: length two-thirds
of the shell: outer lip gently curved, not folding inwards: inner lip forming a thin glaze on that part of the body-whorl which lies within the month, and broadly reflected orer the lower part : pillar very short and flexuous : fold or plait toothlike and strong, winding obliquely along the pillar: operculum horny, long and wing-like; the inner part has the aspect of a Ciristellaria, with a nearly terminal spire; the whole surface of the operculum is marked by puckered lines of growth, and the outer part is slightly and irregularly scored by curred and other scratch-like striæ. L. $0 \cdot 75$. B. $0 \cdot 4$.

Var. 1. subuluta. Smaller and narrower, with an elongated spire. A. subulatus, S. Wood, Crag. Moll. pt. 1. p. 170, t. xix. f. $7 a, b$.

Tar. 2. tenella. Bony milk-white : foot lanceolate and slender. Shell smaller, thinner, semitransparent, more glossy, and of a paler hue, sometimes without bands; the soung have the middle of each whorl smooth. A. tenellus, Lovén, Ind. Moll. Scand. p. 11.

Tar. 3. bulloformis. Smaller and regularly oval, with a much shorter spire.

Habitat : Sandy bays, at low-water mark of spring tides, to about 20 f .; not uncommon, and widely distributed. Capt. Beechey dredged a dead specimen in 145 f . off the Mull of Galloway. Var. 1. Fishguard and the Hebrides ; rare. Var. 2. Muddy sand in 8090 f., Shetland. Var. 3. Loch Fyne, in mud, 40-50 f. (A. MrNab). This species occurs in a fossil state at Belfast (Grainger) ; boulder-clay in Caithness (Peach); Red and Coralline Crag at Sutton (Wood); post-glacial beds in Norway, 50-100 feet, some specimens retaining their coloured bands (Sars); lower Crag of Antwerp (Nyst); Italian tertiaries (Scacchi and others); Germany, Greece, and Vienna Basin (Hörnes). The 1st variety is described by Wood from the Red Crag at Sutton. A. tornatilis ranges from the Loffoden Isles (Sars), and Iceland (Steenstrup), to the Egean (Forbes); depths recorded $10-100 \mathrm{f}$. The variety tenella inliabits sandy
mud in deep water on the Scandinarian coast (Lovén and $\mathrm{Mr}^{\prime}$ Andrew).

It makes a shallow hole or burrow in the sand, and is rather sluggish. Forbes and Hanley say that, when handled, it gives out a milky fluid tinged with purple. My largest specimen is not quite an inch in length. Very juvenile conchologists call these shells "barrels."

This is the Turbo ovalis of Da Costa, Auricula bifasciata of Martini, and Speo bifasciatus of Risso (his $S$. tornutilis being fossil and apparently a different species); the young is Tornatella pusilla of Forbes, T. pellucida of Macgillivray, and possibly T. puncto-striata of Professor C. B. Adams from Massachusetts ; the fry is T. globularis of Forbes.

Voluta heteroclita of Montagu, said to be from Dunbar, is one of Laskey's more than suspicious discoveries; it is described as having a reversed spire and being a quarter of an inch long. Forbes and Hanley refer this, with doubt, to the present genus. It may be a young exotic land shell, of the Achatina family.

Genus V. BULLA*, Klein. PI. VIlI. f. 5.

Body gelatinous or fleshy, not containable within the shell: mantle thickened at its edges, and folded behind : head snoutshaped: tentacles more or less distinct, but forming a continuation of the head: eyes not perceptible in every species; when present they are placed at the base of the tentacular disk: foot rery large, expanded on each side in the shape of broad lobes or flaps, which serve as fins for swimming, and cover part of the shell and of the upperside of the body: gizzard composed of 3 horny equal-sized oval plates.

Shrll oval: spire involute, usually concealed: mouth extending the whole length of the shell: pillar sometimes furnished with a fold or plait: operculum none.

[^176]Bulla was also used by Rumph, previously to Klein, but not in a generic sense. De Montfort cites 32 vernacular names by which the shell was known in different countries; he called the genus Bullus. Leach proposed Hamincea or Haminea and Roxania for our two indigenous species; the first of these names was given in 'Turton's tract on conchology.
A. Thin ; crown imperforate, and spire wholly concealed.

## 1. Bulla hy'datis*, Limé.

B. hydatis, Linn. S. N. p. 1183; F. \& H. iii. p. 530, pl. cxiv. D. f. 7, and (animal) pl. UU. f. 3.

Bony gelatinous, when fully extended and in motion of an elongated oval shape and nearly as long again as the shell; colour variable, usually a mixture of purplish-brown, cinereous, and orange-yellow, disposed in minute granular or confluent specks: head large, notched in front: tentacles united, so as to form a small squarish lobe or disk, somewhat narrower and indented behind: eyes very distinct, placed far back on the tentacular disk, and not very close together ["closely set," F. \& H.]; they are black, and each lies in the centre of a minute circular lucid spot: foot sinuous, capable of being considerably dilated and extended; the side-lobes are often reflected over the greater part of the shell: gizzard encircled by a cartiliaginous or muscular ring, with the alimentary canal issuing from its centre; plates dark purplish-brown or chocolate, somewhat resembling the shells of a Chiton. (Montagu and Clark).

Sheil roundish-oval, fragile, semitransparent and glossy : sculpture, extremely numerous, delicate, spiral strix, besides lines of growth; the striæ are scarcely perceptible unless with microscopic aid: epidermis yellowish-brown, thicker than is usually the case in this family: colour greenish-yellow, with the cromn and pillar white: spire concealed; the crown or apex is obliquely indented or slightly umbilicate: mouth irregularly elliptical, rather narrow (although not much contracted) above, and pear-shaped below; total length exceeding that of

[^177]the spire: outer lip more or less curved, not folding inwards; it projects beyoud the crown: inner lip forming a broad and Hexuous glaze : pillar short, solid, smooth, and curved. L. 1. B. 0.75.

Var. globosa. Smaller, thinner, globular, pale jellowishgreen or creamcolour.

Habitat: Mud-flats and ooze in the littoral and laminarian zones, on the coasts of Hants, Dorset, Devon, and Cornwall; Sark, in 15-20 f. (J. G. J.) ; Jersey (Dodd and Jordan); Manorbeer, near Tenby (J. G. J.); Birterbuy Bay, co. Galway (Farran); Bantry Bay (Mrs. Puxley and Leach); Cork Harbour (Humphreys); Ralhriggan in Dublin Bay (Turton); ? Scarborough (Bean); ? Dunbar (Laskey). A local species. The variety was taken by Mr. Clark at Exmouth. It is impossible to define exactly the geological and geographical range of B. hydatis; because two European species have been confounded by authors under that name. It is said by Cantraine and others to occur in the Italian tertiaries ; and there is no doubt that it inhabits the Atlantic shores of France and Portugal, both sides of the Mediterranean, the Adriatic, and Ægean, at depths of 0-69 f.; Canary Isles (M‘Andrew).

More than thirty years have elapsed since I had the good fortune to observe, in company with my late friend Mr. William Clark, hundreds of these creatures, in the shallow and slushy pools left by the tide near high-water mark on Dawlish Warren; soon afterwards, owing to a shifting of the sands, these pools disappeared, and with them the Bulla. When it swam or floated, the side-lobes of the foot were withdrawn from the shell and spread out like a pair of fins. The shell is occasionally ristorted, having either a rude spiral groove below the apex or a depression behind the pillar.

It is the B. ampulla of Pennant (not of Linné), $B$. navicula of Da Costa, B. cornea of Lamarck (who erroneously referred to it the B. Cranchii of Leach), B. papyracea of Ulysses' Travels (fide Dillwyn), and Hamincea Cuvieri of Leach; the young appears to be the B. utriculus of Risso (not of Brocchi), and, according to Scacchi, the $B$. pisum of Delle Chiaje.
B. elegans (H. elegans) of Leach is much smaller, oblong, narrower, and more solid, with the outer lip not projecting beyond the crown. Dr. Leach records it from Tenby, Swansea, and the Devon coast ; but I believe he was misinformed as to at least the first two of these places. I lave it in the Turtonian collection. Mr. Lukis and Mr. Macculloch found it at Herm, and I dredged a fragment in Guernsey; so that this species may be looked for on our southern coasts. It is common in the Mediterranean, and is probably the $H$. folliculus of ${ }^{\circ}$ Menke.

Another species, equally doubtful as a native of our seas, is B. dilatata of Leach. This differs from B. hydatis in its much smaller size, depressed shape, microscopical and more close-set spiral sculpture, and in its widely expanded mouth, the upper corner of which projects far beyond the crown, in a wing-like fashion. Falmouth (Leach); Dublin Bay (coll. Turton); Cork Harbour (Humphreys); Loire-Inférieure (Cailliaud); Ile de Rhé, in the Gulf of Gascony (J. G. J.); Grand Canary (M'Andrew). B.pemphis of Philippi (from the Red Sea) and $B$. virescens of Sowerby (from Pitcairn's Island) are allied to the present species.
B. Solid; crown perforated and exposing part of the spire.

## 2. B. utrículus*, Brocchi.

B. utrioulus, Brocehi. Conch. foss. Subap. i. p. 633, t. I. f. $6 a, b$. B. Cranchii, F. \& H. iii. p. 533 , pl. exiv. D. f. 8, 9 , and (animal) pl. VV. f. 2.

Body greyish-white, faintly tinged above with brownishyellow: mantle thick, protruded behind, and folding over the crown of the shell as well as partly over its underside: head very large and flexible, wedge-shaped in front: tentacles triangular or ear-shaped, turned back over the front of the shell, and covering nearly one-third of it: eyes, none perceptible : foot squarish, truncated in front, rounded behind, and forming on each side a broad triangular flap, which is folded over part of the head and tentacles : ovary yellow, visible through the shell.

Shell oval, with a tendency to become cylindrical, rather solid, scmitransparent and glossy: sculpture, numerous spiral strix or impressed lines, which are visible to the naked eye; towards each end they are stronger, and alteruately large and small (sometimes two or three smaller strix between two of the larger size), and they are throughout closely punctate in consequence of the interstices being crossed by fine longitudinal striæ; the spiral striæ are much slighter in the middle of the shell, which in the young is usually quite smooth : epidermis reddish-brown; it is chiefly persistent on the spiral striæ, which are therefore darkly lineated: colour pale yellowish or ereamcolour, occasionally milk-white: spire partly exposed; crown perforated, and obliquely encircled by a thick angular rim : mouth as in the last species, but narrower; its length exceeds that of the spire: outer lip not much curved in the middle, nor folding inwards; it projects a little beyond the crown : inner lip slight : pillar short, thick, and flexuous; at its base is a rather strong fold, which makes the lower part of the mouth appear channelled; behind the pillar is a small and groove-like umbilicus. L. $0 \cdot 5$. B. $0 \cdot 3$.

Var. oblonfa. Smaller, longer in proportion to its breadth, and more cylindrical.

[^178][^179]deaux, fide Leach); Torbay and Plymouth (coll. Turton); Falmouth (Cranch, fide Leach, Cocks, and Hockin); Dogger bauk (Parke); Scarborough (Bean); Northumberland (Alder); Berwick Bay (Johnston and Mennell); Arran Isles, co. Galway (Barlee); Cork Harbour (Humphreys); co. Antrim (Hyndman) ; western coasts of Scotland (Barlee and others) ; Moray Firth (Gordon) ; Aberdeen (Macgillivray); Shetland (M'Andrew and others). I dxedged a single specimen of the variety in Loch Fyne. B. utriculus occurs in the Antwerp Crag and Bordeaux tertiaries (Nyst); upper miocene bed near Antibes (Macé); Italian tertiaries (Brocchi and others); Vienna basiu (Hörnes). Its present distribution extends from Finmark (Sars) to the Canary Isles (MI'Andrew), both sides of the Mediterranean (Cantraine, Weinkauff, and others), Adriatic (Brocchi and Brusina), and Ægean (Forbes); depths 20-140 f.

Its habits are sluggish. The head supports the front of the shell, while the foot forms the base of the living cushion. In the north it seems to be a favourite food of the haddock.

This specics was at first considered by Brocchi the $B$. striatu of Bruguière. Leach called it B. Cranchii, Johnston B. punctura, and Nyst B. utricula. B. modesta of Risso is probably the young. It may also be the B. puncto-striata of Mighels and Adams, from the eastern coasts of North America.
B.striuta was described by Turton as British, under the name of $B$. alba. I cannot, on such authority, recognize it as indigenous. His specimens (two in number) have evidently been acted upon by muriatic acid, so as nearly to remove the outer and coloured layer. Dr. Gordon kindly sent me for inspection two specinens collected in North Uist and at Durness. How ther got
so far north is not easily explicable. I entertain a high opinion of Dr. Gordon's accuracy ; but I must reserve my faith in the present case until I see a living specimen from Scotch waters. B. striata inhabits the Mediterranean, Adriatic, and Black Sca; and Drouet has recorded it from the Azores. The only other Atlantic habitat, of which I am aware, is Faro in Algarve, where M•Andrew procured it.
B. media of Philippi (a common West-Indian shell) was erroneously described by Montagu as B. ampulla of Linné, the locality which he gave being Falmouth Harbour. Possibly B. utriculus was meant. Laskey must have been determined to find it also at Dunbar ; for it figures in his list of the shells of North Britain !

## Genus VI. SCAPHANDER*, De Montfort. Pl. VIII. f. 6.

Bony fleshy, not containable within the shell : mantle thick, folded behind : head oblong, broad, and depressed: tentacles united, and forming part of the head : eyes wanting : foot dilated, with narrow and reflected side-lobes: yizard large, composed of 3 calcareous plates; the larger two (which form the sides) are ear-shaped or triangular, and the smallest (which lies between the others) is irregularly oval, and donbled.

Shell pear-shaped or oval, spirally striated : spire involute, entirely concealed in the adult; crown obliquely truncated, perforated in the young: mouth extending the whole length of the shell, contracted behind, and expanding in front : piller smooth, and blunt-edged : operculum none.

The curious gizzard was described and figured by the Cavalier Gioeni in 1783 as the type of a new family of multivalve shells, to which he proposed to give his own name! Modern naturalists have been more modest, and have contented themselves with striving for a sort of

[^180]vicarious immortality, by associating the names of their wives with their real or supposed discoveries. Gioenia, as a genus, was adopted by Bruguière ; Retz substituted for it Tricla. This strange mistake was exposed and rectified by Draparnaud.

An obsolete synonym of the present genus is Assula of Schumacher.

## Scaphander ligna'rius*, Limné.

Bulla lignaria, Linn. S. N. p. 1184 . S. lignarive, F. \& H. iii. p. jobt, pl. cxiv. F. f. 3, and (animal) pl. VV. f. 5 , as S. lignaria.
Bony fleshcolour, orange, bromnish-yellow, or creamcolour : mantle folded over the underside of the shell and the lower part of the crown or apex : head shield-like, wedge-shaped and rounded or slightly indented in front: tentacles forming a single squarish lobe, being a continuation of the head; this lobe has angular or ear-shaped corners on the upper or hinder part: eyes, none perceptible: foot bulky, of an oval shape, squarish, corresponding and coextensive with the head in front, expanded and bluntly notched behind; the side-lobes trequently overlap part of the shell: [odontophore, rhachis wanting; uncini arranged in a single row, claw-shaper, crencllated on the hinder margin towards the point; outer side winged, with a crest at the base (Lovén).]

Suell pear-shaped, peaked or acuminated at the top, and expanded at the base, rather solid, nearly opaque, and somewhat glossy: sculpture, numerous spiral striæ or fine grooves, which (owing to the size of the shell) are very conspicnons; they are equally strong in erery part, and are equidistant, except at the top (where they become more or less crowded), and also except an occasional slighter intermediate stria; the interstices of the spiral striæ or grooves are crossed by fine and close-set longitudinal striæ, which often give the former a punctate appearance; the whole surface is covered with close-set microscopic spiral lines and with equally numerous and minute longitudinal strire, producing by their intersection a slight cancellation : epidermis orange or tawny, passing into chestnut : colour, under the epidermis, yellowish-white or

[^181]creamcolour; young and half-grown specimens are often adorned with narrow reddish-brown zones, parallel and alternating with the white spiral strix and their walls: spire loosely coiled, not exposed in the adult, being coated over by successive deposits from the hinder lobe of the mantle: crown obliquely indented, and encircled by an angular rim; it is perforated in the young and fry, so as to show the outer part of the spire: mouth narrow above, and dilated below, with a rounded base; its length exceeds that of the spire: outer lip not much curved in the middle; it projects beyond the cromn, forming in that part an obtuse angle: inner lip broad and flexuous, consisting of a rather thick glaze: pillar arched, visible throughout by holding the shell upside down. L. 2.33. B. $1 \cdot 5$.

Var. 1. alba. White, with a creamcolour epidermis.
Var. 2. curta. Smaller and shorter, but not haring the compactly convoluted spire and comparatively small mouth of S. librarius.

Habitat: All our coasts: it usually frequents the coralline zone, ranging as deep as 90 f. ; but. Dr. Landsborough says that " at Whiting Bay, in Arran, it may be taken by digging in the sand at ebb tide." The lst variety is generally diffused, but rare. Var 2. Shetland. This species occurs in the quaternary and upper tertiary beds at Belfast (Grainger) ; Greenock (Robertson) ; and the Red and Coralline Crag (Wood) ; as well as throughout Belgium, France, Italy, Germany, and the southern parts of Europe. Its distribution, in a living state, extends from Finmark (Danielssen and Sars) to Gibraltar (M'Andrew), and through the Mediterranean, Adriatic, and Egean ; depths 8-60 f.

This voracious mollusk does not despise any kind of animal food, from minute Foraminifera to the sea-mouse or Aphrodita, the spines of which I found in the gizzard of one individual. Corbula gibba is evidently a favourite morsel; and I have observed Dentalium entalis, Odostomia rufa, and Ditrupa arietina in other specimens.

George Humphreys mentions Cylichna cylindracea also. The Dentalium and Ditrupa, when sticking in the gizzard, look like spits through joints of meat. According to Laudsborough ('Zoologist,' 1843, pp. 87, 88) "though they scem to indulge very freely as to quantity, they appear to be wiser than our biped gourmands; for they keep to one dish. In every one of the specimens I procured, the capacious gullet was filled with the fry of Mactrel subtruncata. The gullet was in the form of a cornsack, quite distended, for each contained some scores of these little bivalve shells in an unbroken state. The sack, however, gradually emptied itself into the gizzard; and in this shelly mill the shells and their contents were reduced to powder, or rather a fine paste, well fitted, no doubt, to be wholesome nutriment for the industrious little marine miller." The plates of the gizzard are white, with the middle portion of the inside brownish-yellow and raised, the centre being white and ground down by use. The side-plates slope from a boss in the centre to a sharp edge; and the intermediate or small plate resembles an opera hat: in the young it is not unlike Ancylus lacustris. Among other wonderful tales of the sea, the Guernsey fishermen will tell you that the Scaphander bites off a portion of the outer lip of its shell, when it finds itself a prisoner in the trawlnet! It is preyed on by the haddock. A monstrosity in my collection has the crown deeply and widely channelled.

Risso described it as S. lignarius and S. giganteus; the fossil shell of the same species is probably his S. taryionius. Bulla zonata of Turton and S. Brownii of Leach are the young; I once thought (but wrongly) that the former might be $S$. librarius of Lovén.

Of the last-named species I obtained a very young specimen in my Shetland dredgings. S. librarius is much smaller than $S$. lignarius, of an oval shape, having the spire compactly coiled, and the mouth consequently more contracted. It inhabits the Scandinavian coasts, in from 20 to 150 f ., and (fide Torell) Iceland.

## Genus VII. PHILI'NE*, Ascanius. Pl. VIII. f. 7.

Body semioval, gelatinous and slimy, not containable within the shell: mantle shicld-like, covering the shell and gill-plume: head oblong, wedge-shaped in front: tentacles not distinct, but forming part of the head: eyes wanting : foot broad, folded on each side as a flap, which together with the pallial disk and head give the animal a quadrilobate appearance: gizzard composed of three calcareous plates, which in some species are shuttle-shaped and equal in size, and in other species are similar to those of Scaphander: odontophore without any rhachis or central tooth ; the uncini are clawshaped, and arranged in single or double file.

Suelu wholly internal (being concealed under the mantle), and thin: spire loosely coiled, small, and truncated: mouth very large and open, not always as long as the spire: piller sharp-edged, flexuous, and visible throughout.

A description and figure of this genus by Professor Ascanius were published in the 33rd volume of the Transactions of the Royal Academy of Sciences at Stockholm for 1772 , the species on which it was founded being the Bulla aperta of Linné. The 'Zoological Journal' for 1827 contains a valuable and interesting account by Mr. Clark of several British species which he examined in a living state.

[^182]It is the genus Lobaria of Müller, and Bullaea of Lamark; the former was carelessly referred by Rang to the shelless genus Acera (" acère") of Cuvier.
> A. Haring a chain-like or punctate sculpture ; spire conspicuous.

## 1. Philine scabra*, Müller.

Brolla scabra, Müll. Zool. Dan. ii. p. 41, t. lxxi. f. 10-12. P. scabra, F. \& II. iii. p. $\overline{5} 43$, pl. cxiv. e. f. 4,5 , and (animal) pl. YV. f. I, as Bullea scabra.

Body elongated, whitish or creamcolour, sometimes minutely speckled with black : mantle folded over the crown and underside of the shell, ending behind in two angular points: head large, broad, and gibbous; the upper part or tentacular disk is rounded behind, and marked lengthwise by a slight darkish line of division: foot oval and very large, wedge-shaped in front, and rounded behind; side-lobes broad: gizarcl-plates shuttleshaped and equal-sized, haring a flat rib down the middle with a small depression on each side: [odontophore armed with two rows of uncini ; inner ones much the larger, lobed on the inside and jagged; outer ones minute and plain-edged (Lovén).]

Shell resembling in shape a miniature Scaphander lignarius, but more eylindrical; it is of a delicate texture, semitransparent, and of a glistening and iridescent lustre : sculpture, numerous and close-set spiral and parallel rows of minute oval dots which are interworen and arranged like the links of a chain; some of these rows being intermediate, and apparently squeezed or compressed at the sides, become merely fine lines; the front edge or base of the mouth and top of the outer lip are exquisitly fringed with sharpish points, like short teeth of a comb: colour clear white when the shell is extracted from the animal, afterwards becoming milk-white: spire slightly prominent: whorls 3 ; the body-whorl (as usual in this genus) is disproportionately large and roluminous; the other two are small, with an indistinct and thickened nuclens: suture deep and channelled: mouth acute-angled above, and greatly expanded below, with a squarish base: outer lip gently eurred, folding inwards on the upper part;

[^183]the top of this lip is below the spire; inner corner cloven or excavated, so as to cause a disjunction of the suture in front and a partial separation of the body-whorl from the next: inner lip forming a rather thick and broad glaze. L. $0 \cdot 2$. B. $0 \cdot 1$.

Habitat: Living in sand at low-water mark of spring tides, Gwyllyn vase, Falmouth (Barlee and Miss Vigurs, fide Cocks) ; Hayle and Falmouth (Hockin) ; Porthcurnow Cove, near the Land's End (Miss Lavars) ; Mounts Bay, Penzance (Templer) ; Scarborough (Bean and J. G. J.) ; Northumberland coast (Alder) ; Dogger bank, Coquet, and Berwick Bay (Mennell) ; Berwick (Johuston) ; Tenby (Lyons) ; Cork, in stomach of the black sole (Humphreys) ; co. Galway (Barlee) ; co. Antrim (Hyndman and Waller) ; west of Scotland and the Hebrides (Barlee and others) ; Moray Firth (Gordon); Aberdeenshire (Macgillivray and Dawson) ; Shetland (Forbes and others) : muddy sand and mud, 3-85 f. Coralline Crag, Sutton (Wood) ; glacial bed in Norway, 50-70 feet (Sars) ; Nice (Risso) ; Palermo (Philippi). Inhabiting Greenland (Möller) ; Iceland (Steenstrup) ; Scandinavia, from the Loffoden Isles (Sars) to Kullaberg in Skåne (Lilljeborg); Vigo Bay (M‘Andrew); Gulf of Lyons (Martin); Spezzia (Doria) ; Sicily (coll. Petit): depths recorded 150-140 f.

From the stomachs of a flounder (Müller) and haddock (Gordon). A comparatively gigantic specimen was kindly presented to me by my old and esteemed friend Mr. Waller, who dredged it at Groomsport ; it measures four lines by two and a quarter.

Very distinct from Bulla scabra of Chemnitz, which does not even belong to the present genus. Dillwyn called our shell B. pectinata ; Risso described it (apparently) as Scaphander patulus; Leach (according to

Turton) gave it the name of S. catenatus; it is the Bullca granulosa of Sars, partly the Bullaa angustata of Philippi, Bullaea catena and Bullea catenulifera of Macgillivray, and Bulla dilatata of S. Wood.
P. lima (Utriculus Lima) of Brown is stated by him to have been found by Mr. Stewart Kerr at Greenock; and it would therefore be a glacial fossil of the Clyde beds. It is allied to $P$. scabra, but differs from that species in haring a smaller and compact crown, a more produced spire, and a less patulous mouth. It is the Bulla lineolata of Couthouy, and probably the Bullaa punctate of Möller (not of Clark), its existing distribution being confined to the eastern coasts of North America and to Grcenland.

## 2. P. caténa*, Montagu.

Bulla catena, Mont. Test. Br. (i.) p. 215, t. 7. f. 7. P. catena, F. \& H. iii. p. 545, pl. cxiv. e. f. 6, 7, and (animal) pl. UU.f.4, as Bulllea catena.

Body on the upper part yellowish-white; the shield or anterior portion, and the lateral lobes caused by the reflexion of the foot on the back, are sprinkled with close-set rery minute reddish-brown points; the posterior part of the body is divided into one or tro digitations. (Clark.)

Shell oval, compressed and expanding outwards, of delicate but not fragile texture, semitransparent and glossy : sculpture, numerous and close-set spiral rows of minute links, arranged in a chain-like fashion, which rary in shape from roundishoval to oblong, besides occasional intermediate lines as in P. scabra; the edge of the mouth (especially at its base and on the upper part of the outer lip) is finely scalloped by the continuation of the spiral sculpture: colour as in the last species: spire extremely small, but prominent: whorls 2-3, similar (except in size) to those in the last species: suture narrow, deep, and channelled: mouth equalling about three-fourths of the circumference of the shell, broadly oval, contracted abore by the periphery, with a bluntly rounded (or almost truncated)

[^184]base: outer lip flexuous, slightly indented or concave in the middle; the top is level with the spire, the shell being placed mouth downwards; inner corner cloven, and producing the same partial disconnexion of the body-whorl as in the last species: inner lip forming a broad and thickened glaze. L. 0.15. B. $0 \cdot 1$.

Var. zona. Rather more depressed, with a belt of clear white in the middle, taking in from eight to ten of the chainlike rows.

Habitat: Exmouth, alive in rock-pools at the time of the lowest spring tides (Clark) ; on different parts of the coasts of South Devon, Cornwall, and Dorset (Montagu, Tyacke, fide Forbes's MS., J. G. J., and others) ; Guernsey (Barlee and J. G. J.) ; Tenby (J. Adams and J. G. J.) ; Manorbeer near Tenby, and Langland Bay near Swansea (J. G. J.) ; Scarborough (Bean and J. G. J.) ; Northumberland (Alder) ; Berwick Bay (Johnston) ; Cork (IIumphreys, from the stomach of a sole, and J. G. J.) ; Miltown-Malbay, co. Clare (Harvey, fide Thompson) ; Arran Isles, co. Galway (Barlee) ; Bundoran, co. Donegal (J. G. J.) ; Dublin Bay (Walpole and J. G. J.) ; Lamlash, Isle of Bute (Landsborough) ; Skye (Barlee); Firths of Forth and Clyde (Brown); Shetland (Barlee). The variety is from Bigberry Bay, near Plymouth (Montagu), and Guernsey (coll. Turton and J. G. J.). P. catena occurs in the Coralline Crag at Sutton (Wood, as Bullea sculpta) ; Palermo (Calcara, as B. punctata). Its extraBritish distribution, as a recent species, appears to be southern, and comprises the Loire-Inférieure (Cailliaud), Mediterranean, from the Gulf of Lyons (Martin) to Sicily (Maravigna and Philippi), and Æyean, in 119 f. (Forbes).
The gizzard resembles that of $P$. scabra, but is smaller and has a shorter midrib. My largest specimens
are from Galway and Shetland, and measure nearly two lines in length.

Montagu refers the Bulla punctata of Adams (Linn. Trans.) to this species : I believe he was right in doing so. It is probably the Bullaa angustata of Bivona (according to Philippi), and the Scaphander catenatus of Leach's 'Synopsis.'

## 3. P. angula'ta*, Jeffreys.

SHecl rhomboidal, depressed, fragile, transparent and glossy: sculpture, numerous rows of very fine spiral striæ, composed of oral and almost microscopic dots, and appearing punctate ; the upper part of the body-whorl is angulated or margined by a sharpish keel, between which and the suture is a flattened space marked with 5 of the spiral striæ and sloping towards the spire; there is also a tendency to angularity in other parts; edge of the mouth plain or smooth: colour clear white, becoming opaque in dead specimens which have been picked out of shell-sand; occasionally one or two transparent zones may be seen, as in the variety of $P$. catena: spire extromely small, slightly prominent: whorls $2-3$, conspicuous; the outer edge of each is keeled or ridged: suture deep and channelled: mouth squarish, remarkably wide and large, nearly truncated at the base: outer lip forming an obtuse angle at the junction of the front and base; the top is higher than the spire, and it projects outwards (but all my specimens are more or less broken in this part); inner corner deeply and widely cloven, so as to make the disjunction of the outer whorl from the next very conspicuous: inner lip forming a narrow but thick ledge or fold, behind which is a slight depression. L. 0.1. B. 0.075 .

Habitat: Larne, co. Antrim, Hebrides, and Shetland, in 60-80 f. (J. G. J.) ; Aberdeenshire (Dawson). It is apparently rare.

The keeled spire will serve to distinguish this from any other species of Philine in the present section.

[^185]
## 4. P. quadrat ta*, Searles Wood.

Bullaa quadrata, S. Wood in Ann. N. H. iii. p. 461, pl. vii..f. 1. P. quadrata, F. \& H. iii. p. 541, pl. cxiv. e. f. 2, 3.

Bodr whitish and semitransparent: head rounded : tentacles not separate: eyes wanting: foot oblong, symmetrical and eren with the head in front: yizzard minute ; plates elliptical.

Shell squarish-oval, convex, contracted or compressed on the upper part bolow the spire, and bluntly angulated in the middle: it is not very thin, is semitransparent, and when fresh of a glistening lustre: sculpture, numerous rows of fine spiral striæ, which are composed of minute oval dots and appear punctate ; these strix are irregularly disposed, being in some parts more close together than in others, and they here and there form intermediate and slight lines; the upper part of the body-whorl is thickened and rounded, and the middle is furnished with a blunt and slight spiral rib, which is usually visible also within the mouth ; the top of the outer lip is delicately scalloped: colour white, crrstalline when extracted from the animal : spire small, more or less sunken; apex obscure: whorls $2-3$, rounded; the inner ones are minute: suture deep: mouth broadly oval, contracted above by the periphery, and expanded below, with the base obliquely curved and somewhat truncated: it occupies about two-thirds of the underside of the shell : outer lip nearly straight in front and forming an obtuse angle at the junction of that part with the base ; the top is rather higher than the spire, and projects outwards; outer corner bluntly angular or rounded; inner corner receding and acute-angled, but not exhibiting any further disjunction of the outer whorl from the next: inner lip broad and thick. L. $0 \cdot 25$. B. $0 \cdot 2$.

Habitat : Mud and sand, Dogger bank (Mennell and J. G. J.); Whitburn (Abbes and Howse, fide Alder); Arran Isles, co. Galway (Barlee); Moray Firth (Gordon) ; Aberdeenshire (Dawson) ; Orkneys, 12-40 f. (Thomas, fide Forbes) ; Shetland, 3-76 f. (M‘Andrew and others) ; Coralline Crag, Sutton (Wood) ; postglacial beds in Norway, 60-100 feet (Sars). Its exist-

[^186]ing distribution beyond our seas, as at present known, includes Nordland and Finmark, from 20 to 150 f . (Lovén and others), Greenland (Sars), and Massachusetts Bay (Stimpson).

The young and fry are more globose than the adult; in the former the spire is proportionally smaller and more depressed or umbilicate, and in the latter it is rudimentary and consists of only half a whorl. The fry is perfectly smooth and very glossy. In all these respects the present species differs from $P$. angulata.

It is the $P$. scutulum of Lovén, and $P$. formosa of Stimpson, the types of which I have examined.

5. P. puncta ${ }^{\text {ta }}$ *, Clark.

Bullaa punctata, Clark in Zool. Journ. iii. p. 339. P. punctata, F. \& IF. iii. p. 547 , pl. exiv. e. f. 8,9 , and (animal) pl. UU. f. 5, as B. punctata.

Body oblong-oval, above dirty white, marked with the finest longitudinal dark close lines, mixed with minute streaks and points, giving the whole surface a dark cloudcoloured sombre aspect [" tinged and speckled with reddishbrown on a yellowish ground," F. \& H., ex fig. Alder]; hinder part digitated or lobed, and yellowish-white [" Its capital disk seems different in shape, and much shorter and broader than that of cotena, and the margin of the mantle is not laminated," F. \& H.]; gizzerd minute, cylindrical, and yellow. (Clark.)

Sable oval, convex, but somewhat compressed in the middle, of delicate texture, nearly transparent, and glossy: sculpture, extremely numerous and close-set spiral rows of minute rings or impressed circular dots, which are not united or chain-like, but appear punctate; edge of the mouth plain at its base and slightly scalloped at the top of the outer lip: colour as in all the foregoing species: spire very small, but prominent: whorls 2 , similar to those of the other species: suture narrow, deep, and channelled : mouth regularly oval, rounded at the base: outer lip flexuous, widely indented or slightly concare in the middle; the top lies somewhat below the spire ; outer corner bluntly angulated, and projecting; inner corner

[^187]cloven and causing a disconnexion of the outer whorl from the next: inner lip narrow, folding over the pillar, behind which is a depression or approach to an umbilicus. L.0.1. B. $0 \cdot 075$.

Habitat: With P. catena at Exmouth (Clark); Torbay (Clark and J. G. J.) ; Burrow Island, near Saltash (Barlee and Hanley); Land's End and Hayle (Hockin); Whitesand Bay and Guernsey (J. G. J.) ; Scarborough (Bean and J. G. J.); Northumberland coast, with P. catena, "rarely found alive in pools among the rocks within tide-marks" (Alder); bays near Swansea, Barmouth and Bundoran (J. G. J.) ; Miltown-Malbay, co. Clare (Harvey); Kilkee in the same county, and Bumdoran (Mrs. IIancock, fide Thompson) ; Bantry Bay (Norman); Dublin Bay (Warren and B. W. Adams) ; Cumbrae (Landsborough and Robertson); The Minch (J. G. J.) ; Loch Maddy (M‘Intosh) ; Aberdeenshire (Macgillivray and Dawson); off Troup Head on the same coast, in 60 f. (Thomas, fide F. \& H.) ; Shetland (J. G. J.). Floröen in Norway (Sars, as P. pusilla); Bohuslän (Malm, as P. quadrata) ; Algiers, 3 fr f. (M‘Andrew) ; Ægean, 119 f . (Forbes, as Bullaer alata). An examination of the types has enabled me to determine the above synonyms.
B. Sculpture latticed̉; spire conspicuous.
6. P. pruino'si*, Clark.

Bullaa pruinosa, Clark in Zool. Journ. iii. p. 339. P. pruinosa, F. \& If. iii. p. 549, pl. exiv. f. f. 1, 2 .

Bodr oblong (" conrex above, flat beneath," Clark; " parum. depressum," Lovén); it is white, the tentacular disk and all the margins being speckled with snowy points : mantle open along the back, extended behind, and indented in the middle:

[^188]margin jagged : mouth having a transrerse orifice, and armed with a pair of horny jaws: tentucles united to form a large squarish-oral disk, which is notched in front: foot rery large; sole as broad as it is long, somewhat exceeding half the length of the whole body ; it is indented on each side in front; sidelobes ming-like, thick, and folding back, with jagged edges: gizzurl none: but, instead of this organ, the stomach is furnished with two horny and finely shagreened plates, one on each side : gills arranged in a single coarsely pectinated plume, situate under the shell. (Lovén, and Clark's MS.)

Shell oral. tumid, but compressed or pinched in below the apex, more solid than any of its congeners, nearly opaque, glossy in the young only: sculpture, numerous strong and irregular longitudinal wrinkly striæ (fringed at their edges) and finer spiral strix, which by intercrossing give the surface a reticulated and frosty aspect, or that of lacework; the reticulation is less distinct in full-grown specimens; the rery young have spiral rows of circular dots, as in $P$. punctatu; edges of the mouth plain : colour white, with frequently a broad tamny band round the middle and a tinge of the same bue on the apper part; these markings are rather evanescent, and appear to be superficial: spire very small, sunk below the apex or cromn, which is considerably thickened: whorls $2 \frac{1}{2}$, irregularly twisted and indistinct: sutwe deep and excarated: mouth oral, contracted above by the periphery and inflexion of the outer lip, curred below ; it occupies about two-thirds of the under surface: outer lip fiexuons, widely indented in the middle, and bending inwards abore; edge often thick; the top slightly exceeds the crown in height; outer corner rounded; inner comer receding and acute-angled: imer lip broad and rather thick on the upper part, oceasionally forming in the middle a tooth-like process or fold (in one specimen conserted into a cluster of minute pearls), behind which is a distinct umbilical groore or depression. L. $0 \cdot 25$. B. $0 \cdot 2$.

Tar. dilututa. Nearly smooth, more expanded and somewhat angular at the sides, and abruptly attennated towards the crown. L. 0.075 . B. 0.05 .

Habitat: Dredged off Budleigh Salterton (Clark); Plymouth (Webster) ; Falmouth, in trawl-refuse (Miss Vigurs, fide Cocks); Whitburn, dredged and from the stomachs of fish (Howse, fide Alder); Loch Fyne and

Hebrides (Barlee and others); Firth of Forth (Fleming, fide F. \& H.) ; Moray Firth (Gordon); Aberdeenshire (Dawson) ; Shetland (Barlee and J. G. J.): depths 1870 f. Bohuslän (Lovén); Norway, in 30-60 f., sandy mud (Danielssen). The variety is from Shetland:
"The animal flaps the sides of the foot upwards and downwards, as if beating the water, with considerable quickness, especially when first taken from the sea." (Clark's MS.)

The fry is devoid of sculpture; it differs from that of $P$. quadrata (which is also smooth) in being much smaller at the top, and in having the sides angulated and projecting.

## C. Smooth ; spire conspicuous.

## 7. P. nittida*, Jeffreys.

Shell oblong, convex, very thin and fragile, nearly transparent, and of a polished lustre: sculpture, none on the bodywhorl; but the spire has two keels or ridges, one at the outer edge of each whorl, and the other in the middle, giving this part an angulated appearance: colour clear-white, becoming opaque in dead specimens: spire flattened, placed somewhat obliquely; it is quite exposed and occupies the top of the shell: whorls $2 \frac{1}{2}$, irregularly twisted, but distinct: suture deep and excarated: mouth oval, truncated above, wide and rounded below; its area equals about two-thirds of the under surface: outer lip expanded, squarish at the top, and gently curved in the middle; it is level with the spire, viewed mouth downwards, and is below it, viewed mouth upwards ; outer corner angular and projecting ; inner corner considerably receding and acute-augled: inner lip forming a broad glaze on the upper part, and reflected on the pillar; there is no umbilical groove or depression. L. $0 \cdot 075$. B. $0 \cdot 05$.

Habitat: Skye (J. G. J.) ; Haroldswick Bay, Unst
(Dawson). It is as yet rare. My Skye specimen has the remains of the mantle still adhering to the spire on the outside, showing that the shell is internal. Being minute, I have carefully compared all the specimens (half a dozen) with the fry of other species of Philine, as well as with those of Utriculus and Acera. I cannot identify this with auy of them. In the last two genera the firy has the same cylindrical shape as the adult, and the first whorl or nucleus of the spire is nipple-shaped.

Plyline sinuata of Stimpson (from 6 f., sand, in Boston Harbour) appears to be allied to the present species; but the spire of the North-American shell is represented as rounded instead of carinated or angular.

## D. Smooth; spire indistinct.

## 8. P. aperta*, Linné.

Bulla aperta, Linn. S. N. p. 1183. P. aperta, F.\& H. iii. p. 539, pl. cxiv. e. f. 1, and (animal) pl. UU. f. 1, as Brelléa aperta.

Body broadly oral, rather conrex abore and fiat underneath, slimy, and of a cousistency between gelatinaus and fleshy, pale fellowish-white or sometimes nearly clear white, with numerous minute snowy specks: mantle shield-like, with a membranous margin in front, and forming behind an angular lobe which corers the erown of the shell: head or anterior disk somerhat elougated, gently curved or squarish in front (now and then slightly notched in the middle of this part), and truncated behind : tentacles, or eyes, none: foot flexible, usually rounded in front, with a membranous margin; side-lobes thickened and folded back; these lobes, with the head-disk and pallial shield, give a quadripartite appearance to the animal: gizzard composed of three calcareous plates, united by a strong cartilage; they are concare on the outside, and corered orer with a thin tightly stretched membrane; two of the plates, which flank the sidos, have the shape of an inequilateral triangle, and are equal-sized; the third is smaller and lozenge-

[^189]VOL. IV.
shaped, lying at the base between the two lateral plates; cach plate has two small holes (muscular impressions?) in the middle : odontophore, thachis wanting; uncini 12-15, arranged in a single row, claw-shaped, and furnished on the inner side with a jagged crest.

Shell squarish oval, depressed in front, very thin and fragile, semitransparent, glossy, and iridescent: sculpture, plaitlike and irregular lines of growth, and a few extremely slight and more irregular spiral lines, which latter are not discernible except with a lens and at certain angles of light; the texture, examined under a microscope, rescmbles curdled milk: colour whitish, with sometimes two or thrce clear streaks across the back: spire very loosely coiled, with the nuclens extremely small and concealed by a shelly deposit from the hinder lobe of the mantle; it is always more or less indented, and in the young is slightly umbilicate: mouth roundish-oval, of enormous size compared with that of the convoluted portion, and occupying seven-eighths of the under surface; it is obliquely truncated above, and rounded below : outer lip dilated, with a sinuous and very thin edge; the upper part slopes outwards, and projects considerably beyond the spire ; inner corner receding and acute-augled : inner lip spread over the pillar, and forming at the angle where it meets the outer lip a thick and shapeless callus: pillar sharp and flexuous; there is no umbilical groove or depression. L. $0 \cdot 85 . \quad$ B. 0.7 .

Var. patula. Smaller, with the mouth larger and more expanded.

Habitat: Sand, from low-water mark of spring tides to 50 f ., on all our coasts between the Firth of Forth (Forbes) and Jersey (Dodd). It seems to attain its largest dimensions in the Bristol Channel; specimens which I found in Swansea Bay are nearly an inch and a quarter in length. The variety is from Tenby, Dublin Bay, and Counemara. I am not aware that this species has occurred in a fossil state except at Belfast, where Mr. Grainger observed it. Its existing distribution comprises the Atlantic sca-board from Upper Norway to the Canaries, the Mediterranean, Adriatic, and Egean, at depths rarying from 4 to 110 f . ; speci-
mens from the Cape of Good Hope (the original locality giren by Linnée, Australia, and New Zealand appear to be specifically identical with those from the north of Europe.

Its burrow or track is not unlike the run of a mole. When placed in a dish of sea-water, its gliding motion is so slow and gradual as to be perceptible only, by marking the distance traversed. Mr. Daniel detected sessile Foraminifera in its gizzard; one now before me contains an Echinocyamus pusillus. Sometimes the plates of the gizzard, instead of being convex on the inner side, become concave by the continual process of shell-crushing. According to Lovén the fry is enclosed in a spiral shell, and swims by means of a vibratile headveil or lobe ; it is eyeless, but furnished with an operculum ; the eggs are extremely numerous, and arranged in a single row, forming a very long and loosely twisted rope like a necklace ; thesc are enveloped in oval gelatinous and transparent capsules. Another, but less precise, description of the spawn has been lately published in the 'Comptes Rendus' by Lacaze-Duthiers (who, however, does not allude to Lovén's account) ; and he notices some double embryos. The gizzard was first made known and figured by Colonna, who mistook it for an operculum. Müller gave full particulars of this curious instrument ; but he left it to posterity to inquire its use. Strauge to say, this great zoologist seems to have imagined that the shell of this species (which he calls Bulla candida) belonged to some other mollusk, which had served as food for his Lobaria! The spire is visible in Baltic specimens, and consists of between two and three whorls ; this is clearly shown in the admirable illustrations which accompany the first volume of the work of Meyer and Möbins on the fauna of Kiel Bay.

Plancus says that the fishermen in his time called this shell " amygdala marina" (sea-almond); it is the Philine quadripartita of Ascanius, Lobaria quadrilobu of Müller, Bulla bulla of Da Costa, and Bullaa planciana of Lamarck; the fry is Bulla emarginatu of Adams. In Gmelin's edition of the 'Systema Naturæ' it is placed among the Testacea as Bulla aperta, and among the Mollusca as Lobaria quadriloba. Among the synonyms quoted by Martini in his 'Conchylien-Cabinet,' is the fanciful one of " unguis humana," derised from Colonna; the genders are thus treated somewhat in the German fashion. Pfeiffer named the South African specimens Bullaa Capensis, and Philippi B. Schroeteri. These, like the European, vary in convexity, size of the convoluted portion, and height of the outer lip. I have in vain attempted to discover a single character by which they can be distinguished.

And now, good Reader, I should be sorry if you have complained of my being too voluminous. I never professed to make this a manual; nor have I yet quite done. Let me remind you of the advice given by Sencea (De Ira, Lib. iii. c. 31. § 3), "Age potius gratias pro his quæ accepisti : reliqua expecta, et nondum plenum te esse gaude. Inter voluptates est, superesse quod speres."

The next volume will complete the work, and contain an account of the few remaining Pleurobranchiata, the Nudibranchs (by Mr. Alder), the marine Pulmonobranchs, the Pteropods, and the Cephalopods, a Supplement to the volumes already published, and other useful matter, besides plates (plain and coloured) by Mr.

Sowerby, to represent all the species and remarkable varieties of British shells. Most of these plates are engraved, and the colouring is in progress.

## ERRATA.

Page 2S, lines 12-13 from bottom, omit the words" $R$. Ballice of Thompson."
47 , line 14 from bottom, for " L. 0.01 " read " L. 0.1."
55 , line 6 from bottom, for "Cuaplidee" read "Capulide."
C8, line 5 from top, for "AKera" read "Acera."
84, line 6 from bottom, for "Christophori" read "Cristofori."
91, line 16 from top, for "Broun " read "Bronn."
108, line 7 from bottom, for " 1862 " read " 1826. ."
167, line 13 from top, for "was (although loosely)" read "(with others) was."
193, line 3 from top, for "Mangilia" read "Pleurotoma."
209, line 4 from bottom, for "Renieri" read "Renier."
217, line 1 ? from bottom, for "south-west" read " north-west."
265, after CERITHIIOPSID E, for "Gray" read " P. P. Carpenter."
301, Triton nodiferus. In strictness the specific name ought to be xodifer.
314, lines 5 and 12 from top, for "L. brunnea" read "L.minima." 350, line 15 from top, for "Pleurotomatide" read "Plenrotomide." 359, line 15 from top, for "Manglia " read "Mangilia." 360, for "PLEUROTOMATID $\mathrm{E}^{2}$ " read "PLEUROTOMIDE." Pletrotoma is certainly feminine (from $\pi \lambda \in v \rho o v$ and $\tau \cup \mu \dot{\eta}$ ), and not (as Philippi would have it) neuter. I was at first misled by his stating that those who make Pleurotoma a noun of the first declension, and of the feminine gender, offend against the laws of grammar (M.oll. Sic. ii, p. 165, footnote). Anatomia, apotome, and epitoma or epitome, formed from the same verb ( $\tau \dot{\prime} \mu \nu \omega)$, are all feminine.
381, line 4 from top, omit the words "Hanley described it as $P$. Metcalfei."
" line 8 from top, for " $P$. costatum" read " $P$. costata."
, line l! from top, for " $P$. proximum" read " $P$. proxima."
386, lines 7-8 from bottom, onit the words "and Raphitoma polita of Brusina."
" line 8 from bottom, omit the words " $P$. rigra of Potiez and Michaud."
388, line 9 from bottom, for "Hanley" read "Reere."
397, line 14 from bottom, after "probably" add "and in part." 399, line 13 from bottom, for "wegde-shaped" read "wedgeshaped."

| Species. |
| ---: | ---: | ---: | :--- | :--- | :--- | :--- |

This Table (excluding doubtful cases) shows, with regard to the British seas, 114 northem and sonthern, 46 peculiarly northern, and 12 peculiarly southern species; 10 other species have not yet been noticed on avy foreign coast. The following species occur in our newer tertiaries, riz.: -Turritella polaris, T. reticulata, Scalaria Grenlandica, Acirsa borealis, Natica affinis, N. Smithii, Velutina undata, V. lanigera, Trichotropis insignis, Admete viridula, Cerithium tuberculatum, Buccinum Granlandicum, B. plicosum, Trophon clathratus, T. craticulatus, Fusus despectus, F. latericeus, Columbelle Holböllii, Plezrotoma pyramidalis, Cylichna striata, and Philine lima; all these, except Cerithiuin tuberculatum, inhabit the arctic seas. Of the species given in the present Table as fossil, 24 are peculiarly northern, and 4 peculiarly southern; the rest are common to both dirisions.

## INDEX то VOL. IV.

The synonyms, as well as the names of spurious species, and of species, genera, and other groups which are not described in this volume, are in italics.-The figures in smaller type refer to the page in which the description of species, genera, and higher groups will be found.

## EXPLANATION OF PLATES.

Frontispiece.
Ianthina and float.

## Plate I.

Fig. 1. Rissoa parva.
2. Barleeia rubra.
3. Jeffreysia diaphana.

Fig. 4. Skenea planorbis.
5. Homalogyra atomus.
6. Cacum trachea.

Plate II.
Fig. 1. Turritella terebra.
2. Truncatella truncatula.
3. Scalaria communis.

Fig. 4. Aclis supranitida.
5. Odostomia spiralis.

## Plate III.

Fig. 1. Ianthina rotundata.
2. Stilifer Turtoni.
3. Eulima polita.
4. Natica catena.

Fig. 5. Adeorbis subcarinatus.
6. Lamellaria perspicu.
7. Velutina levigata.

## Plate IV.

Fig. 1. Torellia vestita.
2. Trichotropis borealis.
3. Aporrhaïs pes-pelecani. Plate V.
Fig. 1. Purpura lapillus.
2. Buccinum undatum.
3. Buccinopsis Dalei.

## Plate VI.

Fig. 1. Lachesis minima.
2. Trophon muricatus.
3. Fusus antiquus.

Fig. 4. Nassa reticulata.
5. Columbella haticeti.

Plate ViI.
Fig. 1. Defrancia linearis.
2. Pleurotoma turricula.
3. Marginella levis.

## Plate VIII.

Fig. 1. Cylichna cylindracea.

1. Odontophore of C. alba.
2. Utriculus obtusus.
3. Acera bullata.

Fig. 4. Actaon tornatilis.
5. Bulla hydutis.
6. Scaphander lignarüus.
7. Philine aperta.

[^0]:    * Slightly striated.

[^1]:    * Milk-white.

[^2]:    * Latticed.

[^3]:    * Reticulated.

[^4]:    * Resembling R. cimex.

[^5]:    * So narned out of compliment to the author of the present work.

[^6]:    * From its punctured surface ; literally, a pricking.

[^7]:    * Inhabiting deep water.

[^8]:    * Inhabiting the Shetland seas.

[^9]:    * Ribbed.

[^10]:    * Little.

[^11]:    * Not remarkable.

[^12]:    * Membranous.

[^13]:    * Slightly ribbed.

[^14]:    * The nearest, i.e. to $R$. vitrea.

[^15]:    * Glassy.

[^16]:    * Very beautiful.

[^17]:    * Shining.

[^18]:    * Loose (referring to the convolutions of the spire).

[^19]:    * For cingillum, a small girdle.

[^20]:    VOL. IV,

[^21]:    * Inhabiting Ulva lactuca.

[^22]:    * See vol. iii. p. 337.

[^23]:    * Named in honour of the late George Barlee, Esq., a zealous and indefatigable conchologist.
    + Red.

[^24]:    * A compliment paid to the author by his friend Mr. Joshua Alder.

[^25]:    * Of an opal hue.

[^26]:    * Globular.

[^27]:    * Named after Dr. David Skene, a friend and correspondent of Solander.

[^28]:    * Flat-coil.

[^29]:    * A flat circle.

[^30]:    * From its being marked with rings like a windpipe; the Latin word is properly trachia.

[^31]:    * Smooth.

[^32]:    * A diminutive from turris, a tower.
    $\dagger$ A borer.

[^33]:    * Diminutive from truncatus, cut off.

[^34]:    * Having a small truncation.

[^35]:    * From scala, a ladder.

[^36]:    * Ann. \& Mag. N. II. 3rd ser. xvi. p. 397.
    $\dagger$ See voi. i. (Introduction) pp. xxxy and xaxvi.

[^37]:    * Named after a daughter of Dr. Turton.

[^38]:    * Common.

[^39]:    * Named in honour of the discoverer, Miss Emma Trevelyan.

[^40]:    * Small-barred: diminutive of clathrata, from the Linnean specific name clathrus.

[^41]:    * Unparalleled.

[^42]:    * A tapeworm.

[^43]:    * Exceedingly glossy.

[^44]:    * Named out of compliment to Mrs. Gulson, a lady at Exmouth, to encourage ber inclination for natural history.

[^45]:    * Mouth of the shell furnished with a tooth; per syncopen for Odon. tostomia.

[^46]:    * Ann. \& Mag. N. H. Dec. 1850.

[^47]:    * Smallest.

[^48]:    * Snowy, for snow-white; properly nivea.

[^49]:    * Slightly lopped or cut off.

[^50]:    * A twig; more correctly clavulus, a small nail?

[^51]:    * Named in honour of the late Dr. F. C. Lukis, an excellent naturalist at Guernsey.

[^52]:    * Having the aspect of a Rissoa.

[^53]:    * Pale.

[^54]:    * Having a conical appearance.

[^55]:    * Umbilicate.

[^56]:    * Pointed.

[^57]:    * Remartable.

[^58]:    * Furnished with a plait or fold.

[^59]:    * Engraved.

[^60]:    * Slanting.

[^61]:    * Divided crosswise.

[^62]:    * Obscure (metonymically).

[^63]:    * Punctured here and there.

[^64]:    * Wreathed.

[^65]:    * Uncommon.

[^66]:    * Covered with latticework, like a window.

[^67]:    * Hollowed out.

[^68]:    * Resembling a flight of steps.

[^69]:    * Reddish.

[^70]:    * Milk-white.

[^71]:    * Not Turbo gracilis of Brocchi, which is a miocene fossil, nor C. graeilis of De Koninek, which is palæozoic.

[^72]:    * Iittle.

[^73]:    * A small pin for a head-dress, used by Italian women in ancient and modern times.

[^74]:    * Most glossy.

[^75]:    * From its violet colour.

[^76]:    * Rounded.

[^77]:    * Stake-bearing; or from its style-like apex.

[^78]:    * Named after Dr. Turton.

[^79]:    * Having a narrow mouth.

[^80]:    * Haring two thread-like marks.

[^81]:    * Perhaps an emendation of the word natice, given to this shell by Aldrovandi, and derived from its supposed natatory habit.

[^82]:    * Icelandic.

[^83]:    * Inhabiting Greenland.

[^84]:    * Dirt-coloured.

[^85]:    * From its chan-like rows of spots.

[^86]:    * Dedicated to Mr. Joshua Alder of Newcastle-on-Tyne, a distinguished British zoologist.

[^87]:    * Named in memory of the author of 'Testacea Britannica.'

[^88]:    * Approaching a circle.

[^89]:    * Somewhat keeled.

[^90]:    * From the plate-like or scaly shape of the mantle.

[^91]:    * Transparent.

[^92]:    * Ve ety; name (not classical) derived from the epidermis.
